**Abstract** Abnormal energy regulation may significantly contribute to the pathogenesis of obesity, diabetes mellitus, cardiovascular disease, and cancer. For rapid control of energy homeostasis, allosteric and posttranslational events activate or alter activity of key metabolic enzymes. For longer impact, transcriptional regulation is more effective, especially in response to nutrients such as long chain fatty acids (LCFA). Recent advances provide insights into how poorly water-soluble lipid nutrients [LCFA; retinoic acid (RA)] and their metabolites (long chain fatty acyl Coenzyme A, LCFA-CoA) reach nuclei, bind their cognate ligand-activated receptors, and regulate transcription for signaling lipid and glucose catabolism or storage: (i) while serum and cytoplasmic LCFA levels are in the 200  $\mu$ M–mM range, real-time imaging recently revealed that LCFA and LCFA-CoA are also located within nuclei (nM range); (ii) sensitive fluorescence binding assays show that LCFA-activated nuclear receptors [peroxisome proliferator-activated receptor- $\alpha$  (PPAR $\alpha$ ) and hepatocyte nuclear factor 4 $\alpha$  (HNF4 $\alpha$ )] exhibit high affinity (low nM  $K_d$ 's) for LCFA (PPAR $\alpha$ ) and/or LCFA-CoA (PPAR $\alpha$ , HNF4 $\alpha$ )—in the same range as nuclear levels of these ligands; (iii) live and fixed cell immunolabeling and imaging revealed that some

cytoplasmic lipid binding proteins [liver fatty acid binding protein (L-FABP), acyl CoA binding protein (ACBP), cellular retinoic acid binding protein-2 (CRABP-2)] enter nuclei, bind nuclear receptors (PPAR $\alpha$ , HNF4 $\alpha$ , CRABP-2), and activate transcription of genes in fatty acid and glucose metabolism; and (iv) studies with gene ablated mice provided physiological relevance of LCFA and LCFA-CoA binding proteins in nuclear signaling. This led to the hypothesis that cytoplasmic lipid binding proteins transfer and channel lipidic ligands into nuclei for initiating nuclear receptor transcriptional activity to provide new lipid nutrient signaling pathways that affect lipid and glucose catabolism and storage.

**Keywords** L-FABP · ACBP · PPAR $\alpha$  · HNF4 $\alpha$  · CRABP · Fatty acid · Transgenic mice

### Abbreviations

LCFA	Long chain fatty acids
L-FCFA-CoA	Long chain fatty acyl Coenzyme A
L-FABP	Liver fatty acid binding protein
A-FABP	Adipocyte FABP
H-FABP	Heart FABP
K-FABP	Keratinocyte FABP
I-FABP	Intestinal FABP
B-FABP	Brain FABP
ACBP	Acyl CoA binding protein
CRABP	Cellular retinoic acid binding protein
PPAR	Peroxisome proliferator-activated receptor
HNF4 $\alpha$	Hepatocyte nuclear factor-4 $\alpha$
RA	Retinoic acid
RXR	Retinoic acid X receptor
SCP-2	Sterol carrier protein-2
WT	Wild-type

## Introduction

Long chain fatty acids (LCFA) have been known for some time to serve as components of biological membranes and are also used for metabolic fuel. LCFA are not only precursors of signaling molecules; they are also endogenous ligands [1–3] for nuclear receptors that initiate transcription of multiple genes involved in LCFA ( $\beta$ -oxidation, lipoprotein) and glucose metabolism. Concomitantly, LCFA down-regulate genes involved in insulin signaling (e.g. protein tyrosine phosphatase) (rev. in [4–6]). Abnormal activation of the nuclear peroxisome proliferator-activated receptors (PPARs) contributes to lipotoxicity associated with obesity, insulin resistance, type 2 diabetes, and hyperlipidemia (rev. in [5, 7]).

Mammals have evolved both short/rapid acting and long/slower mechanisms to control metabolism. Rapid allosteric control and posttranslational modification activate/deactivate enzymes or alter protein stability within seconds to minutes [5]. Most effective for longer-lasting control (hours to days) is transcriptional regulation of at least two types of receptors [8]: (i) hydrophilic ligands (e.g. diazapines) bind with cell surface membrane receptors, activating cascades of second messengers, which transmit signals to transcription factors that control expression of target genes; and (ii) in contrast, hydrophobic ligands (fatty acids, retinoic acid, vitamins, hormones) must actually enter the cell and be transported to the nucleus, interacting with intracellular and nuclear receptors that serve as nutrient sensors [8, 9]. These hydrophobic ligands act as modulators of transcription factors, exerting regulatory functions directly at the gene level [8]. Because nuclear receptors such as PPAR isoforms ( $\alpha$ ,  $\beta$ ,  $\gamma$ ), HNF4 $\alpha$ , thyroid receptor (T<sub>3</sub>R), glucocorticoid receptor (GR), liver X receptor (LXR), retinoic acid X receptor (RXR), and others regulate transcription of genes involved in lipid and glucose metabolism [5, 9–13], there is great interest in discovery of pharmaceutical antagonists of these receptors to reduce/prevent the deleterious effects of LCFA and LCFA-CoA in obesity, diabetes mellitus, and cardiovascular disease. This focus has led to important discoveries that certain hydrophobic xenobiotics and metabolites/analogues of LCFA including LCFA-CoA are high-affinity ligands that inhibit transcriptional activity of their respective nuclear receptor.

However, the identity of endogenous ligands for PPAR $\alpha$  and HNF4 $\alpha$  has been elusive. Clearly, dietary LCFA regulate activity of PPAR $\alpha$  and HNF4 $\alpha$  to induce transcription of genes encoding enzymes and proteins of LCFA and carbohydrate metabolism in cells [14–20] and animals [21], but until recently it was not clear whether LCFA themselves versus their metabolites LCFA-CoA exhibit the

requisite characteristics generally acknowledged as hallmarks of physiologically significant ligands: (i) presence in the nucleus, but at levels sufficiently low not to saturate the nuclear receptors, (ii) high affinity binding, with  $K_{d}$ s in the range of physiological concentrations of the ligands in nuclei; (iii) ligand-induced conformational change in the nuclear receptor; and (iv) ligand-induced alterations in coregulator recruitment to the nuclear receptor [7, 22–25]. Further, until recently little was known regarding how hydrophobic ligands [e.g. LCFA, LCFA-CoA, retinoic acid (RA)] could be transported to the nucleus.

Since elevated levels of LCFA and LCFA-CoA are characteristic of several chronic metabolic disorders, including obesity, diabetes mellitus, hyperlipidemia, and cardiovascular disease [26], it is important to resolve mechanism(s) that regulate intracellular and nuclear LCFA/LCFA-CoA concentrations for optimal LCFA and glucose metabolic homeostasis [27]. This review focuses on recent evidence supporting one hypothesis, “exemplified for liver, that transfer and channeling of LCFA to PPAR $\alpha$  in the nucleus can be mediated by L-FABP” (Fig. 1).

### Dietary LCFA Activate Nuclear Receptors PPAR $\alpha$ and HNF4 $\alpha$ : Functional Data

Early studies of PPAR $\alpha$  and HNF4 $\alpha$  ligand specificity illustrate the difficulty in determining the nature of the endogenous ligands of these ligand-activated nuclear receptors. High-fat diets increase PPAR $\alpha$ -activated gene expression, especially of L-FABP and  $\beta$ -oxidative enzymes, stimulating LCFA  $\beta$ -oxidation, regardless of whether dietary LCFA are polyunsaturated,

**Fig. 1** Selective cooperation between L-FABP and PPAR $\alpha$  in branched-chain fatty acid signaling to the nucleus. BCFA, branched-chain fatty acid; L-FABP, liver fatty acid binding protein; RXR $\alpha$ , retinoic acid X receptor  $\alpha$ ; 9 *cis*-RA, 9 *cis*-retinoic acid

monounsaturated, or saturated [13, 16, 21]. While straight-chain LCFA (unsaturated > saturated) stimulate PPAR $\alpha$  transactivation [14, 16, 18, 23, 28], they are relatively non-selective and effective on all three PPAR isoforms ( $\alpha$ ,  $\beta$ ,  $\gamma$ ) [29]. In contrast, branched-chain LCFA (pristanic acid, phytanic acid) selectively activate only PPAR $\alpha$  [29], particularly in liver [30], and more effectively than any other dietary LCFA or synthetic peroxisome proliferator drugs [29, 31]. Plasma of healthy individuals contains <10  $\mu$ M phytanic and <3  $\mu$ M pristanic acid, levels that activate PPAR $\alpha$  in cultured cells [29]. In patients with peroxisomal disorders (Refsum, Zellweger, and other peroxisomal abnormalities), plasma phytanic and pristanic acid levels rise to 8,000 and 80  $\mu$ M, respectively [29, 32].

While together these data suggest that the LCFA activate PPAR $\alpha$ , nutritional studies and activation assays do not discriminate whether dietary LCFA are themselves PPAR $\alpha$  ligands, induce endogenous PPAR $\alpha$  ligands, or are metabolized to active PPAR $\alpha$  ligands [16]. Early studies with radioligand binding assays indicated that saturated LCFA and VLCFA (except for arachidonic acid) were very poorly or not bound by PPAR $\alpha$  (see below). However, this apparent contradiction of dietary saturated LCFA and very long chain fatty acids (VLCFA) directly activating PPAR $\alpha$  [21] was recently resolved by showing that metabolites of saturated LCFA and VLCFA (LCFA-CoA and VLCFA-CoA) are the actual high-affinity PPAR $\alpha$  ligands [2, 3]. Mouse studies lend further support for the potential importance of LCFA-CoA in regulating PPAR $\alpha$ : (i) peroxisome proliferators induce expression of acyl-CoA oxidase (AOX) and bifunctional protein (BPE), the first two enzymes of the  $\beta$ -oxidation pathway [33], and increase the level of CoA thioesters of peroxisome proliferators [34, 35]; (ii) 2-bromopalmitate, a general inhibitor of fatty acid thioesterification, inhibits bezafibrate induction of peroxisomal proliferation [36]; (iii) AOX gene ablation increases serum VLCFA, and since VLCFA-CoA are not  $\beta$ -oxidized in AOX-null mice, they accumulate and hyperactivate PPAR $\alpha$  [37]. Conversely, ablation of the adrenoleukodystrophy gene (prevents VLCFA and/or VLCFA-CoA from being transported to peroxisomes) increases VLCFA (but not VLCFA-CoA) levels and does not alter PPAR $\alpha$  activity [38]. These data show that gene alterations resulting in high acyl-CoA elicit PPAR $\alpha$  activation, while gene alterations leading to reduced acyl-CoA result in PPAR $\alpha$  inactivation.

With HNF4 $\alpha$  activation, dietary saturated fatty acids increase plasma levels of lipid rich lipoproteins (VLDL, LDL, HDL) and their constituent apolipoproteins, while dietary unsaturated fatty acids decrease plasma levels of these lipoproteins and their apolipoproteins [39]. This fatty acid nutrient regulation of serum lipids and lipoproteins has been ascribed to transcriptional modulation of HNF4 $\alpha$

activated genes encoding apolipoproteins (AI, AII, B, CIII) [40, 41]. Dietary fatty acids modulate HNF4 $\alpha$  transactivation in a highly selective manner, consistent with LCFA-CoA representing the activating ligand rather than LCFA (rev. in [42–45]). Mutations in HNF4 $\alpha$  form the basis of mature onset diabetes of the young (MODY-1), while agonist LCFA-CoA ligands rescue MODY-1 mutants of HNF4 $\alpha$  in transactivation assays [45].

In summary, the above data show that dietary LCFA regulate the PPAR $\alpha$ - and HNF4 $\alpha$ -mediated transcription of genes involved in LCFA and glucose metabolism. However, it was not clear from earlier studies whether LCFA and their acyl CoA represented the endogenous ligands of these nuclear receptors. For LCFA and LCFA-CoA to represent physiologically significant endogenous ligands they must meet the classical criteria of ligand-activated nuclear receptors (summarized in Table 1). These criteria provide a mechanistic framework accounting for current observations, and establish LCFA and LCFA-CoA as physiologically relevant ligands for these nuclear receptors.

#### *LCFAs and LCFA-CoAs must be Present Within the Nucleus*

Serum LCFA levels exceed the solubility of LCFA (1–100  $\mu$ M) by several orders of magnitude: 200–600  $\mu$ M under normal conditions, 1 mM under fasting, and up to 8 mM in Refsum's disease, diabetes, cancer, and sepsis (rev. in [29, 32, 46]). Because LCFA are potent detergents and thus toxic at higher concentrations, serum LCFA are almost completely bound by albumin such that the concentration of free unbound LCFA available for uptake into cells is quite low, 2–67 nM, depending on the assay (rev. in [46]). Still, cultured cells can generally take up unbound LCFA from media very rapidly ( $t_{1/2}$  of minutes) into the cytoplasm (rev. in [46]). Because of their potent detergent action at high concentration, once taken up the LCFA are rapidly (sec to min) converted to LCFA-CoA by fatty acyl

**Table 1** Essential criteria for LCFA or LCFA-CoA activated nuclear receptors: PPARs and HNF4 $\alpha$

	Criterion
1	LCFA or LCFA-CoA levels in nuclear envelope and nucleoplasm are low (nM range)
2	Nuclear receptors have high affinity (nM $K_d$ s) for LCFAs or LCFA-CoAs
3	LCFA or LCFA-CoA binding alters nuclear receptor conformation
4	LCFA or LCFA-CoA binding alters cofactor recruitment

CoA synthase activity at the plasma membrane—a process that can be facilitated by certain fatty acid binding proteins in the cytoplasm (rev. in [46, 47]). While LCFA-CoA are less potent detergents than LCFA, cellular LCFA-CoA levels are generally 10–100 fold lower than LCFA levels because the LCFA-CoA are more rapidly utilized for metabolism (esterification, oxidation), regulation of receptor/enzyme activity, and/or transport to nuclei to potentially regulate transcriptional activity of LCFA-CoA dependent nuclear receptors (rev. in [27, 48, 49]).

However, to be physiologically significant ligands and regulators of nuclear receptors, these LCFA and/or their LCFA-CoA metabolites must: (i) be able to enter nuclei and (ii) nucleoplasmic concentrations of these ligands must be in the same affinity range as the nuclear receptors for these ligands. Whether these ligands enter nuclei was originally addressed by purifying nuclei through subcellular fractionation, in which it was determined that LCFA and LCFA-CoA were detectable [50–54]. However, such experiments could not discriminate contributions from contaminating adherent endoplasmic reticulum (ER) fragments and ligand binding to nuclear membranes, versus actual distribution into nucleoplasm. These potential problems were resolved by real-time confocal and/or multiphoton imaging of a naturally-occurring fluorescent, slowly metabolizable LCFA (*cis*-parinaric acid) as well as non- and poorly-metabolizable synthetic fluorescent LCFA (NBD-stearic acid, BODIPY-C16, BODIPY-C12) and a non-hydrolyzable fluorescent synthetic LCFA-CoA (BODIPY-C16-S-S-CoA) in intact living cells [55–57]. While much of the fluorescent LCFA and LCFA-CoA was present outside the nucleus, significant amounts also colocalized with a nucleic acid dye such that the intracellular distribution was of the order: outside the nucleus  $\gg$  nuclear membrane  $>$  more dense structures within the nucleoplasm  $>$  diffuse nucleoplasm [56]. Thus LCFA and LCFA-CoA are indeed present in nuclei and, more importantly, distributed throughout the nucleoplasm of both fixed and live cells.

Secondly, measurement of LCFA and LCFA-CoA concentrations within the nucleus was initially also addressed by chemical analysis of nuclei isolated by subcellular fractionation, in which nuclear LCFA and LCFA-CoA concentrations were measured in the high  $\mu\text{M}$  range (rev. in [55, 56]). Such experiments could not discriminate contributions due to esterase activity on LCFA-CoA and more complex lipids to release LCFA, redistribution of LCFA and LCFA-CoA from other intracellular sites, or differences in the proportion of LCFA and LCFA-CoA in the nuclear envelope versus nucleoplasm. In later experiments, real-time confocal and multiphoton imaging of naturally-occurring and synthetic fluorescent LCFA and LCFA-CoA in living cells measured nucleoplasmic LCFA levels at 39–

69 nM [55, 56] and nucleoplasmic LCFA-CoA levels at  $<10$  nM [56], levels consistent with earlier calculations [48, 49].

#### *PPAR $\alpha$ and HNF4 $\alpha$ must Exhibit Specific, High Affinity (nM $K_d$ s) for LCFA and/or LCFA-CoA*

While LCFA are currently considered putative, physiologically significant endogenous ligands of PPAR $\alpha$ , earlier data did not support this hypothesis. As initially measured by radioligand competition and indirect binding assays, PPAR $\alpha$  had a low affinity for unsaturated LCFA (10–50  $\mu\text{M}$   $K_d$ s), and did not bind saturated LCFA or LCFA-CoA [15, 17]. These  $\mu\text{M}$   $K_d$ s would be several orders of magnitude higher than nuclear LCFA and LCFA-CoA concentrations. Unanswered was whether LCFA or LCFA-CoA alter conformation of PPAR $\alpha$  and/or alter coactivator binding, both hallmarks of ligand-activated nuclear receptors (rev. in [1, 2]). More recent data utilizing new assays not requiring separation of bound from free lipidic ligands (LCFA, LCFA-CoA) showed that radioligand binding assays produce significant levels of non-specific binding [15] and underestimate PPAR $\alpha$  affinities for LCFA [46] and LCFA-CoA [58, 59]. The newer fluorescence-based assays showed that PPAR $\alpha$  has high affinity (1–20 nM  $K_d$ s) for unsaturated LCFA, saturated LCFA-CoA, unsaturated LCFA-CoA, unsaturated and saturated VLCFA-CoA, and branched-chain BCFA-CoA, as well as similar or somewhat weaker affinity for fibrates and branched-chain fatty acids (both PPAR $\alpha$  agonists) [1–3, 60]. In contrast, saturated LCFA, saturated VLCFA, and unsaturated VLCFA (PPAR $\alpha$  agonists) as well as glitazones (PPAR $\gamma$  agonists) do not or only weakly bind to PPAR $\alpha$  [2, 3, 61, 62]. LCFA-CoA binding to PPAR $\alpha$  did not require hydrolysis of LCFA-CoA to the free acid form (LCFA), since PPAR $\alpha$  bound non-hydrolyzable *S*-hexadecyl-CoA (S-C16-CoA) with high affinity ( $K_d = 10$  nM) [2, 3].

In the case of HNF4 $\alpha$ , earlier studies on the HNF4 $\alpha$  ligand binding domain (LBD) suggested that HNF4 $\alpha$  did not contain a ligand binding site for either LCFA or LCFA-CoA [63]. Indeed, initial studies using radioligand competition and indirect binding assays showed that the full-length HNF4 $\alpha$  had low affinity for unsaturated LCFA-CoA (1–4 mM  $K_d$ s) and did not bind saturated LCFA [24, 42, 64]. Further, LCFA, but not LCFA-CoA, was bound by truncated HNF4 $\alpha$  ligand binding domain (LBD) constructs that were missing both the N-terminal domains and more importantly the C-terminal F domain (52.5% of the protein) [64]. This reversal of ligand specificity was primarily due to deletion of the C-terminal F domain since deletion of the N-terminal domains had little effect on ligand affinity or specificity [64]. Confirming the effect of C-terminal F-domain truncation on

ligand specificity, X-ray crystallography of truncated HNF4 $\alpha$  constructs detected only bound LCFA [64]. Since LCFA-CoA are very unstable under conditions necessary for crystallization of HNF4 $\alpha$  (i.e. several weeks at room temperature) [65], lack of the terminal F domain, instability of LCFA-CoA under crystallization conditions, and the fact that HNF4 $\alpha$  exhibits thioesterase activity [65, 66] could account for LCFA-CoA not being observed by x-ray crystallography [24, 65, 67, 68]. Interestingly, the LCFA binding site identified by X-ray crystallography is located within a classic LBD [66–68], has weak affinity for LCFA [24, 45, 64] and does not alter its conformation in response to LCFA binding [24, 66–68]. More recent fluorescence data have shown that both unsaturated and saturated LCFA-CoA are bound in a second site with high affinity (i.e. low nM  $K_{dS}$ ) by full-length HNF4 $\alpha$  [24, 45, 64, 66]. LCFA-CoA binding was subsequently confirmed by mass spectrometry of full-length HNF4 $\alpha$  [66]. Mass spectrometry also detected a second ligand binding site which was discrete from the LCFA-CoA binding site, bound only LCFA, and bound LCFA in this site were not displaced by adding exogenous LCFA [66]. While X-ray crystallography studies also showed that the bound LCFA could not be displaced by exogenous LCFA, it is not known if the LCFA binding site determined by mass spectrometry is identical to that determined by X-ray crystallography. Since LCFA bound to HNF4 $\alpha$  did not alter structure, and LCFA that are poorly metabolized to LCFA-CoA do not affect HNF4 $\alpha$  transactivation [42, 45], the physiological function if any of the LCFA bound within the HNF4 $\alpha$  second ligand site remains to be shown.

In summary, PPAR $\alpha$  (exhibits high affinity for unsaturated LCFA and nearly all LCFA-CoA and VLCFA-CoA, but not saturated LCFA or VLCFA). Thus select LCFA and all LCFA-CoA/VLCFA-CoA satisfy the high affinity and location requirements for physiologically significant ligands that activate PPAR $\alpha$  [1]. These data help to explain why dietary or exogenous saturated LCFA and both saturated and unsaturated VLCFA alter transcriptional activity of PPAR $\alpha$  even though they are weak ligands. In contrast, select LCFA-CoA (but not unsaturated or saturated LCFA) satisfy the high affinity requirements for ligands that enhance or inhibit full-length HNF4 $\alpha$  transactivation [45, 66]. What remains to be shown, however, is whether LCFA or LCFA-CoA directly bind with PPAR $\alpha$  or HNF4 $\alpha$  in nuclei of living cells.

#### *LCFA and LCFA-CoA Binding must Alter PPAR $\alpha$ and HNF4 $\alpha$ Conformation*

Recent studies by circular dichroism, quenching of intrinsic aromatic amino acid fluorescence, and protease susceptibility have all demonstrated that LCFA and/or LCFA-CoA

alter the conformation of PPAR $\alpha$  and HNF4 $\alpha$  (rev. in [2, 3, 66]). All high affinity (but not low/no affinity) endogenous or synthetic ligands alter PPAR $\alpha$  conformation [2, 3]. Likewise, high affinity (but not low/no affinity) endogenous or synthetic ligands alter conformation of full-length HNF4 $\alpha$  [24, 64] as well as HNF4 $\alpha$  constructs retaining the C-terminal F-domain, which is the largest F domain (near 80aa) of any nuclear receptor examined to date [64]. Finally, circular dichroism studies of HNF-4 $\alpha$  in the absence and presence of various acyl-CoA ligands demonstrated that saturated versus polyunsaturated acyl-CoA differentially altered HNF-4 $\alpha$  secondary structure conformation [64], suggesting that different lipid ligands could modulate HNF-4 $\alpha$  activity by inducing conformational changes in the structure of HNF-4 $\alpha$  [64].

#### *LCFA and LCFA-CoA Alter Cofactor Recruitment to PPAR $\alpha$ and HNF4 $\alpha$*

It has been shown that high affinity (but not low/no affinity) endogenous or synthetic LCFA and LCFA-CoA alter PPAR $\alpha$  coactivator binding [2, 3]. Conversely, select LCFA-CoA but not LCFA alter DNA binding and/or coactivator recruitment to HNF4 $\alpha$  (rev. in [42, 43, 45]).

#### *Potential Roles of LCFA and LCFA-CoA Binding Proteins in Regulating Nuclear Receptors*

Fatty acid binding proteins represent a large family of soluble proteins that bind LCFA and, in most cases LCFA-CoA, with high affinity (rev. in [46]). Although these proteins were generally named after the tissue in which they were first discovered, most occur in multiple tissues. For example, liver fatty acid binding protein (L-FABP) is expressed at highest amounts in liver and intestine, as well as in lower quantities in kidney and several other tissues (rev. in [4, 46, 69–75]). All tissues examined to date express one or more FABP (L-FABP, adipose A-FABP, intestine I-FABP, heart H-FABP, brain B-FABP), often at a relatively high level, representing as much as 2–5% of cytosolic protein and concentrations of 200–1,000  $\mu$ M depending on genetic status [76], sex (rev. in [46, 69]), physiological status (rev. in [46]), and induction by peroxisome proliferators (rev. in [46]). In addition, all tissues examined contain the ubiquitous acyl CoA binding protein (ACBP), usually present at several fold-lower levels than the FABPs in the same tissue (rev. in [27, 48, 49, 77, 78]). ACBP and various FABPs are generally expressed at highest levels in tissues that exhibit the highest LCFA metabolic activity, such as liver and heart (rev. in [27, 48, 49, 77, 78]). ACBP in combination with select FABPs may

regulate the nuclear concentration of LCFA and LCFA-CoA by one or more of the following mechanisms.

*ACBP and FABPs have Ligand Affinities in the Same Range as those of Nuclear Receptors*

To effectively transport and donate bound LCFA and/or LCFA-CoA, ACBP and FABPs must have affinities in the same range or slightly weaker than those exhibited by nuclear receptors, such as PPAR $\alpha$  and HNF4 $\alpha$  described previously, and indeed this parallel affinity is the case. For example, native liver L-FABP exists in two isoforms which exhibit high affinity for LCFA ( $K_{dS}$  of 8–60 nM, depending on the isoform) and LCFA-CoA ( $K_{dS}$  of 14–110 nM, depending on the isoform) [59]. L-FABP binds unsaturated LCFA with 2–3 fold higher affinity than saturated LCFA, while affinities for both types of LCFA-CoA are more similar (rev. in [59, 79]). ACBP exhibits a higher affinity, but only for LCFA-CoA ( $K_{dS}$  of 0.6–7 nM) [48, 49, 80]. ACBP binds LCFA-CoA with the following order of affinities: saturated > unsaturated > polyunsaturated [80, 81]. However, it must be noted that some studies based on titration microcalorimetry, a method that uses relatively high concentrations of proteins and ligands (e.g. 130,000 nM), yields  $K_{dS}$  of 1–10 nM for ACBP (rev. in [48, 49, 82]) while  $K_{dS}$  for L-FABP are 1,000 nM [83]. The reasons for the discrepancy are not clear but may be related to the fact that fluorescence binding assays use very low concentrations of proteins and ligands (e.g. 180 nM) below the critical micellar concentration of the LCFA-CoA ligand [59, 80], while titration microcalorimetry uses relatively high concentrations of proteins and ligands (e.g. 130,000 nM) above the critical micellar concentration of LCFA-CoA ligand (rev. in [48, 49, 82]). While LCFA-CoA levels above the critical micelle concentration apparently do not affect calculation of binding affinities for proteins with very high affinities such as with ACBP for LCFA-CoA, titration microcalorimetry with lower LCFA-CoA binding affinity proteins such as L-FABP results in underestimation of the binding affinity by one to two orders of magnitude. These data indicate that while ACBP is a higher LCFA-CoA affinity protein than L-FABP, the difference is not 1,000-fold, but rather in the range of 10–50 fold depending on the ligand. Further, the physiological significance of both proteins in LCFA-CoA metabolism was confirmed by a variety of studies indicating that not only ACBP, but also L-FABP [27, 79, 84] enhance acyl transferase enzymes (GPAT, ACBP) in vitro (rev. in [85]). Additionally, studies with livers of gene targeted mice indicate that, while ACBP alters both fatty acyl CoA pool size and acyl chain distribution [81], L-FABP alters cytosolic fatty acyl CoA binding capacity, albeit not fatty acyl

CoA pool size [86]. Thus, both L-FABP and ACBP exhibit physiologically significant LCFA-CoA affinities, slightly weaker or in the same range as PPAR $\alpha$  and HNF4 $\alpha$ —consistent with these proteins being able to effectively donate bound LCFA and LCFA-CoA to the nuclear receptors.

*FABPs Enhance LCFA Uptake into the Cell: Role in LCFA-CoA Pool Size*

Studies with transfected cells overexpressing FABPs (L-FABP, I-FABP, A-FABP, H-FABP) and with cultured primary hepatocytes from L-FABP null mice show that FABP enhance LCFA uptake 1.5–5 fold (rev. in [46, 79, 87–92]). FABPs may enhance LCFA uptake either by acting as acceptors from plasma membrane LCFA transport/translocase proteins and/or by enhancing intracellular metabolism of LCFA (rev. in [46, 79, 87–92]).

Since FABPs enhance LCFA uptake, they may thereby increase intracellular LCFA pool size and thus increase intracellular availability of LCFA for targeting to the nucleus. Consistent with this possibility are: (i) FABPs can extract LCFA from membranes and increase their solubility in aqueous buffer (rev. in [46, 79, 87–89]). (ii) The LCFA binding sites of native L-FABP isolated from liver are 76% occupied by LCFA (rev. in [79]). (iii) Studies with L-FABP gene-ablated mice indicate that L-FABPs accounts for 90% of the cytosolic LCFA binding capacity in liver (rev. in [46, 93]). Despite these findings, however, studies with gene-targeted mice indicate that L-FABP gene ablation does not decrease liver LCFA pool size [93] or LCFA-CoA pool size [86]. L-FABP gene ablation did alter LCFA-CoA acyl chain distribution [86]. The lack of effect on LCFA and LCFA-CoA pool sizes may be explained by the fact that L-FABP enhances the activities of both catabolic (oxidative) and anabolic (esterification) pathways of LCFA metabolism—thereby maintaining the respective pool sizes. For example, tissue levels of FABPs correlate with LCFA oxidative activity [94–97] and L-FABP expression enhances LCFA (via LCFA-CoA) oxidation with isolated liver mitochondria [98, 99], in transfected cells overexpressing L-FABP [92], and in wild-type as compared to L-FABP null mice [86, 91, 93, 100–102]. Furthermore, L-FABP stimulates LCFA esterification (via LCFA-CoA) with isolated liver microsomes [79, 85, 89, 103], in transfected cells overexpressing L-FABP (rev. in [46, 104]), and in wild-type as compared to L-FABP null mice [86, 91, 93, 102]. In contrast to L-FABP, ACBP increases LCFA-CoA pool size by extracting LCFA-CoA from membranes (rev. in [81]), in yeast overexpressing ACBP [105], and in transgenic mice overexpressing ACBP [81]. Interestingly, ACBP also enhances LCFA catabolic (oxidation) and anabolic (esterification) pathways of LCFA metabolism in vitro [58, 81, 87, 106, 107] and in vivo [81].

In summary, since tissue total (cytosol plus membranes) LCFA-CoA concentrations are generally 10–100 fold lower than LCFA concentrations, these studies indicate that hepatic L-FABP and ACBP levels are sufficient to extract almost all available LCFA and LCFA-CoA from membranes and from cytosol (rev. in [46, 48, 49, 79]). Furthermore, ACBP expression increases LCFA-CoA pool size, while L-FABP expression does not alter either LCFA or LCFA-CoA pool size, likely due to its higher affinity for LCFA-CoA as compared to L-FABP.

#### *FABPs Enhance LCFA Intracellular Trafficking*

Studies with a variety of cultured cell lines overexpressing L-FABP [46, 108–112] and with hepatocytes from wild-type and L-FABP gene-ablated mice [91] indicate that several members of the FABP family (L-FABP, I-FABP) enhance LCFA intracellular diffusion/trafficking. There have been no published reports, to our knowledge, examining the effect of FABPs or ACBP on LCFA-CoA diffusion/transport through the cytoplasm. Thus, based on the finding that FABPs facilitate intracellular transport and trafficking of bound LCFA, the possibility that FABPs may facilitate LCFA trafficking to/into nuclei for interaction with nuclear receptors must be considered. By analogy it may be predicted that the LCFA-CoA binding proteins (e.g. L-FABP, ACBP) may likewise facilitate trafficking of this ligand into nuclei.

#### *FABPs Enhance LCFA and LCFA-CoA Distribution into Nuclei, both Nuclear Membrane and Nucleoplasm*

LCFA binds to purified nuclei only in the presence of L-FABP [113]. However, such in vitro studies do not discriminate whether L-FABP only transfers bound LCFA to the cytoplasmic face of the nuclear envelope or actually facilitates LCFA transport into nuclei. This issue was recently addressed by use of confocal and multiphoton microscopy of naturally-occurring, slowly-metabolizable fluorescent LCFA (*cis*-parinaric acid) and non- or very poorly-metabolizable synthetic fluorescent LCFA (NBD-stearic acid, BODIPY-C16, BODIPY-C12) and LCFA-CoA (BODIPY-C16-S-S-CoA) [55–57]. Real-time imaging of these probes in live L-cell fibroblasts overexpressing L-FABP and in cultured primary hepatocytes from L-FABP null mice demonstrated that L-FABP enhances distribution of: (i) LCFA into nuclei, both into nucleoplasm and within the nuclear envelope, and (ii) LCFA-CoA into nuclei, primarily diffuse in nucleoplasm with less within the nuclear membrane. Thus, L-FABP distributes LCFA and LCFA-CoA to and into nuclei, but unknown is whether

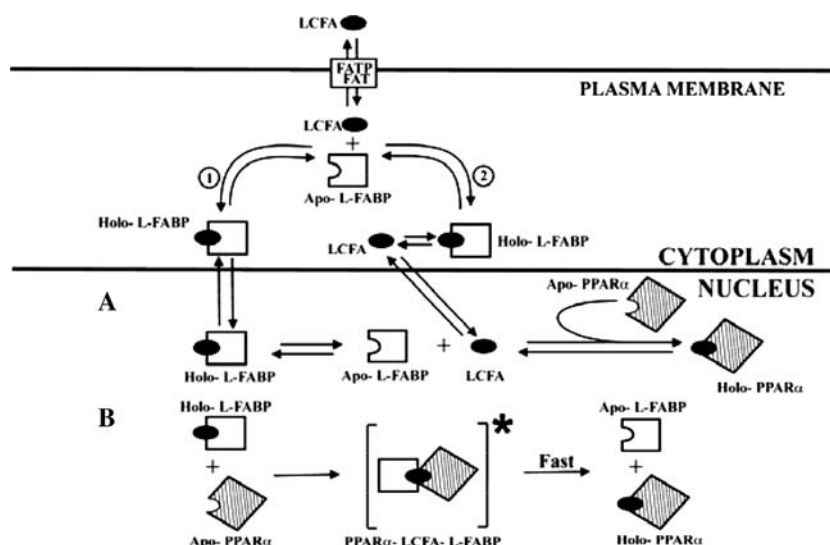

L-FABP cotransfers bound LCFA/LCFA-CoA through the nuclear envelope into the nucleoplasm (Fig. 2, Pathway 1), or just to the nuclear envelope for subsequent release and diffusion of LCFA/LCFA-CoA into the nucleoplasm (Fig. 2, Pathway 2). Nuclear pores are sufficiently large to accommodate diffusion not only of the LCFA and LCFA-CoA ligands (<1 kDa) but also of 14 kDa L-FABP complexes with these ligands (rev. in [56]).

#### *FABPs, ACBP, and CRABP-2 Enter Nuclei (Fig. 2, Pathway 1): Role of Ligands*

Several members of the FABP family have been detected in nuclei and nucleoplasm, as shown by confocal imaging of living cells expressing GFP-tagged FABPs, indirect immunofluorescence confocal imaging of fixed cells, and immunogold electron microscopy of fixed cells: L-FABP in nuclei of hepatocytes as well as transfected cells (L-cells, ES cells) [56, 85, 114], H-FABP in cardiac myocytes as well as in transfected CV1 and 3T3-L1 cells [115, 116] K-FABP in transfected CV1, 3T3-L1, and COS1 cells [116, 117], and CRABP-2 in MCF7 cells [118, 119]. In L-cell fibroblasts overexpressing L-FABP (0.4% of cytosolic protein, 10 fold lower than in liver), L-FABP exhibited punctate and clustered distribution in the nucleoplasm [56]. However, when transfected into adipocytes, L-FABP is not detected in nuclei—suggesting that nuclear localization of some members of the FABP family may be cell type specific (rev. in [4]). Furthermore, the localization of FABPs in nuclei as well as cytoplasm is specific for select members of the FABP family, since another member of the FABP family, CRABP-1, is not detected in nuclei [118].

Similarly, a member of a separate LCFA-CoA binding protein family, i.e. ACBP, has also been detected in nuclei. Immunofluorescence microscopy, confocal microscopy and immunogold electron microscopy detect significant amounts of ACBP in nuclei of fixed transfected cells (CV1, 3T3-L1, COS7) overexpressing ACBP [117, 120, 121], rat and mouse hepatoma cells that normally express high amounts of ACBP [120, 121], as well as normal rat and mouse liver hepatocytes [120, 121]. This pattern of distribution was also detected by immunofluorescence confocal microscopy of endogenous ACBP in mouse hepatoma cells (Fig. 3e–h). To assure that this distribution was not due to a fixation or immunolabeling artifacts, a recently developed approach was used for real-time imaging of ACBP in living cells [122]. Purified recombinant ACBP was chemically labeled with small (<1 kDa) fluorescent tags such as Cy5, incorporated into living cells, and intracellular distribution was examined by confocal microscopy (Fig. 3e–h) [123]. ACBP (Fig. 3e) and the nuclear marker Hoechst 33342 (Fig. 3f) were then simultaneously imaged through

**Fig. 2** Mechanisms of LCFA transfer from L-FABP to PPAR $\alpha$  within the nucleus. Suggested pathways by which L-FABP may deliver LCFAs to PPAR $\alpha$ : (A) diffusional and (B) collisional/complex

separate photomultipliers. When only colocalized pixels were shown (Fig. 3g), it was apparent that ACBP was significantly colocalized with the DNA binding dye in nuclei of living cells. A pixel fluorogram indicated that 22% of ACBP was colocalized with nuclei (Fig. 3f). These results in living cells confirm the findings of immunofluorescence and immunogold labeling of fixed cells and indicate that significant amounts of ACBP are distributed to nuclei.

While these data clearly show that many members of the FABP family can enter nuclei, it is less clear whether ligands enhance FABPs targeting/transport into the nucleoplasm (Fig. 2, Pathway 1). Some fluorescence imaging studies have shown that ligands enhanced distribution of GFP-A-FABP, GFP-K-FABP, and GFP-CRABP-2 (but not GFP-CRABP-1) into nuclei of living COS1 cells [116, 118]. In contrast, another study using immunolabeling fluorescence microscopy and confocal microscopy showed that ligands did not alter the distribution of ACBP, A-FABP, and K-FABP into nuclei of fixed transfected CV1 or 3T3–L1 cells [117]. The reasons for the discrepancy are not known, but may relate to the cell type, FABP expression level, use of live versus fixed cells, use of GFP vs antibodies to decorate the FABPs, or other as yet unresolved factors.

In summary, several members of the FABP family as well as ACBP are present at significant levels in nuclei and nucleoplasm—consistent with these small sized proteins being able to enter nuclei through the nuclear pores. A cluster of basic amino acids in some FABPs (e.g. C-terminal region of A-FABP and K-FABP) and a cluster of lysine residues (far C-terminal region) of ACBP, both apparent only in the respective three-dimensional folded protein structures, have been suggested to resemble a nuclear localization signal [117]. However, the fact that

yeast ACBP does not contain such a region, but nevertheless is significantly localized to nuclei suggests that additional as yet unresolved factors are involved [117]. Finally, several, but not all, studies indicate that ligands can enhance the distribution of the FABPs into nuclei under at least some conditions—suggesting cotransport of FABP-ligand complexes through the nuclear pores into the nucleoplasm.

#### *FABPs Directly Bind Nuclear Receptors*

Growing evidence indicates that multiple members of the FABP family interact directly with nuclear receptors, especially PPARs and RAR (Table 2). For example, co-immunoprecipitation, immunofluorescence colocalization, and transactivation assays (despite some disagreement regarding enhancement or inhibition of transactivation [116, 117]) suggest that several members of the FABP family interact with nuclear receptors to transfer bound ligands: CRABP-2 with RAR [116, 118, 119, 124]; A-FABP and K-FABP with PPAR $\gamma$  and  $\beta$  isoforms, respectively, but not PPAR $\alpha$  [116, 117]; H-FABP with PPAR $\alpha$  [116]; ILBP with farnesoid X receptor (FXR), an interaction augmented by bound bile acid [125]. Likewise, transactivation, coimmunoprecipitation, two-hybrid assay, and immunofluorescence colocalization indicate that L-FABP binds with both PPAR $\alpha$  (Fig. 2, L-FABP/PPAR $\alpha$  complex) and PPAR $\gamma$  [18, 56, 126]. However, such indirect assays do not provide direct proof of physical association between the FABP family of proteins with their respective nuclear receptors. The finding that L-FABP does not contain an LXXLL domain characteristic of proteins bound by PPAR $\alpha$  [18] suggests that L-FABP either interacts with PPAR $\alpha$  through an unidentified domain, or that these

Cytoplasmic LCFA and LCFA-CoA binding proteins enter nuclei, bind with nuclear receptors with high affinity for LCFA/LCFA-CoA, and thereby regulate transcriptional activity of nuclear receptors

<sup>a</sup> Interaction augmented by bound bile acid

assays do not demonstrate direct molecular interaction. With the latter possibility, positive results with the above assays could arise from L-FABP interacting with intermediary protein(s) that in turn bind to PPAR $\alpha$ , L-FABP enhancing release of endogenous PPAR $\alpha$  ligands [16], and/or L-FABP enhancing formation of additional LCFA metabolite(s) which binds PPAR $\alpha$  as exemplified by LCFA-CoAs [2, 3, 47, 127–129].

Despite these reservations, several recent studies have provided molecular details of FABP/nuclear receptor interaction, including intermolecular distance between the

proteins, affinity of the proteins for each other, conformational changes upon interaction, and the mechanism(s) whereby ligand cargo is transferred between these proteins. Physical interaction between purified CRABP-2 and RAR proteins was indicated by coimmunoprecipitation [118]. Likewise, physical interaction between purified A-FABP and PPAR $\gamma$  as well as between K-FABP and PPAR $\beta$  has been shown by coimmunoprecipitation [116]. Circular dichroism has shown that interaction of purified L-FABP and PPAR $\alpha$  alters protein conformation [57]. Likewise, a fluorescence resonance energy transfer (FRET) demonstrated that purified L-FABP binds PPAR $\alpha$  with high affinity [57]. Finally, FRET between purified L-FABP and PPAR $\alpha$  showed these proteins interacting with very close intermolecular distance, i.e. a few angstroms [57]. This was confirmed by immunofluorescence and immunogold electron microscopy. Although L-FABP overexpressed in transfected L-cell fibroblasts has been detected in nuclei, most of this distribution appeared distinct from that of PPAR $\alpha$  [56]. However, subsequent double immunogold electron microscopic observations in cultured primary hepatocytes indicate that significant amounts of L-FABP and PPAR $\alpha$  in the punctately distributed regions of the nucleoplasm are in close proximity [57].

In summary, both indirect (coimmunoprecipitation, two hybrid, transactivation) and direct (circular dichroism, FRET-based  $K_d$ s, FRET-based intermolecular distance in fixed cells, immunogold EM) binding assays show that FABPs interact with select nuclear receptors (PPAR isoforms, RAR, and HNF4 $\alpha$ ). The ligand-dependence of these

interactions remains to be elucidated. Taken together, these studies indicate that the FABPs may selectively cooperate with the respective nuclear receptors in providing a signaling pathway for LCFA metabolism. However, molecular mechanisms and physiological impact of these interactions remain to be resolved.

#### ACBP Directly Binds Nuclear Receptors: HNF4 $\alpha$

ACBP, a member of a separate LCFA-CoA binding protein family, interacts directly with the nuclear receptor HNF4 $\alpha$  (Table 2). A model similar to that for the L-FABP/PPAR $\alpha$  interaction (Figs. 1, 2) is illustrated in Fig. 4. In this model, ACBP interacts with the ligand binding domain of HNF4 $\alpha$  to elicit a conformational change and/or transfer bound LCFA-CoA ligand to elicit a conformational change which in turn alters coregulator recruitment and transactivation. Whether other LCFA-CoA binding proteins compete with ACBP for binding and differentially modulating transcriptional activity of this nuclear receptor is not known (Fig. 4). This model is supported by both indirect and direct interaction assays.

Indirect assays such as coimmunoprecipitation, mammalian two hybrid, and transactivation indicate that ACBP

directly interacts with HNF4 $\alpha$  [120]. It has been reported that HNF4 $\alpha$  transactivation is stimulated by saturated acyl-CoAs like C14:0- and C16:0-CoA, and inhibited by polyunsaturated C18:2-, C18:3-, C20:5-CoA thioesters [130]. Thus, depending on the LCFA-CoA species bound to ACBP, the type of ACBP/LCFA-CoA complex may regulate the type of interaction/activation observed.

While such indirect assays do not provide direct proof of physical association between ACBP with this nuclear receptor, perhaps the strongest direct evidence to date that these lipid binding proteins may physically interact with nuclear receptors has been obtained for the ACBP/HNF4 $\alpha$  complex [120, 122]: (i) interaction of pure ACBP and HNF4 $\alpha$  proteins significantly altered the protein secondary structure; (ii) HNF4 $\alpha$  bound ACBP with high affinity ( $K_d \sim 60$ –110 nM); (iii) the intermolecular distance between HNF4 $\alpha$  and bound ACBP determined by FRET was 73 Å; (iv) double immunofluorescence labeling confocal microscopy FRET demonstrated an intermolecular distance of 53 Å between HNF4 $\alpha$  and bound ACBP in fixed cells; (v) double immunogold electron microscopy showed an intermolecular distance of 43 Å between HNF4 $\alpha$  and bound ACBP [120]. These molecular interactions were specific, since ACBP did not interact with/bind  $\beta$ -galactosidase (a cytosolic enzyme), Sp1 (a coregulator of nuclear receptors) and GR (glucocorticoid receptor in the nucleus). However, recent evidence from our laboratory indicates that HNF-4 $\alpha$  interacts with multiple LCFA-CoA binding proteins, not just ACBP, as demonstrated by in vitro FRET between fluorescent tagged L-FABP and HNF4 $\alpha$  as well as between ACBP and HNF4 $\alpha$  (not shown).

In summary, both indirect (coimmunoprecipitation, yeast two hybrid, mammalian two hybrid, transactivation) and direct (circular dichroism, FRET-based  $K_d$ s, FRET-based intermolecular distance in fixed cells, immunogold EM) binding assays show that ACBP interacts with select nuclear receptors (HNF4 $\alpha$ ). Again, the ligand-dependence of these interactions remains to be elucidated. Taken together, these studies indicate that ACBP may also selectively cooperate with a nuclear receptor (HNF4 $\alpha$ ), analogous to FABPs cooperating with nuclear receptors (PPARs), in providing a signaling pathway for LCFA metabolism.

#### Interaction Between Nuclear Receptors (HNF4 $\alpha$ , PPAR $\alpha$ ) and ACBP/FABP in Liver

If FABP/ACBP directly channel ligands to nuclear receptors, this could represent a significant mechanism of gene regulation. This direct association of ACBP with HNF-4 $\alpha$  would ensure HNF-4 $\alpha$  binding to LCFA-CoA while precluding the availability of LCFA-CoA for interaction with

**Fig. 4** Suggested modulation of HNF-4 $\alpha$  transactivation by specific acyl-CoA ligands, and acyl-CoA-binding proteins ACBP and L-FABP. The DNA sequence shown in the diagram is a specific response element in promoters of HNF-4 $\alpha$  target genes. AF-1, DBD, AF-2, LBD, F are HNF-4 $\alpha$  activation function 1 (ligand-independent), DNA-binding domain, activation function-2 (ligand-dependent), ligand binding domain, and F-regulatory domain at the C-terminus of HNF-4 $\alpha$  molecule, respectively. L, ACBP, L-FABP are denotations for ligands (saturated-round shape, or polyunsaturated-square shape), acyl-CoA binding protein and liver fatty acid binding protein, respectively. SRC-1/p300 are complexes of coactivators which contribute to increasing the transcription when recruited by HNF-4 $\alpha$  to the target gene promoter. SREBP-1 is a transcription factor reported to negatively regulate HNF-4 $\alpha$  transcription activity. In this model, it is assumed that depending on the structure of HNF-4 $\alpha$  ligand or on the interaction of HNF-4 $\alpha$  with ligand binding proteins like ACBP and L-FABP, the conformation of HNF-4 $\alpha$  is significantly altered—thereby resulting in recruiting of either coactivator complexes (such as SRC-1/p300) or corepressor transcriptional factors like (SREBP-1)

PPAR $\alpha$ . Since LCFA-CoA are endogenous, high-affinity ligands of both HNF-4 $\alpha$  [24] and PPAR $\alpha$  [2, 3], this would shift the balance of transcriptional regulation to HNF-4 $\alpha$ . The binding of saturated LCFA-CoA to HNF-4 $\alpha$  would result in increased HNF-4 $\alpha$  activity [24] and decreased PPAR $\alpha$  activity (due to lack of availability for binding and activation) [2], while unsaturated LCFA-CoA would decrease HNF-4 $\alpha$  activity and possibly increase or decrease PPAR $\alpha$  activity. Similarly, L-FABP binding to either PPAR $\alpha$  or HNF-4 $\alpha$  could provide a direct route of transport for both LCFA and LCFA-CoA, while ensuring that these ligands interacted exclusively with one nuclear receptor and preventing their interaction with the other.

Moreover, interaction of ACBP with HNF-4 $\alpha$ , both in the presence and absence of ligands, directly stimulates HNF-4 $\alpha$  transactivation [120], while ACBP inhibits PPAR $\alpha$  transactivation [62, 117]. Since HNF-4 $\alpha$  and PPAR $\alpha$  both regulate downstream transcription through the binding of similar DR1 sequences [43, 131], ACBP may again shift the transcriptional control to HNF-4 $\alpha$ , rather than PPAR $\alpha$ , by allowing preferential DNA binding by HNF-4 $\alpha$ . Given that HNF-4 $\alpha$  and PPAR $\alpha$  compete for the same co-activators and co-repressors (rev in [132]), cross-talk between these nuclear receptors could represent a pertinent tool for maintaining energy homeostasis in the liver, and FABP/ACBP may function to regulate this cross-talk.

#### *Interaction of Proteins within Nuclear Receptor/ Coregulator Complexes: HNF4 $\alpha$ , Coactivators, and Corepressors*

The interaction of HNF-4 $\alpha$  with ACBP (Fig. 4) and PPAR $\alpha$  with L-FABP (not shown) is thought to elicit downstream alterations in coactivator and corepressor protein association (Fig. 4). To date, however, there are very few if any data directly demonstrating the individual interactions between specific proteins in such complexes. A first approach to study multi-protein nuclear receptor complexes by triple immunolabeling confocal fluorescence microscopy and FRET (fluorescence resonance energy transfer) was applied to HNF4 $\alpha$ . Rat hepatoma cells in culture were demonstrated to express detectable amounts of HNF-4 $\alpha$ , coactivators of HNF4 $\alpha$  (SRC-1, p300) and corepressors of HNF4 $\alpha$  (SREBP-1) by Western blotting (not shown). Rat hepatoma cells were fixed and labeled with primary antibodies (rabbit anti-HNF-4 $\alpha$ , mouse anti-p300, mouse SREBP-1, goat anti-SRC-1) and with fluorescent dye-labeled secondary antibodies (i.e. FITC-anti-mouse IgG, Cy3-anti-rabbit IgG, Cy5-anti-goat IgG). If three proteins

are closely bound into a complex, by this technique it would be possible to detect Cy5 sensitized emission at 680 nm by excitation of FITC at 488 nm, as excitation of FITC at 488 nm could result in FRET from FITC to Cy3, which in turn would be followed by FRET from Cy3 to Cy5. Two examples demonstrate the feasibility of this approach.

First, triple immunolabeling confocal FRET imaging of fixed cells demonstrated specific physical complex formation between HNF4 $\alpha$  and coactivators (SRC-1 and p300) in fixed cells (Fig. 5). Excitation of FITC/p300 at 488 nm, resulted in: (i) a fluorescence image with emission at 530 nm from p300 molecules inside hepatoma cells (Fig. 5a); (ii) a FITC  $\rightarrow$  Cy3 FRET image with emission at 600 nm, from HNF-4 $\alpha$  molecules (Fig. 5b) due to close interaction of HNF-4 $\alpha$  with p300; (iii) a Cy3  $\rightarrow$  Cy5 FRET image with emission at 680 nm from SRC-1 molecules closely associated to HNF-4 $\alpha$  molecules (Fig. 5c). Images obtained with excitation of Cy3 at 568 nm and Cy5 at 647 nm are shown in Fig. 5d–i; by direct excitation of Cy3/HNF-4 $\alpha$  both HNF-4 $\alpha$  and SRC-1 molecules were detected, being associated within a FRET distance of less than 100 Å.

Second, triple immunolabeling confocal FRET imaging of fixed cells demonstrated that, in contrast to the coactivator p300, the corepressor SREBP-1 was not detected within a complex of HNF4 $\alpha$  with SRC-1 (Fig. 6). Thus, excitation of FITC/SREBP-1 resulted in a fluorescence emission image of SREBP-1 (Fig. 6a), a FRET image of Cy3/HNF-4 $\alpha$  (Fig. 6b) but not a further FRET image of Cy5/SRC-1 (Fig. 6c) suggesting that the cells contained HNF-4 $\alpha$  molecules that were complexed with SREBP-1, but these complexes did not contain SRC-1. Excitation of Cy3/HNF-4 $\alpha$  resulted in emission fluorescence image of HNF-4 $\alpha$  (Fig. 6e) and FRET image of SRC-1, indicating that a subpopulation of HNF-4 $\alpha$  molecules were associated with SRC-1; the fact that no FITC  $\rightarrow$  Cy3  $\rightarrow$  Cy5 FRET image from SREBP-1  $\rightarrow$  HNF-4 $\alpha$   $\rightarrow$  SRC-1 (Fig. 6a–c) was detected in panel C even though there were HNF-4 $\alpha$ /SRC-1 complexes, strongly indicates that SREBP-1 was not associated with HNF-4 $\alpha$  that was complexed with SRC-1. This was in agreement with previous publications reporting SREBP-1 as a negative coregulator of HNF-4 $\alpha$ , by reporter gene assays [133].

These triple-immunolabeling confocal imaging FRET studies illustrate for the first time the direct physical proximities of coactivators and corepressors with a nuclear receptor (HNF4 $\alpha$ ) involved in fatty acid and glucose metabolism. What remains to be done is to apply these approaches to resolve the effects of the LCFA-CoA binding proteins (ACBP, FABPs) on these intermolecular interactions.

**Fig. 5** Interaction of HNF-4 $\alpha$  with coactivators p300 and SRC-1. T-7 cells were labeled with primary antibodies against p300, HNF-4 $\alpha$  and SRC-1 and secondary antibodies conjugated to FITC, Cy3 and Cy5, respectively. **a** FITC/p300 detected with excitation at 488 nm; **b** Cy3/HNF-4 $\alpha$  detected with excitation of FITC at 488 nm, due to FRET; **c** Cy5/SRC-1 detected with excitation of FITC at 488 nm, due to double FRET. **d–f** show images in *green*, *red* and *blue* channels, respectively, when excited at 568 nm (for Cy3); fluorescence Cy5 in F is due to FRET; **g–i** show fluorescence images in channels *green*, *red* and *blue* channels, when excited at 647 nm (for Cy5)

**Fig. 6** Interaction of HNF-4 $\alpha$  with coactivator SRC-1 and corepressor SREBP-1. T-7 cells were labeled with primary antibodies against SREBP-1, HNF-4 $\alpha$  and SRC-1 and secondary antibodies conjugated to FITC, Cy3 and Cy5, respectively. **a** FITC/SREBP-1 detected with excitation at 488 nm; **b** Cy3/HNF-4 $\alpha$  detected with excitation of FITC at 488 nm, due to FRET; **c** Cy5/SRC-1 detected with excitation of FITC at 488 nm, due to double FRET. **d–f** show images in *green*, *red* and *blue* channels, respectively, when excited at 568 nm (for Cy3); fluorescence of Cy5 in F is due to FRET; **g–i** show fluorescence images in channels *green*, *red* and *blue* channels, when excited at 647 nm (for Cy5)

#### Direct Channeling of Ligands between FABPs and Nuclear Receptors

Several studies with purified proteins indicate that by binding to nuclear receptors, different FABPs may directly

channel bound ligands to the receptors. For example, CRABP-2 transfers bound retinoic acid (a poorly soluble nuclear regulatory ligand) to the nuclear receptor RAR in vitro [116] via transient collisional interactions (rev. in [4, 118, 119, 124]). Likewise, A-FABP directly channels

bound ligands to PPAR $\gamma$ , but K-FABP does not [116]. However, complexes of these proteins all appeared to be transient collisional interactions. Whether this is the case for interactions between other FABPs or ACBP with nuclear receptors remains to be shown.

## Summary/Conclusions

The past few years have seen great advances in our understanding of potential contributions of FABPs and ACBP to nuclear signaling mediated through PPARs, RAR, and HNF4 $\alpha$ . The overall picture that is emerging is illustrated by Fig. 2, Pathway 1. In this proposed scheme, FABPs and ACBP enhance uptake of lipidic ligands (LCFA, RA, and/or LCFA-CoA), bind these ligands with high affinity in the cytoplasm, cotransport this cargo to nuclei and through the nuclear pores into the nucleoplasm, form complexes with nuclear receptors exhibiting even higher affinity for the respective ligands, and directly channel this cargo to the respective nuclear receptors to regulate receptor activation. Thus, the FABPs and ACBP may act as nutrient sensors [1, 4, 5]. For example, LCFA-mediated PPAR $\alpha$  activation enhances L-FABP transcription (rev. in [23]) while PPAR $\alpha$  gene ablation reduces L-FABP expression, especially during fasting [13, 134, 135]. These data suggest that by transporting LCFA (or LCFA-CoA) to PPAR $\alpha$  in the nucleus, L-FABP may in part regulate its own expression (rev. in [5, 18]). These data suggest that other FABPs and ACBP may also in part regulate their own expression.

**Abstract** Whether neurosteroids regulate the synthesis of long chain polyunsaturated fatty acids in brain cells is unknown. We examined the influence of 17- $\beta$ -estradiol (E2) on the capacity of SH-SY5Y cells supplemented with  $\alpha$ -linolenic acid (ALA), to produce eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA) and docosahexaenoic acid (DHA). Cells were incubated for 24 or 72 h with ALA added alone or in combination with E2 (ALA + E2). Fatty acids were analyzed by gas chromatography of ethanolamine glycerophospholipids (EtnGpl) and phosphatidylcholine (PtdCho). Incubation for 24 h with ALA alone increased EPA and DPA in EtnGpl, by 330 and 430% compared to controls ( $P < 0.001$ ) and DHA by only 10% ( $P < 0.05$ ). Although DHA increased by 30% ( $P < 0.001$ ) in ALA + E2-treated cells, the difference between the ALA and ALA + E2 treatments were not significant after 24 h (Anova-1, Fisher's test). After 72 h, EPA, DPA and DHA further increased in EtnGpl and PtdCho of cells supplemented with ALA or ALA + E2. Incubation for 72 h with ALA + E2 specifically increased EPA (+34% in EtnGpl,  $P < 0.001$ ) and DPA (+15%,  $P < 0.001$ ) compared to ALA alone. Thus, SH-SY5Y cells produced membrane EPA, DPA and DHA from supplemental ALA. The formation of DHA was limited, even in the presence of E2. E2 significantly favored EPA and DPA production in cells grown for 72 h. Enhanced synthesis of ALA-elongation products in neuroblastoma cells treated with E2 supports the hypothesis that neurosteroids could modulate the metabolism of PUFA.

**Keywords** Docosahexaenoic acid · Eicosapentaenoic acid · Docosapentaenoic acid · Estradiol · Long-chain PUFA synthesis · Ethanolamine-glycerophospholipids · Phosphatidylcholine · Neuroblastoma cells

## Abbreviations

DHA	Docosahexaenoic acid (22:6n-3)
DPA	n-3 Docosapentaenoic acid (22:5n-3)
E2	17- $\beta$ estradiol
EPA	Eicosapentaenoic acid (20:5n-3)
ER	Estrogen receptors
EtnGpl	ethanolamine glycerophospholipids
ALA	$\alpha$ -Linolenic acid
MUFA	Monounsaturated fatty acids
PPAR	Peroxisome proliferator-activated receptors
PtdCho	Phosphatidylcholine
PtdSer	Phosphatidylserine
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
TEFA	Trienoic fatty acids
THA	Tetracosahexaenoic acid (24:6n-3)

## Introduction

Clinical and epidemiological studies suggest that both n-3 polyunsaturated fatty acids (PUFA) [1] and estrogens [2] influence memory and cognition and protect neurons from degenerative or inflammatory processes. Neonatal neuronal cells synthesize neurosteroids, in which they promote the dendritic growth, spinogenesis and synaptogenesis [3]. Steroid hormones also act as trophic factors in the brain

under a variety of normal and pathological conditions [4]. On the other hand, studies using stable isotope tracer methods in men and women (reviewed in Ref. [5]) and clinical studies in steroid-treated subjects [6, 7] have suggested that estrogens regulate the metabolic fate of the essential PUFA, 18:3n-3 ( $\alpha$ -linolenic acid, ALA) and 18:2n-6 (linoleic acid, LA), i.e., their  $\beta$ -oxidation to acetylCoA or their conversion into long-chain derivatives. The end product of ALA metabolic conversion, docosahexaenoic acid (DHA, 22:6n-3) is the major structural and functional n-3 PUFA in the membranes of brain and retinal cells (reviewed in Ref. [8, 9]). One notable effect of DHA at the cellular level, comparable to that of neurosteroids, is to activate the expression of neuronal differentiation genes and to stimulate the neurite outgrowth [10, 11].

DHA is supplied directly by dietary fats rich in long-chain n-3 PUFA (fat fishes and marine oils), or by hepatic synthesis [12] through successive desaturations and elongations of ALA. Upstream of DHA, the conversion of ALA produces two major membrane long-chain derivatives, eicosapentaenoic acid (EPA, 20:5n-3) and n-3 docosapentaenoic acid (n-3 DPA or DPA, 22:5n-3). In normal physiological conditions, EPA and DPA do not accumulate in the brain, contrary to DHA. It has been demonstrated in rodents that the extent to which the liver produces and delivers ALA-derived DHA to the brain (and other tissues) depends on the concentration of DHA in the diet [13, 14]. Brain endothelial cells and glial cells may also provide neurons with newly formed DHA, suggesting that synthesis of long-chain n-3 PUFAs is a constitutive process in the brain [15–17]. Whether estrogens and neurosteroids regulate the brain lipid metabolism and the balance of long-chain PUFA in neural membranes is unknown.

The extent to which dietary ALA contributes to the n-3 long-chain PUFA status in brain tissue throughout a human's life remains to be clarified. Stable isotope tracer studies in human adults suggest that only a small percentage of the ingested ALA that is not stored or oxidised is available for conversion to DHA [18–20]. In this respect, gender-related differences may be particularly informative since less ALA appeared to be converted to DHA in men than in women [21–23]. This is supported by the observation that there are compositional differences in the blood lipids of men and women that are not due to dietary habits; women have higher DHA concentrations in plasma phosphatidylcholine, triacylglycerol and non-esterified fatty acids than do men [24]. Actually, EPA and DPA are the principal metabolic products of orally-administered ALA in the blood of young men [21]. Moreover, differences in DHA status of pregnant women at varying gestational ages suggest that changes in the hormonal status may produce

variations in metabolic capacity for long-chain PUFA synthesis [25, 26]. Changes in the blood lipid fatty acid compositions of human adults after steroid treatment also suggest that estrogens promote the metabolic conversion of PUFA [6, 7]. In summary, it is suggested that steroid hormones like estrogen regulate the metabolic fate of ALA through its partitioning between anabolic and catabolic pathways (reviewed in Ref. [5]).

We have shown that n-3 PUFA metabolism in human neuroblastoma SH-SY5Y cells reflects the physiological limitation of DHA synthesis [27]. This study uses the same model to determine whether 17- $\beta$ -estradiol (E2), the most potent biological form of estrogen, promotes ALA conversion into membrane long-chain derivatives. We examined the effect of E2 on the incorporation of ALA-elongation products in phospholipids of growing cells. Neuroblastoma cells in culture are spontaneously depleted in DHA, and they respond to graded concentrations of non-esterified DHA by increasing their membrane DHA to physiological values [28]. These cells also increase their membrane EPA, DPA and DHA in response to supplemental ALA, though the maximum incorporation of ALA-derived DHA into phospholipids is 70% lower than that of supplemental DHA dosed at matched concentrations [27]. Since the SH-SY5Y cells can produce membrane EPA, DPA and DHA from supplemental ALA, this model is convenient for studying the regulation of long-chain n-3 synthesis. In this study, we examined the capacity of E2 to modulate the restoration of long-chain n-3 PUFAs in the membrane phospholipids of growing cells supplemented with ALA.

## Experimental Procedure

### Culture

SH-SY5Y cells were obtained from the European Collection of Animal Cell Culture (Porton Down, Salisbury, UK). Cells were plated out on 75-cm<sup>2</sup> flasks, grown for 3 days in DMEM with 10% FCS, and incubated for 24 or 72 h with 10 ml of this medium containing the E2-vehicle (CTRL), 10 nM E2 alone (E2), 30  $\mu$ M ALA alone (ALA), or E2 plus 30  $\mu$ M ALA (ALA + E2). In the group ALA + E2, E2 was dosed at two concentrations, 0.5 or 10 nM. The sodium salts of ALA (Nu-Chek Prep, Elysian, MN, USA) were directly dissolved in the medium at 37 °C [28, 29]. E2 in the parent solution was dissolved in ethanol (vehicle); the final concentration of ethanol in all batches was equal to 0.1% (preliminary trials with control cultures in 10% FCS showed that ethanol had no effect at this concentration on cell growth and phospholipid fatty acid composition).

## Lipid Analysis

Membrane fatty acid compositions were analyzed on triplicate flasks. The composition of each flask was determined by capillary gas chromatography of the ethanolamine-glycerophospholipids (EtnGpl) and the phosphatidylcholine (PtdCho). The phosphatidylserine (PtdSer) was also analyzed in control cells. The cells were trypsinized, harvested by centrifugation and washed with phosphate buffer saline (PBS) containing 50  $\mu\text{M}$  fatty acid-free albumin (Sigma Chimie, Saint Quentin Fallavier, France) to remove free fatty acids. The total lipids were extracted from one volume of cell homogenate with four volumes of chloroform/methanol (2:1, by vol) in the presence of 0.005 % (by weight) butyl-hydroxytoluene (BHT). The lipid bottom phase was washed, dried, solubilized in chloroform and stored at  $-80\text{ }^{\circ}\text{C}$  until separation of phospholipid classes by solid-phase extraction on 500 mg-prepacked aminopropyl cartridges (J.T. Baker, Deventer, The Netherlands) [28, 29]. The cartridges were equilibrated beforehand with eluent I (isopropanol/chloroform, 1:2, by vol). Each sample of total lipids was dried under nitrogen, resolubilized in 250  $\mu\text{l}$  of eluent I and deposited onto a single-use cartridge, which was immediately eluted successively with 3 ml of eluent I, 3 ml of diethylether/acetic acid (98:2, by vol), 1 ml of acetonitrile, 8 ml of acetonitrile/*n*-propanol (3:1, by vol) to recover the phosphatidylcholine (ChoGpl) fraction, and then with 2 ml of acetonitrile/*n*-propanol (1:1, by vol) and 3 ml of methanol to recover the EtnGpl fraction (the latter consisted in a mixture of phosphatidylethanolamine and 1-*O*-alkylenyl-2-acyl glycerophosphoethanolamine). The PtdSer fraction was recovered by eluting with isopropanol/methanolic HCl (4:1, vol/vol). The three phospholipid fractions were dried under a nitrogen flux and transmethylated by methanol at  $90^{\circ}\text{C}$  in the presence of  $\text{BF}_3$ . The fatty acid methyl esters were extracted, washed and injected through the on-column injector of a gas chromatograph equipped with a retention gap and a CP-WAX 52 CB bonded fused-silica capillary column of a 0.25 mm i.d. and 60-m length (Varian, Les Ullis, France). The oven temperature was programmed for 79–212  $^{\circ}\text{C}$ , at a heating rate of 4  $^{\circ}\text{C}/\text{min}$ . The instrument responses attributable to fatty acid methyl esters (excluding dimethylacetals) were automatically integrated in proportion to their masses, and their factor response and Kovats's equivalent chain length (ECL) were compared with standard compounds. The fatty acid methyl ester of 20:3n-9 (ECL =  $20.6 \pm 0.05$ ) was identified by reference to the peak specifically found in liver phospholipids of n-3 deficient rats (routinely reared in our laboratory). The corresponding elongation product, 22:3n-9, was identified in the cell phospholipids by comparing the ECL value of this peak to the ECL of 20:3n-9 incremented by two points (ECL of 22:3n-9 =  $22.6 \pm 0.05$ ).

## Statistical Analysis

We used “Statview + Graphics” software (Abacus Concepts Inc., Berkeley, CA, USA). Means were compared by one way-analysis of variance followed by post hoc analysis. Fisher multiple comparison test was used to compare differences in fatty acid contents among the eight treatments, each of the different group defining one item of one category, the treatment category (anova-1), i.e., CTRL, E2, ALA and ALA + E2 at 24 and 72 h, respectively.

## Results

### Distribution of n-3 Long-chain PUFA in Cell Phospholipids

The concentrations of EPA, DPA and DHA in the EtnGpl, PtdSer and PtdCho fractions of cells grown for 72 h in standard conditions are reported in Fig. 1. The sum EPA + DPA + DHA accounted for  $140 \pm 8$  mmol/mol of EtnGpl,  $75.5 \pm 8.6$  mmol/mol of PtdSer and  $15.3 \pm 1.6$  mmol/mol of PtdCho. Thus, the EtnGpl fraction from control cells contained 1.8- and 9.1-times more n-3 long chain PUFAs than PtdSer and PtdCho. DHA was the major n-3 long-chain PUFA in EtnGpl ( $95 \pm 8.7$  mmol DHA/mol of EtnGpl, or  $4.75 \pm 0.4$  mol DHA %). In the PtdSer fraction, EPA (25 mmol/mol PtdSer or 1.25 mol %), DPA (21 mmol/mol PtdSer or 1.05 mol %) and DHA (29 mmol/mol PtdSer or 1.45 mol %) were distributed almost equally (Fig. 1). Thus, the EtnGpl fraction of SH-SY5Y cells contained 1.8-time more n-3 long-chain PUFAs and three times more DHA than PtdSer. Owing to this specific composition, we focused on the impact of E2 and ALA supplementation within the EtnGpl fraction.

### Effect of Culture Stage on the Standard Phospholipid Fatty Acid Composition

The duration of culture changed the fatty acid composition in non-supplemented cells cultured for 24 or 72 h with 10% FCS. In the EtnGpl fraction (Table 1, CTRL-72 h vs. CTRL-24h), there was a significant increase of 18:1n-9 (+29%), 18:1n-7 (+18%) and of the n-9 long-chain trienoic fatty acids (TEFA), 20:3n-9 (+115%) and 22:3n-9 (+20%). The total n-6 fatty acids decreased by 24%, mainly 22:4n-6 (–39%) and 22:5n-6 (–33%). The n-3 fatty acids also tended to decrease with the duration of culture (not significant at  $P < 0.001$ ). In the PtdCho fraction (Table 2, CTRL-72 h vs. CTRL-24 h), the 18:1n-9 content also increased by 29%, and that of 16:1n-9 by 12%, while the n-6 fatty acids decreased by 39%. The increase of MUFA in PtdCho was

**Fig. 1** Distribution of the n-3 long-chain PUFAs in the EtnGpl, PtdSer and PtdCho fractions of SH-SY5Y cells grown for 72 h in a medium containing 10% FCS. Values are expressed in mmol of fatty acid/mol of phospholipid

mainly compensated by a decrease of the major saturated fatty acids, 16:0 (–15%) and 18:0 (–7%). These data show that, in the absence of ALA supplementation, the status in EPA, DPA and DHA did not “spontaneously” improved with the duration of culture. However, it is noteworthy that the n-9 TEFA increased, indicating that the SH-SY5Y cells have the constitutive capacity to produce  $\Delta$ 6- and  $\Delta$ 5-desaturated long-chain fatty acids.

#### Response of Cells to ALA Alone

Cells responded to 24 h incubation with 30  $\mu$ M ALA by increasing EtnGpl the two main elongation-products of ALA, EPA (+330%,  $P < 0.001$ ) and DPA (+430%,  $P < 0.001$ ) (Table 1, ALA-24 h vs. CTRL-24h). The DHA content also increased by 10% (significant only at  $P < 0.05$ , not reported in Table 1). After 72 h of incubation with 30  $\mu$ M ALA alone, EPA had increased by 780% ( $P < 0.001$ ), DPA by 850% ( $P < 0.001$ ) and DHA by 65% ( $P < 0.001$ ) (Table 1, ALA-72 h vs. CTRL-24 h). Thus, the growing cells had markedly increased their production of membrane EPA, DPA and DHA throughout the 72 h incubation with supplemental ALA. The increase of EPA, DPA and DHA mainly occurred at the expense of the n-9 TEFA (–38 and –51% at 24 and 72 h, respectively, compared with CTRL-24 h) and of n-6 PUFA (–20 and –55%). The same significant changes were observed in the PtdCho

fraction (Table 2); in comparison with control cells cultured for 24 h, EPA increased in the PtdCho of ALA-supplemented cells by 900 and 1,000% at 24 and 72 h, respectively, DPA by 567 and 1,130%, and DHA by 22 and 67%. These data clearly indicate that SH-SY5Y cells are able to synthesize all the long-chain n-3 fatty acids from the precursor ALA and strongly suggest that the production of neoformed DHA is limited in comparison with that of EPA and DPA.

#### Effect of E2 on the Response of Cells to ALA

The incubation of cells for 24 or 72 h with 0.5 nM E2 (data not shown) or 10 nM E2 alone had no effect on EPA, DPA and DHA (Table 1, E2-24 h vs. CTRL-24 h, and E2-72 h vs. CTRL-72 h). By itself, E2 had no significant impact on the fatty acid profile in non-supplemented cells.

The incubation with 30  $\mu$ M ALA and 10 nM E2 during 24 h led to a significant increase (+30%,  $P < 0.001$ ) of DHA in EtnGpl (Table 1, ALA + E2-24 h vs. E2-24 h). As stated in the above paragraph, DHA increased by only 10% ( $P < 0.05$ ) upon incubation with ALA alone (Table 1, ALA-24 h vs. CTRL-24 h, not significant at  $P < 0.001$ ). Thus, E2 produced a small gain of neoformed DHA upon the 24 h treatment with ALA + E2, though the difference in DHA between the two groups (ALA + E2 vs. ALA alone) was not significant at  $P < 0.001$  (Table 1). In brief, the sole effect of E2 after 24 h was to improve the statistical level of significance of the DHA increase observed in cells supplemented with ALA compared to non-supplemented cells.

The incubation with ALA + E2 resulted after 72 h in a further increase of EPA (+34%) and DPA (+15%) compared to cells incubated with ALA alone (Table 1, ALA + E2-72 h vs. ALA-72 h). However, there was no additional effect on DHA upon incubation with ALA + E2 compared to incubation with ALA alone (Table 1, ALA + E2-72 h vs. ALA-72 h). Therefore, E2 differentially promoted the production of the different ALA-derived long-chain fatty acids. E2 mainly increased EPA and DPA after 72 h.

The individual data of EPA, DPA and DHA are presented under a piled form in Fig. 2. The upper panel of Fig. 2 shows that incubation of cells for 72 h with 30  $\mu$ M ALA and 10 nM E2 induced the sum EPA + DPA + DHA to increase ( $P < 0.001$ ) in comparison with incubation with ALA alone. This gain in n-3 long-chain PUFAs affected EPA and DPA, not DHA. The same trend was observed at 72 h with the dose of 0.5 nM E2, although it did not reach a significant level. The lower panel of Fig. 2 shows that the TEFAs decreased with ALA supplementation and further decreased in the presence of 0.5 or 10 nM E2 ( $P < 0.04$ ),

**Table 1** Fatty acid composition (mol%) in EtnGpl of cells incubated for 24 or 72 h with vehicle, 30  $\mu$ M ALA, 10 nM E2, or 30  $\mu$ M ALA plus 10 nM E2 (mean  $\pm$  SD;  $n = 3$  flasks per treatment)

which indicated that cells responded to ALA + E2 treatment by decreasing the production of n-9 TEFAs and by increasing that of ALA-elongation products. Since ALA + E2 modified in an opposite manner the production of long-chain n-3 PUFAs and that of n-9 TEFAs, we used the ratio of the sum [EPA + DPA + DHA] to the sum [20:3n-9 + 22:3n-9] as a biochemical marker of the propensity of ALA-supplemented cells to produce membrane long-chain n-3 PUFAs. The values of the  $\Sigma$ n-3/ $\Sigma$ TEFA ratio are reported in Fig. 3. The figure shows that combining ALA supplementation, incubation with E2 and prolongation of treatment produced the greatest increase ( $P < 0.005$ ) of this ratio, both in EtnGpl and PtdCho.

## Discussion

We studied the effect of estradiol on the conversion of ALA to long-chain products by neuroblastoma cells. The

results on ALA supplementation in growing SH-SY5Y cells support our previous data that ALA is efficiently converted into EPA, DPA and DHA [27]. We had previously shown that the formation of membrane DHA occurs only within a very restricted range of concentration of its upstream precursors (either ALA, EPA or DPA), whereas that of DPA from ALA or EPA follows a saturating dose-response pattern [27]. Moreover, it has been shown in primary culture that rat astrocytes dosed with ALA incorporate DPA into their membranes, not DHA [30]. The response of SH-SY5Y cells to ALA is thus particularly efficient, although their membrane incorporation of neoformed DHA is readily limited in comparison with that of DPA. We suggested that the formation of DHA in these cells is constitutively limited, or possibly submitted to down-regulation [27].

In physiological conditions, endogenous DPA is produced in the endoplasmic reticulum by successive desaturations and elongations of ALA. DPA is further

SFA saturated fatty acids, MUFA monounsaturated fatty acids, TEFA trienoic fatty acids

elongated and desaturated into tetracosahexaenoic acid (THA, 24:6n-3) that moves to peroxisomes and is shortened into DHA by one cycle of  $\beta$ -oxidation (Sprecher's pathway) [31, 32]. We have suggested that limitation of the peroxisomal step of DHA synthesis could account for the membrane accretion of its upstream metabolites, EPA and DPA [27]. In contrast, the incorporation of supplemental DHA into SH-SY5Y cell phospholipids follows a dose-response saturation curve that is comparable to the curve of DHA repletion in the brain of newborn rats deprived of n-3 fatty acids and fed after weaning a diet enriched in microalgal DHA [28]. Therefore, the uptake and phospholipid acylation of preformed DHA is fully operational in SH-SY5Y cells, whereas the terminal synthesis of DHA is limited, possibly at the peroxisomal step. The present study addressed the question of the estrogen action on the conversion pathway.

In cells incubated with ALA alone compared to non-supplemented cells, DHA increased in EtnGpl by 10%

( $P < 0.05$ ) after 24 h and by 104% ( $P < 0.001$ ) after 72 h. In the presence of 10 nM E2, the neoformed DHA increased in comparison with matched control cells by 30 and 110%, at 24 and 72 h, respectively ( $P < 0.001$ , Table 1). In the PtdCho fraction, DHA increased after 24 h by 22 and 44%, in the absence and in the presence of E2, respectively, and by 200 and 325% after 72 h. Thus, E2 slightly enhanced the formation of ALA-derived DHA in cells cultured for 24 h, though the combination of ALA with E2 did not produce a greater content in membrane DHA compared to supplementation with ALA alone. Moreover, the impact on DHA was weak and transient, since E2 did not favor higher DHA content after 72 h. It clearly appeared that prolongation of incubation (from 24 to 72 h) with ALA resulted by itself in a more marked increase of membrane DHA. However, the prolongation of incubation also resulted in the membrane accretion of EPA and DPA, and E2 at 10 nM augmented this time-dependent effect. In parallel, the n-9 TEFAs decreased with the

**Fig. 2** Distribution of n-3 long-chain PUFAs (*upper panel*) and n-9 TEFA (*lower panel*) in EtnGpl of SH-SY5Y cells cultured for 24 or 72 h in a medium containing 10% FCS and 30  $\mu$ M ALA used alone or in combination with 0.5 or 10 nM E2. Values are expressed in mol% of total fatty acids in EtnGpl (see Table 1 for individual mean values and SD). Different superscripts correspond to significant differences in the sum of n-3 PUFAs (*upper panel*,  $P < 0.001$ ) or in the sum of n-9 TEFA (*lower panel*,  $P < 0.04$ )

prolongation of incubation with ALA, and E2 accentuated this decrease. We propose to use the ratio of the sum of n-3 long-chain products to the sum of n-9 TEFAs as a biochemical marker of the restoration of the n-3 status in cultured cells. The ratio values were almost identical in EtnGpl and PtdCho (insert of Fig. 3); therefore it may be supposed that changes of this ratio in membranes reflect sizeable metabolic changes in cells. The data reported in Fig. 3 clearly show that incubation with ALA restored the n-3 PUFAs status in a time-dependent manner and that the combination of ALA with E2 produced the highest “ratio

**Fig. 3** Values of the sum of n-3 long-chain PUFAs to the sum of n-9 TEFA ratio in EtnGpl of cells cultured for 24 or 72 h in a medium containing 10% FCS and 30  $\mu$ M ALA used alone or in combination with 10 nM E2. Different superscripts correspond to different ratio values ( $P < 0.005$ ). The insert illustrates the correlation between the ratio values in PtdCho and EtnGpl

of restoration”. With a ratio value of 1, the non-supplemented cells must be considered as being deficient in n-3 long-chain PUFAs; the ratio increased four times after 24 h of incubation with ALA, eight times after 72 h (time effect) or 12-times when cells were exposed to ALA + E2 during 72 h. In summary, the increase of EPA and DPA was the major change induced by E2 after 72 h incubation of cells with ALA and E2. Although E2 favored the production of membrane EPA and DPA, its effect was not sufficient to complete that of DHA. Mitochondrial oxidation of ALA could not account for the limited production of neoformed DHA since supplemental ALA was efficiently converted into EPA and DPA (ALA was not more degraded in the presence of E2 than in its absence). The whole data suggest that E2 mainly produced the progressive membrane accumulation of the major upstream metabolic precursors of DHA, EPA and DPA.

The growing SH-SY5Y cells are able to incorporate preformed (non-esterified) DHA in their phospholipids. We previously showed that the maximum incorporation of preformed DHA into neuroblastoma cell phospholipids matches that of rat brain membranes [28]. Therefore, the limitation in membrane DHA production does not seem to be due to alteration of acylCoA synthesis or to impairment of esterification into phospholipids. We assume that production of membrane DHA is limited at the stage of DHA terminal synthesis, possibly at the peroxisomal step. The peroxisomal shortening of THA to DHA involves complex trafficking of the very long-chain acylCoA between the endoplasmic reticulum and the peroxisomes [32], which could be impaired in SH-SY5Y cells. We have previously

shown that the SH-SY5Y cells express the mRNAs encoding for the main enzymes of peroxisomal  $\beta$ -oxidation, though the mRNA abundances of the L- and D-bifunctional peroxisomal proteins were particularly low in standard conditions of culture [27]. We suggested that the low expression of proteins or enzymes related to the peroxisomal function could form a “metabolic bottleneck”. In this respect, hormonal, coactivators or other environmental signals including stimulants of peroxisomal activities would be necessary for completing the DHA synthesis in these cells.

#### Putative Mode of Action of E2

Estrogens exert their action on cell functions through genomic and non-genomic pathways. E2 binds to specific nuclear receptors (estrogen receptors, ER) which dimerize and directly bind to response elements of DNA; E2 may also interact with membrane receptors coupled to the activation of protein G-dependent kinases, producing changes in gene expression through the recruitment of other transcription factors (reviewed in [33]). A broad range of E2-responsive genes can be regulated by these mechanisms, including those involved in brain functions (reviewed in [34]). Our hypothesis is that changes in the transcription of lipid metabolism genes could account for the effect of E2 on the production of membrane n-3 long-chain PUFAs in ALA-supplemented cells. The transcription of most of these genes, notably those encoding desaturases [35, 36] and peroxisomal enzymes [37–39], are regulated by nuclear receptors which are recruited to the target promoters upon the binding of exogenous compounds (peroxisome proliferators) or of endogenous ligands (PUFA and PUFA-derived signaling molecules). We have shown that the mRNAs of the three peroxisome proliferator-activated receptors (PPAR) isoforms ( $\alpha$ ,  $\beta/\delta$  and  $\gamma$ ) are expressed in SH-SY5Y cells [27], and unpublished results from our laboratory indicated to us that the ER $\beta$  isoform (*ESR2* human gene) is also expressed in these cells. Numerous studies have shown that complex cross-talks exist between the PPAR and ER signaling pathways, depending on the gender [40–42] and on tissue or cell specificity [43–45]. There is also evidence that transcription of PPAR $\alpha$  itself can be triggered by E2 [46]. On the other hand, chemical agonists of PPAR $\alpha$  have been shown to alter the expression of estrogen-metabolizing enzymes, notably the 17- $\beta$ -hydroxysteroid dehydrogenase type IV (*17BHS-4* human gene) [47]. It must be emphasized that the 17BHS-4 gene product, also known as D-bifunctional protein or multifunctional protein-2, is that involved in the peroxisomal  $\beta$ -oxidation of both estradiol and very long-chain fatty acids [48, 49], and precisely in the  $\beta$ -oxidation

of THA to DHA [50–52]. It is tempting to speculate that an E2-dependent stimulation of the PPAR-signaling pathway may modulate the membrane fatty acid composition through changes in the expression of PUFA metabolizing genes. In conclusion, our data suggest that estradiol is able to modulate the upstream production of membrane n-3 long-chain PUFA by neural cells in culture.

**Abstract** Healthy term infants ( $n = 244$ ) were randomized to receive: (1) control, soy-based formula without supplementation or (2) docosahexaenoic acid–arachidonic acid (DHA + ARA), soy-based formula supplemented with at least 17 mg DHA/100 kcal (from algal oil) and 34 mg ARA/100 kcal (from fungal oil) in a double-blind, parallel group trial to evaluate safety, benefits, and growth from 14 to 120 days of age. Anthropometric measurements were taken at 14, 30, 60, 90, and 120 days of age and 24-h dietary and tolerance recall were recorded at 30, 60, 90, and 120 days of age. Adverse events were recorded throughout the study. Blood samples were drawn from subsets of 25 infants in each group. Capillary column gas chromatography was used to analyze the percentages of fatty acids in red blood cell (RBC) lipids and plasma phospholipids. Compared with the control group, percentages of fatty acids such as DHA and ARA in total RBC and plasma phospholipids were significantly higher in infants in the DHA + ARA group at 120 days of age ( $P < 0.001$ ). Growth rates did not differ significantly between feeding groups at any assessed time point. Supplementation did not affect the tolerance of formula or the incidence of adverse events. Feeding healthy term infants soy-based formula supplemented with DHA and ARA from single cell oil

sources at concentrations similar to human milk significantly increased circulating levels of DHA and ARA when compared with the control group. Both formulas supported normal growth and were well tolerated.

### Introduction

Docosahexaenoic acid (22:6 $\omega$ 3; DHA) and arachidonic acid (20:4 $\omega$ 6; ARA) are long-chain polyunsaturated fatty acids (LCPUFAs) that accumulate rapidly in the brain from the last trimester of fetal gestation until at least 2 years of age [1, 2]. Human breast milk provides DHA and ARA for growth as well as retinal and central nervous system development and function [3–7]. Infants unable to breast-feed or weaned from breastfeeding now benefit from supplementation of DHA and ARA in many commercial infant formulas. Supplementation of DHA and ARA from single cell algal and fungal sources at median worldwide human milk levels [8–10] in both premature and term infants has resulted in red blood cell (RBC) concentrations of the LCPUFAs comparable to those of breast-fed infants [11–13]. Clinical evidence of improved visual acuity and cognitive development in term infants up to 18 months of age [12, 14–18] and enhanced growth in premature infants [19, 20] has resulted from inclusion of DHA and ARA at worldwide human milk levels in milk-based formulas. In addition, a follow-up study of 4-year-olds who received formula supplemented with DHA and ARA at those levels as infants, demonstrated visual and IQ maturation similar to that of breast-fed subjects [7].

Not all infants can tolerate a cow's milk-based formula, and some parents prefer a vegetarian product. Primary clinical indications for discontinued use of cow's milk-based formula include immunoglobulin E-mediated milk allergy (commonly associated with eczema), documented lactose intolerance following infectious diarrhea, lactase deficiency, and galactosemia [21, 22]. In such instances, soy-based formulas have been endorsed by The American Academy of Pediatrics as a safe and effective alternative [21]. An estimated 25–36% of formula-fed infants in the United States receive a soy-based infant formula at some time in the first year of life [21, 22].

To date, no published data are available for supplementation of soy-based infant formula with DHA and ARA. Given the extensive use of soy-based formulas and the developmental advantages afforded by routine supply of exogenous DHA and ARA in cow's milk-based formulas, we felt it prudent to examine the growth, tolerance, and possible benefits of supplementation in a soy-based matrix. In this study we examined the effects of a soy-based formula supplemented with single cell oil sources of DHA and ARA at worldwide human milk levels on growth, tolerance, and the percentage of DHA and ARA (i.e., vegetarian sources) in RBCs and plasma phospholipids when fed to term infants from 14 to 120 days of age.

## Experimental Procedure

### Subjects

Healthy term infants were recruited at 13 pediatric centers in the United States for a double-blind, randomized, controlled parallel group study. Eligible participants were 12–16 days of age, had a minimum birth weight of 2,500 g, and solely received formula at least 24 h prior to randomization. Exclusion criteria included: history of underlying disease or malformation that could interfere with growth and development; large-for-gestational-age infants whose mothers were diabetic; breastfeeding within 24 h prior to randomization; evidence of formula intolerance or poor intake at time of randomization; weight at randomization less than 98% of birth weight; enlarged liver or spleen; or plans to move outside of the study area within the study time frame (120 days).

Parents or guardians provided written informed consent prior to enrollment. The research protocol and informed consent forms adhered to the Declaration of Helsinki (including the October 1996 amendment) and were approved by the institutional review board/ethics committee of each participating institution. The study was conducted in compliance with good clinical practices.

### Study Protocol

Two hundred and forty-four infants (control,  $n = 120$ ; DHA + ARA,  $n = 124$ ) enrolled in the study were stratified by gender and randomized to receive one of two formulas: (1) control, soy formula without supplementation (Enfamil ProSobee<sup>®</sup>, Mead Johnson & Company, Evansville, IN) or (2) DHA + ARA, soy formula supplemented with a minimum of 17 mg DHA/100 kcal from algal oil and 34 mg ARA/100 kcal from fungal oil (Enfamil ProSobee<sup>®</sup> LIPIL<sup>®</sup>, Mead Johnson & Company, Evansville, IN). Aside from the addition of DHA and ARA, the formulas were identical in all other respects. The supplemented levels of DHA and ARA were similar to reported median amounts of DHA (~0.3% by weight of fatty acids) and ARA (~0.6%) found in human milk worldwide [8–10].

Infants received study formulas from 14 to 120 days of age. Body weight and length, head circumference, and atopic dermatitis scores were recorded at 14, 30, 60, 90, and 120 days of age. Evidence of atopic dermatitis was determined using the SCORAD index [23] which quantifies the extent, distribution, and severity of rashes and the presence and severity of associated itching and sleep loss. Parents or guardians completed a family history of allergy and a survey of possible factors in the home and child care environments that might affect the infant's risk of atopy, such as cigarette smoke, pets, dust, and mold. At each study visit following initial enrollment at 14 days of age, parents or care givers completed a questionnaire on dietary intake and tolerance from the previous 24 h. Adverse events were monitored throughout the study period.

### Blood Sample Analysis

At five investigative sites, blood samples from a subset of infants (25 per group) were collected by venipuncture into EDTA Vacutainer tubes at 14 and 120 days of age. Only sites with experience handling clinical blood samples and appropriate sample storage facilities provided blood samples. For fatty acid analysis, plasma and RBC were separated by centrifugation and frozen. Samples were shipped on dry ice to the Retina Foundation of the Southwest (Dallas, TX) where lipids were isolated, fractionated, and analyzed by capillary column gas chromatography as previously described [12]. Fatty acid methyl esters from RBC lipids and plasma phospholipid fractions were expressed as a percentage of total fatty acids by weight. Outcomes were expressed as percentages of DHA, ARA, and other fatty acids in RBC phosphatidylethanolamine (PE) and phosphatidylcholine (PC) fractions, total RBC lipids, and plasma phospholipids. A portion of

the blood sample was also used for comprehensive metabolic panel of blood chemistry analyses including glucose, cholesterol, triglycerides, electrolytes, and kidney, liver, and pancreas function markers.

### Statistical Analysis

Statistical comparisons were made between control and DHA + ARA formula groups. Analyses were performed using SAS version 8 (Cary, NC). Weight gain from 14 to 120 days was the primary outcome used to establish that formulas supported adequate growth. The sample size was chosen to be able to detect a 3 g/day difference in weight gain with 80% power ( $\alpha = 0.05$ ; one-tailed). For all subsequent comparisons,  $P$  values are based on two-tailed tests. Analysis of variance was used to analyze formula intake, stool frequency and characteristics, anthropometrics (achieved growth, length, and head circumference), SCORAD grade, and blood lipid and chemistry data. Analysis of covariance was used to analyze growth rate. Race, gender, family history of allergy, home and child care environments, study discontinuation rate, and adverse events were analyzed by Fisher's Exact test. The van Elteren test, stratified by study site, was used to analyze metabolic blood panel results.

## Results

### Infants

Of the original 244 infants enrolled, three infants (control,  $n = 2$ ; DHA + ARA,  $n = 1$ ) did not receive study formula and were excluded from subsequent analyses. At study entry (14 days of age) infants in the control group were significantly heavier and longer than those in the DHA + ARA group (Table 1), although head circumference did not differ significantly between groups. Groups were similar for race and gender distribution, family history of allergy, and home and child care environments (data not shown). A total of 182 infants (control,  $n = 86$ ; DHA + ARA,  $n = 96$ ) completed the study.

**Table 1** Infant characteristics at study entry

	Control	DHA + ARA
Total number of subjects	118	123
Number of male/female	66/52	67/56
Weight (g) <sup>a</sup>	3,677.8 ± 45	3,575.4 ± 44*
Length (cm) <sup>a</sup>	52.3 ± 0.2	51.8 ± 0.2*
Head circumference (cm) <sup>a</sup>	36.1 ± 0.1	35.8 ± 0.1

<sup>a</sup> Mean ± standard error

\* Significant difference between groups,  $P < 0.05$

### Growth and Tolerance

Growth rate, as assessed by mean daily gains of weight, length, and head circumference, did not differ statistically between groups from 14 to 120 days of age (Table 2). The mean achieved weight was significantly higher for infants in the control versus the DHA + ARA group at 30 and 90 days of age ( $P < 0.05$ ; data not shown). The mean achieved weight for males (Fig. 1, upper panel) and females (lower panel) in both formula groups, however, fell between the 25th and 75th percentile of normal infant weight-for-age when plotted on the US Centers for Disease Control (CDC) standard growth chart [24]. Mean achieved length was higher for infants in the control group at all time points ( $P < 0.05$ ; data not shown) and mean achieved head circumference did not differ significantly between groups at any assessed time point (data not shown).

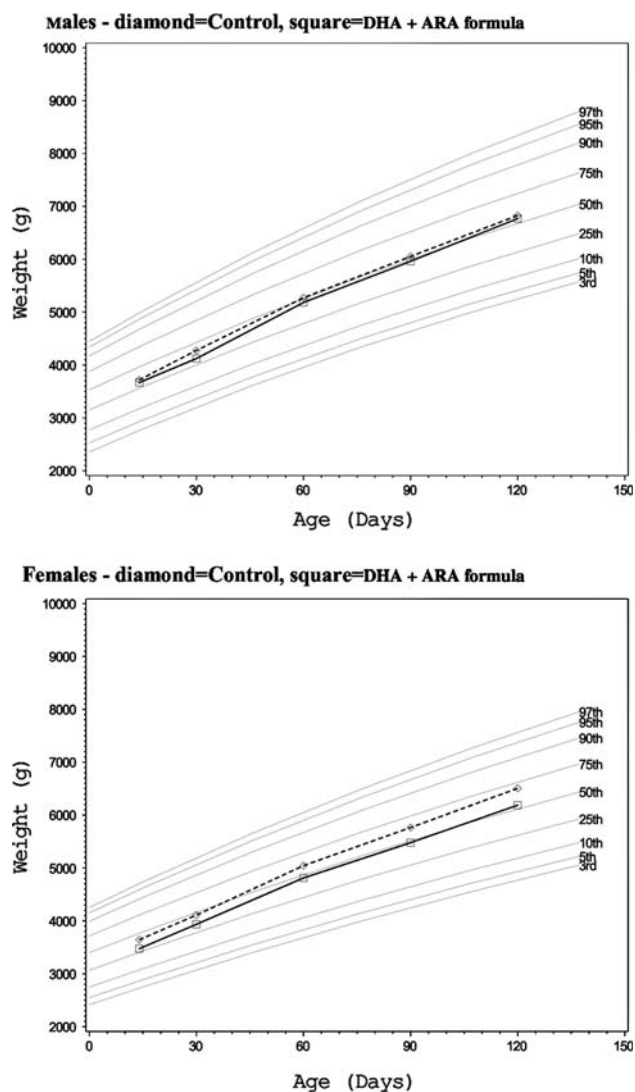

Formula intake, stool frequency, and stool characteristics were similar for infants in both groups (data not shown). Both formulas were well tolerated as reported by parental assessment of fussiness, diarrhea, and constipation, with the only difference between groups being a higher incidence of excessive gas in the control group than the DHA + ARA group at 60 days of age (15% vs. 5%;  $P = 0.026$ ). Minimal incidence of atopic dermatitis, as assessed by mean SCORAD indices, was noted for infants in each study group at all time points. For example, at 120 days of age mean SCORAD values were  $2.9 \pm 0.76$  for the control group ( $n = 85$ ) versus  $2.3 \pm 0.72$  for the DHA + ARA group ( $n = 93$ ,  $P = 0.374$ ). Given the SCORAD index range of 0–103 with disease severity indicated by a higher score, mean values from this study signified a very low occurrence of atopic dermatitis.

There were no significant differences between groups for total discontinuation rates (control,  $n = 32$  [27%] vs. DHA + ARA,  $n = 27$  [22%];  $P = 0.37$ ) or for discontinuation due to feeding-related issues (control,  $n = 23$  [19%] vs. DHA + ARA,  $n = 19$  [15%];  $P = 0.615$ ). The most common reasons for discontinuation were diarrhea (control,  $n = 8$ ,  $n = 5$ ), vomiting ( $n = 8$ ,  $n = 4$ ), and fussiness ( $n = 6$ ,  $n = 6$ ). Significant differences between groups in adverse events included gastroesophageal reflux

**Table 2** Mean weight, length, and head circumference growth rates from 14 to 120 days of age

<sup>a</sup> Mean ± standard error

**Fig. 1** Mean achieved weights of male participants (*upper panel*) and female participants (*lower panel*) with CDC reference percentiles (3–97) from 14 to 120 days of age. Control formula group, *diamonds*; DHA + ARA formula group, *squares*

(control,  $n = 13$  vs. DHA + ARA,  $n = 3$ ;  $P = 0.009$ ) and incidence of metabolic or nutritional difficulties (control: weight loss,  $n = 3$ ; poor weight gain,  $n = 2$ ; Type 1 Glutaric Acidemia,  $n = 1$  vs. DHA + ARA:  $n = 0$  for any category;  $P = 0.013$ ). Serious adverse events were reported for 12 infants (control,  $n = 6$ ; DHA + ARA,  $n = 6$ ). In each of these cases, the investigator stated that the serious adverse event was unrelated to the study product.

#### Blood Lipids and Blood Chemistry

No significant differences in mean fatty acid percentages were detected between groups for total RBC lipids or plasma phospholipids at 14 days of age in a subset of

infants (control,  $n = 25$ ; DHA + ARA,  $n = 22$ ; data not shown). Results from infants at 120 days of age are reported in Table 3. In the  $\omega 3$  fatty acid family, the percentage of DHA in total fatty acids was significantly higher in total RBC lipids from infants in the DHA + ARA group versus the control (6.23 vs. 2.47%,  $P < 0.001$ ; Table 3). DHA was also significantly higher in plasma phospholipids in infants from the DHA + ARA group (5.04 vs. 1.67%,  $P < 0.001$ ). Percentages of  $\alpha$ -linolenic acid (18:3 $\omega 3$ ; ALA) and docosapentaenoic acid (22:5 $\omega 3$ ) in total RBC lipids ( $P = 0.019$  and  $P < 0.001$ , respectively) and plasma phospholipids ( $P < 0.001$  for both fatty acids) were significantly lower in the DHA + ARA group.

In the  $\omega 6$  fatty acid family, ARA as a percentage of total fatty acids was significantly higher in total RBC lipids from infants in the DHA + ARA group versus the control (16.27 vs. 13.97%,  $P < 0.001$ ). ARA was also significantly higher in plasma phospholipids in infants in the DHA + ARA group (13.46 vs. 7.33%,  $P < 0.001$ ). Mean percentages of linoleic acid (18:2 $\omega 6$ ),  $\gamma$ -linolenic acid (18:3 $\omega 6$ ), eicosadienoic acid (20:2 $\omega 6$ ), dihomo- $\gamma$ -linolenic acid (20:3 $\omega 6$ ), and docosapentaenoic acid (22:5 $\omega 6$ ) were significantly lower in total RBC lipids and plasma phospholipids from infants in the DHA + ARA group as compared with the control (see individual  $P$  values in Table 3). Fatty acid profiles of RBC PE and PC fractions were not reportable due to technical problems during analysis. There were no statistical differences in blood chemistry profiles between groups at 14 or 120 days of age (data not shown).

#### Discussion

The present study showed that a soy-based infant formula supplemented with DHA and ARA supported growth rates and tolerance of term infants as well as commercially available soy-based formula without these fatty acids, and increased DHA and ARA status similar to milk-based formulas with similar levels of added DHA and ARA. The American Academy of Pediatrics Task Force on Clinical Testing of Infant Formulas [25] stated that rate of weight gain (g/day) is the most beneficial component of the clinical evaluation of infant formula and recommended that a difference in weight gain of more than 3 g/day over 3–4 months be considered nutritionally significant. Our study found no differences in rate of weight gain over the 4-month study. Daily gains in length and head circumference (cm/day) also did not differ between the formula groups. In addition, weights in both groups, when compared with CDC infant reference data [24], fell between the 25th and 75th percentiles of both male and female weight-for-age growth curves. Although achieved weight means were significantly higher at 30 and 90 days of age and achieved

length means were higher in the control group at all time points, these differences were consistent with those upon study entry, when the control group was significantly heavier and longer on average than the DHA + ARA group.

Questions have been raised as to how some other components of soy formulas (e.g., phytoestrogens) affect growth and long-term health [21, 22]. Previous clinical reports, however, have demonstrated that soy-based formulas promoted normal growth in term infants [21, 22, 26–28]. In addition, a study of adults found that long-term growth, health, and reproductive outcomes are comparable between individuals who received soy- or cow's milk-based formula as infants [29]. The American Academy of Pediatrics has concluded that soy based formulas are safe and effective feedings for infants whose nutritional needs are not met by human milk or cow's milk formula [21]. Our study adds further support to this conclusion and demonstrates that the addition of DHA and ARA at levels similar to those found in worldwide breast milk does not negatively influence growth [29].

Both the marketed control and the DHA + ARA supplemented soy-based formulas were well tolerated by infants in this study as evidenced by similarities in parental assessment of tolerance, formula intake, stool frequency and characteristics, and low occurrence of atopic dermatitis throughout the study. Serum chemistry values for a wide

variety of metabolic parameters were similar for infants in both groups at 14 and 120 days of age. Rates of study discontinuation and adverse events were similar between formula groups and incidence of serious adverse events was low and deemed unrelated to the study products by participating physicians. Previous clinical evidence also indicates infant tolerance of soy-based formulas, with favorable comparison to cow's milk-based formula [22, 30, 31]. Our study demonstrated that the soy-based control formula and soy-based formula supplemented with DHA and ARA were equally well tolerated by infants, with very low incidence of allergic manifestations.

Concentrations of DHA and ARA in RBC and plasma phospholipids have been widely evaluated as outcomes in studies of milk-based formula-fed and breast-fed infants [3, 6, 11–17, 32–34]. In the current study, mean fatty acid percentages were similar between control and DHA + ARA groups at 14 days of age. Similar to trials with term infants fed milk-based formulas [12, 32–34], infants fed a soy-based formula supplemented with DHA and ARA had significantly higher percentages of fatty acids as DHA and ARA in RBC lipids and plasma phospholipids at 120 days of age than infants fed an unsupplemented soy-based formula. Previously published levels of RBC and plasma phospholipid DHA and ARA from a clinical trial of term infants fed a control milk-based formula without DHA or ARA [12] were similar to those of infants fed the control

soy-based formula in this study. For example, mean total RBC DHA and ARA percentages for infants fed control soy-based formula in the current study were 2.47 and 13.97%, respectively, compared with 2.52 and 13.9%, respectively, for control milk-based formula in the earlier study [12]. Likewise, the RBC and plasma phospholipid DHA and ARA values for infants fed milk-based formulas supplemented with 0.32–0.36% of fatty acids as DHA and 0.64–0.72% as ARA [12, 13] were similar to concentrations measured in those blood fractions in the DHA + ARA group in the current study. Blood levels of DHA and ARA measured in infants in the DHA + ARA group at 120 days of age also were similar to those demonstrated in breast-fed infants where representative breast milk contained 0.29% DHA and 0.56% ARA [12]. For example, total RBC DHA and ARA were 6.23% and 16.27%, respectively, for the DHA + ARA group in the current study, compared with 4.97% and 15.9%, respectively, for the breast-fed group and 6.77% and 17.1%, respectively, for the supplemented milk-based formula in the earlier study [12]. Thus, the addition of DHA and ARA to soy-based formula produces similar responses in blood DHA and ARA as addition of similar levels to milk-based formula, as well as similar responses as comparable levels of breast milk DHA and ARA. The significant increase at 120 days of age in the DHA + ARA group further suggests that feeding term infants a soy-based formula supplemented with preformed DHA and ARA increases the levels of circulating DHA and ARA available for brain and retinal development and functions similarly to breast-fed infants [12, 18].

Significant differences in percentages of other PUFA in RBC lipids and plasma phospholipids seen in the DHA + ARA group compared with control also parallel, for the most part, changes seen in previous studies of milk-based formulas [12, 13, 16, 17, 32–34]. Lower blood levels of DHA precursors ALA (18:3 $\omega$ 3) and docosapentaenoic (22:5 $\omega$ 3), and ARA precursors linoleic (18:2 $\omega$ 6),  $\gamma$ -linolenic (18:3 $\omega$ 6), and dihomo- $\gamma$ -linolenic (20:3 $\omega$ 6), as well as eicosadienoic (20:2 $\omega$ 6) and docosapentaenoic (22:5 $\omega$ 6) acids in the DHA + ARA group were consistent with supplemental feeding or feeding higher levels of DHA and ARA, as previously noted [13, 16, 17, 34]. Breast-fed infants have also been shown to have lower percentages of linoleic acid and ALA in total RBC and plasma phospholipids [12] and lower linoleic acid in RBC PC and PE [32] than infants fed control milk-based formula without added DHA and ARA. Blood levels of linoleic acid and ALA were comparable among infants fed human milk with 0.29% DHA and 0.56% ARA and infants fed milk-based formula with 0.36% DHA and 0.72% ARA in the earlier study [12], and infants fed soy-based formula with 0.32% DHA and 0.64% ARA in the current study; mean total RBC and plasma phospholipid linoleic acid across the three groups ranged from 10.9% to

12.58% and 20.2% to 21.49%, respectively, and mean ALA values for both blood fractions across all three groups were less than 0.2%. Our data demonstrate that the addition of DHA and ARA to soy-based formula results in similar responses in blood PUFA levels at similar levels of DHA and ARA in milk-based formulas and in breast milk [12], and provide further evidence that the conversion of ALA and linoleic acid to DHA and ARA, respectively, does not compensate for lack of dietary DHA and ARA [13].

Supplementation of formulas with DHA and ARA is now a widely accepted method of attempting to reproduce concentrations typical of human breast milk and to parallel developmental benefits. The current study is unique in comparing growth, tolerance, and blood chemistry outcomes between infants who received commercially available soy-based formulas with or without DHA and ARA supplementation. Both formulas supported normal growth of infants, and tolerance for each formula was similar between groups. Supplementation of soy-based formula with preformed DHA and ARA from single cell oil sources also resulted in circulating levels of DHA and ARA comparable to previous clinical data from breast-fed infants and infants who received cow's milk-based formula supplemented with median worldwide levels of DHA and ARA. These results demonstrate that feeding soy-based formulas supplemented with DHA and ARA supports infant growth and achieves increased levels of circulating DHA and ARA.

**Abstract** Disorders of the metabolism of essential fatty acids (EFAs) are related to atopic dermatitis (AD). Concentrations of dihomogamma-linolenic acid (DGLA), an EFA, in the serum of AD patients are lower than those in healthy volunteers. Recently we developed a fermented DGLA oil, and examined whether oral administration of DGLA prevents development of dermatitis in NC/Nga mice, which spontaneously develop human AD-like skin lesions. NC/Nga mice were fed a diet either containing or not containing DGLA for 8 weeks under in air-uncontrolled conventional circumstances. Clinical skin severity scores were significantly lower in mice fed DGLA than in mice not fed it. Scratching behavior and plasma total IgE levels were also reduced in the DGLA group, in association with histological improvement. DGLA suppressed clinical severity of skin lesions dose-dependently, with an increase in DGLA contents in phospholipids of skin, spleen, and plasma. Discontinuation of DGLA administration resulted in the onset of dermatitis and a decrease in DGLA contents in skin, spleen, and plasma. These findings indicate that oral administration of DGLA effectively prevents the development of AD in NC/Nga mice, and that DGLA in

phospholipids is a compound of key importance in the development and prevention of dermatitis.

### Introduction

Atopic dermatitis (AD) is a chronic and relapsing skin disorder associated with allergic inflammation, and is related to disorders of polyunsaturated fatty acid metabolism. Among these fatty acids, dihomogamma-linolenic acid (DGLA, 8,11,14-eicosatrienoic acid) may be a compound of key importance, since DGLA concentration in the serum of AD patients was significantly lower than in that of healthy volunteers [1], and DGLA is metabolized to anti-inflammatory eicosanoids such as those of the prostaglandin (PG) 1-series and 15-hydroxyeicosatrienoic [2–4]. With the goal of increasing the DGLA level in AD patients, clinical trials have been performed using oil containing gamma-linolenic acid (GLA, 6,9,12-octadecatrienoic acid), the precursor of DGLA, and some have found that GLA was effective for AD [5, 6]. However, GLA was sometimes not effectively converted to DGLA in AD patients, resulting in insufficient increases in DGLA concentration and an insufficient therapeutic effect [7, 8].

Although DGLA exists widely in the human body and daily animal-source foods, it had not been available previously. Therefore, there were only a few pioneering studies in which DGLA ethyl ester were fed to rats and rabbits [9, 10]. Recently, a new fermentation technique using an oleaginous fungus *Mortierella alpina* has recently been established, enabling industrial production of DGLA-containing oil [11].

DGLA oil consists almost entirely of triglycerides, in which the proportion of DGLA is approximately 40%. As expected, DGLA contents of liver and serum were increased much more effectively in rats fed DGLA oil than in those fed GLA oil [12]. These findings suggest the possibility that oral intake of DGLA may increase DGLA contents in skin and prevent AD. In the present study, the effects of oral administration of DGLA on AD were examined using NC/Nga mice, which spontaneously develop AD-like skin lesions that are pathologically and immunologically quite similar to those found in human AD [13–15]. We also determined the DGLA content in skin, and examined whether it is related to the severity of AD in NC/Nga mice.

## Experimental Procedures

### Mice

We used male and female NC/Nga mice maintained in air-uncontrolled conventional circumstances. These mice manifested severe skin lesions very similar to those of human AD [13]. The mice were fed a defined diet with or without DGLA from 5 to 12 weeks of age. The care and handling of the animals were in accordance with the ‘Tokyo University of Agriculture and Technology Animal Experiment Guidelines, April 2001’.

### Diet and Reagents

The mice were given a pellet diet and water ad libitum. The diet was a modified AIN-76A containing 5% (w/w) lipids, which consisted of a mixture of DGLA oil, corn oil, lard, or olive oil. DGLA oil is a triglyceride oil extracted from the fungus *Mortierella alpina*. In brief, the oil was extracted from the biomass of *M. alpina* obtained by fermentation [11], and purified by traditional edible oil refining procedures to obtain an oil containing approximately 40% DGLA. The fatty acid composition of each diet administered is shown in Table 1. Fatty acid compositions of diets were adjusted to be similar to each other, for the amounts of total  $n - 6$  fatty acids (LA + GLA + DGLA) to be approximately 40%. The DGLA content in DGLA diet was 0.6 g/kg diet, while DGLA contents in the high-, medium-, low-, and very-low-DGLA diets were 0.5, 0.24, 0.13, and 0.06 g/kg diet, respectively. Mice ( $n = 7$ ) were fed diet for 8 weeks, from 5 to 12 weeks of age. In the discontinuation experiment, mice were fed high-DGLA diet from 5 to 10 weeks of age, and the control or high-DGLA diet for the final 2 weeks, i.e., from 66 to 79 days of age. All chemicals used were purchased from Sigma-Aldrich, unless otherwise

**Table 1** Fatty acid composition of lipids in each experimental diet

Diet	Fatty acid composition (%) <sup>a</sup>						
	16:0	18:0	18:1	18:2	18:3	20:3	Others
Control	15.1	6.4	34.5	39.5	nd	nd	4.5

Others include  $\alpha$ -linolenic acid and small amounts of saturated fatty acids

**Fig. 1** Experimental designs of the diets and the digestion period. The fatty acid composition of each diet is indicated in Table 1

indicated. The experimental designs of the diets and the digestion period are summarized in Fig. 1.

### Clinical Skin Severity Score and Scratching Analysis

Clinical features of dermatitis were scored two to four times a week, from 10 to 12 weeks of age, according to criteria described previously [13], which consisted of five major clinical signs and symptoms of AD: itching, erythema/hemorrhage, edema, excoriation/erosion, and scaling/dryness. The scratching behavior of the mice was recorded and analyzed at 10 and 12 weeks of age using a SCLABA system (Noveltec Inc., Kobe, Japan), a novel analyzer that quantifies the scratching behavior of mice for a fixed period of time [16]. Scratching behavior was quantified as the frequency and duration of scratching per 20 min in the double-blind evaluation.

## Histological Examination and Plasma IgE Determination

Dorsal skin specimens were fixed in 10% formalin. The fixed specimens were embedded in paraffin, and sliced sections were stained with hematoxylin and eosin. Total plasma IgE was measured by a sandwich ELISA (Yamasa Co., Chiba, Japan).

## Fatty Acid Analysis

Dorsal skin, spleen, and plasma were stored in a freezer ( $-80^{\circ}\text{C}$ ), and analyzed as soon as possible. Lipids in these specimens were extracted by chloroform/methanol according to the Folch methods [17], and separated into neutral lipids and phospholipids by thin-layer chromatography with silica gel 60 (Merck, Darmstadt). The solvent system consisted of hexane/diethyl ether (7:3, by vol). Fatty acid residues in the phospholipid fractions were analyzed as described previously [18]. In brief, each fraction with an additional internal standard (pentadecanoic acid) was incubated in methanolic HCl at  $50^{\circ}\text{C}$  for 3 h for transmethylation of fatty acid residues. Fatty acid methyl

esters were extracted with *n*-hexane and analyzed by capillary gas-liquid chromatography.

## Statistical Analyses

The clinical skin severity scores were analyzed by two-way analyses of variance (ANOVA), and followed by Dunnett multiple comparison test. The other data were analyzed by Dunnett multiple comparison test or two-tailed unpaired Student's *t*-test.

## Results

### Clinical Severity of Skin Lesions of NC/Nga Mice Fed DGLA

Neither body weight nor weight gain differed between the two groups (data not shown). Clinical signs of dermatitis were effectively prevented by oral intake of DGLA (Fig. 2a, b). Although the score gradually increased, and reached  $9.14 \pm 1.03$  (mean  $\pm$  SEM) at day 84 in control mice fed no DGLA, it seldom increased and was in fact

**Fig. 2** Prevention of dermatitis by DGLA in NC/Nga mice. Typical overall status of control (a) and DGLA-fed (b) mice at 84 days of age (Blue pigment was applied to quantify scratching.) (c) Clinical skin severity scores for control (closed circles) and DGLA-fed (open circles) mice. (d) Frequency of scratching per 20 min of control (closed bars) and DGLA-fed (open bars) mice. Each value represents the mean  $\pm$  SEM of seven mice. \* $P < 0.05$ , \*\* $P < 0.01$  versus control

significantly lower in mice fed DGLA ( $1.57 \pm 0.43$  at day 84) (Fig. 2c) ( $P < 0.01$  by ANOVA). Since itching is one of the most important unpleasant symptoms of AD, we attempted to quantify itching by analyzing the scratching behavior using an SCLABA system. Scratching behaviors were recorded as frequency and duration of scratching per 20 min, and were significantly reduced at 70 and 84 days of age in mice fed DGLA (Fig. 2d). Histological examination at 84 days of age revealed that oral intake of DGLA prevented epidermal hyperplasia, dermal edema, and infiltration of inflammatory cells in dorsal skin (Fig. 3a, b). At 84 days of age, total plasma IgE levels were very high in control mice ( $64.2 \pm 15.1 \mu\text{g/ml}$ ) and significantly lower in mice fed DGLA ( $15.6 \pm 1.4 \mu\text{g/ml}$ ).

#### Dose-dependency of Effects of DGLA and Incorporation of DGLA in Skin

Neither body weight nor weight gain differed among groups (data not shown). The decrease in clinical severity of skin lesions caused by DGLA was dose-dependent (Fig. 4), and the clinical skin severity was significantly reduced only in the high-DGLA group ( $P < 0.05$  by ANOVA). Scores were relatively low in the medium- and low-DGLA groups, though they were not significantly reduced. The score in the very-low-DGLA group was almost the same as that in the control group.

**Fig. 3** Prevention by DGLA of histological skin lesions and elevation of total plasma IgE levels in NC/Nga mice. Hematoxylin and eosin-stained sections of dorsal skin specimens of control (a) and DGLA-fed (b) mice ( $\times 100$ ). c Total plasma IgE levels of control (closed bars) and DGLA-fed (open bars) mice. Each value represents the mean  $\pm$  SEM of seven mice.  $**P < 0.01$  versus control

**Fig. 4** Clinical skin severity scores of mice in the control (closed circles) and high- (open circles), medium- (open rhombuses), low- (open squares) and very-low-DGLA (open triangles) groups. Each value represents the mean  $\pm$  SEM of seven mice

We quantified fatty acids in phospholipids of the dorsal skin to determine whether the DGLA content in skin was increased by oral intake of DGLA (Fig. 5). The DGLA content in phospholipids was  $0.75 \pm 0.10\%$  (mean  $\pm$  SEM)

**Fig. 5** Fatty acid composition of phospholipids of dorsal skin (a), spleen (b), and plasma (c) in control (closed bars) and very-low (hatched bars), low- (wavy-lined bars), medium- (gray bars), and high-DGLA (open bars) groups. Each value represents the mean  $\pm$  SEM of seven mice. \* $P < 0.05$ , \*\* $P < 0.01$  versus control

of total fatty acids in the control group, and increased dose-dependently to reach  $3.89 \pm 0.20\%$  in the high-DGLA group. The ARA content was  $13.95 \pm 0.48\%$  in the control group, and also increased gradually to reach  $17.45 \pm 0.58\%$  in the high-DGLA group. The content of LA, which was decreased in diets with DGLA supplementation, decreased dose-dependently with the dose of DGLA. The proportions of other fatty acids in skin were unchanged by DGLA ingestion (data not shown). In the spleen, fatty acid composition differed from that in skin, e.g., the proportion of ARA was relatively high. However, the effects of DGLA ingestion were similar to those in skin; the DGLA content increased drastically, the ARA content increased slightly, the LA content decreased, and the DHA content remained unchanged with DGLA ingestion. The effects of DGLA on fatty acids in plasma were also similar, though the ARA level was rather low in the control group and increased drastically with an increase in the DGLA content in the diet.

#### Effects of Discontinuation of DGLA Ingestion

Neither body weight nor weight gain differed among the groups (data not shown). The clinical skin severity score in

the discontinuation group was low at first, but increased soon after and was significantly higher than that in the continuation group after day 72 (Fig. 6) ( $P < 0.05$  by ANOVA). DGLA contents in skin, spleen, and plasma were significantly decreased in the discontinuation group, to almost the same level as in control mice fed no DGLA throughout the experiment. The LA content increased significantly, while changes in ARA and DHA levels were rather small (Fig. 7).

#### Discussion

Oral administration of DGLA markedly suppressed the development of dermatitis in NC/Nga mice under air-uncontrolled conventional circumstances. DGLA reduced not only the clinical skin severity of dermatitis, but also scratching behavior and plasma total IgE levels. DGLA decreased the clinical severity of skin lesions in dose-dependent fashion, with an increase in DGLA contents in phospholipids of skin, spleen, and plasma. Furthermore, discontinuation of DGLA administration resulted in the onset of dermatitis and the decrease in DGLA contents in skin, spleen, and plasma. These findings show that oral administration of DGLA is very effective in preventing the development of dermatitis in NC/Nga mice, and that DGLA in phospholipids is a compound of key importance in both the development and prevention of dermatitis.

Although the efficacy of DGLA in preventing dermatitis was strong, the mechanism by which it does so is unclear.

**Fig. 6** Clinical skin severity scores of mice fed DGLA until day 79 (continuation group, closed circles), or fed DGLA until day 66 and no DGLA from days 66 to 79 (discontinuation group, closed triangles). Each value represents the mean  $\pm$  SEM of seven mice

**Fig. 7** Fatty acid composition of phospholipids of dorsal skin (a), spleen (b), and plasma (c) in the continuation (closed bars) and discontinuation (lined bars) groups. Each value represents the mean  $\pm$  SEM of seven mice. \* $P < 0.05$ , \*\* $P < 0.01$  versus control

One of mediators related to the effects of DGLA may be the unique eicosanoids derived from DGLA, since various eicosanoids have been found to affect the immune system. PGE1 and 15-hydroxyeicosatrienoic acid, which have unique functions, including anti-inflammatory effects [3] and inhibition of leukotriene B<sub>4</sub> production [5], are candidate mediators of the effects of DGLA. Indeed, both were detected in the skin in guinea pigs fed GLA [19]. It will be of great interest to determine whether these eicosanoids are involved in mediating the prevention of dermatitis in NC/Nga mice. The existence and involvement of the candidate mediators in various tissues were examined at the next stage.

DGLA was incorporated and increased in contents not only in skin and plasma, but also in the spleen. In a previous study, DGLA levels were increased in liver and serum in rats fed DGLA [12]. These findings suggest that oral administration of DGLA increases systemic concentrations of DGLA. Although the increase in DGLA in skin is clearly

of greatest importance, systemic increases in DGLA concentration may have systemic effects as well, such as the suppression of the plasma total IgE level. Determination of fatty acid profiles showed that ARA contents in skin, spleen, and plasma were also increased dose-dependently by DGLA, and were higher in the high-DGLA group, in which AD was prevented the most effectively. This indicates that a portion of DGLA must be metabolized to ARA in mice, which is thought to be reasonable because DGLA is the direct precursor of ARA in the biosynthetic pathway of essential fatty acids. However, the increase in ARA did not trigger allergy or inflammation here, although  $n - 6$  fatty acids are reported to trigger inflammation [20]. This is interesting evidence that the increase in omega-6 fatty acids does not always induce inflammation.

Since NC/Nga mice are widely considered to be a suitable model for human AD, oral administration of DGLA may be useful for preventing human AD. If this DGLA oil is useful, it must be ingested because its DGLA content is high, i.e., approximately 40% of this oil consists of DGLA. Another important finding of the present study is that both the DGLA content in skin and efficacy in prevention of dermatitis were related to the DGLA content in plasma. This suggests that the DGLA content in skin and expected efficacy in preventing dermatitis can be estimated by monitoring the DGLA content in plasma. The kinetics of absorption of DGLA in humans needs to be determined.

In this study, we have demonstrated the marked efficacy of DGLA in preventing dermatitis in NC/Nga mice. Human studies and examination of the mechanisms by which DGLA exerts these effects are needed.

## The Percentage of n-3 Highly Unsaturated Fatty Acids in Total HUFA as a Biomarker for Omega-3 Fatty Acid Status in Tissues

Ken D. Stark

**Abstract** A blood biomarker of omega-3 fatty acid intake and tissue status could serve as a modifiable risk factor for cardiovascular disease. The percentage of omega-3 highly unsaturated fatty acid (HUFA  $\geq 20$  carbons and  $\geq 3$  double bonds) in the total HUFA pool (the n-3 HUFA score) was examined as a potential blood biomarker of omega-3 fatty acids in tissues. The fatty acid composition of total lipid extracts (TLE) and phospholipid (PL) fractions were determined for plasma and erythrocytes samples of human subjects ( $n = 20$ ) and the n-3 HUFA score and the sum of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) were compared. Omega-3 fatty acids in blood and tissues of rats ( $n = 31$ ) and pigs ( $n = 48$ ) were also determined and the associations were compared. The n-3 HUFA score is more consistent across plasma and erythrocytes, with strong correlations between TLE and PL in plasma ( $r = 0.93$ ) and erythrocytes ( $r = 0.94$ ). The n-3 HUFA score was less variable and blood levels correlated strongly with various animal tissues. The n-3 HUFA score is a useful blood biomarker that does not require the isolation of the PL class thereby supporting high throughput analyses. The strength of association between the n-3 HUFA score and disease risk needs to be examined.

**Keywords** Omega-3 fatty acids · Docosahexaenoic acid · Eicosapentaenoic acid · Biomarker · Plasma · Erythrocyte

### Introduction

Dietary supplementation with omega-3 fatty acids from fish oil has been demonstrated to significantly reduce the risk of death from coronary heart disease (CHD) and sudden cardiac death in secondary prevention trials [1]. Higher dietary intake and higher blood levels of omega -3 fatty acids, specifically eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA), are associated with decreased risk of sudden cardiac death in western populations [2–4]. The mechanism of the prevention of sudden cardiac death has not been fully elucidated but is likely related to anti-arrhythmic [5] and lowered resting heart rates [6]. EPA and DHA mediated triacylglycerol-lowering, anti-hypertensive, and anti-inflammatory effects may also reduce CHD risk [7, 8]. This mounting evidence has led to several recommendations for the intake of omega-3 fatty acids for optimal heart health [9].

The fatty acid composition of adipose tissue is considered to be the best choice for the assessment of long-term dietary intake of fatty acids due to a slow turnover rate, with blood fractions reflecting shorter-term intakes [10]. Given the invasiveness of adipose tissue biopsies, a blood based biomarkers would be preferred for large observational and clinical trials. Recently it has been proposed that the level of EPA + DHA in erythrocyte membranes (the Omega-3 Index) could be used as a new risk factor for CHD mortality [11]. The selection of the Omega-3 Index over other blood based biomarkers is based largely on a single study demonstrating a significant correlation between erythrocytes and cardiac tissue [12] as compared with plasma but other measures of assessing these omega-3 long-chain polyunsaturated fatty acids (LCPUFA) or highly unsaturated fatty acids (HUFA,  $\geq 20$  carbons and  $\geq 3$  carbon-carbon, double bonds) in blood do exist and are

untested. In particular, the use of the percentage of omega-3 HUFA in the total HUFA pool as a biomarker of omega-3 fatty acid status has been defined previously [13] and has been demonstrated to have the potential to have smaller coefficient of variation and better correlate with plasma and erythrocytes [14]. This is based on the competition between these fatty acids for the sn-2 position of phospholipids (PL) and the use of the term HUFA over LCPUFA tends to emphasize the important physiological difference from other PUFA in addition to the longer chemical carbon chain length. The HUFA pool is largely dominated by arachidonic acid (AA, 20:4n-6) in Western diets. Increased omega-3 fatty acid intake increases tissue levels of EPA and DHA and decreases other HUFA, an antagonistic effect that was observed originally by Mohrhauer and Holman [15].

In the present study, the use of EPA + DHA as a marker for omega-3 fatty acid status is compared to the use of the percentage of omega-3 HUFA in total HUFA (n-3 HUFA score) in human blood samples. As these biomarkers have the potential to be developed into a risk factor for chronic disease, total lipid extracts (TLE) and PL fractions were examined. A fatty acid risk factor derived from TLE would be advantageous as it would facilitate high throughput analyses to a much greater extent than a specific lipid fraction such as PL. The ability of omega-3 fatty acid blood biomarkers to correlate with omega-3 fatty acid levels in various tissues was also examined in rat and in pig tissues.

## Methods

### Human Blood Samples

Blood samples were obtained at Wayne State University in Detroit, MI as previously described [16]. The study was approved by the Wayne State University Human Investigations Committee and informed consent was obtained from all participants. Briefly, fasting blood samples (15 ml) were collected by venipuncture into heparinized tubes. Samples were kept cold (4 °C) until centrifuged (5 min × 2,000g) to separate plasma from erythrocytes and each fraction was frozen and stored at –75 °C until analysis. Women with known fatty acid metabolism disorders and diabetics were excluded from the study. Twenty-five samples from non-pregnant women were analyzed. TLE were prepared from plasma [17] and erythrocyte [18] with an internal standard (23:0, or 22:3n-3; Nu-Check Prep, Elysian, MN, USA). An aliquot of TLE from each sample was taken and PL fractions were isolated by thin layer chromatography using a mixture of heptane/diethyl ether glacial acetic acid (60:40:2 by volume) as described previously [19]. Both the TLE and PL

preparations were then methylated with boron trifluoride in methanol (14% wt./vol.; Alltech Assoc., Deerfield, IL, USA) [20]. The fatty acid methyl esters were analyzed by capillary gas chromatography according to Salem et al. [21] on an Agilent 6890N gas chromatograph (Agilent, Palo Alto, CA, USA) with a 0.25 mm × 30 m DB-FFAP column (J&W Scientific, La Palma, CA, USA).

### Rat Tissue Samples

Animal tissues were obtained from male Long-Evans rats raised on diets either adequate or deficient in omega-3 fatty acids as described previously [22–24]. Experimental procedures were approved by the Animal Care and Use Committee of the National Institute on Alcohol Abuse and Alcoholism, NIH. Briefly, pregnant (3-day gestation) Long Evans rats were purchased from Charles River (Portage, MI, USA) and placed on an essential fatty acid adequate diet and raised in an animal facility under conventional conditions. At 2-day post-natal males pups from 10 litters were randomly allocated to one of five groups containing ten pups each. The control group was allowed to be dam-reared while the other four groups were hand-reared on artificial milk. The fat content of the artificial milk consisted of hydrogenated coconut oil/medium chain triglyceride fat supplemented with ethyl esters of specific fatty acids (Nu-Check Prep) including 18:1n-9 ethyl ester, 18:2n-6 ethyl ester, 22:6n-3 ethyl ester, and 22:5n-6 ethyl ester. All four of the milks contained 18:2n-6 while the others were supplemented with 1% DHA, 1% docosapentaenoic acid (DPA, 22:5n-6), 1% DHA : DPA (2:1). Therefore, three of the diets (including dam-reared) were adequate in omega-3 fatty acid content, while two were omega-3 fatty acid deficient. Rats were raised and eventually transferred to a pelleted diet containing the same fat profile. The adult male rats were then sacrificed at approximately 20 weeks of age. Plasma, erythrocytes, liver, heart, brain, and adipose tissues were collected following decapitation and frozen at –80 °C until fatty acids from TLE were analyzed as described above. Detailed fatty acid compositions will be presented elsewhere. Samples for each and every tissue were successfully collected and analyzed for 31 rats. Seven of these rats were dam-reared with another 14 of these rats consuming adequate amounts of omega-3 fatty acids as DHA. Ten rats were on omega-3 fatty acid deficient diets.

### Pig Tissue Samples

Tissues from pigs fed varying levels of fatty acids as described elsewhere [25, 26] were examined according to

omega-3 fatty acid biomarkers. The study methods and procedures were approved by the Shur-Gain Agresearch Animal Care Committee. Pregnant Yorkshire-Landrace sows (Maple Leaf Foods Agresearch, Burford, ON, Canada) were randomly fed either a control diet or a diet high in  $\alpha$ -linolenic acid (18:3n-3) from ~1 week prior to parturition until weaning. The diets consisted of base commercial pig feed (Shur-Gain Feed # 694, Guelph, ON, Canada) containing 477 g/kg of corn, 270 g/kg of soy bean meal, 75 g/kg of wheat middlings, 74 g/kg of whey powder, 36.2 g/kg of fish meal, 10 g/kg of limestone, 7 g/kg of dicalcium phosphate, 3.3 g/kg of salt, and 17.6 g/kg of a vitamin/mineral supplement. The control diet consisted of the base pig feed supplemented with 50 g/kg of sunflower oil, while the high- $\alpha$ -linolenic acid diet consisted of the same base pig feed supplemented with 15 g/kg of sunflower oil and 35 g/kg of flaxseed oil. The feeds were similar in levels of saturates and monounsaturates and varied with respect to linoleic and  $\alpha$ -linolenic acid (1.9% vs. 17.8% and 61.9% vs. 45.4% of total fatty acids for  $\alpha$ -linolenic acid in the low- and high- $\alpha$ -linolenic acid and linoleic acid (18:2n-6) in the low- and high- $\alpha$ -linolenic acid feeds, respectively). The piglets in the present study suckled from their respective sows consuming either the control or high- $\alpha$ -linolenic acid. At 14 days old, suckling pigs per dietary treatment were randomly allocated to several different nurseries. After weaning, pigs consumed diets with the same  $\alpha$ -linolenic acid content as their respective sows until the end of the study. Pigs were anesthetized and killed at 14, 35, or 49 days old for tissue fatty acid analysis. Blood samples were anti-coagulated with citrate. Liver, brain, and carcass from which the viscera were removed were completely homogenized four times using a Hobart Grinder with 0.12 cm dye. Total lipids of plasma and portion of homogenized liver, carcass, and brain were extracted into chloroform-methanol (2:1, v/v). Non-esterified heptadecanoic acid (Sigma, St. Louis, MO, USA) was added as an internal standard to an aliquot of the total fatty acid extract to quantitate total lipids. Total lipids were then recovered and saponified in methanolic potassium hydroxide (60 g potassium hydroxide/L-methanol) for 1 h at 100 °C and the fatty acids were converted to fatty acid methyl esters using 14% boron trifluoride-methanol at 100 °C for 30 min (Sigma) under nitrogen. Fatty acid methyl esters were analyzed by gas liquid chromatography using a capillary column (J&W Scientific DB-23, 30 m  $\times$  0.25 mm, ID), in a Hewlett-Packard 5890A gas liquid chromatograph (Palo Alto, CA, USA) with automated sample delivery and injection (Hewlett-Packard 7671A) and peak integration (Hewlett-Packard 3393 integrator). Total lipid fatty acids were quantified on the basis of the proportion in each chromatogram of the corresponding internal standard added to each sample.

## Data Analysis and Statistics

Individual fatty acids were determined and ratios and sums of interest were calculated. These included the sum of 20:5n-3 + 22:6n-3, the ratio of total n-3 PUFA divided by total n-6 PUFA, and the percentage of n-3 HUFA in total HUFA. The impact of including 22:5n-3 (DPAn-3) in the summation of 20:5n-3 + 22:6n-3 was also examined. HUFAs were considered to be fatty acids with  $\geq 20$  carbons in length and  $\geq 3$  carbon-carbon, double bonds. The equation for calculation was:  $(20:3n-3 + 20:5n-3 + 22:5n-3 + 22:6n-3)/(20:3n-3 + 20:5n-3 + 22:5n-3 + 22:6n-3 + 20:3n-6 + 20:4n-6 + 22:4n-6 + 22:5n-6 + 20:3n-9) \times 100$ . A comparison of TLE and PL fractions in plasma and erythrocytes were compared by two-way ANOVA. Mean comparisons for the rat and pig tissues were made by ANOVA. Tukey's Honestly Significantly Different (HSD) test was used for individual mean comparisons when significant *F*-values were determined. Pearson's correlations were also determined to examine the association of the n-3 HUFA score in blood fractions with other blood measures of omega-3 fatty acid status, and the associations between blood fractions and various tissues in rats and pigs. The corresponding n-3 HUFA score and EPA + DHA correlations between blood and animal tissues were compared by Fisher's Exact Z-test. All statistics were completed with SPSS for Windows statistical software (release 11.5.1; SPSS Inc., Chicago, IL, USA).

## Results

### Comparison of the Omega-3 Status of Different Blood Fractions in Humans

The percentage of EPA and DHA in blood of the present study participants was low with a relatively low level of variance in each fraction and as determined by various indices (Table 1). The percentages of EPA and DHA were compared according to plasma versus erythrocytes and TLE versus PLs by two-way ANOVA. The percentage of EPA in plasma was significantly higher ( $P < 0.001$ ) as compared with erythrocytes with no significant effect of the TLE versus the PL isolate. A significant interactive effect ( $P < 0.001$ ) was determined for the percentage of DHA with all four individual means significantly different by Tukey's HSD ( $P < 0.05$ ) testing. Plasma TLE contained the lowest percentage of DHA followed by plasma PL, erythrocyte PL, and erythrocyte TLE containing the highest. The interactive effect observed for DHA persisted for the EPA + DHA values, EPA + DPAn-3 + DHA, the n-3 HUFA score and the ratio of total n-3 PUFA to total n-6 PUFA ( $P < 0.001$  for all except  $P = 0.016$  for the n-3

<sup>4</sup> EPA + DHA = 20:5n-3 + 22:6n-3

<sup>5</sup> n-3 HUFA Score = % of omega-3 HUFA in total HUFA

HUFA score). The EPA + DHA values were significantly lower in plasma TLE and the highest in erythrocyte TLE with plasma PL and erythrocyte PL demonstrating no difference. Including DPAn-3 in the sum of EPA + DHA resulted in each mean being significantly different by

Tukey's HSD as the mean values all increased (approximately 20% in plasma to 2.14  $\pm$  0.63 in TLE and 3.16  $\pm$  0.80 in PL, and approximately 33% in erythrocytes to 5.08  $\pm$  0.73 in TLE and 4.30  $\pm$  0.6 in PL). The individual means were also significantly different for each ratio of n-3/n-6. The individual mean differences for the n-3 HUFA scores were restricted to erythrocyte TLE being significantly higher than plasma TLE and PL (*P* < 0.001) but not erythrocyte PL (*P* = 0.075).

The n-3 HUFA scores from plasma and erythrocyte TLE were significantly correlated with other measured markers of omega-3 status except the % EPA in erythrocyte PL (Table 1). Correlations between TLE and PL fractions within a blood fraction were particularly strong with *r* = 0.93 for plasma TLE and PL n-3 HUFA scores and *r* = 0.94 for erythrocyte TLE and PL n-3 HUFA scores. Corresponding correlation coefficients within a biomarker were: *r* = 0.94 for plasma TLE EPA + DHA and PL EPA + DHA and *r* = 0.92 for erythrocyte TLE EPA + DHA and PL EPA + DHA; *r* = 0.93 for plasma TLE EPA + DPAn-3 + DHA and PL EPA + DPAn-3 + DHA and *r* = 0.92 for erythrocyte TLE EPA + DPAn-3 + DHA and PL EPA + DPAn-3 + DHA; and *r* = 0.92 for plasma TLE n-3/n-6 and PL n-3/n-6 and *r* = 0.92 for erythrocyte TLE n-3/n-6 and PL n-3/n-6.

#### Associations of Blood n-3 HUFA Scores to Tissue Levels of Omega-3 Fatty Acids in Animals

The n-3 HUFA score and the EPA + DHA sum both vary in magnitude across various tissue and organs in the control animals (Figs. 1, 2). In the TLE of tissues analyzed from dam reared rats, the n-3 HUFA score and the EPA + DHA values were the highest in brain at 51.3  $\pm$  1.3 and 12.18  $\pm$  0.62%, respectively. Liver, heart, and adipose TLE had similar n-3 HUFA scores, but different omega-3 indices. Plasma and erythrocytes were statistically similar by both the n-3 HUFA score and EPA + DHA, but a larger sample size would likely elicit a difference between plasma and erythrocytes by EPA + DHA values as a post hoc paired *t*-test between plasma and erythrocyte EPA + DHA values indicate a significant difference (*P* < 0.05). These observations were reflected in the tissues of the pigs on the control diet; however there were smaller differences between the various tissues particularly when the omega-3 status was expressed as the n-3 HUFA score (Fig. 2). The pig brain tissue had the highest n-3 HUFA score and EPA + DHA-value (27.4  $\pm$  2.9 and 6.7  $\pm$  1.3%, respectively). In the pig, the n-3 HUFA scores for plasma, liver, and carcass were all significantly lower than the brain score, but did not differ from each other, while the EPA + DHA-values were all significantly different from

**Fig. 1** The n-3 HUFA scores and EPA + DHA values of total lipid extracts from tissues of dam-reared rats. Mean  $\pm$  SD,  $n = 7$ . Different *alpha* superscripts indicate significantly different values ( $P < 0.05$ ) by Tukey's Honestly Significant Difference Test following significance by one-way ANOVA ( $P < 0.05$ ). EPA eicosapentaenoic acid (20:5n-3), DHA docosahexaenoic acid (22:6n-3), HUFA highly unsaturated fatty acid ( $\geq 20$  carbons,  $\geq 3$  carbon-carbon double-bonds)

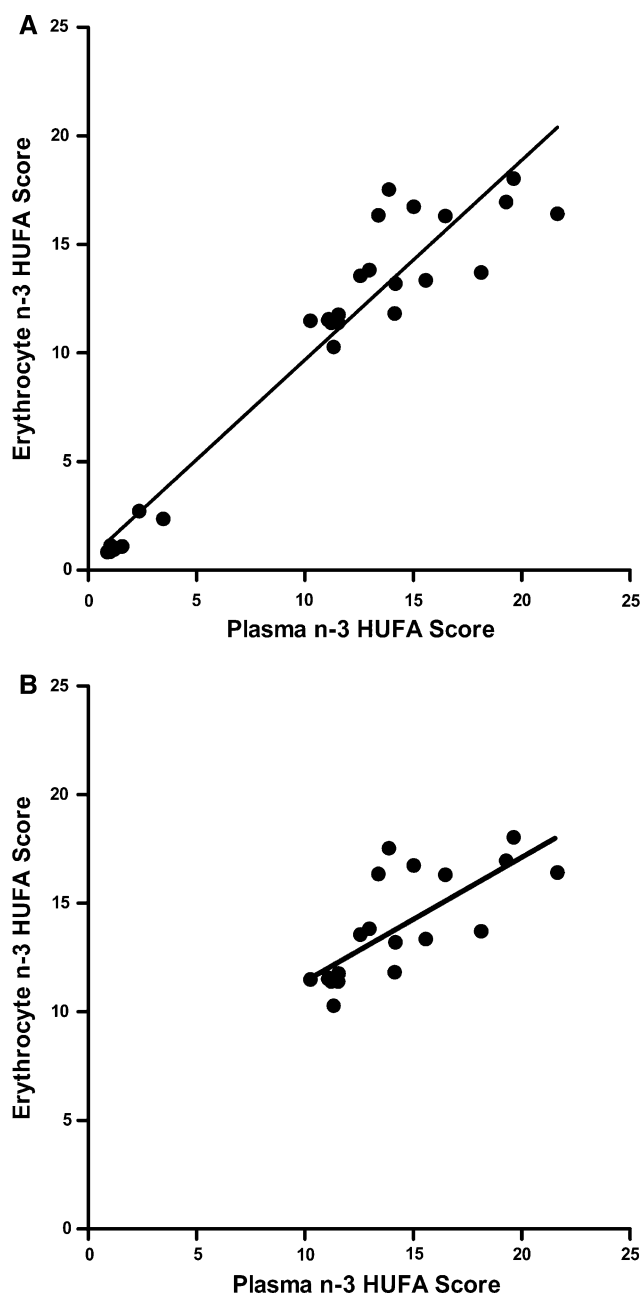

**Fig. 2** The n-3 HUFA scores and EPA + DHA-values of total lipid extracts from tissues of pig raised on a control diet. Mean  $\pm$  SD,  $n = 25$ . Different *alpha* superscripts indicate significantly different values ( $P < 0.05$ ) by Tukey's Honestly Significant Difference Test following significance by one-way ANOVA ( $P < 0.05$ ). EPA eicosapentaenoic acid (20:5n-3), DHA docosahexaenoic acid (22:6n-3), HUFA highly unsaturated fatty acid ( $\geq 20$  carbons,  $\geq 3$  carbon-carbon double-bonds)

each other with carcass EPA + DHA having the lowest value ( $0.19 \pm 0.12\%$ ). The sum of EPA + DPAn-3 + DHA reflected the sum of EPA + DHA statistically for tissues from both rats and pigs (data not shown). The ratio of n-3/n-6 for individual tissues tended to resemble the pattern of n-3 HUFA score, except adipose n-3/n-6 was significantly less than n-3/n-6 in liver and heart and similar to n-3/n-6 in plasma and erythrocytes in the rat and liver n-3/n-6 was significantly higher than plasma and carcass (data not shown).

The amount of omega-3 fatty acids in plasma and erythrocyte can correlate well with various organ tissues by the n-3 HUFA score, the EPA + DHA sum and the ratio of total n-3 to n-6 PUFA (Tables 2, 3). Correlations between n-3 HUFA score blood markers with the various tissues tended to be more robust than those determined by EPA + DHA and to a lesser extent the ratio of n-3/n-6. In a sample of rats that included both omega-3 deficient and omega-3 adequate rats, both plasma, and erythrocytes were significantly correlated with liver, heart, brain, and adipose tissue. The correlations between blood n-3 HUFA scores and liver were significantly greater than the corresponding EPA + DHA values by Fisher's exact Z-test ( $P < 0.001$ ). The correlations between n-3 HUFA scores in blood and adipose were also significantly greater than corresponding n-3/n-6 correlations.

Removing the omega-3 deficient animals from the analysis results in increased error in correlation determination as evidenced by increased SD for slope and Y-intercepts (Fig. 3) and resulted in generally lower correlations between omega-3 status in blood markers and tissues. In the omega-3 adequate rats, all of these n-3 HUFA score correlations remained significant ( $P < 0.05$ ) except for plasma n-3 HUFA score and heart n-3 HUFA score ( $r = 0.42$ ,  $P = 0.06$ ). For the EPA + DHA-values, heart and adipose indices correlated to neither plasma nor erythrocytes, and plasma and liver EPA + DHA did not correlate. Correlations based on the sum of EPA + DPAn-3 + DHA (not shown) resulted in slight but not significant increases in selected correlations as compared to EPA + DHA. However, the significant differences between correlations for EPA + DHA and the n-3 HUFA score for plasma-heart and erythrocyte-adipose in the omega-3 adequate rats disappeared when DPAn-3 was added to EPA and DHA. There was no increase in the correlation between plasma and liver EPA + DHA when DPAn-3 was added. Also in the omega-3 adequate rats, the n-3/n-6 ratio correlations were slightly more robust than the sum of EPA + DHA. The n-3/n-6 correlation between erythrocyte and heart was lower than the corresponding n-3 HUFA score correlation ( $P < 0.05$  by Fisher's exact Z-test). The n-3/n-6 correlations for blood and adipose tended to be stronger than the n-3 HUFA score correlations, but did not reach significance (plasma-adipose,  $P = 0.052$ , and erythrocyte-adipose,  $P = 0.070$  by Fisher's exact Z-test).

Correlations for the omega-3 biomarkers between plasma TLE and liver, carcass, and brain TLE from pigs feed varying amounts of omega-3 fatty acids were also determined and compared. The n-3 HUFA score and n-3/n-6 ratio correlations were similar and tended to be higher than the correlations based on the sum of EPA + DHA (Table 3) with the inclusion of DPAn-3 in the sum making no difference (not shown). Plasma correlated with all

**Fig. 3** The n-3 HUFA score of total lipid extract of erythrocytes versus plasma. **a** Omega-3 deficient and adequate rats ( $n = 31$ ). Slope =  $0.9197 \pm 0.04807$ ,  $Y$ -intercept =  $0.4874 \pm 0.5743$ . **b** Omega-3 adequate rats only ( $n = 21$ ). Slope =  $0.5716 \pm 0.1157$ ,  $Y$ -intercept =  $5.685 \pm 1.673$ . HUFA highly unsaturated fatty acid ( $\geq 20$  carbons,  $\geq 3$  carbon-carbon double-bonds)

values except brain by EPA + DHA ( $r = 0.10$ ,  $P = 0.50$ ) and EPA + DPAn-3 + DHA ( $r = 0.13$ ,  $P = 0.37$ ). Although the n-3 HUFA score and n-3/n-6 correlations tended to be stronger than the EPA + DHA correlations (with and without DPAn-3), the differences did not reach significance by Fisher's Exact Z-test.

## Discussion

The n-3 HUFA score is a suitable biomarker for omega-3 status in human blood and appears to offer several advantages over the sum of EPA + DHA. The present study demonstrates that (1) the differences between TLE and PL lipid classes of blood fractions are minimal when omega-3 fatty acid status is expressed as the n-3 HUFA score as compared with EPA + DHA and n-3/n-6; (2) the association between omega-3 fatty acid status in blood with various tissues was more robust when predicted by the n-3 HUFA score for liver, heart and brain as compared to EPA + DHA and for heart when compared to n-3/n-6.

Plasma and erythrocytes tend to be the blood fractions analyzed most often, although whole blood, platelets and leukocytes have been analyzed as well. Platelets and leukocytes require extra isolation steps that limit their utility as potential biomarkers. Erythrocytes, due to a longer half-life, have been considered to reflect diet intakes over a longer period as compared with plasma. However, this assumption fails to account for the short half-lives of fatty acids in erythrocyte membranes (7–9 h) [27]. Consistent with the short half-lives of erythrocyte fatty acid membranes, recent evidence suggests that erythrocytes respond to dietary interventions in a similar time course as do plasma pools, possibly through active fatty acid exchange [28]. Differences in fatty acid composition between blood fractions as observed in the EPA + DHA values in plasma TLE ( $1.72 \pm 0.57\%$ ) and erythrocyte TLE ( $3.43 \pm 0.67\%$ ) in the present study are reflective of the lipid class characteristics of the blood fraction. The lipid classes of tissues have been presented previously [29]. Erythrocytes contain  $\sim 32\%$  phosphatidyl choline,  $21\%$  phosphatidyl ethanolamine, and have a large cholesterol component ( $30\%$ ), while plasma tends to be dominated by triacylglycerols ( $49\%$ ) with  $24\%$  phosphatidyl choline,  $16\%$  cholesteryl esters, and minor contributions from phosphatidyl ethanolamine.

Expressing the plasma and erythrocyte omega-3 status in TLE as the n-3 HUFA score reduces the differences between the different blood fractions by focusing on the HUFA pool. Glycerolipid synthesis typically results in a saturated fatty acid (14:0, 16:0, 18:0) in the *sn*-1 position and a 16 or 18 carbon unsaturated fatty acid (16:1n-7, 18:1n-7, 18:1n-9, 18:2n-6, and 18:3n-3) in the *sn*-2 position of the molecule. HUFA such as EPA, DHA, and AA are not extensively incorporated in triacylglycerols. HUFA tend to be *trans*-esterified into the *sn*-2 position of PLs, reflecting their structural and cell-signaling roles in membranes. In addition, phosphatidyl ethanolamine has a tendency to have greater amounts of DHA *trans*-esterified into the *sn*-2 position as compared with phosphatidyl choline [30]. While the isolation of the PL class of plasma

and various tissues is preferred for examining cell membrane composition, this requires an extra analytical step that would prove difficult to automate for high-throughput analyses. Examining the amount of omega-3 HUFA in the total HUFA pool in TLE is a good reflection of the status of the *sn*-2 position of PLs. The correlations between the n-3 HUFA score in plasma TLE and PL was 0.93 and in erythrocyte TLE and PL was 0.94 in the present study.

There is significant evidence to conclude that omega-3 HUFAs are important for supporting optimal brain and heart function, likely at the level of cellular membrane structure [6, 11, 31]. The ability to predict omega-3 HUFA levels in these tissues is highly relevant for determining the utility of a biomarker. In the present study, the associations between various tissues and blood fractions tended to be stronger when expressed as n-3 HUFA score as compared with EPA + DHA. This was particularly evident when omega-3 deficient animals were excluded from the analyses (Table 2) as predicting the linear relationship is more variable with the smaller range in the data (Fig. 3). Associations as determined by n-3 HUFA scores tend to be more robust and are well-suited for examinations in humans given that the minimum n-3 HUFA score in plasma TLE in the present human sample was 12.99%.

As presently described, the n-3 HUFA score is more inclusive than EPA + DHA as DPAn-3 is part of the equation. Evidence for DPAn-3 specific health benefits is very limited and impossible to isolate from EPA and DHA [32, 33]. However the content of DPAn-3 can be equivalent and often higher than EPA with the notable exception being plasma [24] and increased DPAn-3 can decrease the production of AA-derived eicosanoids [33]. The inclusion of DPAn-3 in the sum of EPA + DHA resulted in minor but non-significant increases in the correlations between blood and tissues. The stronger correlations between tissues with the n-3 HUFA score appears to be attributed less

to the inclusion of DPAn-3 and more to the use of a relative expression as the ratio of n-3 to n-6 PUFA also appeared more robust than the summation of EPA + DHA.

The EPA + DHA blood levels in the present human sample are at the low end of the range observed in humans [34]. This is a reflection of the low and homogeneous intake of omega-3 fatty acids in the present population [14] even as compared with other North Americans [35, 36]. Although the present findings are limited to a small and tightly defined human sample, the observations are supported by similar observations in rat and pig studies. While the present evidence for the use of the n-3 HUFA score is far from conclusive, it is substantial enough to provoke further comparisons in larger studies; in particular, associations with disease risk are required. However, determining the n-3 HUFA score is easily completed on new and existing fatty acid composition data, and as demonstrated by the present study, is not dependent on a specific blood fraction.

**Abstract** This study examined the dietary effects of enzymatically modified sesame oil with caprylic acid (structured lipids, SL) and phytosteryl esters (PE) on blood lipid profiles and cardiovascular parameters of spontaneously hypertensive rats (SHR) fed high-fat and high-cholesterol (HFHC) diets. The dietary groups were: normal diet (control), sesame oil (SO), SL, SO fortified with PE (SOP), and SL fortified with PE (SLP). After 9 weeks of feeding, the body weights, liver weights, and liver weight/body weight ratios in all HFHC-fed groups were higher than controls. Plasma total and LDL cholesterol levels in all HFHC-fed groups were similar to one another but higher than those in controls. Plasma HDL cholesterol levels in rats fed SOP and SLP were higher than those in controls or rats fed SO and SL. Plasma HDL/total cholesterol ratios in rats fed SOP and SLP were similar to those in controls and were higher than those in rats fed SO and SL. There was no difference in plasma lipid profiles between rats fed SO and SL. Arterial blood pressures (BP) in conscious HFHC-fed rats were similar to those in controls whereas heart rates (HR) in all HFHC-fed groups were similar to one another but were higher than that in controls. These findings demonstrate that (1) the dietary effects of SL on plasma lipid profiles and resting BP and HR are similar to those of SO, (2) PE had positive effects on plasma lipid profiles, and (3) 9-week intake of SL and PE did not have pronounced effects on resting BP but induced tachycardia in SHR.

## Introduction

Structured lipids are triacylglycerols that have been restructured by incorporation of new fatty acids to change the composition and positional distribution of

fatty acids from the native state by chemical or enzymatic methods [1]. Among several types of structured lipids, MLM-type structured lipids are triacylglycerols comprising medium chain fatty acids esterified at *sn*-1,3 positions and long chain fatty acids at *sn*-2 position of the glycerol backbone. MLM-type structured lipids can be synthesized by attaching medium chain fatty acids into long chain triacylglycerols (LCT) with the help of *sn*-1,3 regiospecific lipases. These MLM-type structured lipids are expected to have different physiological attributes from LCT, the typical triacylglycerol forms of many edible fats and oils, because of the presence of both medium chain and long chain fatty acids in the same triacylglycerol molecules. For example, when compared to LCT, they are expected to deliver the energy more rapidly via oxidation of the more hydrophilic medium chain fatty acids and less likely to be deposited in the adipose tissue due to the predominant transportation of medium chain fatty acids via the portal vein to the liver rather than through the lymphatic system [1–5]. Therefore, MLM-type structured lipids with proper balance of medium chain fatty acids and long chain fatty acids, such as essential fatty acids (e.g., linoleic acid) and hypocholesterolemic fatty acids (e.g., oleic acid [6]), might have positive effects on blood lipid profiles and cardiovascular status of humans as well as meeting essential fatty acid requirements while providing the benefits of medium chain fatty acids described above. Although MLM-type structured lipids are expected to have different physiological attributes from LCT, there are few studies evaluating the dietary effects of MLM-type structured lipids, especially their effects on cardiovascular status of animals and humans.

On the other hand, phytosterols are known to have hypocholesterolemic effects by lowering plasma total and low density lipoprotein (LDL) cholesterol levels without affecting plasma high density lipoprotein (HDL) cholesterol levels in humans and some animals, such as rabbits [7–10]. The cholesterol-lowering mechanisms of phytosterols in humans are still not known in detail. Recently, the inhibited absorption of cholesterol in intestine arising from chemical structure similarities between phytosterols and cholesterol is believed to be the main mechanism of their hypocholesterolemic effects [11]. Besides, other mechanisms such as competition with cholesterol for solubilization in dietary mixed micelles, co-crystallization with cholesterol to form insoluble mixed crystals, and interference with the hydrolysis process by lipases and cholesterol esterases are suggested to be responsible for their hypocholesterolemic effects [11]. However, phytosterols have limitations as dietary supplements because they have very poor solubilities in edible oil and have very high melting points. To overcome such physical problems of

free phytosterols, phytosteryl esters (fatty acid ester forms of phytosterols) are preferred in food formulation. Because phytosteryl esters have much enhanced solubility in oils and much lower melting point compared to their corresponding phytosterols, they can be easily incorporated into a wide variety of diets and fat/oil-based diets and food products. Moreover, many recent studies have shown that phytosteryl esters can also effectively reduce plasma total and LDL cholesterol levels similar to phytosterols in humans [12–15].

The aim of our study was to investigate the dietary effects of sesame oil-based MLM-type structured lipids and phytosteryl esters on the blood lipid profiles and cardiovascular parameters of spontaneously hypertensive rats (SHR), a widely studied animal model of cardiovascular disorders (e.g., essential hypertension) of humans [16, 17]. The principal hypotheses of our study were: (1) the dietary effects of the structured lipids (MLM-type triacylglycerols) on the blood lipid profiles and cardiovascular status of SHR would be different from those of original sesame oil (LCT; i.e., LLL-type); and (2) dietary phytosteryl esters would have positive effects on the blood lipid profiles in SHR.

## Materials and Methods

### Materials

Sesame oil was purchased from Spectrum Organic Product, Inc. (Petaluma, CA, USA). Caprylic acid (C8:0, purity >98%) was obtained from Aldrich Chemical Company (Milwaukee, WI, USA). Phytosteryl esters (from vegetable oil deodorizates) were donated by Cargill Inc. (Minneapolis, MN, USA). Lipozyme RM IM, an *sn*-1,3 regiospecific immobilized lipase from *Rhizomucor miehei* was provided by Novozymes North America, Inc. (Franklinton, NC, USA).

### Structured Lipids Synthesis

The sesame oil-based structured lipids (MLM-type) were synthesized by Lipozyme RM IM-catalyzed acidolysis reaction of sesame oil with caprylic acid as described previously [18].

### Fatty Acid Profiles of Fat Source

Total and positional fatty acid profiles of fat sources of experimental diets were analyzed according to the procedures described previously [18].

## Rats

All animal studies were performed according to the National Institutes of Health Guide for the Care and Use of Laboratory Animals (NIH Publications No. 80–23) revised in 1996. All protocols were approved by the Animal Care and Use Committee of the University of Georgia. Four-week-old male SHR ( $n = 30$ ) were obtained from Harlan (Madison, WI, USA). They were randomly assigned to one of five different dietary groups described below ( $n = 6$  per group). The rats were individually housed in cages under controlled temperature ( $21 \pm 1$  °C) and lighting (12 h light/dark cycle). The rats were fed diets and water ad libitum for 9 weeks. Diet intakes were recorded daily and body weights were measured weekly. After the cardiovascular measurements described below, the rats were killed by decapitation and then their organs (liver, heart, and kidney) were removed and weighed.

## Diets

Normal diet for the control rats was purchased from Lab-diet (Brentwood, MO, USA). The fat and cholesterol contents of the normal diet were 4.5 and 0.02% of total diet weight, respectively. The high-fat and high-cholesterol (HFHC) diets were prepared and pelleted by Research Diets (New Brunswick, NJ, USA). Four different kinds of HFHC diets were made for four different dietary groups: *sesame oil (SO)*, *structured lipids (SL)*, *sesame oil fortified with phytosteryl esters (SOP)*, and *structured lipids fortified with phytosteryl esters (SLP)* (Table 1). The four formulations for HFHC dietary groups were identical in composition, except for the type of fat. The HFHC diets contained SO, SL, SOP, or SLP as a fat source (20% of total diet weight), respectively. Dietary cholesterol was adjusted to 0.56% of total diet weight in all HFHC diets. The amount of phytosteryl esters added in the HFHC diets for the groups SOP and SLP was adjusted to 0.54% of total diet weight (2.4 g/2,000 kcal) approximately corresponding to a therapeutic level (1.5–3.0 g/day) for hypocholesterolemic effects in humans [14, 15, 19–25]. All HFHC diets were almost isoenergetic (diets for groups SO and SL, 4.54 kcal/g; diets for groups SOP and SLP 4.50 kcal/g).

## Surgeries, Blood Collection and Cardiovascular Measurements

Twelve hours before the surgeries were performed, all rats were deprived of food. Water was freely available. All rats

were anesthetized with pentobarbital sodium (50 mg/kg, i.p.) and a catheter (PE-50) was placed in a femoral artery to record systolic arterial blood pressure (SBP), diastolic arterial blood pressure (DBP), pulse pressure (PP), and mean arterial blood pressure (MAP) [26, 27]. The catheters were exteriorized to the back of the neck and all wounds were liberally coated with triple antibiotic (neomycin, polymixin B, and bacitracin) ointment (Fougera, NY, USA) and then sutured. The arterial catheter was connected to a pressure transducer that was coupled to a computerized data acquisition system (PowerLab Chart, version 4.0.4, ADI Instruments, Colorado Springs, CO, USA) to record resting arterial blood pressures and heart rate (HR), which was derived from PP by way of an internal cardiota-chometer in the data acquisition system [26, 27]. Once the resting cardiovascular parameters were recorded, 2 mL of blood was taken via the arterial catheter for subsequent determination of plasma lipid profiles described below. The rats were returned to their home cages in a room maintained on a 12 h light/dark cycle. Food and water were freely available. The rats were given 2 days to recover from the above surgeries. On the day of data recording, the arterial catheter of each conscious rat was connected to the pressure transducer and recording equipment as described above.

## Plasma Lipid Profiles

Blood plasma samples were analyzed to determine total, HDL, and LDL cholesterol, and triacylglycerol levels. Total and HDL cholesterol levels were determined by the cholesterol oxidase method with Equal reagents (Equal Diagnostics, Exton, PA, USA), respectively. Plasma triacylglycerols levels were determined by the glycerol phosphate oxidase method with Amresco reagents (Amresco Inc., Solon, OH, USA). The measurements were conducted using a Roche/Hitachi 717 analyzer (Roche Diagnostics, Indianapolis, IN, USA). Plasma LDL cholesterol level was calculated using the Friedwald calculation,  $LDL \text{ cholesterol} = \text{total cholesterol} - (\text{triacylglycerol} / 5 + \text{HDL cholesterol})$ .

## Statistical Analysis

The data are presented as mean  $\pm$  SEM and were analyzed by one-way or repeated-measures analysis of variance (ANOVA) [28] followed by Student's modified *t* test with the Bonferroni correction for multiple comparisons between means using the error mean square (EMS) terms from the ANOVA [29]. A value of  $P < 0.05$  denoted statistical significance.

## Results

### Fatty Acid Compositions of Fat Sources

Total and positional fatty acid compositions of fat sources of experimental diets are given in Table 2. Major fatty acids of control diet were oleic acid (27.2 mol%), linoleic acid (26.5 mol%), palmitic acid (20.2 mol%), and linolenic acid (17.6 mol%). Accordingly, the fat in the control diet originated from a mixture of animal fat and vegetable oil (see Table 1 legend). Two major fatty acids of sesame oil were oleic acid (37.0 mol%) and linoleic acid (48.4 mol%). The total content of palmitic acid in sesame oil was 10.0 mol%. Whereas, structured lipids presented reduced total contents of palmitic acid (3.1 mol%), oleic

acid (19.4 mol%), and linoleic acid (30.0 mol%), respectively, compared to the original sesame oil. Total caprylic acid content of structured lipids was 45.8 mol%. The content of caprylic acid found at *sn*-2 position of the structured lipids was 3.7 mol%. Major fatty acids present at the *sn*-2 position of original sesame oil (oleic acid, 40.2 mol%; linoleic acid, 57.3 mol%) remained almost intact at that position in the structured lipids (oleic acid, 36.4 mol%; linoleic acid, 57.2 mol%). The incorporation of caprylic acid into *sn*-1,3 positions, as we intended by using Lipozyme RM IM (an *sn*-1,3 regiospecific lipase) in the synthesis of structured lipids, reached 66.8 mol%. These results demonstrate that MLM-type structured lipids were successfully produced from sesame oil and caprylic acid.

### Diet Intake, Weight Gain and Food Efficiency Ratio

The total diet intakes, weight gains and food efficiency ratios (FER, weight gain for 9 weeks/diet intake for 9 weeks) in the five dietary groups are summarized in Table 3. The diets began when the rats were 4 weeks old and continued until they were 13 weeks old. Although the rats in each group ate similar (*P* > 0.05, for all comparisons) amounts of food, the HFHC dietary groups, i.e., the rats fed SO, SL, SOP, and SLP put on more (*P* < 0.05, for

all comparisons) weight, and accordingly had higher (*P* < 0.05, for all comparisons) FER values than the control group.

### Body and Organ Weights

After 9 weeks of feeding, the body weights, organ (liver, heart, and kidney) weights, and organ weights to body weight ratios of HFHC dietary groups were compared to those of control rats fed normal diet. The body weights (BW) of the groups SO (333 ± 7 g), SL (339 ± 12 g), SOP (319 ± 7 g), and SLP (338 ± 7 g) were substantially greater than that of control group (304 ± 4 g), respectively (*P* < 0.05, for all comparisons). The liver weights (LW) and liver weight to body weight ratios (LW/BW × 1,000) of the rats fed SO (LW = 17.1 ± 0.6 g; LW/BW × 1,000 = 51.3 ± 1.1), SL (LW = 16.6 ± 0.7 g; LW/BW × 1,000 = 48.9 ± 0.6), SOP (LW = 16.5 ± 0.7 g; LW/BW × 1,000 = 51.5 ± 1.3), and SLP (LW = 17.3 ± 0.7 g; LW/BW × 1,000 = 51.2 ± 1.9) were substantially greater than those of control rats (LW = 9.6 ± 0.5 g; LW/BW × 1,000 = 31.6 ± 3.1), respectively (*P* < 0.05, for all comparisons). Whereas, the heart weights, heart weight to body weight ratios, kidney weights, and kidney weight to body weight ratios of the rats fed SO, SL, SOP, and SLP were similar to those of control rats (data are not shown; *P* > 0.05, for all comparisons).

**Table 3** Total diet intake, weight gain and food efficiency ratio

	Dietary group				
	Control	SO	SL	SOP	SLP
Diet intake (g/day)	16 ± 1	15 ± 1 <sup>†</sup>	15 ± 1 <sup>†</sup>	15 ± 1	16 ± 1
Weight gain (g/9 weeks)	263 ± 4	303 ± 8 <sup>*†</sup>	296 ± 9 <sup>*†</sup>	284 ± 7 <sup>*</sup>	296 ± 7 <sup>*</sup>
FER <sup>a</sup>	16 ± 1	36 ± 1 <sup>*†</sup>	35 ± 1 <sup>*†</sup>	35 ± 1 <sup>*</sup>	34 ± 1 <sup>*</sup>

## Plasma Lipid Profiles

Plasma lipid profiles in the five dietary groups are shown in Fig. 1. The plasma total and LDL cholesterol levels and LDL to total cholesterol ratios were similar ( $P > 0.05$ , for all comparisons) in all HFHC dietary groups but were higher ( $P < 0.05$ , for all comparisons) than those in the control group. However, the plasma HDL cholesterol levels in the rats fed phytosteryl esters, i.e., the groups SOP and SLP were higher than those in the control group and the other HFHC dietary groups such as SO and SL ( $P < 0.05$ , for all comparisons). Furthermore, the plasma HDL to total cholesterol ratios in the groups SOP and SLP were also higher ( $P < 0.05$ , for all comparisons) than those in the groups SO and SL and were similar ( $P > 0.05$ , for all comparisons) to that in the control group. The plasma triacylglycerol levels were similar ( $P > 0.05$ , for all comparisons) in all HFHC dietary groups but were lower ( $P < 0.05$ , for all comparisons) than that in the control group. On the other hand, no distinct differences were found in the overall plasma lipid profiles between groups SO and SL ( $P > 0.05$ , for both comparisons).

## Resting Cardiovascular Parameters in Anesthetized Rats

Resting values for the cardiovascular parameters in the five dietary groups recorded under pentobarbital anesthesia are summarized in Fig. 2. Resting parameters in the control group were similar to those reported previously [30–32]. As can be seen, resting SBP values in the HFHC dietary groups were lower than those in the control group

( $P < 0.05$ , for all comparisons). Resting DBP value in the rats fed SL was lower than that in the control group ( $P < 0.05$ , for both comparisons). The PP values in the rats fed SOP or SLP were lower than that in the control group ( $P < 0.05$ , for both comparisons). Resting HR value of the rats fed SO was higher than that of the control rats ( $P < 0.05$ , for both comparisons). On the other hand, all resting arterial blood pressures, i.e., SBP, DBP, PP, and MAP and resting HR in the rats fed SL tended to be slightly lower than those in the rats fed SO but the differences were not significant ( $P > 0.05$ , for both comparisons).

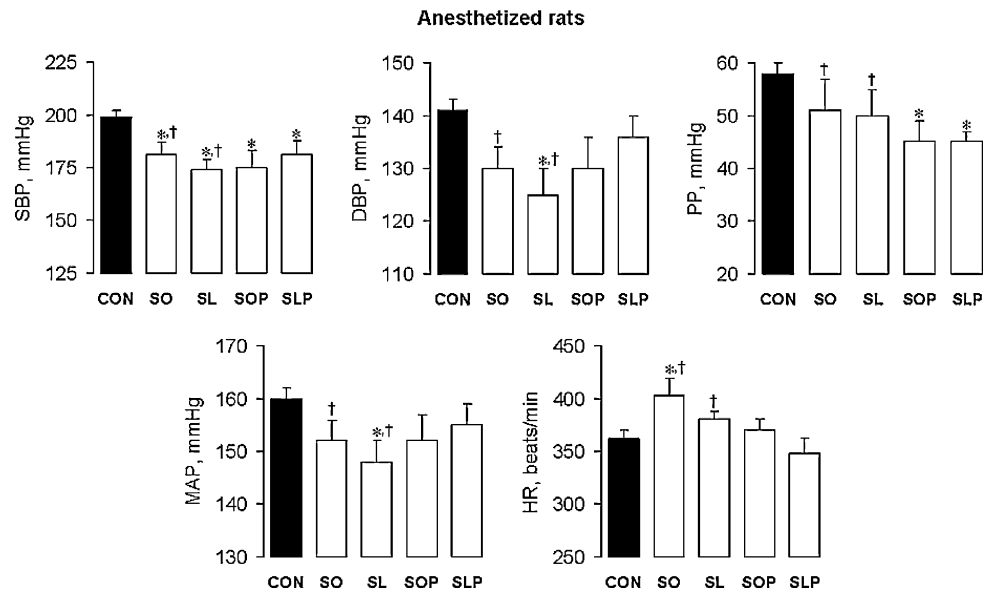

## Resting Cardiovascular Parameters in Conscious Rats

Resting values for the cardiovascular parameters in the five dietary groups of conscious rats are summarized in Fig. 3. Resting parameters in the control rats were similar to those reported previously [33–35]. As can be seen, resting HR values in all HFHC dietary groups were substantially higher than that in the control rats ( $P < 0.05$ , for all comparisons). However, resting arterial blood pressures, i.e., SBP, DBP, PP, and MAP in all HFHC dietary groups were similar to those in the control group ( $P > 0.05$ , for all comparisons), with one exception. Specifically, the PP value for the rats fed SLP was lower than that of the control rats ( $P < 0.05$ , for both comparisons). On the other hand, all resting arterial blood pressures tended to be slightly lower in the group SL than in the group SO; whereas, resting HR tended to be slightly higher in the group SL than in the group SO. However, the differences were not significant ( $P > 0.05$ , for both comparisons).

The data are presented as mean  $\pm$  SEM. \* $P < 0.05$ , versus control. † $P > 0.05$ , SO versus SL

## Discussion

### Effects of Dietary MLM-Type Structured Lipids

The present study showed that the dietary effects of MLM-type structured lipids produced from sesame oil and caprylic acid on the plasma lipid profiles in SHR were not different from those of original sesame oil. The major rationale for MLM-type structured lipids development is based on (1) the difference in the metabolic aspects of long chain fatty acids by their positional distribution in triacylglycerol and (2) the rapid metabolism of medium chain fatty acids in triacylglycerol. The long chain fatty acids at the *sn-2* position of the triacylglycerol are preferentially absorbed and stored in humans compared to the long chain

fatty acids located at the *sn-1,3* positions since triacylglycerols are hydrolyzed into free fatty acids and *sn-2* monoacylglycerols by lipoprotein lipase, and *sn-2* monoacylglycerols readily form mixed micelles with bile salts [36, 37]. The medium chain fatty acids are poorly transported through the lymphatic system [38]. Instead, they are readily absorbed and transported through the portal system especially when they are at the *sn-1,3* positions in triacylglycerol and this leads to more rapid absorption of MLM-type structured lipids compared to LCT [4, 37–39]. The total contents of the principal long chain fatty acids (e.g., palmitic, oleic, and linoleic acids) of original sesame oil were reduced in the structured lipids due to their replacement with caprylic acid. However, their *sn-2* positional contents were similar in both sesame oil and

**Fig. 3** Dietary effects on resting cardiovascular parameters in *conscious rats*: systolic arterial blood pressure (SBP); diastolic arterial blood pressure (DBP); pulse pressure (PP); mean arterial blood pressure (MAP); heart rate (HR). Treatment groups: CON, control; SO, sesame oil; SL, structured lipids; SOP, sesame oil fortified with phytosteryl esters; SLP, structured lipids fortified with phytosteryl esters. The data are presented as mean  $\pm$  SEM. \* $P < 0.05$ , versus control. † $P > 0.05$ , SO versus SL

structured lipids because most caprylic acids were incorporated at *sn*-1,3 positions in the structured lipids. Therefore, the similarity in *sn*-2 positional fatty acid profiles between sesame oil and structured lipids as well as more efficient absorption of structured lipids compared to sesame oil might be the reasons for the lack of difference in their dietary effects on plasma lipid profiles.

On the other hand, the effects of *sn*-1,3 positional fatty acid profiles of both oils on plasma lipid profiles were also shown to be comparable to each other. Cater et al. [40] suggested that medium chain fatty acids including caprylic acid might be hypercholesterolemic and hypertriglyceridemic. They found that a medium chain triacylglycerol diet, where 43% of total dietary calories were provided as caprylic acid and capric acid tended to increase plasma LDL cholesterol and triacylglycerol levels in humans compared to a high oleic acid oil diet even though the medium chain triacylglycerol diet slightly lowered plasma LDL cholesterol level compared to a high palmitic acid oil diet [40]. Accordingly, the structured lipids should have been more hypercholesterolemic and more hypertriglyceridemic than original sesame oil because of their reduced content of oleic acid and considerable high content of caprylic acid. However, the present study showed that both SHR fed sesame oil and those fed structured lipids presented similar plasma total and LDL cholesterol levels as well as similar plasma triacylglycerol levels. It is very complicated to distinguish between the dietary effects of total and individual fatty acids. Nevertheless, the possible explanations are: first, the caprylic acid contents of our experimental diets containing structured lipids (i.e., diets for structured lipids dietary group and structured lipids fortified with phytosteryl esters dietary group) were approximately 18% of total dietary calories, which was considerably lower than the caprylic acid levels in their diets [40]; and second, the effects of caprylic acid, which are mostly located at *sn*-1,3 positions in the structured lipids were counterbalanced by the reduced contents of major long chain fatty acids, such as palmitic, oleic, and linoleic acids present at the same positions even though the individual fatty acids would have different effects.

#### Effects of Dietary Phytosteryl Esters

The present study showed that the plasma HDL cholesterol levels were distinctly increased in the rats fed phytosteryl esters (i.e., the rats fed sesame oil fortified with phytosteryl esters and those fed structured lipids fortified with phytosteryl esters) compared to control rats or those fed sesame oil or structured lipids alone. Moreover, the plasma HDL/total cholesterol ratios in the rats fed phytosteryl esters were similar to that in control rats. These results indicate

that dietary phytosteryl esters have positive effects on blood cholesterol profiles in SHR, as reported in humans and rabbits by others [8–10]. However, the phytosteryl esters-fed rats presented higher plasma total and LDL cholesterol levels as well as higher plasma LDL to total cholesterol ratios than control rats. These results are probably related to the fact that the diets containing phytosteryl esters have higher dietary fat and/or dietary cholesterol levels than control diets. In the case that the phytosteryl esters-fed rats are administered with the same levels of dietary fat and/or dietary cholesterol to those of the control diets, they are expected to present reduced plasma total and LDL cholesterol levels compared to the levels reported in the present study. The effects of high dietary fat levels in SHR are additionally discussed below.

#### Effects of High Dietary Fat Levels

The body weights, liver weights and liver weight to body weight ratios were higher in all HFHC dietary groups compared to the controls. In addition, the HFHC diets increased plasma total and LDL cholesterol levels compared to normal diets. As such, it appears that high dietary fat and/or cholesterol levels induce obesity and fatty liver in SHR. In contrast, heart and kidney weights and their weights to body weight ratios in the HFHC dietary groups were similar to those of the controls. The heart weights of SHR are higher than in normotensive control rats and this hypertrophy is a direct result of the higher blood pressures in SHR [16, 41]. Accordingly, the lack of effect of the HFHC diets on heart weights in the SHR is in line with the lack of major effects of the diets on resting arterial blood pressures in conscious SHR (see below).

The finding that resting systolic blood pressures of the HFHC dietary groups were lower than in controls under pentobarbital anesthesia suggests that arterial compliance was increased by these diets. This is a provocative finding and suggests that the timing and duration of high-fat feeding as well as the state of consciousness of the animal plays a major role in the expression of the changes in cardiovascular status. The finding that resting arterial pressures of the conscious HFHC dietary groups were not different to the control group is also provocative since there is evidence that high-fat diets increase arterial pressures in normotensive rats [42, 43]. The finding that the resting heart rates of the HFHC dietary groups were higher than in the controls suggests that these diets affect cardiac pacemaker activity. Whether this is due to direct effects on pacemaker cells (i.e., effects on intrinsic pacemaker activity) or changes in the release of sympathetic and parasympathetic neurotransmitters and/or their signaling mechanisms remains to be determined.

## Summary

The present study demonstrates that the dietary effects of sesame oil-based MLM-type structured lipids on the plasma lipid profiles and cardiovascular parameters (resting arterial blood pressures and heart rates) of SHR are not different from those of original sesame oil (LCT). Dietary phytosteryl esters have positive effects on the plasma cholesterol profiles in SHR. However, our findings have the limitation of applicability to humans because the rat models have traditionally not been as ideal as other rodent models (e.g., hamsters and guinea pigs) for testing the effects of dietary lipids on blood lipid and lipoprotein lipid profiles [44]. Despite the lack of obvious effects of 9-week intake of structured lipids and phytosteryl esters on resting arterial blood pressures, lower or higher dietary intakes of these compounds may have positive effects on cardiovascular status of SHR. However, these different diets elicit tachycardia in SHR. Moreover, it is important to recognize the distinct possibility that the effect of high fat diets on blood pressure, heart rate and other cardiovascular parameters may differ in SHR compared with normotensive rats.

**Abstract** Abnormal distribution of plasma fatty acids and increased inflammation are prominent features of metabolic syndrome. We tested whether these components of metabolic syndrome, like dyslipidemia and glycemia, are responsive to carbohydrate restriction. Overweight men and women with atherogenic dyslipidemia consumed ad libitum diets very low in carbohydrate (VLCKD) (1504 kcal:%CHO:fat:protein = 12:59:28) or low in fat (LFD) (1478 kcal:%CHO:fat:protein = 56:24:20) for 12 weeks. In comparison to the LFD, the VLCKD resulted in an increased proportion of serum total n-6 PUFA, mainly attributed to a marked increase in arachidonate (20:4n-6), while its biosynthetic metabolic intermediates were decreased. The n-6/n-3 and arachidonic/eicosapentaenoic acid ratio also increased sharply. Total saturated fatty acids

and 16:1n-7 were consistently decreased following the VLCKD. Both diets significantly decreased the concentration of several serum inflammatory markers, but there was an overall greater anti-inflammatory effect associated with the VLCKD, as evidenced by greater decreases in TNF- $\alpha$ , IL-6, IL-8, MCP-1, E-selectin, I-CAM, and PAI-1. Increased 20:4n-6 and the ratios of 20:4n-6/20:5n-3 and n-6/n-3 are commonly viewed as pro-inflammatory, but unexpectedly were consistently inversely associated with responses in inflammatory proteins. In summary, a very low carbohydrate diet resulted in profound alterations in fatty acid composition and reduced inflammation compared to a low fat diet.

### Abbreviations

VLCKD	Very low carbohydrate ketogenic diet
LFD	Low fat diet
PL	Phospholipid
CE	Cholesteryl ester
CVD	Cardiovascular disease
RDA	Recommended daily allowance
BMI	Body mass index
IL	Interleukin
TNF- $\alpha$	Tumor necrosis factor- $\alpha$
VEGF	Vascular endothelial growth factor
IFN- $\gamma$	Interferon- $\gamma$
EGF	Epidermal growth factor
MCP-1	Monocyte chemotactic protein-1
ICAM-1	Intracellular cellular adhesion molecule-1
VCAM-I	Vascular cellular adhesion molecule-I
NF- $\kappa$ B	Nuclear factor-kappa B

CRP	C-reactive protein
TAG	Triglycerides

## Introduction

Development of metabolic syndrome (insulin resistance syndrome) is associated with altered composition of circulating fatty acids characterized by higher saturated fatty acids (14:0, 16:0), higher palmitoleic acid (16:1n-7, the MUFA product derived from palmitic acid), higher dihomono- $\gamma$ -linolenic acid (20:3n-6, the precursor of arachidonic acid), and lower levels of linoleic acid (18:2n-6) [1]. The effect of dietary fatty acid composition on circulating fatty acids [2] is not well understood. Two recent studies demonstrated that consumption of a diet higher in saturated fat resulted in lower circulating palmitic acid (16:0) in cholesteryl ester compared to a diet low in saturated fat [3, 4], a paradox likely explained by the level of carbohydrate [5] whose increase is known to be associated with de novo fatty acid synthesis [6] and decreased fatty acid oxidation. We have previously described a comparison between a very low carbohydrate diet (VLCKD) and a low fat diet (LFD) in subjects with features of metabolic syndrome. A notable finding was an inverse relationship between dietary and plasma saturated fatty acids (SFA). The VLCKD, with three-fold greater dietary SFA than the LFD, showed a consistently greater reduction in plasma SFA compared to the LFD [7].

Metabolic syndrome is generally defined by high fasting glucose, triglycerides (TG), blood pressure and waist circumference, and low HDL cholesterol. Resistance to the effects of insulin provides a metabolic basis for changes in these disparate physiologic markers as well an increasing number of associations that extend beyond the original description of the syndrome almost 20 years ago [8]. New features that appear to be associated with metabolic syndrome include disturbed circulating fatty acid composition, perturbed lipid metabolism and increased oxidative stress and inflammation [9]. Fatty acids contribute to overall inflammatory balance by several mechanisms. In macrophages, SFA activate toll-like receptor signaling leading to activation of nuclear factor-kappa B (NF- $\kappa$ B) and expression of cyclooxygenase-2 [10, 11]. NF- $\kappa$ B is a transcription factor that regulates over 100 genes, many with an established role in inflammatory responses and atherosclerosis, and may therefore represent a crucial link between fatty acids, metabolic syndrome and atherogenesis [12]. Arachidonic acid (20:4n-6) in membranes is commonly assumed to have a deleterious effect on overall inflammatory balance because of its enzymatic conversion to proinflammatory, proaggregative, and vasoconstrictive

eicosanoids (e.g., prostaglandin E<sub>2</sub>, thromboxane A<sub>2</sub>, leukotrienes B<sub>4</sub>). Arachidonic acid is also capable of non-enzymatic conversion to other proinflammatory bioactive products (F<sub>2</sub>-isoprostanes) via interaction with molecular oxygen. In contrast, eicosanoids derived from the 20-carbon n-3 PUFA, eicosapentaenoic acid (20:5n-3), have less potent inflammatory effects [13]. A recent report showed a marked increase in the plasma 20:4n-6/20:5n-3 ratio in subjects consuming a VLCKD, while CRP, a marker of constitutive inflammation, decreased slightly [14]. The relations between inflammatory markers and arachidonic acid metabolism are complex [15], and may be further modified by the level of dietary carbohydrate.

Carbohydrate restriction is generally effective at ameliorating those physiologic markers associated with metabolic syndrome: high fasting glucose and insulin, and particularly the atherogenic dyslipidemia characterized by high TG and low HDL [16–19]. The effects are presumed to be attributed to better regulation of plasma glucose and insulin levels and improvement in the hyperinsulinemia/insulin resistance that are fundamental features of metabolic syndrome. Here we evaluated circulating fatty acid composition in three lipid fractions as well as a large number of inflammatory markers and show that a VLCKD results in profound alterations in fatty acid composition and reduced inflammatory markers to a greater extent than a low fat diet.

## Materials and Methods

### Study Design and Subjects

Details of this investigation have been described previously [7]. In brief, 40 overweight men and women aged 18–55 year with a BMI >25 kg/m<sup>2</sup> participated in this 12 week randomized, controlled, dietary intervention trial comparing a VLCKD to a LFD. All participants were required to have atherogenic dyslipidemia defined by moderately elevated TG (150 to 500 mg/dl) and low HDL [<40 (men) or <50 (women) mg/dl]. The two dietary groups were balanced for gender, age and BMI. Exclusion criteria were any metabolic and endocrine disorders, use of glucose-lowering, lipid-lowering or vasoactive prescriptions or supplements, consumption of a VLCKD, or weight loss >5.0 kg in the past 3 months. Habitual physical activity was maintained throughout the study intervention and was documented daily. Blood was drawn at baseline and after 12 week of diet intervention in the morning after a 12 h overnight fast and a 24 h abstinence from alcohol and strenuous exercise. All procedures were approved by the Institutional Review Board of the University of Connecticut, and all participants provided written informed consent.

## Dietary Intervention

Subjects received individual and personalized dietary counseling from Registered Dietitians during the dietary intervention. No explicit instructions were provided regarding caloric intake for either diet to allow expression of any non-cognitive aspects on food intake. Subjects received weekly follow-up counseling during which body mass was measured, compliance was assessed, and further dietetic education was provided. Dietary intake and compliance was assessed with detailed and weighed 7-day food records at baseline, during weeks one, 6, and 12, and was analyzed for energy and macro/micronutrient content using NUTRITIONIST PRO™ (Version 1.5, First Databank Inc, The Hearst Corporation, San Bruno, CA, USA). The nutrient analysis program had no missing values for the nutrients reported and the database was extensively updated with new foods and individualized recipes. All subjects were given a multi-vitamin/mineral complex that provided micronutrients at levels  $\leq 100\%$  of the RDA.

The main goal of the VLCKD was to restrict carbohydrate to a level that induced a low level of ketosis. Subjects monitored their level of ketosis daily using urine reagent strips. In this diet there were no restrictions on the intake of fat from saturated and unsaturated sources or the intake of cholesterol. Examples of foods consumed by the subjects included unlimited amounts of beef, poultry, fish, eggs, oils and heavy cream; moderate amounts of hard cheeses, low carbohydrate vegetables and salad dressings; and small amounts of nuts, nut butters and seeds. Subjects restricted fruit and fruit juices, dairy products (with the exception of heavy cream and hard cheese), breads, grains, pasta, cereal, high carbohydrate vegetables, and desserts. Subjects were instructed to avoid all low carbohydrate breads and cereal products, and were limited to a maximum of one sugar alcohol-containing, low carbohydrate snack per day.

The LFD was designed to provide  $<10\%$  of total calories from saturated fat and  $<300$  mg cholesterol. Foods encouraged included whole grains (breads, cereals, and pastas), fruit/fruit juices, vegetables, vegetable oils, low-fat dairy and lean meat products. Standard diabetic exchange lists were used to ensure a macronutrient balance of protein ( $\sim 20\%$  energy), fat ( $\sim 25\%$  energy), and carbohydrate ( $\sim 55\%$  of energy).

## Blood Analyses

Whole blood was collected into tubes with no preservative or EDTA and centrifuged at  $1500 \times g$  for 15 min and  $4^\circ\text{C}$ , and promptly aliquoted into separate storage tubes which were stored at  $75^\circ\text{C}$  until analyzed for serum fatty acid composition and plasma inflammatory markers. An aliquot

of anti-coagulated whole blood ( $\sim 3$  ml) was sent to a certified medical laboratory (Quest Diagnostics, Wallingford, CT, USA) for a white blood cell differential count.

## Inflammatory Biomarkers

The Evidence Investigator™ Biochip Array technology (Randox Laboratories Ltd, UK) that uses sandwich chemiluminescent immunoassays to simultaneously detect multiple analytes from a single sample was used to determine the following serum cytokines and adhesion molecules: IL-6, IL-8, vascular endothelial growth factor (VEGF), TNF- $\alpha$ , IFN- $\gamma$ , epidermal growth factor (EGF), monocyte chemoattractant protein-1 (MCP-1), intracellular cellular adhesion molecule-1 (ICAM-1), vascular cellular adhesion molecule-1 (VCAM-1), E-selectin, P-selectin and L-selectin. In addition, serum C-reactive protein (CRP) was determined on an IMMULITE Automated Analyzer using the commercially available immulite chemiluminescent enzyme immuno-metric assay (Immulite®, Diagnostic Products Corp, Los Angeles, CA, USA) and plasma plasminogen-activator inhibitor-1 (PAI-1) was determined utilizing the Luminex 200 analyzer (Luminex Corp, Austin, TX, USA) using an immunoassay kit from LINCO Research.

## Fatty Acid Composition

Serum lipids were extracted according to the method of Bligh–Dyer whereby mixtures of plasma, methanol, chloroform and water were prepared such that lipid is recovered in a chloroform layer. The resulting lipid extracts were maintained under an atmosphere of nitrogen following extraction and kept frozen prior to additional processing. Immediately prior to lipid class separation, lipid samples were dried under a gentle stream of nitrogen, rediluted in  $50 \mu\text{l}$  of chloroform and prepared for lipid class separation. Lipid classes including total TAG, PL and CE were separated on commercial silica gel G plates (AnalTech, Newark, DE, USA). The chromatographic plates were developed in a solvent system consisting of distilled petroleum ether (bp  $30\text{--}60^\circ\text{C}$ ):diethyl ether:acetic acid (80:20:1, by vol). Following development, the silica gel plates were sprayed with a methanolic solution containing  $0.5\%$  2,7-dichlorofluorescein which was then used to visualize lipid classes under ultraviolet light. Desired corresponding lipid bands were then scraped into Teflon line screw cap tubes. The samples were then transesterified with boron trifluoride (10%) in excess methanol (Supelco, Bellefonte, PA, USA) in an  $80^\circ\text{C}$  water bath for 90 min. Resulting fatty acid methyl esters were extracted with water and petroleum ether and stored frozen until gas chromatographic analysis was performed.

Lipid class fatty acid methyl ester composition was determined by capillary gas chromatography. Methyl ester samples were blown to dryness under nitrogen and resuspended in hexane. Resulting fatty acid methyl esters were separated and quantified with a Shimadzu capillary gas chromatograph (GC17) utilizing a 30 m Restek free fatty acid phase (FFAP) coating and EZChrom software. The instrument temperature was programmed from 190 to 240 °C at 7°C/min with a final hold of 10 min, separating and measuring fatty acid methyl esters ranging from 12:0 to 24:1. The detector temperature was 250 °C. Helium carrier gas was used at a flow rate of 1.4 ml/min. and a split ratio of 1:25. Chromatographic data was collected and processed with EZChrom software (Scientific Products, CA, USA). Fatty acids were identified by comparison to authentic fatty acid standards and quantitated with peak area and internal standard. Resulting data are expressed in percent composition. Individual peaks, representing as little as 0.05% of the fatty acid methyl esters, were distinguished.

#### Statistical Analyses

All statistical analyses were done with Statistica software (StatSoft Inc, Tulsa, OK, USA). A 2 × 2 ANOVA with

one between effect (VLCKD vs. LFD) and one within effect (Week 0 vs. Week 12) was used to compare biochemical responses over time in both groups. Significant main or interaction effects were further analyzed using a Fishers LSD post hoc test. Relationships among selected variables were examined using Pearson's product-moment correlation coefficient. The alpha level for significance was set at 0.05.

## Results

### Dietary Intake and MetS Responses

Dietary nutrient intake and responses of MetS biomarkers will be presented elsewhere [7]. In brief, subjects in both groups reduced energy intake to approximately 1500 kcal/day, but the diets had markedly different macronutrient distributions based upon the analysis of individual diet records (VLCKD, %CHO:fat:protein = 12:59:28) and (LFD, %CHO:fat:protein = 56:24:20) (Table 1). Dietary saturated fat and cholesterol intake were significantly higher during the VLCKD than the LFD. The LFD led to improvements in some metabolic markers, but subjects following the VLCKD had consistently greater weight loss,

**Table 1** Daily nutrient intake and serum cholesterol responses of men and women who consumed low carbohydrate and low fat diets

decreased adiposity, improved glycemic control and insulin sensitivity and more favorable TAG, HDL-C and total cholesterol/HDL-C ratio responses. In addition to these markers for MetS, the VLCKD subjects showed more favorable responses in alternative indicators of atherogenic dyslipidemia and cardiovascular risk: postprandial lipemia, apo B, apo A-1, the apo B/Apo A-1 ratio, LDL particle distribution and postabsorptive and postprandial vascular function. Most striking, we reported that despite a three-fold higher intake of dietary saturated fat during the VLCKD compared to the LFD, circulating saturated fatty acids in TAG and CE were significantly decreased, as was 16:1n-7, an endogenous marker of lipogenesis. There were profound changes, as well, in other fatty acids in circulating TG, PL, and CE fractions (Tables 2–4).

#### Circulating Triglyceride Fatty Acids

Compared to the LFD, consumption of the VLCKD resulted in a significantly greater increase in TG n-6 PUFA, mainly attributed to a marked increase in arachidonic acid: 17 of 20 subjects in VLCKD showed marked increases while only 7 of 20 subjects on LFD showed increases in 20:4n-6 and these were more modest in amplitude (Table 2). In both groups, n-3 PUFA was decreased due largely to lower  $\alpha$ -linolenic acid (18:3n-3) and 20:5n-3. The n-6/n-3 and arachidonic/eicosapentaenoic acid ratios were, on average, nearly doubled in response to the VLCKD and virtually unchanged by the LFD: 15 of 20 subjects on VLCKD showed increases in the n-6/n-3 ratios, while only 8 of 20 of the LFD showed increases. In contrast to the response in 20:4n-6, the metabolic intermediates in the biosynthetic pathway, especially 20:3n-6, were decreased after the VLCKD. As previously reported, total MUFA was unchanged but 16:1n-7 and total SFA was significantly decreased in response to the VLCKD.

#### Circulating Phospholipid Fatty Acids

The pattern of fatty acid changes seen in the TAG fraction was also found in circulating phospholipids: consumption of the VLCKD was associated with an increase in n-6 PUFA, again primarily due to a distinct increase in 20:4n-6 (Fig 1a), whereas 18:3n-6 and 20:3n-6 were markedly decreased (Table 3). The VLCKD was associated with a significant reduction in 18:3n-3, 18:4n-3, 20:4n-3, and 20:5n-3. However docosahexaenoic acid (22:6n-3) was increased so that total n-3 PUFA was not significantly changed. Compared to the LFD, ingestion of the VLCKD resulted in a significant increase in total PUFA and the ratio of n-6/n-3 (Fig. 1b) and arachidonic/eicosapentaenoic acid

(Fig. 1c). In comparison to the LFD, total MUFA was significantly decreased in response to the VLCKD due to significant decreases in the most abundant MUFA, 18:1n-9, and a consistent reduction in 16:1n-7.

#### Circulating Cholesteryl Ester Fatty Acids

The patterns of CE fatty acid responses to diet resembled that in TG and PL, and in general were more dramatic in this lipid fraction (Table 4). Total n-6 PUFA was significantly increased in response to the VLCKD due to a large increase in 18:2n-6 and a smaller increase in 20:4n-6: most of the VLCKD group showed a significant increase in 20:4n-6 while only five of the LFD group showed an increase. On the other hand total n-3 PUFA was significantly decreased due to a reduced proportion of 18:3n-3 and 20:5n-3 in response to the VLCKD but, similar to other fractions, there was an increase in 22:6n-3. The n-6/n-3 and arachidonic/eicosapentaenoic acid ratios were unchanged in response to the LFD but increased sharply after consumption of the VLCKD. Total MUFA decreased in response to the VLCKD, again due to a reduced proportion of 18:1n-9 and a striking decrease in 16:1n-7.

#### Inflammatory Markers

Both diets led to a similar significant reduction in the acute phase reactant C-reactive protein (–23%), VEGF (–21%), P-selectin (–11%), and a trend for EGF (–38%), and V-CAM (–6%); however, there was an overall greater anti-inflammatory effect associated with the VLCKD as evidenced by significantly greater decreases in the proinflammatory cytokine TNF- $\alpha$  (–32 vs. –12%), the chemokines IL-8 (–33 vs. 4%) and MCP-1 (–24 vs. –5%), and the adhesion molecules E-selectin (–34 vs. –14%) and I-CAM (–17 vs. –3%) (Table 5). There was also a trend for a greater reduction in IL-6 (–35%) in response to the VLCKD ( $P = 0.07$ ). Plasminogen-activator inhibitor-1 (PAI-1) has antifibrinolytic functions, and was also reduced more in subjects consuming the VLCKD compared to LFD (–34 vs. –8%). There was no effect of the interventions on leukocyte subpopulations.

#### Correlations

The results described above are surprising in that consumption of the VLCKD showed substantially greater increases in arachidonic acid and the arachidonic/eicosapentaenoic acid and n-6/n-3 ratios that are commonly viewed as contributing to an overall proinflammatory state,

**Fig. 1** Individual responses in serum phospholipid arachidonic acid (20:4n-6) (a), the n-6/n-3 ratio (b) and the arachidonic/eicosapentaenoic acid ratio (20:4n-6/20:5n-3) (c) in subjects who consumed a

very low carbohydrate ketogenic diet (VLCKD) or a low fat diet for 12 weeks. *Shaded bars* indicate mean responses

while simultaneously there was a significant decrease in many inflammatory markers. An analysis of these data bears out the idea that changes in the fatty acid proxies were consistently inversely associated with responses in most of the inflammatory markers we measured (Fig. 2). The fatty acid with the most consistent positive association with changes in inflammatory markers was palmitoleic acid (16:1n-7). The correlations between weight loss and changes in inflammatory markers were generally small and not significant. As shown in Fig. 3 for two of the more important markers TNF- $\alpha$  and IL-8, there is essentially no correlation.

## Discussion

Because of the continued emphasis on dietary recommendations for cardiovascular disease and general health, the relation between dietary fat intake and plasma fatty acids and inflammatory markers is of great importance. The

findings presented here support our hypothesis that the components of metabolic syndrome are distinctly those that respond favorably to reduction in dietary carbohydrate [19]. Responses in fatty acid composition to the VLCKD in this study were exactly opposite to the fatty acid profile recently shown to be associated with development of metabolic syndrome over a 20 year period in previously healthy men (i.e., higher circulating 14:0, 16:0, 16:1n-7, 18:1n-9, 18:3n-6, and 20:3n-6, and lower levels of 18:2n-6) [1]. Abnormal fatty acid composition and inflammatory status are now recognized as prominent features of metabolic syndrome, and are reliably improved in subjects consuming a low carbohydrate diet compared to a low fat diet.

Acute ingestion of carbohydrate clearly induces an increase in reactive oxygen species and activation of pro-inflammatory pathways [9], and isocaloric high carbohydrate [20] and high glycemic [21] diets are associated with increased biomarkers of inflammation. In the context of hypocaloric diets, we showed that reducing dietary total

**Fig. 2** Associations between changes in markers of inflammation and changes in PL arachidonic acid (a), and the 20:4n-6/20:5n-3 ratio (b). Individual bars represent Pearson correlation coefficients (\**P* < 0.05)

and saturated fat only had a small effect on circulating inflammatory markers whereas reducing carbohydrate led to considerably greater reductions in a number of proinflammatory cytokines, chemokines, and adhesion molecules. These data implicate dietary carbohydrate rather than dietary fat as a more significant nutritional factor contributing to inflammatory processes; although increased fat in the presence of high carbohydrate may be

particularly deleterious. Dietary carbohydrate also has a fundamental role in determining fatty acid composition of lipids and membranes, and it is the endogenous fatty acids (as opposed to the exogenous dietary fatty acids) that influence inflammation by acting as ligands for receptors or transcription factors that regulate inflammatory signaling cascades or serving as substrates for proinflammatory bioactive products.

**Fig. 3** Associations between weight loss and changes in TNF- $\alpha$  and IL-8

Despite the two diet groups consuming roughly the same caloric intake and all losing at least some weight, there were larger reductions in the VLCKD group in TNF- $\alpha$ , IL-8, MCP-1, PAI-1, E-selectin and I-CAM, while these markers showed little change on low fat suggesting that it is the macronutrient composition not weight loss or caloric reduction that is key. Most of the inflammatory markers did not correlate with weight loss. A correlation would not have proved that weight loss caused change in inflammatory markers but the lack of correlation makes it extremely unlikely. As shown in Fig. 3, there is essentially no correlation and if anything the associations tend to go in the opposite direction of what is expected if weight loss caused change in markers. In both cases, individuals with the largest reductions in inflammatory markers tended to be in the middle of the weight-loss range. The question of weight loss as a stimulus versus a response has been raised before with regard to other effects of carbohydrate restriction. Our group [22] and others [16, 18, 23] have consistently shown that there is a benefit to atherogenic dyslipidemia, glycemic control, and insulin from reduction in carbohydrate independent of weight loss. We therefore suggest that reduction in carbohydrate is primary, and weight loss (more precisely caloric restriction) is not the controlling variable.

One of the most striking responses in fatty acid composition was the increase in arachidonic acid and total n-6 PUFA in subjects consuming a VLCKD. Rather than being a negative factor within lipid membranes, increased arachidonic acid appears to be a beneficial outcome of weight-reducing diets associated with greater lipolysis [24]. The increase in plasma arachidonic acid only in response to the low carbohydrate diet is best explained by decreased degradation presumably due to less interaction with reactive oxygen species [25]. Increased production from 18:2n-6 was unlikely since the metabolic intermediates 18:3n-6 and 20:3n-6 were reduced in all three circulating fractions and there was no increase in 20:3n-9, which typically occurs in cases where PUFA anabolism is increased [13, 25]. Since

arachidonic acid was elevated in all circulating fractions, a shift from other pools is unlikely. This is supported by the fact that fat loss was only moderately greater on the VLCKD compared to the LFD (−5.6 vs. −3.7 kg), and by week 12, the rate of weight loss on both diets was low. Given that daily dietary contribution of arachidonic acid is on the order of 0.5% of the total body pool [26] also suggests reduced degradation as the major explanation. Thus, an increase in the proportion of arachidonic acid resulting from a diet that restricts carbohydrate may be due to lower catabolism (i.e. better preservation) and therefore reduced formation of proinflammatory products. The consistent inverse associations between changes in arachidonic acid and responses in inflammatory markers indicate that the adverse effects of arachidonic acid are due to metabolites produced subsequent to its release from membranes rather than the proportion of the intact fatty acid.

The 19% rise in PL arachidonic acid in the low carbohydrate group (from 11.54 to 13.70 wt%) is consistent with the change seen after 12 weeks of a very low calorie diet in a more obese population (e.g., from 9.16 to 11.77 wt%) [24]. Given the regulatory role of arachidonic acid as a ligand for PPAR and in gene expression (e.g., fatty acid synthase) [27], this degree of rise in 20:4n-6 has the potential to influence fuel partitioning. In the obese Zucker rat, the increase in liver PL arachidonic acid from 22.68 to 25.23 wt% (an 11% change) induced by feeding 18:3n-6 was associated with significant reductions in food intake and body fat content [28].

Scenarios associated with less oxidative stress should result in better preservation of the substrate arachidonic acid, due to the interaction of free radicals with several steps in its metabolism. Inflammatory cytokines are known to increase production of hydroxyl radicals which in turn initiate arachidonic acid release and breakdown. The VLCKD in this study resulted in significantly greater reductions in several proinflammatory markers including TNF- $\alpha$ , E-selectin, ICAM-1, and IL-8, that were related to

the increase in arachidonic acid. The significantly greater reduction in TNF- $\alpha$  in subjects following the VLCKD is of interest in that it is one of the agents known to activate NF- $\kappa$ B a major transcription factor regulating cytokines, chemokines and adhesion molecules (TNF- $\alpha$ , MCP-1, IL-8, E-selectin, and ICAM-1) [12, 29]. The reduction in all of these agents by the VLCKD suggests that the antiinflammatory effects of carbohydrate restriction may be mediated via down regulation of NF- $\kappa$ B expression [30]. We have previously found that guinea pigs fed high-cholesterol atherogenic diets demonstrated significant increases in aortic TNF- $\alpha$ , an effect that was attenuated by reduction in dietary carbohydrate [31].

Hypercaloric high carbohydrate feeding stimulates the production of several fatty acids including 16:0, the major lipogenic product, and palmitoleic acid (16:1n-7), the product of  $\Delta$ 9 desaturase. Palmitoleic acid is a minor constituent in dietary fat and its increase is a marker of lipogenesis [32] and its presence has been linked to higher levels of adiposity [33, 34]. In this study, the VLCKD resulted in concurrent reductions in both 16:0 and 16:1n-7 in both TG and CE lipid fractions despite an increase in dietary saturated fat load. The significant reduction in dietary saturated fat in the LFD led to little decrease in total saturates and essentially no change in 16:1n-7, with one subject actually showing a drastic increase. The greater decrease in circulating SFA in response to carbohydrate restriction may have contributed to the larger decline in several inflammatory markers that are regulated by NF- $\kappa$ B [10, 11]. The decrease in circulating saturated fatty acids on the VLCKD is likely due to greater oxidation of the saturated fat from both diet and endogenous lipolysis, and a reduction in de novo lipogenesis.

In summary, carbohydrate restricted diets that are proportionately high in saturated fatty acids show very different results from what might be expected [7, 18]. A VLCKD significantly increases arachidonic acid levels, presumably due to a better preservation as a result of reduced oxidative stress and decreased inflammation. Sparing of arachidonic acid (by reducing its degradation to oxy-lipids) may provide a signaling mechanism by which dietary carbohydrate restriction favorably alters lipid metabolism and inflammatory processes [27].

**Abstract** Antigen tumor markers employed in monitoring therapeutical approaches are limited by their specificity (Sp) and sensitivity (Se). The aim of this study was to investigate the suitability of a lipid tumor marker derived from ether-linked phospholipids and to compare it with others usually assayed in clinical practice. Complex lipids from normal and pathological breast, lung, and prostate tissue were isolated and analyzed by TLC and c-GLC methods. Results were compared as pooled samples, or by means of the averaged percent changes with respect to the composition observed in the normal tissue of the same

patient. Sp, Se, negative-predictive (NPV) and positive-predictive values (PPV) were established for conventional markers and for the proposed lipid-derived marker. Results demonstrated that the content of monoenoic fatty acyl chains was significantly increased in total lipids, phosphatidylethanolamine, and especially in ethanolamine-containing ether lipids of neoplastic tissues with respect to their corresponding normal ones. Major changes were observed in the plasmalogen sub-fraction where the ratio monoenoic/saturated fatty acids can distinguish with high Se normal tissues from either benign or neoplastic tissues from breast, lung, or prostate lesions. Analyses of fatty acyl chains from ethanolamine-containing plasmalogens provided a reliable tumor marker that correlated with high Se and linearity with metastases spreading. This fact may be useful in prognosis of the most frequently observed human cancers.

## List of abbreviations

ADAG	Alkyldiacylglycerols
BL	Benign (lesions or tissues)
C	Normal
CEA	Carcinoembryonic antigen
ChoGpl	Choline glycerophospholipids
EtnGpl	Ethanolamine glycerophospholipids
FAs	Fatty acids
FAMES	Fatty acid methyl esters
GEDE-A	1-O-alkyl-2,3-diacyl- <i>sn</i> -glycerol
GEDE-E	1-O-alkenyl-2,3-diacyl- <i>sn</i> -glycerol
NEO	Neoplastic (lesions or tissues)
NPV	Negative-predictive value

PakCho	Plasmanylcholine (1- <i>O</i> -alkyl-2-acyl- <i>sn</i> -glycero-3-phosphocholine)
PakEtn	1- <i>O</i> -alkyl-2-acyl- <i>sn</i> -glycero-3-phosphoethanolamine (plasmanylethanolamine)
PlsCho	Plasmenylcholine (1- <i>O</i> -alk-1'-enyl-2-acyl- <i>sn</i> -glycero-3-phosphocholine)
PlsEtn	1- <i>O</i> -alk-1'-enyl-2-acyl- <i>sn</i> -glycero-3-phosphoethanolamine (plasmenylethanolamine)
PtdEtn	Diacyl- <i>sn</i> -glycero-3-phosphoethanolamine
PtdCho	Diacyl- <i>sn</i> -glycero-3-phosphocholine
PPV	Positive-predictive value
PSA	Prostatic specific antigen
PUFAs	Polyunsaturated fatty acids
Se	Sensitivity
Sp	Specificity

## Introduction

Plasmalogens make up approximately 18% of the total phospholipid mass in humans; however, their content varies widely among tissues. The bulk of the 1-*O*-alk-1'-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (plasmenylethanolamine or PlsEtn) pool may represent up to 70% of the ethanolamine phospholipids depending on the tissue analyzed [1]. 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (plasmanylethanolamine or PakEtn) and diacyl-*sn*-glycero-3-phosphoethanolamine (PtdEtn) represent the other species present in the ethanolamine glycerophospholipids (EtnGpl) [1]. Concerning neutral lipids, several authors proposed alkyldiacylglycerols (ADAG) as a lipid class marker for malignant tissues. Important contributions in this field were made by Snyder et al. [2, 3], Mangold and Paltauf [4], and Nagan and Zoeller [1] among others. Traditionally, an excess of 1% ADAG in neutral lipids may indicate malignant degeneration, and values observed may be as high as 6% [4]. As a general rule, amounts of PakEtn + PlsEtn over 4% of total phospholipids correlated with neoplastic transformation [4]. However, this reference parameter was obtained comparing lipid compositions from neoplastic and normal tissue samples (of the same type) obtained from donors or normal subjects free from cancer lesions. A meaningful comparison should only be plausible between tumorous and healthy tissue samples of the same patient [4]. Lin et al. [5] performed a study in which hepatocellular carcinomas were compared with the residual hepatic tissue free from tumor cells. They found that ADAG in the neutral lipid fraction exhibited an increased concentration of hexadecyl-glycerol and lower proportions of C18-glycerol ethers in hepatocellular carcinomas with

respect to non-malignant liver tissue. In spite of the fact that higher concentrations of neutral ADAG and cholesterol were found in this kind of tumor, no differences between levels of ether-linked phosphoglycerides, triacylglycerides, and lipid phosphorous were observed [3, 5]. So far, no similar studies have been carried out. Thus, no information concerning PakEtn and PlsEtn content and their fatty acid composition has been reported for normal and pathological samples from the same patient. This may be due to problems with surgical protocols, since the collection of cancer and normal tissues from the same patient is not easy. We explored in detail if there was a compositional marker derived from the fatty acyl pattern of polar and/or neutral lipids and if it correlated with the metastatic dissemination of the most prevalent cancers in our country (and probably in most industrialized nations). Several samples of lung, breast, and prostate cancer tissues were taken and studied in comparison with normal tissues obtained from the same patient in order to investigate which lipid profile (if any) correlated better with histopathological characteristics of cancer tissues and/or predicted metastatic spreading of the primary tumor. Tumor markers usually employed in clinical practice were also determined and compared with the results obtained from lipid analyses.

## Experimental Procedure

### Chemicals

All solvents used were HPLC grade from Carlo Erba, Milan, Italy. Standards for thin-layer chromatography (TLC) and capillary gas-liquid chromatography (c-GLC) were purchased from Nu-Check-Prep., Elysian, MN. 2',7'-Dichlorofluorescein, boron trifluoride in methanol (14%), phospholipase C from *Bacillus cereus* (type IV, 1,500 U/mg protein),  $\beta$ -mercaptoethanol, sphingomyelin, PtdCho, PtdEth, inorganic salts and other chemicals used in sample preparation and processing were from Sigma Chem. Co., St. Louis, MO.

### Patients and Tissue Samples

Lung, breast, and prostate tissues were obtained by surgical procedures and analyzed with the written consent of the patients. This study followed the Helsinki protocol for handling human specimens. Patients were recruited from five public and private health institutions and the survey involved a total of 677 paired samples (C: normal, BL: hyperplastic-displastic, and NEO: malignant tissues from the same patient) collected for 6 years. In most cases samples were obtained surgically. Other samples were

obtained by performing a 3-mm needle disposable punch biopsy using a ultrasound guide. This procedure provides approx. 9 mg of tissue, enough for performing all the analyses. Two portions of tissue from each patient were analyzed, one from a pathological lesion and the other from (assumed) normal tissue. Each portion was divided into two sub-portions. One of them was processed for histopathological examination (PBS with 10% formalin) and the other for lipid analyses. Normal tissue surrounding the lesion was checked for any infiltration of abnormal cells. Suspicious normal samples were excluded from the study together with the corresponding paired (pathological) sample. Each sample was identified with an encrypted code which did not include any information concerning the origin and/or characteristics of the tissues examined. Thus, pathologists, biochemists, and laboratory technicians processed the samples under a blind protocol. At the end of the study, histopathological classification, biochemical determinations, and clinical stage of the samples were

revealed and correlated with lipid analyses. For each type of pathological tissue the clinical state of patients and also the criteria for classification of samples (benign or neoplastic) were evaluated following international scores such as those recommended by the American Joint Committee on Cancer Staging, World Health Organization, or Gleason scale [6–8]. Presence and localization of metastases were explored by specific medical studies such as magnetic resonance, X-ray computed tomography, and radioisotopic densitography. Table 1 shows a summary of the main characteristics of patients and samples.

#### Blood Samples and Biochemical Markers

Morning fasting blood samples were obtained from the antecubital vein on the day of tissue collection. Plasma was separated by centrifugation in the cold at  $600 \times g$  (15 min), aliquoted, frozen at  $-20\text{ }^{\circ}\text{C}$  (no more than one week), and

**Table 1** Main characteristics of subjects and samples analyzed

	Tissue

Mesenchymal tumor		(6; 2.7) (11; 4.9)	
Hamartoma		(8; 3.5) (15; 6.6)	

At the time of recruitment most patients (71%) were hospitalized for medical tests and/or antitumor treatment (chemotherapy, surgery, radiation, or a combination of these procedures). The meanings of the superscript letters is as follows:

<sup>a</sup> Mean age (range)

<sup>b</sup> (*n*<sub>F:female</sub>; % female with respect to total sample) (*n*<sub>M:males</sub>; % males with respect to total sample)

<sup>c</sup> At the time of sampling, expressed as the mean ± 1SD (standard deviation)

<sup>d</sup> Weight loss (cancer patients) within the preceding 6 months expressed as (mean ± 1SD; percentage with respect to initial weight)

<sup>e</sup> Classification based on the American Joint Committee on Cancer Staging, World Health Organization, or Gleason Score

used for tumor marker determinations. Marker antigens assayed were (cut-off in parenthesis): total PSA (<5 ng/ml), CA-125 (<35 UI/ml), CA-15.3 (<30 UI/ml), CA-19.9 (<25 UI/ml), and CA-27.29 (<38 UI/ml). Determinations were performed according to the procedures recommended by manufacturers of the commercial kits (streptavidin technology of ELISA from Boehringer-Mannheim Immunodiagnosics, Germany, ES-300 BM auto-analyzer), or Abbott Lab., Buenos Aires, Argentina (AXSYM auto-analyzer). CEA (<5 ng/ml) was also determined by enzyme immunoassay (SRL, Fukuoka, Japan). Sensitivity (Se), specificity (Sp), positive predictive value (PPV), and negative-predictive values (NPV) were defined and calculated as described in detail by Kuralay et al. [9]. Briefly, for all samples correctly or incorrectly identified by the histological, laboratory, or other complementary studies as being malignant or benign (nonmalignant) were defined as true positive (TP), false positive (FP), true negative (TN), and false negative (FN). The term “positive” was referred to histological by proven malignant sample while benign tissues were referred as “negative” histological findings. Se was defined as  $TP/(TP + FN)$ , Sp as  $TN/(TN + FP)$ , PPV as  $TP/(TP + FP)$ , and NPV as  $TN/(FN + TN)$ .

#### Lipid Analyses

Samples were homogenized on ice with PBS (pH: 7.4, 100  $\mu$ l per mg wet tissue) using a Potter-Elvehjem glass-Teflon homogenizer. An aliquot of 20  $\mu$ l was taken for

protein measurement [10] and the remainder was treated with Folch reactive [11]. After processing the samples according to Folch methodology, an aliquot of the final extract was taken to determine total lipid content gravimetrically [12] on a XP56-Delta Range Mettler Toledo balance. The evaporated residue was used for quantitative phosphorus determination according to Chen et al. [13]. Another aliquot was analyzed as described by Park et al. [14] in order to separate neutral ether lipids (ADAG) into their components, 1-*O*-alkyl-2,3-diacyl-*sn*-glycerol (GEDE-A), 1-*O*-alkenyl-2,3-diacyl-*sn*-glycerol (GEDE-E), and triacylglycerides (TAG). The remainder of the total lipid extract was separated into various phospholipid subclasses using thin-layer chromatography (TLC) with a biphasic solvent system [15]. TLC was performed in hermetic pre-equilibrated cubes (Sigma Chem. Co., St. Louis, MO) on pre-coated silica gel 60 plates from Merck (Darmstadt, Germany). Phospholipid bands were visualized under ultraviolet light after spraying with 2',7'-dichlorofluorescein solution and exposure to ammonia vapor. Lipids were identified comparing them with pure standards run in the same plate. In order to separate plasmalogens and DAG components from the PtdCho and PtdEth fractions the spots were scrapped-off and quantitatively eluted with chloroform/methanol (1:2, by vol). Isolated PtdCho and PtdEth were incubated with phospholipase C following the method of Mangold and Totani [16]. The resulting diacylglycerides were then acetylated with acetic anhydride/pyridine (10:5, by vol), and the products were separated by TLC using hexane/diethyl

**Table 2** Marker antigens in plasma samples from patients with breast, lung, and prostate tumors

<sup>a</sup> <35 UI/ml

<sup>b</sup> <30 UI/ml

<sup>c</sup> <25 UI/ml

<sup>d</sup> <38 UI/ml

<sup>e</sup> <5 ng/ml

**Fig. 1** Correlation between number of confirmed metastases (NCM) and various antigen markers for breast, lung and prostate. Number of neoplastic samples processed was smaller than the total number of patients studied since only those cases with confirmed number of metastases were included (101, 129, and 73 for breast, lung, and prostate, respectively)

ether/acetic acid (90:10:1, by vol) as first solvent system and toluene as second developing solvent [17]. Bands were scrapped-off the plate and transmethylated using F<sub>3</sub>B (14% in methanol) under nitrogen atmosphere for 45 min at 80 °C. Monopentadecanoin was added to all the tubes as an internal standard. Fatty acid methyl esters (FAMES) from the ether lipid species were separated from the aldehyde derivatives by TLC using toluene as a solvent and quantitatively analyzed using a Hewlett Packard HP 6890 Series GC System Plus (Avondale, PA) equipped with a terminal computer integrator [18].

#### Graphic Software and Statistical Treatment of Data

Data were reported as the mean  $\pm$  1 standard deviation (SD). Statistical significance was tested by student *t*-test or by ANOVA (analysis of variance) plus Bonferroni test.

Correlation and regression analyses and data plotting were performed with the aid of Systat (version 12.0 for Windows) from SPSS Science (Chicago, IL), Sigma Scientific Graphing Software (version 8.0) from Sigma Chem. Co. (St. Louis, MO), and/or GB-STAT Professional Statistics Program (version 4.0) from Dynamic Microsystems Inc. (Silver Springs). Multivariable regression analyses were performed as described by Kleinbaum and Kupper [19].

## Results and Discussion

### Patients and Tumor Markers

Our study was carried out with a representative (characteristic) population of neoplastic samples, composed of a typical distribution of cancer types (Table 1). Histopathological data were in agreement with previous

studies performed in Western countries [20]. Tumor marker levels (Table 2) were also in accordance with data previously reported for each kind of tumor [21–24]. These values of tumor markers are often useful for monitoring the evolution of patients; however, some of them may not be helpful in detecting recurrence. For example, we found that CA-125, CA-19.9, CA-27.29, CEA, and total PSA remained unaltered in a significant proportion of cases in which large spreading of primary tumors was detected by other tests such as radioisotopic and/or X-ray scanning (data not shown). Total PSA was the antigen that showed the best correlation with clinical status. Notwithstanding, it was within normal values in 12% patients with prostate cancer detected by digital rectal and scanner exams, and then corroborated by histological studies after needle punch biopsy. Moreover, spreading of primary prostatic or breast tumors with bone metastases was not correlated with a significant raise in any of the antigen markers tested in 22 and 31% of the samples analyzed, respectively. In addition, approximately 25% of patients with metastatic dissemination of primary lung cancer (especially in central nervous system and liver) showed no significant changes with respect to the starting level of the antigenic markers.

Sp and Se of tumor markers are topics under continuous evaluation. The ideal marker would be a molecule which only appears in patients with a specific malignancy, and it would correlate directly with stage and response to treatment. Up till now, no tumor marker has met this requirement. Thus, establishment of a biochemical index for either diagnosis of cancer, or management of patients with neoplastic diseases remains as one of the important goals to be achieved in cancer research. It is accepted that measurement of one antigen concentration in plasma is not recommended as a useful diagnostic tool in malignancy.

**Fig. 2** Linear correlation between plasma levels of antigens CA-15.3 and CA-27.29 was determined as described in “[Experimental Procedure](#)” for 148 patients with breast cancer

In this regard, multivariable regression analyses of data in relation to tumor marker concentrations and clinical status of patients (summarized in Figs. 1 and 2, and in Tables 2 and 3) led us to these conclusions: (1) high levels of conventional markers did not directly correlate ( $r^2 < 0.80$ ) with both stage and /or spreading of the primary tumor. (2) simultaneous determinations of two or more antigenic tumor markers did not improve PPV and NPV values ( $0.58 < r^2 < 0.73$ ), and (iii) specifically, tumor markers CA-15.3 and CA-27.29 were directly proportional between them ( $r^2 = 0.97$ ). Thus, simultaneous determinations of these two antigens do not offer advantages over the measurement of each marker alone. These statements confirm previous suggestions and findings made by other researchers [25–30] and answered the question raised by Klee et al [31]. It is important to remark that even the association of two or three of these markers (CA-125 + CA-15.3 + CEA; CA-125 + CA-19.9 + CEA; or PSA + CEA for breast, lung, and prostate cancers, respectively) could not significantly improve PPV and NPV values compared with prognosis or spreading predictions based on determinations of the primary marker alone (Table 3).

The optimal interpretation of tumor markers requires knowledge about both methodological limitations and the course of the disease in a particular patient. Even in those cases where these conditions were met, the correlation with clinical status was poor. For that reason we explored the usefulness of other tumor markers derived from ether lipid

**Table 3** Sensitivity (Se), specificity (Sp), and negative- and positive-predictive values (NPV; PPV) of marker antigen levels tumors from human breast, Lung, and Prostate

	Tissue	Parameters			
		Se	Sp	NPV	PPV
CA-125	Breast	84	90	90	95

Results were expressed as  $\mu\text{g}$  of each lipid subclass per mg protein, and they correspond to the mean  $\pm$  SD of the number of samples indicated as *n*. Statistically different ( $P < 0.01$ ) \* compared with C, \*\* compared with BL.

compositional analysis of biopsy samples to perform histopathological studies.

#### Lipids and Fatty Acyl Composition of Ether Lipids as Tumor Markers

As a first approach in searching for a new lipid marker for human tumor tissues, we followed the strategy employed in this kind of investigation, that is, to compare pooled results between normal and malignant tissues classified according to their histopathological criteria and obtained from different patients. Table 4 shows data obtained from the analyses of neutral and polar ether lipid subclasses among normal, BL and NEO samples from breast, lung, and prostate human tissues. Results corresponded to absolute amounts of lipids ( $\mu\text{g}$  per mg tissue protein). They were pooled and averaged as a function of their histopathological classification on the day of collection. In agreement

with previous studies from other researchers we found that tumor tissues were significantly enriched in GEDE-A and GEDE-E [4, 32–34]. Interestingly, concerning lung, no differences were found between normal and BL samples. Similar conclusions can be obtained examining the data obtained from PakEtn, PlsEtn, PakCho and PlsCho. Notwithstanding, the EtnGpl sub-fraction exhibited higher Se than ChoGpl since changes observed in ethanolamine-containing plasmalogens were more pronounced than those of choline. Drastic modification of data interpretation occurred when the results were separately compared. We calculated the amount of each lipid subclass with respect to the content of the same lipid in normal sample from the same patient. Table 5 shows the mean values obtained after these calculations. Data were expressed as ratios of the absolute amount of lipids ( $\mu\text{g}/\text{mg}$  protein). In the tumors studied, we found significant differences between normal, BL, and NEO samples. Moreover, differences observed among groups were even more evident than those observed

**Table 5** Mean values of ratios between the content of ether lipids in benign (BL) or neoplastic (NEO) and normal (C) samples in human breast, lung, and prostate tissues

Tissues Histopathology	Breast		Lung		Prostate	
	BL	NEO	BL	NEO	BL	NEO
<i>n</i>	74	148	40	186	56	173
GEDE-A	4.2 ± 0.2*	10.1 ± 0.3**	1.9 ± 0.1*	3.9 ± 0.2**	1.5 ± 0.1*	4.7 ± 0.1**
GEDE-E	3.5 ± 0.4*	5.8 ± 0.2**	1.8 ± 0.2*	3.2 ± 0.1**	2.4 ± 0.2*	4.8 ± 0.2**
PakEtn	4.1 ± 0.1*	7.0 ± 0.2**	2.0 ± 0.2*	4.5 ± 0.2**	1.9 ± 0.1*	5.6 ± 0.1**
PlsEtn	2.7 ± 0.1*	6.9 ± 0.1**	3.1 ± 0.2*	6.3 ± 0.3**	3.5 ± 0.2*	7.8 ± 0.1**
PakCho	1.8 ± 0.1*	4.7 ± 0.2**	1.5 ± 0.1*	3.9 ± 0.1**	2.1 ± 0.1*	3.9 ± 0.2**
PlsCho	2.0 ± 0.2*	5.4 ± 0.1**	2.0 ± 0.2*	4.2 ± 0.2**	3.0 ± 0.2*	5.1 ± 0.2**

Results were expressed as the mean of ratios between the absolute amount ( $\mu\text{g}/\text{mg}$  protein) of each lipid subclass in BL or NEO samples and the content measured in normal tissues from the same patient  $\pm$  1SD of the number of analyses indicated as *n*. SD of normal samples was between 8 and 19% of the mean value depending on the group of samples analyzed

Statistically significant ( $P < 0.01$ ) \* compared with control, \*\* compared with BL

in the previous analyses (Table 4). Thus, using this type of analysis all the groups were statistically different from each other.

As reported by other authors [4, 32–34], pooled samples had a lower proportion of PakEtn or PakCho than PlsEtn or PlsCho. We calculated the relative proportion of GEDE-A to GEDE-E, and the PakEtn/PlsEtn and PakCho/PlsCho ratios. The content of GEDE-A compared to GEDE-E decreased in NEO samples from the three tissues studied, while the proportion between plasmanyl- and plasmeryl-derived compounds (in both PE and PC) increased in BL and in NEO sample tissues with respect to the normal ones. An important conclusion was that changes in EtnGpl were more pronounced than those in ChoGpl. Analytical ratios shown in Table 6 would be useful for the classification of samples according to their histopathological characteristics. However, there were two major problems with these calculations: (a) except in the case of plasmalogen ratios, no differences were found between BL and normal samples, and (b) they did not reflect the fact that individual samples may not differ from the mean values obtained for the corresponding histopathological group and, consequently, they would be misclassified. Considering PakEtn/PlsEtn and PakCho/PlsCho ratios as the most discriminating biomarkers, 31.4, 26.2 and 12.5% of NEO samples from breast, lung and prostate (respectively) were classified as normal samples when compared with the means shown in Table 4. However, they became malignant when comparisons were made against those values obtained from normal tissue from the same patient. Using the same strategy of comparison, BL samples from breast, lung and prostate were 25.0, 20.1 and 11.3% misclassified. These records were similar to those obtained using the conventional primary antigenic tumor markers as discriminators.

As a second approach to find a more reliable lipid tumor marker, analyses of fatty acyl composition of each ether lipid subclass isolated from normal and pathological samples were carried out. Significant changes in fatty acyl composition were easily observed directly on the chromatograms even without ulterior calculations of peak areas (data not shown). This pattern represented a “finger print” and it was a constant finding in the samples analyzed. The main changes observed involved the proportion of monoenoic to saturated fatty acids and also the relative amount of PUFAs to saturated fatty acids. For these reasons, the absolute amount (nmoles per mg protein) of fatty acyl chains in each lipid subclass from normal, BL and NEO samples was calculated and used to obtain several analytical ratios. A few selected (statistically significant) ratios were presented in Table 7. They were expressed as the percent change calculated by comparing the absolute content of fatty acyl chains of BL or NEO samples with the

Statistical differences ( $P < 0.01$ ) were noted as \* for BL or NEO vs. control, and \*\* for NEO vs. BL

amount measured in the normal tissue of the same patient. Similar calculations were made concerning the fatty acyl composition of GEDE-A, GEDE-E, and DAG. However, in those cases the statistical differences, though significant, were of lesser extension. Thus, we focused our attention in fatty acyl composition of PakEtn and PlsEtn sub-fractions. Ratios allowed the differentiation not only of NEO samples from normal tissue, but also of BL from NEO samples with high Se and Sp. These statistical differences almost disappeared when ratios were calculated in pooled samples since values of SD were notoriously increased. This fact can be attributed to a marked variability observed in the baseline contents of fatty acyl chains among patients under different nutritional conditions, concomitant pathologies, therapeutical approaches, hormonal status, gender, age, and other factors which are not easily controlled. In agreement with this, reports from other laboratories have attempted to characterize plasma fatty acyl profile in patients undergoing benign and/or neoplastic illness with a variable success [35–37].

From the data reported in Table 7 we calculated Se, Sp, NPV, and PPV for the different lipid markers studied. The best results were obtained for  $\Sigma$  monoenoic/ $\Sigma$  saturated fatty acids in PlsEtn showing major changes with minor dispersion together with an excellent correlation with clinical

status of patients. Se and Sp were between 96 and 100%, and NPV and PPV values were both over 97%. Figure 3 shows correlation studies between the lipid marker and the spreading capacity of primary tumors. Interestingly, in all of the tumors studied we found a linear correlation, ( $0.96 < r^2 < 0.98$ ) that agreed with the clinical prognosis of each kind of damage. It seems that this lipid marker does not depend on the nature of the tumor, but it clearly reflects the metastatic potential of the primary cancer even when an accurate quantification of this condition is so difficult to obtain. Extrapolation of the regression lines to zero metastases yielded values of percent change ( $\Sigma$  monoenoic/ $\Sigma$  saturated) PlsEtn FAs which would correspond to a tumor with a hypothetically null spreading capacity. These values were similar to those obtained for BL samples (Table 7). Thus, the proposed marker has an excellent correlation with clinical status of the patient, especially number of metastases. Probably, it may be limited to the follow-up of the patient and to distinguish between BL and NEO samples in conflicting histopathological examinations in which complementary studies would be required. A population study at large scale may confirm the utility of the marker in prognosis, but our results are promising. We demonstrated that this highly sensitive marker is, at least, equally or even better than the existing clinical chemistry tumor markers.

**Fig. 3** Correlations between the relative content of monoenoic fatty acyl chains in PlsEtn and number of confirmed metastases (NCM) in 101 breast, 129 lung, and 73 prostate neoplastic samples. Calculations were done upon the percent change of the amount of monoenoic fatty acyl chains in PlsEtn of neoplastic samples with respect to normal tissue of the same patient. We included only those patients in which complementary studies confirmed the presence and number of metastases. Linear regression coefficients were calculated electronically using the software mentioned in “[Experimental Procedure](#)”

Surprisingly, the early findings reported in this field on lipid biochemistry have not been further developed for decades. So, we expect that our contribution may stimulate future research in this area.

## Conclusions

To the best of our knowledge, this is the first time that a biochemical marker derived from composition studies of ethanolamine-containing plasmalogens provides a reliable index capable of distinguishing between BL and NEO tissues, and it correlates linearly with metastases spreading *in vivo*. Lipid analyses were performed with minor amounts of tissue and may be carried out with a relatively low number of complex instruments. Samples could be obtained during punch needle biopsy for histopathological examination. Results displayed high Se and excellent clinical correlation, and they would have interesting applications in prognosis of the most frequently observed human cancers.

**Abstract** The effect of unsaturated fatty acids on the abundance of  $\Delta 6$  desaturase (D6D) mRNA and the fatty acid composition of HepG2 cell membranes was examined. Supplementation of HepG2 cells with oleic acid (18:1n-9, OA), linoleic acid (18:2n-6, LA),  $\alpha$ -linolenic acid (18:3n-3, ALA), arachidonic acid (20:4n-6, AA) or eicosapentaenoic acid (20:5n-3, EPA) reduced D6D mRNA abundance by  $39 \pm 6.6$ ,  $40 \pm 2.2$ ,  $31 \pm 5.2$ ,  $55 \pm 4.8$ , and  $52 \pm 5.0\%$ , respectively, compared with control cells. Despite the reduction in D6D mRNA abundance, the level of D6D conversion products (20:3n-9, EPA and AA) in OA, ALA and LA supplemented cells, respectively, was elevated above that in control cells. Our results suggest that although unsaturated fatty acids decrease the abundance of D6D mRNA by as much as 50%, the conversion of

polyunsaturated fatty acids and accumulation of long chain polyunsaturated fatty acids (LCPUFA) in HepG2 cell phospholipids continues to occur.

### Introduction

$\Delta 6$  desaturase (D6D) is the first and rate-limiting enzyme involved in the desaturation and elongation of 18 carbon polyunsaturated fatty acids (PUFA) to long chain PUFA (LCPUFA). Dietary studies indicate that hepatic D6D mRNA expression is induced by diets low in linoleic acid (18:2n-6, LA) and  $\alpha$ -linolenic acid (18:3n-3, ALA) and suppressed by diets rich in vegetable or marine oils [1–3]. D6D mRNA expression may be used as a surrogate marker for the activity of the enzyme as some studies in rodent have shown that the suppression of D6D mRNA expression by dietary PUFA is

associated with reduced D6D activity [3, 4]. Nuclear run-on analysis suggests that the suppression of D6D mRNA expression by PUFA is due to regulation at the transcriptional level [3], supposedly via peroxisome proliferators-activated receptors (PPARs), which bind to peroxisome proliferator-activated receptor response elements (PPRE) on the D6D gene [5–7]. There appears to be species differences in response to PPAR agonists. PPAR agonists cause hepatic peroxisome proliferation, hepatomegaly and, with prolonged administration, hepatocarcinogenesis, in rodents [8] yet human hepatocytes and HepG2 cells do not exhibit peroxisome proliferators-dependent peroxisome proliferation or induction of peroxisome proliferator-associated genes [9]. While D6D appears to be the rate-limiting step in the desaturation–elongation pathway, the overall regulation of the pathway and the correlation between D6D mRNA expression and the fatty acid composition of cell lipids is unclear and may involve several points of metabolic control. This study aimed to examine the effect of fatty acid supplementation on the mRNA abundance of D6D and fatty acid composition of HepG2 cells, a human cell line commonly used to study LCPUFA metabolism.

## Materials and Methods

### Materials

DMEM, FBS, penicillin, streptomycin and trypsin were purchased from JRH Biosciences (Victoria, Australia). FFA and authentic lipid standards were obtained from Nu-Check-Prep Inc (Elysian, MN, USA). BSA was from Sigma (St Louis, MO, USA). All other chemicals and reagents were of analytical grade.

### Cell Culture

HepG2 cells (human hepatoma cell line) were obtained from American Type Culture Collection (Rockville, MD, USA) and cultured in DMEM supplemented with 10% FBS, 2 mM L-glutamine, 50 U/ml penicillin and 37.5 U/ml streptomycin. A series of experiments were performed to determine the cell culture conditions that produced the greatest accumulation of DHA in HepG2 cell phospholipids following supplementation with ALA, without a significant reduction in cell number or viability (data not shown). These conditions are described herein. Cells were grown and seeded into 6-well plates and supplemented with fatty acids bound to BSA as described previously [10]. Stock solutions of FFA were prepared in ethanol at a concentration of 10 mg/ml and diluted in serum free medium to achieve final concentrations of 71  $\mu$ M OA, 71  $\mu$ M LA, 72  $\mu$ M ALA, 66  $\mu$ M AA or

66  $\mu$ M EPA. These concentrations effectively elevated the accumulation of the supplemented fatty acid above that observed in control cells whilst maintaining cell viability. The final concentration of ethanol in the media was 0.2%. Control cells were cultured in serum-free medium supplemented with an equivalent concentration of ethanol and BSA. After 48 h incubation with fatty acid-supplemented media, the cells were harvested for fatty acid or RNA extraction. Cells were used between passage 15 and 20. Cell viability was assessed by trypan blue exclusion.

### Fatty Acid Analysis

Lipids were extracted from cells with chloroform/methanol (2:1, by vol) according to the method of Folch et al. [11]. Phospholipids were separated from other lipid classes by TLC (Silica Gel 60 H Merck Darmstadt, Germany) and transesterified by methanolysis to form fatty acid methyl esters (FAME). The resulting FAME were separated and quantified by gas chromatography as described previously [10].

### RNA Extraction

Total RNA was isolated using a commercially available kit (Qiagen, CA, USA). Real-time quantitative PCR analysis (Corbett Rotorgene, Sydney, Australia) using SYBR<sup>®</sup> green fluorescence was used to determine the abundance of D6D mRNA relative to the house keeping gene, cyclophilin A using the comparative  $C_T$  (Threshold cycle) method. Two  $\mu$ g of total RNA was reverse transcribed with random hexamers according to the manufacturers instructions (Ambion, Austin, TX, USA). Each amplification mixture (20  $\mu$ l) contained 0.5  $\mu$ l of cDNA, 90 nM forward D6D primer (5'-CTG CCAACTGGTGGGAATCATC), 90 nM reverse D6D primer (5'-ACAAACACGTGCAGCATGTTC) and PCR master mix (Stratagene, La Jolla, CA, USA). Published primer sequences were used for the forward and reverse D6D primers [12]. The forward and reverse cyclophilin A primers were 5'-GGTTGGATGGCAAGCATGTG and 5'-TGCTGG TCTTGCCATTCCTG, respectively. DNA sequences of the amplification products were determined by direct sequencing to confirm their identities with reported cDNA sequences of corresponding proteins [13] (GenBank Accession Number AF084559).

### Statistical Analysis

Fatty acid analyses were performed on means of at least three separate replicates. Mean D6D mRNA abundance

was compared from at least five separate replicates. ANOVA and Bonferroni post hoc statistical tests (SPSS Inc. Chicago, IL, USA) were used to compare means following fatty acid supplementation. Statistical significance was defined as ( $P < 0.05$ ). Data are expressed as mean  $\pm$  standard error (SE).

## Results

### $\Delta 6$ Desaturase mRNA Abundance

In cells supplemented with OA, LA, ALA, AA or EPA, the abundance of D6D mRNA was significantly ( $P < 0.05$ ) reduced by  $39 \pm 6.6$ ,  $40 \pm 2.2$ ,  $31 \pm 5.2$ ,  $55 \pm 4.8$  and  $52 \pm 5.0\%$ , respectively (Fig. 1) compared with control cells maintained in serum-free media with BSA. Analysis of D6D mRNA abundance before fatty acid supplementation and then at 1, 2, 6, 12, 24 and 48 h following supplementation with  $72 \mu\text{M}$  ALA showed a significant reduction in D6D mRNA abundance at 24 h (data not shown). However, following 48 h supplementation, the time after which the medium was refreshed, the D6D mRNA abundance was equivalent to that observed in cells harvested immediately prior to supplementation. The suppression of D6D mRNA was not specific to any particular class of fatty acid as all fatty acids tested suppressed D6D mRNA abundance. Western blot analysis of HepG2 whole cell protein lysates using polyclonal rat antibodies [14] did not adequately identify the D6D protein in HepG2 cells (data not shown).

**Fig. 1** Relative abundance of  $\Delta 6$  desaturase mRNA compared with the housekeeping gene, cyclophilin A, in HepG2 cells following 48 h supplementation with oleic acid (18:1n-9, OA), linoleic acid (18:2n-6, LA),  $\alpha$ -linolenic acid (18:3n-3, ALA), arachidonic acid (20:4n-6, AA) and eicosapentaenoic acid (20:5n-3, EPA) compared with control cells (BSA). Values are means  $\pm$  SE of at least five replicates. Values with different symbols are significantly different ( $P < 0.05$ ) from each other by one-way ANOVA with Bonferroni post-hoc analysis

### Fatty Acid Analysis

The fatty acid composition of HepG2 cell phospholipids following supplementation with fatty acids is shown in Table 1. Despite the reduction in D6D mRNA abundance by all fatty acids examined, the concentration of D6D conversion products (20:3n-9, AA and EPA), in respective OA, LA and ALA supplemented cells were elevated above that observed in control cells. There was a significant increase in the level of OA and its product, 20:3n-9, in cells supplemented with  $71 \mu\text{M}$  OA. In HepG2 cells supplemented with  $71 \mu\text{M}$  LA, the level of LA and AA in cell phospholipids increased significantly ( $P < 0.05$ ) compared with control cells. In ALA-supplemented cells, the level of ALA, EPA, DPA and DHA in cell phospholipids was increased. Following supplementation with  $66 \mu\text{M}$  AA, the level of AA in HepG2 cell phospholipids increased dramatically, as did the level of 22:5n-6, which increased tenfold from  $0.17 \pm 0.01\%$  total fatty acids in control cells to  $1.73 \pm 0.10\%$  total fatty acids. In HepG2 cells supplemented with  $66 \mu\text{M}$  EPA, the level of EPA in cell phospholipids increased from  $0.14 \pm 0.02\%$  total fatty acids in control cells to  $14.95 \pm 0.51\%$  total fatty acids. The level of DPA and DHA also increased significantly ( $P < 0.05$ ) (Table 1).

## Discussion

The mRNA abundance of D6D in HepG2 cells was significantly reduced following supplementation with OA, LA, ALA, AA or EPA compared with control. Dietary PUFA is reportedly a major regulator of D6D mRNA expression [15] which may influence the accumulation of LCPUFA in cell membranes. The suppression of D6D mRNA abundance by PUFA has been described previously in human neuroblastoma cells [16] and HepG2 cells [3]. However, these studies did not correlate D6D mRNA expression with the fatty acid composition of cell lipids. Nara et al. [12] showed that the abundance of D6D mRNA was reduced by approximately 50% in HepG2 cells supplemented with AA, EPA and DHA for 24 h whereas OA had no effect. The difference in the effect of OA between our study and that of Nara et al. [12] may be due to their inclusion of insulin and dexamethasone, two hormones that influence the expression of PPAR [17] and indeed, D6D [18].

In vivo studies also demonstrate that dietary OA does not affect D6D mRNA expression [1–3, 19], which may be attributed to mechanisms in vivo that are not apparent in vitro. One study suggests that D6D mRNA expression may be modulated indirectly by the metabolic state of the animal. In rats supplemented with the PPAR $\alpha$  agonist

**Table 1** Fatty acid composition of HepG2 cell phospholipids of cells supplemented with oleic acid (18:1n-9, OA), linoleic acid (18:2n-6, LA),  $\alpha$ -linolenic acid (18:3n-3, ALA), arachidonic acid (20:4n-6, AA) or eicosapentaenoic acid (20:5n-3, EPA). Values are means  $\pm$  SE of at least three replicates

Values with different superscripts are significantly different from each other ( $P < 0.05$ ) within each fatty acid group by one-way ANOVA with Bonferroni post-hoc test

WY14643, the fatty acid oxidation enzymes, acyl CoA oxidase, L-bifunctional protein and cytochrome P450 4A1 were all significantly induced within 4 h of treatment, with maximum induction occurring at 28 h [20]. D6D mRNA abundance was not significantly elevated at 4 h and it was only after 28 h that significance was reached [20]. The increased expression of D6D mRNA after 28 h suggests that its induction was secondary to the induction of the oxidation enzymes by WY1463 and may be compensatory. Interestingly, the level of OA in liver phospholipids was elevated [20] following treatment with WY14643 and may indicate an increased synthesis of OA de novo, as occurs in essential fatty acid deficient states. Moreover, PPAR agonists induce peroxisome proliferation in rodents [21]. Therefore, changes in fatty acid metabolism may also be attributable to the increased demand for fatty acids as constituents of phospholipids in the expanding peroxisome population [9]. It is questionable whether the changes in the fatty acid composition of cell lipids is directly attributable to the increased mRNA expression of D6D by WY14643 but rather the increased demand for fatty acid oxidation as a result of PPAR activation. The effect of D6D mRNA expression on the fatty acid composition of cell lipids is still unclear.

Despite a reduction in D6D mRNA abundance by up to 50%, the accumulation of fatty acid conversion products was increased compared with control cells. The fatty acid composition of cell lipids may be influenced by various

parameters and highlights the need to examine D6D mRNA expression concurrent with the expression of oxidation enzymes and enzyme activity. Further studies that examine the effect of D6D overexpression by transfection of a D6D expression vector or the effect of knockdown of D6D mRNA by short interfering RNA, on the fatty acid composition of cell lipids, may help in describing a relationship between the two.

# Fourier Transform Near Infrared Spectroscopy: A Newly Developed, Non-Invasive Method To Measure Body Fat

## Non-invasive body fat content measurement using FT-NIR

**Abstract** An FT-NIR technique is reported to provide a fast, accurate and low cost method of determining in-vivo human body fat content. The body fat content of 353 healthy subjects (154 males and 199 females) of various height, weight, and age were measured by FT-NIR and compared to 420 subjects investigated by magnetic resonance imaging (MRI). The procedure involved scanning each subject's upper ear that provided a necessary reflectance surface and proved representative of the subject's subcutaneous fat content. The average FT-NIR spectrum was compared to a reference mixture with known and similar fat content and composition to that of humans. The FT-NIR response was incorporated into an empirical equation using the ratio of subcutaneous to total body fat from MRI data, taking into account the subject's gender, height, weight and age. The results on the two data sets were similar and demonstrated that the FT-NIR technique can be used to obtain a measure of the body fat content of individuals, similar to that using MRI. In addition, the

FT-NIR was used to more accurately monitor the fat content of sleep apnea patients.

### Introduction

According to a recent Statistics Canada Report 57% of men and 40% of women in Canada are considered overweight or obese<sup>1</sup> [1]. Overweight is defined by a body mass index (BMI) of >25, and obesity >30, and it is linked to several diseases, including hypertension, diabetes mellitus, hyperlipidemia, coronary artery disease, obstructive sleep apnea, and cancers of the breast, uterus, prostate and colon [1, 2]. The BMI guidelines assume that body mass is closely associated with body fatness [3]. However, some overweight individuals are not necessarily overfat (e.g., bodybuilders), while others having a normal BMI have a high percentage of their body weight as fat [3]. This suggests that we need a more reliable indicator of obesity for actual body fat measurement.

BMI is one of several ways to determine body fat or monitor obesity. Other techniques include skinfold thickness, circumference, bioelectrical impedance, dual energy X-ray absorptiometry, underwater weighing, computed tomography, and near-infrared interactance. The vast majority of these measurements are indirect and based on

assumptions and models. Magnetic resonance imaging (MRI) has been used as a more reliable technique, but it is expensive and inaccessible. As a result, we have developed a new technique to directly scan and evaluate subcutaneous body fat content in humans using Fourier Transform near infrared (FT-NIR) spectroscopy. The FT-NIR response can be compared to reference materials with known fat content and composition or used in an empirical equation with height, weight, gender and age as covariates.

The use of near infrared spectroscopy to determine fat content in humans was first reported in 1984 [4]. Ruchti et al. [5] reported the use of bovine fat as a reference material in their NIR determinations of the human fat content. We have shown that there are significant differences between bovine and human fat in composition, and since the FT-NIR signal is based on the fatty acid profile of the fat, a more appropriate reference material was developed that more closely resembled the human fatty acid composition [6]. Recent improvements in the resolution of FT-NIR spectroscopy coupled with chemometric analysis has allowed for the complete fatty acid profiling of fats and oils including *trans* fatty acids [7–9].

## Methods

### Subjects

Data were obtained from five different locations in Ontario: Mississauga City Hall, Mississauga South Common Mall, Mississauga River Grove Community Centre, Mississauga Meadowvale Community Centre, and Fitness Corner, Port Elgin. A total of 353 subjects (199 females and 154 males) were scanned, and their height, weight, and age recorded (as provided by the subjects). All subjects were required to read the information sheet describing the procedure and then sign a consent form.

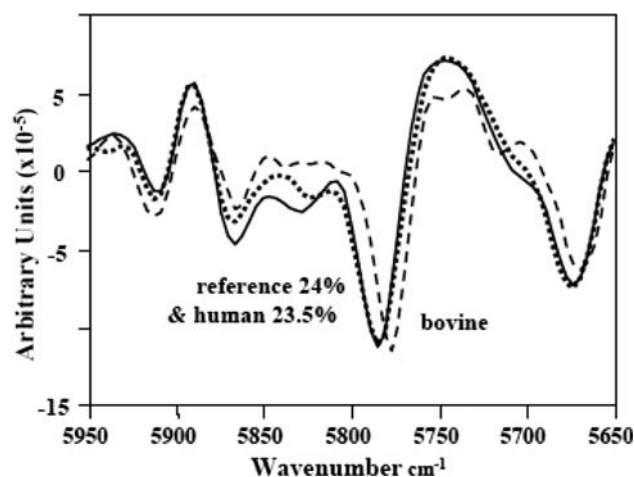

### FT-NIR Methods and Procedures

A Matrix-F FT-NIR Spectrometer equipped with a standard fibre optic probe from Bruker Optics in combination with OPUS (Optics Users Software) software was used to obtain the spectra. Several body parts were examined to obtain reliable and intense spectra. Most abdominal and arm measurements proved unusable because of high dispersion and low signal to noise ratio. It was found that the upper ear yielded the best spectral characteristics for this study with the least amount of background noise and water interference, and strong reflectance signal. The resulting absorption spectra were a composite of different components in the sample. The fibre optic probe carrying the near infrared

light was held against the back of the subjects' upper ear to avoid eye contact; see demonstration of technique in [10]. On average five measurements of five scans each per subject were taken (for a total scan time of 25 s) and the resulting absorption spectra were averaged. The averaged spectrum was then integrated focusing on the frequencies associated with the fat peaks to obtain the FT-NIR response. This response proved to be related to subcutaneous fat of the subjects, and was matched against the FT-NIR response of the reference material with a known fat content [6].

### FT-NIR Reference Material

Preliminary results indicated that bovine fat used by Ruchti et al. [5] did not resemble human body fat composition and hence could not be used as a FT-NIR reference. Figure 1 shows the second derivative spectra of human, reference material and bovine fat; the latter showed a more pronounced peak for saturated fatty acids and less unsaturated fatty acids compared to human fat. In addition, a clear chemical shift of about  $8\text{ cm}^{-1}$  wavenumbers was evident in the bovine fat at  $5,777\text{ cm}^{-1}$  compared to human fat spectrum at  $5,785\text{ cm}^{-1}$ . This chemical shift and the profile differences have a significant effect on the quantitative determination in near infrared spectroscopy. A more suitable reference material was prepared consisting of water, fat, and protein, which more closely resembled human body fat profile (Fig. 1). To generate a calibration curve, the FT-NIR response of increasing amounts of fat in the reference material was measured (Fig. 2). These results were used to obtain the calibration curve (Fig. 3). The underlying protein signal from the cartilage was established by purchasing pig's ears and measuring the FT-NIR

**Fig. 1** Second derivative spectra for bovine, human, and the reference material: *dashed line*, bovine; *dotted line*, reference 24%; *solid line*, human 23.5%

**Fig. 2** FT-NIR response in the fat region of the reference materials containing 0–51% fat: solid line 0%; dotted line 5%; dashed line 10%; solid line 24%; dotted line 33%; dashed line 41%; solid line 51%

spectra with the skin plus fat layer, and after removal of the outer layers, recording the signal of the cartilage.

#### FT-NIR Empirical Equation

The fat content measurement results using the reference material with known fat content were verified by developing an empirical equation. This equation was based on the existing body surface area equations [11, 12] and the ratio of subcutaneous to total fat content from MRI studies taking gender and age into consideration, which were combined with the FT-NIR response. It was assumed that the total body fat volume could be determined by measuring the body surface area multiplied by the thickness of subcutaneous fat layer. The values of the FT-NIR response were substituted for the thickness of subcutaneous fat layer in these equations.

**Fig. 3** Calibration curve for fat content determination

#### Magnetic Resonance Imaging Methods and Procedures

Methods and procedures for the collection of MRI data were published [13].

#### Results

Representative values for both female and male subjects are shown in Table 1. Their body fat content was measured by FT-NIR spectroscopy and determined using the calibration curve (Fig. 3).

A number of subjects were compared according to height, weight, age, BMI and fitness level to observe differences in their fat content (Table 2). One pair is shown in Fig. 4, which shows the second derivative spectrum for male subjects 1007 and 1010. Subject 1007 was involved in bodybuilding activities, while subject 1010 is an average male. Both subjects were of a similar weight and height with a similar BMI. The FT-NIR spectrum for subject 1010 in Fig. 4 shows more intense fat peaks than that for subject 1007, indicating a higher body fat content. The data in Table 2 demonstrate that BMI is an unreliable measure of body fat content, and confirms the findings by other that fat percentage measurements are more informative than BMI [3].

An empirical equation was developed based on the assumption that subcutaneous fat thickness, substituted by FT-NIR response and multiplied by body surface area generates subcutaneous fat volume. The surface area was determined using existing body surface area equations [11, 12]. The ratio of subcutaneous to total adipose tissue was obtained from MRI data that was necessary to convert the FT-NIR response (subcutaneous) to total body fat content. Figure 5 shows the MRI data for subcutaneous/total adipose tissue ratio with respect to age and gender. As can be seen, at a younger age, almost 95% of the adipose tissue for males and 97% for females is stored subcutaneously. A separate empirical equation for males and females was developed using the body surface area equations and MRI ratio of subcutaneous to total adipose tissue, and incorporating a factor for the FT-NIR response. These equations are shown below:

$$\text{Female TBF} = \frac{64.719N \times W^{0.51456} \times H^{0.42246}}{(-0.001A + 0.989)W}$$

$$\text{Male TBF} = \frac{64.719N \times W^{0.51456} \times H^{0.42246}}{(-0.003A + 0.997)W}$$

TBF total body fat; N NIR response; W weight in kg; H height in cm; A age in years.

The scanned data for 353 subjects were re-analyzed for body fat content using the FT-NIR empirical equations, and

Mean and standard deviations for all females were: age  $43 \pm 14$  years; height  $163 \pm 7$  cm; weight  $64 \pm 10$  kg; FT-NIR response  $0.39 \pm 0.11$ ; BMI  $24 \pm 4$ ; body fat content by FT-NIR  $29 \pm 8\%$ . Mean and standard deviations for all males were: age  $39 \pm 16$  years; height  $178 \pm 7$  cm; weight  $82 \pm 13$  kg; FT-NIR response  $0.22 \pm 0.09$ ; BMI  $26 \pm 3$ ; body fat content by FT-NIR  $16 \pm 7\%$ . The percent (%) body fat content for each of the subjects was calculated using the equations and the reference material

comparing the results to those using the FT-NIR reference material. Setting the intercept at 0, a significant linear correlation was found ( $R^2 = 0.94$ ) tested using a two-tailed paired  $t$  test ( $P < 0.0001$ ), as shown in Fig. 6 (all data). Table 1 includes the determination of percent (%) body fat using the reference material and the empirical equation for each of the representative male and female subjects (the last two columns). The results using the empirical equation were

dependent upon subjects accurately reporting their height and weight, which may explain some minor discrepancies between the two data sets. These equations are very sensitive to age, weight and the NIR response. For example a change of 0.02 in the NIR response would result in 1% drop in body fat %, and in some minor cases up to 2% drop in both female and male subjects. The same is true for the age coefficient. Switching the empirical equation for males and females

**Table 2** Effect of physical activity on subject's body fat content

ID No.	Gender	Age	Height (cm)	Weight (kg)	Activity level	FT-NIR fat response	BMI	FT-NIR Fat %

**Fig. 4** Second derivative comparisons for two subjects with the same BMI but different body fat content: *dotted line*, volunteer 1007; *Solid line*, volunteer 1010

**Fig. 5** Subcutaneous to total fat ratio with respect to age for males and females as determined by MIR: SAT, Subcutaneous Adipose Tissue; TAT, Total Adipose Tissue; MRI, magnetic resonance imaging

result in a fat % difference of up to 2%. This is due to the difference in the slope of subcutaneous to total ratio in males and females (see Fig. 5). Figure 6 also shows that the majority of male subjects are located at the lower end of the scale, whereas female subjects are located at the higher end of the scale confirming that, on average, females have more body fat than males [3].

A comparison between the FT-NIR data for 353 subjects in Ontario and MRI data for 420 subjects from the St. Luke's-Roosevelt Hospital in New York was subsequently performed. The FT-NIR and MRI data for 39 pairs of subjects were matched according to gender, age, height and weight. Table 3 shows representative comparisons for 10 female pairs and 10 male pairs. The  $R^2$  value for all 39 pairs was 0.96 with a two-tailed  $P$  value of  $P = 0.0468$ . The last two columns in Table 3 show the % fat content measured by the FT-NIR and MRI for the paired subjects. The only discrepancies would be similar to the example

**Fig. 6** Comparison of two FT-NIR methods for determining fat content for males and females

provided in which a body builder is compared to an average person with similar weight and height (Table 2). Although the two subject groups were measured using two different techniques (FT-NIR and MRI) the results show a remarkable resemblance in body fat content. The comparison of these two groups was to some extent justified since both groups were from North America with similar life styles and diets.

The FT-NIR technique was recently applied to also monitor body fat content of sleep apnea patients. The patient was diagnosed with obstructive sleep apnea having an Apnea Hypopnea Index (AHI) of 15.2 (event/h); below 10 is considered normal. The person's weight was 81.8 kg and height 1.74 m for a BMI of 27.0. The patient then underwent a weight loss program losing 6.8 kg, which corresponded to a 9% drop in body fat content as measured by FT-NIR (25–16%), or a decrease in BMI from 27.0–24.8. A subsequent obstructive sleep apnea test showed a marked improvement in the AHI down from 15.2 to 2.5 (event/h).

## Discussion

The body fat content of 353 subjects was measured by FT-NIR spectroscopy and determined using the calibration curve. The results were confirmed by calculating the fat volume using an empirical equation that was developed based on substituting the FT-NIR response for the subcutaneous fat thickness and the body surface area. A comparison between FT-NIR and MRI data for 39 pairs of subjects were matched according to gender, age, height and weight ( $R^2 = 0.96$ ,  $P = 0.0468$ ). Both groups were from North America with similar life styles and diets.

The newly developed method based on FT-NIR shows the potential for a quick, accurate and relatively inexpensive determination of human body fat content. Previous NIR studies were not successful since dispersive NIR technology

and inappropriate reference materials were used [4, 5]. The discovery of using the back of the upper ear providing a suitable reflectance surface for the NIR light, as well as, the finding that the fat layer was representative of the subcutaneous fat in the human subjects proved to be important steps in this research. The reflectance of NIR light could not be obtained by measuring other body parts due to dispersion of the NIR light. The MRI data established that a high percentage of body fat was stored subcutaneously (Fig. 5), which was used to correlate the subcutaneous fat layer on the back of the upper ear to the whole body fat content. The significant correlation of the FT-NIR to the MRI data suggests that the upper ear was representative of the whole body fat content when measured using FT-NIR spectroscopy.

Although, the FT-NIR and MRI tests were performed on different subjects at different locations and times, the correlation between the results of the two techniques is notable and the similarities are gender neutral with no obvious differences for scanning male or female subjects. The similarity of life styles and diets between the two study groups allowed for a comparison of the two techniques. The ultimate test of acceptance for the FT-NIR technique would be a direct validation using both techniques and several groups of male and female subjects, old and young, normal and obese.

These results demonstrate the potential of using FT-NIR to measure the body fat content of human subjects rapidly and accurately providing data comparable to the more costly and less accessible MRI technique. The FT-NIR technique is a low cost, portable and safe method that could prove valuable to determine the fat content of individuals being treated for obesity and sleep apnea and to more accurately monitor weight loss. The FT-NIR method has already been used for fatty acid profiling of fats and oils and there is the potential of doing the same for humans.

## Editorial

Eric J. Murphy

Published online: 31 January 2008  
© AOCs 2008

Dear Readers:

In their Letter to the Editor in this issue of *Lipids*, Drs. Bosetti and Toscano highlight an important issue: the need for the persons involved as reviewers in the peer-review system to disclose potential conflicts of interest regarding the manuscript or the authors.

Certainly someone who has a financial stake in the area of research presented in a submitted manuscript should declare potential conflicts of interest without regard to which side of the peer-review system that individual belongs. For instance, if someone from a competing company is asked to review a manuscript that could impact the reviewer's own projects and downstream drug revenue, the reviewer should declare that conflict to the assigned Associate Editor. The Associate Editor will consult with either the assigning Senior Associate Editor or me to determine whether that person should continue in the review of the said manuscript. Although this is a clear-cut issue, what about those of us who reside primarily in the academic arena? Here, people can be ruthless if they perceive that another person's work intrudes into their domain. In short, I have just been scooped! Under this circumstance, the best way to prevent the scoop by a reviewer is to delay the other individual's manuscript, through such means as tardy reviews and a request for a large number of unnecessary experiments or by rejecting the manuscript

altogether. Hence, how do we police this behavior, which is clearly not well defined and is highly variable? Whereas we try on the editorial side to weed out the "unfair" reviews, we first must catch them. We strive to do our best in this area and overall I think our efforts are commendable.

Overall, I think that our own collective maliciousness is often more damaging than all of the big-time financial conflicts of interest. When I was interviewed for the Editor-in-Chief position, I repeated a statement that I learned from my mentor, Professor Lloyd Horrocks. That is, be fair in the review process, and combine this fairness with a great deal of rigor. I train my postdoctoral fellows to review manuscripts with fairness and rigor. I teach my students and post-doctoral fellows the mantra, "Likes and dislikes have no place in science." Whether I like or dislike a person does not affect my decision during a review or in making a decision at the level of Editor-in-Chief. Fairness with rigor is the absolute key to the process.

So what about disclosures? At *Lipids*, we formally ask all authors to disclose any potential conflicts of interest regarding the submitted manuscript. For most of us, this is a minor issue. For my lab, every manuscript submitted to *Lipids* has an inherent conflict in that I am Editor-in-Chief. I make such a disclosure and, like all other authors, suggest potential reviewers and editorial staff; but from there on I am blinded to the process just like everyone else. But these types of disclosures are the easy ones.

The issue raised by Bosetti and Toscano is with the review side. At *Lipids*, we ask reviewers to note any scientific misconduct issues in manuscripts, but should we also ask them to note any potential conflicts? I for one have always expected reviewers to know when to recuse themselves, and over the years I have seen numerous people do this, running the gamut from big names in the field to emerging stars to graduate students reviewing their first manuscript. So these

types of people once again fall into the category that Lloyd spoke about all those many years ago.

I think the cause for concern is those individuals who are quite ambitious but lack ambition. This is something Stephen R. Lorenz, a three-star US Air Force general noted to a group of young, newly commissioned officers. He told them to surround themselves with people with ambition, not with ambitious people. The key element is that scientists who recuse themselves voluntarily are people perhaps with ambition, but who certainly are not ambitious. They are team players who recognize the fact that, despite their best efforts, they just cannot be fair to the authors during the review process, and to be fair, they recuse themselves. The ambitious scientists are those individuals who recognize that they can help themselves by harming others through the review process.

How do we ultimately police these individuals? At this point, it is impossible, as we are all subject to the frailties that come from being human. I, like French philosopher

Jean-Jacques Rousseau (1712–1778), feel that most of us are good and will strive to do the right thing. For those reviewers who do not fit into this model, we need to be vigilant at the editorial level to limit the impact that these types of people have on the peer-review process.

My best wishes to everyone for a prosperous and healthy New Year.

Sincerely,

## Is It Time to Standardize Ethics Guiding the Peer Review Process?

Francesca Bosetti · Christopher D. Toscano

Received: 11 October 2007 / Revised: 30 October 2007 / Accepted: 30 October 2007 / Published online: 29 November 2007  
© AOCs 2008

**Abstract** While most scientific journals have well defined ethics requirements for authors, very few journals explicitly specify the ethics standards that govern the actions of editors, editorial board members, and reviewers. We believe it is time to create a standardized policy for all medical and scientific journals that guides the ethical conduct of all stakeholders in the peer review process.

**Keywords** Ethics · Conflict of interest · Peer review

In their recent article, James et al. [1] comment on the role of medical journals and the peer review process in the assessment of the cardiovascular risk of rofecoxib (Vioxx<sup>®</sup>), a selective cyclooxygenase-2 (COX-2) inhibitor. The authors conclude that the commercial success of rofecoxib, despite the existence of convincing data regarding its severe cardiovascular risks, provides a case-study of the failure of the medical journals and peer review process in directing appropriate drug usage. While it is an important review of the COX-2 inhibitor controversy in its own right, we believe that the article by James et al. indirectly raises a more general issue on the need for more stringent standards of ethical conduct for all participants in the peer review process. With the current movement to formalize the ethical regulations and guidelines for activities in science [2], we propose that it is time for universal adoption of standardized and written guidelines by peer-reviewed scientific

journals regarding the ethical conduct of all stakeholders in the peer review process.

While most scientific journals have well defined ethics requirements for authors, very few journals explicitly specify, in writing, the ethics standards that govern the actions of editors, editorial board members, and reviewers. In fact, it has been determined that of journals that require conflict of interest disclosures by authors, more than 50% do not currently require editors or reviewers to disclose financial or other conflicts of interest [3]. With two of the major publishers of scientific journals, Elsevier and Blackwell Publishing, and the HHS Office of Research of Integrity having offered suggested guidelines for ethical conduct in the peer review process [4–6], it is staggering that this number of peer-reviewed journals has been slow to adopt a standardized, written policy of ethics governing editors, reviewers and authors alike.

We submit that it is time for all scientific journals to adopt a standardized and written code of ethics which governs all stakeholders in the peer review process and not just the authors of manuscripts. This endeavor should be undertaken via the guidance of the Editors-in-Chief and should include at the minimum:

- (1) An explicitly stated policy in the Journal and its website regarding the ethical standards expected of authors, editors and reviewers.
- (2) A mandated disclosure of real or perceived conflicts of interest of authors, editors, members of the editorial board and reviewers during the submission process.
- (3) A detailed mechanism for editors or reviewers with real or perceived potential conflict of interests to recuse themselves from assignments that represent a conflict of interest.

F. Bosetti (✉) · C. D. Toscano  
Brain Physiology and Metabolism Section,  
National Institute on Aging, National Institutes of Health,  
Bethesda, MD 20892, USA  
e-mail: francesc@mail.nih.gov

We by no means suggest that the above measures be accepted as the sole measures for standardizing ethics in the peer review process. Other entities, as stated above, have provided more comprehensive guidelines for ethical conduct for all participants in the peer review process [4–6]. Our objective in writing this letter, however, is to begin the long overdue dialog regarding the adoption of written ethical guidelines by scientific journals for all stakeholders in the peer review process. We feel that creating standardized guidelines for all medical and scientific journals will prevent conflict of interest controversies involving the peer-review process. Further and most important, these ethical guidelines will act to increase the trust of both authors and readers in a fair and ethical peer review process, with the ultimate goal of improving the quality and credibility of science.

## Octacosanol Administration to Humans Decreases Neutral Sterol and Bile Acid Concentration in Feces

Sylvia Keller · Franziska Gimmler ·  
Gerhard Jahreis

Received: 8 June 2007 / Accepted: 18 October 2007 / Published online: 15 November 2007  
© AOCS 2007

**Abstract** To investigate octacosanol (OC) metabolism in humans and its influence on cholesterol metabolism, two studies were conducted. In the first study ten healthy women received daily 30 mg OC for a period of 4 weeks. Blood and feces samples were collected at baseline and after the intervention. Serum concentrations of total cholesterol, LDL cholesterol, and HDL cholesterol were not altered following OC administration. Concentrations of excreted cholesterol end products decreased with the intervention (neutral sterols:  $24.6 \pm 9.7$  mg/g vs.  $20.3 \pm 7.5$  mg/g dry matter,  $P < 0.05$ ; bile acids:  $6.47 \pm 3.89$  mg/g vs.  $4.03 \pm 2.26$  mg/g dry matter,  $P < 0.05$ ). OC was not detected in serum samples, but the fecal OC concentration increased after the intervention period ( $11 \pm 7$   $\mu$ g/g vs.  $817 \pm 179$   $\mu$ g/g dry matter,  $P < 0.05$ ). In the second kinetic study on three participants, OC was identified in serums after oral application of 50 mg OC within 8 h. The decrease in the concentration of fecal cholesterol end products may underline a systemic effect of OC on cholesterol metabolism, even though the serum cholesterol levels were not influenced.

### Introduction

Octacosanol (OC) is a main component of the fatty alcohol mixture policosanol, which is found in plant waxes. There is evidence suggesting that fatty alcohols modulate the serum cholesterol concentration in human subjects [1]. In various human studies, a daily supplement of 5–20 mg policosanol decreased the LDL cholesterol concentration between 19 and 31% and the total cholesterol (TC) concentration between 13 and 23%. Long-term studies have shown that HDL cholesterol levels increased in the range of 8–29% [2]. A daily dose of 40 mg policosanol seems to be effective in reducing the serum triacylglycerol concentration [3]. Comparative studies have demonstrated that policosanol used for the treatment of hypercholesterolemia is equally or even more effective, than the use of statins [4–6]. In contrast, Cubeddu et al. [7] found no additional effect of a policosanol-statin combination in comparison to statin alone. Apart from the study by Cubeddu et al. [7], none of two other placebo-controlled studies have revealed an influence of a daily 20 mg policosanol supplement on cholesterol levels [8, 9]. Moreover, in a randomized, double blind, placebo-controlled study, the intake of up to 80 mg/day of policosanol did not affect the serum LDL cholesterol concentration in patients with hypercholesterolemia or

combined hyperlipidemia [10]. In view of these findings, current policosanol doses seem to be ineffective for improving serum cholesterol profiles.

The conversion of fatty alcohols to fatty acids (FAs) was discovered by Rizzo et al. in 1987 [11]. Octacosanoic acid was produced when human fibroblasts were incubated with OC. This conversion of fatty alcohol into FAs via oxidation has been corroborated *in vivo*. Following oral administration of OC, the corresponding octacosanoic acid was identified in animal plasma [12]. Hence, octacosanoic acid was postulated as the active metabolite of OC [13]. Moreover, the effects of fatty alcohols are often equated to their respective FAs. Thus, these FAs were used as test substances in several studies [14–17].

However, fatty alcohols may themselves have an influence on the physiological processes. Being the main component of policosanol, OC was often employed as a test substance, but triacontanol was also shown to exert an influence on cholesterol synthesis *in vitro* [18, 19]. To date, the mechanisms through which policosanol lowers cholesterol levels have not yet been elucidated. Studies indicate that fatty alcohols inhibit synthesis of endogenous cholesterol, without a direct inhibition of the activity of HMG-CoA reductase, a key enzyme involved in the biosynthesis of cholesterol. Policosanol may reduce HMG-CoA reductase activity by depressing *de novo* synthesis and/or stimulating degradation of HMG-CoA reductase [20–22]. In addition, it was found that policosanol-related suppression of HMG-CoA reductase activity is mediated indirectly through AMP-kinase activation [19].

Most of the studies related to pharmacokinetics and metabolism of OC in human and animal subjects were performed using radioactively labeled OC [23–26]. A study examining the absorption and metabolism of unlabeled fatty alcohol in humans has not yet been found in the current literature. In animals fed unlabeled fatty alcohol mixtures, policosanol was not detected in the small intestine, liver, adipose, and plasma [27]. In contrast, OC was measured in plasma samples of rats and monkeys, which had been orally administered 60 mg policosanol/kg and 10 mg policosanol/kg, respectively [12]. These findings point to a direct absorption of the fatty alcohols in the mucosa cells without complete conversion to FA metabolites.

The aim of the two studies was to investigate OC metabolism in humans and its influence on cholesterol metabolism. Therefore, methods for determining OC and octacosanoic acid in human serum and feces were established. The effect on the total body cholesterol pool was examined with reference to the concentrations of serum cholesterol, and the fecal cholesterol end products [neutral sterols (NSs) and bile acids (BAs)].

## Materials and Methods

### Study Conditions

Ten healthy women (age:  $25.5 \pm 2.7$  years; BMI:  $21.5 \pm 2.8$  kg/m<sup>2</sup>) with normal to mildly elevated TC concentrations (TC:  $5.39 \pm 0.87$  mmol/l) participated in the first study. Pregnant subjects or those with diabetes mellitus, and subjects on medication for lowering lipid levels were excluded. All participants were informed about the study conditions in both verbal and written form. Written consent was given by participating subjects. The local Ethics Committee of the Friedrich Schiller University of Jena approved the study protocol.

The participants received a daily dose of 30 mg OC for 4 weeks. They were instructed to maintain their usual eating habits and to ingest one 10 mg OC capsule at each principal meal. The last capsule was administered 1 h before blood samples were drawn. Preparation of the OC capsules involved homogenizing and dosing 10 mg OC (Lesstanol<sup>®</sup>/Natural OC > 90%, Garuda inc., Exeter, CA, USA) and 200 mg glucose into gelatin capsules.

Blood samples were obtained from fasting subjects at the beginning and at the end of the study, in addition to collecting 24-h feces samples. Serum was separated from blood cells by centrifugation at 1,700g for 10 min at room temperature and stored at  $-80$  °C until analysis. Aliquots of feces samples were lyophilized, milled, and stored at  $-20$  °C. The participants completed two 3-day dietary records prior to the sample collection days in order to itemize the food intake, especially the fat and cholesterol consumption.

In a separate second study, three volunteers consumed a total of 50 mg OC within 8 h. The dose was divided into five 10 mg applications and was administered 8, 6, 4, 2, and 1 h before drawing blood samples. Serum samples were pooled before analysis.

### Parameter for Cholesterol Metabolism

Cholesterol concentrations in serum (TC, LDL cholesterol, and HDL cholesterol) were determined after enzymatic preparation as previously described [28]. Concentrations of fecal NSs (cholesterol, coprostanol, coprostanone, cholestanol, cholestanone) and fecal BAs (primary BAs: cholic acid, chenodeoxycholic acid; secondary BAs: deoxycholic acid, iso-deoxycholic acid, 12-keto deoxycholic acid, lithocholic acid, iso-lithocholic acid) were determined using gas chromatography according to a method established by Keller and Jahreis [29].

## Octacosanol Analysis

For OC analysis, either 6 ml serum or 200 mg of lyophilized feces were added to vessels containing the internal standard (20 µg tricosanol for serum samples, 200 µg tricosanol for feces samples). Hydrolysis of esterified fatty alcohols was established by applying freshly prepared ethanolic sodium hydroxide. Proteins were precipitated with methanol and OC extraction was carried out by using of trichloromethane. *N,O*-bis(trimethylsilyl)-trifluoro acetamide was employed to silylate the fatty alcohols.

The OC trimethylsilyl ethers from serum samples were measured using GC-MS (GCMS-QP5000, Shimadzu, Kyoto, Japan). The procedure for serum OC analysis followed an optimized temperature program (200 °C for 2 min, 10 °C/min to 240 °C, 1 °C/min to 255 °C, 255 °C for 1 min, 4 °C/min to 270 °C, 1 °C/min to 274 °C) using a capillary column (ZB5, 30 m, 0.25 mm, 0.25 µm; Phenomenex, Torrance, CA, USA). The sample (5 µl) was injected in split mode (1:10) at 280 °C. Helium served as the carrier gas at a constant linear velocity of 35 cm/s. The interface temperature was adjusted to 300 °C. The mass spectrometric detection was realized in multi ion current mode with  $m/z = 397.45$  amu for tricosanol as an internal standard and  $m/z = 467.6$  amu for OC. Analysis of fecal OC was performed using a gas chromatograph Shimadzu GC 17A (Kyoto, Japan, capillary column: Optima δ3, 30 m, 0.25 mm, 0.25 µm, Macherey Nagel, Dueren, Germany). The injection of 1 µl sample solution was carried out in split mode (1:50) at 280 °C. Hydrogen was used as the mobile phase at a constant velocity of 45 cm/s. The temperature of the flame ionization detector was kept at 300 °C. The oven temperature was raised from 70 °C to 220 °C (70 °C for 2 min, 10 °C/min to 180 °C, 2 °C/min to 220 °C, 220 °C for 5 min).

## Octacosanoic Acid Analysis

To determine octacosanoic acid in human feces and serum samples, an aliquot of 100 mg fecal fat or 15 mg serum lipid extract was prepared to form FA methyl esters (FAMES) as described previously [30]. Analytical measurement of the saturated FAs (C4:0, C10:0, C12:0, C13:0, C14:0, C15:0, C16:0, C17:0, C18:0, C20:0, C21:0, C22:0, C23:0, C24:0, C25:0, C28:0) was carried out using the GC-FID (GC 17A, Shimadzu Kyoto, Japan) equipped with a capillary column (DB 225 MS, 60 m, 0.25 mm, 0.25 µm, Agilent, Palo Alto, CA, USA).

## Data Handling and Statistical Methods

Evaluation of the dietary records was carried out using the software PRODI<sup>®</sup> (5.0 expert, Nutri-Science, Freiburg,

Germany). Chromatogram analysis was conducted employing LabSolutions Software Class 5000<sup>®</sup> and GCMSsolution<sup>®</sup> (Shimadzu, Kyoto, Japan). Statistical analyses of the experimental results were accomplished utilizing SPSS<sup>®</sup> for Windows<sup>®</sup> (version 11.5.1, SPSS Inc., Chicago, IL, USA) with the paired *t*-test. The statistical test criteria for a probability level (*P*) less than 0.05 was necessary for a sample concentration difference to be considered as significant when performing baseline intervention comparisons. The results were stated as mean ± standard deviation.

## Results

### Dietary Records

Evaluation of the 3-day dietary records revealed no differences in daily fat and cholesterol intake between baseline and intervention (Table 1).

### Parameter of Cholesterol Metabolism

Intervention with OC did not influence cholesterol concentrations in the serum samples (Table 2). The concentrations of TC, LDL cholesterol, and LDL/HDL were reduced in their means, but no significance could be verified. The concentration of the cardio-protective HDL cholesterol did not rise after intervention with OC.

TC total cholesterol

<sup>a</sup> Mean of cholesterol concentrations (mmol/l) ± SD

<sup>b</sup> Data were generated using paired *t*-test

The fecal concentration of total NSs was significantly reduced after intervention with OC. The concentration of excreted cholesterol itself did not differ between baseline and intervention samples (Table 3). The total fecal concentration of BAs decreased after intervention with OC due to a significant reduction of secondary BAs.

#### Parameter of Octacosanol Metabolism

Octacosanol trimethyl silyl ethers could not be identified in the serum samples collected in the first study. In the pooled serum of the second study, we succeeded in determining silylated OC qualitatively. On measuring the fragment  $m/z = 467.6$  amu, two different peaks were visible (Fig. 1a). After adding the OC standard to this serum sample, the

peak at 29.8 min could be identified as OC (Fig. 1b), though it could not be quantified.

The fecal concentration of OC was significantly elevated after intervention in comparison to the baseline concentration (Fig. 2, Table 4). However, it was also found that two study participants were low-converters of cholesterol. There are indeed different patterns of colonic neutral steroid conversion in the human population [31]. In the high-converters accounting for the majority of the human population, more than 50% of cholesterol is transformed into coprostanol by the microflora. In contrast, low-converters have a conversion rate below 50% and are identifiable by high fecal cholesterol and low coprostanol concentrations [29]. In this study, results of the OC concentration in the feces samples of the two low-converters were excluded from statistical analysis, because chromatographic co-elution of OC and cholesterol occurred, when the excretion of cholesterol was exceptionally high.

The octacosanoic acid metabolite of OC could not be identified in any of the serum samples after the intervention. Independent of the OC intervention, octacosanoic acid was excreted to a small extent with feces (Table 4). The fecal saturated FA pattern after the intervention was unchanged in comparison to the baseline FA pattern.

#### Discussion

In the current study involving ten healthy women receiving a daily dose of 30 mg OC for a period of 4 weeks, two major effects were observed. Firstly, the concentration of circulating cholesterol in blood remained unaltered after OC supplementation, and secondly, fecal concentration of cholesterol in the form of NSs and BAs was decreased, due possibly to a reduction of the total body cholesterol pool.

<sup>c</sup> Data were generated using paired *t*-test

In addition to efficient cholesterol homeostasis in healthy subjects, the sustained TC and LDL cholesterol concentrations may be explained by the small study population or the short period of supplementation. In addition, a daily dose of 30 mg OC may have been ineffective. In other studies, a reduction in the TC and LDL cholesterol concentrations occurred after six or more weeks [32]. However, Hernández et al. [33] found decreased LDL cholesterol concentrations after 4 weeks of a daily 20 mg-policosanol supplementation in a double blind, placebo-controlled study. The results of our study are consistent with the study of Lin et al. [9], which also revealed no changes in lipid parameters during a 4-week intervention with a daily dose of 20 mg policosanol.

Although the circulating cholesterol concentration remained unchanged after OC supplementation, there was a significant decrease in the concentration of the excreted cholesterol products NSs and BAs. The excretion of NSs and BAs strongly depends, in addition to other factors, on the consumed dietary fat. However, the evaluation of the 3-day dietary records revealed neither a difference in the fat, nor in the cholesterol intake between the baseline and the intervention period.

The reduction in the total body cholesterol pool may have several explanations, e.g., a down-regulated cholesterol absorption in the small bowel, a diminished hepatic

cholesterol synthesis, an up-regulated hepatic BA synthesis, and finally, an elevated cholesterol and/or BA excretion. It has in fact been shown that fatty alcohols are capable of suppressing cholesterol synthesis by indirectly inhibiting the key enzyme HMG-CoA reductase in hepatoma cells in vitro [19]. Moreover, the total body cholesterol pool may decrease as a result of a reduced hepatic cholesterol synthesis. Additionally, Shefer et al. [34] have emphasized that a change in the rate of hepatic cholesterol synthesis may influence the production of BAs. Thus, HMG-CoA reductase may function as a secondary regulatory mechanism for BA production [34]. A reduced cholesterol synthesis in the liver would result in a diminished BA production and subsequently in decreased cholesterol and BA excretion. Contrary to this hypothesis, results obtained from an in vivo study supplementing policosanol in hamsters did not substantiate a reduced cholesterol synthesis after policosanol treatment [35].

To date, no one has succeeded in detecting the unlabeled fatty alcohols and their corresponding FAs in the serum following oral administration of unlabeled fatty alcohols in human subjects. Further, it could not be demonstrated in humans that fatty alcohols are themselves absorbed and are capable of inducing a systemic effect [18]. We were not able to detect OC in the serum samples in our first study. The applied dose of 20 mg/day and an absorption rate of approximately 10% [18] may have been too low to allow verification of OC in serum samples. Assuming absorption of 5 mg of OC at a rate of 10% in an average serum volume of 2.5 l in healthy adults, then an absolute amount of 0.01 mg OC should be detectable in the 5 ml serum samples. In the serum samples from the second kinetic study in which three participants consumed 50 mg OC within 8 h the identification of OC was confirmed. Therefore, the presence of OC in the serum samples provided the evidence for a direct absorption of the non-metabolized fatty alcohols. In fact, a direct absorption of OC in plasma after oral administration has been documented in studies in rats and monkeys [12]. However, this finding is inconsistent

with earlier assumptions from Hargrove et al. [36], who postulated that fatty alcohols are already converted to FAs in the mucosa cell.

Experiments with [<sup>3</sup>H]-OC indicated that fatty alcohols are excreted mainly via the feces [23]. The results of our study corroborate this excretion pathway as seen by the significant increase in the concentration of fecal OC after supplementation. Furthermore, we noted a baseline excretion of OC in all study participants. However, a bacterial synthesis of fatty alcohols in the colon or even a dietary intake could explain this baseline excretion of OC. Contrary to our findings, no excretion of fatty alcohols was observed in the control group feces in the study with hamsters by Ng et al. [37].

Although results of studies with human fibroblasts indicate a conversion of OC to octacosanoic acid [12], to date, this metabolism has not been verified in humans. Our results from analysis of fecal and serum samples could not confirm the formation of octacosanoic acid from OC, though a serum concentration of octacosanoic acid below the limit of detection cannot be excluded.

Thus, study data suggest the absorption of non-metabolized OC, which is detectable in serum after oral consumption of OC. In addition, although the serum cholesterol concentration was not influenced, the decrease in the concentration of the fecal cholesterol end products may underline a systemic effect of OC on cholesterol metabolism.

**Abstract** We investigated the genetic contributions to carotid atherosclerosis and insulin resistance in Chinese patients with primary hypercholesterolemia. A family study of probands from the outpatient clinics in patients with high low-density-lipoprotein cholesterol levels was conducted. A total of 62 families (360 subjects) underwent carotid ultrasonography and insulin resistance measurement. The correlation coefficients of carotid intima-media thickness (IMT) were high among spouse, parent–offspring, and sibling pairs (0.39, 0.38 and 0.35, respectively). All insulin indices and IMT had significant estimates of heritability, of which fasting insulin had the highest heritability ( $0.410 \pm 0.104$ ,  $P = 0.0001$ ), followed by homeostasis model assessment (HOMA) ( $0.395 \pm 0.108$ ,  $P = 0.0001$ ). The estimated heritability of IMT was

significant ( $0.185 \pm 0.103$ ,  $P = 0.025$ ) but not of plaque score. Bivariate genetic coefficient between IMT and HOMA was  $0.569 \pm 0.292$ , while the environmental coefficient was  $0.028 \pm 0.103$ . The study confirms a relationship between insulin resistance and atherosclerosis and, in particular, between insulin resistance and the thickening of the arterial wall. Moreover, it shows that genetics influence both insulin resistance and atherosclerosis, implying that the management of insulin resistance may benefit the prevention of atherosclerotic disease in familial hypercholesterolemia.

## Abbreviations

CA	Carotid atherosclerosis
CCA	Common carotid artery
ECCA	Extracranial carotid artery
FRSPH	Familial-related severe primary hypercholesterolemia
HDL-C	High-density lipoprotein density
HOMA	Homeostasis model assessment
hs-CRP	High-sensitivity C-reactive protein
IMT	Intima-media thickness
LDL-C	Low-density lipoprotein cholesterol

## Introduction

Carotid atherosclerosis (CA) is a subclinical disease associated with cardiovascular disease and risk factors among ethnic Chinese [1, 2]. Although hypertension and related

atherosclerotic risk factors are associated with the progression of CA, genetic factors also play an important role [3–5]. Previous familial aggregation studies showed significant heritability on the carotid artery intima-medial thickness (IMT) and plaque scores [4, 6, 7]. Moreover, genome-wide linkage results showed several genomic loci for determining carotid IMT trait [7–10].

Although there is evidence of genetic components for CA traits, there are several issues yet to be answered. First, the inconsistent genomic loci from genome-wide linkage results have implied genetic heterogeneity over genetic components controlling trait. Second, geographic and racial/ethnic variations of CA has been reported [5–7, 11–15], however, little information is available in ethnic Chinese. Moreover, previous studies have shown that age, gender, insulin resistance, diabetes, metabolic syndrome, and family history were related to CA [9, 16–22]; however, association of these factors with CA have not been simultaneously examined in a family-based genetic study. In addition, hereditary factors have not been studied in ethnic Chinese. We designed a family-based genetic study that focused on ethnic Chinese, where the probands were recruited from hyperlipidemic clinics, in order to explore the genetic correlation and heritability of various CA traits. We also collected information on confounding factors, especially on metabolic syndrome and insulin resistance, to investigate the association with CA.

## Materials and Methods

### Study Subjects

This family study was conducted in hyperlipidemic outpatient clinics after developing standard procedures for recruiting probands and their family members in the university hospital [23]. Familial hypercholesterolemia screening was conducted in 2002 at the lipid clinic of the National Taiwan University Hospital and consecutive patients were recruited as proband. These probands were diagnosed as having familial-related severe primary hypercholesterolemia (FRSPH) on the basis of having low density lipoprotein-cholesterol (LDL-C) levels in themselves and in two or more first-degree relatives that were above 190 mg/dL and/or the presence of tendinous xanthomas within the kindred [24]. The spouses and first-degree relatives were invited to participate in the study.

Individuals with some types of secondary hyperlipidemia, including nephrotic syndrome, obstructive liver disease, or hypothyroidism, and those who refused to provide informed consents, were excluded. The response rate was 90%. The genetic basis of FRSPH is heterogeneous. The most common autosomal dominant form of FH

is caused by mutation in the LDL receptor gene (LDLR) on chromosome 19 in band 19p13.2. There are a number of other less frequent forms of this disorder. They include type B hypercholesterolemia which is caused by ligand-defective apolipoprotein B-100 (APOB), and autosomal dominant hypercholesterolemia 3 (HCHOLA3) which is caused by mutation in the PCSK9 gene. In addition, the differences in frequencies of specific mutations between populations should be considered. Instead of absence of genetic confirmation, we defined our study subjects as FRSPH [24]. All of the subjects received a detailed medical history review and physical examination.

The design was family study, based on the hypercholesterolemic patient as a proband and the first-degree relatives were recruited [25]. The study was approved by the Institutional Review Board of the National Taiwan University Hospital, and all of the subjects gave their informed consent. The procedure of collecting data was standardized, and was followed by the physicians and assistants in measuring the variables. We recruited a total of 360 members in the 62 families, which included three to six patients of hypercholesterolemia in each family, into our study. The subjects underwent examinations for anthropometric measurements, blood pressure, lipid profile, and carotid ultrasound measurements. Information on family history and medical diseases was obtained from each participant by trained assistants, using a structured questionnaire. Patient's socio-demographic characteristics, lifestyle, personal and family history of diseases, and history of hospitalization were also collected. Regular exercise habit was defined as the participants undertaking sports and leisure physical activity daily. Blood pressure was measured after resting for 10 min, with the subjects in the sitting position, while body weight was measured using a calibrated balance. Body mass index was calculated as weight (kilogram) divided by height (meter) squared. The circumference of the smallest part of waist and the thickest part of the hip in the standing position were also measured.

### Blood Chemistry and Lipid Measurement

Overnight fasting (>12 h) blood samples were collected for measurements of glucose, total cholesterol, high-density lipoprotein cholesterol (HDL-C), and triglyceride by standard enzymatic methods with an automatic multi-channel chemical analyzer (Hitachi 7450, Hitachi Corp., Tokyo, Japan) in the central laboratory of the National Taiwan University Hospital. LDL-C value was calculated by the Friedewald's formula [26]. Blood samples for glucose analysis were drawn into glass test tubes, each containing 80 mol/L fluoride/oxalate reagents. After centrifugation at 4 °C, 1,500g for 10 min, glucose levels were measured on

the supernatant by enzymatic assay (Merck 3389 commercial kit, Germany) in an Eppendorf 5060 autoanalyzer.

For the following assays, blood samples were first centrifuged at 3,000 rpm for 15 min within 30 min of collection, and then stored at  $-70^{\circ}\text{C}$  until assayed. Serum insulin level was measured using a Microparticle Enzyme immunoassay (AxSYM Insulin, Abbott Diagnostic, Tokyo, Japan). Serum high-sensitivity C-reactive protein (hs-CRP) was measured using a chemi-luminescent enzyme-labeled immunometric assay (Immulite C-Reactive Protein, Diagnostic Products Co., Los Angeles).

### Insulin Resistance Indices

Several measurements and parameters were used for insulin resistance indices. First, fasting insulin and glucose levels were used because fasting hyperinsulinemia was considered an important indicator of insulin resistance [27]. Second, homeostasis model assessment (HOMA) using the formula:  $[\text{fasting insulin (mU/L)} \times \text{fasting glucose (mg/dL)} \times 0.05551] / 22.5$  was also used [28]. The numbers of metabolic syndrome components, defined by high blood pressure, high waist circumference, high fasting glucose, high triglyceride and low HDL-C status, were also utilized. Finally, we defined the metabolic syndrome status according to the criteria of the number of components more than or equal to three [29].

### Extracranial Carotid Artery Ultrasound Measurements

The protocol and methods of CA measurements have been reported previously [1, 2, 30]. A Hewlett-Packard SONO 4500 ultrasound system (Andover, MA, USA) with a 3–11 MHz real-time B-mode scanner was used for evaluation, which included observation of the longitudinal and transverse views of the extracranial carotid artery (ECCA) bilaterally. An experienced ultrasonographer performed carotid ultrasonography while the patient was supine with the neck extended in a mild lateral rotation. Carotid end-organ disease was assessed by maximal IMT at the common carotid artery (CCA) and by ECCA plaque score. Two measurements of maximal IMT at CCA 0–20 mm proximal to the carotid bifurcation were obtained bilaterally. For future and subsequent off-line analysis, all scans were recorded on super-VHS videotape. Observers were blinded to the subjects' health status and risk factors. Intra-class correlation coefficients of intra-observer were about 0.70–0.87 for both sides of CCA IMT measurements, as reported previously [31].

Method for quantifying plaque score has been described previously [1, 31]. Briefly, a focal thickening of IMT with

$>50\%$  of thickness than the adjacent IMT was considered as an atherosclerotic plaque. A grade was assigned for each chosen segment: grade 0 for normal or no observable plaque; grade 1 for a small plaque with diameter stenosis  $<30\%$ ; grade 2 for a medium plaque with 30–49% diameter stenosis or multiple small plaques; grade 3 for one large plaque with 50–99% diameter stenosis or multiple plaques with at least one medium plaque; and grade 4 for 100% occlusion.

Extracranial carotid artery segments, including the proximal and distal CCA ( $>20$  and 0–20 mm distal to the bulb bifurcation, respectively), bulb, internal carotid artery, and external carotid artery, were examined bilaterally. The plaque score was calculated by adding up the plaque grades of ten segments of the ECCA. Reproducibility of the plaque grade scoring expressed good agreement with a kappa value of 0.70 [1, 31].

### Statistical Analysis

Carotid atherosclerosis and insulin resistance indices, including fasting insulin, glucose and HOMA values, were presented in mean and standard deviation. We specified the above values by gender. Skewness and kurtosis of triglyceride, fasting glucose, insulin, and HOMA values were large due to a non-normal distribution. Logarithm-transformed variables were used for further genetic analysis but due to familial correlation, the statistical difference between genders was not tested. We have four IMT measurements at CCA for each participant, so mixed effect models can be applied in the analysis to increase the detection power in limited study samples. The mixed models were used to test the significance of contributions of IR indices to IMT of CCA and plaque score values in all family members [32].

The intra-familial correlation coefficients of carotid atherosclerosis traits were measured in different pairs, including spouse, parent–offspring, and siblings, by the FCOR program in SAGE [33]. Heritability estimates of carotid indices in the families were estimated by the variance component model, which was incorporated in the SOLAR software [34].

## Results

### Description of Study Participants

Compared with men, women tended to be older and to have higher total cholesterol, HDL, and LDL cholesterol levels, as well as lower waist circumference, uric acid, fasting insulin, HOMA values (Table 1). BMI and blood pressure

**Table 1** Demographic and insulin resistance index risk profiles in the family study (by gender)

in women were comparable with those in men. Carotid atherosclerosis indices, including IMT and plaque scores, were similar between genders. Most patients had hyperlipidemic status, educational level  $\geq 9$  years, and regular exercise habits. Their jobs were business and official work. Men had higher proportions of smoking and alcohol drinking habits. The prevalence rates of metabolic syndrome, defined by AHA/NHLBI criteria, were 15.9% in men and 17.2% in women.

#### Predictor of Carotid Atherosclerosis by Insulin Resistance Indices

We estimated the effects of association between carotid atherosclerosis and various insulin resistance indices (Table 2) using the mixed models. In the univariate model, all insulin resistance indices were associated well with IMT. The magnitude of effects was reduced somewhat after age and gender adjustment. In the multivariate models that incorporated age, gender, obesity, married status, smoking, drinking, education and sport habits, the insulin resistance indices of fasting insulin, glucose, HOMA were still significant predictors for IMT values ( $P = 0.030$ ,  $0.003$ , and  $0.019$ , respectively). Metabolic syndrome component numbers and status were non-significant predictors for IMT in multivariate models. For plaque scores, most of the estimated parameters were not statistically significant in the multivariate models, and only fasting glucose was a significant predictor for plaque score ( $0.00325 \pm 0.00107$ ,  $P = 0.003$ ). Insulin resistance indices were associated with IMT values, not with plaque scores.

#### Familial Correlation and Heritability

In all of the family members, there were 45 spouse pairs, 266 parent–offspring pairs, and 236 sibling pairs. Familial correlation coefficients and heritability estimates were shown in Table 3. The coefficients of parent–offspring and sibling pairs were higher than those of spouses in insulin resistance and carotid atherosclerosis indices. Among these, the IMT coefficients were higher among spouse, parent–offspring, and sibling pairs (0.389, 0.376, and 0.354, respectively). Gender specific parent–offspring correlation coefficients varied much: mothers had higher coefficients than fathers in insulin resistance indices (0.426 in mother–daughter, 0.322 in mother–son, 0.043 in father–daughter, and  $-0.083$  in father–son for HOMA, respectively).

For IMT values, the coefficients were equal in mother–daughter and father–son pairs (0.454 and 0.489, respectively). The coefficients of plaque scores varied much and

<sup>a</sup> Adjusted covariates in multivariate models included age, gender, obesity, married, smoking, drinking, education, and sport habits

high in sibling and spouse pairs. All insulin resistance indices and IMT had significant heritability estimates, and the highest heritability values were fasting insulin ( $0.410 \pm 0.104$ ,  $P = 0.0001$ ), then HOMA ( $0.395 \pm 0.108$ ,  $P = 0.0001$ ). The estimated heritability of IMT was significant ( $0.185 \pm 0.103$ ,  $P = 0.025$ ) but the plaque score heritability was not statistically different.

Genetic and environmental correlation between CA and insulin resistance in bivariate models showed that genetic correlation coefficients were higher (0.999 in HOMA vs.

insulin and 1.00 in IMT vs. plaque score). Genetic coefficients between IMT and HOMA were  $0.569 \pm 0.292$  and environmental coefficients were  $0.028 \pm 0.103$ .

## Discussion

The study confirms a relationship between insulin resistance and atherosclerosis and, in particular, between insulin resistance and the thickening of the arterial wall. Moreover,

**Table 3** Familial correlation coefficients, heritability and standard error estimates for insulin resistance indices and carotid atherosclerosis in the study population

Familial pair type	Number of pairs	Correlation coefficients				
		Fasting insulin	Fasting glucose	HOMA	Intima media thickness	Plaque score
Spouse	45	0.140	0.013	0.155	0.389	0.451
Parent–offspring	266	0.219	0.056	0.222	0.376	0.135
Sibling	236	0.255	0.188	0.201	0.354	0.301
Mother–daughter	84	0.410	0.015	0.426	0.454	0.016

<i>P</i> value		0.0001	0.018	0.0001	0.025	0.212

it shows that genetics influence both insulin resistance and atherosclerosis. This family-based study on ethnic Chinese clearly demonstrated the association between insulin resistance indices and CA, which showed significant heritability values among the study subjects. The more novel component of this study is the effort to consider joint genetic determinants of IMT and insulin resistance.

The relationship between insulin resistance indices and IMT had been previously demonstrated among young Italian women [16]. Although some studies did not show an association of insulin resistance and carotid IMT [35, 36], most studies have shown a positive relation between insulin resistance and carotid IMT [16, 37, 38]. The implications of the study involve several aspects. First, as ascertained from hyperlipidemic patients, family members showed significant familial aggregation of insulin resistance indices and CA. These findings also echoed results in other population-based studies [18, 22, 39, 40]. Our study differentiated two traits of CA, i.e., IMT and plaque score. IMT had higher heritability and familial correlation than plaque score in the study population, while advanced plaque score did not have significant heritability, which were different from those of Mexican American families [10]. Moreover, heritability for IMT was higher for the spouse than for the parent–offspring and sibling, which implied that common environmental factors were as important as genetic factors. Insulin resistance coefficients were ten times higher in the mother–daughter than in the father–daughter, indicating that maternal transmission of glucose metabolism and insulin resistance was much more important than paternal transmission. The hypothesis of excess maternal transmission in diabetes and related traits has been postulated [41]. The mechanisms of female predominance in terms of transmission were proposed as the unique maternal genetic and environmental effects [42], with gestational diabetes having a strong effect on offspring diabetic risk [43]. Our data showed a higher heritability from maternal lineage than paternal one.

We emphasized the relationship between insulin resistance indices and CA, which were taken into consideration together. For predicting CA, various insulin resistance indices, such as fasting insulin, glucose, HOMA, and metabolic syndrome components, had positive effects on IMT, but not plaque scores. High plaque scores were an indicator of more advanced CA, which was evident in men over 40 years of age and in post-menopausal women. With regards to plaque scores, this study did not show a significant heritability between family members whom only IMT values were affected by markers of insulin resistance. The relative young age in these families, with a mean age of 39 and 45 years in men and women, respectively, might be the reason of lack of heritability. As age increases, the association of plaque severity with insulin resistance might be

more apparent [10, 22, 39, 40, 44]. Our participants were in a higher education and official job and tended to maintain a healthy lifestyle, which may blunt the progress of carotid atherosclerosis. Social class disparities in atherosclerosis were observed among general population: adults in US with higher social class keeping a healthier lifestyle, such as exercise and smoking cessation [45].

The strength of our study includes the complete measurements of insulin resistance indices and CA, and the focus on hypercholesterolemic proband populations. The study limitation is that we cannot separate the pure genetic factors from shared common household factors in the estimates of heritability. The high genetic correlation observed seems counterintuitive since this parameter requires that there is a significant heritability to both traits separately. Relatively small sample size in this study may limit the power, especially after being stratified by different relative pairs.

In conclusion, our finding confirms significant heritability for IMT and HOMA, in line with many previous studies, and demonstrates a moderately high genetic correlation between these two traits, implying that common genes contribute to variation in both traits. The association and heritability of insulin resistance and CA were evident among hypercholesterolemic proband families. The results imply that potential pleiotropy exists among these traits. As knowledge of clinical phenotypes and the technical improvement in post-human genome era, the genetic locus of complex traits, such as insulin resistance and CA will be revealed in the near future.

**Abstract** Liver and intestine are major sites of apo A-I synthesis in mammals. ABCA1 is reported to be involved in the secretion of nascent HDL from cultured intestinal cells. However, whether ABCA1 participates in the secretion of nascent HDL from the intestine has not been assessed directly in vivo. This study examined the effect of a synthetic LXR-agonist “TO” on the lymphatic transport of HDL in thoracic duct-cannulated rats. The feeding of a TO-containing diet resulted in an increased transport of cholesterol and apo A-I in the lymph  $d > 1.063$  g/ml lipoprotein fraction than did the feeding of a control diet without TO. The transport of cholesterol in whole lymph was lower, whereas the transport of apo A-I was higher, in the TO group. The abundance of mRNAs for ABCA1 and apo A-I in the intestine was increased in the TO group. Furthermore, although the TO-containing diet reportedly increased the serum HDL concentration in intact mice and rats, no such effect was observed in the cannulated rats. The LXR agonist stimulated in vivo the synthesis of nascent HDL by increasing reciprocally the mRNA for

ABCA1 and apo A-I in the intestine, thereby contributing to an increase in the circulating HDL.

**Keywords** ABCA1 · Apo A-I · Intestine · Lymph · LXR/RXR · Nascent HDL

## Abbreviations

ABC	ATP-binding cassette transporter
LXR	Liver X receptor
RXR	Retinoid X receptor
SREBP-1	Sterol regulatory element binding protein-1
TO	TO-901317

## Introduction

Clinical studies have established a negative correlation between the level of high density lipoprotein (HDL) cholesterol in serum and frequency of ischemic heart disease [1]. HDL particles play a role in a reverse transport process by which excessive cholesterol is pulled out from the peripheral tissues and transferred to the liver.

The serum HDL is believed to be synthesized from precursor HDL, which is secreted by the liver and intestine, or during the catabolism of triacylglycerol-rich lipoproteins [1]. ATP-binding cassette transporter A1 (ABCA1) is a lipid pump that effluxes cholesterol and phospholipids from the cells to apolipoprotein (apo) A-I [2]. ABCA1-deficient mice had low HDL cholesterol levels [3] and human ABCA1 transgenic mice had increased plasma HDL cholesterol levels [4], demonstrating the importance of ABCA1 in the formation of HDL. Liver X receptor (LXR) forms a hetero dimer with the retinoid X receptor (RXR)

and this dimer binds to the LXR response element in the promoter sequence of ABCA1 [5]. As ligands of LXR, several oxidized cholesterol, such as 22(R)-hydroxycholesterol have been identified [6]. Furthermore, Repa et al. reports that when LXR $\alpha/\beta$  double knock-out mice and C57BL/65/129SV mice as the wild type were fed a diet containing 0.2% cholesterol and TO-901317 (TO) as an LXR agonist, the abundance of the intestinal ABCA1 mRNA increased only in the wild type mice [7].

ABCA1 is abundant in not only macrophages but also the liver and small intestine [8]. Recent studies suggest that significant numbers of HDL particles are assembled at the hepatocyte surface [9, 10]. In addition, it has been reported that the expression of ABCA1 in macrophages has a minimal contribution to plasma HDL levels [11]. Timmis et al. [12] demonstrated that hepatic ABCA1 is essential for the lipidation of nascent apo A-I and the maintenance of the majority of the plasma HDL pool.

Although the physiological role of ABCA1 in the small intestine has yet to be clarified, Ohama et al. [13] showed that ABCA1 protein is expressed at the basolateral site of CaCo-2 cells, the expression is enhanced by incubating the cells with LXR/RXR agonists, and the efflux of cholesterol is induced by apo A-I at the basolateral but not apical site. The study therefore suggests that ABCA1 may be involved in vivo in the formation and secretion of intestinal HDL, but this hypothesis has not been demonstrated in vivo. In this study, we evaluated the role of intestinal ABCA1 expression in the lymphatic transport of HDL in rats with permanent cannulation of the thoracic duct. Our results demonstrate that a LXR agonist increases the lymphatic HDL transport from the intestine by promoting reciprocally ABCA1 and apo A-I expression.

## Materials and Methods

### Animals and Diet

Male SD rats, 8-weeks old, obtained from Seiwa Experimental Animals (Fukuoka, Japan) and maintained in a temperature-controlled room (23 °C), were trained to consume a control diet twice a day from 10:00–11:00 and 16:00–17:00, respectively, for 5 days. The control diet was based on the AIN-93G [14] formulation as described previously [15] and supplemented with soybean oil (100 g/kg diet) and cholesterol (10 g/kg diet). To the control diet was added TO-901317 (TO: Cayman, MI, USA) at 0.056 g/kg diet (TO diet). The amount was based on the report showing that the effective level of TO is 3 mg/kg body weight in a meal [7]. On day 6, all the rats were anesthetized with Nembutal prior to permanent cannulation of the thoracic duct lymph as described previously [15]. Briefly, a

cannula (SH silicon tube, 0.5 mm i.d. and 1.0 mm o.d., Kaneka Medics, Osaka, Japan) filled with heparinized saline was inserted into the thoracic duct and secured within the abdominal cavity. The rats were returned to their cages and provided with the control diet or the TO diet twice a day as just described. On day 9, the rats were attached to a long PE cannula (0.58 mm i.d. and 0.97 mm o.d., Becton Dickinson and Company, MD, USA) to collect the lymph. The end of the cannula was 5–10 cm below the bottom of the cage in order to allow the lymph to drain into the cannula. The lymph was collected for 20 min, and the rats were then given free access to the control diet or TO diets for 30 min. At this time, the lymph was collected every hour for 7 h. The lymph was collected in a tube containing an inhibitor for lecithin-cholesterol acyltransferase, 1 mM 5,5'-dithionitrobenzoic acid in 0.75 M phosphate buffer solution. After fibrin was removed, ethylenediaminetetraacetic acid at a final concentration of 0.01% was added to the lymph solutions. The lymph was subjected to ultracentrifugation to isolate the lymph  $d > 1.063$  g/ml fraction as described below. The rats were anesthetized with diethylether and sacrificed by collecting aortic blood. The intestine was immediately excised and then divided into proximal and distal sites to strip the mucosa for the total RNA preparation. The liver was also excised and used for RNA preparation and lipid determination.

The rats had free access to deionized water throughout the feeding periods and during lymph collection. Experiments were carried out following the Guidelines for Animal Experiments at the Faculty of Agriculture and the Graduate Course, Kyushu University, Fukuoka, Japan, and Law No.105 and Notification (No. 6) of the Government of Japan

### Measurement of mRNA Levels for Specific cDNA in the Intestinal Mucosa and the Liver

Total cellular RNA was isolated from the small intestine and liver using guanidium thiocyanate/cesium chloride ultracentrifugation as described by Sato et al. [16] and used for Northern blotting as described by Thomas [17]. Hybridization was performed in hybridization solution containing cDNA labeled with [ $\alpha$ -<sup>32</sup>P] deoxycytidine triphosphate (dCTP) (3,000 Ci/mmol, ICN Co., CA, USA) using a multiprime DNA labeling system (Amersham Pharmacia Biotech, Tokyo, Japan) according to the manufacturers instruction, as described elsewhere [16]. Rat cDNAs for ABCA1 (GenBank No.: NM178095, GeneID: 313210), G5 (GenBank No.: NM053754, GeneID: 114628) and G8 (GenBank No. NM130414, GeneID: 155192), and apo A-I [18] were cloned from rat liver cDNA by the

reverse transcription PCR method. Rat ABC G5 and G8 and sterol regulatory element binding protein (SREBP)-1 cDNAs were cloned full length. Rat ABC A1 cDNA was partly cloned: 392 bp from bp 2,616 to 3,007. The primer sequences were 5'-CAAGGTATCGGGGTCCAATG (5'-primer) and 5'-CATTATGCTGGGGACAGACT (3'-primer) for ABCA1, 5'-GCTGGCCATGGGTGAGCTGCC TTTCTG and 5'-TCTTACCTATCTGCTAATCAGGTAG TCC for ABCG5, 5'-ATGGCTCAGACGACCAAAGAGG AGA and 3'-TGAACATCACCAATCTTGAATTGAC for ABCG8 and 5'-ATGAAAGCTGCAGTGTGGCTGCC and 5'-CGGTCACTAAGCGTTCAGCTTCTTCTTTTT for apo A-I. All cDNA sequences were ensured by a DNA autosequencer (Gene Rapid, Amersham Pharmacia Biotech, Tokyo, Japan) to match the reported sequences. The apo A-IV cDNA clone as a plasmid was provided by Gordon [19]. Human ribosomal 18s RNA cDNA clones as a plasmid were obtained from American Type Culture Collection (Rockville, MD, USA). Quantification of the hybridization signals was carried out with a bio-imaging analyzer (BAS-1000, Fuji Photo Film Co., Tokyo, Japan). The results were expressed as a relative value after normalization to ribosomal 18s RNA.

#### Preparation of Lymph HDL Fraction

The lymph was adjusted to a density of 1.063 by addition of KBr, and ultracentrifuged at  $100,000\times g$  (Beckman TLA100.2 rotor, Beckman Instruments, USA) for 20 h at 15 °C. Lipoprotein fractions of density  $>1.063$  g/ml and density  $<1.063$  g/ml were designated as the HDL fraction and non-HDL fraction, respectively.

#### Measurement of Serum and Liver Lipid Concentrations

Serum triacylglycerol, total cholesterol and phospholipid levels were measured using enzyme assay kits (Triglyceride *G* Test, Cholesterol *C* Test and Phospholipid *B* Test, respectively). The kits were purchased from Wako Pure Chemical Industries, Osaka, Japan. Serum HDL-cholesterol levels were measured using a precipitate and enzymatic assay kit (HDL-C 2: Daiichi Chemical Industry, Tokyo, Japan). Liver lipids were extracted by the method of Folch et al. [20] and cholesterol [15], triacylglycerol [21] and phospholipid [8] levels were measured as described elsewhere. The lipids of the lymph HDL and non-HDL fractions were extracted by the method of Folch et al. [20] and cholesterol levels were measured by gas liquid chromatography as described elsewhere [15]. The apo A-I level was determined by immuno electrophoresis

using anti rat apo A-I rabbit serum and expressed as arbitrary units against a reference serum from rats [16].

#### Statistical Analysis

The data were expressed as the mean  $\pm$  SEM. The significance of differences was determined with Student's *t* test. The statistical analysis was carried out with Statcel (OMS, Saitama, Japan) and Microsoft Excel 2000 (Microsoft, Redmond, WA, USA). Differences were considered to be statistically significant at  $P < 0.05$ .

#### Results

During the training period (day 1–5), all the rats consumed a control diet twice a day ( $16.2 \pm 0.4$  and  $15.0 \pm 1.1$  g/day for the control and TO groups, respectively,  $n = 6$ ). After the operation (day 7–8), rats consumed the control diet and TO diet, respectively, twice a day ( $11.1 \pm 0.9$  and  $10.1 \pm 1.6$  g/day for control and TO group, respectively). As expected, food consumption was lower at day 7–8 than day 1–5. At day 9, both groups of rats consumed the diet for 30 min ( $5.2 \pm 0.4$  and  $5.2 \pm 0.9$  g for the control and TO groups, respectively). The type of diet had no significant effect on food consumption.

Although there was no difference in the lymph flow prior to the feeding of the control and TO diets, consumption of the TO diet resulted in a remarkable reduction in lymph flow ( $8.52 \pm 0.99$  ml/7 h and  $4.80 \pm 1.13$  ml/7 h for the control and TO groups, respectively,  $P < 0.05$ ). The TO diet also resulted in a reduction in lymph flow ( $13.7 \pm 1.62$  ml/7 h and  $8.21 \pm 0.780$  ml/7 h for the control and TO groups, respectively,  $P < 0.05$ ) and the rate of transport of cholesterol ( $14.0 \pm 1.37$  mg/7 h and  $9.02 \pm 0.70$  mg/7 h for the control and TO groups, respectively,  $P < 0.05$ ), triacylglycerols ( $341.7 \pm 31.2$  mg/7 h and  $220.9 \pm 25.9$  mg/7 h for the control and TO groups, respectively,  $P < 0.05$ ), and phospholipids ( $32.4 \pm 3.5$  mg/7 h and  $25.2 \pm 2.1$  mg/7 h for the control and TO groups, respectively) in our preliminary study.

As shown in Fig. 2a, the TO diet resulted in a decrease in the transport of cholesterol for 7 h in the total lymph and  $d < 1.063$  g/ml fraction. However, the transport for 7 h in the  $d > 1.063$  g/ml fraction was greater in the TO group than the control group. As shown in Fig. 2b, the lymphatic output of apo A-I was higher in the TO group. Such a difference was attributed to an increased output of apo A-I in the  $d > 1.063$  g/ml fraction in the TO group (Fig. 2).

Table 1 and Fig. 1 shows the relative abundances of the mRNAs for ABC proteins, apoproteins, and SREBP-1 in intestinal mucosa and liver isolated from rats after the of

**Fig. 1** The mRNA expression of ABCA1, ABCG5, ABCG8, ApoE, SREBP-1, ApoA-I and ApoA-IV were analyzed by Northern blot analysis. Signals were quantitated by image analysis. Each value was normalized for the ribosomal RNA 18S signal

**Fig. 2** The effect of dietary TO on cholesterol contents (a) and apo A-I contents of total lymph and non-HDL and HDL fractions (b) collected for 7 h. Values for six rats per group are means  $\pm$  SEM. Values for apo A-I are represented as the area of the immunoprecipitation by immuno electrophoresis. Asterisk, significantly different from the control group,  $P < 0.05$

lymph was collected. The abundance of mRNAs for ABCA1, G5 and G8, apo A-I, and SREBP-1 in the proximal intestine was higher in the TO group than the control group. The extent of the increase was most prominent for the ABCA1 mRNA. The TO diet also resulted in an increase in mRNA abundance for ABC proteins, apo A-I and SREBP-1, in the distal intestine. In the liver, the TO diet resulted in an increased abundance of mRNAs for ABC proteins and SREBP-1. However, there was no significant difference in apo A-I mRNA abundance between the dietary groups. The extent of the increase for ABCG5/8 mRNA abundance in the liver appeared to be greater than that for the corresponding ABCA1. The consumption of TO had no significant effect on the mRNA abundance for apo A-IV and apo E in the intestine and liver.

The TO diet resulted in an increased concentration of triacylglycerol in serum ( $257 \pm 33$  for the TO diet and  $100 \pm 33$  mg/dl for the control diet,  $n = 6$ ,  $P < 0.05$ ). The concentration of triacylglycerols in the liver was also higher in the TO than control group ( $79.9 \pm 10.9$  versus  $12.0 \pm 1.9$  mg/g liver, respectively,  $n = 6$ ,  $P < 0.05$ ). There was no significant difference in the concentration of HDL-cholesterol in serum between the groups ( $17.9 \pm 3.0$  and  $18.9 \pm 2.5$  mg/dl for the TO and control group, respectively,  $n = 6$ ,  $P > 0.1$ ).

## Discussion

The present study showed that consumption of TO, an artificially made LXR agonist, resulted in an elevation of cholesterol and apo A-I levels in the lymph  $d > 1.063$  g/ml fraction. Although it remains to be determined if cholesterol and apo A-I exist simultaneously as a lipoprotein particle such as a nascent HDL, Green et al. reported that rat intestine secretes discoidal HDL in the lymph  $d > 1.063$  g/ml fraction [23]. Furthermore, Wu et al. [24] and Imaizumi et al. [25] showed that rat intestine actively produces apo A-I, which is used as a constituent of chylomicrons and nascent HDL in the lymph. Accordingly, the present study suggests that the LXR agonist increases the secretion of nascent HDL particles from the intestine.

Recent studies have established that the lipidation of HDL apoproteins occurs primarily after their secretion and that ABCA1 is a crucial participant in the early lipidation of newly secreted apo A-I [26]. The present study showed that the TO diet resulted in increased mRNA levels of ABCA1 and apo A-I suggesting increased levels of these proteins in the intestinal mucosa. That the apo A-I levels in the lymph and the HDL fraction were higher in the TO group than in the control group indicates indirectly the active synthesis of apo A-I in the intestinal mucosa.

**Table 1** Relative mRNA levels for ABC proteins, apoproteins and SREBP1 in the proximal intestine and liver in rats fed the control and TO diet

	Liver		Proximal intestine		Distal intestine	
	Control	TO	Control	TO	Control	TO
ABCA1	100 ± 13.6	188 ± 10.8*	100 ± 36.0	1127 ± 99.0*	100 ± 15.7	1557 ± 273*
ABCG5	100 ± 28.4	629 ± 96.5*	100 ± 16.6	284.0 ± 10.1*	100 ± 6.3	194 ± 10.6*
ABCG8	100 ± 15.9	996 ± 272*	100 ± 20.4	324.0 ± 6.7*	100 ± 6.9	262 ± 28.6*

Values are means ± SEM;  $n = 6$  per group. The significance of difference between the two diet groups of liver and proximal and distal intestines was analyzed by Student's  $t$  test

\* Significantly different from rats fed the control diet ( $P < 0.05$ )

Although ABCA1 protein levels were not determined in the present study, the increased HDL-cholesterol level in the lymph in the TO group suggests an increased level of ABCA1 protein at the basolateral site of the intestine, because it is reported that LXR/RXR ligands enhance the expression of ABCA1 on the basolateral surface of CaCo-2 cells [13, 27, 28] and efficient basolateral cholesterol efflux occurs during the absorption of dietary cholesterol in chickens [29]. It is also reported that apo A-I is secreted independent of lipids and that the lipid-poor apo A-I can accept cholesterol from ABCA1 which plays a role in the TG-rich lipoprotein-independent transport of cholesterol across the intestinal epithelial cells [13, 27, 28]. Accordingly, it is likely that the TO-diet -dependent increase in the transport of HDL-cholesterol is attributable to the increased expression of ABCA1 and apo A-I.

Feeding mice a TO-containing diet has been reported to result in an increased level of HDL cholesterol [7]. In our preliminary study, in rats whose thoracic lymph duct was not cannulated, the TO diet resulted in an increased serum HDL cholesterol concentration compared with the control diet ( $36.4 \pm 1.2$  and  $26.4 \pm 1.7$  mg/dl for the TO and control groups, respectively,  $n = 5$ ,  $P < 0.05$ ). As shown in the present study, however, there was no significant difference in the serum HDL-cholesterol level in the cannulated rats indicating that the increase in intestinal HDL synthesis caused by the TO contributes to the elevation in the serum HDL level. Brunham et al. [30] treated mice with the synthetic LXR agonist GW3965. GW3965 significantly increased plasma HDL cholesterol levels in wild-type mice and mice lacking hepatic ABCA1, and this effect was completely abrogated in mice lacking intestinal ABCA1. They have insisted that activation of intestinal ABCA1 can lead to an increase in HDL level. Therefore, in this study, serum HDL level in cannulated rats did not arise because of lacking HDL derived from lymph secreted from intestine.

The ABCA1 gene has a responsive site for the complex LXR/RXR ligand [6]. No such responsive element has been reported for the apo A-I gene in the mouse or rat. In fact, apo A-I gene in the liver and intestine of mice remained unaffected by a LXR agonist [31]. Alternatively, a rise in the apo A-I mRNA level caused by a LXR agonist has been reported in chondrocytes from chick embryo tibiae [32] and epithelial cells from canine gallbladder [33]. Therefore, it remains possible that an increased efflux of cholesterol from the basolateral site through an ABCA1-mediated pathway triggered a change in the apo A-I mRNA abundance. Therefore, there may be an indirect regulatory mechanism by which LXR agonists act on apo A-I expression in rat intestine.

In the present study, the extent of the change in the abundance of mRNAs for the ABCA1 and ABCG5/8 genes, which have the responsive element for the LXR/RXR gene differed between the intestine and liver. Namely, the effect of TO was prominent in the intestine for ABCA1 and in the liver for ABCG5/8. These results indicate that there exists a mechanism regulating tissue-dependent expression of ABCA1 and ABCG5/8 due to the TO-diet. According to Tamehiro et al. [34], there are two types of ABCA1 transcripts: a LXR-responsive element-dependent transcript which is found in the intestine and the peripheral tissues including macrophages and a novel liver-type promoter which is activated by sterol regulatory element-binding protein-2. Expression of the latter is suppressed by dietary cholesterol in experimental animals. The intestine contains only the peripheral-type transcript, whereas the liver has both types. In the present study, the diet contained cholesterol, hence resulting in a less prominent increase in abundance for the liver type ABCA1 mRNA than for the intestine type ABCA1 mRNA. It remains unclear why the TO-diet exerted a more pronounced change in the abundance of ABCG5/8 mRNA in the liver than intestine.

In the present study, the TO diet resulted in an elevation of SREBP-1 mRNA abundance 1.7-fold higher than the control diet. In contrast, Brunham et al. [30] reported that administration of GW3965 as an agonist of LXR to wild-type mice elevated the level of SREBP1c mRNA to 30-fold compared to the vehicle administration without cholesterol input. The different response to LXR agonist appears to be the amount of cholesterol in the diet, feeding period of the agonist and the amount of the agonist injected.

Dietary fat has been reported to increase lymph flow [35]. In the present study, it was found that the TO-diet resulted in a decreased lymph flow compared to the control. The suppression appears to be relevant to a decrease in the transport of lymphatic cholesterol, triacylglycerols, and phospholipids. The suppression of lymph flow may be partly due to the decrease in intestinal nitric oxide (NO), the expression of which was suppressed by a LXR agonist [36]. In fact, NO production in the gut has been reported to increase gastrointestinal peristaltic motion [37]. Thus, the inhibition of NO production by the agonist may lower lymph flow, thereby delaying lipid absorption. Alternatively, the TO-diet may have increased intestinal fluid flow from the mucosal site to the luminal site thereby resulting in an increase in sterol transport from the mucosal site to the luminal site in mice fed an LXR/RXR agonist [38]. Furthermore, it remains the possibility that TO-diet might influence the bile acid synthesis thereby influence the absorption of cholesterol [39].

In summary, the present study demonstrated for the first time that treatment with a LXR agonist promotes the transport of lymph HDL possibly by enhancing reciprocally the expression of the ABCA1 and apo A-I genes.

**Abstract** The aim of the present study was to relate brachial artery intima-media thickness (IMT) and the grey scale median of the intima-media complex (IM-GSM) to traditional cardiovascular risk factors and markers of inflammation and oxidative stress. In the Prospective Study of the Vasculature in Uppsala Seniors (PIVUS) study, a population-based study of 1016 subjects aged 70, brachial artery IMT and IM-GSM, who were evaluated by ultrasound. Lipids, thirteen markers of inflammation and nine markers of oxidative stress were measured. The Framingham risk score was related to IMT ( $p < 0.0001$ ), but not to the IM-GSM. In univariate analysis, HDL-cholesterol, serum triglycerides, fasting glucose, smoking, HOMA insulin resistance index and oxidized LDL levels were related to IMT. HDL and LDL-cholesterol, triglycerides, VCAM-1, e-selectin, leukocyte count, conjugated diens,

baseline conjugated diens (BCD)-LDL, antibodies to ox-LDL, the GSSG/GSH glutathione ratio and homocysteine were related to IM-GSM. In multiple regression models, HDL-cholesterol, fasting glucose and oxLDL levels were the independently related to IMT ( $p = 0.01$ – $0.04$ ), while serum triglycerides, BCD-LDL and the GSSG/GSH ratio were independently related to IM-GSM ( $p = 0.0001$ – $0.004$ ). In conclusion, in addition to traditional lipid variables, markers of oxidative stress were associated with both thickness and echogenicity of the brachial artery intima-media complex. Thus, both thickness and echogenicity of the brachial artery intima-media complex might be useful biomarkers in the future.

## Introduction

The IMT of the carotid artery is a commonly used measure of atherosclerosis. IMT of the carotid artery has been shown to be reduced by intensive statin treatment [1] and to predict cardiovascular events in epidemiological cohort studies [2]. It has recently been shown that brachial artery IMT is correlated to common carotid artery IMT [3]. Thus, also brachial artery IMT might serve as a marker of cardiovascular risk.

Although several studies have evaluated the echogenicity of carotid artery plaque as the GSM by image analysis [4, 5], few attempts have been made to characterize the intima-media complex with a similar grey scale analysis. It is evident from the visual inspection of the intima-media complex in both the carotid and brachial artery that a great variation in echogenicity does exist.

However, the usefulness of this information has however not yet been studied.

In order to validate the usefulness of the evaluation of the brachial artery IMT and GSM of the intima-media complex (IM-GSM), these two brachial artery characteristics were related to traditional cardiovascular risk factors included in Framingham risk score and the metabolic syndrome (MetS). Furthermore, since both inflammation and oxidative stress have been advocated to play an important role in the development of atherosclerosis, we used data from the PIVUS study, a population-based cohort study initiated in more than 1000 subjects aged 70 living in the community of Uppsala, Sweden [6], to study the relationships between brachial artery IMT and GSM of the intima-media complex and traditional risk factors as well as markers of inflammation and oxidative stress. The hypothesis tested was that both the brachial artery IMT and GSM of the intima-media complex would be related to traditional risk factors. This hypothesis is biologically plausible, since carotid artery IMT [2], as well as echolucent plaques predict future cardiovascular events [7].

## Material and Methods

### Subjects

The eligible subjects were all aged 70 living in the community of Uppsala, Sweden. The subjects were chosen from the register of community inhabitants and were invited in a randomized order. The subjects received an invitation by letter within 2 months of their 70th birthday. Of the 2025 subjects invited, 1016 subjects participated giving a participation rate of 50.1%.

The study was approved by the Ethics Committee of the University of Uppsala and the participants gave informed consent.

### Basic Investigation

The participants were asked to answer a questionnaire about their medical history, smoking habits, and regular medication.

All subjects were investigated in the morning after an over-night fast. No medication or smoking was allowed after midnight. After recording their height, weight, abdominal and hip circumference, an arterial cannula was inserted in the brachial artery for blood sampling (and later regional infusions of vasodilators, see Ref. 6]. Thereafter, the ultrasonographic evaluation took place in the contralateral arm.

Blood pressure was measured by a calibrated mercury sphygmomanometer in the non-cannulated arm to the nearest mmHg after at least 30 min of rest and the average of three recordings was used. Traditional lipid variables and fasting blood glucose were measured by standard laboratory techniques. From these data, the Framingham risk score was calculated [8].

Approximately 10% of the cohort reported a history of coronary heart disease, 4% reported stroke and 9% diabetes mellitus. Almost half the cohort reported some cardiovascular medication (45%), with antihypertensive medication being the most prevalent (32%). Fifteen percent reported use of statins, while insulin and oral antiglycemic drugs were reported in 2 and 6%, respectively (see Ref. 6 for details).

As the participation rate in this cohort was only 50%, we carried out an evaluation of cardiovascular disorders and medications in 100 consecutive non-participants. The prevalences of cardiovascular drug intake, history of myocardial infarction, coronary revascularization, antihypertensive medication, statin use and insulin treatment were similar to those in the investigated sample, while the prevalences of diabetes, congestive heart failure and stroke tended to be higher among the non-participants (see Ref. 6 for details).

### Brachial Artery IMT and GSM

The brachial artery was assessed by external B-mode ultrasound imaging 2–3 cm above the elbow (Acuson XP128 with a 10-MHz linear transducer, Acuson Mountain View, California, USA). The image was digitized and imported into the AMS (Artery Measurement Software) automated software [9, 10] for dedicated analysis of IMT and GSM. A maximal 10-mm segment with good image quality was chosen for analysis.

The program automatically identifies the borders of the IMT of the far wall and the inner diameter of the vessel and calculates IMT and the diameter from around 100 discrete measurements through the 10-mm long segment. This automated analysis was capable of being manually corrected if not found appropriate on visual inspection.

A Region Of Interest (ROI) was placed manually around the intima-media segment that was evaluated for IMT and the program calculates the intima-media GSM (IM-GSM) from analysis of the individual pixels within the ROI on a scale from 0 (black) to 256 (white). The blood was used as the reference for black and the adventitia was the reference for white. See Fig. 1 for an illustration of the measurements.

The mean length of the evaluated segment was 6.9 (SD 1.9) mm when subjects with a segment recording less

**Fig. 1** Measurement of intima-media thickness (IMT) and echogenicity (grey scale median) of the intima-media complex (IM-GSM) of the brachial artery far wall. A region of interest (ROI) is created by the computer software used and manually adjusted if necessary. The length of this ROI is 5–10 mm. In this figure, a strict rectangular ROI has been indicated for graphical reasons, but in practice the ROI is very tightly adjusted by use of about 200 measurement points to closely fit the blood-intima interface and the media-adventitia interface. IMT is measured by the mean of about 100 thickness measurements and IM-GSM by the median of the grey scale of all pixels included in the ROI

than 3 mm were excluded, leaving 945 subjects with valid recordings.

The digitized measurements were repeated in 30 random subjects giving coefficients of variations for IMT and IM-GSM of 7.8 and 5.0%, respectively.

#### Insulin Resistance and the Metabolic Syndrome

Serum insulin was measured by an enzymatic-immunological assay (Boehringer Mannheim). HOMA insulin resistance index was defined as: fasting blood glucose  $\times$  serum insulin/22.5 [11].

The metabolic syndrome was defined according to the NECP/ATP III criteria [12]. Three of the following five criteria should be fulfilled: Blood pressure  $>130/85$  mmHg or antihypertensive treatment, fasting blood glucose  $>5.6$  mmol/l, serum triglycerides  $>1.7$  mmol/l, waist circumference  $>102$  cm in men and  $>88$  cm in women, HDL-cholesterol  $<1.0$  mmol/l in men and  $<1.3$  in women.

#### Markers of Inflammation

High sensitive CRP was measured in human serum by an ultra sensitive particle enhanced immunoturbidimetric

assay (Orion Diagnostica, Espoo, Finland) on a Konelab 20 autoanalyser (Thermo Clinical LabSystems, Espoo, Finland). The inter assay coefficient of variation was 3.2%.

Cytokines, chemokines and adhesion molecules were analysed on the Evidence<sup>®</sup> array biochip analyser (Randox Laboratories, Ltd, Crumlin, UK) [13].

The functional sensitivity for the different inflammatory markers were as follows: IL-1 alpha: 0.5 pg/ml, IL-1 beta: 0.8; IL-2: 4.1, IL-4: 2.8; IL-6: 0.3, IL-8: 1.5, IL-10: 1.0; INF-gamma: 1.8, TNF-alpha 1.8, MCP-1 19.4, ICAM-1: 18.6, VCAM-1:3.1, e-selectin 3.1, p-selectin 11.2, l-selectin 32.8, CRP: 0.1, Leukocyte count 0.2.

Due to a poor sensitivity for IL-1 alpha and beta, IL-4 and IL-10 with a large number of subjects with undetectable levels, these four cytokines were excluded from the analysis.

#### Markers of Oxidative Stress

Baseline conjugated dienes of LDL (BCD-LDL) were measured by using a method validated and reported in detail before [14]. For BCD-LDL, the coefficients of variance for within-assay and between-assay precision were 4.4 and 4.5%, respectively. Enzyme-linked immunosorbent assay (ELISA) kits (Merckodia, AB) were used to determine serum oxidized LDL, within-assay variation coefficient was 6.3% and between-assay CV was 4.7%, respectively [15]. ELISA kit (BioMedica) was applied to assay autoantibodies to Ox LDL (oLAB), with intra assay and inter assay values 4.3 and 6.0%, respectively. All glutathione indices, CD and TAOC values were measured and calculated as described previously [16]. Homocysteine was measured by using an Enzyme Immunoassay method (Axis-Shield Diagnostics Ltd) with an intra assay coefficient of 6.8%.

Markers of inflammation and oxidative stress were not evaluated in the young healthy reference sample

#### Statistics

Non-normally distributed variables were log-transformed in order to achieve a normal distribution. This was, however, not achieved for some of the variables. ANOVA or Mann–Witney *U* test was therefore used to evaluate differences between groups. Relationships between continuous variables were evaluated by Pearson's and Spearman's correlation coefficients and multiple regression analysis. Two-tailed significance values were given with  $p < 0.05$  regarded as significant. StatView (SAS inc, NC; USA) was used for calculations.

## Results

### Basic Statistics of Risk Factors, Brachial Artery IMT and IM-GSM

Basic risk factor statistics and data on brachial artery IMT and IM-GSM in the PIVUS sample are given in Table 1.

### Relationship between Brachial Artery IMT and IM-GSM

Brachial artery IMT and IM-GSM were inversely correlated ( $r = -0.07$ ,  $p = 0.025$ ).

### Relation to Framingham Risk Score

Of the evaluated brachial artery characteristics, IMT, but not IM-GSM, was related to Framingham risk score (see Table 2 for details).

Of the variables in the Framingham risk score, HDL-cholesterol, smoking and fasting glucose were significantly related to brachial artery IMT. Both LDL and HDL-cholesterol were related to IM-GSM (see Table 2 for details).

**Table 1** Basic characteristics and major cardiovascular risk factors in the sample

<i>n</i>	1016
Females (%)	50.2
Height (cm)	169 (9.1)
Weight (kg)	77 (14)
Waist circumference (cm)	91 (12)
BMI (kg/m <sup>2</sup> )	27.0 (4.3)
Waist/hip ratio	0.90 (0.075)
SBP (mmHg)	150 (23)
DBP (mmHg)	79 (10)
Heart rate (beats/min)	62 (8.7)
Serum cholesterol (mmol/l)	5.4 (1.0)
LDL-cholesterol (mmol/l)	3.3 (0.88)
HDL-cholesterol (mmol/l)	1.5 (0.42)
Serum triglycerides (mmol/l)	1.3 (0.60)
Fasting blood glucose (mmol/l)	5.3 (1.6)
Currently smoking (%)	11
IMT (mm)	0.41 (0.08)
IM-GSM (units)	104 (39)

Means are given with SD in parenthesis. *SBP* Systolic blood pressure, *DBP* Diastolic blood pressure, *BMI* Body mass index, *IMT* brachial artery intima-media thickness, *IM-GSM* the grey scale median of the intima-media complex (IM-GSM)

**Table 2** Univariate relationships between brachial artery intima-media thickness (IMT), the grey scale median of the intima-media complex (IM-GSM) and Framingham risk score and individual cardiovascular risk factors included in the score, as well as serum triglycerides, body mass index (BMI), waist circumference and the HOMA index

	IMT	IM-GSM
Framingham risk score	0.14 (0.0001)	-0.04 (0.18)
SBP	0.05	-0.01
DBP	0.02	-0.06
LDL-cholesterol	<0.01	0.10 (0.003)
HDL-cholesterol	-0.18 (0.0001)	0.14 (0.0001)

Smoking (pack-years)	0.10 (0.003)	0.03
Fasting glucose	0.11 (0.001)	-0.03
BMI	0.05	-0.05
Waist circumference	0.05	-0.03
HOMA index	0.08 (0.033)	-0.05

Pearson's correlation coefficients are given with *p*-values in parenthesis if <0.05

See Table 1 for abbreviations. *HOMA* Homeostatic model assessment

### Relations to the Metabolic Syndrome

None of evaluated brachial artery characteristics were significantly different when subjects with the metabolic syndrome were compared with those without.

However, when related to the five different components included in the MetS definition, IMT was related to HDL-cholesterol, serum triglycerides and fasting glucose, but not to blood pressure or waist circumference. IM-GSM was related to HDL-cholesterol and serum triglycerides, but not to the other three components of the MetS (see Table 2 for details).

The HOMA insulin resistance index was significantly related to IMT, but not significantly to IM-GSM. BMI was not related to any of the brachial artery indices (see Table 2 for details).

### Inflammatory Markers

Brachial artery IMT was not significantly related to any of the inflammatory makers (see Table 3), while IM-GSM was inversely correlated with VCAM-1, e-selectin and leukocyte count.

### Oxidative Stress Markers

Of the oxidative stress markers, only the level of oxidized LDL was related to brachial artery IMT. IM-GSM, on the

**Table 3** Univariate relationships between brachial artery characteristics and markers of inflammation and oxidative stress

	IMT	IM-GSM	Median	10th to 90th percentile

GSSG/GSH ratio	0.02	0.26 (0.0001)	0.082	0.057–0.127

Spearman's correlation coefficients are given with *p*-values in parenthesis if <0.05. Median and the 10th to 90th percentile are given to the right. *IM* intima-media, *IMT* Intima-media thickness, *TNF* Tumor necrosis factor, *IL* Interleukin, *MCP* Monocyte chemoattractive protein, *ICAM* Intracellular adhesion molecule, *VCAM* Vascular cell adhesion molecule, *CRP* C-reactive protein, *Ox LDL* Oxidized LDL, *oLAB* antibodies against oxLDL, *CD* Conjugated diens, *BCD* Baseline CD, *TAOC* Total antioxidant capacity, *TGSH* Total glutathion level, *GSSG* oxidized glutathione, *GSH* reduced glutation

other hand, was related to oxidized LDL antibody, CD and homocysteine in a negative way and to BCD-LDL, GSSG and the GSSG/GSH ratio in a positive way.

#### Multiple Regression Models

In the first multiple regression model, brachial artery IMT was the dependent variable. The independent variables were the traditionally risk factors, inflammatory markers and markers of oxidative stress that in the univariate analysis showed a *p*-value less than 0.05 when related to IMT (see Tables 2, 3 for details). Also gender was included as an independent variable.

As could be seen in Table 4, HDL-cholesterol (inversely), oxLDL and fasting glucose were the variables being independently related to brachial artery IMT in the regression model. The R<sup>2</sup> for this model with only significant variables included was 0.07.

In the second multiple regression model, brachial artery IM-GSM was the dependent variable. Like in the first

**Table 4** Multiple regression analysis with brachial artery intima-media thickness (IMT) as the dependent variable and the traditional risk factors, markers of inflammation and oxidative stress being related in univariate analysis (see Tables 3, 4, 5 for details) as independent variables together with gender (coded 0 for males and 1 for females)

	Partial correlation coefficient	<i>p</i> -value
Gender	-0.14	0.0001
HDL-cholesterol	-0.09	0.019
Smoking (pack-years)	0.03	0.34
OxLDL	0.09	0.016
Fasting glucose	0.08	0.024
Serum triglycerides	0.02	0.66

*OxLDL* Oxidized LDL

model above, the independent variables were the traditionally risk factors, inflammatory markers and markers of oxidative stress that in the univariate analysis showed a *p*-value less than 0.05 when related to IM-GSM (see Tables 2, 3 for details). Gender was also included as an independent variable.

**Table 5** Multiple regression analysis with brachial artery intima-media grey scale median (IM-GSM) as the dependent variable and the traditional risk factors, markers of inflammation and oxidative stress being related in univariate analysis (see Tables 3, 4, 5 for details) as independent variables together with gender (coded 0 for males and 1 for females)

	Partial correlation coefficient	<i>p</i> -value
Gender	0.07	0.045
HDL-cholesterol	0.06	0.10
Serum triglycerides	−0.12	0.004
LDL-cholesterol	0.01	0.75
VCAM-1	0.01	0.85
e-selectin	−0.02	0.48
Leukocyte count	−0.01	0.80
GSSG/GSH ratio	0.23	0.0001
BCD-LDL	0.18	0.0001
Homocysteine	−0.06	0.064

See Table 3 for abbreviations

In this second multiple model, serum triglycerides (inversely), the GSSG/GSH ratio and BCD-LDL were independently related to IM-GSM (see Table 5 for details). The R<sup>2</sup> for this model with only significant variables included was 0.13.

## Discussion

The present study showed that the Framingham score was related to brachial artery IMT, but not to IM-GSM. However, when the individual risk factors were analyzed, risk factors related to lipid metabolism included in the Framingham risk score or the metabolic syndrome were related to IM-GSM. Furthermore, when oxidative stress and inflammatory markers were also analysed in multiple regression models, both traditional lipid variables and markers of oxidative stress were independently associated with both IMT and IM-GSM, while markers of inflammation were not.

### Strength of the Association and the Issue of Multiple Testing

In the present study most of the significant associations (except for the glutathione ratio) showed correlation coefficients that were rather modest (0.10–0.15), despite being highly significant, and the biological relevance might be questioned. It should, however, be emphasized that most such relationships are attenuated with age and higher values are usually seen in younger subjects with fewer disorders and medications. Furthermore, the multiple regression models show several factors to determine IMT

and IM-GSM so that no single factor would be of uttermost importance limiting the correlation coefficients.

Although the primary aim of the present study was to investigate the relationships between brachial artery IMT and IM-GSM vs. established risk factors in order to see if these measurements were related to the risk factors in a plausible way, and thereby justify the future measurement of these vascular wall characteristics in the brachial artery, we also had information on multiple markers of inflammation and oxidative stress and added those to the study in order to obtain a more complete picture, since both inflammation and oxidative stress have been suggested as being involved in atherosclerosis.

By doing so, many correlation tests were performed. Since this was a study of exploratory character, we did not adjust for multiple testing (which by applying the Bonferroni correction would result in a critical *p*-value of 0.00075) and report unadjusted *p*-values to give a more broad view. Using this approach, it is evident that some of the relationships reported might be false positive, but it must be emphasized that all significant relationships are directed in the hypothesized direction and all are biologically highly plausible. However, it is obvious with this approach that all findings must be considered with great caution until reproduced by others.

### Measurements of Brachial Artery IMT and IM-GSM

In the present cohort of elderly subjects it was possible to evaluate brachial artery far-wall IMT and IM-GSM in the vast majority of patients (94%), when the criteria of at least 3 mm length of evaluable intima-media complex was applied. A proper measurement in the near wall was much harder to obtain and was therefore not included in the present study. The reproducibility (CV) of the IMT and IM-GSM were in the range of 5–8%, being satisfactory.

While IMT is an established measure of the vascular wall [1, 2], the IM-GSM is less commonly used. GSM analysis has previously mainly been performed on plaques and then found to be related to histological features of the plaque, such as the elastin and calcium content, as well as to the size of the lipid-rich necrotic core [17]. However, the histological correlate to variations in the IM-GSM has not been evaluated. The finding the IM-GSM was related to some of the common risk factors, as well as to markers of inflammation and oxidative stress, does, however, suggest that the IM-GSM is a measure that is of biological relevance.

The intimal reflection line is included in the measurement of IM-GSM. Our experience is that the echogenicity of this reflection line is most often related to the echogenicity of the more darker space below. Furthermore, since the intimal reflection line only consists of 10–20% of all

pixels in the ROI, it is not believed that the inclusion of this part would distort the measurement of IM-GSM.

#### Relationships to the Framingham Risk Score

The Framingham score was only related to brachial artery IMT, but not to IM-GSM. The reason for this is not clear since when analyzing the different components in the Framingham risk score, LDL-cholesterol and HDL-cholesterol were both related to IM-GSM.

Of the different components in the Framingham score, HDL was most closely related to both IMT and IM-GSM in an independent way. Thus, low levels of HDL were associated with both a thick and echolucent intima-media complex. This relationship seems biologically plausible, since low levels of HDL, as well as a thick intima-media complex and echolucent plaques are predictive of future cardiovascular events [2, 7].

#### Relationships to the Metabolic Syndrome

Despite the fact that brachial artery IMT was related to three of the five components of the MetS and IM-GSM was related to two of them, no alterations in IMT or IM-GSM were seen in subjects with the MetS. This was clearly contrary to the original hypothesis and emphasizes that the metabolic syndrome is composed of different clinical entities, rather than a uniform pathogenetic mechanism.

One of the proposed uniting mechanisms in the syndrome is abdominal obesity, but no relationship was seen between waist circumference and IMT or IM-GSM. On the other hand, another proposed unifying mechanism of the syndrome, insulin resistance, was found to be related to IMT. This relation was, however, weak and of borderline significance.

#### Relationships to Inflammatory Markers

Different inflammatory markers, such as CRP, a number of cytokines, adhesion molecules and leukocyte count have all been found to be related to carotid artery IMT in previous studies [18–26].

In the present study, no markers of inflammation, including CRP, were related to brachial artery IMT. Although several investigators have reported a relationship between CRP and carotid artery IMT [19, 21, 23, 25, 27], a number of studies were not able to find such a relationship [20, 22, 28–31]. Thus, the role of CRP as a determinant of IMT in the carotid and brachial arteries is still far from being clear.

In contrast to IMT, several of the inflammatory markers measured in the present study were related to the grey scale of the intima-media complex. In the past, grey scale analysis has only been applied to overt atherosclerotic plaque and a relationship between echolucent plaque in the carotid artery and CRP levels have been reported [32, 33]. The present study expands that knowledge of a relationship between inflammation and the grey scale of the intima-media complex in the brachial artery. It should, however, be pointed out that these relationships were rather weak and did not persist in the multiple regression models.

#### Relationships to Oxidative Stress Markers

Previous studies have shown both markers of intracellular oxidative stress, such as glutathione [27], and markers of lipid peroxidation, such as oxLDL and oxLDL antibodies [34–39] to be related to carotid artery IMT, although not every study has been able to reproduce these results [40, 41]. In the present study, oxLDL was the major oxidative marker measured being related to brachial artery IMT. This was valid also after adjustment for traditional risk factors and was of the same magnitude as the relationships between IMT and HDL-cholesterol or fasting glucose.

Both markers of the intracellular oxidative stress defense (the GSSG/GSH ratio) and the defense against LDL oxidation (BCD-LDL) were independently related to brachial artery IM-GSM after adjustment of traditional risk factors and inflammatory markers.

Glutathione, an intracellular antioxidant widely distributed in human tissues, acts as a cofactor for glutathione peroxidase. This enzyme reduces  $H_2O_2$ , a reactive oxidant species produced during the course of metabolism, to oxidized glutathione (GSSG) and water [42]. The low levels of the GSSG/GSH ratio that characterized subjects with an echolucent intima-media complex could be a result of a low glutathione peroxidase activity, indicating a reduced antioxidant activity.

Thus, although the exact histological correlates of the IM-GSM are not known, these data suggest that oxidative mechanisms, together with circulating lipids, might play a part in the determination of brachial artery IM-GSM.

#### Clinical Usefulness

Since clinical atherosclerosis is uncommon in the brachial artery, it is not likely that measurements of IMT and IM-GSM in the brachial artery would be a useful tool for atherosclerosis detection. However, since we detected an association between IM-GSM and lipids, as well as

markers of oxidative stress, IM-GSM might be used for risk prediction in the future, but first it has to be shown in prospective studies that IM-GSM is a predictor for future cardiovascular events with an additive value to conventional risk factors.

### Limitation of the Study

The present sample was limited to Caucasians aged 70. Caution should therefore be made in drawing conclusions with regard to other ethnic- and age groups.

The present study had a moderate participation rate. Therefore, we carried out an evaluation of cardiovascular disorders and medications in 100 consecutive subjects who did not wish to participate [6]. The prevalences of cardiovascular drug intake, history of myocardial infarction, coronary revascularization, antihypertensive medication, statin use and insulin treatment were similar to those in the investigated sample, while the prevalences of diabetes, congestive heart failure and stroke tended to be higher among the non-participants.

In conclusion, the present study showed that in addition to traditional lipid variables, markers of oxidative stress were independently related to both thickness and echogenicity of the brachial artery intima-media complex, suggesting that an evaluation of both the thickness and echolucency of the brachial artery intima-media complex to be of value to study the atherosclerotic process and cardiovascular risk.

**Acknowledgments** The outstanding work performed at the endothelium laboratory by Nilla Fors, Jan Hall, Kerstin Marttala and Anna Stenborg in the collection and processing of the data is gratefully acknowledged. We also wish to thank the staff at Analytical Biochemistry at AstraZeneca for performing the analyses of cytokines, chemokines, and adhesion molecules. The financial support from Uppsala University, the Thureus foundation and AstraZeneca R&D is highly valued.

## Apoptotic Effects of Dietary and Synthetic Sphingolipids in Androgen-Independent (PC-3) Prostate Cancer Cells

**Abstract** Stress-induced activation and metabolism of plasma membrane sphingolipids results in intracellular ceramide accumulation and has been shown to induce apoptosis in human prostate cancer cells. This effect has been observed using synthetic ceramide analogs, such as C6-ceramide; however, the effects of naturally-occurring sphingolipids, such as C18-ceramide and sphingomyelin (CerPCho), on apoptosis and prostate cancer cell proliferation have not been examined. The results of the present study demonstrate that natural (CerPCho, C18-ceramide) and synthetic (C6-ceramide) sphingolipids reduced PC-3 cell proliferation by  $15 \pm 1.8$ ,  $17 \pm 2.5$ , and  $46 \pm 2.1\%$ , respectively ( $P < 0.05$ ). These reductions in proliferation were due, in part, to increased cellular apoptosis. Treatment of PC-3 cells with CerPCho and C18-ceramide significantly increased apoptosis by  $3.0 \pm 0.8$  and  $3.6 \pm 0.6\%$ , respectively, compared to the untreated control, while the synthetic C6-ceramide significantly increased apoptosis by  $55.7 \pm 0.4\%$ . C6-ceramide-induced apoptosis was associated with cell cycle arrest in the G<sub>2</sub>/M phase, decreased extracellular signal-regulated kinase (ERK1/2) signaling and activation of the cell cycle regulatory protein, retinoblastoma (pRb).

Treatment of PC-3 cells with C18-ceramide and CerPCho did not alter cell cycle distribution, pRb or ERK1/2 activation. Taken together, these results suggest that natural and synthetic sphingolipids induce apoptosis in PC-3 cells via distinct signaling mechanisms and potencies.

### Introduction

Prostate cancer is the second leading cause of cancer related death in the United States [1]. Although the 5-year survival rate of prostate cancer is nearly 100% when detected during early stages of the disease, the survival rate plunges to only 33% in those patients with metastatic, androgen-independent prostate cancer [1]. Androgen-independent prostate cancer is very resilient and largely chemoresistant, primarily due to defects in apoptotic signaling. Strategies to circumvent defective apoptotic signaling may sensitize these chemoresistant cells to undergo apoptosis.

The membrane sphingolipid sphingomyelin (CerPCho) plays an important role in regulation of cell signaling and apoptosis. In response to cellular stress, the phosphatidylcholine (PtdCho) headgroup of CerPCho is cleaved by sphingomyelinase (SMase), resulting in accumulation of ceramide. Accumulation of ceramide can alter membrane fluidity and modulate signal transduction cascades leading to cell cycle arrest and/or apoptosis [2–7]. Ceramide-induced apoptosis is an important mechanism by which damaged cells are efficiently destroyed and removed. However, alterations in CerPCho metabolism during

carcinogenesis results in decreased ceramide accumulation and resistance to apoptosis [8].

Mammalian cells have several enzymes which limit accumulation of ceramide, so that undamaged cells do not unnecessarily undergo apoptosis. Ceramide can be converted back to CerPCho via CerPCho synthase, while glucosylceramide synthase reduces the toxicity of ceramide via glycosylation [2, 6, 9]. Ceramidase converts ceramide to sphingosine which is ultimately converted to sphingosine-1-phosphate, an anti-apoptotic compound [6]. Many cancer cell types overexpress these enzymes, leading to lower basal levels of ceramide and increased resistance to chemotherapeutic agents that induce ceramide accumulation [9–13]. Androgen-independent prostate cancer cells (designated PC-3 cells) also appear to have defects in accumulation of ceramide resulting in resistance to apoptosis. Although the exact mechanism is currently unknown, it appears that the inability of these cells to accumulate ceramide is independent of de novo ceramide synthesis [14].

Sphingolipids are of particular interest in anticancer therapy due to the apoptotic effects of their metabolites, particularly ceramide. One possible strategy to accumulate ceramide in tumors cells is via delivery of dietary sources of CerPCho. Dietary CerPCho has previously been shown to inhibit the progression of colon cancer in mice and the formation of preneoplastic hepatic lesions in rats due to altered sphingolipid metabolism and reduced intracellular ceramide concentrations [15, 16]. Synthetic ceramides (short acyl group, <C<sub>8</sub>) have previously been shown to induce apoptosis in an androgen-independent, multi-drug resistant prostate cancer cell line [14]; however, there are concerns that synthetic ceramide accumulation may result in different cellular effects than their natural sphingolipid derived ceramide counterparts (long acyl group, >C<sub>16</sub>). Naturally-occurring sphingolipids, such as CerPCho, are found in a variety of food products and are efficiently absorbed postprandially. However, the apoptotic effects of such naturally-occurring dietary sphingolipids in the prostate are largely unknown. Therefore, the present study examines the ability of exogenous CerPCho to induce apoptosis in the chemoresistant PC-3 cell line.

## Materials and Methods

### Reagents

CerPCho, C6-ceramide, PtdCho, 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), ribonuclease A, and propidium iodide were obtained from Sigma-Aldrich Co (St. Louis, MO, USA). C18-ceramide was obtained from Fisher Scientific (Fairlawn, NJ, USA). The

Annexin V-FITC apoptosis detection kit was purchased from Oncogene Research Products (San Diego, CA, USA). The ECL Plus Western Blotting Detection Reagents kit was purchased from Amersham Biosciences (Piscataway, NJ, USA). Phospho-p44/42 mitogen activated protein kinase (MAPK) [Thr202/Tyr204] (p-ERK 1/2), p44/42 MAPK (total ERK 1/2), phospho-pRb [Ser807/811] (pRb), pRb (4H1) monoclonal (total pRb), phospho-cdc2 (p-cdc2), total cdc2, anti-rabbit horseradish peroxidase (HRP)-linked IgG, and anti-mouse HRP-linked IgG were purchased from Cell Signaling Technology, Inc. (Beverly, MA, USA). Media and tissue culture supplies were obtained from Invitrogen Corporation (Carlsbad, CA, USA).

### Cell Culture and Lipid Preparation

Human prostate cancer cells (PC-3, ATCC #CRL-1435) were maintained in RPMI 1640 supplemented with 10% fetal bovine serum at 37 °C, 5% CO<sub>2</sub>, and 90% relative humidity. Upon reaching 90% confluency, cells were trypsinized and seeded into the appropriate tissue culture vessels for each experiment. C6-ceramide was solubilized in DMSO and added to growth medium at a solvent concentration at 0.5%. CerPCho was solubilized in methanol and added to growth medium at a solvent concentration of 0.25%. C18-ceramide and PtdCho were solubilized in a chloroform:methanol (1:1) solution and added to growth medium at a solvent concentration of 0.25%. Growth medium containing the lipids was sonicated for 30 min at 37 °C followed by passage of the medium through a 0.2- $\mu$ m sterile filter.

### Cell Proliferation

To determine the effects of CerPCho, C6-ceramide, C18-ceramide, and PtdCho on PC-3 cell proliferation, cells were seeded in 96-well tissue culture plates at an initial concentration of  $2.5 \times 10^4$  cells/well. Following an overnight incubation, cells were treated with CerPCho, C18-ceramide, C6-ceramide, and PtdCho at the indicated concentrations and time intervals. After incubation, cell proliferation was determined by the MTT assay as described previously [17]. Changes in cellular proliferation are expressed as a percent of control (given as 100%).

### Annexin V-FITC Binding

PC-3 cells were seeded in 60-mm dishes at an initial concentration of  $10^6$  cells/dish and treated with CerPCho (244  $\mu$ M), C18-ceramide (353  $\mu$ M), C6-ceramide

(63  $\mu\text{M}$ ), or vehicle alone for 24 h. Following the indicated treatments, cells were collected and analyzed according to the directions provided by the Annexin V-FITC apoptosis detection kit (Oncogene Research Products). In brief, media was collected from each dish and cells were trypsinized from the dishes and washed using PBS. Annexin V-FITC was added to each sample followed by 15 min incubation at room temperature in the dark. Medium containing Annexin V-FITC was removed and cells were resuspended in a propidium iodide solution and stored on ice away from light until analyzed. For each sample, a digital micrograph was taken (200 $\times$  magnification) under bright field conditions, as well as under green and blue fluorescent filters. Cells expressing only green fluorescence under the blue filter were considered early apoptotic. Cells expressing green/red or red fluorescence were considered late apoptotic. The percentage of apoptotic cells was determined by dividing the total number of early and late apoptotic cells by the total number of cells as counted under bright field. Significant difference from the untreated control is designated by  $^*(P < 0.05)$ .

#### Flow Cytometry

PC-3 cells were seeded in 60-mm dishes at an initial concentration of  $10^6$  cells/dish. Following the indicated treatments with CerPCho, C18-ceramide, C6-ceramide for 24 h, or vehicle alone cells were collected and analyzed according to the procedure of Darzynkiewicz et al. [18]. In brief, media was collected from each dish and cells were trypsinized from the dishes and washed using PBS containing 0.1% bovine serum albumin. The cells were fixed in 70% ethanol and stored at 4  $^\circ\text{C}$  until analysis. For analysis, cells were washed using PBS, centrifuged at 1250 $\times g$ , resuspended in a propidium iodide staining solution containing ribonuclease A, and incubated for 30 min at room temperature away from light. A minimum of 20,000 events per sample was measured for DNA content by propidium iodide staining using the BD FACS Calibur flow cytometer and cell cycle distribution was determined using the software program Modfit<sup>®</sup>.

#### Cell Harvesting and Immunoblotting

PC-3 cells were seeded in 60-mm dishes at an initial concentration of  $10^6$  cells/dish. Following the indicated treatments cells were harvested and protein concentrations for each sample were determined using the bicinchoninic acid assay. Crude proteins isolated and separated on a 10% SDS-polyacrylamide gel and transferred to a nitrocellulose membrane. Immunoblot was performed using

primary antibodies (phospho-ERK1/2, total-ERK1/2, phospho-pRb, total-Rb, phospho-cdc2, total-cdc2) at recommended dilutions in TTBS (1  $\times$  tris buffered saline (TBS) with 0.1% Tween-20) overnight at 4  $^\circ\text{C}$ . Following incubation with secondary antibodies, protein signals were visualized on autoradiography film, and quantified by densitometry using Scion imaging software (Frederick, Maryland).

#### Statistical Analysis

Statistical significance was determined using two-way analysis of variance with Tukey's post hoc comparisons ( $n = 3$ ). Differences were considered significant at  $P < 0.05$ .

## Results

### Sphingolipids Reduce PC-3 Cell Proliferation

The concentration dependent effects of PtdCho, CerPCho, C18-ceramide, and C6-ceramide on PC-3 cell proliferation (24 h) are given in Fig. 1a. Proliferation of PC-3 cells was significantly decreased by  $13.4 \pm 2.3\%$ , and  $15.1 \pm 1.8\%$  following treatment with 122 and 244  $\mu\text{M}$  CerPCho, respectively ( $P < 0.05$ ), compared to untreated controls. C18-ceramide reduced cell proliferation by 15–17% at all concentrations tested while the negative control PtdCho did not affect proliferation. Cell proliferation was significantly decreased by  $21 \pm 3.6$ ,  $35 \pm 3.4$ , and  $46 \pm 2.1\%$  following treatment with 6, 16, and 63  $\mu\text{M}$  C6-ceramide, respectively ( $P < 0.05$ ), compared to untreated controls.

PC-3 cells treated with CerPCho and C18-ceramide exhibited only modest reductions in proliferation over time (Fig. 1b). CerPCho (244  $\mu\text{M}$ ) reduced PC-3 cell proliferation by  $17 \pm 1.8$ ,  $13 \pm 1.8$ , and  $18 \pm 1.8\%$  at 24, 48, and 72 h post-treatment, respectively ( $P < 0.05$ ), compared to untreated controls. C18-ceramide (353  $\mu\text{M}$ ) reduced proliferation by  $17 \pm 2.5$ ,  $19 \pm 1.7$ , and  $22 \pm 3.3\%$ , respectively ( $P < 0.05$ ), compared to untreated controls. C6-ceramide (63  $\mu\text{M}$ ) reduced proliferation by  $46 \pm 2.1$ ,  $68 \pm 2.6$ , and  $72 \pm 3.6\%$  at 24, 48, and 72 h post-treatment, respectively ( $P < 0.05$ ), compared to untreated controls. PtdCho (253  $\mu\text{M}$ ) did not reduce cell proliferation.

### Sphingolipid-Induced Apoptosis

CerPCho (244  $\mu\text{M}$ ) and C-18 ceramide (353  $\mu\text{M}$ ) significantly increased the amount of apoptotic cells by nearly

**Fig. 1** Concentration and time dependent effects of PtdCho, CerPCho, C18-ceramide, and C6-ceramide on PC-3 cell proliferation. Cell proliferation was measured using the MTT assay. **a** PC-3 cells were treated 24 h with increasing concentrations of PtdCho (closed circles), CerPCho (open circles), C18-ceramide (closed triangles), and C6-ceramide (open triangles) (**b**) PC-3 cells were treated for increasing time intervals with PtdCho (253 µM, closed circles), CerPCho (244 µM, open circles), C18-ceramide (353 µM, closed triangles), and C6-ceramide (63 µM, open triangles). Significant difference from the untreated control is designated by \* ( $P < 0.05$ ).

twofold as compared to the untreated control ( $P < 0.05$ ) (Table 1). The increase in total apoptosis induced by CerPCho and C18-ceramide was represented by an increase in the population of early apoptotic cells. C6-ceramide significantly induced a 16-fold increase in the population of apoptotic cells as compared to the untreated control, and significantly increased the population of late apoptotic cells ( $P < 0.05$ ).

#### Exogenous Sphingolipids Do Not Alter PC-3 Cell Cycle Distribution

The effects of ceramides on cell cycle distribution are given in Table 2. CerPCho significantly increased the population of apoptotic cells sevenfold as compared to the untreated control ( $P < 0.05$ ) without affecting the proportions of cells in the G<sub>1</sub>, S, and G<sub>2</sub> phases. C18-ceramide increased apoptosis was nearly sixfold that of the untreated cells; however, this was not statistically different from the untreated control ( $P = 0.1$ ). C18-ceramide did not alter the ratios of cells in the G<sub>1</sub>, S, and G<sub>2</sub> phases

**Table 1** Apoptosis of PC-3 cells treated with CerPCho (244 µM), C18-ceramide (353 µM), C6-ceramide (63 µM), or vehicle treated control was measured by Annexin V-FITC staining following 24 h treatment

	Total apoptosis (%)	Early apoptosis (%)	Late apoptosis (%)
Control	3.6 ± 0.3	1.5 ± 0.3	2.1 ± 0.3
CerPCho	6.6 ± 0.8*	3.6 ± 0.8*	3.0 ± 0.7
C18-ceramide	7.2 ± 0.6*	4.4 ± 0.6*	2.7 ± 0.3
C6-ceramide	59.3 ± 0.4*	3.5 ± 1.0	55.8 ± 0.7*

\* Significant difference from the untreated control ( $P < 0.05$ )

compared to the control. C6-ceramide alone significantly increased the population of apoptotic cells to  $41 ± 1.0%$  as compared to  $1.8 ± 1.0%$  apoptosis of the untreated control ( $P < 0.05$ ) and induced a twofold increase in the population of cells in the G<sub>2</sub> phase of the cell cycle while reducing the populations of G<sub>1</sub> and S phase cells five and twofold, respectively, compared to the untreated control ( $P < 0.05$ ).

#### Inhibition of ERK1/2 by C6-ceramide but not CerPCho and C18-ceramide

The concentration and time dependent effects of the sphingolipids on ERK1/2 are given in Fig. 2. Treatment with CerPCho (Fig. 2a, b) and C18-ceramide (data not shown) did not reduce ERK1/2 at any concentration tested. ERK1/2 activation decreased in a concentration and time dependent manner following treatment with C6-ceramide (Fig. 2c, d). The decrease in ERK1/2 activation was greatest at 12 h post-treatment, with a small rebound in activity observed 24 h post-treatment.

**Table 2** Cell cycle analysis of PC-3 cells treated with CerPCho (244 µM), C18-ceramide (353 µM), C6-ceramide (63 µM), or vehicle treated control was measured by flow cytometric techniques following 24 h treatment

	Apoptosis (%)	G1 (%)	G2 (%)	S (%)
Control	1.8 ± 1.8	36.2 ± 0.9	34.0 ± 1.2	30.0 ± 1.6
CerPCho	13.3 ± 2.5*	31.0 ± 1.4	36.2 ± 1.3	32.8 ± 2.5
C18-ceramide	10.4 ± 5.6	29.7 ± 3.7	33.3 ± 0.9	37.0 ± 3.4
C6-ceramide	40.7 ± 1.0*	7.0 ± 2.0*	77.6 ± 1.9*	15.4 ± 0.1*

\* Significant difference from the untreated control ( $P < 0.05$ )

**Fig. 2** Concentration and time dependent effects of CerPCho and C6-ceramide on ERK1/2 activation. **a** Active ERK1/2 (p-ERK1/2) was measured by immunoblot in PC-3 cells following 24 h treatment with CerPCho (0–244  $\mu$ M). **b** Time dependent (0–24 h) activation of ERK1/2 following treatment of cells with 244  $\mu$ M CerPCho. **c** Active ERK1/2 (p-ERK1/2) was measured by immunoblot in PC-3 cells following 24 h treatment with C6-ceramide (0–63  $\mu$ M). **d** Time dependent (0–24 h) activation of ERK1/2 following treatment of cells with 63  $\mu$ M C6-ceramide. All experiments were performed independently at least three times with an  $n = 3$ . Total ERK1/2 (t-ERK1/2) was used as the loading control

### Sphingolipid-Induced Activation of Cell Cycle Regulatory Proteins

The concentration and time dependent effects of CerPCho and C6 ceramide on pRb and cdc2 activation are given in Fig. 3. Treatment with CerPCho (Fig. 3a) and C18-ceramide (data not shown) did not affect activation of pRb or cdc2 at any concentration tested. pRb activation (dephosphorylation) increased in a concentration and time dependent manner following treatment with C6-ceramide (Fig. 3b). The increase in pRb activation was greatest at 6 h post-treatment. However, C6 ceramide did not alter the activity of cdc2 at any concentration tested.

### Discussion

Humans consume 115–140 g of sphingolipids per year from sources such as meat, dairy, fruits, legumes, and vegetable products [19–21]. Plasma lipoproteins contain significant amounts of sphingolipids such as CerPCho and ceramide [22], suggesting that dietary sphingolipids reach peripheral tissues and may influence a variety of cellular processes including proliferation and apoptosis [21]. Dietary sphingolipids, such as CerPCho, localize in the plasma membrane of cells and release ceramide intracellularly in response to cellular stress, resulting in ceramide accumulation and apoptosis [2–7]. Many cancer cell types overexpress enzymes which limit ceramide accumulation, thereby increasing resistance to chemotherapeutic agents that induce apoptosis [12, 13, 23]. Several studies suggest that overwhelming the cancer cell with short acyl synthetic

**Fig. 3** Concentration and time dependent effects of CerPCho and C6-ceramide on pRb and cdc2 phosphorylation. **a** pRb and cdc2 phosphorylation was measured by immunoblot in PC-3 cells following 24 h treatment with CerPCho (0–244  $\mu$ M) or following treatment with 244  $\mu$ M CerPCho for 0–24 h. **b** pRb and cdc2 phosphorylation

was measured by immunoblot in PC-3 cells following 24 h treatment with C6-ceramide (0–63  $\mu$ M) or following treatment with 63  $\mu$ M C6-ceramide for 0–24 h. All experiments were performed independently at least three times with an  $n = 3$ . Total pRb and total cdc2 was used as the loading control

ceramides may mitigate the effects of these enzymes and result in increased apoptosis [14, 24]. However, to date, the antiproliferative effects of naturally-occurring ceramides have not been explored.

The results of the present study show that naturally-occurring ceramides, CerPCho and C18-ceramide, and the synthetic C6-ceramide can reduce PC-3 cell proliferation via apoptosis. The apoptotic effects of C6-ceramide were more robust than those of the CerPCho and C18-ceramide. This is most likely due to differences in the uptake, metabolism, and/or cellular localization of long versus short chain acyl ceramides. Long acyl chain ceramides and CerPCho (containing long acyl chain ceramide) are unable to penetrate the plasma membrane without metabolic stimulation, [3, 7, 16, 25], whereas, short acyl chain ceramides, such as C6-ceramide, are able to penetrate the plasma membrane thereby significantly increasing intracellular ceramide concentrations.

Several studies have demonstrated that cellular ceramide accumulation inhibits the proliferation of monoblastic leukemia, glomerular mesangial, and vascular smooth muscle cells via reduced ERK1/2 activity and increased apoptosis [26–28]. In agreement with these previous reports, the present study shows that C6-ceramide inhibited ERK1/2 activity and increased apoptosis in the PC-3 cell line. Short acyl ceramides have been shown to induce G<sub>0</sub>/G<sub>1</sub> cell cycle arrest [29]. However, in the present study, G<sub>2</sub>/M arrest was observed following treatment of PC-3 cells with C6-ceramide, despite activation of pRb, the major G<sub>0</sub>/G<sub>1</sub> cell cycle check point protein. We hypothesize that G<sub>0</sub>/G<sub>1</sub> cell cycle arrest was not observed because of the significant amount of cellular apoptosis induced by C6-ceramide 24 h following treatment [30, 31]. Surprisingly, changes in cdc2 activity, a cell cycle check point protein in the G<sub>2</sub>/M phase, were not observed upon treatment of PC-3 cells with C6-ceramide. A possible explanation for this observation is that a majority of those cells arrested in the G<sub>2</sub>/M phase following C6-ceramide treatment may already be undergoing apoptosis [32]. In contrast to C6-ceramide, naturally-occurring long acyl chain ceramides did not alter cell signaling or cell cycle distribution, yet a modest increase in PC-3 apoptosis was observed. The mechanism by which long acyl chain ceramides induce apoptosis in the PC-3 cell line remains to be elucidated.

The results of the present study suggest that naturally-occurring and synthetic sphingolipids reduce proliferation of androgen-independent prostate cancer cells via increased apoptosis. Increased dietary consumption of naturally-occurring long acyl chain sphingolipids may represent a novel chemopreventive strategy to increase prostate cancer cell apoptosis via intracellular ceramide accumulation. Dietary feeding studies are necessary to further support this hypothesis.

**Abstract** It is well known that sphingolipids specifically exist in the terrestrial mammal epidermis and correlate with skin barrier functions. However, the lipid properties of the marine mammal epidermis have not been examined in detail. We thus investigated the chemical composition of lipid components, especially sphingolipids, in the black epidermis (outer skin) of Antarctic minke whales (six mature and six immature specimens). Complex lipid fractions mainly contained cerebroside (CE), cholesteryl sulfate and sphingomyelin (SM), as well as two glycerophospholipids. Moreover, in the superficial layer of the black epidermis, CE was richly abundant but phospholipids were scarce. As component fatty acids, the non-hydroxy monounsaturated very long chain fatty acids (VLFA) within 34 carbons were generally present in CE and SM in the black epidermis. CE also consisted of  $\alpha$ -hydroxy fatty acids with monounsaturation within C34 (17%) and a slight proportion of  $\omega$ -hydroxy ones (32:1 and 34:1), the latter being probably derived from acyl-CE. Component sphingoid bases of both sphingolipids were predominantly 4-sphingenine (64%), followed by a C16 analogue (21%). When comparing these by different

maturities, mature whales showed sphingolipid profiles with higher levels of unsaturated fatty acids and with shorter sphingoid base chains than those of immature ones. Component analysis revealed that CE sugars were 67% glucose and 33% galactose, and  $\alpha$ -hydroxy fatty acids only bound to galactose.

## Introduction

The skin is the largest biological organ, and it is in constant contact with the outside world. It functions as a barrier to maintain homeostasis in the body. In particular, the superficial epidermis of terrestrial mammals, such as humans, forms the stratum corneum consisting of an intercellular lipid matrix [1]. The intercellular space of the stratum corneum contains 40–50% ceramide, 20–33% cholesterol, 7–13% free fatty acid, 0–7% cholesteryl sulfate, and 0–20% cholesteryl ester [2, 3]. Ceramides, the most predominant intercellular lipid, are enzymatically derived from cerebroside and sphingomyelin synthesized in epidermal cells [4, 5]. The ceramide is localized in the stratum corneum and has a role in its barrier properties. It has been reported that sphingolipids and their hydrolyzing enzymes are also present in the epidermis of some terrestrial mammals, including pigs and mice [6–10]. Moreover, it was found that enzyme suppression could impair epidermal barrier properties [5, 11]. Therefore, epidermal lipids are generally regarded as playing an important role in the maintenance of the barrier against

excessive transcutaneous water loss in terrestrial mammals. Additionally, in terrestrial mammals, the chemical composition of epidermal sphingolipids has been investigated in detail [7, 12, 13].

In contrast, the properties of epidermal barrier functions in marine mammals, which are not exposed to dry stress, have not been examined in detail, although they may have greatly differing barrier requirements to terrestrial mammals.

Since the whale, a marine mammal, has been utilized as an oil source in the past, intensive research has been carried out into the chemical composition of their fat [14–19]. It was found that the pilot whale epidermis contains cerebroside and sphingomyelin by TLC analysis [20]; however, chemical research on lipids in the whale epidermis, which hardly contains any fat, is very limited. Thus, we used the outer black epidermis of minke whales of different ages and investigated the chemical compositions of the lipid components, especially sphingolipids.

## Materials and Methods

### Materials

The present study was approved by the Animal Experimental Committee of Obihiro University of Agricultural and Veterinary Medicine in accordance with the Guiding Principles for the Care and Use of Research Animals. Antarctic minke whales *Balaenoptera bonaerensis* were obtained from the Japanese Whale Research Program under Special Permit in the Antarctic (JARPA) in the 2004/2005 seasons. All the whales used in the present study were killed by explosive harpoons which have been recognized as the best humane killing method of whales by the International Whaling Commission and provided by the Schedule III (Capture) in the International Convention for the Regulations of Whaling. Twelve male whales were divided into two groups, with each six mature and immature whales, according to body length and body weight. Average body length and weight ( $\pm$  standard deviation) were 8.4 ( $\pm$ 0.4) m and 6.5 ( $\pm$ 0.5) t for mature whales, respectively, and 6.3 ( $\pm$ 0.9) m and 2.9 ( $\pm$ 1.1) t for immature ones, respectively. Whale skins with black and fatty epidermis were cut from the back of each whale on the ship and were immediately frozen. Then, the fatty and black (approximately 0.4 mm thick) epidermis specimens were carefully separated with a knife. As for one black epidermis specimen from the mature whale, a superficial layer (24 wt%) and inner layer (76 wt%) were respectively separated.

### Extraction and Detection of Total Lipids

Black and fatty epidermis samples (5 g) were extracted twice with chloroform–methanol (2:1, v/v) and once with chloroform–methanol (1:2, v/v) for 1 h, respectively, after homogenization (Polytron, Kinematica, Switzerland). After filtration using filter paper (Advantec No. 2, Toyo Roshi Kaisha, Japan), the extracts were combined and washed once with water in a ratio of chloroform–methanol–water (8:4:3, v/v/v) [21]. After partition, the lower phase was concentrated to dryness using a rotary evaporator, and the lipids were weighed to yield the total lipids (175–220 mg from black epidermis). Total lipids were analyzed by silicic acid TLC (Silica gel 60, 0.25 mm, Merck, Germany) with hexane–diethylether–acetic acid (80:20:1, v/v/v) and chloroform–methanol–water (65:25:4, v/v/v) to detect neutral and complex lipids, respectively. CE species were visualized after spraying with anthrone/sulfuric acid, followed by heating. Free ceramide was detected with chloroform–methanol–water (90:10:1, v/v/v).

### Separation of Complex Lipids and Sphingolipids from the Epidermis

A part (150 mg) of total lipids obtained from the black epidermis were subjected to silicic acid column chromatography. Neutral and complex lipid (47–59 mg) fractions were eluted from the column with chloroform and methanol, respectively [22]. Additionally, a part (30 mg) of the complex lipid fraction from three whales was hydrolyzed with 0.4 M KOH/methanol at 37 °C for 2 h [23], then placed in Sep-Pak Plus Silica Cartridges (Waters, Milford, USA). After removing the neutral lipids from the cartridge with chloroform and chloroform/acetic acid (99:1, v/v), CE was eluted with chloroform–methanol (2:1, v/v), and SM was eluted with chloroform–methanol (1:4, v/v) [24]. The CE fraction also contained cholesteryl sulfate and lactosylceramide. Also, a part of each complex lipid fraction was separated by preparative silicic acid TLC (Silica gel 60, 0.25 mm, Merck, Germany) with chloroform–methanol–water (65:25:4, v/v/v), and CE with two main bands, made visible by spraying the plate with 0.001% primuline solution followed by UV irradiation, was respectively recovered from the silica gel.

### Methanolysis and TMS-Derivatization of Lipids

The lipid samples (1 mg) were reacted with 5% HCl/methanol at 100 °C for 3 h. After cooling, the fatty acid methyl esters were extracted three times with *n*-hexane

after the addition of water. Sphingolipid fractions (1 mg) were reacted with 1 M HCl/methanol at 70 °C for 18 h to analyze sphingoid base [25]. After removing the fatty acid methyl esters three times with *n*-hexane, the lower phase was adjusted to pH 10 by the addition of 4 M NaOH. The sphingoid base released was then extracted three times with diethylether after the addition of water. Sphingoid bases were converted to TMS-ether derivatives. Fatty acid methyl ester fractions of CE were also converted to TMS-ether derivatives to determine  $\omega$ -hydroxy fatty acid. In the CE fractions, the residue (water phase) was dried by evaporation under a nitrogen gas, in which methylglycosides were converted to TMS-ethers [26]. Standard D-mannose, D-glucose and lactose monohydrate (Wako, Osaka, Japan) were also prepared in the same way.

### HPLC Analysis

The alkaline stable lipid fractions after alkaline hydrolysis of total lipids were analyzed by normal-phase HPLC according to the method of Sugawara and Miyazawa with slight modification under the following conditions [27]. Instrument: Shimadzu LC-10AD (Kyoto, Japan); mobile phase—solvent A: chloroform and solvent B: methanol–water (95:5 *v/v*); gradient (solvent B%): 0–15 (1–25%), 15–25 (25–90%), 25–30 min (90–95%), hold for 10 min, 40–45 min (95–1%); column: LiChrospher Si 60 (column size, 250 mm  $\times$  4 mm i.d.; particle size: 5  $\mu$ m, Merck, Germany); flow rate: 1 ml/min; injection volume: 20  $\mu$ l; column temperature: 40 °C; detector: Shimadzu ELSD-LT (70 °C, 350 kPa). The amounts of CE and SM were calculated from the calibration curves of standard CE (lower spot from the bovine brain, Doosan Serdary Research Laboratories, Toronto, Canada) and SM (from the bovine brain, Sigma, St Louis, USA). All data are averages  $\pm$  SD of independent experiments from three whales.

### GC and GC–MS Analyses

Fatty acid methyl esters and sphingoid base-TMS-ether derivatives were analyzed using a Shimadzu GCMS-QP2010 (Kyoto, Japan) under the following conditions. Column: ULBON HR-1 (50 m  $\times$  0.25 mm i.d., 0.25  $\mu$ m, Shinwa Chemical Industries, Japan); temperature program for fatty acid analysis: 80–180 (15 °C/min), 180–320 °C (2 °C/min), held at 320 °C for 35 min; temperature program for sphingoid base analysis: 150–260 (8 °C/min), 260–320 °C (2 °C/min), held at 320 °C for 2 min; carrier gas: helium; detect: EI 70 eV. Fatty acid methyl esters (same conditions with GC–MS as above-mentioned) and methylglycoside–TMS ethers were analyzed using a

Shimadzu GC-2010 (Kyoto, Japan) equipped with FID under the following conditions. Column ULBON HR-1 (50 m  $\times$  0.25 mm i.d., 0.25  $\mu$ m, Shinwa Chemical Industries, Japan); temperature program: 80–180 (15 °C/min), 180–250 (2 °C/min), 250–300 °C (4 °C/min); carrier gas: nitrogen. The double bonds were estimated just by comparing GC retention times. Analytical data of lipid analyses for total and complex lipids and sphingolipid fractions are averages from six independent experiments, and means  $\pm$  SD are presented. Analytical data for sugars are averages from two independent experiments.

### Statistical Analysis

Statistical significance for lipid profiles between mature and immature whales was evaluated by analysis of variance (ANOVA). The *P* value <0.05 was regarded as statistically significant.

## Results and Discussion

### Fatty Acid Compositions of Total Lipids in Black and Fatty Epidermis

Yields of total lipids obtained from the fatty and black epidermis of six mature whales and their fatty acid compositions are shown in Table 1. The average total lipid content of six whale fatty epidermis was 72.3%. At least 23 fatty acids from C14 to C22, including unsaturated fatty acids, were detected, with oleic acid (18:1) and palmitoleic acid (16:1) the major components. Also, a significant amount (13.3%) of n-3 highly unsaturated fatty acids (HUFA), including icosapentaenoic acid (20:5), docosapentaenoic acid (22:5) and docosahexaenoic acid (22:6), were present. In contrast, the average total lipid content of six whale black epidermis was 4.0%, which was considerably lower than that of the fatty epidermis. Thirty-four fatty acids from C14 to C34 were detected as component fatty acids (Table 1). Major fatty acids of the black epidermis were 18:1 and 16:1, in common with the fatty epidermis; however, the former was high and the latter was low compared to the fatty epidermis. Also, arachidonic acid (20:4) was much higher than the fatty epidermis. The composition of 20:5 was close to that of the fatty epidermis, whereas 22:5 and 22:6 were low. As a noteworthy difference, the black epidermis contained very long chain ( $\sim$ C34) monounsaturated fatty acids, which could not be detected in the fatty epidermis.

Although it was reported that icosenoic acid (20:1) was characteristically high in the blubber and muktuk of marine mammals [28], it was a minor constituent (0.8–1.6%) in

whale skins. The proportion of HUFA in the whale fatty epidermis was lower than that of seals (approximately 20% 20:5 and 22:6) and higher than that of narwhals (5%).

## Lipid Components in the Black Epidermis

Silicic acid TLC of total lipids from the black epidermis of mature whales is shown in Fig. 1. As neutral lipid classes, five components including acylsterol (AS), triacylglycerol (TAG), free fatty acids (FFA), free cholesterol (FS) and diacylglycerol (DAG) were detected (Fig. 1A). As complex lipid classes, five components including cerebroside (CE), lactosylceramide (LC), phosphatidylethanolamine (PE), cholesteryl sulfate (CS), phosphatidylcholine (PC) and sphingomyelin (SM) were found (Fig. 1b). CE and SM were largely found with two upper and lower spots on TLC. When complex lipids obtained from superficial (24 wt%) and inner (76 wt%) layers were analyzed by TLC (Fig. 1c), the former contained a high amount of CE and the latter contained a high amount of phospholipids such as PC and SM. LC was only detected in the superficial layer.

A small spot with a positive reaction to the anthrone reagent above the CE spot was found (Fig. 1c), although it was hardly detected from total lipids of the whole black epidermis (Fig. 1b). It was considered to be an acyl-CE, since it disappeared after alkaline hydrolysis (data not shown). Free ceramide was found in extremely small amounts (data not shown).

It was thus shown that CE and SM were present in complex lipid fractions from the black epidermis of Antarctic minke whales as major sphingolipids, as in other

**Fig. 1** Lipid components in the mature whale black epidermis. **a** Hexane–diethyl ether–acetic acid (80:20:1, v/v/v); **b, c** chloroform–methanol–water (65:25:4, v/v/v). Inner and outer indicate the complex lipid fractions of inner (76 wt%) and superficial (24 wt%) layers of the black epidermis, respectively. AS Acylsterol, TAG triacylglycerol, FFA free fatty acid, FC free cholesterol, DAG diacylglycerol, CE cerebroside, PE phosphatidylethanolamine, LC lactosylceramide, CS cholesteryl sulfate, PC phosphatidylcholine, SM sphingomyelin

whales [20]. Moreover, CE increased in the superficial layer, accompanied by a decreased level of phospholipids, as previously described in other cetaceans (*Phocena phocena*) [29]. Epidermal lipids, except for sphingolipids, contained relatively higher levels of FFA and sterol lipids including CS, FC and AS. It can be said that lipid composition of the whale black epidermis is similar to that of the human stratum corneum [2, 3].

#### Fatty Acid Compositions of Complex Lipid Fractions in the Black Epidermis

Fatty acid compositions of complex lipid fractions from the black epidermis from six mature whales are shown in Table 2. The proportion of complex lipid fraction of total lipids was 34.8%. Thirty-two non-hydroxy fatty acids from C14 to C34, 14  $\alpha$ -hydroxy fatty acids from C22 to C34 and four dimethylacetals with C18 and C20 were detected. As the proportions of three components, non-hydroxy fatty acids were predominant at 88% followed by 10% dimethylacetals and 2% hydroxy fatty acids. Major non-hydroxy fatty acids were 18:1, 16:0 and stearic acid (18:0). The compositions of saturated fatty acids, including 16:0 and 18:0 as well as VLFA within C34 (18%), were higher than those of total lipids. Major  $\alpha$ -hydroxy fatty acids were hydroxy lignoceric acid (24h:0), hydroxy nervonic acid (24h:1) and hydroxydocosenoic acid (22h:1). Very long chain hydroxymonoenoic acids within C34 were also significantly present.

Since dimethylacetals are released from acidic hydrolysis of the alkenylether bond, the existence of this compound indicates that the complex lipid fractions contained plasmalogen. It was assumed that the proportion of plasmalogen in complex lipid fractions was approximately 20%, since plasmalogen has one alkenylether and one acyl moiety. As for terrestrial animals, our previous research showed that chicken skin contained a significant amount of plasmalogen (in submission). Further study is needed to clarify the physiological function of skin plasmalogen.

#### Contents and Fatty Acid Compositions of Cerebroside and Sphingomyelin in the Black Epidermis

The contents of CE and SM in the black epidermis were 5.7 and 4.2% of the total lipids, respectively. The total sphingolipid content (9.9%) was lower than the porpoise epidermis [29], indicating that epidermal sphingolipid contents significantly differ among species, although it is necessary to take the different analytical method into consideration.

Fatty acid compositions of CE and SM fractions of three mature whales are shown in Table 3. CE consisted of 23 non-hydroxy fatty acids and 16 hydroxy fatty acids, the former being predominant (82%). Major non-hydroxy fatty acids were 24:0, 24:1 and 16:0. Hydroxy fatty acids consisted of not only  $\alpha$ -hydroxy types ranging from C22 to C34, but also two  $\omega$ -hydroxy types (32h:1 and 34h:1), the latter in a slight amounts (4.5%). Major  $\alpha$ -hydroxy fatty acids were 24h:0, 24h:1 and 22h:1. SM consisted of 21 non-hydroxy fatty acids and 2  $\alpha$ -hydroxy acids (22h:1 and 24h:1), the former accounting for almost all the total (96.7%). Major non-hydroxy fatty

*CE* Cerebroside, *SM* sphingomyelin

acids were 24:1, 24:0 and 16:0. The proportion of major VLFA, including 32:1 and 34:1, of SM was lower than CE.

It was considered that ω-hydroxy fatty acids detected from CE fractions after alkaline hydrolysis were derived from acyl-CE, which is present in small amounts in the epidermal superficial layer as shown in Fig. 1c. The proportion of ω-hydroxy fatty acids was only 0.8% of the total acids of CE, which was considerably lower than the 3% in the pig [7]. Additionally, human and pig epidermal CE generally consist of almost all saturated fatty acids of both non-hydroxy and hydroxy types [4, 7], whereas whale epidermal CE consist of abundant monounsaturated fatty acids. Moreover, human and hairless mouse epidermal SM contained a significant amount of hydroxy fatty acids (11 and 45%, respectively) [10], whereas whale epidermal SM predominantly consisted of non-hydroxy fatty acids.

#### Sphingoid Base Composition of Cerebroside and Sphingomyelin in the Black Epidermis

Compositions of sphingoid bases from CE and SM fractions are shown in Table 4. CE consisted of 11 dihydroxy bases and 3 trihydroxy bases, the latter being only minimal

**Table 4** Sphingoid base compositions (mol%) of sphingolipids in the black epidermis

Sphingoid bases	CE	SM
d14:1 <sup>4trans</sup>	2.1 ± 0.1	3.1 ± 0.2

*CE* Cerebroside, *SM* sphingomyelin, *d* dihydroxy, *t* trihydroxy

(4%). The component sphingoid base predominantly consisted of 4-sphingenine (d18:1), followed by a C16 analogue of 4-sphingenine (d16:1). Sphingoid base

compositions of SM almost corresponded with those of CE, except for having no trihydroxy base.

The major component sphingoid base of whale epidermal sphingolipids was d18:1, corresponding to that of other terrestrial mammals, including humans, pigs and murine [4, 7, 10, 12, 30]; however, the proportion of trihydroxy base was considerably lower than human [4] and pig epidermis [7, 12]. As minor components, human and murine epidermis contained d20:1 [4] and d17:1 [10], respectively, whereas the whale black epidermis characteristically contained sphingoid bases with shorter chain lengths (<C16).

#### Comparison of Lipid Profiles Between Mature and Immature Whales

Lipid profiles of mature and immature whale epidermis are shown in Table 5. In the fatty epidermis, only non-hydroxy fatty acids were detected, and consisted of more than 80% unsaturated fatty acids (UFA). Particularly, the HUFA (20:5, 22:5 and 22:6) of immature whales showed a significantly higher proportion than mature ones. In the black epidermis, the differences between mature and immature whales were slight in terms of lipid yield and proportion of complex lipid fraction. Moreover, the proportions of complex lipid constituents such as non-hydroxy fatty acids (87–88%),  $\alpha$ -hydroxy acids (2%) and dimethylacetals (10–11%) hardly showed any difference between the two whale groups. However, the proportion of UFA of mature whales was significantly higher than immature ones. In CE and SM fractions from three whales, mature whales epidermis generally contained more UFA than immature ones. As for the component sphingoid base, the d16:1/d18:1 ratio generally showed higher values in mature whales than immature ones. As for sphingolipid contents, mature and immature whales contained high levels of CE and SM, respectively, although they were not statistically significant due to great individual differences.

Taken together, it was shown that the sphingolipids in the whale black epidermis were sugar- and phosphorylcholine-binding types, having characteristic chemical properties of fatty acids with monounsaturations and sphingosine base with shorter carbon lengths, compared to terrestrial mammals, which became marked with maturity.

#### Composition Data of Cerebroside in the Black Epidermis

Composition data of cerebroside from the black epidermis are summarized in Table 6. CE consisted of glucose and galactose in a ratio of 67:33. Moreover, glucose and galactose at more than 85% were detected in the upper and

lower spots of CE on TLC, respectively. The upper spot contained almost only non-hydroxy fatty acids (>95%), while the lower spot contained non- and  $\alpha$ -hydroxy acids by 46 and 54%, respectively. Sphingoid base hardly showed any differences in either CE spot.

In animal epidermis, it was reported that galactocerebroside was present in pig epidermal cells, accounting for 13% of total CE [12]. The pig galactocerebroside mainly consisted of fatty acids with shorter chains, such as C16 non-hydroxy fatty acid and C14–C16  $\alpha$ -hydroxy acids, than glucocerebroside (C16–C30 as non-hydroxy fatty acids and C18–C30 as  $\alpha$ -hydroxy acids). On the other hand, whale

epidermal galactocerebroside (33% of total CE) was higher than in pigs and consisted of fatty acids with very long chains, although non-hydroxy fatty acids consisted of a slightly shorter chain (~C28) than glucocerebroside. Since the galactocerebroside was probably derived from epidermal melanocytes [12], it was assumed that galactocerebroside was abundantly present in the whale black epidermis with a high amount of melanin pigment. Menon et al. assumed that glycoconjugate, namely cerebroside, in the lamellar body of the cetacean epidermis may be important for cell-to-cell adhesion and be consistent in part with their water barrier requirements, or may contribute to streamlining due to a reduction in frictional resistance [29]. This study also revealed that whales accumulate cerebroside, but not free ceramide, in the superficial layer of the epidermis. Moreover, in general, the aliphatic chains in the ceramides of the terrestrial mammals are mainly long-chain saturated fatty acids with a high melting point and are mostly in a solid crystalline or gel state, exhibiting low lateral diffusion properties with low permeability at physiological temperatures [31]. These lipids have an obvious role in the barrier properties of the skin, limiting loss of water even in a dry environment on land. In contrast, whale epidermal lipids not only serve a similar role to the terrestrial mammal epidermis such as the prevention of efflux of body components, but also increase the proportion of unsaturated fatty acids to adapt to the colder skin surface temperatures in their habitats. An increased level of unsaturated sphingolipids would offer certain advantages such as protection from thermal crystallization of lipids at low seawater temperatures, and greater flexibility on a molecular level to provide superior streamlining [29]. Additionally, sphingoid bases with a relatively shorter chain may be important to maintain cellular membrane fluidity. These features probably become prominent in grown whales.

# Capturing Proteins that Bind Polyunsaturated Fatty Acids: Demonstration Using Arachidonic Acid and Eicosanoids

**Abstract** Polyunsaturated fatty acids (PUFA) and their biological derivatives, including the eicosanoids, have numerous roles in physiology and pathology. Although some eicosanoids are known to act through receptors, the molecular actions of many PUFA remain obscure. As the three-dimensional structure of eicosanoids allows them to specifically bind and activate their receptors, we hypothesized that the same structure would allow other proteins to associate with PUFA and eicosanoids. Here, we demonstrate that biotinylation of arachidonic acid and its oxygenated derivatives 5-hydroxyeicosatetraenoic acid (5-HETE) and leukotriene (LT) B<sub>4</sub> can be used to pull down associated proteins. Separation of proteins by two-dimensional gel electrophoresis indicated that a large number of proteins bound each lipid and that proteins could distinguish between two enantiomers of 5-HETE. Individual proteins, identified by matrix assisted laser desorption/ionization-time of flight mass spectrometry, included proteins that are known to bind lipids, including albumin and phosphatidylethanolamine-binding protein, as well as several novel proteins. These include cytoskeletal proteins, such as actin, moesin, stathmin and coactosin-like protein, and G protein signaling proteins, such as Rho GDP dissociation inhibitor 1 and nucleoside diphosphate kinase B. This method, then, represents a relatively simple and straightforward way to screen for proteins that directly associate with, and are potentially modulated by, PUFA and their derivatives.

**Keywords** Leukotrienes · 5-Hydroxyeicosatetraenoic acid · Moesin · Stathmin · Coactosin-like protein · Rho GDP dissociation inhibitor 1 · Nucleoside diphosphate kinase B

## Abbreviations

ARA	Arachidonic acid
ACH	Arachidic acid
HETE	Hydroxyeicosatetraenoic acid
HpETE	Hydroperoxyeicosatetraenoic acid
LT	Leukotriene
MALDI-TOF	Matrix assisted laser desorption/ionization-time of flight
PUFA	Polyunsaturated fatty acid
RBL	Rat basophilic leukemia

## Introduction

Polyunsaturated fatty acids (PUFA) play important roles in health and disease. For example, increasing the consumption of  $\omega$ -3 PUFA reduces the risk of coronary heart disease [1–3] and decreases ischemic heart disease [4, 5]. On the other hand, the  $\omega$ -6 PUFA arachidonic acid (ARA) can form  $\omega$ -6 eicosanoids that exacerbate arrhythmogenic events [6, 7] and decreasing excessive  $\omega$ -6 eicosanoid action can reduce the risk of ischemic heart disease [8–10]. Although these PUFA have profound effects on physiology, the specific actions of PUFA at the molecular and cellular levels are diverse and poorly understood.

Chemically, PUFA include long chain hydrocarbon molecules with numerous carbon–carbon double bonds. The double bonds represent sites of chemical reactivity

e-mail: brocko@umich.edu

with potential for enzymatic modification. For example, ARA is a twenty carbon PUFA with four double bonds (20:4). It can be modified by the enzyme 5-lipoxygenase, which inserts molecular oxygen at the fifth carbon to produce 5(*S*)-hydroperoxyeicosatetraenoic acid (5(*S*)-HpETE; reviewed in [11]). This PUFA can be modified by peroxidases to produce 5(*S*)-hydroxyeicosatetraenoic acid (5(*S*)-HETE), a biologically active monohydroxylated PUFA. Alternatively, 5(*S*)-HpETE can be further metabolized along the 5-lipoxygenase pathway to produce the dihydroxylated PUFA leukotriene (LT) B<sub>4</sub> or the glutathione-containing LTC<sub>4</sub>. Whereas ARA induces apoptosis in neurons [12] and in leukemic cells [13, 14] or activates a variety of cell types [15, 16], LTB<sub>4</sub> and 5(*S*)-HETE are best known as chemoattractants and activators of leukocytes, and LTC<sub>4</sub> is recognized to promote contraction of smooth muscle and secretion of mucus from goblet cells (reviewed in [17]). Thus, enzymes recognize specific PUFA and alter them to produce a variety of novel constructs that have unique functions. The multitude of products that can be produced from ARA are called eicosanoids, whereas the smaller group produced solely by the 5-lipoxygenase pathway are the LT.

Structurally, the carbon–carbon double bonds in PUFA provide a degree of rigidity that is not found in saturated FA. As a result, each of the PUFA and their derivatives has a unique three-dimensional structure. This structure allows these lipids to interact with specific receptors. For example, LTB<sub>4</sub> binds to and activates two G-protein coupled receptors, the high affinity BLT<sub>1</sub> [18] and the lower affinity BLT<sub>2</sub> [19]. Similarly, LTC<sub>4</sub> activates two other receptors, CysLT<sub>1</sub> and CysLT<sub>2</sub>. Consistent with the high specificity of lipid for protein, LTB<sub>4</sub> does not activate CysLT<sub>1</sub> or CysLT<sub>2</sub> at physiological concentrations, and LTC<sub>4</sub> does not activate BLT<sub>1</sub> or BLT<sub>2</sub>. Relevant to this study, the interaction of these eicosanoids with their receptors results in conformational changes of the receptors with their consequential activation. This suggests that, if PUFA associate with non-receptor proteins, they may alter protein shape, resulting in modification of protein function.

We hypothesized that the distinctive structure of PUFA and eicosanoids should allow them to interact with specific soluble proteins other than traditional receptors. For example, it is known that ARA can bind directly to protein phosphatase 5 [20], binds to [21] and activates [22] S100A8/A9, and directly activates a GTP-binding protein in neutrophils [23]. Here, we describe a method for objectively capturing proteins that associate with PUFA and eicosanoids. We use proteins from the rat basophilic leukemia (RBL-1) cell line because it is mast cell like, in that it releases ARA, makes LT and responds to LT.

## Materials and Methods

### Cells and Cell Lysates

RBL cells (RBL-1, American Type Culture Collection, Manassas, VA) were grown under 5% CO<sub>2</sub> in Minimal Essential Medium alpha (Invitrogen) with 10% fetal bovine serum, 182 units/mL penicillin G sodium, 182 µg/mL streptomycin sulfate, 455 µg/mL amphotericin B. 2 × 10<sup>7</sup> cells were suspended in lysis buffer (137 mM NaCl, 10 mM phosphate buffer, pH 7.4, 2.7 mM KCl, 1 mM EGTA, protease inhibitor cocktail (Roche Applied Science, Indianapolis, IN), sonicated, centrifuged at 14,000 × g (5 min, 4 °C) and supernatant collected as total soluble proteins from RBL cells.

### Isolation of PUFA-Binding Proteins

PUFA (ARA, ACH, 5(*S*)-HETE, 5(*R*)-HETE, or LTB<sub>4</sub>) were biotinylated using the EZ-Link Biotin PEO-Amine kit (Pierce, Rockford IL), according to manufacturer's directions. Briefly, PUFA were diluted to 10 mg/mL in 2-(*N*-morpholino)ethane sulfonic acid (MES) buffer, pH 4.5, mixed with biotin (21 mg/mL) and 1-ethyl-3-[3-dimethyl aminopropyl] carbodiimide hydrochloride crosslinker (20 mg/mL), with mixing on rotator for 2 h at RT. Total soluble proteins from RBL cells were mixed with FA-biotin solution, without purification of the FA-biotin preparation, at an approx 1:1 molar ratio, on rotator for 1 h at RT. Samples of the cell protein/FA-biotin preparation were mixed with avidin immobilized on beaded agarose (Pierce) for 1 h at RT and centrifuged 1 min at 3,000 × g. The resulting pellet was washed three times with TBS and FA-binding proteins recovered by elution with 400 mM NaCl in PBS. In some experiments, the supernatant, partially depleted of FA-binding proteins, was mixed with additional immobilized avidin and centrifuged to remove remaining FA-binding proteins, producing a protein fraction that was highly depleted of FA-binding proteins.

### Gel Electrophoresis and Protein Identification

Protein samples were dialyzed overnight in PBS with stirring at 4 °C, mixed with SDS-PAGE sample buffer, boiled, separated by SDS-PAGE using a 12% Tris-HCl gel and stained with Coomassie. For two-dimensional gel electrophoresis, samples were mixed with isoelectric focusing buffer and separated using ReadyStrip IPG strips, pH 3–10, in the Protean IEF Cell (Bio-Rad Laboratories, Hercules CA). After focusing, strips were equilibrated

using iodoacetamide, separated by SDS-PAGE using a 12% Tris-HCl gel and stained with Coomassie. Isolated proteins were subjected to matrix assisted laser desorption/ionization-time of flight (MALDI-TOF) ms and tandem ms, with fragments sequenced by the Michigan Proteome Consortium at the University of Michigan. Initial analysis involved searching the NCBI nr database; subsequent analysis included BLAST searching the SwissProt database for proteins matching all peptide sequences from tandem mass spectrometry. Calculated kDa and *pI* values for proteins were obtained through SwissProt.

### Densitometric Analysis

Regions of images from SDS-PAGE results were analyzed using ImageJ 1.33, with quantitation of grayscale values of pixels measured by ImageJ and plotted using GraphPad Prism 3.00.

## Results

### Isolation of Fatty Acid-Associated Proteins

Soluble proteins were used in this study, excluding membrane-associated proteins, which have extensive hydrophobic regions that would interact non-specifically with various FA (although many soluble proteins will also have accessible hydrophobic regions). As a first evaluation, proteins from these total soluble protein preparations were separated into those proteins that could be pulled down using different FA and those that were resistant to capture. Here, the polyunsaturated ARA (20 carbon, 4 double bonds) was compared with the saturated arachidic acid (ACH, 20:0). An initial evaluation of the proteins captured by fatty acids indicated that a surprisingly large number of proteins associated with both ARA and ACH (Fig. 1a). Prominent bands could be readily identified in the fatty acid-associated samples, which were largely absent from the fatty acid-depleted samples. Densitometric analysis of a region of the ARA-depleted sample (lane 2) and the ARA-associated samples (lane 3) indicated two major peaks that were unique to the latter sample (Fig. 1b). In addition, while many bands were associated with both ARA (lane 3) and ACH (lane 5), some bands appeared to be more abundant in one than the other (Fig. 1c), suggesting some degree of specificity. In control experiments, essentially no protein bound to beads alone or to beads after incubation with biotin alone without fatty acid, as determined by SDS-PAGE analysis of fractions eluted from washed beads processed in parallel (not shown).

**Fig. 1** Separation of ARA-associated proteins from proteins that do not associate with ARA from total soluble proteins of RBL1 cells. **a** SDS-PAGE analysis. Total soluble proteins of RBL1 cells (“total”) were incubated with either ARA-biotin or ACH-biotin and the proteins that associated (“assoc”) with the fatty acids were captured using avidin agarose. The remaining proteins, depleted of fatty acid-associated proteins, are also presented (“depl”). >, more abundant in ARA-assoc than ARA-depleted; <, more abundant in ACH-assoc than ARA-assoc. **b** Densitometric analysis of regions of ARA-depleted (2) and ARA-associated (3) lanes; region denoted by bar adjacent to lane 3. **c** Densitometric analysis of regions of ARA-associated (3) and ACH-associated (5) lanes; region corresponds to bar at lane 5

### Identification of Some ARA-Associating Proteins

The large number of proteins that were pulled down by FA in this protocol indicated that additional separation steps would be required to identify individual FA-associating proteins. Parallel separation of total proteins and ARA-associated proteins by 2-dimensional gel electrophoresis again supported the conclusion that this protocol was capturing a subset of total proteins that bound ARA (Fig. 2).

Some of the most abundant (heavily staining) proteins that associated with ARA were identified by MALDI-TOF

**Fig. 2** Two-dimensional separation of total soluble proteins compared with ARA-associating proteins from RBL1 cells. **a** Total soluble proteins. **b** ARA-associating proteins. Coomassie-stained spots were analyzed by MALDI-TOF ms/ms and sequenced peptides used to identify proteins. Abbreviations refer to proteins detailed in Table 1. Migration of molecular weight markers indicated at right of (b)

mass spectrometric analysis followed by database searches. In each case, individual peptide sequences were further queried by BLAST search for unique identities. For example, one protein provided the peptides FEEL-NADLFR, TTPSYVAFTDTER, IINEPTAAAIAYGLDK and TFTNAVVTVPAYFNDSQR; the first three peptides are shared by various heat shock proteins, including heat shock-related 70 kDa protein 2 (HSP72), but the fourth peptide is unique to heat shock cognate 71 kDa protein (HSP7C). The position of this protein on the two-dimensional gel, and some others that were positively identified, is indicated in Fig. 2b. Additional proteins that were identified as ARA-associating proteins are provided in Table 1, grouped according to function, with predicted kDa and pI values. Supporting their identification were correlations between the kDa and calculated pI values of the proteins and the position of the spots on the gels. Also, when peptide sequences were species specific, the identified isoform was from rat (or from mouse, if a rat protein sequence was not in SwissProt), consistent with these proteins being produced in a rat cell line.

## Identification of Proteins Associating with 5-HETE and LTB<sub>4</sub>

As noted above, 5(*S*)-HETE can be a significant product of 5-LO metabolism of ARA. Several studies have examined the importance of the stereochemistry on function by comparing the effects of 5(*S*)- versus 5(*R*)-HETE. In short, some effects can be induced by both [24], whereas others are stereospecific [25, 26]. We compared 5(*S*)- vs. 5(*R*)-HETE in their capacity to bind proteins. Remarkably, both enantiomers retained many proteins (Fig. 3). Also, the similarity between the two sets of proteins was very high. Importantly, the major differences between the proteins were seen in horizontal groups of proteins (boxed in Fig. 3), which commonly represent proteins with different degrees of post-translational modification. Indeed, identification of selected pairs of spots using MALDI-TOF mass spectrometry verified that they were identical, recognized as Rho GDP-dissociation inhibitor 1 (GDIR), eukaryotic translation initiation factor 5A-2 (IF5A2), coactosin-like protein (COTL1) and SH3 domain-binding glutamic acid-rich-like protein 3 (SH3L3). Typically, 5(*S*)-HETE selectively captured the more acidic version and 5(*R*)-HETE bound the more basic protein. Additional proteins identified from the 5(*S*)-HETE gel are listed in Table 2.

Finally, two-dimensional gel separation of proteins that associated with LTB<sub>4</sub> revealed at least 20 proteins (not shown). A partial list of the most abundant proteins is given in Table 2. These are grouped according to known roles.

## Discussion

This study presents a relatively simple and straightforward approach for capturing proteins that associate with PUFA and their derivatives. An asset of the approach is that it allows novel interactions to be discovered objectively. Through this approach, we have identified groups of proteins involved in protein synthesis, cytoskeletal function, Rho functioning and glycolysis that can associate with ARA. Some of these same proteins and roles are also shared with 5-HETE, suggesting that it can act like a second messenger akin to ARA. Perhaps most surprisingly, several proteins were found to associate with LTB<sub>4</sub>, a lipid mediator whose actions are thought to be solely receptor-mediated. This suggests that at least some of the effects of LTB<sub>4</sub>, as well as 5-HETE and ARA, may be through direct lipid-protein interactions.

Lipids, due to their hydrophobic nature, are first thought to associate with membranes. However, PUFA may have higher affinities for certain proteins than for membranes. For example, PUFA will partition into liposomal membranes in an aqueous solution, but will leave those

**Table 1** Identification of some of the proteins that associate with ARA

Enzyme	Abbrev.	Accession	kDa	pI	Role(s)
Elongation factor 1-gamma	EF1G	Q68FR6	50	6.31	Protein synthesis; probably anchors the complex to other cellular components
Elongation factor 2	EF2	P05197	95.3	6.41	Protein synthesis; promotes the GTP-dependent translocation of the nascent protein chain
Eukaryotic translation initiation factor 5A-2	IF5A2	Q9GZV4	16.8	5.38	Protein synthesis; promotes the formation of the first peptide bond
Actin, cytoplasmic 1	ACTB	P60711	41.7	5.29	Motility
Moesin	MOES	O35763	67.7	6.16	Probably involved in connections of major cytoskeletal structures to the plasma membrane
Stathmin	STMN1	P13668	17.3	5.76	Prevents assembly and promotes disassembly of microtubules; Binds to two alpha/beta-tubulin heterodimers
Rho GDP-dissociation inhibitor 1	GDIR	Q99PT1	23.4	5.12	Inhibits dissociation of GDP from and the subsequent binding of GTP to Rho proteins
Nucleoside diphosphate kinase B	NDKB	P19804	17.3	6.91	Synthesis of nucleoside triphosphates other than ATP; negatively regulates Rho activity
Triosephosphate isomerase	TPIS	P48500	26.8	6.89	D-glyceraldehyde 3-phosphate = glyceroone phosphate
Alpha-enolase	ENOA	P04764	47.1	6.16	Glycolysis, growth control, hypoxia tolerance, allergic responses, fibrinolysis
L-lactate dehydrogenase A chain	LDHA	P04642	36.5	8.45	Anaerobic glycolysis; (S)-lactate + NAD+ = pyruvate + NADH
Peroxiredoxin-1	PRDX1	Q63716	22.1	8.27	Redox regulation; eliminating peroxides; regulating H2O2
Heat shock cognate 71 kDa protein	HSP7C	P63018	70.9	5.37	Chaperone
Phosphatidylethanolamine-binding protein 1	PEBP1	P31044	20.8	5.47	Binds ATP, opioids and PE; Serine protease inhibitor
Serum albumin [Precursor]	ALBU	P02770	68.7	6.09	Regulates colloidal osmotic pressure of blood; binds water, Ca(2+), Na(+), K(+), fatty acids, hormones, bilirubin and drugs

Proteins were identified by BLAST search of SwissProt using at least two peptide sequences obtained by MALDI-TOF ms/ms analysis of two-dimensional gel samples. Abbreviation and SwissProt accession numbers, as well as predicted kDa and pI obtained using sequence analysis tools at SwissProt, are included

**Fig. 3** Selected region of 2-D PAGE analysis of proteins that associate with 5(*S*)-HETE versus 5(*R*)-HETE. **a** 5(*S*)-HETE-associated proteins. **b** 5(*R*)-HETE-associated proteins. Region corresponds to approx. 10–37 kDa and pI 4.5–8. Abbreviations refer to proteins detailed in Table 2

membranes to associate with added albumin [27]. Furthermore, ARA will leave albumin to associate with classical fatty acid-binding proteins (FABP), again due to differences in affinity. This indicates that soluble proteins, like albumin and FABP, can have higher affinities for PUFA than do liposomal membranes.

An important question may be whether previous studies support any of the PUFA-protein interactions here. That is, are any of these interactions biologically important, or do they just reflect the interaction of a lipid with a hydrophobic portion of a protein? First, the unique profile of proteins observed for each of the PUFA/eicosanoids argues against all of the interactions being non-specific interactions. Second, the capture of albumin, while not surprising, serves as a positive control. Albumin is recognized to serve the physiologically important function of regulating the colloidal osmotic pressure of blood through its binding of fatty acids, cations, hormones, bilirubin and drugs. Perhaps most intriguing is the case of the Rho GDP-dissociation inhibitor 1 (GDIR). It is well established that PUFA, including ARA, activate the production of reactive oxygen species in leukocytes [28, 29]. The GTP-bound (activated) form of Rac is required for activation of NADPH oxidase [30]. In resting leukocytes, GDIR inhibits the activation of Rac by directly binding to the GDP-bound (inactive) form of Rac, preventing guanine-nucleotide exchange and activation. In a comparison of the ability of different lipids to

alter GDIR binding, ARA and other PUFA, but not saturated fatty acids, caused almost complete dissociation of GDIR from Rac, leading to activation of Rac [31]. The identification of the same protein binding to 5(*S*)-HETE suggests that this derivative of ARA may also modulate Rac activation through GDIR. Finally, similar approaches using biotinylation of 15-deoxy- $\Delta^{12,14}$ -prostaglandin  $J_2$  have been used to show that this PGD<sub>2</sub> metabolite interacts with cytoskeletal [32, 33] and mitochondrial [34] proteins. These results underscore the versatility of this approach and strengthen the assertion that ARA metabolites may directly interact with proteins.

The role of PUFA to alter protein–protein interactions, demonstrated for GDIR [31], may also apply to other results from this study. Heat shock cognate 71 kDa protein (HSP7C) was found to bind ARA. ARA has been shown to cause the dissociation of two HSP proteins, approx. 70 and 90 kDa, from protein phosphatase 5, leading to inactivation and degradation of the phosphatase [35], suggesting, at least that the interaction of ARA with HSP7C may serve to dissociate it from target proteins. In contrast with this, ARA has been shown to promote a physical interaction between phospholipase C- $\gamma$  and a multimeric activating protein, AHNAK [36]. Similarly, ARA promotes translocation of p47-phox [37] and assembly of the NADPH oxidase complex [38]. Thus, PUFA may alter protein functions by facilitating the assembly or disassembly of protein complexes.

Many of the oxidized lipids that are produced from PUFA are relatively unstable and reactive. For example, the 5-LO product LTA<sub>4</sub> has been shown to form stable adducts with nucleotides through covalent binding [39, 40]. Also, lipid hydroperoxides may be decomposed by antioxidants to produce DNA-reactive electrophiles [41]. Relevant to this study, biotinylated derivatives of 15-HETE have been shown to form complexes with proteins that are stable enough to withstand SDS-PAGE and electrophoretic transfer [42]. This suggests that some lipid-protein associations may be very stable.

Another interesting finding relates to L-lactate dehydrogenase A chain (LDHA), which is known to mediate the conversion of lactate to pyruvate, with concomitant generation of NADH from NAD<sup>+</sup>. Either transient hypoxia [43] or ischemia [44] produces a rapid release of arachidonic acid associated with a marked increase in lactate and decreases in pyruvate and ATP. It seems possible that arachidonic acid might directly associate with LDHA and inhibit lactate dehydrogenase activity.

Proteins also show specificity for specific PUFA. For example, the different FABP clearly favor certain PUFA over others [45]. Similarly, 5-lipoxygenase, which initiates the synthesis of LTs from ARA, prefers ARA over other PUFA [46] and was detected in ARA-associated proteins

**Table 2** Identification of some of the proteins that associate with 5(S)-HETE and LTB<sub>4</sub>

Enzyme	Abbrev.	Accession	kDa	pI	Role(s)
5s-HETE binding prots					
Elongation factor 2	EF2	P05197	95.3	6.41	Protein synthesis; promotes the GTP-dependent translocation of the nascent protein chain
Eukaryotic translation initiation factor 5A-2	IF5A2	Q9GZV4	16.8	5.38	Protein synthesis; promotes the formation of the first peptide bond
Coactosin-like protein	COTL1	Q9CCQ16	15.9	5.28	Binds to F-actin in a calcium-independent manner; has no direct effect on actin depolymerization
Tropomyosin alpha-4 chain	TPM4	P09495	28.5	4.66	Binds to actin filaments in muscle and non-muscle cells; in non-muscle cells, implicated in stabilizing cytoskeleton actin filaments
Stathmin	STMN1	P13668	17.3	5.76	Destabilizes microtubules; binds to two alpha/beta-tubulin heterodimers
Rho GDP-dissociation inhibitor 1	GDIR	Q99PT1	23.4	5.12	Inhibits dissociation of GDP from and the subsequent binding of GTP to Rho proteins
SH3 domain-binding glutamic acid-rich-like protein 3	SH3L3	Q91VW3	10.5	5.02	Could act as a modulator of glutaredoxin biological activity
LTB <sub>4</sub> binding prots					
Actin, cytoplasmic 2	ACTG	P63259	41.8	5.31	Motility
Profilin-1	PROF1	P62963	15	8.46	Complexes with actin
Nucleoside diphosphate kinase B	NDKB	P19804	17.3	6.91	Synthesis of nucleoside triphosphates other than ATP; negatively regulates Rho activity
Fructose-bisphosphate aldolase A	ALDOA	P05064	39.4	8.3	Glycolysis: D-fructose 1,6-bisphosphate = glycercane phosphate + D-glyceraldehyde 3-phosphate
Peroxioredoxin-1	PRDX1	Q63716	22.1	8.27	Redox regulation; eliminating peroxides; regulating H2O2
Serum albumin (Precursor)	ALBU	P02770	68.7	6.09	Regulates colloidal osmotic pressure of blood; binds water, Ca(2+), Na(+), K(+), fatty acids, hormones, bilirubin and drugs

Proteins were identified by BLAST search of SwissProt using at least two peptide sequences obtained by MALDI-TOF ms/ms analysis of two-dimensional gel samples. Abbreviation and SwissProt accession numbers, as well as predicted kDa and pI obtained using sequence analysis tools at SwissProt, are included

but not in the ACH-associated proteins (not shown). Also, certain proteins were more abundant in the ACH-associated fraction than in the ARA-associated fractions (Fig. 1), suggesting specificity. This specificity must, at least in part, be due to the shape and structure of the PUFA. This specificity of protein for PUFA may be so exquisite that it may distinguish between stereochemistry of a hydroxyl group, as seen in the difference between the proteins that bind 5(S)- and 5(R)-HETE (Fig. 3).

The specificity of protein for PUFA points to a drawback of the approach used in this study. Since the biotin moiety is at the carboxyl terminus, proteins that specifically target that site will be missed. For example, FA associate with classical FABP, like the human epidermal-FABP, with the carboxyl group of the FA directly interacting with side chains of key amino acids within the FABP [47]. As a result, this approach did not capture these well-known FABP, and perhaps many other proteins.

Another drawback of this approach is that it will not reveal which proteins interact directly with lipids, as opposed to those that associate indirectly by binding to a true PUFA-associating protein. For example, it is possible that the different cytoskeletal proteins (e.g., actin, moesin, stathmin, coactosin-like protein, profilin) may have been pulled down together, with only one of these proteins truly associating with ARA.

In summary, we present a relatively simple stepwise approach for the discovery of proteins that associate with PUFA and their derivatives. This approach can be used with any lipid with a free carboxyl terminus. Given the large number of proteins that were observed on the two-dimensional gels presented here, it appears that PUFA interact with many proteins. The diversity of PUFA and PUFA derivatives suggests that numerous interactions can be discovered with this approach.

**Abstract** Fatty acid analysis is an important research tool, and indices derived from essential fatty acid contents serve as useful biomarkers related to cardiovascular and other chronic disease risk. Both clinical and basic studies of essential fatty acid composition are becoming ever larger in magnitude leading to delays while the rather laborious lipid analyses are performed. A robotic transesterification procedure has been developed for high-throughput analysis of plasma fatty acid methyl esters. In this approach, robots perform most steps including plasma and reagent transfer, transesterification reaction via heating at 80 °C in open tubes with multiple reagent additions, followed by two-phase extraction and transfer of lipid extracts to GC vials. The vials are then placed directly onto a GC autosampler carousel for robotic sample injection. An improved fast GC method is presented in which the peaks

of interest are eluted within 6 min. This method is readily scalable to prepare and analyze 200 samples per day (1,000 samples per week) so that large clinical trials can be accommodated.

**Keywords** Robotic transesterification · Plasma fatty acid methyl esters · Fast gas chromatographic · High throughput sample preparation · High throughput gas chromatography · Essential fatty acids

## Introduction

Fatty acids are important components of biological membranes and their measurement is useful from a variety of biological perspectives. The chain length, degree of unsaturation and other structural features of fatty acids are one determinant of the physico-chemical properties of biological membranes [1, 2]. Essential fatty acids are the focus of many compositional [3–5], physiological [6–8], behavioral [9–14] and metabolic experiments [15–19]. The n-3 polyunsaturates eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA) have been inversely associated with several disease states in epidemiological studies [20–23]. They antagonize the n-6 polyunsaturated arachidonic acid (20:4n-6, AA) and the eicosanoids that are produced from it [24, 25]. Moreover, the blood stream contents of these n-3 and n-6 polyunsaturates provide an important biomarker of cardiovascular disease risk [21, 22, 24]. EPA and DHA intake and tissue content have been related to sudden cardiac death and arrhythmias [26–29]. These observations have led to many clinical experiments and more recently large clinical trials (e.g., GISSI study [30], primary prevention CVD [31],

AREDS2 [32], DINO infant [33], NINDS Alzheimer's [34]), where the effects of increased EPA and/or DHA intake are examined in various pathological states.

Thus the analysis of fatty acid profiles in tissues, particularly blood components, has become increasingly important as endpoints in clinical trials, as biomarkers in cross-sectional studies and as measures of compliance. Such trials may generate very large numbers of samples for analysis necessitating quick, efficient and inexpensive analytical methods for fatty acid analysis. The standard methods for such analysis typically involve total lipid extraction followed by a laborious transmethylation procedure, methyl ester extraction, concentration and gas chromatographic analysis. It is typical for this labor-intensive methodology to consume 2 days of a skilled chemist's efforts for 10–20 samples. As a result, it has not been generally feasible to study thousands of subjects where each subject in a clinical trial can generate many samples. Clearly, a high throughput method for fatty acid analysis is needed.

In previous work from our laboratory, a simplified chemical procedure was developed for lipid transmethylation [35] that was based upon the Lepage and Roy procedure [36]. A method for fast gas chromatography of the typical profile of fatty acid methyl esters found in biological samples was also introduced [35, 37]. This paper presents a complete method for robotic transmethylation and analysis of plasma lipids. Plasma is directly reacted without prior lipid extraction, as in the Lepage and Roy method, and a robot carries out the reaction, methyl ester extraction and sample concentration, leaving the sample in a GC autosampler vial ready for injection. A faster method for GC analysis is also presented here. Together, these methods are efficient and cost effective. They may potentially increase laboratory productivity by an order of magnitude. These procedures may be used as the basis for a high-throughput method suitable for analysis of large populations such as are found in clinical trials.

## Materials and Methods

### Reagents and Plasma Samples

Acetyl chloride, 2[6]-di-*tert*-butyl-*p*-cresol (butylated hydroxytoluene, BHT), analytical grades methanol, hexane and toluene, and  $K_2CO_3$  were purchased from Sigma-Aldrich Chemical Co. (St Louis, MO, USA). BHT was added to methanol (50  $\mu$ g BHT/sample) to prevent fatty acid oxidation. The internal fatty acid standards (23:0 methyl ester, and 22:3n-3) and external (GLC-462) were purchased from Nu-Chek Prep (Elysian, MN, USA). Internal standard solutions were prepared by dissolving

them, respectively, in the methanol BHT solution at a concentration of 250  $\mu$ g/ml. Blood was collected by venipuncture into a heparinized tube and was immediately centrifuged for 5 min at 2,000 $\times$ g. The resulting plasma was then aliquoted in batches of 5 ml, frozen and stored at  $-80$  °C. The 13 mm  $\times$  100 mm Pyrex disposable culture tubes for transesterification reactions were purchased from PGC Scientific (Frederick, MD, USA).

For the robotic transesterification procedure, Stock A and Stock B reagents were prepared in bulk. The 2.4 ml of Stock Solution A required initially for the reaction of 100–200  $\mu$ l aliquots of plasma included 1.9 ml of methanol, 100  $\mu$ l of acetyl chloride, 0.3 ml of toluene, and 100  $\mu$ l each of the two internal standard solutions (containing 25  $\mu$ g of 23:0 and 20  $\mu$ g of 22:3n-3 as ethyl esters). Each 900  $\mu$ l volume of Stock B solution was comprised of 740  $\mu$ l of methanol, 40  $\mu$ l of acetyl chloride solution, and 120  $\mu$ l of toluene.

### Robotic Apparatus

A 1.5-m long Freedom EVO robot equipped with a liquid handling arm (LH-arm), a multi-channel 1-ml syringe pipetting system with an integrated liquid detection system and liquid detection disposable tips, a robotic manipulator arm, a fast wash pump and a syringe wash station, low disposable tips ejector option, and a nitrogen manipulation station was purchased from Tecan US Inc. (Research Triangle Park, NC, USA). The working space on the Tecan deck also includes other peripherals such as tip rack with a waste tip disposal station, twelve 13-mm test tube carrier racks each with a capacity to hold up to 16 plasma vials along the *y*-axis, three troughs for holding reagents, a reaction block, and a heated GC vial sample block. The layout of the robotic deck is illustrated in Fig. 1. The Tecan EVOware™ scripting programming language is used to control the robotic arm and other modules. The temperature regulated GC vial sample block and the heating-cooling reaction block were custom made by J-Kem Scientific Inc. (St Louis, MO, USA) and are under computer control. The reaction block is composed of a hot plate connected to a chiller through a cryogenic solenoid valve which regulates the flow of cooling liquid. The GC vial sample plate and reaction block hot plate are an array containing 16  $\times$  12 holes to hold a maximum of 192 GC vials (13-mm diameter) and 192 reaction tubes of 13  $\times$  100 mm dimension, respectively. Both the reaction block and GC vial block are controlled by a digital temperature controller either via a local module or by a program driver that was incorporated into the software of the Tecan programming command set running under Windows. The robot was encased in a hood fabricated by

**Fig. 1** Diagrammatic representation of the layout of the robotic deck

Airline Hydraulics (Bensalem, PA, USA) and is connected at the top to an exhaust outlet and is well ventilated.

## Instrumentation

### Fast GC Analyses

Analyses were performed on an Agilent 6890N Network Gas Chromatograph (Agilent Technologies, Palo Alto, CA, USA) equipped with a split/splitless injector, a 7683 automatic liquid sampler and flame ionization detector. The GC was also equipped with a 208-V power supply to enable fast temperature ramping. The column used was a DB-FFAP of 15 m × 0.1 mm i.d. × 0.1 μm film thickness (J&W Scientific from Agilent Technologies, Palo Alto, CA, USA). Instrument control and data collection was performed by a GC Chemstation, Rev. B.01.01 (Agilent Technologies, Palo Alto, CA, USA). Temperature program was as follows: initial conditions, 150 °C with 0.25 min hold; ramp 35 °C/min to 200 °C, 7 °C/min to 225 °C with a 3.2 min hold and then 80 °C/min to 245 °C with 2.75 min hold. Instrumental conditions were as follows: carrier gas was H<sub>2</sub> at a flow rate of 56 cm/s and a constant head pressure of 344.7 kPa; FID detector set at 250 °C; air and N<sub>2</sub> make-up gas flow rates of 450 and 10 ml/min; respectively, with a split ratio of 100:1; sampling frequency of 50 Hz; autosampler injections of 2 μl volume. Run time for a single sample was 11 min with all the fatty acid peaks of interest eluting within 8 min of the injection time. The sample injection-to-injection time was 16 min including a re-equilibration time of 1.50 min. The liner used was split with a cup containing no glass wool.

For the development of a faster GC method, a constant flow mode of 0.6 ml/min was used using the same column as above. Temperature program was as follows: initial conditions, 160 °C with 0.10 min hold; ramp 60 °C/min to

220 °C with a 0.5 min hold, 80 °C/min to 175 °C, 70 °C/min to 230 °C with 1.82 min hold, 70 °C/min to 220 °C with 0.96 min hold, and final ramping at 60 °C/min to 245 °C with 2.40 min hold. Instrumental conditions were as follows: carrier gas was H<sub>2</sub> at a starting flow rate of 58 cm/s and a starting head pressure of 344.7 kPa; FID detector set at 250 °C; air and N<sub>2</sub> make-up gas flow rates of 450 and 10 ml/min, respectively; split ratio of 100:1; sampling frequency of 50 Hz; autosampler injections of 2 μl volume. Run time for a single sample was 8.69 min with all the fatty acid peaks of interest eluting within 5.8 min of the injection time. The sample injection-to-injection time was 12 min, including a re-equilibration time of 1.50 min. The data was quantified according to a method previously described [35].

## Transesterification Methods

The standard Lepage and Roy transesterification method [36] was used as the reference point for comparisons to samples generated by the robotic method. All manipulations were performed under a nitrogen atmosphere. Briefly, 200 μl of plasma and 100 μl each of the two internal standard solutions (providing 25 μg of 23:0 and 20 μg of 22:3n-3 methyl ester) were added to 13 mm × 100 mm borosilicate or Pyrex screw-capped glass tubes, followed by an addition of 2 ml of a methanol:hexane (4:1 v/v) mixture. Samples were vortexed and the tubes were placed on ice, and then acetyl chloride (200 μl) was added dropwise while swirling the tubes. The tubes were tightly capped under nitrogen, and heated at 100 °C for 60 min. Afterwards, the samples were placed on ice, uncapped, and neutralized by the addition of 5 ml of a 6% solution of K<sub>2</sub>CO<sub>3</sub>. The tubes were recapped and vortexed for 1 min followed by centrifugation for 2 min at 3,000 rpm on a refrigerated tabletop centrifuge at 9 °C to separate the

mixture into two phases and the upper (organic) phase was collected. The extraction procedure was repeated on the lower phase by adding 0.5 ml of hexane, vortexing and centrifuging. The organic phases were combined and evaporated under nitrogen to a volume of 75–100  $\mu\text{l}$ . This solution was transferred to a GC vial, and the vial was crimped under nitrogen for FAME analysis by GC. All reactions were performed in sextet in a well ventilated fume hood.

#### Automated Robotic Transesterification Procedure

For robotic transesterification procedure Stock A and Stock B reagents were freshly prepared in bulk as stated above. The hexane solution and the bulk stock solutions A and B were placed in three different Teflon troughs. Plasma sample vials were placed on the carrier racks and clean uncapped pyrex tubes were labeled and placed in the reaction block (Fig. 1). The robot was initialized and the prompt for the number of samples to be processed is answered. Then the liquid handling arm (LH-arm) picks up disposable tips, aspirates 100–200  $\mu\text{l}$  of plasma per tip, and then dispenses the plasma into the reaction tubes on the reaction block. Tips are ejected into a waste tip dispenser for biohazardous waste (labeled as “plasma disposable tips waste station” in Fig. 1) between plasma samples to avoid cross-contamination. The process is repeated until all plasma samples have been pipetted into reaction tubes. The LH-arm then obtains a fresh set of eight disposable tips and adds 800  $\mu\text{l}$  of stock solution A to each reaction tube three times (2.4 ml total). The tips are then ejected into a general purpose waste tip dispenser. The program then issues a command to the reaction block to heat to 80 °C for 2.5 h. During the course of the 2.5 h reaction time, five additions of 0.9 ml each of stock B solution (every 20 m) are performed by the robot to prevent complete drying of the reaction tubes as well as to compensate for evaporation of the solution and to complete the transesterification reaction. This multiple addition helps to wash down the sides of the tubes and thus yield a complete reaction. Also after each round of addition of the stock B solution, the LH-arm was stationed away from the reaction block in order to minimize exposure of the robot arm pneumatics to corrosive vapors arising from the heated reaction tubes. However, corrosion is still a possibility and so the instrument accuracy is validated every day by weighing a certain volume of liquid that is dispensed by the LH-arm. After the last addition, the reaction block was allowed to cool to 25 °C via a command issued by the program. This sets the solenoid sensor to open to allow chilled fluid (10 °C) to circulate around the reaction block to bring the

temperature down to 20 °C within approximately 30 min. The LH-arm picks up a fresh set of disposable tips, aspirates 700  $\mu\text{l}$  of hexane from the third trough and dispenses this into each of the reaction tubes. After this task is performed, the tips are ejected. The LH-arm obtains fresh tips, aspirates 400  $\mu\text{l}$  of the upper hexane phase and dispenses it at the bottom of the reaction tube, forcing the hexane to mix with the aqueous phase as it passes thru. This mixing step is repeated 20 times followed by the ejection of the tips. It was observed that 15–20 hexane aspirations for extraction of FAMEs was sufficient since fewer than 15 aspiration cycles resulted in incomplete extraction and more than 20 aspiration cycles did not produce any benefit. The LH-arm then obtains a fresh set of disposable tips and aspirates from the reaction tubes 250  $\mu\text{l}$  of the upper phase hexane solution. The system is able to detect the position at which it becomes immersed in the hexane solution as it is lowered into the tube through detection of a change in pressure (or by capacitance for detection of the interface between the two liquids). The hexane is transferred into GC vials positioned in the GC vial block. Tips must be changed prior to mixing or sampling a new set of tubes. Since only the tips come in contact with sample tube contents and a new tip is used for each step, there is no possibility of sample cross-contamination. The GC vials can be heated in order to concentrate the sample through hexane evaporation.

## Results and Discussion

### Validation of Robotic Transmethylation Procedure

In a previous publication from this laboratory, we demonstrated that a simplification of the Lepage and Roy procedure could produce valid results [35]. In that work an “open tube” method was implemented that was amenable to robotic application. This chemical procedure was transferred to a robotic procedure as described above. A bulk plasma sample was transmethylated by the fully automated robotic method and the results compared to the standard Lepage and Roy procedure ( $n = 6$ ). A second set of samples were similarly treated with the robotic procedure, and the hexane extracts were subjected to heating in the GC vial station in order to concentrate the extract further (Table 1). The mean values for each fatty acid concentration are similar in the three methods. The coefficients of variation are as good or better in the robotic method as the standard method. The fatty acid percentages in the three methods are very similar. The robotic method was in this way validated for plasma analysis. We have run the robotic method with an  $n$  of up to 40 samples and obtained similar results. The fatty acids measured here are

the common ones reported for many other mammalian tissue analyses as well.

Fatty acid extraction using 10% decane in pentane has also been used as an alternative extraction solvent. During heating in the GC vial block, the pentane is easily evaporated leaving mainly the decane volume containing the methyl esters. It is also possible to leave an open GC vial on the GC autosampler and allow it to evaporate prior to analysis. We encountered some difficulties with dripping during the LH-arm transfer of pentane to the GC vials. However, this problem was overcome by first aspirating and dispensing pentane prior to sample transfer.

Another difficulty is the leaching of organic compounds from the disposable tips. The black tips used for capacitance based detection are worse in this respect, in our experience. These impurities elute primarily in the first

1.5 min of the GC run. They create difficulties for automated peak integration of minor peaks of 10–14 carbons with zero or one double bonds. Tips from a variety of vendors have given similar results, however, the clear tips used in pressure-based sensing exhibit a lower level of leaching.

#### Improvements in the Fast GC Method

We earlier developed a Fast GC method utilizing a DB-FFAP column of dimensions 15 m × 0.1 mm i.d. × 0.1 µm film thickness. A high temperature program was used in which all the fatty acid peaks of interest eluted within 8 min of injection, with a sample to sample injection time of 16 min (Fig. 2a). An attempt was made to further

Fig. 2 Improvements in Fast GC methods for separation of a mixed FAME external reference standard

shorten the GC run times using an aggressive, single ramp method of 40 °C or 50 °C/min and starting from 135 to 150 °C up to 240 °C. However, this approach resulted in overlaps of critical peaks found in a 28 component quantitative standard (Nu Chek Prep 462); 18:1n-9, 18:1n-7 and 24:1n-9, 22:6n-3 were the overlapping peak pairs in this case. A method was then developed based on the constant flow mode of operation in which the oven temperature was ramped up and down to effect critical pair separation. With this method, peaks of interest eluted in less than 6 min and sample-to-sample injection time was under 13 min allowing for the elution of cholesterol (Fig. 2b). An initial hold time of 0.10 min and starting temp of 160 °C was used. We observed that even a small decrease in the hold time or a slight increase in the initial oven temperature results in coelution of the 10:0 and 12:0 peaks with the solvent peak. Similarly, small changes (e.g., 0.10 m) in the hold times after the temperature ramps resulted in a loss of peak separation. Use of the constant pressure mode instead of the constant volume mode using an identical temperature program led to an increase of 1 min in analysis time but maintained good separation of peaks. GC Methods have been published where the fatty acid components elute within 2 min [38], however these methods are not feasible for the analysis of FAMES from plasma samples due to the coelution of several critical pairs (18:1n-9, 18:1n-7 and 24:1n-9, 22:6n-3) which then prevent correct quantitation.

The improved fast GC method that we have developed has been applied to the separation of plasma fatty acid methyl esters. In both the former method and the faster method, all of the peaks of interest are well separated, even with the shorter analysis time with the improved method (Fig. 3). The concentrations of human plasma fatty acids obtained by the robotic method and determined by both fast GC and by the improved GC method are presented in Table 2. Very similar results were obtained for each fatty acid concentration and its percentage of total fatty acids, and the CV values were similar between the two. Thus the faster GC method is suitable for fatty acid analyses of human plasma and can significantly reduce analytical run times.

Detecting the liquid interface is one of the most critical steps in developing a high throughput transesterification automation application. The Tecan robot integrated liquid detection system employs two different physical principles: detection of changes in capacitance (c-LLD) or pressure (p-LLD). Both types of detection have been used in our studies. The capacitance-based system is useful for detecting an alkane–aqueous interface. This was used in collecting the upper phase as interface detection is followed by a 1-mm retraction into the organic layer. Pressure detection detects an air–liquid interface. This is useful when aspiration of only the upper organic phase is desired, such as when transferring the methyl ester extracts into GC vials or during the mixing phase when upper phase is squirted thru the lower phase.

The simplified transmethylation procedure used here dispensed with several steps once considered to be necessary. These steps include addition of cold acetyl chloride drop-wise, working under a nitrogen atmosphere, base addition for reaction mixture neutralization, vortexing, centrifugation and multiple extractions. Results in Table 1 and also our previous analysis [35] demonstrate that these steps are unnecessary or can be replaced by simple pipetting procedures that the robotic arm can perform. Such procedures were devised to overcome difficulties in implementing robotic processes that mimic the traditional chemical procedure. For example, vortexing can be performed by a robot using specialized apparatus, but it is a slow process whereby one sample at a time is mixed. Similarly, some robots are capable of centrifuging samples with integrated centrifuges, but this is a laborious, technically challenging and time-consuming process. What is required is for the organic and aqueous phases to be well mixed and then separated to effect methyl ester extraction. This has been achieved here by repeated mixing by aspirating the upper phase, moving the tip to the bottom of the tube and rapidly dispensing the organic solvent thru the aqueous phase. The organic phase can then be transferred into GC vials after the phases have settled and concentrated further for fast GC analysis, if necessary. Use of an internal

standard has obviated the need for complete upper phase transfer and multiple extractions. The use of fast GC also makes possible the analysis of a lower concentration of solutes and, if an appropriate amount of plasma is used, no organic phase concentration may be required. Alternatively, if a microanalysis is required where sample is limited, the organic phase can be concentrated by heating the GC vial rack, and multiple extractions may be performed to increase solute concentrations.

The robotic method described here has been applied to the simultaneous analysis of larger numbers of samples. For example, preliminary experiments transmethylated and analyzed the same bulk plasma sample 40 times. When multiple sets of eight samples are to be analyzed, the program may perform the mixing steps, change tips, wait for a prescribed length of time, and then perform the transfer of the upper phase extract into the GC vials. Another alternative that may improve overall efficiency with a larger number of samples is to perform the mixing step on two sets of eight samples, and then return to the first set for upper phase transfer to GC vials. This creates a delay time that will allow adequate phase separation and also maintain a controlled and constant interval for mixing and sampling for each set of tubes to be processed. This method is then amenable to the analysis of 192 samples in one batch. In

combination with the rapid GC methodology presented, two GCs can process the 192 samples within 1 day. This method then results in an order of magnitude increase in productivity and makes possible large clinical studies.

This method may then be used for both cross-sectional studies of populations and for monitoring compliance in interventional trials with fatty acid supplements and for the use of essential fatty acid related parameters as biomarkers for disease or disease risk. It should also be noted that where more detailed information is required concerning lipid class and molecular species content, that mass spectrometric techniques may be used for highly efficient analyses [39–41].

Analysis of about 200 samples per day would generate over 5,000 peaks per day that must be correctly assigned and entered into spreadsheets. This is a non-trivial task that

requires automation. It will be the next step in development of a high throughput system for analysis of large sets of clinical samples.

**Abstract** An assay involving a finger stick and filter paper blood spotting was developed to determine polyunsaturated fatty acid (PUFA) levels in blood. Capillary whole blood from a finger stick was blotted on antioxidant impregnated filter paper, air dried, saponified and methylated using sodium hydroxide and boron trifluoride in methanol. The method differed from those described previously because separation of plasma and red blood cells (RBCs) was not needed, thin-layer chromatography (TLC) was not required to separate phospholipids, initial extraction of lipids before transesterification was not necessary, and the fatty acid methyl ester (FAME) method was able to methylate steryl esters, free fatty acids, and sphingomyelins. Twenty-six subjects provided blood samples by finger stick and venipuncture. Levels of long-chain polyunsaturated fatty acids (LC-PUFA) from capillary whole blood were correlated with those from RBCs and PLs in venous blood ( $P < 0.001$ ,  $R^2$  ranged from 0.64 to 0.86). Although highly significant ( $P < 0.002$ ), the  $R^2$  values for the correlation between arachidonic acid (ARA) levels in capillary whole blood with ARA levels in RBCs and plasma phospholipids (PLs) were relatively lower ( $R^2 = 0.31$ – $0.41$ , respectively). Results indicate that the described finger stick assay represents a fast, reliable method to measure specific LC-PUFA levels.

### Abbreviations

AOCS	American Oil Chemists' Society
ARA	Arachidonic acid
DHA	Docosahexaenoic acid
DPAn-6	Docosapentaenoic acid
EPA	Eicosapentaenoic acid
FAME	Fatty acid methyl esters
LC-PUFA	Long-chain polyunsaturated fatty acids
PLs	Plasma phospholipids
PUFA	Polyunsaturated fatty acids
RBCs	Red blood cells
TLC	Thin-layer chromatography

### Introduction

The fatty acid composition of red blood cells (RBCs) and plasma phospholipids (PLs) is commonly used to evaluate certain medical conditions, estimate nutritional status, and measure compliance of investigational drug use in clinical trials. Only a few investigators have developed and described methods to measure quickly the levels of fatty acids in blood using techniques other than venipuncture. Ohta et al. [1] described a method for analyzing the fatty acids in plasma lipids from a 50  $\mu$ L finger-tip blood sample. The method involved initial separation of whole blood into plasma and red blood cells (RBCs) and needed thin-layer chromatography (TLC) prior to fatty acid methyl ester (FAME) analysis to isolate the phospholipid fraction [1]. Inoue et al. [2] described a method of fatty acid analysis using a dried blood spot on filter paper to screen for adrenoleukodystrophy, an x-linked recessive disorder characterized by progressive demyelination of cerebral white matter and adrenal insufficiency. This method

involved initial extraction of the blood lipids from the filter paper matrix prior to methanolysis with MeOH/HCL [2]. Ichihara et al. [3] described a finger stick and FAME technique to analyze the fatty acid composition of glycerolipids in blood or breast milk. These authors developed a method to prepare BHT impregnated filter paper to collect blood. However, free fatty acids, steryl esters, and sphingomyelins were not methylated using the reported alkaline methanolysis FAME procedure [3]. Finally, Marangoni et al. [4] described a finger stick assay to analyze the fatty acid composition of circulating lipids. In their analysis, percentage levels of fatty acids in blood total lipids from a finger stick were analyzed in volunteers who consumed differing amounts of fish and meat. The samples obtained had high levels of triglycerides and not only phospholipids since total blood lipids were analyzed. Correlations between fatty acids in venous blood and capillary whole blood were not provided. These authors used MeOH/HCL as a methylating agent and not  $\text{BF}_3/\text{MeOH}$  as recommended by the American Oil Chemists' Society (AOCS) [5]. In some studies, it appears that acid-catalyzed procedures using MeOH/HCL result in incomplete transesterification of triglycerides [6].

Presently, the most common method of measuring PUFA levels in blood involves venipuncture. However, this method is often time consuming, involves an invasive technique for blood collection, and is costly. Standard analysis using venipuncture to determine PUFA levels in RBCs and PLs involves several steps, including: (1) the collection of whole blood, (2) the separation of whole blood into RBCs and plasma by centrifugation, (3) the washing of the RBCs with isotonic saline to remove white cell and plasma contamination, (4) the organic extraction of the total lipids from the RBCs and plasma, (5) the separation of PLs by TLC, and (6) the saponification and methylation of the RBC total lipids and PLs for analysis by gas chromatography.

The purpose of this paper is to describe an accurate, inexpensive, and minimally invasive finger stick assay to measure LC-PUFA levels in capillary whole blood. The method described here differs from those used previously because separation of plasma and RBCs is not needed, TLC is not required to separate phospholipids, initial extraction of lipids before transesterification is not necessary, and the FAME method is able to methylate steryl esters, free fatty acids, and sphingomyelins. Further, the method described herein uses  $\text{BF}_3/\text{MeOH}$  as a methylating agent as recommended by the AOCS [5]. Mean mole percent LC-PUFA levels in capillary whole blood are compared with those from RBCs and PLs in venous blood. Correlations based on the type of assay used (finger stick or venipuncture) are reported for several important LC-PUFA [docosahexaenoic acid (DHA), docosapentaenoic acid (DPA<sub>n</sub>-6),

eicosapentaenoic acid (EPA), and arachidonic acid (ARA)]. These correlations are particularly useful because LC-PUFA levels in RBCs and PLs are most often used as indicators of dietary intake of these fatty acids.

## Materials and Methods

Twenty-six healthy subjects between the ages of 25 and 66 volunteered to participate. The study was approved by the New England Institutional Review Board, Wellesley, MA, and written informed consent was obtained prior to enrollment. Volunteers were recruited at Martek Biosciences Corporation where the study was conducted. The sample may have included individuals who routinely consume omega-3 dietary supplements.

### Venipuncture Assay

Samples were taken from both fasting and non-fasting subjects. Using standard phlebotomy techniques, approximately 4 ml of whole blood was collected from each subject by venipuncture and placed into an EDTA vacutainer tube. The tubes were centrifuged to separate the plasma from the RBCs. The RBCs were washed two times with isotonic saline to remove plasma and white blood cell contamination. The plasma and RBCs were purged with nitrogen and stored at  $-80\text{ }^\circ\text{C}$  until analysis. Plasma and erythrocyte lipids were extracted using the methods described by Folch [7] and Bligh and Dyer [8], respectively. Plasma (400  $\mu\text{l}$ ) and RBCs (500  $\mu\text{l}$ ) were used for extraction. The phospholipid fraction was isolated from the plasma total lipids by TLC on silica gel plates developed in a 60:40:3 ratio solution (v/v/v) of hexane:ether:acetic acid. Internal standard (23:0 fatty acid) was added to the plasma phospholipid subfraction and RBC total lipids. We used 23:0 fatty acid as an internal standard because it is not typically detected in the analyses described here. The lipids were saponified with 0.5 N NaOH in methanol, and the resulting fatty acids were methylated using 14%  $\text{BF}_3$  in methanol at  $100\text{ }^\circ\text{C}$  for 30 min and then extracted with hexane. The FAMES were separated by capillary column gas chromatography on an Agilent Series 6890 System equipped with a 30 m FAMEWAX<sup>TM</sup> (Restek, State College, PA) column. A 48:1 split flow ratio with helium as a carrier gas and a programmed temperature gradient ( $130\text{--}250\text{ }^\circ\text{C}$ ) was used. FAMES were identified by flame ionization detection. Retention times were compared to a mixed fatty acid methyl ester standard from NuChek Prep (Elysian, MN). Fatty acids were quantified by comparison to the 23:0 internal standard (NuChek Prep Elysian, MN). Concentrations of fatty acids were not reported in the

present study because blood volumes from the finger stick assay were not determined.

### Finger Stick Assay

BHT impregnated filter paper squares (Whatman 3MM chromatography paper, Whatman Inc.) were prepared according to the methods described by Ichihara et al. [3]. These authors demonstrated that BHT minimized fatty acid oxidation. A drop of capillary blood was obtained from each subject by piercing the fingertip with a lancet device (BD Genie™ Lancet, Emergency Medical Products). A piece of filter paper was applied to the finger. The blood sample was dried overnight at room temperature and then stored for 1 day at  $-80\text{ }^{\circ}\text{C}$ , the standard storage temperature for RBCs and plasma. The filter paper samples were transferred to test tubes with 23:0 fatty acid internal standard, directly saponified with NaOH, and methylated with 14%  $\text{BF}_3$  in methanol with no prior extraction step. The resultant FAMES were analyzed by gas chromatography using the aforementioned method except that a split flow of 20:1 was used. The finger stick assay involved direct

transesterification and methylation of the fatty acids without prior lipid extraction.

### Statistical Analyses

All statistics were conducted using Minitab™. Means, standard deviations, and ranges were calculated for levels of PUFA in capillary whole blood and for PUFA in RBCs and PLs from venous blood. One-way ANOVA with the post hoc Tukey's test was used to determine significant difference between levels of PUFA from the assays. Spearman's rank correlation was used to determine the strength of the association between each assay and levels of LC-PUFA. An  $\alpha = 0.05$  was used to determine statistical significance.

### Results

Table 1 shows the mean mole percent levels, their standard deviations and ranges for the fatty acids obtained from each assay. Not surprisingly, values for most mean mole percent

Different superscripts indicate significant differences between groups,  $P < 0.05$

levels of fatty acids from RBC, PLs, and capillary whole blood differed significantly ( $P < 0.05$ ) from each other because each sample type contained differing amounts of triglyceride, phospholipid, free fatty acids, and steryl esters. There was substantial inter-individual variation in levels of LC-PUFA as demonstrated by the wide range of values.

For only two fatty acids (18:1n-7 and 20:5n-3) from capillary whole blood, RBCs, and PLs, the values for mean mole percent levels were not significantly different ( $P > 0.05$ ). Of the 22 fatty acids considered, the values for mean mole percent fatty acid levels from capillary whole blood and PLs were not significantly different for 9 fatty acids. Values for capillary whole blood and RBCs mean mole percent fatty acid levels were not significantly different for five fatty acids. For PLs and RBCs, mean mole percent fatty acid levels were not significantly different for seven fatty acids.

No assay had consistently higher or lower mole percent values compared with the other assays. However, the mean mole percent value for DHA was about 150% lower in capillary whole blood than in RBCs and PLs.

Table 2 shows the correlations between levels of certain LC-PUFA in capillary whole blood with those from RBCs and PL in venous blood. The association between LC-PUFA levels in RBC and PLs is also provided. Capillary whole blood DHA, EPA, and DPA n-6 mole percent levels were highly correlated to those in RBCs and PLs (see Figs. 1, 2 for DHA). Although highly significant ( $P < 0.002$ ), the  $R^2$  values for the correlation of ARA levels in capillary whole blood with ARA levels in RBCs

and PLs were relatively low ( $R^2 = 0.31$  and  $0.41$ , respectively). Notably, the  $R^2$  values for the correlation of ARA between capillary whole blood and RBCs and PLs were higher than those for the correlation of ARA between RBCs and PLs ( $R^2 = 0.24$ ).

## Discussion

The present study describes an accurate, inexpensive, and minimally invasive finger stick assay to measure LC-PUFA levels in capillary whole blood. Measures of DHA and ARA are particularly important because these LC-PUFA are present in the brain, retina, and other neural tissues [9]. LC-PUFA have well established benefits for infant cognitive and visual function [10–14], cardiovascular health [15–21], and may play an important role in neural and visual health during the aging process [22–25].

**Fig. 1** Relationship between mole percent DHA levels from capillary whole blood and RBC DHA levels from venous blood in subjects with variable LC-PUFA intakes

**Fig. 2** Relationship between mole percent DHA levels from capillary whole blood and PL DHA from venous blood in subjects with variable LC-PUFA intakes

**Table 2** Correlations for LC-PUFA from the finger stick and venipuncture assays

Fatty acid	$P$ value	$R^2$ value
DHA C22:6n-3		
Finger stick versus RBCs	<0.001	0.74
Finger stick versus PLs	<0.001	0.86
RBC versus PLs	<0.001	0.84
EPA C20:5n-3		
Finger stick versus RBCs	<0.001	0.68
Finger stick versus PLs	<0.001	0.64
RBC versus PLs	<0.001	0.71
DPA C22:5n-6		
Finger stick versus RBCs	<0.001	0.74
Finger stick versus PLs	<0.001	0.77
RBC versus PLs	<0.001	0.49
ARA C20:4n-6		
Finger stick versus RBCs	0.002	0.31
Finger stick versus PLs	<0.001	0.41
RBC versus PLs	<0.012	0.24

Due to differing dietary intakes of PUFA, there was substantial inter-individual variation in levels found in RBCs, PLs, and capillary whole blood as demonstrated by the wide ranges of values. It is evident that the majority of mean mole percent levels of fatty acids from RBCs, PLs, and capillary whole blood were significantly different from each other. These differences probably reflected differing amounts of triglyceride, phospholipid, free fatty acids, and steryl esters in each sample type.

For DHA, the mean mole percent value was much lower in capillary whole blood than in RBCs or PLs. Since phospholipid is the predominant lipid class in RBCs it is reasonable to expect a higher level of DHA in RBCs and PLs compared with that found in capillary whole blood. One of the limitations of the finger stick assay is that it uses whole blood total lipids rather than RBCs and plasma phospholipids. This may produce results that show artificially lower levels of DHA due to the presence of less DHA-containing lipid components such as triglycerides. This is particularly relevant in individuals with hyperlipidemia. This problem may be ameliorated by asking subjects to fast before the blood draw.

Levels for DHA, DPAn-6 and EPA from both assays were highly correlated ( $P < 0.001$ ,  $R^2$  ranged from 0.64 to 0.86). However, the correlation between ARA from capillary whole blood and ARA from RBCs and PLs was not as strong as compared to the other LC-PUFA. As suggested by Ichihara et al. [3], correlation with ARA may be improved when the ARA level is expressed as a proportion of fatty acids, using the ratio ARA/(EPA + DHA) as an indicator of n-6/n-3 status. The ratios calculated from both assays were highly correlated for RBCs ( $R^2 = 0.91$ ,  $P < 0.001$ ) and for PLs ( $R^2 = 0.93$ ,  $P < 0.001$ ). Although the ratio ARA/(EPA + DHA) improves the correlation with ARA and provides information about n-6/n-3 status, it does not provide specific information about the level of ARA. The narrow range of levels for ARA also may account for the low  $R^2$  values for the resulting correlations. For DHA, EPA, and DPAn-6, the range of levels is much greater than that found for ARA. The narrow range of levels for ARA is found in diets that contain differing amounts of ARA and other PUFA.

DHA has been shown to incorporate into the steryl ester fraction and to be circulating as a free fatty acid [26]. We used the AOCS recommended  $\text{BF}_3/\text{MeOH}$  methylating agent because free fatty acids, steryl esters, and sphingomyelins are not methylated using the alkaline methanolysis FAME procedure. The  $\text{BF}_3/\text{MeOH}$  FAME method will methylate these lipid classes and therefore give a more accurate assessment of blood PUFA status [26]. Notably, the  $\text{BF}_3/\text{MeOH}$  FAME method is appropriate for measuring fatty acid levels in whole blood because the triglycerides are transesterified.

Although Ohta et al. [1] described a method for the rapid analysis of plasma phospholipids, the method involved initial separation of the whole blood into plasma and RBCs and included a TLC step prior to FAME analysis to isolate the phospholipid fraction. Both procedures are eliminated in our method as the whole blood is directly methylated without prior whole blood or TLC separation.

The finger stick assay described here represents a rapid, minimally invasive, and cost effective method to determine LC-PUFA levels, notably DHA and EPA, in capillary whole blood. The assay may be useful for the determination of subject compliance in clinical trials, particularly when LC-PUFA are administered.

**Abstract** Omega-3 polyunsaturated fatty acid (PUFA) dietary intakes and tissue levels are positively associated with various health benefits. The development of cost efficient, high throughput methodologies would enable research in large clinical and population studies, and clinical fatty acid profiling. Microwave heating for the transesterification of blood fatty acids was examined. Samples were collected by venous puncture and fingertip prick onto chromatography paper. Aliquots of serum, plasma, erythrocytes and whole blood were prepared from venous blood. Boron trifluoride in methanol was used for transesterification but sample preparation and heating varied. Fatty acid determinations and markers of omega-3 fatty acid status including the sum of eicosapentaenoic acid and docosahexaenoic acid, the ratio of total n-3 PUFA to n-6 PUFA, and the percentage of n-3 highly unsaturated fatty acids (HUFA,  $\geq 20$  carbons and  $\geq 3$  carbon-carbon double bonds) in total HUFA were compared. Quantitative determinations indicate that microwave transesterification results in significantly lower estimates of monounsaturates and polyunsaturates, possibly through incomplete transesterification of triacylglycerols. However, qualitative estimates of omega-3 fatty acid status were relatively similar. Fingertip prick blood collection combined with

direct transesterification by microwave may be a very rapid method to estimate omega-3 fatty acid status for selected applications.

**Keywords** Plasma · Erythrocytes · Whole blood · Fingertip · Omega-3 fatty acid · EPA · DHA · HUFA

## Abbreviations

BF <sub>3</sub> /	Boron trifluoride in methanol
MeOH	
BHT	Butylated hydroxytoluene
DHA	Docosahexaenoic acid (22:6n-3)
DMA	Dimethyl acetal
EDTA	Ethylene diaminetetraacetic acid
EPA	Eicosapentaenoic acid (20:5n-3)
FAME	Fatty acid methyl ester
HUFA	Highly unsaturated fatty acids
PUFA	Polyunsaturated fatty acid
TLC	Thin layer chromatography
17:0 PC	1,2-Diheptadecanoyl- <i>sn</i> -glycero-3-phosphocholine
17:0 TG	Triheptadecanoin

## Introduction

Epidemiological and interventional trials have shown that n-3 polyunsaturated fatty acids (PUFA), specifically docosahexaenoic acid (22:6n-3, DHA) and eicosapentaenoic acid (20:5n-3, EPA) have significant cardio-protective effects [1–5]. These cardio-protective effects are mediated through various mechanisms including anti-arrhythmia [5, 6], anti-thrombosis [7], triacylglycerol-lowering [8],

and heart rate-lowering [9]. An intake of 750 mg/d has been proposed as a target intake to provide significant anti-arrhythmic benefits, as well as additional cardiovascular benefits [10]. Blood measures of n-3 PUFA have been demonstrated to be a biomarker of dietary n-3 PUFA intake [11]. It has been proposed that n-3 fatty acid measures in blood could be developed into an independent risk factor for coronary heart disease mortality [12]. Large-scale clinical, intervention and population-based studies are needed to support the use of blood measures of n-3 PUFA as a risk factor for cardiovascular disease.

The conventional determination of fatty acids in blood is a multi-step process that requires highly trained manual labor. High throughput and cost efficient determinations of fatty acids would enable large research initiatives and support routine fatty acid profiling during clinical screening. Fast gas chromatography for the determination of fatty acids in human blood has been demonstrated previously [13, 14]. It has also been demonstrated that fatty acid methyl esters (FAMES) can be prepared by direct transesterification without prior lipid extraction [15–17] and that these steps can be made amenable to robotics [14]. Fingertip prick blood sampling techniques can also eliminate the requirement for a trained phlebotomist for sample collection [18–20] and the samples absorbed on chromatography paper can be directly transesterified to yield for FAMES for gas chromatography analysis [20]. FAME preparation remains time-consuming with conventional methylation often requiring 1 hour with convectional heat to catalyze the reaction [20,21], although reaction times as short as 10 min have been utilized when the transesterification of sphingolipids is not of interest [21,22]. Microwave irradiation has been substituted for convectional heating during the production of FAMES from phospholipids isolated from brain

lipids [23], but this technique has neither been adapted widely nor tested exhaustively.

In the present study, the use of direct microwave transesterification was compared to the traditional use of convectional heat for the preparation of FAMES. A primary interest was the determination of n-3 PUFA status by rapid methods from venipuncture and fingertip prick blood samples. Biomarkers of n-3 PUFA status compared include EPA + DHA with and without the addition of docosapentaenoic acid (22:5n-3, DPAn-3), the ratio of total n-3 PUFA to total n-6 PUFA, and the percentage of n-3 highly unsaturated fatty acids ( $\geq 20$  carbons,  $\geq 3$  carbon-carbon, double bonds, HUFA) in total HUFA [24]. Analyses of fingertip blood samples were compared to analyses performed on erythrocyte and plasma total lipid extracts, plasma phospholipids, and whole blood total lipids with and without prior lipid extraction.

## Methods

### Blood Samples

Blood was collected on one occasion by venous puncture and by fingertip prick (see below for details) from a fasted male subject, 21 years of age for initial qualitative comparisons. The samples were prepared under a series of conditions (see Table 1 for a summary). A quantitative and qualitative comparison between convectional block heating and microwave heating for transesterification was completed on blood collected on a single occasion from a fasted male subject, 25 years of age. The study and methods were reviewed and received clearance from the Office of Research Ethics at the University of Waterloo.

**Table 1** Blood collection and sample preparation conditions

Sample	Abbreviation	Collection	Extraction	Methanolysis
Serum total lipids	Serum	Venous	Yes	Convectional heat 60 min
Plasma total lipids	Plasma	Venous	Yes	Convectional heat 60 min
Plasma phospholipid	Plasma PL	Venous	Yes	Convectional heat 60 min

### Finger Prick Samples

Finger prick blood samples were obtained by puncturing the fingertip with a sterile, disposable, lancing device (A.R. Medicom Inc., Montreal, QC, Canada). Blood was absorbed on a thin strip (3.0 cm × 0.5 cm) of chromatography paper (Analtech, Newark, DE) as the processing of chromatography paper for fatty acid analysis produced no peaks during gas chromatography in agreement with previous findings [20]. The incorporation of 2,6-di-*tert*-butyl-4-methylphenol (butylated hydroxytoluene, BHT) into the absorbent was not necessary as samples in the present study were not stored, but prepared immediately after collection [20]. Each fingertip prick blood sample consisted of enough blood to saturate approximately 0.5 cm × 1.0 cm of chromatography paper. This section of chromatography paper with absorbed blood was cut into and completely submerged in the transesterification solvents to prevent combustion during heating, particularly with microwave heating. Conventional extraction of lipids was bypassed for the fingertip prick samples and they were prepared by direct transesterification with boron trifluoride in methanol (BF<sub>3</sub>/MeOH, 14% w/v; Alltech Associates, Deerfield, IL) with the addition of hexane.

### Venous Blood Samples

Venous blood was collected from the antecubital vein by a trained technician into 10 ml evacuated tubes (Vacutainer; Becton Dickinson, Franklin Lakes, NJ) with ethylene diaminetetraacetic acid (EDTA) as an anticoagulant for plasma, erythrocyte and whole blood preparations and without EDTA for serum preparations. Whole blood from the EDTA blood collection was aliquoted (100 µl each) into borosilicate glass tubes (13 mm × 10 mm, Fisher Scientific). Strips of chromatography paper were dipped into collected whole blood to compare blood collected from the antecubital vein to fingertip prick collected blood. Plasma and erythrocytes, and serum were prepared from EDTA blood and clotted blood, respectively, by centrifugation at 3,000 rpm for 15 min. The erythrocytes were washed twice with 3 ml of sodium chloride solution (0.9% in water, B. Braun Medical, Irvine, CA) to remove plasma and leukocytes. Washed erythrocytes were aliquoted by weight (0.16–0.18 g) for preparation of FAMES.

### Conventional Sample Preparation

Total lipids from plasma, serum and whole blood samples were extracted according to the method described by Folch et al. [25]. Briefly, 3 ml chloroform:methanol (2:1 v/v)

containing an 3.33 µg/ml of an internal standard (22:3n-3 ethyl ester; Nu-Chek Prep, Elysian, MN) and 50 µg/ml BHT (Sigma–Aldrich Inc., St. Louis, MO) was added to each 100 µl sample and vortexed for 1 min. Sodium phosphate solution (500 µl of 0.5 M) was added, and samples were mixed by inversion and centrifuged at 3,000 rpm for 5 min. The organic phase was collected, evaporated to dryness under nitrogen gas and lipids were redissolved in 300 µl of hexane for direct transesterification or 100 µl of chloroform for phospholipid isolation (plasma only). Erythrocytes were prepared according to Reed et al. [26]. Briefly, 1 ml of cold methanol (containing 50 µg BHT and 20 µg 22:3n-3 ethyl ester internal standard) was added to erythrocytes (0.16–0.18 g) and vortexed for 1 ml to lyse cells. Chloroform (1 ml) was then added, followed by vortexing and storage overnight at –80 °C. The following day, samples were thawed, vortexed, and then centrifuged at 3,000 rpm for 10 min. The supernatant was collected, and the remaining pellet was reextracted using 2 ml chloroform:methanol (1:1 v/v). The extracted supernatants were combined and 1.8 ml of water was added to separate the aqueous and organic phases [27]. The organic phase was collected and lipids isolated as described for plasma, serum and whole blood.

Plasma phospholipids were also isolated by thin layer chromatography (TLC) [28]. Briefly, total lipid extracts of plasma were applied to silica gel plates (Whatman, Clifton, NJ) and lipids were separated using a mixture of heptane: diethylether: methylene chloride (60:40:2 by volume; J.T. Baker, Phillipsburg, NJ). Samples were run alongside a TLC reference standard (TLC 18–5 A, Nu-Chek Prep, Elysian, MN), visualized with 2',7'-dichlorofluorescein (Sigma, St. Louis, MO) under ultraviolet light and the phospholipid band collected for transesterification.

Total lipid extracts of serum, plasma, erythrocytes, and whole blood and plasma phospholipids in 300 µl of hexane were transesterified using 1 ml of BF<sub>3</sub>/MeOH (14% w/v) without prior saponification as described previously [21] with convectional heat by a block heater for 60 min at 90°C. The use of convectional heat by block heater for 60 min was also used on a set of fingertip blood samples. The use of convectional heat for only 15 min was also examined on whole blood and fingertip prick blood samples.

### Direct Microwave Transesterification

Fingertip blood on chromatography paper, whole blood on chromatography paper, and whole blood dropped directly into the solvents were prepared by direct microwave transesterification using 1 ml BF<sub>3</sub>/MeOH (14% w/v) with the addition of 300 µl of hexane with BHT added.

A commercial microwave oven (model MW8107WAC, 1,000 W; Emerson, Toronto, ON) was used at power level 4 for 45 s for the transesterification of fatty acids to FAMES. Lower power settings or less time proved to be insufficient to carry out the reaction, and more aggressive reaction conditions did not improve results and increased the risk of explosion (data not shown). Although the settings were optimal for our commercial microwave oven, it is important to note that these settings differed from those presented previously [23]. This is likely due to high variation in household microwave ovens. After heating by microwave, samples were allowed to cool to room temperature and the FAMES collected in the hexane after the addition of additional hexane and deionized water. The hexane layer containing the FAMES was collected, dried to a volume of 100  $\mu$ l and capped under nitrogen, and stored at  $-80^{\circ}\text{C}$  until analysis by gas chromatography.

### Quantitative Comparisons

Initial qualitative results warranted further investigation between the use of direct transesterification for FAME generation by convectional and microwave heating. Whole blood samples (50  $\mu$ l each) were aliquoted directly into 1 ml  $\text{BF}_3/\text{MeOH}$  (14% w/v) with the addition of hexane (300  $\mu$ l). BHT and an internal standard (22:3n-3 methyl ester, Nu-Chek Prep) were added to the hexane previously. Samples were then heated by either block heating (60 min at  $90^{\circ}\text{C}$ ) or microwave heating (power level 4 for 45 s) as described above. Note that 22:3n-3 ethyl ester, an internal standard we use to indicate complete transesterification for convectional techniques was not completely transesterified by microwave transesterification as both methyl and ethyl esters of 22:3n-3 were detected when only 22:3n-3 ethyl ester was included. Concentrations of individual fatty acids were determined based on the peak area of a calibrated internal standard (22:3n-3 methyl ester) after peak areas were adjusted by individual peak response factors as determined by a 28 component qualitative standard mixture GLC-462, Nu-Chek Prep).

The transesterification of fatty acids bound specifically to triacylglycerols or phospholipids was examined. Triheptadecanoin (17:0 TG, Nu-Chek) and 1,2-diheptadecanoyl-*sn*-glycero-3-phosphocholine (17:0 PC, Avanti Polar Lipids Inc., Alabaster, AL) were purchased and FAMES prepared by direct transesterification methods with convectional and microwave heat.

### Gas Chromatography Analysis

Analyses were performed on a Shimadzu 17-A gas chromatograph (Shimadzu, Columbia, MD) with a fused silica

capillary column (DB-FFAP), 30 m  $\times$  0.25 mm inner diameter  $\times$  0.25  $\mu$ m film thickness (J&W Scientific, Agilent Technologies, Palo Alto, CA). A Shimadzu AOC-17 automatic injector was used, and 2  $\mu$ l of each sample were injected, at a split ratio of 8:1 and injector temperature of  $250^{\circ}\text{C}$ . Samples were detected with a flame ionization detector at  $250^{\circ}\text{C}$ . The temperature program consisted of an initial temperature of  $130^{\circ}\text{C}$  with 1 min hold, ramp  $4^{\circ}\text{C}/\text{min}$  to  $178^{\circ}\text{C}$ ,  $1^{\circ}\text{C}/\text{min}$  to  $195^{\circ}\text{C}$  with 17 min hold, and  $40^{\circ}\text{C}/\text{min}$  to  $245^{\circ}\text{C}$  with 12 min hold. Pressure was held constant at 106 kPa, and the carrier gas was  $\text{H}_2$ . Shimadzu Class-VP software was used for integration. Peaks with retention times and fatty acids were detected as compared to an external standard (GLC-462).

### Gas Chromatography Mass Spectrometry (GC-MS) Analysis

Individual peaks, particularly dimethyl acetal (DMA) peaks were confirmed with GC-MS analysis on a 3800 gas chromatograph equipped with a Varian 4000 ion trap mass spectrometer in external EI mode (Varian Canada Inc., Mississauga, ON). DMAs were identified with target ion mass to charge ratios ( $m/z$ ) of 255, 281 and 283 for 16:0 DMA, 18:1 DMA and 18:0 DMA, respectively [29,30]. The fatty acid methyl esters in hexane were injected onto a DB-FFAP 30 m  $\times$  0.25 mm i.d.  $\times$  25  $\mu$ m film thickness, capillary column (J&W Scientific from Agilent Technologies, Mississauga, ON) interfaced directly onto the ion source with helium as the carrier gas. Initial column temperature was  $50^{\circ}\text{C}$  with a 1 min hold followed by a  $30^{\circ}\text{C}/\text{min}$  ramp to  $130^{\circ}\text{C}$ , an  $8^{\circ}\text{C}/\text{min}$  ramp to  $175^{\circ}\text{C}$ , a  $1^{\circ}\text{C}/\text{min}$  ramp to  $210^{\circ}\text{C}$ , and a  $30^{\circ}\text{C}/\text{min}$  ramp to  $245^{\circ}\text{C}$  with a 30 min hold at the end. The injector and transfer line were maintained at  $260^{\circ}\text{C}$  and  $250^{\circ}\text{C}$ , respectively. The source temperature and manifold temperatures were 180 and  $50^{\circ}\text{C}$ , respectively. The low mass range was selected as 50  $m/z$  to exclude air and water contaminants, and the high mass range was 400  $m/z$  to include the full range of fatty acid methyl esters. A target total ion count of 20,000 was selected with a maximum ionization time of 65,000  $\mu$ s, and an emission current of 25  $\mu$ A for the ion trap. In addition, a 3  $\mu$ Scan average for each data point resulting in a 0.55 s maximum scan time was utilized.

### Data Analyses and Statistics

The fatty acid composition of blood samples and common biomarkers for expressing omega-3 PUFA status were determined. These included EPA + DHA, EPA + DPAn-

Values are means ± SD,  $n = 4$ . SFA saturated fatty acids; DMA dimethyl acetal; MUFA monounsaturated fatty acids; PUFA polyunsaturated fatty acids. Fatty acids with different alphabetical superscripts are statistically different by Tukey's HSD after significant  $F$  value by one-way ANOVA,  $P < 0.01$

3 + DHA, the ratio of n-3 to n-6 PUFA and the % of n-3 HUFA in total HUFA. The equation for calculation of the % of n-3 HUFA in total HUFA was:  $(20:3n-3 + 20:5n-3 + 22:5n-3 + 22:6n-3)/(20:3n-3 + 20:5n-3 + 22:5n-3 + 22:6n-3 + 20:3n-6 + 20:4n-6 + 22:4n-6 + 22:5n-6 + 20:3n-9) \times 100$ . The qualitative determinations of various blood fractions were compared by one-way ANOVA with comparisons of individual means by Tukey's Honestly Significantly Difference (HSD) tests as were whole blood samples including fingertip prick samples that varied by preparation techniques. Due to the number of statistical comparisons made, significance was inferred when  $P < 0.01$ . The comparisons of quantitative determinations in human blood and with standards were made by paired  $t$ -tests with significance

inferred at  $P < 0.05$ . All values are expressed as means ± SD.

## Results

### Blood Fractions

The fatty acid composition of human blood is dependent on the blood fraction collected (Table 2). Fatty acid compositions of serum and plasma total lipid extracts were similar, while plasma phospholipid and erythrocyte total lipid had significantly higher percentages of saturated fatty acids and lower percentages of monounsaturated fatty

**Fig. 1** The effects of transesterification by convectional heat for 60 min and 15 min or by microwave on lipid extracts from whole blood and blood absorbed on chromatography paper from a fingertip prick. acids, and slightly lower polyunsaturated fatty acids. A closer examination of the polyunsaturated fatty acids indicate that in plasma and serum total lipid, the significantly higher amounts linoleic acid (18:2n-6) are responsible for this difference, as the HUFAs such as arachidonic acid (20:4n-6, AA) and DHA are higher in the erythrocytes and plasma phospholipid. These differences are to be expected and are largely dictated by differences in the lipid classes, with plasma and serum total lipids containing lipoproteins with significant amounts of triacylglycerols and cholesterol esters [31] that contain a higher proportion of oleic (18:1n-9) and linoleic acid, and lower proportions of HUFAs.

In the present blood samples, there were higher proportions of HUFAs, except EPA and 20:3n-6 in erythrocytes. Erythrocytes also had much lower levels of 18:2n-6 and 16:0, but higher levels of 18:1n-9, 24:1n-9 (found mainly in sphingolipids) and dimethyl acetals (DMAs, derived from the methylation of plasmalogens). Differences in plasma phospholipids and erythrocytes is largely determined by the higher proportion of inner leaflet membranes with significantly higher amounts of phosphatidylethanolamine in erythrocytes as compared to phosphatidylcholine dominated monolayers of lipoproteins [31]. Whole blood total lipid fatty acid compositions reflect the mixture of erythrocyte and plasma total lipids with fatty acid percentages falling intermediary of the two extremes.

### Convectional Versus Microwave Heat

The use of convectional heat at 90 °C for 60 min, convectional heat at 90 °C for 15 min and microwave heat at power level 4 for 45 s for the transesterification of lipid extracts from whole blood and fingertip prick blood on chromatography paper demonstrated significant differences in fatty acid composition (Fig. 1). Direct transesterification of fingertip blood by microwave methylation differed from the other methods to the greatest degree. Specifically, the

percentage of saturates was significantly higher and the percentage of monounsaturates were lower with direct microwave transesterification. Interestingly, prior lipid extraction of whole blood followed by microwave methylation resulted in values more similar to those obtained by transesterification mediated by convectional heat, suggesting that sample matrix was affecting microwave transesterification. In regards to PUFA, the differences were less pronounced. An additional experiment comparing microwave transesterification on whole blood lipid extract, whole blood dipped in chromatography paper, whole blood added directly to the solvent mixture, and fingertip prick blood on chromatography paper was completed (Fig. 2). Direct transesterification of fingertip prick blood on chromatography paper and whole blood without prior lipid extraction (on chromatography paper or directly

dropped in solvents) resulted in similar determinations which were different than when lipids were previously extracted. Individual fatty acid results are presented in detail in Supplementary Table I.

### Quantitative Determinations

Quantitative determinations of fatty acids ( $\mu\text{g/ml}$ ) in whole blood using convectional heating and microwave indicated a greater number of significant differences as compared to

when the data was expressed as a relative percentage of total fatty acids (Table 3). The total fatty acid concentration tended to be lower with microwave methylation (2180  $\pm$  46 vs. 1704  $\pm$  46,  $P = 0.052$ ). There was no difference in the concentration of total saturates, although there were significantly lower determinations of 22:0, 23:0 and 24:0, possibly reflecting lower rates of transesterification of sphingolipids. Total monounsaturated fatty acids as determined by microwave transesterification were significantly lower and only 58% of the total monounsaturates as determined by convectional heat. The determinations of

**Fig. 3** The amount of heptadecanoic acid (17:0) determined from triheptadecanoin (17:0 TG) and diheptadecanoyl phosphatidylcholine (17:0 PC) by transesterification with convectional and microwave heat. Values are means  $\pm$  SD,  $n = 4$ . \*Significantly different from convectional heat by paired  $t$ -test,  $P < 0.05$

PUFAs were also significantly lower with microwave with microwave determinations being only 68% of the convectional heat. Within the PUFAs, the 18 carbon PUFAs tended to reflect the determinations in monounsaturates with microwave determinations being only 60% of convectional heat while HUFA determinations by microwave were 75% of convectional determinations with no difference in the n-6 versus n-3 HUFAs. Interestingly, DMA estimates were slightly, but not significantly higher when prepared by microwave transesterification.

Direct transesterification of 17:0 TG and 17:0 PC standards by convectional and microwave heating indicated that convectional heating resulted in estimates relative similar to theoretical yields. Determinations by microwave heating tended to be lower than convectional heating for phospholipids ( $P = 0.06$ ), but were significantly lower for triacylglycerols ( $P = 0.01$ ) (Fig. 3).

#### Biomarkers of n-3 Status

Biomarkers of n-3 PUFA status were determined for all qualitative analyses including different blood fractions and different methodologies (Fig. 4). The range of values were:  $1.28 \pm 0.02$  to  $2.52 \pm 0.04$  for EPA + DHA;  $1.76 \pm 0.03$  to  $4.74 \pm 0.06$  for EPA + DPAn-3 + DHA;  $20.10 \pm 0.15$  to  $22.14 \pm 1.26$  for the % of n-3 HUFA in total HUFA; and  $0.073 \pm 0.001$  to  $0.168 \pm 0.003$  for n-3/n-6. The lowest value for each biomarker came from serum or plasma and the highest value came from erythrocytes, except for the % on n-3 HUFA in total HUFA. Expressing

values as the % of n-3 HUFA in total HUFA resulted in a much tighter range across methodologies. As a result, the lowest value (fingertip prick blood transesterified with convectional heat) was different only from the highest value (plasma phospholipid). The highest value (plasma phospholipid) was statistically similar to serum, plasma, erythrocyte and 15 min convectional transesterified whole blood lipid extract determinations.

Overall, microwave heating tended to result in slightly higher estimates in biomarkers of n-3 PUFA status as compared with convectional heating for 60 min, but differences were not consistent when compared to convectional heating for 15 min. When expressed as the % of n-3 HUFA in total HUFA, the increases with microwave heating were not present.

#### Discussion

The conventional methods for fatty acid determinations compared in the present study are by no means exhaustive, but were focused on incorporating several common methods used to estimate n-3 PUFA levels in human blood samples. Although a major focus was on examining the utility of microwave transesterification, the analysis of various blood fractions including fingertip blood were compared to promote a more comprehensive understanding of measures of n-3 PUFA. The use of microwave heating for transesterification of fatty acids for analysis by gas chromatography has potential, but it appears utility may be limited to rapid, qualitative estimates of n-3 PUFA status with some loss of precision and accuracy. Fingertip prick blood sample collection however, proved to be an effective and inexpensive method for whole blood sample collection when only total lipid fatty acid composition is of interest as demonstrated previously [20].

There is very limited literature examining the use of microwave energy for driving fatty acid transesterification reactions [23,32]. The present study is the first to document significant limitations in the use of microwave transesterification in place of convectional transesterification. The present study indicates that direct microwave transesterification of whole blood can result in significantly higher qualitative estimates of saturated fatty acids and lower estimates of monounsaturated fatty acids. Quantitative analyses indicate that the determination of saturated fatty acids by microwave transesterification is in fact similar to convectional heat, but that polyunsaturates and monounsaturates in particular are significantly underestimated. Very low determinations of monounsaturates (mainly 18:1n-9) and 18:2n-6 specifically among PUFAs suggested that transesterification rates may differ by lipid class. The use of 17:0 TG and 17:0 PC confirmed that microwave

**Fig. 4** Values of n-3 fatty acids biomarkers as determined from various blood fractions and by various analytical methods. Values are means  $\pm$  SD,  $n = 4$ . Bars with different alphabetical superscripts within a grouping are statistically different by Tukey's HSD after significant  $F$  value by one-way ANOVA,  $P < 0.01$

transesterification had significant discrepancies with the transesterification of triacylglycerols as compared with convectional heat. These differences may partly explain differences observed in quantitative and qualitative estimates of fatty acid composition. Microwave transesterification also resulted in lower determinations of fatty acids associated with sphingolipids such as 24:1n-9, a phenomenon previously observed and duplicated in the present study when BF<sub>3</sub>/MeOH direct transesterification by convectional heating is <60 min [21].

The use of microwave heating for the preparation of FAMES requires further research. In the present study, we were biased towards one-step direct transesterification methods that are more suitable for robotic automation. Whole blood is a challenging matrix to analyze given that it is a mixture of lipid classes with mono- and bi-layer membranes and various proteins. Limitations with the use of microwave heating may be reduced if other approaches are examined rather than just direct transesterification. Sample preparation techniques such as the isolation of individual lipid classes and the saponification of lipids prior to derivatisation may be more amenable to microwave based methylation. Increasing the percentage of BF<sub>3</sub> in methanol, or the use of catalysts other than BF<sub>3</sub>/MeOH

may improve quantitative fatty acid determinations with microwave transesterification. Using research scale microwave synthesizers appears relevant, although these instruments are considerable more expensive than household microwave ovens. These alternative approaches may however introduce other limitations such as an increase in sample handling time and the loss of free or esterified fatty acids in multi-step techniques, and the increased risk of generating methoxy-substituted fatty acids with higher BF<sub>3</sub> concentrations [33].

Despite the limitations of microwave driven transesterifications of blood samples, we have found that it has utility. Although the quantitative estimates by microwave transesterification were lower than by convection transesterification, the decrease in accuracy was consistent for n-3 and n-6 HUFAs. Therefore, when the data is expressed as the % of n-3 HUFA in total HUFA, the absolute values determined with microwave transesterification are very close to values determined by convectional heating. Therefore when direct microwave transesterification is combined with fingertip prick blood collection and fast gas chromatography [13,14] n-3 PUFA status for a single individual can be determined in under 30 min. This is quicker than dietary assessment tools, and is particularly

useful when screening research participants for n-3 PUFA intervention studies and other blood biochemical parameters are not of interest.

The present findings also support further consideration of the % of n-3 HUFA in total HUFA as a universal blood biomarker for n-3 HUFA status [24]. The tight range of this biomarker across various blood fractions and methods in the present study as compared to other markers provides a significant advantage in knowledge translation and public health targets. Adding 750 mg of EPA + DHA to the typical North American diet as proposed for significant cardioprotection [10] without changing in other fatty acid intakes should result in a % of n-3 HUFA in total HUFA of 44% using equations developed by Lands et al. [34]. A target of 40% of n-3 HUFA in total HUFA corresponds to a lower risk of mortality from myocardial infarction [35,36] and roughly corresponds to an EPA + DHA value of 8% of total fatty acids in erythrocytes [12].

The use of the % of n-3 HUFA in total HUFA as an n-3 biomarker, and microwave heating require further assessment. For the % of n-3 HUFA in total HUFA, determinations across individuals consuming a range of n-3 PUFA, and an assessment of the ability of this biomarker to predict disease risk are required. In addition, the % of n-3 HUFA in total HUFA largely characterizes the *sn*-2 position of membrane phospholipids [24] and therefore health/disease associations may be limited to *sn*-2 related physiological mechanisms. Fatty acid biological effects mediated by 18:2n-6 and 18:3n-3 for example, may not be represented by this biomarker. The use of direct microwave transesterification for preparation of FAMES also requires testing across a wider range of fatty acid compositions. Additional modifications and testing of microwave transesterification/methylation is definitely required, however it can serve as a rapid, qualitative assessment of n-3 fatty acid status. The potential application of cheap, rapid qualitative methods for clinical screening is dependent not only on further developments of such methods, but also continued efforts to associate n-3 biomarkers to disease risk so that healthy recommendations and targets can be made that will allow specificity and sensitivity evaluations of these high throughput, novel methods.

**Acknowledgements** Operating funds were provided by a start-up award from the University of Waterloo and infrastructure was purchased through a Canada Foundation of Innovation and the Ontario Research Fund matching grants. K.D.S. received partial salary support through a GENESIS Young Investigator Award and J.M.A held a NSERC Undergraduate Student Research Award for a portion of the study.

**Abstract** Stearoyl-CoA desaturase (SCD) catalyzes the formation of monounsaturated fatty acids from saturated fatty acids. It plays a key role in lipid metabolism and energy expenditure in mammals. In mice, four SCD isoforms (SCD1–4) have been identified. Here we report the identification of cDNA sequences corresponding to SCD1, SCD2 and SCD3 of golden hamster. The deduced amino acid sequences of these hamster SCD (hmSCD) isoforms display a high degree of homologies to their mouse counterparts (mouse SCD). Polyclonal antibodies specific to rodent SCDs detected proteins of predicted size in the human embryonic kidney 293 cells transfected with hmSCD cDNAs. Microsome fractions prepared from these cells also displayed increased SCD activity versus cells transfected with vector alone. Real-time reverse transcription-polymerase chain reaction analysis revealed the highest expression of hmSCD1 in liver and adipose tissue, while the highest hmSCD2 expression was detected in the brain. Very low levels of hmSCD3 mRNA can be detected in the tissues tested. This report is the first description of three SCD isoforms in the hamster and will provide useful

tools in the further study of fatty acids metabolism in this species.

**Keywords** Stearoyl-CoA desaturase · Hamster

## Abbreviations

Bp	Base pair(s)
cDNA	DNA complementary to RNA
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
HDL	High density lipoprotein
kb	Kilobase(s) or 1,000 bp
PCR	Polymerase chain reaction
RT	Reverse transcription
SCD	Stearoyl-CoA desaturase
TLC	Thin-layer chromatography
VLDL	Very low density lipoprotein
CDS	Coding sequence

## Introduction

Stearoyl-CoA desaturase (SCD) catalyzes the formation of monounsaturated fatty acids from long-chain saturated fatty acids [1]. In mammalian systems, this is the first committed step in the formation of unsaturated fatty acids. The mammalian SCD enzyme is an integrated endoplasmic reticulum (ER) membrane-protein. Its function requires two additional polypeptides: NADH-cytochrome b5 reductase and cytochrome b5. The SCD protein is comprised of over 62% non-polar amino acid residues and is largely embedded in the ER membrane, with active sites exposed to the cytosol. A site-directed mutagenesis study confirmed that clusters of histidine-rich motifs are required

for catalytic activity [2]. The preferred substrates for SCD are palmitoyl-CoA and stearoyl-CoA, which are converted into palmitoleoyl-CoA and oleoyl-CoA, respectively.

Recent studies suggest that mammalian SCD plays an important role in lipid metabolism and energy balance [3]. The naturally occurring SCD1-deficient mouse strains (asebia mouse) displayed impaired hepatic triglyceride and cholesterol ester biosynthesis, as well as a deficiency in wax ester and alkyl diacylglycerol. The SCD1<sup>-/-</sup> mice also have low plasma triglyceride levels in the very low density lipoprotein (VLDL) particle and reduced VLDL secretion from the liver. Dietary supplementation of triolein or tripalmitolein cannot normalize hepatic and plasma triglyceride levels [4]. SCD1<sup>-/-</sup> mice are also resistant to diet-induced weight gain and diabetes and display an attenuated obesity phenotype in a leptin-deficient background [5]. Human epidemiology studies have demonstrated a reverse correlation between hepatic SCD activity and plasma levels of high density lipoprotein (HDL) [6]. In cultured macrophage cells, SCD expression inhibited ABCA1-mediated cholesterol efflux [7]. It has been proposed that monounsaturated fatty acids phosphorylate and destabilized ABCA1 through a phospholipase D2 pathway [8]. Macrophages isolated from type 2 diabetic patients displayed increased SCD activity compared to non-diabetic controls, correlating with increased atherosclerosis risk in diabetes patients [9]. Taken together, these data suggest that SCD1 has potential implications in metabolic syndromes associated with dyslipidemia, obesity and type 2 diabetes.

Four SCD (SCD1–4) isoforms have been characterized in the mouse [10, 11]. All four mouse SCD (mSCD) genes are located in a 200 kb stretch on chromosome 19. It has been suggested that all the four mSCD genes are derived from tandem gene duplication events [10]. Two SCD isoforms have been identified in humans. Human SCD1 is the human ortholog of mSCD1 and displays similar tissue distribution [12]. Human SCD5 does not have a mouse ortholog, but displays a tissue distribution pattern similar to mSCD2 [13, 14].

The golden Syrian hamsters have been used as a valuable animal model for studying lipoprotein cholesterol metabolism and atherosclerosis. Compared to other rodent models, the hamster has the advantage of a lipoprotein profile similar to that of humans, largely due to the presence of the endogenous cholesterol ester transfer protein (CETP) activity [15]. Similar to humans, plasma non-HDL cholesterol and triglycerides levels increase in response to a diet rich in cholesterol and fatty acids in hamsters. Hamsters also develop early atherosclerosis lesions similar to those found in the early stages of human disease [16, 17]. Therefore, hamsters appear to be a good model to study the effect of SCD on lipoprotein cholesterol metabolism and the early stages of atherosclerosis. However, the

hamster SCD (hmSCD) isoforms and their expression patterns have not been reported.

Here we report the identification and characterization of hmSCD1, hmSCD2 and hmSCD3. We show that all three cDNAs encode polypeptides with SCD activity. Real-time reverse transcription (RT)-polymerase chain reaction (PCR) analysis shows that the tissue distribution of hmSCD isoforms is similar to that of mSCD's, with the highest expression of SCD1 detected in adipose tissue and liver, and highest SCD2 expression detected in brain. To our knowledge, this is the first report on the three hmSCD isoforms. The identification and characterization of the hmSCD isoforms should facilitate our study of lipoprotein metabolism in relation to fatty acid desaturation in this animal model.

## Materials and Methods

### Animals

Male golden Syrian hamsters were obtained from Harlan (Indianapolis, IN, USA) and housed individually in stainless steel suspended rodent cages with free access to normal rodent diet (Purina 5001) and water. For tissue collection, hamsters were sacrificed by CO<sub>2</sub> euthanasia. White adipose tissue, heart, brain, liver, kidney, intestine, lung and skeletal muscle samples were collected, rinsed in phosphate-buffered saline, quick frozen in liquid nitrogen and stored at –80 °C. Use of hamster was approved by the Institutional Animal Care and Use Committees of the American Association for Accreditation of Laboratory Animal Care and Lilly Research Laboratories in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals.

### Cloning of Hamster SCD cDNAs

Gene-specific primers corresponding to regions of the translation start and termination codons of hmSCD1 and hmSCD2 were designed using the cDNA sequences of mouse and rat SCD isoforms. The forward primer for hmSCD1 is 5'-ATGCCGGCCCACATGCTCCAAGAGAT, and the reverse primer for hmSCD1 is 5'-TCAGC-TACTCTTGTGACTCCCGTCTCCA; the forward primer for hmSCD2 is 5'-ATGCCGGCCCACATACTGCAAGAGATG and the reverse primer for hmSCD2 is 5'-GAACAGGAAGTCAAGACCCACACTC. Gene-specific primers corresponding to regions of the translation starting and termination codons of hmSCD3 were designed according to the cDNA sequence of published hmSCD3 (FAR-17c). The forward primer for hmSCD3 is 5'-GCCACCATGCCAGG

ACACTTGCTAC and reverse primer for hmSCD3 is 5'-TC AGCCACTCTTGCAGCTCCCATCTCC.

The PCR was performed using the high-fidelity pfx DNA polymerase (Invitrogen, Carlsbad, CA, USA) and the gene-specific primers with cDNA prepared from hamster liver or brain as template. PCR reaction products were directly cloned into the pCRII-TOPO vector (Invitrogen, Carlsbad, CA, USA). Three clones for each gene were amplified and sequenced. In all genes, 100% consensus was reached among different clones for each gene.

For subcloning into mammalian expression vectors, each hmSCD cDNA was cut from the pCRII-TOPO vector with appropriate restriction endonucleases, separated on a 1.2% agarose gel and purified with the Qiaquick gel purification kit from Qiagen (Valencia, CA, USA). The purified cDNA fragments were ligated into the similarly restriction-digested mammalian expression vector pcDNA3.1 and transformed into H101B competent cells (Invitrogen, Carlsbad, CA, USA). The resulting subcloned products, pcDNA3.1-hmSCD1, pcDNA3.1-hmSCD2 and pcDNA3.1-hmSCD3, were confirmed by restriction digestion.

#### Real-time Polymerase Chain Reaction

Total RNA from hamster tissue samples was isolated using the Trizol reagent following protocols recommended by the manufacturer (Invitrogen, Carlsbad, CA, USA). RNA samples were treated with DNase I and extracted with phenol/chloroform to remove any contaminating genomic DNA. The first strand cDNA was prepared by RT with 2 µg of RNA in a 20 µl reaction volume using the Superscript II kit (Invitrogen). Quantitative sequence detection was carried out on an ABI PRISM 7700 instrument (Applied Biosystems, Foster City, CA, USA) using the Universal Master Mix from Applied Biosystems following recommended conditions (Applied Biosystems Foster City, CA, USA). The nucleotide probes and primers for hmSCD1, hmSCD2, hmSCD3 and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were designed using Primer Express version 2.0 (Applied Biosystems), and were synthesized by Operon Biotechnologies, Inc. (Huntsville, AL, USA). Primer and probe sequences are listed in Table 1. The PCR cycle number at which each assay target reached the threshold detection line ( $C_t$  value)

for each gene was determined. The difference in  $C_t$  value ( $\Delta C_t$ ) between each SCD isoform ( $unkn-C_t$ ) and GAPDH ( $GAPDH-C_t$ ) was calculated as  $\Delta C_t = unkn-C_t - GAPDH-C_t$ . The relative abundance of mRNA normalized against that of GAPDH for each SCD isoform in each sample was calculated using the following equation: relative mRNA level =  $2^{\Delta C_t}$ . The difference in  $\Delta C_t$  value ( $\Delta \Delta C_t$ ) between SCD isoforms was used to compare mRNA abundance between different SCD isoforms in the same tissue using the formula  $\Delta \Delta C_t = unkn1 \Delta C_t - unkn2 \Delta C_t$ .

#### Statistical Methods

For the analysis of hmSCD mRNA levels in hamster tissues, same tissue samples from two different animals were collected and RNA isolated separately. RT-PCR reaction was run as quadruplicate for each RNA sample.  $C_t$  values and relative mRNA abundance were calculated for each PCR reaction. Mean values and standard deviations were calculated from the eight  $\Delta C_t$  values using the  $\Delta \Delta C_t C_t$  as described [18].

#### Cell Transfection, Immunoblotting and Stearoyl-CoA Desaturase Activity

Human embryonic kidney (HEK) 293 cells grown on 10 cm culture dishes were transiently transfected with plasmid DNA using Lipofectamine reagent (Invitrogen) following the recommended protocol. Cells were collected 48 h after transfection and microsomes were prepared using the differential centrifugation method as described earlier [13]. Microsome fractions were re-suspended in buffer A (50 mM Tris pH. 7.5, 250 mM sucrose, 1 mM EDTA and 0.1 mM DTT) and stored at  $-80^\circ\text{C}$  until use.

Microsome membranes (40 µg) were separated on a pre-cast 10% SDS polyacrylamide gel (Invitrogen) and transferred to nylon membranes. Immunoblotting analysis was performed with goat polyclonal antibodies SC-14720 and SC-14722 from Santa Cruz Biotechnology (Santa Cruz, CA, USA) followed by Alexa Fluor 680-conjugated goat anti-rabbit IgG (Invitrogen). Immunoblots were developed

**Table 1** Primer and probe sequences used in real-time RT-PCR reaction

	Forward primer	Reverse primer	Probe
HmSCD1	ctccggaagcctgcagaat	ggcggatgtcttctcca	cgggagaagcagaagaccgttccc

and visualized with the Odysse Infrared Imaging System (Li-Cor Inc, Lincoln, NE, USA).

The thin-layer chromatography (TLC) method was employed for the measurement of desaturase activity using  $^{14}\text{C}$ -labeled stearoyl-CoA as substrate (55  $\mu\text{Ci}/\mu\text{mol}$ , ARC, St Louis, MO, USA) as described earlier [13]. Each reaction mixture contained 0.2  $\mu\text{Ci}$  of  $^{14}\text{C}$ -labeled stearoyl-CoA and 50  $\mu\text{g}$  of microsome fraction from transfected cells. Saturated and monounsaturated fatty acid methyl esters were separated by 10%  $\text{AgNO}_3$ -impregnated TLC using hexane/diethyl ether (9:1) as developing solution. Following chromatography, the plate was air dried and exposed to a phosphor image screen. A Molecular Imager FX equipment (Bio-RAD, Hercules, CA, USA) was used to visualize and quantify the  $^{14}\text{C}$ -labeled fatty acids. Band intensities corresponding to saturated and monounsaturated fatty acids were used to calculate the percentage of conversion and enzyme activity.

## Results

### Cloning and Identification of Hamster Stearoyl-CoA Desaturase Isoforms

We first attempted to see if hmSCD sequences are available in the National Center for Biotechnology Information database. In the database, one cDNA sequence (FAR-17c, L26956) is described as golden hmSCD. FAR-17c was initially identified as an mRNA induced by androgen in male golden hamster's flanking tissue [19] but displayed high homology to mSCD1. Therefore, it was listed as hmSCD. However, a more detailed sequence alignment of the amino acid sequence of FAR-17c with that of mSCD isoforms revealed that it is more closely homologous to mSCD3 than to mSCD1 and mSCD2. The sequence of the first 10 amino acids in the N-terminal of FAR-17c is MPGHLLEEM, which is 100% identical to that of mSCD3. In contrast, the sequence of first 10 amino acids of mSCD1 and mSCD2 are MPAHMLQEIS and MPAHILQEIS, respectively. The predicted amino acid sequence of FAR-17c is 91.2% identical to that of mSCD3, but only 86.2% identical to mSCD1 and 82.5% to mSCD2. These data suggest that FAR-17c is the golden hamster ortholog of mSCD3.

Alignment of the nucleotide sequences showed more than 90% homology between the mouse and rat SCD1 and also between mouse and rat SCD2. The first 25 nucleotides of mSCD1 coding sequence (CDS) are 100% identical to those of rat SCD1. The last 25 nucleotides of mSCD1 CDS differ from those of rat SCD1 by only one nucleotide. Similarly, there is only one nucleotide difference found in the first 25 nucleotides of mouse and rat SCD2 CDS. Since

golden hamster DNA sequences are also very homologous to that of mouse and rat, we speculated that the first and last 25 nucleotides of hmSCD1 and hmSCD2 would be also highly homologous to those of mouse and rat SCD1 and SCD2. To clone the hmSCD1 and hmSCD2 cDNA, we designed primers according to the first and last 25 nucleotides of rat SCD1 and SCD2 CDS. PCR was performed using the pfx DNA polymerase and cDNA libraries prepared from mRNA of hamster liver and brain tissues, respectively. PCR products were directly cloned into the PCR cloning vector pCRII-TOPO. Plasmid DNA was isolated from several clones of each PCR reaction and sequenced. In all three SCD isoforms, 100% consensus was reached among different clones for each gene.

Figure 1 shows the predicted amino acid sequences of hmSCD1, hmSCD2 and hmSCD3. The hmSCD1 cDNA has an open reading frame (ORF) with a predicted peptide of 358 amino acids. The predicted hmSCD1 peptide is 94.1% identical to the amino acid sequence of mSCD1 and 92.5% identical to that of rat SCD1. The hmSCD2 cDNA has an ORF with a predicted peptide of 359 amino acids. The predicted hmSCD2 peptide is 94.7 and 96.1% identical to the amino acid sequences of mouse and rat SCD2, respectively. The hmSCD3 cDNA has an ORF with a predicted peptide of 354 amino acids and is 91.2% identical to that of mSCD3. Table 2 shows the identity and similarity among the predicted amino acid sequences of the various rodent SCD isoforms. The nucleotide sequences of hmSCD1 and hmSCD2 cDNA have been submitted to Genbank under the accession number EU003989 and EU003990, respectively.

### Expression and Enzymatic Activities of Hamster SCD Isoforms

To determine if the hmSCD cDNA's we cloned code for active SCDs, these cDNA's were subcloned into mammalian expression vector pcDNA3.1. HEK 293 cells were transiently transfected with either vector DNA or plasmid DNA encoding the three hmSCD isoforms. Microsome fractions were prepared from these transfected cells and immunoblotting analysis was performed. Figure 2a shows the immunoblotting data using a goat polyclonal antibody specific for SCD1 and SCD3 of mouse and rat (SC-14720). A polypeptide about 40 kDa was detected in 293 cells transfected with either hmSCD1 or hmSCD3. These bands likely represent the hmSCD1 and hmSCD3, respectively, because the same antibody detected bands of similar size in cells transfected with rat SCD1 and SCD3 (data not shown). SC-14720 also detected a faint band at the same size in both vector and pcDNA-hmSCD2 transfected cells. These bands likely represent the endogenous human SCD1

**Fig. 1** Alignment of the predicted amino acid sequences of hamster SCD1 (*hmSCD1*), hamster SCD2 (*hmSCD2*), hamster SCD3 (*hmSCD3*), mouse SCD1 (*mSCD1*), mouse SCD2 (*mSCD2*) and mouse SCD3 (*mSCD3*). protein in 293 cells because the band in vector (pcDNA3) transfected cells has a similar intensity to that appearing in cells transfected with pcDNA-hmSCD2. A different antibody, SCD-14722 was used to detect the hmSCD2 in 293 cells. This antibody was raised against mSCD2 and it

detected a 40 kDa band present only in 293 cells transfected with pcDNA3.1-hmSCD2 (Fig. 2b).

The TLC method was employed for the measurement of desaturase activity using <sup>14</sup>C-labeled stearoyl-CoA as substrate. As shown in Fig. 2c, the microsomal fraction

**Fig. 2** Expression and enzymatic activity of hamster SCD isoforms. **a** Microsome fractions (40  $\mu$ g) from HEK 293 cells transiently transfected with pcDNA3.1 (*vector*), pcDNA3.1-hmSCD1 (*SCD1*), pcDNA3.1-hmSCD2 (*SCD2*) or pcDNA3.1-hmSCD3 (*SCD3*) were separated on a SDS-PAGE gel and probed with an antibody recognizing the N-terminal peptide of mouse SCD1. The molecular weight markers indicated are alcohol dehydrogenase (41 kD) and

BSA (71 kD). **b** Immunoblotting analysis of the same microsome fractions with a SCD2-specific antibody. **c** Representative images of TLC plates showing the substrate and product of the SCD reaction using microsome fraction of 293 cells transfected with pcDNA3.1 (*vector*), pcDNA3.1-hmSCD1 (*hmSCD1*), pcDNA3.1-hmSCD2 (*hmSCD2*) and pcDNA3.1-hmSCD3 (*hmSCD3*). Positions of the methyl esters of  $^{14}$ C-labeled stearic acid and oleic acid are marked

prepared from 293 cells transfected with the various hmSCD cDNA isoforms displayed increased SCD activity compared to microsomes from vector-transfected cells. Each reaction mixture contained same amount of microsome fraction as judged by total protein concentration. Due to the potential different reactivity of SCD antibodies used toward different hmSCD isoforms, as well as different transfection efficiency, we could not accurately assess if similar amount of SCD proteins are present in each reaction. Thus, a quantitative comparison of enzyme activity between the different hmSCD isoforms was not possible. Nevertheless, our data suggest that all three hmSCD isoforms encode proteins with functional SCD activity.

#### Tissue Distribution of Hamster SCD mRNAs

To determine the tissue distribution of the three hmSCD isoforms, specific real-time PCR primers and probes for the three hmSCD isoforms were designed in regions that differ among the three cDNA sequences. Total RNA was isolated from white adipose tissue, brain, heart, liver, lung, kidney, intestine and skeletal muscle of hamsters. First strand cDNA was synthesized with the Superscript cDNA synthesis kit (Invitrogen). Real-time PCR reactions were carried out using the isoform-specific primers and probes and cDNA prepared from different hamster tissues. Quadruplicates PCR reaction was run for each cDNA samples.

The relative mRNA levels of different SCD isoforms in different tissues were calculated from  $C_t$  values of each PCR reaction normalized using the  $C_t$  value of GAPDH from the same cDNA prep. As shown in Fig. 3a, the highest hmSCD1 mRNA level was detected in white adipose tissue and liver. The highest SCD2 mRNA levels were detected in the brain, white adipose tissue and liver

(Fig. 3b). In general, SCD3 mRNA was detectable in several hamster tissues including liver, lung and white adipose tissue (Fig. 3c). However, the overall level of SCD3 mRNA was very low with the  $C_t$  values nearing the lower limit of detection (40 cycles). Therefore, the comparison of SCD3 mRNA level between different tissues might not be accurate.

We also tried to determine the relative abundance of each hmSCD isoforms in the same tissue by comparing delta  $C_t$  values in each tissue. Figure 4 shows the comparative mRNA levels of each SCD isoform in white adipose tissue, brain and liver. While SCD1 was the predominant isoform expressed in hamster white adipose tissue and liver (Fig. 4a, c), SCD2 mRNA seemed to be the predominant isoform in the brain (Fig. 4b). On the other hand, mRNA levels of hmSCD3 were very low compared to either hmSCD1 or hmSCD2 in all the tissues tested.

#### Discussions

Among the rodent species, the hamster is the species with lipid metabolism most similar to humans. It has been a widely used as animal model for the study of dyslipidemia and atherosclerosis [15]. Unlike the mouse or rat, the hamster has lower plasma HDL levels due to the presence of endogenous CETP activity [20]. It has been used to study the effects of bile acid sequestrants,  $\alpha$ -1 adrenergic inhibitor and doxazin on lipid levels and aortic fatty streak formation. The HMG-CoA reductase inhibitor lovastatin has been shown to inhibit the formation of atherosclerotic lesions in hamsters fed a high-fat diet [16].

The SCD is a key enzyme in lipid metabolism in mammals. Four SCD isoforms have been identified from the mouse and rat. Only one SCD isoform has been

**Fig. 3** Tissue distribution of hamster SCD mRNA's determined by real-time quantitative PCR analysis. **a** Histogram shows the relative mRNA levels of hmSCD1 in adult hamster white adipose tissue (*W*), brain (*B*), heart (*H*), kidney (*K*), intestine (*In*), liver (*Li*), lung (*Lu*) and skeletal muscle (*Mu*). The relative mRNA abundance was calculated by the delta  $C_t$  ( $\Delta C_t$ ) method using mRNA of GAPDH as internal standard. For each tissue, two samples from two different animals were analyzed and quadruplicate PCR reactions were run for each

sample. Mean values and standard deviations were calculated from the eight  $\Delta C_t$  values representing the two tissue samples. The mRNA level of hmSCD1 in white adipose tissue was set at 100. **b** Relative mRNA levels of hmSCD2 in adult hamster tissues. described in the hamsters (FAR-17c). In this report, we describe for the first time the identification and characterization of hmSCD1, hmSCD2 and hmSCD3. The predicted amino acid sequences of hmSCD1, hmSCD2 and hmSCD3 displayed high degree of homology to their mouse or rat orthologs. Using a real-time RT-PCR method, we showed that the expression pattern of hmSCD1, hmSCD2 and hmSCD3 is similar to their mouse counter parts. Finally, we presented data showing that all three hmSCD isoforms encode proteins with functional SCD activity.

Sequence analysis revealed that the previously cloned FAR-17c is the hmSCD3. FAR-17c was originally cloned as an androgen-dependent gene in the flank organs of hamster [19]. Northern blot analysis detected a band that migrated similarly to 18S RNA in the sebaceous glands and liver, and weakly in the lungs. There was also a strong band at the 28S position in the brain tissue of female hamster. However, the Northern blot analysis for FAR-17c was performed using the full length hmSCD3 cDNA as probe. Due to the high level of homology at the nucleotide sequence level in the CDS region of hmSCD isoforms, it is

possible that the full length SCD3 cDNA probe could also detect SCD1 and SCD2 mRNA. Zheng et al. [11] reported tissue distribution data of mSCD1, mSCD2 and mSCD3 using cDNA's corresponding to the respective 5' UTR region as probes. They show that SCD3 expression is limited to mouse skin, whereas the highest SCD1 mRNA level was detected in liver and the highest SCD2 mRNA level was detected in brain. To accurately measure the relative mRNA level of the hmSCD isoforms, we designed our real-time PCR primers and probes in regions that displayed the least homology among the three cDNA sequences. The tissue distribution pattern of hmSCD isoforms measured through our real-time PCR method is very similar to the reported expression pattern of SCD isoforms in the mice [10, 11].

Mouse SCD4 has been shown to be expressed exclusively in the heart and its expression is induced by a high-carbohydrate fat-free diet and by a liver-X-receptor agonist in mice [10]. The rat ortholog of mSCD4 has not been published. However, one cDNA sequence in Genbank (XM\_574671) shows the highest homology to mSCD4 and

**Fig. 4** Relative mRNA level of different SCD isoforms in adult hamster white adipose tissue, brain and liver. **a** Histogram shows the relative mRNA levels of hmSCD1, hmSCD2 and hmSCD3 in adult hamster white adipose tissues. The mRNA level of hmSCD1 in white adipose tissue was set at 100. **b** Histogram shows the relative mRNA

levels of hmSCD1, hmSCD2 and hmSCD3 in adult hamster brain. The mRNA level of hmSCD2 in brain tissue was set at 100. **c** Histogram shows the relative mRNA levels of hmSCD1, hmSCD2 and hmSCD3 in adult hamster liver. The mRNA level of hmSCD1 in liver was set at 100

is probably the rat ortholog of SCD4. We attempted several PCR reactions using primers corresponding to regions of translation start and termination codes of XM\_574671. However, this effort did not yield any successful cDNA clones. Thus, we have not been able to clone the hamster ortholog of mSCD4 at the present time.

Ideta et al. [19] reported no desaturase activity from the African green monkey kidney cells (COS7) transfected with a expression vector encoding FAR-17c cDNA under the control of SV40 promoter. Using the TLC method and <sup>14</sup>C-labeled stearoyl-CoA as substrate, we investigated the desaturase of the three hmSCD cDNAs. The microsome fraction from HEK 293 cells transfected with the hmSCD1, hmSCD2 and hmSCD3 displayed increased SCD activities compared to microsome fraction from HEK 293 cells transfected with the vector alone. Additionally, antibody specific to rodent SCD protein detected polypeptides with predicted size from the transfected cells. These data suggest that all three hmSCD isoforms reported here encode polypeptides with functional SCD activities. Using the microsome fraction from Hela cells transfected with cDNA of different mSCD isoforms, Miyazaki et al. [21] reported that mSCD1, mSCD2 and mSCD4 can use both palmitoyl-coenzyme A (16:0) and stearoyl-coenzyme A (18:0) as substrate whereas mSCD3 can only use palmitoyl-coenzyme A as substrate [21]. Our data suggest that hmSCD3 can also use stearoyl-coenzyme A as substrate under our experimental conditions. The discrepancy between these two studies is not clear at this time. The difference in the cell-type used between the two reports might contribute to the different results. It is also possible that hmSCD3 prefer palmitoyl-coenzyme A (16:0) as substrate but can also use stearoyl-coenzyme A (18:0) in the absence of palmitoyl-coenzyme A. Further studies are needed to determine the substrate selectivity of hmSCD isoforms.

Two SCD isoforms, SCD1 and SCD5 have been identified in humans. Human SCD1 showed the highest level of homology to mouse and rat SCD1 and displayed a similar expression pattern as mSCD1. The expression pattern of hmSCD1 shown here is also similar to that of human and mSCD1 with the highest expression detected in adipose tissue and liver. SCD1 null mice [5] are resistant to high fat diet-induced adiposity and insulin resistance. They also displayed greatly reduced plasma VLDL and triglyceride levels, but no significant changes in LDL and HDL cholesterol level. Since cholesterol metabolism in hamster displayed more similarity to that of humans, it would be interesting to investigate the effect of SCD1 inhibition on cholesterol metabolism and the development of atherosclerosis in hamster under hypercholesterolemic conditions.

The highest mRNA level of hmSCD2 was detected in the brain of adult hamster (Fig. 4b). This expression pattern is

similar to that of mSCD2 in adult mice and SCD5 in adult human and bovine [22]. In the mice, SCD2-deficient resulted in a skin permeability barrier defect in the neonates. Compared to wild type mice, plasma triglycerides levels decreased in the neonatal mSCD2<sup>-/-</sup> mice but not adult mSCD2<sup>-/-</sup> mice [23]. These data suggest that mSCD2 is required for the liver and skin development during embryonic and neonatal stages. Adult mSCD2<sup>-/-</sup> mice displayed twisted tail suggesting SCD2 is also required for normal tail development. However, neuronal defect was not described in the SCD2<sup>-/-</sup> mice. Thus the function of rodent SCD2 or human and bovine SCD5 in central nervous system of adult animals remains to be delineated.

The mRNA levels of hmSCD3 was very low or barely detectable in the tissue we tested that include adipose tissue, brain, heart, liver, kidney, lung, intestine and skeletal muscle. In the mice, it was reported that SCD3 expression was limited to the skin [11]. We did not test the skin tissues of hamster for SCD3 expression at the current study. Future studies are needed to understand the expression and function of hmSCD3.

In summary, here we report for the first time the identification of hmSCD1 and hmSCD2. We also show that the previously identified hmSCD (FAR-17c) is the hmSCD3. The identification and characterization of hmSCD isoforms will provide useful tools in our study of lipoprotein metabolism and atherosclerosis in this animal model.

**Abstract** The  $\Delta 9$ -fatty acid desaturase is a key enzyme in the synthesis of unsaturated fatty acids. The fatty acid composition of membrane phospholipids in *Psychrobacter urativorans* is characterized by a high degree of desaturation at  $\Delta 9$  position. Based on CODEHOP-mediated PCR strategy, a novel gene designated as *PuFAD9*, putatively encoding a  $\Delta 9$ -fatty acid desaturase (*PuFAD9*), was isolated from *P. urativorans*. The gene consists of 1,455 bp and codes for 484 amino acids. Analysis of the amino acid sequence reveals three histidine clusters and a hydrophathy profile, typical for membrane-bound desaturases. Activity of the *PuFAD9* protein, recombinantly expressed in *Escherichia coli* was confirmed by GC-MS analysis of the cellular fatty acid composition. It was found that the ratio between palmitoleic and palmitic acid in *E. coli* cells heterologously expressing the *PuFAD9* gene was significantly affected by IPTG induction and the growth temperature.

### Introduction

Fatty acid desaturases belong to a family of enzymes that catalyze  $O_2$ -dependent dehydrogenation [1]. They have been found in prokaryotes, lower and higher eukaryotes [2]. There are three classes of fatty acid desaturases: soluble acyl carrier protein desaturases, membrane-bound acyl-CoA desaturases and acyl-lipid desaturases. Despite the differences in cellular localization and substrate spectra, three classes of desaturases share several common characteristics regarding their reaction mechanism, including the requirement of molecular oxygen, NAD(P)H, an electron transport system (ferredoxin-NADP<sup>+</sup> oxidoreductase and ferredoxin, or cytochrome *b*<sub>5</sub> reductase and cytochrome *b*<sub>5</sub>) [3]. Each fatty acid desaturase creates an unsaturated bond at a fixed position by “counting” from the carboxyl end of the fatty acids. Incorporation of the first *cis*-double bond at the central (C9–C10) position catalyzed by  $\Delta 9$ -desaturases has an essential effect on membrane physical properties [4], because the balance between saturated and unsaturated fatty acids (UFAs) is, probably, of higher importance than the type of UFA in membrane phospholipids [5]. This event is also a crucial step in polyunsaturated fatty acid (PUFA) synthesis pathways, since all other desaturases require the existence of a previous double bond at the  $\Delta 9$  position of the fatty acid [6]. Although a number of integral membrane or membrane-bound  $\Delta 9$ -desaturase genes have been isolated [7] and the related information was submitted to the public databases, these enzymes are less well understood than the soluble  $\Delta 9$ -ACP desaturases. One of the reasons for that is the difficulties in obtaining sufficient quantities of these purified enzymes [8]. Heterologous expression of membrane proteins in appropriate hosts would provide

enough material for biochemical analysis and the analysis of their structure–function relationships [9–12].

*Psychrobacter urativorans* DSM 14009 (formerly named as *Micrococcus cryophilus* ATCC 15174) has an unusual fatty acid composition of its membrane phospholipids, containing at least 95% monounsaturated fatty acids (C16:1 $\Delta$ 9 and C18:1 $\Delta$ 9) [13]. The desaturase activity and regiospecificity of *P. urativorans* were studied in in vivo experiments, revealing the presence of a highly active and membrane-bound  $\Delta$ 9-fatty acid desaturase [14–16]. In this study, we report identification and cloning of a gene from *P. urativorans* encoding for  $\Delta$ 9-fatty acid desaturase and its functional characterization by heterologous expression in *Escherichia coli*.

## Experimental Procedures

### Chemicals and Enzymes

All chemicals were purchased from Fluka (Buchs, Switzerland). Restriction endonucleases, T4 DNA ligase, Taq DNA polymerase and Pfu DNA polymerase were obtained from Fermentas (St Leon-Rot, Germany).

### Bacterial Strains

*P. urativorans* DSM 14009 was purchased from the German Resource Center for Biological Material (DSMZ, Braunschweig, Germany). *E. coli* DH5 $\alpha$  (Clontech, Staint-Germain-en-Laye, France) strain was routinely used for gene cloning and plasmid propagation. *E. coli* Rosetta (DE3) (Novagen, Merck Chemicals Ltd., Nottingham, UK) supports translation of rare codons and therefore was used as host for heterologous expression of the desaturase from *P. urativorans*. All strains were stored and cultivated as recommended by the suppliers.

### PCR-Based Cloning

Genomic DNA of *P. urativorans* was isolated using the standard phenol/chloroform precipitation protocol [17]. Degenerate primers were designed using CODEHOP strategy (<http://bioinformatics.weizmann.ac.il/blocks/codehop.html>) as follows: DE1 (CGGATCCACCACA GGCANGTNGAYRA) and DE2 (CGAAGATGTGGTGG AAGTTGTGRTANCCYTC). They were used for the CODEHOP PCR and demonstrate high identity to certain regions of putative *Psychrobacter arcticus* 273-4 (GenBank accession no. YP\_264647) and *Psychrobacter*

*cryohalolentis* K5 desaturases (GenBank accession no. YP\_580264).

Subsequently, the primers EX1 (CACCTACTATAA TCCATACAAGTTATTGTTAT) and EX2 (GATAGAGG GAAGGAGAARCGT) were derived from the flanking regions of those two genes. MD1 (GTTCTATCTTTAGT-CAAGTCTGGAATGT) and MD2 (CGCTTAGTATTGA CTCACCATTTCACT) are the gene-specific primers derived from the DNA fragment obtained by the CODEHOP PCR. Another two PCR reactions were carried out using the primers EX1 and MD1, and EX2 and MD2, respectively, to get the information of the whole gene sequence. Gene fragments, obtained after each PCR were purified by gel-extraction (QIAGEN, Hilden, Germany) and sequenced directly or after ligation into the vector of pGEM<sup>®</sup>-T Easy (Promega, Mannheim, Germany).

### Sequence Analysis

Sequence analysis was carried out using a BLAST search program (<http://www.ncbi.nlm.nih.gov/blast/>). Multiple sequence alignment of putative  $\Delta$ 9-desaturases was performed with Clustalx1.81 [18]. The distribution of the hydrophobic amino acids was analyzed using Kyte–Doolittle hydropathy scale with a window size of 19 (<http://www.expasy.ch/cgi-bin/protscale.pl>) [19]. Transmembrane (TM) regions of the protein were predicted with TMHMM (transmembrane Hidden Markov Model) (<http://www.cbs.dtu.dk/services/TMHMM/>) [20]. The signal sequence analysis was done using a signal peptide prediction server (<http://www.cbs.dtu.dk/services/SignalP-3.0/>) [21].

### Construction of Plasmid for Gene Expression in *E. coli*

The full-length gene encoding a desaturase-like protein from *P. urativorans* was amplified by PCR using primers McB (CGGGATCCATGATTGCAAAAACAGCAAT) and McX (CCGCTCGAG TACTAAGCGGCTTTGCT). The *Bam*HI and *Xho*I restriction endonuclease sites in the primer sequences are underlined. The PCR product was isolated and digested with *Bam*HI and *Xho*I restriction endonucleases and then ligated into the pET21a(+) expression vector (Novagen, Darmstadt, Germany). Positive transformants were screened on LB agar plates with ampicillin and chloromycetin resistance. The resultant positive plasmid, named as pEPUD9, was validated by control PCR, restriction enzyme digestion and subsequent sequencing.

### Expression of Desaturase from *P. urativorans* in *E. coli*

Individual colonies of *E. coli* Rosetta (DE3) cells transformed with the plasmid pEPUD9 were grown in 5 mL LB medium containing 100 µg/mL ampicillin and 34 µg/mL chloramphenicol at 37 °C until OD<sub>600</sub> reached approximately 1. Then aliquots of the cultures were taken to inoculate 400 mL of fresh LB medium supplemented with corresponding antibiotics. Cells were cultivated until the OD<sub>600</sub> value reached 0.6–0.8, then IPTG was added at a final concentration of 0.4 mM and the incubation was shifted to different temperatures (15, 25 and 37 °C). At various intervals after addition of IPTG, the cells were harvested from 50 mL culture. Centrifugation was done at 5,000g for 15 min at 4 °C. The pellets were washed once with MOPS–NaOH buffer (pH 7.5, 50 mM) that contained 10 mM MgCl<sub>2</sub>, and stored at –80 °C until use. Control experiments were performed under the same experimental conditions using *E. coli* transformants containing empty plasmid pET21a(+).

### Preparation of Membranes

The frozen cells were thawed at room temperature and resuspended in appropriate volume of lysis buffer (MOPS–NaOH buffer (pH 7.5, 50 mM) containing 10 mmol/L MgCl<sub>2</sub>, 1 mmol/L PMSF, 0.1 U/mL DNase) and lysed by sonication. The lysate containing soluble proteins and solubilized membranes was clarified by centrifugation at 16,100g for 15 min at 4 °C. The supernatant was subjected to ultracentrifugation at 100,000g for 40 min at 4 °C to separate membrane and soluble protein fractions.

### Gel-Electrophoresis and Western Blotting Analysis

Aliquots of soluble, insoluble, and membrane fractions were analyzed for protein expression by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) [22] on a 12% polyacrylamide gel followed by either Coomassie staining or Western blotting. For the latter detection method, the bands were transferred onto a nitrocellulose membrane using a Trans-Blot SD Semi-Dry Electrophoretic Transfer Cell (Bio-Rad, Munich, Germany) at a constant voltage of 15 V for 30 min at room temperature. The blotting and detection were done using T7 tag antibody HRP conjugate (Novagen, Merck Chemicals Ltd., Nottingham, UK) according to the manufacturer's instructions.

### Analysis of Total Cellular Fatty Acid Composition

About 40 mg of *E. coli* cells (wet weight) were resuspended in 1 mL of 15% (w/v) NaOH in methanol/water

(1:1, by vol) and saponified according to the MIDI protocol (Microbial Identification System, Microbial ID Inc., Newark, DE, USA). After saponification, the pH of reaction solution was adjusted to 2.0 with HCl (aq). Then, the fatty acids were extracted with diethyl ether. The extract was subsequently dried over anhydrous magnesium sulfate and trimethylsilyl (TMS)-derivatized. TMS derivatives were separated and analyzed by Gas chromatography-mass spectrometry (GC-MS) (GCMS QP2010, Shimadzu, Japan). The GC was equipped with a 30-m FS-supreme column (internal diameter 0.25 mm, film thickness 0.25 µm) using helium as carrier gas with a linear velocity of 30 cm/s. The column temperature program was composed of an initial hold at 140 °C for 1 min, ramping at 2 °C per min to 240 °C, followed by heating until 300 °C with 30 °C per min, and a final hold at 300 °C for 6 min. The injector temperature was 250 °C.

## Results

### Cloning of the *PuFAD9* Gene

A DNA fragment of about 400 bp was amplified from *P. urativorans* using CODEHOP primers DE1 and DE2 [23], which were derived from two sequences, RIHHKHVDD and EGYHNFHHIF corresponding to the highly conserved histidine motifs of putative Δ<sup>9</sup>-desaturases in *P. cryohalolentis* K5, *Pseudoalteromonas haloplanktis* TAC125 and other strains shown in Fig. 1. The amplified DNA-fragment showed a high identity to putative desaturase genes in *P. cryohalolentis* K5 (84%) and *P. arcticus* 273-4 (83%). For identification of the unknown parts of the gene, two subsequent PCR reactions were carried out using primers EX1 and MD1, EX2 and MD2 (see “[Experimental Procedures](#)”). After the full gene sequence was deduced from the sequences of the three PCR products, the resulting sequence information was confirmed by sequencing both strands of the target gene and submitted to GenBank (accession no. EF617339). The nucleotide sequence had an open reading frame of 1,455 bp, designated as *PuFAD9*, encoding a 484 amino acid polypeptide with a calculated molecular weight of 55 kDa and a theoretical isoelectric point of 8.88.

### Comparison of Amino Acid Sequences

A Blast search revealed that the primary structure of the putative desaturase from *P. urativorans* was quite similar to those of other known Δ<sup>9</sup>-fatty acid desaturases, with a 79% identity to *P. arcticus* 273-4, a 78% identity to *P. cryohalolentis* K5, a 67% identity to *Psychrobacter* sp.

**Fig. 1** Multiple alignments of amino acid sequences of putative  $\Delta 9$ -desaturase of *Psychrobacter cryohalolentis* K5 (GenBank accession no. ABE74780), *Pseudoalteromonas haloplanktis* TAC125 (GenBank accession no. CAI87932), *Pseudoalteromonas atlantica* T6c (GenBank accession no. ABG42531), *Shewanella amazonensis* SB2B (GenBank accession no. ABL98402), *Shewanella baltica* OS155 (GenBank accession no. ABN63646), *Shewanella frigidimarina*

NCIMB 400 (GenBank accession no. ABI69986), and *Shewanella denitrificans* OS-217 (GenBank accession no. ABE53526) using Clustalx1.81 [18]. Three conserved histidine clusters (one of HXXXXH and two of HXXXHH) are indicated by the boxes numbered 1, 2, and 3. The overlines with an arrow indicate the sequences used for designing the primers DE1 and DE2

PRwf-1 and a 50% identity to *Acinetobacter* sp. ADP1. Figure 2 shows the distribution of the hydrophobic amino acids of *P. urativorans* desaturase, typical for a membrane protein, as identified using the Kyte–Doolittle hydropathy scale [19]. The histidine-rich motifs, HXXXXH (155–160), HXXXHH (192–196) and HXXXHH (329–333), which are highly conserved among membrane-bound acyl-CoA and

acyl-lipid desaturases and proposed to form the potential diiron active site [24], are shown as the bold “H” in Fig. 2. The prediction of TM helices by TMHMM [20] indicated that the deduced protein contained four hydrophobic domains between amino acids 104–126, 136–158, 250–269 and 273–295, which would be long enough to span the membrane bilayer twice, with both the N- and C-termini

**Fig. 2** Kyte–Doolittle Hydropathy plot derived from the amino acid sequence of *P. urativorans* desaturase. A window size of 19 amino acids was used to search for a transmembrane region in this protein. The hydrophobic residues are shown above zero, whereas the hydrophilic residues are below zero

facing the cytosol. This prediction is consistent with the topology model of  $\Delta 9$ -stearoyl-CoA desaturase from other species [25, 26]. A possible N-terminal signal (MIA-KTAMGLPLKGLRLA) sequence was also predicted by SignalP-NN [21, 27].

#### Heterologous Expression of *PuFAD9* in *E. coli*

The *PuFAD9* gene was cloned into pET21a(+) *E. coli* expression vector, resulting in the target protein, fused with a T7 tag at N-terminus. Protein expression has been performed as described in “Experimental Procedures”. *E. coli* cells transformed with empty pET21a(+) vector cultivated under the same conditions were used as negative control. Since the target protein expressed in *E. coli* contained a T7 tag at the N-terminus, its detection has been achieved by Western blot, using the T7 tag antibody. Results showed that protein bands corresponding to an approximate molecular weight of 60 kDa, were present in lysate and membrane fractions of the recombinant *E. coli* cells (data not shown). However, the predominant portion of the protein was incorporated into cellular membrane. The reason why the molecular weight was a bit larger than the predicted value has not been clarified, besides the fact that some additional amino acids came from the fused T7 tag.

*E. coli* itself contains type II fatty acid synthase rather than fatty acid desaturases. Four major fatty acids, C14:0 (myristic acid), C16:0 (palmitic acid), C16:1 $\Delta 9$  (palmitoleic acid), and C18:1 $\Delta 11$  (*cis*-vaccenic acid), among which palmitate, palmitoleate, and *cis*-vaccenate are components of the membrane phospholipids, are found in *E. coli* cells.

**Fig. 3** Gas chromatograms of TMS derivatives of C16 fatty acids isolated from *E. coli* Rosetta (DE3) cells transformed with the control vector pET21a (+) (a); or cells expressing the recombinant plasmid pEPUD9 (b). The peak at the retention time of 23.2 min was identified as 3-trimethylsilyloxymyristic acid according to MS data. 3-Hydroxymyristic acid is a component of the hydrophilic outer membrane polysaccharides [28]

Two minor components, C12:0 (lauric acid) and 3-hydroxymyristic acid are found exclusively in the hydrophilic outer membrane polysaccharides [28]. GC-MS analysis of trimethylsilylated derivatives of cellular fatty acids indicated changes in the pattern of palmitate and palmitoleate in *E. coli* cells upon expression of *PuFAD9* (Fig. 3). The amount of palmitoleate increased from 34 to 88%, while the amount of palmitate decreased from 66 to 11% during expression at 15 °C. This result demonstrates that *PuFAD9* from *P. urativorans* indeed encodes a  $\Delta 9$ -fatty acid desaturase that can be actively expressed in *E. coli*.

#### In Vivo Study of *P. urativorans* $\Delta 9$ -Fatty Acid Desaturase Expressed in *E. coli*

The optimal growth temperature for *P. urativorans* in the psychrophilic habitat is 18–22 °C [29]. To investigate the temperature effect on functional expression of the desaturase in *E. coli*, cells transformed with pEPUD9 plasmid were harvested 6 h after expression at 15, 25 and 37 °C (Fig. 4). The ratio of palmitoleic to palmitic acid in the recombinant cells at 15 °C was 2.4 times smaller than at 25 °C, which fitted well with the levels of the expressed enzyme detected by western blotting at both temperatures. Although Western blot shows that the protein is expressed (Fig. 4b), no accumulation of palmitoleic acid was observed at 37 °C, probably due to the loss of enzyme activity at this temperature which is compatible with the maximum growth temperature limit of *P. urativorans* at 25 °C. The  $\Delta 9$ -desaturase in recombinant cells was not

**Fig. 4** The ratio of palmitoleic acid to palmitic acid (**a**) and western blotting analysis (**b**) of the cells transformed with pEPUD9 after the expression for 6 h at 15, 25 and 37 °C. For western blot, *E. coli* cultures (equal to 1 mL of cell suspension with  $OD_{600} = 0.2$ ) were pelleted by centrifugation and heated with SDS loading buffer at 95 °C for 10 min

detectable before the addition of IPTG to the culture, indicating that the *PuFAD9* gene was strictly regulated. The desaturation level of C16 fatty acids was 79% at 25 °C whereas only 61% at 15 °C when measured 6 h after induction. These results suggest that the conversion of palmitic acid into palmitoleic acid catalyzed by this desaturase can be controlled by expression time and temperature.

## Discussion

Cloning and expression of the genes coding for the desaturases and elongases which are critical enzymes involved in the biogenesis of most of the PUFAs, have important biotechnological potential [7]. Introduction of the  $\Delta 9$ -desaturase gene into cells capable of producing an UFA can enhance the conversion to palmitoleic acid and oleic acid as starting compounds of UFAs. Particularly when a putative electron transport partner or a gene coding for another desaturase is combined with the  $\Delta 9$ -desaturase by a recombinant DNA technology, the improved productivity of some desired PUFAs could be expected [30]. In this sense, besides the soluble  $\Delta 9$ -ACP desaturases, the other two classes of membrane-bound  $\Delta 9$ -desaturases in different species could be regarded as alternative desaturase resource for more efficient production of PUFAs. However, although most research has been done on the  $\Delta 9$  acyl-lipid desaturase isolated from cyanobacteria [31–34], the number of prokaryotic  $\Delta 9$ -desaturase enzymes that have been investigated in detail is much smaller than those from fungi [35, 36], higher plants [10, 37], fish [38] and mammals [39]

so far. In the present study, a novel gene that encodes a membrane-bound  $\Delta 9$ -fatty acid desaturase from *P. urativorans* has been cloned and, to our knowledge, for the first time, successfully expressed in *E. coli*. The product of this gene fused with T7 tag has an approximate molecular mass of 60 kDa. Enzymatic activity of the target protein was confirmed by GC-MS analysis of the cellular fatty acid composition, to demonstrate that this enzyme was expressed in the heterologous host in active form and the desaturation reaction can be carried out in an *E. coli* host cell effectively. Growth temperature has an effect not only on the synthesis, but also on the activity of the desaturase, which was reflected by desaturation of palmitic acid. It is very likely that the *P. urativorans* desaturase expressed in *E. coli* accepted electrons from the host's ferredoxin [40]. However, further work is needed to clarify the electron transport system and substrate specificity of the enzyme.

**Acknowledgments** This work is part of the joint project between Nanjing University of Technology and the University of Stuttgart on Biosystems Engineering of Desaturation, which is in the framework of a Baden-Wuerttemberg—Shanghai/Jiangsu Exchange Program on Systems Biology and Biosystems Engineering.

# Developmental, Hormonal, and Nutritional Regulation of Porcine Adipose Triglyceride Lipase (ATGL)

Received: 24 July 2007 / Accepted: 6 December 2007 / Published online: 10 January 2008  
© AOCS 2008

**Abstract** Adipose triglyceride lipase (ATGL) is a newly identified lipase. We report for the first time the porcine ATGL sequence and characterize ATGL gene and protein expression *in vitro* and *in vivo*. Adult pig tissue expresses ATGL at high levels in the white adipose and muscle tissue relative to other tested tissues. We show that within the white adipose tissue ATGL is expressed at higher levels in the adipocyte than in the stromal-vascular fraction. Additionally, ATGL expression increases dramatically in the subcutaneous adipose during adipose development and maturation, as well as during *in vitro* adipogenesis. Peroxisome proliferator-activated receptor gamma transcript levels increased concomitant with ATGL gene expression, suggesting a possible role in the regulation of ATGL by adipogenic regulators. *In vitro* treatment of differentiated primary pig preadipocytes with insulin and forskolin decreased ATGL gene expression in a dose-dependent manner, suggesting ATGL transcript levels are hormone sensitive. *In vivo* experimentation showed that calorie-

restriction in gilts resulted in increased ATGL mRNA and protein levels in subcutaneous and peri-renal fat tissues. Our data demonstrate that ATGL expression reacts to hormonal stimuli and plays a role in catecholamine-induced lipolysis in porcine adipose tissue.

## Introduction

Due to a variety of similar physiological and anatomical characteristics, including a tendency to overeat, pigs are used as models for human diseases including obesity and cardiovascular disease [1, 2]. Understanding the lipolytic pathway in pigs has an application to researchers of human diseases. Lipase enzymes catalyze the breakdown of stored triglycerides, a process known as lipolysis, to fatty acids and glycerol. Adipose triglyceride lipase (ATGL), a newly discovered lipase, hydrolyzes the first ester bond of stored triglycerides, releasing nonesterified free fatty acids [3]. ATGL protein is associated with lipid droplets and is found at high levels in adipose tissue, but is also present in other tissues that have lipid stores [4]. ATGL activity has been shown to be required for all PKA-stimulated fatty acid and glycerol release in murine embryonic fibroblast adipocytes [5] and is the rate-limiting step in hormone-induced lipolysis [3, 6]. The product, diacylglycerol, is hydrolyzed by activated hormone sensitive lipase (HSL), which has a higher substrate affinity for diacylglycerol than triglyceride [6]. Thus, ATGL and HSL work in concert to mobilize free fatty acid stores from lipid storing tissues.

Fasting has been shown to increase ATGL transcript levels in mice [7]. Human obesity is associated with decreased catecholamine-induced lipolysis and decreased HSL expression in adipocytes [8]. A study of the level of HSL and ATGL gene expression showed that the abundance of the two transcripts in human adipose tissue was highly correlated to habitual dietary conditions during a low calorie diet [8]. This suggests a common regulatory mechanism(s) for the two genes [8]. Studies in mice suggest that dexamethasone induces ATGL gene expression, whereas tumor necrosis factor alpha, isoproterenol, and insulin downregulate ATGL gene expression in 3T3-L1 preadipocytes [7, 9]. However, regulation of ATGL at the molecular level remains unclear. The role ATGL plays in tissues during adipogenesis and times of calorie restriction as well as the transcriptional response to metabolic stimuli in most mammals is unknown. Our experiments are the first to characterize ATGL gene expression in pigs. We investigated pATGL gene expression in various tissues, in the subfractions of the adipose, during development, during *in vitro* preadipocyte differentiation, and after food restriction.

## Materials and Methods

### Animals

All *in vitro* work was performed using adipose tissue collected from Landrace pigs: primary preadipocyte culture (7–12 day old pigs, 6 piglets total), tissue fractionation and tissue distribution (120 days), ontogeny (embryo, 105 days of gestation; adult, 120 days; 3 pigs per group). The adipose is a rapidly developing tissue with rapid histological changes occurring during late gestational and early post-natal development, thus samples from 105 days fetal and 6 days post-natal were included in the ontogeny study [10, 11]. The calorie restriction study used 12 adult (164 days of age) commercially crossbred ovariectomized gilts weighing between 80–100 kg with a mean weight of 79 kg. Six were fed a calorie restricted (1 kg/days) diet while control pigs were fed *ad libitum* ~3 kg/days for two weeks before tissue collection. At the conclusion of the experiment, the control group gained an average of 8.2 kg and the calorie restricted group lost an average of 2.5 kg. Samples were collected from the subcutaneous adipose (inner and outer) and the peri-renal adipose (pad proximate the kidneys). Protein and total RNA were isolated for use in immunoblotting and quantitative real-time RT-PCR, respectively. All animal procedures were approved by the institutional animal care and use committee.

### RNA Isolation and Preparation of cDNA for Cloning

RNA was isolated from pig adipose samples using Trizol™ (Invitrogen) according to the manufacturer's instructions. RNA quality was assessed by agarose gel electrophoresis. Approximately 1 µg of total RNA was reverse transcribed according to the manufacturer's instructions (Invitrogen Life Technologies—M-MLV reverse transcriptase) [12].

### ATGL Cloning and Design of Primers

cDNA from pig adipose was used as a template for PCR. Two sets of primers were designed according to two porcine sequences: The Institute for Genome Research (TIGR) database sequences TC276632 and TC277702. The TIGR sequences showed homology to human (Genbank accession numbers: AY894804, NM\_020376), mouse (AJ278476, AK031609), and cow (XM\_864571) ATGL cDNA. A MJ Research PTC-200 thermal cycler and DNA Taq polymerase (Invitrogen) were used for all PCR reactions. The PCR products were separated by electrophoresis on a 1% agarose gel and the appropriate band(s) excised and gel extracted using the Qiagen Gel Extraction Kit. The product was then ligated to the pCR 2.1-TOPO vector using the TOPO TA Cloning Kit (Invitrogen). Positive clones were sequenced by The Ohio State University sequencing core facility using an Applied Biosystems 3730 DNA Analyzer. The resulting sequences confirmed sequence identity by homology to the mouse and human by identification of characteristic enzyme domains. Real-time primers were then designed to measure ATGL gene expression (“F2” 5'-GCACCTTCATTCCC GTGTAC-3', “R2” 5'-CGAGAGATGTGCAAGCAGGG-3'). Primers were designed to span genomic introns, thus avoiding amplification of genomic DNA possibly present in RNA samples. PCR reactions using F2/R2 primers were optimized for use in real-time PCR.

### Real-Time PCR Detection of Total Gene Expression

Real-time PCR was performed using SYBR green I nucleic acid dye (Molecular Probes Invitrogen detection technologies) on an ABI 7300. AmpliTaq Gold™ (Applied Biosystems, Roche New Jersey) was used in all real-time reactions as was the following thermal profile: 95 °C 10 m, 40 cycles of 94 °C 30 s, 60 °C 60 s, and 82 °C 30 s. The  $C_T$  values for the internal control (cyclophilin) and target genes, as determined by the ABI software, were used to calculate gene expression using the  $2^{-\Delta\Delta C_t}$  method [13]. All target genes were normalized to cyclophilin and

displayed as a relative fold-change. Randomly selected samples from all real-time runs were resolved by agarose gel electrophoresis to ensure the production of one product. In addition, dissociation/melting curves yielded single peaks, indicating a single product with lack of primer dimers. “No template” negative controls were included in all PCR reactions to detect possible contamination.

#### Protein Isolation and Immunoblotting

Approximately 80 mg of tissue was homogenized in 800  $\mu$ l of lysis buffer (1% Triton X-100, 150 mM NaCl, 20 mM HEPES pH 7.5, 10% glycerol, 1 mM EDTA, 100 mM NaF, 100  $\mu$ M sodium orthovanadate, 1 mM PMSF, and 10  $\mu$ l/ml commercial protease inhibitor cocktail). The protein content of cell lysate was determined using the bicinchoninic acid (BCA) Protein Assay Kit (Pierce Chemical). Samples were separated by SDS-PAGE using the mini-Protean system (Bio-RadHer). The protein was wet-transferred to a PVDF membrane (Amersham Biosciences Hybond-P<sup>TM</sup>), blocked in 5% nonfat dry milk (NFD) in 1x-TBST (0.1% Tween 20) and incubated overnight at 4 °C with primary antibody specific to ATGL (Cayman Chemical, 1:1000) in 5% NFD. After washing in 1x-TBST, blots were incubated with the appropriated HRP-conjugated secondary antibody for 1 h at room temperature. Blots were washed before addition of ECL plus<sup>TM</sup> (Amersham Biosciences) and bands were detected with Hyperfilm<sup>TM</sup> (Amersham Biosciences).

#### Porcine Stromal-Vascular and Adipocyte Cell Fractionation

Adipose tissue (5 g) was removed from 120 day old pigs, minced, and incubated with 3.2 mg/ml collagenase II (Sigma-Aldrich) for 1 h in a shaking waterbath (180 rpm, 37 °C) to separate adipose tissue into adipocyte and stromal-vascular fractions (SVF). After treatment, the suspension was passed through a 100  $\mu$ m nylon cell strainer to remove undigested tissue. The filtrate was centrifuged at 200 $\times$ g for 5 min and the top layer (adipocyte fraction) and the pellet (SVF) were collected for RNA isolation [14]. Separation of fractions was verified by marker genes delta like homolog 1 (DLK1) (preadipocyte) [12, 15] and peroxisome proliferator-activated receptor (PPAR $\gamma$ ) (adipocyte) [12, 16].

#### Primary Pig Preadipocyte Culture and Differentiation

The separated stromal-vascular portion of the tissue fractionation was plated in DMEM supplemented with 10% fetal bovine serum (FBS) and antibiotics. The media was

refreshed every 24 h until confluence ( $\sim$ 5 days) and during the differentiation protocol. The cells were differentiated similar to our previous publication [17]. Briefly, 1 day after confluence cells were treated with 80 nM dexamethasone for 2 days followed by 5  $\mu$ g/ml insulin, 5  $\mu$ g/ml transferrin, 0.5 mM isobutyl-1-methyl-xanthine, and 5 ng/ml selenium for 4 days. Cells were maintained in growth media until 10 days post-differentiation before use in experiments resulting in approximately 60% differentiation. This method is based on those published by Hausman and colleagues [18–20]. The cells were serum starved for 6 h before treatment with insulin, epinephrine, or forskolin for 12 h. Samples were immediately frozen at  $-80$  °C after collection.

#### Bioinformatics and Statistical Analyses

ClustalX was used for multiple amino acid sequence alignment [21]. Genedoc<sup>TM</sup> was used for creation of cDNA and amino acid alignment figures. Gene expression data were subjected to a one-way ANOVA procedure of SAS<sup>TM</sup> (SAS Inst., Inc.) followed by Fisher's Protected LSD. Comparison of two means was accomplished by a Student's *t*-test [22]. The minimum level of significance was set at  $P < 0.05$ .

## Results

#### ATGL cDNA and Amino Acid Sequences

We identified several partial pig ATGL sequences in The Institute for Genomic Research (TIGR) database that were homologous to human (Genbank accession #AY894804) and murine ATGL (#AK031609). Porcine ATGL cDNA (Genbank accession #EU047807) was cloned using primers designed based on these sequences (Fig. 1). Analysis of amino acid homology shows that porcine ATGL protein is more homologous to the mouse (83%) than the human (78%). The first 180 amino acids of the ATGL protein represent the patatin domain (PFAM accession PF01734) which is responsible for the lipolytic activity of ATGL (Fig. 2) [23, 24]. Porcine ATGL has a hydrophobic domain (Leu309-Ser396) which may be necessary for association with the lipid-droplet [23, 24]. The consensus sequence within the patatin domain for the serine lipase motif (GXGXXG) was GCGFLG and the serine hydrolase motif (GXSXG) was GASAG in all three species compared.

#### ATGL Gene Expression Levels Differ between Adipose Tissue Fractions

Among the tissues analyzed, pig white adipose, skeletal muscle, and cardiac muscle tissues showed the highest

**Fig. 1** Porcine ATGL cDNA sequence. The full length pig ATGL cDNA (Genbank accession #EU047807) is shown with start and stop codons (underlined) at +4 and +1462, respectively

```

relative gene expression of ATGL (Fig. 3a). Skeletal muscle expression of ATGL is of comparable magnitude to that of the subcutaneous white adipose. Cardiac muscle showed higher expression on average than the intestine, kidney, liver, lung, and spleen. Western blot data show that ATGL protein levels in white adipose are much higher than other tissues (Fig. 3b).

The adipose tissue is composed of two general fractions, the SVF and the adipocyte fraction. The SVF accounts for at least one half of the cells of the adipose and includes fibroblasts, macrophages, and preadipocytes (mesenchymal stem cells) [25]. It is important to determine which adipose tissue subfraction is expressing ATGL because it lends insight into the role of the gene product in the whole tissue. While collagenase digestion and the subsequent separation are not absolute, we show (Fig. 3c) that delta like homolog 1 (DLK1), a preadipocyte marker gene, is significantly

higher in the SVF and that PPAR $\gamma$ , an adipocyte marker gene, is significantly higher in the adipocyte fraction, indicating effective separation. Our data showed (Fig. 3c) that ATGL expression was, on average, 14-fold higher in the adipocyte fraction compared to the SVF, suggesting that adipocytes dominantly express ATGL in adipose tissue and that ATGL expression may be induced during adipogenesis.

#### Ontogeny of ATGL Gene Expression in the Adipose and During Differentiation of Primary Pig Preadipocytes

To confirm the induction of ATGL during in vivo adipose development, we collected subcutaneous fat tissue from embryonic day E105, 6 day, and 120 day old pigs ( $n$  of

**Fig. 2** Amino acid sequence alignment of pig, human, and mouse ATGL. *Black shading* indicates identical amino acids and *gray shading* indicates amino acids in the same R groups. The patatin domain is located between the *filled arrows* (110–L178) and the hydrophobic domain between the *unfilled arrows* (L309–S396). Within the patatin domain, the glycine-rich, serine lipase motif (GXGXXG) is *underlined* as well as the serine hydrolase motif (GXSXG). *Dashes* represent gaps in the amino acid sequence that are necessary for alignment according to the default parameters of ClustalX

pigs = 3 for each time point) and expression of ATGL at mRNA and protein levels was quantified by real-time RT-PCR and Western blot analyses, respectively. Embryonically, porcine subcutaneous fat tissue expresses very low levels of ATGL when compared to the levels detected in adults (Fig. 4a). Even at 6 days after birth, pigs have relatively low levels of ATGL. The dramatic increase in ATGL during development was further confirmed at the protein level by immunoblotting (Fig. 4b). This suggested that adipogenesis or tissue maturation resulted in increased ATGL expression. In order to study if preadipocyte differentiation resulted in an increase in ATGL transcript, primary pig preadipocytes were grown in culture and differentiated. During differentiation, we found that levels of ATGL increased concomitantly with differentiation. We

showed (Fig. 4) that increases in PPAR $\gamma$  in the pig during maturation occurred simultaneously with ATGL gene expression and that PPAR $\gamma$  and ATGL gene expression increased during adipogenesis (Fig. 5).

#### Hormonal Effects on ATGL Gene Expression in Differentiated Primary Pig Adipocytes

In order to determine if ATGL transcript levels were sensitive to hormonal signals, we cultured, differentiated, and treated primary pig pre-adipocytes with an anabolic and catabolic compound. Fully differentiated pig adipocytes treated with insulin for six hours showed a statistically significant decrease in ATGL gene expression (Fig. 6a). As

**Fig. 3** ATGL gene expression in pig tissues and adipose tissue fractions. (a) Total RNA was isolated from various pig tissues. The mRNA expression of porcine ATGL was determined by quantitative real-time RT-PCR and expressed as a ratio to cyclophilin mRNA. The tissue distribution of the porcine ATGL gene expression was also assessed by RT-PCR, followed by agarose gel electrophoresis and ethidium bromide staining. Cyclophilin was used as a housekeeping gene control. (b) Equal amounts of protein from whole tissue lysates were separated by SDS-PAGE and protein expression levels were determined by immunoblotting using an antibody specific to ATGL. Beta-actin is provided as an internal control. (c) Relative ATGL gene expression in the adipocyte and stromal-vascular (SV) fraction of digested tissues from two 12 day old piglets. Total DLK1 expression, a preadipocyte marker, is shown in addition to PPAR $\gamma$  expression, an adipocyte marker, both of which are normalized to cyclophilin

previously discussed, isoproterenol decreases ATGL transcript levels in mice. Isoproterenol binds the beta-adrenergic receptors, leading to activation of protein kinase A (PKA) signaling. In order to show a role for PKA signaling in ATGL gene expression, we used the specific PKA activator, forskolin. We found that forskolin decreased ATGL gene expression in a dose-dependent manner (Fig. 6b), providing a role for PKA signaling in the regulation of ATGL transcript levels.

#### Sensitivity of ATGL Expression to Calorie Restriction in the Peri-renal and Subcutaneous Fat Depots

The regulation of ATGL expression is unknown, although it has been shown that ATGL gene expression is decreased

**Fig. 4** ATGL expression during development of the pig. (a) Total RNA was isolated from 70-day old fetal, 6-day old and 120-day old pig adipose tissues. Porcine ATGL, DLK1 and PPAR $\gamma$  expressions in pig adipose tissue at three different ages were analyzed by quantitative real-time RT-PCR. Bar charts represent data from at least three animals per group performed in duplicate and are corrected for cyclophilin. Data reported as means  $\pm$  SEM. The level of ATGL expression at day 140 was significantly higher than those of the fetus and 6-day old pigs (ANOVA,  $P < 0.01$ ). The levels of DLK1 expression in fetal adipose tissue were significantly lower than those at day 6 and 140 (ANOVA,  $P < 0.001$ ). PPAR $\gamma$  expression increased with increasing age (b) ATGL and PPAR $\gamma$  protein was measured by Western blot analysis;  $\beta$ -actin was used as an internal control

by insulin and epinephrine in vitro. The decreases in ATGL gene expression due to individual hormones in vitro, both catabolic and anabolic, suggest that ATGL expression in

**Fig. 5** ATGL gene expression during differentiation. Total RNA was isolated from d0 to d9 during adipogenic differentiation of adipose stromal-vascular cells. The mRNA expression of ATGL and PPAR $\gamma$  genes was determined by quantitative real-time RT-PCR and expressed as a ratio to cyclophilin mRNA. The bars indicate means  $\pm$  SEM (the number of pigs = 3)

vivo may be sensitive to metabolic hormones. Our data show that ATGL expression is increased by calorie restriction in the peri-renal and subcutaneous fat depots of pigs (Fig. 7). Hormone sensitive lipase (HSL) gene expression does not significantly change during calorie restriction. The lipolytic activity of HSL serves as an internal control because it is regulated at the protein level by PKA-mediated phosphorylation. Interestingly, DLK1 increased dramatically in the adipose of calorie-restricted pigs. We used immunoblotting to confirm the increased expression of ATGL at the protein level in the peri-renal and subcutaneous fat of the pig (Fig. 8a, b).

## Discussion

Triglycerides stored in white adipose tissue (WAT) represent the primary energy storage form in animals. When caloric intake does not meet caloric expenditures, the body relies on the process of lipolysis in WAT to provide non-esterified fatty acids to tissues as an energy substrate. The regulation of lipolysis is an incompletely understood

**Fig. 6** Sensitivity of ATGL gene expression to hormonal signals in vitro. The differentiated porcine adipocytes in culture were treated with insulin and forskolin at indicated doses for 12 h. The mRNA expression of ATGL gene was determined by quantitative real time RT-PCR and expressed as a ratio to cyclophilin mRNA. The bars indicate means  $\pm$  SEM (the number of pigs = 3)

process which can vary greatly between species. This variability is largely due to species-specific differences in sensitivity to hormonal stimuli caused by variations in hormone receptor abundance and sequence [26]. In addition, the existence of lipases that have not been characterized adds a new dimension of complexity. Do inter-species variations in lipase enzyme sequence and/or function determine a species' or individual's unique lipolytic system? ATGL is a newly identified lipase that has only been described in a few mammalian species.

The 180 amino acids at the N-terminal were identified as a patatin-like domain in the Pfam protein family database. The patatin-like domain overlaps with the  $\alpha/\beta$  hydrolase domain located at amino acids 25–240. These domains contain a glycine-rich motif (GXGXXG) and the active

**Fig. 7** ATGL gene expression in ad libitum versus calorie-restricted pigs. The ad libitum group was fed 3 kg/days and the calorie restricted group was fed 1 kg/days of a grower diet for 9 days. Total RNA isolated from peri-renal and subcutaneous adipose tissues was analyzed by quantitative real-time RT-PCR for ATGL, HSL and DLK1. Cyclophilin expression was used as a housekeeping gene control

**Fig. 8** ATGL protein levels in ad libitum versus calorie-restricted pigs. Total protein isolated from two groups was subjected to Western blot analysis for ATGL protein ATGL protein levels in (a) perirenal and (b) subcutaneous fat  $\beta$ -actin was used to indicate equal sample loading

serine hydrolase motif (GX SXG). The patatin-like domain also contains a brummer box (BB) that is conserved across patatin-like domain-containing proteins belonging to the nutrin family of proteins [24]. We show a high level of sequence conservation across species. In addition, the hydrophobic area of the protein from Leu309-Ser396 shows conserved homology. The hydrophobic domain has been shown to be associated with ATGL localization to the lipid-droplet [23]. Mutations within the hydrophobic domain of ATGL do not affect whole-cell lipase activity; however, ATGL cannot effectively localize to the adiposome. Localization of ATGL to the lipid droplet is essential for hydrolysis of stored triglyceride, explaining the phenotype presented by patients suffering from neutral lipid storage disorders (NLSDs) [23]. In addition, of the 12 identified single nucleotide polymorphisms in humans with three SNPs changing amino acids sequences, some have been correlated with free fatty acid, serum glucose levels, and the risk for type II diabetes [27]. However, the pig amino acid sequences at these SNP sites are identical to the sequences of normal human ATGL. Amino acids 267–300 are variable between species and no significant conservation is seen near the carboxyl terminus of the ATGL after amino acid 470. The pig sequence data supports the biological and evolutionary advantage to maintaining the patatin-like domain and the hydrophobic domain of ATGL across species.

ATGL has been shown to be associated with the lipid droplet [4]. Therefore, it is logical to assume that tissues with a greater abundance of accumulated triglyceride, and thus a larger lipid droplet, will have increased levels of ATGL. High relative expression of ATGL in WAT is consistent with expression in mice; however, ATGL gene expression in pig muscle seems to be high relative to most tissues tested [28]. Pig muscle ATGL expression is probably due to the presence of adiposomes (lipid droplets in the cells) within the muscle fibers themselves as well as the presence of intramuscular fat. Both skeletal and cardiac muscle use fatty acids as a preferred fuel substrate under certain conditions. ATGL gene expression in muscle was shown to be high while protein levels were not. The reason for this is unclear; however, one might explain this by differences in translation efficiencies or degradation rates between the tissues. NLSDs in humans are the result of mutations in both alleles of the ATGL gene and are characterized by ectopic fat droplet presence in leukocytes, bone marrow, skin, and muscle [23]. In addition, ATGL knockout mice accumulate large amounts of lipid in the heart causing premature death [29]. ATGL (+/–) mice presented cardiac triglyceride content at twice the level of wild-type mice [29]. Thus, the presence of ATGL may allow for enhanced catecholamine-induced hydrolysis of stored lipid in the mature porcine.

This indicates that embryonic and post-natal pigs have immature adipose tissues that are not effective at high levels of lipolysis and beta-oxidation, suggesting a reliance on a consistent supply of nutrients from the mother. Also, newborn piglets increase body fat mass from 3% to 15% by weaning at 21 days of age [30] with dramatic increases in fat cell size and expression of adipocyte marker genes [31]. High ATGL expression in the adult is probably due to a large population of mature adipocytes in adipose tissue, which was supported by the increased expression of adipogenic marker gene, PPAR $\gamma$ , and reduction in expression of preadipocyte marker gene, DLK1. Downregulation of DLK1 expression would theoretically allow for maximal adipocyte differentiation in rapidly growing piglets. It is important to note that DLK1 gene expression levels were very high in the embryo and dramatically decreased in the 6 d and adult pig, resulting in reduction of anti-adipogenic activities of DLK1 during *in vivo* differentiation of adipose tissue. PPAR $\gamma$  showed an inverse relationship to DLK1 and a direct relationship to ATGL as we stated previously concerning tissue fractionation. It is important to note that ATGL expression levels have been shown to be altered in states of obesity. For instance, genetically obese (ob/ob) mice have been shown to have decreased ATGL transcript levels in white adipose compared to normal weight controls suggesting a role for ATGL transcript regulation in body fat mass control [7]. Interestingly, ATGL-deficient mice exhibit fat cell hypertrophy and mild obesity [29]. These states suggest that ATGL function plays a role in whole body lipid content. Although the possible association of ATGL with whole body lipid content in pigs has not been studied, ATGL transcription levels may influence carcass adipose and meat quality.

The *in vitro* and *in vivo* data suggests that ATGL gene expression is controlled directly or indirectly by adipogenesis. Adipogenesis is a complex process regulated in large part by PPAR $\gamma$ . Transfection of 3T3-L1 cells with ATGL promoter-luciferase constructs followed by treatment with a PPAR $\gamma$  ligand resulted in transactivation, indicating that ATGL gene expression may be controlled by PPAR $\gamma$  mediated signals [28]. PPAR $\gamma$  may directly regulate ATGL gene transactivation by binding to the promoter of the ATGL gene or indirectly increase ATGL gene expression levels by upregulating an adipogenic factor that regulates ATGL expression. This suggests that ATGL transactivation may be controlled by an adipogenic transcription factor such as PPAR $\gamma$  [22]. However, further studies to elucidate this relationship are needed.

Decreased ATGL transcript levels due to insulin treatment are likely caused by phosphoinositide-3 kinase (PI3K) signaling events. Binding of insulin to the insulin receptor leads to PI3K and Akt activation. In a mouse adipocyte cell line, 3T3-L1, insulin-mediated ATGL

decrease was rescued by a PI3K inhibitor [28]. We showed that forskolin treatment also decreased ATGL transcript levels. Forskolin activates adenylyl-cyclase, resulting in increased intracellular cyclic AMP levels and the activation of PKA signaling. PKA signaling affects many cellular processes and activation of this pathway may directly or indirectly regulate ATGL transcription. Calorie-restriction increases ATGL, catecholamine, and glucocorticoid levels, as well as decreases levels of insulin. Translating the data between the two systems is complex. Calorie restriction in the pig most likely decreased serum insulin levels compared to the *ad libitum* group. This may reduce the potent inhibition of PI3K signaling via insulin stimulation as seen *in vitro*. Also, calorie restriction-induced glucocorticoid release may also increase ATGL expression as did dexamethasone *in vitro*. The inconsistency resides in the response to catecholamine-induced PKA signaling with ATGL decreasing *in vitro* but increasing *in vivo* when catecholamine levels should be higher than the *ad libitum* group. This incompatibility may be due to interactions between the hormonal signaling pathways *in vivo* which cannot be, or are difficult to, recapitulate in culture.

The calorie-restriction experiment yielded a novel finding; restriction increased DLK1 gene expression. This may be explained by a proportional increase in the number of SV cells per gram of tissue as adipocytes lose lipid mass during restriction. Alternatively, DLK1 may play, as of yet, an undefined role in the adipose during times of calorie restriction [32]. The upregulation of DLK1 may function to prevent cells within the adipose from undergoing differentiation, thus maintaining preadipocytes in times of a negative energy balance and possibly leading to an increased population of preadipocytes. This is supported by transgenic overexpression of DLK1 in mouse adipose tissue, resulting in decreased fat mass and increased endogenous DLK1 gene expression [15]. Alternatively, food restriction results in decreased adipose tissue mass by inhibition of adipogenesis and catabolic events such as lipolysis, which may have led to the indirect upregulation of the DLK1 gene expression. In adipose tissue, expression of the DLK1 antisense decreased amounts of endogenous DLK1 and promoted adipocyte differentiation, whereas overexpression of the DLK1 gene inhibited adipocyte development *in vitro* [33]. In addition, our previous studies clearly indicate that overexpression of the DLK1 gene in adipose tissue of transgenic mice inhibited adipocyte development and knockout of the DLK1 gene induced the obesity phenotype in mice [15, 34]. In pigs, DLK1 served as a reliable preadipocyte marker as shown by greater expression of DLK1 in the subcutaneous adipose of embryonic pigs and the stromal-vascular tissue fraction of adult pigs [12].

The sensitivity of the pig ATGL gene to hormonal stimuli both in vitro and in vivo suggests a role for ATGL in hormone-induced lipolysis. Before the identification of ATGL, HSL was regarded as the hormonally-controlled master regulator of lipolysis. The mechanisms that control ATGL-mediated initiation of lipolysis are not understood. While some researchers report that ATGL is affected by hormonal stimuli, others speculate that ATGL is only involved in basal lipolysis. Though our study does not directly measure lipolysis we do show that ATGL gene and protein expression are altered by hormonal stimuli in vitro and in vivo, respectively, suggesting that hormonally sensitive signaling pathways converge on factors that effect ATGL gene expression. Both anti- and pro-lipolytic hormones downregulated ATGL in the pig, similar to that reported in mice. It has been shown that PKA activating compounds, such as epinephrine and forskolin, induce lipolysis while decreasing ATGL gene expression levels, suggesting that ATGL may not be regulated at a transcriptional level. It has been shown that ATGL is not a direct substrate of PKA and there are no data showing evidence of regulation at a protein level [3]. It is also important to note that ATGL gene and protein expression levels increase during calorie restriction. Previous studies showed that feed restriction in pigs results in decreased transcript levels in some genes (fatty acid synthase, lipoprotein lipase, leptin) involved with energy partitioning [35–37]. During food restriction in our study, pig insulin levels should be lower than during ad libitum feeding which would allow for ATGL levels to increase. However, epinephrine levels in restricted pigs would also be elevated on average in comparison to ad libitum fed pigs. This suggests that individual hormones tested in vitro do not accurately recapitulate the complex metabolic signals that undoubtedly intersect on ATGL. Further elucidation of the biochemical regulation of ATGL enzyme activity may clarify the intricacy between whole body metabolism and the convergence of hormonal signaling effects on ATGL.

**Abstract** Palmitoylated Wnt proteins comprise a conserved family of secreted signaling molecules associated with variety of human cancers. WIF domain of the human WIF (Wnt inhibitory factor)-1 is sufficient for Wnt binding and signaling inhibition. Detailed interactions between Wnt and WIF-1 are not known. Computational docking was employed to identify a possible fatty acid binding site in the WIF domain. A putative binding site was identified inside the domain. WIF domain exhibited the highest affinity for C16:0–C18:0 (–22 kJ/mol free energy of binding) fatty acids. The results suggest a role of the WIF domain as a palmitoyl binding domain required for WIF-1 binding to palmitoylated Wnt and signaling inhibition.

### Introduction

Palmitoylated wingless-type (Wnt) proteins comprise a conserved family of secreted signaling molecules [1]. They play key roles during embryogenesis and adult tissue homeostasis. Canonical Wnt proteins bind to the Frizzled (Fz)/low-density-lipoprotein-receptor-related protein (LRP) complex at the target cell surface (Fig. 1). These cell surface receptors can transduce a signal through several cytoplasmic proteins eventually leading to the transcription of target genes. Aberrant regulation of the Wnt pathway is associated with variety of human cancers and degenerative diseases [2].

Wnt antagonists interrupt binding of Wnts to their receptors [3]. Antagonists form two functional classes. Members of the sFRP class (which includes secreted Frizzled-related proteins (sFRP) [4], WIF (Wnt inhibitory factor)-1 [5–10] and Cerberus [11]) bind to the Wnt proteins and inhibit their ability to interact with the receptor complex. Members of the Dickkopf class [12] inhibit Wnt signaling by binding to the LRP component of the Wnt receptor complex. Interactions between Wnts and their antagonists remain elusive due to the lack of tertiary structures.

The Wnt inhibitory factor-1 is a secreted protein of 379 amino acid residues that binds to palmitoylated Wnt protein and inhibits its activity [5]. WIF domain (about 140 residues) of WIF-1 is sufficient for Wnt binding and signaling inhibition. The tertiary structure of the WIF domain was solved using NMR spectroscopy [6]. The unexpected association between detergent Brij-35 [dodecylpoly(ethylene glycol) ether]<sub>23</sub> and the WIF domain suggests its affinity for alkyl chains and palmitoylated Wnts. Removal of the palmitate leads to the loss of Wnt activity. Wnt proteins are difficult to purify due to inefficient secretion [13], high degree of insolubility [1]; the WIF domain tends to precipitate [6]. Thus detailed interactions between

**Fig. 1** Role of palmitoylation in Wnt signaling. Canonical Wnt signaling pathway is initiated when palmitoylated Wnt binds to the Frizzled and LRP5/6 receptor complex at the cell surface. Loss of palmitoyl or presence of WIF domain leads, by unknown mechanism, to inactivation of signal transduction. This study aims to propose thermodynamically favorable interactions between palmitoylated Wnt and WIF domain

palmitoylated Wnt and WIF-1 remain hardly approachable by traditional biochemical methods. Computational studies presented here aim to determine a possible fatty acid binding site in the WIF domain and propose thermodynamically favorable interactions in the Wnt signaling pathway associated with variety of cancers and intercellular communication.

## Experimental Procedures

Twenty conformers representing the NMR structure of the WIF domain of the human WIF-1 were downloaded from the Protein Data Bank (PDB ID code 2D3J). The average structure of 20 conformers was calculated and each conformer was aligned with it individually. The RMSD (root mean square deviation) between the average structure and individual conformers was calculated. The best fitting (lowest all-atom RMSD value, 0.57 Å) conformer (MODEL 1 from 2D3J file) was selected for docking studies. As a control experiment, palmitic acid (C16:0) was docked with all of the 20 WIF domain conformers. The same fatty acid binding site with similar C16:0 conformations and free energy of binding ( $\Delta G_{\text{binding}}$ ) was identified in all of the 20 WIF domain conformers (Supplementary Fig. 1).

Structures of fatty acids were constructed manually using program ACD/ChemSketch 10.02. Energy minimization of the three-dimensional structures was performed using CHARMM force field [14] as implemented in the ChemSketch prior to docking.

Molecular docking was carried out using program AutoDock 4.0 [15] in order to identify possible binding sites and conformations of fatty acids, estimate  $\Delta G_{\text{binding}}$ . The estimation function of  $\Delta G_{\text{binding}}$  is based on an empirical function derived by linear regression analysis of a set of diverse protein-ligand complexes with known inhibition constants in the AutoDock 4.0. All torsions of fatty acids except double bonds were unconstrained during the docking. The protein was treated as a rigid body. Docking was accomplished using the Lamarckian genetic algorithm (LGA) with the following modifications of the default parameters leading to higher accuracy of calculations. Atomic interaction energy grid maps were calculated with 0.3 Å (the default is 0.375 Å) grid spacing. The WIF domain was placed in a  $39 \times 90 \times 39$  Å box. The space of the box covered the whole WIF domain and the space beyond. Thus identification of the fatty acid binding site both on the surface and inside the domain was possible. A hundred conformers of each fatty acid were generated during the docking experiment (Suppl. Fig. 2). The maximum number of energy evaluations was set to  $1 \times 10^6$ .

## Results and Discussion

To aid the experimental analysis of interactions between the palmitoylated protein Wnt and its antagonist WIF-1, binding of fatty acids to the available tertiary structure of the WIF domain was investigated. The surface of the WIF domain was probed to identify sites that are energetically most favorable for interaction with the flexible ligand.

Fatty acid docking revealed no binding sites at the outer surface of the WIF domain. A hydrophobic binding site was observed between hydrophobic residues of strand 4 (Phe65, Trp67) and 8 (Val128/130/132) surrounded by Leu12, Leu14 and Val110 inside the domain (Fig. 2). Residues Phe65 and Trp67 are highly conserved within the WIF domains (also identified in the extracellular domains of Ryk (receptor-like tyrosine kinase) [16], Wnt binding protein) although their function remains unknown. Leu12 is not associated with any secondary structure element and may serve as a flexible boundary of the entry point for alkyl chain into the hydrophobic site.

Free energies of fatty acid binding to the WIF domain were estimated.  $\Delta G_{\text{binding}}$  decreased gradually from approx.  $-14$  to  $-22$  kJ/mol for saturated fatty acids C8:0–C16:0 (Fig. 3). A steady increase of  $\Delta G_{\text{binding}}$  was observed for fatty acids with a longer alkyl chain. Unfavorable  $\Delta G_{\text{binding}}$  for longer acids might be explained by steric hindrances between limited-size binding site and fatty acids. It is noteworthy that the lowest  $\Delta G_{\text{binding}}$  of approx.  $-22$  kJ/mol was observed for C16:0–C18:0 in case

**Fig. 2** Docking of fatty acids inside the hydrophobic site of the WIF domain. *Light grey arrows* represent fragments of the  $\beta$ -strands 1 (Leu14), 4 (Phe65, Trp67), and 8 (Val128/130/132) [6]. Carbon backbone and carboxyl group of the C8:0 (−14.6 kJ/mol), C16:0 (palmitic acid, −24.9 kJ/mol), and *trans*-9 C18:1 (−24.5 kJ/mol) lowest  $\Delta G_{\text{binding}}$  solutions are shown as *black*, *grey* and *light grey stick* models, respectively. Coordinates of the complex are provided as the electronic supplementary material (PDB file)

**Fig. 3** Free energy of binding between the WIF domain and various fatty acids. The *inset* shows  $\Delta G_{\text{binding}}$  for unsaturated fatty acids. Average values were derived from five fatty acid conformers exhibiting the lowest  $\Delta G_{\text{binding}}$ . RMSD between five lowest energy conformers increased from 0.75 to 2.9 Å with increasing length of fatty acid chain (C8–C24) (Suppl. Fig. 3). The height of the *error bar* is equal to the standard deviation in all of the figures

of saturated fatty acids. This suggests that the WIF domain might serve as the palmitoyl binding domain during the binding between palmitoylated Wnt and WIF-1.

No significant differences in the  $\Delta G_{\text{binding}}$  between even and odd chain fatty acids were observed. The influence of double C–C bonds on  $\Delta G_{\text{binding}}$  remained negligible in the case of C16:0 versus *cis*-9 C16:1 (Fig. 3, an inset). Interestingly, the *trans*-9 C18:1 lowest energy conformer exhibited the  $\Delta G_{\text{binding}}$  of −24.5 kJ/mol (Fig. 2) while the corresponding *cis*-9 C18:1 conformer docked with the  $\Delta G_{\text{binding}}$  of −18.2 kJ/mol. The identified differences between C18 fatty acid isomers probably could be explained by limitations of the program as no specific interactions between double C–C bond and WIF domain were observed (Fig. 2). However, it is tempting to speculate that Wnt signaling might be regulated using alternative saturated or unsaturated alkyl chains on the Wnt proteins.

To summarize, the putative fatty acid binding site was identified inside the WIF domain of the Wnt antagonist human WIF-1 using the computational docking method. The WIF domain exhibited the highest affinity for C16:0–C18:0 (−22 kJ/mol free energy of binding). The results suggest a possible role of the WIF domain as a palmitoyl binding domain required for WIF-1 binding to palmitoylated Wnt. Although molecular docking and NMR studies indicate high affinity of the WIF domain for alkyl chains, determination of the tertiary structure of palmitoylated Wnt in complex with its antagonist WIF-1 are highly desirable for the understanding of Wnt signaling pathway.

**Abstract** Atorvastatin calcium (AC) is a second-generation 3-hydroxy-3-methylglutaryl-CoA reductase inhibitor approved for clinical use as a lipid lowering agent. AC, the world's best selling drug is associated with poor oral bioavailability and serious adverse effects like rhabdomyolysis on chronic administration. A biodegradable nanoparticulate approach was introduced here with a view to improving the efficacy and safety of AC. Poly lactide-co-glycolic acid (PLGA) nanoparticles containing atorvastatin calcium were prepared using two stabilizers i.e. didodecyl dimethyl ammonium bromide (DMAB) and Vitamin E tocopheryl polyethylene glycol 1000 succinate (Vit E-TPGS) using a co-solvent approach by emulsion-diffusion-evaporation method. AC loaded PLGA nanoparticles prepared using DMAB and Vit E-TPGS were found to be  $120.0 \pm 4.2$  nm and  $140.0 \pm 1.5$  nm (z-average) in size respectively. In vitro release studies at pH 7.4 revealed a zero order release profile for nanoparticles.

Efficacy and safety parameters of the prepared nanoparticles against marketed formulation were evaluated in high fat diet fed (hyperlipidemic) rats. It was found that atorvastatin calcium nanoparticles were equally effective in comparison to Lipicure<sup>®</sup>, at a 66%-reduced dose in treating the hyperlipidemia characterized by alterations in PTC, LDL-C, VLDL-C, HDL-C, PTG and PGL in the high fat diet fed rats. On the other hand, when evaluated for safety, nanoparticulate formulation showed no/negligible myotoxicity characterized by lower PC, BUN, CK, LDH and AST levels in comparison to the marketed formulation.

## Introduction

Statins are the treatment of choice for the management of hyperlipidemia because of their proven efficacy.

Atorvastatin, the leading drug among statins, inhibits the enzyme 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG CoA) reductase resulting in reduced cholesterol synthesis. The salt form of the drug, atorvastatin calcium is most widely used for the treatment of hyperlipidemia. The statin market is increasing globally because of the associated risk of cardiovascular disorders with elevated lipid profiles.

All the drug candidates of statin group exhibit varied absorption rates upon oral administration. The oral absorption of atorvastatin is 30% and bioavailability is only 12% [1]. Atorvastatin is absorbed primarily from the intestine and to a lesser extent from the stomach and pre-systemic metabolism is the major cause for the poor bioavailability. Lau et al. [2] showed that saturable transport system involves in the hepatic uptake of atorvastatin in rats *in vivo*. Metabolic studies in animals revealed that more than 98% of the dose of atorvastatin was recovered in the feces within 48 h [3]. It was also reported that atorvastatin is metabolized extensively by cytochrome P-450 3A4 which was found extensively in the gut wall and liver [4].

Patients under statin treatment sometimes suffer from a number of serious adverse effects such as myopathy and rhabdomyolysis. The incidence of statin-induced rhabdomyolysis is low in clinical trials in which high risk patients were excluded. However, increased scrutiny shows that the incidence is higher when applied outside of these trials [5, 6]. The detailed mechanism is unknown but it was suggested that inhibition of HMG-CoA reductase may directly cause this myotoxicity [7]. It was thought that the exposure of statins to extrahepatic tissues leads to adverse effects, with diminutive pharmacological effect [8]. The most common explanations include the deficiency of one of three main end products: cholesterol deficiency with secondary abnormal membrane behavior, coenzyme Q<sub>10</sub> deficiency causing abnormal mitochondrial respiratory function, or prenylated protein abnormalities causing imbalances in intracellular protein messaging [9]. The root cause is related to increased distribution or accumulation of atorvastatin calcium in the muscles.

We hypothesize that oral nanoparticulate formulations by virtue of their unique uptake mechanism and sustained release of the loaded drug would improve the efficacy of atorvastatin and at the same time reduce the associated side effects. Therefore, the present work deals with the development of atorvastatin calcium nanoparticles using a biodegradable polymer, poly(lactide-*co*-glycolate) (PLGA) and their evaluation in hyperlipidemic rats for efficiency as well as safety.

## Experimental Procedure

### Nanoparticle Preparation and Characterization

Nanoparticles of AC were prepared by an emulsion–diffusion–evaporation technique with modifications [10]. AC has poor solubility in routinely used organic solvents, thus a co-solvent approach was adopted to formulate nanoparticles using poly(ethylene glycol) 400 (PEG 400) (S.d. fine-chem, India). 0.5 ml PEG 400 was used to dissolve required amount of AC (2.5–25 mg) while 50 mg PLGA (50:50) molecular weight 38,400 Da (Boehringer Ingelheim, Germany) was dissolved in 2.5 ml ethyl acetate followed by mixing both the solutions (organic phase) at room temperature. The organic phase was then added to the 5 ml aqueous phase containing either DMAB (Aldrich, USA) or Vit E-TPGS (Peboc, UK) as stabilizer at 1% *w/v* strength. This is homogenized at 15,000 rpm for 5 min using a high-speed homogenizer (Polytron PT4000, Switzerland) to form emulsion. The organic solvent was allowed to diffuse overnight at room temperature, which was facilitated by adding 20 ml water. The prepared nanoparticles were characterized using a zeta sizer (Nano ZS, Malvern Instruments, Malvern, UK) for size (average of 5 measurements for one batch) and zeta potential (average of 20 measurements for a batch). Three batches with each stabilizer were prepared in the same manner. The surface morphology of nanoparticles was analyzed by AFM (Veeco Bioscope II) that was attached with a Nikon eclipse TE 2000-S microscope. The system was run by Nanoscope software. The nanoparticles suspension was placed on the silicon wafer with the help of a micropipette and allowed to dry in air. The microscope was vibration damped and measurements were made using commercial pyramidal Si<sub>3</sub>N<sub>4</sub> tip (Veeco's CA, USA). The cantilever used for scanning had a length of 325 μm and a width of 26 μm with a nominal force constant 0.1 N/m.

The drug-loading was optimized by preparing the particles at different initial loadings (5–50% *w/w* of polymer). Entrapment efficiency is the percentage of drug incorporated in the nanoparticles. It was determined by centrifuging (25,000g and 10,000g for 5 min, respectively, for DMAB and Vit E-TPGS stabilized nanoparticles) the drug-loaded nanoparticles and separating the supernatant and pellet. The pellet was washed and dissolved in ethyl acetate followed by extraction of the drug. The drug content in the pellet and supernatant were analyzed using a validated HPLC method [11].

## In Vitro Drug Release Studies

The release of atorvastatin calcium from the nanoparticles was determined by a dialysis membrane method. Freshly made PLGA nanoparticles of DMAB or Vit E-TPGS (single batch is approximately 20 ml), were centrifuged (at 25,000g for DMAB and 10,000g, for 5 min, for Vit E-TPGS stabilized particles) and redispersed in 2 ml of phosphate buffer and put in the dialysis bags (Sigma) with a molecular mass cut-off of 12,000 Da. The bags were suspended in vials containing 5 ml phosphate buffer (pH 7.4). All the vials were kept in a shaking water bath maintained at 37 °C and 100 rpm. The release medium was completely replaced with 10 mM phosphate buffer at pre-determined intervals of 2, 4, 6, 8, 12 and 24 h on first day followed by sampling at 24 h interval every day till the release was observed. The amount of atorvastatin calcium released in the medium was estimated using HPLC method.

## Animals

Male Sprague-Dawley (SD) rats (180–200 g) were procured from the central animal facility of the Institute. The animals were housed in standard polypropylene cages (three rats/cage) and maintained under controlled room temperature ( $22 \pm 2$  °C) and humidity ( $55 \pm 5\%$ ) with 12 h light and 12 h dark cycle. All the rats were fed with commercially available rat normal pellet diet (NPD) (Amrut Diet, New Delhi) and water ad libitum, prior to the dietary manipulation. The guidelines of committee for the purpose of control and supervision of experiments on animals (CPCSEA), Government of India were followed and prior permission was sought from the institutional animal ethics committee for conducting the study.

## Development of Hyperlipidemic Rats

Except for the control group, which was fed NPD all the other group animals were fed high fat diet (HFD). The HFD comprises 58% fat, 25% protein and 17% carbohydrate, as a percentage of total kcal. The composition is described in Table 1 and preparation of HFD is described elsewhere [12].

## Experimental Design

The rats were divided into seven groups of  $n = 6$ . One group received NPD and all other groups received HFD. Groups receiving HFD were again divided into no treatment, and treatment groups. After 4 weeks, the animals

**Table 1** Composition of high fat diet

Ingredients	Diet (g/kg)

were treated with Lipicure<sup>®</sup> (HLI), AC loaded nanoparticles of DMAB (HAD) & Vit E-TPGS (HAE), and blank nanoparticles of DMAB (HBD) & Vit E-TPGS (HBE). Treatment was carried out for 2 weeks till the end of the sixth week. Drug treatment groups (HLI, HAD & HAE) received a dose of atorvastatin calcium equivalent to 3 mg/kg atorvastatin, through the oral route using an oral gavage needle. The blank nanoparticle groups (HBD & HBE) received the blank nanoparticles containing an equivalent polymer amount, which was associated with the AC nanoparticle dose. Dosing frequency was once every 3 days in the case of nanoparticles and daily for the commercial formulation (Table 2). Blood sampling was done after two, four, six, seven, and eight weeks and various biochemical parameters related to hyperlipidemia and atorvastatin toxicity were studied.

## Estimation of Biochemical Parameters

Plasma total cholesterol levels (PTC), plasma triglyceride levels (PTG), high-density lipoprotein cholesterol (HDL-C), plasma glucose levels (PGL), plasma creatinine levels (PC), blood urea nitrogen levels (BUN) were estimated using commercially available diagnostic kits (Accurex<sup>®</sup> kits.). Plasma enzyme activities of creatinine kinase (CK), lactate dehydrogenase (LDH) and aspartate transaminase

(AST) were estimated using commercially available diagnostic kits (Pointe Scientific Inc., USA and Crest Biosystems, India, respectively). Low-density lipoprotein cholesterol (LDL-C) levels were calculated using the Friedewald formula [13].

## Results and Discussion

### Nanoparticle Preparation and Characterization

Previous reports from our laboratory clearly indicate that water insoluble drugs can be efficiently loaded onto PLGA nanoparticles using various surfactants [10, 14–17]. However, considering the poor solubility of AC in common organic solvents used to make nanoparticles, a co-solvent approach [10] was adopted with suitable modifications. The particle preparation process was optimized for varied drug loading using DMAB and Vit E-TPGS as surfactants. The previous findings from our laboratory indicate that DMAB can lead to particles of about 80–200 nm in size irrespective of the polymer molecular weight, copolymer composition and the drug used [15–17] depending upon the process conditions. Furthermore, the studies indicate that the in vivo fate of these carrier systems is strongly influenced by their size, where the circulation times were thought to be dictated by their size and the release profiles by molecular weight and copolymer composition [16]. On the other hand, literature reports indicate that Vit E-TPGS is a surfactant with the natural ability to increase the absorption across the GIT [18–20], therefore, Vit E-TPGS was used as a second surfactant to make the AC loaded particles and compared with the particles made of DMAB for their efficacy. The blank particles (without the drug) made of DMAB and Vit E-TPGS as surfactants were found to be in the size range of 95 and 201 nm, respectively, whereas a slight increase in the size was observed for the drug loaded particles with DMAB as surfactant, which corroborates our previous findings as well as the literature reports that drug loading would add on to the size [10, 15,

16, 20–22]. However, such effect was not seen with Vit E-TPGS, rather a drastic decrease in the particle size was observed, which remains to be understood (Table 3). The zeta potential values of the particles are indicative of the surfactant nature, where, DMAB lead to cationic particles on contrary Vit E-TPGS resulted in negatively charged particles. The polydispersity index for both the formulations indicates the preparations have a very narrow polydispersity, the characteristic highly desirable in drug delivery applications (Table 3). Furthermore, these particles were characterized by Atomic Force Microscope for shape and size and the results obtained clearly indicate that the particles are spherical in shape with smooth surfaces (Fig. 1) and the size of the particles was comparable with that of the size obtained by zeta sizer measurements.

### In Vitro Release Studies

Nanoparticles were prepared using a biocompatible and biodegradable copolymer PLGA. The release of drug from the biodegradable particles occurs through several mechanisms of which the release mediated through (1) diffusion (2) surface erosion (3) bulk degradation and (4) a combined degradation/diffusion process are of importance [22]. No initial burst effect was observed with either of the formulations prepared using DMAB and Vit E-TPGS as the surfactant. A constant release rate for a period of 30 days was observed at an average release rate of 85.01 and 87.55  $\mu\text{g}/\text{day}$  for DMAB and Vit E-TPGS particles, with 50% of the drug being released in 15 days (Fig. 2a, b). The cumulative release was fitted into different release models: zero order, first order, Higuchi's square root plot, and Hixon–Crowell cube root plot. The model giving a correlation coefficient close to unity was taken as the order of release. A zero order release pattern was observed with DMAB and Vit E-TPGS stabilized nanoparticles with  $r^2$  of 0.990 and 0.987. We have also fitted the data for the first part of the release curve ( $M_t/M_\infty < 0.6$ ) into the Korsmeyer-Peppas equation ( $M_t/M_\infty = Kt^n$ ) and we got n values of 0.367 and

**Table 3** Characteristics of the nanoparticles used in the present study

Parameters	Blank nanoparticles		AC loaded nanoparticles <sup>b</sup>	
	DMAB	TPGS	DMAB	TPGS
Size (nm)	95.6 ± 4.8	201.0 ± 2.6	120.0 ± 4.2	140.0 ± 1.5
Polydispersity index	0.310 ± 0.005	0.170 ± 0.004	0.126 ± 0.007	0.150 ± 0.020

Values are depicted as mean ± SD ( $n = 6$ )

<sup>a</sup> pH of the nanoparticles was in the range of 4.5–6.0

<sup>b</sup> Initial drug loading is 20% w/w of polymer

**Fig. 1** Atomic force micrographs of atorvastatin calcium loaded nanoparticles prepared using DMAB (a) and Vit E-TPGS (b) as the stabilizer

0.366 for DMAB and Vit E-TPGS particles, however the regression was very poor with  $r^2$  0.928 and 0.892, respectively, making it difficult to comment on the mechanism of the drug release.  $M_t/M_\infty$  is the fraction of drug released up to time  $t$ ,  $K$  is the kinetic constant and  $n$  is the release exponent indicative of the release mechanism. From the values, it can only be understood that the mechanism by which the drug was released is non-Fickian. The chances are more towards a non-fickian case II release because of the good  $r^2$  value obtained with the zero order profile.

Traditionally, polymers that undergo surface erosion (polyanhydrides) are expected to release the entrapped drug at zero-order rate, where degradation and release show a strong correlation, in contrast, polymers that undergo bulk erosion (PLGA) are expected to release the entrapped drug primarily by diffusion followed by degradation showing a weak correlation between the degradation and release profile [22, 23]. However, no study has been

**Fig. 2** In vitro release of atorvastatin calcium from DMAB (a) and vit E-TPGS (b) particles in phosphate buffer at pH 7.4 and values are depicted as mean  $\pm$  SD ( $n = 3$ )

reported in the literature, to see if the final manipulation of those surface-eroding and bulk-eroding polymers into implants, microparticles, nanoparticles would change the fate of release kinetics. A series of studies conducted in our laboratory as well as by other workers with many water insoluble drugs using PLGA in the form of nanoparticles did show zero-order release profiles [14, 16, 17]. On the other hand, we did observe a Higuchi release pattern for molecules like ellagic acid, where the particles were made by a co-solvent approach leading us to conclude that the incorporation of PEG-400 would have made the difference [10, 21]. However, the present study with AC nanoparticles demonstrating the zero-order release profile does not support the foregoing statement. Taking together all the possibilities, it appears that the drug release kinetics is not only influenced by the polymer, but also by the final form of the product (implant, nano-microparticle), the drug, preparation process, sink conditions, sample withdrawal (aliquot or complete replacement of the medium) etc. On a different note, in vitro release studies with polymeric particulate systems might not be of real significance, considering the difficulties involved in establishing IVIVC,

**Fig. 3** Plasma total cholesterol levels (a) and plasma triglyceride levels (b). nevertheless, such studies would certainly give an insight for new polymers that are synthesized.

#### In Vivo Efficacy Parameters

The study revealed that after 4 weeks of HFD treatment the biochemical parameters PTC, PTG (Fig. 3a, b), and LDL-C levels were elevated, where as HDL-C levels decreased significantly (Fig. 4a, b). The plasma glucose levels were also elevated with this treatment (Fig. 5). During the fourth and sixth weeks different groups were treated as described in Table 2. Competitive inhibition of HMG CoA reductase by the AC decreases intracellular cholesterol synthesis. The associated reduction in concentration induces LDL-receptor expression leading to an increase in LDL-C clearance from plasma. Two direct mechanisms have been suggested for

**Fig. 4** Plasma LDL-cholesterol levels (a) and HDL-cholesterol levels (b). NPD- normal pellet diet, HFD- high fat diet only, HLI- hyperlipidemic rats treated with commercial formulation (Lipicure<sup>®</sup>), HAD- hyperlipidemic rats treated with DMAB stabilized nanoparticles of AC, HAE- hyperlipidemic rats treated with Vit E-TPGS stabilized nanoparticles, HBD- hyperlipidemic rats treated with blank DMAB stabilized nanoparticles, HBE- hyperlipidemic rats treated with blank TPGS stabilized nanoparticles. the reduction of triglycerides by atorvastatin calcium. Firstly, marked inhibition of cholesterol synthesis would impair the assembly and secretion of VLDL particles, of which cholesterol is an essential component, therefore causing a reduction in triglyceride levels. Secondly, reduction in hepatic cholesterol levels would lead to an increase in LDL-receptor expression and hence increased binding of VLDL and LDL particles reduction in both cholesterol and triglyceride levels [24]. There have been a number of clinical trials reporting the HDL-C increasing beneficial effect of atorvastatin [25], however, there is no established mechanism explaining this phenomenon. Another pleiotropic effect of atorvastatin includes insulin sensitization through which it reduces the glucose levels to some extent. Post hoc analysis of the West of Scotland

Coronary Prevention Study (WOSCOPS) observed an intriguing and unexpected significant reduction in the development of diabetes with statin therapy, suggesting a potential for regulating multiple complications associated with type II diabetes [26]. Recently atorvastatin treatment of insulin-resistant, fructose-fed hamsters appeared to ameliorate hepatic insulin resistance based on an increase in the tyrosine phosphorylation status of insulin receptors [27].

At the end of treatment (after six weeks) both the types of drug nanoparticles and commercial formulation of atorvastatin calcium had shown almost equal effects in assuaging the elevated levels of PTC, PTG, VLDL, LDL-C and reducing HDL-C levels. The exciting outcome of this study is that nanoparticles are as efficient as the commercial formulation although the nanoparticles were used at one-third the dose of the commercial formulation. Nanoparticles have been reported to increase the absorption of the encapsulated drugs when compared to the suspension form or any simple formulation type of the drug [28, 29]. By the virtue of enhanced absorption and the sustained release of drug these nanoparticles might have shown equal effects as the commercial formulation, which was given once daily. From this we can say that a once-in-3-days regimen of nanoparticles matched the once-daily regimen of the commercial formulation and showed a similar trend in the assuaging of different efficacy parameters during the treatment and elevation of the same parameters during the follow up after stoppage of treatment.

The literature has reported improved particle uptake in vivo and in vitro cell culture models when nanoparticles

**Fig. 6** Activities of different enzymes, SGOT (a), LDH (b) and CK (c). NPD- normal pellet diet, HFD- high fat diet only, HLI- hyperlipidemic rats treated with commercial formulation (Lipicure<sup>®</sup>), HAD- hyperlipidemic rats treated with DMAB stabilized nanoparticles of AC, HAE- hyperlipidemic rats treated with Vit E-TPGS stabilized nanoparticles, HBD- hyperlipidemic rats treated with blank DMAB stabilized nanoparticles, HBE- hyperlipidemic rats treated with blank TPGS stabilized nanoparticles. were coated with mucoadhesive polymers such as chitosan or surfactants like Vit E-TPGS as well as the size dependent uptake, where smaller particles are absorbed better than larger ones [10, 14–16, 18]. Therefore, the present investigation aimed at screening two different formulations made of distinctly different surfactants DMAB and Vit E-TPGS, where DMAB leads to particles of smallest size as discussed in the foregoing sections, on the other hand, Vit E-TPGS with ability to enhance the absorption across the GIT. In our previous studies we have seen distinct differences in the bioavailability with different sized particles, where smaller particles showed better circulations times [16]. In the present study, we have not seen any difference in the efficacy of the two formulations though there is a significant difference in the particle size (Table 3) further supporting the hypothesis described above, that the size and nature of the surfactant can

**Fig. 7** Plasma creatinine levels (a) and blood urea nitrogen levels (b). NPD- normal pellet diet, HFD- high fat diet only, HLI- hyperlipidemic rats treated with commercial formulation (Lipicure<sup>®</sup>), HAD- hyperlipidemic rats treated with DMAB stabilized nanoparticles of AC, HAE- hyperlipidemic rats treated with Vit E-TPGS stabilized nanoparticles, HBD- hyperlipidemic rats treated with blank DMAB stabilized nanoparticles, HBE- hyperlipidemic rats treated with blank TPGS stabilized nanoparticles. Values are depicted as mean  $\pm$  SEM ( $n = 6$ ). \*\*\* $P < 0.001$ , \*\* $P < 0.01$ , \* $P < 0.05$ , **a** HLI versus all other groups; **b** HAD and HAE versus all other groups at that week

influence the overall performance of the formulations. After six weeks, the treatment was stopped and the same parameters were followed until the biochemical parameters matched the HFD control animals. The levels elevated gradually with time and reached the HFD control levels at the end of the 8th week. Though the nanoparticulate AC showed similar/better effects in comparison to Lipicure<sup>®</sup>, at a 66%-reduced dose, the formulations did not show any activity beyond sixth week, which was comparable to Lipicure<sup>®</sup> treated groups and this could be due to particle elimination or limited dose administered in comparison to the Lipicure<sup>®</sup> (3.75 vs. 11.25 mg total dose) (Table 2). The elevation trend of efficacy parameters of both types of nanoparticles from sixth to eighth week is completely overlapped with the trend followed by the commercial formulation. On the other hand the blank nanoparticles

were equivalent to the HFD group indicating least possible effect of nanoparticles as such without the drug.

During the treatment period (four to six weeks) the treatment groups (Lipicure<sup>®</sup> and both the nanoparticles formulations) effectively reduced the PTC, PTG, VLDL-C, LDL-C levels and elevated the HDL-C, however, the same was found to increase and decrease in the case of HDL-C by the seventh week and further matched the HFD group by the eighth week. The intriguing finding in the study is the effectiveness of the nanoparticulate groups at a 66%-reduced dose in comparison to Lipicure<sup>®</sup>.

#### Safety Parameters

Concern over the safety of the HMG-CoA reductase inhibitors, or statins, followed the worldwide withdrawal of cerivastatin in 2001, a drug that had been thought to be relatively free of serious adverse effects over the 4 years it was marketed [29]. Further concern followed documentation of the hazards of rosuvastatin after regulatory approval by the US Food and Drug Administration (FDA) and marketing [30]. Nowadays, there are increasing numbers of reports on the atorvastatin associated complications. The elimination half-life of atorvastatin is longer when compared with some other statins. There are more chances of tissue accumulation of AC on repeated administration. Due to its long elimination half-life and the presence of detectable plasma levels of active metabolites for a prolonged period of time (>24 h), AC can accumulate in the plasma, achieving a steady state drug concentration after multiple doses. After a single atorvastatin dose on day 1, drug concentrations increased more than proportionally with a 5–80 mg dose range. Atorvastatin equivalent concentrations achieved a steady state by the third day of multiple dosing [31].  $C_{max}$  and AUC increased more than proportionally with dose during multiple administrations. Atorvastatin accumulation was 1.6-fold and 3.3-fold on the 22nd day after once- and twice-daily administration, respectively. From the efficacy parameters, it is evident that the nanoparticulate formulations are equally effective to Lipicure<sup>®</sup> at a 66%-lower dose, on the other hand, nanoparticulate formulations showed no/negligible toxicity, which could be due the following two reasons, (1) nanoparticles can protect the drug from being degraded, instant metabolism and can release the entrapped drug at a sustained rate all contributing to improved efficacy and reduced toxicity, (2) nanoparticles can modify the tissue distribution and could be quite different from the native drug distribution profiles.

There were no significant changes in CK levels with the commercial formulation and nanoparticulate formulation (Fig. 6). AST levels and LDH levels were increased with HLI treatment (Fig. 6). Commercial AC formulation

increased the levels of PC, which are indicative of muscle as well as kidney toxicity, which was not observed with nanoparticles (Fig. 7a). A similar case is with the other marker measured for renal failure, BUN (Fig. 7b). All these toxicity parameters if raised were only with the commercial formulation and not with the nanoparticles. Overall, the nanoparticles at reduced dose and frequency showed no adverse effects without compromising the efficacy.

The Clinical Advisory on Statins made a significant step towards standardization of the terms in myotoxicity [32]. Rhabdomyolysis required muscle symptoms with marked creatine kinase elevation typically substantially greater than ten times the upper limit of the normal, with a creatinine elevation consistent with pigment nephropathy and usually with brown urine with myoglobinuria. Although this is an improvement over prior classifications, the requirement that creatine kinase exceed ten times the upper limit of normal is arbitrary and excludes some cases of serious muscle toxicity. It is also unclear why the diagnosis of rhabdomyolysis, a muscle disorder, should require evidence of renal impairment. There is no specific biomarker available to date for the statin induced myotoxicity. Elevation of PC with or without elevation of CK is generally used to establish the myotoxicity of statins with elevation of other parameters like LDH, AST, and BUN [33, 34].

The remarkable observation of this study was that the adverse effects of atorvastatin calcium were suppressed when nanoparticles were used. The reason could be the reduced total dose and frequency with sustained release of the nanoparticles resulting in reduced accumulation of the drug upon chronic treatment. It is well established that the adverse effects of atorvastatin calcium are dose dependent. From the literature it is evident that chronic treatment with atorvastatin calcium results in accumulation and exposure of statins to extra hepatic tissues leading to adverse effects [35]. Lipid lowering drugs may induce necrotizing myopathy of the direct type. The fundamental change may be a disturbance of the integrity of the plasma membrane of the muscle fiber, allowing an efflux of calcium ions into the fiber which leads to over contraction and breakdown of the contractile apparatus and to a disturbance of protein synthesis and mitochondrial metabolism, culminating in death of the fiber. This reaction is dose-dependent [35].

## Conclusion

The possible approaches in managing hyperlipidemia include life style management and drug therapy. However, drug therapy was adopted very rapidly by physicians as well

as patients. After the introduction of atorvastatin onto the market, it has become the best selling drug in this category. However, there have been certain reports recently reporting the toxicity of atorvastatin. The feasibility of nanoparticulate delivery of AC, capable of releasing the entrapped drug in a sustained fashion over a period of time has been evaluated in hyperlipidemic rats. The study clearly demonstrates the proof of the concept that drug delivery systems can improve the performance of the drugs and minimize the side effects (Table 4), in this case AC nanoparticulate formulations.

**Abstract** Lysophosphatidylcholine (LysoPtdCho) levels are elevated in sera in patients with atherosclerosis and in atherosclerotic tissue. Previous studies have shown that reactive chlorinating species attack plasmalogens in human coronary artery endothelial cells (HCAEC), forming lysoPtdCho and lysoPtdCho–chlorohydrin (lysoPtdCho–ClOH). The results herein demonstrate for the first time that lysoPtdCho–ClOH is elevated over 60-fold in human atherosclerotic lesions. In cultured HCAEC, 18:0 lysoPtdCho–ClOH led to a statistically significant increase in P-selectin cell-surface expression, but unlike 18:1 lysoPtdCho did not lead to cyclooxygenase-2 protein expression. These data show that 18:0 lysoPtdCho–ClOH is elevated in atherosclerotic tissue and may have unique pro-atherogenic properties compared to lysoPtdCho.

**Keywords** Myeloperoxidase · Reactive chlorinating species (RCS) · Plasmalogen · P-selectin

### Abbreviations

RCS	Reactive chlorinating species
LysoPtdCho	Lysophosphatidylcholine
ClOH	Chlorohydrin

lysoPtdCho–ClOH	Lysophosphatidylcholine–chlorohydrin
PtdCho–ClOH	Phosphatidylcholine–chlorohydrin
FFA–ClOH	Free fatty acid chlorohydrin
HCAEC	Human coronary artery endothelial cells
MPO	Myeloperoxidase
GC–MS	Gas chromatography–mass spectrometry
ESI–MS	Electrospray ionization–mass spectrometry
HOCl	Hypochlorous acid
LDL	Low-density lipoprotein
2-ClHDA	2-chlorohexadecanal

### Introduction

Lysophosphatidylcholine (LysoPtdCho) is elevated in atherosclerotic lesions from monkey [1], rat [2], and human [3] and may be an important pro-atherogenic mediator. LysoPtdCho comes from a variety of sources including the enzymatic action of a variety of phospholipase A<sub>2</sub>s (PLA<sub>2</sub>) on low-density lipoprotein (LDL) and membrane phosphatidylcholine (PtdCho) [4]. Numerous studies have shown that serum levels of lysoPtdCho are elevated from patients that have chronic inflammatory conditions such as renal failure on hemodialysis [5], diabetes [6], cancer [7], asthma [8], and atherosclerosis [9].

Activated monocytes and a subpopulation of macrophages release myeloperoxidase (MPO), which is an enzyme that catalyzes the production of reactive chlorinating species (RCS) such as hypochlorous acid (HOCl) [10]. Levels of MPO are elevated in atherosclerotic plaques

[11], as well as MPO-derived oxidation products such as 3-chlorotyrosine [12] and 2-chlorohexadecanal (2-ClHDA) [3]. It has been shown that phosphatidylcholine-chlorohydrins (PtdCho–ClOHs) are produced from isolated LDL treated with physiologically-relevant concentrations of HOCl [13]. PtdCho–ClOHs have been shown to elicit ATP depletion and necrosis in HL60, U937, Jurkat, and THP-1 cells [14, 15]. Additionally, Dever et al. [15] demonstrated that 25–50  $\mu\text{M}$  PtdCho–ClOHs increased leukocyte adhesion to mouse artery segments by P-selectin expression [16] and increased caspase-3 activity [15]. There are several classes of phospholipase A<sub>2</sub> (PLA<sub>2</sub>) that function to release the *sn*-2 fatty acid chains from the glycerol backbone of PtdCho, thereby potentially releasing free fatty acid-chlorohydrins (FFA–ClOHs). FFA–ClOHs cause ATP depletion [15] and cell death of erythrocytes [17] and endothelial cells [18]. In particular, administration of linoleic acid monochlorohydrin elicited decreased muscle tension using an isolated guinea-pig heart papillary muscle preparation [6].

Plasmalogens are a subclass of glycerophospholipids enriched in the cells of the cardiovascular system, and is thought to play an important role in normal heart function, as well as serve as an endogenous lipoprotein antioxidant [19]. Recently, our lab and others have shown that RCS attack of plasmenylcholine in liposomes and in human coronary artery endothelial cells (HCAEC) yields lysoPtdCho [20, 21] and lysoPtdCho-chlorohydrin (lysoPtdCho–ClOH) [21–23]. Additionally, we have shown that HOCl preferentially targets lysoPtdCho in comparison to PtdCho [22]. Since lysoPtdCho is elevated in atherosclerotic lesions and is preferentially targeted by RCS in vitro, the present study was designed to determine that lysoPtdCho–ClOH levels increase in atherosclerotic lesions. We show here, for the first time, that lysoPtdCho–ClOH is elevated in atherosclerotic lesions, and that lysoPtdCho–ClOH induces P-selectin cell-surface expression on HCAEC.

## Materials and Methods

### Lipids

Lysoplasmenylcholine (1-*O*-hexadec-1'-enyl-GPC) was prepared from bovine heart lecithin and purified as described previously [24]. 1-*O*-Hexadec-1'-enyl-2-heptadec-10'-enyl-GPC (16:0–17:1 plasmenylcholine), 1-*O*-hexadec-1'-enyl-2-octadec-9'-enyl-GPC (16:0–18:1 plasmenylcholine), and 1-*O*-hexadec-1'-enyl-2-nonadec-10'-enyl-GPC (16:0–19:1 plasmenylcholine) were synthesized by an anhydrous reaction utilizing 1-*O*-hexadec-1'-enyl-GPC and heptadec-10'-enyl chloride, octadec-9'-enyl chloride, and nonadec-10'-enyl chloride, respectively, as precursors and

dimethylaminopyridine as a catalyst. The reactions were purified sequentially by normal phase HPLC and then by reversed phase HPLC. Purity of the plasmalogen fraction was confirmed by ESI-MS and quantified by GC following acid methanolysis using arachidic acid as an internal standard. 16:0–17:1 and 16:0–19:1 plasmenylcholine were treated with tenfold molar excess HOCl [25, 26], which simultaneously cleaved the vinyl ether bond and formed 17:0 and 19:0 lysoPtdCho–ClOH, respectively. The desired reaction product, lysoPtdCho–ClOH, was purified by HPLC, quantified by Bartlett [27], extracted in chloroform and stored at –20 °C under N<sub>2</sub>. All other materials were of the highest grade available and were purchased from Sigma-Aldrich or Fisher.

### Cell Culture

HCAEC (Cell Applications) were seeded onto 60 or 35-mm<sup>2</sup> 6-well tissue culture dishes and cultured in EGM-2-MV (Lonza) at 37 °C in a 5% CO<sub>2</sub> and 95% air atmosphere. Experiments were performed on ~80% confluent monolayers (~1 × 10<sup>6</sup> cells/60-mm<sup>2</sup> dish) between passages 5 and 9. HCAEC growth medium was replaced with growth medium containing 2% FBS for 4–6 h prior to experiments. Lipids were dried under a stream of nitrogen and reconstituted in ethanol at a concentration of 0.1% (v/v) per well. Lipids were mixed with EGM-2MV and added by pipette to each dish dropwise for a final concentration of 1–50  $\mu\text{M}$ , while control dishes received 0.1% ethanol vehicle mixed into EGM-2MV.

### Human Tissue

Atherosclerotic and normal aortic tissue was collected from human postmortem autopsy specimens as authorized by Saint Louis University Institutional Review Board Protocol #10014. In general, tissues were harvested 6–12 h post-mortem and then were sequentially rinsed, and submerged in PBS supplemented with 100  $\mu\text{M}$  diethylenetriamine-pentaacetic acid and 100  $\mu\text{M}$  butylhydroxytoluene, frozen in liquid N<sub>2</sub>, and stored at –80 °C until analysis. Normal tissue was collected from subjects showing no overt indications of atherosclerotic vascular disease. Frozen tissue was weighed and then crushed in a liquid nitrogen-chilled mortar and pestle. Lipids and internal standards 17:0 and 19:0 lysoPtdCho–ClOH were added to the crushed tissue in methanol/chloroform/saline (2.5:1.5:1 v/v/v). After 5 min, chloroform was added resulting in a 1:1:0.8 methanol/chloroform/saline ratio [28]. The extracted organic phase was stored in chloroform at –20 °C under N<sub>2</sub> until analysis.

## Electrospray Ionization–Tandem Mass Spectrometry

Lipid extracts were reconstituted in methanol containing 10  $\mu$ M NaOH and analyzed by ESI–MS in the direct infusion mode at a flow rate of 1–3  $\mu$ L/min using Thermo Electron TSQ Quantum Ultra instrumentation. The choline glycerophospholipids yield intense  $[M + Na]^+$  adduct ions by electrospray ionization in the positive ion mode. Tandem mass spectrometry was performed on selected ions (collision energies were  $\sim$ 32–38 eV). To detect lysoPtdCho and lysoPtdCho– molecular species, survey scan and neutral loss scanning of 95 amu (NL 95) was employed. Spectra were averaged at 3–5 min and processed utilizing Xcalibur software (Thermo), and molecular species were quantified by comparing the ion intensity of individual molecular species to that of the internal standards. The differences in  $^{13}\text{C}$  isotope effects ( $Z_1$ ) between the endogenous 16:0 and 18:0 lysoPtdCho–C1OH and the internal standards 17:0 and 19:0 lysoPtdCho–C1OH were corrected [29].

## P-selectin Surface Expression

P-selectin expression on the surface of HCAEC was measured by a modified ELISA with nonpermeabilized monolayers using a modified version of the method described by Willam et al. [30]. HCAEC, grown to confluence in 24-well plates, were incubated with indicated lipids in Hanks' buffer for 5 min at 37  $^{\circ}\text{C}$  in 95%  $\text{O}_2$ /5%  $\text{CO}_2$ . At the end of incubations, buffer was quickly removed and cells were immediately fixed with 1% paraformaldehyde overnight at 4  $^{\circ}\text{C}$ . Cells were then washed 3 times with PBS and then blocked with Tris-buffered saline containing 0.1% Tween 20 (v/v) supplemented with 0.8% BSA (w/v) and 0.5% fish gelatin (w/v) for 1 h at 24  $^{\circ}\text{C}$ . Primary goat polyclonal antibody (1:500) for P-selectin (Santa Cruz) was used before treatments with horseradish peroxidase-conjugated rabbit-anti-goat secondary antibody (1:5,000). Subsequently, each well was incubated in the dark with the 3,3',5,5'-tetramethylbenzidine liquid substrate system. Reactions were stopped by the addition of sulfuric acid, and color development was measured with a microtiter plate spectrophotometer (Wallac) at 450 nm [3].

## Western Blotting

HCAEC monolayers in 60-mm<sup>2</sup> dishes were exposed to various experimental conditions in the presence of 2% FBS-supplemented EGM-2-MV. At the end of the treatment, the medium was aspirated from the dishes and monolayers were rinsed with PBS. Cells were scraped in

SDS sample buffer containing DTT, boiled, and subjected to SDS-PAGE utilizing 10% polyacrylamide gels followed by transfer of proteins to polyvinylidene difluoride (PVDF)-plus membranes (GE Waters) for Western blot analysis. Blots were probed with an antibody to COX-2 (1:1,000) (Zymed) and an HRP-conjugated secondary antibody (1:7,000) (Sigma). Blots were stripped (0.1 M glycine, pH 2.5) and, following extensive washing, re-probed with an antibody to  $\beta$ -actin (1:5,000) (Abcam) and probed with an HRP-conjugated goat-anti-rabbit (1:7,000) (Sigma). Immunoreactive bands were visualized by exposure to autoradiographic film following incubation with enhanced chemiluminescence reagent (GE Healthcare).

## Data Analysis

Data were normalized to the respective control mean values and are expressed as means  $\pm$  SEM. Statistical analyses of data were performed by *t*-test and  $P \leq 0.05$  was considered statistically significant.

## Results

Lipid extracts from both atherosclerotic and normal human aorta samples were analyzed by ESI–MS. Previous studies have shown that unsaturated lysoPtdCho is present in higher levels of atherosclerotic lesions [3] and that MPO-derived oxidation products such as 3-chlorotyrosine [12] and the  $\alpha$ -chlorofatty aldehyde, 2-ClHDA [3], have been detected in lesions. Since MPO-derived RCS have been shown to attack lysoPtdCho to produce lysoPtdCho–C1OH [21–23], ESI–MS was used to assess lysoPtdCho–C1OH accumulation in atherosclerotic lesions. Initial inspection of the spectra from normal and atherosclerotic tissue in the positive ion mode show noticeable differences, qualitatively revealing an increase in lysoPtdCho molecular species, which include  $m/z$  518, 542, 544, 546, and 566, corresponding to 16:0, 18:2, 18:1, 18:0, and 20:4 lysoPtdCho, respectively (Fig 1a). Neutral loss scanning of 95 amu, which corresponds to the combined neutral loss of the trimethylamine and HCl [22], was utilized to detect chlorinated choline glycerophospholipid species. Figure 1b (traces 1 and 2) shows molecular ions with NL 95 scanning of lipid extracts from normal tissue extracted in the presence of synthetic internal standards 17:0 and 19:0 lysoPtdCho–C1OH at  $m/z$  582 and 610, respectively. Figure 1b (traces 3 and 4) shows molecular ions with NL 95 scanning from atherosclerotic tissue extracted in the presence of synthetic internal standards (e.g.,  $m/z$  582 and 610) and demonstrate the appearance of 18:0 lysoPtdCho–C1OH at  $m/z$  596. Atherosclerotic tissue also contains 16:0 lysoPtdCho–C1OH ( $m/z$  568).

**Fig. 1** 18:0 LysoPtdCho–C1OH is detected in atherosclerotic tissue. Lipids from normal and atherosclerotic aorta were analyzed by ESI–MS in positive ion mode with spectra from a survey scan shown in a and neutral loss scanning of 95 amu (b). The spectra of molecular ions from normal tissue (spectra 1 and 2) show the synthetic internal standards 17:0 and 19:0 lysoPtdCho–C1OH at  $m/z$  582 and 610, respectively. The spectra of molecular ions atherosclerotic tissue contain 16:0 lysoPtdCho–C1OH at  $m/z$  568, 18:0 lysoPtdCho–C1OH at  $m/z$  596, and the synthetic internal standards (spectra 3 and 4)

Utilizing neutral loss scanning of 95 amu, the relative abundance of 18:0 and 16:0 lysoPtdCho–C1OH were compared to the relative intensities of the internal standards for quantification. Atherosclerotic tissue contains approximately 69-fold more 16:0 lysoPtdCho–C1OH and 82-fold more 18:0 lysoPtdCho–C1OH than normal tissue (Fig. 2). However, 18:0 lysoPtdCho–C1OH is about 10.7-fold more abundant than 16:0 lysoPtdCho–C1OH. This likely reflects the abundance of 18:1 lysoPtdCho compared to 16:1 lysoPtdCho in atherosclerotic tissue (see Fig. 1a, spectra 2). Other unsaturated lysoPtdCho molecular species, such as 18:2 and 20:4 lysoPtdCho (e.g.,  $m/z$  544 and 566, respectively), are elevated in atherosclerotic tissue compared to

**Fig. 2** 16:0 and 18:0 LysoPtdCho–C1OH molecular species are elevated in atherosclerotic tissue. Lipids from normal and atherosclerotic aorta tissue were extracted and analyzed by direct infusion ESI–MS using neutral loss scanning of 95 amu in positive ion mode. Quantification of 16:0 and 18:0 lysoPtdCho–C1OH was performed by comparison to the relative intensities of the internal standards 17:0 and 19:0 lysoPtdCho–C1OH, respectively, as described in “Materials and Methods”

control tissue (Fig. 1a). The accumulation of these unsaturated lysoPtdCho molecular species in atherosclerotic vascular tissue has previously been shown [3], which likely reflect phospholipase A<sub>1</sub> or lipase activity directed at phosphatidylcholine or alternatively RCS attack of unsaturated plasmenylcholine molecular species [3]. It should be appreciated that lysoPtdCho molecular species containing multiple chlorohydrin residues were not observed in atherosclerotic tissue as well as in our previous in vitro studies [22]. These findings are similar to those of Panasenko et al. [31] who showed that multi-chlorohydrin species are unstable and degrade to short-chained lysoPtdCho molecular species.

Endothelial activation, and subsequent dysfunction, is recognized as a major hallmark in the development and progression of atherosclerosis [32]. LysoPtdCho induces a wide range of pro-atherogenic effects [33], however the effects of lysoPtdCho–C1OHs are unknown. Two critical events in the development of atherosclerosis are cell-surface expression of proteins that tether blood monocytes to inflamed endothelium and release of chemotactic molecules [34]. Figure 3 shows that 10  $\mu$ M 18:0 lysoPtdCho–C1OH elicits HCAEC surface expression of P-selectin at levels similar to that elicited by platelet activating factor [3]. The results suggest that lysoPtdCho–C1OH may function to recruit leukocytes to the endothelium by inducing an increase in coronary artery endothelial cell surface expression of P-selectin, an adhesion factor implicated in the development of vascular inflammation [35].

Cyclooxygenase-2 (COX-2) is an inducible enzyme that catalyzes the production of prostaglandin H<sub>2</sub> (PGH<sub>2</sub>) from phospholipid-derived arachidonic acid [36, 37]. COX-2 is

**Fig. 3** P-selectin is expressed on the surface of HCAEC following 18:0 lysoPtdCho-C1OH treatment. HCAEC were treated with Hank's buffer alone (control) or buffer containing 10  $\mu$ M 18:0 lysoPtdCho-C1OH for 5 min. A modified ELISA was utilized to assay P-selectin cell surface expression and is expressed as increased absorbance,  $P < 0.01$

highly expressed in atherosclerotic plaques [38] and increased COX-2 expression in endothelial cells has been shown to increase prostacyclin production [39]. Under normal conditions, prostacyclin has a variety of effects in the vasculature, including inhibiting platelet aggregation and adhesion, relaxing smooth muscle cells, and inhibiting leukocyte activation and adhesion [40]. Palmitoyl lysoPtdCho has been shown to induce COX-2 protein expression in vascular endothelial cells [41–43]. Our previous studies showed that unsaturated lysoPtdCho is elevated in human atherosclerotic plaques [3]. Robust COX-2 protein expression was elicited in HCAEC by 50  $\mu$ M 18:1 lysoPtdCho, whereas only slight induction of COX-2 was seen following 50  $\mu$ M 18:0 lysoPtdCho, and no COX-2 expression was observed after treatment with 18:0 lysoPtdCho-C1OH (Fig. 4).

**Fig. 4** 18:1 LysoPtdCho induces COX-2 protein expression. HCAEC were treated with vehicle or were treated with 1, 10, or 50  $\mu$ M (in triplicate) of various lysoPtdCho for 8 h. Western blotting was performed for COX-2 and  $\beta$ -actin

## Discussion

Myeloperoxidase is found in human atherosclerotic lesions [11] and is localized in the shoulder regions of the plaque [44]. Products from MPO-derived RCS attack of tissue targets include, 3-chlorotyrosine, which is elevated sixfold in human atherosclerotic vascular tissue compared to normal vascular tissue [45]. Previous studies have shown that RCS attack of plasmalogen choline leads to the formation of unsaturated lysoPtdCho [20, 21] and  $\alpha$ -chlorofatty aldehyde [46] (Scheme 1). Furthermore unsaturated lysoPtdCho is targeted by RCS leading to the production of lysoPtdCho-C1OH [21, 22] (Scheme 1).  $\alpha$ -Chlorofatty aldehydes [3], were the first chlorinated lipids found in atherosclerotic lesions and are elevated  $\sim$ 1400-fold in atherosclerotic aorta. In this study, we utilized a soft ionization technique, ESI-MS/MS, and determined that human atherosclerotic tissue contains 69-fold more 16:0 and 82-fold more 18:0 lysoPtdCho-C1OH than normal tissue. Similar to our previous in vitro studies, only chlorohydrins derived from monoenoic lysoPtdCho molecular species were detected which likely reflects the instability of the lysoPtdCho chlorohydrins produced from polyunsaturated molecular species of lysoPtdCho [31].

LysoPtdCho is elevated in atherosclerotic lesions [3] and in sera of people with atherosclerosis [9]. Interestingly the mechanism leading to the production of unsaturated molecular species of lysoPtdCho (e.g. 20:4 lysoPtdCho as observed as  $m/z$  566 in Fig. 1a) reflects a combination of activation of phospholipase A<sub>1</sub> lipase activities and RCS attack of plasmalogen choline molecular species. The results from this study demonstrate that 18:1 lysoPtdCho induces increased COX-2 protein expression in HCAEC. There are contradictory reports on the role of COX-2 in the development of atherosclerosis. Recent studies show that prostanoid synthases, such as those responsible for the synthesis of PGE<sub>2</sub>, PGD<sub>2</sub>, PGF<sub>2</sub> $\alpha$ , PGI<sub>2</sub>, and TXA, differentially couple with upstream COX-1 and COX-2 and that colocalization is essential for terminal prostanoid production. Prostanoid synthases preferentially localize to either COX isozyme, and some localize to both COX-1 and COX-2 depending on the stimulus [47]. It appears that the addition of a chlorohydrin moiety across the alkene bond led to the ablation of the robust increase in COX-2 protein induced by 18:1 lysoPtdCho in HCAEC. The elevation of 18:1 lysoPtdCho in atherosclerotic tissue may confer anti-atherogenic properties in endothelial cells by increasing COX-2 protein expression and prostacyclin production. If this is the case, chlorohydrin formation of 18:1 lysoPtdCho due to RCS attack, leads to a molecular species that is unable to elicit COX-2 expression. If, however, 18:1 lysoPtdCho induces preferential coupling of pro-atherogenic PGE<sub>2</sub> or TXA to COX-2, further oxidation to 18:0

**Scheme 1** Scheme of RCS attack of plasmenylcholine to yield 18:1 lysoPtdCho and 18:0 lysoPtdCho–ClOH. RCS attacks plasmenylcholine resulting in the release of an  $\alpha$ -chlorofatty aldehyde and unsaturated molecular species of lysoPtdCho. LysoPtdCho undergoes further oxidation by RCS to yield lysoPtdCho–ClOH

lysoPtdCho–ClOH would prevent further pro-atherogenic prostaglandin production.

Previous studies have demonstrated that 2-ClHDA is a potent neutrophil chemoattractant, while unsaturated lysoPtdCho increases P-selectin surface expression on HCAEC [3, 20]. The results from this study show that 18:0 lysoPtdCho–ClOH also leads to increased P-selectin surface expression on HCAEC, which may function to recruit more MPO-containing leukocytes to sites of inflammation. RCS attack of plasmenylcholine may lead to the production of molecular species that lead to both leukocyte attraction and adhesion. Collectively these data suggest that lysoPtdCho–ClOH in injured blood vessels may propagate inflammation by facilitating leukocyte recruitment through a mechanism leading to P-selectin surface expression on endothelial cells.

Collectively the data presented herein show that lysoPtdCho–ClOH accumulate in human atherosclerotic tissue and have a potential role in the inflammatory state of the atherosclerotic lesion. It will be important in future studies to determine the accumulation and role of these lipids in early stages of atherosclerotic tissue as well as determine the tissue distribution of lysoPtdCho–ClOH at lesion sites as well as adjacent tissue. It will also be of great importance to determine that lysoPtdCho–ClOH are associated with oxidized LDL in the subintima. It would then follow that levels of 16:0 and 18:0 molecular species of lysoPtdCho–ClOH in blood LDL could potentially serve as a marker of coronary artery disease risk. It would be of interest as well to determine the choline glycerophospholipid, lysoPtdCho and lysoPtdCho–ClOH molecular species profile in diet-controlled studies comparing diets enriched in either monoenoic, saturated or cardioprotective  $\omega$ -3 fatty acids. Further studies on these novel chlorinated lipids as

well as other blood-borne chlorinated lipids derived from MPO activity may prove to be important in the development of biomarkers for cardiovascular disease.

**Abstract** The objective of the present study was to compare the effects of *cis*-9,*trans*-11 + *trans*-8,*cis*-10 conjugated linoleic acid (CLA) mixture to those of *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture and linoleic acid (LA) on lipoprotein profile, hepatic lipids, body composition and digestibility of dietary fat in hamsters ( $n = 17$ ) fed diets containing 2% of experimental fat (w/w) for 28 days. The *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture showed higher LDL cholesterol concentrations than LA and the *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture. The *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture induced similar plasma LDL cholesterol and hepatic lipid concentrations, and coefficient of digestibility as LA, indicating no effect of the *trans*-8,*cis*-10 CLA isomer on these lipid parameters. On the other hand, the *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture induced higher plasma VLDL cholesterol and triglycerides than LA and the *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture. The *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture also induced the highest plasma glucose concentrations compared with

the two other groups, indicating an impairment of glycemic control. No differences in body composition were noted between the three groups. The present results thus show that the *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture can deteriorate plasma VLDL cholesterol and triglycerides in hamsters, possibly due to an increased flux of glucose.

### Introduction

Conjugated linoleic acid (CLA) represents a series of heterogeneous polyunsaturated fatty acids that exist as positional and geometric isomers of conjugated octadecadienoic acid (18:2) varying in double bonding pattern. Unlike linoleic acid (LA), which is a single unique molecule, several different CLA isomers are possible depending on which carbon atom the double bonds are relocated and the resulting isomeric reconfigurations [1]. CLA is found in foods such as beef and lamb, as well as dairy foods derived

from these ruminant sources, formed largely as a result of rumen microbial isomerisation of dietary linoleic acid as well as desaturation of octadecanoic acid derivatives. Of these, the predominant geometric isomer of CLA in foods is the *cis-9,trans-11* C18:2, followed by *trans-7,cis-9* C18:2, *cis-11,trans-13* C18:2, *trans-8,cis-10* C18:2 and the *trans-10,cis-12* C18:2 [2]. CLA produced chemically is available as dietary supplement, usually containing equal amounts of *cis-9,trans-11* CLA, and *trans-10,cis-12* CLA as well as a proportion of other fatty acids [3]. The most dominant CLA isomer in milk fat is *cis-9,trans-11* C18:2. Recent work has shown that this isomer can be transformed into *trans-8,cis-10* C18:2 by heating butterfat under specific conditions [4].

A number of animal studies, primarily in rodents, showed that the consumption of CLA results in beneficial effects on plasma lipids and lipoproteins [5–9], atherogenic risk [8, 10] and body fat accumulation [5, 9, 11, 12]. In the majority of the animal studies, the CLA preparations used have been either individual *cis-9,trans-11* CLA isomer (90%), *trans-10,cis-12* CLA isomer (90%) or mixtures of CLA isomers, i.e. usually mixtures of 30–40% of each of the *cis-9,trans-11* and *trans-10,cis-12* isomers, the residue consisting of various less common isomers [13]. The effects of CLA on plasma lipids and body composition have been first attributed specifically to the *trans-10,cis-12* CLA isomer [14–16]. However, CLA does not appear to produce identical results in all studies due to variations in experimental conditions such as age, dose, duration of the study, animal species, food consumption, body weight and initial metabolic status. A recent study conducted in our laboratory [17] showed that *trans-10,cis-12* CLA isomer fed to hamsters had an undesirable effect on plasma lipids by increasing LDL cholesterol concentrations but had no impact on body composition.

Until now, most investigations have studied the effects of the individual or mixed *cis-9,trans-11 + trans-10,cis-12* CLA isomers, and few have addressed the effects of *trans-8,cis-10* CLA isomer on plasma lipoproteins. In the present study, we thus compared, under isoenergetic conditions, the effects of a mixture of *cis-9,trans-11 + trans-8,cis-10* CLA isomers to those of a mixture of *cis-9,trans-11 + trans-10,cis-12* CLA isomers and LA on plasma and hepatic lipids, body composition and other related metabolic parameters in hamsters. The highest concentration of *trans-8,cis-10* CLA isomer that could be obtained was 35% in the *cis-9,trans-11 + trans-8,cis-10* CLA mixture, since individual purified *trans-8,cis-10* CLA isomer was not available on the market. Although it was highly speculative due to lack of scientific data, we hypothesized that the *cis-9,trans-11 + trans-8,cis-10* CLA mixture would induce different effects on plasma and hepatic lipids as well as on body composition than the *cis-9,trans-11* and *trans-10,cis-12* CLA mixture in hamsters.

## Experimental Procedures

### Experimental Diets

All animals were assigned to one of the three experimental diets varying in CLA isomers, namely a 50:50 *cis-9,trans-11 + trans-10,cis-12* CLA mixture, a CLA mixture consisting of *cis-9,trans-11 + trans-8,cis-10* (as approximately 40% *cis-9,trans-11* CLA and 35% *trans-8,cis-10* CLA), and LA. The latter fatty acid was used as the reference fatty acid. The CLA mixtures were supplied by Natural ASA (Hovdebygda, Norway). The fatty acid composition of the three experimental groups is shown in Table 1.

Table 2 shows the composition of the experimental diets (ED). Except for lard, which was purchased from a local supermarket, all dietary ingredients were provided by MP Biomedical Inc (Aurora, OH). To minimize the oxidation of the fatty acids, BHT was added to the diets [18]. As confirmed by bomb calorimetry using an automatic adiabatic calorimeter (Model 1241, Parr Instruments, Moline, IL), the three purified diets were isoenergetic, providing 4.7 kcal/g each. Diets were also found to be isonitrogenous and isolipidic. The protein content of each diet ( $N \times 6.25$ ) (20–22% w/w) was assayed by Leco FP-528 (ISO 34/SC 5, Principle of Dumas). The lipid content of each diet measured by Manual Soxtec System HT6 (Tecator AB, Box70.S-2601, HOGANAS, Sweden) was approximately 12.0–12.6% (w/w). The dry matter of each diet was also measured by Fisher Econo Temp Laboratory Oven Model 30G. The percentage of water obtained from the samples was between 6 and 6.5% (w/w).

**Table 1** Fatty acid composition of the three experimental fats (Provided by Natural ASA)

Fatty acid	LA	<i>cis-9,trans-11 + trans-10,cis-12</i> CLA	<i>cis-9,trans-11 + trans 8,cis-10</i> CLA

### Experimental Animals

Fifty-one growing golden Syrian hamsters (Charles River laboratories, St-Constant, QC, Canada) weighing 50–60 g on arrival were housed individually in plastic cages. The temperature ( $20 \pm 2^\circ\text{C}$ ) and relative humidity (45–55%) of the animal room were constant, and the hamsters were kept under a daily light–dark cycle (0900 to 2100). Upon arrival, hamsters were maintained on a ground non purified (NPD) commercial diet (Purina, St Louis, MO) for 6 days to adapt them to their new environment. Following this adaptation period, they were then randomly assigned to one of the three dietary groups on the basis of their body weight and feed intake during the 6-day adaptation period ( $n = 17$  per group). They were then gradually transferred to their respective purified diet differing in lipid source by feeding a mixture of ground NPD and experimental diet over a 5-day period (25%ED/75%NPD for 3 days, 50%ED/50%NPD for 1 day and 75%ED/25%NPD for 1 day).

Experimental diets and tap water were provided once daily on an ad libitum basis for a 28-day period. Records of food intake and body weight were taken every morning. This protocol was approved by the Animal Care Committee of Laval University according to the guidelines of the Canadian Council on Animal Care.

At day zero, prior to the 28-day feeding 100%ED period, measurements of body composition were taken when the hamsters were on front in the Piximus apparatus (Lunar, Madison, WI). After a 12-h fast, animals were weighed and anaesthetized with isoflurane in order to proceed to the measurement of body fat and lean mass with the help of X-ray from the sternum to the tail of the hamster. At the end of the 28-day feeding 100%ED period, similar body composition measurements were taken before sacrifice.

On day 18–20, hamsters were transferred to individual stainless-steel wire bottom mesh cages, for a 3-day feces collection. Feces were weighed and stored at  $-80^\circ\text{C}$  until further analysis.

### Laboratory Analyses

After 28 days on experimental diets and after a 12-h overnight fast, immediately after body composition measurements, blood samples were collected by cardiac puncture in tubes containing disodium EDTA (0.05%). After blood collection, hamsters were quickly sacrificed by asphyxia with  $\text{CO}_2$ . Epididymal tissue and liver were rapidly removed, weighed, and frozen in liquid nitrogen and stored at  $-80^\circ\text{C}$  until subsequent analysis. Plasma was separated by centrifugation at 2,500 rpm for 10 min. An aliquot of plasma was frozen at  $-80^\circ\text{C}$  for further total lipid, glucose and insulin determinations. Another aliquot was stored at  $4^\circ\text{C}$  until the next day.

The day following blood sampling, lipoproteins were separated from fresh plasma by ultracentrifugation (TL-100 Tabletop Ultracentrifuge, Beckman, Palo Alto, CA) at 100,000 rpm and  $15^\circ\text{C}$  for 120 min using a TLA-100.4 rotor. The density of plasma samples was adjusted to 1.063 g/ml by adding a solution of NaBr–NaCl 1.478 g/ml [19]. A two-step density gradient was formed by layering the density-adjusted plasma underneath NaCl solution ( $d = 1.006$  g/ml). Triglyceride-rich lipoproteins, chylomicrons and very low-density lipoproteins (VLDL) ( $d < 1.006$  g/ml), low-density lipoproteins (LDL) ( $1.006 < d < 1.063$  g/ml) and high-density lipoproteins (HDL) ( $1.06 < d < 1.21$  g/ml) were then fractionated. Coomassie blue (5% w/w) was used as a dye to locate the lipoprotein fractions. Plasma cholesterol and triglycerides were measured in these lipoproteins as well as in the total fresh plasma using the Triglycerides/GB and CHOD-PAP enzymatic kits (Roche Diagnostics, Laval, Quebec). Phospholipids in plasma were determined using Phospholipids B Enzymatic colorimetric Method (Wako Chemicals USA).

According to the method of Folch et al. [20], hepatic lipids were extracted with chloroform/methanol (2:1, v/v). Hepatic triglycerides and cholesterol were then measured using the Triglycerides/GB and CHOD-PAP enzymatic kits (Roche Diagnostics, Laval, Quebec), as described above.

Plasma glucose was measured with a glucose oxidase method [21] using a glucose analyzer (Technicon RA-TX), and the plasma insulin level was measured by radioimmunoassay using rat insulin standards and polyethylene glycol for separation [22].

In order to determine fecal fat content, extraction with anhydrous diethyl ether (Soxtec System HT 1043 Extraction Unit; Tecator Inc., Höganäs, Sweden) after acid

hydrolysis (4M HCL) for 30 min (Soxtec System 1047 Hydrolysing Unit; Tecator Inc.) was performed on lyophilized and ground feces [23].

### Statistical Analysis

Results were analyzed using the general linear model (GLM) procedure of the Statistical Analysis System (SAS Institute, Cary, NC, USA). When statistically significant diet effects were detected by ANOVA (at a probability level inferior to 0.05), Tukey's studentized range (HSD) test was performed to identify differences among diet groups. However data on fecal fat content were log-transformed in order to normalize their distribution prior to statistical analysis. All data, including those on fecal fat content, are presented in tables as non-transformed means  $\pm$  SEM. Pearson correlation coefficients were used to quantify the univariate associations among variables.

## Results

### Food Intake and Body Weight and Composition

At the end of the 28-day experimental period, hamsters displayed similar daily food intake and body weight gain regardless to the lipid source (Table 3).

### Plasma Lipids

The CLA mixtures used in this study differently affected LDL cholesterol as well as VLDL cholesterol and triglyceride concentrations (Table 4). The *cis-9,trans-11 + trans-10,cis-12* CLA mixture induced higher LDL cholesterol concentrations than the *cis-9,trans-11 + trans-8,cis-10*

**Table 3** Mean food intake and body weight of male hamsters fed the five purified diets for 28 days

	LA	<i>cis-9,trans-11 + trans-10,cis-12</i> CLA	<i>cis-9,trans-11 + trans-8,cis-10</i> CLA
Mean food intake (g/day)	6.7 $\pm$ 0.2	7.0 $\pm$ 0.2	6.5 $\pm$ 0.1
Initial body weight (g)	69 $\pm$ 1	70 $\pm$ 1	67 $\pm$ 1
Final body weight (g)	99 $\pm$ 2	102 $\pm$ 2	97 $\pm$ 2
Body weight gain (g)	30 $\pm$ 2	31 $\pm$ 1	30 $\pm$ 2

Values are mean  $\pm$  SEM. For abbreviations see Table 1

Number of animals:  $n = 17$ , except for *cis-9,trans-11 + trans-10,cis-12* CLA,  $n = 16$

Diets were similar in content, except for the source of fat: LA linoleic acid, CLA conjugated linoleic acid having different isomerisation

CLA mixture and LA. On the other hand, feeding the *cis-9,trans-11 + trans-8,cis-10* CLA mixture increased VLDL cholesterol and triglyceride concentrations compared to LA and the *cis-9,trans-11 + trans-10,cis-12* CLA mixture.

### Plasma Glucose and Insulin

The *cis-9,trans-11 + trans-8,cis-10* CLA mixture showed the highest plasma glucose concentration compared to the other two groups. However, no significant differences were observed for plasma insulin among the three experimental diets (Table 5).

### Hepatic Lipids

Hepatic cholesterol concentrations of the animals fed the *cis-9,trans-11 + trans-10,cis-12* CLA mixture were

Values are mean  $\pm$  SEM. Number of animals:  $n = 17$ , except for *cis-9,trans-11 + trans-10,cis-12* CLA,  $n = 16$

Diets were similar in content, except for the source of fat: LA linoleic acid; CLA conjugated linoleic acid having different isomerisation

<sup>a,b</sup> Mean values within a row not sharing a common letter were significantly different ( $P < 0.05$ )

**Table 5** Glycemia and insulinemia of male hamsters fed the five purified diets for 28 days

	LA	<i>cis</i> -9, <i>trans</i> -11 + <i>trans</i> -10, <i>cis</i> -12 CLA	<i>cis</i> -9, <i>trans</i> -11 + <i>trans</i> -8, <i>cis</i> -10 CLA
Glycemia (mmol/L)	14 ± 1 <sup>a</sup>	15 ± 1 <sup>a</sup>	18 ± 1 <sup>b</sup>
Insulinemia (pmol/L)	444 ± 144	381 ± 92	507 ± 186

Values are mean ± SEM. Number of animals:  $n = 17$ , except for *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA,  $n = 16$

Diets were similar in content, except for the source of fat: LA linoleic acid; CLA conjugated linoleic acid having different isomerisation

<sup>a,b</sup> Mean values within a row not sharing a common letter were significantly different ( $P < 0.05$ )

significantly lower to those of animals fed either LA and the *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture. No difference was observed neither on hepatic triglyceride concentrations nor on liver weight between the three dietary groups (Table 6).

#### Body Composition

The hamsters from the three diet groups had a similar weight gain (30–31 g/day on the average) (Table 3). In accordance with this result, no difference was observed neither in body composition (lean mass, fat mass, total (fat + lean) mass, percentage fat, bone mass content and bone mass density) nor in the weight of epididymal fat pads between our three experimental groups (Table 7).

#### Fat Digestibility

The *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture and LA feeding led to lower fecal fat content than the *cis*-9,

*trans*-11 + *trans*-10,*cis*-12 CLA mixture (Table 8). We also calculated a coefficient of digestibility of dietary fat [(fat intake – fat excreted)/fat intake] in order to take into account fat intake in addition to fecal fat. Based on those calculations, the *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture and LA had thus similar and higher coefficient of digestibility than the *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture (Table 8).

#### Discussion

Previous and current researches have focused their attention on the *cis*-9,*trans*-11 isomer and *trans*-10,*cis*-12 isomer and the CLA mixture composed of these two forms usually at a ratio of approximately 50:50 because they are produced in high quantities successfully by various methodologies. There is however, an increasing awareness that the other isomers may be responsible for certain metabolic changes [24]. Recently, a CLA mixture composed of *cis*-9,*trans*-11 + *trans*-8,*cis*-10 isomers has been produced. The results of the present study demonstrate that feeding a CLA mixture composed of *cis*-9,*trans*-11 + *trans*-8,*cis*-10 isomers induced higher plasma concentrations of VLDL cholesterol and triglycerides concomitant with higher plasma glucose compared with LA and the *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture in hamsters.

The *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA mixture induced similar plasma LDL cholesterol and hepatic lipid concentrations, and coefficient of digestibility than LA, indicating no effect of the *trans*-8,*cis*-10 CLA isomer on these parameters. The *trans*-10,*cis*-12 isomer has been previously identified, rather than the *cis*-9,*trans*-11, as the ingredient being responsible for the biological effects on plasma lipids [5, 6, 14, 17]. In the present study, our data show that the *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture can increase LDL cholesterol and decrease hepatic cholesterol as previously did the *trans*-10,*cis*-12 isomer in

hamsters under physiological isoenergetic conditions [17]. These results suggest that the *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture may cause redistribution of cholesterol between serum and tissues leading to a lower level of hepatic cholesterol but a higher level of LDL cholesterol. Because this redistribution can result in part from variations in VLDL secretion and hydrolysis into the circulation and less affinity of LDL particles with LDL receptors following *trans*-10,*cis*-12 CLA feeding in hamsters, further studies on VLDL and LDL metabolism are thus necessary to gain more insight into this controversial result.

In the present work, reductions in hepatic cholesterol observed following *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture may also be attributed to decreased intestinal absorption of dietary fats. The *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture indeed lowered the coefficient of digestibility of dietary lipids and enhanced fecal fat content compared with LA. These results agree well with those of

Terpstra et al. [25] observing increased energy lost in feces of mice fed *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture. Yeung et al. [26] have also shown a greater fecal neutral lipid (cholesterol and coprostanol) output in *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture fed hamsters and noted a downregulation of intestinal acyl CoA: cholesterol acyltransferase (ACAT) activity, an enzyme involved in the esterification and storage of intestinal cholesterol, associated with increased fecal sterols in hamsters following CLA mixture supplementation. According to Wrenn et al. [27], intestinal cholesterol is esterified before it is assembled in the chylomicrons and secreted into the lymphatic system. We thus hypothesized that the *cis*-9,*trans*-11 + *trans*-10,*cis*-12 CLA mixture may interfere with the absorption of dietary fats and cholesterol either by interfering with the action of intestinal fatty acid-binding proteins or by inhibiting ACAT activity in intestinal cells or both.

The most novel result of the present study is the demonstration that the *cis*-9,*trans*-11 + *trans*-8,*cis*-10 CLA

**Table 8** Mean fecal fat content and coefficient of digestibility of dietary fat in male hamsters fed the three purified diets

<sup>d</sup> Coefficient of digestibility = (fat intake – fat excreted)/fat intake

mixture increased plasma VLDL cholesterol and triglyceride concentrations. It is unlikely that this effect can be attributed to the *cis-9,trans-11* CLA isomer contained in the mixture since in a previous study using similar experimental conditions than this one [17], feeding hamsters with the *cis-9,trans-11* isomer only did not modify VLDL composition as compared to LA. There is thus a high possibility that the *trans-8,cis-10* CLA found at 35% in this mixture might be the physiologically active CLA isomer regarding VLDL cholesterol and triglyceride concentrations in the present study. However, because there were 18% of other minor isomers such as *cis-cis-9,11* & *10,12* + *trans-trans* 8,10 & 9,11 & 10,12 in this CLA mixture (Table 1), we cannot completely exclude a contribution of those minor isomers in the deterioration of VLDL composition.

Based on normal fasting glucose concentrations of 3.6–9.5 mmol/L in hamsters [28], it appears that the lard-based diet in golden Syrian hamsters induced hyperglycemia under our control conditions (LA group). In the present study, the *cis-9,trans-11* + *trans-8,cis-10* CLA mixture compared with LA and the *cis-9,trans-11* + *trans-10,cis-12* CLA mixture worsened the existing hyperglycemia of our hamsters from 14 to 18 mmol/L, although plasma insulin levels were not different among the three experimental groups. There is a possibility that an increased hepatic lipogenesis stimulated by an increased flux of glucose could explain, at least in part, some of the increase of VLDL triglycerides in the animals fed the *cis-9,trans-11* + *trans-8,cis-10* CLA mixture. We also observed a slight positive correlation between VLDL triglycerides and percentage body fat ( $r = 0.31$ ,  $P = 0.007$ ,  $n = 50$ ), suggesting a slightly greater transport of free fatty acids from adipose tissue to the liver that can also be used for de novo hepatic VLDL triglyceride synthesis. However, plasma free fatty acid concentrations have not been measured to support this explanation. The impact of the *cis-9,trans-11* + *trans-8,cis-10* CLA mixture on glucose tolerance, however, remains to be studied further.

In conclusion, we confirmed part of our hypothesis that the effects of *cis-9,trans-11* + *trans-8,cis-10* CLA mixture on plasma lipids differed from those of *cis-9,trans-11* + *trans-10,cis-12* CLA mixture by causing a deterioration of VLDL cholesterol and triglycerides associated with increased plasma glucose. Future studies are thus required to study the impact of the *cis-9,trans-11* + *trans-8,cis-10* CLA mixture on hepatic VLDL secretion into the circulation, on postheparin lipoprotein lipase and hepatic triglyceride lipase activities in plasma as well as on insulin sensitivity.

# Combining Results of Two GC Separations Partly Achieves Determination of All *cis* and *trans* 16:1, 18:1, 18:2 and 18:3 Except CLA Isomers of Milk Fat as Demonstrated Using Ag-Ion SPE Fractionation

**Abstract** Milk fat is a complex mixture of geometric and positional isomers of monounsaturated and polyunsaturated, including short-, long- and branch-chain fatty acids (FAs). There has been partial success to resolve this mixture of FAs using different GC temperature programs, or a combination of GC isothermal and temperature programs. To overcome the problem associated with overlapping isomers prior silver-ion separation was recommended. However, this procedure is time consuming and not practical for routine analysis. In addition, previous methods focused mainly on the *trans* and *cis* isomers of 18:1. The present method takes advantage of differences in the relative elution times between different types of FAs. The method involved analyzing each milk fat using the same highly polar 100-m capillary column and GC instrument, and conducting two separations using temperature programs that plateau at 175 and 150 °C. The relative shift among the geometric and positional isomers at these two temperature settings was enough to permit identification of most of the *trans* and *cis* 16:1, 18:1 and 20:1, the *c/t*-18:2 and the *c/c/t*-18:3 isomers found in milk

fat. The identity of these FAs was confirmed by prior separation of the total fatty acid methyl esters (FAMES) of milk fat using Ag<sup>+</sup>-SPE columns, and comparing the fractions to the total milk fat. The Ag<sup>+</sup>-SPE technique was modified to obtain pure saturated, *trans*- and *cis*-monounsaturated and diunsaturated FAMES. By combining the results from these two separate GC analyses, knowing the elution order, it was possible to determine most of the geometric and positional isomers of 16:1, 18:1, 20:1, 18:2 and 18:3 without a prior silver-ion separation. Only few minor FAs could not be resolved, notable the conjugated linoleic acid isomers that still required the complimentary Ag<sup>+</sup>-HPLC separation. The two GC temperature programs have been successfully used to routinely analyze most FA isomers in total milk and beef fats in about 200 min without the use of prior silver-ion separations.

**Keywords** Gas chromatography · Ag-ion SPE · Milk fat · *cis* and *trans* isomers

## Abbreviations

Ag <sup>+</sup> -HPLC	Silver ion-high performance liquid chromatography
Ag <sup>+</sup> -TLC	Silver ion-thin layer chromatography
CLA	Conjugated linoleic acid
FA	Fatty acid
FAME	Fatty acid methyl ester
GC	Gas chromatography
HPLC	High-performance liquid chromatography
MUFA	Monounsaturated fatty acid
PHVO	Partially hydrogenated vegetable oil
PUFA	Polyunsaturated fatty acid
SPE	Solid phase extraction
SFA	Saturated fatty acid

## Introduction

Considerable efforts have been made in the past few years to modify the profile of milk fats by increasing such fatty acids (FAs) as rumenic (9*c*11*t*-18:2) and vaccenic acids (11*t*-18:1), as well as essential FAs and the long-chain polyunsaturated fatty acids (PUFAs), but their comprehensive analysis has proven challenging. Milk fat is already a complex mixture of up to 400 different FAs [1]. These can be short or long (4–26 carbons), branched or not, saturated, unsaturated (0–6 double bonds) or conjugated, and there are all possible geometric and positional isomers of mono-, di-, highly unsaturated poly- and conjugated FAs. Some FAs also contain hydroxyl, keto, or cyclic functional groups. By far the most common and convenient method to analyze such a complex mixture of FAs is by gas chromatography (GC) as their fatty acid methyl esters (FAMES). There is general agreement that 100 m highly polar flexible fused-silica capillary columns are absolutely mandatory to help resolve this isomeric mixture [2–7]. Most researchers have used the 100% cyanopropylpolysiloxane coated phases (CP-Sil 88 by Varian Inc.; SP 2560 by Supelco Inc.; HP88 by Agilent Technol.) [2–13], while others have chosen slightly less polar phases equivalent to 70% cyanopropylpolysiloxane (BPX-70 by SGE Co. [14, 15] or CP Select by Varian Inc. [16]) that are slightly longer (BPX-70 at 120 m, and CP Select at 200 m) but more stable because these stationary phases are bonded.

The ideal method would be a single GC analysis but this is currently not possible. Therefore, several different approaches have been used to analyze the complete FA composition of milk fat. We developed a GC temperature program starting at 45 °C to resolve the short-chain FAs followed by a plateau temperature at 175 °C during the elution of the 18:1 isomers to resolve as many of the 16:1, 18:1 and 18:2 isomers as possible [3, 5, 9]. Decreasing the plateau temperature to 170 [11] or 165 °C [7], or introducing two plateau stages at 100 and 175 °C [13], did not improve the separation. To provide a definitive composition of many of these FA isomers, a prior separation of geometric isomers was introduced using silver ion-thin layer chromatography (Ag<sup>+</sup>-TLC) followed by a GC analysis of the fractions at a low isothermal temperature of 120 °C that resolved all the 18:1 isomers except 6*t*-8*t*-18:1 and 6*c*-8*c*-18:1 [2, 3, 5–8, 14]. Prior fractionation using Ag<sup>+</sup>-TLC has also been used to identify overlapping isomers in the 16:1 [17], 18:2 [18], and 18:3/20:1 [19] regions.

An alternative approach was to resolve the total milk fat FAMES using one GC column to resolve the total milk lipids, followed by second GC operation at isothermal temperatures between 160 and 180 °C with a 100-m highly polar column to resolve the 18:1 isomers. The isothermal GC separations were performed using either the same [13,

20], or a different GC column [2, 17–19]. Some isothermal separations gave a partial resolution of 15*t*-18:1 from 9*c*-18:1, but with little improvement in the separation of the remaining 18:1 isomers. This approach requires two separate GC analyses and addressed only the resolution of 18:1 isomers, while ignoring overlapping in the 16:1, 18:2 and 18:3/20:1 regions.

Another technique was recently reported in which the FAMES from milk fat were analyzed by GC using the 100-m highly polar columns, and the *cis*- and *trans*-18:1 isomers were isolated using reversed-phase HPLC followed by GC analyses [14]. This method is complicated involving two different instruments, at least three GC separations, and again only addressing the overlapping 18:1 isomers.

The analyses of the different conjugated linoleic acid (CLA) isomers is particularly challenging since many of the isomers do not separate under any of the isothermal or temperature program GC conditions [5, 6, 9, 12], even at isothermal conditions at 120 °C [3]. Therefore, regardless of the GC method used, a complimentary Ag<sup>+</sup>-HPLC separation will be necessary to resolve most of the CLA isomers [21]. The final CLA isomer composition can then be determined by combining the GC and Ag<sup>+</sup>-HPLC results [5, 6].

It is interesting to note that operating the GC under different isothermal temperature conditions has been shown to resolve overlapping peaks by taking advantage of differences in the relative elution times of different FA families. For example, the 20:1 and 18:3 isomers were resolved by decreasing the temperature from 180 to 155 °C that partly reversed the elution order of the 20:1 and 18:3 isomers relative to each other [22]. Several overlapping saturated FAMES were also identified amongst the 18:1 and 18:2 isomers in milk fat by conducting isothermal separations between 130 and 190 °C [18].

In the present communication a GC method is described in which total milk lipids were analyzed using the same 100-m polar capillary column and two complementary GC temperature programs that resolved most of the 16:1, 18:1, 18:2, 18:3 and 20:1 isomers without the need for a prior argentation or reversed-phase chromatographic separation. Employing the two complementary GC temperature programs took advantage of changes in the elution order at different temperatures, the high efficiency of the 100-m polar capillary column to resolve FA isomers, and consistent column characteristics and detector responses when using the same GC column for both temperature programs. Partial support for the identity of the FAME isomers in milk fat was obtained by comparing the results with separations prepared using silver ion-solid phase extraction (Ag<sup>+</sup>-SPE) columns recently available from Supelco Inc. (Bellefonte, PA). The separation of saturated, *trans*, *cis*, dienes, and trienes FAME fractions was achieved by

modifying the solvent system reported recently for the Ag<sup>+</sup>-SPE columns [23]. In this study, four milk lipids were selected that differed greatly in their total *trans*-18:1 content and isomer profile to demonstrate the effectiveness of resolving FAME pairs in the 16:1, 18:1/18:2, and 18:3/20:1 regions, particularly when adjacent isomers had large asymmetric distributions.

## Materials and Methods

Selected milk fats were obtained from a previous study [24]. They were transesterified using NaOCH<sub>3</sub> as previously described [5, 25]. Details of the Ag<sup>+</sup>-HPLC methodology for the complimentary separation and analysis of the CLA isomers were previously published [3, 5, 26]. All chemicals and solvents were of analytical grade.

### Ag<sup>+</sup>-SPE Cartridges

Ag<sup>+</sup>-SPE cartridges (750 mg/6 mL) were purchased from Supelco Inc. (Bellafonte, PA). Before use, the cartridges were conditioned with 4 mL of acetone to remove any moisture followed by 4 mL of hexane. Total methylated lipids (about 1 mg total FAMEs in 1 mL hexane) were applied onto the column and eluted with 6 mL volumes of hexane containing increasing amounts of acetone: 99:1 (v/v) eluted saturated FAMEs, 96:4 (v/v) eluted mono-*trans* FAMEs plus the *t/t* FAME isomers of CLA; 90:10 (v/v) eluted mono-*cis* FAMEs plus the *c/t* FAME isomers of CLA; 0:100 (v/v) eluted dienoic FAMEs. This was followed by 3% acetonitrile in acetone to elute trienoic FAMEs, and 6% acetonitrile in acetone to elute tetraenoic FAMEs. All fractions were taken to dryness in a stream of N<sub>2</sub>, reconstituted in an appropriate volume of hexane for analysis by GC.

### Gas Chromatography (GC)

A Hewlett Packard Model 5890 Series II GC was used and equipped with a flame ionization detector operated in splitless mode and flushed 0.3 min after injection, an autosampler (HP Model 7673), a 100-m CP-Sil 88 fused capillary column (Varian Inc., Mississauga, ON) and a software program (Agilent ChemStation, Version A.10). Injector and detector temperatures were kept at 250 °C. Hydrogen was used as carrier gas at a flow rate of 1 mL/min and for the flame ionization detector at 40 mL/min. The other gases were purified air at 250 mL/min and N<sub>2</sub> makeup gas at 25 mL/min. The injection volume was 1 µL of FAME mixtures containing about 1–2 µg/µL. The three

temperature programs evaluated are summarized in Table 1. Each milk fat was routinely analyzed using the three GC programs in series in this study but only the results of the 175 and 150 °C programs were used in determining the final analysis.

### FAME Standards

The FAMEs were compared to a GC reference standard (#463) and spiked with a mixture of four positional CLA isomers (#UC-59M) and long-chain saturated FAMEs 21:0, 23:0 and 26:0; all FAMEs were obtained from Nu-Chek Prep Inc. (Elysian, MN). A branch-chain FAs standard was available from Matreya Inc. (Pleasant Gap, PA). Identification of the *trans*-18:1, 16:1 and 20:1 isomers are based on principles of silver-ion separation, selected isomers in the GC reference standard #463, and on comparison with previously published reports [2, 3, 5, 19, 27]. A few *t/t*- and *c/t*-18:2 and *c/c/t*-18:3 standards were available, i.e., 9*t*12*t*-18:2 in GC standard #463, and previously synthesized 9*c*12*t*- and 9*t*12*c*-18:2, and 9*c*12*c*15*t*-, 9*c*12*t*15*c*- and 9*t*12*c*15*c*-18:3 [4]. The assignment of the remaining *c/t*-18:2 isomers was based on GC chromatographic principles, known diet related metabolites, and on comparison with previously published reports [18, 28]. It is important to evaluate each GC column with the standards given there are slight differences between columns even from the same supplier [5, 29].

### Combining Selective Sections from the Two GC Programs

It was found that comprehensive FA analysis could be achieved by combining the results of the 175 and 150 °C temperature programs. The 175 °C results were used as the quantitative reference, while the results at 150 °C were used to complement or correct these data. When selecting

**Table 1** Details of the three GC temperature programs evaluated

Descriptions	175 °C	163 °C	150 °C
Initial temperature (°C)	45	45	45
Time (min)	4	4	4
First rate of increase (°C/min)	13	13	13
Plateau temperature (°C)	175	163	150
Time (min)	27	37	47
Second rate of increase (°C/min)	4	4	4
Final temperature (°C)	215	215	215
Time (min)	35	40	35
Total time (min)	86	103.8	110.33

groups of FAs to be corrected, the beginning and end position of the FA cluster should be baseline resolved and each cluster should contain the same FAs from both GC separations. In the case of the 18:1 isomers the region from 4*t*-18:1 to 19:0/15*c*-18:1 was selected, for the 16:1 isomers the 4*t*-16:1 to 17:0/13*c*-16:1 region was selected, and for the 20:1/18:3 isomers the 18:3*n*-6 to 18:3*n*-3/13*c*-20:1 region was used. The 175 °C results were calculated as relative percent of total FAMES, while only the integrated values were used from the 150 °C results to calculate the corrected composition. If a specific FA was resolved in both chromatographic separations, the 175 °C value was chosen. Sample calculations are provided in the [Results and discussion](#) and in the tables. It should be noted that in attempting to calculate FAs present in trace amounts by difference, these can at times result in negative values. The short-chain FAs from 4:0 to 11:0 were corrected for mass discrepancy using the correction factors published by Wolff et al. [30].

## Results and Discussions

To evaluate this method, four milk fats were selected from a recent study in which cows were fed a barley-corn based concentrate containing a mixture of 4.5% sunflower oil and 0.5% fish oil in which the concentrate to forage ratio was 50:50 [24]. These milk fats showed great differences in the total *trans*-18:1 content and isomer distribution. One milk fat contained 3% total *trans*-18:1 and showed a pattern of 18:1 isomers general seen in commercial milk fats in Canada [5, 6] (Fig. 1, milk fat A), while the other three milk fats selected contained much higher levels of total

**Fig. 1** Partial GC chromatogram of the four milk fats selected (A–D) are shown from 18:0 to 18:2*n*-6. The total *trans*-, 10*t*- and 11*t*-18:1 content of each of the milk fats is listed on the left hand side. The *trans*- and *cis*-18:1 isomers are identified. The 175 °C GC temperature program was used for the analysis of these milk fats; see specifics of GC program in Table 1

*trans*-18:1 (13–21%) that is often observed when diets with a high concentrate (consisting of corn, barley or wheat, etc.) to forage ratio, and/or PUFAs are fed. In these samples the predominant *trans*-18:1 isomer was either 11*t* (Fig. 1, milk fat B), 10*t* (Fig. 1, milk fat D) or both (Fig. 1, milk fat C). The separations shown in Fig. 1 were those obtained using the temperature program with a plateau at 175 °C. Except for the milk fat low in total *trans* (Fig. 1, milk fat A), most of the *trans*-18:1 isomers from 6*t*-8*t*- to 11*t*-18:1 were not well resolved that often leads to misidentification of the isomers.

Three separate GC temperature programs were evaluated in this study (Table 1). Decreasing the temperature at the plateau from 175 to 163 and 150 °C resulted in a marked improvement in the separation of the isomers 6*t*-8*t*- to 11*t*-18:1 (Fig. 2). The resolution of these isomers is crucial when evaluating milk fats with increased levels of total *trans*-18:1 to determine whether 11*t*- (Fig. 2, milk fat B) or 10*t*-18:1 (Fig. 2, milk fats C and D) was predominantly produced. At 175 °C the isomers adjacent to the major *trans*-18:1 isomers were barely recognizable, while at 150 °C all isomers were clearly resolved. The decrease in temperature from 175 to 150 °C resulted in an increase in the elution times of the *trans*-18:1 isomers relative to the saturated FAs (carbon number increased by about 0.2), which improved the resolution of the *trans* isomers, while the elution times of the *cis*-18:1 isomers relative to the saturated FAs remained virtually the same. This relative shift among the geometric 18:1 isomer with temperature resulted in 15*t*-18:1 eluting between 9*c*- and 11*c*-18:1 at 163 °C, and coeluting with 11*c*-18:1 at 150 °C (Fig. 2). There was also a reversal in the elution sequence of 16*t*- and 14*c*-18:1; at 175 °C 16*t*-18:1 eluted slightly before, at 163 °C coeluted with, and at 150 °C slightly after 14*c*-18:1. Confirmation of identification will be provided based on silver ion separation, see below.

## Confirmation of 18:1 Isomers Using Ag<sup>+</sup>-SPE Separated Fractions

To establish identification of all the geometric and positional 18:1 isomers in total milk FAMES, fractions were prepared using Ag<sup>+</sup>-SPE cartridges to separate the total milk fat FAMES based on the number and geometric configuration of double bonds. The procedure using Ag<sup>+</sup>-SPE columns was modified to yield highly purified fractions of saturated, mono *trans* plus *t,t*-CLA, mono *cis* plus *c/t*-CLA, and diene FAMES; the more polyunsaturated fractions are not presented. The Ag<sup>+</sup>-SPE fractions obtained from each of the milk fats were compared to the total FAME mixture from each milk fat at 175 °C (Fig. 3), 163 °C (Fig. 4) and 150 °C (Fig. 5). In each of these

**Fig. 2** Partial GC chromatogram of three milk fats (B–D) are shown from 4*t*- to 12*c*-18:1 that contained a high total *trans*-18:1 content. Separations were performed using the 175 °C (top row), 163 °C (middle row) and 150 °C (bottom row) GC programs. Selected *trans*- and *cis*-18:1 isomers are identified to indicate the changes in the elution order of these 18:1 isomers with temperature

figures the region between 9*c*-18:1 and 18:2*n*-6 was enlarged and inserted for clarity in the partial GC chromatogram of total milk fat.

Each of the temperature programs provided a slightly different separation that made possible the identification of all the *trans*-18:1 isomers either directly or indirectly by difference (Figs. 3, 4, 5). The isomers 4*t*- to 11*t*-18:1 were

**Fig. 3** Partial GC chromatogram of milk fat C separated using GC program 175 °C and showing the 18:0 to 18:2*n*-6 region. An enlargement of the 11*c*-18:1 to 11*t*15*c*-18:2 is inserted for clarity. The *trans*, *cis* and diene fractions isolated from total milk fat FAMES using Ag<sup>+</sup>-SPE columns and are compared to the total milk fat FAMES. The structure of all the *t/t*-18:2 isomers, except 9*t*12*t*-18:2 is unknown. The assignments of most *c/t*-18:2 isomers and methyl 11-cyclohexylundecanoate (17cyclo) is tentative, and based on comparison with some standards (9*c*12*t*-18:2 and 9*t*12*c*-18:2) and on previously published reports [4,18,19]

best resolved at 150 °C (Fig. 5). The 12*t*-18:1 isomer was only free of interfering *cis*-18:1 isomers at 175 °C (Fig. 3); at both 163 and 150 °C it coeluted with 6*c*-8*c*-18:1 (Figs. 4, 5). On the other hand, 13*t*-/14*t*-18:1 coeluted with 6*c*-8*c*-18:1 at 175 °C (Fig. 3) and with 9*c*-18:1 at 163 and 150 °C (Figs. 4, 5). The 15*t*-18:1 isomer coeluted with 9*c*-18:1 at 175 °C and with 11*c*-18:1 at 150 °C, but was resolved at 163 °C (Fig. 4). Generally, either the GC separations at 175 °C (Fig. 3) or 150 °C (Fig. 5) provided an adequate separation of 16*t*- and 14*c*-18:1.

The 6*c*-8*c*-18:1 isomers are generally minor components in milk fat but they can be determined by difference from

**Fig. 4** Partial GC chromatogram of milk fat B separated using GC program 163 °C and showing the 18:0 to 18:2*n*-6 region. An enlargement of the 11*c*-18:1 to 11*t*15*c*-18:2 is inserted for clarity. For remaining description see caption Fig. 3

**Fig. 5** Partial GC chromatogram of milk fat C separated using GC program 150 °C and showing the 18:0–18:2n-6 region. An enlargement of the 11c-18:1–11t15c-18:2 is inserted for clarity. For remaining description see caption Fig. 3

the 13*t*/14*t*-18:1 peak at 175 °C (Fig. 3), or from the 12*t*-18:1 peak at 163 and 150 °C (Figs. 4, 5). The predominant 9*c*-18:1 isomer contained 10*c*- and 15*t*-18:1 at 175 °C (Fig. 3), and 10*c*- plus 13*t*/14*t*-18:1 at 163 and 150 °C (Figs. 4, 5). Unfortunately, the minor 10*c*-18:1 isomer cannot be resolved from the 9*c*-18:1 peak under any of these temperature conditions; and even at an isothermal condition at 120 °C a separation was not often always possible because of the predominance of the 9*c*-18:1 isomer [5, 6, 31]. The 11*c*- and 12*c*-18:1 isomers are free of interferences at 175 °C (Fig. 3) and 163 °C (Fig. 4), however, at 150 °C 15*t*- coeluted with 11*c*-18:1 (Fig. 5). The isomers 13*c*-, 15*c*- and 16*c*-18:1 all coeluted with *t,t*- or *c/t*-18:2 isomers using all GC programs (Figs. 3, 4, 5). In the case of 13*c*-18:1, the coeluting *t,t*-18:2 isomer was similar in abundance, while 16*c*-18:1 was a minor component compared to the coeluting *c/t*-18:2 isomers (Fig. 5).

### Representative Calculations of the 18:1 Isomers

The region from 4*t*-18:1 to 15*c*-18:1/19:0 in the 175 and 150 °C GC separations was chosen to calculate all the 18:1 isomers except 16*c*-18:1, since it encompasses all the same FAs in both chromatograms, and the terminal FAMES were base line resolved. Table 2 lists each of the peaks identified in both chromatograms. Also included in Table 2 is the best GC program, or combination of programs to calculate the correct composition for each of the 18:1 isomers. To determine the concentration of any FA isomer from the 150 °C results, simply multiply the ratio of area counts of that FA over the total area count of 4*t*-18:1 to 15*c*-18:1/19:0 at 150 °C by the total relative percent of all FAMES from 4*t*-18:1 to 15*c*-18:1/19:0 at 175 °C. Examples of

several FAs are included in Table 2. Several 18:1 isomers could not be resolved using this method, i.e., 6*t*-8*t*-, 6*c*-8*c*-, 13*t*/14*t*-, and 9*c*/10*c*-18:1. The first two groups of isomers have never been resolved by GC, while the last two pairs can be resolved, but only at low isothermal conditions after prior argentation separation. Unequivocal identification of all the *trans*- and *cis*-18:1 can be obtained by analyzing the *trans* and *cis* fraction from Ag<sup>+</sup>-SPE at a low isothermal temperature condition of 120 °C that resolved the isomers except 6*t*-8*t*-18:1 (Fig. 6) and 6*c*-8*c*-18:1 (results not presented). These results have been previously reported [3, 5, 6, 8, 17, 19], and therefore will not be discussed further.

### Resolution of the 18:2 Isomers

Seldom discussed is the presence of *t,t*- and *c/t*-18:2 isomers in the region between 13*c*-18:1 and 18:2n-6, with few exceptions [4, 18, 19]. The peaks in this region were enlarged and appropriately inserted in Figs. 3, 4, 5, and the isolated diene fraction from each of the milk fats was included in each of these figures. In general, the *t,t*-18:2 isomers eluted ahead of the *c/t*-18:2 isomers on these GC columns in the region between 13*c*-18:1 and 9*t*13*c*/8*t*12*c*-18:2. The magnitude of the interferences of these *t,t*-18:2 isomers in total milk fat was not previously recognize; see diene fraction in Figs. 3, 4, 5. Selectively using the 175 and 150 °C program provides a more accurate estimate of the *cis*-18:1 isomers among these 18:2 dienes. The structure of most of the *t,t*-18:2 isomers remain to be identified, other than 9*t*12*t*-18:2, for which a standard is available. However, this isomer is only present as a trace component in milk fat.

The major *c/t*-18:2 peak in milk fat was 9*t*13*c*- plus 8*t*12*c*-18:2 that was partially resolved at 150 °C (Fig. 5). The 8*t*13*c*- plus 9*c*12*t*-18:2 isomers coelute with 16*c*-18:1 and they were partially resolved at all the temperatures. The third group of *c/t*-18:2 isomers include 9*t*12*c*-, 11*t*15*c*- plus an unknown *c/t*-18:2 isomer evident from the separations. The identification and resolution of the *c/t*-18:2 isomers in milk fat are of particular interest since they arise as intermediates of PUFA metabolism by rumen bacteria, for instance, 11*t*15*c*-18:2 is a metabolite of 18:3n-3. Therefore, many of the *t,t*- and *c/t*-18:2 isomers in milk fat might be different from those found in partially hydrogenated vegetable oils (PHVOs) that arise by random processes. Canola and soybean oils that contain both 18:2n-6 and 18:3n-3 were shown to give rise to four major (9*t*13*c*-, 9*c*12*t*-, 9*t*12*c*-, 9*c*15*c*-18:2) and seven minor isomers (9*t*12*t*-, 8*t*12*c*-, 8*t*13*c*-, 8*c*13*c*-, 9*t*15*c*-, 10*t*15*c*- and 9*c*13*c*-18:2) during partial hydrogenation [32]. If the *trans* containing dienoic FA isomers are confirmed as contributing to the development of coronary heart disease [33],

**Table 2** Resolution of the geometric and positional 18:1, 16:1 and 20:1/18:3 isomers using the two GC programs

<sup>c</sup> *M* Total % FAMEs of 4*t*-16:1 to 13*c*-16:1/17:0 from GC results at 175 °C

<sup>d</sup> *N* Total area response of FAMEs 4*t*-16:1 to 13*c*-16:1/17:0 from GC results at 150 °C

<sup>e</sup> *P* Total % FAMEs of 18:3*n*-6 to 18:3*n*-3/13*c*-20:1 from GC results at 175 °C

<sup>f</sup> *Q* Total area response of FAMEs 18:3*n*-6 to 18:3*n*-3/13*c*-20:1 from GC results at 150 °C

Calculating the concentration of 9*t*-18:1 taken from the 150 °C results:

% [9*t*-18:1] = (area count of 9*t*-18:1 at 150 °C) (*X* % total FAMEs of 18:1 region)/(*Y* total area count of 18:1 region at 150 °C)

Calculating the concentration of 6*c*-8*c*-18:1 using values from both GC programs:

% [6*c*-8*c*-18:1] = [(area count of 12*t*/6*c*-8*c*-18:1 at 150 °C) (*X* % total FAMEs of 18:1 region)/(*Y* total area count of 18:1 region at 150 °C)] – [% 12*t*-18:1 taken from 175 °C results]

Calculating the concentration of 15*t*-18:1 using values from both GC programs:

% [15*t*-18:1] = [(area count of 11*c*/15*t*-18:1 at 150 °C) (*X* % total FAMEs of 18:1 region)/(*Y* total area count of 18:1 region at 150 °C)] – [% 11*c*-18:1 taken from 175 °C results]

Calculating the concentration of 9*c*/10*c*-18:1 using values from both GC programs:

% [9*c*/10*c*-18:1] = [% 9*c*/10*c*/15*t*-18:1 taken from 175 °C results] – [% 15*t*-18:1, calculation shown above]

then the differences in the *c/t*-18:2 isomer composition between milk fat and PHVOs will need to be examined closer to differentiate these two *trans*-containing fats. The

combination of these two GC programs will be helpful to provide this information.

**Fig. 6** Partial GC chromatogram of the 18:1 region of the *trans* fraction isolated from all four milk fats selected (A–D) using Ag<sup>+</sup>-SPE chromatography and analyzed by GC operated isothermally at 120 °C. Details regarding the Ag<sup>+</sup>-SPE separation are provided in [Materials and methods](#) section

### Resolution of FA Isomers in the 16:1 Region

The 16:1 region is as complex as the 18:1 region, consisting of overlapping C17 branch-chain FAs, and *cis*- and *trans*-16:1 isomers. Precht and Molkentin [17] demonstrated with human milk fat that an inaccurate identification of these FAs leads to wrong conclusions as to a potential cause of coronary heart disease. These authors confirmed the identity of each of these FAs after prior separation using Ag<sup>+</sup>-TLC and subsequent GC analysis of the fractions. In this study, we evaluated the results of the three GC temperature programs to see whether the FA composition of milk fat can be determined without prior argentation fractionation.

The separation of two milk fats is presented because the high content of total *trans* FAs markedly affected the 16:1 profile. The GC separation of a milk fat with a low content of total *trans* fat and analyzed using the 175 °C program is shown in Fig. 7, and the milk fat with a higher total *trans* content is shown in Fig. 8. In each figure the total milk fat separation was compared with the *trans*, *cis* and saturated

fractions obtained using the  $\text{Ag}^+$ -SPE columns. At 175 °C both of the 17:0 branch-chain FAs coeluted, 17:0 iso with 6*t*- to 8*t*-16:1, and 17:0 anteiso with 7*c*- and 13*t*-16:1 (Figs. 7, 8). The *trans*-16:1 isomers were present as small peaks in the milk fat with a low total *trans* content; only small peaks corresponding to 9*t*- and 11*t*-/12*t*-16:1 were evident in the total milk fat (Fig. 7). On the other hand, when the total *trans* content was high, it was difficult to differentiate 17:0 iso among the *trans*-16:1 isomers, and the contribution of 13*t*- and 7*c*-16:1 to 17:0 anteiso were not negligible (Fig. 8). Several of the *trans*- and *cis*-16:1 isomers were well resolved using the 175 °C program, such as 9*t*-, 10*t*-, 11*t*-/12*t*-, 9*c*-, 10*c*-, 11*c*- and 13*c*-16:1 (Figs. 7, 8), while the minor isomers 12*c*- and 14*t*-16:1 coeluted with 17:0 at 175 °C. The assignment of the geometric 16:1 isomers was based on argentation chromatographic principles (number and geometric configuration of double bonds), on several authentic FAME standards, and on agreement with published reports in which the isomers were confirmed by GC/MS [17].

Lowering the plateau from 175 to 150 °C caused a similar relative shift among the *trans*- and *cis*-16:1 isomers as was observed among the 18:1 isomers, resulting in an altered pattern of elution of these FA isomers (Fig. 9). For example, at 150 °C there was a near baseline resolution of 8*t*- and 9*t*-16:1, but now 11*t*-/12*t*-16:1 and 7*c*-16:1, 13*t*-16:1 and 17:0, and 11*c*- and 14*t*-16:1 coeluted. There was also a shift of the branch-chain FAs relative to both the *trans*- and *cis*-16:1 isomers, such that 17:0 iso now coeluted with 9*t*-16:1, and 17:0 anteiso with 9*c*-16:1. At 150 °C several *trans*- and *cis*-16:1 isomers were well

**Fig. 7** Partial GC chromatogram of milk fat A separated using GC program 175 °C and showing the 16:1 region. The total milk FAMES were compared to the *trans*, *cis* and saturated FA fractions isolated from total milk fat FAMES using  $\text{Ag}^+$ -SPE columns. Details regarding the  $\text{Ag}^+$ -SPE separation are provided in [Materials and methods](#). The assignments of several FAs were based on available standards (17:0, branch-chain FAs, and 9*t*- and 9*c*-16:1), while the others are based on silver-ion chromatographic principles and on a previously published report [17]

**Fig. 8** Partial GC chromatogram of milk fat D separated using GC program 175 °C and showing the 16:1 region. The total milk FAMES were compared to the *trans*, *cis* and saturated FA fractions isolated from total milk fat FAMES using  $\text{Ag}^+$ -SPE columns. For remaining description see caption Fig. 7

resolved, such as 4*t*- to 8*t*-, 10*t*-, 10*c*-, 12*c*-, 13*c*- and 14*c*-16:1 (Fig. 9). A section is included in Table 2 that summarizes the *trans*- and *cis*-16:1 isomers, and how best to determine the concentration of each of these isomers. For the 16:1 isomers the region from 6*t*-8*t*- to 17:0/13*c*-18:1 was selected.

The individual *trans*-16:1 isomers isolated from the four milk fats by  $\text{Ag}^+$ -SPE are compared at the two GC temperature programs (Fig. 10). The separations were improved for each of the milk fats by decreasing the temperature from 175 to 150 °C, and there was a partial resolution of the 11*t*-/12*t*-16:1 pair at 150 °C. It is of

**Fig. 9** Partial GC chromatogram of milk fat C separated using GC program 150 °C and showing the 16:1 region. The total milk FAMES were compared to the *trans*, *cis* and saturated FA fractions isolated from total milk fat FAMES using  $\text{Ag}^+$ -SPE columns. For remaining description see caption Fig. 7

**Fig. 10** Comparison of the *trans*-16:1 isomers from the *trans* fraction isolated using  $\text{Ag}^+$ -SPE columns of all four milk fats (A–D) that were separated by GC using the 175 and 150 °C temperature program. The assignments were based on silver-ion chromatographic principles and on a previously published report [17]. A partial separation of the 11*t*- and 12*t*-16:1 isomers was observed at 150 °C

interest to note that the *trans*-16:1 isomers have a similar pattern as the *trans*-18:1 isomers, except being two carbons shorter. The milk fat with the predominant 11*t*-18:1 isomers (Fig. 2, milk fat B) had 9*t*-16:1 as the major *trans*-16:1 isomers (Fig. 10, milk fat B), and the milk fat with the predominant 10*t*-18:1 isomers (Fig. 2, milk fat D) had 8*t*-16:1 as the major *trans*-16:1 isomers (Fig. 10, milk fat D). On the other hand, the milk fat enriched with both 10*t*- and 11*t*-18:1 (Fig. 2, milk fat C) contained high amounts of both 8*t*- and 9*t*-16:1 (Fig. 10, milk fat C). Peroxisomal oxidation is a well-recognized process of FAs metabolism in cells in which FAs are chain-shortening [34]. The CLA isomers were also observed to convert to 16:2 products in rats [35, 36]. This is the first report demonstrating that altering the *trans*-18:1 profile affected the *trans*-16:1 isomer composition consistent with the expected peroxisomal oxidation products from the *trans*-18:1 isomers. It is unlikely that the *trans*-16:1 isomers were formed by biohydrogenation from C16 PUFA (16:2 or 16:3) precursors, analogous to 18:2*n*-6 and 18:3*n*-3 giving rise to *trans*-18:1 in ruminants [10–13, 20, 28], since C16 PUFAs were not present in the cow's diet. Furthermore, the presence of the peroxisomal oxidation products in milk fat does not exclude the possibility of their formation in other tissues and then being transferred into milk. It should be noted that the remaining milk fats from this feeding study [24] from which these four examples were selected also showed the same pattern in of the *trans*-18:1 and *trans*-16:1 isomers (data not shown).

### Resolution of FA Isomers in the 20:1/18:3 Region

The 20:1/18:3 region in milk fat consists mainly of a mixture of overlapping *cis* and *trans*-20:1 and geometric

**Fig. 11** Partial GC chromatogram of milk fat A separated using GC program 175 °C and showing the 20:0 to 20:2 region. The total milk FAMES were compared to the *trans*, *cis* and diene fractions isolated from total milk fat FAMES using  $\text{Ag}^+$ -SPE columns, and the GC standard #463 spiked with the CLA isomers and 21:0. The assignments of several FAs were based on available standards, on silver-ion chromatographic principles, and on previously published reports [4, 17, 27, 39]. The peaks in the diene fraction isolated using  $\text{Ag}^+$ -SPE and eluting before 20:2*n*-6 are *t/t*- or *c/t*-20:2 isomers that were confirmed by high-resolution selected-ion mass spectrometry [39] but their structure remains unknown

and positional 18:3 isomers. The predominant FAs in this region are 9*c*- and 11*c*-20:1 and 18:3*n*-3, with minor amounts of 13*c*-20:1 and 18:3*n*-6 (Figs. 11, 12). However, depending on the diet fed to dairy cows, substantial amounts of either *trans*-20:1, *clclt*-18:3, or both can be present. The dairy cows in this study were fed a 50:50 forage to concentrate mixture containing sunflower oil that was high in 18:2*n*-6 [24], and therefore the milk fat had significantly elevated levels of *trans*-20:1 isomers (*trans* fraction), and only trace amounts of the 18:3 isomers (diene fraction) (Figs. 11, 12). Dairy cows fed diets supplemented with either soybean or canola oil would be

**Fig. 12** Partial GC chromatogram of milk fat C separated using GC program 150 °C and showing the 20:0–20:2 region. The total milk FAMES were compared to the *trans*, *cis* and diene fractions isolated from total milk fat FAMES using  $\text{Ag}^+$ -SPE columns, and the GC standard #463 spiked with the CLA isomers and 21:0. For remaining description see caption Fig. 11

expected to have a more complex pattern of *trans*-20:1 and *c/c/t*-18:3 isomers in the milk fat, since these oils contain substantial amounts of 18:3n-3 compared to sunflower oil used in the feeding study from which these milk fats were taken [24]. There were two unknown peaks in the diene fraction near 20:0 (labeled unknown, ‘?’) that appear to elute in the *c,t,t*- and *t,t,t*-18:3 region, but their identification will need to be confirmed by GC/MS.

The major *trans*-20:1 isomers were resolved from the *cis*-20:1 isomers at both 175 and 150 °C, i.e., the isomers 6*t*- to 13*t*-20:1 eluted well ahead of 9*c*-20:1 in both 175 and 150 °C (Figs. 11, 12). The unresolved 15*t*-/16*t*-20:1 pair was resolved from the *cis*-20:1 isomers only at 175 °C (Fig. 11), while 13*c*-20:1 was well separated at 150 °C (Fig. 12). However, the minor 14*t*-20:1 isomer could not be separated using either temperature program. The major *c/c/t*-18:3 isomers in the milk fat are 9*c*12*c*15*t*- and 9*t*12*c*15*c*-18:3 with trace amounts of 9*c*12*t*15*c*-18:3. The 9*c*12*c*15*t*-18:3 isomer eluting shortly after 18:3n-6, the 9*t*12*c*15*c*-18:3 isomers was best resolved from the 20:1 isomers at 150 °C (Fig. 12). A similar shift in the 20:1 and 18:3 isomers with temperature was previously reported by Wolf [22]. A summary of the FAs in the 20:1/18:3 region ranging from 18:2n-6 to 18:3n-3 is included in Table 2 and the GC program that is best used for their analysis.

Only the *trans*-20:1 isomers profile of the high *trans* containing milk fats are compared in Fig. 13. The low total *trans* milk fat (milk fat A) was not included since the *trans*-20:1 isomers in this sample were present only in trace amounts. The unresolved pair of 15*t*-/16*t*-20:1 was the predominant peak among the *trans*-20:1. This is the first report showing evidence that the pattern of the *trans*-18:1 isomers in milk fat were similar to the *trans*-20:1 isomers, except for being two carbons longer. The milk fat with the predominant 11*t*-18:1 isomer (Fig. 2, milk fat B) gave rise to increased levels of 13*t*-20:1 (Fig. 13, milk fat B), while the milk fat with the predominant 10*t*-18:1 isomer (Fig. 2, milk fat D) gave rise to 12*t*-20:1 (Fig. 13, milk fat D). The milk fat contained similar amounts of 10*t*- and 11*t*-18:1

**Fig. 13** Comparison of the *trans*-20:1 isomers from the *trans* fraction isolated using  $\text{Ag}^+$ -SPE columns of milk fats B to D that were separated by GC using the 175 °C temperature program. The assignments were based on silver-ion chromatographic principles and on a previously published report [27]

(Fig. 2, milk fat C) gave rise to both 12*t*- and 13*t*-20:1 (Fig. 13, milk fat C). This suggests that the *trans*-18:1 isomers were chain-elongated to the *trans*-20:1 isomers. Analogous to the argument above for the *trans*-16:1 isomers, the origin of *trans*-20:1 isomers could not have been C20 PUFAs, but the site of chain-elongation is not clear.

### Resolution of CLA Isomers

There was no difference in the separation of the CLA isomers using either of the two temperature programs; 9*c*11*t*-, 7*t*9*c*- and 8*t*10*c*-18:2 coeluted, as well as 9*c*11*c*- and 11*t*13*c*-18:2 and most of the *t,t*-18:2 isomers (10*t*12*t*- to 7*t*9*t*-18:2) (Figs. 11, 12). However, some of the isomers were resolved at both temperatures, such as 9*t*11*c*-, 10*t*12*c*-, 11*c*13*t*- and 11*t*13*t*-18:2. Lowering the GC temperature to 120 °C was successful in resolving the *trans*-18:1 isomers, but it did not further resolve the CLA isomers [3]. Therefore, a complete resolution of all the CLA isomers still requires the use of a complimentary  $\text{Ag}^+$ -HPLC technique, since the separation of the CLA isomers is not possible by any GC program [5, 21, 26, 37]. The argument has often been made that the isomers coeluting with the major CLA isomer 9*c*11*t*-18:2 can be estimated as constant percentage of total CLA [13]. However, such an assumption may not be valid when analyzing milk and meat fats from ruminants fed different diets that greatly impact the rumen bacterial population [5, 6, 38]. Preliminary results from a survey of North American milk and meat samples show substantial amounts of 7*t*9*c*-18:2 that occasionally are present at similar levels as 9*c*11*t*-18:2 in these fats [6]. Not separating these isomers will lead to inaccuracies and misinterpretations of FA metabolism in these animals.

There are two major interferences in the CLA region with GC analysis, 21:0 [3, 5, 29, 39] and several isomers of 20:2 [39]. The elution of 21:0 depends on the polarity of the GC column, and slight differences in polarity caused 21:0 to elute anywhere between 9*t*11*c*- and 9*c*11*c*/11*t*13*c*-18:2 [3, 5, 6, 29, 39] using the 175 °C GC program. Therefore, inclusion of 21:0 is necessary for all GC standards for analyzing CLA [5, 6]. Using the same GC column and decreasing the temperature from 175 to 150 °C increased the elution time of 21:0 relative to the CLA isomers. In the present separation 21:0 eluted with 9*t*11*c*-18:2 at 175 °C (Fig. 11), and between 10*t*12*c*- and 9*c*11*c*/11*t*13*c*-18:2 at 150 °C (Fig. 12). Several 20:2 isomers were identified in the diene fraction that eluted in the CLA region and may result in misidentification of minor *c,c*- and *t,t*-CLA isomers at both temperatures (Figs. 11, 12). The presence of 20:2 isomers in the CLA region was previously confirmed by GC/MS using high-resolution select-ion recording at  $m/z$  322.2872 [39].

### The FA Composition of the Milk Fats

The complete FA composition of all four milk fats as determined by combining the results of the two GC temperature programs are presented in Table 3; and the individual *trans* and *cis* isomer of 16:1, 18:1 and 20:1/18:3 are listed separately in Table 4. Most of the geometric and positional isomers of the MUFAs in milk fat were analyzed without prior separation of the total milk FAMES. The isomers were confirmed by comparison to milk fat fractions isolated using Ag<sup>+</sup>-SPE columns. There are some isomers that could not be resolved apart from those that cannot be resolved even at 120 °C (6*t*/7*t*-16:1, 6*t*-8*t*-18:1, 6*c*-8*c*-18:1, 4*t*-11*t*-20:1), and they included 11*t*/12*t*-16:1, 13*t*/14*t*-18:1, 9*c*/10*c*-18:1, 15*t*/16*t*-20:1, 9*c*/14*t*-20:1 and 11*c*-20:1/*tcc*-18:3 (Table 4). In some cases one of the two FAs is present in milk fat in trace amounts (10*c*-18:1, 14*t*-20:1, *ctc*-18:3). Identification of some isomers (11*t*- and 12*t*-16:1, 13*t*- and 14*t*-18:1, 15*t*- and 16*t*-20:1) if required, will require the more elaborate prior argentation chromatographic separation followed by GC analyses at low isothermal conditions [3, 5, 17, 19]. The individual *t/t*- and *c/t*-18:2 are not separately listed in the Table 4 because the identity of most of these isomers will need to be confirmed by GC/MS, while the *c/c/t*-18:3 were only present in trace amounts. The proposed current GC method in this communication was successfully applied for the analysis of beef and muskox lipids [40], and the method is now fully described.

### Reason for Choosing the Two GC Temperature Programs for Milk Fat Analysis

It is well known that the analysis of milk and beef fat requires the use of GC temperature programs rather than isothermal GC conditions. On the other hand, isothermal GC conditions were proven to be sufficient to resolve the FA isomers of PHVO mainly because plant oils and fats are devoid of short-chain and branch-chain FAs, and do not contain significant amounts of C16 and C20 PUFAs that would give rise to complex mixtures of 16:1 and 20:1 geometric and positional isomers during partial hydrogenation or deodorization. For this reason, an official method was successfully established to analyze the FA isomers of PHVOs using an isothermal GC program, since these oils/fats contain only 18:1, 18:2 and 18:3 isomers [41–43]. However, it is becoming increasingly evident that the analysis of milk fat requires more than one GC temperature program as previously recommended [5]. There are too many unresolved FAs that necessitated a prior separation of the total milk fat FAMES using argentation chromatographic techniques. However, the latter procedures are

Some FA pairs cannot be resolved using either GC programs

lengthy, require a certain amount of expertise, and are not practical for routine analyses. The present method of analyzing total milk fat using the 175 and the 150 °C temperature programs takes advantage of differences in the elution times of different types of FAs with temperature to resolve most of the FAs in milk fat. We considered selecting the 163 °C GC temperature program either by itself or in combination of other GC programs because it was possible to resolve 15*t*-18:1. However, this single advantage was outweighed by an insufficient separation of the 6-8*t*- to 11*t*-18:1 isomers, and many other unresolved overlaps in the remaining chromatogram. Choosing the 175 and the 150 °C temperature programs maximized the differences between the FA families sufficiently to determine most of the different FA isomers, some by differences.

Identification of the geometric and positional isomers of 16:1, 18:1, 18:2, 18:3 and 20:1 was accomplished by

Values in brackets are minor coeluting FA isomers that cannot be resolved using either GC program

comparing the total milk lipids with fractions isolated by argentation chromatographic techniques. In this case, the silver-ion separation was accomplished using Ag<sup>+</sup>-SPE

columns. The solvent mixtures were modified to provide pure fractions of saturated, *trans*- and *cis*-monounsaturated and diunsaturated FAMES. The Ag<sup>+</sup>-SPE method proved to be easier and in general gave improved separations compared to those obtained using Ag<sup>+</sup>-TLC [5, 6]. Combining the results from these two separate GC analyses, and establishing the elution order of most FA isomers, made it possible to determine many of the geometric and positional isomers of 16:1, 18:1, 20:1, 18:2 and 18:3 without a prior silver ion chromatographic separation. Only few minor FAs remained unresolved notably the CLA isomers that still require Ag<sup>+</sup>-HPLC separation. The total time required for the two GC temperature program was about 200 min per sample.

**Abstract** Negative ion mass spectrometric techniques, for compounds having good ionization properties, such as pentafluorobenzyl derivatives, are believed to be more sensitive than positive ion methods. Preparation of PFB oximes of fatty aldehydes from crude lipid extracts is problematic due to the release of free aldehydes from plasmalogens during derivatization. Accordingly, in these studies plasmalogens were removed by silicic acid column chromatography prior to pentafluorobenzyl derivatization. This simple purification step to remove plasmalogens is shown to facilitate the quantification of long-chain aldehydes by analysis of their pentafluorobenzyl oxime derivatives utilizing gas chromatography–mass spectrometry in the negative ion chemical ionization mode. The limit of detection for long chain fatty aldehydes using this method is 0.5 pmol and it is linear over two orders of magnitude. Silicic acid column chromatography followed by electrospray ionization mass spectrometry demonstrated that plasmalogens were removed (the detection limit for this analyses was  $\leq 0.3$  pmol). Furthermore, we have exploited the utility and sensitivity of this method to identify increases in hexadecanal and octadecanal in 3-amino-1,2,4-triazole treated human neutrophils.

### Introduction

Lipid oxidation through a variety of enzymatic and non-enzymatic mechanisms can lead to the formation of

aldehydes [1, 2]. The generation of aldehydes from polyunsaturated fatty acids through the attack of reactive oxidizing species is considered particularly facile and leads to the formation of aldehydes such as 4-hydroxynonenal (HNE) and malondialdehyde (MDA) [3–5]. Both, HNE and MDA have been extensively studied and are involved in numerous signaling pathways [1, 2, 6]. Besides short-chain aldehydes, the formation of long-chain aldehydes such as 2-chlorohexadecanal (2-ClHDA) and 2-hexadecenal is also known [7, 8]. 2-ClHDA is a neutrophil chemoattractant and can also inhibit endothelial nitric oxide synthase [9, 10]. Thus, knowledge of the overall load of aldehydes can provide an insight into the pathogenesis of diseases related to oxidative stress.

Aldehydes have been measured by a variety of techniques including spectrophotometry [11, 12] and mass spectrometry. Derivatization techniques that introduce electron-withdrawing groups enhance the sensitivity of analyte signal using negative ion mode detection [13]. Hence, pentafluorobenzyl (PFB) oxime derivatization of aldehydes followed by gas chromatography-mass spectrometry (GC–MS) analysis has been a commonly employed technique for aldehyde quantification. Mass spectrometric determination of PFB oximes has been performed by electron impact [14] and negative ion chemical ionization (NICI) [15]. While most of these studies were performed for short-chain aldehydes, detection of long-chain aldehydes in biological tissue has not been studied in depth. We have previously quantified  $\alpha$ -chlorinated fatty aldehydes and 2-hexadecenal as their PFB oximes utilizing GC–MS in NICI mode [7, 8]. However, for measurement of long-chain saturated aldehydes in biological tissue, thin layer chromatography (TLC) separated aldehydes were oxidized to the corresponding acids, followed by their quantification as bromophenacyl esters [16].

Plasmalogens are a major phospholipid subclass in many mammalian tissues [17]. Plasmalogens contain a masked fatty aldehyde in the *sn*-1 position and in presence of acidic conditions this aldehyde is released [17, 18]. This property of plasmalogens may impede the utilization of some derivatization techniques that can be applied for lipid analyses. It is likely that the conversion of free fatty aldehydes to PFB oximes in crude lipid extracts will lead to the release of fatty aldehydes from plasmalogen pools potentially rendering this technique ineffective. In this report, we separate plasmalogens from aldehydes prior to their derivatization utilizing silicic acid column chromatography. After removal of plasmalogens from crude lipid extracts long-chain aldehydes can then be quantified following conversion to their PFB oximes with subsequent analysis in the NICI mode. We use the method to detect changes in the aldehyde content of 3-amino-1,2,4-triazole (ATZ) treated human neutrophils.

## Experimental Procedures

### Materials

Hexadecanal and octadecanal were synthesized using Dess-Martin oxidation as described [19]. [*d*<sub>4</sub>]-Hexadecanal was synthesized utilizing Mancuso oxidation of [*d*<sub>4</sub>]-hexadecanol, which was prepared by reduction of the corresponding acid. A similar procedure has been described earlier [9]. Bovine heart phosphatidylcholine (PC), 1,2-dihexadecanoyl-*sn*-glycero-3-phosphocholine (di-16:0 GPC) and 1,2-diicosanoyl-*sn*-glycero-3-phosphocholine (di-20:0 GPC) were purchased from Avanti Polar Lipids. 1-*O*-hexadec-1'-enyl-2-octadec-9'-enoyl-*sn*-glycero-3-phosphocholine (16:0–18:1 pPC) was synthesized as described previously [20] and *N*-octadecanoyl sphingosylphosphorylcholine (18:0 SM) was purchased from Matreya, Inc. Human coronary artery endothelial cells (HCAEC) were purchased from Cambrex and maintained according to manufacturer's protocol. Silicic acid columns (1 ml) were purchased from Sigma. All other reagents were obtained either from Sigma or Fisher.

### Silicic Acid Column Separation

Organic extracts of either HCAEC or neutrophils were obtained after a modified Bligh and Dyer extraction [21]. [*d*<sub>4</sub>]-hexadecanal was added in methanol as the internal standard during extraction. Organic extracts were dried and resuspended in 500  $\mu$ l chloroform. Each extract was loaded onto a pre-equilibrated Silicic acid column (pre-equilibration was performed with 10 ml chloroform) and eluted with 5 ml of chloroform. The void and elute fractions were collected in 15 ml screw-top tubes, and these fractions were sequentially dried under nitrogen and aldehydes were derivatized to their PFB oximes for GC–MS analysis. In parallel studies bovine heart PC (150  $\mu$ g) was suspended in 500  $\mu$ l chloroform and subjected to silicic acid column chromatography. The void and elute fractions were sequentially dried under nitrogen, resuspended in a 4:1 mixture of methanol/chloroform and subjected to direct-infusion electrospray ionization tandem mass spectrometry (DI-ESI-MS/MS). Following silicic acid column chromatography, organic extracts were dried and resuspended in a 4:1 mixture of methanol/chloroform (1 ml). These were injected onto the electrospray ionization interface (TSQ Quantum Ultra, Thermo-Fisher Corporation) at a flow rate of 3  $\mu$ l/min (after addition of the internal standard di-20:0 PC at 1.3 pmol/ $\mu$ l). Spectra were averaged over 3–5 min and processed utilizing Xcalibur software. Ions were monitored in the positive ion mass scan mode. The limit of detection for this specific assay for plasmalogens at

dilutions similar to those used for analyses is  $\leq 0.3$  pmol (in 1 ml).

### PFB Oxime Derivatization and GC–MS Analysis

Silicic acid column chromatography column-purified extracts or known amounts of aldehydes or lipids (100  $\mu\text{g}$ ) were taken, dried and derivatized to their respective PFB oximes utilizing PFB hydroxylamine as the reagent. The PFB oximes were resuspended in 50–100  $\mu\text{l}$  of petroleum ether and analyzed by GC–MS as described earlier [8]. The analyses were performed either by mass scan analysis from  $m/z$  100 to 800 or by selected ion monitoring (SIM) of the  $[\text{M}-\text{HF}]^-$  ion of the PFB oximes of respective aldehydes. The ions monitored for the PFB oximes of hexadecanal, octadecanal and  $[d_4]$ -hexadecanal were  $m/z$  415,  $m/z$  443 and  $m/z$  419, respectively.

### Limit of Detection

HCAEC were incubated on 60 mm plates to confluency. The media was discarded and the cells were scraped with 1:1 mixture of methanol/saline (1 ml  $\times$  2). Varying amounts of  $[d_4]$ -hexadecanal were added in methanol (0–50 pmol). Organic extracts collected using a Bligh and Dyer extraction were subjected to silicic acid column chromatography. The chloroform extracts were derivatized by PFB hydroxylamine and analyzed by GC–MS for  $[d_4]$ -hexadecanal. The area under the curve was integrated using the Chemstation software and plotted against the amount of  $[d_4]$ -hexadecanal added.

### Neutrophil ATZ Treatment

Human neutrophils were isolated from whole blood as described earlier [9]. A total of  $0.5 \times 10^6$  neutrophils/ml were incubated in the presence or absence of 10 mM ATZ at 37  $^\circ\text{C}$  for 10 min. The reactions were terminated with the addition of methanol containing 20 pmol of  $[d_4]$ -hexadecanal as the internal standard. Following an extraction, samples were subjected to silicic acid column chromatography. Column eluates were derivatized and analyzed by GC–MS. The calculations were based on linear response curves generated for hexadecanal and octadecanal against  $[d_4]$ -hexadecanal.

## Results

Plasmalogens are a subclass of lipids with a vinyl ether bond at the *sn*-1 position. The vinyl ether bond is readily

**Fig. 1** Vinyl ether susceptibility of PFB hydroxylamine derivatization. 16:0–18:1 pPC (a), di-16:0 GPC (b) and 18:0 SM (c) were derivatized by PFB hydroxylamine and analyzed by GC–MS in the NICI utilizing the mass scan mode. Representative chromatograms obtained are shown. Each condition was repeated three times

susceptible to breakdown under acidic [17, 18] and oxidative conditions [7, 16, 22]. Since PFB hydroxylamine derivatization requires acidic conditions we tested the stability of the vinyl ether bond, the acyl ester and the amide bond under derivatization conditions. Derivatization was performed in the presence of 16:0–18:1 pPC, di-16:0 GPC and 18:0 SM and the derivatives were analyzed by GC–MS. As shown in Fig. 1, the vinyl ether bond in plasmalogens degrades to generate the PFB oxime of hexadecanal (Fig. 1a). For reference, the chromatogram, mass spectrum and fragment ions of the PFB oxime of hexadecanal are provided as supplementary data (supplementary data Fig. 1). However, the acyl ester bonds and the amide bond are stable (Fig. 1b, c). Thus to quantify aldehydes, which would be of similar structure to the alkenyl chains of plasmalogens, prior separation is necessary.

To separate plasmalogens from aldehydes, we used silicic acid column chromatography. Pre-equilibrated silicic acid columns were loaded with bovine heart PC in chloroform. Bovine heart PC was chosen because it contains  $\sim 33\%$  plasmalogens. The void and the chloroform elute were collected and analyzed by DI-ESI-MS/MS. As seen in Fig. 2, the sodiated adduct of plasmalogens present at  $m/z$  764.7 and 790.7 in bovine heart PC (Fig. 2a) are absent in the chloroform elute after silicic acid column chromatography (Fig. 2b). The major PC species are outlined in supplementary data (Table 1). The internal standard seen at  $m/z$  868.8 (sodiated adduct of di-20:0 GPC) was added for comparison after silicic acid column chromatography. Thus, it was concluded that silicic acid column chromatography would successfully be able to separate the plasmalogens and since aldehydes are neutral lipids they should readily elute in chloroform. Following this, the aldehydes could be derivatized to their PFB oximes and analyzed by GC–MS.

**Fig. 2** Silicic acid column chromatography: 150  $\mu\text{g}$  of bovine heart PC was analyzed either directly (**a**) or after silicic acid column separation (**b**) by DI-ESI-MS/MS. The internal standard di-20:0 GPC was added just prior to analysis

**Table 1** Major phosphatidylcholine (PC) species in bovine heart by DI-ESI-MS/MS

$m/z$ of $[\text{M}+\text{Na}]^+$	Molecular species
750.7	32:3 GPC
764.7	34:2 pPC
766.7	34:1 pPC
780.7	34:2 GPC
782.7	34:1 GPC
790.7	36:4 pPC
792.7	36:3 pPC

806.7	36:3 GPC
808.7	36:2 GPC
810.7	36:1 GPC
868.8	40:0 GPC (internal standard)

Column 1: The  $m/z$  of sodiated adducts ( $[\text{M}+\text{Na}]^+$ )

Column 2: The numbers denote the total carbons and double bonds present at the  $sn-1$  and the  $sn-2$  position of the PC species

GPC glycerophosphatidylcholine species with acyl chains at the  $sn-1$  and the  $sn-2$  position; pPC denotes plasmenylcholine species

To test limit of detection of our method we synthesized  $[d_4]$ -hexadecanal and added it to HCAEC prior to Bligh and Dyer extraction. The cellular extracts were separated on a silicic acid column, derivatized and analyzed for  $[d_4]$ -hexadecanal. Figure 3 shows the plot of the amount of  $[d_4]$ -hexadecanal added against the area under the chromatographic peak for  $[\text{M}-\text{HF}]^-$  ion of its PFB oxime at  $m/z$  419. The lowest amount we were able to easily detect was 0.5 pmol (inset). The dashed line represents 95% confidence limits of the linear detection curve.

Further, we treated human neutrophils with ATZ, an inhibitor of hydrogen peroxide scavenging enzymes such as catalase (EC 1.11.1.6) [23] and myeloperoxidase (EC 1.11.1.7) [24]. It was anticipated that ATZ would increase fatty aldehyde levels since it reduces the removal of reactive oxygen species by catalase. Indeed, as shown in Fig. 4, ATZ causes an increase in hexadecanal and octadecanal. The calculations were based on linear response curves generated for hexadecanal and octadecanal against the internal standard,  $[d_4]$ -hexadecanal (supplementary data Fig. 2). Collectively, these data suggest the sensitivity and utility of the method for quantification of long-chain aldehydes under biologically relevant conditions.

**Fig. 3** Limit of detection: varying amounts of  $[d_4]$ -hexadecanal (0–50 pmol) was added to HCAEC prior to extraction. The cell extracts were then separated over a Si column and analyzed by GC–MS after derivatization. The figure shows the linear plot of the integrated area under the curve for chromatographic peak of  $m/z$  419 against the known initial amount of  $[d_4]$ -hexadecanal. The individual points represent the mean with standard deviation of the measured area for that amount. The *dashed lines* represent the 95% confidence limits of the linear curve. The inset shows magnification of the lower end of the plot. GraphPad Prism (GraphPad Software, Inc, CA) was used for curve plotting and statistical analyses

## Discussion

Quantification of long-chain aldehydes as PFB derivatives from crude lipid extracts of biological tissue poses a special problem due to the presence of masked aldehydes in plasmalogens. Earlier, TLC separation has been used to separate polar lipids such as plasmalogens from long-chain aldehydes prior to their detection after oxidation to the acid followed by bromophenacyl esterification and liquid chromatography. Results from this study demonstrated that plasmalogens are targeted by free radicals but this method was not quantitative and employed radioactivity [16]. Additionally, others have employed HPLC with UV detection yielding a sensitivity for detection of  $\sim 6$  pmol [12, 25]. These methods are time-consuming, employ acidic conditions used for TLC separation, and the sensitivity of these assays for aldehyde measurement is less than that described in the method herein. In the present method we have separated plasmalogen phospholipids from fatty aldehydes by a simple silicic acid column step. Conversion of the partially purified fatty aldehydes to their pentafluorobenzyl oximes followed by GC–MS analyses using negative ion chemical ionization allows very sensitive (limit of detection of 0.5 pmol and a linear range of two orders of magnitude), rapid and accurate measurements of fatty aldehydes from biological tissues. Furthermore, we have used this new methodology to demonstrate increases in hexadecanal in ATZ-treated human neutrophils.

**Fig. 4** Long-chain aldehydes increase in ATZ treated neutrophils. Isolated human neutrophils were treated with 10 mM ATZ for 10 min. The amount of hexadecanal and octadecanal in untreated and treated neutrophils was measured utilizing  $[d_4]$ -hexadecanal as the internal standard as outlined in “Experimental Procedures”

Several groups including ours have shown that vinyl ether linked diglycerides (e.g., AAG) are present in cells. This method for the measurement of long chain fatty aldehydes could have some aldehydes generated from AAG since this diglyceride co-elutes with the neutral lipids present in the void and chloroform elute of the silicic acid column. In the present study we have shown that fatty aldehydes range between  $\sim 20$  and  $120$  pmol/ $10^6$  neutrophils. Others have shown that cytochalasin B primed human neutrophils have AAG levels up to  $1.2$  pmol/ $10^6$  neutrophils while basal AAG levels are two orders of magnitude less [26]. Thus, it is unlikely that AAG in neutrophils would significantly effect the fatty aldehyde determinations in these studies. Additionally TLC of crude lipid extracts has been used to separate plasmalogens and AAG from long-chain aldehydes prior to their measurement [16]. Our studies comparing TLC separation with silicic acid column chromatography indicate a modest increase in fatty aldehyde measurement using TLC purification over silicic acid column chromatography (data not shown). This likely reflects the masked aldehyde release from alkenyl bond containing lipids due to the presence of acetic acid in conventionally used TLC solvent systems [27].

Taken together these studies demonstrate the utility of a novel method to quantitate long chain fatty aldehydes that couples the ease of silicic acid column chromatography to remove plasmalogens with the sensitivity of quantifying their PFB oxime derivatives. It is likely that this technique will be extremely useful in measuring these lipids in tissues that are susceptible to oxidative stress.

**Abstract** A new method applying sensitive and selective liquid chromatography coupled with mass spectrometry (LC/MS/MS) for analyzing tertiary-butylhydroquinone (TBHQ) and its metabolites in rat serum was validated. Using an extracted ion chromatogram (EIC) of  $m/z$  149, free TBHQ was observed in rat serum after dosing TBHQ at 350 mg/kg to male and female Sprague–Dawley (SD) rats. Four major metabolites of TBHQ were identified—a TBHQ-sulfate, two TBHQ-sulfate-derived substances and a TBHQ-glucuronide through MS<sup>n</sup> spectra. Besides its simplicity, the sample treatment allows one to obtain a very good recovery of analysts, namely around 95%. This result suggests that the method described here is useful for the analysis of TBHQ and its metabolites in rat serum. Moreover, the metabolism of TBHQ was investigated using the method. After oral administration, TBHQ appear to be more completely absorbed and bio-transformed by males than females, which may result in higher acute oral toxicity of TBHQ for males than females.

**Keywords** Tertiary-butylhydroquinone (TBHQ) · Metabolites · Liquid chromatography–ion trap mass spectrometry (LC/ITMS)

## Introduction

Tertiary-butylhydroquinone (TBHQ) is one of the most commonly used antioxidants for preventing lipid peroxidation because of its chemical stability, availability and low cost [1, 2]. The toxicological effects of TBHQ, however, have been the subject of controversy in recent years [3–6]. Because of its possible toxicity, most countries of the world have regulations for controlling the use of TBHQ in food applications. For example, TBHQ is permitted in fatty foods up to a maximum limit of 200 mg/kg in China and USA, whereas it has not been approved as a food antioxidant yet in Japan and the European Union.

To evaluate the safety of TBHQ, several methods have been carried out for the analysis of TBHQ in body fluids as well as foods including Fourier transform infrared (FTIR) spectroscopy, colorimetry, UV–visible photometry, electroanalytical–voltammetry, paper and thin-layer chromatography, gas and liquid chromatography [7–11]. Most of these methods require long analysis times and laborious sample treatment techniques in addition to low resolution. Meanwhile, it has been found that they are limited in studying biological samples, such as analysis of metabolites, which is a very important study in the pharmacokinetics and toxicology of TBHQ. These reasons have prompted the need to establish an effective and convenient method for evaluating safety by analytical monitoring of TBHQ and its metabolites.

HPLC coupled with mass spectrometry (MS) is currently unique technique being developed for monitoring antioxidant content and studying compound structure. In particular, MS/MS triple quadrupole mass spectrometry in the multiple reaction monitoring modes (MRM) provides excellent speed, sensitivity and selectivity. In our previous study, we established a rapid, sensitive, precise and accurate quantitative method for the measurement of TBHQ in commercial edible oil by liquid chromatography/tandem mass spectrometry (LC/MS/MS) [12].

For this paper, we developed a fast and precise HPLC/MS/MS method capable of quantifying TBHQ and its metabolites in rat serum (biological sample) after oral administration.

## Experimental Procedure

### Reagents

The purity of TBHQ (J & K Chemica, Augsburg, Germany) was better than 98%. Methanol and acetonitrile (Fisher Scientific, Pittsburgh, PA) were of HPLC grade. Water was purified using a Milli-Q gradient system (Millipore Corporation, Genay Cedex, France).

### Animal Handling and Sample Collection

Adult Sprague–Dawley (SD) rats, weighing  $160 \pm 10$  g, were obtained from Department of Laboratory Animal Science of Peking University (Beijing, China). Both male and female rats were used in each experiment. The rats were maintained on the basal diet and tap water throughout the study and were not fasted before dosing, as dosing after an overnight fast resulted in mortality [13].

To identify the metabolites of TBHQ, the rats were divided into two groups (four rats/group). Rats in group 1, as control group, were assigned to receive corn oil at a gavage dose of 1 ml, respectively. Rats in group 2 were to receive TBHQ dissolved in corn oil at a gavage dose of 350 mg/kg, respectively. All rats at 1.2 h after oral administration were killed by cutting behind their heads using scissors. And then, the blood samples from the rats' necks were immediately collected into EP (Epoxy epoxide) tubes (0.5 ml of blood sample/rat).

To study distributions of TBHQ and its metabolites in rat serum, the rats were divided into four groups (six rats/group). Group 1–4 were to receive corn oil at a gavage dose of 1 ml, and TBHQ dissolved in corn oil at gavage doses of 7, 350 and 700 mg/kg, respectively. After oral administration, serial blood samples (0.25 ml sample/rat) were collected from tail using clip at 0.08, 0.25, 0.5, 1, 2, 3,

5, 7, 9, 12, 24 and 48 h. Following centrifugation of the blood samples at 12,000 rpm/min for 20 min, each serum sample was collected and stored at  $-20^{\circ}\text{C}$  until analyzed.

### Metabolite Identification

During metabolite identification, serum samples were analyzed only after a simple pretreatment procedure to avoid losing any possible metabolite. Three times the volume of methanol was added to deposit proteins. After centrifugation at 12,000 rpm/min for 20 min, the upper liquid was transferred to a filter with a  $0.22\ \mu\text{m}$  membrane.

The serum samples were analyzed using liquid chromatography–ion trap mass spectrometry (LC/ITMS) on an Agilent 1100 Series LC/MSD Trap system (Wilmington, PA) consisting of a G1312A binary pump, a G1306 A diode array detector, a G1313A automatic sample injector, a G1316A column oven, an G1379A on-line vacuum degasser, and electrospray ionization (ESI) source. The injection volume was  $1\ \mu\text{l}$ . The mobile phase was a mixture of methanol and water (60:40 v/v) pumped at 0.15 ml/min. For ESI, the nebulizer flow was at 35 psi and the drying gas flow was at 8 l/min and  $350^{\circ}\text{C}$ . Free TBHQ in serum was analyzed by extracted ion chromatograms (EICs) of its  $\text{MS}^2$  characteristic product ion. Major metabolites of TBHQ were distinguished from complex serum matrix by  $\text{MS}^1$  analysis, and then they were identified by their characteristic product ion mass spectra of  $\text{MS}^n$  analysis.

### Quantitative Analysis of TBHQ and its Metabolites in Rat Serum

Each rat serum sample ( $100\ \mu\text{l}$ ) was diluted with water ( $100\ \mu\text{l}$ ), and then ethyl acetate (1 ml) was added for lipid–lipid extraction. The mixture was vortexed for 3 min on a roller shaker and centrifuged at 12,000 r/min for 20 min. The organic phase (ethyl acetate) was then separated from the aqueous phase. The ethyl acetate extracts were collected and evaporated to dryness at  $25^{\circ}\text{C}$  under a gentle stream of nitrogen gas, and the residue was finally dissolved in  $100\ \mu\text{l}$  methanol for TBHQ quantitative analysis. As for the aqueous phase,  $200\ \mu\text{l}$  of methanol was added to deposit proteins, and after centrifugation  $100\ \mu\text{l}$  of the final supernatant was transferred to a sample bottle for quantitative analyses of the metabolites.

TBHQ was quantified using an external standard prepared in a blank serum matrix with a concentration range of 49–5,030  $\mu\text{g/l}$ . Due to lack of standards, the metabolites were semi-quantified using TBHQ as standard. The stock standard solution containing about 1 mg/ml of TBHQ in

methanol was prepared and shielded from light and stored at 4 °C for a maximum of one month for analysis. The matrix-assisted standards were prepared in the same way as the samples. To evaluate accuracy and precision, we prepared and analyzed six serum samples, each containing three different concentrations of TBHQ (328, 998, 1,969 µg/l). The precision was obtained as the inter-day and intra-day coefficient of variation [relative standard deviation (RSD %)]. The limit of detection (LOD) was considered as the concentration that produced a signal-to-noise (S/N) ratio of 3. The recovery was determined by comparing the peak areas of TBHQ obtained for the samples (328, 998, 1,969 µg/l,  $n = 6$ ) that were subjected to the extraction procedure with those obtained from blank serum that were spiked post-extraction at the corresponding concentrations.

TBHQ and its metabolites contents in non-pretreatment and post-pretreatment serum samples were determined for evaluating the stability after samples were stored at –20 °C for 1, 2, 3 and 7 days and at room temperature for 12 and 24 h.

#### Statistical Analysis

Data are presented as mean  $\pm$  SD. The results were statistically analyzed by analysis of variance (ANOVA) followed by Fisher's test. Differences were considered significant at  $P < 0.01$ .

## Results and Discussion

### Metabolite Identification by LC/ITMS

Analysis of standard solution of TBHQ showed that TBHQ was well ionized to parent ion  $m/z$  165 with the retention time of 5.3 min in negative ionization mode, while TBHQ had no response in positive ionization mode. In the  $MS^2$  spectrum (Fig. 1), the product ions of  $m/z$  165 were  $m/z$  149 and  $m/z$  108. The main product ion  $m/z$  149 was due to the methyl cleavage from tertiary butyl of TBHQ and the other product ion  $m/z$  108 came from the cleavage of tertiary butyl of TBHQ. In order to avoid the serum interference, extracted ion chromatograms (EICs) of the main product ion  $m/z$  149 were used to identify free TBHQ in rat serum. In Fig. 2, an apparent peak of the main product ion  $m/z$  149 was observed at the retention time of 5.3 min in rat serum after 350 mg/kg of oral administration. This indicates the presence of free TBHQ in rat serum following oral administration.

Total ion chromatograms (TICs) obtained in positive and negative ionization modes in Fig. 3 showed that

**Fig. 1**  $MS^2$  product ion spectrum and the predominant fragmentation patterns of TBHQ

**Fig. 2** EICs of  $m/z$  149 ( $MS^2$ ) observed in rat serum following oral administration of corn oil and TBHQ, respectively

possible metabolites were found in the region with retention time of 3–4 min in the negative ionization mode, while no metabolites were observed in the positive ionization mode. Mass spectral analysis of the peak of metabolites revealed four major ionic parent masses  $[M-H]^-$  at  $m/z$  245 (M1),  $m/z$  305 (M2),  $m/z$  327 (M3) and  $m/z$  341 (M4) (Fig. 4).

$MS^2$  and  $MS^3$  mass spectra of the major metabolites of TBHQ are given in Fig. 5. For M1 ( $[M-H]^-$  at  $m/z$  245), a major product ion was  $m/z$  165 (loss of  $SO_3$ ) using LC/ $MS^2$  (Fig. 5a1).  $MS^3$  spectral analysis showed that the product ions of  $m/z$  165 were  $m/z$  149 (loss of the methyl of tertiary butyl of TBHQ) and  $m/z$  108 (loss of the tertiary butyl of TBHQ), as evident in Fig. 5a2, consistent with the fragmentation pathway of TBHQ (Fig. 1). The characteristic fragmentation pathway of  $m/z$  245 (M1) can be noted in Fig. 6 [14]. The metabolite M1 was identified as a direct sulfate conjugate of TBHQ.

$MS^2$  and  $MS^3$  spectra of M2 ( $[M-H]^-$  at  $m/z$  305) and M3 ( $[M-H]^-$  at  $m/z$  327) were shown in Fig. 5b, c, respectively. Using LC/ $MS^2$ , a major product ion was  $m/z$  245, for both M2 and M3 (Fig. 5b1, c1).  $MS^3$  spectral analysis indicated that product ions of  $m/z$  245 were  $m/z$  165 and  $m/z$  81, as evident in Fig. 5b2 and c2, consistent

**Fig. 3** Total ion chromatograms (MS<sup>1</sup>) observed in rat serum following oral administration of corn oil and TBHQ, respectively

**Fig. 4** Average spectrum of the peak with retention time of 3–4 min following oral administration of TBHQ, obtained by subtracting the average spectrum in the region of 3–4 min following oral administration of corn oil

with the fragmentation pathway of M1. So both M2 and M3 were derived from M1 (a sulfate conjugate of TBHQ). However, the structures of M2 and M3 have not yet been completely identified in the present studies.

For M4 ( $[M-H]^-$  at  $m/z$  341), MS<sup>2</sup> spectral analysis (Fig. 5d1) showed that a major product ion was  $m/z$  165 (from loss of  $C_6H_6O_6$ ), the other product ions were  $m/z$  175, a characteristic product ion of glucuronide conjugates [15], and  $m/z$  113 (the loss of  $CO_2$  and  $H_2O$  from  $m/z$  175). MS<sup>3</sup> spectral analysis from Fig. 5 d2 indicated that product ions of  $m/z$  165 were  $m/z$  149 and  $m/z$  108, which are MS–MS product ions of TBHQ. The characteristic fragmentation

**Fig. 6** Fragmentation pathway of  $m/z$  245 (M1)

**Fig. 7** Fragmentation pathway of  $m/z$  341 (M4)

pathway of  $m/z$  341 (M4) can be seen in Fig. 7. M4 was identified as a glucuronide conjugate of TBHQ.

The results indicate that besides free TBHQ, TBHQ is mainly metabolized to a TBHQ-sulfate, a TBHQ-glucuronide and two derivatives from TBHQ-sulfate in rat serum after oral administration. These findings are consistent with those results reported in the literature [13, 16]. Astill et al. reported that 57–74% of the administered TBHQ was eliminated in the urine as the sulfate conjugate. Ikeda et al. observed metabolites consisted of TBHQ-glucuronide, TBHQ-sulfate and unidentified polar substances in rat urine by thin-layer radiochromatography following sample treatment with  $\beta$ -glucuronidase and sulfatase.

### Serum Distribution of TBHQ and its Metabolites

As evident in Fig. 8, TBHQ and its metabolites were able to be separated very well and the separations did not suffer from interference of rat serum substrate using LC/ITMS. Therefore, TBHQ's  $MS^2$  characteristic product ion and its  $MS^1$  product ions based on extracted ion chromatograms (EICs) were employed for quantitation of free TBHQ and semi-quantitation of its metabolites in rat serum.

The concentration of TBHQ in rat serum was quantified using an external standard prepared in a blank matrix. The calibration curve was obtained by plotting the peak area of EIC  $m/z$  149 ( $MS^2$ ) against the concentration of TBHQ. The calibration curve ( $Y = 401.2X + 39,958.9$ ) showed good linearity over the concentration range of 49–5,030  $\mu\text{g/l}$  with the coefficient ( $r^2$ ) of 0.9985. The detection limit of TBHQ for serum samples was 14  $\mu\text{g/l}$  ( $S/N = 3$ ). The recoveries of TBHQ in serum ( $n = 6$ ) were  $96.1 \pm 11.9$ ,  $93.4 \pm 6.7$  and  $95.5 \pm 9.4\%$ . The intra-day relative standard deviations (RSDs) ( $n = 6$ ) were 14.8, 10.3 and 7.7% and the inter-day RSDs over three consecutive days were 20.6, 14.4 and 8.3%. The results show that the method could be used for quantifying TBHQ in rat serum.

Under the adopted LC/ITMS conditions, peaks of TBHQ and its metabolites appear with retention times of 5.3 and 3–4 min, respectively. The nearness of their chromatographic retention times suggests that the polarities

and **b3** for M1; **c1**, **c2** and **c3** for M2; **d1**, **d2** and **d3** for M3; **e1**, **e2** and **e3** for M4. Error bars represent SD

of TBHQ and its metabolites are quite similar. The  $MS^1$  response of a compound is decided by its polarity to some extent. So, using TBHQ standards, the semi-quantification of its metabolites is acceptable for metabolic kinetics study. In the research, the  $MS^1$  responses of per unit concentration were defined to be equivalent for TBHQ and its metabolites; the calibration curve was obtained by plotting the peak area of EIC  $m/z$  165 against the concentration of TBHQ. The coefficient ( $r^2$ ) of the calibration curve

( $Y = 817.2X - 74268.5$ ) was 0.9893, suggesting that the curve could work well for semi-quantifying the metabolites of TBHQ in rat serum.

The stabilities of TBHQ and its metabolites in post-pretreated and non-pretreated serum samples were evaluated by putting the samples at  $-20^\circ\text{C}$  for 24, 48 h, 3 and 7 days and at room temperature for 12 and 24 h. The results indicate that TBHQ and its metabolites in post-pretreated serum samples were stable at  $-20^\circ\text{C}$  within

7 days and RSDs were less than 6.3%; post-pretreated samples were stable at room temperature within 24 h and with RSDs of less than 7.1%; in non-pretreated samples they were stable at  $-20^{\circ}\text{C}$  for 7 days with RSDs of less than 8.3%. Afterwards samples were stored at  $-20^{\circ}\text{C}$  for 24, 48 h, 3 and 7 days and at room temperature for 12 and 24 h. In the experiment, the samples used for quantitation of TBHQ and its metabolites were stored at  $-20^{\circ}\text{C}$  for 7 days.

The acceptable daily intake (ADI) was 0–0.7 mg/kg body weight allocated by the Joint FAO/WHO Expert Committee on Food Additives (JECFA). Generally, rats could tolerate poisons approximately ten times higher than humans. The  $\text{LD}_{50}$  for TBHQ was found to be between 700 and 1,000 mg/kg for rats [15]. On the basis of this information, rats were administered TBHQ with a single dose of 7, 350 or 700 mg/kg. After a single dose of 700 mg/kg TBHQ, two male rats died within 2 h, whereas no female rats died.

The serum concentrations of TBHQ and its metabolites M1–M4 of both male and female rats after oral administration of TBHQ at doses of 7, 350 and 700 mg/kg were determined (Fig. 9). The serum levels of TBHQ reached peaks at 0.08–0.50 h after oral administration of 350 and 700 mg/kg TBHQ, and then the concentrations decreased rapidly and TBHQ disappeared from the serum after 5 h, as shown in Fig. 9a1 and a2, while the concentration of free TBHQ in the serum samples at the dose of 7 mg/kg was not detected because it was lower than the limit of detection. Following oral administration of 7, 350 and 700 mg/kg TBHQ, the maximum levels of M1 (Fig. 9b1, b2, b3), M3 (Fig. 9d1, d2 and d3) and M4 (Fig. 9e1, e2, e3) were observed at 0.25–1.00 h in rat serum, while the maximum levels of M2 (Fig. 9c1, c2, c3) were observed at 3.00–7.00 h. The concentrations of M1–M4 decreased slowly and most metabolites had been eliminated from the serum after 24–48 h. Meanwhile, it was observed in the experiment that after oral administration of 350 and 700 mg/kg (except 7 mg/kg), the total concentrations of TBHQ in serum were much higher for males than for females during the metabolic process ( $P < 0.01$ ). It seems that TBHQ could be more completely absorbed by males than by females after oral administration, which may result in higher acute oral toxicity of TBHQ for males than females. This may explain why two males ( $n = 6$ ) died, but no females ( $n = 6$ ) died at the high dose of 700 mg/kg. Meanwhile, it was also found that the serum concentrations of M1, M3 and M4 appeared to be much higher for males than females ( $P < 0.01$ ) during the metabolic process, while that TBHQ and M2 appeared no significant differences between male and female ( $P > 0.05$ ). These results suggest that one or two of the metabolites M1, M3 and M4 are likely to be poisonous,

but further toxicological studies on these metabolites are required to elucidate it.

## Conclusions

A rapid and sensitive LC/ITMS method with simple treatment of samples was established for accurate quantitation of TBHQ and semi-quantitation of its metabolites in rat serum. Moreover, apparent sex difference in the metabolism of TBHQ were found. After oral administration, TBHQ appears to be more completely absorbed and bio-transformed by males than females, which may result in higher acute oral toxicity of TBHQ for males than females.

**Abstract** Polymorphisms of the human  $\Delta$ -5 (*FADS1*) and  $\Delta$ -6 (*FADS2*) desaturase genes have been recently described to be associated with the level of several long-chain n-3 and n-6 polyunsaturated fatty acids (PUFAs) in serum phospholipids. We have genotyped 13 single nucleotide polymorphisms (SNPs) located on the *FADS1–FADS2–FADS3* gene cluster (chromosome 11q12–13.1) in 658 Italian adults (78% males; mean age  $59.7 \pm 11.1$  years) participating in the Verona Heart Project. Polymorphisms and statistically inferred haplotypes showed a strong association with arachidonic acid (C20:4n-6) levels in serum phospholipids and in erythrocyte cell membranes (rs174545 adjusted *P* value for multiple tests,  $P < 0.0001$  and  $P < 0.0001$ , respectively). Other significant associations were observed for linoleic (C18:2n-6), alpha-linolenic (C18:3n-3) and eicosadienoic (C20:2n-6) acids. Minor allele homozygotes and heterozygotes were associated to

higher levels of linoleic, alpha-linolenic, eicosadienoic and lower levels of arachidonic acid. No significant association was observed for stearidonic (C18:4n-3), eicosapentaenoic (C20:5n-3) and docosahexaenoic (C22:6n-3) acids levels. The observed strong association of *FADS* gene polymorphisms with the levels of arachidonic acid, which is a precursor of molecules involved in inflammation and immunity processes, suggests that SNPs of the *FADS1* and *FADS2* gene region are worth studying in diseases related to inflammatory conditions or alterations in the concentration of PUFAs.

### Introduction

Polyunsaturated fatty acids (PUFAs) are known to play crucial roles in various cellular functions—for example, as components of the cell membrane and precursors of important mediators of inflammation, such as eicosanoids [1]. They can affect membrane fluidity and cholesterol content and influence the generation of signaling molecules. Several studies have reported an association between PUFAs and the development and outcomes of several complex diseases [2–7].

The levels of PUFAs greatly depend on diet and metabolic pathways. The key enzymes in PUFA metabolism are the  $\Delta$ -5 and  $\Delta$ -6 desaturases, which are encoded by the *FADS1* and *FADS2* gene, respectively [8–10]. These two genes are located on the desaturase gene cluster on chromosome 11 (11q12–13.1). This cluster also includes a *FADS3* gene that shares 52 and 62% sequence identity with

the above-mentioned genes, respectively, as well as a cytochrome b5-like domain and a multiple membrane-spanning desaturase region. Consequently, it is surmised that *FADS3* encodes for another desaturase of as-yet unknown activity [8].

Schaeffer et al. [11] recently reported the association of single nucleotide polymorphisms (SNPs) in the *FADS1–FADS2* gene cluster with the levels of n-6 and n-3 fatty acids in serum phospholipids. However, they did not test this association in erythrocyte cell membranes. Erythrocytes provide a simple, highly suitable model for the study of fatty acid metabolism, because these cells lack desaturase and elongase enzymes and their membrane fatty acid composition closely resembles that of circulating lipoproteins, which in turn are assembled in the liver. Moreover, erythrocyte fatty acids are less influenced than serum phospholipids by short-term variations in dietary intake and can, therefore, be considered as suitable biological markers of relatively long time periods (weeks or a few months) [13]. *FADS* gene polymorphisms may contribute to the regulation of the levels of several PUFAs in various tissues; as such, they may be involved in disorders related to different arrangements of PUFA composition.

The aim of this study was to test—in a Northern Italian population of cardiovascular patients—the hypothesis that *FADS1*, *FADS2*, and *FADS3* gene polymorphisms correlate with the levels of fatty acids in serum phospholipids and erythrocyte membranes.

## Methods

### Study Population

Northern Italian subjects were recruited as a part of a cardiovascular survey study, the Verona Heart Project (VRHP). Details on the enrolment criteria have been described elsewhere [13].

In the present study we genotyped a total of 658 subjects who had been referred for coronography due to cardiovascular disease. These patients were not on lipid-lowering treatment, and data on their PUFA levels were available.

Each patient was characterized for possible confounders of PUFA levels, such as age (mean  $59.7 \pm 11.1$  years), gender (78% males), body mass index (BMI; mean  $26.03 \pm 3.38$  kg/m<sup>2</sup>), hypertension (50%), smoking status (58% smokers), plasma triglycerides (TGs;  $3.80 \pm 0.97$  mM), high-density lipoprotein (HDL) cholesterol ( $1.30 \pm 0.38$  mM), low-density lipoprotein (LDL) cholesterol ( $3.80 \pm 0.97$  mM), total cholesterol ( $5.72 \pm 1.08$  mM), diabetes (12%) and status of cardiovascular disease [414 individuals had coronary atherosclerotic disease (CAD), as established by angiography, and 244

individuals had angiographically documented normal coronary arteries].

The study was approved by our Institutional Review Board. Written informed consent was obtained from all patients.

### Measurement of Fatty Acid Levels

Fatty acids levels were measured as previously described [14]. Blood samples were collected after an overnight fast, transported to the laboratory within 1 h and processed immediately. Analyses of the serum phospholipids (100  $\mu$ l) and erythrocyte membranes (250  $\mu$ l packed erythrocytes hemolyzed in an equal volume of double distilled water) fatty acids were performed on total lipids extracted using 4.5 ml isopropanol:chloroform (11:7, v:v) containing 0.45 mM 2,6-di-ter-*p*-cresol/l as antioxidant. A gas-chromatographic method [Hewlett Packard 5980 chromatograph equipped with an HP-FFAP phase column (length 25 m, internal diameter 0.2 mm, phase column 0.3  $\mu$ m); Hewlett Packard, Palo Alto, CA] based on a direct fatty acid transesterification technique was used, as previously described [12]. The peaks were identified and quantified by comparison with commercially available reference fatty acids (Sigma, St. Louis, MO). Fatty acid C17:0 was used as the internal standard. The areas of the peaks were measured and subsequently quantified using a PC Vectra QS/16S equipped with HP-3365 Chem Station software (Hewlett Packard) working with the operative system Microsoft Windows 3.0. The level of each fatty acid was expressed as grams per 100 g total fatty acid methyl esters (% by wt). Fatty acids from C12:0 to C26:0 were measured, and unidentified peaks accounted for <0.5% of the total. Each sample was analyzed in duplicate, and all coefficients of variation were <5%.

Some descriptive statistics on fatty acid values are given in Table 1.

### SNPs and Genotyping

Thirteen SNPs tagging the most common haplotypes of the *FADS* gene region from the reported European Community Respiratory Health Survey (ECHRS) study [11] and six additional SNPs from the HapMap project (<http://www.hapmap.org>) were selected. Table 2 presents a description of the SNPs used. Figure 1 shows the position of the SNP relative to *FADS* gene cluster region.

Genotyping was performed using the same methods and in the same laboratory as previously described [11]. Briefly, genotyping was performed using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) to detect allele-specific primer extension products (Mass Array, Sequenom, San Diego,

**Table 1** Fatty acid content in serum phospholipids and erythrocyte membrane

VRHP Verona Heart Project, SNP single nucleotide polymorphism

Position in basepairs was derived from dbSNP Build 126, based on NCBI Human Genome Build 36.1 (March 2006) of chromosome 11. Allele frequency was calculated in the VRHP study population (*n* = 658)

**Fig. 1** Location on chromosome 11, gene position and structure of the *FADS1*–*FADS2*–*FADS3* gene cluster. Horizontal arrows indicate the direction of gene transcription. Vertical bars indicate exons. The position of markers used is shown at the bottom

CA). The primers for the PCR analyses were designed using Sequenom's MASSARRAYASSAYDESIGN program.

The SNP association analysis was performed using R, a free software environment for statistical computing and graphics [15]. Haplotypes were reconstructed and analyzed using the haplo.glm function of the R library HAPLO.STATS (<http://mayoresearch.mayo.edu/mayo/research/biostat/plusfunctions.cfm>) [16].

#### Statistical Analysis

##### a. Fatty acids

Fatty acid levels were treated as quantitative traits. The distribution of each PUFA is summarized by mean and standard deviation values. All potential confounders, such as age, gender, BMI, smoking status and CAD status, were included as covariates in the statistical models.

##### b. SNP Analysis

Hardy–Weinberg equilibrium was tested for each SNP locus, and significance was ascertained by the permutation tests implemented in the JENOWHE program, which is part of the Jenoware project (<http://medgen.univr.it/jenoware> by Dr. Luciano Xumerle). Lewontin's disequilibrium coefficient  $D'$  and the squared correlation coefficient ( $R^2$ ) were estimated. Pairwise linkage disequilibrium was calculated for each pair of SNPs. Linear regression models including covariates were used for testing the association of SNPs with quantitative traits.

##### c. Haplotypes Analysis

Generalized linear regression models were used analyzing haplotype association with quantitative traits, assuming an additive inheritance model. Haplotype frequency was inferred from the investigated SNPs by an EM algorithm calculating maximum likelihood estimates given the genotypes on unknown phase (<http://www-gene.cimr.cam.ac.uk/clayton/software/>). Haplotype analysis was performed either by using haplotypes from all the 13 SNPs (from rs174544 up to rs1000778; 612 fully genotyped subjects) or by focusing on the windows of consecutive SNPs within linkage disequilibrium (LD) blocks. The windows of LD blocks were determined according to the method proposed by Kamatani [17]. All haplotypes with an estimated frequency higher than 2% were modeled. Each possible haplotype combination per individual entered the model as a weighted observation according to the approach 'EM by the method of weights' [18]. Rare haplotypes (frequency <2%) were pooled and included in the model as a group called 'haplo.rare'.

##### d. Estimation of Significance Values

The significance value of each association was estimated by permuting the phenotype and performing that statistical analysis in at least 1000 replicates and counting the number of replicates that presented a value greater than the value obtained from the statistical analysis of the original data set. This procedure was performed for single SNPs (10,000 replicates for each phenotype), 13-SNP haplotypes (1000 replicates for each phenotype and 10,000 replicates for phenotypes showing stronger association) and haplotype block-based association analysis (10,000 replicates for each LD block and phenotype).

##### e. Multiple Testing

Adjustment for multiple tests was achieved by estimating the significance level of the single test taking into account the number of statistical tests computed for either single SNP or haplotype analyses.

- SNPs. Due to a possible high LD between some of the SNPs, the estimated number of effective loci of the 13 SNPs was calculated according to the spectral decomposition method by Nyholt [19]. The nominal significance level of a single test was conservatively adjusted by a correction factor calculated as the number of effective loci  $\times$  the 14 analyzed fatty acids (seven fatty acids in serum phospholipids + seven fatty acids in erythrocyte membrane, respectively). The  $P$  values of single tests were multiplied by the correction factor, and adjusted  $P$  values of greater than 1 were set to 1. All  $P$  values of single SNP analyses reported in the paper are the adjusted  $P$  values.
- Haplotypes. The significance level of the statistical tests was set to the significance level of a single test (i.e. 0.05) divided by the sum of 1 (analysis of the 13 SNPs haplotype) plus the number of LD blocks identified in the cluster region  $\times$  the number of phenotypes investigated. The  $P$  values for the haplotype analyses reported here are not corrected for multiple tests.

## Results

### PUFAs in Serum and Erythrocyte Membranes

The content of fatty acids in serum and the erythrocyte membrane for seven n-6 and seven n-3 PUFAs was determined in 658 individuals from Northern Italy, as shown in Table 1. All coefficients of variations of PUFA measurements were less than 5%.

**Fig. 2** Association analysis of 13 single nucleotide polymorphisms (SNPs) in the *FADS* gene cluster with the levels of polyunsaturated fatty acids in serum phospholipids and the erythrocyte membrane of 658 individuals. In each graph and for each SNP, the *first bar* represents the reference, which is the mean level of the PUFA for major allele homozygotes. The *height of the second and third bars* indicates the percentage change in the PUFA level in heterozygotes and minor allele homozygotes, respectively, calculated as the

difference between the value for that PUFA and the reference value, divided by the reference value. The *vertical lines* indicate standard errors. *Asterisks* indicate significances after correction for multiple testing from general linear regression analyses: \* $P < 0.05$ , \*\* $P < 0.001$ , \*\*\* $P < 0.0001$ . Table 1 in the [Electronic Supplementary Material](#) reports the PUFA mean levels for each SNP stratified by genotype as well as the significance ( $P$  value) of the statistical test comparing the PUFA mean levels among the genotypes

A significant correlation ( $P < 0.0001$ ) between serum and erythrocyte membrane was observed for each of the PUFAs (Table 1).

### Genetic Structure of the Region

Genotyping was performed with 13 SNPs in the *FADS* gene cluster. All genotyped SNPs were found to be polymorphic in the VRHP study. The minor allele frequency (MAF) ranged from 9 to 41%, as shown in Table 2. The frequency of most SNPs ranged between 20 and 30%, with only one SNP (rs2524299) showing a MAF  $< 10\%$  (9.1%). The mean genotyping success rate (GSR) was 99.0%, with the lowest GSR being 97.4%. The genotype distribution for each SNP was consistent with Hardy–Weinberg equilibrium. Three LD blocks were observed in the gene cluster [17]: block-1 from rs174545 to rs3834458; block-2 from rs2524299 to

rs174589; block-3 from rs174611 to rs174627. Markers rs174545 and rs3834458 located in a highly preserved LD block (block-1) and markers rs174556 and rs174561 located in the same LD block showed a particularly high correlation ( $R^2 > 0.98$ ). As haplotype analysis was performed on each of the three LD blocks and on the entire 13-SNP window, the significance at the nominal level of 5% for a single test was set to  $P = 0.00089$  [i.e.  $0.05 / [(1 + 3) \times 14]$ ; see [Methods](#)]. Therefore, a haplotype association was considered to be significant after multiple test adjustment when  $P < 0.00089$ .

### Association of PUFAs with Single SNPs

The results of the single SNP association analysis with fatty acids (658 individuals) are summarized for serum phospholipids or the erythrocyte membrane by graphical

**Fig. 2** continued

representation in Fig. 2; for more detailed results, see Table 1 in the [Electronic Supplementary Material](#).

The association study was performed by adjusting the PUFA level for potential confounders (i.e. age, gender, BMI, smoking status and CAD status). In order to adjust for multiple testing the *P* values of the single tests were multiplied by 112 (eight effective loci  $\times$  the 14 analyzed fatty acids). After this correction, highly significant results were observed for the majority of the SNPs and serum phospholipids or erythrocyte membrane for arachidonic acid in the region from rs174545 up to rs174570 (adjusted-*P* values  $<0.0001$  for serum and for erythrocyte membranes). Carriers of the minor variants showed significantly lower levels of arachidonic acid. Carriers of the minor alleles of rs174545, rs3834458, and rs174583 also showed significant associations with an increase in the serum phospholipid n-3 fatty acid alpha-linolenic acid, while carriers of the minor alleles of SNPs rs174545 up to rs3834458, and rs174583, rs174589, rs174611 and rs174627 showed a significant association with an

increased level of eicosadienoic acid (C20:2n-6) in serum phospholipids. In erythrocyte membranes, the rare variants of rs174545, rs3834458, rs174570, and rs174583 showed significant associations with an increase in linoleic acid, and rs174545 up to rs3834458, and rs174583 showed significant associations with an increase in eicosadienoic acid (C20:2n-6).

Similar significant results were also observed in the subgroup of individuals without coronary heart disease (244/658 individuals; data not shown).

#### Association of PUFAs with the Genetic Region

Haplotypes were reconstructed with all 13 SNPs. Table 3 shows the estimated 13-SNP haplotype frequency for haplotypes showing a frequency of more than 2%. Six common haplotypes can be seen to account for 74% of the estimated haplotypes and rare haplotypes to account for the remaining 26%. The two most common haplotypes (haplo.base and haplo.4; Table 3) carry major alleles at each

Fig. 2 continued

SNP locus, with the exception of rs498793, which shows the minor allele in haplo.base. The association study was performed with each one of the seven PUFAs investigated in both serum phospholipids and in erythrocyte membranes, as shown in Table 4. The results reveal a significant

association (threshold after multiple test adjustment:  $P < 0.00089$ ) between the *FADS* cluster haplotypes and the level of arachidonic acid in serum phospholipids and in the membrane of red blood cells (RBCs) (Table 4). No other significant association was observed.

**Table 3** *FADS* gene cluster haplotype frequencies

Haplotype	rs174545	rs174556	rs174561	rs3834458	rs174570	rs2524299	rs174583	rs174589	rs498793	rs174611	rs17831757	rs174627	rs1000778	Haplotype frequency

haplo.rare	*	*	*	*	*	*	*	*	*	*	*	*	*	0.2597

*Haplo.rare* all of the haplotypes showing an individual frequency below 2%, *haplo.base* the more frequent haplotype; it is used as a reference in generalized linear models in the association analyses with PUFA

### Association of PUFAs with three LD Blocks in the *FADS* Gene Cluster

For further refining of the genetic data, we carried out an association analysis between the *FADS* gene cluster LD block and PUFA levels. The LD block structure and frequency of haplotypes within the three LD blocks are shown in Table 5.

Table 6 shows the results of the LD block-based haplotype association analysis performed for the seven PUFAs in the serum and RBC, respectively. This table shows non-corrected *P* values. After correction for multiple tests the haplotype associations with the PUFA levels remained statistically significant (nominal level of 5% for a single test) only for arachidonic acid (serum: blocks 1, 2, 3; RBC: blocks 1, 2). No significant association was observed for linoleic, alpha-linolenic, stearidonic, eicosadienoic, eicosapentaenoic and docosahexaenoic acids.

### Discussion

We report here the association of 13 *FADS* gene cluster polymorphisms and the level of several PUFAs in serum phospholipids (SP) and the membrane of red blood cells (RBC), as measured in 658 Italian individuals. We observed a very strong association between arachidonic acid levels in SP, as has been reported previously [11], and, for the first time, in RBCs. Weaker but still significant associations were observed between single SNPs and linoleic (SP), alpha-linolenic (SP, RBC) and eicosadienoic

**Table 4** Thirteen-SNP haplotype association analysis

PUFA	Acid name	Haplotype analysis <i>P</i> value <sup>a</sup>	
		Serum	Red blood cells
C18:2n-6	Linoleic	0.49	0.0122
C18:3n-3	Alpha-linolenic	0.25	0.0541
C18:4n-3	Stearidonic	0.57	0.35
C20:2n-6	Eicosadienoic	0.0081	0.15
C20:4n-6	Arachidonic	<0.0001***	0.0002***
C20:5n-3	Eicosapentaenoic	0.70	0.44
C22:6n-3	Docosahexaenoic	0.68	0.30

<sup>a</sup> *P* value: Significance level of the model containing the genetic factor (haplotypes) versus the model without the genetic factors. *P* values were not adjusted for multiple tests. Arachidonic acid showed a significant association in serum phospholipids and in erythrocyte membrane (=significant association after correction for multiple tests; \*\*\* *P* < 0.00089; see Methods). Eicosadienoic showed an association in serum phospholipids, and linoleic acid showed an association in erythrocyte membranes, but both these associations were not significant after correction for multiple tests

<sup>a</sup> PUFA names preceded with a 's\_' or a 'e\_' are referred to serum or erythrocyte membrane, respectively

<sup>b</sup> *P* value: Significance level of the model containing the genetic factor versus the model without the genetic factor. *P* values are not corrected for multiple testing. Covariates are included in the models. \*\*\* Significant *P* values after adjustment for multiple tests ( $P < 0.00089$ )

<sup>c</sup> Effect and haplotypes: The sign (+/–) indicates the effect of the reported haplotypes, that is the increase or decrease of PUFA level with respect to the reference haplotype of each LD block. Only the haplotypes with a significant ( $P < 0.05$ )  $\sigma$ -value in the Generalized Linear Model are reported. Haplotypes are indicated by the Hap id reported in Table 5. ns, No statistically significant effect

(SP, RBC) acids. In particular, SNP rs174583 was associated with all the three acids. Significant associations were also confirmed in the subgroup of individuals without coronary heart disease.

The *FADS* gene cluster was studied using 13 SNPs tagging the most common haplotypes. These 13 SNPs span a region that contains three *FADS* genes, including the *FADS3* gene. *FADS3* is a gene with an unknown function, although it is presumed to have a desaturase activity on the basis of its sequence homology with the other *FADS* genes.

The LD block structure of the whole region was studied in order to detect sub-regions of highly correlated SNPs that ideally represent the smallest and non-redundant source of variability that can be used independently in the association analyses of the region. Three LD blocks were identified (see Table 5). Block 1 (four SNPs, from rs174545 to rs3834458) contains three SNPs in the *FADS1* gene and one SNP between the *FADS1* and *FADS2* genes; block 2 (three SNPs, from rs2524299 to rs174589) contains three SNPs in the *FADS2* gene; block 3 (three SNPs,

rs174611 to rs174627) contains one SNP in the *FADS2* gene and two SNPs between the *FADS2* and *FADS3* genes. A similar LD structure was also observed in the ECHRHS study by Schaeffer et al. [11]. It is noteworthy that the strongest association was observed with arachidonic acid levels, confirming the results of the previous study [11] (see Table 7). Furthermore, in accordance with the results of Schaeffer et al., the most frequent haplotype shows an opposite effect with respect to all the other haplotypes, indicating that the most common haplotype exerts a different effect from all other haplotypes (see Table 7). Therefore, the *FADS* gene cluster polymorphisms are likely to contribute to the variability of PUFA levels in the short-term the serum component (as initially indicated by Schaeffer et al. [11]) and in medium-term compartments, such as erythrocytes (as indicated in this study). Although detailed information on their mode of action remains elusive, PUFAs appear to affect many different biological systems (hormone production, lipid peroxidation products, transcription events, membrane structure and function), and it can be argued that they act at a fundamental level that is common to most cells [20]. At the present time, we cannot know whether the association described here could be extended to long-term compartments, such as adipose tissue, or generalized to other tissues. However, Baylin et al. recently described an association of the rs3834458 marker, mapping in the LD block-1 of the present paper, with serum and adipose tissue PUFA levels [21]. This result suggests that *FADS* gene cluster polymorphisms may

affect the PUFA levels of long-term compartments as well as short- and medium-term compartments. To the best of the authors' knowledge, no study has actually reported whether the studied polymorphisms are functionally related to desaturase activity or whether they simply tag the true and still unknown causal genetic variant.

Since arachidonic acid is the precursor of prostaglandins, leukotrienes and related compounds, all of which have important roles in inflammation and in the regulation of immunity, *FADS* gene polymorphisms now represent novel candidates to be studied in eicosanoid-related disorders. However, PUFA levels are expressed as a percentage of total lipids and not as an absolute value (e.g. concentration). Therefore, we were able to detect relative differences in the PUFA levels due to the genetic component but we were unable to study mechanisms as these depend on the absolute value of PUFA levels (i.e. concentration).

Desaturase activity represents only a part of the mechanisms involved in the regulation of PUFAs, and several other components, such as sex, diet, age, BMI and hypertension, are factors known to be associated with variations in the levels of PUFAs [22–25].

The association of single SNPs with the levels of linoleic, alpha-linolenic and eicosadienoic acids indicates that *FADS* gene polymorphisms are likely to influence the levels of several PUFAs. Linoleic and alpha-linolenic acids are a substrate of  $\Delta$ -6 desaturase (*FADS2* gene), and eicosadienoic acid is the product of the elongation process of linoleic acid. Therefore, these associations may reflect a

The haplotype with highest frequency (CTT) is associated to higher levels of arachidonic acid (all the other haplotypes are associated to lower levels)

relationship with  $\Delta$ -6 desaturation activity. The lack of association with the other PUFAs may be due to a true absence of any association with causative genetic factors or to the effect of other factors, such as diet, or other processes involved in the regulation of the proportion of different types of PUFAs. For example, studies reporting that docosahexaenoic acid level does not strongly correlate with dietary intake indicate an independent regulation of docosahexaenoic acid [22].

Overall, the results of this study suggest that *FADS1* and *FADS2* gene polymorphisms are likely to be important factors contributing to the variability in PUFA levels in several tissues, such as serum phospholipids, tightly regulated tissues as the phospholipid membrane and in tissues with low turnover [21].

In conclusion, the association of the *FADS1* and *FADS2* gene region—but not the *FADS3* gene region—indicates that polymorphisms of these two genes contribute to the variability of several PUFAs, such as linoleic, alpha-linolenic, eicosadienoic acids and, most of all, arachidonic acid. As modifications in PUFA levels have been observed in several diseases, these genes may therefore represent a susceptibility factor worth investigating.

**Acknowledgments** We thank Patrizia Pattini (Department of Internal Medicine, University of Verona) for her excellent help in measuring serum and erythrocyte fatty acids. This work was supported by grants from Italian Ministry of University and Research, Veneto region, and by the German National Genome Research Network (NGFN).

**Abstract** This study aimed to clarify the molecular mechanisms of age-specific hepatic lipid accumulation accompanying hyperinsulinemia in a peroxisome proliferator-activated receptor  $\alpha$  (PPAR $\alpha$ ) (+/–):low-density lipoprotein receptor (LDLR) (+/–) mouse line. The hepatic fat content, protein amounts, and mRNA levels of genes involved in hepatic lipid metabolism were analyzed in 25-, 50-, 75- and 100-week-old mice. Severe fatty liver was confirmed only in 50- and 75-week-old mice. The hepatic expression of proteins that function in lipid transport and catabolism did not differ among the groups. In contrast, the mRNA levels and protein amounts of lipogenic enzymes, including acetyl-coenzyme A carboxylase-1, fatty acid synthase, and glycerol-3-phosphate acyltransferase, enhanced in the mice with fatty liver. Elevated mRNA and

protein levels of lipoprotein lipase and fatty acid translocase, which are involved in hepatic lipid uptake, were also detected in mice with fatty liver. Moreover, both protein and mRNA levels of sterol regulatory element-binding protein-1 (SREBP-1), a transcription factor regulating lipid synthesis, had age-specific patterns similar to those of the proteins described above. Therefore, the age-specific fatty liver found in the PPAR $\alpha$  (+/–):LDLR (+/–) mouse line is probably caused by age-specific expression of SREBP-1 and its downstream lipogenic genes, coordinated by the increased uptake of lipids. All of these factors might be affected by age-specific changes in serum insulin concentration.

SREBP-1	Sterol regulatory element-binding protein-1
T1	Short chain-specific 3-ketoacyl-CoA thiolase

## Introduction

Fatty liver disease is divided into two broad categories: alcoholic fatty liver disease and nonalcoholic fatty liver disease. The etiologic factors of the two entities are quite different, but the pathologic changes of the liver are nearly the same. Simple fatty liver, as the basic process of fatty liver disease, is the most common cause of abnormal liver function and can progress to steatohepatitis, cirrhosis, and even hepatocellular carcinoma through a metabolic pathway [1]. Fatty liver is also found frequently among persons infected with hepatitis C virus [2, 3]. Furthermore, nonalcoholic fatty liver disease is strongly associated with obesity, visceral fat accumulation, insulin resistance, and so on [4–8]. It is also recognized as a risk factor of cardiovascular diseases [9].

Insulin resistance and hyperinsulinemia are known to be central to the development of fatty liver [10]. Insulin is an anabolic hormone that promotes the synthesis and storage of carbohydrates, lipids, and proteins, as well as inhibiting their degradation and release into the circulation [11]. A high level of insulin may be one of the factors leading to the development of fatty liver, although the underlying mechanisms remain elusive. The insulin-responsive transcription factor participating in hepatic lipid metabolism has been identified as sterol regulatory element-binding protein-1 (SREBP-1) [12]. SREBP-1 is one of the SREBPs that belong to the basic helix-loop-helix-leucine zipper family of transcription factors; it plays an essential role in the regulation of lipogenesis [13–15]. Studies have shown that elevated SREBP-1 levels were associated with fatty liver in *ob/ob* mice and transgenic mice [14], whereas the disruption of SREBP-1 reduced the expression of lipogenic enzymes as well as the triglyceride content in liver of *Lep<sup>ob</sup>/Lep<sup>ob</sup>* mice [15].

It is also known that peroxisome proliferator-activated receptors (PPARs), the ligand-activated nuclear receptors, mediate the critical transcriptional regulation of genes associated with lipid homeostasis [16]. There are three PPAR isoforms, designated PPAR $\alpha$ , PPAR $\beta$  (also called  $\delta$ ), and PPAR $\gamma$ , which exhibit distinct tissue distribution

[17]. PPAR $\alpha$  is expressed at high levels in the liver, kidney, and heart [17]. PPAR $\alpha$ -null [PPAR $\alpha$  ( $-/-$ )] mice chronically fed a high fat diet or fasted for a short-term often develop severe fatty liver, because of their considerably diminished hepatic  $\beta$ -oxidation capacity [18]. We have reported that PPAR $\alpha$  regulates mitochondrial fatty acid catabolism under constitutive conditions in the liver [19], heart [20], and kidney [21], although many publications have presented that PPAR $\alpha$  mainly regulates peroxisomal  $\beta$ -oxidation through the experiments by activating its ligands [22, 23]. Our recent studies using PPAR $\alpha$  ( $-/-$ ) mice indicated that it also plays a protective role in different pathological conditions such as alcoholic liver disease [24] and proximal tubular cell injury induced by acute fatty acid toxicity [25]. In contrast, PPAR $\beta$  is ubiquitously expressed [17]. The role of PPAR $\beta$  in liver is still controversial, although a recent paper proposed that PPAR $\beta$  might regulate hepatic expression of genes modulating glucose homeostasis [26]. PPAR $\gamma$  is the well-known major PPAR form in white adipose tissue, however, is poorly expressed in liver [17]. Liver-specific PPAR $\gamma$  disruption contributes in protecting mouse liver from the development of steatosis in leptin-deficient mice [27], which suggests that PPAR $\gamma$  may play an important role in hepatic triglyceride accumulation.

In addition, low-density lipoprotein receptor (LDLR) also plays an important role in hepatic lipid uptake [28]. LDLR-null [LDLR ( $-/-$ )] mice often develop atherosclerosis [29], obesity and severe hyperlipidemia [30] on a high-fat diet.

We have recently developed a novel mouse line, PPAR $\alpha$  ( $+/-$ ):LDLR ( $+/-$ ) mice by mating PPAR $\alpha$  ( $-/-$ ) and LDLR ( $-/-$ ) mice [31]. The average body weight increased around the age of 50 and 75 weeks compared with that at the age of 25 weeks, and then rapidly dropped nearly to the level of 25-week-old mice until at the age of 100 weeks. Serum insulin concentrations were also changed in the age-specific manner (25-week-old mice,  $368 \pm 119$  pg/ml; 50-week-old mice,  $1,021 \pm 205$  pg/ml; 75-week-old mice,  $652 \pm 198$  pg/ml; 100-week-old mice,  $356 \pm 91$  pg/ml), which was coincident with the changes of body weight [31].

This mouse line represents obesity, visceral fat accumulation, hypertriglyceridemia, severe fatty liver, and hyperinsulinemia (after 25–30 weeks of age) [31]. Therefore, the PPAR $\alpha$  ( $+/-$ ):LDLR ( $+/-$ ) mice may be useful for the long-term study of these metabolic diseases. To clarify the molecular mechanism of age-specific fatty liver in the PPAR $\alpha$  ( $+/-$ ):LDLR ( $+/-$ ) mice may be important for the prevention and treatment of liver diseases and metabolic disorders and their complications in human. However, the precise mechanism of pathogenesis of these symptoms remains unclear.

As such, we aimed to clarify the molecular mechanism of age-specific lipid accumulation in the PPAR $\alpha$  (+/–):LDLR (+/–) mice.

## Materials and Methods

### Animals

PPAR $\alpha$  (–/–) mice (hybrids of Sv/129 cross C57BL/6N genetic background) were produced as described previously [32], and LDLR (–/–) mice (hybrids of Sv/129 cross C57BL/6J genetic background) were obtained from Jackson Laboratories (Bar Harbor, ME, USA). LDLR (–/–) mice were crossbred with PPAR $\alpha$  (–/–) mice to obtain the PPAR $\alpha$  (+/–):LDLR (+/–) mice, as described previously [31]. All mice were genotyped by polymerase chain reaction (PCR) analysis from tail genomic DNA. Since age-specific abnormalities were not seen in female PPAR $\alpha$  (+/–):LDLR (+/–) mice, male mice were adopted. All mice were housed in a specific pathogen-free barrier facility with a 12/12-h dark–light cycle, and fed a standard chow and water ad libitum. Male 4-week-old mice ( $n = 20$ ) were randomly divided into four groups. The mice of each group ( $n = 5$ ) were killed by cervical dislocation after 6-h food deprivation at the age of 25, 50, 75 and 100 weeks, respectively, according to the symptoms of the age-specific obesity. Liver tissues were removed and cut in some pieces, and some were subjected to histological analysis. The others were quick-frozen on dry ice, and stored at  $-80^{\circ}\text{C}$  until used. Experimental procedures were performed in accordance with protocols approved by the Institutional Animal Care and Research Advisory Committee.

### Histological Analysis

The removed liver tissue of the four experimental groups (25-, 50-, 75- and 100-week-old mice,  $n = 5$  in each group) was fixed in 4% paraformaldehyde in phosphate-buffered saline at  $4^{\circ}\text{C}$  overnight and equilibrated in 30% sucrose overnight. The tissue was embedded at the optimal cutting temperature. Ten-micrometer frozen sections were prepared (three sections were selected every five sections from the serial section of each mouse for each experimental group). Then the sections were incubated with oil red O solution for 10 min, followed by washing with 60% isopropanol and counter staining with hematoxylin. Five microscopic fields in the pericentral area of liver lobuli were randomly selected in each section and photomicrographed at a magnification of  $200\times$ . The proportion of areas of lipid droplets stained with oil red O to those of hepatocytes was

assessed by morphometric analysis using MetaView software (Universal Imaging Corp, Downingtown, PA, USA).

### Biochemical Analysis

Total lipids were extracted from the liver samples from the mice in the four experimental groups according to Folch's method with minor modifications [33]. Briefly, frozen liver pieces (50 mg) were homogenized in 2.1 ml of chloroform/methanol (2:1, v/v) to extract lipids and incubated at  $37^{\circ}\text{C}$  for 40 min. After the incubation and removing insoluble substances, 0.2 ml of water was added to the extract in order to make two phases. The lower phase was carefully collected, and 0.83 volume of chloroform/methanol/water (3:48:47, v/v/v) so called "theoretical upper phase" was added and vigorously mixed to re-extract. Then the lower phase was carefully collected again and combined to dry under nitrogen gas. The dried samples were dissolved into 125  $\mu\text{l}$  of 2-propanol and centrifuged at  $10,000\times g$  for 3 min to remove insoluble substances. The supernatant was subjected to the determination of triglycerides and free fatty acids using the Triglyceride E-WAKO kit (Wako Pure Chemical Industries Ltd., Osaka, Japan) and the NEFA C-WAKO kit (Wako Pure Chemical Industries Ltd.), respectively.

Microsomal triglyceride transfer protein (MTP) activity was measured with the MTP assay kit (Roar Biomedical, New York, NY, USA). The MTP source was prepared with liver homogenate according to the manufacturer's protocol. Donor vesicles (10  $\mu\text{l}$ ) containing fluorescent neutral lipid (triglyceride) and acceptor vesicles (10  $\mu\text{l}$ ) were incubated with 20  $\mu\text{l}$  of liver homogenate (containing 15  $\mu\text{g}$  protein) in the total volume of 400  $\mu\text{l}$  of assay buffer at  $37^{\circ}\text{C}$  for 4 h. MTP activity was then measured as an increase in fluorescence intensity at an excitation wavelength of 465 nm and an emission wavelength of 535 nm.

### Messenger RNA Determination

Total RNA from frozen liver samples of mice in the four experimental groups was isolated using the RNeasy mini kit according to the manufacturer's protocol (Qiagen GmbH., Hilden, Germany). RNA was treated with DNase (Qiagen GmbH., Hilden, Germany) to remove residual contaminating genomic DNA. The amount and quality of RNA was determined by spectrophotometry. To confirm the purity of the RNA samples, the total RNA (3  $\mu\text{g}$ ) was subjected to 1% formaldehyde agarose gel-electrophoresis, and then visualized under UV light. The RNA samples were transferred to cDNA by SuperScript<sup>TM</sup> First-Strand Synthesis System with the oligo-dT primer (Invitrogen Life Technologies, Carlsbad, CA, USA). Final concentration of

each sample was adjusted at 20 ng/μl. We designed gene-specific primers using Primer Express Software (Applied Biosystems, Foster City, CA, USA). The sequences and GenBank accession numbers of the primer sets are listed in Table 1. Most of the standard plasmid DNAs for real-time quantitative PCR were constructed by the pT7Blue T-Vector System and the Wizard Plus SV Minipreps DNA Purification System (Promega Co., Madison, WI, USA). The standard plasmid DNAs of acyl-coenzyme A (CoA) oxidase (ACO), lipoprotein lipase (LPL), and SREBP-1 were constructed with the pGEM-T Easy Vector System I (Promega Co.). Real-time quantitative PCR was performed using the SYBR® Premix Ex Taq™ (Applied Biosystems) on the ABI Prism 7700 Sequence Detection System (Applied Biosystems). We ran each sample (25 ng of cDNA) in triplicate final concentration of 0.4 μM of each primer set. The PCR condition was set to 95 °C for 10 s, followed by 40 cycles of 95 °C for 5 s and 60 °C for 34 s.

Fold change in target mRNA relative to glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was calculated according to the method reported by Livak and Schmittgen [34]. After completion of the real-time quantitative PCR, baseline limits were set according to the manufacturer (i.e., at least three cycles before the rise of the earliest amplification). The threshold was set to lie in the middle of the exponential phase of the amplification plot, so that efficiency values truly reflect the reaction dynamic at the cycle threshold ( $C_T$ ). Relative quantification of gene expression was evaluated by utilizing the comparative  $C_T$ . The  $C_T$  value for each mRNA reaction was subtracted from the respective  $C_T$  value of the GAPDH as

an internal control, resulting in the  $\Delta C_T$  value. The  $\Delta C_T$  value of the 25-week-old mice group was arbitrarily used as a constant that was subtracted from all other  $\Delta C_T$  values to determine the  $\Delta\Delta C_T$  value. The fold change was then generated for each mRNA by calculating  $2^{-\Delta\Delta C_T}$ .

#### Preparation of Whole Liver Lysate and Nuclear Fraction for Western Blotting

The frozen liver tissue of mice in the four experimental groups (50 mg) was lysed with 200 μl of 20 mM sodium phosphate buffer (pH 7.4) containing 250 mM sucrose, 10 mM EDTA, and protease inhibitors, using a high-speed mixer homogenizer. The homogenate was centrifuged at 8,000×g for 5 min at 4 °C, and the supernatant was used as whole liver lysate. Meanwhile, nuclear extract was isolated using a nuclear extraction kit (Sigma, St. Louis, MO, USA) to analyze transcription factors. Briefly, 100 mg of liver tissue was added to 1 ml of lysis buffer containing 10 mM HEPES, pH 7.9, 1.5 mM MgCl<sub>2</sub>, 10 mM KCl, 1 mM dithiothreitol, and protease inhibitors. The tissue was homogenized and centrifuged at 11,000×g for 20 min at 4 °C. The pellet was resuspended in 140 μl of extraction buffer containing 20 mM HEPES, pH 7.9, 1.5 mM MgCl<sub>2</sub>, 0.42 M NaCl, 0.2 mM EDTA, 25% glycerol, 1 mM dithiothreitol, and protease inhibitors. After centrifugation at 20,000×g for 5 min at 4 °C, the pellet was collected, suspended with 100 μl of 20 mM sodium phosphate buffer (pH 7.4), and used as the nuclear fraction. Whole liver lysate or nuclear fraction (100 μl each) was added with 100 μl of

20 mM sodium phosphate buffer (pH 7.4) containing 2% (w/w) sodium dodecyl sulfate (SDS), sonicated twice, and subjected to Western blotting.

### Western Blotting

The protein concentration of the whole liver lysate and nuclear fraction was determined using the BCA protein assay kit (Applied Biosystems). Whole liver lysate or nuclear fraction (60 µg protein) was loaded in each well, and subjected to 10% SDS-polyacrylamide gel electrophoresis (PAGE), except for acetyl-CoA carboxylase-1 (ACC-1) and fatty acid synthase (FAS) which were subjected to 6% SDS-PAGE. Proteins were then transferred to a nitrocellulose membrane at 10 V, 2 mA/cm<sup>2</sup> for 1.5 h, except ACC-1 and FAS which were transferred under 10 V, 2 mA/cm<sup>2</sup> for 5 h. The membrane was incubated with the primary antibody followed by the secondary alkaline phosphatase-conjugated goat anti-rabbit IgG antibody (Strattech Scientific Ltd., Newmarket, UK) (1:2,000 dilution). Primary antibodies were used as follows: anti-long chain acyl-CoA synthase (LACS), anti-medium chain acyl-CoA dehydrogenase (MCAD), anti-ACO, anti-short chain-specific 3-ketoacyl-CoA thiolase (T1), anti-peroxisomal D-type bifunctional protein (DBF), anti-peroxisomal thiolase (PT), and anti-liver fatty acid-binding protein (L-FABP) antibodies were prepared as described previously [19, 35, 36]. The following antibodies were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA): anti-ACC-1 (FL-114), anti-FAS (C-20), anti-LDLR (C-20), anti-LPL (H-53), anti-fatty acid translocase (FAT) (H-300), anti-SREBP-1 (H-160), anti-PPAR $\alpha$  (H-98), anti-PPAR $\beta$  (H-74), anti-PPAR $\gamma$  (H-100), anti- $\beta$ -actin (H-196), and anti-histone H3 (FL-136). Anti-glycerol-3-phosphate acyltransferase (GPAT) was purchased from ABNOVA (Abnova Co., Taipei, Taiwan). Dilution was performed 200-fold for most of the antibodies commercially available, except for anti- $\beta$ -actin and anti-histone H3 (250-fold), anti-GPAT (750-fold). The band intensity was quantified by densitometric scanning with the software Image Quant Version 5.2 (Molecular Dynamics, Sunnyvale, CA, USA). The band intensity for the proteins involved in  $\beta$ -oxidation and L-FABP was normalized to that of  $\beta$ -actin, and those for the nuclear proteins were normalized to that of histone H3. The result was subsequently expressed as the fold changes relative to that of 25-week-old PPAR $\alpha$  (+/-):LDLR (+/-) mice.

### Statistical Analysis

Statistical analysis was performed using SPSS program (SPSS 10.0, SPSS Science, Chicago, Illinois, USA).

One-way ANOVA with repeated measure of the age factor was used to analyze group differences. Total freedom value was shown as *F*, and freedom values between groups and within groups are expressed in parentheses. If a significant interaction was observed, Scheffe' post hoc testing was used to determine pairwise differences between mean. A *P* value of less than 0.05 was considered to be statistically significant. Data were expressed as mean  $\pm$  standard deviation (SD).

## Results

### Histological and Biochemical Analysis in Liver Samples

To examine hepatic morphological conditions in the mice, the liver sections were stained with oil red O, which specifically detects neutral lipids such as triglycerides. The area stained with oil red O increased by 2- to 2.5-fold in 50- and 75-week-old mice compared with 25-week-old mice, then decreased in 100-week-old mice similar to the level of 25-week-old mice [*F* (3, 16) = 17.771, *P* = 0.000; 25- vs. 50-week-old mice, *P* < 0.01; 50- vs. 100-week-old mice, *P* < 0.01; and 75- vs. 100-week-old mice, *P* < 0.05, respectively] (Fig. 1a, b). In addition, the hepatic triglycerides and free fatty acids increased by approximately threefold until the age of 50 weeks and later decreased with aging, which are consistent with the previous report [31] [triglycerides: *F* (3, 16) = 17.773, *P* = 0.000; 25- vs. 50-week-old mice, *P* < 0.01; 50- vs. 100-week-old mice, *P* < 0.01; and 75- vs. 100-week-old mice, *P* < 0.01; free fatty acids: *F* (3, 16) = 8.187, *P* = 0.003; 25- vs. 50-week-old mice, *P* < 0.01; 50- vs. 100-week-old mice, *P* < 0.01] (Fig. 1c, d).

### Analysis of Genes Related to the Synthesis of Fatty Acids and Triglycerides

Figure 2 shows the expression levels of the enzymes involved in lipid synthesis such as ACC-1, FAS, and GPAT at the age of 25, 50, 75 and 100 weeks. Both the mRNA and protein levels of ACC-1 increased by approximately twofold in 50- and 75-week-old mice compared with 25-week-old mice, and then decreased in 100-week-old mice to the level of 25-week-old mice [mRNA levels: *F* (3, 16) = 17.167, *P* = 0.000, 25- vs. 50-week-old mice, *P* < 0.01; 50- vs. 100-week-old mice, *P* < 0.01; and 75- vs. 100-week-old mice, *P* < 0.01; protein levels: *F* (3, 16) = 9.850, *P* = 0.001, 25- vs. 50-week-old mice, *P* < 0.01; 50- vs. 100-week-old mice, *P* < 0.01; and 75- vs. 100-week-old mice, *P* < 0.05]. FAS exhibited similar age-specific changes in both the mRNA and protein levels [mRNA: *F* (3, 16) = 16.864, *P* = 0.000; protein: *F* (3, 16) = 10.225, *P* = 0.001], as well as GPAT

CV denotes central vein, and each bar indicates 50  $\mu$ m. **b** Morphometric analysis of oil red O-stained liver sections. Fifteen pericentral areas of liver lobuli were photomicrographed in each mouse, and the areas of lipid droplets were quantified as described in “Materials and Methods”. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). \*  $P < 0.05$ , and \*\*  $P < 0.01$  between the indicated groups. The contents of hepatic triglycerides (**c**) and free fatty acids (**d**). All of the manipulations were as described in “Materials and Methods”. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). \*  $P < 0.05$ , and \*\*  $P < 0.01$  between the indicated groups

[mRNA:  $F(3, 16) = 16.520$ ,  $P = 0.000$ ; protein:  $F(3, 16) = 13.052$ ,  $P = 0.000$ ].

#### Analysis of Genes Related to the Uptake of Fatty Acids and Triglycerides

The hepatic levels of the proteins that function in hepatic lipid uptake are displayed in Fig. 3. The expression of LDLR decreased in 50-week-old mice compared with 25-week-old mice, and then increased in 100-week-old mice approximately to the level of 25-week-old mice [mRNA:  $F(3, 16) = 5.982$ ,  $P = 0.010$ ; protein:  $F(3, 16) = 5.058$ ,  $P = 0.017$ ; 50- vs. 25-week-old mice,  $P < 0.05$ ]. In contrast, the expression of LPL increased in 50- and 75-week-old mice than that in 100-week-old mice [mRNA:  $F(3, 16) = 6.717$ ,  $P = 0.007$ ; protein:  $F(3, 16) = 8.796$ ,  $P = 0.002$ ; 50- vs. 100-week-old mice,  $P < 0.05$ ; 75- vs. 100-week-old mice,  $P < 0.05$ ]. The expression of FAT increased by approximately 1.5- to 2-fold in 50- and 75-week-old mice compared with 25-week-old mice, and

then decreased in 100-week-old mice approximately to the level of 25-week-old mice [mRNA:  $F(3, 16) = 16.548$ ,  $P = 0.000$ ; protein:  $F(3, 16) = 13.802$ ,  $P = 0.000$ ; 25- vs. 50-week-old mice,  $P < 0.01$ ; 50- vs. 100-week-old mice,  $P < 0.01$ ; and 75- vs. 100-week-old mice,  $P < 0.05$ ]. Whereas, the hepatic mRNA levels of fatty acid transport protein (FATP) and hepatic TG lipase (HTGL) were similar among all the groups [FATP:  $F(3, 16) = 0.680$ ,  $P = 0.581$ ; HTGL:  $F(3, 16) = 0.399$ ,  $P = 0.757$ ].

#### Analysis of Genes Participating in Fatty Acid Catabolism and Triglyceride Secretion

Next, we determined both the mRNA and protein levels of enzymes involved in both mitochondrial and peroxisomal fatty acid  $\beta$ -oxidation. Figure 4 shows the results for LACS, MCAD, and ACO, which are representative enzymes of fatty acid  $\beta$ -oxidation. There were no significant changes in mRNA expression among the different age groups for all the enzymes [LACS:  $F(3, 16) = 1.112$ ,  $P = 0.382$ ; MCAD:  $F(3, 16) = 1.112$ ,  $P = 0.382$ ; ACO:  $F(3, 16) = 1.112$ ,  $P = 0.382$ ].

**Fig. 2** Hepatic expression of lipogenic enzymes in  $PPAR\alpha (+/-):LDLR (+/-)$  mice at the age of 25, 50, 75, and 100 weeks. **a** Changes in the expression of ACC-1, FAS, and GPAT at the presented ages. The expression was determined by real-time PCR method, normalized to that of GAPDH, and subsequently expressed as the fold changes relative to that of 25-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). \*  $P < 0.05$ , and \*\*  $P < 0.01$  between the indicated groups. **b** Western blot analysis of ACC-1, FAS, and GPAT. The band intensity was quantified densitometrically, normalized to that of  $\beta$ -actin, and subsequently expressed as the fold changes relative to that of 25-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). \*  $P < 0.05$ , and \*\*  $P < 0.01$  between the indicated groups

(3, 16) = 1.033,  $P = 0.413$ ; ACO:  $F(3, 16) = 0.660$ ,  $P = 0.592$ ] (Fig. 4a). These protein amounts were also constant among the groups (Fig. 4b, c). Furthermore, no differences were found in the expression and protein amounts of other genes such as T1, DBF, and PT, which are also involved in  $\beta$ -oxidation (data not shown).

We also investigated the expression of L-FABP and MTP, which are representative proteins participating in intracellular lipid trafficking in hepatocytes and secretion of triglycerides from hepatocytes, respectively. No differences of the gene expression and protein amounts of L-FABP were

detected [mRNA:  $F(3, 16) = 1.984$ ,  $P = 0.170$ ; protein:  $F(3, 16) = 2.157$ ,  $P = 0.146$ ] (Fig. 5a, b). The gene expression and activities of MTP were also unchanged among the groups [mRNA:  $F(3, 16) = 3.429$ ,  $P = 0.052$ ; activity:  $F(3, 16) = 2.387$ ,  $P = 0.120$ ] (Fig. 5c, d).

#### Determination of the Expression of Transcription Factors

We further evaluated the expression of transcription factors regulating hepatic lipid homeostasis. As comparison, we also presented the results of 50-week-old  $PPAR\alpha (+/+):LDLR (-/-)$  mice, which exhibit no

**Fig. 4** Hepatic expression of fatty acid  $\beta$ -oxidation enzymes in  $PPAR\alpha (+/-):LDLR (+/-)$  mice at the age of 25, 50, 75 and 100 weeks. **a** Changes in mRNA levels of LACS, MCAD, and ACO at the presented ages. The expression was determined by real-time PCR method, normalized to that of GAPDH, and subsequently expressed as the fold changes relative to that of 25-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). **b** Western blot analysis of LACS, MCAD, and ACO. Whole liver lysate (60  $\mu$ g of protein) was loaded in each lane. The band of  $\beta$ -actin was used as a loading control. Results are representative of three independent experiments. Results are expressed as mean  $\pm$  SD ( $n = 5$ )

hepatic steatosis and obesity [31]. Both the mRNA and protein levels of  $PPAR\alpha$  tended to increase until the age of 75 weeks, but markedly dropped in 100-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice [mRNA:  $F(3, 16) = 9.608$ ,  $P = 0.002$ ; protein:  $F(3, 16) = 8.747$ ,  $P = 0.002$ ; 50- vs. 100-week-old mice,  $P < 0.01$ ; 75- vs. 100-week-old mice,  $P < 0.01$ ] (Fig. 6). The expression levels of  $PPAR\alpha$  in 50- and 75-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice were higher than expected, but those in 100-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice were much lower compared with 50-week-old  $PPAR\alpha (+/+):LDLR (-/-)$  mice.

**Fig. 5** Analysis of L-FABP and MTP in  $PPAR\alpha (+/-):LDLR (+/-)$  mice at the age of 25, 50, 75 and 100 weeks. **a** The mRNA levels of L-FABP. The levels were determined by real-time PCR method, normalized to that of GAPDH, and subsequently expressed as the fold changes relative to that of 25-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). **b** Western blot analysis of L-FABP (upper panel) and quantification of the protein amounts (lower panel). Whole liver lysate (60  $\mu$ g of protein) was loaded in each lane. The band intensity was quantified densitometrically, normalized to that of  $\beta$ -actin, and subsequently expressed as the fold changes relative to that of 25-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). **c** The mRNA levels of MTP. The levels were determined by real-time PCR method, normalized to that of GAPDH, and subsequently expressed as the fold changes relative to that of 25-week-old  $PPAR\alpha (+/-):LDLR (+/-)$  mice. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). **d** The activity of MTP. All of the procedures were as described in “Materials and Methods”. Results are mean  $\pm$  SD ( $n = 5$ )

On the other hand, no differences were found at the mRNA and protein levels of  $PPAR\beta$  [mRNA:  $F(3, 16) = 1.164$ ,  $P = 0.327$ ; protein:  $F(3, 16) = 1.150$ ,  $P = 0.331$ ] and  $PPAR\gamma$  [mRNA:  $F(3, 16) = 3.472$ ,  $P = 0.059$ ; protein:  $F(3, 16) = 3.350$ ,  $P = 0.064$ ] (Fig. 6).

The hepatic mRNA and protein levels of SREBP-1 increased by 1.5- to 2-fold in 50- and 75-week-old mice compared with 25-week-old mice, then decreased in 100-week-old mice approximately to the level of 25-week-old mice [mRNA:  $F(3, 16) = 12.319$ ,  $P = 0.001$ ; protein:  $F(3, 16) = 12.965$ ,  $P = 0.000$ ; 25- vs. 50-week-old mice,  $P < 0.01$ ; 50- vs. 100-week-old mice,  $P < 0.01$ ; and 75- vs. 100-week-old mice,  $P < 0.05$ ] (Fig. 6).

**Fig. 6** Hepatic expression of transcription factors in PPAR $\alpha$  (+/-):LDLR (+/-) mice at the age of 25, 50, 75 and 100 weeks. **a** Changes in mRNA levels of PPAR $\alpha$ , PPAR $\beta$ , PPAR $\gamma$ , and SREBP-1. The expression was determined by real-time PCR method, normalized to that of GAPDH, and subsequently expressed as the fold changes relative to that of 25-week-old PPAR $\alpha$  (+/-):LDLR (+/-) mice. As comparison, data obtained from 50-week-old PPAR $\alpha$  (+/+):LDLR (-/-) mice are shown as #50. Results are expressed as means  $\pm$  SD ( $n = 5$ ). \*  $P < 0.05$ , and \*\*  $P < 0.01$  between the indicated groups. **b** Western blot analysis of PPARs and SREBP-1. Results are expressed as mean  $\pm$  SD ( $n = 5$ ). #50, 50-week-old PPAR $\alpha$  (+/+):LDLR (-/-) mice; \*  $P < 0.05$ , and \*\*  $P < 0.01$  between the indicated groups

## Discussion

Fatty liver presents an excessive accumulation of lipids in hepatocytes. The cause of lipid accumulation in liver may possibly be due to enhanced de novo lipogenesis, activating lipid uptake, lowering lipid catabolism, and reducing lipoprotein secretion rates. Development of studies in this field has contributed to a better understanding of the cause of fatty liver in spite of remaining unknown problems [37].

In the present study, we confirmed the finding described in our previous paper that severe fatty liver was found in

50- and 75-week-old PPAR $\alpha$  (+/-):LDLR (+/-) mice [31]. The gene expression and the amounts of proteins participating in lipogenesis and lipid uptake were increased in 50- and 75-week-old mice compared with 25- and 100-week-old mice. Notably, enhanced gene expression and protein amounts of transcription factor SREBP-1 were also detected only in the 50- and 75-week-old mice, which presented severe fatty liver. Several studies using different animal models demonstrated that the development of fatty liver was not necessarily associated with the changes in the molecules involved in lipogenesis and/or lipid uptake [38–41]. To date, there has not been enough evidence to conclude that enhanced lipogenesis and/or lipid uptake is the consequence of hepatic steatosis. Therefore, increased expression of these genes is considered to be the cause of the hepatic lipid accumulation in our mouse model.

FAS, ACC-1, and GPAT are key enzymes in de novo fatty acid and triglyceride synthesis in mammals. SREBP-1 is well-known as the dominant transcription factor regulating gene expression of these lipogenic enzymes in the liver [13]. FAS [42], ACC-1 [42] and GPAT [43] are also known to be regulated by SREBP-1. In our study, gene expression of FAS, ACC-1, GPAT, and SREBP-1 was changed simultaneously in accordance with the extent of lipid accumulation (Figs. 1, 2, 6). These results indicate that severe fatty liver in PPAR $\alpha$  (+/-):LDLR (+/-) mice is associated with increased expression of SREBP-1 and its downstream lipogenic genes.

Insulin is known to stimulate hepatic lipid synthesis by selectively up-regulating the expression of SREBP-1 [12, 44–46]. Various studies have indicated that insulin regulates the expression of SREBP-1 principally at the transcriptional level in vivo [44, 45] as well as in vitro [46]. The regulation by insulin is considered to be a result of activating several SREBP-1 responding motifs in its promoter region [47]. In our study, both the mRNA and protein levels of the mature form of SREBP-1 changed in the age-specific manner (Fig. 6b, e), and the changes were consistent with those in serum insulin concentration on the basis of the result from the previous study [31]. Therefore, we propose that insulin probably up-regulates the age-specific expression of SREBP-1 in PPAR $\alpha$  (+/-):LDLR (+/-) mice. It is conceivable that this up-regulation also occurs at both the transcriptional and post-translational levels. Of interest, Okamoto et al. [48] reported that the SREBP-1 expression in brain was affected by age, the mRNA levels of which increased between 4 and 80 weeks of age and did not decrease in aged rats (over 80 weeks of age). Neither hormones nor metabolic changes affect those of SREBP-1. This difference in liver and brain indicates that the age-specific SREBP-1 expression in liver in our PPAR $\alpha$  (+/-):LDLR (+/-) mice is quite unique.

Other important molecules in this study, LPL and FAT increased in 50- and 75-week-old mice and decreased in 100-week-old mice (Fig. 3). The expression of LPL and FAT is known to be regulated by PPAR $\alpha$ , because ligand-activating experiments showed induction of the expression of LPL [49] or FAT [50]. In our study, the mRNA and protein amounts of PPAR $\alpha$  presented age-specific changes in PPAR $\alpha$  (+/-):LDLR (+/-) mice, all of which were lower than those in PPAR $\alpha$  (+/+):LDLR (-/-) mice (Fig. 6). In our experimental conditions (constitutive conditions), the expression of PPAR $\alpha$  is probably much lower than that of PPAR $\alpha$  in the conditions activated by PPAR $\alpha$  ligands. Meanwhile, PPAR $\alpha$  target genes such as LACS, MCAD, ACO, and L-FABP were unchanged among all the groups [14, 17] (Figs. 4, 5). Therefore, we consider that other factors except PPAR $\alpha$  activation probably contribute to the age-specific expression of LPL and FAT in the PPAR $\alpha$  (+/-):LDLR (+/-) mice. To date, several pieces of evidence have supported the stimulatory functions of insulin on fatty acid uptake, through regulating FAT and LPL in cardiac myocytes [51], skeletal muscle [52], and adipose tissue [53], although little is known about the effect of insulin on the expression of them in liver. Considering the close association between changes in expression of FAT and LPL and those in serum insulin concentration described in the previous paper [31], our findings suggest that insulin probably plays some roles in the regulation of lipid uptake in the liver by inducing the expression of LPL and FAT (Fig. 3).

The mechanism of the age-specific changes in serum insulin concentration found in PPAR $\alpha$  (+/-):LDLR (+/-) mice is still obscure. Experimental disruption of PPAR $\alpha$  improves insulin resistance in LDLR (-/-) mice [54] and apolipoprotein E-null mice [55]. In our PPAR $\alpha$  (+/-):LDLR (+/-) mice, higher expression of PPAR $\alpha$  than expected might contribute to the induction of insulin resistance in 50- and 75-week-old mice, while lower expression of PPAR $\alpha$  after 75 weeks of age might lead to the improvement of insulin resistance [31]. Furthermore, insufficient gene expression of LDLR might contribute to the development of hyperlipidemia, which is also considered an important factor in the development of fatty liver and insulin resistance.

Decreases in hepatic lipid accumulation in 100-week-old mice may be caused by spontaneous improvement of hyperinsulinemia and the resultant down-regulation of lipogenic enzymes. On the basis of the concept that PPAR $\alpha$  deficiency can ameliorate insulin sensitivity in the insulin-resistant status [3, 54, 55], it is postulated that these phenomena found in 100-week-old mice might be related to spontaneous reduction in PPAR $\alpha$  expression. However, its precise mechanism remains unclear. Since several studies have indicated that aging leads to a decrease in the activity

and the expression of PPAR $\alpha$  in rat liver [56, 57], heart [58] and spleen [59], we speculate that aging seems to be one of the contributors of PPAR $\alpha$  reduction in 100-week-old PPAR $\alpha$  (+/-):LDLR (+/-) mice. Further study is needed to address this issue.

In conclusion, the development of the fatty liver found in PPAR $\alpha$  (+/-):LDLR (+/-) mice is linked with the elevated hepatic expression of SREBP-1 and its downstream genes involved in lipogenesis, accompanied by increased lipid uptake. Insulin appeared to play a predominant role in age-specific hepatic lipid accumulation in this mouse line. Our observations will be helpful to increase understanding of hepatic lipid homeostasis and may contribute to the overall knowledge of the onset of fatty liver diseases accompanying the metabolic syndrome.

**Abstract** Transgenic Late-onset OBesity (LOB) rats slowly develop a male-specific, autosomal dominant, obesity phenotype with a specific increase in peri-renal white adipose tissue (WAT) depot and preserved insulin sensitivity (Bains et al. in *Endocrinology* 145:2666–2679, 2004). To better understand the remarkable phenotype of these rats, the lipid metabolism was investigated in male LOB and non-transgenic (NT) littermates. Total plasma cholesterol (C) levels were normal but total plasma triacylglycerol (TAG) (2.8-fold) and hepatic TAG content (25%) was elevated in LOB males. Plasma VLDL-C and VLDL-TAG levels were higher while plasma apoB levels were 60% lower in LOB males. Increased hepatic TAG secretion explained the increased VLDL levels in LOB

males. The hepatic gene expression of FAS, SCD-1, mitochondrial (mt)GPAT, and DGAT2 was up-regulated in both old obese and young non-obese LOB rats. Lipoprotein lipase (LPL) activity in heart and epididymal white adipose tissue (WAT) was unchanged, while LPL activity was increased in peri-renal WAT (30%) and decreased in soleus muscle (40%). Moreover, FAS, SCD-1 and DGAT2 gene expression was increased in peri-renal, but not in epididymal WAT. Basal lipolysis was reduced or unchanged and  $\beta$ -adrenergic stimulated lipolysis was reduced in WAT from both old obese and young non-obese LOB rats. To summarize, the obese phenotype of LOB male rats is associated with increased hepatic TAG production and secretion, a shift in LPL activity from skeletal muscle to WAT, reduced lipolytic response in WAT depots and a specific increase in expression of genes responsible for fatty acid and TAG synthesis in the peri-renal depot.

### Introduction

Obesity is associated with insulin resistance and ectopic TAG storage in skeletal muscle and liver [1–4]. An increased free fatty acid (FFA) release from adipocytes and changed adipocytokine production in adipose tissue is probably of major importance for the development of ectopic lipid storage and insulin resistance [1, 3–5]. The dyslipidemia associated with insulin resistance is characterised by high plasma levels of TAG and apolipoprotein (apo) B, and low levels of HDL-cholesterol (C) in humans

[3, 6]. In insulin-resistant rodent models, such as ob/ob mice and Zucker rats, plasma levels of TAG, apoB and total C are increased, while HDL-C levels are largely unchanged [7–9].

The LOB rat (Late-onset OBesity) model, first described by Bains et al. [10], develops a male-specific, late-onset, central obesity despite a normal intake of low fat diet. These rats were originally generated to study the regulation of the vasopressin/oxytocin (VP/OT) locus targeting human GH to the posterior pituitary [11]. However, as previously reported [1] one of the lines differed from the other lines since it slowly developed an obesity phenotype with unusual characteristics. The most pronounced change in the LOB rats was an approximately threefold increase in the peri-renal fat depots in LOB males compared to NT littermates. This increase was almost entirely attributed to an increase in adipocyte number [10]. Remarkably, despite severe central obesity, transgenic rats were able to retain a normal glucose metabolism with a heightened insulin sensitivity compared to non-transgenic (NT) littermates. It is likely that the preserved adipocyte size in the context of obesity and the increased plasma adiponectin levels [5] observed in the LOB rats [10] to a large extent contributed to the normal glucose metabolism in this obese phenotype.

Obesity associated with normal adipocyte size and preserved insulin sensitivity is a unique feature compared to other existing rodent models of obesity with insulin resistance. This phenotype therefore clearly differentiates the LOB rats from obese insulin resistant rodents like the obese (ob/ob) mouse [4, 12] and the Zucker (fa/fa) rat [13].

The underlying genetic cause of the phenotype seen in LOB rats has yet to be determined. Here we sought to analyse the changes in lipid and lipoprotein metabolism in both old obese and young non-obese LOB rats in an attempt to identify potential mechanisms that favor central fat deposition in these rats.

## Materials and Methods

### Animals

Experiments were performed following Institutional and National guidelines. All rats were bred and housed under controlled conditions (22 °C, 12 h light, 12 h dark cycle), with access to food and water ad libitum. The diet was standard rat chow (3.4% fat, 18.8% protein, 3.7% fibre, 3.8% ash, 60.3% carbohydrate, 15.6 MJ/kg (Special Diet Services, Witham, UK). The male rats were 10–12 months of age at sacrifice if not otherwise stated. At this age the LOB rats are severely obese and weighed ~30% more than their controls as previously described [10]. For all

studies, control animals referred to as NT are non-transgenic littermates from the same strain colonies.

### Plasma Analyses

TAG and total cholesterol concentrations (cholesterol + cholesteryl esters) were determined by enzymatic colorimetric assays (MPR2: TG/GPO-PAP and Chl/CHOD-PAP, Boehringer Mannheim, Germany). The intra-assay coefficient of variation (CV) was 3% for the TAG assay and 4% for the cholesterol assay. Plasma apolipoprotein B (apo B) and apolipoprotein E (apo E) concentrations were determined by an electroimmunoassay (EIA) as previously described [14, 15]. The intra- and inter-assay CV for the apo B assay was 5.3 and 8.6% respectively. Plasma glucose concentrations were measured by the MPR3 Glucose/GOD-PAP method (Boehringer Mannheim). Serum FFA concentrations were measured with a NEFA kit (Wako Chemicals, Neuss, Germany).

Lipoprotein profiles were obtained by gel filtration using fast protein liquid chromatography (FPLC) equipment (Pharmacia Upjohn, Uppsala, Sweden) as previously described [16]. TAG and total cholesterol concentrations were determined with enzymatic colorimetric assays as described above. VLDL ( $d < 1.006$  g/ml), IDL/LDL ( $d$  1.006–1.063 g/ml) and HDL ( $d$  1.063–1.21 g/ml) are indicated based on the elution profile of density fractions after sequential ultracentrifugation.

ApoB in the FPLC fractions was determined by western blotting as previously described [17] using enhanced chemiluminescence (ECL) protocol (Amersham Pharmacia Biotech, Buckinghamshire, UK).

### In Vivo Hepatic Triacylglycerol Secretion and Clearance

TAG secretion rate in vivo was measured by intravenous administration of Triton WR1339 [16, 18]. Plasma TAG levels were analysed as described above, and hepatic TAG secretion rate was calculated from the slope of the curve and expressed as micromoles per hour per gram liver. The plasma TAG clearance rate was calculated as the ratio between hepatic TAG secretion rate and the basal plasma TAG levels before Triton WR1339 administration ( $\mu\text{mol}/\text{min}; \mu\text{mol}/\text{ml}$ ).

### Total Amount of Lipids in the Liver

Frozen liver was homogenized in ice-cold double distilled water (6 ml/g tissue). Total lipid content was then extracted from the homogenate according to Bligh and Dyer [19]. After evaporation of the chloroform phase under a stream of  $\text{N}_2$  the extracted lipids were dissolved in isopropanol.

TAG and total cholesterol concentrations were determined as described above.

### Lipoprotein Lipase Activity

Lipoprotein lipase activity in heart, skeletal muscle and white adipose tissue (WAT) depots was determined according to the method of Peterson et al. [20]. The substrate emulsion used was Intralipid<sup>®</sup>, labelled with [<sup>3</sup>H]-triolein (Dr Krabisch, Lund University, Lund, Sweden). Samples were incubated in triplicates at 25 °C. Liberated fatty acids were extracted [21] and quantified in a liquid scintillation counter. Activity was expressed as mU/g tissue (1 mU = 1 nmol FFA released per minute).

### β-Adrenergic Stimulated Lipolysis

Isolated fat cells were obtained using a method similar to that previously described by Rodbell [22] with the modifications made by Gause et al. [23]. For each incubation, 100 µl of the 50/50 cell-suspension was added to plastic vials containing 2 ml incubation medium, supplemented with 4% BSA (fraction V, Sigma Chem.), in the absence (basal lipolysis) or presence of 10<sup>-5</sup> M isoproterenol (Isoproterenol, Noradrenaline, Sigma Chem.). In parallel, 100 µl 50/50 cell-suspension was added to Dole's solution, for subsequent extraction of lipids [24]. After incubation for 2 h at 37 °C, cells and medium were separated by centrifugation (2,400 rpm, 3 min) through silicon oil (Kebo Lab, Spånga, Sweden). The glycerol content in the medium was determined using an enzymatic colorimetric assay (GY105, Randox, Randox Laboratories, United Kingdom) and taken as an index of lipolysis. The rate of lipolysis was expressed as nmol glycerol released per mg TAG.

### cDNA Synthesis and Quantitative Real-Time PCR

Total RNA was isolated with TRIZOL<sup>®</sup> Reagent (Invitrogen). To remove contaminating DNA, total RNA was treated with DNA-free<sup>™</sup> (Ambion, Austin, TX, USA). First-strand cDNA was synthesized with SuperScript<sup>™</sup> First-Strand Synthesis System (Invitrogen). Quantitative real time PCR analyses were performed with Applied Biosystems 7500 Real-Time PCR System (96 wells). All samples were analysed in triplicates. The expression data were normalized against the endogenous control acid ribosomal phosphoprotein P0 (36B4). The expression of 36B4 was not influenced by the introduced transgene. The relative expression levels were calculated according to the formula  $2^{-\Delta Ct}$ , where  $\Delta Ct$  is the difference in threshold cycles (Ct) values between the target gene and the 36B4 endogenous control. Each gene, except for PPAR $\gamma$ 2 (see below), was

analysed using FAM<sup>™</sup> labelled probes obtained from TaqMan<sup>®</sup> Gene Expression Assays (Applied Biosystems): FAS (fatty acid synthase, Rn00569117\_m1), SCD-1 (stearoyl-CoA desaturase-1, Rn00594894\_g1), DGAT1 (acyl-CoA:diacylglycerol O-acyltransferase 1, Rn00584870\_m1), DGAT2 (acyl-CoA:diacylglycerol O-acyltransferase 2, Rn01506781\_m1), mtGPAT (mitochondrial glycerol-3-phosphate acyltransferase, Rn00568620\_m1), Adiponectin (adipocyte complement related protein of 30 kDa, Rn00595250\_m1) and FABP4 (fatty acid binding protein 4, Rn00670361\_m1). For PPAR $\gamma$ 2 (peroxisome proliferator activated receptor  $\gamma$ 2), specific primers (forward: 5'-TT TTATGCTGTTATGGGTGAACTCT-3', reverse: 5'-AG TGCTCATAGGCAGTGCATCA-3') was used to amplify a 86 bp long fragment of rat PPAR $\gamma$ 2 cDNA (Acc No. NM\_013124).

### Statistical Analysis

Values are expressed as means  $\pm$  SEM. Comparisons between groups were made by one-way Analysis of Variance (ANOVA) followed by Bonferroni test for pairwise differences in multiple groups or using Student's *t*-test. When appropriate, values were normalized by transformation to logarithms. A difference of  $P < 0.05$  was considered significant: NS = non-significant.

## Results

### Plasma Lipids and Lipoprotein Profiles

As has been shown previously [10], total plasma cholesterol (C) levels were normal (Fig. 1a) but total plasma TAG levels were elevated  $\sim$ 2.8-fold in 10- to 12-month-old LOB males (Fig. 1b). Size-exclusion chromatography analysis showed a marked increase in both VLDL-C and TAG levels (Fig. 2a, b) while LDL-C and HDL-C levels were slightly lower in LOB rats. This analysis was performed on three separate occasions with each analysis giving similar results. Surprisingly, in spite of the elevated levels of VLDL, apo B levels were  $\sim$ 60% lower in LOB males compared to NT males (Fig. 2c). No significant changes were detected in plasma levels of apo E (NT  $100.0 \pm 6.4$  vs. LOB  $105.8 \pm 6.7$  expressed as percent of NT,  $n = 10$ ) or free fatty acid (FFA) levels (NT  $0.31 \pm 0.04$  vs. LOB  $0.38 \pm 0.08$  mM,  $n = 6$ ).

### Hepatic Triacylglycerol Secretion Rate

It was subsequently investigated whether the increase in plasma VLDL levels was due to an increased hepatic TAG secretion. Hepatic TAG secretion in vivo was measured by

**Fig. 1** Plasma total cholesterol and TAG levels. Total cholesterol (a) and TAG (b) concentrations were determined in LOB rats (LOB) and non-transgenic littermates (NT) by enzymatic colorimetric assays as described in “Materials and Methods”. The animals were sacrificed between 0900 and 1100 hours without prior fasting. Results are presented as means  $\pm$  SEM,  $n = 6$ . \* $P < 0.05$  LOB versus NT rat (unpaired Student’s  $t$ -test)

administering Triton WR1339 via the tail vein. LOB rats showed a significant increase in hepatic TAG secretion compared with NT male rats (Fig. 3a, b). To estimate the peripheral tissues ability to remove TAG from the circulation, the plasma TAG clearance rate was calculated. LOB males had significantly higher plasma TAG clearance rate when compared to NT rats (Fig. 3c).

#### Lipid Content in the Liver

To investigate whether hepatic lipid content changed in parallel with hepatic TAG secretion, hepatic TAG and C content were measured (Table 1). Hepatic TAG content

**Fig. 2** Size distribution of serum lipoproteins and serum levels of apoB. Size distribution of serum lipoproteins in LOB rats (LOB) and non-transgenic littermates (NT) rats is shown for total cholesterol (a) and TAG (b) concentrations. The density classes of lipoproteins obtained by sequential ultracentrifugation, VLDL ( $d < 1.006$  g/ml), IDL/LDL ( $d 1.006$ – $1.063$  g/ml) and HDL ( $d 1.063$ – $1.21$  g/ml) are indicated. Data was obtained from pooled serum from six rats in each group. Similar results were obtained in three separate experiments. Below the lipoprotein profiles are Western blot data showing apoB in the fractions; assayed as described in “Materials and Methods”. Briefly, in each lane adjacent FPLC fractions were pooled in pairs (9  $\mu$ l each). Serum apo B concentrations (c) were determined by an electroimmunoassay as described in “Materials and Methods”. Results are presented as means  $\pm$  SEM,  $n = 5$ . The animals were killed between 0900 and 1100 hours without prior fasting. \* $P < 0.05$  LOB versus NT rats (unpaired Student’s  $t$ -test)

was significantly higher in LOB rats compared to non-transgenic rats. However, there was no significant difference in hepatic total cholesterol content.

**Fig. 3** Hepatic TAG secretion and plasma TAG clearance rate in vivo. TAG secretion rate in vivo from LOB rats (LOB) and non-transgenic littermates (NT) rats was measured after i.v. administration of Triton WR1339 (500 mg/kg). Serum TAG were determined before (0 min) and 60, 120, 180 and 240 min after Triton administration (a). TAG secretion rate was calculated from the slope of the curves (b). TAG clearance rate (ml/min) was calculated as the ratio between hepatic TAG secretion rate and the basal plasma TAG levels before Triton WR1339 administration ( $\mu\text{mol TAG}/\text{min}:\mu\text{mol}/\text{ml}$ ) (c). Results are presented as means  $\pm$  SEM,  $n = 7$ . \* $P < 0.05$  LOB versus NT rats (unpaired Student's *t*-test)

#### Hepatic Gene Expression

The marked increase in hepatic TAG secretion and the parallel increase in hepatic TAG content lead us to investigate the gene expression of five different hepatic enzymes involved in de novo lipogenesis or TAG synthesis. Figure 4 shows that the mRNA expression of FAS, SCD1, mtGPAT and DGAT2 was up-regulated in both old (10–12 months) and young (1.5–2 months) LOB rats compared to NT rats. However, the expression of DGAT1 was significantly higher only in old LOB rats.

#### Lipoprotein Lipase Activity

The importance of lipoprotein lipase (LPL) for the turnover of TAG-rich lipoproteins is well documented [25]. The activity of lipoprotein lipase (LPL) is an important first step in plasma TAG clearance and FFA delivery to adipose and muscle tissues. Lipoprotein lipase activity was therefore measured in heart, soleus muscle and the peri-renal and epididymal white adipose tissue (WAT) depots. There were no significant differences in heart or epididymal WAT LPL activity between LOB rats and NT rats (Fig. 5a, c). However, LPL activity was higher in peri-renal WAT ( $\sim 30\%$ ) and lower in soleus muscle ( $\sim 40\%$ ) in LOB rats (Fig. 5b, d). This shift in LPL activity ratio between adipose and muscle tissues would favour an increased TAG deposition into the peri-renal adipose depot that would contribute to the increased central obesity observed in LOB rats [10].

#### Adipose Tissue Gene Expression

Fatty acids liberated by LPL are re-esterified in adipocytes to TAG. An alternative source of fatty acids for TAG synthesis is de novo lipogenesis. Gene expression of some enzymes important for lipogenesis and TAG synthesis were therefore determined in epididymal and peri-renal WAT. As shown in Fig. 6, the gene expression of SCD-1 and DGAT1 was not different between LOB rats and their controls in epididymal WAT. Unexpectedly, FAS and DGAT2 mRNA levels were lower in LOB rats in this WAT depot. In contrast to the findings in epididymal WAT, the

expression of all these genes except DGAT1, was significantly higher in peri-renal WAT of LOB rats than in lean littermates (Fig. 6). These results indicate a marked difference in regulation of genes involved in fatty acid and TAG synthesis between the WAT depots.

**Table 1** Lipid content in liver

Groups	Liver triacylglycerol ( $\mu\text{mol/g}$ liver)	Liver total cholesterol ( $\mu\text{mol/g}$ liver)
NT	$7.8 \pm 0.2$	$4.6 \pm 0.1$
LOB	$9.1 \pm 0.2^*$	$4.9 \pm 0.2$

The content of triacylglycerol and total cholesterol in liver of LOB and non-transgenic littermate controls (NT) rats was determined as described in “Materials and Methods”. Animals were sacrificed at 12 months of age. Results are presented as means  $\pm$  SEM,  $n = 5$ –6.

\*  $P < 0.05$  LOB versus NT rat (unpaired Student's  $t$ -test)

Our previous study [10] has shown that LOB rats are more sensitive to a PPAR $\gamma$  agonist, and moreover, treatment with PPAR $\gamma$  agonists have shown to reduce adipocyte size [13] and increase adiponectin mRNA levels in adipocytes [26]. Hence, mRNA expression of PPAR $\gamma$ 2 was also measured in epididymal and peri-renal WAT from LOB and NT rats. There was a trend towards higher expression of PPAR $\gamma$ 2 in both epididymal and peri-renal WAT from LOB as compared to NT littermates (epididymal WAT ( $2^{-\Delta\text{Ct}}$ ): LOB,  $0.033 \pm 0.009$ , NT,  $0.022 \pm 0.016$ ,  $n = 5$ –6, peri-renal WAT ( $2^{-\Delta\text{Ct}}$ ): LOB,  $0.095 \pm 0.023$ , NT,  $0.069 \pm 0.030$ ,  $n = 4$ –5). In our previous study, it was shown that LOB males had markedly higher plasma levels of adiponectin [10]. To determine if the increased plasma levels of adiponectin were associated with changed gene expression, adiponectin mRNA was measured in both WAT depots. Interestingly, adiponectin mRNA levels were not significantly different between LOB males and littermate NT controls (epididymal WAT ( $2^{-\Delta\text{Ct}}$ ): LOB,  $3.42 \pm 0.19$ , NT,  $3.22 \pm 0.04$ ,  $n = 4$ –5, peri-renal WAT ( $2^{-\Delta\text{Ct}}$ ): LOB,  $2.57 \pm 0.10$ , NT,  $2.46 \pm 0.12$ ,  $n = 4$ ).

Another unique model of obesity associated with preserved insulin sensitivity is the FABP4 (aP2) null mouse [27] on a ob/ob background [28]. We therefore measured FABP4 mRNA expression in WAT depots. There was no significant difference in FABP4 mRNA levels between LOB males and littermate controls (epididymal WAT ( $2^{-\Delta\text{Ct}}$ ): LOB,  $1.77 \pm 0.08$ , NT,  $1.48 \pm 0.08$ ,  $n = 4$ , peri-renal WAT ( $2^{-\Delta\text{Ct}}$ ): LOB,  $2.30 \pm 0.20$ , NT,  $1.83 \pm 0.16$ ,  $n = 4$ ).

### $\beta$ -Adrenergic Stimulated Lipolysis

We next investigated the lipolytic response in peri-renal and epididymal WAT using glycerol release from isolated adipocytes as an index of lipolysis during non-stimulated conditions (basal lipolysis) and during  $\beta$ -adrenergic stimulation.  $\beta$ -adrenergic stimulated lipolysis was lower in both peri-renal and epididymal WAT from LOB rats compared

to non-transgenic rats (Fig. 7a, b). Basal lipolysis was significantly lower in epididymal WAT, but unchanged in peri-renal WAT, from LOB versus NT rats (Fig. 7b). Lipolysis was also investigated in 2-month-old non-obese LOB rats. The basal lipolysis in epididymal and peri-renal WAT was similar in young NT and LOB rats (data not shown). The isoproterenol ( $10^{-5}$  M) stimulated lipolysis in epididymal WAT was  $33.3 \pm 0.8$  and  $18.0 \pm 0.7$   $\mu\text{M/mg}$  TAG (mean  $\pm$  SD,  $n = 2$ ) in young NT and LOB rats, respectively. The isoproterenol ( $10^{-5}$  M) stimulated lipolysis in peri-renal WAT was  $33.3 \pm 1.6$  and  $16.5 \pm 0.7$   $\mu\text{M/mg}$  TAG (mean  $\pm$  SD,  $n = 2$ ) in young NT and LOB rats, respectively. The similar findings in the young non-obese LOB rats and old obese LOB rats indicate that the obesity did not cause the decreased lipolysis of LOB rats.

### Discussion

In contrast to most other obese rodent models [4, 13, 29, 30], the LOB rats have unchanged plasma levels of insulin and glucose as well as normal or improved insulin sensitivity and glucose tolerance [10]. Possible clues to the well preserved glucose homeostasis in the context of marked obesity were the previous findings of high plasma levels of adiponectin and unchanged adipocyte size [10]. The obese phenotype was not explained by GH deficiency, since GH treatment of LOB rats, increased body weight gain and the size of the peri-renal fat depot [10]. In addition, other GH deficient lines did not show this obese phenotype [1]. Moreover, LOB rats did not show increased food intake or decreased body temperature [10]. The genetic basis of this phenotype is currently under investigation and is unclear. It may result from a combinational effect of transgene insertion and transgene expression, since the phenotype only manifests in a single line. The intriguing obesity of these rats prompted us to further investigate lipid and lipoprotein metabolism in more detail to gain further understanding of the phenotype of LOB rats. We report here that the specific growth of the peri-renal WAT depot was associated with a unique regulation of LPL activity and genes involved in fatty acid and TAG synthesis in that depot.

An increased hepatic TAG secretion and not a decreased turnover of circulating TAG resulted in increased plasma VLDL-TAG levels. Interestingly, increased hepatic TAG secretion is also observed in ob/ob mice and Zucker rats [7, 9, 29]. In contrast to the obese Zucker rat [29], the LOB rats showed enhanced calculated TAG clearance indicating a fundamental difference in TAG metabolism. Opposite to the findings in LOB rats, insulin resistant rodent models also have increased total plasma cholesterol [7, 9] and apo B levels [8]. The increase in hepatic TAG content was

**Fig. 4** Hepatic mRNA expression. Hepatic mRNA expression of FAS (a), SCD-1 (b), DGAT1 (c), DGAT2 (d) and mtGPAT (e) in young non-obese (1.5–2 months) and old-obese (10–12 months) LOB rats compared with non-transgenic littermates (NT). The animals were sacrificed between 0900 and 1100 hours without prior fasting. The mRNA levels were measured with Applied Biosystems 7500 Real-Time PCR System (96 wells). All samples were analysed in triplicates and expression data normalized against the endogenous control 36B4. Results are presented as means  $\pm$  SEM,  $n = 5-7$ . \* $P < 0.05$  LOB versus NT rats (unpaired Student's  $t$ -test)

much less pronounced in the LOB rats than observed in ob/ob mice [9] and Zucker rats [7]. We conclude that de novo lipogenesis in the liver was likely enhanced in LOB rats

since the lipolysis in WAT was reduced in the context of increased hepatic TAG content and secretion. Expression of the lipogenic genes, like FAS and SCD-1 was increased

**Fig. 5** Lipoprotein lipase activity. Lipoprotein lipase (LPL) activity in heart (a), soleus muscle (b), epididymal white adipose tissue (WAT) (c) and peri-renal WAT (d) from 12-month-old LOB rats and non-transgenic littermates (NT). Animals were sacrificed between 0900 and 1200 hours. Lipoprotein lipase activity was analysed as described in “Materials and Methods”. Results are presented as means  $\pm$  SEM,  $n = 6$ . \* $P < 0.05$  LOB versus NT rats (unpaired Student's  $t$ -test)

in both young and old LOB males. Mitochondrial (mt)GPAT and DGAT2 mRNA, genes important in TAG synthesis were also up-regulated. Increased hepatic expression of mtGPAT results in increased hepatic TAG secretion and mild hypertriglyceridemia [31]. Over-expression of DGAT2 in the liver results in liver steatosis without changed hepatic TAG secretion [32]. The exact role of DGAT2 in VLDL assembly is not clear, since silencing DGAT2 in fat fed mice decreases both hepatic steatosis and TAG secretion [33]. On the other hand, hepatic over-expression of DGAT1 is specifically related to increased hepatic TAG secretion and also results in increased adipose tissue mass [32]. Therefore, the higher DGAT1 expression in old LOB rats probably contributes to the increased hepatic TAG secretion.

Interestingly, the increase in VLDL in LOB rats was accompanied by a  $\sim 60\%$  reduction in apoB. The mechanisms behind the low plasma apoB levels remain to be explored. However, hepatic insulin resistance and hyperinsulinemia is accompanied with increased hepatic secretion of apoB [6] and insulin prevents apoB secretion [34]. Therefore, the preserved insulin sensitivity of LOB rats [10] might contribute to low plasma apoB levels.

LPL activity was increased specifically in the peri-renal WAT. With the lower LPL activity in skeletal muscle of LOB rats, these changes contribute to a shift in fatty acid flux towards the peri-renal depot [25]. A similar shift in

LPL activity from muscle to adipose tissue has been described for the insulin-resistant obese Zucker rat [35, 36], indicating that this shift in LPL activity might be a general phenomena of obesity. Thus, the changed balance in LPL activity towards the peri-renal WAT would result in an increased availability of TAG-derived fatty acids in that tissue.

The increased LPL activity would not lead to increased TAG synthesis in the peri-renal WAT depot if balanced by decreased capacity for TAG synthesis. The increased expression of mtGPAT and DGAT2 in peri-renal WAT of LOB rats indicated increased capacity for TAG synthesis. The expression of DGAT2 is higher than DGAT1 in adipose as indicated in this study and by others [37]. Ob/ob mice, high fat fed mice and IRS2 $^{-/-}$  mice showed increased DGAT2 and decreased DGAT1 expression in WAT [38]. In contrast, LOB rats showed unchanged DGAT1 expression. The mechanisms behind the changed expression of DGAT1 and DGAT2 in LOB rats remain unclear.

Interestingly, hepatic lipogenesis is increased, but expression of lipogenic genes are unchanged in WAT in overt human obesity [39]. Therefore, it was of interest that FAS and SCD-1 expression was up-regulated in LOB peri-renal fat but not in epididymal fat. Increased SCD-1 expression may be of importance in obesity since SCD-1 knock-out in ob/ob mice resulted in a dramatic decrease in their body weight [40]. The increased SCD-1 expression in

**Fig. 6** Adipose tissue mRNA expression. Epididymal and peri-renal white adipose tissue (WAT) mRNA expression of FAS (a), SCD-1 (b), DGAT1 (c), DGAT2 (d) in 10- to 12-month LOB rats compared with non-transgenic littermates (NT). The animals were sacrificed between 0900 and 1100 hours without prior fasting. The mRNA levels were measured with Applied Biosystems 7500 Real-Time PCR System (96 wells). All samples were analysed in triplicates and expression data normalized against the endogenous control 36B4. Results are presented as means  $\pm$  SEM,  $n = 4-6$ . \* $P < 0.05$  LOB versus NT rats (unpaired Student's  $t$ -test)

liver and peri-renal WAT in LOB males may thus contribute to their specific increase in peri-renal WAT.

In the LOB rat,  $\beta$ -adrenergic stimulated lipolysis was lower in peri-renal and epididymal WAT compared with NT rats. Non-stimulated or basal lipolysis was significantly lower in the epididymal depot and tended to be lower also in peri-renal WAT. Since the peri-renal depot is preferentially enlarged in LOB rats, differences in lipolysis cannot fully explain the growth of that WAT. Interestingly, corresponding results were obtained with young males before their obese phenotype is evident. This finding suggests that both peri-renal and epididymal WAT

depots in young non-obese LOB male rats are predisposed to a reduced lipolytic response. Recently, it was reported that isolated adipocytes derived from the subcutaneous depot of obese subjects were larger and showed unchanged catecholamine-induced lipolysis but markedly enhanced basal lipolysis [41]. Insulin resistant ob/ob mice and Zucker rats also display increased adipocyte size and increased basal lipolysis per cell [13, 42, 43]. Therefore, the lower basal lipolysis observed in LOB rats is in sharp contrast to the findings in obese humans and obese insulin resistant rodents [10] and again could contribute to a preserved insulin sensitivity [1].

**Fig. 7** Basal and  $\beta$ -adrenergic stimulated lipolysis in white adipose tissue (WAT). Peri-renal and epididymal WAT depots were freshly dissected and adipocytes acutely isolated by collagenase incubation. Incubation was then performed in absence (basal lipolysis) or presence of isoproterenol ( $10^{-5}$  M). Glycerol release from isolated adipocytes was used as an index of lipolysis. Basal and  $\beta$ -adrenergic stimulated lipolysis in peri-renal WAT (a) and epididymal WAT (b) from 12-month-old LOB and NT rats were investigated. Results are presented as means  $\pm$  SEM. Peri-renal lipolysis was investigated in five LOB and three NT rats, while epididymal WAT lipolysis was investigated in five NT and five LOB rats. Comparisons between groups were made by one-way analysis of variance (ANOVA), followed by Bonferroni test between individual groups.  $*P < 0.05$  basal lipolysis LOB versus NT rats,  $\#P < 0.05$   $\beta$ -adrenergic stimulated lipolysis LOB versus NT rats

Another important factor for insulin sensitivity is the adipocyte-derived hormone adiponectin [5]. Obese humans and obese insulin resistant rodent models show decreased adipose expression of adiponectin mRNA and plasma adiponectin levels [30, 44, 45]. In contrast, LOB rats have elevated plasma adiponectin levels [10]. We report here that adiponectin mRNA expression is unchanged suggesting the increased plasma levels of adiponectin in LOB rats is primarily due to expanded visceral WAT mass. Recently, ob/ob mice over-expressing adiponectin were shown to become even more obese but with improved insulin

sensitivity [46]. Similar to LOB rats, the adiponectin transgenic ob/ob mice showed smaller adipocytes and increased DGAT1 expression and LPL activity in WAT [46]. Thus, the LOB rat resembles this adiponectin transgenic ob/ob mouse.

In summary, LOB male rats show increased hepatic TAG production, a shift in LPL activity from skeletal muscle to WAT, reduced TAG lipolysis in WAT depots and a specific increase in genes responsible for fatty acid and TAG synthesis in the peri-renal depot.

Several findings in the old obese LOB rat were also observed in the young lean animals, including reduced lipolysis and altered expression of genes involved in lipogenesis and TAG synthesis, indicating that the obesity per se was not the cause of these hepatic and adipose tissue-specific changes in lipid metabolism in the LOB rat.

In view of the most surprising feature of the LOB phenotype, that obese LOB male rats exhibit enhanced insulin sensitivity [10], it seems likely that the quality of the adipose tissue is most important for the metabolic consequences of obesity. Thus, enhanced capacity of TAG production, decreased or unchanged basal lipolysis and preserved adiponectin expression of adipocytes would be part of a response that hinders fatty acids from ectopic storage and the subsequent development of insulin resistance.

**Abstract** Eicosapentaenoic acid (EPA) (1.8 g/day) was administered to 12 chronic hepatitis C patients receiving combination therapy of pegylated interferon (PEG-IFN)  $\alpha$ -2b and ribavirin for 48 weeks (EPA group). Twelve patients were not administered EPA (control group). All patients also received vitamin E and C (300, 600 mg/day, respectively) during the therapy. Serum alanine aminotransferase improved to a normal level in 8 of 12 patients from the EPA group and 6 of 12 patients from the control group after 12 weeks. Lymphocyte counts decreased significantly after 8 weeks in the control group, but not the EPA group. T-helper (Th) 1 decreased after 4 weeks in the control group, but not in the EPA group (two-way ANOVA;  $P < 0.05$ ). Th1/Th2 ratios were elevated in 9 of 12 patients

in the EPA group, and 3 out of 12 in the control group ( $P < 0.05$ ) after 8 weeks. After 12 weeks, the arachidonic acid/EPA molar ratio of erythrocyte membrane phospholipid correlated negatively with the leukocyte count ( $n = 24$ ,  $r = -0.439$ ,  $P < 0.05$ ) and the neutrophil count ( $n = 24$ ,  $r = -0.671$ ,  $P < 0.02$ ). The hemoglobin level improved after 48 weeks compared with 24 weeks in only the EPA group. These findings suggest that EPA supplementation may be useful in therapy for chronic hepatitis C.

## Introduction

Hepatitis C virus (HCV) infection is one of the main causes of chronic liver disease and the most common cause of hepatocellular carcinoma [1, 2]. Increased oxidative stress caused by mitochondrial injury [3], hepatocellular iron accumulation [4], and the direct effect of the HCV core protein [5], in addition to reactive oxygen species production related to the immune response [6], are reported in HCV-infected patients, and enhanced oxidative stress has been shown to be involved in the progression to hepatic fibrosis and hepatocellular carcinoma [7–10]. In a previous study, we observed decreased polyunsaturated fatty acids (PUFA) in phospholipids of mononuclear cells and plasma  $\alpha$ -tocopherol, and increased thiobarbituric acid reactive substances (TBARS) in HCV-infected patients, and suggested that these findings may accompany enhanced oxidative stress [11]. Improvement in fatty acid composition and the serum alanine aminotransferase (ALT) level was observed in HCV-infected patients who were

administered vitamin E [12], and a significant decrease in eicosapentaenoic acid (EPA) in phospholipids of mononuclear cells during combination therapy of interferon (IFN)  $\alpha$ -2b and ribavirin and a significant correlation between the arachidonic acid (ARA)/EPA molar ratio and the serum ALT level were seen in chronic hepatitis C patients [13].

A major therapeutic goal in HCV-infected patients is to achieve early eradication of the virus, and combination therapy using pegylated (PEG)-IFN  $\alpha$ -2b and ribavirin induces a higher sustained virological response than interferon monotherapy [14, 15]. However, hematological abnormalities, mainly hemolytic anemia resulting from the oxidative damage to membranes, are a known side effect of combination therapy [15, 16].

The deformability and vulnerability of erythrocyte membranes to oxidative stress is affected by the fatty acid composition of membrane phospholipids [17]. Dietary n-3 PUFA has been shown to influence signaling complexes and to suppress T-cell cytokines *in vivo* by altering T-cell raft composition [18]. EPA has a wide variety of physiological actions such as regulating the T-helper (Th) 1-type response associated with chronic inflammatory disease and antagonizing the production of inflammatory eicosanoids from ARA [19]. EPA supplementation in patients with chronic hepatitis C is reported to improve ribavirin-related anemia [20], and it was suggested that the increased EPA level in erythrocyte membranes may be associated with increased membrane fluidity and viscoelastic properties of erythrocyte membranes [21]. We also reported that EPA supplementation improved the serum ALT level and prevented a decrease in lymphocyte counts, which were significantly decreased from the baseline during the treatment in non-EPA supplemented patients receiving combination therapy of IFN  $\alpha$ -2b and ribavirin, and suggested the usefulness of EPA supplementation for the treatment of HCV-infected patients [22]. However, longer and more detailed research is required to confirm its efficacy.

The aim of the present study was to confirm the effectiveness of EPA supplementation combined with vitamin E and C for the prevention of hematological abnormalities and improve the immune cell response in chronic hepatitis C patients receiving PEG-IFN  $\alpha$ -2b and ribavirin combination therapy. Therefore, we administered EPA with vitamin E and C for 48 weeks, and examined the effects on hematological and immunological parameters.

## Experimental Procedures

### Subjects

Twenty-four chronic hepatitis C patients with genotype 1b and high viral load ( $\geq 10^5$  IU/ml) (13 males and 11

females) treated at Kagawa Prefectural Central Hospital were enrolled in the present study. Patients with detectable hepatitis B virus surface antigen, other potential causes of chronic liver disease, human immunodeficiency virus infection, poorly controlled diabetes mellitus, or cardiovascular disease were excluded.

### Study Design

We obtained written informed consent from all patients and randomized them into an EPA supplementation group (EPA group: seven males and five females,  $62.5 \pm 2.5$  year) and a no supplementation group (control group: six males and six females,  $56.7 \pm 2.4$  year). Patients in the EPA group received 1,800 mg/day of EPA ethyl ester (EPADEL S600, Mochida Pharmaceutical Co. Ltd., Tokyo, Japan). Six capsules (300 mg EPA ethyl ester/capsule) were administered per day orally after three meals (two capsules after each meal) for 48 weeks. All patients in both groups received 300 mg/day of vitamin E (Juvela, one tablet contains 50 mg of tocopherol acetate, Eisai, Tokyo, Japan) and 600 mg/day of vitamin C (Cinal, one packet contains 200 mg of ascorbic acid, SHIONOGI & CO., LTD., Osaka, Japan) orally, in addition to injections of PEG-IFN  $\alpha$ -2b (PegIntron, Schering-Plough K. K., Osaka, Japan) once a week for 48 weeks, and daily oral ribavirin (Revetol, Schering-Plough K. K., Osaka, Japan) for 48 weeks. At the baseline no significant differences were observed in the distribution of the histological diagnosis for grading inflammation or staging fibrosis. Patients graded as inflammation 1, 2, 3 and unknown included 7, 1, 2 and 2 in the EPA group and 7, 4, 1 and 0 in the control group, respectively, and the number of patients staged as 1, 2, 3, 4 and unknown included 2, 3, 3, 2 and 2 in the EPA group and 4, 5, 1, 2 and 0 in the control group. The patients were required to avoid iron or other antioxidant supplements during the treatment period.

Blood samples were obtained from each patient immediately before the initiation of therapy (0 week) and 4, 8, 12, 24 and 48 weeks after the start of therapy.

The experiment was designed in accordance with the principles of the Declaration of Helsinki of the World Medical Association and was approved by the Ethics Committee of Kagawa Prefectural Central Hospital.

### Analytical Methods

We determined routine clinical laboratory parameters, such as erythrocyte, leukocyte and platelet counts, hemoglobin level, and serum ALT and aspartate aminotransferase (AST) activities. Flow cytometry was used to characterize and distinguish CD<sup>4+</sup> T cells as Th1 or Th2, as defined by

their cytokine production (IFN- $\gamma$  and IL-4, respectively). To determine the rate of blastogenesis of lymphocytes by phytohemagglutinin (PHA), lymphocytes isolated from heparinized peripheral blood were used. After adding PHA (10  $\mu\text{g/ml}$ ), lymphocytes ( $1 \times 10^5$  counts) were incubated for 64 h at 37 °C under 5% CO<sub>2</sub>. Then, <sup>3</sup>H-thymidine was added and they were incubated for 8 more hours. After harvesting the cells, <sup>3</sup>H-thymidine incorporated into cells was determined using a liquid scintillation counter. The ratio of <sup>3</sup>H-thymidine incorporation into PHA-treated cells to the control without PHA was calculated [stimulation index (SI)].

Plasma was separated by centrifugation of blood samples containing EDTA-2Na at 1,600 $\times$ g for 15 min at 4 °C. The erythrocyte layer was drawn off into another tube and washed three times with saline (4 °C) to determine the fatty acid composition in erythrocyte membrane phospholipids. All samples were stored at –80 °C until assayed.

The  $\alpha$ -tocopherol concentration in plasma was determined according to a modification of the method of Milne et al. [23], as described previously.

Total lipids were extracted from erythrocyte membranes suspended in saline by the method of Bligh and Dyer [24]. Phospholipids were separated by one-dimensional thin-layer chromatography using a silica gel plate (Silica Gel 60; Merck, Darmstadt, Germany) and a solvent system of petroleum ether/ethyl ether/acetic acid (80:20:1, v/v). The spots corresponding to phospholipids were scraped from the plate and transmethylated for 2 h at 90 °C using acetylchloride:methanol (5:50, v/v). A known amount of heptadecanoic acid (17:0) was used as an internal standard. Fatty acid methyl esters were analyzed by gas-chromatography (Model GC-14A; Shimadzu, Kyoto, Japan) as described previously [12].

#### Statistical Analysis

Values are expressed as the means  $\pm$  standard errors (SE). Statistical analyses were done using SPSS v. 13.0 (SPSS Inc., Chicago, IL, USA). Two-way ANOVA was performed to assess the presence or absence of an EPA  $\times$  time interaction. Significance of difference during the treatment was examined using Friedman's test followed by Wilcoxon *t* test with Bonferroni correction post hoc analysis. Group differences were tested for significance using the Mann–Whitney *U* test. Differences between observed and expected frequency were tested using Fisher's test. Correlation coefficients were calculated using Spearman's rank-correlation analysis. All *P* values are two-tailed and values of *P* < 0.05 were taken as indicating significance.

## Results

### Completion of the Assigned Therapy

Four patients in the control group changed hospitals after 24 weeks and discontinued the treatment. Two patients in each group discontinued the treatment between 24 weeks and 37 weeks under the direction of a physician, because they had no virologic response. One patient in the EPA group changed therapeutic measures because of neuropsychiatric symptoms after 30 weeks under the advice of a doctor. Consequently, in this study, all patients were analyzed until 12 weeks for the early response, and the long-term observation results of 15 patients (6 patients in the control group and 9 patients in the EPA group) were analyzed until the end of therapy (48 weeks).

### Clinical Data up to 12 weeks

BMI and clinical data up to 12 weeks of therapy are shown in Table 1. No significant differences were observed in the dose of PEG-IFN  $\alpha$ -2b or ribavirin during treatment between the two groups. The serum ALT level decreased significantly in the EPA group (*P* < 0.01), but not in the control group. The blood cells were significantly decreased during the therapy in both groups (Friedman's test). However several differences were observed between the groups. In the control group, the lymphocyte count decreased significantly after 8 weeks, whereas no significant decrease was observed in the EPA group. The neutrophil count decreased significantly after 8 weeks of therapy in both groups; however, the counts in the EPA group were significantly higher than those in the control group at 8 weeks and 12 weeks. The platelet count in the EPA group was significantly decreased only at 4 weeks and was maintained the basal level thereafter, whereas a significant decrease was observed throughout the observation period in the control group. The hemoglobin level decreased significantly following 4 weeks of therapy in both groups. Serum albumin did not change throughout therapy in either group. The plasma  $\alpha$ -tocopherol level increased significantly at 4 weeks and was maintained at a high level throughout therapy in both groups.

### T Cell Subsets and Lymphocyte Blastogenesis up to 8 weeks

The Th1 in the control group decreased significantly (*P* < 0.05), but the Th1 in the EPA group was maintained at the basal level during the observation periods (two-way ANOVA; *P* < 0.05, Table 2). As a result, the Th1/Th2 balance improved in the EPA group compared with the

PHA phytohemagglutinin, SI stimulation index, % percentage of lymphocytes

\*\* *P* < 0.01, \* *P* < 0.05; compared with 0 week (Friedman's test followed by Wilcoxon's test with Bonferroni correction). \*\*\* *P* < 0.05 compared with control group (Mann–Whitney *U* test), control group; *n* = 12, EPA group; *n* = 12

control group, as shown in Fig. 1. The SI of the PHA-induced lymphocyte blast formation test in the EPA group was significantly higher compared with that of the control

group at 4 weeks of therapy, but the SI did not increase significantly during therapy in either group. HCV RNA disappeared in 3 of 12 (25.0%) in the EPA group and 5 of

**Fig. 1** Th1/Th2 ratio in the EPA group (filled circles), and the control group (open circles), before and after 8 weeks of treatment. A significant increase was observed in the EPA group compared with the control group (Fisher's test)

12 (41.7%) in the control group at 12 weeks ( $P > 0.50$ , Fisher's test).

#### Fatty Acid Composition of Erythrocyte Membrane Phospholipids up to 12 weeks

In the EPA group, EPA and docosapentaenoic acid (DPA) increased significantly ( $P < 0.01$ , respectively) after EPA supplementation and the EPA level was elevated to two times the basal level after 12 weeks, but in the control group, EPA did not change during therapy (Table 3). Conversely, the ARA/EPA ratio decreased markedly only in the EPA group (two-way ANOVA;  $P < 0.05$ ).

#### Correlation between Clinical Data and ARA/EPA Ratio in Phospholipids of the Erythrocyte Membrane after 12 weeks

Considering all individuals as a group, negative correlations between ARA/EPA ratio in erythrocyte membrane phospholipids and leukocyte count ( $n = 24$ ,  $r = -0.439$ ,  $P < 0.05$ ) and neutrophil count ( $n = 24$ ,  $r = -0.671$ ,  $P < 0.05$ ) were observed. Also, the ARA/EPA ratio in erythrocyte membrane phospholipids correlated negatively with lymphocyte count in the control group ( $n = 12$ ,  $r = -0.671$ ,  $P < 0.05$ ), but there was no such correlation in all patients.

#### Clinical Data at the End of Therapy

Nine subjects in the EPA group (six males and three females,  $61.1 \pm 3.3$  year) and six subjects in the control group (four males and two females,  $58.7 \pm 2.8$  year) were able to continue the treatment for 48 weeks. Erythrocyte count, hemoglobin level and platelet count for 48 weeks are shown in Fig. 2. Erythrocyte count, hemoglobin level and platelet count decreased significantly up to 24 weeks in both groups. In the EPA group, the erythrocyte count tended to improve at 48 weeks of therapy compared with 24 weeks (Fig. 2a). Hemoglobin level and platelet count in the EPA group increased significantly at 48 weeks compared with 24 weeks, but no significant improvement was observed in the control group (Fig. 2b, c). Accordingly, significant increases in hemoglobin level and platelet count were observed in the EPA group compared with the control group at 48 weeks (hemoglobin level;  $P < 0.05$ , platelet count;  $P < 0.05$ , Fisher's test). Mean levels of leukocyte count, neutrophil count and lymphocyte count decreased in both groups up to 48 weeks. However, leukocyte and lymphocyte counts increased in five of nine patients in the EPA group and one of six patients in the control group, respectively, although the difference was not significant ( $P > 0.10$ , Fisher's test). Serum ALT level improved in four of six subjects in the control group and seven of nine subjects in the EPA group by the end of therapy ( $P = 1.0$  Fisher's test). At the end of therapy, HCV RNA had disappeared in five of six (83.3%) subjects in the control group and six of nine (66.7%) subjects in the EPA group ( $P > 0.5$ , Fisher's test).

#### Discussion

In the present study, we evaluated the effects of EPA supplementation combined with vitamin E and C in chronic hepatitis C patients receiving PEG-IFN  $\alpha$ -2b and ribavirin combination therapy for 48 weeks. As shown in Table 3, EPA in erythrocyte membrane phospholipids increased significantly in the patients who received daily oral EPA ethyl ester capsules. Plasma  $\alpha$ -tocopherol levels also increased in all patients at 4 weeks after the beginning of therapy. These results reflected good compliance with orally administered EPA and vitamin E.

In IFN  $\alpha$ -2b and ribavirin combination therapy, hematologic abnormalities have been observed as a common side effect [25, 26]. Although the mechanism remains uncertain, it may be due to both hemolytic anemia caused by ribavirin [27] and bone marrow suppression caused by IFN [28, 29]. Ribavirin-induced hemolytic anemia is thought to be caused by accumulation of ribavirin in

erythrocytes and oxidative stress in the erythrocyte membrane [30]. In the present study, erythrocyte counts and hemoglobin levels markedly decreased in both groups after 4 weeks of the therapy. However, over long-term (48 weeks) observation, the erythrocyte count tended to increase and the hemoglobin level improved significantly in the EPA group. Although the exact mechanism of these effects was unclear, it is thought that the increased level of EPA may be associated with the increased membrane fluidity and viscoelastic properties of erythrocyte membranes [31, 32], allowing erythrocytes to avoid erythrophagocytic extravascular destruction during IFN and ribavirin combination therapy, as suggested by Ide et al. [20]. The long-term outcome is not yet known, but it is thought that EPA administration over the long-term may improve stability and prevent destruction of erythrocytes.

Poynard et al. [33] reported decreases in leukocyte and lymphocyte counts during IFN therapy either in combination with ribavirin or as monotherapy. In the present study, the lymphocyte count in the EPA group did not decrease compared with the basal level, but the leukocyte count decreased significantly in both groups after 4 weeks of therapy. These results are similar to those in our previous study [22], in which EPA supplementation for 24 weeks in chronic hepatitis C patients receiving combination therapy of IFN  $\alpha$ -2b and ribavirin prevented decreases in leukocyte and lymphocyte counts. It was reported that the side effects caused by PEG-IFN  $\alpha$ -2b/ribavirin combination therapy were more serious compared with those caused by IFN  $\alpha$ -2b because PEG-IFN  $\alpha$ -2b is a conjugated protein and its

metabolism and excretion are prolonged [15, 25, 26]. This may explain some of the differences between the observations in these past studies and the present study. The neutrophil count was higher in the EPA group compared with the control group at 8 and 12 weeks. The neutrophil count was reported to decline rapidly within the first 2 weeks of therapy [28]. A decrease in the neutrophil count is one of the main causes of therapy discontinuation. The phagocytosis of neutrophils is thought to play a role in virus eradication. Therefore, the prevention of a decrease in neutrophil count by EPA supplementation can be expected to contribute to HCV elimination, but this was unclear in the present study. In addition, the leukocyte count and neutrophil count in all subjects, and lymphocyte count in the control group, correlated negatively with the ARA/EPA ratio in erythrocyte membrane phospholipids. The significantly lower ARA/EPA level observed in the erythrocyte membrane suggests the same effect of EPA supplementation in other cell membranes. EPA supplementation induced significant increases in EPA and DPA, but not docosahexaenoic acid (DHA). Cell membrane phospholipids are characterized by having high PUFAs, such as ARA, EPA and DHA. Changing the fatty acid composition of immune cells affects phagocytosis, T-cell signaling and antigen presentation capability [34], and lipid composition in rafts, especially n-3 PUFAs, modulates immunological cell functions [18].

A high level of T-helper 2 cytokines is observed in chronic hepatitis C patients [30]. Combination therapy aims to increase type 1 cytokine expression in order to

**Fig. 2 a** Erythrocyte count in the patients observed over 48 weeks. switch the T-cell phenotype from type 2 to type 1, as well as to inhibit the early phase of viral infection [30]. Type 1 cytokines, IL-2, IFN- $\gamma$  and tumor necrosis factor (TNF)- $\alpha$  induce activation of cytotoxic lymphocytes and recruitment of natural killer cells and macrophages, which induce destruction of HCV-infected cells. It was reported that EPA supplementation had no effect on the proportions of T lymphocytes, T-helper cells, cytotoxic T cells, natural killer cells, or B lymphocytes in healthy subjects [35–37]. In the present study, however, the Th1/Th2 balance was elevated in 75% of subjects in the EPA group at 4 weeks, during the early stage of treatment, and it was higher than in the control group, in which it was elevated in 25% of subjects. Therefore, it is suggested

that EPA administration may have beneficial immunomodulatory effects, although no virological effects were observed.

In conclusion, EPA supplementation with vitamins E and C prevented a decrease in the lymphocyte count and elevated the Th1/Th2 balance in the early stage of therapy, and in the long-term, it induced an improvement in the erythrocyte count and hemoglobin level in chronic hepatitis C patients during combination therapy with PEG-IFN  $\alpha$ -2b and ribavirin. These observations suggested that EPA supplementation with antioxidative vitamins may be useful when administered with combination therapy for HCV-related chronic hepatitis. More long-term prognosis research should be performed to confirm this treatment.

# Conjugated Linoleic Acids and CLA-Containing Phospholipids Inhibit NO Formation in Aortic Endothelial Cells

Kimberly J. Jenko · Jack Y. Vanderhoek

Received: 11 December 2007 / Accepted: 12 February 2008 / Published online: 12 March 2008  
© AOCS 2008

**Abstract** This study examined the effects of five CLA isomers and the non-conjugated LA on nitric oxide (NO) production, an important modulator of vasodilation, inflammation, and cytotoxicity. Bovine aortic endothelial cells (BAECs) were pretreated with pure CLAs (c9, c11-, c9, t11-, t9, t11-, t10, c12-, c11, c13-CLA) and the non-conjugated c9, c12-analog, then stimulated by the ionophore A23187 followed by fluorescence monitoring of NO production. CLAs (5  $\mu$ M) decreased NO formation in the range of 20–40% relative to non-fatty acid-treated controls with the t9, t11- and t10, c12-CLAs being the most effective. The inhibitory effect of either of these CLAs was not time dependent over a 120 min time interval. Phosphatidylcholine (PC) and phosphatidylethanolamine (PE) play crucial roles in membrane structure and cell signaling. Since CLAs are usually esterified in these phospholipids (PLs), the effects of three CLA-containing PLs and 2-linoleoyl-PC on NO production by A23187-stimulated BAECs were also examined. c9, t11-CLA-PC and 2-linoleoyl-PC dose-dependently inhibited NO production over a 60–1,000  $\mu$ M concentration range whereas c9, c11-CLA-PC and c9, t11-CLA-PE were ineffective. Both c9, t11-CLA-PC and linoleoyl-PC exhibited a time-dependent decrease in NO production from 5 to 120 min. The results of the present study suggest that the influence of several C18 polyunsaturated fatty acids incorporated into cellular phospholipids on the A23187-induced formation of NO by BAECs is strongly dependent on the positional and geometric nature of the double bonds.

**Keywords** CLA isomers · NO · Endothelial cells · Phospholipids · Linoleic acid

## Abbreviations

BAEC	Bovine aortic endothelial cells
CLA	Conjugated linoleic acid
DAN	2, 3-Diaminonaphthalene
ECGS	Endothelial cell growth supplement
FBS	Fetal bovine serum
FU	Fluorescence units
L-Gln	L-Glutamine
HBSS	Hank's balanced salt solution
NO	Nitric oxide
NOS	Nitric oxide synthase
c9, c11-CLA-PC	1-Stearoyl-2-(c9, c11-octadecadienoyl)-sn-glycerol-3-phosphocholine
linoleoyl-PC	1-Stearoyl-2-linoleoyl-sn-glycerol-3-phosphocholine
c9, t11-CLA-PC	1-Stearoyl-2-(c9, t11-octadecadienoyl)-sn-glycerol-3-phosphocholine
c9, t11-CLA-PE	1-Stearoyl-2-(c9, t11-octadecadienoyl)-sn-glycerol-3-phosphoethanolamine
PL	Phospholipid

## Introduction

Nitric oxide has emerged as an important signaling molecule that is involved in the regulation of a number of physiological and pathophysiological situations. For example, NO is a major mediator of endothelial function

K. J. Jenko · J. Y. Vanderhoek (✉)

and depending on the cell type and concentrations, it has been shown to have both vasoconstrictor and vasodilator effects [1]. In certain inflammatory and neurodegenerative diseases, NO appears to have both cytoprotective and cytotoxic effects [2, 3]. Nitric oxide can be produced by either the constitutive (c) or inducible (i) isoforms of NOS. A number of posttranslational control mechanisms, including acylation, phosphorylation and translocation, regulate the cNOS, including the NOS present in endothelial cells (eNOS) [4]. Among its many effects, calcium also plays an important role in stimulating eNOS but not iNOS [5]. Several reports have shown that the ionophore A23187, commonly used to increase intracellular calcium concentrations, stimulated NO production by eNOS in endothelial cells and macrophages [4–8] but was ineffective in increasing NO formation cells containing iNOS [9, 10].

Conjugated linoleic acid is a family of conjugated di-unsaturated fatty acids consisting of a number of positional and *cis/trans* isomers of linoleic acid. These CLAs were found to be present in foods such as beef and dairy products obtained from ruminant animals. Although we, as well as others, have shown that CLA is incorporated into the phospholipid fraction of cellular membranes [11, 12], it appears that nearly all studies examining the biological effects of CLA have used the free fatty acid form of this lipid.

Several studies have reported varying effects of CLA isomers on NO formation. Coen et al. [13] determined that treatment of bradykinin-stimulated BAECs with a mixture of CLA isomers increased nitrite (a product of NO) production up to 50% relative to bradykinin-treated cells. On the other hand, Eder and coworkers [14] reported that incubation of HAECs with either c9, t11- or t10, c12-CLA decreased NO production relative to untreated cells. Treatment of interferon  $\gamma$ -stimulated mouse macrophages, lipopolysaccharide-enhanced murine macrophages and lipopolysaccharide/interferon  $\gamma$ -stimulated mouse mesangial cells with a CLA isomeric mixture all resulted in decreased NO formation relative to control cells [15, 16].

As none of these studies addressed the effects of all, currently commercially available, individual CLA isomers on NO production, we decided to determine how these isomers affected NO formation by BAECs stimulated by the ionophore A23187. Since Ohashi et al. [17] reported that several phospholipids stimulated NO production in BAECs, we hypothesized that CLA-containing PLs could directly affect NO formation. Consequently, we also examined whether (and if so, how) certain CLA containing PLs influenced NO release from both non-stimulated and A23187-stimulated BAECs.

## Materials and Methods

The c9, c11-, c9, t11-, t9, t11-, t10, c12-, and c11, t13-CLA isomers were purchased from Matreya Inc. (Pleasant Gap, PA, USA). 1-stearoyl-2-(c9, t11-octadecadienoyl)-*sn*-glycerol-3-phosphocholine (18:0–18:2 (c9, t11) PC), 1-stearoyl-2-(c9, c11-octadecadienoyl)-*sn*-glycerol-3-phosphocholine (18:0–18:2 (c9, c11) PC), 1-stearoyl-2-(c9, t11-octadecadienoyl)-*sn*-glycerol-3-phosphoethanolamine (18:0–18:2 (c9, t11) PE), and 1-stearoyl-2-linoleoyl-*sn*-glycerol-3-phosphocholine (18:0–18:2 PC) were synthesized by Avanti Polar Lipids, Inc. (Alabaster, AL, USA). BAECs were obtained from the Coriell Institute for Medical Research (Camden, NJ, USA), and the DMEM/F12 50/50 mix, penicillin–streptomycin, HBSS (without phenol red), trypsin-EDTA, and FBS solution were purchased from Mediatech, Inc. Heparin, ECGS from bovine pituitary, HEPES, EDTA, fatty acid-free BSA, NAD, L(+) lactic acid, sodium nitrite, 2,3-diaminonaphthalene, A23187 and L-glutamine were purchased from Sigma-Aldrich, Corp. (St Louis, MO, USA).

### Cell Culture of BAECs

BAECs were grown in Corning T-150 flasks with 20 ml DMEM/F12 medium supplemented with 15% FBS, ECGS (0.02 mg/ml), heparin (0.05 mg/ml), penicillin–streptomycin (1,000 I.U., 1,000  $\mu$ g/ml), and incubated at 37 °C in 5% CO<sub>2</sub> for 3–4 days as previously described [18]. After reaching approximately 90% confluence, the cells were subcultured by removing the growth media, washed twice with 5 ml EDTA solution [1 $\times$  HBSS supplemented with HEPES (12 mg/ml) and EDTA (4 mg/ml), pH 7.4], and detached from the flask with 2 ml 1 $\times$  trypsin-EDTA solution for 1 min. After addition of 6 ml growth media to the flask, an aliquot of cells was counted in a hemocytometer. To each Corning T-25 flask containing 3 ml of growth media, 130,000 cells were added. Only BAECs from passage numbers 8–10 were used.

### Preparation of CLA-BSA Solutions and Phospholipid Solutions

CLA-BSA complexes were prepared by mixing the appropriate amounts of CLA and 2% BSA-DMEM/F12 solution as previously described [18] and added to the cells for 18 h. Phospholipid solutions were prepared by first evaporating the chloroform under nitrogen from the appropriate amount of PL solution followed by the addition of 2% complete media in DMEM/F12. The solution was sonicated using a sonifier cell disruptor (Heat Systems-ultrasonics, Inc. Plainview, NY, USA) twice at 0 °C for 10 s at a setting of 30 and further diluted with 2% complete

media. Four milliliters of the phospholipids mixtures (60, 250  $\mu$ M, 1 mM final concentration) were added to the flasks containing 130,000 cells/flask for 18 h at 37  $^{\circ}$ C.

### NO Assay

The nitric oxide protocol was modified from procedures reported by Rathel et al. [19] and Misko et al. [20]. After 18 h, control cells or cells pretreated with CLA-BSA or PL solutions were rinsed twice with 2.5 ml HBSS. Four milliliters HBSS (without phenol red) pH 7.4, were added followed by addition of 2  $\mu$ M DAN (final concentration) and 2  $\mu$ M A23187 (final concentration). After incubating at 37  $^{\circ}$ C for 5 or 20 min with the DAN reagent, triplicate samples of 200  $\mu$ l each of the cell media were removed by pipette and transferred directly into a 96 well plate and the reaction was terminated with the addition of 5  $\mu$ l of 2.8 N NaOH. Fluorescence measurements were immediately taken using a Synergy<sup>TM</sup> HT multi-detection microplate reader (BioTek Instruments, Inc. Winooski, VT, USA) with excitation at 360 nm and emission read at 460 nm.

To confirm that the formation of NO could be inhibited (using this protocol), cells were treated with either 0.5 or 5 mM L-glutamine/HBSS (final concentration) for 30 min followed by the addition of 2  $\mu$ M each of A23187 and DAN. After an additional 5 and 20 min, triplicate samples were removed and measured for fluorescence with the microplate reader.

All data expressed in fluorescent units (FUs) were generated by subtracting fluorescence values measured in unstimulated cells from fluorescence values generated from A23187-stimulated cells treated with or without various agents.

### LDH Activity Assay and Statistical Analysis

Cell viability was assessed by determining lactate dehydrogenase release into the medium as previously described [18]. Viability measurements of BAECs treated with either CLA isomers (or CLA-containing PLs) and A23187 were not significantly different from either resting cells or cells stimulated with A23187 alone (results not shown). Data were analyzed by Student's *t* test and one-way ANOVA.

## Results

In order to determine the effect of CLA isomers and CLA-containing PL on NO production in resting cells, BAECs were treated with t10, c12-CLA (concentration range 0.3–100  $\mu$ M) but failed to produce any significant change in NO production compared to cells not treated with CLA. Similar results were obtained with c9, c11-, c9, t11-, t9,

t11-, and c11, t13-CLA (not shown). Likewise, NO production was not significantly affected when resting BAECs treated with 60–1,000  $\mu$ M c9, c11-CLA-PC were compared to untreated control cells. In view of these results, it was decided to examine the effects of CLAs and CLA-PLs on stimulated BAECs.

Treatment of cells with ionophore A23187 stimulated NO formation in a dose-dependent manner as shown in Fig. 1. Although 0.1  $\mu$ M A23187 had no effect, 0.5, 1 and 2  $\mu$ M increased NO production from  $1,456 \pm 412$  FU to  $9,940 \pm 324$  FU ( $n = 4$ ) relative to non-stimulated cells (after 5 min, non-stimulated cells generated  $9,222 \pm 1,083$  FU,  $n = 5$ ). Cells incubated with A23187 for 5 or 20 min produced similar quantities of NO but a 17% decrease was observed over a 120 min incubation period (Fig. 1 insert). To confirm that NO production in this system could be inhibited by a known NO inhibitor, the effect of glutamine was tested [21]. Pre-incubation of BAECs with 5 mM glutamine for 30 min followed by treatment with 1  $\mu$ M A23187 for 5 or 20 min decreased NO formation by  $33 \pm 16$  and  $46 \pm 22\%$ , respectively ( $P < 0.05$ ,  $n = 4$ , Fig. 2).

The effects of various CLA isomers on NO production by A23187-stimulated BAECs are shown in Fig. 3. Cells were first incubated for 18 h with either 2% BSA or 2% BSA complexed with 5  $\mu$ M pure CLA isomer. After washing the cells to remove the BSA or CLA-BSA, the cells were treated with 2  $\mu$ M A23187 and 2  $\mu$ M DAN for

**Fig. 1** The effect of A23187 on NO production in BAECs. BAECs (130,000 per flask) were treated for 18 h with 4 ml of 2% complete medium. Next, the cells were rinsed with HBSS and incubated at 37  $^{\circ}$ C with different concentrations of A23187 followed by 2  $\mu$ M DAN (final concentration). Samples were collected after either 5 (*ldiamonds*) or 20 (*filled squares*) min and measured for fluorescence. The results are expressed as fluorescence units. The values are mean  $\pm$  SD from four experiments. *Insert*: with incubation times greater than 5 min, the DAN was added 10 min prior to the collection of samples and then analyzed for fluorescence

**Fig. 2** The effect of L-glutamine on NO formation by A23187-stimulated BAECs. BAECs (130,000 per flask) were placed in T-25 flasks containing 3 ml growth media/flask and grown for 24 h. The cells were rinsed and treated for 18 h with 4 ml of 2% complete media. After washing with HBSS, the cells were incubated at 37 °C for 30 min with 4 ml 5 mM L-Gln/HBSS (final concentration). Next, 1  $\mu$ M A23187 and 2  $\mu$ M DAN (final concentrations) were added and after either 5 or 20 min, samples were collected and assayed for fluorescence. The results of single samples from four experiments are expressed as fluorescence units. The numbers above the columns indicate % control values. The values are mean  $\pm$  SD. \*\*  $P < 0.05$  when compared to A23187 control

**Fig. 3** The effect of 5  $\mu$ M CLA isomers and linoleic acid on NO production by A23187-stimulated BAECs. BAECs (130,000 per flask) were treated for 18 h at 37 °C with either 4 ml of 2% BSA or 4 ml 2% BSA complexed with 5  $\mu$ M (final concentration) of c9, t11-, c9, c11-, t10, c12-, t9, t11-, 11, 13-CLA, and linoleic acid. After washing the cells, 2  $\mu$ M A23187 (final concentration) and 2  $\mu$ M DAN were added and samples were collected after 5 min and analyzed for fluorescence. Values are expressed as % control compared to BSA/A23187 (100%) and are generated from four experiments. The numbers above each column indicate % control values. The values are mean  $\pm$  SD. \*  $P \leq 0.01$ , \*\*  $P \leq 0.05$  when compared to A23187 control

5 min followed by fluorescence measurements to determine NO formation. Treatment of BAECs with t9, t11-CLA resulted in a decrease of  $42 \pm 7.1\%$  ( $P \leq 0.01$ ,  $n = 4$ ) in NO formation which was somewhat greater than that observed with t10, c12-CLA ( $33 \pm 11$ ,  $P \leq 0.01$ ,  $n = 4$ ). The c9, c11-, c9, t11-, and the c11, t13-CLA isomers were somewhat less effective ( $29 \pm 12$ ,  $27 \pm 13$  and  $20 \pm 13\%$ , respectively,  $P \leq 0.05$ ,  $n = 4$ ). Linoleic acid, the corresponding non-conjugated c9, c12-isomer, decreased NO production by  $17 \pm 16\%$  ( $n = 4$ ). Similar results were observed with 60 and 120  $\mu$ M CLA concentrations (results not shown).

We next examined whether CLA-containing PLs could influence NO formation in A23187-stimulated BAECs. The structures of these PLs as well as the non-conjugated linoleoyl-PC are shown in Fig. 4. BAECs were treated for 18 h with either 2% complete medium or 2% medium containing 60, 250 or 1,000  $\mu$ M PLs. After rinsing, the cells were treated with 2  $\mu$ M A23187 and 2  $\mu$ M DAN for 20 min followed by NO determinations. As shown in Fig. 5 (top), 1,000  $\mu$ M c9, t11-CLA-PC decreased NO formation  $31 \pm 5.3\%$  ( $P \leq 0.01$ ,  $n = 5$ ) with smaller decreases observed at 60 and 250  $\mu$ M. Changing the head group to PE (c9, t11-CLA-PE) did not result in any inhibitory potency which was also observed with c9, c11-CLA-PC (Fig. 5 bottom). On the other hand, 1,000  $\mu$ M of the non-conjugated linoleoyl-PC analog resulted in a  $37 \pm 13\%$  ( $P \leq 0.01$ ,  $n = 9$ ) inhibition of NO formation (Fig. 5 bottom).

To determine whether the inhibitory effects of certain CLA-pretreated BAECs on NO production were dependent on the incubation time of these cells with A23187, time

**Fig. 4** Structures of phospholipids. Structures of c9, c11-CLA-PC, c9, t11-CLA-PC, c9, t11-CLA-PE, and 2-linoleoyl-PC

**Fig. 5** The effect of conjugated and non-conjugated octadienoic acid-containing PLs on NO production in A23187-stimulated BAECs. The protocol is the same as described in the legend of Fig. 3 except BAECs were treated at 37 °C with either 4 ml 2% complete media or 4 ml 2% complete media containing 60, 250, or 1,000 μM c9, t11-CLA-PC, linoleoyl-PC (Fig. 5 top) and c9, c11-CLA-PC, c9, t11-CLA-PE (Fig. 5 bottom). Samples were collected 20 min after A23187 addition and analyzed for fluorescence. Values are expressed as % control compared to 2% complete media/A23187 (100%) and are generated from four experiments. The numbers above each column indicate % control values. The values are means  $\pm$  SD. \*  $P \leq 0.01$ , \*\*  $P \leq 0.05$  when compared to the A23187 control (=100%)

course experiments were carried out. BAECs were first pretreated with 5 μM t9, t11-CLA for 18 h, then exposed to A23187 for 5 min which resulted in a  $42 \pm 7\%$  ( $n = 4$ ) reduction in NO formation relative to A23187-stimulated cells (Fig. 6, top). Increasing the incubation time after A23187 stimulation to 120 min, adding the DAN 10 min prior to collection of samples, and taking fluorescence readings did not result in a statistically significant change in decreased NO production ( $28 \pm 14\%$ ,  $n = 6$ ). Similar results were obtained with t10, c12-CLA (results not shown). Using the same approach with BAECs pretreated with 1,000 μM c9, t11-CLA-PC followed by a 5 min incubation with A23187 resulted in a  $20 \pm 15\%$  ( $n = 5$ ) decrease in NO formation whereas 120 min after stimulation with A23187 produced a  $45 \pm 11\%$  ( $n = 6$ ) reduction in NO generation (Fig. 6, bottom). This figure also showed that the c9, c11-CLA-PC isomer was about half as effective

120 min after A23187 stimulation since NO production had decreased by  $24 \pm 12\%$  ( $n = 5$ ) compared to control values. Finally, the non-conjugated linoleoyl-PC analog exhibited the largest time dependent effect. Pretreatment of BAECs with 1,000 μM linoleoyl-PC followed by stimulation with A23187 decreased NO formation  $21 \pm 13\%$  ( $n = 5$ ) after 5 min and by  $76 \pm 15\%$  ( $n = 6$ ) after 120 min compared to control cells after these incubation periods (Fig. 6, top).

## Discussion

Coen et al. [13] showed that bradykinin stimulation of BAECs pretreated with a CLA isomeric mix, consisting primarily of the c9, t11- and t10-c12-isomers, potentiated

**Fig. 6** The effect of incubation time on NO production by A23187-stimulated BAECs. BAECs (130,000 per flask) were treated for 18 h at 37 °C with either 5 μM (final concentrations) of t9, t11-CLA complexed with 2% BSA in DMEM/F12 as described in the legend of Fig. 3, or with 1,000 μM 2-linoleoyl-PC, c9, t11-CLA-PC, or c9, c11-CLA-PC in 2% complete media as indicated in the legend of Fig. 5. After washing the cells, 2 μM A23187 (final concentration) was added at time 0 followed by addition of 2 μM DAN (final concentration) either right after A23187 for the 5 min (light shaded bar) time point or at 10 min prior to collection of samples at 20 (checkered bar) and 120 (dark shaded bar) min and analyzed for fluorescence. Values are expressed as % control compared to A23187 stimulation after these incubation times, and are the average of triplicate samples from two or three experiments. The values are mean  $\pm$  SD. \*  $P \leq 0.01$ , \*\*  $P \leq 0.05$  when compared to A23187 control (=100%)

NO formation up to 40%. Others reported that these two CLA isomers or a mixture of CLA isomers decreased NO production by various cells stimulated by lipopolysaccharide and/or interferon- $\gamma$  [14–16, 22]. In contrast to other investigators, we used A23187 as the cellular stimulus in this study of the effects of pure CLA isomers on NO generation by BAECs. We observed that pretreatment of BAECs with 5  $\mu$ M of either t9, t11-, t10, c12-, c9, c11-, c9, t11- or c11, t13-CLA followed by A23187 stimulation for 5 min decreased NO production in the range of 20–42% compared to untreated cells stimulated with A23187. The non-conjugated linoleic acid was the least effective of the unsaturated fatty acids tested. As a number of reports have determined that the CLA concentration in human serum was between 7 and 70  $\mu$ M [23, 24], our finding that 5  $\mu$ M CLA is an effective concentration suggests that this is within the physiological concentration range of this fatty acid. Interestingly, neither we nor the other groups (using different cells, stimuli, experimental conditions and higher concentrations of CLA) found more than 40% inhibition of NO formation [13–15, 22]. These results suggest that there is little structural selectivity of the octadecadienoic acids for the NOS since the location and *cis/trans* isomerism of the double bonds do not appear to be major determinants for decreasing NO formation. This contrasts with our findings of much greater selectivity of CLA isomers for inhibiting the cyclooxygenase–prostanoid complex in platelets and endothelial cells [12, 25]. Furthermore, we as well as others [14] have observed that higher concentrations (up to 120  $\mu$ M) of different CLA isomers did not produce stronger inhibitory effects on NO production. A possible explanation for this apparent non-concentration effect is that pretreatment of BAECs with various CLA isomers could generate an intermediate metabolite whose formation is already at maximal capacity at 5  $\mu$ M CLA and whose inhibitory effect is maximized at about 40%. Although no significant differences in NO production between most of the CLA isomers was observed, there was a statistically significant difference ( $P \leq 0.05$ ) between cells pretreated with t9, t11-CLA and c11, t13-CLA. Possible explanations for the different results obtained by Coen et al. [13] using bradykinin and our results with A23187 include the use of different experimental conditions (e.g. incubation times with stimulus, CLA composition and concentrations used) and that receptor-mediated events involve different pathways and mechanisms than ionophore-modulated reactions.

It has been well established that pretreatment of cells with unsaturated fatty acids leads to their incorporation into the cellular lipids, especially the PL fraction. We and others have shown that supplementation of the growth media with CLA isomers resulted into their esterification into membrane PLs [11, 12]. Since Ohashi et al. [17] had

reported that 1-palmitoyl-2-oleoyl-PC and its PE and PS analogs enhanced endothelial nitric oxide synthase, we examined whether treating BAECs with various CLA-containing PLs could affect NO production. Pretreatment of BAECs with 1,000  $\mu$ M, c9, t11-CLA-PC decreased A23187-activated NO formation by 31% after 20 min whereas both c9, t11-CLA-PE and c9, c11-CLA-PC were ineffective. However, the inhibitory effectiveness of linoleoyl-PC (37%) was comparable to that of c9, t11-CLA-PC. These results suggest that efficacy of PL on A23187-stimulated NO production are dependent both on the nature of the fatty acid esterified in the two position of the PL as well as the identity of the PL head group. It is interesting to note that while pretreatment of BAECs with c9, t11- and c9, c11-CLA resulted in comparable decreases in NO formation after A23187 stimulation, only the c9, t11-CLA-PC was effective when added in the PL form. One possible explanation is that when BAECs are pretreated with CLA isomers, they become incorporated into a variety of PLs, some (or all) of which may inhibit NO production. Hence it is feasible that the inhibitory PL of the c9, t11-CLA is the PC form whereas the inhibitory PL of the c9, c11-CLA isomer is not the PC analog but may be another PL class.

A number of mechanistic possibilities can be envisaged to explain the inhibitory effects of the CLA isomers on A23187-induced NO formation. In view of Li's reports that eicosapentaenoic acid and docosahexaenoic acids modified the lipid composition in caveolae of endothelial cells and modulated the cellular eNOS activity as well as a number of studies that have documented incorporation of CLA into cellular lipids [11, 12, 26, 27], it is possible that this CLA-induced modification of lipid milieu (or the addition of certain CLA-containing phospholipids) could have a negative effect on the eNOS activity in BAECs. Another possible mechanism could involve a cyclooxygenase metabolite. It is well known that A23187 stimulates cytosolic phospholipases to release arachidonic acid which can then be metabolized to cyclooxygenase products such as prostacyclin [28]. Furthermore, a number of studies have documented a relationship between NO production and prostanoid formation including a recent one by Niwano who reported that beraprost, a stable analog of prostacyclin, stimulated eNOS activity in BAECs [3, 29]. Since c9, t11- and t10, c12-CLA isomers were reported to inhibit macrophage phospholipase A<sub>2</sub> activity and we, as well as others, have shown that CLA isomers decreased the formation of cyclooxygenase products in endothelial cells, it is possible that CLA pretreatment of BAECs decreased production of endogenously generated prostacyclin (or other cyclooxygenase metabolites) which could explain the decrease in NO formation observed in our study [13, 14, 25, 30].

The 2-linoleoyl-PC, c9, t11-CLA-PC and the c9, c11-CLA-PC all exhibited a time-dependent inhibitory effect on A23187-stimulated NO formation by BAECs over a 2-h period, with the 2-linoleoyl-PC being the most effective (76% decrease), followed by c9, t11-CLA-PC (45% decrease) with the c9, c11-CLA-PC (24% decrease) and t9, t11-CLA (28% decrease) being the least potent. These results suggest that certain octadecadienoic acid-containing PLs may have both short and long term effects on the NO synthase system. Although the mechanism of this time-dependent effect is unknown, one can speculate that these PLs may be slowly converted to other, more effective, inhibitors of the NO synthase system.

In conclusion, the results of this report indicate that pretreatment of BAECs with five different CLA isomers decreased A23187-stimulated NO production between 20 and 40% relative to non-CLA treated controls. Furthermore, our study is the first to demonstrate that when testing certain CLA-containing PLs, e.g. the c9, t11-CLA-PC and the 2-linoleoyl-PC analog, on this system, NO production was inhibited (whereas two other CLA-containing PLs were ineffective) and that this inhibition was time dependent. These results support the hypothesis that CLA-containing PLs may directly influence specific enzymatic systems, e.g. nitric oxide synthases, in the cellular milieu.

**Abstract** Focal contacts (FC) are membrane-associated multi-protein complexes that mediate cell-extracellular matrix (ECM) adhesion. FC complexes are inserted in detergent-resistant membrane microdomains enriched in phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P<sub>2</sub>); however, the influence of membrane lipid composition in the preservation of FC structures has not been extensively addressed. In the present work, we studied the contribution of membrane lipids to the preservation of renal epithelial cell adhesion structures. We biochemically characterized the lipid composition of membrane-containing FC complexes. By using cholesterol and PtdIns(4,5)P<sub>2</sub> affecting agents, we demonstrated that such agents did not affect any particular type of lipid but induced the formation of new FC-containing domains of completely different lipid

composition. By using both biochemical approaches and fluorescence microscopy we demonstrated that phospholipid composition plays an essential role in the *in vivo* maintenance of FC structures involved in cell-ECM adhesion.

## Introduction

Tissue organization depends on structures that enable cells to attach to the extracellular matrix (ECM). Focal contacts (FC), the most stable points of cell tethering to the ECM, are multi-protein complexes that reach the outside of the cell from the cytoplasm through the cell membrane and contact the actin-cytoskeleton inside the cell with ECM proteins [1, 2]. FC assembly occurs by the binding of the integrin-extracellular domain to the ECM proteins followed by the interaction of the  $\beta$ -integrin cytoplasmic domain with talin, which, in turn, binds vinculin [3–5]. The acidic phospholipid, phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P<sub>2</sub>), acts as a regulator of both actin dynamics and FC turnover [6], and many cytoskeleton proteins involved in cell adhesion bind PtdIns(4,5)P<sub>2</sub> in order to be

either activated or inactivated [7]. It is accepted that both vinculin activation and integrin binding to talin are dependent on plasma membrane local availability of PtdIns(4,5)P<sub>2</sub> [8].

Both talin and vinculin need to be inserted into the phospholipid bilayer to form FC plaques. Earlier *in vitro* studies have demonstrated that the insertion of either vinculin or talin into the lipid bilayer depends on the bilayer phospholipid composition [9]. On the other hand, it has been reported that many of the molecular components that regulate cell-ECM adhesion are associated with cholesterol-enriched detergent-resistant membrane microdomains (DRM), which are also enriched in PtdIns(4,5)P<sub>2</sub> [10]. It is considered that the specific interactions with phosphoinositides could serve to recruit cytoskeletal proteins to particular membrane domains, in which specific lipids are thought to be accumulated [10].

In spite of the relevance that membrane lipids appear to have for FC assembly, there are no previous reports on the membrane lipid composition where FC are located *in vivo* or on how changes in local membrane composition contribute to FC maintenance.

In the present study, we first performed the biochemical characterization of the membrane domains where FC complexes are located in renal papillary collecting duct cells. Thereafter, by combining biochemical and immunofluorescence studies, we obtained experimental evidence showing how specific changes in the membrane lipid composition *in vivo* are a sufficient condition to affect the maintenance of FC, thus demonstrating that membrane lipid composition plays a central role in the maintenance of cell-ECM adhesion.

## Materials and Methods

Silicagel plates for thin layer chromatography (TLC) were from Merck. X-ray film was obtained from the Eastman Kodak Co. Neomycin, LiCl, methyl- $\beta$ -cyclodextrin, Collagenase Type II, Fast 3,3'-diaminobenzidine tablets and monoclonal antibodies against vinculin and talin and phalloidin-FITC were from the Sigma Chemical Co (St. Louis, MO, USA). Biotinylated anti PtdIns(4,5)P<sub>2</sub> was from Echelon Biosciences Inc. (Lake City, UT), FITC-conjugated goat F(ab)<sub>2</sub> to mouse IgG was from Jackson ImmunoResearch Inc. (West Grove, PA) and ABC complex/HRP Kit was from Dako Lab (Glostrup, Denmark). Protein A/G PLUS Agarose was obtained from Santa Cruz Biotechnology Inc (Burlingame, CA). All culture reagents were from Gibco (Gibco, Invitrogen, USA). All other reagents and chemicals were of analytical grade (Sigma, Merck or Mallinckrodt) and purchased from local commercial suppliers.

## Animals and Tissue Preparation

Adult male Wistar rats were sacrificed by cervical dislocation and both kidneys removed. Renal papillae were isolated by scalpel and scissors dissection and sliced (0.5 mm thick) by using a Stadie-Riggs microtome. Papillary slices were collected in ice-cold 10 mM Tris-HCl, pH 7.4, containing 140 mM NaCl, 5 mM KCl, 2 mM MgSO<sub>4</sub>, 1 mM CaCl<sub>2</sub> and 5.5 mM glucose (TBS) and incubated at 37 °C in a metabolic shaking bath either in the absence or in the presence of membrane-affecting agents: 5 mM methyl- $\beta$ -cyclodextrin or 1 mM neomycin or 10 mM LiCl for 30, 10 or 120 min, respectively. Incubations were stopped on ice and immediately homogenized in 10 vol of a solution 0.25 M sucrose containing 25 mM Tris-HCl, pH 7.4, 3 mM MgCl<sub>2</sub>, 2 mM EGTA, 1 mM PMSF, 10  $\mu$ g/mL aprotinin and 1 mM Na<sub>3</sub>VO<sub>4</sub> and, successively centrifuged at 860 g for 10 min, 8,000 g for 20 min, and 105,000 g for 60 min; the resultant pellet corresponding to microsomal fraction was used for further studies.

## Detergent-Resistant Membrane Isolation

Triton X-100 insoluble membrane fractions were performed by the two-step centrifugation process described by Ito et al. [11]. Briefly, microsomes were resuspended in one vol of ice-cold PBS containing 1 mM PMSF, 10  $\mu$ g/mL aprotinin and 1 mM Na<sub>3</sub>VO<sub>4</sub>. Then, one volume of 0.2% (v/v) Triton X-100 in PBS was added, mixed and incubated at 4 °C for 20 min. Samples were layered on 30% (w/v) sucrose and centrifuged at 225,000g at 4 °C for 2.5 h. Pellets were discarded and supernatants diluted with 0.1% Triton X-100 in PBS up to 10% (w/v) sucrose and centrifuged at 225,000g at 4 °C for 2.5 h. The resultant pellet contained the Triton X-100 insoluble membrane fraction while supernatants were considered as the soluble membrane fraction (S fraction). Throughout this paper we termed DRM as the 0.1% Triton X-100 insoluble membranes that sediment in 10% sucrose after centrifuging for 2.5 h at 225,000 g. For the biochemical studies we used DRM isolated from microsomal fractions instead of the plasmatic membrane because in our experimental conditions no detergent resistant pellet was obtained from the isolated endoplasmatic reticulum. Thus, our microsomal DRM only represented resistant domains from the plasmatic membrane.

## Lipid Analysis

Total lipids were obtained in the lower chloroformic phase of the Bligh and Dyer extraction procedure [12]. From total

lipid extracts, individual phospholipids and phosphoinositides were separated and quantified as previously reported [13, 14], and the cholesterol content determined by the method based on the cholesterol-oxidase enzyme reaction [15]. Phospholipid biosynthesis was studied by incubating papillary slices in TBS containing 0.1  $\mu\text{Ci/mL}$  of [ $^{32}\text{P}$ ]-sodium orthophosphate ([ $^{32}\text{P}$ ]-Pi) at 37 °C in a metabolic shaking bath. After 60 min incubation, samples were homogenized, DRM and S fractions obtained, and phospholipids and polyphosphoinositides separated. Radioactive lipids were visualized by autoradiography and iodine vapors and quantified by liquid scintillation counting.

#### Fatty Acid Determination

Following phospholipid separation by TLC, spots were scraped off and stored under nitrogen atmosphere at  $-20$  °C. The lipids were *trans*-esterified with acetyl chloride in methanol at 100 °C for 1 h. After cooling,  $\text{K}_2\text{CO}_3$  was added, and the methyl esters were extracted with benzene. Thereafter, the extracts were evaporated under stream of nitrogen and stored at  $-20$  °C. Methyl esters were analyzed by gas chromatography using a Gas Chromatograph (Series GC-8A) equipped with a flame ionization detector and 30 m  $\times$  0.25 mm DR-23 capillary column. The temperature was programmed from 175 to 240 °C at a rate of 3 °C/min. Nitrogen was used as the carrier gas. The chromatographic peaks were identified by comparison of the retention time with those of standards and the percentage composition of each fatty acid was calculated from the proportionality of peak areas by an automatic integrator.

#### Phospholipid Determination

For the quantification of phospholipids, specific areas of the TLC plates were scraped off and digested with 70% perchloric acid in the presence of ammonium molybdate (0.5%), for 2 h in a heating block at 180 °C. The resulting inorganic phosphate was assayed with a Fiske–Subbarow reagent [16].

#### Immunoprecipitation and Western Blot Analysis

Aliquots containing 100  $\mu\text{g}$  of protein of DRM or S fractions were pre-cleared by incubation at 4 °C with protein A/G Plus-Agarose and, after centrifugation, supernatants were incubated at 4 °C for 1 h with 2  $\mu\text{g}$  of monoclonal antibody against PtdIn(4,5)P2 (plus 2.5  $\mu\text{g}$  of rabbit anti-mouse IgM) or monoclonal antibody against vinculin.

Thereafter, protein A/G Plus-Agarose was added and incubated overnight at 4 °C with gentle shaking. The immunoprecipitates were washed three times with HNTG buffer (20 mM Hepes pH 7.5, 150 mM NaCl, 0.1 % (v/v) Triton X-100 and 10 % w/v glycerol), resuspended in Laemmli buffer and boiled for 5 min prior to Western blot analysis. Proteins were resolved in 8 % SDS-PAGE, electrotransferred to PVDF membranes and detected with the antibody of interest. Primary interaction was evidenced by using ECL Kit (GE Healthcare Life Sciences). When necessary, membranes were stripped and reprobed with the antibody of interest and evidenced with the ABC/HRP complex and 3, 3'-diaminobenzidine. The intensity of each band was estimated by optical densitometry with a Gel-Pro Analyzer version 3.1 (Media Cybernetics, USA).

#### Cell Culture and Fluorescence Microscopy

Primary culture of papillary collecting duct cells was performed by means of Stokes et al.'s procedure [17]. Briefly, renal papillae were minced to 1–2 mm<sup>3</sup> pieces and incubated at 37 °C in sterile TBS containing 0.1% (w/v) collagenase under 95% O<sub>2</sub>/5% CO<sub>2</sub> for 40 min. From collagenase digestion, a “crude-pellet”, containing most papillary cell types and tubular elements, was obtained by centrifugation at 175 g for 10 min. The pellet was washed twice and resuspended in Dulbecco's modified Eagle's medium (DMEM) with F-12 (1:1), 10% (v/v) fetal bovine serum, 100 U/mL penicillin and 100  $\mu\text{g/mL}$  streptomycin, and an “enriched-papillary collecting duct pellet” was obtained by centrifuging at 60 g for 1 min. Pellets were resuspended in DMEM-F12 and aliquots placed on sterile dry-glass coverslips. After 96 h, the cells grown on coverslips were incubated at 37 °C in TBS containing 1 mM neomycin, 5 mM CD or 10 mM LiCl for 10, 30 min, or 24 h, respectively, and then the cover slips were transferred to cold PBS. For immunofluorescence labeling cells were washed with PBS and fixed with methanol (at  $-20$  °C for 10 min) and acetone (at  $-20$  °C for 4 min), blocked with 3% (v/v) goat normal serum in PBS. After fixation, cells were stained with mouse anti vinculin or mouse anti talin overnight at 4 °C in goat serum containing PBS. Detection of primary antibodies was performed with FITC conjugated F (ab)<sub>2</sub> fragment goat anti-mouse IgG (Jackson Immuno Research) secondary antibody. Finally, cells were washed in PBS and mounted using Vectashield Mounting Media (Vector Lab) and stored at 4 °C until analysis. Specimens were examined with an Olympus FV300 Confocal Microscopy (Model BX61), with an acquisition software FluoView version 3.3 provided by the manufacturer. The confocal images were analyzed using the Image-Pro Plus version 5.1.2 software (Media Cybernetics, USA). All

adhesion sites (focal contacts) in 10–15 randomly selected cells were analyzed for generation of quantitative data sets for each treatment, and three independent experiments were performed. Cells were examined with a 100X Plan Apo oil objective (NA 1.4), resulting in a pixel length of 0.1388  $\mu\text{m}$  after performing the spatial calibration. To even out background variations in our immunofluorescence images, we applied a “flatten filter”. To select the intensity range of the objects (focal contacts) to be counted, we applied the software command to perform the “segmentation” of the image. The total number of vinculin- and talin- immunostained FC per cell was counted. To do so, the contour of each cell in the confocal image (area of interest) was manually drawn by using the mouse pointer of the program.

### Statistics

Results were expressed as mean  $\pm$  SE. We used the unpaired *t*-test for comparison between DRM and S fractions. Data from control and different treatments were analyzed by ANOVA and significant differences were assessed by “a posteriori” Dunnett Multiple Comparisons test ( $P < 0.05$ ).

## Results

### Renal Papillary Focal Contact (FC) Complexes are Localized in Specific Detergent-Resistant Membranes

We first evaluated the presence of FC proteins vinculin and talin in 0.1% Triton X-100 resistant (DRM) and soluble (S) fractions. As seen in Fig. 1a, anti-vinculin recognized a

116-kDa band in both fractions. By contrast, anti-talin recognized a 225-kDa band only in the DRM fraction (Fig. 1b). It is considered that PtdIns(4,5)P<sub>2</sub> is an essential lipid for FC stabilization [1, 2]; therefore, we next determined whether vinculin and talin were associated with PtdIns(4,5)P<sub>2</sub> in both DRM and S fractions. Thus, PVDF membranes were stripped and retested with anti PtdIns(4,5)P<sub>2</sub> antibody. Two bands were clearly detected in DRM but not in the S fraction (Fig. 1c). The highest molecular mass band ( $\sim$ 225 kDa) was compatible with PtdIns(4,5)P<sub>2</sub> association with talin, while the second band (molecular mass  $\sim$ 116 kDa) was consistent with PtdIns(4,5)P<sub>2</sub> bound to vinculin. In order to confirm whether vinculin and talin were, in fact, bound to PtdIns(4,5)P<sub>2</sub>, we immunoprecipitated DRM and S fractions with anti-PtdIns(4,5)P<sub>2</sub> and then, vinculin and talin were detected by Western blot. In DRM, both vinculin and talin were pulled down by PtdIns(4,5)P<sub>2</sub> antibody, while no bands were evident in immunoprecipitates from the S fraction (Fig. 1d, e). To verify the presence of assembled FC complexes in DRM, talin–vinculin interaction was addressed by performing an immunoprecipitation with anti-vinculin and then, talin was detected by Western blot in the precipitate. As seen in Fig. 1f, a positive band (molecular mass  $\sim$ 225 kDa) was obtained with anti talin, thus reflecting vinculin–talin association. The presence of vinculin bound to PtdIns(4,5)P<sub>2</sub>, together with talin–vinculin association in DRM, constitute the biochemical expression of the existence of FC complexes in DRM isolated from rat renal papillae.

### Biochemical Characterization of FC-Containing DRMs

Once established that FC complexes were located in DRM, we characterized the DRM lipid composition in

**Fig. 1** Biochemical protein-characterization of DRMs from renal papillary cells. DRM and S fractions were obtained from renal papillae as described in “Materials and Methods”, and equivalent amounts of protein were resolved by electrophoresis and immunoblotted for vinculin (a) and talin (b). Representative membranes were

stripped and evaluated for PtdIns(4,5)P<sub>2</sub> (c). DRM and S were immunoprecipitated (IP) for PtdIns(4,5)P<sub>2</sub> (d, e), and for vinculin (f) and then immunoblotted (IB) with the indicated antibody. Results correspond to a representative experiment of five individual assays

**Fig. 2** Lipid characterization of DRM (black) and S fractions (white). Endogenous content of cholesterol (a), individual phospholipids (b), and polyphosphoinositides (c) was determined on DRM and S aliquots, according to the methodology described for each kind of molecule. **d** [ $^{32}$ P]-phospholipids ratio and **e** [ $^{32}$ P]-PtdIns and [ $^{32}$ P]-PtdIns(4)P<sub>2</sub> plus [ $^{32}$ P]-PtdIns(4,5)P<sub>2</sub> ratio. (Mean  $\pm$  SE,  $n = 5$ ). \*Significantly different from the S fraction,  $P < 0.05$ . PLS phospholipids

comparison with the S fractions. As seen in Fig. 2a, cholesterol concentration was ten times higher in DRM than in S fractions (Fig. 2a). With respect to the phospholipid profile (Fig. 2b), DRM showed a 70% increase in sphingomyelin (CerPCho), accompanied by a 30% increase in phosphatidylethanolamine (PtdEtn) and a 40% decrease in phosphatidylserine (PtdSer) but no differences were found in phosphatidylcholine (PtdCho) and phosphatidylinositol (PtdIns) concentrations. The study of individual phospholipid fatty acid composition revealed that DRM are enriched in arachidonic acid mainly due to PtdEtn, which doubled its content with respect to PtdEtn in S fractions (Table 1). The amount of DRM-polyphosphoinositides, PtdIns(4)P and PtdIns(4,5)P<sub>2</sub>, was several times higher

than in the S fraction, denoting the massive accumulation of these acidic phospholipids in our papillary DRM (Fig. 2c). In order to determine whether or not DRM-associated phospholipids were metabolically active, we evaluated [ $^{32}$ P]-Pi incorporation into phospholipids. [ $^{32}$ P]-Pi specific activity, expressed as [ $^{32}$ P]-Pi per nmol of each phospholipid, was obtained and the DRM/S ratio calculated for each individual phospholipid. As seen in Fig. 2d, [ $^{32}$ P]-Pi incorporation was more than three times higher in DRM than in S fraction. It is known that PtdIns(4)P and PtdIns(4,5)P<sub>2</sub> are formed by PtdIns phosphorylation by specific kinases. As a reflection of such a dynamic process, we analyzed the ratio between [ $^{32}$ P]-PtdIns and [ $^{32}$ P]-PtdIns(4)P plus [ $^{32}$ P]-PtdIns(4,5)P<sub>2</sub> in DRM and S

Phospholipids present in both DRM and soluble fraction were isolated and specific fatty acid profile was determined for each phospholipid as described in “Materials and Methods”. The table shows the results of one representative experiment ( $n = 3$ )

fractions. As seen in Fig. 2e, the DRM ratio was around half of the S fraction ratio, reflecting that polyphosphoinositide synthesis in DRM is twice higher than in the S fraction.

Altogether, these results demonstrate that FC complexes are located in cholesterol-CerPCho-polyphosphoinositide-enriched membrane domains, which show an exceptionally high phospholipid biosynthesis with respect to the S fraction (Fig. 2d). The high polyunsaturated PtdEtn content, plus the enrichment in polyphosphoinositides, suggests that such DRM correspond to the inner leaflet of the plasma membrane, which is consistent with the fact that FC are the cytoplasmic face of the cell contact site [18].

#### Effect of Membrane-Affecting Agents in DRM Compositions

Methyl- $\beta$ -cyclodextrin (CD), a known cholesterol-depleting agent, decreased cholesterol content by 35%, and also induced an overall change in phospholipid profile (Fig. 3a). The most significant change was the great augmentation in CerPCho and PtdIns, counterbalanced by the decrease in PtdCho and PtdEtn content, while PtdIns(4)P and PtdIns(4,5)P<sub>2</sub> did not significantly change.

Neomycin, a known PtdIns(4,5)P<sub>2</sub> sequestering agent [19, 20], provoked an unexpected 60% loss in cholesterol concentration, which was accompanied by a slight decrease in CerPCho and PtdSer, and an increase in PtdEtn content. Neomycin also increased PtdIns(4,5)P<sub>2</sub> by 65% while PtdIns(4)P concentration fell about 10% (Fig. 3b).

The treatment with LiCl, which blocks phosphoinositides synthesis [21], evoked an increase in cholesterol and CerPCho content by 35 and 25%, respectively, accompanied by a decrease in PtdCho, an important PtdIns and PtdSer enrichment. No changes in PtdEtn content were observed. Both PtdIns(4)P and PtdIns(4,5)P<sub>2</sub> contents were diminished, accounting for a 50 and 25% decrease, respectively (Fig. 3c).

These results show that instead of evoking an effect on a single membrane lipid, each membrane-affecting agent appears to induce an unexpected overall change in the DRM-lipid profile, thus bringing about a DRM of different lipid composition.

#### Influence of Changes in DRM Lipid Composition on FC Maintenance

In order to obtain a morphological correlation of the biochemical findings, we performed primary cultures of collecting duct cells and studied the FC by immunofluorescence microscopy. As shown in Fig. 4a, vinculin-

**Fig. 3** Changes in lipid composition of DRMs after treatment with membrane-affecting agents. Renal papillary slices were treated with **a** 5 mM CD, **b** 1 mM Neomycin, or **c** 10 mM LiCl, and DRMs were isolated. Variation of cholesterol, individual phospholipids, and polyphosphoinositides is expressed as percentage of control (Mean  $\pm$  SE,  $n = 5$ )

stained FC appeared as bright and elongated structures (arrowheads). Vinculin immunoreactivity was also observed diffusively distributed in the cytoplasm. By contrast, talin immunoreactivity was exclusively found in

**Fig. 4** Effect of changes in DRM lipid composition on FC plaques. Cultured collecting duct cells were treated with 5 mM CD, 1 mM Neo, or 10 mM LiCl. After fixation, cells were immunostained with antibodies against vinculin (a, d, g, j) and talin (b, e, h, k), and with FITC-phalloidin (c, f, i, l). Primary monoclonal interactions were evidenced by using goat anti-mouse IgG–FITC secondary antibody and analyzed with confocal microscopy. Representative images of three independent experiments are shown. Scale bar 20  $\mu$ m. Quantization of the number of vinculin-stained and talin-stained FC per cell were calculated by the image analysis program, and performed as described in “Materials and Methods”. Bar graphs results are expressed as mean  $\pm$  SE. \*Significantly different from control,  $P < 0.01$

FC, appearing as abundant bright plaques morphologically heterogeneous (Fig. 4b, arrowheads).

Treatment of cultured cells with CD caused dissipation of vinculin-stained FC (Fig. 4 and quantitative analysis). Immunoreactivity increased in discrete zones of the plasma membrane (arrowhead) and was also accumulated in the perinuclear zone (Fig. 4d). Talin-stained FC were also affected by CD and an unusual accumulation in specific zones of the plasma membrane was also observed (Fig. 4e, arrowhead and quantitative analysis). Taken together, these results demonstrate that although a fraction of vinculin and talin remained in the plasma membrane, the assembly of these proteins in FC was almost completely impaired by CD. Consistent with the dissipation of FC, CD induced almost complete disappearance of stress fibers. F-actin appeared as a cortical network in rounded cells (Fig. 4f, arrowhead), typical of isolated–detached cells but not of cells that constitute organized epithelial tissues.

As seen in Fig. 4g and quantitative analysis, the specific PtdIns(4,5)P<sub>2</sub> sequestering agent neomycin induced almost complete loss of both vinculin- and talin-stained FC. Both proteins appeared densely accumulated in the cytosol with a punctuate appearance neighboring the nucleus (Fig. 4g, h). Consistent with the dissipation of FC, stress fibers

almost disappeared and arrangements of peripheral actin-based structures were evident (Fig. 4i, arrowhead). Phalloidin-stained images also allowed us to visualize cells that were in the process of retraction (Fig. 4i, asterisk).

The treatment of culture cells with LiCl induced a decrease in the number of vinculin-stained FC per cell (Fig. 4j and quantitative analysis). By contrast, neither the quantity of talin-stained FC nor F-actin distribution in cultured cells was affected (Fig. 4k, l, and quantitative analysis). The preservation of actin organization in stress fibers explains the maintenance of cellular morphology observed after LiCl treatment (Fig. 4l).

## Discussion

In the present report, we biochemically studied FC complexes obtained from rat renal papillae and then defined their morphological correlation in papillary collecting duct cells primary cultures. By using a two-step centrifugation procedure and changing sucrose concentration, we were able to demonstrate that FC complexes are part of a detergent resistant membrane fraction, highly enriched in cholesterol and phosphoinositides and whose phospholipid constituents are subjected to a very high turn-over.

FC has been previously associated with detergent resistant domains and also with local membrane accumulation of PtdIns(4,5)P<sub>2</sub> [22] and it has been recently shown that they can regulate membrane order [23], thus supporting the notion that actin-containing cytoskeleton can promote lateral segregation of cholesterol–sphingomyelin enriched detergent resistant domains [24]. However, a direct demonstration of the existence of such resistant domains and their biochemical characterization has not been reported before. Here, we were able to detect the FC complex in a Triton X-100 resistant lipid domain and we propose that the lipid composition of such DRM corresponds to the physiological environment where FC are inserted.

For the isolation of DRM we used a low Triton X-100 concentration (0.1%). It has been demonstrated in stomach smooth muscle that at such a detergent and similar sucrose concentration most of vinculin was efficiently solubilized while sphingomyelin remained insoluble [24]. Consistent with this observation, we also found the bulk of vinculin in the soluble fraction, but this fraction of vinculin did not correspond to the FC–vinculin since it did not interact with PtdIns(4,5)P<sub>2</sub> nor with talin. Moreover, talin, which is immediately degraded by calpain if it is not assembled into FC, was only found in the detergent resistant domain. Since vinculin, besides being part of FC, can also form adherent junctions, it is possible that the bulk of the solubilized vinculin corresponds to vinculin present in adherent junctions, as suggested previously [23].

FC cannot be detected in histological preparations from intact tissue, but they can be observed in cultured cells. Therefore, we took advantage of the fact that cultured papillary collecting duct cells preserve their tendency to interact with their self-formed ECM, mimicking their behavior in intact tissue. Therefore, we established a parallelism between the biochemical data obtained from papillary microsomes and the morphological observations from immunofluorescence microscopy performed in primary cultures of collecting duct cells. By using such experimental strategy, we demonstrated that membrane lipid composition affects the *in vivo* preservation of FC as clearly shown by the immunofluorescence images. At first, we showed that the various membrane-affecting agents differently affect FC, depending on their capacity to change the membrane lipid composition. Consistent with previous observations in smooth muscle cells [24], the treatment with CD did not lead to DRM elimination. Instead, CD induced cholesterol decrease but also membrane lipid redistribution, which resulted in a net increase of the CerPCho content in DRM. It has been reported that DRM serves as a platform for PtdIns(4,5)P<sub>2</sub> accumulation induced by FC proteins [22], and that such PtdIns(4,5)P<sub>2</sub> accumulation serves to stabilize the assembled FC [6].

However, here we show that, although polyphosphoinositides were still accumulated in CD-treated DRMs, FC did not persist assembled as seen in the immunofluorescence images. Based on these observations, we can suggest that polyphosphoinositide accumulation in DRM is not sufficient to stabilize FC; but polyphosphoinositides must be included in a DRM with a specific lipid composition in order to guarantee an efficient FC stabilization.

The effect of neomycin on cytoskeleton organization has currently been attributed to a failure in the PtdIns(4,5)P<sub>2</sub> availability to bind cytoskeletal proteins but the membrane lipid composition was not studied [22]. The present results clearly show that apart from its well known action as PtdIns(4,5)P<sub>2</sub> sequestering-agent, neomycin simultaneously evokes a dramatic decrease in the DRM cholesterol content. Therefore, we suggest that the deleterious effect of neomycin on FC can be due not only to the loss of PtdIns(4,5)P<sub>2</sub> availability but also to a decrease in cholesterol content, which with no doubt changes the physico-chemical properties of the new formed DRM.

It has been previously shown that LiCl dissipates FC in neural cells [22]. However, here we show that the inhibition of polyphosphoinositide synthesis by LiCl induces a restructuration rather than a dissipation of FC. It is known that FC are hierarchical structures where additional FC proteins assemble as they mature. Talin is the first protein that forms FC, while vinculin is added thereafter [25]. Thus, even without vinculin, talin-containing FC can still be present, thus conforming the minimal FC assembling. Thus, the apparent controversy with the previous observations [22] resides in the fact that the authors studied only vinculin-stained but not talin-stained FC. It is known that vinculin has to be bound to PtdIns(4,5)P<sub>2</sub> to stay in FC plaques [26]. The selective dissipation of vinculin from assembled FC can be explained considering their different affinities for membrane lipids. Thus, vinculin binding to PtdIns(4,5)P<sub>2</sub> is of low affinity, while binding to PtdIns is of high affinity but does not serve to assemble vinculin into FC [27]. Thus, the lowering in PtdIns(4,5)P<sub>2</sub> content, together with the high increase in PtdIns produced by LiCl, may account for the dissipation of vinculin from FC. By contrast, talin has high affinity to bind PtdIns(4)P [27], thus the decreased concentration of DRM–PtdIns(4)P, could be still enough to bind talin. On the other hand, it appears that the new DRM conformation, where cholesterol and CerPCho increased their concentration, could result favorable to stabilize talin-containing FC. Moreover, it has been reported that LiCl affects 20:4n-6 turnover by altering the expression of cPLA<sub>2</sub> [28]; however, whether or not such effect is also involved in the dissipation of vinculin-containing FC needs further demonstration.

Investigations on the interaction of the cytoskeleton components with artificial membranes, and in more detail with membrane lipids were started in the 1980s [29]. However, no direct evidence on the effect of changes in the membrane lipid composition in biological membranes on FC structures exists. It is currently considered that PtdIns(4,5)P<sub>2</sub> is the membrane phospholipid that plays the crucial role in the maintenance of assembled FC. However, our results demonstrated that such pool of polyphosphoinositides has to be part of a domain of specific lipid composition to serve as a membrane lipid stabilizing FC plaques. Among membrane lipids, and taking in consideration that the decrease in cholesterol was a common feature in the deleterious effect of CD and Neo, we suggest that the enrichment in cholesterol is in fact the crucial lipid for evoking the lipid environment to maintain the FC plaques assembled.

We used the various membrane affecting agents only as a tool to study the influence of membrane lipid composition on FC maintenance. However, it is of interest to point out that both neomycin and LiCl are pharmacological agents of known nephrotoxic effects. In this context, our results could be also pharmacologically relevant. Indeed, neomycin is an aminoglycoside antibiotic known to cause tubular necrosis [30, 31]. Thus, the disruption of the cell-extracellular matrix adhesion demonstrated by the present data could be an explanation for the deleterious effect caused by neomycin treatments since it is known that epithelial cells have to be bound to the extracellular matrix in order to survive and not die by anoikis. On the other hand, LiCl is used for the treatment of some human mental diseases [32, 33] and it is known that long-term treatment with this agent provokes alterations in the renal capacity for concentrating urine [34]. Although the pharmacological dose is lower (0.8–1 mM) than the concentration that we used, chronic low doses could also affect FC. The impairment of vinculin-contained FC reported here could be a primary cause that progressively affects cell-ECM adhesion, thus affecting renal function. Moreover, the alteration in membrane lipid composition, mostly cholesterol enrichment, could disturb the location or the function of membrane transporter systems involved in normal renal tubular physiology, thus affecting the urine concentration process.

In conclusion, in this work we show evidence about the importance of the lipid composition of the specific membrane lipid domain, where FC are included, and suggest that it could be relevant for the maintenance of the structures that tether the collecting duct epithelial cells to the extracellular matrix.

**Acknowledgments** We thank Mr. Roberto Fernández for confocal microscope technical assistance.

**Abstract** Subjects with echolucent carotid plaques have an increased risk of ischemic cerebrovascular events independent of degree of stenosis. Low plasma lipoprotein lipase (LPL) activity promotes a proatherogenic lipid profile, and delayed chylomicron clearance is a risk factor for atherosclerosis. This study was conducted to determine plasma LPL activity and postprandial metabolism of triglycerides in relation to carotid plaque morphology. Plaque echogenicity was assessed by B-mode ultrasound and analysis of the grey scale median (GSM). Echolucent plaques were defined as  $GSM \leq 63$  (the median) and echogenic plaques as  $GSM > 63$ , and 57 subjects with carotid plaques and 38 subjects without carotid plaques were recruited. Blood samples were collected before and at 2-h interval for 8 h after a standard high fat meal. LPL activity and mass was determined before and after heparin administration. Postheparin LPL activity was decreased in

subjects with echolucent plaques compared to subjects with echogenic plaques ( $P = 0.06$ ) and to controls ( $P = 0.04$ ). Plaque echogenicity increased linearly with increasing levels of postheparin LPL activity ( $P = 0.02$ ) and mass ( $P = 0.03$ ). Subjects with echolucent plaques had delayed postprandial clearance of chylomicron triglycerides compared to controls ( $P = 0.04$ ). Low postheparin LPL activity due to attenuated mobilization of LPL from capillary endothelium may play an important role in the formation of echolucent plaques by modulation of postprandial lipids and subsequent fat accumulation in the arterial wall.

## Introduction

Postprandial lipemia is a physiological phenomenon occurring several times a day. Elevated postprandial levels of triglyceride-rich lipoproteins (TRLs) have been associated with both coronary [1] and carotid [2] artery atherosclerosis. Zilversmit [3] proposed that atherosclerosis, at least in part, is a postprandial disease, and hypothesized that accumulation of triglyceride-rich dietary lipoproteins promoted formation of atherosclerosis, due to reduced clearance and thereby prolonged exposure of the vascular wall to TRL. More recent studies provide new perspective to this hypothesis by reporting a particular efficient penetration and selective retention of chylomicron remnants in sites of lesion formation [4]. The “response to retention” hypothesis of atherosclerosis suggests that intimal deposition is proportional to the concentration of circulating plasma lipoproteins [5].

Triglycerides in the core of TRL in circulating blood are hydrolyzed by the action of endothelial cell-bound lipoprotein lipase (LPL) representing the principal enzyme that removes triglycerides from the bloodstream [6]. The functional pool of LPL is anchored to heparin sulphate proteoglycans (HSPGs) at the surface of vascular endothelium, and only low levels are found in the circulation [6]. Unfractionated heparin has higher affinity for LPL than heparin sulphate, and heparin infusion will therefore displace LPL from the endothelial surface into circulating blood [7]. The amount of LPL released after a bolus dose of heparin is used as a measure of functional LPL and assumed to reflect the LPL availability at the endothelial surface [8]. A deficiency of LPL is associated with increased plasma levels of chylomicrons, suggesting that triglyceride hydrolysis is important for the clearance of these particles [9]. Furthermore, LPL has also been shown to enhance the uptake of remnant lipoproteins by the liver [10].

The carotid arteries are readily accessible to ultrasound imaging and evaluation of atherosclerotic plaque morphology. Plaques that appear echolucent are lipid-rich, covered by a thinner fibrous cap, whereas echogenic plaques have higher content of fibrous tissue and calcification [11]. Studies have shown that echolucent carotid plaques are associated with high risk for ischemic cerebrovascular events (CVE) independent of the degree of stenosis [12]. The purpose of the present study was to investigate whether plaque echolucency was associated with lowered plasma LPL activity, elevated postprandial triglycerides, and delayed clearance of postprandial TRL in subclinical carotid stenosis.

## Materials and Methods

### Study Participants

The study was performed at the Clinical Research Centre at the University Hospital of North Norway in Tromsø.

The participants were recruited from a population health study (the fifth survey of The Tromsø Study in 2001), which included ultrasound examination of the carotid arteries. Subjects were eligible for the plaque group if they were aged 56–80 years and had one plaque or more in the carotid bifurcation or internal carotid artery at the screening with a plaque thickness of  $\geq 2.5$  mm and plaque morphology classified as echolucent (grade 1) or echogenic (grade 4) according to the Gray–Weale criteria [13]. Subjects in the same age groups without plaques in their carotid arteries were used as controls. Exclusion criteria included the following conditions: regular use of lipid-lowering drugs or

oral anticoagulants, cancer or other serious life-threatening medical conditions, hypothyroidism, renal, hepatic, or psychiatric disease, and current abuse of alcohol or drugs. Coronary artery disease (CAD) was defined as prior or present angina pectoris, myocardial infarction and peripheral vascular disease. Cerebrovascular event (CVE) was defined as transient ischemic attacks, stroke and amaurosis fugax. The study included 57 subjects with and 38 subjects without carotid plaques. Informed written consent was obtained from the participants, and the regional ethical committee approved the study.

### Ultrasound Examination

The ultrasound examination was performed as described previously [14, 15]. Plaque morphology in terms of echogenicity was assessed by analysis of grey scale content of the plaques and calculation of grey scale median (GSM). Assessment of plaque morphology was made in all plaques present in the near and far walls of the common carotid, the bifurcation, and the internal carotid arteries on both sides (12 locations). All examinations and measurements of all plaques were recorded on videotapes. Stored B-mode images were subsequently transferred to a personal computer and digitized into frames of  $768 \times 576$  pixels of 256 grey levels each (0 = black and 256 = white) with the use of a commercially available video grabber card (meteor II/Matrox Intellicam). Measurements of plaque area were made with the use of the Adobe Photoshop image-processing program (version 7.0.1), by tracing around the perimeter of each plaque with a cursor. The grey-level distribution and grey-scale median (GSM) of each plaque was calculated. Normalization of GSM was performed according to the method by El-Barghouty [16]. A fixed area of the lumen of the carotid artery (300 pixels), the brightest area of the innermost adventitia adjacent to the plaque (150 pixels), and the plaque were marked. The plaque image was normalized by adjusting linearly their grey tonal range so that the lumen were assigned a GSM of 1 and the adventitia 200 [17]. After standardization, the GSM of the plaques were re-calculated. In subjects with more than one plaque, the standardized GSM of the total plaque area was estimated as a weighted mean of the GSM value of each single plaque.

The area of each plaque was divided by the total area of plaques in each subject, and this fraction was multiplied with each plaques normalized GSM value. All scores were added to calculate the total normalized GSM score for each subject. Echolucent plaques were defined as GSM at or below the median ( $\leq 63$ ) and echogenic plaques as plaques with a GSM above the median ( $>63$ ).

## Fat Tolerance Test

A fat-tolerance test was conducted using a test meal prepared from standard porridge cream containing 70% of calories from fat of which 66% saturated fat, 32% mono-unsaturated fat and 2% polyunsaturated fat. A weight-adjusted meal (1 g fat/kg body weight) was served at 8:00 a.m. and consumed within 15 min. Blood samples for isolation of chylomicrons (CM), and serum- and plasma preparations were collected before the meal and every second hour during the next 8 h.

## Isolation of Chylomicrons and Measurements of Serum Lipids and Apolipoproteins

Chylomicrons were isolated by over-layering 8 ml EDTA plasma with 5 ml of NaCl solution (density 1.006 kg/l NaCl solution with 0.02% sodium azide and 0.01% EDTA) in a cellulose nitrate tube (Beckman Instruments Inc, CA, USA) and centrifuged in a Beckman SW40 Ti swinging bucket rotor at 20,000 rpm for 1 h at 4 °C. The CM, with Svedberg flotation (Sf) rates > 400, were carefully removed by aspiration from the top of the tube, divided into three aliquots in cryovials, flushed with nitrogen, and frozen at –70 °C until further analysis.

Serum lipids were analysed on a Cobas Mira S (Roche Diagnostics, F. Hoffmann-La Roche Ltd, Basel, Switzerland) with reagents from ABX Diagnostics (Montpellier, France). Total cholesterol (CHOD-PAP) and triglycerides (GPO-PAP) were measured with enzymatic colorimetric methods. Low-density lipoprotein (LDL) and high-density lipoprotein cholesterol were measured by selective inhibition colorimetric assays (LDL cholesterol direct and HDL cholesterol direct, respectively, ABX Diagnostics). Serum apolipoprotein AI (apo-AI) and apolipoprotein B (apo-B) were analysed by turbidimetry on Cobas Mira S with reagents from ABX Diagnostics, whereas apolipoproteins CII and CIII were analysed by turbidimetry with reagents from Kamyia Biomed Comp (Seattle, WA, USA). Serum apolipoprotein E (apoE) was measured by an enzyme-linked immunosorbent assay, Apo-Tek ApoE<sup>TM</sup> (PerImmune Inc., Rockville, MD, USA) and genotyping of apoE was performed according to Hixson and Vernier [18] with slight modifications.

## Lipoprotein Lipase Measurements

Eight hours after ingestion of the test meal, blood was drawn into vacutainers (Becton Dickinson) containing heparin as anticoagulant and the heparinized blood was immediately placed on ice. Unfractionated heparin was given as a bolus injection (100 IU/kg body weight) on the contra-lateral arm

to mobilize LPL from the endothelial surface into the circulation. A second blood sample was obtained exactly 15 min after heparin administration and immediately placed on ice. Heparinized plasma was recovered within 30 min by centrifugation (2,000×g for 10 min) at 4 °C, divided into aliquots of 1.0 ml in cryovials, flushed with nitrogen, and frozen at –70 °C until further analysis. LPL activity was determined as described by Olivecrona et al. [7]. In short, sonicated emulsion of <sup>3</sup>H-oleic acid-labelled triolein in 20% Intralipid (Fresenius Kabi) was used as substrate. Samples were preincubated for 2 h on ice with 0.5 vol goat antibodies to hepatic lipase (HL) to suppress HL activity. LPL activity is expressed in mU/ml corresponding to nanomole of fatty acids released per millilitre per minute. The samples were quantitated in triplicate, and postheparin plasma from pooled normal control persons were used to correct for inter-assay variation. LPL mass was measured in heparin plasma with a commercial ELISA kit (MARKIT-M LPL ELISA, Dainippon Sumitomo Pharma Co., Ltd., Osaka, Japan) according to the instructions made by the manufacturer.

## Statistics

Subjects with carotid plaques were divided in two groups, the echogenic group, defined as GSM > 63 (*n* = 28) and the echolucent group, defined as GSM ≤ 63 (*n* = 29). The extent of postprandial triglyceridemia was assessed by the total area under the curve (AUC) and incremental area under the curve (AUC<sub>i</sub>) for plasma triglycerides and plasma chylomicron triglycerides, and by the triglyceride response (TGR), defined as the average of the two highest postprandial triglyceride concentrations minus baseline concentrations. Continuous variables are presented as mean [95% confidence interval (CI)], and categorical data as proportions (*n*). Serum triglycerides, LPL activity, apolipoprotein CII and CIII were not normally distributed and therefore logarithmically transformed. Differences in continuous and categorical variables between groups were analyzed by ANOVA and the  $\chi^2$  test, respectively. When indicated by a *F* value below 0.05, a post hoc test using the Bonferroni method was performed to identify significant group differences. Linear trends were tested by multiple regression analysis. Differences between groups in total and chylomicron triglycerides over time were analyzed by general linear models (GLM). All analyses were performed using SPSS (SPSS Inc. Chicago, Illinois, USA) for windows software, version 14.0.

## Results

Characteristics of the study participants, including carotid plaque characteristic, are shown in Table 1. There were no

**Table 1** Baseline characteristics of the study participants with echolucent and echogenic carotid plaques and subjects without carotid plaques (controls)

	Echolucent ( <i>n</i> = 29)	Echogenic ( <i>n</i> = 28)	Controls ( <i>n</i> = 38)	<i>P</i> values
Male (%)	55 (16)	54 (15)	50 (19)	0.9
Age (years)	68.7 (66.2–71.2)	70.2 (68.0–72.5)	68.0 (66.0–70.0)	0.3
Currently smoking (%)	18 (5)	29 (8)	24 (9)	0.6
Body mass index (kg/m <sup>2</sup> )	25.5 (24.1–26.9)	26.4 (24.8–28.0)	27.4 (25.8–27.3)	0.1
Systolic blood pressure (mmHg)	127 (120–135)	131 (123–139)	129 (124–135)	0.7
Diastolic blood pressure (mmHg)	74 (68–78)	75 (71–78)	75 (72–78)	0.9
CVE (%)	0	4 (1)	5 (2)	0.5
CAD (%)	14 (4)	18 (5)	13 (5)	0.9
Diabetes (%)	3 (1)	7 (2)	0	0.3
Hypertension (%)	21 (6)	32 (9)	29 (11)	0.6

Grey scale median (pixels)	40.4 (36.2–44.7)	88.6 (81.7–95.6)		<0.001

Values are means (95% CI) or percentages (*n*)

significant differences between groups with regard to traditional risk factors. None of the participants had experienced TIA, one had experienced amaurosis fugax and two had experienced stroke. There were no differences in regular use of drugs or presence of CAD between groups. The median GSM value was 63.0 pixels (range 19.0–137.0) (Table 1). Except for GSM, no differences in plaque characteristics were observed between the echolucent and echogenic plaque groups.

Fasting lipid and apolipoprotein levels are shown in Table 2. Subjects with echolucent plaques had lower HDL cholesterol levels than subjects with echogenic plaques and

controls. To further investigate the relation between plaque echogenicity and HDL cholesterol linear regression analysis was performed. HDL cholesterol increased linearly across tertiles (T) of GSM (HDL T1 = 1.28 mmol/l (0.92–1.79), HDL T2 = 1.59 mmol/l (1.35–1.87), HDL T3 = 1.79 mmol/l (1.53–2.03), *P* for trend = 0.04). The ratio between total and HDL cholesterol was significantly higher in subjects with echolucent plaques compared to controls. In addition, subjects with echolucent plaques had lower apo-AI levels, and the ratio between apo-B and apo-AI was significantly higher in subjects with carotid plaques than the control group (Table 2). The apo-CII/apo-CIII

**Table 2** Fasting lipid and apolipoprotein levels in subjects with echolucent and echogenic carotid plaques, and in subjects without carotid plaques (controls)

	Carotid plaques		Controls ( <i>n</i> = 38)	<i>P</i> values
	Echolucent ( <i>n</i> = 29)	Echogenic ( <i>n</i> = 28)		
Total cholesterol (mmol/l)	6.45 (5.91–7.00)	6.43 (5.98–6.88)	6.07 (5.69–6.46)	0.4
LDL cholesterol (mmol/l)	4.14 (3.76–4.51)	4.17 (3.80–4.54)	3.76 (3.46–4.06)	0.1
HDL cholesterol (mmol/l)	1.59 (1.36–1.82)	1.74 (1.52–1.95)	1.77 (1.63–1.91)	0.4
Total triglycerides (mmol/l)	1.27 (0.99–1.56)	1.08 (0.83–1.33)	1.13 (0.96–1.30)	0.5
Total cholesterol/HDL cholesterol (ratio)	4.31(3.73–4.90)	3.98 (3.53–4.42)	3.56 (3.28–3.84)	0.04
Apolipoprotein AI (g/l)	1.13 (1.24–1.43)	1.40 (1.30–1.51)	1.44 (1.36–1.51)	0.3
Apolipoprotein B (g/l)	1.13 (1.06–1.21)	1.14 (1.07–1.21)	1.04 (0.98–1.11)	0.09
Apolipoprotein CII (mg/l)	41.8 (34.1–49.5)	38.8 (32.6–45.0)	38.7 (34.8–42.6)	0.7
Apolipoprotein CIII (mg/ml)	102.3 (85.8–118.8)	97.7 (81.3–114.1)	98.1 (87.2–109.2)	0.9
Apolipoprotein E (mg/l)	42.1 (36.7–47.5)	40.7 (35.5–45.8)	45.7 (40.5–50.9)	0.3
Apo-B/Apo-AI (ratio)	0.87 (0.79–0.94)	0.85 (0.76–0.94)	0.74 (0.68–0.80)	0.03
Apo-CII/Apo-CIII (ratio)	0.41 (0.38–0.44)	0.41 (0.37–0.46)	0.41 (0.38–0.44)	0.9

Values are means (95% CI)

ratio was equal in all groups. The apoE genotype did not differ between groups, where 57% of the participants had the E3/3 isoform, 30% E3/4, 1% E4/4, 0% E2/2, 9% E2/3 and 2% had the E2/4 isoform.

Plasma levels of pre- and postheparin LPL activity, LPL mass and LPL specific activity are shown in Table 3. Postheparin LPL activity was decreased in subjects with echolucent plaques (112.2 mU/ml, 96.6–130.3 mU/ml) (mean, 95% CI) compared to subjects with echogenic plaques (137.3 mU/ml, 118.9–158.5 mU/ml,  $P = 0.06$ ) and to controls (137.5 mU/ml, 121.6–155.5 mU/ml,  $P = 0.04$ ). The differences between groups remained unchanged after adjustments for age, BMI, use of  $\beta$ -blockers, apoE polymorphism, and serum concentrations of apo-CII and apo-CIII. Similar differences between groups were found in postheparin LPL mass, whereas the specific activity for postheparin LPL was equal between groups. To further investigate the relationship between LPL and plaque echogenicity (GSM), trend analysis revealed a significant increase in GSM across tertiles of postheparin LPL activity ( $P = 0.02$ ) and LPL mass, whereas no linear trend was found for GSM across tertiles of LPL specific activity (Fig. 1). The relations between GSM and postheparin LPL activity and LPL mass remained significant after adjustment for age, BMI, use of  $\beta$ -blockers, apoE polymorphism, and serum concentrations of apo-CII and apo-CIII ( $P = 0.03$  and 0.046, respectively). Univariate analyses were

conducted to determine predictors of GSM. Different fasting and postprandial lipid parameters, age, sex, BMI, apolipoproteins, and LPL activity were tested. Postheparin LPL activity was the only variable that correlated significant with GSM ( $r = 0.32$ ,  $P = 0.02$ ).

Plasma concentrations of CM-triglycerides (upper panel) and total triglycerides (lower panel) after ingestion of the test meal are shown in Fig. 2. Subjects with echolucent plaques had significantly higher levels of CM-triglycerides 6 and 8 h after ingestion of the meal compared to controls even after adjusting for age, sex, smoking status, use of  $\beta$ -blockers, and fasting CM-triglyceride levels (Fig. 2, upper panel). Six hours after the meal the CM-triglyceride level tended to be higher in subjects with echolucent plaques compared to echogenic plaques ( $P = 0.06$ ). Repeated measurement analysis was performed to identify differences between groups over time. The postprandial CM-triglyceride-curve (time  $\times$  group) was significantly different ( $P = 0.004$ ) between echolucent plaques and controls, and not significantly different between the plaque groups ( $P = 0.3$ ) (Fig. 2, upper panel). The postprandial triglyceride-curve (time  $\times$  group) tended to be different ( $P = 0.08$ ) between echolucent plaques and controls, and not significantly different between the plaque groups ( $P = 0.2$ ) (Fig. 2, lower panel). No differences between groups were observed with regard to TGR, AUC and AUCi for triglycerides and CM-triglycerides (Table 3).

## Discussion

In the present study we investigated postheparin LPL activity and postprandial levels of TRL in plasma from subjects with subclinical carotid plaques and healthy controls. To the best of our knowledge, the present study is the

**Fig. 2** Line graphs showing time-course concentrations of chylomicron triglycerides (*upper panel*) and total triglycerides (*lower panel*) after a fat tolerance test in subjects with echolucent ( $n = 29$ ) and echogenic ( $n = 28$ ) carotid plaques, and in subjects without carotid plaques (controls,  $n = 38$ ). Values are means  $\pm$  SEM. \* $P < 0.05$  for difference between echolucent and control groups

first to report a distinct decrease in LPL activity associated with echolucent carotid plaques and a linear increase in plaque echogenicity with increasing postheparin LPL activity. The decreased postheparin LPL activity was accompanied by delayed clearance of TRL in subjects with echolucent plaques.

Several studies support the concept that postprandial TRL are predictors for the presence, severity, and progression of atherosclerotic diseases [1, 2]. Despite the fact that plaque morphology is established as an independent risk factor for CVE, only few studies have focused on the relation between postprandial TRL and qualitative aspects of the carotid plaques. In patients with neurological symptoms and significant stenosis ( $\geq 50\%$ ) of the relevant carotid artery, plaque echogenicity, assessed by GSM, was in univariate analysis negatively associated with BMI, fasting triglycerides, triglyceride response, and VLDL/chylomicron remnant in blood collected 4 h after a fat-rich meal. However, multiple regression analysis revealed only fasting triglycerides and IDL cholesterol as independent predictors for GSM, and concluded that increased plasma

levels of TRL predicted echolucency of carotid plaques [19]. In a case-control study including patients with neurological symptoms and  $\geq 50\%$  carotid stenosis, Kofoed et al. [20] confirmed increased levels of fasting and postprandial TRL in patients with echolucent plaques with the most pronounced findings in women.

Neither the triglyceride response nor the AUC for TRL were higher in subjects with echolucent carotid plaques in our study. The reason(s) for the apparent differences between our and previous findings is not known, but many potential explanations exist. First, we recruited participants with subclinical carotid plaques from a population-based survey in contrast to patients attending an outpatient clinic with neurological symptoms [19, 20]. Patients are expected to have more pronounced lipid disturbances with increased fasting triglycerides and severe disease, and both fasting triglycerides [19] and severity of disease (1) are established predictors for postprandial triglyceridemia. Second, both age [21] and BMI [19] are determinants for both postprandial triglyceridemia and GSM. In our study, no age or BMI differences appeared between groups. In contrast, both age and BMI were predictors for GSM in patients with carotid plaques and neurological symptoms [19]. Altogether, our study supports previous findings that neither the triglyceride response nor AUC for TRL are independent predictors for carotid plaque echolucency.

Previous studies on the relation between plaque morphology and postprandial triglycerides did not assess clearance of TRL from the circulation since TRL in plasma was not measured more than 4 h after the meal [19, 20]. Thus, for the first time, we report a delayed clearance of TRL in subjects with echolucent carotid plaques. A delayed clearance would imply a prolonged postprandial triglyceridemia and lead to an unfavourable translocation of cholesteryl-esters from HDL to CM [22]. Experimental studies also suggest that plasma accumulation of remnant lipoproteins is not just an associated feature of an atherogenic lipoprotein profile, but that TRL remnants themselves contribute to the pathogenesis of atherosclerosis. Chylomicron remnants in the intima of the vascular wall are derived from postprandial lipoproteins [23], and TRL can be taken up directly by macrophages without prior modification and form foam cells [24]. Chylomicron remnants contain 40 times more cholesterol per particle than do LDL particles, and consequently, exposure and retention of apo-B48 lipoproteins in the arterial wall may pose a significant atherogenic risk [25]. Our finding of a delayed clearance of TRL in subjects with echolucent carotid plaques support the concept that prolonged exposure of the vessel wall to TRL remnants may promote the formation of echolucent carotid plaques.

In our study, delayed clearance of postprandial TRL in subjects with echolucent carotid plaques was associated with decreased postheparin LPL activity. The decreased

LPL activity may be due to lowered specific enzyme activity or attenuated mobilization of LPL from the capillary endothelium. In our study, the specific activity of postheparin LPL was similar in all groups, but lowered LPL activity in subjects with echolucent plaques was associated with attenuated mobilization of LPL mass, and linear relations were established between plaque echogenicity (GSM) and LPL activity and mass. These findings do suggest that attenuated mobilization of LPL from capillary endothelium was the main reason for decreased postheparin LPL activity in subjects with echolucent plaque. However, it remained to be settled whether attenuated mobilization of LPL is due to actual lowered concentration of LPL at the endothelial surface or incomplete release of LPL by heparin from the endothelial surface. CM clearance, both lipolysis and hepatic uptake, is sensitive to LPL activity [26, 27]. Thus, decreased LPL activity may slow CM clearance in both stages. Both environmental and genetic factors are known to affect LPL activity [26]. In the present study, neither age, use of  $\beta$ -blockers, nor apoE polymorphisms and serum concentrations of apo-CII and apo-CIII could explain decreased LPL activity in subjects with echolucent carotid plaques.

LPL activity contributes to the regulation of HDL cholesterol and partly explains the inverse relation between postprandial TRL and HDL cholesterol [26]. Even though HDL cholesterol was not significantly decreased among subjects with echolucent carotid plaques, HDL cholesterol increased significantly with plaque echogenicity providing further support for the hypothesis that HDL cholesterol is a predictor for plaque morphology in carotid stenosis [28].

In conclusion, subjects with echolucent carotid plaques had decreased postheparin LPL activity accompanied by a delayed clearance of postprandial TRL. Thus, our findings support a novel property of LPL in determining plaque morphology most probably by subsequent modulation of postprandial TRL.

**Abstract** The purpose of this research was to develop an infrared spectroscopic technique (Fourier transform infrared spectroscopy with attenuated total reflectance system; FTIR-ATR) for non-invasive measurement of saturated and unsaturated fatty acid compositions in human oral mucosa obtained from three nationalities; Iranian, Vietnamese, and Indonesian. The histogram patterns of fatty acid compositions for three nationalities suggest that the pattern of unsaturated fatty acids were quite different, although the distribution profiles of fatty acid to lipid ratios in FTIR-ATR has a similar normal pattern with small difference in skewness and mode. The second derivative infrared spectra of the mucosal tissues in the wavenumber regions from 1,600 to 1,760  $\text{cm}^{-1}$  and 2,800 to 3,050  $\text{cm}^{-1}$  were analyzed with partial least squares (PLS) multivariate regression analysis method. With this analysis method we compared predicted values with the measured values of ten categorized fatty acid compositions, i.e., **a**(saturated C17 or lower), **b**(C16:1 + C17:1), **c**(C18:0), **d**(C18:1), **e**(C18:2), **f**(saturated C20 or longer), **g**(C20:3 + C20:4), **h**(C22:1 + C24:1), **i**(C22:6), **j**( $\gamma$ C18:3). Almost all fatty acid compositions of oral mucosa were well predicted with differences between predicted and measured values within  $\pm 5\%$  of total, however, errors were relatively larger in minor components such as C22:6 than major components.

## Introduction

Dietary fatty acids including saturated, monounsaturated and polyunsaturated fatty acids play important physiological roles for human health [1]. Epidemiological research using fatty acid compositional analyses of human body fluids or tissues may be important for assessment of the effectiveness of dietary fatty acids on the physiology of the human body. However, the measurement of fatty acid compositions in tissues involves tedious and time-consuming procedures for extraction and derivatization of fatty acids from tissues for subsequent analyses with gas-chromatography or high-performance liquid chromatography. This standard method may not be practically suitable for large scale (more than several thousands of subjects) epidemiological research, because it would take a long time to measure fatty acid compositions of a large sample size even with high-throughput gas- or liquid-chromatographic techniques.

On the other hand, vibrational spectroscopy such as Raman, near-infrared and mid-infrared spectroscopy may provide useful techniques to measure lipid compositions in food and human body-derived samples such as blood,

saliva, lipoproteins and oral mucosa [2–7]. Especially, Whittaker et al. [3] reported that Fourier-transform infrared spectroscopy with attenuated total reflectance (FTIR-ATR) could be used for rapid discrimination of food-borne bacteria with their extracted fatty acid methyl esters and multivariate statistical analysis. We reported [4] that polyunsaturated fatty acid species in dietary oils could be predicted using FTIR-ATR system. We also reported [5] that non-destructive FTIR-ATR measurement of human oral mucosa could monitor diurnal changes of polyunsaturated fatty acids in the mucosa. With these spectroscopic and statistical methods, we may complete fatty acid compositional analysis for epidemiological studies on a large scale in a much shorter time. Lam et al. [6] also reported that FTIR and chemometrics revealed low density lipoprotein oxidation with protein conformational changes and provided a simple rapid technique for measuring primary and secondary oxidation products.

The purpose of this research was to determine whether FTIR-ATR technique used for measurement of the infrared spectrum of oral mucosa *ex vivo* may predict fatty acid compositions in the mucosa and to explore at what level of identification of fatty acid species could be achieved by multivariate analysis. If this analysis technique provided reasonably reliable results for the assay of fatty acid compositions, this would greatly shorten time from sampling to getting results and lower the costs because only a minimum amount of reagent would be necessary for fatty acid analysis with the use of the multivariate statistical analysis. This would then become a suitable method for epidemiological and clinical researches.

## Materials and Methods

### Preparation of Oral Mucosa

A total of 425 oral mucosal samples from Iranian (100 samples), Indonesian (175 samples), and Vietnamese (150 samples) subjects were collected for epidemiologic research by the team of Nagoya City University (Dr. S. Tokudome as the leader). Those oral mucosal tissues after collecting with cotton-wiping were suspended in 0.25 M sucrose with phosphate buffered saline (PBS; 50 mM Na<sub>2</sub>-K-phosphate buffer and 0.7% NaCl, pH 7.3) and frozen with dry-ice to ship to Japan. The samples were then stored at –80 °C until use. After thawing, the oral mucosal samples were washed in sucrose-free phosphate buffered saline two times with centrifugation at 5,000g for 5 min. The mucosal pellet (soft solid) thus obtained was directly subjected, after separation with a spatula, in part to Fourier transform infrared spectral analysis with an attenuated total reflectance (ATR) probe (diamond ATR), and the other

part to methyl-esterification for fatty acid analysis with gas chromatography-mass spectrometry.

### Fatty Acid Determination by Gas Chromatography–Mass Spectrometry

The washed mucosal pellet was suspended in 50 µl of PBS buffer, and dried with flushing with N<sub>2</sub> gas. To the dried sample was added 0.15 ml of methanolic HCl (5%; GL-Science, Japan) and 0.35 ml of dehydrated methanol, and heated at 100°C in dry-bath unit for 4 h in Teflon-coated screw-capped glass tubes. The resulting fatty acid methyl esters, after cooling, were extracted in 1 ml of hexane (Nakarai Tesque Co., Japan), and stored until use at –20 °C. Before measurement, the hexane phase was dried by flushing with N<sub>2</sub> gas, and dissolved in 10 µl of hexane. 0.8 µL of the sample solution in hexane was injected into a gas chromatography-mass spectrometry system (GC; Agilent technologies: MS, GC-Mate II, JEOL, Japan) with a capillary column (BPX-70, SGE Co., Japan; 30 m in length, 0.32 mm in internal diameter, and 0.25 µm in film thickness). The temperature program in gas-chromatography was set at 100 °C for 2 min, and raised linearly from 100 to 250 °C at a 10 °C/min rate, and kept at 250 °C for 8 min. Identification of fatty acids was carried out using standard fatty acid methyl esters (Funakoshi, Japan) and mass spectrum of each fatty acid methyl ester. In some cases, fatty acid methyl esters thus obtained from oral mucosa were filtered and purified through Florisil-column (Florisil-SepPak Plus cartridges, Waters, MA, USA) to remove some sterols and hydroxyl fatty acids if occurred. Initially the column was washed with hexane-diethylether (85:15) extensively and then 100% hexane, and fatty acid methyl esters obtained in hexane were applied to the column, and washed with hexane-diethylether (95:5), and then eluted by hexane-diethylether (85:15), and concentrated by N<sub>2</sub> gas flushing. This Florisil-column treatment of fatty acid methyl esters could not change principally the gas chromatographic pattern of oral mucosa-derived fatty acid methyl esters appeared in the region from C14 to C24 fatty acids.

### Fatty Acid Analysis by Fourier-Transform Infrared Spectroscopy with Partial Least Squares (PLS) Regression Analysis

For measurement of the mucosal pellet, we used Fourier-transform infrared spectroscopy with a diamond attenuated total reflectance system (FTIR-ATR system; TravelIR, SensIR (Smiths Detection Co. at present), Columbus, OH, USA). Nearly 0.5 µl of the mucosal pellet was placed on

the surface of the ATR probe and dried by air-blowing for 1 min, and measured at  $4\text{ cm}^{-1}$  resolution with 48 accumulations. The duplicate data for one sample were averaged and used for calculation. The spectral data were transformed to the second derivative form and normalized adjusting the intensity at  $1,650\text{ cm}^{-1}$  to a constant value.

We reported previously [8] that the ratio  $[2850]/[1650]$  in the second derivative form of infrared spectrum had a good linear correlation with the lipid (triacylglycerol) to protein ratio (mg/mg). This relationship is also true for the ratio  $[2850]/[1540]$ , and in this paper we have adopted this  $[2850]/[1540]$  ratio for a large number of human mucosal tissues. The reason is that the accidental contamination of water or water vapor influences the absorption spectrum at around  $1,650\text{ cm}^{-1}$  more than that at  $1,540\text{ cm}^{-1}$ , and thus the ratio  $[2850]/[1540]$  may be more robust to this contamination than the ratio  $[2850]/[1650]$ .

For predicting the fatty acid composition from the infrared spectrum of tissues, it may be necessary to obtain information of fatty acids from the spectrum including the profile of unsaturated bonds (*cis*-alkene,  $\text{HC}=\text{CH}$ ; peak position and intensity at around  $3,010\text{ cm}^{-1}$ ), profile of methyl ( $-\text{CH}_3$ ; peak position and intensity at around  $2,875\text{ cm}^{-1}$ ), profile of methylene ( $-\text{CH}_2-$ ; peak position and intensity at around  $2,850\text{ cm}^{-1}$ ), profile of fatty ester ( $-\text{C}(=\text{O})-\text{O}-\text{R}$ ) or free fatty acid carboxylate ( $-\text{C}(=\text{O})\text{O}^-$ ; peak position and intensity at around  $1,740$  or  $1,710\text{ cm}^{-1}$ , respectively). The infrared spectral intensity itself is also dependent on the sample handling such as change of contact area of the samples on the ATR probe, and this artifactual variation of intensity may be corrected by normalization of the spectrum by adjusting the protein infrared absorbance at  $1,650$  (amide I) or  $1,540\text{ cm}^{-1}$  (amide II) to a constant value.

To adopt a wide variety of fatty acid compositions, it may be reasonable to select samples randomly with various ratios  $[2850]/[1540]$  or  $[2850]/[1650]$ , for building Partial Least Squares (PLS) models, as the change of ratio  $[2850]/[1540]$  did not practically reflect any specific fatty acid change, but reflected the integrated changes of all fatty acids. The information of the infrared spectrum including absorption intensity of methylene may be used for PLS model building, and a wider range of spectral intensities should be adopted for ameliorating the fitness of unknown sample data to the PLS model.

Partial least squares (PLS) regression analysis for the FTIR-ATR spectrum of oral mucosa was done using Sirius software (PRS; Bergen, Norway). As a model learning process, 6–8 samples with known fatty acid compositions were used, and the IR absorption data between  $3,050$  and  $2,800\text{ cm}^{-1}$ , and between  $1,750$  and  $1,600\text{ cm}^{-1}$  were extracted into spread sheet software (as Excel files, Microsoft), and transferred to the PLS software. Increasing

the number of samples for the model learning process to 10 could not improve results. The PLS model was constructed up by setting the cross validation to 2 as a stop criterion and the maximum number of components to 6. After a suitable PLS model was constructed for subsets such as **a**(saturated C17 or lower), **b**(C16:1 + C17:1), **c**(C18:0), **d**(C18:1), **e**(C18:2), **f**(saturated C20 or longer), **g**(C20:3 + C20:4), **h**(C22:1 + C24:1), **i**(C22:6), and **j**( $\gamma$ C18:3), those components were predicted for the unknown mucosal samples. Oral mucosa contained a certain amount of odd-numbered fatty acids and very-long-saturated fatty acids (longer than C22), and these components were summarized with other fatty acids. The number of classified species of fatty acids for prediction by PLS analysis was controlled to less than 10 in order to shorten the working time of the PLS software.

## Results

Figure 1a shows typical second derivative and absolute (insert) infrared (IR) spectra of human oral mucosal pellet, and the fatty methylene IR absorption originated from CH symmetric stretching mode was observed at around  $2,850\text{ cm}^{-1}$  and protein amide II at around  $1,540\text{ cm}^{-1}$ . The intensity ratio ( $[2850]/[1540]$ ) between  $2,850\text{ cm}^{-1}$  and  $1,540\text{ cm}^{-1}$  in the second derivative spectrum was calculated and the distribution of the ratio values is shown in Fig. 1b as histograms for three nationalities: Iranian, 100 samples; Indonesian, 170 samples; Vietnamese, 150 samples. The intensity ratio at around 0.16 was the mode, and from 0.12 to 0.2 the distribution of the intensity ratio showed nearly normal distribution, but a little distorted shape.

Five groupings were temporarily made using the distribution of ratio  $[2850]/[1540]$  for mucosal samples according to classes as shown in Fig. 1b, and four samples were randomly picked up from each group. Then fatty acid composition of each sample was determined with gas chromatography-mass spectrometry as shown in Fig. 2a. In oral mucosa, fatty acids from C14:0 to C26:0 were mainly observed and it was noticed that long saturated even- and odd-numbered fatty acids were abundant in oral mucosa. Among polyunsaturated fatty acids (PUFA), C18:2n-6 was also abundant, while small amount of C18:3n-6 ( $\gamma$ -linolenic acid), C20:3n-6, C20:4n-6 (arachidonic acid; AA) and C22:6n-3 (docosahexaenoic acid; DHA) were also detected. In Fig. 2a' shown was an example of a little contaminated pattern. The pattern of fatty acid methyl esters from oral mucosa (an example shown in Fig. 2a) was not basically changed by florisisil-column treatment, suggesting no hydroxyl fatty acids content. In minor components there were many atypical fatty acid peaks and

**Fig. 1** Infrared spectrum of oral mucosa measured by FTIR-ATR system in the second derivative and absolute spectrum (insert) forms (a), and the normalized distribution of methylene/amide II ratios ( $[2850]/[1540]$ ) for three nationalities (b). The distributions of the ratio as histograms show distinct features among three nationalities (100–170 samples). Those mucosal samples were collected in a city in Iran or Vietnam (Ho Chi Minh City) or Indonesia (Semarang)

those showed typical fatty methyl ester mass fragment patterns (containing ex.,  $m/z = 74$  and  $87$ ). At present those minor peaks were not identified in this paper.

In Fig. 2b, the relationships between fatty acid contents (percentage in all fatty acids) and infrared absorption intensity ratios ( $[2850]/[1540]$ ) was shown for each sample. In the case of saturated fatty acids (C14 to C26) and monounsaturated fatty acids (MUFA) no correlations were observed for Iranian samples with infrared absorption ratio ( $[2850]/[1540]$ ). No correlation was observed for other

nationalities either. On the other hand, the amount of PUFA may have a weak but significant negative correlation ( $R = -0.56$ ;  $P < 0.05$ ,  $n = 20$ ) with the ratio of the infrared absorption bands. However, this correlation could not be observed in other nationalities (Indonesia and Vietnam) samples (data not shown).

The intensity of methylene  $2,850 \text{ cm}^{-1}$  band may be affected by both the amount of total fatty acids and the balance between saturated and unsaturated fatty acids, and even the species of unsaturated fatty acids such as linoleic

**Fig. 2** A gas chromatographic pattern of fatty acids of oral mucosa, a typical case in (a) and a low contaminated form in (a'), and the correlations between fatty acid composition and the [2850]/[1540] ratio (b). The fatty acid methyl esters and some sterol compounds formed after 5% methanolic HCl treatment of oral mucosa were extracted in hexane and injected into gas chromatography-mass spectrometry. Total ion chromatogram was shown in (a). In (a') inserted pattern, contaminated broad bands were shown in circles. The correlations between saturated or mono-unsaturated or polyunsaturated fatty acid compositions and the infrared methylene to amide II absorbance ratio showed almost no correlations for saturated and mono-unsaturated fatty acids. Exceptionally polyunsaturated fatty acid (PUFA) compositions, mainly linoleic acid, in Iranian samples showed good correlation with the infrared absorbance ratios [2850]/[1540]

and eicosatetraenoic acids, may affect the methylene infrared absorption intensity differently. The increase in polyunsaturated fatty acid may contribute to the intensity of  $2,850\text{ cm}^{-1}$  less than that of saturated or monounsaturated fatty acids. The intensity of band at  $2,850\text{ cm}^{-1}$  may result from integration of all fatty acids in the mucosa.

In Table 1, the present fatty acid compositional data are compared with the published human oral mucosal fatty acid compositions [9, 10]. Although the origin of oral mucosal tissues were very different, the compositions of saturated (S) C14–17, C18:0, C18:1, and C18:2 were comparable for these three cases. The composition of monounsaturated (M) C16–17 of the present case was

much larger than the other two reports (12.5 vs. 4–5), and this may be caused by including the composition of C17:1 in the present case. The other two reports did not show the chromatographic patterns and the content of C17:1. Fatty acid composition of oral mucosa shows very different profile from that of other organs, and C22:4, C22:5, C20:5, and C22:5 which are frequently observed in internal organ cells such as liver, brain and blood cells could be hardly detected in oral mucosa. However, C20:3 and C20:4 (n-6 fatty acids) and C22:6 (n-3 fatty acid) were detected in oral mucosa, and those may be used as markers of those polyunsaturated fatty acid contents in the body.

### Partial Least Square Regression Analysis of Mucosal Fatty Acids

Figure 3 shows the second derivative infrared spectra of several samples after normalizing the amide I band intensity. The spectral regions (windows) used were 1,600–1,750  $\text{cm}^{-1}$  and 2,800–3,050  $\text{cm}^{-1}$ . These regions were used for evaluation of the relative amount of fatty acids against the amount of proteins in the mucosa and of the

balance between saturated and unsaturated fatty acids with different chain length and extent of unsaturation. Especially the extent of unsaturation could be detected by the infrared absorption peak position and shape originated from *cis*-alkene (HC=CH) CH stretching mode usually observed at around 3,010  $\text{cm}^{-1}$  [5, 7].

Next these spectroscopic data were analyzed using PLS software (Sirius), and the data of fatty acid compositions for the corresponding samples were also analyzed. Both the

**Fig. 3** Examples (from the Iranian samples) of infrared spectra in the second derivative form of oral mucosa with normalizing the absorbance at 1,649  $\text{cm}^{-1}$  (amide I) to a constant value ( $-0.002$ ). **(a)** Second derivative spectra for 11 examples (overlaid) in two wavenumber windows. **(b)** An example spectrum used for the PLS analysis after combining the two wavenumber regions. For PLS model construction, these two wavenumber regions (protein region at around 1,650  $\text{cm}^{-1}$  and fatty acid region at around 2,850  $\text{cm}^{-1}$ ) were used, because these regions contain enough information to obtain relative contents of saturated and unsaturated fatty acids

**Fig. 4** Correlation plots between predicted and measured values of the fatty acid groups (a to f). In these cases the correlation coefficient ( $R^2$ ) was almost 0.98–1.00 after a suitable PLS model was constructed

for ten subjects. SEV (standard error of validation) for each regression analysis was noted from 0.000 to 0.261, and the component numbers used for the regression were from 6 to 9

spectroscopic and fatty acid compositional data were used to construct the suitable PLS models and to determine some PLS parameters including the number of groups in cross validation and stop criteria for cross validation, and the maximum number of components with a significant level of 0.05. Here we represented data for Iranian samples, however, the data for the other two countries showed similar results as long as we used the learning data of their own countries for construction of PLS model.

Figure 4 shows the results of plots for [measured] (m) vs. [predicted] (p) values after construction of PLS model for the composition (%) of fatty acid(s) or fatty acid groups of Iranian samples. All plots showed good correlations with the coefficient of almost 1.00. In this case, the fatty acids or fatty acid groups are (a) saturated fatty acids including

C14, C15, C16, C17 acids, (b) monounsaturated C16 and C17 acids, (c) stearic acid (C18:0), (d) oleic acid (C18:1), (e) linoleic acid (C18:2), (f) very-long-chain saturated fatty acids including C20, C22, C24, C25, C26, C28 acids. Other fatty acids and fatty acid groups were also evaluated (not shown here), for (g) C20:3 + C20:4, (h) C22:1 + C24:1, (i) C22:6, and (j)  $\gamma$ C18:3, and similar results were obtained. The minor fatty acid,  $\gamma$ C18:3, could be hardly detected clearly for Indonesian and Vietnamese samples. The discrimination of the gas chromatographic peak whether alpha- or gamma-linolenic acid was done by a mass spectrometric technique comparing with the mass spectrum of the standard fatty acid methyl esters as shown in Fig. 5.

Under this condition of PLS regression analysis we tried to predict fatty acid compositions of mucosal samples

**Fig. 5** Comparison of mass spectra of C18:3 methyl ester isomers. In (a), mass spectrum of oral mucosal C18:3 methyl ester with molecular ion ( $M^+$ ) at  $m/z = 292$ . In (b), the mass spectrum of authentic  $\alpha$ -linolenic acid (C18:3n-3) methyl ester was shown. The presence of fragment ions at 249.2 in (a) and 249.9 in (b) show mucosal C18:3 is not  $\alpha$ -linolenic acid, but  $\gamma$ -linolenic acid (C18:3n-6) mainly

which were not used in the learning process for constructing PLS parameters. A part of results is shown in Table 2. In this table, the predicted and the measured values of fatty acid compositions were shown in percent. The difference between the predicted and observed values were within  $\pm 5\%$  of total fatty acids, depending on the species of fatty acids. Some samples showed a little worse prediction, and these samples contained unusual contaminants as detected in the gas chromatographic patterns (Fig. 2a'), which might be caused in part through the sampling of oral mucosa. When the relative deviation from the measured value was denoted as DM (%; deviation from the measured value), the averaged DM for compositional groups (a to f) with relatively higher contents over 10% of all fatty acids was 10.8 DM (%;  $\pm 8.4$  SD). For minor components (group g to j) with relatively lower contents below 5% of all fatty acids, the averaged DM was 35 DM(%; $\pm 20$  SD), and this large DM value for minor components may be resulted partly from background noise and some contamination in the gas chromatography and FTIR.

Figure 6 shows the distributions for fatty acid groups (c, d, e, i) in 34 samples of Iranian subjects after

predicting the compositions. The distribution profile of long saturated fatty acid (C18:0) represented the mode was at 13–17 (%) with long lobe up to 37(%), while unsaturated C18 fatty acids (C18:1 and C18:2) showed a little distorted bell-shaped distributions, and these data showed similar mean values to the measured samples. The distribution of C18:0 (c) was similar to that of saturated C14 to C17 fatty acids (a), and also the distribution of C18:1 (d) is similar to that of monounsaturated C16 to C17 (b) (data not shown). A minor component (C22:6 (i)) showed wide range of distribution, and fractions with very low content of C22:6 was remarkable. The distribution of C20:3 + C20:4 (g) was similar to that of C22:6 (data not shown).

Figure 7 shows the distributions of measured fatty acids of oral mucosa obtained from Vietnamese (Vn) and Indonesian (Id). The distribution of C18:0 was similar in both nationalities, whereas that of C18:1 or C18:2 was different in both. The distribution of C22:6 shows the content of C22:6 in the Vietnamese samples was a little higher on average than that of Indonesian.

When comparing Fig. 6 with Fig. 7, the contents of C18:0 and C18:1 were higher in Fig. 6 (Iranian) than in Fig. 7 (Vn and Id), whereas those of C18:2 and C22:6 were lower in Fig. 6 than in Fig. 7. These differences in fatty acid contents, such as lower contents of polyunsaturated fatty acids in the Iranian group than in the Vietnamese and Indonesian groups, may be easily recognizable in these histograms, and thus the compositional analysis of fatty acids by FTIR-ATR and PLS methods may become possible and suitable for rough screening of oral mucosal samples when noise and contamination levels in the measurement of mucosal samples with FTIR and GCMS are adequately suppressed.

## Discussion

This paper has described infrared spectroscopic and multivariate analysis methods to quantitate the relative amounts of various fatty acids in human oral mucosa. This technique may provide ideally a great advantage to fatty acid analysis in the fields of food science, preventive medicine and epidemiology.

We have demonstrated that the fat to protein ratios ([2850]/[1540] ratios) showed a nearly Gaussian distribution for each nationality. However, the distribution profile of [2850]/[1540] ratio for each nationality had a slightly different feature (in skewness and mode). For example, for Iranian samples the profile showed a larger contribution from the lower ratios, and for Indonesian samples a larger contribution from higher ratios. For Vietnamese samples the mode value (0.18) was larger

than that (0.16) of other samples (Iranian and Indonesian). The intensity at 1,650 or 1,540  $\text{cm}^{-1}$  may correspond to the amount and density of oral mucosal proteins on the surface of ATR probe, and this intensity may not be changed practically when normal test subjects were used and contact area of the sample on the ATR probe was constant. This infrared absorption peak ratio ([2850]/[1540] or [2850]/[1650]) may, practically, correspond to the relative amount of fatty acids in the oral mucosal sample comparing with the amount of protein, and actually the ratio, [2850]/[1650], has a linear correlation with the triglyceride/protein ratio as we have reported previously [8], and it is also true for the ratio [2850]/[1540]. As the contact area of the dried pellet sample on the ATR probe is hard to control experimentally and exactly, it was necessary to use this ratio [2850]/[1540] for assaying the relative changes of lipids or fatty acids in mucosal samples. This ratio in the oral mucosa may be related to the extent of dietary intake and accumulation of lipids in body tissues, and thus to the life style of the nation on average.

The ratio of infrared absorptions, [2850]/[1540], is not directly related to the content of specific fatty acid, but related to a complex integration of each saturated and unsaturated fatty acids or roughly to the amount of total fatty acids as described in the method section. It might be exceptional that the [2850]/[1540] ratio for Iranian samples

had a weak inversed relationship with the amount of polyunsaturated fatty acids (mainly C18:2) as shown in Fig. 2b (right). For other nationalities there was no relationship between the [2850]/[1540] ratio and the amount of polyunsaturated fatty acids.

Thus, the ratio of infrared absorptions, [2850]/[1540], may be mainly referred to the relative amount of total fatty acids compared to the amount of proteins, and 20 samples were picked out for fatty acid determination using gas chromatography-mass spectrometry. These samples were selected impartially from the group with wide range of distribution of the [2850]/[1540] ratio. After obtaining the information for the fatty acid compositions and normalized infrared spectra of the mucosal samples, we proceeded to the multivariate analysis to construct suitable PLS regression parameters. It was important to obtain the normalized spectra (second derivative form), which were adjusted to the same value for the amide I infrared absorption intensities of the selected mucosal samples.

Many papers have been published recently concerning multivariate analysis methods for fatty acid compositional analyses [11–14] using vibrational spectroscopy. These papers have proved that vibrational spectroscopies such as Raman, near-infrared, and mid-infrared spectroscopy are useful in combination with multivariate analyses such as the PLS (partial least squares) regression analysis method

**Fig. 6** Histograms for four predicted fatty acid compositions of 34 oral mucosal samples (Iranian). In these histograms, the x-axes represent the contents in % of the fatty acids

for the prediction of fatty acid compositions in biological materials, for example in adipose tissues. These methods may have a great advantage in the analysis of fatty acids and other biomolecular compositions as these analyses can

be done very rapidly for a large number of samples compared to normal chromatographic methods.

Beattie et al. [12] reported that the bulk unsaturation parameters and abundance of polyunsaturated fatty acids of several adipose tissues could be predicted by Raman spectroscopy using multivariate analysis. In that report, the Raman spectra of adipose tissues from several species in the range between 800 and 1,800  $\text{cm}^{-1}$  were used for analysis, and the correlation coefficients of the contents of several major fatty acids were reported to be from 0.8 to 0.97. They reported that Raman analysis has the advantage of giving good correlation coefficients without the need for prior solvent extraction steps in the analysis. On the other hand, Ripoche and Guillard [13] reported when using FTIR that the prediction of fatty acid composition of unextracted adipose tissue gave poor correlation coefficient ( $R^2 = 0.69\text{--}0.79$ ). Improvement of the coefficient in our case (Fig. 4) may result mainly from using less noisy second derivative infrared spectra in the selected wavenumber regions. Afseth et al. [14] reported using Raman and near-IR spectroscopic methods and that Raman spectroscopy was suitable for predicting the total level of unsaturation, and both Raman and near-IR spectroscopy were feasible for rapid quantification of fat composition in complex food model systems.

It may be important to apply vibrational spectroscopy including mid-IR spectroscopy to the estimation of fatty acid compositions in biological tissues and model mixtures with selecting the normalized absorption—wavenumber sets. These sets of the spectra contain information regarding the quality and quantity of both methylene ( $\text{CH}_2$ ) stretching mode and *cis*-alkene (originated from unsaturated fatty acids;  $\text{HC}=\text{CH}$ ) CH stretching mode with comparing relative intensities of those bands with protein amide I or II band intensity. Basically the fatty acid compositions (% of total fatty acids) may be determined with information regarding to the length of fatty chains and the degree of unsaturation in fatty acids, and the length of fatty chains may affect principally the intensity and peak position of infrared absorption of the methylene stretching mode and the degree of unsaturation may affect the intensity and peak position of alkene infrared absorption. The methylene infrared absorption could be measured at around 2,850  $\sim$  2,920  $\text{cm}^{-1}$ , and the intensity and shape of the absorption peaks may contain necessary information regarding the length of the fatty chains and a part of the methylene absorption shape may be affected by the extent of unsaturation and position of unsaturated bonds through changing the packing mode of lipid membranes or micelles.

On the other hand, the infrared absorption of *cis*-double bond(alkene) could be measured at around 3,010  $\text{cm}^{-1}$ , and the intensity and shape of the alkene peak may contain

**Fig. 7** Histograms for four measured fatty acids compositions of oral samples from Vietnamese and Indonesian subjects. In these histograms, the x-axes represent contents in % of the fatty acids. Vn, Vietnamese; Id, Indonesian

the information about the extent of unsaturation and the position of the double bonds [4]. The infrared absorption for *trans*-double bond could be measured [15] at  $966\text{ cm}^{-1}$ , however, in the normal human tissue the content of *trans*-unsaturated fatty acids may be negligible. Furthermore we employed the second derivative form of the infrared spectra, which enhanced the quality of the absorption peak position and shape as shown in Fig. 3.

Based on these considerations, it may be reasonable for the prediction of fatty acid compositions by PLS regression analysis to use the normalized infrared spectrum between  $2,800$  and  $3,050\text{ cm}^{-1}$ . Actually the correlation coefficient for each fatty acid, as shown in Fig. 4, was high enough for prediction of fatty acid compositions of oral mucosa. However, it should be noted that the PLS models presented are not universal.

**Abstract** This paper describes the inhibitory activities of cholesterol derivatives such as cholesterol, sodium cholesteryl sulfate, cholesteryl-5 $\alpha$ , 6 $\alpha$ -epoxide, cholesteryl chloride, cholesteryl bromide, and cholesteryl hemisuccinate (compounds **1–6**, respectively) against DNA polymerase (pol), DNA topoisomerase (topo), and human cancer cell growth. Among the compounds tested, compounds **2** and **6** revealed themselves to be potent inhibitors of animal pols, and the IC<sub>50</sub> values for pols were 0.84–11.6 and 2.9–148  $\mu$ M, respectively. Compounds **2**, **3** and **6** inhibited the activity of human topo II, with IC<sub>50</sub> values of 5.0, 12.5 and 120  $\mu$ M, respectively. Compounds **2**, **3** and **6** also suppressed human cancer cell (promyelocytic leukemia cell line, HL-60) growth, and LD<sub>50</sub> values were 8.8, 20.2 and 72.3  $\mu$ M, respectively, suggesting that cell growth inhibition had the same tendency as the inhibition of topoisomerases rather than pols. Compounds **2** and **6** arrested the cells in S and G2/M phases, compound **3** arrested the cells in the G2/M phase, and these compounds also increased sub-G1 phase in the cell cycle. These results suggested that the effect of cell cycle arrest might be effective on both pols and topoisomerases activities. From these findings, the action mode of cholesterol derivatives as anti-cancer compounds is discussed.

## Introduction

DNA polymerase (pol) catalyzes the addition of deoxyribonucleotides to the 3'-hydroxyl terminus of primed double-stranded DNA (dsDNA) molecules [1]. The human genome encodes 14 pols which conduct cellular DNA synthesis [2]. Eukaryotic cells reportedly contain three replicative types: pols  $\alpha$ ,  $\delta$ , and  $\epsilon$ , mitochondrial pol  $\gamma$ , and at least twelve repair types: pols  $\beta$ ,  $\delta$ ,  $\epsilon$ ,  $\zeta$ ,  $\eta$ ,  $\theta$ ,  $\iota$ ,  $\kappa$ ,  $\lambda$ ,  $\mu$ , and  $\sigma$  and REV1 [3].

DNA topoisomerases (topos) are key enzymes that control the topological state of DNA. There are two classes of topoisomerases: type I enzymes, which act by transiently nicking one of the two DNA strands, and type II enzymes, which nick both DNA strands and are dependent on ATP, are involved

in many vital cellular processes that influence DNA replication, transcription, recombination, integration and chromosomal segregation [4].

DNA metabolic enzymes such as pols and topoisomerases are not only essential for DNA replication, repair and recombination, but are also involved in cell division. Selective inhibitors of these enzymes are considered as a group of potentially useful anti-cancer and anti-parasitic agents, because some inhibitors suppress human cancer cell proliferation and have cytotoxicity [5–8].

Cholesterol is a steroid alcohol that is essentially insoluble in aqueous solutions. In mammals, it is normally solubilized by its association with other lipids, such as phospholipids or bile acids; thus, most cholesterol is found in cell membranes, plasma lipoproteins, and bile [9]. Cholesterol can be esterified with a fatty acid to form cholesteryl esters [10]. The latter form discrete lipid droplets in cells, especially in cells of steroidogenic tissues, and in the lipid core of low-density lipoproteins in blood [11]. Most cholesterol is synthesized by the liver and other tissues, including the adrenal glands and reproductive organs. Some cholesterol is absorbed from dietary sources. The most common sterol of eukaryotes is a key constituent of cell membranes and works as the precursor of bile acids, cholecalciferol (vitamin D) and steroid hormones including cortisol, cortisone, aldosterone and sex hormone progesterone in vertebrates [12].

The purpose of this study was to find the novel bioactivity of cholesterol and its related compounds. Herein, we describe the inhibitory activities of various cholesterol derivatives against DNA metabolic enzymes such as pols and topoisomerases, and cellular proliferation processes such as DNA replication of human cancer cells (HL-60). It was discussed that cholesterol derivatives could have anti-cancer activity.

## Materials and Methods

### Materials

Six cholesterol-related compounds—cholesterol (compound 1), sodium cholesteryl sulfate (compound 2), cholesteryl-5 $\alpha$ , 6 $\alpha$ -epoxide (compound 3), cholesteryl chloride (compound 4), cholesteryl bromide (compound 5) and cholesteryl hemisuccinate (compound 6), aphidicolin, camptothecin, and etoposide were purchased from Sigma-Aldrich (St Louis, MO, USA). The chemical structures of the compounds are shown in Fig. 1. Nucleotides and chemically synthesized DNA template-primers, such as poly(dA) and oligo(dT)<sub>12–18</sub>, and radioisotope reagents such as [<sup>3</sup>H]-dTTP (2'-deoxythymidine 5'-triphosphate) (43 Ci/mmol) were purchased from GE Healthcare

**Fig. 1** Structures of cholesterol derivatives. Compound 1: cholesterol, compound 2: sodium cholesteryl sulfate, compound 3: cholesteryl-5 $\alpha$ , 6 $\alpha$ -epoxide, compound 4: cholesteryl chloride, compound 5: cholesteryl bromide, and compound 6: cholesteryl hemisuccinate

Bio-Science Corp. (Buckinghamshire, UK). Supercoiled pBR322 plasmid dsDNA was obtained from Takara Bio Inc. (Kyoto, Japan). All other reagents were of analytical grade and were purchased from Nacalai Tesque, Ltd (Kyoto, Japan).

### Enzymes

Pol  $\alpha$  was purified from the calf thymus by immuno-affinity column chromatography, as described by Tamai et al. [13]. Recombinant rat pol  $\beta$  was purified from *E. coli* JM $\beta$ 5, as described by Date et al. [14]. The human pol  $\gamma$  catalytic gene was cloned into pFastBac, and histidine-tagged enzyme was expressed using the BAC-TO-BAC HT Baculovirus Expression System according to the supplier's manual (Life Technologies, MD, USA) and purified using ProBoundresin (Invitrogen Japan, Tokyo, Japan) [15]. Human pols  $\delta$  and  $\epsilon$  were purified by the nuclear fractionation of human peripheral blood cancer cells (Molt-4) using the second subunit of pols  $\delta$  and  $\epsilon$ -conjugated affinity column chromatography, respectively [16]. Recombinant human His-pol  $\lambda$  was overexpressed and purified according to a method described by Shimazaki et al. [17]. Fish pol  $\delta$  was purified from the testis of cherry salmon (*Oncorhynchus masou*) [18]. Fruit fly pols  $\alpha$ ,  $\delta$  and  $\epsilon$  were purified from early embryos of *Drosophila melanogaster*, as described by Aoyagi et al. [19, 20]. Pols I ( $\alpha$ -like) and II ( $\beta$ -like) from a higher plant, cauliflower inflorescence, were purified according to the methods outlined by Sakaguchi et al. [21]. The Klenow fragment of pol I from *E. coli* was purchased from Worthington Biochemical Corp. (Freehold, NJ, USA). *Taq* pol, T4 pol, T7 RNA polymerase

and T4 polynucleotide kinase were purchased from Takara (Kyoto, Japan). Bovine pancreas deoxyribonuclease I was obtained from Stratagene Cloning Systems (La Jolla, CA, USA). Purified human placenta topoisomerase I and II were purchased from TopoGen, Inc. (Columbus, OH).

### DNA Polymerase Assays

The reaction mixtures for pol  $\alpha$ , pol  $\beta$ , plant pols and prokaryotic pols have been described previously [22, 23], and those for pol  $\gamma$ , and pols  $\delta$  and  $\epsilon$  were as described by Umeda et al. [15] and Ogawa et al. [24], respectively. The reaction mixture for pol  $\lambda$  was the same as that for pol  $\beta$ . For pols, poly(dA)/oligo(dT)<sub>12–18</sub> (A/T = 2/1) and dTTP were used as the DNA template-primer and nucleotide (i.e., 2'-deoxyribonucleotide 5'-triphosphates, dNTP) substrate, respectively.

The cholesterol derivatives (i.e., compounds 1–6) were dissolved in dimethyl sulfoxide (DMSO) at various concentrations and sonicated for 30 s. Aliquots of 4  $\mu$ l of sonicated samples were mixed with 16  $\mu$ l of each enzyme (final amount 0.05 units) in 50 mM Tris-HCl (pH 7.5) containing 1 mM dithiothreitol, 50% glycerol and 0.1 mM EDTA, and kept at 0 °C for 10 min. These inhibitor-enzyme mixtures (8  $\mu$ l) were added to 16  $\mu$ l of each of the enzyme standard reaction mixtures, and incubation was carried out at 37 °C for 60 min, except for *Taq* pol, which was incubated at 74 °C for 60 min. Activity without the inhibitor was considered 100%, and the remaining activity at each concentration of the inhibitor was determined relative to this value. One unit of pol activity was defined as the amount of enzyme that catalyzed the incorporation of 1 nmol of dNTP (i.e., dTTP) into synthetic DNA template-primers within 60 min at 37 °C under the normal reaction conditions for each enzyme [22, 23].

### Measurement of DNA Topoisomerase Activity

The catalytic activity of topo I was determined by detecting supercoiled plasmid DNA (i.e., form I) in its nicked form (i.e., form II) [25]. The topo I reaction was performed in 20  $\mu$ l of reaction mixture containing 10 mM Tris-HCl (pH 7.9), pBR322 DNA (250 ng), 1 mM EDTA, 150 mM NaCl, 0.1% bovine serum albumin (BSA), 0.1 mM spermidine, 5% glycerol, 2  $\mu$ l of DMSO dissolved cholesterol-related compounds (i.e., compounds 1–6), and 2 units of topo I. The catalytic activity of topo II was analyzed in the same manner except that the reaction mixture contained 50 mM Tris-HCl (pH 8.0), 120 mM KCl, 10 mM MgCl<sub>2</sub>, 0.5 mM ATP, 0.5 mM DTT, supercoiled pBR322 DNA (250 ng) and 2 units of topo II [25]. The reaction mixtures were incubated

at 37 °C for 30 min, followed by 1% SDS and 1 mg/ml proteinase K digestion, and then 2  $\mu$ l of loading buffer was added, consisting of 5% sarkosyl, 0.0025% bromophenol blue and 25% glycerol. To study the binding of enzyme and DNA based on mobility shifts, SDS denaturation and proteinase K digestion were omitted. The mixtures were subjected to 1% agarose gel electrophoresis in TBE buffer. Agarose gel was stained with ethidium bromide (EtBr) and the DNA was visualized under UV light.

### Other Enzyme Assays

The primase activity of pol  $\alpha$ , the activities of T7 RNA polymerase, T4 polynucleotide kinase and bovine deoxyribonuclease I were measured by standard assays according to the manufacturer's specifications, as described by Tamiya-Koizumi et al. [26], Nakayama et al. [27], Soltis et al. [28], and Lu and Sakaguchi [29], respectively.

### Investigation of Cytotoxicity on Cultured Cells

To investigate the effects of cholesterol derivatives (i.e., compounds 1–6) on cultured cells, human blood corpuscle cells, derived from a cancer patient, such as promyelocytic leukemia cell line HL-60 and acute T lymphoblastic leukemia cell line Molt-4, and normal peripheral blood mononuclear cells (HPBMC) were used. HL-60 cells (IFO 50022) and Molt-4 cells (IFO 50362) were supplied by the Health Science Research Resources Bank (Osaka, Japan). HPBMC was obtained from Dainippon Sumitomo Pharma Co. Ltd (Osaka, Japan). The cells were routinely cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum, 100  $\mu$ g/ml streptomycin, 100 unit/ml penicillin, and 1.6  $\mu$ g/ml NaHCO<sub>3</sub>. They were cultured at 37 °C in standard medium in a humidified atmosphere of 5% CO<sub>2</sub>-95% air. The cytotoxicity of the compounds was investigated as follows. High concentrations (10 mM) of the compounds were dissolved in DMSO and stocked. Approximately  $1 \times 10^4$  cells per well were inoculated in 96-well micro plates, and then the compound stock solution was diluted to various concentrations and applied to each well. After incubation for 24 h, the survival rate was determined by MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) assay [30] and trypan blue stain method [31].

### Cell Cycle Analysis

The cellular DNA content for cell cycle analysis was determined as follows: Aliquots of  $3 \times 10^5$  HL-60 cells were harvested into a 35-mm dish, and incubated with

medium containing compounds **2**, **3** and **6** for various times. The cells were then washed with ice-cold PBS three times by centrifugation, fixed with 70% (v/v) ethanol, and stored at  $-20^{\circ}\text{C}$ . DNA was stained with PI (3,8-diamino-5-[3-(diethylmethylammonio)propyl]-6-phenylphenanthridinium diiodide) staining solution for at least 10 min at room temperature in the dark. Fluorescence intensity was measured by FACSCanto flow cytometer in combination with FACSDiVa software (BD (Becton, Dickinson and Company), NJ, USA).

## Results

### Effects of Cholesterol Derivatives on Mammalian DNA Polymerases $\alpha$ , $\beta$ and $\lambda$

The chemical structures of cholesterol (compound **1**) and its related compounds (i.e., compounds **2–6**), which were commercially available, are shown in Fig. 1. First, the inhibitory activity of calf pol  $\alpha$ , rat pol  $\beta$  and human pol  $\lambda$  against 100  $\mu\text{M}$  of each compound was investigated (Fig. 2). In mammalian pols, pol  $\alpha$  and pols  $\beta$  and  $\lambda$  were used as representative replicative pols and repair/recombination-related pols, respectively [2, 3]. Compounds **2** and **6** significantly inhibited the activities of these pols, and the other compounds had no influence on the activities of

**Fig. 2** Effect of cholesterol derivatives on the activities of mammalian pols. One hundred  $\mu\text{M}$  of each compound and aphidicolin was incubated with calf pol  $\alpha$ , rat pol  $\beta$  and human pol  $\lambda$  (0.05 units each). Pol activities were measured as described in the “Materials and Methods” section. Enzymatic activity in the absence of the compound was taken as 100%. Data are the mean  $\pm$  SEM of three independent experiments

mammalian pols, although compounds **4** and **5**, which consist of one halogen atom, slightly inhibited pol  $\lambda$  activity. As a positive control, we measured the inhibition of these pol activities using the same concentration (i.e., 100  $\mu\text{M}$ ) of aphidicolin, which is a known inhibitor of replicative pols  $\alpha$ ,  $\delta$  and  $\epsilon$ , and the inhibitory effect on pol  $\alpha$  of compounds **2** and **6** was stronger than that of aphidicolin. Compound **2** showed the strongest inhibition of pols  $\alpha$ ,  $\beta$  and  $\lambda$  activities in the tested compounds, and 50% inhibition was observed at doses of 2.8, 1.7 and 0.84  $\mu\text{M}$ , respectively (Table 1). When activated DNA (i.e., DNA digested by bovine deoxynuclease I) was used as the DNA template-primer instead of poly(dA)/oligo(dT)<sub>12–18</sub> (A/T = 2/1), the mode of inhibition by these compounds did not change (data not shown).

### Effects of Cholesterol Derivatives on Human DNA Topoisomerases I and II

We next, as the secondary screening for DNA metabolic enzyme inhibition, investigated the inhibitory effects of compounds **1** to **6** against human topoisomerase I and II, which have single-stranded and dsDNA nicking activity, respectively [4]. As shown in Fig. 3a, 100  $\mu\text{M}$  of compounds **2** and **6** significantly inhibited the activity of topo I, and  $\text{IC}_{50}$  values were 7.5 and 25.0  $\mu\text{M}$ , respectively (Table 1). These results suggested that the inhibitory activity of these cholesterol-related compounds between mammalian pols and human topo I had the same tendency (Fig. 2). On the other hand, topo II inhibition was shown by 100  $\mu\text{M}$  of compounds **2**, **3** and **6**, and the other compounds, **1**, **4** and **5** were not affected (Fig. 3b). Camptothecin and etoposide, which are known topo I and topo II inhibitors, respectively, also inhibited the nicking activities of topoisomerases I and II with  $\text{IC}_{50}$  values of 85 and 70  $\mu\text{M}$ , respectively (Fig. 3). These findings showed that compounds **2** and **6** were stronger inhibitors of topo I than camptothecin, and compounds **2** and **3** were stronger inhibitors of topo II than etoposide.

### The Effects of Cholesterol Derivatives on Various DNA Polymerases and other DNA Metabolic Enzymes

Compound **2** inhibited the activities of mammalian pols tested (i.e., pols  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\epsilon$  and  $\lambda$ ), with an  $\text{IC}_{50}$  value of 0.84–9.1  $\mu\text{M}$  (Table 1). The pol  $\lambda$  inhibitory effect of compound **2** was the strongest in mammalian pols. Compound **6** also had inhibitory effects against the mammalian pols tested, and selectively inhibited pols  $\beta$  and  $\lambda$ , which are family X pols [32, 33], with  $\text{IC}_{50}$  values of 2.9 and 6.3  $\mu\text{M}$ , respectively (Table 1). This compound moderately suppressed the activities of the pol A family (i.e., pol  $\gamma$ )

**Table 1** IC<sub>50</sub> values of cholesterol derivatives for the activities of various DNA polymerases and other DNA metabolic enzymes

Enzyme	IC <sub>50</sub> values of compounds (μM)					
	1	2	3	4	5	6

Compound 1: cholesterol, Compound 2: sodium cholesteryl sulfate, Compound 3: cholesteryl-5 $\alpha$ , 6 $\alpha$ -epoxide, Compound 4: cholesteryl chloride, Compound 5: cholesteryl bromide, Compound 6: cholesteryl hemisuccinate

These compounds were incubated with each enzyme. Enzymatic activity was measured as described in "Materials and Methods". Enzyme activity in the absence of the compounds was taken as 100%

and pol B family (i.e., pols  $\alpha$ ,  $\delta$  and  $\epsilon$ ) [32], and 50% inhibition was observed at concentrations of 131 and 89.2–148  $\mu$ M, respectively. The inhibitory effect of compound 2 on mammalian pols was stronger than that of compound 6.

Furthermore, compounds 2 and 6 inhibited animal pols from fish (cherry salmon) pol  $\delta$ , and insects (fruit fly) pols  $\alpha$ ,  $\delta$  and  $\epsilon$  at almost the same concentration as the inhibition of mammalian pols (Table 1). On the other hand, these compounds had no significant influence on the activities of pols I ( $\alpha$ -like pol) and II ( $\beta$ -like pol) from plants (cauliflower) and prokaryotes such as the Klenow fragment of *E. coli* pol I, *Taq* pol and T4 pol.

In the DNA metabolic enzymes tested, the activities of human topoisomerase II were inhibited by not only compounds 2 and 6, but also compound 3, and the order of the inhibitory effect was as follows: compound 2 > compound 3 > compound 6 (Table 1). These compounds did not influence the activities of the other DNA metabolic enzymes tested, including calf primase of pol  $\alpha$ , T7 RNA

polymerase, T4 polynucleotide kinase and bovine deoxyribonuclease I.

To determine whether the inhibitor resulted in binding to DNA or the enzyme, the interaction of compounds 2, 3 and 6 with dsDNA was investigated based on the thermal transition of dsDNA with or without the compound. The T<sub>m</sub> of dsDNA with an excess amount of each compound (100  $\mu$ M) was measured using a spectrophotometer equipped with a thermoelectric cell holder. In the concentration range used, no thermal transition of T<sub>m</sub> was observed, whereas ethidium bromide used as a positive control, a typical intercalating compound, produced clear thermal transition. These observations indicated that these compounds did not intercalate to DNA as a template-primer, and the compound might directly bind to the enzyme and inhibit its activity.

Furthermore, we studied the mechanism of the inhibitory effect of cholesterol derivatives on human cancer cells.

**Fig. 3** Effect of cholesterol derivatives on human topoisomerase I and II. **a** topoisomerase I and **b** topoisomerase II. Supercoiled plasmid DNA was mixed with the enzyme and 100  $\mu$ M of compounds **1–6**, and camptothecin and etoposide dissolved in DMSO (lanes 3–8, and 11 and 12, respectively). Lanes 1–2 and 9–10, no compounds. Lanes 2–8 and 10–12, 2 units of topoisomerase enzyme; lanes 1 and 9, no enzyme. Plasmid DNA of 0.25  $\mu$ g was added to each of the lanes. Photographs of ethidium bromide-stained gels are shown

### Effects of Cholesterol Derivatives on Cultured Human Cancer Cells

Pols and topoisomerases have recently emerged as important cellular targets for chemical intervention in the development of anti-cancer agents. Cholesterol and its related compounds (i.e., compounds **1–6**) could, therefore, be useful in chemotherapy and we investigated the cytotoxic effect of six compounds against three cultured cells of human blood corpuscles, two human leukemia cell lines, HL-60 and Molt-4, and HPBMC. HL-60 is a mutant cell line, which has a p53 gene deletion, and Molt-4 is a normal cell line, which has a p53 gene. As shown in Fig. 4a, 50 and 100  $\mu$ M of compound **2** had the strongest growth inhibitory effect on HL-60 cancer cell line in the tested compounds, and compounds **3** and **6** were the second strongest, and cell proliferation was not influenced by the other compounds. The suppression of cell growth had the same tendency as the inhibition of topoisomerase II among the compounds (Fig. 3b), suggesting that the cause of cancer cell influence might be the activity of topoisomerase II. On the other hand, the same concentrations of aphidicolin, camptothecin and

etoposide, which are inhibitors of replicative pols, topoisomerase I and topoisomerase II, respectively, completely suppressed the growth of HL-60 cells (Fig. 4a).

The influence of compounds **1–6** on Molt-4 cell growth showed the same tendency as that on HL-60 cells, and the cell growth effect on the HL-60 cell line had almost the same cytotoxicity as that on the Molt-4 cell line (Fig. 4b), suggesting that p53 protein expression had no relation to cell growth inhibition by cholesterol derivatives, which are selective inhibitors of pols and topoisomerases. The normal blood corpuscle cell line, HPBMC, was not influenced the growth by these compounds (Fig. 4c). As a result, compounds **2**, **3** and **6** could selectively inhibit the growth of human cancer cells, and could be come anti-cancer drugs.

Therefore, we concentrated our efforts on compounds **2**, **3** and **6**, and aphidicolin (a representative pol inhibitor) and etoposide (a representative topoisomerase inhibitor) against HL-60 cells in the latter part of this study. Compounds **2**, **3** and **6**, aphidicolin and etoposide suppressed HL-60 cell growth in a dose-dependent manner, and 50% cytotoxicity of these compounds was observed at doses of 8.8, 20.2, 72.3, 7.0

**Fig. 4** Effect of cholesterol derivatives on the proliferation of human cultured blood corpuscle cell growth. Each compound (50 and 100  $\mu$ M) was added to the culture of a leukemia cell line HL-60 (a) and Molt-4 (b), and normal peripheral blood mononuclear cells (HPBMC) (c). The cells were incubated for 24 h, and the rate of cultured cell growth inhibition was determined by MTT assay [30] for cancer cells (i.e., HL-60 and Molt-4) and by trypan blue stain method [31] for HPBMC. Cell growth inhibition of the cancer cells in the absence of the compound was taken as 100%. Data are the mean  $\pm$  SEM of five independent experiments

#### Effects on the Cell Cycle Progression of Compounds 2, 3 and 6

Next, we analyzed whether compounds 2, 3 and 6 affected the cell cycle distribution of each compound-treated cell. The cell cycle fraction was recorded after 6, 12 and 24 h of treatment with the LD<sub>50</sub> value of each compound, and the ratio of the four phases (i.e., sub-G1, G0/G1, S and G2/M) in the cell cycle is shown in Fig. 5. Consequently, among cells treated with compound 2 for time-dependent incubation, the population of cells in the S and G2/M phases increased (1.3- and 2.8-fold increase of S and G2/M phases for 24 h incubation, respectively), and the percentage of cells in the G1 phase significantly, 2.0-fold, decreased for 24 h (Fig. 5a). The cell cycle effect of compound 6 had the same tendency as that of compound 2 (Fig. 5b). Aphidicolin, which is a replicative polys (i.e., polys  $\alpha$ ,  $\delta$  and  $\epsilon$ ) inhibitor, moderately arrested the cell cycle in the S phase (Fig. 5d), and etoposide, which is a classical topo II inhibitor, 4.6-fold strongly arrested the cell cycle in the G2/M phase (Fig. 5e). Compounds 2 and 6, therefore, might be effective in the inhibition of both polys and topoisomerases for the incubation of cells, because these compounds inhibited the activities of mammalian polys and human topoisomerases, and the inhibitory effect on polys was the almost same as that on topoisomerases in vitro (Table 1). On the other hand, compound 3 led to an increase in the population of HL-60 cells in the G2/M phase (6.4–24.2%), to decrease the population of cells in the G1 phases (65.0–32.8%), and the S phase was hardly affected (25.9–29.4%) for 24 h (Fig. 5b), suggesting that this compound arrested the G2/M phase in the cells by inhibition of topoisomerase II. These results indicated that the cell cycle arrest of cancer cells by cholesterol derivatives might be affected by the inhibitory activities of both polys and topoisomerases.

and 1.5  $\mu$ M, respectively, after 24 h of treatment. These results showed that the LD<sub>50</sub> value in vivo of compounds 2, 3 and 6 on HL-60 cells was almost the same as IC<sub>50</sub> values in vitro on polys and/or topoisomerases.

We investigated in more detail which inhibition by these compounds is effective for cancer cell proliferation, that of polys or topoisomerases.

As shown in Fig. 5, all compounds tested, which inhibited the activities of polys and/or topoisomerases, also time-dependently increased the sub-G1 phase (i.e., the rate of DNA fragmentation in HL-60 cells) in the cell cycle. The findings suggested that these compounds induced DNA fragmentation in the cells, and the effect of the compounds must involve a combination of growth arrest and cell death. These cholesterol derivatives, therefore, should be

**Fig. 5** The effect of compounds **2**, **3** and **6** on the cell cycle. HL-60 cells were incubated with 8.8  $\mu\text{M}$  of compound **2** (a), 20.2  $\mu\text{M}$  of compound **3** (b), 72.3  $\mu\text{M}$  of compound **6** (c), 7  $\mu\text{M}$  of aphidicolin (d) and 1.5  $\mu\text{M}$  of etoposide (e) for 0, 6, 12 and 24 h. Cell cycle distribution was calculated as the percentage of cells in sub-G1, G0/G1, S and G2/M phases. All experiments were performed three times

considered the lead compound in potentially useful cancer chemotherapy agents.

## Discussion

As described in this report, we found that some cholesterol derivatives, such as sodium cholesteryl sulfate (compound **2**), cholesteryl-5 $\alpha$ , 6 $\alpha$ -epoxide (compound **3**), and cholesteryl hemisuccinate (compound **6**), inhibited the activities of DNA metabolic enzymes, such as pols and/or topos, and also suppressed human cancer cell

growth (Figs. 2–4, Table 1). In particular, compounds **2** and **6** might be potent and selective inhibitors of animal pols and topos, and compound **3** could be a specific inhibitor of human topo II. The suppression of cell growth had the same tendency as the inhibition of topo II rather than pols and topo I among the cholesterol derivatives, suggesting that the cause of cancer cell influence might be the activity of topo II. To analyze the cell proliferation and growth of topo II in cancer cells, studies on the effects of small interfering RNAs (siRNA) of topo II-treated cells are now underway in our laboratory.

**Table 2** Clog *P* values and calculated p*K*<sub>a</sub> values of cholesterol derivatives

Compound	Clog <i>P</i>	p <i>K</i> <sub>a</sub>

Compound **1**: cholesterol, Compound **2**: sodium cholesteryl sulfate, Compound **3**: cholesteryl-5 $\alpha$ , 6 $\alpha$ -epoxide, Compound **4**: cholesteryl chloride, Compound **5**: cholesteryl bromide, Compound **6**: cholesteryl hemisuccinate

Unless otherwise noted, both the Clog *P* values and p*K*<sub>a</sub> values of compounds **1–6** were obtained from the calculated properties in SciFinder Scholar, which were originally calculated using Advanced Chemistry Development (ACD/Lab) Software V8.14 for Solaris (ACD/Labs)

ND: not detected

We focused on the calculated log *P* (Clog *P*) value (partition coefficients for octanol/water) and p*K*<sub>a</sub> of the cholesterol derivatives as chemical properties (Table 2). The values of Clog *P*, which indicate hydrophobicity, in compounds **1–6** were almost in the same range (8.07–11.71). Since compounds **2** and **6** inhibited the activities of mammalian and fish pols and human topo I in the cholesterol derivatives tested (Table 1, Figs. 2, 3a), the low p*K*<sub>a</sub> value of the compounds must be important for inhibition. These findings suggested that acidic moieties, such as sulfate and hemisuccinate groups, could be essential, and did not influence the hydrophobicity of the compound in inhibition. In particular, compound **2** showed the strongest inhibition in the tested compounds, and it was revealed that the inhibition of pols and topos activities by compound **2** influenced not only cell proliferation but also the cell cycle. These observations indicated that the sulfate group of compound **2** might be important for inhibition. Djuric et al. [34] reported that compound **2** had little effect on the proliferation of both MCF-7 and MCF-10 cells, which are human breast tumor cell line and human normal-like human breast cell line, respectively, and the different data between their report and our results may be the different species of human cancer cell lines. The more detailed mechanism by which compound **2** inhibits cell growth will be addressed in further studies.

Cholesterol is a lipid partly provided by the diet, although only about 20–25% of human body cholesterol comes from food, the rest being made by the body itself [11]. A person of average weight will have rather more than 100 g of cholesterol in their body and the body makes about 700 mg of cholesterol each day. The actual amount varies with the individual and also with the amount

received from food. If the amount supplied in the diet is reduced, the body compensates by making more for itself. The body normally has more cholesterol than it needs and some of the excess is made into bile salts, which help with the digestion of fat. It is this excess cholesterol in the body which some consider harmful in relation to coronary heart disease, gallstones, and cancer.

In the human body, cholesterol derivatives such as cholesteryl sulfate (compound **2**) and cholesteryl-5 $\alpha$ , 6 $\alpha$ -epoxide (compound **3**) were produced by cholesterol sulfotransferase [35] and autoxidation [12], respectively. Compound **2** is a second messenger of the  $\eta$  isoform of protein kinase C mediating squamous differentiation, and inhibits the tumor promotional phase in mouse skin carcinogenesis [35]. Detailed studies on the action mechanism of the inhibition between tumor promotion and pols/topos activities are currently being undertaken. Compound **2** is present at approximately 300  $\mu$ g/100 ml (i.e., 6.1  $\mu$ M) in human body [36], and this concentration is almost the same inhibitory dose in pols/topos activities and cancer cell growth. This finding suggests that the results in this in vitro report may directly influence anti-cancer effects in the in vivo human body. Since synthesized derivatives from cholesterol in the body may possible work in anti-cancer activity, a diet containing cholesterol prevents cancer disease.

**Abstract** Cholesterol oxidation products (COPs) have been considered as specific *in vivo* markers of oxidative stress. In this study, an increased oxidative status was induced in Wistar rats by feeding them a high-fat diet (cafeteria diet). Another group of animals received the same diet supplemented with a combination of two different antioxidants, ascorbic acid (100 mg/kg rat/day) and sodium selenite (200 µg/kg rat/day) and a third group fed on a control diet. Total and individual COPs analysis of the different diets showed no differences among them. At the end of the experimental trial, rats were sacrificed and serum cholesterol, triglycerides and COPs were measured. None of the diets induced changes in rats body weight, total cholesterol and triglycerides levels. Serum total COPs in rats fed on the high-fat diet were 1.01 µg/ml, two times the amount of the control rats (0.47 µg/ml). When dietary antioxidant supplementation was given, serum total COPs concentration (0.44 µg/ml) showed the same levels than those of the rats on control diet. 7β-hydroxycholesterol, formed non-enzymatically via cholesterol peroxidation in the presence of reactive oxygen species, showed slightly lower values in the antioxidant-supplemented animals compared to the control ones. This study confirms the importance of dietary antioxidants as protective factors against the formation of oxysterols.

**Keywords** Antioxidants · Ascorbic acid · Cafeteria diet · COPs · Lipid oxidation

### Introduction

Cholesterol is an unsaponifiable lipid prone to oxidation by reactive oxygen species (ROS), light, UV light, ionizing radiation, chemical catalysts, enzymatic reactions and other oxidizing conditions, leading to the formation of cholesterol oxidation products (COPs) [1–2]. Some studies have pointed out that COPs can be absorbed from the diet in rats [3–6].

It has been demonstrated that COPs may produce a wide range of adverse biological outcomes including cytotoxicity, apoptosis, mutagenesis, carcinogenesis, diabetes and metabolic disorders, their main negative effect being the development of atherosclerosis [7–13]. Also, it has been shown that the presence of COPs in diet promotes fatty streak lesion formation in several different animal models of atherosclerosis [6].

In this context, certain oxysterols, 7β-hydroxycholesterol and 7-ketocholesterol, have been suspected not only as oxidative stress inducers, which are associated with an increase in the risk of atherosclerosis [14–16] but also as specific markers of oxidative stress [17]. There is evidence that oxidized lipoproteins play a key role in the pathogenesis of atherosclerosis and especially both oxysterols are found at significantly increased levels in atherosclerotic lesions [14, 18–20].

The endogenous formation of oxysterols in relation to the influence of the type of diet and the consumption of antioxidants has hardly been studied so far [21–22]. Some data suggest that a greater intake of antioxidative vitamins such as vitamin E, vitamin C and β-carotene are associated with a reduced risk of atherosclerotic vascular disease [23], which may happen through different mechanisms such as inhibition of LDL oxidation, cell lipid peroxidation and cell-mediated oxidation of LDL and reduction in blood cholesterol levels [24]. In this sense, ascorbic acid could limit lipid

M. Menéndez-Carreño · D. Ansorena (✉) · F. I. Milagro · J. Campión · J. A. Martínez · I. Astiasarán

e-mail: dansorena@unav.es

peroxidation, protecting partially oxidized LDL against further oxidative modification [25]. On the other hand, selenium is known to play an important role in cytoprotection against cholesterol oxide-induced vascular damage in the vascular wall of rats [26]. Combinations of selenium and vitamin E have been shown to contribute to protection of the vascular endothelium and to control the oxidative status and altered lipid metabolism in the liver [27–28]. No data have been found about the combination of selenium and vitamin C.

In this article, we hypothesized that the dietary intake of a combination of two different antioxidants (ascorbic acid and selenium) could prevent cholesterol oxide formation in rats fed on a high-fat diet.

## Materials and Methods

### Animals, Diets and Experimental Design

Male Wistar rats, supplied by the Applied Pharmacobiology Center (CIFA, Pamplona, Spain), were housed at 21–23 °C with a 12 h light cycle (8:00 a.m. to 8:00 p.m.) and assigned into three different dietary groups. One group of animals (Control group, C) were fed a standard pelleted diet (Harlan Iberica, Barcelona, Spain) containing 16.62% of the energy as protein, 73.16% of the energy as carbohydrate and 10.22% of the energy as lipids by dry weight. The second group of animals (Cafeteria, Caf) was fed on a high-fat diet in order to generate a diet-induced obesity model as previously reported [29]. High-fat diet components were *paté*, bacon, chips, cookies, chocolate and chow with proportions 2:1:1:1:1:1 and the diet was given to each rat daily. The composition of this Cafeteria diet was 9.26% of the energy as protein, 31.58% of the energy as carbohydrates and 59.15% of the energy as lipids by dry weight (430 kcal/100 g in the Cafeteria diet vs. 350 kcal/100 g in the pelleted diet). Cafeteria diet was supplemented in a third group of animals (Caf + Aox) with a daily dose of vitamin C (100 mg/kg rat) + sodium selenite (200 µg/kg rat) both mixed into the food. Animals had *ad libitum* access to water and food during the experimental trial. Body weight was recorded daily. At the end of the experimental period (72 days), animals were sacrificed by decapitation and blood and tissue samples were immediately collected and weighed. All the procedures were performed according to national and institutional guidelines of the Animal Care and Use Committee at the University of Navarra.

### Diet Composition

Moisture was determined according to the Association of Official Analytical Chemists (AOAC) method [30]. Total fat

was determined by an extraction with petroleum ether according to the AOAC [31]. Protein was analyzed using the Kjeldahl method for the determination of nitrogen [32], using 6.25 as the factor to transform nitrogen into protein. Ash was determined by incineration using the method of the AOAC [33]. Quantitative fat extraction was made with a chloroform–methanol mixture using the method of Folch et al. [34]. Cholesterol content was analyzed by gas chromatography according to Kovacs et al. [35]. Derivatization to obtain the trimethyl silyl ethers of cholesterol was performed. A Perkin-Elmer Autosystem XL gas chromatograph equipped with an HP1 column (30 m × 0.25 mm × 0.1 µm) was used. The oven temperature was 265 °C. The temperature of both the injection port and detector was 285 °C. Cholesterol identification and quantitation was done by using pure 5 $\alpha$ -cholestane (Sigma, St Louis, MO, USA) as an internal standard, where 1 ml was added to the sample as a solution (2 mg/ml), previously to the extraction procedure. A Perkin-Elmer Turbochrom programme was used for quantitation. COPs determination in diets was performed using 0.5 g of the Folch extract of the correspondent diet adding 1 ml of 19-hydroxycholesterol (20 µg/ml) as internal standard. Ten milliliters of 1 N KOH solution in methanol were then added to perform a cold saponification at room temperature for 20 h, in darkness and under continuous agitation in an orbital shaker (Rotaterm P; Selecta, Barcelona) at 100 rpm. The unsaponifiable material was extracted with diethyl ether and purified by silica SPE according to Guardiola et al. [36]. COPs were finally eluted from the cartridge with acetone. Samples solutions of COPs were derivatized to trimethylsilyl (TMS) ethers according to a modified version of the method described by Dutta et al. [38]. After drying the solvent, 400 µl of Tri-Sil reagent were added and the tubes were kept at 60 °C for 45 min. The solvent was evaporated under a stream of nitrogen and the TMS-ether derivatives were dissolved in 400 µl of hexane. Dissolved samples were filtrated prior to GC-MS analysis in order to avoid damage to the capillary column. Gas chromatography-Mass spectrometry analysis was performed on a CG 6890N Hewlett Packard device coupled to a 5975 Mass Selective Detector (Agilent Technologies, Inc., CA, USA). The TMS-ether derivatives of COPs were separated on a capillary column Varian VF-5ms CP8947 (50 m × 250 µm × 0.25 µm film thickness) (Varian, France). Oven temperature conditions were optimized in order to achieve a proper separation of the individual compounds. The oven was programmed with an initial temperature of 75 °C, heated to 250 °C at a rate of 30 °C/min, raised to 290 °C at rate of 8 °C/min, and finally, it was raised to 292 °C at a rate of 0.05 °C/min. High purity helium was used as the carrier gas at a flow rate of 1 ml/min. The inlet pressure used was 13.40 psi. The injector temperature was 250 °C and the transfer line to detector at 280 °C. The samples were

injected in a splitless mode with an injection volume of 1  $\mu$ l. The mass spectrometer was operated in electron impact ionization (70 eV). Identification of the peaks was made by the characteristic ion fragmentation of the standard substances and the quantification was made using select ion monitoring program using the internal standard method.

### Serum Measurements

Serum triacylglycerides were determined with the RAN-DOX kit (Randox Laboratories LTD, UK) and cholesterol level with the Cholesterol-CP kit (Haribo, ABX diagnostic, Montpellier, France). All these measurements were adapted for COBAS MIRA equipment (Roche, Switzerland). COPs in serum were analyzed following the method described in Menéndez-Carreño et al. (in press) [37]. Lipids from serum were extracted from serum according to a modified version of the method described by Folch et al. [34] using chloroform–methanol (2:1; v/v). One milliliter of serum was introduced into a centrifuge tube, and 6 ml of chloroform and 3 ml of methanol were added. After shaking on vortex for 1 min, samples were then centrifuged at 4,000 rpm for 15 min to facilitate phase separation using a Hermle Z320 centrifuge (Apeldoorn, The Netherlands). The chloroform (lower) layer was transferred to a test tube taking care of not transferring any solid material which remains at the interface between the upper and lower phases. Ten milliliters of 1 N KOH solution in methanol and 1 ml of stock solution of the internal standard, 19-hydroxycholesterol (20  $\mu$ g/ml), were then added to perform a cold saponification at room temperature for 20 h, in darkness and under continuous agitation in an orbital shaker (Rotatorm P; Selecta, Barcelona) at 100 rpm. A total of 100 mg/kg of butylhydroxytoluene was added as an antioxidant in order to avoid COPs artifact formation during the saponification. The extraction of the unsaponifiable material, the purification and further analysis of COPs was exactly the same as explained above for the determination of COPs in diets.

### Statistical Analysis

All results are expressed as means  $\pm$  standard deviations of the mean. The differences between the groups were evaluated by one-way ANOVA, and Tukey post hoc test was applied when suitable (SPSS 15.0 packages for Windows, Chicago, IL, USA). A level of probability of  $p < 0.05$  was set as being statistically significant. A Pearson correlation test was performed between COPs content in the diets and in the serum samples.

### Results

Control (C) and cafeteria diets (Caf and Caf + Aox diets) presented different macronutrient profiles, as shown in Table 1, especially in relation to the fat content, seven times higher in cafeteria diets. This diverse macronutrient distribution of the diets led to 20% more energy in both high-fat diets in comparison to the standard one. Regarding the cholesterol content, it was significantly lower in chow diet than in the two cafeteria ones, and a similar trend was detected for the COPs content, being 7.5 times higher in the cafeteria diets. Analyzing specifically oxysterols, 7-ketocholesterol was the main oxysterol in all the three diets (Table 2), being less abundant in the control one and more abundant in the cafeteria diets.

These results led to percentages of cholesterol oxidation significantly higher in C (0.68%) than in Caf and Caf + Aox diets, which did not show significant differences between them (0.25 and 0.24%, respectively). However, the total oxysterol content of the diet was much higher in both cafeteria diets with no differences between them, suggesting that the antioxidant supplementation of the diet does not affect the amount of oxysterols ingested.

Whereas the body weight of the animals at the beginning of the experimental trial was similar within the three groups, the two groups fed on cafeteria diets gained significantly more weight than rats fed chow pellets (Table 3).

**Table 1** General composition (g/100 g) and energy value (kcal/100 g) for the three tested diets

	Control diet (C)	Cafeteria diet (Caf)	Cafeteria selenium vitamin C diet (Caf + Aox)
Moisture (g/100 g)	12.13 $\pm$ 0.10 a	25.55 $\pm$ 0.10 b	25.33 $\pm$ 0.04 b
Total fat (g/100 g)	4.03 $\pm$ 0.4 a	28.32 $\pm$ 0.14 b	28.33 $\pm$ 0.08 b
Protein (g/100 g)	14.75 $\pm$ 0.08 c	9.97 $\pm$ 0.10 a	9.98 $\pm$ 0.07 a
Carbohydrates (g/100 g)	64.93 $\pm$ 0.11 c	33.90 $\pm$ 0.17 a	34.02 $\pm$ 0.13 a
Ash (g/100 g)	4.16 $\pm$ 0.07 b	2.25 $\pm$ 0.08 a	2.35 $\pm$ 0.04 a
Energy (kcal/100 g product)	354.99 $\pm$ 0.37 a	430.45 $\pm$ 1.87 b	430.38 $\pm$ 0.84 b

Results are expressed as means  $\pm$  standard deviations,  $n = 10$ . Values in the same row bearing different letters are significantly different ( $p < 0.05$ )

**Table 2** Cholesterol content and cholesterol oxidation products of the three tested diets

	Control diet (C)	Cafeteria diet (Caf)	Cafeteria selenium vitamin C diet (Caf + Aox)
7 $\alpha$ -Hydroxycholesterol ( $\mu\text{g/g}$ fat)	0.11 $\pm$ 0.01 a	0.57 $\pm$ 0.01 b	0.55 $\pm$ 0.02 b
7 $\beta$ -Hydroxycholesterol ( $\mu\text{g/g}$ fat)	0.07 $\pm$ 0.00 a	0.44 $\pm$ 0.01 b	0.44 $\pm$ 0.03 b
5,6 $\beta$ -Epoxycholesterol ( $\mu\text{g/g}$ fat)	n.d.	1.44 $\pm$ 0.08 a	1.47 $\pm$ 0.10 a
5,6 $\alpha$ -Epoxycholesterol ( $\mu\text{g/g}$ fat)	n.d.	0.33 $\pm$ 0.02 a	0.36 $\pm$ 0.04 a
Cholestanetriol ( $\mu\text{g/g}$ fat)	0.04 $\pm$ 0.00 a	0.18 $\pm$ 0.01 b	0.21 $\pm$ 0.0 b
25-Hydroxycholesterol ( $\mu\text{g/g}$ fat)	n.d.	n.d.	n.d.
7-Ketocholesterol ( $\mu\text{g/g}$ fat)	0.47 $\pm$ 0.0 a	2.42 $\pm$ 0.11 b	2.31 $\pm$ 0.09 b
Cholesterol (mg/100g)	2.75 $\pm$ 0.15 a	58.02 $\pm$ 4.07 b	57.95 $\pm$ 5.13 b
Total COPs ( $\mu\text{g/g}$ fat)	0.70 $\pm$ 0.02 a	5.39 $\pm$ 0.11 b	5.34 $\pm$ 0.38 b
Percentage of cholesterol oxidation (%)	0.68 $\pm$ 0.02 b	0.25 $\pm$ 0.03 a	0.24 $\pm$ 0.03 a

Cholesterol and individual COPs were analyzed in quadruplicate in the three different diets. Total COPs is the sum of all individual COPs detected. Percentage of cholesterol oxidation (%) = (total COPs diet/cholesterol diet)  $\times$  100. Results are expressed as means  $\pm$  standard deviations,  $n = 10$ . Values in the same row bearing different letters are significantly different ( $p < 0.05$ )

**Table 3** Body weight changes of rats fed on three different diets

	Control diet (C)	Cafeteria diet (Caf)	Cafeteria selenium vitamin C diet (Caf + Aox)
Initial weight (g)	260.6 $\pm$ 16.4 a	263.9 $\pm$ 21.87 a	268.1 $\pm$ 21.82 a
Final weight (g)	427.6 $\pm$ 32.4 a	533.5 $\pm$ 79.78 b	512.1 $\pm$ 62.26 b
Weight gain (g)	167.0 $\pm$ 18.9 a	269.6 $\pm$ 62.65 b	244.0 $\pm$ 45.01 b

Results are expressed as means  $\pm$  standard deviations,  $n = 10$ . Values in the same row bearing different letters are significantly different ( $p < 0.05$ )

As no significant differences were found for weight gain between the two cafeteria diets and the weights of their white adipose tissue depots were similar (data not shown), we can conclude that antioxidant addition did not affect animals weight, adiposity and growth.

Regarding the analysis of serum lipid metabolites, neither total cholesterol nor triglyceride levels differed among the three groups of rats (Table 4). Although HDL-cholesterol was not measured in the C group, no differences were found between the two cafeteria-fed groups.

In this study, seven different COPs were analyzed in serum rats from the three experimental groups; 7 $\alpha$ -hydroxycholesterol, 7 $\beta$ -hydroxycholesterol, 5,6 $\beta$ -epoxycholesterol, 5,6 $\alpha$ -epoxycholesterol, cholestanetriol, 25-hydroxycholesterol and 7-ketocholesterol, but only 7 $\alpha$ -hydroxycholesterol, 7 $\beta$ -hydroxycholesterol, cholestanetriol and 7-ketocholesterol could be quantified in all the serum samples (Table 4). Cholestanetriol was detected in all the cafeteria-fed animals, but only in seven and six out of ten samples in Caf + Aox and C groups, respectively.

As a result of this dietary treatment over 72 days, the most abundant serum oxysterol in all the three groups was 7-ketocholesterol. Its levels reached 38.3% of total COPs in the case of the control group and 52.2 and 47.7% for the

Caf and Caf + Aox animals. The total amount of serum oxysterols was significantly increased in rats fed on the cafeteria diet compared to the C group, with significant increments in all the oxysterols quantified (Table 4). However, the Caf + Aox diet decreased the different serum oxysterol concentrations to the levels of the control rats, which in the case of 7 $\beta$ -hydroxycholesterol, was even significantly lower than that of the control animals.

In summary, as shown in Fig. 1, animals fed on the cafeteria diet showed a higher percentage of serum oxysterols than the control rats, indicating a pro-oxidant effect of the diet. However, the supplementation of this diet with antioxidants resulted in a normalization of the circulating oxysterol levels, demonstrating a protective effect of the supplementation that could have beneficial effects on different metabolic features related to glycemia control and atherogenesis.

## Discussion

High-fat diets have been traditionally used for generating overweight in rats, the cafeteria diet being a variation of them [29]. As a result, animals might develop obesity,

**Table 4** Lipid metabolites and cholesterol oxidation products in serum of rats fed on three different diets

	Control diet (C)	Cafeteria diet (Caf)	Cafeteria selenium vitamin C diet (Caf + Aox)
Cholesterol (mg/dl)	78.36 ± 10.15 a	79.69 ± 12.59 a	79.46 ± 12.93 a
HDL (mg/dl)	n.a.	27.59 ± 3.80 a	27.31 ± 4.35 a

insulin resistance, hyperglycemia, fatty liver, oxidative stress, and, in some cases, lipid metabolism disturbances. Our model of obesity in rats, in agreement with previous results of our own group, achieves adiposity and weight gain but does not induce fasting hypertriglyceridemia or hypercholesterolemia [29, 38].

In this study, it was found that oxidative stress was effectively induced by the high-fat diet, as the levels of total COPs were significantly higher than those of the control group. This pro-oxidant effect of the cafeteria diet has been associated with an impairment of some obesity-related features such as non-alcoholic fatty liver, diabetes and atherogenesis [39], and the supplementation of this diet with a high dose of ascorbic acid has recently been reported to protect against body weight gain and adiposity [40]. However, in this study, the diet supplementation with a lower dose of vitamin C induced no changes in body weight and adiposity during the assayed period. The use by other authors of similar or higher doses of vitamin C during long periods has shown no toxic or deleterious effects in similar animal models [41–44].

Rats fed on very high cholesterol diets usually present increased serum oxysterol levels [22]. Other studies have shown that, although a cholesterol-rich diet supplemented with vitamins E and C induces hypercholesterolemia in rabbits, it was able to reduce lipid peroxidation and lipoprotein modification [45]. Ringseis and Eder [21] pointed out that, as a consequence of antioxidant-induced inhibition of lipid peroxidation, it is reasonable to assume that the formation of COPs in animal tissues would be inhibited by these compounds, although this effect requires more studies. On the other hand, in vitro trials have demonstrated that cholesterol is susceptible to oxidation under selenium deficiency-induced oxidative stress [46]. In that study, a significant increase in the amounts of 7-hydroxycholesterol was detected due to the selenium deficiency. In fact, selenium has been widely used as an antioxidant, with doses of up to 2  $\mu$ g/g body weight in rats [47–48], and has been reported to protect from vascular damage induced by COPs [32]. The effect of dietary selenium on the reduction of COPs formation in the serum could be mediated by GSH-dependent selenoperoxidases, such as GPx, which have been implicated in the defence against oxidized low density lipoproteins [49]. In this sense, different papers showed a significant correlation between dietary selenium concentration and GPx levels [50–53].

This study also showed that the control group, which had a standard feeding, led to COPs concentrations in the serum being significantly lower than those animals fed on a high-fat diet (cafeteria group). The values for total COPs both for control and modified groups were similar to those found by Mahfouz and Kummerov [22] in rats fed on high cholesterol diets for 4 months. The cafeteria diet did not affect the total serum cholesterol and triglyceride levels as

expected, but increased the serum COPs levels. Increasing dietary vitamin C and selenium in a high-fat diet prevented the oxidation of circulating cholesterol.

Thus, the intake of the antioxidants mixture included in the cafeteria diet can efficiently decrease the oxidation process affecting cholesterol. As total cholesterol levels were not modified by the different dietary treatments, the percentage of cholesterol oxidation also showed significant differences between the cafeteria diet and the others.

One remarkable finding is the fact that serum  $7\beta$ -hydroxycholesterol levels in the Caf + Aox diet group were even slightly lower than those obtained for the control group. Ringseis and Eder [21] demonstrated that insufficient vitamin E in the diet increased the formation of  $7\beta$ -hydroxycholesterol in rats fed on salmon oil. Most of the  $7\beta$ -hydroxycholesterol is formed non-enzymatically via cholesterol peroxidation in the presence of ROS [54]. As  $7\beta$ -hydroxycholesterol is formed in the presence of ROS, it is likely influenced by the antioxidative status [21]. Yoshida et al. [55] measured  $7\alpha$ -hydroperoxycholesterol,  $7\beta$ -hydroperoxycholesterol and 7-ketocholesterol as well as  $7\alpha$ -hydroxycholesterol and  $7\beta$ -hydroxycholesterol were measured as total 7-hydroxycholesterol in samples of human plasma because their usefulness for the assessment of oxidative stress in animal and in vivo experiments. They concluded that  $7\beta$ -hydroxycholesterol may be a better biomarker for oxidative stress than  $7\alpha$ -hydroxycholesterol. As the consumption of selenium and antioxidants suppresses ROS formation by different mechanisms [56], it is reasonable to suppose that endogenous formation of  $7\beta$ -hydroxycholesterol could have been suppressed by the high intake of vitamin C and selenium. In fact, no correlation was found between the level of  $7\beta$ -hydroxycholesterol in the diet and in its content in the serum samples ( $r = 0.26$ ,  $p < 0.05$ ) pointing to an endogenous formation of this compound.

Arca et al. [57] found that familial combined hyperlipidemia patients are prone to a condition of oxidative stress, as shown by the presence of increased levels of COPs. Thus, oxidative stress should be taken into account to explain the increased cardiovascular risk in these patients. Moreover,  $7\beta$ -hydroxycholesterol and 7-ketocholesterol are biomarkers for oxidative stress in patients with atherosclerosis [17], and it has been demonstrated the interconversion of these compounds in humans [58]. 7-Ketocholesterol was the most abundant oxysterol in the three groups of rats, showing a positive correlation [ $r = 0.66$ , ( $p < 0.01$ )] with the data obtained from the diet.

In conclusion, the concentrations of oxysterols were influenced by the dietary fat, but also by the vitamin C and selenium intake. The fact that the concentration of COPs was reduced by increasing dietary vitamin C and selenium supply confirms the importance of antioxidants as a

protective factor against the formation of oxysterols from a high-fat dietary pattern.

## Erucic Acid is Differentially Taken up and Metabolized in Rat Liver and Heart

Cameron C. Murphy · Eric J. Murphy ·

**Abstract** Because X-linked adrenoleukodystrophy is treated using erucic acid (22:1n-9), we assessed its metabolism in rat liver and heart following infusion of [ $^{14}\text{C}$ ]22:1n-9 (170 Ci/kg) under steady-state-like conditions. In liver, 2.3-fold more tracer was taken up as compared to heart, accounted entirely by increased incorporation into the organic fraction (4.2-fold). The amount of tracer entering the aqueous fraction, which represents  $\beta$ -oxidation, was not different between groups; however a significantly elevated proportion of tracer was in the heart aqueous fraction. In both tissues, 76% of the radioactivity found in the organic fraction was esterified in neutral lipids, while only about 10% was found esterified into phospholipids. In liver, 56% of lipid radioactivity was found in cholesteryl esters, whereas in heart 64% was found in triacylglycerols. Because 22:1n-9 can be chain shortened, we assessed tracer metabolism using phenacyl fatty acid derivatives esterified from saponified esterified neutral lipid (triacylglycerol/cholesteryl ester) and phospholipid fractions. In heart esterified neutral lipids, 75% of tracer was recovered as 22:1n-9 and only 10% as oleic acid

(18:1n-9), while in liver only 25% of the tracer was recovered as 22:1n-9, while 50% was found as stearic acid (18:0) and 10% as 18:1n-9. In liver and heart phospholipids, the tracer was distributed amongst the n-9 fatty acid family. Thus, 22:1n-9 under went tissue selective metabolism, with conversion to 18:0 the dominant pathway in the liver presumably for export in the neutral lipids, while in heart it was found primarily as 22:1n-9 in neutral lipids and used for  $\beta$ -oxidation.

## Introduction

X-linked adrenoleukodystrophy (X-ALD) is characterized by elevated very long chain saturated fatty acids (VLCFA) in plasma [1, 2] and in tissue [2, 3]. The clinical manifestations of X-ALD include adrenal insufficiency and rapid demyelination in the central nervous system (CNS) [4]. Accompanying this demyelination is a rise in brain cholesteryl ester mass [5, 6], which is extensively esterified with 26:0 [2]. Lorenzo's oil (LO) is a dietary therapy with restricted saturated fatty acid ingestion in combination with ingestion of a triacylglycerol (TAG) form of erucic acid (22:1n-9), which effectively reduces plasma levels of VLCFA found in X-ALD patients [7–9]. Although the use of LO is controversial because early studies demonstrated the absence of 22:1n-9 from the brain of treated patients [7, 10, 11] and because of its limited effectiveness in ameliorating the progression of CNS demyelination in patients with advanced X-ALD [7–9]. Recent evidence indicates that it has a strong potential in limiting the onset of CNS demyelination following early intervention in X-ALD patients [12–14]. The lack of elevated 22:1n-9 in brains from treated X-ALD patients suggests limited uptake into the CNS, perhaps as a result of poor movement of 22:1n-9 across the blood brain barrier (BBB). Recent work from our laboratory demonstrates that 22:1n-9 crosses the BBB and is found esterified into brain esterified neutral lipid (NL) and phospholipid (PL) pools as primarily 18:1n-9 due to the rapid chain shortening of 22:1n-9 [15]. The entry and metabolism of 22:1n-9 in the brain supports the results of recent clinical trials demonstrating that LO reduces clinical symptoms of X-ALD when administered early in life [12–14].

Although we have studied the metabolism of 22:1n-9 in the brain [15], previous studies have focused on its metabolism in the heart due to its reported impact on heart physiology [16, 17]. In cultured cells, 22:1n-9 is rapidly esterified into TAG and to a lesser extent into PL pools [18–21]. Similar results are reported in isolated organs [22–25], and in intact animals [26–28]. Although 22:1n-9 is poorly oxidized to CO<sub>2</sub> [29, 30], it is quickly converted into oleic acid (18:1n-9) *in vivo* and in isolated tissues and cultured cells [15, 18, 19, 24, 26–28, 31–35]. This conversion is presumably through peroxisome localized  $\beta$ -oxidation [19, 33, 36], although a possible mitochondrial pathway for 22:1n-9 oxidation can not be excluded [26, 27]. Whole liver and liver cells are capable of converting 22:1n-9 into 18:1n-9 more efficiently than other organs and cell types [18, 28–32], leading to the conclusion that liver plays a central role in 22:1n-9 utilization with other organs utilizing 18:1n-9 exported from liver after 22:1n-9 chain shortening [33].

However, in most of these previous studies examining 22:1n-9 metabolism *in vivo*, the animals were fed high oil

diets rich in 22:1n-9. Under these experimental conditions, peroxisomal  $\beta$ -oxidation is increased, thus increasing the conversion of 22:1n-9 to 18:1n-9 in cultured heart and liver cells [19, 33, 36, 37]. In contrast, constant exposure of the brain to 22:1n-9 alters the pools in which it is found esterified, with minimal impact on 22:1n-9 chain shortening to 18:1n-9 [15]. Pulse infusion studies using labeled 22:1n-9 *in vivo* also demonstrate an increase in chain shortening even in animals fed with regular diets [26–28]. In these studies, the initial concentration of 22:1n-9 is much higher than its normal physiological levels found in plasma. These conditions would distort 22:1n-9 metabolism because 22:1n-9 esterification into PL or TAG pools is concentration dependent [22]. Similar concentration dependence is observed for 20:4n-9 targeting to heart lipid pools, where under non-physiologically high concentrations it is incorporated into TAG pools [38–40], whereas under conditions using a steady-state tracer infusion, 20:4n-6 is predominantly targeted to PL pools [41]. This demonstrates the utility of the method used herein to study fatty acid metabolism under conditions in which there is minimal alteration of the plasma unesterified fatty acid concentration during infusion of the radiotracer. Thus, high superphysiological concentrations (mM range) of labeled 22:1n-9 used in experiments with perfused organs and cultured cells would significantly alter 22:1n-9 metabolism. Until now, no studies have been done to study 22:1n-9 metabolism in heart and liver under steady-state conditions using low 22:1n-9 concentrations that do not perturb plasma concentrations found in intact animals fed with a regular diet.

Previously, we have demonstrated that under steady-state-like conditions 7% of infused [<sup>14</sup>C]22:1n-9 is recovered as [<sup>14</sup>C]18:0 from plasma [15], suggesting possible contamination of the tracer. Although the chemical purity of the tracer was >92% pure by GLC, no 18:0 was observed [15]. This observation led us to propose that 22:1n-9 may be rapidly converted into saturated fatty acids (SFA) in liver and then exported into plasma. Despite the fact the 22:1n-9 conversion into monounsaturated fatty acids has been extensively studied, only one study addressed the question of 22:1n-9 conversion into SFA, but this study was done using cultured heart cells [21], demonstrating a need to more fully understand the dynamics of 22:1n-9 metabolism in liver and heart of intact animals.

In the present study, we extend our previous work using samples from our previous study [15] to examine the uptake and incorporation of [<sup>14</sup>C]22:1n-9 into liver and heart lipids as well as its metabolism under steady-state-like conditions using a well established infusion protocol where normal plasma fatty acid concentrations are unaltered by tracer infusion [42–48]. We demonstrate that 2.3-

fold more [ $^{14}\text{C}$ ]22:1n-9 was taken up into liver as compared to heart and that the bulk of [ $^{14}\text{C}$ ]22:1n-9 radioactivity was incorporated into the NL, mainly into heart TAG and into liver cholesteryl esters (CE) pools, while significantly lesser amounts were esterified into liver and heart PL (<10%). In NL fraction, the bulk of the radioactivity in heart was recovered as 22:1n-9, while in liver NL the bulk of the radioactivity was recovered as 18:0. These data indicate that under steady-state-like conditions, the predominant pathway for 22:1n-9 metabolism in liver is conversion into 18:0 and subsequent incorporation into NL pool, mainly into CE, whereas in the heart, the bulk of 22:1n-9 is incorporated into the NL pool as 22:1n-9 and then presumably used for  $\beta$ -oxidation.

## Materials and Methods

### Animals

Male Sprague-Dawley rats (150–200 g) were obtained from Charles River Laboratories (St. Louis, MO) and maintained on standard laboratory rat chow diet (Purina rodent chow) and water ad libitum. This study was conducted in accordance with the National Institutes of Health Guidelines for the Care and Use of Laboratory Animals (NIH Publication 80-23) under an animal protocol approved by the IACUC at the University of North Dakota (Protocol 0110-1).

### Tracer Preparation

Tracer preparation was performed as previously described [15]. Briefly, the custom synthesized [ $^{14}\text{C}$ ] 22:1n-9 (specific activity 53 mCi/mmol, Moravak Biochemical, Brea, CA) was solubilized in 5 mM Hepes (pH 7.4) buffer containing “essentially fatty acid free” bovine serum albumin (50 mg/mL; Sigma Chemical Co, St. Louis, MO). Solubilization was facilitated using a bath sonicator for 45 min at 45 °C. Tracer was infused at a dose of 170  $\mu\text{Ci}/\text{kg}$  [15, 49]. Previously we determined tracer purity to be >92% by GLC, based upon total peak area [15]. Because we reported 6.5% of the tracer in plasma was found as [ $^{14}\text{C}$ ]18:0, we assessed radiochemical purity of the [ $^{14}\text{C}$ ]22:1n-9 using HPLC analysis and found that the radiochemical purity of the tracer was >99%.

### Rat Surgery and Tracer Infusion

Rat surgery and tracer infusion was performed as previously described [15]. Briefly, rats were anesthetized with halothane (1–3%) and PE-50 catheters inserted into the femoral artery and vein. Using an infusion pump (BS-8000,

Braintree Scientific, Inc., Braintree, MA), awake rats were infused 3–4 h following recovery from anesthesia with 170  $\mu\text{Ci}/\text{kg}$  of [ $^{14}\text{C}$ ]22:1n-9 via the femoral vein over 10 min at a constant rate of 0.4 mL/min to achieve steady-state-like plasma radioactivity. Prior to and during the infusion, arterial blood samples (200  $\mu\text{L}$ ) were taken to determine plasma radioactivity (see Golovko et al. [15]). Following infusion, the rats were killed using pentobarbital (100 mg/kg, intravenous). Liver and heart were rapidly removed and frozen in liquid nitrogen. The tissue was stored at  $-80\text{ }^\circ\text{C}$  until used.

### Blood Extraction

To account for the contribution of residual blood to tissue radioactivity, whole blood was extracted using a two-phase extraction [50]. Residual blood in heart and liver was estimated to be 24 and 17%, respectively based upon literature values [51, 52]. Previously using this infusion protocol, we demonstrated that 95% radioactivity in blood is found as free fatty acid, whereas 2.5% is found in phospholipids, and 2.5% is found in triacylglycerols [41, 53].

### Tissue Lipid Extraction

To determine tracer incorporation into liver and heart individual lipid compartments, lipids were extracted using a two-phase extraction procedure [50]. Briefly, frozen tissues were pulverized under liquid nitrogen temperatures into a fine homogeneous powder and lipids from the tissue powders were extracted using chloroform/methanol (2:1 by vol) in a Tenbroeck tissue homogenizer. The tissue mass in grams was multiplied by a correction factor of 1.28 to convert it to an equivalent value in mL [54], which represents one volume. The tissue was homogenized in 17 volumes of chloroform-methanol (2:1 by vol), the solvent removed and the homogenizer rinsed with 3 volumes of chloroform/methanol (2:1 by vol). This rinse was added to the original sample and 4 volumes of 0.9% KCl solution were added to the combined lipid extract. The extract was mixed by vortexing and the phases separated by centrifugation. The upper aqueous phase and proteinaceous interphase were transferred to a 20 mL scintillation vial for counting. The lower organic phase was washed twice with 2 mL of theoretical upper phase (chloroform/methanol/water, 3:48:47 by vol) and the phases again separated by centrifugation. Each wash was removed and added to the previously removed upper phase. The lower organic phase was then dried under nitrogen and then dissolved in hexane-2-propanol (3:2 by vol) containing 5.5% water.

To analyze tracer metabolism to other fatty acids and its subsequent distribution within esterified fatty acids found

in NL and PL fractions, lipids from liver and heart tissue (200 mg, wet weight) were extracted using single phase extraction procedure [55, 56]. Briefly, tissue powder was homogenized in 1.8 mL hexane/2-propanol (3:2 by vol) per 0.1 g tissue and quantitatively transferred to a test tube. The homogenizer was rinsed with an additional 3 mL of hexane/2-propanol (3:2 by vol) and added to the original extract. The protein-containing residue was pelleted by centrifugation and the lipid bearing organic fraction was removed and stored under a N<sub>2</sub> atmosphere at –80 °C until it was used to assess tracer elongation and chain shortening.

#### Thin Layer Chromatography

Tissue PL were separated by thin layer chromatography (TLC) on heat-activated Whatman silica gel-60 plates (20 cm × 20 cm, 250 μm) using two different solvent systems. The first system used a chloroform/methanol/acetic acid/water (60:30:3:1 by vol) solvent system that resolves cardiolipin (Ptd<sub>2</sub>Gro), phosphatidic acid (PtdOH), and ethanolamine glycerophospholipids (EtnGpl) [53]. Because this first system does not separate phosphatidylserine (PtdSer) and phosphatidylinositol (PtdIns), these two phospholipids were separated using a chloroform/methanol/acetic acid/water (50:37.5:3.5:2 by vol) solvent system [57]. Phospholipids were visualized using iodine vapor.

Heart and liver NL were separated by TLC on heat-activated Whatman silica gel-60 plates (20 cm × 20 cm, 250 μm) and developed in petroleum ether/diethyl ether/acetic acid (70:30:1.3 by vol) solvent system that resolves cholesterol, cholesteryl esters, diacylglycerols, nonesterified fatty acids, and triacylglycerols [58].

All lipid fractions were identified using authentic standards (Doosan–Serdary, Englewood Cliffs, NJ, and NuChek Prep, Elysian, MN). Bands corresponding to the appropriate lipid fractions were removed from the TLC plate by scraping and transferred into 20 mL liquid scintillation vials and 0.5 mL of water was added followed by 10 mL of Scintiverse BD (Fisher Scientific, Pittsburgh, PA). Radioactivity was quantified by liquid scintillation counting using a Beckman LS 5000 CE liquid scintillation counter.

#### Analysis of Tracer Conversion in Esterified NL and PL Fractions

To determine the elongation and chain shortening of the infused tracer by heart and liver, extracted heart and liver lipids were separated into PL and NL fractions using silicic acid column chromatography (Clarkson Chemical Co., Inc., Williamsport, PA) [59]. To remove nonesterified fatty

acids from the NL fraction, it was then separated by TLC as described above using the petroleum ether/diethyl ether/acetic acid (70:30:1.3 by vol) solvent system, except that lipid fractions were visualized using 6-*p*-toluidino-2-naphthalenesulfonic acid [60]. TAG and CE were collected by scraping the bands off the TLC plate, and were then extracted off the silica by adding 1.5 mL of water followed by three successive washes of the aqueous phase with 3 mL of hexane/2-propanol (3:2 by vol). For each wash, the elution mixture was vigorously mixed for 1 min by vortexing and the two phases were separated by centrifugation. The upper lipid-containing phase was aspirated and saved for fatty acid analysis and subsequent washes were added to this original wash.

Fatty acids from PL fraction and from the combined TAG and CE fractions were separated and quantified after conversion to their corresponding phenacyl esters [61, 62]. Briefly, solvent containing the PL and TAG/CE lipid fractions was removed under a stream of nitrogen and the lipids subjected to saponification at 100 °C for 30 min in 2% KOH in ethanol, which was then acidified with HCl. The released fatty acids were extracted with hexane, the hexane evaporated using nitrogen, and phenacyl esters were then prepared by the addition of acetone containing 2-bromoacetophenone (10 mg/mL) (Sigma) and triethylamine (10 mg/mL) (Sigma) followed by heating at 100 °C for 5 min followed by addition of acetic acid (2 mg/mL) and then the samples were heated for an additional 5 min.

Individual fatty acid phenacyl esters were separated by high performance liquid chromatography (HPLC) on a C-18(2) Luna column (Phenomenex, Torrance, CA) as previously described [15] with a modified elution program that allows resolution of VLCFA. Fatty acids were identified using fatty acid standards (NuChek Prep, Elysian, MN) converted to phenacyl esters. The HPLC system was controlled by a Beckman 127 solvent module (Fullerton, CA). The eluent was monitored at 242 nm using a Beckman 166 ultraviolet/visible light detector. The gradient system used was composed of water (solvent A) and acetonitrile (solvent B). Column temperature was maintained at 37 °C. The flow rate was 1 mL/min, and the initial percentage of B was 80%. The percentage of B was increased to 90% over 1 min at 350 min, increased to 96% over 1 min. at 490 min, and returned to 80% over 1 min at 550 min. Eluent from HPLC containing individual fatty acid phenacyl esters was concentrated by reducing the volume to 1 mL under a stream of nitrogen and 15 mL of Scintiverse BD was added and the samples were mixed by vortexing. After mixing, all samples were allowed to stabilize for at least 1 h before the radioactivity was quantified by liquid scintillation counting using a Beckman LS 6500 liquid scintillation counter.

## Statistical Analysis

Statistical analysis was done using InStat (GraphPad, San Diego, CA) and a two-tailed, unpaired Student's *t* test. Values were considered statistically significant when  $p < 0.05$ .

## Results

### Plasma Curve

The plasma curve for these awake, male rats infused with  $[14\text{-}^{14}\text{C}]22:1\text{n-}9$  (i.v.) was previously published [15] and indicates that the radiotracer was near steady-state-like conditions and that the plasma concentration of unesterified (free) 22:1n-9 is 6  $\mu\text{M}$ .

### Uptake and Distribution of 22:1n-9 in Liver and Heart

In liver and heart, the amount of tracer, expressed as nCi/g ww, found in the total extract, in the organic fraction (lipid containing), and in the aqueous fraction, which represents products of  $\beta$ -oxidation [41, 63, 64] was determined (Fig. 1). Under steady-state-like conditions, significantly more tracer was taken up by the liver (2.3-fold) as compared to the heart. When the unilateral incorporation coefficient for liver and heart uptake was calculated [41–45], which normalizes the amount of tracer taken up into a given tissue by the amount of tracer infused into the rat, the liver had taken up significantly more tracer (2.3-fold) as compared to heart (data not shown). The percentage of the infused tracer removed by the heart was  $0.82 \pm 0.33\%$ , while that removed by the liver was  $1.63 \pm 0.45\%$ . Again, using this calculation, the liver removed 2.0-fold more tracer than did heart. The increase in liver total uptake was

**Fig. 1** Uptake of  $[14\text{-}^{14}\text{C}]22:1\text{n-}9$  by heart and liver values are expressed as mean  $\pm$  SD, where  $n = 5$  heart and  $n = 6$  for liver. The \* indicates statistical significance from liver,  $p < 0.05$

accounted for by a significantly higher incorporation of tracer (4.2-fold) into the liver organic fraction as compared with heart. However, no differences were found between liver and heart in amount of tracer found in the aqueous fraction. However, in heart a significantly greater proportion of radioactivity was found in the aqueous fraction ( $63.2 \pm 5.8\%$ ) as compared to liver ( $22.9 \pm 2.9\%$ ), indicating that in the heart 2.8-fold more tracer underwent  $\beta$ -oxidation relative to the liver.

### Distribution of Tracer in Liver and Heart Lipid Pools

To determine into which lipid compartments the tracer entered in liver and heart, the incorporation of the tracer into individual lipid fractions was determined (Fig. 2). Significantly more tracer (nCi/g ww) went into liver total PL, unesterified (free) fatty acids, and CE as compared to heart (Fig. 2, top panel). However, the amount of tracer entering into the TAG pool was not different between groups. These values illustrate two important points. First, that very little tracer entered into the phospholipid pools.

**Fig. 2** Distribution of infused  $[14\text{-}^{14}\text{C}]22:1\text{n-}9$  amongst different heart and liver lipid fractions values are expressed as mean  $\pm$  SD, where  $n = 5$  heart and  $n = 6$  for liver. The \* indicates statistical significance from liver,  $p < 0.05$ . In the top panel, values are expressed as nCi/g ww, while in the bottom panel, these values are expressed as percent of total organic fraction radioactivity. PL: phospholipids; FFA: free fatty acids; TAG: triacylglycerols; CE: cholesteryl esters

Second, that the amount of tracer entering the CE pool was tremendously different between groups.

However, it is also important to determine the proportion of tracer targeted to each of the respective lipid pools (Fig. 2, lower panel). Under steady-state-like conditions, the bulk of the infused tracer in heart was found in TAG pool ( $63.7 \pm 4.4\%$ ), while the remainder was distributed between the total PL, unesterified (free) fatty acids, and CE. In stark contrast, in liver the bulk of the infused tracer was found in CE ( $55.6 \pm 5.1\%$ ), with the remaining tracer distributed between the other lipid fractions. These data indicate that under steady-state-like conditions the intact liver targets 22:1n-9 for esterification into different lipid metabolic pools than in the heart.

### Distribution of Tracer in Individual Phospholipid Classes

The distribution of the infused tracer in liver and heart individual PL classes was also determined and values are expressed as % of total phospholipid radioactivity (Fig. 3). In both liver and heart, the bulk of the infused tracer was incorporated into *CholGpl*, *CerPCho*, and *EtnGpl*. The rest of the tracer was found distributed amongst the other phospholipids.

### Metabolism of [ $^{14}\text{C}$ ]22:1n-9 to Other Fatty Acids in Liver and Heart

To determine whether the infused [ $^{14}\text{C}$ ]22:1n-9 was chain elongated or shortened, we determined the distribution of radioactivity found in other monounsaturated and

**Fig. 3** Distribution of infused [ $^{14}\text{C}$ ]22:1n-9 amongst individual heart and liver phospholipid classes values are expressed as mean  $\pm$  SD, where  $n = 5$  heart and  $n = 6$  for liver. The \* indicates statistical significance from liver,  $p < 0.05$ . *CerPCho* sphingomyelin, *ChoGpl* choline glycerophospholipids, *PtdSer* phosphatidylserine, *PtdIns* phosphatidylinositol, *EtnGpl* ethanolamine glycerophospholipids, *PtdOH* phosphatidic acid, *Ptd<sub>2</sub>Gro* cardiolipin

saturated fatty acids in the total phospholipid fraction from liver and heart (Fig. 4). We observed minimal of elongation of [ $^{14}\text{C}$ ]22:1n-9 to [ $^{16}\text{C}$ ]24:1n-9 in liver and heart, however we did find that in liver and heart PL fractions,  $64.2 \pm 10.9\%$  and  $41.1 \pm 8.2\%$  of radioactivity, respectively, was found in products derived from chain shortening of [ $^{14}\text{C}$ ]22:1n-9. The terminal pool was found to be 18:1n-9, in which form  $41.8 \pm 5.4\%$  and  $30.8 \pm 6.6\%$  of the tracer was found in liver and heart PL, respectively. Limited carbon recycling into SFA was found in liver and heart, as only  $6.9 \pm 2.3\%$  of the tracer was found in liver PL SFA (mainly as 18:0,  $3.0 \pm 1.3\%$ ) and only  $7.0 \pm 3.3\%$  of the tracer was found in the heart PL SFA fraction (mainly as 16:0,  $4.2 \pm 3.2\%$ ).

Similar to the PL pool in liver and heart, the combined TAG/CE pool contained products of chain shortening, mainly in the form of 18:1n-9 form. However, the distribution into this pool was much lower ( $12.9 \pm 3.1\%$  and  $10.0 \pm 1.7\%$  in liver and heart, respectively) than what was observed in the PL pool. These data support previous observations showing that 22:1n-9 is readily chain shortened and that it accumulates as 18:1n-9 as the terminal pool. Limited carbon recycling into SFA was found in the heart TAG/CE fraction (Fig. 5). In stark contrast, in the liver TAG/CE fraction,  $54.2 \pm 9.0\%$  of the tracer was recovered in SFA form, mainly as 18:0 ( $48.4 \pm 4.5\%$ ). These data support our assumption that 22:1n-9 was rapidly converted into 18:0 in liver, which can then be exported into plasma, thereby accounting for our observation of 6.5% of the tracer in the plasma being in the form of [ $^{14}\text{C}$ ]18:0.

**Fig. 4** Distribution of radioactivity amongst different fatty acids derived from the total tissue phospholipid fraction. Values are expressed as mean  $\pm$  SD, where  $n = 5$  heart and  $n = 6$  for liver. The \* indicates statistical significance from liver,  $p < 0.05$ . These values are expressed as percent of total phospholipid fraction radioactivity. The abbreviations are: 16:1: palmitoleic acid; 18:1: oleic acid; 20:1: gondoic acid; 22:1: erucic acid; 24:1: nervonic acid; 16:0: palmitic acid; 18:0: stearic acid; 20:0: arachidic acid; 22:0: behenic acid; 24:0: lignoceric acid

## Discussion

Although 22:1n-9 metabolism has been extensively studied in different model systems, it is important to note that in these other studies, the experimental conditions used may dramatically impact normal 22:1n-9 metabolism, potentially impacting interpretation. For example, feeding animals high oil diets or diets rich in 22:1n-9 increases the ability of the liver and heart to oxidize 22:1n-9 [19, 33, 36, 37], thus providing metabolic results that are difficult to interpret and perhaps erroneous relative to more steady-state conditions. Because the metabolism of 22:1n-9 is concentration dependent [22], it is important to use studies that avoid perturbing the normal plasma concentration of the fatty acid of interest [41]. Recently, we demonstrated the uptake into and metabolism of [14- $^{14}$ C]22:1n-9 in rat brain [15]. Herein, we present data from hearts and livers isolated from the rats used in our previous study [15]. Unlike the many other studies examining 22:1n-9 metabolism, this is the first study to examine liver and heart 22:1n-9 metabolism under steady-state-like conditions.

Under these steady-state-like conditions, 2.3-fold more tracer was incorporated into liver as compared with heart (Fig. 1). These data are consistent with results showing increased liver uptake relative to that by heart under a number of experimental conditions. Following pulse infusion (i.v.) with [14- $^{14}$ C]22:1n-9, liver radioactivity is 10–15 fold higher than that found in heart, kidneys, or spleen radioactivity after pulse i.v. infusion of [28]. Similar results are observed following pulse infusion of tritiated 22:1n-9 [26, 27]. We did not see such a large difference

between heart and liver uptake, this is more than likely because the concentration of labeled 22:1n-9 used in pulse infusion experiments was about 10-fold higher than that used in our experimental paradigm, certainly high enough to alter the normal plasma concentration of 22:1n-9. This is critical because liver fatty acid uptake is directly related to fatty acid plasma concentration [65], which is consistent with our lower difference between liver and heart uptake at steady-state conditions.

Furthermore, targeting of tracer to lipid pools is also highly dependent upon tracer concentration. We observed that 7 and 16% of the tracer was in the unesterified free fatty acid (FFA) fraction, in heart and liver, respectively (Fig. 2), which is substantially lower than those obtained under other experimental conditions when concentrations of [14- $^{14}$ C]22:1n-9 are in the mM range. Under these supra-physiological conditions, 80% of the tracer is recovered in the unesterified FFA fraction in perfused liver [24], 36–90% of the tracer in this fraction in hepatocytes [18, 34], and 20–62% of the tracer in this fraction in perfused heart [23, 25, 26, 66]. While we find only 23% of the infused [14- $^{14}$ C]22:1n-9 was found in the aqueous fraction of the liver, this value was two times higher than that observed in vitro [24, 34, 35]. These data indicate that under steady-state-like conditions, more 22:1n-9 that entered the liver was subjected to  $\beta$ -oxidation rather than esterified into lipids. Thus, the concentration of infused tracer is critical for not only tissue uptake, but metabolism of the tracer by the tissue as well as distribution of tracer into specific metabolic pools.

In liver and heart, the bulk of the infused [14- $^{14}$ C]22:1n-9 found in the organic fraction was incorporated into the NL fractions, but the targeting to individual NL (TAG and CE) was radically different between liver and heart (Fig. 2). However, the distribution of radioactivity between the total PL and NL fractions was similar for liver and heart, which is consistent with tracer distribution between these fractions following pulse-infusion [26, 27], in perfused heart [22, 23, 25, 66], in perfused liver [24, 35], and in hepatocytes incubated with 22:1n-9 [34]. Interestingly, 22:1n-9 distribution between PL and NL fractions is independent of fatty acid concentration used for heart perfusion [22]. We also found that the tracer was mainly found in CholGpl, CerPCho, and EtnGpl in liver and heart phospholipids (Fig. 3), which appears to be independent of experimental conditions, since a similar distribution was shown in heart cell cultures [20], in liver cell cultures [67], and in perfused heart [22].

We [15] and others have shown that 22:1n-9 is readily converted into 18:1n-9 through chain shortening pathway in various organs and cell types [18, 19, 24, 26–28, 31–35], however none of these studies have addressed conversion of 22:1n-9 to other fatty acids under steady-state-like

conditions or its conversion into saturated fatty acids (SFA). Previously we found that >91% of the infused tracer was recovered as plasma 22:1n-9, with 6.5% of the tracer found in plasma found as 18:0 under steady-state-like conditions [15]. Because the radiochemical purity of the custom-synthesized tracer was >99% for [14-<sup>14</sup>C]22:1n-9 (as shown by radiochemical HPLC analysis), it is unlikely that the 18:0 was derived from the tracer, but rather via conversion of 22:1n-9 to 18:0 in liver through carbon recycling followed by export into plasma. This is consistent with our observation reported herein that the liver took up significantly more tracer and that by others demonstrating that the liver has a central role in 22:1n-9 metabolism [33].

In brain, we demonstrated that [14-<sup>14</sup>C]22:1n-9 is chain shortened predominantly to [10-<sup>14</sup>C]18:1n-9 [15]. In livers and hearts isolated from these same rats, we demonstrate that 31 and 42% of PL radioactivity was found as 18:1n-9, respectively (Fig. 4). These results confirm previous reports showing that 22:1n-9 is quickly converted into 18:1n-9 in all models studied [15, 18, 19, 24, 26, 27, 31–35]. Presumably, this conversion is through peroxisome localized  $\beta$ -oxidation [33, 36, 68]. In contrast, 80% of heart NL radioactivity was recovered as 22:1n-9 in which TAG radioactivity represents 70% of total lipid radioactivity. This is consistent with the observation that up to 80% of heart TAG radioactivity remains in 22:1n-9 form after pulse infusion of [<sup>14</sup>C]22:1n-9 [26, 28]. These data indicate that the heart TAG pool may serve as a transient pool for 22:1n-9 before its  $\beta$ -oxidation, similar to the proposed role for TAG pools comprised of other fatty acids in heart [41, 53] and this role may be independent of the 22:1n-9 concentrations used in the experiment.

Although 22:1n-9 conversion into monounsaturated FA has been extensively studied, no studies have demonstrated the conversion of 22:1n-9 into SFA in liver and only one study addressed this conversion in cultured heart cells [21]. In the present study, we demonstrate that half of the tracer conversion was limited in the heart as it was found in [14-<sup>14</sup>C]22:1n-9 (Figs. 4 and 5), which is consistent with results from cultured heart cells [21]. The high amount of radioactive 18:0 in the liver esterified NL fraction explains our previous observation that 7% of infused [14-<sup>14</sup>C]22:1n-9 is found as radioactive 18:0 in plasma [15].

There are two possible explanations for the high rate of conversion of the tracer into SFA. First, the tracer could be chain shortened to 18:1n-9 that is then saturated via the reversal of the  $\Delta$ -9 desaturase. However, there is no evidence for a reversal of  $\Delta$ -9 desaturase activity. Second, the complete  $\beta$ -oxidation of 22:1n-9 and recycling of the radioactive carbons for 18:0 biosynthesis. This is not without precedence, as in brain a significant portion

(>30%) of infused fatty acid radiotracer is found as radioactive amino acids made via Krebs cycle intermediates within a 10 min time frame [63, 64]. Hence, the rapidity of these processes has been observed in the past and is an important indicator of how fast these processes work in vivo.

In summary, under steady-state-like physiological conditions more of the infused [14-<sup>14</sup>C]22:1n-9 (2.3-fold) was taken up by the liver as compared to heart. It is important to note that significantly more tracer was targeted for  $\beta$ -oxidation in the heart as compared to liver, consistent with the high distribution of radioactivity into heart TAG pools. This is significant because these pools have a high rate of incorporation in vivo [53], consistent with a high degree of turnover to provide fatty acids for  $\beta$ -oxidation. In both tissues, the bulk of tracer radioactivity was incorporated into the esterified NL fraction, found mainly in TAG in heart and CE in liver. In the heart NL fraction, the radioactivity was found predominantly as 22:1n-9, whereas it was mainly found as 18:0 in liver NL fraction, demonstrating a rapid conversion of 22:1n-9 into saturated fatty acids. The underlying importance of this finding is that during the treatment of X-ALD using LO, which contains a high level of 22:1n-9, its ingestion may lead to an increase in saturated fatty acid burden. Because patients on LO have a restricted saturated fatty acid diet our finding may have clinical ramifications. The high levels of [<sup>14</sup>C]18:0 found in liver TAG/CE is consistent with the presence of this fatty acid (6.5%) in the plasma of rats, indicating that the liver rapidly (<10 min) metabolized the [14-<sup>14</sup>C]22:1n-9 and exported the TAG/CE containing the [<sup>14</sup>C]18:0 into the plasma. Collectively, these data indicate that under steady state-like conditions, the liver has a greater capacity to take up 22:1n-9 as compared with heart, where significant amounts of this fatty acid is metabolized to form saturated fatty acids, while in the heart this fatty acid remains more intact and it is targeted for pools destined for use in heart for  $\beta$ -oxidation.

**Acknowledgments** The authors thank Dr. Carole Haselton for her excellent surgical and technical assistance and editorial suggestions and Mrs. Cindy Murphy for typing and preparation of the manuscript. ## NPC1L1 and SR-BI are Involved in Intestinal Cholesterol Absorption from Small-Size Lipid Donors

**Abstract** In the human intestinal content after a meal, cholesterol is dispersed in a complex mixture of emulsified droplets, vesicles, mixed micelles and precipitated material. The aim of this study was to determine the contribution of the main intestinal cholesterol transporters (NPC1L1, SR-BI) to the absorption processes, using different cholesterol-solubilizing donors. Cholesterol donors prepared with different taurocholate concentrations were added to an apical medium of differentiated TC7/Caco-2 cells. As the taurocholate concentrations increased, cholesterol donor size decreased (from 712 to 7 nm in diameter), which enhanced cholesterol absorption in a dose-dependent manner (38-fold). Two transport processes were observed: (1) absorption from large donors exhibited low-capacity transport with no noticeable transporter contribution; (2) efficient cholesterol absorption occurs from small lipid donors ( $\leq 23$  nm diameter), mainly due to NPC1L1 and SR-BI involvement. In addition, bile acids significantly increased mRNA and protein expression of NPC1L1, but not of SR-BI. In conclusion, bile acids present in the intestinal lumen and the micelles enhance intestinal cholesterol transport into the cell by two different regulatory processes: by reducing the lipid donor size, so

that small-size mixed micelles can more easily access brush-border membrane transporters, and by increasing the expression level of the enterocyte NPC1L1. These mechanisms could account for the important inter-individual variations observed in cholesterol intestinal absorption.

**Keywords** Cholesterol absorption · NPC1L1 · SR-BI · Bile acids · Vesicle · Mixed micelles

### Abbreviations

BA	Bile acids
CL	Cholesterol
DCA	Deoxycholic acid
DMEM	Dulbecco's modified Eagle's medium
NPC1L1	Niemann–Pick C1-like 1
SR-BI	Scavenger receptor class B type I
TCA	Taurocholic acid

### Introduction

Dietary and biliary cholesterol (CL) absorption contributes, along with regulation of CL biosynthesis, to maintaining a tight control of CL homeostasis. However, the mechanisms of intestinal CL absorption are not yet fully understood. They involve a multistep process which is regulated by multiple genes and different protein-facilitated processes at the enterocyte level. The scavenger receptor class B type I (SR-BI) is a membrane glycoprotein. When localized at the brush-border membrane, it facilitates intestinal absorption of CL and other lipid nutrients [1–4]. Recently, the Niemann–Pick C1-like 1 (NPC1L1) transporter was identified as being critical to CL absorption [5–7]. However, its involvement in intestinal CL absorption is not fully

understood and its cell surface and/or intracellular localization is still debated. While some reports indicate that NPC1L1 is located at the cell surface in animal enterocytes [7–9] and Caco-2 cells [1, 10, 11], others describe NPC1L1 as being an intracellular [12], endosomal protein [5]. Moreover, very recent studies have confirmed the presence of NPC1L1 in both regions [1, 13, 14]. Some authors have proposed that the observed differences in the cellular location of NPC1L1 might depend on the differentiated state of the cultured cells [10]. NPC1L1 possibly cooperates with SR-BI to mediate intestinal CL absorption in humans [1, 8]. Members of the ATP-binding cassette (ABC) family are involved in efflux processes. ABCG5 and ABCG8 constitute apical sterol export pumps that promote active efflux of CL from enterocytes back into the intestinal lumen for excretion [15, 16], thus limiting intestinal CL absorption. ABCA1 located at the basolateral membrane of the enterocyte is involved in the efflux process of CL towards circulating HDL lipoproteins [17–19]. The respective roles of these transporters are still under investigation.

Within the gut lumen, dietary CL is emulsified with triglycerides and other lipids into oily droplets (1–100  $\mu\text{m}$ ) [20]. As intraluminal fat digestion occurs, vesicles are generated at the surface of emulsions which are then partly dispersed in mixed micelles [21]. Vesicles are large unilamellar aggregates (40–100 nm), and mixed micelles have a much smaller size ( $\sim 10$  nm). Little is known about intestinal absorption of CL from vesicles, while micelle CL absorption is thought to be essential. Bile acids (BAs) are mainly present in mixed micelles and even in vesicles, but also exist in monomer form [20]. BAs are required for efficient CL absorption; in the absence of BAs, CL absorption is markedly reduced [22, 23]. They are recognized as being important lipid-solubilizing molecules. However, several investigators have reported that the best BA for lipid solubilization is not the best for intestinal CL absorption [24–26]. The role that BA plays in facilitating CL absorption by the enterocytes may thus extend beyond their CL solubilization properties.

Very little information is available about the possible interactions between the various kinds of dispersed lipid aggregates present in the intestinal lumen and the different intestinal CL transporters. Thus, we hypothesized that BAs incorporated into lipid-donors are involved in the CL absorption regulation processes through direct or indirect interactions with intestinal cholesterol transporters (NPC1L1 and SR-BI). The data obtained with differentiated human intestinal TC7/Caco-2 cells show, for the first time, that donor size and/or BA per se play a key role in the regulation of intestinal CL absorption through several interactions with CL transporters.

## Materials and Methods

### Materials

Trypsin–EDTA, nonessential amino acids, antibiotics and cell culture media were obtained from Gibco BRL (Cergy Pontoise, France). Cell culture materials were obtained through Becton Dickinson (Le Pont de Claix, France). Mouse monoclonal IgG raised against the external domain (amino acids 104–294) of human SR-BI, also known as CLA-1, was purchased from BD Transduction Laboratories (Lexington, KY, USA). Polyclonal antibodies to NPC1L1 raised in rabbit against an external domain (amino acids 596–610) were purchased from Abcam (Cambridge, UK). The specificity of NPC1L1 antibodies was checked using blocking peptide (Cayman Chemical, Ann Arbor, MI, USA). [ $^3\text{H}$ ]-CL (1.44/TBq/mmol) was purchased from Amersham International (Little Chalfont, UK). Radioactivity was measured by liquid scintillation counting (TRi-Carb 1600 Packard, Meriden, CT, USA) in the presence of Emulsifier Safe for aqueous media or Insta-Fluor Plus for all organic samples obtained through Perkin-Elmer (Waltham, MA, USA).

### Measurement of Lipid Donor Size

As an estimate of the size of the lipid particles, the intensity-weighted mean diameter (z-average diameter) and the polydispersity index were determined by photon correlation spectroscopy (Zetasizer Nano ZS, Malvern Instruments, Malvern, UK; 633-nm He–Ne laser) at 25 °C. All measurements were performed with 10-min runs, and results are expressed as mean values of at least three measurements [27].

### Cell Culture Conditions

The TC7 cells, a clone of human intestinal cell-line Caco-2, were used between passages 30 and 50 as previously described [28, 29]. Stocks of cells were cultured in Dulbecco's Modified Eagle Medium (DMEM) containing 25 mM glucose, supplemented with 1% nonessential amino acids and 20% heat-inactivated (30 min, 56 °C) fetal calf serum in a 10%  $\text{CO}_2$  humidified incubator at 37 °C. When the cells reached 70–80% confluence, monolayers were subcultured at  $2.5 \times 10^5$  cells in 0.25% trypsin–EDTA (1 mM) on 23.1-mm-diameter PET culture inserts (1  $\mu\text{m}$  pore size). The inserts were fitted into six-well culture plates with 1 ml apical and 2 ml basolateral culture medium. The experiments were performed on day 21 after plating; i.e., after cells had reached confluence and made a tight monolayer as checked by transepithelial electrical resistance.

## Absorption Measurement

CL donors at a final concentration of 2 mM phosphatidylcholine, 0.03 mM monoacylglycerol, 0.5 mM oleic acid sodium salt, 0.1 mM CL and traces of [<sup>3</sup>H]-CL were obtained with 2, 3, 4, 5, 6 and 8 mM taurocholic acid (TCA). TCA-free CL donors were also prepared; one part was used without treatment (0) and the other part was sonicated for 10 min at 4 dB (0s) (Sonifier 250, Branson, Danbury, CT, USA). CL donors were added to the apical side and cells were incubated for 3 h at 37 °C, as previously published [28]. At the end of the experiment, the radioactivities of the basolateral and apical media were measured. Cell CL was extracted using hexane/isopropanol (3/2 V/V). Cell proteins were extracted using a membrane protein extraction kit (Pierce, Rockford, IL, USA) and quantified (BCA kit from Pierce). When necessary, before CL donor addition, cells were incubated for 2 min with antibodies diluted in DMEM (8 µg/ml anti-SR-BI, 5 µg/ml anti-NPC1L1).

## Western Blot Analysis

Cell proteins were denatured in sample buffer containing SDS and β-mercaptoethanol, separated by 10% SDS-PAGE (10% acrylamide gels), and electroblotted onto nitrocellulose membranes (Pierce). Nonspecific binding sites were blocked using 5% non-fat dried milk followed by overnight incubation at 4 °C with primary antibodies directed against NPC1L1 (1/200) or SR-BI (1/2,000). After washing, the membranes were incubated with peroxidase-labeled antibody raised against rabbit IgG (NPC1L1 detection) or mouse IgG (SR-BI). Blots were developed by chemiluminescence detection for NPC1L1 and SR-BI (Pierce). Loading controls were performed on the same membrane with GAPDH or β-actin. Apparent molecular mass was determined using standards (Fermentas, Vilnius, Lithuania). Protein expression levels were quantified using a Bio-1D++ gel image analysis system (Vilber-Lourmat, Marne la Vallée, France).

## RNA Isolation, Reverse Transcription, and Real-Time PCR

Total RNA was isolated from incubated cells using TRIzol reagent (Invitrogen, Carlsbad, CA, USA). One microgram of each RNA was reverse-transcribed by random priming, using MMLV enzyme (Invitrogen, Carlsbad, CA, USA). Five microliters of each cDNA, from a final reaction volume of 100 µl, were used for real-time PCR, which was performed on Mx3005P (Stratagene, La Jolla, CA, USA) using qPCR Mastermix Plus SYBR green I (Eurogentec, Liege Science Park, Belgium). The primers used are listed

in Table 1. Constitutively expressed 18S rRNA was measured as an internal standard for sample normalization. Relative mRNA levels were calculated using the comparative threshold cycle ( $2^{-\Delta\Delta C_t}$ ) method [30]. Each PCR was performed in triplicate.

## Data Analysis

Results are expressed as mean (±SD) values of nmol CL accumulated into the cell per cellular protein milligram ( $n = 3$ ). Differences between data were explored using one-way analysis of variance (ANOVA) for factorial, nonrepeated values, and using Fischer test, with  $P$  values  $\leq 0.05$  considered significant. SPSS 11.0 software (SPSS Inc., Chicago, IL, USA) was used for statistical analysis.

## Results

### CL Donor-size and TCA Concentration

Cholesterol donors were prepared in the presence or not of TCA, and their diameter was measured (Table 2). Without TCA, very large particles ( $1,025 \pm 24$  nm) were obtained which decreased in size after sonication ( $46 \pm 3$  nm). In the presence of increasing TCA concentrations (2–8 mM), chosen within physiological range [20, 31], the CL donor diameter varied from  $712 \pm 25$  to  $7 \pm 1$  nm. At 4 mM TCA, small donors with diameters of  $<50$  nm (vesicles) were found in the medium. Mixed micelles were observed for TCA concentrations  $\geq 5$  mM. The smallest CL donor ( $7 \pm 1$  nm) was obtained with 8 mM TCA. Higher TCA concentrations were not used because of their cellular toxicity.

### Regulation of CL Cell Absorption by TCA Concentration and Lipid Donor Size

Because of the heterogeneity of the parental population of Caco-2 cells, the selected experimental model was the TC7 clone of the human intestinal cell-line, which had previously been characterized for cholesterol absorption studies

8	7 ± 1	7.37 ± 1.64	4.49 ± 0.74* (61%)	5.28 ± 0.47* (72%)

CL cell uptake was measured after 3 h of incubation of TC7 cells with several CL donors added to the apical medium. The donors were prepared either without TCA (0 and 0s mM) or with TCA. Antibodies directed at SR-BI or NPC1L1 were added or not (control) before incubation with lipid donors. Percentages were determined as compared to the respective control values, \* $P < 0.05$ , \*\* $P < 0.01$

[29]. When the TCA concentration was increased (from 2 to 8 mM; Fig. 1a; Table 2), CL cell absorption was markedly enhanced ( $\times 11$ ). The intercept on the  $x$ -axis of the extrapolated line obtained for high absorption values gave a TCA concentration of 3.9 mM.

Cholesterol cell absorption increased as the lipid donor size decreased (Fig. 1b), and exhibited two different processes. The first one ( $R^2 = 0.998$ ), observed with large donors and vesicles (1,025–47 nm), was particularly slow and exhibited a low transport capacity. CL cell absorption was increased ninefold when vesicles (47 ± 5 nm) were compared to large particles (1,025 ± 24 nm). The second one ( $R^2 = 0.882$ ), only observed with micelle donors

(18–7 nm), was much more efficient. Indeed, CL cell absorption was increased 38-fold using mixed micelles (7 ± 1 nm) as compared to large particles (1,025 ± 24 nm). The calculated maximal donor diameter promoting efficient cell absorption was  $23.49 \pm 0.27$  nm, which fitted with the mixed micelle size [5]. To test the role of BA in these processes, TCA-free donors were prepared. Using the small TCA-free donors, the CL cell absorption was increased ( $\times 4$ ) compared to when the large ones were used (Table 2). Thus, the donor size is an important factor per se in the regulation of CL absorption by BA, but other regulations can take place.

#### Contribution of NPC1L1 and SR-BI to CL Absorption Processes

To quantify the involvement of the main intestinal CL transporters in the absorption processes from each lipid donor, cell absorption was measured in the presence or not (control) of specific antibodies directed at NPC1L1 and SR-BI, added to the apical medium (Table 2). These antibodies were inefficient at modulating the CL cell absorption from large donors (1,025 ± 24 nm), but they significantly reduced CL cell absorption from small donors. The inhibitory effect of anti-NPC1L1 and anti-SR-BI abruptly increased in the presence of very small donors ( $\leq 45$  nm), i.e., from 4mM TCA. The most important effect was observed in the presence of mixed micelles (56% NPC1L1 inhibition, 47% SR-BI inhibition) at 6 mM TCA. For the smallest CL donor used (7 ± 1 nm), the inhibitory effects of antibodies were reduced, so a saturation process was observed. Using lipid donors of comparable sizes obtained with or without TCA (47 and 46 nm, respectively), similar reductions (43–49 for NPC1L1 and 46–27% for SR-BI, respectively) were observed in both cases. Thus, the presence of BA is not essential for the interactions between lipid donors and intestinal transporters. These data

**Fig. 1** Effects of TCA concentration (a) and CL donor size (b) on CL cell absorption (nmol/mg). Results are expressed as mean ± SD ( $n = 3$ ), \* $P < 0.05$

confirm that BA regulation takes place at the brush-border membrane, where intestinal cholesterol transporters are mainly localized.

#### NPC1L1 and SR-BI Protein Expression Levels

NPC1L1 and SR-BI protein levels were quantified in TC7 cells after incubation with different CL donors. NPC1L1 protein level increased in a dose-dependent manner with TCA concentrations (Fig. 2a). A fivefold increase in NPC1L1 protein level ( $7.03 \pm 0.76$  vs.  $1.49 \pm 0.13$  relative levels) was observed after cell incubation in the presence of donors prepared with (8 mM) or without (0 mM) TCA, respectively. Comparable protein expression level was obtained using TCA-free particles with either very large or small diameters. Thus, the mixed micelle size is not involved in this regulation path; TCA is efficient per se. Conversely, the SR-BI protein level was unchanged,

**Fig. 2** Effects of TCA concentration on NPC1L1 (a) and SR-BI (b) protein expression levels in TC7 cells. Two different TCA-free lipid donors were used, one with large (0) and one with small diameters obtained after sonication (0s). Expression levels were corrected to GAPDH for NPC1L1 and to  $\beta$ -actin for SR-BI. Results are expressed as the mean  $\pm$  SD ( $n = 3$ ), \* $P < 0.05$

whatever the experimental conditions (Fig. 2b). TCA was not able to modulate its expression level, but post-transcriptional regulations which regulate the transporter activity and/or its turnover may take place.

#### Regulation of SR-BI and NPC1L1 Gene Expression by Bile Salts

To confirm the ability of BA to up-regulate the NPC1L1 expression at mRNA level, we treated TC7 cells with TCA or deoxycholic acid (DCA) for 3 h. Both treatments induced a significant increase in the NPC1L1 mRNA level (Fig. 3a), but were inefficient at modulating SR-BI transcription levels (Fig. 3b). It is worth noting that the well-known FXR target gene small heterodimer partner (SHP) was also up-regulated by this BA treatment (data not shown).

**Fig. 3** Effect of BA on NPC1L1 (a) and SR-BI (b) mRNA expression levels in TC7 cells. Differentiated cells were incubated in the presence of 100  $\mu$ M TCA or 100  $\mu$ M DCA added to the apical medium. NPC1L1 and SR-BI expression were evaluated by quantitative RT-PCR and corrected with 18S rRNA gene expression. Results are expressed as mean  $\pm$  SD ( $n = 3$ ), \* $P < 0.05$ , \*\* $P < 0.01$

## Discussion

After a meal, dietary and biliary CL are present in the human intestinal content in the form of a complex mixture of emulsified droplets, vesicles, mixed micelles as well as precipitated material [20, 21]. Different CL transporters located at the enterocyte brush-border have recently been identified [10, 32], which has raised the key issue of possible interactions between components of CL donors and intestinal transporters with regard to CL absorption.

First, we observed that CL donor size is one determinant of CL cell transport. Indeed, the CL cell transport was increased fourfold after a marked size reduction (from 1,025 to 46 nm) of BA-free lipid donors (Table 2). Moreover, when lipid donors with increased TCA concentrations were dispersed, the CL donor size decreased and CL transport increased in a dose-dependent manner up to 38-fold (Table 2), exhibiting a negative relationship (Fig. 1b). Such a correlation is in agreement with a recent *in vivo* study showing that cholic acid supplementation enhances CL absorption in humans [33], and this has already been suggested by an *in vitro* study indicating that CL transfer from TCA micelles is faster than from other donor particles not containing bile salts [34]. Two different absorption processes were observed (Fig. 1b). With very large donors, a poorly efficient absorption process independent of NPC1L1 or SR-BI transporters takes place. It is likely a passive process [35]. In contrast, with small donors (mixed micelles), NPC1L1 and SR-BI contribute to a very efficient CL cell uptake. The minimum TCA concentration enabling efficient CL absorption (i.e., 3.9 mM) was comparable to the critical micellar concentration of TCA (around 4 mM) in such conditions. Indeed, when the BA concentration exceeds the critical micellar concentration, as occurs *in vivo* [20, 31], mixed micelles formed from vesicles made of amphipathic lipids and CL, leading to small-size donors (7–12 nm). This clearly means that efficient intestinal CL absorption requires both mixed micelles and intestinal CL transporters. The main reason for this is that enterocytes have an apical brush-border membrane made of many microvilli where the CL transporters (NPC1L1 and SR-BI) are present in Caco-2 cells [1, 10, 11]. The space between the microvilli ranges from 5 to 20 nm. To optimally access this space, CL donors should likely not be larger than it; indeed, we found in this work that the maximum donor size for efficient CL absorption is about 23 nm.

However, for a lipid donor size of the same order of magnitude (46 or 47 nm), the addition of TCA enhanced CL cell absorption twofold (Table 2). In addition, BA (TCA or DCA) up-regulated the NPC1L1 mRNA and protein levels (Figs. 2, 3). Thus, for the first time, we demonstrated that BAs also regulate intestinal CL absorption by activating an intracellular pathway, leading to an increase in the NPC1L1

protein level. Such a regulation of NPC1L1 by BA has already been suggested, with five days of dietary cholic acid supplementation increasing CL absorption in NPC1L1 (+/+) mice, but not in NPC1L1 (–/–) mice [7]. The presence of such an intracellular regulation explains why CL absorption was enhanced by increasing the BA level in mixed micelles [10]. It also indicates that the effects of BA on CL absorption are not solely due to their detergent capacity, in line with some previous experiments [24–26]. The molecular regulations induced by BA are unknown, but BAs are activating ligands of the farnesoid X receptor, a nuclear receptor with established roles in BA and lipid metabolisms [36]. After stimulating this nuclear receptor expression, intestinal CL transport was altered as well as the expression level of ABC family transporters [37]. The hypothesis that farnesoid X receptor is involved in the intracellular path induced by BA to up-regulate the NPC1L1 expression levels is currently under investigation. Surprisingly, SR-BI expression levels were not regulated by BA in this study. However, BAs were unable to regulate SR-BI expression levels in the rat model [38], whereas a reduction of the SR-BI protein levels was observed in mice with altered bile delivery and impaired CL absorption [39]. Experimental conditions may explain these differences, since only acute regulations could be observed in the present study (cells were incubated for just 3 h for sustained viability).

In conclusion, CL solubilized in mixed micelles can access the brush-border membrane transporters more easily, and is thus efficiently absorbed. In addition, BA absorbed by the enterocyte can elicit *per se* an intracellular signaling pathway which increases the expression of the main intestinal CL transporter, NPC1L1. Thus intestinal CL absorption is regulated by both the size and the components of the mixed micelles. In this context, these data confirm that the physicochemical environment of the lumen plays a major role in CL absorption efficiency. This can account, at least in a large part, for the important inter-individual variations observed in the rate of CL intestinal absorption.

**Abstract** This study examines the effect of diacylglycerol (DAG) oil consisting mainly of 1,3-species on fat oxidation as a possible mechanism for anti-obesity. We examined the following: (1) the long-term (23-week) effects of a DAG oil diet on the development of obesity; (2) the effect of a single ingestion of DAG oil on fat oxidation; and, (3) the short-term (2-week) effect of a DAG oil diet on fat metabolism in rats. Rats fed a DAG oil diet accumulated significantly less body fat compared to rats fed a triacylglycerol (TAG) oil diet, each oil possesses a similar fatty acid composition. More  $^{14}\text{C}$ - $\text{CO}_2$  was expired and less  $^{14}\text{C}$ -radioactivity was incorporated into visceral fat after administration of a tracer emulsion containing 1,3-[oleoyl- $^{14}\text{C}$ ] diolein compared to [carboxyl- $^{14}\text{C}$ ] triolein. Indirect calorimetry showed respiratory quotients were significantly lower in the DAG oil diet group than in the TAG oil diet group. More  $^{14}\text{C}$ - $\text{CO}_2$  was expired and less  $^{14}\text{C}$ -radioactivity was incorporated into visceral fat in the DAG oil diet group than in the TAG oil diet group after a single intragastric administration of [carboxyl- $^{14}\text{C}$ ] triolein. These results suggest the following. (1) DAG oil has an inhibitory effect on diet-induced fat accumulation. (2) 1,3-DAG, a major component of DAG oil, is more susceptible to oxidation. (3) A short-term ingestion of DAG oil increases fat utilization at the whole body level and results in increased oxidation of dietary fat. The stimulated fat oxidation might be one explanation for the anti-obesity effect of long-term DAG oil ingestion.

### Introduction

The metabolic syndrome can be defined as a state of metabolic dysregulation characterized by insulin resistance, obesity, and a predisposition to type 2 diabetes, dyslipidemia, premature atherosclerosis, and other diseases [1–3]. Especially in individuals with abdominal obesity, metabolic syndrome is the result of an imbalance between energy intake and energy expenditure. Therefore, food ingredients affecting energy expenditure may help people manage their weight.

Diacylglycerol (DAG) as a natural component of various edible oils, contains only two esterified fatty acyl chains in contrast to triacylglycerol (TAG). DAG oil is an edible oil containing 80–90% of DAG, approximately 70% of DAG exists as 1,3-DAG, and its energy value is practically the same as ordinary oil containing TAG [4–6]. Results from studies in animals and humans demonstrate that DAG oil has metabolic characteristics distinct from those of TAG oil, although the two have a similar fatty acid composition, and that these characteristics can be beneficial in preventing and managing the accumulation of visceral fat and the postprandial elevations of triacylglycerol in serum and chylomicron [4, 5, 7–15]. Kimura et al. [16] reported that DAG oil infusion in rats led to higher fat oxidation compared with TAG oil, although the two have a similar fatty acid composition. Saito et al. [17] reported that compared with a TAG oil-containing meal, a DAG oil-containing meal tended to produce significantly lower

postprandial respiratory quotient (RQ) in healthy humans. Kamphuis et al. [18] also reported that consumption of DAG oil in place of TAG oil increased fat oxidation in healthy humans. These previous results indicated that a single ingestion of DAG oil increases fat oxidation, and also indicated that DAG oil might be more easily oxidized than TAG oil. In addition, a short-term ingestion of DAG oil, instead of TAG oil, increased  $\beta$ -oxidation and its related gene expression in either liver or intestine of rodents [9–11, 19]. These results also indicated that a short-term ingestion of DAG oil might increase fat oxidation in the whole body and that might induce the oxidation of dietary fat and/or body fat. Therefore, the aim of this study was to examine the effect of DAG oil ingestion on fat oxidation as a possible mechanism for anti-obesity. This study was composed of three experiments:

1. In Experiment 1, we examined the long-term effects of DAG- and TAG-oil (having similar fatty acid compositions) on the development of obesity in rats.
2. In Experiment 2, we investigated the effect of a single ingestion of DAG oil on fat oxidation using 1(3), 2-[oleoyl- $^{14}\text{C}$ ] diolein ( $^{14}\text{C}$ -1(3),2-diolein), 1,3-[oleoyl- $^{14}\text{C}$ ] diolein ( $^{14}\text{C}$ -1,3-diolein) in comparison with [carboxyl- $^{14}\text{C}$ ] triolein ( $^{14}\text{C}$ -triolein).
3. In Experiment 3, we studied the effect of short-term (2-week) DAG oil ingestion on fat metabolism in comparison with TAG oil.

## Experimental Procedure

### Test Oils

DAG oil was prepared by esterifying glycerol with fatty acids from soybean oil and rapeseed oil using the method of Huge-Jensen et al. [20]. TAG oil was prepared by mixing rapeseed oil, safflower oil, and perilla oil. The fatty acid compositions of the TAG and DAG oils, analyzed by gas chromatography, are shown in Table 1. The fatty acid composition of the DAG oil was very similar to that of the TAG oil. The DAG concentration of the DAG oil was 85.8 g/100 g and the ratio of 1(3),2- to 1,3-DAG was 32.5:67.5.

### Materials

[Carboxyl- $^{14}\text{C}$ ] Triolein ( $^{14}\text{C}$ -triolein; Purity: >97%, Specific activity: 3.0–4.4 GBq/mM) was purchased from Perkin Elmer Life Science, Inc (Boston, MA, USA). 1(3),2- [oleoyl- $^{14}\text{C}$ ] Diolein ( $^{14}\text{C}$ -1(3),2-diolein; Purity: >95%, Specific activity: 629 MBq/mM) and 1,3- [oleoyl-

**Table 1** Fatty acid compositions of TAG and DAG oils<sup>a</sup>

<sup>a</sup> Percentage by weight

1- $^{14}\text{C}$ ] diolein ( $^{14}\text{C}$ -1,3-diolein; Purity: >95%, Specific activity: 492 MBq/mM) were obtained from Daiichi Chemical Co., Ltd. (Tokyo, Japan). Casein, cellulose powder, mineral mixture AIN-76, vitamin mixture AIN-76 (containing choline bitartrate), and  $\alpha$ -potato starch were obtained from Oriental Yeast (Tokyo, Japan). Casein sodium, sucrose, lecithin (from egg), and 1 N sodium hydroxide solution were purchased from Wako Pure Chemical Industries, Ltd (Osaka, Japan). Bovine serum albumin, xanthan-gum, and ethanolamine were purchased from Sigma Chemical Co. (St. Louis, MO, USA).

### Tracer Emulsion with $^{14}\text{C}$ -Labeled Fat

The tracer emulsion with  $^{14}\text{C}$ -labeled fat was prepared in the same manner as in a previous report, with minor modification [21]. The “[ $^{14}\text{C}$ ] TAG emulsion” (w/w) contained  $^{14}\text{C}$ -triolein (1.74 kBq/g) in TAG oil (4.61%); the “[ $^{14}\text{C}$ ] 1(3),2-DAG emulsion” (w/w) contained  $^{14}\text{C}$ -1(3),2-diolein (1.74 kBq/g) in DAG oil (4.61%), and the “[ $^{14}\text{C}$ ] 1,3-DAG emulsion” (w/w) contained  $^{14}\text{C}$ -1,3-diolein (1.74 kBq/g) in DAG oil (4.61%). Each tracer emulsion contained casein sodium (4.61%), sucrose (11.88%), cellulose powder (0.92%), mineral mixture AIN-76 (0.81%), vitamin mixture AIN-76 (0.23%), bovine serum albumin (1.92%), xanthan-gum (0.23%), lecithin (from egg) (0.19%) and distilled water (74.56%), and was prepared through emulsification by sonicator.

### Animals and Experimental Design

The animal experiments were performed with the approval of the Ethics Committee for Experimental Animals of the

Kao Corporation. The animals were housed in a temperature- and humidity-controlled environment ( $22 \pm 2^\circ\text{C}$ ,  $55 \pm 10\%$ ) under a 12-h light/dark cycle. Male SD rats (7 weeks old) used in Experiments 1 and 3 or 2 were purchased from CLEA Japan (Tokyo, Japan) or Charles River Japan (Kanagawa, Japan), respectively. During the acclimatization periods (7-days), they had free access to a commercial rodent diet CE-2 (CLEA Japan) and to drinking water.

In Experiment 1, we investigated the long-term effects of DAG oil on development of obesity. After acclimatization periods, the rats were divided into three groups ( $n = 7/\text{group}$ ). The body weight of each group was approximately equal. Each rat ingested either the low-TAG, TAG, or DAG oil diet for a 23-week period (Table 2). The energy values for each diet were calculated from the macronutrient composition, using values of 16.7, 16.7, 38.9, and 39.6 kJ/g for carbohydrate, protein, DAG and TAG oil, respectively. All rats were allowed access to water and food ad libitum. Food intake was recorded every 3 or 4 days. A week before the final day of Experiment 1, the amounts of food consumed and of feces in a 48-h period were measured and fat contents of the diets and of the feces were extracted according to the method used by Jeejeebhoy et al. [22]. Calculation of fat digestibility was based on the fat contents of diets and of feces. On the final day of Experiment 1, a blood sample was collected via the abdominal aorta from the anaesthetized rats under non-fasting conditions between 9 and 11 am. The fat pads were then dissected from each rat, and the weight of visceral fat (retroperitoneal, epididymal, mesenteric, and perirenal fats), and inguinal fat were determined. Serum triacylglycerol, total cholesterol, and glucose concentrations were determined using the following enzyme assay kits, respectively: L-type Wako TG-H; L-type Wako CHO-H; and L-type Glu2 (all from Wako, Osaka, Japan). Serum insulin and leptin were measured using rat insulin and

leptin enzyme immunoassay (EIA) kits (both from Morinaga, Yokohama, Japan) according to the manufacturer's instructions.

In Experiment 2, we compared  $^{14}\text{C}$ -1,3-diolein (Exp.2-1) and  $^{14}\text{C}$ -1(3),2-diolein (Exp.2-2) with  $^{14}\text{C}$ -triolein in fat oxidation. After acclimatization periods on the commercial rodent diet (CE-2), the rats were divided into two groups: Exp.2-1 ( $^{14}\text{C}$  1,3-DAG group versus  $^{14}\text{C}$  TAG group, ( $n = 12/\text{group}$ )), and Exp.2-2 ( $^{14}\text{C}$  1(3),2-DAG group versus  $^{14}\text{C}$  TAG group, ( $n = 12/\text{group}$ )). The body weight of each group was approximately equal (Exp.2-1:  $^{14}\text{C}$  1,3-DAG group and  $^{14}\text{C}$  TAG group =  $293.4 \pm 2.5$  g and  $294.7 \pm 2.6$  g, Exp.2-2:  $^{14}\text{C}$  1(3),2-DAG group and  $^{14}\text{C}$  TAG group =  $303.6 \pm 4.0$  g and  $306.0 \pm 3.5$  g). After intragastric administration of each tracer emulsion (7.23 g; 12.33 kBq/kg rat body weight of " $^{14}\text{C}$  TAG emulsion", " $^{14}\text{C}$  1(3),2-DAG emulsion", or " $^{14}\text{C}$  1,3-DAG emulsion"), rats were placed in individual, airtight metabolic cages (Sugiyama-gen, Tokyo, Japan) and maintained for 22 h at  $22 \pm 2^\circ\text{C}$ . Air was drawn through the cages at 300 mL/min. The air entering the cage was first passed through 1 N sodium hydroxide solution to remove atmospheric carbon dioxide and then passed through silica gel blue (Wako Pure Chemical Industries, Ltd) to remove water vapor. The gas expired by the rats was trapped in a trough gas collection chamber containing 50% ethanolamine solution (300 mL). A 1-mL aliquot of the expired  $^{14}\text{C}$ -CO<sub>2</sub> was collected at 2, 4, 6, 8, 10, and 22 h after administration of each tracer emulsion. At 22 h after administration of each tracer emulsion, the rats were euthanized and blood, liver, and white adipose tissues as visceral fat (mesenteric, epididymal, perirenal and retroperitoneal) were collected for radioactivity measurement.

In Experiment 3, we investigated the effects of short-term ingestion of DAG oil on fat oxidation in the whole body (Exp.3-1) and on  $^{14}\text{C}$ -triolein oxidation as dietary fat (Exp.3-2), in comparison with TAG oil.

In Exp.3-1, after acclimatization periods, the rats were divided into two groups ( $n = 7/\text{group}$ ). The body weight of each group was approximately equal. Each rat ingested either a TAG or a DAG oil diet for 2 weeks (Table 2). All rats were allowed access to water and food ad libitum. After the 2-week ingestion of each diet, the respiratory metabolic performance of each rat was measured using an indirect calorimetric system. (Oxymax Respirometer system v5.61, Columbus Instruments, Columbus, OH, USA). In the respiration chamber, each rat was allowed access to water and each diet ad libitum. Each metabolic chamber had a 5 L. Air flow through the chambers, and expired airflow from the chambers was adjusted to 2.0 L/min and 1.0 L/min, respectively. Oxygen consumption (VO<sub>2</sub>), carbon dioxide exhaustion, and spontaneous motor activity were measured and recorded, from 5 pm on the first day

**Table 2** Composition of the diets

Ingredient	Dietary group(g/100 g diet)		
	Low-TAG	TAG	DAG
TAG oil	5.0	20.0	–
DAG oil	–	–	20.0
$\alpha$ -Potato starch	66.5	41.5	41.5
Sucrose	–	10.0	10.0
Casein	20.0	20.0	20.0
Cellulose	4.0	4.0	4.0
Mineral mix <sup>a</sup>	3.5	3.5	3.5
Vitamin mix <sup>b</sup>	1.0	1.0	1.0

<sup>a</sup> AIN-76 prescription

<sup>b</sup> AIN-76 prescription + choline bitartrate (20 g/100 g)

until 4 pm of the second day, every 10 min for the 23-h period, and then the average values of each hour-period were determined. The RQ value was calculated using an Oxymax respirometer system and the following formula: RQ = carbon dioxide exhaustion/oxygen consumption. The spontaneous motor activity of each rat was examined with SCANET SV-10 (Toyo Sangyo Co., Ltd., Toyama, Japan). The fat oxidation value was calculated using the method of Ishihara et al. [23]. The motor activity was assessed as a single count when the animal moved from one region of the measurement area, which was optically divided by multiple lenses, to a neighboring region.

In Exp.3–2, after acclimatization periods, the rats were divided into two groups ( $n = 8/\text{group}$ ). The body weight of each group was approximately equal. Each rat ingested either a TAG or a DAG oil diet for 2 weeks (Table 2). All rats were allowed access to water and food ad libitum. After a 2-week ingestion of each diet, each rat was intragastrically given a “[ $^{14}\text{C}$ ] TAG emulsion”, then was placed in an individual airtight metabolic cage and maintained for 22-hour with collection of aliquots for trapping of ( $^{14}\text{C}\text{-CO}_2$ ) in the same manner as Experiment 2. At 22-hour after administration of the [ $^{14}\text{C}$ ] TAG emulsion, the rats were euthanized and blood, liver, and white adipose tissues as visceral fat were collected for radioactivity measurement, as in Experiment 2.

### Radioactivity Measurements

Liver and white adipose tissue samples were weighed and then homogenized in a Polytron homogenizer (Glen Mills Inc., Clifton, NJ, USA). A 250-mg aliquot of homogenate was treated with 1 mL Solvable (Perkin Elmer Life Science, Inc) for 2 h at 50°C and with 200  $\mu\text{L}$  of 30% hydrogen peroxide for 30 min at 50 °C. A 100- $\mu\text{L}$  aliquot of blood sample was treated with 0.5 mL Solvable and

300  $\mu\text{L}$  of 30% hydrogen peroxide. Radioactivity in each aliquot was quantitated by liquid scintillation analyzer (Tri-Carb 2550 TR/LL, Packard Instrument Company, Meriden, CT, USA).

### Statistical Analyses

The data are presented as the mean  $\pm$  SEM. Statistical differences were determined using a student *t*-test or Fisher’s protected least significant difference test. A repeated measures ANOVA was used to investigate changes in energy expenditure and expired  $^{14}\text{C}\text{-CO}_2$  levels. A statistical model was constructed using the effects of treatment, time and interaction of treatment  $\times$  time. In all analysis, significance was defined as  $P < 0.05$ . These statistical calculations were performed with Stat View for Windows, version 5.0 (SAS Institute, Cary, NC, USA).

## Results

### Experiment 1: Effect of Long-Term Ingestion of DAG Oil on Development of Obesity

Consistent with earlier reports [7–11], ingestion of a DAG oil diet significantly reduced body fat accumulation compared with a TAG oil diet in rats.

The TAG oil diet (a high-TAG oil diet) significantly increased body weight and fat pads weight compared with a low-TAG oil diet. On the other hand, rats fed a DAG oil diet accumulated less total visceral, retroperitoneal and inguinal fat weight by 21, 32, and 27%, respectively, as compared with a TAG oil diet (Table 3). No significant difference was observed in the average energy intake and fat digestibility between the TAG and the DAG oil diet groups (Table 3), suggesting that reduced body fat

**Table 3** Body weight, energy intake, body fat weight, and digestibility

Exp.1: Rats were euthanized after a 23-week ingestion of the respective diets, and the body fat weight was determined. Food intake was measured throughout the study. Values are mean  $\pm$  SEM ( $n = 7$ ); those with different letters are significantly different by Fisher’s PLSD,  $P < 0.05$

accumulation in the DAG oil diet group was not related to reduced energy intake. No significant difference was observed in non-fasting serum parameters between the TAG and the DAG oil diet groups, whereas non-fasting leptin level was significantly higher in the TAG oil diet group than the low-TAG oil diet group (Table 4).

### Experiment 2: Comparison of Oxidation in $^{14}\text{C}$ -1,3-Diolein (Exp.2-1) and $^{14}\text{C}$ -1(3),2-Diolein (Exp.2-2) with $^{14}\text{C}$ -Triolein

We investigated the effects of DAG isomers, 1,3-DAG and 1(3),2-DAG, in comparison with TAG, on fat oxidation and incorporation of dietary fat into visceral fat, liver, and blood using  $^{14}\text{C}$ -1,3-diolein,  $^{14}\text{C}$ -1(3),2-diolein, and  $^{14}\text{C}$ -triolein. The expired  $^{14}\text{C}$ -CO<sub>2</sub> is shown in Fig. 1. The

**Fig. 1 a** The expired  $^{14}\text{C}$ -CO<sub>2</sub> in the rats that ingested the commercial rodent diet (CE-2) and received a [ $^{14}\text{C}$ ] 1,3-DAG emulsion compared with a [ $^{14}\text{C}$ ] TAG emulsion in Exp.2-1. *Open squares* represent the [ $^{14}\text{C}$ ] TAG group and *closed squares* represent the [ $^{14}\text{C}$ ] 1,3-DAG group. **b** The expired  $^{14}\text{C}$ -CO<sub>2</sub> in the rats that received a [ $^{14}\text{C}$ ] 1(3),2-DAG emulsion compared with a [ $^{14}\text{C}$ ] TAG

expired  $^{14}\text{C}$ -CO<sub>2</sub> in the rats administered the [ $^{14}\text{C}$ ] 1,3-DAG emulsion ( $^{14}\text{C}$ -1,3-diolein) was increased compared with the [ $^{14}\text{C}$ ] TAG emulsion ( $^{14}\text{C}$ -triolein) (Exp.2-1; Fig. 1a). In contrast, the expired  $^{14}\text{C}$ -CO<sub>2</sub> in the rats administered the [ $^{14}\text{C}$ ] 1(3),2-DAG emulsion ( $^{14}\text{C}$ -1(3),2-diolein) was equal to the [ $^{14}\text{C}$ ] TAG emulsion ( $^{14}\text{C}$ -triolein) (Exp.2-2; Fig. 1b). Table 5 shows the  $^{14}\text{C}$  contents in visceral fat, liver and blood at 22 h after administration of each tracer emulsion. The  $^{14}\text{C}$  content in visceral fat after [ $^{14}\text{C}$ ] 1,3-DAG emulsion administration was significantly less compared to [ $^{14}\text{C}$ ] TAG emulsion (Exp.2-1). In contrast, incorporation of  $^{14}\text{C}$  radioactivity into visceral fat was similar between [ $^{14}\text{C}$ ] 1(3),2-DAG and [ $^{14}\text{C}$ ] TAG emulsion (Exp.2-2). The  $^{14}\text{C}$  contents in liver and blood did not differ between the groups (Exp.2-1 and Exp.2-2).

### Experiment 3: Effect of Short-Term Ingestion of DAG Oil on Fat Oxidation

#### Exp.3-1: Fat Oxidation at a Whole Body Level

Body weight at 2 weeks after ingestion of TAG and DAG oil diets were 360.7 ± 5.3 and 361.8 ± 3.9 g, and energy intakes at 2 weeks were 407.2 ± 9.4 and 405.9 ± 4.0 kJ/rat/day, respectively, with no significant differences between the groups. VO<sub>2</sub>, RQ, fat oxidation, and spontaneous motor activity for the 23-h feeding period in the respiration chamber (with access to water and each diet ad libitum) are shown in Fig. 2. Energy intake for 23 h of the TAG and the DAG oil diets were 267.0 ± 15.3 and 231.7 ± 25.7 kJ/rat, respectively, with no significant

emulsion in Exp.2-2. *Open squares* represent the [ $^{14}\text{C}$ ] TAG group and *closed squares* represent the [ $^{14}\text{C}$ ] 1(3),2-DAG group. Values are expressed as mean ± SEM ( $n = 12$ ). A symbol at each time point indicates a significant difference between the groups by Student's  $t$ -test: \* $P < 0.05$ , \*\* $P < 0.01$ . Significant differences by repeated measures ANOVA are shown under the graphs

Exp.2-1: Rats that ingested the commercial rodent diet (CE-2) were administered either the [ $^{14}\text{C}$ ] 1,3-DAG emulsion or the [ $^{14}\text{C}$ ] TAG emulsion. Exp.2-2: Rats that ingested the commercial rodent diet (CE-2) were administered either the [ $^{14}\text{C}$ ] 1(3),2-DAG emulsion or the [ $^{14}\text{C}$ ] TAG emulsion. At 22-h after administration of each tracer emulsion, the rats were euthanized and blood, liver, and white adipose tissues were collected for radioactivity measurement. The expired  $^{14}\text{C}$ - $\text{CO}_2$  was collected at 2, 4, 6, 8, 10, and 22 h after administration of each tracer emulsion. Values are mean  $\pm$  SEM ( $n = 12$ ).

\* Significantly different from the [ $^{14}\text{C}$ ] TAG group,  $P < 0.05$

difference between the groups.  $\text{VO}_2$  and spontaneous motor activity values were equal between the groups. RQ values in the DAG oil diet group were lower than in the TAG oil diet group. Fat oxidation measurements in the DAG oil diet group at 2, 3, and 9 am were higher than in the TAG oil diet group.

#### Exp.3-2: $^{14}\text{C}$ -Labeled Dietary Fat Oxidation

Body weight at 2 weeks after ingestion of the TAG and the DAG oil diets were  $377.1 \pm 9.7$  and  $370.3 \pm 7.2$  g, and energy intakes at 2 weeks were  $362.9 \pm 15.9$  and  $362.9 \pm 15.7$  kJ/rat/day, respectively, with no significant differences between the groups. The expired  $^{14}\text{C}$ - $\text{CO}_2$  after intragastric administration of [ $^{14}\text{C}$ ] TAG emulsion was significantly higher in the DAG oil diet group compared to the TAG oil diet group following a 2-week ingestion of each diet (Fig. 3). The  $^{14}\text{C}$  contents in mesenteric, epididymal, and perirenal fat were significantly less in the DAG oil diet group than in the TAG oil diet group (Table 6). In addition, the  $^{14}\text{C}$  contents in total visceral fat were less in the DAG oil diet group than in the TAG oil diet group. The  $^{14}\text{C}$  contents in liver and blood did not differ between the groups.

## Discussion

Consistent with previous reports [7–11], a long-term ingestion of DAG oil significantly reduced body fat accumulation compared with TAG oil, which has a similar fatty acid composition. Also consistent with previous reports,

neither energy intake nor fat excretion in feces differed significantly between TAG and DAG oil diets [6, 9], suggesting that reduced body fat accumulation in the DAG oil diet group was not related to reduced energy intake.

Fat balance, calculated as the difference between dietary fat intake and fat oxidation and excretion, has been suggested as a key factor of fat mass regulation [24]. Fat oxidation at the whole-body level must be assessed by indirect calorimetry, whereas dietary fat oxidation is assessed using expired labeled- $\text{CO}_2$  after administration of stable isotope- or isotope-labeled fat. Piers et al. [25] demonstrated using indirect calorimetry that fat oxidation was higher after a single ingestion of a high monounsaturated fat meal compared to a high saturated fat meal. Bessesen et al. [26] reported that the expired  $^{14}\text{C}$ - $\text{CO}_2$  was lower after a single administration of  $^{14}\text{C}$ -stearic acid compared to  $^{14}\text{C}$ -oleic and linolenic acid. Shimomura et al. [27] reported that the diets high in saturated fat were associated with an increase in body weight. The above studies together suggest that increased fat oxidation may contribute to improvement of obesity.

$^{14}\text{C}$ -1,3-DAG-derived  $^{14}\text{C}$ -radioactivity was expired more as  $^{14}\text{C}$ - $\text{CO}_2$  and incorporated less into visceral fat compared to  $^{14}\text{C}$ -TAG. In contrast,  $^{14}\text{C}$ -1(3),2-DAG was metabolized similarly as  $^{14}\text{C}$ -TAG. These results suggest that 1,3-DAG, a major component of DAG oil, is more susceptible to oxidation and less accumulated in visceral fat compared to TAG after a single administration.

Several studies demonstrated that a single ingestion of DAG oil affected fat metabolism differentially from TAG oil. Kimura et al. [16] reported that a single administration of DAG oil emulsion decreased RQ values compared with TAG oil emulsion in rats. Kamphuis et al. [18] reported

**Fig. 2** Changes in  $VO_2$  (a), RQ (b), fat oxidation (c), and spontaneous motor activity (d) for the 23-h feeding period in a respiration chamber after a 2-week ingestion of either the TAG or DAG oil diet in Exp.3–1. *Open circles* represent the TAG oil diet group and *closed circles* represent the DAG oil diet group. Values are expressed as mean  $\pm$  SEM ( $n = 7$ ). Differences in values between the groups by Student's *t*-test: # $P < 0.1$ , \* $P < 0.05$ . Significant differences by repeated measures ANOVA are shown under the graphs

that the ingestion of a DAG oil-containing meal increased fat oxidation in humans. Saito et al. [17] also reported that the ingestion of a DAG oil-containing meal decreased RQ values. The higher susceptibility of 1,3-DAG to oxidation found in this study is consistent with the above previous studies.

The present study also demonstrated that the fat oxidation is higher in 1,3-DAG compared with TAG. In contrast, 1(3),2-DAG is oxidized in a similar manner as TAG. The reason 1,3-DAG and TAG are differentially susceptible to

oxidation is still unclear. The differential metabolic pathway of each acylglycerol may offer an explanation. Kondo et al. [12] demonstrated that 1,3-diolein was hydrolyzed to 1(3)-monoolein and fatty acids, and triolein was hydrolyzed to 1(3),2-diolein, 2-monoolein and fatty acids through digestion by pancreatic lipase in the small intestine in mice. In addition, 1,3-diolein was less susceptible to enzymatic TAG re-synthesis compared with 1(3),2-diolein. Murase et al. [10] reported that the amount of fatty acid, as digestion products, was higher with DAG oil than with

**Fig. 3** The expired  $^{14}\text{C}$ -CO $_2$  in the rats that received the [ $^{14}\text{C}$ ] TAG emulsion after a 2-week ingestion of the TAG or DAG oil diet in Exp.3–2. *Open squares* represent the TAG oil diet group and *closed squares* represent the DAG oil diet group. Values are expressed as mean  $\pm$  SEM ( $n = 8$ ). A symbol at each time point indicates a significant difference between the groups by Student's *t*-test. Blood	0.47 $\pm$ 0.03	0.47 $\pm$ 0.02
Expired CO $_2$	60.73 $\pm$ 1.51	65.43 $\pm$ 0.94*

Exp.3–2: Rats that ingested TAG oil diet or DAG oil diet for 2 weeks were administered the [ $^{14}\text{C}$ ] TAG emulsion. At 22-hour after administration of [ $^{14}\text{C}$ ] TAG emulsion, the rats were euthanized and blood, liver, and white adipose tissues were collected for radioactivity measurement. The expired  $^{14}\text{C}$ -CO $_2$  was collected at 2, 4, 6, 8, 10, and 22 h after administration of [ $^{14}\text{C}$ ] TAG emulsion. Values are mean  $\pm$  SEM ( $n = 8$ )

\* Significantly different from the TAG diet group,  $P < 0.05$

TAG oil in the small intestine of mice. While Nemali et al. [28] reported that the liver, kidney, small intestine, and heart were active organs on  $\beta$ -oxidation. According to these previous reports, decreased TAG re-synthesis and increased fatty acid production in the small intestine may

contribute to the increased oxidation of 1,3-DAG. On the other hand, we hypothesized that the oxidation of 1(3),2-DAG was similar to that of TAG because 1(3),2-DAG is a main digestive product of TAG. However, further detailed experiments are required to clarify these speculations.

In Experiment 3, we demonstrated that a short-term ingestion of DAG oil led to increased fat utilization at a whole-body level, increased dietary fat oxidation, and decreased dietary fat incorporation into visceral fat compared with TAG oil. Murata et al. [19] reported that a 2-week ingestion of DAG oil increased  $\beta$ -oxidation activity, its related enzymes activities, and reduced fat synthesis-related enzyme activities in the liver. Murase et al. [10] also observed that a 10-day ingestion of DAG oil increased  $\beta$ -oxidation in the small intestine in mice. These results suggest that a short-term ingestion of DAG oil may activate hepatic and intestinal  $\beta$ -oxidation at the tissue level. In this study, we revealed for the first time that a short-term ingestion of DAG oil stimulates fat metabolism at a whole-body level. In addition, we demonstrated for the first time that a short-term ingestion of DAG oil resulted in a stimulation of dietary fat oxidation.

In conclusion, this study shows the following: (1) DAG oil has an inhibitory effect on diet-induced fat accumulation compared to TAG oil; (2) 1,3-DAG, a major component of DAG oil, is more susceptible to oxidation compared to TAG or 1(3),2-DAG; and, (3) a short-term ingestion of DAG oil increases fat utilization at a whole-body level, and results in increased oxidation of dietary fat compared to TAG oil. The stimulated fat oxidation might be one explanation for the anti-obesity effect of long-term DAG oil ingestion.

**Abstract** The (–)-gallocatechin gallate (GCG) concentration in some tea beverages can account for as much as 50% of the total catechins, as a result of sterilization. The present study aims to examine the effects of GCG-rich tea catechins on hyperlipidemic rats and the mechanisms associated with regulating cholesterol metabolism in the liver. By performing heat epimerization of (–)-epigallocatechin gallate (EGCG), we manufactured a mixture of catechins that had a GCG content of approximately 50% (w/w). In sucrose-rich diet-induced hyperlipidemic rats, the GCG-rich tea catechins exhibited strong activity in reducing plasma cholesterol and triglyceride concentrations. Furthermore, the hepatic cholesterol and triglyceride concentrations that had increased as a result of the sucrose-rich diet were reduced due to GCG-rich tea catechins consumption. In order to investigate the hyperlipidemic mechanism of GCG-rich tea catechins, we examined the hepatic expressions of LDL receptor and HMG-CoA reductase in hyperlipidemic rats. We further evaluated the action of purified GCG on LDL receptor activity, which is a key contributor to the regulation of cholesterol

concentrations. We found that purified GCG increased LDL receptor protein level and activity to a greater extent than EGCG. In conclusion, our study indicates that GCG-rich tea catechins in tea beverages may be effective in preventing hyperlipidemia by lowering plasma and hepatic cholesterol concentrations.

**Keywords** GCG-rich catechins · Hyperlipidemia · LDL receptor activity

### Abbreviations

EGCG	(–)-Epigallocatechin gallate
GCG	(–)-Gallocatechin gallate
HDL	High density lipoprotein
LDL	Low density lipoprotein
VLDL	Very low density lipoprotein
LDLR	Low density lipoprotein receptor
HMG-CoA	3-Hydroxy-3-methylglutaryl coenzyme A

### Introduction

Hypercholesterolemia is one of the major risk factors for the development of atherosclerosis. Epidemiological studies have been reported which show a significant inverse relationship between the consumption of tea beverages and plasma cholesterol concentration [1, 2]. The health benefits of green tea have been attributed mainly to catechins, particularly (–)-epigallocatechin gallate (EGCG), which is the most abundant catechin in green tea [3, 4]. Animal studies have shown that EGCG inhibited cholesterol absorption and lowered plasma cholesterol concentration [5, 6]. It was found that EGCG enhanced the removal of intravenously injected  $^{14}\text{C}$ -cholesterol from plasma in rats

[7]. This increased clearance rate of cholesterol might have been due to an increased LDL receptor expression, as this is the main mechanism by which cholesterol is removed from the circulation [8]. Kuhn et al. [9] found that EGCG was able to increase LDL receptor protein expression with subsequent up-regulation of LDL receptor gene transcription. Moreover, Bursill and Roach [10] found that EGCG significantly increased LDL receptor binding activity. These studies might explain the effect of EGCG on regulating cholesterol concentration by increasing LDL receptor activity.

Canned and bottled tea beverages are widely consumed in Asian countries and are gaining popularity worldwide. During pasteurization, these products are generally autoclaved at 120 °C for several minutes. It has been known that during pasteurization, considerable amounts (approximately 50%) of catechins undergo epimerization at the two-position to form (–)-catechin, (–)-gallocatechin, (–)-catechin gallate, and (–)-gallocatechin gallate (GCG) [11]. It has been reported that the GCG concentration of total catechins could increase from approximately 1.5% to as much as 50% in some tea beverages [11]. The relatively high GCG concentration in tea beverages is due to the thermal conversion of a major tea catechin, EGCG.

Although the consumption of bottled green tea beverages is increasing, several physiological functions involving the regulation of plasma lipid concentrations have been reported for EGCG; however, studies on GCG-rich tea catechins are limited. Recently, Ikeda et al. [12] found that tea catechins rich in GCG were more effective in inhibiting cholesterol absorption than tea catechins rich in EGCG. In addition, Kobayashi et al. [13] reported that heat-epimerized catechins had identical cholesterol-lowering activity as green tea catechins in cholesterol-fed rats. Except for its inhibitory effect on cholesterol absorption, other mechanisms by which GCG-rich tea catechins reduce plasma lipid concentrations are not known. In the present study, we manufactured a mixture of catechins that contained approximately 50% (w/w) GCG by the heat epimerization of EGCG. By using GCG-rich tea catechins, we evaluated the effect on lipid concentrations in hyperlipidemic rats induced by a sucrose-rich diet. Furthermore, we analyzed the cholesterol and triglyceride concentrations in the liver which is the main tissue that regulates lipid metabolism.

Human and animal cells possess at least two mechanisms for obtaining the cholesterol necessary for the formation of membranes, steroid hormones, and bile acids. They can either obtain this cholesterol by means of receptor-mediated endocytosis of LDL, an event that involves the LDL receptor, or synthesize cholesterol de novo using 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase) as a rate-limiting enzyme [14]. Under certain

conditions, the LDL level in plasma is determined by a balance between the activities of LDL receptor and HMG-CoA reductase in the liver. The LDL receptor has been found to regulate and lower plasma cholesterol concentration, while HMG-CoA reductase, a rate-limiting enzyme that catalyzes the conversion of HMG-CoA to mevalonic acid, is known as the critical enzyme for cholesterol de novo synthesis in our body [15]. In order to study the mechanism of the hypercholesterolemic effect of GCG-rich tea catechins, hepatic LDL receptor activity and HMG-CoA reductase levels were measured. In addition, based on previous studies that evaluated the effect of EGCG on increasing LDL receptor activity, we further analyzed the effect of purified GCG on LDL receptor expression and activity in HepG2 cells.

## Materials and Methods

### Chemical Reagents

(–)-Epigallocatechin gallate (EGCG, E4143) and (–)-gallocatechin gallate (GCG, G6782) were purchased from Sigma (St. Louis, MO, USA) for *in vitro* experiments. Penicillin–streptomycin, Dulbecco's modified Eagle's medium (DMEM), and fetal bovine serum (FBS) were purchased from GIBCO-BRL of Life Technologies (New York, NY, USA). Specific antibodies for LDL receptor and HMG-CoA reductase were purchased from Abcam (ab14056) and SantaCruz (sc-27578), respectively. For measurements of LDL receptor activity, fluorescence probe (BODIPY) labeled LDL was purchased from Molecular probe, Inc (Eugene, OR, USA). For the manufacture of GCG-rich tea catechins, pure EGCG powder was obtained from TEAVIGO™ (94% purity), which was a registered trademark of DSM Nutritional Products (Parsippany, NJ, USA). GCG-rich tea catechins were manufactured by autoclaving the pure EGCG powder at 120 °C for 30 min. The EGCG and GCG concentrations as a result of heat epimerization are shown in Table 1. Initially, we intended to compare the effects of absolute GCG and EGCG *in vivo*. However, we realized that purchasing GCG powder from Sigma-Aldrich in order to include a group of rats administered with only GCG (90~100%) would involve prohibitive costs. Moreover, the EGCG provided by Sigma-Aldrich is too expensive for animal experiments.

**Table 1** EGCG and GCG contents (%) of the GCG-rich tea catechins

	EGCG	GCG	EGCG + GCG
Raw EGCG material	94	0	94
GCG-rich tea catechins	46.6	46.1	92.7

Therefore, due to high material costs, we used pure EGCG powder from TEAVIGO™ and manufactured GCG-rich tea catechins by autoclaving the TEAVIGO™ samples for our in vivo experiments. The purity of EGCG for the in vitro and in vivo experiments was 95 and 94%, respectively. Although we obtained EGCG powder from TEAVIGO™ instead of Sigma-Aldrich, we believe this did not show any different metabolism results between in vitro and in vivo experiments, since the EGCG for each experiment was the same compound and the content of EGCG was similar.

#### Sucrose-Rich Diet-Induced Hyperlipidemic Rats

Studies were carried out using male Sprague-Dawley rats (Orient Bio Company, Korea); each weighing approximately 200 g. The experiments were conducted under the Korea Association for Laboratory Animal Science's guidelines for the care and use of experimental animals. The amerepacific institutional animal care and use committee had approved the use of animals in the experiments. Seven-week-old rats were randomly divided into the following groups: control diet (CD), sucrose-rich diet (SRD), EGCG (E), and GCG-rich tea catechins (G), with six animals per group. All rats were provided free access to experimental diet and fluid for 30 days. The composition of the diets is shown in Table 2 [16]. The CD and SRD groups consumed distilled water. EGCG and the GCG-rich tea catechins were prepared in distilled water (0.2% w/v) and the rats in E and G groups consumed each of the designated fluids ad libitum. The fluids containing EGCG and the GCG-rich tea catechins were freshly prepared, and the intakes were measured on every other day. Body weight and food intakes were measured three times a week.

**Table 2** Composition of the experimental diets

Ingredient	Control diet (CD) (g/kg diet)	Sucrose-rich diet (SRD) (g/kg diet)
Casein	200	200
Corn starch	397.5	0
Sucrose	100	600
Dextrose	130	30
Soybean oil	70	70
Cellulose	50	50
AIN-93G mineral mix	35	35
AIN-93G vitamin mix	10	10
L-Cystine	3	3
Choline bitartrate	2.5	2.5
<i>t</i> -Butylhydroquinone	0.014	0.014

Modified from the AIN-93 purified rodent diet

#### Analysis of Plasma Total Triglyceride, Total Cholesterol, HDL Cholesterol, LDL Cholesterol, and VLDL Cholesterol Concentrations

Venous blood for measuring lipid concentrations was collected from the retro-orbital sinus of the animals on day 30. Plasma samples were separated from the whole blood by centrifugation at 3,000g for 10 min. Plasma total triglyceride, total cholesterol, HDL cholesterol, and LDL cholesterol concentrations were determined according to the protocol provided by DiaSys Diagnostic Systems (Holzheim, Germany). Based on the total cholesterol and HDL cholesterol that were measured, we calculated the VLDL + LDL cholesterol concentration by using modified Friedewald formula [17]. The VLDL + LDL cholesterol level for each sample was obtained using the following formula:

$$\text{VLDL + LDL cholesterol} = \text{total cholesterol} - \text{HDL cholesterol.}$$

#### Analysis of the Total Hepatic Triglyceride and Cholesterol Concentrations

Liver tissue was extracted using the standard Folch [18] extraction technique as described below. Homogenized liver (100 mg, wet weigh) was first mixed with 5 mL methanol containing 0.2% butylated hydroxytoluene, followed immediately by the addition of 10 mL chloroform, and vortexed vigorously for 30 s. The homogenate was centrifuged at 3,000g for 10 min and we separated the homogenate to obtain a crude extract solution. The crude extract was mixed thoroughly with 0.2 times its volume of water, and the mixture was separated into two phases by centrifugation. The upper phase was aspirated; it was completely removed by rinsing the inter-phase three times with small amounts of pure upper phase solvents. The lower organic layer was transferred to a tube and stored at  $-20^{\circ}\text{C}$ . The total hepatic cholesterol and triglyceride concentrations were measured using EnzyChrom Cholesterol Assay Kit (BioAssay Systems, Hayward, CA, USA) and L-Type Triglyceride H reagents (Wako, Osaka, Japan), respectively.

#### Detection of LDL Receptor Activity and HMG-CoA Reductase in the Rat Liver

Low-density lipoprotein receptor and HMG-CoA reductase were detected by using western blotting with specific antibodies [10, 19]. Liver samples and HepG2 cells were lysed using cell lysis buffer (Cell Signaling Technology, Beverly, MA, USA). The protein concentration was determined using a BCA assay kit (Pierce, Rockford, IL, USA). Proteins (30  $\mu\text{g}$ ) were resolved on 10% NuPAGE gels run in an MES buffer system (Invitrogen, Carlsbad,

CA, USA) and transferred to nitrocellulose membranes according to the manufacturer's protocol. Immunoreactive proteins were revealed by enhanced chemiluminescence with ECL+ (Amersham Biosciences, Piscataway, NJ, USA). Anti-actin antibody (Sigma, A2066) was used to assess equal loading of the protein. Quantification of each protein was carried out by using the Image J software program.

#### HepG2 Cell Culture and Catechins Treatment

Human hepatoblastoma cells, HepG2, obtained from American type Culture Collection (Rockville, MD, USA) were used to quantify LDL receptor activity. Cells were seeded into 6-well or 96-well plates (Nunc, Rochester, NY, USA), and were cultured in DMEM supplemented with 10% fetal bovine serum (FBS) and 100 U/mL penicillin–streptomycin (Gibco, Grand Island, NY, USA). Cells were grown for 48 h at 37 °C in an atmosphere of 5% CO<sub>2</sub>. After an additional 24 h of incubation with FBS-free DMEM, cells were incubated for 24 h with DMEM containing different concentrations (0, 10, 50 µM) of the purified tea catechins.

#### Measurement of LDL Receptor Activity with a Fluorescence Detector

After a 48-h period of culture in DMEM supplemented with FBS, cells were switched to DMEM containing 0.5% human serum albumin for an additional 24 h. BODIPY-LDL (20 µg protein/mL) was incubated with HepG2 cells for 2 h at 37 °C. At the end of the incubation period, cells were extensively washed with phosphate-buffered saline, 200 µl (for 96 well) isopropanol was added to each well, and plates were gently shaken using an orbital shaker for 20 min. BODIPY-LDL fluorescence in each of isopropanol extracts was determined using a Victor<sup>2</sup> 1420 multi-label counter (Wallac, Boston, MA, USA) with excitation and emission wavelengths set at 485 and 535 nm, respectively. By representing the total amount of BODIPY-LDL versus time, the specific activity of each sample was expressed as

microgram of LDL protein per minute per milligram cellular protein, as described elsewhere [20].

#### Measurement of LDL Receptor Activity with a Flow Cytometer

Fluorescence was measured with a FACScalibur flow cytometer (BD bioscience, San Jose, CA, USA) equipped with 15 mW, 488 nm, air-cooled argon laser and linked to a Macintosh Quadra 650 computer with CellQuest software (BD bioscience). Forward scatter and side scatter were adjusted to exclude debris and dead cells. The emission of BODIPY LDL was measured at 530 ± 15 nm (FL1-H). Fluorescence signals of FL1-H were recorded on logarithmically transformed intensity scale in a histogram. The LDL receptor activity of each sample was expressed as the mean of FL1-H intensity.

#### Statistical Analysis

Data were presented as mean ± standard deviation (SD). Statistical analyses were performed using one-way ANOVA with post-hoc Tukey–Kramer's tests for comparisons between two groups or multiple groups, respectively. Differences were considered significant at  $P < 0.05$  or  $P < 0.01$ .

## Results

### Effects of EGCG and the GCG-Rich Tea Catechins on the Food Intake, Fluid Intake, and Body Weight Gain of Rats on the Sucrose-Rich Diet

To evaluate the possibility that GCG-rich tea catechins play an effective role in buffering increases in plasma cholesterol and triglyceride levels, we investigated their effects in sucrose-rich diet-induced hyperlipidemic rats. We first examined the food intake, fluid intake, and body weight gain of rats on the sucrose-rich diet (Table 3). The daily food intakes were almost similar between the groups,

**Table 3** Food intake, fluid intake, and body weight gain of rats fed indicated diet and beverage

Group	Diet and beverage	Food intake (g/day)	Fluid intake	Body weight gain (g/30day)
CD	CD + distilled water	22.1 ± 1.9	39.2 ± 7.0	247.1 ± 9.3
SRD	SRD + distilled water	21.0 ± 1.8	37.5 ± 4.6	246.8 ± 8.3
E	SRD + 0.2% EGCG	18.7 ± 1.5*	28.9 ± 4.6*	221.0 ± 9.9*
G	SRD + 0.2% GCG-rich tea catechins	19.0 ± 1.5*	26.1 ± 3.0*	225.0 ± 7.0*

Data are expressed as mean ± SD,  $N = 6$ . Significant differences from the SRD group is shown with an asterisk

CD Control diet, SRD sucrose-rich diet, E EGCG, G GCG-rich tea catechins

\*  $P < 0.05$

whereas fluid intakes were significantly suppressed in the E and G groups. The average food intakes (mean  $\pm$  SD) for the CD, SRD, E, and G groups were  $22.1 \pm 1.9$ ,  $21.0 \pm 1.8$ ,  $18.7 \pm 1.5$  and  $19.0 \pm 1.5$  g/day. The food intakes of E and G groups were significantly decreased about 2 g per day, compared to CD and SRD groups. The average fluid intakes (mean  $\pm$  SD) were  $39.2 \pm 7.0$ ,  $37.5 \pm 4.6$ ,  $28.9 \pm 4.6$ , and  $26.1 \pm 3.0$  g/day for the CD, SRD, E, and G groups, respectively. Although the fluid intakes were decreased significantly in the E and G groups as compared to the CD and SRD groups, the amount of GCG-rich tea catechins consumed by the G group was not significantly different from that of EGCG consumed by the E group. No difference in body weight gain was observed between the SRD and CD groups. However, body weight gain significantly decreased after the consumption of EGCG and the GCG-rich tea catechins. This result is consistent with a previous study that showed that dietary supplementation with EGCG for 1 month attenuated diet-induced obesity and decreased body weight of mice [21]. The reduced food intakes in E and G groups may influence the reduced body weight gain.

#### GCG-Rich Tea Catechins Decreased Plasma Cholesterol and Triglyceride Concentrations Significantly in Sucrose-Rich Diet-Induced Hyperlipidemic Rats

In sucrose-rich diet-induced hyperlipidemic rats, the total plasma cholesterol concentration in the SRD group was elevated to 123.8%, as compared to the CD group. The consumption of GCG-rich tea catechins significantly normalized the plasma cholesterol concentration, which was augmented by the sucrose-rich diet (Fig. 1a). Although EGCG seemed to decrease plasma cholesterol

concentration, significant difference was not observed between E and SRD groups with one-way ANOVA statistical test. The sucrose-rich diet caused an increase in the total plasma triglyceride concentration to 155.5% of the CD group on day 30. Fluids containing EGCG and the GCG-rich tea catechins reduced the total plasma triglyceride concentration to 126 and 120%, respectively. The difference between EGCG and the GCG-rich tea catechins was not clear on the effects of decreasing cholesterol and triglyceride concentrations (Fig. 1b).

The plasma lipoprotein cholesterol concentrations are depicted in Table 4. None of the groups showed a significant alteration in their plasma LDL cholesterol concentrations. The sucrose-rich diet increased HDL cholesterol to 136%, as compared to the level found in the control diet group. The increased HDL cholesterol concentration was almost normalized in the GCG-rich tea catechins-supplemented group. Significant reduction in HDL cholesterol concentration was observed in G group. Instead of direct measurement of VLDL cholesterol, we could calculate VLDL + LDL cholesterol level by using the Friedewald formula. Although the VLDL + LDL cholesterol concentration between SRD and G groups was not significantly different, GCG-rich tea catechins tended to lower the plasma VLDL + LDL cholesterol level. Therefore, the normalized plasma total cholesterol concentration in G group might be attributed to the reduced HDL and VLDL + LDL cholesterol concentrations.

#### Consuming the GCG-Rich Tea Catechins was Effective in Decreasing the Hepatic Cholesterol and Triglyceride Concentrations

The liver is well known as the main tissue that regulates plasma cholesterol and triglyceride concentrations [22].

A sucrose-rich diet has been proven to be lipogenic and elevates the hepatic triglyceride concentration [23]. In this study, it increased hepatic cholesterol concentration to nearly 2.4-fold that of control. Although the increase in cholesterol concentration was significantly attenuated by EGCG and the GCG-rich tea catechins in the fluids, the effects of the E and G groups were similar (Table 5). The hepatic triglyceride concentration was significantly elevated by approximately 160% in the SRD group as compared to the CD group. However, the GCG-rich tea catechins almost normalized the hepatic triglyceride content, whereas EGCG tended to decrease the triglyceride concentration to some degree which was augmented by the sucrose-rich diet (Table 5).

#### Expressions of Hepatic LDL Receptor and HMG-CoA Reductase Remained Unchanged Despite the Administration of EGCG and the GCG-Rich Tea Catechins in Sucrose-Rich Diet-Induced Hyperlipidemic Rats

An increase in the LDL receptor expression is the main mechanism by which cholesterol is removed from circulation [16]. Further, the LDL receptor is reported to be the

**Fig. 2** Effects of GCG-rich tea catechins on the hepatic LDL receptor and HMG-CoA reductase expressions in hyperlipidemic rats. **a** Hepatic LDL receptor and **b** HMG-CoA reductase expressions remained unchanged among the SRD, E, and G groups. CD control diet, SRD sucrose-rich diet, E EGCG, G GCG-rich tea catechins, LDLR LDL receptor

main factor that regulates hepatic lipid concentrations [18]. To confirm the involvement of the LDL receptor in lowering plasma and hepatic lipid concentrations, we examined the hepatic expression of the LDL receptor in the sucrose-rich diet-induced hyperlipidemic rats. The hepatic LDL receptor was elevated by the sucrose-rich diet. Although EGCG was known to increase LDL receptor expression [10], the consumption of EGCG and the GCG-rich tea catechins did not additionally increase LDL receptor expression (Fig. 2a). Figure 2b shows the expression of hepatic HMG-CoA reductase for each group after 30 days of treatment. The sucrose-rich diet did not affect hepatic HMG-CoA reductase expression, and no significant differences were found between the rats supplemented with EGCG and the GCG-rich tea catechins and those in the SRD group.

#### GCG Was More Effective in Increasing the Expression of the LDL Receptor than EGCG

The GCG-rich tea catechins were effective in reducing cholesterol and triglyceride concentrations. Although the expression of the LDL receptor was not changed apparently in the E and G groups, we considered that purified EGCG and GCG could have different effects on LDL receptor expression. Therefore, we further investigated the effect of purified EGCG and GCG on the expression of LDL receptor by using HepG2 cells. Recently, EGCG was reported to increase LDL receptor expression in HepG2 cells [10]. In this study, we revealed for the first time that incubation with GCG (50 μM) significantly increased LDL receptor protein expression (~450% of control, \*\**P* < 0.01) over the effect of EGCG (Fig. 3a, b). This result indicates that the effect of

**Fig. 3** LDL receptor expression in HepG2 cells treated with either EGCG or GCG. **a** LDL receptor protein was determined by using western blotting with a polyclonal anti-LDL receptor antibody. **b** Quantitative results of the LDL receptor expression,  $**P < 0.01$ . *Con* control, *S* simvastatin, *E* EGCG, *G* GCG

GCG on up-regulating of the LDL receptor is significantly greater than that of EGCG, while both EGCG and GCG increase the expression of the LDL receptor.

#### GCG Increased the LDL Receptor Activity to a Greater Extent than EGCG

To confirm the effectiveness of GCG in up-regulating LDL receptor, we measured the LDL receptor activity with a fluorometer by using fluorescence probe, BODIPY labeled LDL. GCG treatment increased LDL receptor activity significantly ( $*P < 0.05$ ), compared to EGCG treatment. LDL receptor activity increased in a concentration-dependent manner by GCG treatment, showing ~2-fold induction over the control at 50 μM (Fig. 4a). Further, to validate the effect of GCG on LDL receptor activity, the association of LDL–LDL receptor was assessed by flow cytometer. Like as evaluated by the fluorometer, GCG treatment increased LDL–LDL receptor association more than EGCG (Fig. 4b). During 24 h treatment of the simvastatin, EGCG, and GCG, mean of FL1-H intensity that represents the LDL–LDL receptor association was 135.2, 138.2, and 150.5% of the control, respectively. Simvastatin, a drug for hyperlipidemia, was used for a positive control. When we measured LDL receptor activity with a flow cytometer, however, it could not detect each cell's fluorescence properly with 50 μM of EGCG and GCG, respectively. Maybe this undetectable result was caused by

strong cell–cell adhesion. Although the effect of GCG was apparent in 50 μM with the fluorometer, observing the fluorescence of each cell with flow cytometer was limited in that concentration due to the strong cell–cell adhesion. This could be related with a previous report that EGCG increased mRNA expressions of cell adhesion proteins in the 25 μM and above concentrations [24]. To sum up, this result strongly suggests that GCG increases the LDL receptor activity effectively, compared to EGCG.

#### Discussion

The aim of this study is to elucidate the effectiveness of GCG-rich tea catechins in modulating cholesterol and triglyceride concentrations in vivo and to investigate the effective mechanisms. We manufactured GCG-rich tea catechins, in which GCG concentration was as high as 50% of the total catechins from the process of heat epimerization. For hyperlipidemic animal experiments, sucrose-rich diet was used to induce hyperlipidemia in rats. This diet-induced hyperlipidemia is relatively similar to the physiological condition that arises as a result of dietary habits such as the consumption of daily food.

Table 3 shows the diet and fluid consumption of each animal group. The daily diet and fluid intakes of the E and G groups were significantly lesser than those of the SRD group. Moreover, the total body weight gains in the E and G groups were greatly decreased, as compared to those in the SRD group. This difference in body weight gain could be attributed to the dietary reduction implemented in the above mentioned groups. Green tea catechins are known to activate many cellular mechanisms for reducing body weight. Studies in adipocyte cell lines and animal models have demonstrated that EGCG inhibits extracellular signal-related kinases (ERK), activates AMP-activated protein kinases (AMPK), modulates adipocyte marker proteins, and down-regulates lipogenic enzymes [25].

A sucrose-rich diet induces hypertriglyceridemia and elevates the triglyceride concentration in the plasma and liver as early as within 3 weeks in rats [16, 23]. Long-term feeding on a sucrose-rich diet results in a steady state of hyperlipidemia and hyperglycemia. Consistent with previous studies, the sucrose-rich diet exerted its lipogenic effect on day 30. The consumption of GCG-rich tea catechins inhibited the hypertriglyceridemia as well as hypercholesterolemia induced by the sucrose-rich diet (Fig. 1). There was no significant difference between EGCG and the GCG-rich tea catechins with regard to reducing the plasma cholesterol and triglyceride concentrations in sucrose-rich diet-induced hyperlipidemic rats.

(–)-Epigallocatechin gallate and the GCG-rich tea catechins decrease plasma lipid concentrations without

affecting the LDL cholesterol level. According to a recent study, LDL cholesterol is not altered significantly by the consumption of green tea catechins in vivo. Bursill and Roach [26] proposed that administration of green tea catechins had no effect on plasma LDL cholesterol concentration in rats. However, other human studies have reported the effect of green tea extracts in decreasing plasma LDL cholesterol concentration. Additional studies of green tea in regulating LDL cholesterol concentration should be carried out including in vivo experiments.

In this study, as compared to the SRD group, the G group showed a significant reduction in HDL cholesterol concentration. Yang et al. [16] reported that all green and black tea extracts, with the exception of those obtained from oolong tea, failed to increase plasma HDL cholesterol concentration in rats; on the contrary, green tea extracts were found to lower HDL cholesterol concentration after 25 days of treatment. Weber et al. [6] also

showed that dietary treatment involving 1% EGCG tended to decrease HDL cholesterol concentration, although there were no significant changes in the HDL level. Therefore, it is necessary to conduct further investigation into the effect of green tea catechins on HDL cholesterol regulation. As regards VLDL + LDL cholesterol concentration, the consumption of GCG-rich tea catechins seemed to decrease VLDL + LDL cholesterol, as calculated using a modified Friedewald formula. The normalization of the sucrose-rich diet-induced total cholesterol induction could be caused by the reduction in VLDL + LDL cholesterol. The decrease in HDL and VLDL + LDL cholesterol levels—effected by the GCG-rich tea catechins—shows that GCG-containing tea drinks can regulate plasma cholesterol concentration. The way in which GCG-containing tea drinks are able to influence these lipoprotein cholesterol concentrations also needs further, more specific investigation.

A sucrose-rich diet elevated the hepatic cholesterol and triglyceride concentrations (Table 5). EGCG and the GCG-rich tea catechins had a similar effect on decreasing hepatic cholesterol concentration. However, the GCG-rich tea catechins almost normalized hepatic triglyceride concentration induced by the sucrose-rich diet. Although green tea extracts were known for reducing hepatic triglyceride content [16], we revealed for the first time that GCG-rich tea catechins were effective on reducing hepatic cholesterol and triglyceride concentrations. Both EGCG and the GCG-rich tea catechins may modulate lipid metabolism in the liver.

A high expression of the LDL receptor is related to plasma cholesterol absorption by the liver, and LDL uptake by the receptor is a compensatory mechanism in terms of cholesterol homeostasis [27]. We investigated the hepatic LDL receptor expression, regarded as the chief mechanism in plasma cholesterol transport [10], in sucrose-rich diet-induced rats. The sucrose-rich diet elevated the hepatic expression of the LDL receptor. It is known that a sucrose-rich diet stimulates the biosynthesis of very low-density lipoproteins in the rat liver [28]. In cultures from rats fed on a sucrose-rich diet, the production of apolipoprotein E was found to be twice the amount produced by the control diet [28]. Moreover, Patsch et al. [29] reported that in the livers of sucrose-fed rats, the abundance of cellular apo A-IV mRNA increased to 185% of the control values. Although a sucrose-rich diet is found to increase lipoprotein-related components, the effect of such a diet on LDL receptor expression is not reported thus far. The consumption of EGCG and the GCG-rich tea catechins did not affect LDL receptor expression in the sucrose-rich diet-induced hyperlipidemic rats (Fig. 2). These catechins seemed to reduce the LDL receptor expression, to some extent, as compared to that found in the SRD group. The increased LDL receptor expression of the SRD group may be regarded as an adaptive response aimed at buffering the higher plasma lipid concentrations induced by the sucrose-rich diet.

Mammalian cells receive cholesterol by the uptake of lipoproteins; they also produce their own cholesterol. Cholesterol synthesis regulation keeps cellular and plasma cholesterol concentrations at a precisely controlled level; moreover, cholesterol synthesis is regulated by the activity of the microsomal enzyme HMG-CoA reductase and is determined by both the amount of protein present and the degree of activation of the enzyme [14]. In our study, we investigated hepatic HMG-CoA reductase expression in sucrose-rich diet-induced hyperlipidemic rats. There was no difference in the HMG-CoA reductase expressions for all animal groups. This result is consistent with a previous report indicating that the activity of HMG-CoA reductase is not affected by Lung Chen tea, a Chinese green tea [30]. Therefore, EGCG and the GCG-rich tea catechins are not

involved in regulating the levels of the rate-limiting cholesterol synthesis enzyme HMG-CoA reductase.

It is evident from *in vitro* and *in vivo* studies that green tea catechins inhibit the intestinal absorption of dietary lipids. Studies *in vitro* indicated that green tea catechin, particularly EGCG, interfered with the digestion and micellar solubilization of lipids, which are critical steps in the intestinal absorption of dietary fat, cholesterol, and other lipids. Based on these results, blocking lipid absorption using tea catechins is likely to be an important way of reducing plasma cholesterol and triglyceride concentrations. In this study, we used hyperlipidemic rats induced by a sucrose-rich diet that contained the same quantity of lipids as the diet of rats in the other groups. Therefore, the effect of the sucrose-rich diet on increasing lipid concentrations could not be attributed to a high dietary fat supply—it was the result of an abnormality in lipid metabolism with respect to lipoproteins. Therefore, we suggest that the inhibition of intestinal lipid absorption is not the main reason for the lipid-lowering effect of tea catechins in the sucrose-rich diet-induced hyperlipidemic rat model. Regarding carbohydrates absorption, it was revealed that black and green tea extracts caused malabsorption of carbohydrates in healthy men [31]. Moreover, *in vitro* experiments have shown that some constituents of green tea inhibited the activity of  $\alpha$ -amylase [32] and  $\alpha$ -glucosidase [33]. However, inhibition of sucrose absorption by green tea catechins has not been reported so far.

Elevated plasma concentrations of LDL and LDL oxidation are recognized as playing an important role in atherogenesis [34] and increasing the efficiency of lipid clearance by raising LDL receptor activity is an efficient way to lower plasma cholesterol concentration [35]. Several *in vitro* and *in vivo* studies have shown that EGCG enhanced LDL receptor activity and decreased lipid concentrations [6, 10]. Bursill and Roach [10] demonstrated that green tea polyphenol, EGCG, increased LDL receptor activity and LDL receptor expression in human cells *in vitro*. In the present work, we reported that GCG had a stronger effect on increasing LDL receptor activity than EGCG in hepG2 cells (Fig. 4). This effect was accompanied by an increase in LDL receptor protein expression (Fig. 3). This mechanism may be pivotal for GCG-rich tea catechins to decrease lipid concentrations.

In our results, there is a discrepancy between the determination of LDL receptor activity by blotting and by a fluorescent method. According to previous reports, LDL receptor mRNA level, amount of LDL receptor protein and functional cellular LDL binding activity were consistent across the three measurements [36]. In that study, human LDL was conjugated to colloidal gold (LDL-gold) and the cell-bound LDL-gold was quantified using silver enhancement solution. However, another study reported

that incubation of liver cells with citrus flavonoids caused a fivefold increase in LDL receptor mRNA level and a twofold increase in LDL binding activity [37]. LDL was radiolabeled with  $^{125}\text{I}$  using the iodine monochloride technique for the measurement of LDL receptor binding activity. Given this, the difference between LDL receptor activity and LDL receptor expression seemed to be dependent on which methods were used to detect the LDL receptor activity. By measuring the fluorescent probe 3,3'-dioctadecylindocarbocyanine (DiI), which is a similar fluorescent material to that used in our study, Munoz et al. [20] revealed that LDL obtained during the walnut diet showed a 50% increase in the association rate to the LDL receptor in human hepatoma HepG2 cells. Therefore, an almost twofold increase of LDL receptor activity in our study can be significantly effective.

The LDL receptor is regulated at the transcriptional level by a family of membrane-bound transcription factors, the sterol response element binding proteins (SREBPs). In response to a decrease in cellular cholesterol availability, SREBP is processed proteolytically, and the active fragment migrates to the nucleus where it interacts with sterol response elements present in the promoter of LDL gene and activates LDL transcription [38]. Kuhn et al. [9] proposed that the up-regulation of LDL receptor expression induced by green tea polyphenols was caused by the inhibition of ubiquitin-mediated degradation of active SREBP-2. He reported that green tea catechin, EGCG, potently inhibited proteasomal activity in HepG2 cells. Significantly, in connection with proteasome inhibition, the cleavage and active SREBP-2/p68 protein expression was enhanced after EGCG treatment. Subsequently, EGCG also increased LDL receptor proteasome expression by inhibiting proteasomal activity and increasing active SREBP-2 expression. With respect to this effect on proteasomal activity, a comparison experiment between EGCG and GCG is needed for elucidating apparent mechanism for regulating LDL receptor expression. Moreover, further studies should analyze the role played by GCG in LDL receptor regulation in the SREBP-2 related transcriptional level.

The results of our study show that GCG-rich tea catechins are effective in reducing cholesterol and triglyceride concentrations in hyperlipidemic rats. This may be consistent with a recent report that GCG-rich tea catechins are more effective in inhibiting cholesterol absorption than EGCG-rich tea catechins [12]. High GCG contents of the GCG-rich tea catechins may cause this effect. Moreover, our experiments support that GCG, a major catechin produced by the heat epimerization from EGCG, has a stronger effect to increase the LDL receptor activity than EGCG. Several structure–activity relationship studies revealed that the difference between the stereoscopic structures of EGCG and GCG contributed to their different

effects [39–41]. An epitome of this is the binding of GCG to the active site of tyrosinase with a greater affinity than EGCG [42]. Furthermore, an electron spin resonance study indicated that the antioxidant activity of GCG was stronger than that of EGCG [43]. This effect of GCG is thought to be a result of the difference in the conformational structure of the epimer, EGCG. Furthermore, in vivo investigations are necessary to clarify the absorption, distribution, and metabolism of GCG, in comparison with EGCG.

Although various physiological functions of EGCG have been reported in many papers, for the first time, this study shows that GCG-rich tea catechins have strong effects on lowering cholesterol and triglyceride concentrations in hyperlipidemic rats. In the process of manufacturing bottled green tea beverages, relatively high amounts of GCG are produced due to the epimerization from EGCG during sterilization. Because some bottled green tea beverages have a GCG content of more than 50%, we may be able to decrease plasma and hepatic lipid concentrations by drinking green tea beverages abundant in GCG-rich tea catechins.

**Abstract** The structural importance of the acyl group in lysophosphatidylcholine (LPC) as substrate of purified bovine lysophospholipase D (lysoPLD) was investigated. Among LPCs with saturated acyl chains, the  $K_m$  value decreased according to the length of the acyl chain (C12–C16) up to the palmitoyl group, while the  $V_m$  value showed no remarkable change. But, the extension of the acyl size to C18, as observed with 1-stearoyl LPC ( $K_m$ , 8.5 mM), rather resulted in a remarkable increase in the  $K_m$  value. Meanwhile, the introduction of one double bond in the C18 saturated acyl chain led to a remarkable reduction in the  $K_m$  value, as observed with 1-oleoyl LPC ( $K_m$ , 0.48 mM). Furthermore, 1-linoleoyl LPC ( $K_m$ , 56  $\mu$ M) with two double bonds exhibited a smaller  $K_m$  value than 1-oleoyl LPC, suggesting that the unsaturation degree might be important in augmenting the binding affinity of LPCs. A similar phenomenon was also observed with 1-arachidonoyl LPC ( $K_m$ , 79  $\mu$ M) or 1-docosahexaenoyl LPC ( $K_m$ , 36  $\mu$ M). Overall, the order of catalytic efficiency ( $V_m/K_m$  value) of those LPCs seemed to be affected by the  $K_m$  value rather than the  $V_m$  value, which differed by at most threefold among LPC derivatives. Next, the introduction of a hydroperoxide group into 1-linoleoyl-LPC or 1-arachidonoyl LPC led to a further reduction in  $K_m$  values

(1-hydroperoxylinoleoyl LPC, 26  $\mu$ M; 1-hydroperoxyarachidonoyl LPC, 33  $\mu$ M), accompanied by a further increase in the  $V_m/K_m$  values. Additionally, phosphatidylcholines (PCs) with an oxidized acyl chain at *sn*-2 position were found to be efficient as 1-palmitoyl LPC as substrates of lysoPLD. Taken together, the catalytic efficiency of LPCs or oxidized PCs as substrates of lysoPLD seems to be determined by the property of the acyl chain, length of the acyl chain, unsaturation degree and oxidation status.

PGPC	1-Palmitoyl-2-glutaroyl- <i>sn</i> -glycero-3-phosphocholine

## Introduction

Lysophospholipase D (lysoPLD) activity is known to catalyze the conversion of lysophosphatidylcholine (LPC) to lysoPA (lysophosphatidic acid), a potent lipid signaling molecule in numerous cellular responses [1]. LysoPLD was first reported to be present in the microsomal fraction [2], and later, extracellular lysoPLD was found to be present in plasma [3], various tissues and body fluids [4–6]. Recently,

extracellular lysoPLD, belonging to the ecto-nucleotide pyrophosphatase/phosphodiesterase family, was shown to correspond to autotoxin, a tumor cell motility-stimulating factor [7]. Thereafter, endeavors to regulate the extracellular lysoPLD activity have been attempted [8].

Concerning the substrates of lysoPLD, only LPC had been considered to be a substrate for serum lysoPLD, but subsequent studies demonstrated that lysoPLD could act on other lysophospholipids [9] and sphingosylphosphorylcholine [10]. Nonetheless, only LPC has been used as a lysoPLD substrate in a routine assay, since LPC, abundantly present in plasma, corresponds to an endogenous substrate. Although the level of LPC in plasma [9–16] amounts up to 200  $\mu\text{M}$ , the concentration of LPA, generated from the hydrolysis of LPC, is limited to the micromolar level [11–13] in human plasma, where lysoPLD is constitutively active [9, 17]. Therefore, it has been suggested that lysoPLD-catalyzed hydrolysis of LPC may be regulated by endogenous factors in vivo. One explanation is that lysoPLD activity in blood may be inhibited by endogenous LPAs, cyclic LPAs and sphingosine 1-phosphate, corresponding to strong inhibitors of lysoPLD [18, 19]. Our recent study indicated that LPAs with unsaturated acyl chains expressed more potent inhibition of lysoPLD than those with saturated acyl chains [19]. It may also be that the amount of free form LPC available for the interaction with lysoPLD can limit the formation of LPA in plasma. In support of this, blood lysoPLD was observed to express affinity for free form LPCs, equilibrated with albumin- and lipoprotein-bound forms in plasma [20]. In addition, the conversion of LPC to LPA in plasma was higher for free forms of unsaturated acyl type LPCs than free forms of saturated acyl type LPCs. Thus, it was assumed that lysoPLD activity in rat plasma might show a preference for unsaturated LPCs over saturated LPCs. However, there has been no extensive study to clarify the structural requirement of acyl group in the hydrolysis of LPCs by purified lysoPLD.

Separately, lysoPLD was reported to convert the bioactive platelet activating factor (1-alkyl-2-acetyl PAF) to 1-alkyl-2-acetyl phosphatidic acid [20, 21]. In addition, lysoPAF was also hydrolyzed by lysoPLD to produce alkyl type LPC, which is physiologically active [21, 22]. From these, lysoPLD was supposed to be implicated in the metabolism of choline glycerophospholipids with an alkyl group at *sn* 1 and a short acyl chain at *sn* 2. In this regard, it was assumed that oxidized phosphatidylcholines (PCs), which accumulate during oxidative damage of membranes, might be substrates for lysoPLD. Nevertheless, there has been no study on the lysoPLD-catalyzed hydrolysis of oxidized PCs.

In this study, the structural requirement of the acyl chain in lysoPLD-catalyzed hydrolysis of LPCs was examined,

and additionally the role of oxidized PCs as substrates for lysoPLD was investigated.

## Experimental Procedures

### Materials

DEAE sephacel, concanavalin A-sepharose, heparin-agarose, phenyl-agarose, choline oxidase, peroxidase (horse radish), soybean lipoxygenase (lipoxygenase Type I-B), phospholipase A<sub>2</sub> (honey bee venom), 2,2'-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) were purchased from Sigma Chemical Co. (St Louis, MO, USA), and 1-linoleoyl LPA and 1-arachidonoyl LPA were from Echelon Co. (Salt Lake City, UT, USA). LPCs, phosphatidylcholines, 1-palmitoyl-2-azeyroyl phosphatidylcholine, 1-palmitoyl-2-glutaryl phosphatidylcholine and 1-alkyl-2-acetoxy-*sn*-glycero-3-phosphocholine (PAF) were procured from Avanti Polar Lipids, Inc. (Alabaster, AL, USA). 1-Linoleoyl LPC, 1-arachidonoyl LPC and 1-docosahexaenoyl LPC were prepared from PLA<sub>2</sub>-catalyzed hydrolysis of the corresponding PC as described previously [23, 24]. 1-Hydroperoxylinoleoyl LPC, 1-hydroperoxyarachidonoyl LPC and 1-hydroperoxydocosahexaenoyl LPC were prepared from soybean lipoxygenase-1-catalyzed oxygenation of the corresponding LPC as reported before [24, 25].

### Purification of LysoPLD from Fetal Bovine Serum

LysoPLD was purified from fetal bovine serum (JRH Biosciences, Inc, Lenexa, KS, USA) according to a slight modification of the previously reported methods [19, 26, 27] employing ammonium sulfate fractionation (30–60%), DEAE sephacel chromatography, concanavalin A sepharose affinity chromatography, heparin agarose affinity chromatography, phenyl agarose hydrophobic interaction chromatography, second DEAE sephacel chromatography and finally FPLC employing a Superpose 12 column. The protein amount was determined by the Bradford method [28]. The purified enzyme possessed a specific activity of approximately 3,700 nmol/h/mg protein in the hydrolysis of 1-palmitoyl LPC.

### Spectrophotometric Assay of LysoPLD Activity

The determination of lysoPLD activity was carried out by measuring the amount of choline released from exogenously added LPC; briefly, lysoPLD (1.6 U) was incubated with 1 mM 1-palmitoyl LPC (MW, 495.6) in 100 mM Tris buffer, pH 9.0 (0.2 ml) containing 500 mM NaCl, 5 mM MgCl<sub>2</sub> and 0.05% Triton X-100 for 30 min at 37 °C. To avoid the interference by artifacts, a short-time (30 min)

incubation was chosen. Then, to the assay mixture was added choline oxidase (3 U/ml) and horseradish peroxidase (1 U/ml) and finally, 2,2'-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) was included to 1 mM. After a 2-min incubation at room temperature, the change of absorbance at 415 nm was determined [26, 27]. One unit is expressed as the capability of lysoPLD to release 1 nmol of choline from 1-palmitoyl LPC per hour at 37 °C.

#### Determination of $V_{\max}$ and $K_m$ Values of LPCs, PAF or Oxidized PCs

LysoPLD (1.6 U) was incubated with various concentrations (0.01–30 mM) of each LPC or oxidized PC in 100 mM Tris buffer, pH 9.0 (0.2 ml) containing 500 mM NaCl, 5 mM  $MgCl_2$  and 0.05% Triton X-100 for 30 min at 37 °C. The amount of choline was determined as described above. The kinetic values were obtained according to Lineweaver–Burk plot analyses as described before [19, 26]. The catalytic efficiency of the substrate is defined as the value of  $V_m/K_m$ .

#### Oxygenation of 1-Linoleoyl LPA and 1-Arachidonoyl LPA

Oxygenation of 1-linoleoyl LPA or 1-arachidonoyl LPA was carried out as described in the previous publication [24, 25]. Briefly describing, each LPA (400  $\mu$ M) was incubated with soybean lipoxygenase-1 (10 U/ml) in 150  $\mu$ l of 50 mM borax buffer pH 9.0. After 10 min, the oxygenation products were loaded into a  $C_{18}$  Sep-pack column (3 cm  $\times$  1 cm), which was washed out with distilled water, and then the products were eluted with methanol. Finally, the methanol elute was concentrated, and used for the inhibition of lysoPLD activity.

#### Inhibition of LysoPLD activity by 1-Hydroperoxylinoleoyl LPA or 1-Hydroperoxyarachidonoyl LPA

LysoPLD (1.6 U) was incubated with 1-palmitoyl LPC (0.2–1.0 mM) in the presence of 1-hydroperoxylinoleoyl LPA or 1-hydroperoxyarachidonoyl LPA of different concentrations in 100 mM Tris buffer, pH 9.0 containing 500 mM NaCl, 5 mM  $MgCl_2$  and 0.05% Triton X-100 for 30 min at 37 °C. The remaining lysoPLD activity was determined spectrophotometrically as described above. The  $K_i$  values were obtained according to Lineweaver–Burk plot analyses as described before [19, 29]. Separately, the  $K_i$  value was determined using a fluorogenic substrate (FS-3) as described previously [19, 30]; lysoPLD was incubated with FS-3 (0.5–4  $\mu$ M) in the presence of each hydroperoxylated LPA in 100  $\mu$ l of 50 mM Tris buffer pH 8.0

containing 140 mM NaCl, 5 mM KCl, 1 mM CaCl, 1 mM  $MgCl_2$  and bovine serum albumin (1 mg/ml) for 30 min at room temperature. The change of fluorescent intensity was measured at 520 nm with the excitation at 480 nm.

#### Statistical Analysis

All statistical analyses were performed using a SPSS program for Windows. Statistical assessments were performed using ANOVA for the initial demonstration of significance at  $P < 0.05$ , followed by post hoc Duncan's multiple-range test [31].

## Results

#### Determination of Kinetic Values of Various Lysophosphatidylcholines as LysoPLD Substrates

Previously [8, 18, 26], it had been reported that lysoPLD activity in rat plasma catalyzed the hydrolysis of LPCs with various acyl groups, and PCs with short acyl chains. However, the study of the role of LPCs as substrates was limited to LPCs with palmitoyl, myristoyl or oleoyl group, despite the availability of LPCs with various acyl groups, saturated or unsaturated. Thus, the structural requirement of the acyl chain for LPCs as substrate of lysoPLD remains to be clarified. Here, lysoPLD activity was determined by measuring the amount of choline released from lysoPLD-catalyzed hydrolysis of LPCs in the assay buffer (Tris buffer, pH 9.0) containing 500 mM NaCl, 5 mM  $MgCl_2$ , and 0.05% Triton X-100. First, when the  $K_m$  value and  $V_m$  value of 1-palmitoyl LPC, displaying a typical pattern of saturation kinetics, were determined by double-reciprocal plot analysis (Fig. 1a), it was found to possess  $K_m$  and  $V_m$  values of 147  $\mu$ M and 2,011 nmol/h/mg, respectively. Similarly, the kinetic values of the other LPCs were also determined (Table 1). Among LPCs with saturated fatty acyl chains, the catalytic efficiency, reflected by the  $V_m/K_m$  value, was observed to be the highest for 1-palmitoyl LPC, followed by 1-myristoyl LPC ( $K_m$ , 273  $\mu$ M;  $V_m$ , 2,622 nmol/h/mg), 1-lauroyl LPC ( $K_m$ , 2,291  $\mu$ M;  $V_m$ , 2,717 nmol/h/mg) and 1-stearoyl LPC ( $K_m$ , 8,512  $\mu$ M;  $V_m$ , 2,244 nmol/h/mg). Thus, the catalytic efficiency appeared to be proportional to the size of the acyl chain (C12–C16) up to the palmitoyl group, but the extension of the acyl size to C18, as observed with 1-stearoyl LPC, resulted in a remarkable decrease. Noteworthy, a similar relationship was also found between the size of the acyl group and the  $K_m$  values, which differed by 320 -fold among saturated acyl type LPCs. Therefore, the order of catalytic efficiency of LPCs seemed to be affected by the  $K_m$  value rather than the  $V_m$  value, which differed by at most threefold among

**Fig. 1** Lineweaver–Burk double reciprocal plot for lysoPLD-catalyzed hydrolysis of LPCs. LysoPLD (1.6 U) was incubated with each LPC in 100 mM Tris buffer (pH 9.0) containing 500 mM NaCl, 5 mM MgCl<sub>2</sub> and 0.05% Triton X-100 for 30 min at 37 °C. **a** 1-Palmitoyl LPC; **b** 1-linoleoyl LPC; **c** 1-hydroperoxylinoleoyl LPC. Data were expressed as means  $\pm$  S.D. of three experimental sets

LPC derivatives. Meanwhile, the introduction of one double bond in the C18 saturated acyl chain led to a remarkable decrease in the  $K_m$  value; 1-stearoyl LPC ( $K_m$ , 8,512  $\mu$ M) vs. 1-oleoyl LPC ( $K_m$ , 477  $\mu$ M). From these, it was supposed that the catalytic efficiency of LPCs might be also governed by the unsaturation degree of the acyl chain. In this regard, LPCs with polyunsaturated fatty acyl chains were tested for their efficiency as a substrate of lysoPLD. As demonstrated in Fig. 1b, the hydrolysis of 1-linoleoyl LPC by lysoPLD followed classical Michaelis–Menten kinetics as observed with 1-palmitoyl LPC (Fig. 1a); the  $K_m$  and  $V_m$  values of 1-linoleoyl LPC were estimated to be 56  $\mu$ M and 2,077 nmol/h/mg, respectively. Thus, the catalytic efficiency of 1-linoleoyl LPC was much greater than that of 1-stearoyl LPC or 1-oleoyl LPC, which contains the same carbon number. In addition, the  $K_m$  value and the  $V_m$  value of 1-arachidonoyl LPC were estimated to be 79  $\mu$ M and 2,100 nmol/h/mg, respectively, and the  $K_m$  value and the  $V_m$  value of 1-docosahexaenoyl LPC were estimated to

be 36  $\mu$ M and 1,116 nmol/h/mg, respectively. In comparison, 1-linoleoyl LPC appeared to express a higher  $V_m/K_m$  value than 1-arachidonoyl LPC or 1-docosahexaenoyl LPC. However, the smallest  $K_m$  value was expressed by 1-docosahexaenoyl LPC, followed by 1-linoleoyl LPC and 1-arachidonoyl LPC. This led to the notion that the property of the acyl chain might affect the catalytic efficiency of polyunsaturated acyl type LPCs. In this regard, we examined the kinetic values of LPCs with oxidized acyl chains.

#### Effect of Oxidation on the Catalytic Efficiency of LPC with Polyunsaturated Fatty Acyl Chains

It is well known that polyunsaturated fatty acids are susceptible to oxidation [32, 33]. Likewise, LPCs with polyunsaturated fatty acyl chains were found to be readily subjected to enzymatic oxygenation [24, 25]. In the attempt to see whether the oxidation could alter the catalytic efficiency of LPCs as substrate, 1-linoleoyl LPC was subjected to enzymatic or non-enzymatic oxidation, and then kinetic values of oxidized LPC were determined. First, when 1-linoleoyl LPC was exposed to non-enzymatic oxidation such as HOCl oxidation or copper ion-catalyzed oxidation, and the kinetic values of oxidized LPC were determined, there was no great change (<10%) of  $V_{max}$  value or  $K_m$  value. Next, 1-linoleoyl LPC was subjected to oxygenation by soybean lipoxygenase-1 to produce 1-hydroperoxylinoleoyl LPC. When the kinetic values of 1-hydroperoxylinoleoyl LPC were determined (Fig. 1c), the  $K_m$  value and the  $V_{max}$  value were estimated to be 26  $\mu$ M and 1,450 nmol/h/mg, respectively (Table 1). Thus, the  $K_m$  value of 1-hydroperoxylinoleoyl LPC was reduced by 2.2-fold, compared to that of 1-linoleoyl LPC ( $K_m$ , 56  $\mu$ M). Additionally, the  $K_m$  value (33  $\mu$ M) of 1-hydroperoxyarachidonoyl LPC decreased by 2.4-fold, compared to that of 1-arachidonoyl LPC. However, the  $K_m$  value of 1-docosahexaenoyl LPC was not altered remarkably after the exposure to soybean lipoxygenase-1. When the  $V_m$  values were compared, there was a modest decrease in the  $V_m$  value after the exposure of each polyunsaturated fatty acyl type LPC to soybean lipoxygenase-1 (Table 1). Taken together, the oxygenation of 1-linoleoyl-LPC or 1-arachidonoyl LPC with soybean lipoxygenase-1 led to some reduction in the  $K_m$  value, thereby leading to a further increase in the  $V_m/K_m$  value; 1-linoleoyl-LPC ( $V_m/K_m$ , 37.5 nmol/h/mg/ $\mu$ M) vs. 1-hydroperoxylinoleoyl-LPC ( $V_m/K_m$ , 56.1 nmol/h/mg/ $\mu$ M) and 1-arachidonoyl-LPC ( $V_m/K_m$ , 27.5 nmol/h/mg/ $\mu$ M) vs. 1-hydroperoxyarachidonoyl LPC ( $V_m/K_m$ , 39.6 nmol/h/mg/ $\mu$ M). However, such an oxygenation failed to affect the  $V_m/K_m$  values of 1-docosahexaenoyl LPC remarkably, suggesting that the beneficial effect of lipoxygenation was not pronounced positively in the case of 1-docosahexaenoyl LPC with six double bonds. In a separate experiment, there

LysoPLD (1.6 U) was incubated with each LPC in 100 mM Tris buffer (pH 9.0) containing 500 mM NaCl, 5 mM MgCl<sub>2</sub> and 0.05% Triton X-100 for 30 min at 37 °C. The kinetic values were obtained according to Lineweaver–Burk plot analysis. Data were expressed as mean  $\pm$  S.D. of three experimental sets. Values were expressed as mean  $\pm$  S.E. of at least three independent experiments. Mean values with the same letter are not significantly different ( $P < 0.05$ ,  $n = 3$ )

was approximately twofold increase of  $K_m$  values after reduction of hydroperoxy group to hydroxyl group; 1-hydroperoxylinoleoyl-LPC ( $K_m$ , 26  $\mu\text{M}$ ) vs. 1-hydroxylinoleoyl-LPC ( $K_m$ , 35  $\mu\text{M}$ ) and 1-hydroperoxyarachidonoyl-LPC ( $K_m$ , 33  $\mu\text{M}$ ) vs. 1-hydroxyarachidonoyl-LPC ( $K_m$ , 46  $\mu\text{M}$ ).

#### Inhibition of LysoPLD by 1-Hydroperoxylinoleoyl LPA or 1-Hydroperoxyarachidonoyl LPA

Since the introduction of a peroxide group into linoleoyl or arachidonoyl chain caused a remarkable increase of binding affinity of LPC toward to lysoPLD, it was supposed that the hydro(pero)xide group might be responsible for the increased affinity of acyl chain to lysoPLD. In an attempt to support this idea, 1-linoleoyl-LPA and 1-arachidonoyl-LPA were oxygenated to produce 1-hydroperoxylinoleoyl-LPA or 1-hydroperoxyarachidonoyl-LPA [24, 25], and the effect of oxygenation on the inhibitory potency of those LPAs was examined. As shown in Fig. 2, it was found that lysoPLD-catalyzed hydrolysis of 1-palmitoyl LPA was inhibited competitively by 1-hydroperoxylinoleoyl LPA in a dose-dependent manner. According to the double-reciprocal plot analysis (Fig. 2a), the  $K_i$  value of 1-hydroperoxylinoleoyl LPA was estimated to be 1.14  $\mu\text{M}$  (Table 2), which was found to be lower than  $K_i$  value (1.8  $\mu\text{M}$ ) of 1-linoleoyl LPA reported previously [19]. Likewise, the  $K_i$  value (2.68  $\mu\text{M}$ ) of 1-hydroperoxyarachidonoyl LPA was smaller than that (3.4  $\mu\text{M}$ ) of 1-arachidonoyl LPA reported previously [19]. Thus, the incorporation of peroxide group markedly enhanced the binding of polyunsaturated acyl type LPAs

toward lysoPLD. Separately, it was found that lysoPLD-catalyzed hydrolysis of FS-3, fluorescent substrate [30], was inhibited by 1-hydroperoxylinoleoyl LPA in a dose-dependent manner at relatively low concentrations. According to the double-reciprocal plot analysis (Fig. 2b), the  $K_i$  value of 1-hydroperoxylinoleoyl LPA was estimated to be 0.14  $\mu\text{M}$  (Table 2), which was found to be lower than the  $K_i$  value (0.21  $\mu\text{M}$ ) of 1-linoleoyl LPA reported previously [19]. Likewise, the  $K_i$  value (0.25  $\mu\text{M}$ ) of 1-hydroperoxyarachidonoyl LPA was smaller than that (0.55  $\mu\text{M}$ ) of 1-arachidonoyl LPA reported previously [19]. Thus, the incorporation of peroxide group markedly enhanced the binding affinity of LPAs with polyunsaturated fatty acyl chain toward lysoPLD.

#### Hydrolysis of Oxidized PCs by LysoPLD

Previous studies [20, 21] indicated that PAF, containing an acetyl group at the *sn*-2 position, could be utilized as a substrate for lysoPLD. Therefore, PCs with short acyl derivatives at *sn*-2 were supposed to be used as lysoPLD substrates. In this respect, the oxidized PCs such as 1-palmitoyl-2-azelaoyl-*sn*-glycero-3-phosphocholine (AzPC) and 1-palmitoyl-2-glutaroyl-*sn*-glycero-3-phosphocholine (PGPC) were tested for their efficacy as substrates of lysoPLD. The hydrolysis of AzPC or PGPC by lysoPLD followed classic Michaelis–Menten kinetics as observed with 1-palmitoyl LPC. In a Lineweaver–Burk plot analysis (Fig. 3a), the  $K_m$  and  $V_m$  values of AzPC were estimated to be 203  $\mu\text{M}$  and 1,533 nmol/h/mg, respectively (Table 3). In

**Fig. 2** Inhibitory effect of LPAs on lysoPLD-catalyzed hydrolysis of 1-palmitoyl LPC or FS-3. **a** LysoPLD (1.6 U) was incubated with 1-palmitoyl LPC (0.2–1.0 mM) in the presence of 1-hydroperoxylinoleoyl LPA in 100 mM Tris buffer (pH 9.0) containing 500 mM NaCl, 5 mM MgCl<sub>2</sub> and 0.05% Triton X-100 for 30 min at 37 °C. Filled diamonds indicate the control, filled squares indicate 0.5 μM, filled triangles indicate 1 μM, filled circles indicate 2 μM, open squares indicate 4 μM. Data were expressed as means ± S.D. of three experimental sets. **b** LysoPLD (1.6 U) was incubated with FS-3 (0.5–4 μM) in the presence of 1-hydroperoxylinoleoyl LPA in 100 μl of 50 mM Tris buffer pH 8.0 containing 140 mM NaCl, 5 mM KCl, 1 mM CaCl<sub>2</sub>, 1 mM MgCl<sub>2</sub> and BSA (1 mg/ml) for 30 min at 25 °C. Filled diamonds indicate control, filled squares indicate 0.03 μM, filled triangles indicate 0.1 μM, filled circles indicate 0.3 μM, open squares indicate 1 μM. Data were expressed as means ± S.D. of three experimental sets

addition (Fig. 3b), PGPC showed the  $K_m$  value of 146 μM and the  $V_m$  value of 2,172 nmol/h/mg. Although the  $K_m$  value of AzPC or PGPC was greater than that of PAF ( $K_m$ , 71 μM), the  $V_m$  value of those oxidized PCs was greater than that of PAF. Overall, the catalytic efficiency ( $V_m/K_m$ ) of AzPC or PGPC was close to that of PAF or 1-palmitoyl LPC.

**Fig. 3** Lineweaver–Burk double reciprocal plot for lysoPLD-catalyzed hydrolysis of oxidized phosphatidylcholines. **a** LysoPLD (1.6 U) was incubated with AzPC in 100 mM Tris buffer (pH 9.0) containing 500 mM NaCl, 5 mM MgCl<sub>2</sub> and 0.05% Triton X-100 for 30 min at 37 °C. **b** LysoPLD (1.6 U) was incubated with PGPC as described in **a**. Data were expressed as mean ± S.D. of three experimental sets

Thus, it is suggested that AzPC and PGPC may be utilized efficiently as a substrates for lysoPLD.

## Discussion

Our present study shows that the  $K_m$  value of LPCs with saturated acyl chains varies greatly (up to 320-folds) according to the length of the acyl chain. It is worth noting that the introduction of one double bond in stearyl LPC led to a remarkable enhancement of binding affinity as illustrated with 1-oleoyl LPC. Furthermore, 1-linoleoyl LPC with two double bonds expressed a much smaller  $K_m$  value than 1-oleoyl LPC, reaffirming that the unsaturation degree might be one of the factors in determining the  $K_m$

**Table 2**  $K_i$  values of 1-hydroperoxylinoleoyl LPA or 1-hydroperoxyarachidonoyl LPA in the inhibition of LysoPLD activity

Acyl group	Spectrophotometric assay, $K_i$ (μM)	Fluorometric assay, $K_i$ (μM)
1-Hydroperoxylinoleoyl	1.14 ± 0.13	0.14 ± 0.01
1-Hydroperoxyarachidonoyl	2.68 ± 0.61	0.25 ± 0.02

LysoPLD (1.6 U) was incubated with 1-palmitoyl LPC (0.2–1.0 mM) in the presence of each LPA as described in Fig. 2. Separately, lysoPLD (1.6 U) was incubated with FS-3 (0.5–4 μM) in the presence of each LPA. The  $K_i$  values were determined as described in Fig. 2, and the values were expressed as mean ± S.D. of three experimental sets

**Table 3**  $K_m$  and  $V_{max}$  values of oxidized phosphatidylcholines

	$K_m$ ( $\mu\text{M}$ )	$V_{max}$ (nmol/h/mg)	$V_{max}/K_m$ (nmol/h/mg/ $\mu\text{M}$ )
AzPC	203 $\pm$ 11	1,533 $\pm$ 134	7.6 $\pm$ 1.0
PGPC	146 $\pm$ 20	2,172 $\pm$ 288	14.9 $\pm$ 1.2
PAF (1-Alkyl-2-acetoyle)	71 $\pm$ 5	1,228 $\pm$ 122	17.3 $\pm$ 2.5

LysoPLD (1.6 U) was incubated with each oxidized PC in 100 mM Tris buffer (pH 9.0) containing 500 mM NaCl, 5 mM  $\text{MgCl}_2$  and 0.05% Triton X-100 for 30 min at 37 °C. The  $K_m$  and  $V_{max}$  values were obtained as described in Table 1. Data were expressed as mean  $\pm$  S.D. of three experimental sets

value of LPCs. Furthermore, such a beneficial effect of unsaturation was more remarkable for 1-docosahexaenoyl LPC. In contrast, the  $V_m$  value of LPCs was less dependent on the type of acyl chain; the differences of  $V_m$  values, among LPCs with saturated acyl chains (C12–C16), were limited to at most threefold. Taken together, the order of catalytic efficiency of LPCs with saturated acyl chains seems to be more intimately related to the  $K_m$  value than the  $V_m$  value of LPCs, suggesting that the catalytic efficiency of LPCs may be determined largely by the binding affinity of the acyl chain. Such a difference in the  $K_m$  values of LPCs might be due to the difference in the micellar concentrations of LPCs, since the  $K_m$  value decreased with increasing length of the acyl chains (C12–C16), inversely proportional to the critical micellar concentration (CMC) values [34, 35]. However, this is not supported by the finding that 1-stearoyl LPC, possessing a smaller CMC value, possessed a higher  $K_m$  value than 1-palmitoyl LPC. Furthermore, the  $K_m$  values of LPCs with saturated fatty acyl chain, possessing smaller CMC values, were greater than those of LPCs with unsaturated acyl chains. Alternatively, it is conceivable that the smaller  $K_m$  values of LPCs may be related to the greater product inhibition of lysoPLD by LPAs [8, 19], produced during the incubation of LPCs with lysoPLD. However, this is not supported by the previous finding that the inhibitory potency of LPAs with saturated acyl chains increases with decreasing length of the acyl chain (C14–C20) [19]. From these, it is supposed that the direct binding of the LPC monomer to the lysoPLD active site is important for lysoPLD-catalyzed hydrolysis of LPCs. It is interesting to find that the structural requirement of the acyl chain in the hydrolysis of LPCs by lysoPLD is somewhat similar to that in the inhibition of lysoPLD by LPAs [19]; the unsaturated fatty acyl type is preferred to the saturated fatty acyl type for the interaction of lysoPLD with either LPCs or LPAs. Moreover, the contributory role of the oxygenated acyl chain was commonly observed in the hydrolysis of LPCs by lysoPLD as well as the inhibition of lysoPLD by LPAs. Taken together, the interaction of lysoPLD with LPCs

seems to be governed strictly by the property of the acyl chain, depending on the length of the acyl chain, the unsaturation degree and the oxygenation of the acyl chain.

A previous report [20, 26] indicated that PCs with short acyl chains as well as PAF could be utilized as a substrate of lysoPLD. The present study with oxidized PCs may add to the list of substrates for lysoPLD. AzPC and PGPC, corresponding to oxidized PCs with oxidized acyl chains at the *sn*-2 position, were also found to be good substrates of lysoPLD. From the similarity of catalytic efficiency between of oxidized PCs and 1-palmitoyl LPC, it is suggested that oxidized PCs can go through the metabolic pathway, which is mediated by lysoPLD *in vivo* [3–5].

Previously, it was reported that the lysoPLD-induced conversion of endogenous unsaturated LPCs was more favorable than saturated LPCs in rat plasma [20]. A possible explanation is that lysoPLD shows a higher affinity for free forms of unsaturated acyl type LPCs than free forms of saturated acyl type LPCs. Therefore, the substrate specificity of lysoPLD for LPCs is supposed to be a primary factor responsible for the conversion of LPCs into LPAs in plasma. In support of this, the order (1-linoleoyl LPC > 1-arachidonoyl LPC ~ 1-palmitoyl LPC > 1-oleoyl LPC > 1-stearoyl LPC) for the yield in the conversion of LPCs to LPAs in plasma [20] seems to agree well with that for catalytic efficiency ( $V_m/K_m$ ) of those LPCs in this present study. However, the substrate specificity of purified bovine lysoPLD toward LPCs seemed to somewhat differ from that reported previously [26]. The discrepancy might be explained by the difference of kinetic analysis used and/or the assay conditions [19, 26, 27]; the previous study employed a prolonged incubation (up to 24 h), where LPAs, produced from the incubation of lysoPLD with LPCs, might have interfered with lysoPLD-catalyzed hydrolysis of LPC through the product inhibition [8].

Here, the structure activity relationship of LPCs as substrates of lysoPLD was established, based on the catalytic efficiency ( $K_m/V_m$ ). Bovine lysoPLD expressed higher substrate specificity for LPCs with unsaturated acyl chains than those with saturated acyl chains. Noteworthy, the oxygenation of the unsaturated fatty acyl chain remarkably reduced the  $K_m$  values of unsaturated fatty acyl type LPCs, resulting in a further increase in catalytic efficiency. In addition, PCs with an oxidized acyl chain were as efficient as 1-palmitoyl LPC or PAF as substrates for lysoPLD. Thus, lysoPLD may be implicated in the metabolism of choline phospholipids such as LPCs, oxidized PCs and PAF. In other words, these choline phospholipids may compete with each other as substrates of lysoPLD in the *in vivo* system. In this regard, it is conceivable that polyunsaturated acyl type LPCs, showing smaller  $K_m$  values, may suppress the lysoPLD-catalyzed hydrolysis of alkyl type LPCs, saturated acyl type LPCs, oxidized PCs or PAF,

expressing higher  $K_m$  values. Furthermore, this may lead to the notion that the level of physiologically active LPAs may be regulated by the level of polyunsaturated acyl type LPCs in the blood, which remains to be clarified in the near future.

**Abstract** Unusual fatty acids with 24, 26, and 28 carbon atoms were found in triacylglycerols (TAGs) isolated from fat body tissue of bumblebee *Bombus pratorum*. The most abundant one was (Z,Z)-9,19-hexacosadienoic acid. Its structure was determined by mass spectrometry after derivatization with dimethyl disulfide and by infrared spectroscopy. ECL (equivalent chain length) values of its methyl ester were determined on both DB-1 and DB-WAX capillary columns. (Z,Z)-9,19-Hexacosadienoic acid is quite rare in nature. So far it has been identified only in marine sponges, and this work is the first evidence of its occurrence in a terrestrial organism. HPLC/MS analysis of the bumblebee TAGs showed that (Z,Z)-9,19-hexacosadienoic acid is present in one third of all TAG molecular species. As it was found in all sn-TAG positions, it is likely that (Z,Z)-9,19-hexacosadienoic acid is transported to tissues. Interestingly, labial gland secretion of *B. pratorum* was found to contain (Z,Z)-7,17-pentacosadiene, a hydrocarbon with markedly similar double bond positions and geometry. Possible biosynthetic relationships between these two compounds are discussed.

### Introduction

In insects, fat body is the major storage site for nutrients. Most lipid stores are triacylglycerols (TAGs). It is assumed that the fat body TAGs originate mainly from dietary fats absorbed by midgut epithelium during times of feeding. In addition, lipid reserves can be biosynthesized de novo from carbohydrates [1]. The fat body is also a key center of metabolism, which responds to the physiological and biochemical needs of insects. Lipids are mobilized in the form of 1,2-diacylglycerols and transported to tissues. Fatty acids (FAs) are known to be essential precursors in the biosynthesis of many important compounds, including eicosanoids, pheromones, cuticular hydrocarbons, and other semiochemicals [2]. It is hypothesized that FAs released from fat body of bumblebee males might serve as precursors of their marking pheromones [3]. The most common FAs found in insect fat bodies are palmitic, palmitoleic, stearic, oleic and linoleic acids [4–6]. The same FAs also prevail in bumblebees, and we have shown that the FA composition as well as the composition of TAGs in this genus are clearly species-specific [7]. Large differences exist among species, whereas variations within the species are substantially less significant. In our effort to prove connections between fat body TAGs and bumblebee male marking pheromones, several species were investigated, including the early nesting bumblebee *Bombus pratorum*. This is a relatively small bee with a bright yellow thorax and strikingly orange tail that is common all over Europe. The fat body of this species was found to

contain rare FAs which have not been detected in any other insect species so far.

In this work we report on long-chain FAs with 24, 26 and 28 carbon atoms found in the fat body of the male bumblebee *B. pratorum*. Possible connections between the most abundant long-chain (*Z,Z*)-9,19-hexacosadienoic acid and labial gland secretion (marking pheromone) components are discussed.

## Materials and Methods

### Insect Material and Sample Preparation

The bumblebee males of *Bombus (Pyrobombus) pratorum* (Linnaeus, 1761) were collected during the summer season 2006 in the north region of the Czech Republic and transported to the laboratory. After immobilization of males in cold ( $-18^{\circ}\text{C}$ ), their peripheral fat bodies were carefully dissected. The fat body tissue from each individual was transferred into a glass vial with 100  $\mu\text{L}$  of  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (1:1, *v/v*) containing di-*tert*-butyl-4-methylphenol (Fluka, Buchs, Switzerland) at a concentration of 25 mg/mL. Samples were sonicated for 15 min and stored at  $-18^{\circ}\text{C}$ .

### Isolation of Triacylglycerols

The tissue was thoroughly crushed using a glass stick and extracted three times with 100  $\mu\text{L}$  of  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (1:1, *v/v*). The combined crude extract was separated on a pre-cleaned glass TLC plate (76 mm  $\times$  36 mm) coated with 0.2 mm of Adsorbosil Plus silica gel [Applied Science Laboratories, Alltech Associates, Inc., Deerfield, IL, USA; with gypsum (12%)] using a hexane/diethyl ether/formic acid (80:20:1) mobile phase. TLC zones were visualized by spraying Rhodamine 6G solution (0.05% in ethanol). The band containing TAGs ( $R_F = 0.6$ ) was scraped off the plate and extracted with 7 mL of freshly distilled diethyl ether. The solvent was evaporated to dryness under argon stream. The samples were reconstituted in chloroform to a concentration of 1% and stored in sealed glass ampoules under argon at  $-18^{\circ}\text{C}$  until analyzed. The absolute amounts of TAGs isolated from samples 1–5 were 0.2, 0.4, 0.8, 0.9, and 0.1 mg, respectively.

### Transesterification and DMDS Derivatization

TAG samples were transesterified using a method described earlier [8]. Briefly, TAGs were dissolved in  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (2:3, *v/v*) in a small glass ampoule. After adding acetyl chloride (Fluka), the ampoule was sealed and placed in a water bath at  $70^{\circ}\text{C}$ . This procedure prevents the loss of volatile FAMES during transesterification. After 90 min the ampoule was opened and the reaction mixture was

neutralized with silver carbonate (Lachema, Brno, Czech Republic). To determine double bond position(s), FAMES were derivatized with dimethyl disulfide (DMDS). The transesterified mixture was filtered through a column with a small amount of silica gel and evaporated to dryness under a stream of argon. The residues were dissolved in 50  $\mu\text{L}$  of DMDS (Merck, Darmstadt, Germany), which was pre-cleaned by filtration through silica gel. A diethyl ether solution of iodine (Lachema, 12.5  $\mu\text{L}$ , 60  $\mu\text{g}/\mu\text{L}$ ) was added and the reaction mixture was shaken for 24 h at laboratory temperature. Finally, hexane (60  $\mu\text{L}$ ) was added, the excess of iodine was removed by 5% solution of sodium thiosulfate, and the hexane layer was separated and directly injected onto the GC column.

### Gas Chromatography/Mass Spectrometry

FAMES and their DMDS derivatives were analyzed using a 6890N gas chromatograph (Agilent, Santa Clara, CA, USA) coupled to a 5975B quadrupole mass spectrometer and equipped with a fused silica capillary column HP-5 ms (30 m  $\times$  0.25 mm, 0.25  $\mu\text{m}$ , Agilent). The carrier gas was helium at 1 mL/min. The injector was operated in splitless mode at  $230^{\circ}\text{C}$ . The temperature program for FAMES:  $40^{\circ}\text{C}$  (1 min), then  $50^{\circ}\text{C}/\text{min}$  to  $140^{\circ}\text{C}$ , then  $3^{\circ}\text{C}/\text{min}$  to  $320^{\circ}\text{C}$  (20 min). The temperature program for DMDS derivatives:  $70^{\circ}\text{C}$  (1 min), then  $10^{\circ}\text{C}/\text{min}$  to  $320^{\circ}\text{C}$  (20 min). Standard 70 eV mass spectra were recorded in the mass range (*m/z*) of 25–600; a 4-min solvent delay was used. The temperatures of the transfer line, ion source and quadrupole were 250, 230 and  $150^{\circ}\text{C}$ , respectively.

### Gas Chromatography/Flame Ionization Detection

FAMES were quantified and their ECL (equivalent chain length) values were determined using an HP 5890A gas chromatograph (Hewlett-Packard, Palo Alto, CA, USA) equipped with a flame ionization detector (FID). Two fused silica capillary columns were used: (a) DB-WAX (30 m  $\times$  0.25 mm, 0.25  $\mu\text{m}$ , J&W Scientific, USA) and (b) DB-1 (30 m  $\times$  0.25 mm, 0.25  $\mu\text{m}$ , J&W Scientific, Folsom, CA, USA). The injector and detector temperatures were 230 and  $250^{\circ}\text{C}$ , respectively. The injector was operated in split mode with a split ratio of 20:1. The carrier gas was hydrogen (87 kPa,  $\bar{u} = 40$  cm/s for DB-WAX and 95 kPa,  $\bar{u} = 41$  cm/s for DB-1); nitrogen was used as make-up gas (25 mL/min). Temperature program: (a)  $45^{\circ}\text{C}$  (2 min), then  $15^{\circ}\text{C}/\text{min}$  to  $150^{\circ}\text{C}$ , then  $4^{\circ}\text{C}/\text{min}$  to  $320^{\circ}\text{C}$  (5 min) (FAME quantification on DB-WAX column); (b) isothermally at  $220^{\circ}\text{C}$  (60 min) (both columns, for determining ECL values). Data were collected with an HP 3393A integrator (Hewlett-Packard). ECL values were calculated from the retention times of FAMES and

co-injected FAME standards (22:0–28:0, both odd and even) using a program written in GW-BASIC [9].

### Gas Chromatography/Infrared Spectroscopy

Double-bond positions were determined using an Agilent 6850 gas chromatograph connected to an Equinox 55 FT-IR spectrometer (Bruker Optics Inc., Ettlingen, Germany). A DB-5 column (30 m × 0.32 mm, 0.25 μm, J&W Scientific) was used for the separations; the injector temperature was 220 °C (splitless mode), while the carrier gas was He at a flow rate of 2.5 mL/min. The temperature program: 50 °C (0 min), then 50 °C/min to 150 °C (0 min), then 1 °C/min to 240 °C (5 min). A liquid nitrogen-cooled photoconductive mercury-cadmium-telluride (MCT) detector was used with an FT-IR resolution of 8 cm<sup>-1</sup>; the light pipe temperature was 200 °C. Methyl (*E*)-hexadec-9-enoate and methyl (*Z*)-hexadec-9-enoate (Applied Science Laboratories; 20 mg/mL in cyclohexane) were used as standards for infrared (IR) spectra of unsaturated methyl esters.

### High-Performance Liquid Chromatography/Mass Spectrometry

HPLC was performed on a TSP liquid chromatograph (Thermo Separation Products, Piscataway, NJ, USA) with an ion-trap mass spectrometric detector (LCQ classic) controlled by Xcalibur software (Thermo Finnigan Corp., San Jose, CA, USA). TAGs were separated on two Nova-Pak C18 stainless steel columns (300 × 3.9 and 150 × 3.9 mm, 4 μm, Waters Corp., Milford, MA, USA) connected in series. The mobile phase was mixed from acetonitrile (A) and 2-propanol (B) [10]. A linear gradient from 0 to 70% of B in 108 min (1.0 mL/min) was followed by a linear gradient to 100% B (150 min, 0.7 mL/min). The columns were kept at 30 °C during analyses. The mobile phase was mixed post-column in a low dead volume T-piece with 100 mM ammonium acetate prepared in 2-propanol/water 1:1 (v/v), at a flow rate of 10 μL/min. The full scan mass spectra were recorded in the mass range (m/z) of 75–1,300, the temperatures of the vaporizer and heated capillary were set to 400 and 200 °C, respectively; the corona discharge current was 4.5 μA. TAGs were identified using the TriglyAPCI software [11] and quantified from reconstructed chromatograms calculated for [M+H]<sup>+</sup> and [M+NH<sub>4</sub>]<sup>+</sup> molecular adducts [7].

## Results and Discussions

### Identification of Fatty Acids

TAGs from fat body of bumblebee males were transesterified and analyzed by GC/MS. Methyl esters of both

saturated and unsaturated FAs were found. To determine the position(s) of double bond(s) in FA chains, DMDS derivatives were prepared [12]. DMDS derivatives of monoenic FAs provided molecular ions M<sup>+</sup> accompanied by less intense ions formed by the loss of methoxy (M<sup>+</sup>-31) and methylthio (M<sup>+</sup>-47) radicals from the molecular ions. The most abundant peaks resulted from α-cleavage between the two carbon atoms originally constituting the double bond, and these ions were denominated A<sup>+</sup> ([CH<sub>3</sub>(CH<sub>2</sub>)<sub>n</sub>CH = S-CH<sub>3</sub>]<sup>+</sup>) and B<sup>+</sup> ([CH<sub>3</sub>-S = CH(CH<sub>2</sub>)<sub>m</sub>COOCH<sub>3</sub>]<sup>+</sup>) in this work. Neutral losses of methanethiol from A<sup>+</sup> and methanol and methanethiol from B<sup>+</sup> were also observed ([A-48]<sup>+</sup>, [B-32]<sup>+</sup> and [B-32-48]<sup>+</sup>, respectively). In the low-mass region, fragment ions of the C<sub>n</sub>H<sub>2n-1</sub> series, [CH<sub>2</sub>=S-CH<sub>3</sub>]<sup>+</sup> (m/z 61), and methyl ester-related ions at m/z 74 and 87 were found.

The most abundant dienoic acid found in *B. pratorum* contained 26 carbons, and the mass spectrum of its methyl ester (M = 406) is shown in Fig. 1a. The corresponding DMDS derivative provided a mass spectrum (Fig. 1b) with a molecular ion at m/z 594, which indicated the formation of a tetrasubstituted acyclic derivative. Therefore, at least

**Fig. 1** Mass spectra of (*Z,Z*)-9,19-hexacosadienoic acid methyl ester (a) and its DMDS derivative (b)

four methylene groups separating the two double bonds were expected [13]. An ion at  $m/z$  500 corresponded to the elimination of both methanethiol and thioformaldehyde. Further losses of methoxy or methylthio radicals resulted in ions at  $m/z$  469 and 453, respectively. As two double bonds existed in the molecule, two pairs of diagnostic ions were expected. However, only two ions were found; the other two diagnostic ions lost neutral molecules giving the secondary fragments. Based on the fragmentation, the spectrum was interpreted as 9,19-hexacosadienoic acid methyl ester. Figure 2 indicates the expected fragments after  $\alpha$ -cleavage between the carbons originally constituting the double bonds, which were labeled  $A^+$ ,  $B^+$ ,  $C^+$ , and  $D^+$  here. The diagnostic ions  $A^+$  and  $D^+$  were found at  $m/z$  145 and 217, respectively;  $D^+$  was the spectrum base peak. The  $B^+$  and  $C^+$  eliminated neutral molecules, either methanethiol, giving  $m/z$  401 ( $[B-48]^+$ ) and  $m/z$  329 ( $[C-48]^+$ ), or both methanethiol and thioformaldehyde, providing  $m/z$  355 ( $[B-48-46]^+$ ) and 283 ( $[C-48-46]^+$ ), respectively. In addition,  $B^+$  eliminated methanol from the methyl ester moiety ( $[B-48-46-32]^+$ ;  $m/z$  323). Ions  $A^+$  and  $D^+$  also provided additional fragments after the elimination of neutral molecules, giving  $m/z$  97 ( $[A-48]^+$ ),  $m/z$  185 ( $[D-32]^+$ ) and  $m/z$  137 ( $[D-32-48]^+$ ). The low-mass region contained ions of the  $C_nH_{2n-1}$  series, the  $m/z$  67, 81, 95, 109 series,  $[CH_2 = S-CH_3]^+$  ( $m/z$  61), and methyl ester-related ions at  $m/z$  74 and  $m/z$  87. The identities of all common FAMES were also confirmed by determining ECL values and comparing them with published data [14].

The geometric configuration of double bonds in 9,19-hexacosadienoic acid methyl ester was determined by IR spectroscopy. Unsaturated dienoic compounds with at least one (*E*)-double bond provide a characteristic strong band at

990–965  $cm^{-1}$  assigned to the  $=C-H$  out-of-plane deformation vibration [15]. Compounds with a (*Z*)-double bond do not provide a signal in this area, but show a typical band from  $=C-H$  stretch absorption at 3,028–3,011  $cm^{-1}$  [16]. The IR spectrum of 9,19-hexacosadienoic acid methyl ester (Fig. 3) did not show any signal that could be attributed to (*E*)-double bond(s). By contrast, a well-resolved band at 3,012  $cm^{-1}$  was found, which indicated the presence of double bond(s) with a (*Z*)-configuration. Other bands were those expected for methyl esters (1,758  $cm^{-1}$  ( $C=O$  stretching), 1,176  $cm^{-1}$  ( $C-O$  stretching), 1,651  $cm^{-1}$  ( $C=C$  stretching), and 718  $cm^{-1}$  ( $-(CH_2)_n$ -skeletal overlapping with  $=CH$  deformation).

Based on the MS and IR data, we have concluded that structure of the most abundant dienoic acid is (*Z,Z*)-9,19-hexacosadienoic acid [(*Z,Z*)-9,19-26:2].

#### ECL values of (*Z,Z*)-9,19-Hexacosadienoic Acid Methyl Ester

To characterize the retention behavior of the (*Z,Z*)-9,19-26:2 methyl ester for future reference, ECL values at 220 °C were determined. The measurements were done in quadruplicate on both nonpolar (DB-1) and polar (DB-WAX) stationary phases, and the values obtained are listed in Table 1.

#### Quantification of Fatty Acids

The compositions of the FAs were determined by GC/FID, because this technique provides almost identical response factors for FAMES [17]. FAs identified in the fat body of *B. pratorum* and their relative abundances are summarized in

**Fig. 2** Labels of the main fragments expected in the EI mass spectrum of the DMDS derivative of (*Z,Z*)-9,19-hexacosadienoic acid methyl ester

**Fig. 3** Infrared spectrum of (Z,Z)-9,19-hexacosadienoic acid methyl ester

**Table 1** ECL values of (Z,Z)-9,19-hexacosadienoic acid methyl ester

Column	ECL $\pm$ SD
DB-WAX	26.461 $\pm$ 0.002
DB-1	25.393 $\pm$ 0.003

Table 2. To compare variations between individuals, results for five bumblebees collected in different localities and at different times during the season are given.

The fat body was found to contain only even FAs, with the exception of pentadecanoic acid, which was present at trace levels. Palmitic acid was the most abundant saturated acid; stearic, myristic, and lauric acids were also detected, but at lower concentrations. FAs with one double bond prevailed in the samples. Oleic acid itself formed about one-third and together with *cis*-vaccenic acid more than half of all acids. The typical position of the double bond in the monoenoic FAs was 9, but FAs with other double bond positions (11 or 13) also occurred. Among polyenoic acids, (Z,Z)-9,19-26:2, linoleic and  $\alpha$ -linolenic acid were detected.

Whereas most of the FAs found in *B. pratorum* are common in bumblebees [7], those with 24 and 26 carbon atoms have not been detected in this genus and they are quite rare in nature. Males of six bumblebee species (*Bombus lucorum*, *B. terrestris*, *B. lapidarius*, *B. hypnorum*, *B. hortorum*, and *B. confusus*) underwent analyses of TAGs in their pool lipids, but none of the species contained fatty acids longer than 22 carbon atoms [7]. 9,19-26:2 has so far been identified only in marine sponges [18–22]. Even there, its concentrations are substantially lower than those of the more common isomer 5,9-26:2. Morales and Lichtfield [18] showed in labeling experiments with *Microciconia prolifera* that 9,19-26:2 is biosynthesized from 9-16:1 by chain elongation followed by  $\Delta^9$  desaturation. The reaction intermediate 19-26:1 was found in high quantities in the sponge. By contrast, *B. pratorum* produces 9-26:1 as the only monoenoic FA with 26 carbons, which might be indicative of a different

biosynthetic pathway (e.g.,  $\Delta^9$  desaturation of 26:0 followed by  $\Delta^{19}$  desaturation). However, no data on the biosynthesis of 9,19-26:2 in bumblebees are available at the moment. 9,19-26:2 has also been found in the marine sponges *Dysidea fragilis* [19], *Halichondria panicea* [20], and *Hymeniacidon sanguinea* [21, 22].

Monounsaturated 9-26:1 and 9-24:1 were detected in *B. pratorum* at trace levels, but they are more common in nature than 9,19-26:2. Several papers reported their presence in both marine [19–26] and freshwater [27, 28] sponges. Their abundances are also low, at percent or sub-percent levels. Marine fish have been shown to contain 9-24:1 in substantially lower quantities than isomeric 15-24:1 [29]. Higher levels of monoenoic 9-24:1 and 9-26:1 were only found in the bacteria *Mycobacterium tuberculosis* [30] and *Francisella tularensis* [31]. So far there has been no evidence of 9,19-26:2, 9-26:1 or 9-24:1 in insects or any other higher organism.

#### Composition of Triacylglycerols

HPLC/MS was employed to elucidate the structures of intact TAGs and thus to reveal how the rare long-chain FAs are bonded to the glycerol backbone [32]. Fat body of *B. pratorum* was found to contain more than 80 different TAG molecular species (Table 3). The most abundant TAGs were those which are common in bumblebees ([16:0, 18:1, 18:1] and [18:1, 18:1, 18:1]). Note that 18:1 might represent oleic and/or *cis*-vaccenic acid, as both of them were detected by GC/MS. Equivalent carbon number (ECN) values of TAGs from *B. pratorum* ranged from 38 to 66, i.e., up to unusually high values for bumblebees [7]. In accordance with GC data, rare long-chain FAs with 24 and 26 carbons were detected. In addition, FAs with 28 carbons and two or one double bonds were found, although at sub-percent levels. 9,19-26:2 occupied at least one position in one-third of all TAG molecular species. Not surprisingly, the most abundant TAGs with this acid also

contained 18:1, 16:1 or 16:0, i.e., the main FAs occurring in this bumblebee. 9,19-26:2 occupied one (e.g., [18:1, 26:2, 18:1], [16:0, 18:1, 26:2]), two (e.g., [26:2, 18:1, 26:2], [26:2, 16:1, 26:2]), or even all three positions ([26:2, 26:2, 26:2]), which is unusual. Other long-chain FAs, 24:1, 24:2, 26:1, 28:1 and 28:2, were found in a small number of TAGs, mostly at very low concentrations. It is important to note that the assignment of FAs to a particular sn position (distinguishing sn-2 from sn-1/3) is based on the intensities of diacylglycerol fragments observed in the mass spectra. Besides the position, the fragment intensities are to some extent also affected by the structures of FAs. Also, unlike GC/FID, TAG response factors in HPLC/APCI-MS are generally not equal. Therefore, the FA positions and quantities of individual TAGs shown in Table 3 are burdened with some uncertainty, which cannot be avoided without using authentic TAG standards. Despite these limitations, HPLC/APCI-MS provided valuable information on TAGs. An example chromatogram showing the separation of TAGs from *B. pratorum* is given in Fig. 4.

#### 9,19-Hexacosadienoic Acid and Labial Gland Composition

FAs identified in the fat body were compared with the composition of the cephalic labial gland secretion of

*B. pratorum* males. Bumblebees use the secretions as scent marks for denoting prominent objects along the patrolling routes. The scent—which contains marking pheromone— attracts females for mating [33]. The composition of labial gland secretions is strictly species-specific. The biosynthesis of the marking pheromone components has not been completely clarified yet [34]. We attempt to explore the idea that FAs stored in the fat body might serve as the precursors of non-terpenic components of the labial gland secretions. The marking pheromone blend of *B. pratorum* contains isoprenoids (farnesol, geranylgeranyl acetate, farnesyl acetate), alcohols (11-octadecenol, hexadecanol [35]), and both saturated and unsaturated hydrocarbons [36, 37]. The hydrocarbon (*Z,Z*)-7,17-pentacosadiene is a medium-abundance component; it forms 9% of the labial gland secretion, which represents about 80% of all hydrocarbons. This rare diene has not been detected in the marking pheromone of any other bumblebee species. One can speculate about its biosynthesis from 9,19-26:2 by decarboxylation [38], as shown in Fig. 5. 9,19-26:2 is bonded in several relatively abundant TAGs in two or even all three positions, which ensures the presence of this acid in the transport of 1,2-diacylglycerols. Thus, the acid might be available to the labial gland for pheromone synthesis. Similar biosynthetic transformations to that proposed for 9,19-26:2 might also apply for 9-24:1 and 9-26:1. The

The most abundant TAGs are shown in bold

CN number of carbon atoms in fatty acids in TAG; DB number of double bonds in the carbon chains of fatty acids

<sup>a</sup> TAG abbreviations reflect the assumed positions of FAs on the glycerol backbone. As APCI MS cannot distinguish between acyls in the sn-1 and sn-3 positions, the TAG abbreviations in the table do not differentiate between these two positions; FA residues in sn-1/3 were ordered by increasing molecular weight

**Fig. 4** HPLC/APCI-MS chromatogram of triacylglycerols isolated from the fat body of male bumblebee *B. pratorum*. The numbers in the upper part of the figure are ECN values

expected products, 8-tricosene and 8-pentacosene, were detected in the labial gland, though only at trace levels. Furthermore, tricosadiene and heptacosadiene are present in minor quantities in the pheromonal gland, which corresponds well with the presence of 24:2 and 28:2 acids in

**Fig. 5** Proposed biosynthesis of (*Z,Z*)-7,17-pentacosadiene in male marking pheromone of *B. pratorum* from (*Z,Z*)-9,19-hexacosadienoic acid

TAGs. Clearly, our findings support the hypothesis about a connection between pheromone biosynthesis and FAs in the fat body, but more research is needed.

### Concluding Remarks

In conclusion, unique FAs with 24, 26 and 28 carbon atoms were identified in the fat body of *B. pratorum*. Among them, (*Z,Z*)-9,19-hexadecadienoic acid was the most

abundant, comprising up to 8% of all FAs. In this work we have also shown remarkable similarities between the structure of this acid and the main hydrocarbon component of the male marking pheromone. Due to the uncommon structure of its acid and labial gland secretion component(s), *B. pratorum* represents a convenient model for studying marking pheromone biosynthesis.

**Abstract** High stearic, low  $\alpha$ -linolenic acid soybean oil (HSSL) has been developed via traditional breeding to serve as a substitute for partially hydrogenated soybean oils used in food manufacturing. The purpose of this study was to estimate the impact on fatty acid intake in the United States if HSSL were substituted for partially hydrogenated soybean oils used in several food categories, including baked goods, shortenings, fried foods, and margarines. Using National Health and Nutrition Examination Survey (NHANES) data (1999–2002), baseline intakes of five fatty acids and trans fatty acids (TFA) were determined at the mean and 90th percentile of fat consumption. Then intakes of these fatty acids were determined after HSSL was substituted for 100% of the partially hydrogenated soybean oils used in these four food categories. The results show that baseline intake of stearic acid is 3.0% energy at the mean and 3.3% energy at the 90th percentile. Use of HSSL could increase stearic acid intake to about 4–5% energy. Mean intakes of TFA could decrease from 2.5 to 0.9% energy, and intake of palmitic acid would remain unchanged. Use of HSSL as a substitute for partially hydrogenated soybean oils would result in changes in the fatty acid composition of the US diet consistent with current dietary recommendations.

## Abbreviations

HSSL	High stearic acid, low $\alpha$ -linolenic acid soybean oil
NHANES	National Health and Nutrition Examination Survey
TFA	Trans fatty acids

## Introduction

The recent United States Food and Drug Administration regulation [1] to require trans fatty acid (TFA) labeling on packaged food products has prompted food manufacturers to find alternatives to partially hydrogenated soybean oils used in formulating bakery products and margarines and in fried foods. Partially hydrogenated soybean oils provided about 9 billion lbs of oil to the diet in the United States [2], and so it is not a small undertaking to find functional alternatives for this amount of oil. For frying applications, alternatives, such as low  $\alpha$ -linolenic acid soybean oil, have been made available to the food industry. Low  $\alpha$ -linolenic acid soybean oil reduces or eliminates the need to hydrogenate prior to use in food processing; thus, the TFA content of foods fried in this oil is also reduced or eliminated.

Bakery products and margarines require the use of solid fats to provide the desired functionality. The choices of solid fats have included animal fats, such as lard, tallow and butter, and tropical oils, such as palm, palm kernel and coconut, but these have nutritional disadvantages in that they contain high amounts of hypercholesterolemic lauric (12:0), myristic (14:0), and palmitic (16:0) saturated fatty acids. In fact, it was the recognition in the 1980s that these saturated fatty acids raise serum cholesterol and thus the

risk of coronary heart disease that prompted population-based dietary advice to reduce their intake. Partially hydrogenated oils were then used by food manufacturers to replace animal fats and tropical oils because it was not known at that time that the TFAs they contain also have adverse effects on blood lipids. Food manufacturers now face the challenge of replacing partially hydrogenated vegetable oils while not reverting to the use of animal fats and tropical oils.

Soybean oils high in stearic acid and low in  $\alpha$ -linolenic acid (HSSL) are being developed using conventional breeding methods to provide a new solid fat alternative for food manufacturers. The stearic acid molecules are positioned at the sn 1,3 positions on the triacylglycerols. The oil provides the functionality of solid fats and can be used in a variety of food applications, such as shortening for baked goods and in margarines. In addition, the high stearic acid coupled with the low  $\alpha$ -linolenic acid composition make this oil suitable for deep fat frying as well.

Although stearic acid is a saturated fatty acid, its consumption does not significantly alter serum total and HDL cholesterol the way other saturated fatty acids, such as lauric, myristic and palmitic acids, do [3]. Numerous clinical studies have shown that the consumption of stearic acid does not raise serum cholesterol levels, even when added to the diet in amounts far in excess of typical intake [4]. Furthermore, clinical studies have shown that stearic acid does not adversely affect other markers of heart health when present in the diet at about twice current intake levels [5, 6]. Thus, HSSL could provide an ideal alternative for food manufacturers needing solid fat functionality and stability while avoiding the negative health consequences associated with certain saturated fatty acids.

If HSSL is to be used instead of partially hydrogenated soybean oil in food formulations, it is important to first determine the impact this use could have on fatty acid intakes. Ideally this substitution would cause TFA intake to decrease, but not at the expense of undesirable changes in intakes of other fatty acids.

The purpose of this study was to estimate the potential dietary impact of substituting HSSL for 100% of the partially hydrogenated soybean oils used in four major food categories: baked goods, margarines, shortenings and frying oils. The impact on mean and 90th percentile intakes of palmitic, stearic, oleic, linoleic, and  $\alpha$ -linolenic acids and TFA was determined for the total US population.

## Materials and Methods

Food and soybean oil consumption data were derived from the National Health and Examination Survey (NHANES 1999–2002) [7], which were the most recent data available

at the time of the study. The NHANES (1999–2002) is a complex, multistage, probability sample designed to be representative of the civilian US population. The survey collects one-day food intake data, in addition to nutrition, demographic, and health information. The NHANES survey over-samples minorities, low-income groups, and children, and statistical weights are provided by the National Center for Health Statistics to adjust for the differential probabilities of selection. Participants included 9,965 subjects in 1999–2000 and 11,039 subjects in 2001–2002. The NHANES is a large survey specifically designed to allow the estimation of food and nutrient intakes by the US population. The NHANES and its predecessor surveys have been used by the US Department of Agriculture for more than 70 years to estimate food and nutrient intake and to evaluate the impact of proposed policy changes.

The NHANES database does not have fatty acid compositions for the hydrogenated soybean oil component of foods; therefore, we extrapolated from the USDA's database of the fatty acid profiles, including trans fatty acids, of 214 foods [8]. When this database did not provide the fatty acid profiles for specific versions of hydrogenated soybean oils used to prepare certain foods, these fatty acids were estimated, using information from the fats/oils industry [Banks D (2003) Approximate composition of hydrogenated soy oils used in nine broad food categories, personal communication]. The methods used to assign these fatty acid profiles to hydrogenated soybean oils in foods have been described previously [9]. Exponent's proprietary software program FARE version 7.95<sup>TM</sup> was used to conduct the intake and substitution analyses. Other publicly available statistical software programs such as SAS or STATA can be used to evaluate data from NHANES and the USDA. The FARE<sup>TM</sup> software is currently used by the Center for Food Safety and Applied Nutrition (CFSAN) within the US Food and Drug Administration.

Two versions of HSSL, HSSL1 and HSSL2, were evaluated. These two versions differ primarily in their stearic and linoleic acid contents. The lower stearic acid content of HSSL1 is associated with a higher content of linoleic acid. Conversely, the higher content of stearic acid in HSSL2 is accompanied by a lower content of linoleic acid. The fatty acid compositions of HSSL1 and HSSL2 compared to regular soybean oil and partially hydrogenated soybean oil are shown in Table 1. The analyses substituted these two versions of HSSL for the partially hydrogenated soybean oils in the following food categories:

- All baked goods: including yeast breads and rolls, quick breads, cakes, cookies, pies, pastries, crackers, salty snacks, pancakes, and waffles
- Home use shortenings

**Table 1** Fatty acid compositions of two versions of HSSL, regular soybean oil, and hydrogenated soybean oil

Fatty acid	Regular soybean oil [8] % Fatty acids	Hydrogenated soybean oil [19]	HSSL1	HSSL2
Palmitic	10.1	10.8	9.3	8.0
Stearic	3.6	12.1	18.7	30.0
Oleic	21.2	30.2	19.8	23.2
Linoleic	51.3	4.4	44.5	37.1
Linolenic	6.8	0.2	3.1	3.0
TFA	0.7	32.8	0.39	0.5

*HSSL1* High stearic low linolenic acid soybean oil version 1, *HSSL2* high stearic low linolenic acid soybean oil version 2, *TFA* trans fatty acids

- French fries, and all fried meat, poultry, and fish (commercially and home-prepared)
- Margarines (stick, tub, and light varieties)

The three forms of margarines were assigned the following formulations: stick margarine, 80% fat, of which 50% was HSSL, 10% was partially hydrogenated soybean oil, and 20% was regular soybean oil; tub margarine, 70% fat, of which 33% was HSSL, 2% was partially hydrogenated soybean oil and 35% was regular soybean oil; and light spreads, 40% fat, of which 19% was HSSL, 1% partially hydrogenated soybean oil and 20% regular soybean oil. The fatty acid compositions of these oils are provided in Table 1.

Data on fatty acid intakes were generated on the total population mean and 90th percentile. Intakes of palmitic, stearic, oleic, linoleic, and  $\alpha$ -linolenic acids, and TFA were evaluated. The data are expressed as percent of total energy intake (% energy), which was calculated by multiplying grams of fatty acid/day at the mean (or 90th percentile) by 9 cal/g and dividing by the total energy at the mean (or 90th percentile).

## Results

This analysis used food consumption data from NHANES (1999–2002) to determine baseline fatty acid intakes from the diet, and then fatty acid intakes were determined after replacement with either HSSL1 or HSSL2 for partially hydrogenated soybean oil in foods in the four categories of interest. Figures 1 and 2 provide the results of these analyses.

The results show that the US diet provided on average 3.0% energy from stearic acid. At the 90th percentile of total fat intake, stearic acid provided 3.3% energy. Use of HSSL1 or HSSL2 resulted in an increase in mean intake of

stearic acid from a baseline of 3.0–3.7 or 4.5% energy, respectively. For 90th percentile consumers of fat, use of HSSL1 or HSSL2 resulted in an increase in intake of stearic acid from 3.3% energy to 4.3% or 5.4% energy, respectively.

Use of either HSSL resulted in decreases in TFA intake from a baseline mean of 2.5% (3.0% at the 90th percentile) to 0.9% energy. This reduction was accompanied by no increase in palmitic acid intake. Substitution of either HSSL for partially hydrogenated soybean oil also produced increases in mean and 90th percentile intakes of linoleic acid of about 1.5–2% energy, decreases in mean and 90th percentile intakes of oleic acid of about 1% energy, and slight increases in the intake of  $\alpha$ -linolenic acid.

## Discussion

This study demonstrates the overall positive dietary impact of using HSSL to replace partially hydrogenated soybean oil in four food categories: baked goods; home-use shortenings; French fries and fried meat, poultry and fish; and margarines and spreads. Mean intake of TFA could decrease to 0.9% energy from 2.5–3.0% energy with no concomitant increase in palmitic acid. Intake of stearic acid could increase from a baseline mean of 3.0% energy (3.3% at the 90th percentile) to about 4% energy for average consumers of fat and to about 5% energy for 90th-percentile consumers of fat. Intakes of linoleic and  $\alpha$ -linolenic acids could increase, and intakes of oleic acid decrease; these changes maintain or improve the fatty acid intake of the diet to be more in line with current dietary recommendations [3]. The categories chosen for substitution were ones for which HSSL has appropriate functionality and so the potential to be selected by food manufacturers. One limitation of the study is that the actual impact of HSSL on the diet will depend on how and to what degree food manufacturers select HSSL to replace partially hydrogenated oils, and cannot be fully characterized until reformulation is complete.

The effects of stearic acid on cardiovascular health endpoints have been extensively studied and recently reviewed [4–6, 10–17], and will not be reviewed in detail here. It has long been recognized that stearic acid does not share the hypercholesterolemic effects of shorter chain saturated fatty acids, such as lauric, myristic and palmitic acids [11]. In a recent well-designed and controlled study, Judd et al. [12] compared the effects of diets containing an additional 8% energy from stearic acid (STE) versus lauric + myristic + palmitic acid (LMP) versus TFA versus a blend of stearic acid + TFA (STE/TFA) versus oleic acid (OL) versus carbohydrate (CHO) on blood lipids. The STE diet produced the lowest total cholesterol and low-density

**Fig. 1** US per capita fatty acid intake (% energy) after substitution of HSSL1 in four food categories, mean and 90th percentile

**Fig. 2** US per capita fatty acid intake (% energy) after substitution of HSSL2 in four food categories, mean and 90th percentile

lipoprotein–cholesterol concentrations among the STE, LMP, TFA and STE/TFA diets, and the effects of the STE diet on these endpoints were not different from those observed for the CHO diet. These results are particularly relevant because they demonstrate the effects on plasma lipids of different types of dietary fats that could substitute for each other in food applications. The work of Judd et al. [12] indicates that using a high stearic acid fat to replace partially hydrogenated oil or oils high in lauric, myristic and palmitic acids would result in lower total and LDL cholesterol.

More recent research has sought to determine whether there are any potentially undesirable effects of stearic acid on other cardiovascular health indicators, such as inflammatory markers and hemostatic risk factors. For example, as part of the study by Judd et al. [12] described above, Baer et al. [13] determined the effects of six different diets on a variety of inflammatory markers in healthy men. They found that the STE diet did not result in levels of E-selectin, C-reactive protein, or IL-6 that were different from those found in the CHO group. The STE diet did raise

levels of fibrinogen significantly versus the CHO diet, raising concern that dietary stearic acid could be pro-inflammatory. However, stearic acid did not consistently lead to increased fibrinogen levels in this study, since there were no significant effects on fibrinogen levels by the STE/TFA diet. The fibrinogen concentration on the CHO diet was 2.74 g/L, and on the STE/TFA diet, 2.75 g/L. The amount of stearic acid in the STE/TFA diet, 6.9% energy, in the study by Baer et al. [13] is higher than the 5.0% energy estimated to be the 90th percentile intake of stearic acid in the present study.

Thijssen et al. [5] compared the thrombogenic effects of diets containing comparable fat compositions except for 7% energy as either stearic, oleic or linoleic acids. Healthy male and female subjects consumed each diet for five weeks in a randomized, cross-over design. At the end of each period, ex vivo and in vitro platelet aggregation and variables of coagulation, fibrinolysis and hematology were assessed. There were no differences among the three dietary fatty acids in effects on indices of coagulation and fibrinolytic activity, i.e., Factor VII amidolytic activity, fibrinogen,

prothrombin fragment 1 and 2, plasminogen activator inhibitor, and tissue plasminogen activator (tPA/PAI-1) complexes. There also were no significant effects of diet on ex vivo and in vitro platelet aggregation. When data from male subjects were considered separately from those of female subjects, the ex vivo platelet aggregation time following the linoleic acid diet was prolonged when compared to the stearic acid diet, but there was no difference ( $P < 0.05$ ) between the stearic and oleic acid diets. Mean platelet volume for both male and female subjects was significantly lower following the high stearic acid diet versus the high oleic and high linoleic acid diets. Thijssen and coworkers concluded that their data refute the suggestion that stearic acid is thrombogenic.

In the review by Kris-Etherton et al. [4], it was shown that most clinical trials of the effects of stearic acid on health-related endpoints have used dietary concentrations of stearic acid of about 7–13% energy. Compared to the results shown in this study, these levels are well in excess of what is likely achievable in the US diet. In their review, Kris-Etherton et al. [4] concluded that even if stearic acid intake increased to 9% energy, "...it is unlikely that any adverse effects of this level of stearic acid would be observed". The increase in stearic acid intake from 3.0% energy to about 4–5% energy, as estimated in this study, represents the outer limit of possibility, since it assumed that 100% of the partially hydrogenated soybean oil used in four categories of foods would be replaced by HSSL1 or HSSL2. Thus, the expected intake of stearic acid is likely to be less than 5% energy as the result of using HSSL1 or HSSL2.

Note that the use of either HSSL1 or HSSL2 could result in decreases in TFA intake from a mean of 2.5–0.9% energy. The ability of these oils to replace partially hydrogenated soybean oils used in baked goods accounts for much of their significant potential to reduce intake of TFA while not increasing intake of palmitic acid. A recent clinical study [18] has shown that the use of palm oil to replace partially hydrogenated soybean oil would result in undesirable effects on lipoprotein profiles when compared to soy and canola oils. The authors concluded that palm oil would not be a good substitute for partially hydrogenated fats.

As food manufacturers seek alternatives to partially hydrogenated oils, they must weigh their formulation needs against the need to deliver optimal nutrition. High stearic, low  $\alpha$ -linolenic acid soybean oils provide the opportunity to deliver stability and functionality to a variety of foods while also avoiding the negative health consequences associated with other saturated fatty acids. This study has shown that the use of HSSL1 or HSSL2 to replace partially hydrogenated soybean oil in four food categories could increase the intake of stearic acid from a mean of 3.0%

energy to about 4% energy (at the 90th percentile, 3.3% energy baseline to about 5% energy). This increased level of stearic acid intake is well below the levels studied in numerous clinical trials that have shown no adverse effects on markers of cardiovascular health. Moreover, such a substitution could achieve a significant reduction in the intake of TFA while not increasing the intake of palmitic acid.

**Abstract** An original gas chromatography/mass spectrometry method for quantifying trace amounts of ricinoleic acid (12-hydroxy-*cis*-9-octadecenoic acid) is detailed. Data are presented on trace amounts of ricinoleic acid found in several common vegetable oils and oils extracted from common oil seeds: e.g., ca. 30 ppm in commercial olive oil was the lowest amount; and ca. 2,690 ppm in oil extracted from cottonseeds was the highest amount.

### Introduction

With current testing methods, ricinoleic acid (12-hydroxy-*cis*-9-octadecenoic acid), the characteristic acyl component of castor bean oil [1–3] can only be quantified at the percent level. For quantifying trace amounts of ricinoleic acid, our research group developed a method using gas

chromatography/mass spectrometry (GC/MS). While we were developing this method, we unexpectedly found that ricinoleic acid is in many common vegetable oils.

In this communication, we introduce this method and present the data confirming the presence of ricinoleic acid.

### Materials and Methods

#### Materials and Chemicals

Rapeseeds were supplied by an oil manufacturer; other oil seeds and vegetable oils were purchased from local markets. Standard castor oil, authentic ricinoleic acid (purity 87%) and 3-hydroxyhexadecanoic acid (purity 98%) were from Wako Pure Chemical Industries (Osaka, Japan). Triolein (purity 99%) was from Nu-Chek Prep (Elysian, MN). Other chemicals were of the highest reagent grade available.

#### Preparation of Derivatives from Oil Samples

Samples were ten kinds of vegetable oils and the oils (extracted by the method of Folch et al. [4]) of four kinds of oil seeds. The internal standard (IS), 3-hydroxyhexadecanoic acid (50 µg), was added to each 50 mg sample, and then these samples were methanolized with 0.5 M KOH/methanol (1 mL) and successively methylated with 14% BF<sub>3</sub>/methanol (1.5 mL), under the same conditions as those described in our previous research [5]. After adding a saturated NaCl aqueous solution (5 mL), the resultant fatty acid methyl esters were extracted three times with hexane (3 mL each time). The hexane layers were combined, dehydrated and evaporated to dryness. The residue

K. Yamamoto · A. Kinoshita · A. Shibahara (✉)

containing fatty acid methyl esters was dissolved in hexane (1 mL). This was poured into a glass column (30 cm × 15 mm i.d.) packed with 8 g of Wakogel C-300 (Wako Pure Chemical Industries) and 3 g of anhydrous Na<sub>2</sub>SO<sub>4</sub>. The esters with straight carbon chains were removed from the column by passing through a solution of ether/hexane (10:90, by vol.) (50 mL). The remaining esters with hydroxyl groups on their carbon chains were recovered from the column by passing acetone (50 mL) through. This recovered fraction was evaporated to dryness, dissolved in dehydrated pyridine (0.3 mL), and then trimethylsilylated with 0.2 mL of a reagent mixture [trimethylchlorosilane/*N*-trimethylsilylimidazole/*N,O*-bis(trimethylsilyl)trifluoroacetamide] (1:1:1, by vol.) under the usual conditions. After standing for 10 min at room temperature, the *O*-trimethylsilylated (-OTMS) methyl ester derivatives of each sample were analyzed by GC/MS.

#### Preparation of the Standard Mixtures for the Calibration Curve

Eight different standard mixtures were prepared—each contained different amounts (0, 0.5, 1, 2, 5, 10, 20 and 50 μg) of authentic ricinoleic acid with the same amount (50 μg) of 3-hydroxyhexadecanoic acid (IS). These standard mixtures were methylated, trimethylsilylated, and analyzed by GC/MS. The conditions for methylating and trimethylsilylating were the same as those described above.

#### GC/MS Conditions

The derivatives of fatty acid methyl ester-OTMS were analyzed on an SPB-50 capillary column (30 m × 0.25 mm i.d., 0.25 μm film, chemically bonded type, Supelco, Bellefonte, PA) connected to a Shimadzu QP-2010 mass spectrometer (Kyoto, Japan) with a computer on-line system. The column temperature was programmed at 180 °C isothermally for 2 min, increased to 240 °C at a rate of 3 °C/min, to 290 °C at a rate of 60 °C/min, and held at 290 °C isothermally for 8 min. The other operating conditions were as follows: injector temperature, 280 °C; interface temperature, 280 °C; ion source temperature, 200 °C; carrier gas, helium (linear gas velocity of 35 cm/s); split ratio, 1/25; ionizing energy, 70 eV; and scanning range, 70–400 *m/z* (0.5 s/cycle).

#### Results and Discussion

##### Calibration Curve for Determining the Amounts of Ricinoleic Acid

The eight different standard mixtures were analyzed by GC/MS to get the calibration curve used for determining the trace amounts of ricinoleic acid in the oil samples. Figure 1a shows the mass chromatogram of one of the standard mixtures; methyl 3-hydroxyhexadecanoate-OTMS (derived from the IS) elutes at 11.9 min and methyl ricinoleate-OTMS elutes at 16.9 min.

**Fig. 1** Mass chromatogram of one of the standard mixtures of methyl 3-hydroxyhexadecanoate and methyl ricinoleate after trimethylsilylation (a), and mass spectra of trimethylsilylated derivatives of methyl 3-hydroxyhexadecanoate (b) and of methyl ricinoleate (c). In mass chromatogram A, peak 1 (retention time, 11.9 min) is the trimethylsilylated derivative of methyl 3-hydroxyhexadecanoate (internal standard) and peak 2 (retention time, 16.9 min) is the trimethylsilylated derivative of methyl ricinoleate. Mass spectra (b) and (c) are taken from the tops of peak 1 and peak 2 in mass chromatogram A. Mass spectral elucidations and the GC/MS conditions are given in the text

Figure 1b shows the electron impact mass spectrum of methyl 3-hydroxyhexadecanoate-OTMS. The  $\alpha$ -cleavage at the silyl ether group gives the fragment ions at  $m/z$  175 and at  $m/z$  285. The ion at  $m/z$  343 ( $M^+ - 15$ ) is due to the loss of the methyl group (one of three methyl groups of the silyl group) from the molecular ion at  $m/z$  358. The major ion at  $m/z$  73,  $(CH_3)_3Si^+$ , is a typical ion originating from the trimethylsilylated compound.

In the mass spectrum of methyl ricinoleate-OTMS (Fig. 1c), the  $\alpha$ -cleavage at the silyl ether group gives the fragment ions at  $m/z$  187 and at  $m/z$  299. The migration ion (TMS rearrangement ion) at  $m/z$  270,  $CH_2-CH=CH-(CH_2)_7-C^+(=OTMS)-OCH_3$ , is present, indicating the locations of the hydroxyl group at the C-12 carbon and the double bond at the C-9 and C-10 carbons. These mass spectral elucidations agree with those in other research [6, 7].

With mass chromatography, we traced the fragment ions at  $m/z$  175 (from methyl 3-hydroxyhexadecanoate-OTMS) and at  $m/z$  187 (from methyl ricinoleate-OTMS) from the eight different standard mixtures to get the calibration curve.

The value  $V$ , indicating the peak area ratio of these two fragment ions, is calculated with the following formula:  $V = \text{peak area of the ion at } m/z \text{ 187} / \text{peak area of the ion at } m/z \text{ 175}$ . Plotting the value  $V$  for the eight different standard mixtures (on the  $y$ -axis) against the known amounts of ricinoleic acid (on the  $x$ -axis) gives the calibration curve in Fig. 2. Value  $V$  increases in direct proportion to the increasing amounts of ricinoleic acid (from 0 to 50  $\mu\text{g}$ ). This GC/MS method is suitable for quantifying ricinoleic acid at the ppm level.

### Recovery Test

As the model experiment, 32  $\mu\text{g}$  of standard castor oil was added to 50 mg of triolein. This was analyzed (five times, independently), and there was an average of 95% recovery for ricinoleic acid (6.2% CV).

### Ricinoleic Acid in Common Vegetable Oils and Oil Seeds

Using this method, we analyzed ten kinds of vegetable oils, and all the oils contain ricinoleic acid (Table 1). Figure 3 illustrates the mass spectrum of methyl ricinoleate-OTMS taken from the soybean oil analysis, and it agrees with the spectrum of authentic methyl ricinoleate-OTMS (Fig. 1c).

We considered the possibility that these vegetable oils were contaminated, with castor oil or another contaminant containing ricinoleic acid, in the refining process during

**Fig. 2** Calibration curve for determining the amounts of ricinoleic acid. Known amounts of ricinoleic acid in the eight different standard mixtures are plotted on the  $x$ -axis. The values  $V$ , indicating the peak area ratio of the two fragment ions, are plotted on the  $y$ -axis. The value  $V$  is calculated with the following formula:  $V = \text{peak area of the ion at } m/z \text{ 187} / \text{peak area of the ion at } m/z \text{ 175}$ , where the ion at  $m/z$  187 is from the trimethylsilylated derivative of methyl ricinoleate and the ion at  $m/z$  175 is from the trimethylsilylated derivative of methyl 3-hydroxyhexadecanoate. Each value  $V$  is an average of triplicate determinations

**Table 1** Amounts of ricinoleic acid in common vegetable oils and oils from seeds

Type of oil	Ricinoleic acid (ppm) <sup>a</sup>
Coconut	33 $\pm$ 1
Corn	209 $\pm$ 6
Cottonseed	1,695 $\pm$ 80
Extracted from seed <sup>b</sup>	2,688 $\pm$ 397
Olive	31 $\pm$ 1

<sup>c</sup> We found an isomer of ricinoleic acid in rice bran oil. The details will be reported elsewhere

**Fig. 3** Mass spectrum of trimethylsilylated derivative of methyl ricinoleate, taken from the soybean oil analysis

production. To check this, we directly extracted oil from four kinds of oil seeds (according to the method of Folch et al. [4], routinely used in lipid laboratories). In these cases, as well, ricinoleic acid is quantified (Table 1).

From our data, we may conclude that many common vegetable oils and oil seeds contain ricinoleic acid.

This easy and sensitive GC/MS method can be a strong tool for those who need to determine trace amounts of ricinoleic acid in the food, cosmetic or pharmaceutical industries and also in research laboratories.

#### Possible Mechanism for Ricinoleic Acid Biosynthesis

The oil-producing plants (reported here) must have enzyme systems involving ricinoleic acid bioformation. Plant lipid researchers fully understand the biosynthetic pathway for ricinoleic acid in castor bean [3, 8–11]; an enzyme system catalyzes the production of ricinoleate by direct hydroxylation of oleate (*cis*-9-octadecenoate) attaching to phosphatidylcholine (the immediate substrate: oleoyl-

phosphatidylcholine). We do not know, however, if this enzyme system exists in the plants we analyzed.

In addition, fatty acyl hydroxylases and desaturases have similar amino acid sequences and similar reaction mechanisms [7, 9–11]. Our findings may help researchers studying the ricinoleate-synthesizing enzyme and the linoleate-synthesizing enzyme in higher plants.

**Abstract** Fatty acid composition of the adipose tissue of six carnivorous mammalian species (European otter *Lutra lutra*, American mink *Mustela vison*, European Mink *Mustela lutreola*, European polecat *Mustela putorius*, stone marten *Martes foina* and European wild cat *Felis silvestris*) was studied. These species forage to differing degrees in aquatic and terrestrial food webs. Fatty acid analysis revealed significant differences in polyunsaturated fatty acid composition between species. More specifically, our results underline a gradual significant decrease in the docosahexaenoic acid (DHA)/linoleic acid (LNA) ratio of carnivore species as their dependence on aquatic food webs decreases. In conclusion, the use of the DHA/LNA ratio in long-term studies is proposed as a potential proxy of changes in foraging behaviour of semi-aquatic mammals.

### Abbreviations

ARA	Arachidonic acid
ALA	$\alpha$ -Linolenic acid
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
LNA	Linoleic acid
MUFA	Monounsaturated fatty acid
PUFA	Polyunsaturated fatty acid
SAFA	Saturated fatty acid
TFAW	Total fatty acid weight

### Introduction

Recent legal protection and conservation programs allowed many endangered species to re-colonise their habitats. Nevertheless, these species have to cope now with disturbed biotopes and prey populations. The re-colonising success of these species in their disturbed niches suggests a change in their foraging strategies [1, 2]. However, these diet modifications are very difficult to evaluate in a low density context [3]. Indeed, direct observation of faeces analysis give only a snapshot of the animals' diet.

On the other hand, fatty acid storage tissue composition has been successfully used in many cases as an accurate and time-integrating proxy of carnivorous mammals' diets [4–7]. The latter is based on the fact that some dietary fatty acids are stored in the adipose tissues without important modifications and thus can be used as biomarkers [4].

Lipids from aquatic and terrestrial primary producers exhibit differences in fatty acid signatures [8]. Phytoplanktonic microalgae can produce n-3 polyunsaturated fatty acids (PUFAs) in large quantities [8–11]. In contrast, few terrestrial plants (e.g. Berries, Olives) contain significant amounts of  $\alpha$ -linolenic acid (18:3n-3, ALA), whereas many

more synthesize and store large amounts of linoleic acid (18:2n-6, LA) [12]. Highly unsaturated PUFAs (e.g. 20:4n-6; ARA, 20:5n-3; EPA, 22:6n-3; DHA) are involved in a wide range of physiological processes. As most animals lack the specific fatty acid desaturases required to insert double bonds in the n-3 and the n-6 position, these compounds have to be obtained by the animals from their diet [13, 14]. This results in a high conservation of these molecules along food webs, from primary producers to final consumers [15, 16]. Consequently, each type of food web shows a “typical” fatty acid profile [17, 18]. In aquatic food webs n-3 PUFAs dominate over n-6 PUFAs by a factor of 5–20 [17, 19]. The opposite is true for terrestrial food webs where n-6 PUFAs are more abundant than n-3 PUFAs [20]. Thus, we expect that gradual transitions from one food web to another are followed by a gradual evolution of fatty acid proportions. The major aim of this study is to investigate the evolution of PUFA patterns along a gradual transition from aquatic to terrestrial food webs.

In this context, fatty acid composition of the peritoneal fat of six carnivore species (*Mammalia*, *Carnivora*) was analysed. The analysed species (European otter *Lutra lutra*, Linnaeus 1758 American mink *Mustela vison*, Schreber 1777, European mink *Mustela lutreola*, Linnaeus 1761, European polecat *Mustela putorius*, Linnaeus 1758, Stone marten *Martes foina*, Erxleben 1777 and European wild cat *Felis silvestris*, Schreber 1777) were chosen in order to illustrate a continuous decreasing gradient of aquatic food web exploitation (Fig. 1).

## Materials and Methods

### Carnivore Sampling

Six species of two families of carnivores were chosen in order to illustrate a continuous decreasing gradient of aquatic food web exploitation (Fig. 1), and sampled in France between 2002 and 2006. Species were mainly

**Fig. 1** Schematic representation of food source origin of the studied carnivorous mammals. White: fish; clear grey: crayfish; dark grey: amphibians; black: terrestrial food (birds, mammals, fruits, terrestrial invertebrates); Data synthesised from previous studies [35–39]

chosen in the Mustelidae family: (American mink,  $n = 13$ ; European otter,  $n = 17$ ; European mink,  $n = 17$ ; European polecat,  $n = 13$ ; stone marten,  $n = 13$ ) and one species was chosen in the Felidae family (European wild cat,  $n = 14$ ). For ethical, legal and technical reasons, only freshly conserved (maximum 24 h) wild animals killed by road traffic were collected, using existent French networks in animal studies. Peritoneal adipose tissues were sampled and deep-frozen ( $-80\text{ }^{\circ}\text{C}$ ) before the lipid analysis.

### Lipid and Statistical Analysis

Total lipids were extracted from tissue samples with a chloroform/methanol (2:1,  $v/v$ ) mixture [21]. Fatty acid methyl esters were obtained by hydrolysis in methanolic NaOH and esterification in methanolic  $\text{H}_2\text{SO}_4$  [10]. Fatty acid analyses were carried out on a Chrompack CP 9001 gas chromatograph equipped with a Supelco<sup>®</sup> Omegacoax<sup>™</sup> column and a FID detector ( $260\text{ }^{\circ}\text{C}$ ) (split injection; injector temperature:  $260\text{ }^{\circ}\text{C}$ ; carrier gas: helium; oven rise from  $140$  to  $245\text{ }^{\circ}\text{C}$  at  $3\text{ }^{\circ}\text{C min}^{-1}$ ). Individual fatty acid methyl esters are identified by comparing retention times with those obtained from Supelco<sup>®</sup> standards and laboratory standards. Fatty acid methyl esters were quantified using 13:0 as an internal standard that is added before the derivation of fatty acids.

Statistical differences in DHA, LNA and DHA/LNA compositions among sampled species were analysed with the Kruskal–Wallis test and when significant, two-by-two species comparisons were made with the Mann–Whitney  $U$  test. Correlation was calculated with Spearman’s correlation coefficient ( $r_s$ ).  $P$  values less than 0.05 were considered significant.

## Results and Discussion

### SAFA and MUFA Patterns

A total of 87 individuals were analysed for fatty acid composition (Table 1). Saturated fatty acids (SAFA) varied from 29.3 (European otter) to 55.3% (stone marten) of the total fatty acids weight (TFAW). As already observed [4, 22] for other mammals, SAFA are dominated by 16:0 (17.2% of the TFAW for otter, 31.4% for stone marten) and to a lesser extent by 18:0 (4.9% of the TFAW for otter to 22.8% of the TFAW for stone marten).

The monounsaturated fatty acids (MUFA) ranged from 21.4 (stone marten) to 45.0% (European mink) of TFAW. As observed for other carnivorous mammals [4, 22, 23] 18:1n-9 was the dominant fatty acid in MUFA, varying from 20.0 (stone marten) to 40.6% (European mink) of TFAW. Substantial or high levels of 16:1n-7 were also observed, ranging from 1.4 (stone marten) to 8.3% (European otter).

### Variations in PUFA Patterns

The polyunsaturated fatty acids (PUFA) make up 20.1% (American mink) to 29.7% (European polecat) of TFAW, and are dominated by the n-6 FAs (52.4–89.1% of the total weight of PUFA, data not shown). For all sampled species, 18:2n-6 (linoleic acid, LA) counts for more than half of the weight of n-6 PUFAs (data not shown). High concentrations of LNA (from 10.6 to 18.2% of TFAW for otter and

polecat, respectively) were also observed in terrestrial mammalian carnivores in previous studies [4, 24] and certainly reflect the abundance of this FA in terrestrial food webs [12, 18].

In contrast, n-3 FAs show stronger variations ranging from 10.9% (stone marten) to 42.5% (European otter) of total PUFA weight (data not shown) and are dominated by 18:3n-3 ( $\alpha$ -linolenic acid, ALA) as well as by 22:6n-3 (docosahexaenoic acid, DHA) and to a lesser extent by

**Fig. 2** Mean values of four major PUFAs in the peritoneal adipose tissue of the sampled carnivorous mammals, according to their degree of aquatic food web exploitation. For simplification reasons only the DHA and LNA statistical differences are presented. Data labelled with the same letter are not significantly different (Mann–Whitney,  $P < 0.05$ )

22:5n-3 (Table 1). Species with aquatic prey-based diet (Fig. 1) show up to tenfold higher concentrations of DHA than species that predate exclusively on terrestrial prey (Fig. 2). A dietary-influence of DHA and EPA concentrations linked to fish consumption has already been documented for American minks kits fed on a fish-oil supplemented diet [4]. Indeed, DHA is abundant in both marine and freshwater fishes [14, 19]. Although freshwater fishes can also be a source of ALA [8, 25, 26] the high concentration of this FA observed for the European polecat (7.3% of TFAW) is probably not completely due to fish

consumption. Indeed, the results suggest that important ALA amounts of aquatic origin are associated with high DHA amounts, as observed for the European otter and both mink species (Fig. 2). Moreover, European polecats rarely consume fish (Fig. 1) and ALA could come from berries consumption, since berries are known to contain significant amounts of ALA [12]. Furthermore, the European polecat is known to complete its diet with fruits and berries (Fig. 1). In contrast with DHA, the LNA concentration tends to be increased in carnivorous mammals with more “terrestrial” diets (Fig. 2).

The DHA/LNA Ratio

The decrease in DHA as well as the increasing tendency of LNA in carnivorous mammals from aquatic to terrestrial food webs seems to be confirmed when comparing our results to those from other studies (Fig. 3). Indeed, animals foraging strictly in aquatic food webs, such as dolphins or marine seals, are characterized by the highest DHA/LNA ratios whereas freshwater seals exhibit lower DHA/LNA ratios when compared to marine mammals. A previous study successfully used the n-3/n-6 fatty acid ratio to distinguish marine from freshwater populations of genetically related seals [23]. The great abundance of n-6 PUFAs in freshwater food webs has been suggested to be due to a greater terrestrial input of organic matter [18]. Indeed, river food webs are often based on the use of terrestrial plant detrital material by macroinvertebrates [27]. Moreover, in lakes, a recent study has suggested that 22–55% of assimilated carbon by the major freshwater “herbivore” *Daphnia* sp. is derived from terrestrial organic matter [28]

**Fig. 3** Mean values of DHA/LNA ratio in adipose tissue of carnivorous mammals belonging to different food webs. *Dagger*: data estimated from Samuel and Worthy [33]; *double dagger* data estimated from Käkälä and Hyvärinen [23]; *asterisks* data estimated from Grahl-Nielsen et al. [22]. *No symbol*: data from present study. *Above*: DHA/LNA ratio in peritoneal adipose tissue of carnivorous mammals from this study. Data labelled with the same letter are not significantly different (Mann–Whitney,  $P < 0.05$ )

which could be rich in LNA [29]. Thus, inputs of terrestrial organic matter could partially explain the abundance of n-6 PUFAs and more particularly LNA in freshwater food webs. However, terrestrial influence may also occur under the form of phosphorus loading. It has recently been shown that sestonic concentrations of n-3 highly unsaturated fatty acids (such as DHA or EPA) decreased along a trophic state gradient from oligotrophic to eutrophic lakes [30]. For evident reasons the authors established the decrease of DHA with increasing total phosphorus by sampling different lakes. It is tempting to speculate that the decrease of DHA could occur in a given lake over a long-term temporal scale corresponding to its natural eutrophication. This could imply that the DHA/LNA ratios that are observed in a given aquatic food web gradually evolve towards more terrestrial values. However, Müller-Navarra et al. [30] did not mention any increase of LNA with increasing total phosphorus. Nevertheless, phytoplankton composition in eutrophic lakes is often dominated by Cyanobacteria or Chlorophyceae, which do not produce DHA but can contain relatively high amounts of LNA [9, 31].

#### DHA/LNA Ratio Gradient from Aquatic to Terrestrial Food Webs

Because of the terrestrial influence and specific processes occurring in freshwater food webs, the DHA/LNA ratio can distinguish marine from freshwater mammals. For example, dolphins and seals foraging in marine food webs exhibit high DHA/LNA ratios ranging from 11 (Bottlenose dolphin *Tursiops truncatus*) to 11.82 (Ringed seal *Phoca hispida*), whereas freshwater seals exhibit ratios ranging from 2.5 to 5.29 (Fig. 3). Continental carnivorous mammals foraging partially or totally in terrestrial food webs exhibit much lower DHA/LNA ratios, ranging from 0.46 (European otter) to 0.01 (stone marten). More interestingly, the gradual decrease of the ratio is correlated with decreasing aquatic food web exploitation ( $r_s = 0.957$ ,  $P < 0.05$ ) (Fig. 3).

The decrease in the DHA/LNA ratio from aquatic to terrestrial food webs led us to consider DHA/LNA ratio of carnivorous mammals as a proxy evaluating their connection strength to these two types of food webs. Nevertheless, the mean values of the DHA/LNA ratio of the animals sampled in this study exhibit an important individual variability (Fig. 3). As these animals were collected in different geographic areas and at different seasons, this variability could reflect geographical and temporal differences in foraging behaviour [32]. Furthermore, other parameters such as age, sex or physiological state should also be taken into account when considering this variability [22, 33].

Thus, further studies are required to better understand the dietary FA accumulation patterns and their variations

among and within species. Moreover, more attention should be paid on adipose tissue turnover rates in order to establish more precisely the links between DHA/LNA ratio and dietary shifts. Once these parameters are known, it should be possible to determine whether the striking difference in the DHA/LNA ratios between otters and freshwater seals (Fig. 3) is relevant. If so, our results could suggest that the re-colonising otters sampled for this study are more strongly connected to terrestrial food webs than expected. This phenomenon has already been observed for American minks sharing the same biotope with otters. These two species are niche competitors, and their competition in a disturbed biotope can result in a switch of the mink's diet from aquatic to terrestrial prey [1, 34].

In conclusion, we suggest that the DHA/LNA ratio is a useful tool for the assessment of the dietary plasticity of carnivorous mammals. The use of the DHA/LNA ratio in long-term studies could allow to evaluate in which manner changes in foraging behaviour are linked to population dynamics of semi-aquatic species in different geographical areas.

**Abstract** Renal handling of major HDL components was studied by analyzing urine from patients with Fanconi syndrome, a rare renal proximal tubular reabsorption failure, including dysfunction of the kidney HDL receptor, cubilin. A high urinary excretion of apolipoprotein A-I and A-IV corresponding to a major part of the metabolism of these proteins was measured. In contrast, no urinary excretion of apolipoprotein A-II which is more hydrophobic and tighter bound to HDL was found. Control urines displayed absence of the three apolipoproteins. Urinary excretion of phospholipids, triglycerides, cholesterol and cholesterol esters in patients was as low as in controls. In conclusion, these data indicate that the human kidney is a major site for filtered nascent apolipoprotein A-I and A-IV but not for HDL particles.

### Introduction

The high density lipoprotein (HDL) plasma level, including its major protein component apolipoprotein A-I (apoA-I), is inversely correlated to the incidence of cardiovascular diseases [1]. ApoA-I's anti-atherosclerotic properties, have led to a focus on apoA-I metabolism and apoA-I based therapies [2–6]. The plasma level of HDL/apoA-I is correlated to the catabolic rate rather than production rate of apoA-I [7]. Whereas the liver and steroid organs are major site for uptake of HDL lipids, there are diverging data on the catabolism of the HDL particles and protein components.

In studies of elimination of human and murine apoA-I in mice models and hamster apoA-I in hamster, the liver was found to be the major organ for clearance of apoA-I [8–10], whereas in rats the kidney was found to be the major site [11]. These different observations may be due to species differences as well as the apoA-I labeling procedures used. The latter is indicated by a study in rabbits showing that 70% of injected human apoA-I was cleared by the kidneys, whereas <sup>125</sup>I- labeled apoA-I was cleared substantially faster, and predominantly by liver [12]. Furthermore, the

catabolic site of apoA-I may depend on its degree of lipitation and binding strength to the entire HDL particle. Studies of the apoA-I clearance in mice transgenic for human apoA-I indicate that the liver preferentially takes up apoA-I associated to particles [13, 14].

In rodent kidney, apoA-I uptake is accounted for by glomerular filtration and subsequent recognition by cubilin in the proximal tubules leading to endocytosis and degradation [15].

To define the role of the human kidney in HDL clearance we compared the renal handling of HDL apoA-I, apoA-II and apoA-IV and HDL lipid components in human Fanconi syndrome patients with failure in megalin and cubilin-mediated protein re-absorption in the proximal tubules [16].

## Materials and Methods

### Fanconi Syndrome Patients and Specimen Collection

Patients with the rare Fanconi syndrome had the following diagnoses: Dent's disease caused by mutations in the CIC-5 chloride channel (Patients 3–5 and 8); Lowe syndrome (Patients 6 and 7) and autosomal dominant idiopathic Fanconi syndrome (Patients 1 and 2). All patients had well-preserved renal glomerular function estimated by creatinine clearance and had been described previously [16]. Sample collection and calculation of 24 h excretion based on creatinine values was conducted as described [16].

### Urine Analysis

Western blot analysis was conducted using rabbit polyclonal antibodies against apoA-I, apoA-II and apoA-IV. Urine concentrations of apoA-I were measured by an enzyme-linked immunosorbent assay (ELISA) as described [2]. Two-dimensional gel-electrophoresis analysis of urinary apoA-I and A-IV was carried out as described [17]. Lipids were extracted from 60 ml urine samples and phospholipids and cholesterol concentrations determined as described [18–20]. Creatinine,  $\alpha_1$ -microglobulin and albumin were determined as described [16].

### Immunocytochemistry Studies of Human Proximal Tubules

Normal, uninvolved human renal tissue was obtained from resected renal carcinoma kidneys and 0.8  $\mu$ m cryosections prepared [21]. The sections were incubated with rabbit anti-human apoA-I antibody. As negative control, sections were incubated with secondary antibodies alone or non-specific rabbit IgG.

## Results

### Analysis of Urine from Fanconi Patients

Substantial reabsorption of apoA-I in the human proximal tubules was indicated by apoA-I immunoreactivity in lysosomal-like vesicles proximal tubule cells of normal human kidney cortex (Fig. 1). An estimate of the clearance of apoA-I in the kidneys was obtained by analyzing urine of Fanconi patients having failure in tubular reabsorption with high urinary protein excretion.

Western blotting showed a substantial secretion of full-length apoA-I (Fig. 1) and ELISA of patients urine showed apoA-I levels ranging from 7.8 to 178  $\mu$ g/ml (mean  $73 \pm 55$   $\mu$ g/ml, Table 1) corresponding to an excretion of

7	47	173	240	885	187	687	4.3	16
8	108	209	354	685	175	339	5.1	10

205  $\pm$  181 mg apoA-I/24 h with 0.5 g/24 h being the maximum value. No apoA-I was detected in urine from control individuals (sensitivity limit 0.01  $\mu\text{g/ml}$ ). Measurement of urinary creatinine, albumin and  $\alpha_1$ -microglobulin (Table 1) suggested normal filtration rates in the patients.

Western blotting detected also a high apoA-IV content but no apoA-II in the urines. The level of apoA-IV in urine was by semiquantitative immunoblotting of 2-D gels measured to 8–86  $\mu\text{g/ml}$ , (mean 42  $\pm$  30  $\mu\text{g/ml}$ ), corresponding to a total daily urinary excretion of 6–172 mg apoA-IV (mean 120  $\pm$  89 mg/day). This is in the range of what is previously reported [22, 23]. No apoA-II or apoA-IV was detected by western blotting of control urine.

ApoA-I from urine exhibited pre- $\beta_1$  migration in 2-D gel-electrophoresis (Fig. 1) indicating that apoA-I was represented by pre- $\beta_1$  particles or less lipidated including the nascent apoA-I form (which also exhibits pre- $\beta_1$  migration). Low apoA-I lipidation was further indicated by the very low contents of phospholipids, cholesterol, cholesterol esters and triglyceride determined by thin layer chromatography of lipids extracted from urine of patients and controls. In the urine of the two patients (3 and 4) the phospholipid concentrations were 0.82 and 2.87 mg/l, respectively, whereas cholesterol concentrations were 1.59 and 1.92 mg/l, respectively. In two healthy individuals similar phospholipid (0.86 and 0.62 mg/l) and cholesterol (1.21 and 1.45 mg/l) concentrations were measured.

## Discussion

By taking advantage of the fact that Fanconi patients in the urine excretes filtered proteins that otherwise would be reabsorbed in the proximal tubules [16], we measured the urinary content of the major HDL apoA proteins to get further insight into the role of the kidney in HDL clearance. Using proteomic methods apoA-I and apoA-IV have previously been identified in the urine of Fanconi syndrome patients [24], but a comparative quantitative approach has to our knowledge not been done. Although this approach

for estimating normal renal filtration of a protein has its limitations and may underestimate the true values we find it justified because the Fanconi disease has no observed effect on lipoprotein levels [25], glomerular filtration rates and glomerular sieving coefficients [16]. The data showed a high urinary excretion of apoA-I amounting to at least 0.2–0.5 g/day, that is about 50% of the daily synthesis of apoA-I previously estimated to 9–14 mg apoA-I/kg in humans [7, 26].

Consistent with previous data on HDL catabolism in animal models showing a high apoA-I clearance in kidney but a very low HDL cholesteryl ester uptake [10, 11], the data indicate that apoA-I is catabolized in a lipid-poor form. Lipidation of apoA-I and rearrangement into the lipid loaded helix-belt formation [27, 28] may therefore protect apoA-I from catabolism. The absence of this protection may therefore contribute to hypercatabolism of HDL and very low apoA-I and plasma HDL levels in Tangier disease patients with failure in ABCA-1-mediated phospholipid and cholesterol efflux to apoA-I [29–31].

Renal failure surprisingly also causes a decrease in HDL cholesterol [32] but an increase in the fraction of free apoA-I [33] thus indicating that increased extrarenal metabolism of HDL counteracts a failed renal filtration of nascent apoA-I. Hemodialysis of renal failure patients is also reported to further increase the plasma pre- $\beta$  fraction of HDL and free apoA-I [32, 33], indicating that this treatment does not compensate for the absent apoA-I filtration in the kidney

ApoA-II is not excreted in the urine of Fanconi patients, presumably due to the strong hydrophobicity of apoA-II protecting it from dissociation from the HDL particle and subsequent glomerular filtration. Concordant with a stronger association of apoA-II to HDL, transgenic mice overexpressing apoA-II have an increased renal catabolism of apoA-I, presumably displaced from HDL by apoA-II [34].

In conclusion, these data indicate that the human kidney is a major site for filtering nascent apoA-I and A-IV, whereas there is no evidence for filtration of HDL holoparticles.

**Abstract** Transient receptor potential vanilloid subtype 1 (TRPV1) is known as capsaicin (CAP) receptor and activated by CAP. Activation of TRPV1 by CAP increases energy expenditure and thermogenesis in rodents or human. Therefore, TRPV1 may be target for energy expenditure enhancement and thermogenesis. To search for novel TRPV1 agonist, we screened 19 types of foods by using TRPV1-expressing HEK293 cells. TRPV1 was activated by hexane extract of wheat flour, and its functional compounds were 1-monoacylglycerols containing oleic, linoleic, and  $\alpha$ -linolenic acids. Their potencies ( $EC_{50}$ ) were about 50 times larger than that of CAP and their efficacies (maximal response) were about half of that of CAP. TRPV1 was activated by 1-monoacylglycerols (MGs) having C18 and C20 unsaturated and C8–C12 saturated fatty acid (FA). Moreover, 2-MGs having C18 and C20 unsaturated FA acted on TRPV1 with the same potency. On the other hand, no activation of TRPV1 was induced by MGs having C16 and C18 saturated FA, di- or triacylglycerols of C18:1 FA. Pain-relating aversive responses were induced when TRPV1-activating 1-monoacylglycerols (50 mM) was administered subcutaneously into rat hind paw. These effects were inhibited by the co-injection of capsazepine (10 mM) which is a TRPV1 competitive antagonist. These results suggested that these 1-monoacylglycerols activate TRPV1 in vitro and in vivo.

## Introduction

Transient receptor potential vanilloid subtype 1 (TRPV1) is a non-selective cation channel activated by noxious heat ( $>43$  °C), protons, and capsaicin (CAP), a pungent ingredient of red pepper (Fig. 1). TRPV1 is mainly expressed in sensory neurons [1, 2]. TRPV1 functions as nociceptor, and is involved in pungent taste by red pepper intake and pain by inflammation or other stimuli [3]. A variety of natural products and endogenous compounds other than CAP have been identified as the TRPV1 agonists. For example, gingerols and shogaols (pungent compounds of ginger), piperine (pungent compound of black or white pepper), and sanshools (pungent compounds of Japanese pepper) have been identified as natural compounds, and anandamide (arachidonylethanolamide, AEA; Fig. 1) and *N*-arachidonyl dopamine as endogenous TRPV1 agonists [4–6].

**Fig. 1** Chemical structures of capsaicin, 1-oleoylglycerol, anandamide and oleylethanolamide

Activation of TRPV1 plays a role not only in transmission of pungent or pain sensations but also in CAP-induced energy expenditure enhancement and thermogenesis [3, 7, 8]. CAP increases energy expenditure (oxygen consumption) and body temperature by first stimulating the sympathetic nerves and then stimulating adrenaline secretion from the adrenal gland [9–14]. Adrenaline secretion via the activation of sympathetic nervous system plays a key role in energy consumption [15], and it is very important for CAP-induced energy expenditure enhancement. CAP-induced adrenaline secretion and core temperature increment were blocked by pretreatment with capsazepine (CPZ), a TRPV1 competitive antagonist [13, 16]. Recently, it has been reported that CAP intake could not prevent obesity in TRPV1-knockout mice [17] although CAP prevented body fat accumulation in normal rats and mice [18, 19]. These results indicate that TRPV1 activity is very important for CAP-induced anti-obesity. Therefore, TRPV1-activating food ingredients may exert for CAP-like action on energy expenditure enhancement and prevention of obesity that is a serious risk factor for life style-related diseases including impaired glucose and lipid metabolism [20].

In the present study, we screened 19 types of foods by using intracellular  $\text{Ca}^{2+}$  imaging of TRPV1-expressing HEK293 cells. We found that hexane extract of wheat flour increased intracellular calcium concentration ( $[\text{Ca}^{2+}]_i$ ) in TRPV1-expressing HEK293 cells. This extract was fractionated by repeated chromatography, and 1-monoacylglycerols (MGs) having oleic, linoleic, and  $\alpha$ -linolenic acid as acyl components were determined as TRPV1 agonists. These MGs not only activated TRPV1 both in vitro [recombinant TRPV1-expressing HEK293 cells and endogenous TRPV1 expressing mouse dorsal root ganglion (DRG)] and in vivo (hind paw irritancy test). TRPV1 was activated by not only 1-MGs binding C18 and C20

unsaturated and C8–C12 saturated fatty acids (FAs) but also 2-MGs binding C18 and C20 unsaturated FAs. Therefore, TRPV1-activating MGs may be useful for increasing energy expenditure.

## Materials and Methods

### Reagents

Capsaicin and CPZ were purchased from Sigma. Fura-2 AM and fluo-4 AM were obtained from Molecular Probes Inc. (Eugene, OR, USA). All other lipid chemicals such as MGs, diacylglycerol (DGs), triacylglycerols (TGs), FAs and glycerol were of guaranteed reagent grade or higher. These compounds were dissolved in dimethyl sulfoxide (DMSO) and stored at  $-20^\circ\text{C}$ . All food materials were purchased from a local market. Wheat flour was obtained from Nisshin Flour Milling Inc. (Tokyo, Japan).

### Extraction and Purification of Wheat Flour

Wheat flour (1,029 g) was extracted with hexane (10 L), and this extract was purified as shown in Fig. 3. Each fraction was examined for TRPV1 activity by using TRPV1-expressing HEK293 cells. The fraction positive for TRPV1 activity was further purified. Briefly, the hexane extract from wheat flour (7,900 mg) was partitioned with hexane/methanol (MeOH)/ $\text{H}_2\text{O}$  (200/97/3, by vol.). The MeOH layer (3,278 mg) that activated TRPV1 was chromatographed on silica gel (36 mm  $\times$  90 mm) with a stepwise elution of hexane/ethyl acetate (EtOAc) and MeOH. The fraction eluted with EtOAc (Fr. 4, 205 mg) was rechromatographed on silica gel (15 mm  $\times$  120 mm) with hexane/EtOAc (1/1), and Fr. 4–2 (127.6 mg) was obtained as the active fraction. Fr. 4-2 was further purified by solid-phase extraction (MEGA BE-C18, 1 g, 6 mL, BOND ELUT) with MeOH as an eluent, and Fr. 4-2-M (63.2 mg) was obtained as a single spot by thin-layer chromatography (TLC) along with the development of sulfuric acid.

### Identification and Quantification of Monoacylglycerols in Wheat Flour

$^1\text{H-NMR}$  spectra (TMS as the internal standard) were recorded on a JEOL  $\alpha$ -400 instrument (Tokyo, Japan) at 399.65 MHz. The  $^1\text{H-NMR}$  spectra of Fr. 4-2-M ( $\text{CDCl}_3$ ) were  $\delta$  5.35 (2.9H, m),  $\delta$  4.21 (1.0H, dd,  $J = 4.6, 11.2$  Hz, H-1a),  $\delta$  4.15 (1.0H, dd,  $J = 6.0, 11.6$  Hz, H-1b),  $\delta$  3.93 (0.83H, quint,  $J = 5.0$  Hz, H-2),  $\delta$  3.83 (0.19H, d,  $J = 4.8$ ),  $\delta$  3.70 (1.0H, dd,  $J = 4.0, 11.2$  Hz, H-3a),  $\delta$  3.60 (1.0H, dd,  $J = 6.0, 11.2$  Hz, H-3b),  $\delta$  2.77 (2.3H, t,

$J = 6.0$  Hz),  $\delta$  2.35 (3.1H, t,  $J = 7.6$  Hz),  $\delta$  2.05 (3.6H, m),  $\delta$  1.63 (2.4H, m),  $\delta$  1.29 (18.8H, m),  $\delta$  0.89 (3.2H, m).

Quantitative and qualitative analyses of lipids were carried out using TLC with flame ionization detection (TLC-FID) on Iatroskan MK-5 (Mitsubishi Kagaku Iatron Inc., Tokyo, Japan). The analysis conditions were as follows: flow rate of hydrogen, 160 mL/min; flow rate of air, 2.0 L/min; scanning speed, 30 s/scan. The purified sample of wheat flour (Fr. 4-2-M) spotted on the rod-silica gel treated with 3% borate and a 2-stage development system was used to separate the compound classes. The first stage was developed with chloroform, and the second separation comprised the development in chloroform/MeOH/25% ammonia water (700/4/1, by vol.). The total crude MG content in wheat flour was determined with the calibration curve for 1-oleoylglycerol [1-MG (18:1)] as the standard. The samples spotted with the TLC rods were developed twice with hexane/diethyl ether/acetic acid (5/5/0.1, by vol.).

In order to analyze the acyl components in MGs, gas chromatography/mass spectrometry (GC/MS) was performed with HP 6890 Series (Hewlett Packard, CA, USA). WCOT fused silica CP-Sil 88 column (0.25 mm  $\times$  50 m; Varian, Inc., Palo Alto, CA, USA) was used with helium at a flow rate of 1 mL/min for the separation of the sample. The injector temperature was set at 260 °C. The column oven temperature was changed from 160 to 240 °C (3 °C/min). FAs methyl esters from Fr. 4-2-M were obtained by reaction with 0.5 N NaOH/MeOH and 14% BF<sub>3</sub>/MeOH. The GC/MS spectrum of Fr. 4-2-M showed five peaks at 7.37 min (hexadecanoic acid methyl ester; concordance rate, 97%), 9.71 min (octadecanoic acid methyl ester, 97%), 10.47 min (9Z-octadecenoic acid methyl ester, 99%), 11.66 min (9Z, 12Z-octadecadienoic acid methyl ester, 99%), and 13.13 min (9Z, 12Z, 15Z-octadecatrienoic acid methyl ester, 95%).

Direct determination of the MG structure with liquid chromatography/mass spectrometry (LC/MS) was performed using a NANOSPACE 51-1 HPLC system (Shiseido, Tokyo, Japan) connected to an LCQ MS (Thermo Fisher Sci., Waltham, MA, USA). Unison UK-C18 150  $\times$  2 mm (3  $\mu$ m) column (Imtakt, Kyoto, Japan) with a flow rate of 0.2 mL/min was used for the separation of the sample. The linear gradient was used as follows: first condition, acetic acid (0.1%)/acetonitrile (30/70, by vol.); from 0 to 10 min, 1/99 (by vol.); then held up to 20 min. The MS condition used was as follows: ionization, APCI; ion polarity, positive; vaporizer temperature, 250 °C; sheath gas flow rate, 80 arb; aux gas flow rate, 0 arb; discharge current, 5 mA; capillary temperature, 200 °C; and capillary voltage, 10 V. Standard MGs were measured using the selected ion monitoring mode. 1-MGs (16:0 and 18:0) were detected as  $[M + H]^+ - H_2O$ , while others were

detected as  $[M + H]^+$ . The retention times of standard lipids [1-MGs having palmitic (1-MG16:0), stearic (1-MG18:0), oleic (1-MG18:1), linoleic (1-MG18:2), and  $\alpha$ -linolenic acids (1-MG18:3)] were detected at 11.48, 14.92, 12.08, 9.85, and 8.28 min, respectively.

## Animals

Male 6-week-old Sprague-Dawley rats and male 5-week-old C57BL/6 Cr mice (Japan SLC, Shizuoka, Japan) were housed at least for 1 week under conditions of controlled temperature (23  $\pm$  1 °C), humidity (55  $\pm$  5%), and lighting (light on, 7:00–19:00 hours). Food and water were available ad libitum. Animal experiment procedures conformed to the Guidelines for the Care and Use of Laboratory Animals of the University of Shizuoka.

Rats were handled for 1 week to get them habituated to humans for the behavior experiment. On the day of the behavior experiment, the rats were placed individually in transparent cages (21 cm  $\times$  31 cm  $\times$  13 cm) and maintained for at least 10 min in order to stabilize their behavior.

## Measurement of Intracellular Calcium Concentration in TRPV1-Expressing HEK293 Cells and DRG Cells of Mice

HEK293 cells that stably expressed rat-TRPV1 (named as HEK293VR11 cells [21]) were generated according to the methods reported by Caterina et al. with minor modifications [1]. The HEK293VR11 cells were maintained in Dulbecco's modified Eagle's medium containing 10% fetal bovine serum, 100 units/mL of penicillin, 100  $\mu$ g/mL of streptomycin, and 250 ng/mL of amphotericin B at 37 °C under 5% CO<sub>2</sub>/air. The cells were sub-cultured every week, and the highest passage number used was 35. We confirmed that HEK293VR11 cells up to passage 35 showed almost equal responses to CAP.

Measurement of the intracellular calcium concentration ( $[Ca^{2+}]_i$ ) of HEK293VR11 cells was performed using a previously reported method [21]. Briefly, the HEK293VR11 cells were loaded with cytoplasmic calcium indicator fura-2 AM (5  $\mu$ M) or fluo-4 AM (2.5  $\mu$ M) in a loading buffer (5.37 mM KCl, 0.441 mM KH<sub>2</sub>PO<sub>4</sub>, 137 mM NaCl, 0.336 mM Na<sub>2</sub>HPO<sub>4</sub>·7H<sub>2</sub>O, 5.56 mM glucose, 20 mM HEPES, 1 mM CaCl<sub>2</sub>, and 0.1% bovine serum albumin at pH 7.4) at 37 °C for 30 min. The time-dependent changes in fluorescence (fura-2: excitation wavelength of 340 and 380 nm and emission wavelength of 500 nm; fluo-4: excitation wavelength of 485 nm and emission wavelength of 540 nm) were recorded using a CAF-110 fluorospectrophotometer (Jasco, Tokyo, Japan) and analyzed using PowerLab (AD Instruments, NSW,

Australia). The test compounds and extracted fractions of foods were dissolved in DMSO and applied at 0.1 or 0.3% concentration to the cells. In some experiments, CPZ (100  $\mu\text{M}$ , dissolved in DMSO) was added at least 1 min prior to the addition of the test compound. Each data value was expressed as a percent response to 10  $\mu\text{M}$  CAP in each experiment. Curve fitting and parameter estimation were carried out using Prism 4 software (GraphPad Software, San Diego, CA, USA).

Dorsal root ganglia from all spinal levels of male C57BL/6 mice (5–6 weeks old) were rapidly dissected and dissociated by incubation for 20 min in a solution of culture medium [Earl's balanced salt solution with 10% fetal bovine serum, 100 units/mL of penicillin, 100  $\mu\text{g}/\text{mL}$  of streptomycin, 250 ng/mL of amphotericin B, 2 mM L-alanyl-L-glutamine, and 1 $\times$  MEM vitamin solution (Sigma)] containing 1.25 mg/mL collagenase P (Roche, Basel, Swiss). Cells were gently triturated using fire-polished Pasteur pipettes and centrifugated in culture medium to separate cells from debris. Cells were resuspended and plated onto coverslips coated with poly-L-lysine. Cells were cultured in medium with 50 ng/mL nerve growth factor (Sigma). Calcium imaging experiments were performed 18–36 h after plating using fluorescence microscopy. DRG neurons were loaded with fluo-4 AM (5  $\mu\text{M}$ ) for 30 min at 37  $^{\circ}\text{C}$ .

#### Hind Paw Irritancy Test

Pain behaviors such as licking or biting produced by the local injection of chemicals into the hind paw have been used as a model of chemogenic nociception in rats [22, 23]. Experimental methods were similar to those reported previously [5]. Briefly, 15  $\mu\text{L}$  of the test reagent solution (0.5 or 50 mM) in saline containing 5% DMSO and 10% Tween 80 was subcutaneously injected into the hind paw by using a 27-G needle on a 1-mL syringe. The total time spent on licking and biting in the injected paw was measured for 3 min after the injection. In some experiments, CPZ (10 mM) was coadministered with the test solution. Only 1 hind paw was examined per test. The other hind paw was examined at least 24 h after the first experiment.

#### Eye-Wiping Test

The eye-wiping test [24] was used for evaluating the pungency of compounds. Experimental methods were the same as those reported previously [5]. Briefly, using a micropipette, 15  $\mu\text{L}$  of the test solution (0.5 or 5 mM) in saline containing 5% DMSO and 10% Tween 80 was instilled into an eye of the animal. The tip of the micropipette was cut at approximately 10 mm from the top to increase the size of the instillation drop. The number of

wiping movements per minute after the administration was counted. Only 1 eye was examined per test. The other eye was examined at least 24 h after the first experiment.

#### Statistical Analysis

All data were indicated as mean  $\pm$  SEM. These statistical analyses were carried out by using the Prism 4 software. In the aversive behavior tests, the treatment effects were analyzed by one-way ANOVA (nonparametric), and the differences between the mean values were evaluated by using Tukey's multiple comparison test. In other tests, the differences between the compounds and vehicle treatments on different days were evaluated by using the unpaired *t*-test. Similarly, the differences between CPZ treatment and non-treatment on different days were also evaluated by using the unpaired *t*-test. Differences with  $P < 0.05$  were considered to be significant.

## Results

### 1-Monoacylglycerols in Wheat Flour Activate TRPV1

A total of 19 types of food extracts (onion, Chinese chive, garlic, welsh onions (white and green types), shallot, Japanese pepper, myoga (*Zingiber mioga*), perilla, peach, American cherry, Konbu (*Laminaria japonica*), cucumber, tomato, bitter melon, egg plant, apple, kiwi fruit, and wheat flour) were examined for TRPV1 activation by calcium imaging of TRPV1-expressing HEK293 cells. Of all extracts, we found that the hexane extract of wheat flour (300  $\mu\text{g}/\text{mL}$ ) increased the intracellular calcium concentration ( $[\text{Ca}^{2+}]_i$ ) in TRPV1-expressing HEK293 cells, and this activity was half the maximum response to 10  $\mu\text{M}$  CAP (Fig. 2a, e). On the other hand, this extract induced only a small response in native HEK293 cells (Fig. 2b, e). Accordingly, this extract certainly contained specific TRPV1-activating compounds. TRPV1 activation in sensory neurons induces pain or pungent sensation. However, unlike red pepper, wheat flour is not pungent. Therefore, wheat flour may contain a weak-pungent or a non-pungent TRPV1 agonist.

Wheat flour extract was purified by silica gel and octadecyl silica (ODS) column chromatography (Fig. 3). Purified fraction (Fr.) 4-2-M (5  $\mu\text{g}/\text{mL}$ ) increased the  $[\text{Ca}^{2+}]_i$  in the TRPV1-expressing HEK293 cells but not in the native HEK293 cells (Fig. 2c–e). Furthermore, the preadministration of 100  $\mu\text{M}$  CPZ, a TRPV1-specific antagonist, completely inhibited the response in the TRPV1-expressing HEK293 cells to Fr. 4-2-M (15  $\mu\text{g}/\text{mL}$ ) (non-treatment,  $333.4 \pm 26.2$  nM ( $n = 3$ ); CPZ treatment,  $2.50 \pm 0.379$  nM ( $n = 3$ ), values are  $\Delta[\text{Ca}^{2+}]_i$ ). These

**Fig. 2** Transient receptor potential vanilloid subtype 1 is activated by wheat flour extract. Time course of fluorescence changes by fluo-4 AM in TRPV1-expressing HEK293 cells (**a, c**) and parent HEK293 cells (**b, d**) are shown. Triton X-100 (0.1%) was added to obtain maximum fluorescence. (**e**) Calcium responses of the parent (wild-type, open bar) and TRPV1-expressing HEK293 cells (TRPV1, hatched bar) by capsaicin (CAP) and wheat flour extract. These values are mean  $\pm$  SEM ( $n = 3$ ). *Asterisk* indicates a significant difference between each cell type ( $P < 0.01$ )

results clearly show that the purified fraction has a specific TRPV1 activity.

A part of the  $^1\text{H-NMR}$  spectrum of Fr. 4-2-M was fitted with a glycerol portion of 1-palmitoylglycerol:  $\delta$  4.21 (1.0H, dd,  $J = 4.6, 11.2$  Hz, H-1a),  $\delta$  4.15 (1.0H, dd,  $J = 6.0, 11.6$  Hz, H-1b),  $\delta$  3.93 (0.83H, quint,  $J = 5.0$  Hz, H-2),  $\delta$  3.70 (1.0H, dd,  $J = 4.0, 11.2$  Hz, H-3a),  $\delta$  3.60 (1.0H, dd,  $J = 6.0, 11.2$  Hz, H-3b). According to this, Fr. 4-2-M was estimated to be a 1-MG analogue.

In agreement with this speculation, 1-MG peak ( $R_f = 0.586$ ) was mainly detected in the TLC with FID analysis of Fr. 4-2-M (Fig. 4a). A small peak of  $R_f$  0.480 was consistent with the 2-oleoylglycerol [2-MG (18:1)] standard (Fig. 4a). TLC/FID analysis showed that Fr. 4-2-M was composed of mainly 1-MG and small part of 2-MG, but the exact ratio of MGs could not be got because the sensitivity of FTD differed significantly depending on the degree of unsaturation for acyl moiety in MGs.

**Fig. 3** Purification of TRPV1-activating compounds in wheat flour EtOAc, ethyl acetate; MeOH, methanol; ODS, octadecyl silica

The chemical structure of the acyl portion of 1-MG in Fr. 4-2-M could not be identified from the  $^1\text{H-NMR}$  spectra. Therefore, the FA was analyzed by GC/MS after the  $\text{BF}_3/\text{MeOH}$  methanolysis of Fr. 4-2-M to identify the acyl portion of 1-MG. The GC/MS analysis revealed palmitic (16:0), stearic (18:0), oleic (18:1), linoleic, (18:2) and  $\alpha$ -linolenic acids (18:3) as the constituted FAs of 1-MG.

The chemical structures of 1-MGs in Fr. 4-2-M were directly analyzed by LC/MS. 1-MGs of 16:0, 18:0, 18:1, 18:2, and 18:3 FAs were detected in Fr. 4-2-M, and the weight ratios of these 1-MGs were calculated to be 31.2, 0.302, 55.7, 12.5, and 0.302%, respectively (Fig. 4b).

The TRPV1 activities of the five types of 1-MGs were measured using standards in 100  $\mu\text{M}$  concentration. 1-MGs (18:1, 18:2, and 18:3) increased the  $[\text{Ca}^{2+}]_i$  in the TRPV1-expressing HEK293 cells; however, 1-MGs of 16:0 and 18:0 did not (Fig. 5a). These responses were inhibited by 100  $\mu\text{M}$  CPZ (Fig. 5a) and were not observed in the parent HEK293 cells [414  $\pm$  29.3, 411  $\pm$  35.8, 433  $\pm$  35.1 nM for HEK293VR11 cells (100  $\mu\text{M}$ ,  $n = 3$ ), 44.7  $\pm$  8.31, 45.9  $\pm$  7.40, 44.3  $\pm$  9.83 nM for HEK29 cells (100  $\mu\text{M}$ ,  $n = 3$ ), respectively]. Values are  $\Delta[\text{Ca}^{2+}]_i$ , showing a TRPV1-specific action of 1-MGs of 18:1, 18:2, and 18:3. The dose–response curves for TRPV1 activation by 1-MGs containing oleic, linoleic, and  $\alpha$ -linolenic acids were comparable, and their potency ( $\text{EC}_{50}$ ) was 50 to 100 times higher than that of CAP, and their efficacy (% activity in response to 10  $\mu\text{M}$  CAP) was approximately 50% (Fig. 5b;

Table 1). Moreover, the dose–response curve of Fr. 4-2-M [total content of TRPV1-activating MGs (18:1, 18:2, and 18:3) was 68.5% by LC/MS] was roughly consistent with that of 1-MGs of 18:1, 18:1, and 18:3 (Fig. 5c). Consequently, it was concluded that 1-MGs of 18:1, 18:2, and 18:3 were the TRPV1-activating compounds in wheat flour.

The total crude MG content in wheat flour was 197  $\mu\text{g/g}$  by quantitative TLC/FID analysis.

#### Other Foods Containing TRPV1-Activating MGs

Active compounds in wheat flour were identified to be 1-MGs containing oleic, linoleic, and  $\alpha$ -linolenic acids. The hexane extracts of onion (*Allium cepa*) (onion powder; GABAN, Tokyo, Japan) and myoga (*Z. mioga*) also activated TRPV1 in the above described screening. The main active compounds in onion extract were also 1-MGs of 18:1, 18:2, and 18:3 FAs. Myoga extract contained the same 1-MGs (18:2 and 18:3) and additional 2-MGs of 18:2 and 18:3 FAs. The contents of these MGs were as small as the level of wheat flour.

#### TRPV1 Activity of Other Lipid Compounds

Transient receptor potential vanilloid subtype 1 was activated by 1-MGs binding oleic, linoleic, and  $\alpha$ -linolenic acids but not 1-MGs binding stearic and palmitic acids

**Fig. 4** Chromatograms of TLC/FID (a) and LC/MS (b) analysis of purified flour extract (Fr. 4-2-M)

(Fig. 5a). This result suggested that acyl moiety of MG is very important for TRPV1 activity. To decide important acyl moiety of MG, we examined TRPV1 activities for 1-MGs having FAs of varied length. In saturated FAs, 1-MGs (8:0, 10:0, and 12:0) increased  $[Ca^{2+}]_i$  of HEK293VR11 cells. However, by increasing carbon chain length of acyl moiety the effect was reduced (Fig. 6a). Although 1-MG of C18 saturated FA [1-MG(18:0)] could not act on HEK293VR11 cells, 1-MGs of C18 unsaturated

FA [1-MG(18:1, 18:1*trans*, 18:2, 18:3 and 20:4)] increased  $[Ca^{2+}]_i$  of HEK293VR11 cells (Fig. 6a). Moreover, 2-MG of C18:1, C18:2 and C20:4 increased  $[Ca^{2+}]_i$  of HEK293VR11 cells (Fig. 6a). These responses of 1-MGs and 2-MGs on HEK293VR11 cells were inhibited by CPZ, suggesting that these 1-MGs and 2-MG specifically acted on TRPV1 (Fig. 6b). All TRPV1-activated MGs except 1-MG(8:0) had the equivalent TRPV1 potencies ( $EC_{50}$ ) and efficacies (maximum response) respectively (Table 1).

**Fig. 5** Transient receptor potential vanilloid subtype 1 (TRPV1) activities by monoacylglycerols (MGs) as measured by intracellular  $\text{Ca}^{2+}$  concentration in TRPV1-expressing HEK293 cells. **a** White bars indicate TRPV1 activities by 100  $\mu\text{M}$  MGs having 16:0, 18:0, 18:1, 18:2, and 18:3 fatty acids, respectively. Checked bars indicate TRPV1 activities by these MGs after pretreatment with 100  $\mu\text{M}$  capsaizepine

(CPZ). These values are mean  $\pm$  SEM ( $n = 3$ ). Asterisk indicates a significant difference between each cell type ( $P < 0.01$ ). **b, c** Dose-response curves of capsaicin (CAP, closed circle), 1-MGs of 18:1, 18:2, and 18:3 (open circle, open triangle, and open inverted triangle, respectively), and Fr. 4-2-M of wheat flour extract (filled square). These values are mean  $\pm$  SEM ( $n = 3$ –10)

These potency values were 20 to 150 times higher than that of CAP, and these efficacies were half to that of CAP. The potency of 1-MG(8:0) was only large in comparison with MGs, and its  $\text{EC}_{50}$  was 195.9  $\mu\text{M}$  (Table 1). These results suggest that middle-chain and long-chain unsaturated acyl moiety of MGs are very important structure for activating TRPV1.

There are other glycerol-based compounds than MGs, i.e., 1,2-DGs, 1,3-DGs, and TGs. Therefore, we investigated whether or not 1,2-DGs, 1,3-DGs, and TGs binding long acyl chain could activate TRPV1. No responses were

induced by the DGs and TGs used [1,2-DG(16:0); 100  $\mu\text{M}$ , others; 100  $\mu\text{M}$ , Fig. 6a]. Moreover, some FAs (FA, 300  $\mu\text{M}$ ) and glycerol (300  $\mu\text{M}$ ) increased little or no  $[\text{Ca}^{2+}]_i$  of HEK293VR11 cells (Fig. 6c). These results were consistent with previous reports [25, 26].

Anandamide (AEA) and oleoylethanolamide (OEA) were identified as endovanilloids (Fig. 1) [25, 27]. Structure of 1-MGs is similar to that of AEA and OEA. Moreover, It was reported that 2-arachidonyl glycerol ether (2-AGE, noladin ether), which was known as endocannabinoid [28], increased  $[\text{Ca}^{2+}]_i$  of TRPV1-expressing

**Table 1** TRPV1 activation potencies of capsaicin, monoacylglycerols (MGs), anandamide (AEA), oleoylethanolamide (OEA), and 2-arachidonyl glycerol ether (2-AGE)

Compounds	$p\text{EC}_{50}$ ( $-\log \text{M}$ )	$\text{EC}_{50}$ ( $\mu\text{M}$ )	Maximum response (%)	Number of experiments
Capsaicin	$7.09 \pm 0.0310$	0.0819	$99.0 \pm 1.15$	4–10
1-MG(8:0)	$3.71 \pm 0.0710$	195.9	$54.6 \pm 2.84$	3–5
1-MG(10:0)	$4.90 \pm 0.0565$	12.6	$50.6 \pm 1.70$	3–10
1-MG(12:0)	$5.10 \pm 0.0639$	8.01	$44.9 \pm 1.59$	3–10
1-MG(18:1)	$5.32 \pm 0.0518$	4.78	$53.3 \pm 1.96$	3
1-MG(18:1 <i>trans</i> )	$5.41 \pm 0.140$	3.88	$46.8 \pm 3.40$	3–6
1-MG(18:2)	$5.21 \pm 0.0524$	6.19	$50.1 \pm 1.79$	3–5
1-MG(18:3)	$5.07 \pm 0.0380$	5.60	$50.3 \pm 1.41$	3–6
1-MG(20:4)	$5.81 \pm 0.0895$	1.55	$58.6 \pm 2.67$	3–4

2-MG(18:2)	$5.48 \pm 0.0496$	3.34	$59.0 \pm 19.4$	3
2-MG(20:4)	$5.60 \pm 0.0869$	2.54	$59.8 \pm 2.64$	3–7
AEA	$5.69 \pm 0.0126$	2.02	$63.6 \pm 0.546$	3
OEA	$5.60 \pm 0.0554$	2.53	$60.9 \pm 2.42$	3
2-AGE	$5.71 \pm 0.0917$	1.97	$48.3 \pm 2.23$	3

Maximum responses were normalized to the 10  $\mu\text{M}$  CAP-induced response.  $p\text{EC}_{50}$  values and maximum responses are indicated as mean  $\pm$  SEM, and  $\text{EC}_{50}$  is expressed as the mean value

**Fig. 6** Transient receptor potential vanilloid subtype 1 (TRPV1) activities of lipid-related compounds as measured by intracellular  $\text{Ca}^{2+}$  concentration in TRPV1-expressing HEK293 cells. **a** Calcium responses by 1-monoacylglycerols (1-MGs), 2-MGs, diacylglycerols (DGs) and triacylglycerols (TGs). Concentrations of 1-MG(8:0) and 1,2-DG(16:0) were 1,000 and 10  $\mu\text{M}$ , respectively. Other's concentrations were 100  $\mu\text{M}$ . **b** Suppressive effect of capsazepine (CPZ, 100  $\mu\text{M}$ ) on the MGs-induced responses. CPZ was treated 1 min

before samples injection. **c** Calcium responses by fatty acids (FA) and glycerol (300  $\mu\text{M}$ ). **d** TRPV1 activities of 2-arachidonyl glycerol ether (2-AGE), anandamide (AEA), and oleoylethanolamide (OEA) (100  $\mu\text{M}$ ). White bars indicate calcium responses by sample only. Gray bars indicate calcium responses by CPZ treatment 1 min before sample addition. These values are mean  $\pm$  SEM (**a** and **b**:  $n = 3-13$ , **c**:  $n = 3-4$ , **d**:  $n = 3-7$ ). Asterisk indicates a significant difference between each groups with or without CPZ,  $P < 0.05$

HEK293 cells [29]. TRPV1 activities of effective MGs in this study were compared with those of AEA, OEA, and 2-AGE. These compounds increased  $[\text{Ca}^{2+}]_i$  in TRPV1-expressing HEK293 cells in concentration-dependent manner as shown in Table 1. These effects were TRPV1 specific because they were inhibited by CPZ (Fig. 6d). TRPV1 activities of AEA and OEA were in agreement with those of previous reports [29–31]. Additionally, TRPV1 activities of MGs were almost identical to those of AEA, OEA, and 2-AGE (Table 1).

#### Effect of 1-MG(18:1) to Mouse DRG Neurons

Transient receptor potential vanilloid subtype 1 is mainly expressed in sensory neuron of such as DRG and trigeminal nerve [1, 2]. We examined the effect of 1-MG (18:1) to endogenous TRPV1 expressed in mouse DRG neurons.  $[\text{Ca}^{2+}]_i$  of DRG neurons were increased by 100  $\mu\text{M}$

1-MG(18:1), and all these neurons were responded to 10  $\mu\text{M}$  CAP (67 cells, Fig. 7a). On the other hand, small number of neurons were activated by only 10  $\mu\text{M}$  CAP (10 cells, Fig. 7a). The percentage of MG positive neurons/CAP positive neurons was 87%. Moreover, all cells that were activated by 100  $\mu\text{M}$  1-MG (18:1) were significantly inhibited by 100  $\mu\text{M}$  CPZ ( $n = 10$ , Fig. 7b). These results suggested that 1-MG (18:1) also activates endogenous TRPV1 of mouse DRG.

#### Irritant Response after Subcutaneous Injection of Monoacylglycerols into Hind Paw

Activation of TRPV1 in the somatic sensory neurons carries pain signals to the brain. In fact, subcutaneous administration of CAP into mouse or rat hind paws induced licking and biting behaviors, which are the characteristic actions in response to a painful sensation [5, 22, 23, 32].

**Fig. 7** 1-MG (18:1) increases cytosolic  $\text{Ca}^{2+}$  concentration ( $[\text{Ca}^{2+}]_i$ ) in mouse sensory neurons. **a** Two types of representative charts are shown. One is both 100  $\mu\text{M}$  1-MG(18:1)- and 10  $\mu\text{M}$  CAP-positive neuron (unbroken line,  $n = 67$ ), the other is 10  $\mu\text{M}$  CAP-positive and

100  $\mu\text{M}$  1-MG(18:1)-negative neuron (broken line,  $n = 10$ ). **b** 1-MG (18:1)-induced increases in  $[\text{Ca}^{2+}]_i$  were inhibited by capsazepine (CPZ) in mouse DRG neurons ( $n = 10$ )

Thus, we investigated whether the subcutaneous injection of TRPV1-activating 1-MGs into rat hind paw induced an irritant behavior.

From the results obtained, the concentration of TRPV1-activating 1-MGs to produce TRPV1 activation was 100-fold the concentration of CAP; thus, 50 mM 1-MG solution was administered subcutaneously into the rat hind paw. First, we confirmed that vehicle injection elicited no licking and biting behaviors (Fig. 8a). 1-MGs of 18:1, 18:2, and 18:3 induced these behaviors to the same extent or even greater than that induced by 0.5 mM CAP (Fig. 8a). The coadministration of CPZ (10 mM) significantly diminished these irritant responses (Fig. 8b). These data indicated that 1-MGs (18:1, 18:2, and 18:3) activated TRPV1 *in vivo*. As predicted, 1-MG (18:0) and 1, 3-dilinoleoylglycerol (50 mM), which could not activate TRPV1, did not elicit aversive responses (Fig. 8a).

#### TRPV1-Activating MGs have no Pungency

As functional food compounds, pungency is an important factor. Many TRPV1 activators induce a pungent taste. On the other hand, capsiate (a red pepper compound), olvanil (CAP's synthetic analogue), and [10]-shogaol (a ginger compound) were identified to be less or non-pungent TRPV1 agonists [5, 32]. Therefore, we examined the pungencies of the TRPV1-activating MGs by a rat eye-wiping assay. This assay has often been used for evaluating the pungency of plant ingredients and chemical compounds [24]. The number of eye-wiping movements observed during 1 min after 0.5 mM CAP application was approximately 27 times/min (Fig. 8c). On the other hand, 1-MGs of 18:1, 18:2, and 18:3 did not induce eye-wiping movements as well as vehicle (Fig. 8c) although they activated TRPV1 *in vitro* and *in vivo* (Figs. 5, 8a, c). Thus, these MGs were thought to have no pungent taste.

#### Discussion

Since CAP induces energy expenditure enhancement and thermogenesis via the activation of TRPV1 [8], other TRPV1 activators in foods may play a role in energy expenditure. In this study, we searched for food ingredients activating TRPV1. We found that TRPV1 was activated by hexane extract of wheat flour which do not have pungency although most of foods contained TRPV1 activators have pungency such as hot pepper, ginger, and pepper. Active compounds in wheat flour were identified to be 1-MG having oleic, linoleic, and  $\alpha$ -linolenic acids. Lipid-related TRPV1 agonists reported thus far are 12-(*S*)-hydroperoxyeicosatetraenoic acid, AEA, OEA, and 2-AGE [26, 29]. Omega-3 polyunsaturated FAs activated TRPV1 only when TRPV1 sensitivity was high by phorbol 12, 13-dibutyrate (PDBu)-induced phosphorylation [33]. In the present study, we first report that 1-MG or 2-MG containing C18 and C20 unsaturated- or a C8–C12 FAs activated TRPV1, and excited sensory neurons expressing TRPV1. In addition, the TRPV1 activities of such MGs were almost identical to those of AEA, OEA, or 2-AGE (Table 1) [30, 31].

Transient receptor potential vanilloid subtype 1 potencies ( $\text{EC}_{50}$ ) for these MGs were near to those of [6]-gingerol (4.55  $\mu\text{M}$ ) or piperine (2.69  $\mu\text{M}$ ) that are the pungent compounds of ginger or pepper, respectively [5, 34] (Table 1). However, these efficacies (maximum response) for MGs were half for that of CAP (Table 1). On the other hand, TRPV1 activities of such MGs were almost the same levels as that of AEA or OEA, known as endovanilloid (Table 1). Movahed et al. examined TRPV1 activity of endogenous C18 *N*-acylethanolamines having stearic, oleic, linoleic, and  $\alpha$ -linolenic acids [31]. *N*-Acylethanolamine of saturated C18 (stearic acid) did not activate TRPV1, while other *N*-acylethanolamines binding unsaturated C18 FAs activated TRPV1 at the same  $\text{EC}_{50}$ s.

**Fig. 8** Aversive responses of rats induced by TRPV1-activating monoacylglycerols (MGs) after the subcutaneous hind paw injection or eye instillation. **(a)** The total time spent on licking and biting the injected hind paw was measured for 3 min after the injection of the vehicle, capsaicin (CAP, 0.5 mM), MGs (50 mM), and 1,3-dilinoleoylglycerol [1,3-DG (18:2), 50 mM]. **(b)** The total time spent on licking and biting was measured for 3 min after the injection of the

TRPV1-activating MGs (50 mM) with or without capsazepine (CPZ, 10 mM) administration. **(c)** The number of eye-wiping movements was counted for 1 min after the administration of vehicle, CAP (0.5 mM), or TRPV1-activating MGs (50 mM). The values are mean  $\pm$  SEM (a:  $n = 5$ , b:  $n = 4-6$ , c:  $n = 6-12$ ). Different letters indicate significant differences,  $P < 0.05$ . Asterisk indicates a significant difference between the groups with or without CPZ,  $P < 0.05$

These results are consistent with structure activity relationships for TRPV1 activity of MGs in this study. Moreover, we confirmed that TRPV1 was activated by both 1-MG(18:1) having oleic acid and 1-MG(18:1*trans*) having elaidic acid at the same potencies. Geometric configuration (*cis* or *trans*) of acyl moiety in 1-MG affects molecular size, and 1-MG(18:1*cis*) is smaller than 1-MG(18:1*trans*). This result suggested that important thing for TRPV1 activation might be not a molecular size but the existence of double bounds in acyl moiety of MG.

The potency of TRPV1 activation generally correlates with pungency. But some compounds having high lipophilicity, such as capsiate, olvanil and [10]-shogaol, are strong TRPV1 agonists with low or no pungency [5, 32]. The probable reason why capsiate, olvanil, and [10]-shogaol are not pungent is that these substances cannot reach the epithelium-covered TRPV1-expressing trigeminal nerve endings in the mouth or eye due to their high lipophilicity [5, 32]. The TRPV1-activating MGs may have a high lipophilicity because they are lipids with long-chain FAs. In fact, the lipophilicity of 1-MGs of 18:1, 18:2, and 18:3 was higher than that of CAP and roughly equal to that of olvanil, as revealed by ODS-TLC analysis performed with MeOH/water [ratio, 9/1; the  $R_f$  value: CAP, 0.73; olvanil, 0.36; 1-MG (18:1), 0.30; 1-MG (18:2), 0.38; and 1-MG (18:3), 0.43]. Therefore, these MGs are believed to have no pungency and activate TRPV1 via the same mechanism as capsiate, olvanil, and [10]-shogaol.

Capsiate is very low pungent CAP analogue isolated from non-pungent red pepper 'CH-19 Sweet' [35]. Capsiate activates TRPV1 with the same potency [32], and increases energy expenditure via TRPV1 activation as well as CAP [13, 36, 37]. For some people who dislike CAP, CAP is too pungent to intake for increasing energy expenditure. From this point of view, capsiate is very useful as it is very low pungent. MGs which activated TRPV1 also may be useful food ingredients to increase energy expenditure like capsiate.

These MGs are minor constituents in foods. In fact, the total crude MG content of wheat flour was 197  $\mu\text{g/g}$ . However, when vegetable oils are ingested, 2-MGs containing oleic or linoleic acids are produced by the lipase digestion of dietary TGs in the small intestine. TRPV1 is expressed at several locations such as myenteric ganglia and mucosa in the lower gastrointestinal tract, and its activation may be related to provide a sensory integration of chemical, physical, or inflammatory stimuli [38]. Therefore, TRPV1 activation by MGs might participate in the control of digestion or absorption of fat.

In the present study, we identified 1- or 2-MGs containing oleic, linoleic, or  $\alpha$ -linolenic acids as TRPV1 activators in wheat flower, onion, and myoga. MGs binding to not only C18 and C20 unsaturated FAs but also C8–C12 saturated FAs activated recombinant and endogenous TRPV1 in vitro. Moreover, 1-MGs of 18:1, 18:2, or 18:3 acted on the sensory neurons via TRPV1 in vivo. However,

the physiological function through the activation of TRPV1 is not clear now. Study on the effect of 1-MG intake for fat accumulation in rodents is now in progress.

**Abstract** In this work, we assessed the in-vitro effects of eicosapentaenoic acid (EPA; C20:5n-3) and docosahexaenoic acid (DHA; C22:6n-3) (final concentration, 15  $\mu$ M) on T cell blastogenesis, interleukin-2 and -4 (IL-2, IL-4) secretion, fatty acid composition and intracellular oxidative status in type I diabetic patients with or without complications. Con A stimulated lymphocyte proliferation, glucose uptake, intracellular reduced glutathione levels and catalase activity were lower in diabetics as compared to controls, regardless to the presence of complications. EPA and DHA diminished T-lymphocyte proliferation and IL-2 production but enhanced IL-4 secretion in both diabetic

and control groups. No changes in the levels of reduced glutathione and in the activities of catalase and SOD were observed in control T cells cultured in the presence of EPA and DHA. However, in diabetic patients, addition of n-3 PUFA to culture induced an increase in T cell levels of reduced glutathione and hydroperoxide, and in activities of catalase and SOD. Low levels of arachidonic acid (C20:4n-6) were found in plasma membrane phospholipids of lymphocytes from diabetic patients compared to controls. Incubation of lymphocytes with EPA and DHA was associated with an incorporation of these fatty acids in membrane phospholipids. In conclusion, the beneficial effects of n-3 PUFA on T cell functions in type I diabetes could be attributed to their suppressive action and modulation of cytokine secretion, and to the improvement of intracellular oxidative status.

GSH	Reduced glutathione
HDL-C	High density lipoprotein-cholesterol
IDDM	Insulin dependent diabetes mellitus
IL-2	Interleukin-2
IL-4	Interleukin-4
PBL	Peripheral blood lymphocytes
PUFA	Polyunsaturated fatty acids
PL	Phospholipids

ROS	Reactive oxygen species
SOD	Superoxide dismutase
TCR	T cell receptor
TG	Triglycerides

## Introduction

The pathogenesis of diabetes mellitus is multifactorial and hence, abnormalities in the immune system have been well established in type 1 and type 2 diabetic subjects [1–4]. A high susceptibility to infection has been described in diabetes mellitus patients, which may be caused by several defects of the immunological defense mechanism [2]. Impairment of polymorphonuclear leukocyte phagocytosis and reduction in granulocyte phagocytic capacity have been reported with increased plasma glucose concentration in diabetic patients [5]. The most dramatic defect that occurs in diabetes mellitus is related to abnormalities of T cell function. Abnormal lymphocyte subpopulations, decreased numbers and activity of T-cytotoxic cells, the presence of activated T cells, and increased number and activity of natural killer (NK) cells have been reported in diabetes [1, 6, 7].

Type 1 diabetes is an autoimmune disease resulting from the selective destruction of insulin-producing  $\beta$  cells by autoreactive T cells [1, 8]. An in-vivo activation of T cells in diabetes is typically reflected by increased serum levels of their products, namely interleukin-2 (IL-2) and the soluble interleukin-2 receptor (sIL-2R). In fact, the CD4+ T cells involved in the mechanisms underlying type 1 diabetes exhibit predominantly a Th1 phenotype, characterized by the secretion of high amounts of IL-2 and IFN- $\delta$  [9]. Conversely, CD4+ T cells of the Th2 subset may exhibit regulatory functions that control the development of type 1 diabetes [10, 11].

Paradoxically, a reduced in-vitro production of IL-2 upon mitogen stimulation is found in these patients, associated with an impaired proliferation response in mitogen-activated peripheral blood mononuclear cells [1, 12]. In fact, most of the studies have indicated that T cell growth is triggered exclusively by the production of IL-2 and the consequent expression of its surface receptor [13].

Moreover, the impaired immune function in diabetes could be partly associated with insulin deficiency [1], since insulin modulates cell growth and differentiation [14] and mitogen-activated lymphocyte proliferation [15]. In addition, insulin has an anti-inflammatory effect [16]. Glucose is essential for lymphocyte function, and diabetes causes marked changes in lymphocyte metabolism [4].

There is overwhelming evidence for the effects of n-3 polyunsaturated fatty acids (PUFA) on inflammatory

diseases, and they exert beneficial effects in various inflammatory disorders [17]. Dietary n-3 PUFA induce changes in membrane fatty acid composition specially alterations in lipid raft composition, membrane fluidity, receptor distribution; prostaglandin biosynthesis which may influence T cell mediated immune responses [18, 19]. Besides, PUFA have been shown to modulate lymphocyte proliferation, IL-2 production, IL-2 receptor (IL-2R) expression, antigen presentation and natural killer cell activity [19–22]. In addition, the effects of n-3 PUFAs especially EPA (eicosapentaenoic) and DHA (docosahexaenoic acid), on ex vivo lymphocyte functions as judged by mitogen stimulation, have been consistent in both human and animal studies showing suppressed responses [19–22].

Previous studies have demonstrated that n-3 PUFA decrease T cell proliferation [21, 23], cytokine secretion [23], intracellular enzyme activity [24] and gene transcription [25] and modulate antigen presentation through the HLA class I pathway [26]. Additionally, n-3 PUFA suppress T cell proliferative capacity attributed to a reduction in IL-2 production and/or function, and to enhancement of counter regulatory IL-4-driven Th2 cells [27]. Previous studies on the effects of n-3 PUFA on apoptosis in purified T cells indicated that dietary n-3 PUFA preferentially promote apoptosis in a T cell subset exhibiting a Th1 cytokine profile [28]. This exciting observation provides yet another unique mechanism by which n-3 PUFA exert a significant and selective effect on T cell proinflammatory function.

Other factors implicated in different forms of apoptosis are reactive oxygen species (ROS). Several studies have provided evidence for the involvement of ROS in apoptosis of T cell blasts [29]. Apoptosis in these cells is the consequence of changes in mitochondrial permeability and the subsequent release of ROS. Studies performed with primary T cells, however, indicate that the formation of intracellular ROS is necessary for T cell activation and IL-2 secretion but also regulates activation induced T cell apoptosis, therefore suggesting that intracellular ROS could play a role in peripheral T cell homeostasis [30].

The steady-state formation of ROS produced during cell metabolism is normally balanced by a similar rate of consumption by antioxidants. Under normal conditions, protective intracellular enzymes mainly catalase and superoxide dismutase, and cellular non-enzymatic antioxidants such as glutathione prevent ROS accumulation. Oxidative stress may result from imbalance in this pro-oxidant-antioxidant equilibrium. Oxidative stress was found to influence functional characteristics of T lymphocytes with critical implications on proximal and distal T cell receptor (TCR) signaling events [31].

T lymphocyte oxidative stress could originate from environmental free radicals or intracellular enzyme activity.

Diabetes mellitus is associated with increased oxidative stress. Increased production of reactive oxygen species as well as reduced antioxidant defense mechanisms have been suggested to play a role in type 1 diabetic patients [32]. Oxidative stress plays an important role in the etiology of diabetic complications such as atherosclerosis, a major cause of morbidity and mortality in these patients. The following mechanisms are thought to be involved in the increased oxidative stress in diabetes mellitus: hyperglycemia, oxygen free radical generation due to nonenzymatic protein glycosylation, autoxidation of glucose and glycation products, and changes in antioxidant defense systems [32–34].

Despite the various markers of oxidative stress in diabetes mellitus and its implications in the development of diabetes complications, it is not well known whether T lymphocytes affected by this oxidative stress had suppressive proliferative responses to n-3 PUFA supplementation in vitro. In addition, it is still unclear whether impaired lymphocyte proliferation responses occur in diabetic patients with or without complications, and whether EPA and DHA have modulatory effects on cell mediated immune responses in diabetes mellitus regardless to complications.

Therefore, the present study was undertaken to assess in-vitro effects of n-3 PUFA (EPA and DHA) on mitogen-stimulated proliferation, cytokine production, fatty acid composition and oxidant/antioxidant status of T lymphocytes in type 1 diabetic patients with or without complications.

## Materials and Methods

### Subjects

A total of 38 type I diabetic patients were recruited from the Department of Diabetics, University Hospital of Tlemcen (Algeria). Medical records were screened by specialist physicians. The diabetic type I patients were divided into two groups: group I consisted of type I diabetic patients without complications (20 patients); group II consisted of patients with complications. Complications in the diabetic patients included coronary artery disease in ten type I diabetics, diagnosed by clinical symptoms of angina pectoris, electrocardiogram examination or documented myocardial infarction and renal failure (RF) in eight patients, evaluated by significant renal impairment such as abnormal creatinine or macroalbuminuria. All diabetic patients received insulin. In addition, diabetic patients with RF were treated by angiotensin converting enzyme inhibitors. Diabetic patients with coronary artery disease were treated by calcium antagonists.

Twenty-six control subjects were selected. Controls and diabetic subjects were matched with respect to age and body mass index (BMI) as determined by the weight and height of patients. The characteristics of patients are given in Table 1. The study was approved by the ethical committee of the Tlemcen University Hospital and informed written consent was obtained from all the subjects.

### Blood Samples

Samples were collected at approximately the same time each day (between 7 and 8 o'clock in the morning) to

**Table 1** Characteristics of the study groups

	Controls	Type I diabetics	
		Without complications	With complications
Number	26	20	18
M/F ratio	15/11	11/9	10/8
Age (years)	28.50 ± 1.37	29.05 ± 1.82	30.50 ± 2.21
BMI (Kg/m <sup>2</sup> )	22.83 ± 2.42	21.86 ± 1.53	22.17 ± 2.31
Duration of disease (years)	–	5.00 ± 0.52	9.00 ± 1.44
Fasting glucose (mmol/l)	4.72 ± 0.45	8.87 ± 0.52*	12.24 ± 1.51*
Hb A1C (%)	4.50 ± 0.40	7.56 ± 0.81*	9.89 ± 0.50*
Total cholesterol (mmol/l)	5.63 ± 0.51	5.53 ± 0.53	5.87 ± 0.81
Triglycerides (mmol/l)	1.50 ± 0.42	1.65 ± 0.61	2.59 ± 0.23*
HDL-C (mmol/l)	1.82 ± 0.20	1.64 ± 0.43	1.00 ± 0.20*

Values are means ± SD. The significance of the differences between two groups was determined by Student's *t* test. \**P* < 0.05, diabetic subjects versus controls

*BM* body mass index, *HDL-C* high density lipoprotein-cholesterol

minimize diurnal variations, and before morning insulin injection or any drugs used for diabetic patients. Fasting venous blood samples were collected in two heparinized tubes from each patient. From the first blood sample, plasma was collected for analysis of glucose, glycosylated hemoglobin (Hb A1C) and lipids. The second blood sample was used for immediate lymphocyte isolation.

#### Laboratory Methods

##### *Plasma Determination*

Glycosylated hemoglobin levels (Hb A1C) were determined using a Stambio laboratory kit (P350-050, USA). Plasma glucose was determined by the glucose oxidase method using a glucose analyzer (Beckman Instruments, Fullerton, CA, USA). Plasma triglyceride, total cholesterol and HDL-cholesterol contents were determined by using enzymatic methods, according to the instructions furnished with the kit (Boehringer, Mannheim, Germany).

##### *Lymphocyte Proliferation Assay*

Peripheral blood lymphocytes were isolated from heparinized venous blood using differential centrifugation (400g for 40 min) on a density gradient of Ficoll-Paque (pharmacia biotech, UK). The peripheral blood lymphocytes (PBL) at the interface of plasma and Ficoll-Paque were collected and washed twice with RPMI 1640 culture medium (Gibco, USA). After washing and counting, the cells were resuspended in a tissue culture medium at  $2 \times 10^6$  cells/ml. For proliferation assay,  $1.5 \times 10^5$  cells were cultured in triplicate in 200  $\mu$ l of medium RPMI 1640 containing 25 mM HEPES buffer supplemented with 10% heat-inactivated fetal calf serum, L-glutamine (2 mM), 2-mercaptoethanol ( $5 \times 10^{-5}$  M), penicillin (100 UI/ml) and streptomycin (100  $\mu$ g/ml) with or without concanavalin A (Sigma St Louis, MO) at a final concentration of 5  $\mu$ g/ml. This concentration of Con A was found optimal to activate T cells (results not shown). Cultures were performed in 96-well flat-bottomed microtiter plates (Nunc, Paris, France) and maintained at 37 °C in humidified 5% CO<sub>2</sub> atmosphere for 48 h. This culture time was optimal for cytokine secretion. To determine the effects of n-3 PUFA, lymphocytes were also incubated with EPA and DHA (Sigma St Louis, MO) as described by Purasiri et al. [35]. The fatty acids were initially dissolved in ethanol. The stock solution of EPA and DHA in ethanol was diluted in RPMI 1640 culture medium immediately before use (to minimize oxidation) and was added to the cultures at a final concentration of 15  $\mu$ M (final concentration of ethanol 0.1%). Control cells were mixed with equivalent amounts of ethanol to reach a final concentration of 0.1% ethanol. In

preliminary experiments, we have found that this fatty acid concentration (15  $\mu$ M) induced maximal inhibition of lymphocyte proliferation while cell viability was unaffected. After incubation, cells were harvested by washing with RPMI 1640 medium. Cell viability was controlled by trypan blue exclusion test. Proliferation was monitored by direct cell counts, and confirmed by [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide] (MTT; Sigma) assay as described by Mosmann [36].

##### *Interleukin-2 and -4 Quantification*

Aliquots of culture supernatants were used to quantitate IL-2 and IL-4 by using commercially available ELISA kits (R&D System, Oxford, UK), as per instructions furnished by the manufacturer. The results are expressed as pg/ml.

##### *Analysis of Lymphocyte Phospholipid Fatty Acids*

Lipids from T lymphocytes were extracted according to the method of Bligh and Dyer [37]. Phospholipids were separated on silica gel by thin layer chromatography. Fatty acid composition was analysed by gas-liquid chromatography as previously reported [34].

##### *Glucose Uptake by Lymphocytes*

After incubation period, the supernatant of the culture was collected and used for the measurement of glucose as described above. Glucose uptake by lymphocytes after *in vitro* incubation with Con A for 48 h was calculated by comparing the glucose concentration in the supernatant of cultured cells from controls or diabetics with that of glucose in the supernatant without lymphocytes.

##### *Lymphocyte Oxidant/Antioxidant Markers*

##### *GSH Measurement*

Glutathione (GSH) levels were measured using a Bioxytech GSH-400 kit (OXIS International, Inc., Portland, OR, USA). Briefly, cells were resuspended in 500  $\mu$ l of 5% (w/v) metaphosphoric acid and were homogenized. After centrifugation of the homogenate at 3,000g for 10 min, 100  $\mu$ l of the supernatant was transferred to 800  $\mu$ l of 200 mM potassium phosphate containing 0.2 mM diethylenetriamine pentacetic acid and 0.025% (w/v) lubrol. Then 50  $\mu$ l of 12 mM chromogenic reagent and 50  $\mu$ l of 30% NaOH were added, and the mixture was incubated at 25°C for 10 min in the dark. The absorbance at 400 nm was measured, and the GSH concentration was then determined with the GSH standard curve obtained at 400 nm.

### Determinations of Lymphocyte Antioxidant Enzyme Activities

After different incubations and cell collection, lymphocytes were washed once, resuspended in chilled 10 mM phosphate buffer (pH 7.0) containing 0.15 M NaCl, sonicated for 30 s and then centrifuged at 15,000g for 20 min. Aliquots of the supernatant fractions were used to determine the activities of catalase and the total activity of Super-oxide dismutase (Cu, Zn-SOD and Mn-SOD) according to established methods. Briefly, catalase (CAT, EC 1.11.1.6) activity was measured by spectrophotometric analysis of the rate of hydrogen peroxide decomposition at 240 nm [38]. Enzyme activity was expressed as U/mg of protein. The activity of the total SOD was measured by the NADPH oxidation procedure [39] and expressed as units of SOD per mg of protein. Protein content was determined using a Lowry protein kit.

### Determination of Lymphocyte Hydroperoxides

To determine markers of lipid peroxidation, hydroperoxides were measured, in sonicated lymphocyte supernatant, by the ferrous ion oxidation-xylene orange assay (Fox2) in conjunction with a specific ROOH reductant, triphenylphosphine (TPP), according to the method of Nourooz-Zadeh et al. [40]. This method is based on the principle of the rapid peroxide-mediated oxidation of Fe<sup>2+</sup> to Fe<sup>3+</sup> under acidic conditions. The latter, in the presence of xylene orange, forms a Fe<sup>3+</sup>-xylene orange complex which can be measured spectrophotometrically at 560 nm. Hydroperoxide content in the samples was determined as a function of the mean absorbance difference of samples with and without elimination of ROOH by TPP. Calibration was done with standard peroxides such as hydrogen peroxide.

### Statistical Analysis

Data are expressed as mean  $\pm$  SEM. Statistical analysis were carried out using STATISTICA (version 4.1, Statsoft, Paris, France). The significance of the differences between two groups was determined by Student's *t* test. Multiple comparisons were performed using ANOVA followed by the least significant difference (LSD) test.  $P < 0.05$  was considered to represent statistical significant differences.

## Results

### Hb A1C, Plasma Glucose, Cholesterol, Triglyceride and HDL-Cholesterol Levels

Significant differences were found between diabetic and control subjects for plasma glucose and HbA1C levels

which were high in all diabetic patients regardless to complications (Table 1). However, the highest values were apparent in type I diabetes mellitus associated to complications. HDL-cholesterol amounts were lower only in type I diabetes mellitus with complications compared to control and diabetic patients without complications. Plasma triglyceride (TG) levels were significantly increased in type I diabetic patients with complications as compared to these patients without complications and to controls.

### Effects of n-3 Fatty Acids on T cell Blastogenesis

Figure 1 shows that mitogen induced cell proliferation, as expressed by cell number, was significantly diminished in both type I diabetic patients with or without complications, as compared to controls. Con A, a T cell-specific mitogen, significantly stimulated lymphocyte proliferation in both diabetic and control subjects. Addition of insulin to culture medium potentiated Con A-stimulated T cell proliferation in all groups. Addition of EPA and DHA to the culture medium resulted in inhibition of Con A-stimulated lymphocyte proliferation, whether the cells were treated with insulin or not, in both diabetic and control groups (Fig. 2), as shown by the reduction in cell number. Inhibition of lymphocyte proliferation was more pronounced with EPA than DHA. Nonetheless, lymphocyte proliferation was always significantly diminished in diabetic patients, regardless of complications. However, the lowest values

**Fig. 1** Resting and mitogen-stimulated T cell proliferation in diabetic and control subjects.  $1.5 \times 10^5$  cells per well were incubated in 96 well microplates in the presence or absence of concanavalin A (Con A, 5  $\mu$ g/ml) and insulin (Ins, 5  $\mu$ g/ml). Cultures were performed in triplicate for 48 h. Proliferation was monitored by direct cell counts, and confirmed by MTT method. The values are mean  $\pm$  SEM of triplicate assays of subjects composed of following numbers: controls, 26; type I diabetics without complications, 20; type I diabetics with complications, 18. The significance of the differences between two groups was determined by Student's *t* test. Multiple comparisons were performed using ANOVA followed by the least significant difference (LSD) test. The values in diabetic subjects are significantly different ( $*P < 0.05$ ;  $**P < 0.01$ ) as compared to respective control subjects in each incubation. *a*, *b*, *c*, *d* denote significant differences between different incubations within a group ( $P < 0.05$ )

**Fig. 2** Effects of EPA and DHA on mitogen-stimulated T cell proliferation in diabetic and control subjects.  $1.5 \times 10^5$  cells per well were incubated in 96 well microplates in the presence or absence of the following agents: concanavalin A (Con A,  $5 \mu\text{g/ml}$ ), eicosapentaenoic acid (EPA,  $15 \mu\text{M}$ ), docosahexaenoic acid (DHA,  $15 \mu\text{M}$ ),

insulin (Ins,  $5 \mu\text{g/ml}$ ). The values are mean  $\pm$  SEM of triplicate assays. The values in diabetic subjects are significantly different ( $*P < 0.05$ ;  $**P < 0.01$ ) as compared to respective control subjects in each incubation. *a, b, c, d* denote significant differences between different incubations within a group ( $P < 0.05$ )

were observed in diabetic patients with complications. As far as insulin is concerned, its addition to the culture medium did not affect the suppressive effects of EPA and DHA, and the results showed similar patterns as to those obtained with Con A-activated lymphocytes in both control and diabetic subjects (Fig. 2).

#### Effects of n-3 Fatty Acids on Interleukin-2 and Interleukin-4 (IL-2 and IL-4) Production

IL-2 and IL-4 production was increased by Con A in both diabetic and control groups (Table 2). The data showed that T cells in control and diabetic patients stimulated with Con A for 48 h secreted significantly more IL-2 than IL-4. Because Th1 cells secrete high levels of IL-2, Con A appears to have generated a Th1-like phenotype. Insulin exerted no significant effect on IL-2 secretion induced by Con A. However, it induced a significant increase in IL-4 production by Con A stimulated lymphocytes in both diabetic and control groups.

The effects of EPA and DHA on IL-2 production are parallel to those seen on the proliferation responses. IL-2 levels showed a significant diminution following exposure to EPA and DHA. The addition of insulin in these culture mediums did not affect IL-2 production (data not shown). Production of IL-2 by lymphocytes from type I diabetic patients was significantly diminished compared to controls, the lowest values being in diabetics with complications. However, in the presence of insulin and the combination of the two fatty acids, DHA and EPA, IL-2 amounts secreted by Con A stimulated lymphocytes from diabetics were not significantly different from those of controls (Table 2).

Incubation of T lymphocytes with EPA or DHA was associated with significantly higher production of IL-4 in all groups. The greatest production was observed with the combined n-3 PUFA. Adding insulin to culture mediums containing either EPA or DHA did not affect IL-4 production (data not shown). However, addition of insulin to culture medium with the combined n-3 PUFA potentiated the effects of the combined EPA and DHA on Con A-stimulated T cell production of IL-4 in all groups (Table 2). On the other hand, in the presence of n-3 PUFA, IL-4 production by T cells was significantly increased in diabetic patients than in controls.

#### Fatty Acid Composition of Lymphocyte Phospholipids

The basal fatty acid composition of phospholipid of lymphocytes from diabetic patients was significantly different from that of controls (Table 3). In fact, type I diabetic patients showed a significant increase in the proportion of C18:2n-6 and a significant decrease in the proportion of C20:4n-6 in their lymphocyte phospholipids as compared to controls, regardless to the presence of complications.

Lymphocytes stimulated with Con A showed a significant increase in the proportion of C18:1 and a decrease in the proportion of C18:0, C18:2n-6 and C20:4n-6 compared to basal fatty acid composition, in both diabetic and control groups. As expected, the proportion of DHA in phospholipids in lymphocytes incubated with DHA was significantly higher than in cells cultured without DHA. Similarly, the EPA content of phospholipids from lymphocytes incubated with EPA contained significant high proportion of EPA. The

Values are means ± SD. Total of  $1.5 \times 10^5$  cells per well (or  $10^6$  cells/ml) were incubated in 96 well microplates in the presence or absence of the following agents: concanavalin A (Con A, 5 µg/ml), eicosapentaenoic acid (EPA, 15 µM), docosahexaenoic acid (DHA, 15 µM), insulin (Ins, 5 µg/ml) in triplicate assays. Different letters (a, b, c, d, e, f, g) denote significant differences between different incubations within a group ( $P < 0.05$ ). Values with the same letter are not significantly different

\* Comparison between diabetic and control groups  $*P < 0.05$ ;  $**P < 0.01$

† Denote significant differences between uncomplicated and complicated diabetics  $P < 0.05$

concentration of C20:4n-6 (AA) was lower in phospholipids of lymphocytes following exposure to DHA and EPA. These modifications were observed in both control and diabetic groups, regardless to complications. However, lower incorporation of n-3 PUFA and lower loss of AA was observed on diabetic membranes than in controls. The addition of insulin in culture mediums did not affect membrane fatty acid composition (data not shown).

#### Glucose Uptake by Lymphocytes

Glucose uptake by T cells was measured after in vitro incubation for 48 h. As shown in Table 4, glucose uptake by resting lymphocytes from diabetic patients was significantly lower than that from control subjects, the lowest values being in diabetics with complications. The addition of Con A and insulin increased significantly glucose uptake, but the values remained still lower in diabetics than in controls.

Glucose uptake was not affected by the addition of EPA or DHA in the medium. Adding insulin to these mediums did not change glucose uptake in the presence of either EPA or DHA (data not shown). However, in the presence of insulin and the combined n-3 PUFA, glucose uptake by

lymphocytes from diabetics patients was not significantly different from that of control cells (Table 4).

#### Cellular GSH and Hydroperoxide Contents of Stimulated Lymphocytes

Analyses of glutathione levels in T lymphocytes from diabetic patients showed several significant differences from normal controls. First, as shown in Table 5, T lymphocytes from diabetic patients had significantly decreased reduced glutathione levels, the lowest values being in diabetics with complications. Second, in the presence of Con A, lymphocytes exhibited increased intracellular levels of reduced glutathione, and addition of insulin to culture medium potentiated Con A effects in all groups. Third, glutathione levels of control lymphocytes were not sensitive to n-3 PUFA adding in the medium. Adding insulin to these mediums did not change cellular GSH in the presence of either EPA or DHA (data not shown). However, EPA and DHA produced a significant increase in reduced glutathione levels in lymphocytes from diabetic patients, the highest values being in the presence of insulin and combined n-3 PUFA.

**Table 3** continued

	Controls	Type I diabetics	
		Uncomplicated	Complicated
22:6n-3			
Basal	2.47 ± 0.64 <sup>b</sup>	1.98 ± 0.77 <sup>b</sup>	1.77 ± 0.80 <sup>b</sup>
Con A	2.04 ± 0.71 <sup>b</sup>	1.89 ± 0.65 <sup>b</sup>	1.70 ± 0.53 <sup>b</sup>
DHA	5.86 ± 0.89 <sup>a</sup>	3.21 ± 0.38 <sup>*, a</sup>	3.09 ± 0.62 <sup>*, a</sup>
EPA	2.15 ± 0.52 <sup>b</sup>	1.73 ± 0.62 <sup>b</sup>	1.63 ± 0.48 <sup>b</sup>

Values are means ± SEM. Values are expressed as a percentage of total fatty acids. Total of  $1.5 \times 10^5$  cells per well (or  $10^6$  cells/ml) were incubated in 96 well microplates in the presence or absence of the following agents: concanavalin A (ConA, 5 µg/ml), eicosapentaenoic acid (EPA, 15 µM), docosahexaenoic acid (DHA, 15 µM), insulin (Ins, 5 µg/ml) in triplicate assays. Fatty acid composition was determined in resting lymphocytes before any addition (basal), after mitogen addition (Con A), and after n-3 PUFA addition (DHA or EPA). Comparison between diabetic and control groups \* $P < 0.05$

Different letters denote significant differences between different incubations within a group ( $P < 0.05$ ). Values with the same letter are not significantly different

Hydroperoxides, markers of lipid peroxidation, were significantly increased in T lymphocytes from diabetics compared to control values (Table 5). In the presence of Con A, hydroperoxide levels were higher than basal values and the addition of insulin did not affect these levels. Addition of EPA or/and DHA in the culture medium produced significant increases in hydroperoxide levels in all groups. Adding insulin to these mediums did not change hydroperoxide levels in the presence of either EPA or DHA (data not shown). However, in the presence of insulin and combined n-3 PUFA, no significant difference was noted between diabetic and control groups.

#### Lymphocyte Cellular Antioxidant Enzyme Activities

Resting lymphocyte catalase activity was significantly lower in the two groups of type I diabetes mellitus when compared with controls (Table 6). However, no significant difference in basal SOD activity was observed between type I diabetic groups and controls.

In the presence of Con A, catalase and SOD activities were enhanced in lymphocytes from diabetic and control subjects. This effect was amplified when insulin was added to culture medium. Catalase activity was reduced while SOD activity was enhanced in stimulated lymphocytes from diabetics compared to controls. The treatment with n-3 PUFA had no effect on catalase and SOD activities in all groups. Adding insulin to mediums did not change catalase and SOD activities in the presence of either EPA or DHA (data not shown).

**Table 4** Glucose uptake by lymphocytes from diabetic and control subjects

µg/48 h/10 <sup>5</sup> cells	Controls	Type I diabetics	
		Uncomplicated	Complicated
Basal	11.72 ± 3.76 <sup>a</sup>	4.85 ± 1.05*, <sup>a</sup>	3.67 ± 1.03*, <sup>a</sup>
