## Discussion

To gain further insight into the immunomodulatory effects of n-3 PUFA, the present study was conducted to examine in-vitro proliferation of T lymphocytes from diabetic

patients with or without complications and from healthy subjects, cultured with n-3 PUFA, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Behaviour of oxidative stress biomarkers in T lymphocytes was also analyzed. To our knowledge, this is the first study to

investigate the in vitro effects of n-3 PUFA (EPA, DHA) on T lymphocyte proliferation, cytokine production combined to lymphocyte antioxidant/oxidant status in diabetes regarding the influence of metabolic control. In the population studied, abnormalities in lipids (high TG, low HDL-C) were seen only in diabetic patients with complications. However, high fasting glucose and HbA1C levels were observed in all type I diabetics.

In this study, we determined cell proliferation by counting the number of viable cells and by the MTT method. Con A, a T cell specific mitogen, significantly stimulated lymphocyte proliferation in both diabetic and control subjects. T cells in control and diabetic patients stimulated with Con A for 48 h secreted significantly more IL-2 than IL-4. Because Th1 cells secrete high levels of IL-2, Con A appears to have generated a Th1-like phenotype.

We also observed that mitogen-activated lymphocyte proliferation was lower in diabetic patients than that in healthy subjects. Basal and Con A stimulated IL-4 production was not affected by diabetes.

However, IL-2 production was diminished in type I diabetic patients, the lowest values were seen in diabetic patients with complications. Other investigators have also reported that IDDM patients not only showed a depressed response of lymphocytes to T cell mitogen but also lower IL-2 production when compared with matched controls

[1, 5, 6, 9]. The explanation of decreased in vitro proliferative response may be that lymphocyte in diabetic patients are subjected to in-vivo activation of the immune system. In this case, their further in-vitro proliferation will be reduced compared to those from control subjects. It is well known that Con A acts, mainly, on resting (quiescent) T cells. In fact, several studies have reported a significant increase in the percent of in-vivo activated T-lymphocytes in diabetic patients [6, 7, 41], which play a role in the progression of chronic complications [1, 6–9]. Since impaired immune function in diabetes is partly associated with insulin deficiency and activated lymphocytes possess insulin receptors, we were tempted to investigate the effects of insulin on T cell activation. Hence, we have observed that insulin potentiated Con A-stimulated T cell proliferation, indicating that insulin deficiency in diabetes mellitus might be partly responsible for immunosuppression. In addition, insulin has no effect on IL-2 production while it increased IL-4 secretion by lymphocytes, due probably to its anti inflammatory effect [16]. Insulin effect on IL-4 secretion was more pronounced in diabetic patients. This observation is in accordance with previous publications reporting IL-4 secretion in response to insulin in individuals with type 1 diabetes [11] and increased mitogen induced secretion of IL-4 by insulin from PBMCs [42].

We further observed that *in vitro* EPA and DHA significantly reduced lymphocyte proliferation in both diabetic and control groups. The immuno-suppressive action was more pronounced with EPA. The suppressed T-lymphocyte proliferative response of EPA and DHA is supported with the observations of other investigators who have also reported that n-3 PUFA significantly diminished mitogen activated lymphocyte proliferation [19–23]. There are several possible mechanisms as to how n-3 PUFA may exert their inhibitory effects. Firstly, both EPA and DHA reduced IL-2 secretion by Con A-stimulated lymphocytes, suggesting that the suppressed lymphoproliferation is due in part to a reduction in IL-2 production [21, 22]. However, IL-4 production was enhanced by n-3 PUFA. These data are consistent with previous observations showing an increase in IL-4-dependent Th2 proliferation after n-3 PUFA feeding [28], and indicate that n-3 PUFA act differently on distinct T cell subsets. It has been shown that dietary n-3 PUFA shift the Th1/Th2 balance toward the Th2 pole by suppression of Th1 development rather than enhancement of Th2 development [43].

In the presence of combined n-3 PUFA and insulin, lymphocytes from diabetic patients secreted similar amounts of IL-2 but higher levels of IL-4 compared to that from controls, which probably reflected a regulatory effect of n-3 PUFA on Th cell phenotypes in diabetes, in favor of an anti-inflammatory phenotype.

Incubation of lymphocytes with fatty acids *in vitro* resulted in marked alterations in fatty acid composition [18, 19, 44]. Dietary DHA alter T cell plasma membrane microdomain lipid composition and influence the plasma membrane partitioning of signaling proteins that regulate T cell activation *in vivo* [45]. In our study, the addition of DHA or EPA to culture media was accompanied with a predominant composition of DHA or EPA in phospholipids of T cell membrane from control and diabetic patients. These effects appeared to result from alterations in lipid raft composition of T cells, as indicated by several previous investigations [18, 44, 45].

In our study, suppressed proliferation response may be also due to arachidonic acid (AA) substitution by EPA and DHA in lymphocyte membrane phospholipids as observed in our study. We should recall that turnover of membrane phospholipids is an early event in T cell activation which implies arachidonic acid liberation and its metabolism [44]. Similarly, low levels of this n-6 fatty acid, observed in diabetic subjects, may contribute to depressed T cell proliferation in type I diabetes, regardless to complications. Stimulation with Con A also brings about changes in lymphocyte fatty acid composition. Mitogenic activation of lymphocyte is associated with a decrease in the proportions of stearic, linoleic and arachidonic acids and an increase in the proportion of oleic acid, in accordance with other

studies [46]. It is interesting to note that lymphocytes from type I diabetic patients responded to EPA and DHA in a manner similar to those from healthy subjects despite the altered initial fatty acid composition.

Glucose is essential for lymphocyte function, and it is the main energy source for mature lymphocytes, especially at the stage of proliferation after *in vitro* stimulation with mitogens. Diabetes causes marked changes in lymphocyte metabolism [4]. We found that glucose uptake by T lymphocytes was significantly lower in diabetic than in control subjects, the lowest value being in diabetes with complications. In addition, insulin enhanced Con A stimulated glucose uptake by T cells from controls and diabetics. Lymphocyte proliferation in type I diabetes might be also due to the impairment of glucose uptake by lymphocytes. Indeed, EPA and DHA had no effect on *in vitro* glucose uptake by lymphocytes from both control and diabetic subjects. However, in the presence of combined n-3 PUFA and insulin, T cell glucose uptake in diabetic patients was not significantly different from that in controls.

Our results on oxidative stress biomarkers in T lymphocytes showed that these cells are submitted to an oxidative stress in type I diabetes. In fact, abnormalities in glutathione levels were observed in T lymphocytes from diabetic patients compared with cells from healthy controls, with significantly decreased intracellular levels of reduced glutathione (GSH), the lowest values being in diabetes with complications. We have previously reported that oxidative stress is induced by both the increases in free radicals and disturbance of the free radical scavenging system in type I diabetes mellitus [33, 34]. We also observed that Con A involved an increased glutathione level in T lymphocytes in both diabetic and control subjects, and insulin potentiated this effect. It has been demonstrated that enhancement of intracellular GSH concentration results in an increased lymphocyte response to mitogen stimulation [47].

Our findings indicated that catalase activity was reduced while SOD activity was normal in basal T lymphocytes from diabetics. Stimulation with Con A and insulin enhanced catalase and SOD activities in T cells from diabetic and control subjects. Thus, the increase in GSH levels and in catalase and SOD activities could be adaptative responses to oxidative stress following T cell receptor activation.

Hydroperoxides were measured as a marker of lipid peroxidation. We have previously assessed elevated levels of hydroperoxides in plasma from type 1 diabetic patients [34]. High hydroperoxide levels in our diabetic patients could result from their hyperglycemia. Lipid peroxidation is initiated when membrane PUFA interact with ROS which include hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>). Our results showed that basal T cell hydroperoxide levels were increased in diabetic

versus controls. Addition of Con A enhanced hydroperoxide levels following T cell activation in all groups.

As far as the effects of n-3 PUFA are concerned, we found that the hydroperoxide content was increased in T cells from control and diabetic patients. N-3 PUFA are highly susceptible to lipid peroxidation. No changes in the levels of GSH and in the activities of catalase and SOD were observed in control T cells cultured in the presence of EPA and DHA. However, in diabetic patients, addition of n-3 PUFA to culture induced an increase in T cell levels of GSH and hydroperoxide, and activities of catalase and SOD. These findings suggested a defect in the utilization of GSH or an upregulation of the enzymes responsible for GSH production and recuperation of extracellular GSH with a resultant increase in intracellular levels of GSH in diabetic lymphocytes exposed to n-3 PUFA. It was clear that the oxidant/antioxidant status of T lymphocyte from diabetic patients was more sensitive to the presence of n-3 PUFA than those from controls. Interestingly, we noted that in the presence of combined EPA and DHA and insulin, the oxidant/antioxidant status of T lymphocyte from diabetic patients became similar to that found in control subjects, with only minor perturbations in diabetes with complications. We suggested that the diabetic T cells, in the presence of n-3 PUFA, regulate their intracellular oxidative status; this could be considered as one mechanism that resulted in the benefits of n-3 PUFA.

In conclusion, the present study demonstrates that type I diabetes mellitus is associated to in vitro reduced T lymphocyte proliferation, IL-2 secretion and glucose uptake, altered fatty acid composition of T lymphocyte membrane phospholipids and oxidant/antioxidant status, regardless to the presence of complications. EPA and DHA possessed immunosuppressive properties and have similar effects on T cell functions of diabetic patients as in healthy subjects. EPA and DHA inhibit in vitro T cell proliferation, IL-2 secretion and enhance IL-4 production with a shift away from Th1 response to Th2 phenotype. Although EPA and/or DHA alone had no effects on behaviour of oxidative stress biomarkers, combined n-3 PUFA in the presence of insulin improved T cell intracellular oxidative status in type I diabetes mellitus. The beneficial effects of n-3 PUFA on T cell functions in type I diabetes could be attributed to their suppressive action and modulation of cytokine secretion, and to the improvement of intracellular antioxidant status.

**Abstract** To evaluate the anti-inflammatory effects of different dietary oils on ovalbumin-sensitized and -challenged mice. Experimental BALB/c mice were fed with different diets containing 5% corn oil [rich in linoleic acid, 18:2n-6 polyunsaturated fatty acids (PUFA), as a control diet], 5% perilla oil (rich in  $\alpha$ -linolenic acid, 18:3n-3 PUFA) or 5% compound oil containing 50% corn oil and 50% perilla oil, for 5 consecutive weeks. The leukocyte count, inflammatory mediators, and cytokine levels, including proinflammatory and Th1/Th2 cytokines in the bronchoalveolar lavage fluid (BALF) from the mice were determined. The results showed that 5% compound oil administration significantly ( $P < 0.05$ ) decreased eosinophilic infiltration. Dietary perilla oil could not significantly ( $P > 0.05$ ) decrease the eosinophil accumulation or the secretions of inflammatory mediators such as prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), histamine, nitric oxide and eotaxin. However, dietary perilla oil significantly ( $P < 0.05$ ) reduced proinflammatory cytokine (TNF- $\alpha$ , IL-1 $\beta$  and IL-6) and Th1 cytokine (IFN- $\gamma$  and IL-2) production. The production of Th2 cytokine IL-10, but not IL-4 and IL-5, was also significantly inhibited by perilla oil administration. The results suggest that dietary perilla oil might alleviate inflammation via decreasing the secretion of pro-inflammatory cytokines in BALF, but failed to regulate the

Th1/Th2 balance toward Th1 pole during the Th2-skewed allergic airway inflammation.

Ovalbumin-sensitized and -challenged mice

## Introduction

In the modern Western dietary pattern there is an increase in the consumption of total fat and n-6 polyunsaturated fatty acids (PUFAs), but a decrease in n-3 PUFAs and antioxidants. The changes in dietary lipid patterns are potent promoters of many chronic diseases [1]. Asthma, one of the chronic inflammatory airway disorders may be related to dietary lipids [2]. Reasonably, daily modification of the dietary lipid pattern may alleviate asthmatic damage.

Asthma is recognized as a T-helper type 2 (Th2)-skewed allergic disease [3]. Th2-type cells are important in humoral immunity and defense against extracellular pathogens [4] via eosinophilic infiltration, as well as IgE and IgG1 production in vivo [5]. Th2-type cytokines include interleukin (IL)-4, IL-5, IL-6, IL-9, IL-10, and IL-13. IL-4 and IL-13 are implicated in isotype switching of B-cells to produce IgE. IL-5 promotes the differentiation, recruitment, and survival of eosinophils [6]. In contrast to the Th2 cells, Th1 cells are characterized by the production of IL-2, interferon (IFN)- $\gamma$  and tumor necrosis factor (TNF)- $\alpha$ . Th1 cells promote cell-mediated immunity to destroy intracellular pathogens [4], inhibit eosinophilic infiltration, IgE and IgG1 production, and strengthen IgG2a production in vivo [5]. Th1-skewed immune responses are generally pro-inflammatory and may result in autoimmune

and chronic inflammatory diseases. However, Th2-skewed immune responses may cause asthma and allergy [7]. Whether it is possible to maintain the Th1/Th2 balance through dietary modification, especially the dietary lipid pattern, is an important issue in immunology.

Many animal experiments and clinical intervention studies indicate that long-chain n-3 polyunsaturated fatty acids (PUFAs) such as eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) from fish oil have anti-inflammation effects [8]. However, arachidonic acid (ARA, 20:4n-6), which is a component of phospholipids in the cell membrane, may produce ARA-derived eicosanoid inflammatory mediators, e.g. leukotriene (LT) B<sub>4</sub> and prostaglandin (PG) E<sub>2</sub> [9]. It has been found that EPA (n-3 PUFA) supplementation can replace ARA as an eicosanoid substrate to inhibit ARA metabolism and decrease inflammation status resulting from inflammatory eicosanoids [10].

In contrast to linoleic acid (18:2n-6), which is abundant in vegetable oils such as corn oil, and converted to ARA in animal cells [11],  $\alpha$ -linolenic acid (ALNA, 18:3n-3), which exists in green leafy vegetables, as well as some seed and vegetable oils such as flaxseed oil and perilla oil, is a possible precursor of EPA and DHA. However, ALNA use to replicate the effects of EPA or DHA is still not properly justified *in vivo*. Perilla oil is obtained from the seeds of *Perilla frutescens*, and exhibits high n-3 fatty acid ALNA bioavailability [12]. Perilla oil consists of about 50–60% ALNA in the form of triglycerides. ALNA has been recognized as an essential fatty acid in nutrition [13]. Increase uptakes of ALNA have similar effects as EPA and DHA on health and chronic disease control [14]. Weanling NIN wistar rats that consumed 10% perilla seed oil in their diet for 18 weeks suffered no toxicological effects [15]. Generally, perilla oil is valuable more for its medicinal benefit than its flavor, such as uses for chemopreventive effects on tumors [16] and plasma triacylglycerol level [17]. Recently, Kim and Choi [18] indicated that dietary perilla oil showed effects similar to that of fish oil on EPA and DHA accumulation in the hepatic membrane fraction of male Sprague Dawley rats. Perilla seeds are widely used to treat asthma in traditional Chinese medicine. However, the medicinal effects of dietary perilla oil administration on asthmatic airway inflammation have been scarcely discussed. As perilla oil is rich in ALNA, we hypothesized that it has physiological effects, especially in immunomodulation, like EPA and DHA. Thus, perilla oil was selected for study.

This study evaluated the anti-inflammatory and immuno-modulatory potential of perilla oil (rich in n-3 PUFA) using ovalbumin (OVA)-sensitized and -challenged allergic inflammatory murine models. The diet consisted of 5% corn oil (rich in linoleic acid, 18:2n-6) as the control diet. The immune responses in the bronchoalveolar lavage

fluid (BALF) from the experimental mice were determined to evaluate the effects of perilla oil administration on airway inflammation and allergic characteristics.

## Methods

### Materials, Experimental Animals and Feeds

The experimental feed was prepared according to the recommendation of the American Institute of Nutrition AIN-76 [19] and varied only in lipid composition. The basic composition of each feed, expressed in g/100 g, contained 40 g sucrose, 25 g corn starch, 20 g casein, 5 g fiber, 3.5 g mineral mixture, 1 g vitamin mixture, 0.3 g DL-methionine, 0.2 g choline bitartrate and 5 g lipid. The components of each feed were thoroughly mixed and stored at  $-20^{\circ}\text{C}$ . There were three kinds of lipid used in the experiment. Perilla oil (PER) rich in  $\alpha$ -linolenic acid (>60.5%) was purchased from MasterAsia Marketing Co. (Taipei, Taiwan, ROC) as the source of n-3 fatty acid. Corn oil (COR) rich in linoleic acid but poor in  $\alpha$ -linolenic acid (<2%) was purchased from Chang Chi Foodstuff Factory Co. (Taichung, Taiwan, ROC) as a control and the source of n-6 fatty acids. Compound oil (COR-PER) was a mixture containing 50% corn oil and 50% perilla oil.

Female BALB/c ByJNarl mice (6 weeks old) were obtained from the National Laboratory Animal Center, National Applied Research Laboratories, National Science Council in Taipei, ROC and maintained at the Department of Food Science and Biotechnology at National Chung Hsing University College of Agriculture and Natural Resources in Taichung, Taiwan, ROC. The animal room was kept on a 12-h light and 12-h dark cycle. Constant temperature ( $25 \pm 2^{\circ}\text{C}$ ) and humidity were maintained. The mice were housed and kept on a chow diet (laboratory standard diet) to acclimatize for 2 weeks before feeding the experimental diet. After this equilibrium period, the mice were divided into four groups varied by oil source and sensitized treatments: non-sensitized control (PBS/COR,  $n = 12$ ), dietary control (OVA/COR,  $n = 8$ ), OVA/COR-PER ( $n = 8$ ) and OVA/PER ( $n = 9$ ). Each group was fed with the specified experimental diets for 5 consecutive weeks. Mice food intake and body weight were measured twice a week during the study period. There were no differences in food intake, feed efficiency and body weight gain between the four groups.

### OVA-Sensitized and -Challenged Allergic Inflammation Murine Model

To test the effects of n-3 and/or n-6 fatty acids on airway inflammation, the mice (8 weeks old) were sensitized and

challenged to induce allergic airway inflammation. The mouse allergic airway inflammation model was manipulated as described by Lin et al. [20] and Ye et al. [21]. In brief, the mice were sensitized using an intraperitoneal injection (i.p.) of 0.2 ml alum-precipitated antigen containing 8 µg of ovalbumin (OVA, albumin chicken egg grade III, Sigma A-5378, MO, USA) and 2 mg Al(OH)<sub>3</sub> to induce primary immunity after supplementation of the specified experimental diets for 1 week. Two booster injections of this alum-OVA mixture were given 7 and 14 days later, respectively. Non-sensitized control mice received alum-phosphate-buffered saline (PBS, 137 mM NaCl, 2.7 mM KCl, 8.1 mM Na<sub>2</sub>HPO<sub>4</sub>, 1.5 mM KH<sub>2</sub>PO<sub>4</sub>, pH 7.2–7.4, 0.2 µm filtered) only. One week later, the mice were then challenged by aerosolized OVA at a concentration of 5 mg OVA per milliliter PBS for 60 min, twice at 3 day intervals and repeated twice in 24 h. The aerosolized OVA were produced using an ultrasonic nebulizer (sw918, Shinmed). Non-sensitized control mice received PBS only. Two days later, the animals were anesthetized with diethyl ether, exsanguinated using retro-orbital venous plexus puncture and immediately euthanized using CO<sub>2</sub> inhalation. The bronchoalveolar lavage fluid (BALF) was collected and assayed for cytokines and other inflammatory mediators. The experimental design is given in Fig. 1.

#### Collection of BALF and Cellular Differential Counts

The BALF collection and differential cell counts were modified from the methods described by Ye et al. [21]. The mice were anesthetized with diethyl ether, exsanguinated using retro-orbital venous plexus puncture and immediately euthanized using CO<sub>2</sub> inhalation. Using a cannula, their lungs were immediately lavaged through the trachea with 5 aliquots of 0.6 ml Hank's balanced salts solution (HBSS) which was free of ionized calcium and magnesium

**Fig. 1** Sensitization and challenge protocols for inducing allergic airway inflammation. Mice were sensitized with OVA/alum at days 7, 14, 21. The sensitized mice were then challenged twice with aerosolized OVA for 60 min at days 30, 33. The challenge was administered twice a day. All experimental mice were sacrificed at day 35 and their bronchoalveolar lavage fluids (BALF) were collected and analyzed

(HyClone). The bronchoalveolar lavage fluid (BALF) was centrifuged at 400g for 10 min at 4°C. The supernatant (BALF) volume was determined and stored at –70°C for future assay. The cell pellet was resuspended in minimum essential medium (MEM, HyClone) containing 10% bovine serum albumin (HyClone) and the final cell density was  $1 \times 10^6$  cells/ml. Total cells counts were determined with a hemocytometer using the trypan blue dye exclusion method. Cytocentrifuged preparations were stained with Liu's stain for differential cell counts. Based on standard morphologic criteria, a minimum of 200 cells were counted and classified as macrophages, lymphocytes, or eosinophils.

#### Assay Inflammatory Mediators in BALF

##### *Histamine*

The BALF histamine level was determined using the Histamine-ELISA kit (Cat. No. A05890, SPI-BIO). The procedure was carried out according to the manufacturer's instructions for use.

##### *Prostaglandin E<sub>2</sub> (PGE<sub>2</sub>)*

The BALF PGE<sub>2</sub> level was determined using the competitive enzyme immunoassay method (Prostaglandin E<sub>2</sub> Express EIA Kit, Cat. No.500141, Cayman).

##### *Nitric Oxide (NO)*

Aliquots of 80 µl BALF samples and standards (0–100 µM sodium nitrite (Sigma S-2252) dissolved in double distilled water) were pipetted into the 96-microplate wells (Nunc). Aliquots of 160 µl Griess reagent were then added into each well to develop the color. The Griess reagent was freshly prepared from Reagent A and B at a ratio of 1:1 (Reagent A: 2% (w/v) sulfanilamide (Sigma S-9251) dissolved in 2.5% (v/v) phosphoric acid; Reagent B: 0.2% (w/v) N-1-naphthylethylene diamide dihydrochloride (Sigma N-9125) dissolved in 2.5% (v/v) phosphoric acid). After incubation for 10 min, the plate was read on a plate reader (ELISA reader, ASYS/HITECH Jupiter) at 540 nm. Using the standard curve, the NO concentration for each unknown sample was determined.

##### *Protein*

The BALF protein content was analyzed using the Bio-Rad protein assay dye reagent concentrate (Cat. no. 500-0006), according to the accompanying instructions, using a 96-well micro-titre plate.

## Measurement of Cytokine and Chemokine Levels in BALF by an ELISA

*IL-1 $\beta$ , IL-2, IL-4, IL-5, IL-6, IL-10, IFN- $\gamma$  and TNF- $\alpha$*

Cytokine (IL-1 $\beta$ , IL-2, IL-4, IL-5, IL-6, IL-10, IFN- $\gamma$ , TNF- $\alpha$ ) levels in BALF were determined using sandwich ELISA kits, respectively. The IL-1 $\beta$ , IL-2, IL-4, IL-5, IL-6, IL-10, IFN- $\gamma$  and TNF- $\alpha$  concentrations were assayed according to the cytokine ELISA protocol of manufacturer's instructions (mouse DuoSet ELISA Development system, R&D Systems). The sensitivity of these cytokine assays was <15.6 pg/ml.

### *Eotaxin*

The BALF eotaxin concentration was determined using the mouse eotaxin sandwich ELISA kit (Quantikine M murine, R&D Systems). The eotaxin concentration was assayed according to the manufacturer's instructions. The sensitivity of this assay was <15.6 pg/ml.

### Statistical analysis

Data were expressed as means  $\pm$  SD. Data within OVA-sensitized treatment are analyzed using analysis of variance (ANOVA) followed by Duncan's test. Data between the dietary control and non-sensitized control are analyzed using unpaired Student's *t*-test. Differences between the dietary control and non-sensitized control or among OVA-sensitized groups were considered statistically significant if  $P < 0.05$ .

## Results

### The OVA-Sensitization and -Challenge Effects on Differential Indicators in Bronchoalveolar Lavage Fluid (BALF) from BALB/c Experimental Mice

The OVA-sensitization and -challenge effects on differential indicators in BALF from BALB/c experimental mice are shown in Table 1. The results showed that sensitization and challenge with OVA significantly ( $P < 0.05$ ) increased an influx of total leukocytes (increase from  $5.7 \pm 3.4 \times 10^5$  to  $21.5 \pm 14.4 \times 10^5$  cells/mouse) into the lungs and airways. Challenge with OVA significantly increased an infiltration of eosinophils (increase from  $1.9 \pm 1.1$  to  $65.9 \pm 12.4\%$ ) but decreased the monocytes/macrophages (decrease from  $86.3 \pm 11.7$  to  $32.2 \pm 11.5\%$ ) infiltration into the lungs and airways. Challenge with OVA also significantly increased PGE<sub>2</sub> (increase from  $1.18 \pm 0.80$  to  $6.75 \pm 3.95$  ng/mouse)

**Table 1** Effects of OVA-sensitization and -challenge on differential indicators in bronchoalveolar lavage fluid (BALF) from BALB/c experimental mice

Indicators in BALF	Treatments	
	PBS/COR	OVA/COR
<b>Cellularity</b>		
Total cells ( $\times 10^5$ /mouse)	$5.7 \pm 3.4$	$21.5 \pm 14.4^*$
Monocytes/macrophages (%)	$86.3 \pm 11.7$	$32.2 \pm 11.5^*$
Lymphocytes (%)	$11.7 \pm 11.3$	$1.87 \pm 1.69$
Eosinophils (%)	$1.9 \pm 1.1$	$65.9 \pm 12.4^*$
<b>Inflammatory mediators</b>		
Protein ( $\mu$ g/mouse)	$266 \pm 96$	$368 \pm 139$
Eotaxin (pg/mouse)	$270 \pm 108$	$356 \pm 107$
PGE <sub>2</sub> (ng/mouse)	$1.18 \pm 0.80$	$6.75 \pm 3.95^*$
Histamine (pmol/mouse)	$10.40 \pm 3.94$	$9.79 \pm 3.55$
Nitric oxide (nmol/mouse)	$5.10 \pm 1.57$	$5.68 \pm 2.83$
<b>Pro-inflammatory cytokines</b>		
IL-1 $\beta$ (pg/mouse)	$34.3 \pm 26.5$	$29.6 \pm 19.6$
TNF- $\alpha$ (pg/mouse)	$280 \pm 223$	$216 \pm 128$
IL-6 (pg/mouse)	$289 \pm 204$	$257 \pm 134$
<b>Th1-type cytokines</b>		
IFN- $\gamma$ (pg/mouse)	$118.6 \pm 104.8$	$77.6 \pm 56.5$
IL-2 (pg/mouse)	$155 \pm 92$	$167 \pm 46$
<b>Th2-type cytokines</b>		
IL-4 (pg/mouse)	$161 \pm 90$	$161 \pm 84$
IL-5 (pg/mouse)	$265 \pm 196$	$222 \pm 110$
IL-10 (pg/mouse)	$548 \pm 315$	$418 \pm 190$

Data are presented as means  $\pm$  SD ( $n = 6-9$ ). Asterisk (\*) means significantly ( $P < 0.05$ ) different from the PBS/COR group within the same row analyzed using unpaired Student's *t*-test

secretion into the lungs and airways. However, the other measured BALF indicators did not significantly change after OVA sensitization and challenge (OVA/COR group) compared to the sensitization control (PBS/COR) group.

### Effects of Different Dietary Oil on Cellularity of BALF from OVA-Sensitized and -Challenged Mice

Effects of different dietary oils on cellularity of BALF from OVA-sensitized and -challenged mice are shown in Table 2. Total leukocyte count in BALF from experimental mice that consumed the diet containing perilla oil (OVA/COR-PER, OVA/PER) did not significantly change compared to the dietary control (OVA/COR). Among the OVA-sensitized and -challenged groups, dietary compound oil (COR-PER) significantly increased the percentage of monocytes/macrophages (increase from  $32.2 \pm 11.5$  to  $52.7 \pm 18.8\%$ ), whereas decreased that of eosinophils

**Table 2** Effects of different dietary oil on total leukocytes and cell distributions in bronchoalveolar lavage fluid (BALF) from OVA-sensitized and -challenged BALB/c mice

Groups	Total cells ( $\times 10^5$ /mouse)	Monocytes/macrophages (%)	Lymphocytes (%)	Eosinophils (%)
OVA/COR	21.5 $\pm$ 14.4	32.2 $\pm$ 11.5 <sup>a</sup>	1.87 $\pm$ 1.69	65.9 $\pm$ 12.4 <sup>b</sup>
OVA/COR-PER	17.0 $\pm$ 9.7	52.7 $\pm$ 18.8 <sup>b</sup>	0.71 $\pm$ 0.82	46.6 $\pm$ 18.1 <sup>a</sup>
OVA/PER	34.1 $\pm$ 16.6	29.1 $\pm$ 14.8 <sup>a</sup>	2.69 $\pm$ 2.90	68.3 $\pm$ 16.8 <sup>b</sup>

Data are presented as means  $\pm$  SD ( $n = 6-9$ ). Data within the same column not sharing the same superscript letters are significantly different ( $P < 0.05$ ) from each other analyzed using analysis of variance (ANOVA) followed by Duncan's test

**Table 3** Effects of different dietary oil on protein and eotaxin levels in bronchoalveolar lavage fluid (BALF) from OVA-sensitized and -challenged BALB/c mice

Groups	Protein ( $\mu$ g/mouse)	Eotaxin (pg/mouse)
OVA/COR	368 $\pm$ 139	356 $\pm$ 107
OVA/COR-PER	412 $\pm$ 142	371 $\pm$ 124
OVA/PER	478 $\pm$ 63	442 $\pm$ 174

Data are presented as means  $\pm$  SD ( $n = 6-10$ ). Data within the same column are analyzed by analysis of variance (ANOVA) followed by Duncan's test. There is no significant difference among groups. The sensitivity of eotaxin kit was about  $<7.8$  pg/ml

(decrease from  $65.9 \pm 12.4$  to  $46.6 \pm 18.1\%$ ) in BALF. The percentages of lymphocytes in BALF did not significantly differ among groups.

#### Effects of Different Dietary Oil on Inflammatory Mediator Levels in BALF from OVA-Sensitized and -Challenged Mice

Effects of different dietary oil on eotaxin and protein levels in BALF are shown in Table 3. Effects of different dietary oil on inflammatory mediator levels in BALF are shown in Table 4. The results showed that perilla oil administration did not significantly affect protein, eotaxin, and inflammatory mediator levels in BALF.

**Table 4** Effects of different dietary oil on inflammatory mediators of bronchoalveolar lavage fluid (BALF) from OVA-sensitized and -challenged BALB/c mice

Groups	PGE <sub>2</sub> (ng/mouse)	Histamine (pmol/mouse)	Nitric oxide (nmol/mouse)
OVA/COR	6.75 $\pm$ 3.95	9.79 $\pm$ 3.55	5.68 $\pm$ 2.83
OVA/COR-PER	8.21 $\pm$ 6.65	10.15 $\pm$ 6.95	5.41 $\pm$ 1.47
OVA/PER	10.91 $\pm$ 5.04	12.28 $\pm$ 3.80	5.87 $\pm$ 1.70

Data are presented as means  $\pm$  SD ( $n = 6-11$ ). Data within the same column are analyzed by analysis of variance (ANOVA) followed by Duncan's test. There is no significant difference among groups. The detection limit of the kits used in this study: PGE<sub>2</sub> 36 pg/ml; Histamine 0.5 nM

**Table 5** Effects of different dietary oils on the levels of pro-inflammatory cytokines IL-1 $\beta$ , TNF- $\alpha$  and IL-6 in bronchoalveolar lavage fluid (BALF) from OVA-sensitized and -challenged BALB/c mice

Groups	IL-1 $\beta$ (pg/mouse)	TNF- $\alpha$ (pg/mouse)	IL-6 (pg/mouse)

OVA/PER	12.5 $\pm$ 7.1 <sup>a</sup>	108 $\pm$ 60 <sup>a</sup>	141 $\pm$ 53 <sup>a</sup>

Data are presented as means  $\pm$  SD ( $n = 6-11$ ). Data within the same column not sharing the same superscript letters are significantly different ( $P < 0.05$ ) from each other analyzed using analysis of variance (ANOVA) followed by Duncan's test

#### Effects of Different Dietary Oil on the Levels of Pro-inflammatory Cytokines in BALF from OVA-Sensitized and -Challenged Mice

Table 5 shows the effects of different dietary oil on the levels of pro-inflammatory cytokines IL-1 $\beta$ , TNF- $\alpha$  and IL-6 in BALF from OVA-sensitized and -challenged mice through 5 weeks feeding. Sensitization and challenge with OVA did not significantly influence the secretion of pro-inflammatory cytokines, but dietary perilla oil significantly decreased these pro-inflammatory cytokines levels in BALF of OVA-sensitized and -challenged mice.

#### Effects of Different Dietary Oils on the Levels of Th1/Th2 Cytokines in BALF from OVA-Sensitized and -Challenged Mice

To evaluate the effects of different dietary oils on the secretion of Th1/Th2 cytokines in the local tissues of lungs and airways, the amounts of Th1 cytokines (IFN- $\gamma$  and IL-2) and Th2 cytokines (IL-4, IL-5 and IL-10) in BALF were measured (Tables 6, 7). Dietary perilla oil significantly decreased the levels of Th1 cytokines in BALF; IFN- $\gamma$  level decreased from  $77.6 \pm 56.5$  to  $21.9 \pm 27.5$  pg/mouse and IL-2 level decreased from  $153 \pm 42$  to  $110 \pm 28$  pg/mouse (Table 6). The levels of Th2 cytokines IL-4, IL-5, and IL-10 in BALF from experimental mice

**Table 6** Effects of different dietary oils on the levels of Th1-type cytokines in bronchoalveolar lavage fluid (BALF) from OVA-sensitized and -challenged BALB/c mice

Group	IFN- $\gamma$ (pg/mouse)	IL-2 (pg/mouse)
OVA/COR	77.6 $\pm$ 56.5 <sup>b</sup>	153 $\pm$ 42 <sup>ab</sup>
OVA/COR-PER	67.7 $\pm$ 19.7 <sup>b</sup>	175 $\pm$ 64 <sup>b</sup>
OVA/PER	21.9 $\pm$ 27.5 <sup>a</sup>	110 $\pm$ 28 <sup>a</sup>

Data are presented as mean  $\pm$  SD ( $n = 6$ –11). Data within the same column not sharing the same superscript letters are significantly different ( $P < 0.05$ ) from each other analyzed using analysis of variance (ANOVA) followed by Duncan's test

**Table 7** Effects of different dietary oil on the levels of Th2-type cytokines in bronchoalveolar lavage fluid (BALF) from OVA-sensitized and -challenged BALB/c mice

Group	IL-4 (pg/mouse)	IL-5 (pg/mouse)	IL-10 (pg/mouse)
OVA/COR	161 $\pm$ 84	222 $\pm$ 110	418 $\pm$ 190 <sup>b</sup>
OVA/COR-PER	174 $\pm$ 34	206 $\pm$ 43	378 $\pm$ 84 <sup>ab</sup>
OVA/PER	121 $\pm$ 31	137 $\pm$ 55	242 $\pm$ 92 <sup>a</sup>

Data are presented as means  $\pm$  SD ( $n = 6$ –11). Data within the same column not sharing the same superscript letters are significantly different ( $P < 0.05$ ) from each other analyzed using analysis of variance (ANOVA) followed by Duncan's test

were decreased by dietary perilla oil administration (Table 7). Especially, IL-10 levels significantly decreased (decrease from 418  $\pm$  190 to 242  $\pm$  92 pg/mouse).

#### Effects of Different Dietary Oils on the Secretion Ratios of Th1/Th2 Cytokines in BALF from OVA-Sensitized and -Challenged Mice

To compare the secretion ratios between Th1 and Th2 cytokine levels in BALF, the secretion ratios of Th1/Th2 cytokine displayed as IFN- $\gamma$ /IL-4, IFN- $\gamma$ /IL-5 and IFN- $\gamma$ /(IL-4 + IL-5) are shown in Fig. 2. The results showed that sensitization and challenge with OVA slightly decreased the secretion ratio of Th1/Th2 cytokine in BALF. However, dietary perilla oil administration significantly decreased the secretion ratios of Th1/Th2 cytokines in BALF (IFN- $\gamma$ /IL-4, decrease from 0.49  $\pm$  0.32 to 0.15  $\pm$  0.17; IFN- $\gamma$ /IL-5, decrease from 0.36  $\pm$  0.06 to 0.12  $\pm$  0.13; IFN- $\gamma$ /(IL-4 + IL-5), decrease from 0.18  $\pm$  0.10 to 0.07  $\pm$  0.08).

#### Discussion

The purpose of this study was to evaluate the effects of perilla oil administration on airway inflammation using an

**Fig. 2** Effects of different dietary oils on Th1/Th2 cytokine secretion ratios in bronchoalveolar lavage fluid (BALF) from BALB/c mice in an OVA-sensitized and -challenged asthmatic murine model. Data are presented as mean  $\pm$  SD ( $n = 6$ –11). Within the same Th1/Th2 cytokine item not sharing the same letters are significantly different ( $P < 0.05$ ) from each other analyzed using analysis of variance (ANOVA) followed by Duncan's test

allergic asthma animal model. The established animal model significantly increased the flux of total leukocytes, especially eosinophils, as well as PGE<sub>2</sub> release into the bronchoalveolar tissues (Table 1), and slightly increased the Th2-skewed inclination in BALF (Fig. 2) compared to OVA/COR with the PBS/COR group. The levels of non-specific and anti-OVA specific IgE were significantly increased in the sera after OVA-sensitization and -challenge treatments (data not shown). Mice sensitized and challenged with OVA exhibited asthma-like symptoms [20], e.g. allergic airway inflammation, infiltration of differential cells, such as eosinophils, into the lungs and airways, and chemical mediator releases including inflammatory eicosanoids, histamine, Th1/Th2 cytokines, nitric oxide (NO), or eotaxin [3]. This study suggests that an intermediate airway inflammation mouse model was achieved. This airway inflammation mouse model (Fig. 1) might be suitable for evaluating the effects of different dietary lipids on the airway inflammation in vivo. Unfortunately, no significant up-regulation of cytokines occurred as expected in BALF in the established experimental animal model (Table 1). Undoubtedly, this might limit the results interpretation and relevance. Therefore, cytokine levels secreted by lymphocytes from the spleen or other lymphoid organs remain to be further clarified to compensate for the lack in the model.

In this study perilla oil rich in ALNA (18:3n-3) and corn oil rich in linoleic acid (18:2n-6) were selected and subjected to the allergic airway inflammation animal study. The compound oil consisted of n-3/n-6 fatty acid (PER/COR) exhibited the best anti-allergic effects via

significantly decreasing eosinophils, but increasing monocytes/macrophages infiltration into the airways (Table 2). Although lymphocytes in BALF did not significantly change, the decrease in eosinophilic infiltration suggested that compound oil (COR-PER) administration might remodel the inflammatory condition of the airways via decreasing vasodilation, mucus hypersecretion and bronchoconstriction [22, 23]. However, perilla oil administration alone could not significantly change the eosinophilic infiltration status in the airways. The anti-eosinophilic infiltration effect mechanism using a mixture of perilla and corn oils remains to be further clarified. To further clarify the effects of n-3 or n-6 PUFA, this study suggests that an ovalbumin sensitized group fed a diet supplemented with 5% of oil not rich in n-3 or n-6 fatty acids should be added. The added group will be helpful to further decipher the anti-inflammatory effects due to the anti-inflammatory effects of n-3 fatty acids or the lack of inflammatory effects of n-6 fatty acids.

The suppressive effects of n-3 PUFAs, such as EPA and DHA, on the production of arachidonic acid-derived eicosanoids have been reported [2, 24, 25]. Perilla oil was proposed to have anti-inflammatory potential for its high bioavailability of the n-3 fatty acid ALNA (18:3n-3) [12]. Contrary to our hypothesis, dietary perilla oil did not significantly affect the levels of inflammatory mediators in BALF such as protein, eotaxin, PGE<sub>2</sub>, histamine, and nitric oxide (Tables 3, 4). Although the n-3 PUFAs such as EPA and DHA inhibit the production of inflammatory eicosanoids [24, 25], the synthesis of EPA and DHA from their precursor ALNA (18:3n-3) is low efficiency in cells [26, 27]. This study further hypothesized that ALNA (n-3, PUFA) from perilla oil having lower anti-eicosanoid effects than those of EPA and DHA (n-3, PUFA) from fish oil might result from its low conversion efficiency from ALNA to EPA and DHA in vivo. The low conversion efficiency from ALNA to EPA and DHA in vivo might decrease the anti-eicosanoid effect of perilla oil. To further clarify whether or not the ALNA in the perilla oil is converted to EPA or DHA and speculate the mechanisms by which EPA and DHA may cause immuno-modulation, the tissue fatty acid composition of experimental mice should be analyzed. Unfortunately, this study did not analyze the fatty acid composition in relevant cells or tissues. However, Kim and Choi (2005) have analyzed fatty acid composition in tissues and have demonstrated that both dietary corn oil (rich in C18:2n-6, 57.29%) and dietary perilla oil (rich in C18:3n-3, 61.49%) indeed reflected their fatty acid composition upon hepatic microsomal phospholipids of male Sprague–Dawley rats either through 4-day feeding or 4-week feeding [18]. They reported that total n-6 and n-3 fatty acid composition in hepatic microsomal phospholipids of the experimental rats, fed with 10% corn

oil and 10% perilla oil diet through 4-day feeding, were 46.85% ( $\Sigma$ n-6), and 4.47% ( $\Sigma$ n-3), as well as 32.57% ( $\Sigma$ n-6), and 22.58% ( $\Sigma$ n-3, including considerable EPA and DHA), respectively [18]. Comparatively the fatty acid composition of C20:4 in the analyzed tissue were 30.10 and 17.73%, respectively [18]. Although only 5% perilla oil diet was used in this study, this study suggests that the anti-inflammatory activity of dietary perilla oil might be partially via increasing n-3 fatty acid composition, but decreasing C20:4 (arachidonic acid) composition in vivo.

To further elucidate the effects of dietary perilla oil administration on cytokine secretions in BALF, pro-inflammatory cytokines including IL-1 $\beta$ , IL-6 and TNF- $\alpha$ , and Th1/Th2 cytokines were determined. The results revealed that dietary perilla oil administration significantly inhibits the production of pro-inflammatory cytokines, IL-1 $\beta$ , IL-6 and TNF- $\alpha$ , in BALF (Table 5). Undoubtedly, perilla oil administration exhibited anti-inflammatory potential via inhibiting the production of pro-inflammatory cytokines. Since the fatty acid composition (purity) in perilla oil was >99.9%, this study suggests that the effective components in perilla oil are fatty acids but not other components. However, the effective components in perilla oil and their immuno-regulatory mechanism should be further clarified.

Furthermore, this study showed that both Th1 (IFN- $\gamma$  and IL-2) and Th2 (IL-10), especially Th1 cytokine secretions were significantly inhibited by dietary perilla oil, suggesting that perilla oil administration might also have immunosuppressive effects on Th1 cells from OVA-sensitization and -challenge mice (Tables 6, 7). IL-10 is generally synthesized in a lower level at the late stage of inflammation [28, 29] to inhibit Th1 cell and delayed-type hypersensitivity responses [6]. Thus, the decrease in Th1 cytokine production might also result in a significant decrease of IL-10 production in vivo. Recent evidences have indicated that lipid micro domains in the T-cell plasma membrane are remodeled using a dietary lipid consisting of n-3 PUFA, EPA and DHA [30–33]. Long-chain n-3 PUFAs suppress Th1-cell, but not Th2-cell, development [34, 35], and modulate the Th1/Th2 balance toward the Th2 pole [36–38]. The results from this study also exhibited that perilla oil, which is rich in ALNA (n-3 PUFA), regulated the Th1/Th2 balance toward to Th2-skewed inclination in the asthmatic model as compared to corn oil (rich in n-6 PUFA) administration (Fig. 2). The Th2-skewed immune response is disadvantage to allergic diseases.

In conclusion, the results from this study showed that perilla oil administration might alleviate bronchoalveolar inflammation by decreasing the secretion of pro-inflammatory cytokines (TNF- $\alpha$ , IL-1 $\beta$  and IL-6) and Th1 cytokines (IFN- $\gamma$  and IL-2) into the local lung and airway

tissues, but failed to regulate the Th1/Th2 balance toward the Th1 pole during the Th2-skewed allergic airway inflammation.

**Abstract** Postprandial triglyceride-rich lipoproteins (TRL) levels are a predictor for coronary atherosclerosis. The aim of the study was to compare fasting high density lipoprotein (HDL) cholesterol, plasma lipoprotein lipase (LPL) activity, and postprandial TRL between elderly survivors of myocardial infarction (MI) and healthy controls. A case-control study was performed in 44 elderly patients 65–85 years of age with a previous history of MI and 43 age- and sex-matched healthy controls. Each participant underwent physical examination and was given a standard oral fat load with subsequent blood sampling over the next 8 h. Total and chylomicron triglycerides were assessed by area under the curve (AUC), incremental area under the curve (AUC<sub>i</sub>) and triglyceride response (TGR). Elderly MI patients had significantly lower postheparin LPL activity ( $87.4 \pm 36.9$  mU/ml) (mean  $\pm$  1 SD) than healthy controls ( $106.0 \pm 29.0$  mU/ml) ( $P = 0.014$ ). Decreased postheparin LPL activity was accompanied by significant increased and delayed clearance of postprandial TRL. Fasting HDL cholesterol was significantly lower in elderly MI patients than controls ( $1.45 \pm 0.32$  and  $1.66 \pm 0.47$  mmol/l, respectively,  $P = 0.048$ ). Multiple regression analysis revealed postheparin LPL activity as an independent predictor for postprandial TRL and fasting HDL cholesterol. Logistic regressions analysis revealed HDL cholesterol, triglycerides measured 2 h after the oral fat load, and postheparin LPL activity as independent predictors for MI. Our findings indicate that decreased fasting HDL cholesterol is associated with increased postprandial

triglyceridemia which could be a target for life-style and therapeutic interventions in patients at risk for cardiovascular disease.

### Introduction

More than 20 years ago, Zilversmit [1] proposed that atherosclerosis is, at least in part, a postprandial disease, and hypothesized that accumulation of TRL promoted formation of atherosclerosis, due to reduced clearance and thereby prolonged exposure of the vascular wall to TRL. More recent studies provide new perspective to this hypothesis by reporting a particular efficient penetration and selective retention of chylomicron remnants in sites of lesion formation [2, 3]. Patients with coronary artery disease (CAD) have delayed elimination of postprandial TRL [4, 5], and plasma concentrations of postprandial remnants have been related to the progression of coronary lesions [6]. Furthermore, increased and delayed postprandial hyperlipidemia has been reported to be a strong predictor for CAD verified by angiography in middle-aged men with severe disease [4].

Lipoprotein lipase (LPL) is the major lipase in lipoprotein metabolism [7]. The enzyme is synthesized by and released from parenchymal cells in many tissues, and becomes anchored to heparan sulphate proteoglycans (HSPGs) at the endothelial surface [7]. LPL hydrolyzes triglycerides in chylomicrons (CM) and very low-density lipoproteins (VLDL), providing fatty acids to the underlying tissues [8]. A delay in chylomicron clearance would

imply prolonged postprandial hyperlipidemia, which supposedly leads to increased deposition of chylomicron contents in the arterial wall and to an unfavourable translocation of cholesteryl-esters from high density lipoprotein (HDL) to CM [1, 4]. Deficiency of LPL or its cofactor apoCII is known to induce accumulation of CM in plasma, suggesting that triglyceride hydrolysis is important for clearance of these particles [9]. Furthermore, low levels of LPL activity, as encountered in patients with partial LPL deficiency, are associated with premature atherosclerosis and accelerated progression of atherogenesis [10], and low postheparin LPL activity is related to severe angina pectoris in men with angiographically documented CAD [11].

Low HDL cholesterol is known to be a strong and independent risk factor for CAD [12], which remains significant even at old age [13, 14]. In humans, LPL activity contributes to the regulation of HDL cholesterol and may partly explain the inverse relation between postprandial TRL and HDL cholesterol [5, 15, 16]. In addition, postheparin LPL activity is associated with HDL cholesterol [17, 18] and inversely correlated to the magnitude of postprandial hyperlipidemia in normolipidemic patients [19].

The purpose of the present study was to compare fasting HDL cholesterol, plasma LPL activity, and postprandial TRL in elderly patients with a previous history of myocardial infarction (MI) with apparently healthy controls. To address these questions we performed a case-control study among elderly, normotriglyceridemic survivors of acute MI more than a year prior to the investigation and in healthy age- and sex-matched controls. Our hypothesis was that low fasting HDL cholesterol may be a marker of decreased LPL activity accompanied by increased and delayed clearance of postprandial TRL.

## Materials and Methods

### Patients and Study Design

Medical records of consecutive patients between 65 and 85 years of age with the diagnosis acute MI were obtained from the archives at the University Hospital of North Norway in Tromsø. The diagnosis acute MI was verified by diagnostic criteria such as chest pain, pathological ECG and increase in serum concentration of cardiac markers. The inclusion criteria were; suffering of acute MI 1–4 years before the present investigation without any major coronary events (i.e. hospitalization for angina pectoris, reinfarction, coronary angioplasty or ACB surgery) afterwards, both genders, and age between 65 and 85 years at diagnosis. The exclusion criteria were; regular use of drugs interfering with the coagulation system, chronic

inflammatory diseases, renal or liver disease, cancer, hypothyroidism, serious hypertension, abuse of alcohol or drugs, and psychiatric diseases. One age- and sex-matched healthy person for each case was recruited from the general population and invited to a screening visit. At the screening visit, a complete medical history, physical examination and blood samples were taken with special emphasis on exclusion criteria were conducted on both cases and controls. Absence of diseases, and cardiovascular diseases in particular, for the healthy controls were confirmed by searching into their medical records. Height and weight were measured with the patients in light clothing without shoes and body mass index (BMI) was calculated. Blood pressure was recorded in seated position by the use of an automatic device (Dinamap Vital Signs Monitor). Three recordings were made at 1 min intervals, and the mean of the two last values was used in this report. A 75-g oral glucose tolerance test was performed on the first visit. Impaired fasting glucose (fasting plasma glucose 6.1–6.9 mmol/l), impaired glucose tolerance (fasting glucose < 7.0 mmol/l and 2 h plasma glucose from 7.8 to 11.0 mmol/l) and diabetes (fasting glucose  $\geq$  7.0 mmol/l or 2 h plasma glucose  $\geq$  11.1 mmol/l or on antidiabetic treatment) were defined according to WHO criteria. Eligible persons (44 cases and 43 controls) were invited to a second visit during which the participants were subjected to a fat tolerance test. Informed written consent was obtained from the participants, and the Regional Board of Research Ethics approved the study. The study was performed at the Clinical Research Centre at the University Hospital of North Norway in Tromsø.

### Fat Tolerance Test

A fat tolerance test was conducted using a test meal prepared as a standard cream porridge containing 70% of calories from fat of which 66% saturated fat, 32% mono-unsaturated fat and 2% polyunsaturated fat. A weight-adjusted meal (1 g fat per kg body weight) was served at 8:00 a.m. and consumed over a 15 min period. The participants were allowed to drink 350 ml calorie-free beverages (diet soda) and eat an apple during the following 8 h. Blood samples for isolation of CM, and serum and plasma preparations were collected after 12 h fasting, before the meal and every second hour during the next 8 h.

### Measurement of Plasma Glucose, Serum lipids, Apolipoproteins and Isolation of Chylomicrons

Serum was prepared by clotting whole blood in a glass tube at room temperature for 1 h and then centrifuged at 2,000g for 15 min at 22 °C. Blood for plasma preparation was collected into vacutainers (Becton Dickinson, Meylan

Cedex, France) containing 0.129 M sodium citrate (1 vol anticoagulant and 9 vol whole blood) as anticoagulant. Plasma glucose was measured (Gluko-quant Glucose/HK, Roche Diagnostics GmbH, Mannheim, Germany) in fasting plasma and 2 h after a 75 g oral glucose tolerance test according to the manufacturers instructions. Serum lipids were analyzed on a Hitachi 737 Automatic Analyzer (Boehringer Mannheim, Germany) with reagents from the manufacturer. Total cholesterol was measured with an enzymatic colorimetric method (CHOD-PAP) and HDL cholesterol was assayed by the same procedure after precipitation of lower density lipoproteins with heparin and manganese chloride as described by Burstein et al. [20]. Total triglycerides and chylomicron triglycerides concentration was determined with an enzymatic colorimetric test (GPO-PAP). Low-density lipoprotein (LDL) cholesterol was calculated by the formula of Friedewald et al. [21]. Apo-AI and apo-B100 were measured immunochemically by rate nephelometry, using the Array Protein System from Beckman Instruments Inc. (Brea, CA, USA). CM were isolated by over layering 8 ml EDTA plasma with 5 ml of NaCl solution (a density 1.006 kg/l NaCl solution with 0.02% sodium azide and 0.01% EDTA) in a cellulose nitrate tube (Beckman Instruments Inc., CA, USA) and centrifuged in a Beckman SW40 Ti swinging bucket rotor at 20,000 rpm for 1 h at 4 °C. The CM, with Svedberg flotation (Sf) rates >400, were carefully removed by aspiration from the top of the tube divided into three aliquots in cryovials, flushed with nitrogen, and frozen at -70 °C until further analysis.

### Lipoprotein Lipase Activity

Eight hours after ingestion of the test meal, blood was drawn into vacutainers (Becton Dickinson) containing heparin as anticoagulant and the heparinised blood was immediately placed on ice. Unfractionated heparin was given as a bolus injection (100 IU/kg body weight) on the contra lateral arm to mobilize LPL from the endothelial surface into the circulation, and a second blood sample was obtained 15 min after heparin administration and immediately placed on ice. Heparinised plasma was recovered within 30 min by centrifugation (2,000×g for 10 min) at 4 °C, divided into aliquots of 1.0 ml in cryovials, flushed with nitrogen, and frozen at -70 °C until further analysis. LPL activity was determined as described by Olivecrona et al. [22]. In short, sonicated emulsion of <sup>3</sup>H-oleic acid-labelled triolein in 20% Intralipid (Fresenius Kabi, Halden, Norway) was used as substrate. Samples were preincubated for 2 h on ice with 0.5 vol goat antibodies to hepatic lipase (HL) to suppress HL activity. LPL activity is expressed in mU/ml corresponding to nanomole of fatty acids released per millilitre per minute. The samples were quantitated in

duplicate, and postheparin plasma from pooled normal control persons was used to correct for interassay variation.

### Statistics

All variables were checked for frequency distribution. The extent of postprandial hypertriglyceridemia was assessed by the total area under the curve (AUC) and incremental area under the curve (AUCi) for triglycerides and chylomicron triglycerides, and by the triglyceride response (TGR), defined as the average of the two highest postprandial triglyceride concentrations minus baseline concentration. Unpaired *t* test was used to compare differences between groups.  $\chi^2$  (Chi-square) test was used to compare groups on categorical variables. General linear models for univariate analysis of variance were used for adjustments. Pearson's correlation coefficients were used to examine correlations between continuous variables. Linear regression models were used to test linear trends. Multiple linear regression models were used to assess independent predictors of AUCi for serum triglycerides, AUCi for CM and HDL cholesterol. Multiple logistic regression models were performed with case-control status for MI with triglycerides measured 2 h after the fat load, postheparin LPL activity and HDL cholesterol. All analyses were performed using SPSS (SPSS Inc. Chicago, Illinois, USA) for windows software, version 14.0. Two-sided *P* values (<0.05) were considered statistically significant. Values are mean ± SD if not otherwise stated.

### Results

Characteristics of elderly survivors of MI and age- and sex-matched healthy controls are shown in Table 1. Patients had significantly higher frequency of hypertension and lower measured blood pressure and heart rate than healthy controls. The apparent discrepancy between higher frequency of hypertension and actual lowered blood pressure and heart rate among MI patients is most probably explained by their frequent use of  $\beta$ -blockers (Table 1). Elderly MI patients tended to have a higher frequency of diabetes mellitus, but impaired fasting glucose and impaired glucose tolerance were equally distributed between groups.

Serum lipids and apolipoproteins in elderly survivors of MI and their age- and sex-matched controls are shown in Table 2. Elderly MI patients had significantly lower total cholesterol, LDL cholesterol and HDL cholesterol than control persons in crude analysis and after adjustment for BMI, diabetes mellitus and regular use of statins. Apo-AI was lower in MI patients in crude analysis, but the difference between groups disappeared after adjustment for

*P*1, crude analyses; *P*2, adjusted for BMI, presence of diabetes mellitus, and regular use of statins

BMI, diabetes and use of statins. No difference between groups was observed with regard to fasting serum triglycerides.

To investigate the time-course of postprandial triglyceride-rich lipoproteins (TRL) in elderly patients with and without a previous history of MI, the participants were subjected to a standard fat meal, and total serum triglycerides and chylomicron triglycerides were measured over time (Fig. 1 and Table 3). The MI patients had increased peak concentrations of total triglycerides, increased total and incremental AUC, which reached significance after adjustment for BMI, diabetes and use of statins. Even more pronounced differences between groups with regard to

peak concentrations and both total and incremental AUC were observed for chylomicron triglycerides. Statistical adjustments for use of cardiovascular drugs (statins, β-blockers, Ca-antagonists, diuretics) and concurrent diseases (diabetes mellitus and hypertension) among MI patients did not influence differences between groups. The MI patients had significantly higher levels of chylomicron triglycerides 8 h after the fat load (*P* = 0.018). Furthermore, we found a significant correlation between fasting TG and AUC<sub>i</sub> for total triglycerides in patients (*r* = 0.51, *P* = 0.001), but not in controls (*r* = 0.21, *P* = 0.193).

Preheparin LPL activity was similar in the two groups, whereas elderly MI patients had significantly lower

**Fig. 1** Line graph showing postprandial concentrations of total triglycerides (upper panel) and chylomicron triglycerides (lower panel) over time after a standard fat meal in elderly patients with a previous history of myocardial infarction ( $n = 44$ ) and healthy age- and sex-matched controls ( $n = 43$ ). P1 crude analyses, P2 adjusted for BMI, presence of diabetes mellitus, and regular use of statins

(statins,  $\beta$ -blockers, Ca-antagonists, diuretics) and concurrent diseases (Diabetes Mellitus and hypertension) among MI patients did not influence the differences between groups. In the total study population ( $n = 87$ ), postheparin LPL activity was inversely correlated with fasting TG levels ( $r = -0.29$ ,  $P = 0.008$ ), incremental AUC for total triglycerides ( $r = -0.39$ ,  $P < 0.001$ ) and chylomicron triglycerides ( $r = -0.41$ ,  $P < 0.001$ ). Furthermore, a significant positive correlation was found between postheparin LPL activity and fasting HDL cholesterol for both patients ( $r = 0.40$ ,  $P = 0.013$ ) and healthy controls ( $r = 0.34$ ,  $P = 0.037$ ). Multiple linear regression analyses were performed to determine independent predictors for incremental AUC for triglycerides (TG-AUCi), incremental AUC for chylomicron triglycerides (CM-AUCi) and HDL cholesterol (Table 4). Triglycerides measured 2 h after the oral fat load was independent predictors for TG-AUCi, whereas triglycerides measured 2 h after fat load and postheparin LPL activity were significant independent predictors for CM-AUCi. Postheparin LPL activity was the only significant predictor for HDL cholesterol in the model. The included variables in the model explained 51% of the variation in TG-AUCi, 43% of the variation in CM-AUCi, and 19% of the variation in HDL cholesterol.

To study the predictive role of triglycerides measured 2 h after the fat load, postheparin LPL activity and HDL cholesterol for MI in elderly, multiple logistic regression analysis were performed (Table 5). Postheparin LPL activity ( $P = 0.02$ ), triglycerides measured 2 h after the fat load ( $P = 0.05$ ) and HDL cholesterol ( $P = 0.02$ ) were independent predictors for MI in elderly. After adjusting for BMI and statin prescription, postheparin LPL activity ( $P = 0.02$ ) and triglycerides measured 2 h after the fat load response (TGR), and lipoprotein lipase activity during 8 h after intake of a standard fat meal in elderly survivors of myocardial infarction and age- and sex-matched healthy controls

( $P = 0.05$ ) remained as independent predictors in the model.

## Discussion

The present study showed that decreased fasting HDL cholesterol in elderly survivors of MI was associated with lowered postheparin LPL activity accompanied by increased postprandial TRL. To the best of our knowledge, our study is the first to show these metabolic changes in elderly MI patients.

In our study, elderly survivors of MI had increased peak concentrations, elevated AUC and delayed clearance of both total triglycerides and chylomicron triglycerides. Similar findings have previously been reported in middle-aged male subjects with severe CAD [4]. Although other studies have reported delayed clearance of TRL in CAD patients [5, 23], they were not able to demonstrate increased postprandial levels of TRL [5, 23, 24]. Previous studies have shown a significant association between fasting triglycerides and postprandial TRL [5, 24]. A significant correlation between fasting triglycerides and postprandial TRL in elderly MI patients was confirmed in our study, and

multiple regression analysis revealed triglycerides measured 2 h after the fat load as a strong and independent predictor for the magnitude of postprandial increase in TRL and the presence of CAD.

Postprandial lipoprotein changes in healthy persons aged 22–79 years showed that elderly people had significantly increased [25] and prolonged postprandial hypertriglyceridemia compared to healthy young persons [26]. Thus, both age and the presence of CAD are known predictors for increased and delayed clearance of postprandial TRL. Our findings of a pronounced increase in peak concentrations and delayed clearance of postprandial TRL in elderly MI patients may indicate that age contributes to reinforcing the effect on postprandial handling of TRL.

Obesity, insulin resistance, and dyslipidemia including low levels of HDL cholesterol are important elements of the metabolic syndrome [27] associated with increased risk for cardiovascular disease [28, 29] and type 2 diabetes [30]. Insulin resistance is associated with endothelial dysfunction [31] with subsequent impaired metabolism of TRLs by LPLs [32]. Persons with obesity [33] and diabetes mellitus type 2 [34] are reported to have increased levels of postprandial TRLs. In our study, elderly MI patients tended to have higher BMI and to have a higher frequency of diabetes mellitus type 2 than the healthy controls. However, the increased levels of postprandial TRL in elderly MI patients remained significant even after adjusting for BMI and diabetes mellitus.

Statin treatment is known to reduce the postprandial triglyceridemia [35–38] in a Dose-Dependent manner by 5–30% [39]. In the present study, almost 50% of the MI patients regularly used statins. Thus, it is likely correct to assume that the actual difference in postprandial levels of TRL between groups was underestimated in our study. Both non-selective and  $\beta_1$ -selective  $\beta$ -blockers increase fasting plasma triglycerides [40]. In our study, all patients were using  $\beta_1$ -selective  $\beta$ -blockers which are reported not

to affect postprandial TRL [41] and postheparin LPL activity [42]. However, adjustments for use of cardiovascular drugs (statins,  $\beta$ -blockers, Ca-antagonists, diuretics) among MI patients did not influence the differences between groups.

The “response to retention” hypothesis of atherosclerosis suggests that intimal deposition is proportional to the concentration of circulating proatherogenic lipoproteins [43, 44]. Experimental studies suggest that plasma accumulation of remnant lipoproteins is not just an associated feature of an atherogenic lipoprotein profile, but that TRL remnants themselves contribute to the pathogenesis of atherosclerosis. Chylomicron remnants in the intima are derived from postprandial lipoproteins [2, 45], and TRL can be taken up directly by macrophages without prior modification and form foam cells [46]. Apo-B48 containing chylomicron remnants may contain up to 40 times more cholesterol per particle than do LDL particles, and consequently, exposure and retention of apo-B48 containing postprandial lipoproteins in the arterial wall may pose a significant atherogenic risk [2]. The present study supports the hypothesis that both increased and delayed postprandial hyperlipidemia are associated with CAD, and suggests that increased postprandial hypertriglyceridemia is a stronger predictor for CAD in old age. Thus, it may be speculated that increased and delayed postprandial levels of TRL among elderly may contribute to increased risk for CAD in older men and women [47].

The amount of LPL released after a bolus dose of heparin is used as a measure of functional LPL and assumed to reflect the LPL availability at the endothelial surface [22]. Inconsistent data has been reported on postheparin LPL activity in CAD. In two independent studies in young normotriglyceridemic CAD patients, both no change [5] and decreased [17] postheparin LPL activity has been reported. In the latter study, hypertriglyceridemic patients did not have decreased LPL activity [17]. However, a large cohort study among dyslipidemic CAD patients less than 70 years of age showed a significant decrease in postheparin LPL activity [48]. In the present study, normotriglyceridemic elderly survivors of MI had significantly lower postheparin LPL activity than healthy controls. Both environmental and genetic factors are known to affect LPL activity [7]. Postheparin LPL activity decreases with advancing age [25]. Use of  $\beta$ -blockers was earlier reported to inhibit LPL activity [49], whereas more recent studies have shown no influence of regular use of  $\beta$ -blockers [11, 48]. In the present study, the differences in postheparin LPL activity remained significant even after adjustments for use of cardiovascular drugs and concurrent diseases among the MI patients.

Chylomicron clearance, both lipolysis and hepatic uptake, is sensitive to LPL activity [7]. Thus, decreased

LPL activity may slow chylomicron clearance in both stages. In our study, multiple regression analysis revealed that postheparin LPL activity was an independent predictor for both fasting HDL and postprandial TRL. Decreased postheparin LPL activity was associated with low HDL cholesterol and increased postprandial TRL, a lipid profile that is associated with increased risk for atherosclerosis [4, 5, 50]. Genetic studies have reported that individuals, who are heterozygous for LPL mutations that reduce enzymatic activity, are predisposed to premature atherosclerosis [51, 52]. Conversely, a variant of LPL that is associated with increased activity has been shown to protect against coronary heart disease [53]. Thus, our findings support a novel property of LPL in CAD either directly or indirectly by subsequent modulation of HDL cholesterol and postprandial TRL.

In conclusion, elderly MI patients had decreased fasting HDL cholesterol associated with metabolic disturbances such as decreased postheparin LPL activity and increased postprandial triglyceridemia. Increased postprandial triglyceridemia could be a target for life-style changes, i.e. weight loss [54], physical exercise [55] and dietary supplementation of polyunsaturated n-3 fatty acids [38, 56], and therapeutic interventions, i.e. statin treatment [35–37].

**Abstract** Several studies in animals and humans have reported beneficial effects of diacylglycerol (DAG) on lipid and energy metabolism. We assessed the effect of DAG versus triacylglycerol (TAG) treatment on total energy expenditure (TEE), total fat oxidation (Fox) and respiratory quotient (RQ), and measured the oxidation rate of each oil using a respiratory chamber and the  $^{13}\text{C}$ -stable isotope. Eleven healthy subjects participated in a double-blind, randomized crossover study. Subjects consumed an energy maintenance diet consisting of 55% of total calories from carbohydrate, 15% from protein and 30% from fat during both the 3-day pre-chamber and 36-h chamber period. Fifty percent of the fat was test oil, containing either DAG oil or TAG oil. The oxidation rate of ingested test oils was determined by monitoring  $^{13}\text{CO}_2$  excretion in the breath from  $^{13}\text{C}$ -labeled diolein or  $^{13}\text{C}$ -labeled triolein. There were no significant differences in TEE, RQ and total Fox between the DAG and TAG treatment in the overall analysis. In the subgroup analysis, DAG treatment decreased RQ significantly in subjects with a high fat ratio (HFR) compared to TAG treatment. In addition, ingested diolein oxidation in DAG treatment was significantly faster than triolein oxidation in TAG treatment in the HFR group. Enhanced fat utilization with DAG treatment and rapid oxidation of ingested DAG may, at least in part, explain the greater loss of body weight and body fat related to DAG consumption found in the weight-loss studies.

## Introduction

The prevalence of obesity has increased worldwide. Obesity is an important risk factor for chronic diseases such as coronary heart disease, hypertension and diabetes. Genetic predisposition, physical inactivity, and composition of habitual diets are some of the factors identified as causes of obesity [1]. Among these, the amount of dietary fat in a usual diet is considered to be important in the development of obesity [2]. Therefore, it would be beneficial to have a dietary fat with properties of enhanced fat oxidation.

Diacylglycerol (DAG) oil reportedly has nutritional properties distinct from triacylglycerol (TAG) oil due to its different chemical structure [3–5]. Human studies in the US and Japan have demonstrated that long-term ingestion of DAG oil enhanced loss of body weight and body fat, in comparison with TAG oil [6–9]. Animal studies have also shown lower fat accumulation after DAG oil feeding compared to TAG oil feeding [10]. Although the mechanisms are still speculative, these effects are most likely attributable to enhanced  $\beta$ -oxidation in the liver and small intestine [11–13].

Recently, a few studies in humans examined the effect of DAG on fat utilization. Kamphuis et al. [14] showed significantly increased total fat oxidation (Fox) and reduced respiratory quotient (RQ) with DAG consumption compared to TAG consumption, with no difference in total energy expenditure (TEE). Saito et al. [15] reported

significantly lower postprandial RQ and a trend toward higher postprandial energy expenditure after DAG ingestion. Although significantly increased total fat utilization after DAG consumption was found in these studies, whether the oxidation rate of ingested DAG itself contributes to the enhanced total fat utilization is yet to be examined.

The combination technique of the respiratory chamber and fatty acid labeled with  $^{13}\text{C}$  stable isotope enables the accurate determination of ingested fat oxidation during practical daily life activities over a long period of time. The primary objective of this study was to determine the effects of short-term DAG consumption on energy metabolism, with special attention paid to the rate of ingested DAG oxidation.

## Methods

### Subjects

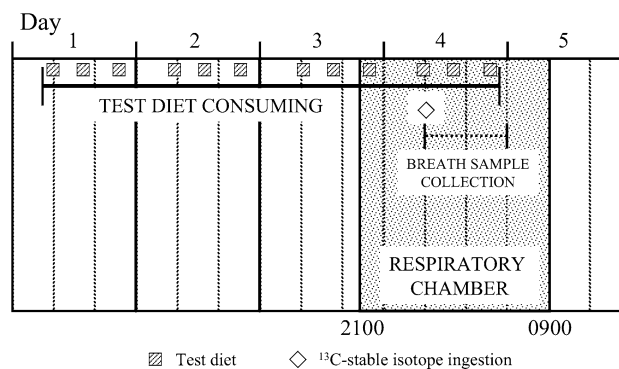

Eight males and six females [age:  $38.5 \pm 5.5$  years; body mass index (BMI):  $24.2 \pm 2.7 \text{ kg/m}^2$ ] were recruited from the local population. After receiving a full explanation of the study, all subjects gave their informed consent to participate in the study, which was approved by the Clinical Research Ethical Committee of Shibuya Core Clinic (Tokyo, Japan). All subjects were healthy according to their medical histories. All were non-smokers, and had no metabolic disorders. The study was performed in accordance with the principles of the Helsinki Declaration.

### Study Design

The study was a randomized, double-blind, placebo-controlled crossover design with three stays in a respiratory chamber. After the first chamber stay, which acclimated the subjects to the process, they were randomized into either the DAG or TAG diet group for the second chamber stay. Then, they had a 4-week rest period before crossing over and receiving the opposite test diet for the third chamber stay. Each test diet was consumed for a 4-day period, including the period of the chamber stay from the night of day 3 until the morning of day 5 (Fig. 1).

### Test Oils

The DAG oil used in the present study was prepared from soybean oil and rapeseed oil in the presence of immobilized lipase [16]. The prepared DAG oil contained more than 80% diacylglycerol and the ratio of 1(3),2-diacylglycerol to 1,3-diacylglycerol was approximately 3:7. TAG oil was prepared by mixing rapeseed, safflower and perilla oils so the fatty acid composition was similar to that of

DAG oil. Fatty acid and glyceride compositions are shown in Table 1. The test oil was served as a mayonnaise-type food that contained 66.3 wt.% of the test oil.

### Test Diet and Chamber Protocol

Total energy intake of the test diet was calculated for each subject by multiplying the subject's estimated basal metabolic rate (BMR) by a physical activity level of 1.4. BMR was estimated using the Harris–Benedict equation [17]. The macronutrient composition of the test diet was made up of 55% of total calories from carbohydrate, 15% from protein and 30% from fat. Fifty percent of the total fat was taken from the test oil served as a mayonnaise-type food. The test diet was allocated as 30% for breakfast, 30% for lunch and 40% for dinner.

Subjects were required to consume the test diet provided by the study investigator for a 4-day period, including the chamber stay. Subjects entered the respiratory chamber at

2100 hours on day 3 and left at 0900 hours on day 5. During the 36-h stay in the respiratory chamber, subjects were served dinner at 2100 hours on day 3, breakfast at 0900 hours, lunch at 1500 hours and dinner at 2100 hours on day 4. In the respiratory chamber, subjects were required to perform two sessions of a 20-min bicycle exercise at a rate of 120 heartbeats/min at 1430 and 2030 hours. The metabolic data in the respiratory chamber were analyzed at 36-h and at 24-h after from entering the respiratory chamber at 2100 hours on day 3 to 2100 hours on day 4.

#### Anthropometrics and Body-Composition Measurement

Body weight, height and whole-body dual-energy X-ray absorptiometry (DEXA, Hologic Inc., QRD 4500 W, Waltham, MA) measurement were performed during the washout period. Measurements of fat mass (FM), fat-free mass (FFM) and body fat ratio (BFR) were made with the use of Hologic Systems Software according to procedures outlined in the Hologic QRD 4500 User's Guide. Body fat ratio (BFR) was calculated using the following equation:  $BFR (\%) = FM/(FM + FFM) \times 100$ .

#### Respiratory Chamber

The whole-room respiratory chamber was a 16-m<sup>3</sup> room with a bed, chair, desk, sink, toilet, exercise bike (Combi Wellness Co. Ltd., Tokyo, Japan), telephone, personal computer, radio and CD player. The room temperature was set at 25 °C, the humidity was set at 50% and the fresh air rate was set at 100 L/min. A fan drew mixed air (sample air) out of the chamber, while fresh air was forced into the chamber by the resulting negative pressure. The air samples were dried using a gas sampling unit (Shimadzu Corp., CPF-8000, Kyoto, Japan) and analyzed using a mass spectrometer (Thermo Fisher Scientific, VG PRIMA  $\delta$ B, Cheshire, UK), which was calibrated biweekly using standard gas (N<sub>2</sub> 78.08%, CO<sub>2</sub> 0.033%, O<sub>2</sub> 20.95% and Ar 0.934%). The flow rate exhausted from the chamber was measured by a mass flow meter (Yamatate Corp., CMQ0200J-K, Tokyo, Japan). The oxygen consumption (VO<sub>2</sub>) and carbon dioxide production (VCO<sub>2</sub>) were calculated using the method reported by Brown et al. [18]. Gas concentration was analyzed every 14 s and data were calculated every 5 min to obtain stable and accurate gas concentration. The gas concentration for 5 min was determined from the mid-point of the least square linear regression lines in this time period. The fresh air was analyzed every hour. TEE was calculated by VO<sub>2</sub> and VCO<sub>2</sub> according to the method of Weir [19]. Total Fox were calculated using the following formula [20]:

$$\text{Total Fox (g/d)} = 1.718 \times \text{VO}_2 - 1.718 \times \text{VCO}_2 - 0.315 \times P$$

The sleeping metabolic rate (SMR) was defined as the lowest mean energy expenditure over three consecutive hours between 0000 and 0800 hours [21]. *P* is protein oxidation (g/d) calculated from protein intake.

#### Oxidation Rate of Ingested Test Oil

<sup>13</sup>C-labeled diolein and triolein, used as probes for measurement of ingested test oil oxidation, were synthesized from <sup>13</sup>C-labeled oleic acid (purity of oleic acid >99%, <sup>13</sup>C >99%, Isotec Inc., OH) and free glycerol using the method described by Watanabe et al. [16] and purified with silica gel liquid chromatography. The glyceride composition of each probe was determined by gas-liquid chromatography (Table 2). The ratio of <sup>13</sup>C-labelled 1(3),2-diolein and 1,3-diolein was approximately 3:7. <sup>13</sup>C-labeled diolein or triolein at a dose of 900 mg was added to the DAG and TAG diets as a portion of breakfast at 0900 hours on day 4. Breath samples were collected into aluminum bags (GL Science Inc., Japan) before breakfast (baseline) and then hourly for a period of 8-h, and again at 10 and 15-h. Enrichment of <sup>13</sup>CO<sub>2</sub> in the breath was analyzed by isotope ratio mass spectrometry (Sercon, ANCA-GSL, UK). The oxidation rates of the <sup>13</sup>C-labeled diolein and triolein were calculated as the dose recovery rate in the breath, described by Murphy et al. [22], with some modification as follows:

$$\begin{aligned} \text{Atom}\% &= {}^{13}\text{CO}_2 / ({}^{12}\text{CO}_2 + {}^{13}\text{CO}_2) \\ &\times 100 \text{ }^{13}\text{C excretion to }^{13}\text{C administered ratio} \\ &= (\text{Atom}\%^{\text{T}} - \text{Atom}\%^{\text{B}}) / 100 \times \text{VCO}_2^{\text{T}} / (M \times 22.4) \end{aligned}$$

where Atom%<sup>B</sup> denotes the Atom% at baseline, Atom%<sup>T</sup> denotes Atom% at each time, VCO<sub>2</sub><sup>T</sup> denotes the VCO<sub>2</sub> measured by the respiratory chamber for 1 h prior to the time point of breath sample collection, and *M* denotes the molar of <sup>13</sup>C-labeled oleic acid administered in diolein or triolein. The <sup>13</sup>C dose recovery in breath (%) was measured for 15 h at each time point after the test meal ingestion. The cumulative dietary triolein or diolein oxidation was

determined from the cumulative values of  $^{13}\text{C}$  dose recovery in breath.

### Statistical Analysis

Data are presented as means  $\pm$  SD. Possible differences in TEE, RQ and total Fox between TAG treatment and DAG treatment were analyzed using a paired *t* test. At first, relationships between the differences in metabolic parameters in TAG versus DAG treatment and the subjects' body compositions were assessed by a Spearman rank correlation coefficient. The subgroup analysis was performed when significant correlation was found. Analysis of variance (ANOVA) models were generated using a PROC MIXED procedure. Repeated measures ANOVA was used to assess the effects of treatment-by-time interactions on delta from the baseline in  $^{13}\text{C}$  doses recovered in breath. Statistical analyses were performed with the SAS systems for Windows (release 8.2, SAS Institute Inc., Cary, NC).

## Results

### Subjects and Baseline Characteristics

Of the 14 subjects enrolled, 2 did not complete the study. One subject discontinued for private reasons and the other subject withdrew for medical reasons unrelated to the study treatment. Of 12 subjects who completed the study, 1 was excluded from the analysis because of menstruation in the respiratory chamber. As a result, the data of 11 subjects (6 men and 5 women) were used for the analysis. The baseline characteristics of subjects are shown in Table 3.

**Table 3** Baseline characteristics of subjects

	All	HFR	LFR
Sex (M/F)	M = 6/F = 5	M = 2/F = 4	M = 4/F = 1

### Energy Expenditure and Substrate Utilization

TEE, RQ and total Fox for 36 h are shown in Table 4. The data from all subjects showed no significant differences in TEE, RQ and total Fox for 36 h between TAG and DAG treatment. TEE in TAG and DAG treatment were 11.52  $\pm$  1.62 and 11.41  $\pm$  1.68 MJ, respectively. The energy intake for all subjects was 8.88  $\pm$  1.01 MJ during the test period per day. This value agreed with the appropriate intake as defined by the guidelines of the Ministry of Health and Welfare in Japan. The energy intake in respiratory chamber stays for 36 h was 12.43  $\pm$  1.42 MJ. Energy balance for 36 h was slightly positive in both groups and did not differ between TAG and DAG treatment (0.91  $\pm$  0.93 and 1.02  $\pm$  1.11 MJ, respectively). During the 24 h inside the respiratory chamber, TEE was 8.18  $\pm$  1.17 MJ in TAG treatment and 8.11  $\pm$  1.18 MJ in DAG treatment. TEE for 24 h did not differ between treatments. Both 36-h TEE and SMR (mean values of two nights in the chamber) positively correlated with FFM in the TAG treatment (FFM vs. 36-h TEE;  $r = 0.745$ ,  $p = 0.009$ , FFM vs. SMR;  $r = 0.718$ ,  $p = 0.013$ ). Mean RQ and total Fox for the 36-h analyses showed no significant differences between the TAG and DAG treatments (RQ; 0.867  $\pm$  0.020 and 0.870  $\pm$  0.020, total Fox; 94.4  $\pm$  29.8 and 90.3  $\pm$  29.8 g, for TAG and DAG, respectively). For 24 h, mean RQ and total Fox also showed no significant differences between TAG and DAG treatments (RQ; 0.867  $\pm$  0.020 and 0.869  $\pm$  0.023, total Fox; 66.9  $\pm$  20.8 and 64.8  $\pm$  22.3 g, for TAG and DAG, respectively).

In order to further examine the metabolic effect of DAG on fat utilization, we conducted a post-hoc subgroup analysis.  $\Delta\text{RQ}$  for each subject was calculated by subtracting the 36-h RQ in the DAG treatment from that in the TAG treatment and their correlation with various anthropometric parameters were examined. Among various parameters, a strong positive correlation of  $\Delta\text{RQ}$  in body fat ratio was found, suggesting enhanced fat utilization in the subjects with higher body fat ratio ( $r = 0.855$ ,  $p < 0.001$ , Fig. 2).

After observing this significant correlation, subgroup analyses were performed with the two subgroups divided by median of body fat ratio (24.4%): the high fat ratio (HFR) group and the low fat ratio group (LFR). The HFR group consisted of six subjects (two men and four women), and the LFR group consisted of five subjects (four men and one woman). At baseline, there were no significant differences in fat-free mass and BMI between the two subgroups (Table 3). In each subgroup, the parameters for energy metabolism were compared between TAG and DAG treatments. Mean RQ for 36 h in the HFR group was significantly lower with DAG treatment than with TAG

**Table 4** Energy expenditure and substrate utilization during 36 hours of treatment with diacylglycerol or triacylglycerol consumption

	TAG			DAG		
	All	HFR	LFR	All	HFR	LFR
TEE (MJ/36 h)	11.52 ± 1.62	11.30 ± 1.52	11.77 ± 1.87	11.41 ± 1.68	11.35 ± 1.86	11.47 ± 1.65

Total Fox (g/36 h)	94.4 ± 29.8	84.7 ± 30.3	106.1 ± 27.7	90.3 ± 29.8	91.9 ± 36.3	88.3 ± 23.7

Values are means ± SD

<sup>a</sup> Significantly lower than TAG on HFR group (paired *t* test): *p* = 0.003

**Fig. 2** Correlation of body fat rate with difference in RQ between DAG and TAG treatment.  $\Delta$ RQ for each subject was calculated by subtracting 36-h RQ in DAG treatment from that in TAG treatment. The relationships between the  $\Delta$ RQ and the subjects' body compositions were assessed by a Spearman rank correlation coefficient ( $r = 0.855$ ,  $p < 0.001$ )

treatment ( $p = 0.003$ ), but the LFR group did not show a difference between the TAG and DAG treatments (Table 4). TEE and total Fox for 36 h did not differ significantly between treatments in each subgroup.

#### Oxidation of Ingested Test Fat

Oxidation of ingested test fat was assessed for 15 h by measuring  $^{13}\text{C}$ -labeled  $\text{CO}_2$  after ingestion of  $^{13}\text{C}$  diolein or  $^{13}\text{C}$  triolein on day 4. The recovery rates of  $^{13}\text{CO}_2$  in the breath peaked at 6 h and had almost returned to baseline at 15 h ( $0.78 \pm 0.22$  and  $0.70 \pm 0.12\%$ , TAG and DAG, respectively). The cumulative recovery of  $^{13}\text{CO}_2$  in the breath of all subjects during the 15-h period is not significantly different between treatment groups ( $29.0 \pm 5.7$  and  $29.4 \pm 4.7\%$ , for TAG and DAG, respectively). Subgroup analyses were performed with the two subgroups. The cumulative values of  $^{13}\text{CO}_2$  in breath over 15 h did not differ significantly between the TAG and DAG treatments (LFR;  $32.0 \pm 4.8$  and  $29.8 \pm 3.8\%$ , HFR;  $26.6 \pm 5.5$  and  $29.1 \pm 5.8\%$ , for TAG and DAG, respectively). The time course of the cumulative recovery rate for  $^{13}\text{CO}_2$  in the

**Fig. 3** Cumulative  $^{13}\text{CO}_2$  recovery in breath over 15 h in the HFR group. Time zero corresponds to the time of [ $^{13}\text{C}$ ] enriched meal ingestion. The cumulative dietary triolein or diolein oxidation determined from cumulative values of  $^{13}\text{C}$  dose recovery in breath. Closed circles, diolein; open circles, triolein. Data are shown as means ± SD. The repeated measures ANOVA showed significant ( $p = 0.008$ ) treatment-by-time interaction in the time course for cumulative recovery of  $^{13}\text{CO}_2$  in the HFR group

HFR group is shown in Fig. 3. The repeated measures ANOVA showed significant ( $p = 0.008$ ) treatment-by-time interaction in the time course for cumulative recovery of  $^{13}\text{CO}_2$  in the HFR group.

#### Discussion

In the present study, the effect of short-term DAG treatment on energy metabolism was investigated with emphasis on the rate of ingested DAG oxidation using the combination technique of a respiratory chamber and fatty acid labeled with  $^{13}\text{C}$ -stable isotope. In the analysis of all subjects, TEE, RQ and total Fox during 36-h showed no difference between TAG and DAG treatments. Because the subjects in our study had various backgrounds, their BMI varied from 19.8 to 29.3  $\text{kg}/\text{m}^2$ , and body fat ratio varied from 18.3 to 38.7%, so the metabolic parameters were greatly influenced by the physical parameters. However, we found that the extent of reduction of RQ caused by DAG treatment had a positive correlation with the body fat

ratio of each subject (Fig. 2). In the post-hoc subgroup analysis, significantly lower RQ was observed in DAG treatment compared to TAG treatment, suggesting that DAG treatment increased fat utilization. Though the results from the post-hoc subgroup analysis provide limited evaluation, it is noteworthy that DAG oil showed an enhanced fat utilization in subjects with higher body fat ratios.

Kamphuis et al. [14] investigated the effect of DAG treatment over 36 h, determined by use of a respiratory chamber. In 12 female subjects (average body fat ratio;  $32.5 \pm 5.3\%$ ), they observed significantly lower RQ but no change in TEE in DAG treatment compared to TAG treatment. These results are consistent with those obtained from the present study with the HFR subgroup with respect to the body fat ratio of the subjects and the extent of the reduction in RQ. Indeed the reductions in RQ level in the study conducted by Kamphuis and in the present study were 0.006 and 0.005, respectively. Although the RQ measured in the respiratory chamber was affected by energy balance, by PFC balance of intake and by the subjects' own background, it is an appropriate predictor of weight loss [23, 24]. The subjects who rely less on fat oxidation have a tendency to gain weight, possibly because they are more prone to store excess energy as fat [25]. The enhanced fat utilization that occurs with DAG oil consumption changes fat balance (fat intake minus fat oxidation). Fat balance over the short-term (days), which is measured by a respiratory chamber, is possibly more closely related to energy balance over the long term (weeks or months) [26]. In the present study, we observed only the difference between DAG treatment and TAG treatment on fat utilization to explain the differences in the effect that DAG oil and TAG oil appears to have on body fat stores. Based on these results, it can be assumed that over the long term DAG oil consumption has a different effect on energy expenditure and energy intake.

Several long-term clinical trials have indicated that DAG consumption results in a loss of body weight and body fat in healthy, non-obese men and women, as well as with obese men and women. In the study with 38 male subjects conducted by Nagao et al. [7], subjects who consumed DAG over 4 months experienced 1.5 kg more reduction in body weight compared to subjects who consumed TAG. Whereas, in the present study, in the HFR subgroup, experienced a total Fox increased of 4 g/d (NS) with DAG consumption compared to TAG consumption, which estimates 0.48 kg of weight loss for 4 months based on the simple extrapolation. In addition, subjects in the present study consumed DAG approximately three-fold more than subjects in the study of Nagao et al. Taking these discrepant levels in total Fox and dosages of DAG into consideration, the increased total Fox on short-term DAG treatment observed from the present study cannot

completely explain the full-extent of weight loss reported in the study of long-term DAG consumption, suggesting that other factors may contribute to the weight loss with a long-term DAG consumption. In C57BL/6J mice, which are a model for diet-induced obesity, the small intestinal  $\beta$ -oxidation activity and mRNA expression of lipid metabolism-related molecules were markedly increased after long-term intake of DAG oil [12]. Further studies are needed to examine the relationship precisely between alteration in energy metabolism and body weight loss associated with long-term DAG consumption.

Ingested fat oxidation was investigated next, to gain further insight into the mechanism responsible for enhanced fat utilization after short-term DAG treatment. The oxidation of ingested fat was assessed using the combination technique of a respiratory chamber and  $^{13}\text{C}$ -labeled diolein or triolein. The mean  $^{13}\text{C}$ -labeled triolein oxidation over 15-h after oral administration was  $29.0 \pm 5.7\%$  in the present study. This level is similar to data reported previously [27, 28]. The rates of ingested  $^{13}\text{C}$ -labeled diolein and triolein oxidation were compared (Fig. 3). The repeated measures ANOVA showed significant ( $p = 0.008$ ) treatment-by-time interaction in the time course for cumulative recovery of  $^{13}\text{CO}_2$  in the HFR group. We found small, but significant, differences in oxidation kinetics between DAG and TAG. This rapid oxidation of ingested DAG may partly explain increased total fat utilization in DAG treatment compared to TAG treatment.

Insulin is the most potent regulator in postprandial fat metabolism through the mediation of lipoprotein lipase (LPL) and hormone-sensitive lipase (HSL) [29]. Saito et al. [15] reported lower postprandial insulin and RQ after loading with a DAG meal compared to a TAG meal. The lower postprandial insulin levels after DAG consumption compared to TAG consumption indicated a smaller stimulus in the direction of fat storage and increased postprandial fat utilization through the regulation of LPL and HSL, which may be associated with the present findings of increased total fat utilization in DAG treatment. The mechanism of pronounced fat utilization of DAG, observed only in the HFR group, is yet to be clarified, and further investigation is needed. Nagao et al. [7] reported that weight loss by long-term DAG consumption was pronounced in the subjects with higher intra-abdominal fat areas, which is partially explained by the present results in the HFR group. 1,3-DAG, a major component of DAG oil, is more susceptible to the beneficial effect against obesity compared to TAG or 1(3),2-DAG; Previous and present results suggest that 1,3-DAG might up-regulate fat utilization leading to greater  $\beta$ -oxidation in the intestine and liver, and/or via insulin action (Fig. 4).

In conclusion, TEE, RQ and total Fox for 36 h in the respiratory chamber showed no differences between DAG

**Fig. 4** Diagrammatic representation of the effects of 1,3-DAG on fat metabolism. The differential metabolic pathway of 1,3-DAG is speculated to up-regulate the fat utilization leading to the greater  $\beta$ -oxidation in intestine and liver, and/or via the insulin action. In the present study, it was shown that oxidation of ingested DAG was more rapid than that of TAG in subjects with a high body fat ratio (HFR). Simultaneously, fat utilization after a DAG meal was greater than that after a TAG meal in HFR subjects. These changes of fat utilization may reduce a body fat storage through the improvement of fat balance under free-living conditions

treatment and TAG treatment in all subjects. However, post-hoc analysis showed that oxidation of ingested DAG was more rapid than that of TAG, and that fat utilization after a DAG meal was greater than that after a TAG meal in HFR subjects. Although further analyses are needed to examine these increases in fat utilization, these changes experienced by HFR subjects may in part explain the greater loss of body weight and body fat found in weight-loss studies after DAG oil consumption.

**Abstract** The early to mid-gestational period (days 28–78) in sheep is the period of most rapid placental development. Maternal nutrient restriction (MNR) in this phase has negative consequences on fetal growth and development, predisposing the fetus to disease in adult life. The influence of MNR on fetal tissue fatty acids has not been reported. Ewes were fed to 50% (MNR) or 100% (control fed) of total digestible nutrients from days 28 to 78 of gestation. At 78 days, fetuses were sacrificed and the fatty acids in fetal liver, lung and muscle as well as maternal and fetal plasma were analyzed. Most fatty acids were not influenced by MNR. The n-3 long chain PUFA eicosapentaenoic acid (20:5n-3, EPA) concentration ( $\mu\text{g}/\text{mg}$ ) was low and more than doubled in the MNR sheep. Similarly, docosapentaenoic acid (22:5n-3, DPA) increased by 60, 19, and 38% in liver, lung, and muscle, respectively. Neither docosahexaenoic acid (22:6n-3, DHA) nor any of n-6 PUFA changed. Arachidonic acid (20:4n-6; ARA) increased in MNR maternal plasma as a percent of total fatty acids only, while

in MNR fetal plasma only EPA increased. These results provide the first indication that MNR in early to mid-gestation influences the profiles of LCPUFA in fetal tissues, and suggest that metabolic processes involving LCPUFA should be considered in evaluations of the impact of maternal nutrition on perinatal health.

## Introduction

The concept of developmental programming during fetal and neonatal life is well established. Extensive epidemiological evidence indicates that the nutritional and hormonal environment encountered by the fetus is a strong determinant of not only fetal growth but also disease risk in later life [1, 2]. These epidemiological findings are strongly supported by an increasing number of animal studies [3] indicating that fetal physiological development and organ sensitivity, including that of the lung, heart, and skeletal muscle, are significantly altered by maternal nutrient restriction (MNR). These adaptations may lead to predisposition of offspring to cardiovascular disease, type II diabetes and obesity in adult life [4–9].

Long chain polyunsaturated fatty acids (LCPUFA) have diverse roles in tissue function. Docosahexaenoic acid (DHA, 22:6n-3) and arachidonic acid (ARA, 20:4n-6) play critical roles in neurodevelopment during the perinatal period [10, 11]. LCPUFA are structural components of cell membranes and DHA is highly concentrated in brain grey matter and retina rod photoreceptors [11, 12]. Evidence from various studies suggests that retinal function and learning

ability may be permanently impaired if there is a reduction in the accumulation of sufficient DHA during intrauterine life [13, 14]. ARA is associated with normal intrauterine growth, including weight and head circumference [15]. The precursors, linoleic acid (LA, 18:2n-6) and  $\alpha$ -linolenic acid (ALA, 18:3n-3), are converted into LCPUFA by alternating desaturation ( $\Delta 6$  and  $\Delta 5$  desaturases) and chain elongation, however most studies indicate that the process is inefficient in humans and primates [16]. In addition to the well-studied ARA and eicosapentaenoic acid (EPA, 20:5n-3)-derived eicosanoids, recent studies indicate that DHA and EPA are substrates for potent bioactive compounds involved in the resolution phase of inflammation [17] and in neuroprotection [18]. Studies in rats demonstrate that n-3 LCPUFA, notably EPA and DHA, modulate the expression and repression in brain of a number of genes that are involved in structure, energy metabolism, neurotransmission, signal transduction and regulation [19–21].

The fatty acid pattern found in the walls of umbilical blood vessels suggests that the essential fatty acid status of a developing fetus is marginally sufficient [22, 23]. Supplementation of pregnant mothers with LCPUFA has been shown to improve offspring LCPUFA status [24]. However, the availability of the PUFA/LCPUFA to the fetus depends not only on the maternal dietary intake but also on the function of the placenta and the many physiological and biochemical adaptations that occur during pregnancy.

The pregnant sheep has been studied extensively to determine the effects of nutrient restriction during various periods of gestation [25]. Apart from these studies, there is a great deal of information on the influence of maternal dietary fatty acids on tissue fatty acids, particularly of the fetus. Tissue fatty acids differ in their sensitivity to diet: ARA is generally much less sensitive to diet than DHA, for instance [12]. The impact of other maternal dietary factors on fetal tissue PUFA is much less studied. Nothing is known about the influence of pure calorie restriction on fetal PUFA, and there are scant data on gene expression or related factors to guide formulation of a rational and grounded hypothesis. We therefore undertook an exploratory study to evaluate the impact of MNR on fetal fatty acids in sheep tissues. The present study was designed to determine the impact of MNR from early- to mid-gestation on profiles of fatty acids in maternal and fetal sheep to better understand the metabolism of LCPUFA in situations of maternal restriction.

## Materials and Methods

### Animals and Tissue Collection

All protocols were approved by the University of Wyoming Institutional Animal Care and Use Committee. Details of

the diet and procedures used have been published elsewhere [7] and will be summarized here. The diet is based on beet pulp solids with fatty acid composition shown in Table 1. 18:2n-6 and 18:3n-3 are the only sources of the respective essential fatty acids, and their ratio of about 9–1 is similar to that of the human western diet. The fatty acids 16:0 and 18:1n-9 make up almost 50% of the balance of the fatty acids.

On day 28 of gestation, ewes were randomly assigned to a control-fed group ( $n = 6$ ; 100% NRC requirements) and a nutrient-restricted group ( $n = 6$ ; fed 50% NRC requirements). On day 78 of gestation ewes were given an overdose of sodium pentobarbital (Abbott Laboratories, Abbott Park, IL) and exsanguinated, and fetuses were removed. Fetal organs including liver, lung and muscle and maternal and fetal plasma were stored in a  $-80^{\circ}\text{C}$  freezer until analyzed.

### Lipid Extraction and Analysis

Organ samples were processed by one step homogenization/extraction/methylation method of Garces and Mancha [26]. About 0.1 g sample was weighted and placed into a Pyrex tube. Two ml heptane, 1.4 ml of freshly made aqueous reagent (methanol: 2,2-dimethyl-3-pentanol: $\text{H}_2\text{SO}_4 = 85:11:4$  by volume) and 1.6 ml of organic reagent (heptane:toluene = 63:37 by volume) were added. Freshly prepared di-heptadecanoyl-phosphatidylcholine (Matreya, Inc Pleasant Gap, PA, USA) was also added as internal standard before extraction. After mixing the contents the tubes were stoppered and placed in a shaking water bath at  $80^{\circ}\text{C}$  for 2 h. Upon cooling, tubes are thoroughly vortexed to yield a homogeneous solution similar in appearance to tissue homogenized by a rotary blade homogenizer. Two ml of saturated NaCl are then added, and after vortexing, phase separation was accomplished by centrifugation at 3,500 rpm for 10 min. The organic layer was removed by nitrogen evaporation.

All the purified FAME was dissolved in 200  $\mu\text{l}$  heptane and stored in a  $-20^{\circ}\text{C}$  freezer until analysis.

**Table 1** Composition of selected fatty acids in maternal feed

	Mean $\pm$ SD (% w/w)
16:0	35.4 $\pm$ 3.8
Other SFA	6.5 $\pm$ 0.6
18:1n-9	12.7 $\pm$ 1.5
Other MUFA	7.1 $\pm$ 0.9
18:2n-6	30.7 $\pm$ 4.3
18:3n-3	3.4 $\pm$ 0.2
18:3 isomers	4.1 $\pm$ 0.1

Total FAME were analyzed by gas chromatography (GC) (Hewlett Packard 5890 series II GC with flame ionization detector; BPX-70 capillary column: 60 m × 0.32 mm I.D. × 0.25 μm film; SGE, Austin, TX, using H<sub>2</sub> as carrier gas). Each fatty acid was identified by GC-Covalent Adduct Chemical Ionization tandem mass spectrometry [27]. Quantitative profiles were calibrated using methyl-17:0 as an internal standard and an equal weight FAME mixture (68A; Nuchek Prep, Elysian, MN) to derive response factors for each FAME. Chromatography conditions and calibration details have been reported previously [28]. The concentration of each fatty acid from 14 to 24 carbons is expressed as μg fatty acid per mg wet tissue weight or mg fatty acid per ml plasma.

### Statistics

Data are expressed as means ± SD. Concentrations of fatty acids in differently fed groups were tested for significant

differences. A *t*-test was performed on a pairwise basis with significance declared at *P* < 0.05. Statistics were calculated using functions provided in Excel 2000 for WinXP (Microsoft, Redmond, WA). No correction for multiple comparisons was applied.

### Results

Table 2 presents weights of the fetuses and several organs. MNR reduced fetal body weight about 21%, with reductions of 16, 21, and 17% in liver, lung, and longissimus dorsi muscle weights, respectively.

Table 3 presents the maternal and fetal plasma fatty acid concentrations, expressed as mg/ml plasma; in cases in which the proportion of fatty acids as a weight percent of total (% w/w) was significant, these data are presented as well. As expected, fetal plasma had enhanced 20:4n-6 and 22:6n-3 compared to maternal plasma, as well as 20:3n-9 (Mead acid). Significant differences in plasma fatty acid concentrations were not found for any fatty acid in either compartment. A 13% decrease in 16:0 as %, w/w was found in fetal plasma due to MNR, while in maternal plasma MNR induced a 24% increase in 18:1 and a 14% decrease in 20:4n-6.

Table 4 presents the effects of MNR fetal liver, lung and skeletal muscle fatty acid composition. MNR did not induce changes in the overwhelming majority of saturated and monounsaturated fatty acid concentrations compared with control group. There was an increase of 24% in

**Fig. 1** LCPUFA composition in Control (filled square) and MNR (open square) fetal sheep tissue. **a** Liver, **b** lung, **c** muscle. \* $P < 0.05$

nervonic acid (24:1n-9) in liver and a 17% increase in the %, w/w of nervonic acid in muscle. Similar to saturates and monounsaturates, there were no changes in n-6 PUFA due to MNR in the three tissues studied.

#### MNR Did Induce Changes in n-3 PUFA

Figure 1 presents selected results for fetal tissue LCPUFA. In liver, 20:5n-3 increased more than twofold, from 0.23 to

0.51 µg/mg, while 22:5n-3 increased 60%, from 0.84 to 1.34 µg/mg. 20:5n-3 increased 2–3 fold in lung and muscle, from lower base levels, and the increases in lung and muscle 22:5n-3 concentrations were similarly attenuated, with only the lung concentration value reaching significance. The muscle 22:5n-3 %, w/w was significant. In stark contrast, 22:6n-3 was not affected by MNR and no trend in means was apparent.

#### Discussion

The literature is replete with studies showing that the fatty acid composition of various diets influence tissue fatty acid composition. In contrast, these are the first results to show that MNR of a single diet alters fatty acid composition of tissues, in this case fetal tissue. Some but not all-long chain n-3 PUFA were selectively altered but not in plasma, with no other major changes in concentrations.

Augmentation of 20:5n-3 and 22:5n-3 but not in 22:6n-3 is reminiscent of a large body of work in humans in which 18:3n-3 intake is increased through the use of supplements [16]. For supplementation of many grams of 18:3n-3 for several weeks, adult human plasma and platelet 18:3n-3, 20:5n-3, and 22:5n-3 are increased, in decreasing order of enhancement, while 22:6n-3 concentrations do not change. This pattern is also seen for breast milk of 18:3n-3 supplemented women [29]. These changes are generally regarded as health-promoting. In the present study, 18:3n-3 concentrations were too low for reliable quantitative analysis due, presumably, to rumen organism saturation of much of the incoming 18:3n-3. However, the pattern of increases in 20:5n-3 and 22:5n-3 in MNR group may be indicative of entry of 18:3n-3 into a similar desaturation/elongation pathway within the fetus. It is widely believed that the final steps in the synthesis of 22:6n-3 (and 22:5n-6) involve the translocation of 24:6n-3 and 24:5n-6 from endoplasmic reticulum to peroxisomes, where partial oxidation by acyl-CoA oxidase generates 22:6n-3 and 22:5n-6 [30]. The regulatory mechanism of these final steps is not established, but could perhaps explain why 22:6n-3 is unaffected by MNR though the upstream intermediates are increased.

Recent studies report that 50% of NRC caloric intake produced ewes with 7.4% of body weight loss during early to mid gestation [7], with fetuses markedly smaller in the restricted group than in the control group. Restricted fetuses exhibited greater right- and left-ventricular and liver weights per unit fetal weight. In addition, maternal and fetal blood glucose concentrations were reduced in MNR groups. Kwon et al. [31] demonstrated that 50% global nutrient restriction markedly reduced concentrations of total  $\alpha$ -amino acids and polyamines in the ovine

maternal and fetal plasma and in fetal allantoic and amniotic fluids at both mid and late gestation. Our data indicate that n-3 LCPUFA are also affected by MNR. The changes observed here due to nutrient restriction operated

specifically on long chain n-3 PUFA in the fetal tissues investigated and did not influence n-6 PUFA in the fetus.

The rate-limiting step in long chain PUFA synthesis is usually considered to be the initial conversion of 18:2n-6

and 18:3n-3 to 18:3n-6 and 18:4n-3 by the action of  $\Delta 6$ -desaturase [32], the product of FADS2 gene, and further synthesis of 20:3(n-6) and 20:4(n-3) requires  $\Delta 5$  desaturase [33], coded by FADS1.  $\Delta 6$  and  $\Delta 5$  desaturase activities have been shown in human fetal liver microsomes from as early as 17 weeks of gestation [34, 35].

Both  $\Delta 6$  and  $\Delta 5$  desaturases are activated by insulin and depressed by glucagon, adrenaline, and glucocorticoids [36]. A considerable body of work has explored the underlying regulatory mechanisms of desaturases and elongases [37–42]. They can be upregulated by peroxisomal proliferator-activated receptor- $\alpha$  (PPAR $\alpha$ ) and sterol-regulatory element binding protein-1 (SREBP-1). PPAR $\alpha$  was required for WY14643-mediated induction of elongase-5 (Elovl-5), Elovl-6, and  $\Delta 5$ ,  $\Delta 6$  and  $\Delta 9$  desaturases. Increased nuclear SREBP-1 is correlated with enhanced expression of Elovl-6,  $\Delta 5$ ,  $\Delta 6$  and  $\Delta 9$  desaturases.  $\Delta 6$  desaturase activity can be downregulated by glucocorticoids and by an increased abundance of LCPUFA products [32, 43, 44]. The promoter region of FADS2 ( $\Delta 6$ -desaturase) contains the response element for the ligand-activated transcription factor PPAR $\alpha$  [40]. Binding of 22:6n-3 to PPAR $\alpha$  suppresses transcription of  $\Delta 6$ -desaturase and so would be expected to down-regulate conversion of LNA to longer-chain PUFA. Nutrient restriction in sheep over the same early period of gestation that we have studied, leads to increased mRNA for PPAR $\alpha$  in fetal adipose tissue [45].

A plausible hypothesis to explain our results is that MNR-induced fetal hypoglycemia induced higher insulin secretion, which may in turn increase desaturase and elongase activities in fetal liver. These may be involved in the regulation of transcription factors, particularly PPAR $\alpha$  and SREBP-1. Decreased amino acids and inadequate energy may also participate in the activation.

20:4n-6 is the most important substrate for synthesis of highly bioactive eicosanoids that regulate many aspects of cellular and tissue metabolism. 20:4n-6 tissue concentrations are much less subject to dietary influence than the n-3 fatty acids in primates [46], and this tighter control may in part explain why the maternal and fetal plasma 20:4n-6 remained stable in MNR, and decreased as a percentage of fatty acids in maternal plasma to do so. The activated desaturases and elongases preferentially impact the n-3 PUFA production pathway leading to the increase of concentrations of 20:5n-3 and 22:5n-3 while not affecting n-6 LCPUFA concentrations. Common use of enzymes for n-3 and n-6 desaturation and elongation, as is also widely believed, does not explain why 20:5n-3 concentrations were more than doubled while 20:4n-6 was unaffected. Either the presence of family-specific (n-3 or n-6) isozymes or differential affinities of the acylation pathways could explain this result.

In conclusion, these data provide the first examination of fatty acid levels in fetal tissues and plasma of MNR ewes. The PUFA data reveal that during early- to mid-gestation, fetal n-3 PUFA are most influenced among fatty acids by nutrient restriction, and these changes do not parallel that of the ewe. Alterations PUFA metabolism in fetal development are known to induce lasting deficiencies in the CNS [47] and thus fetal programming for abnormal conditions in later life is warranted based on these results. Moreover, changes in LCPUFA profiles may provide a marker for identifying those at risk of developing adulthood disease. Knowledge obtained from the effects of restricted fetal nutrition will be useful in developing guidelines for consumption of essential fatty acids by mothers in a manner that is specific to each pregnancy (Fig. 1).

**Abstract** Oat kernels were extracted with methanol, and glycolipid-enriched fractions were prepared using silica solid phase extraction. Using direct infusion electrospray ionization (ESI) tandem mass spectrometry (MS), high performance liquid chromatography (HPLC)-ESI-MS, and HPLC-atmospheric pressure chemical ionization (APCI)-MS, we confirmed previous reports that digalactosyldiacylglycerol (DGDG) was the most abundant glycolipid in oat kernels and confirmed a previous report of the presence of a DGDG mono-estolide in oat kernels. In the current study we also identified several additional natural galactolipid estolides: two new DGDG estolides (di- and tri-estolides), two

trigalactosyldiacylglycerol (TriGDG) estolides (mono- and di-estolides), and one tetragalactosyldiacylglycerol (TetraGDG) estolide (mono-estolide). The levels of total galactolipid estolides in oat kernels were estimated to be about 29% of the total glycolipid fraction. To our knowledge, this report is the first evidence of natural di- and tri-estolides of polar lipids.

TriGDG	Trigalactosyldiacylglycerol
TriGMG	Trigalactosylmonoacylglycerol

## Introduction

Although the major lipid components of most biological membranes are phospholipids, the most abundant lipids of plant chloroplasts are the galactolipids, MGDG and DGDG [1]. In addition to their occurrence in chloroplasts, MGDG and DGDG have been observed in significant levels in oat kernels and other seeds [2]. Smaller amounts of two other galactolipids have also been detected in some plant tissues; TriGDG has been reported in wheat [3], potatoes [4], rice [5], Adzuki beans [6], and pumpkin [5, 7, 9]; TetraGDG has been reported in rice [5].

Hamberg et al. [9] previously reported that oat kernels contain significant amounts of an unusual hydroxy fatty acid, 15(*R*)-hydroxylinoleic acid (avenoleic acid), and later [10] described an unusual galactolipid containing this fatty acid in oat kernels (Fig. 1), containing this fatty acid. The galactolipid was a DGDG with 15(*R*)-hydroxylinoleic acid esterified to the sn-2 position of the glycerol and a third fatty acid esterified to the free OH on the hydroxy fatty acid (Fig. 1). This “acyl-DGDG” is a natural estolide. An estolide is formed when a hydroxy fatty acid is esterified to another fatty acid [11]. Natural estolides are rare, but natural triacylglycerol estolides have been described in the seed oils of three species of *Sebastiania* [11–13], in ergot oil [14], in *Lesquerella* oil [15], and more recently, in castor oil [16]. Synthetic estolides have been prepared from common vegetable oils [17] and from oils that contain hydroxy fatty acids such as those in *Lesquerella* and castor oil [18]. The current study employs HPLC-MS and direct infusion ESI-MS/MS to characterize additional unusual glycolipids in oat kernels and oat oil.

## Materials and Methods

### Materials

Oats (*Avena sativa* L., cv Morton) were grown in the field in Fargo, North Dakota. DGDG for HPLC standardization was purchased from Matreya, Inc., Pleasant Gap, PA.

**Fig. 1** The structure of the DGDG mono-estolide (DGDG 54:6) reported by Hamberg et al. [10]. Exact mass ( $C_{69}H_{118}O_{17}$ ), 1,218.8369 Da; average mass, 1,219.69 Da;  $m/z$  of  $[M + NH_4]^+$  ( $C_{69}H_{122}O_{17}N$ ), 1,236.8707

## Extraction of Lipids

Oat grain was dehulled with a Codema (Codema, Inc., Eden Prairie, MN) compressed air oat dehuller. Oat groats (caryopses) were steamed with a vegetable steamer for 20 min to inactivate hydrolytic enzymes. Enzyme-inactivated groats were ground with a Retsch (Haan, Germany) Z-200 centrifugal mill with a 0.5 mm collar screen. For polar lipid extraction, a sample of 10 g of flour was extracted in 50 ml of methanol in a 150 ml Corex (Corning, New York) centrifuge bottle. Solvent and flour were mixed thoroughly by vortexing and shaking the sealed bottle by hand. The bottle was centrifuged at 1,500g for 15 min to pellet particulates, and the supernatant was removed. The pellet was suspended in 20 ml methanol and shaken vigorously by hand to extract a second time. The bottle was centrifuged as before and the supernatant pooled with the first supernatant. About 15 g of sodium sulfate were added to the extract to remove traces of water, and the extract was filtered through Whatman (Middlesex, UK) #1 filter paper. Solvent was reduced to about 15 ml with a rotary evaporator, using an aspirator to draw a vacuum, with a water bath temperature of 42 °C. The remaining extract was divided into three tubes and evaporated to dryness under nitrogen, on a block evaporator at 48 °C. Samples were stored under nitrogen at –80 °C until further fractionation.

## Glycolipid Fractionation Via Solid Phase Extraction

Crude oat oil extracts (80–200 mg) were dissolved in chloroform/methanol (9:1, by vol). A silica SPE column (10 g silica in a 75 ml column) was equilibrated with chloroform, and the crude extract was applied to the column. Neutral lipids were eluted with 100 ml chloroform/acetone (4:1, by vol). Glycolipids were eluted with 100 ml acetone/methanol (9:1, by vol), and phospholipids were eluted with 100 ml methanol [19]. Solvent was removed by a rotary evaporator under the conditions described above. Several ml of acetone/methanol (9:1, by vol) were added to

each flask, and several grams of sodium sulfate were added to remove moisture. Solvent was removed by pipette and several more ml of solvent added to the flask and mixed before the solvent was removed and pooled with the first aliquot of solvent. The combined aliquots were filtered with Whatman #541 filter paper and evaporated to dryness under nitrogen, on a block evaporator at 48 °C.

Subfractions enriched in the putative Tri- and TetraGDG were generated. Thirty to one-hundred milligrams of the total glycolipid fraction (eluted with acetone/methanol (9:1, by vol) as described above) were loaded onto a silica SPE column equilibrated with chloroform. Subfraction 1 was eluted with 100 ml of chloroform/acetone (1:1, by vol). Subfraction 2, which contained primarily DGDG and its estolides, was eluted with 100 ml chloroform/acetone (1:4, by vol). Subfraction 3, which was enriched in TriGDG and TetraGDG, was eluted with acetone/methanol (9:1, by vol). Solvents were evaporated with a rotary evaporator, and samples were stored dry under nitrogen at –80 °C.

### ESI-MS/MS

An aliquot of the oat total glycolipid SPE fraction in chloroform was combined with solvents, such that the ratio of chloroform/methanol/300 mM ammonium acetate in water was 300:665:35 (by vol) and the final volume was 1 ml. This solution was introduced by continuous infusion into the ESI source on a triple quadrupole MS/MS (API 4000, Applied Biosystems, Foster City, CA), using an autosampler (LC Mini PAL, CTC Analytics AG, Zwingen, Switzerland) fitted with the required injection loop for the acquisition time, and presented to the ESI needle at 30 µl/min. The collision gas pressure was set at 1 (arbitrary units). The collision energy, with nitrogen in the collision cell, was 84 V. The declustering potential was 215 V, the entrance potential was 15 V, and the exit potential was 17 V. The mass analyzers were adjusted to a resolution of 0.7 Da full width at half height. For each spectrum, 9–150 continuum scans were averaged in multiple channel analyzer (MCA) mode. The source temperature (heated nebulizer) was 100 °C, the interface heater was on, +5.5 kV or –4.5 kV was applied to the electrospray capillary, the curtain gas was set at 20 (arbitrary units), and the two ion source gases were set at 45 (arbitrary units). DGDG species were detected by neutral loss (NL) of “341” (digalactose minus H minus H<sub>2</sub>O + NH<sub>4</sub><sup>+</sup>; NL setting, 341.13 Da) to identify the [M + NH<sub>4</sub>]<sup>+</sup> ions of DGDG and DGMG, neutral loss of “503” (trigalactose minus H minus H<sub>2</sub>O + NH<sub>4</sub><sup>+</sup>; NL setting, 503.18 Da) to identify the [M + NH<sub>4</sub>]<sup>+</sup> ions of TriGDG and TriGMG, and neutral loss of “665” (tetragalactose minus H minus H<sub>2</sub>O + NH<sub>4</sub><sup>+</sup>; NL setting, 665.24 Da) to identify the [M + NH<sub>4</sub>]<sup>+</sup> ions of TetraGDG. Sequential neutral loss

scans of the extracts produced a series of spectra with each spectrum revealing a class of lipid species containing a common head group fragment.

Multiple acyl precursor scanning in negative ion mode was combined with head group neutral loss ion scanning to identify and quantify DGDG species with specified individual acyl chains [20]. Briefly, scans of the head group (NL 341 in positive ion mode) and acyl anions (precursors of *m/z* 255.23, 277.22, 279.23, 281.25, 283.28, 295.23, 305.25, 307.26, and 309.28 in negative ion mode) were performed in the DGDG mass range (*m/z* 900–1,050). The neutral loss of 341 scan (to identify the [M + NH<sub>4</sub>]<sup>+</sup> ions of DGDG) was used to quantify the total amount of each galactolipid at each nominal mass in comparison to internal standards (DGDG 16:0/18:0 (0.49 nmol) and DGDG 18:0/18:0 (0.71 nmol)). By integrating data from the acyl precursor scans with those from the neutral loss head group scan, individual molecular species (i.e., with both acyl chains identified) were quantified.

### ESI-MS/MS Product Ion Analysis

The structures of the galactolipid species were discerned by product ion analysis in the positive mode as [M + NH<sub>4</sub>]<sup>+</sup> ions. The solvent was chloroform/methanol/300 mM ammonium acetate in water (300:665:35, by vol). The collision energy was 45 V.

### Normal-Phase HPLC, HPLC-APCI-MS, and HPLC-ESI-MS Methods for Lipid Class Analysis

Normal-phase (NP) polar lipid HPLC analyses were performed on a Hewlett Packard Model 1100 HPLC, with autosampler, and detected by both an HP Model 1100 diode-array UV-visible detector (Agilent Technologies, Avondale, PA) and a Sedex Model 55 ELSD (Richard Scientific, Novato, CA), operated at 40 °C and a nitrogen gas pressure of 2 bars. The column was a LiChrosorb, 3 mm diameter and 100 mm length, 7 micron DIOL (Chrompack, Raritan, NJ). The ternary gradient had a constant flow rate of 0.5 ml/min, with solvent A = hexane/acetic acid (1000:1, by vol), solvent B = isopropanol, and solvent C = aqueous 50 mM ammonium formate. Gradient timetable: at 0 min, 90:10:0, by vol (%A/%B/%C); at 30 min, 58:38:2, by vol; at 40 min, 12:80:8, by vol; at 50 min, 12:80:8, by vol; at 51 min, 50:50:0, by vol; at 52 min, 90:10:0, by vol; and at 60 min, 90:10:0, by vol. Using this method, the retention times of the polar lipid standards were: MGDG, 10.5 min and DGDG, 20.5 min. For HPLC-APCI-MS, the column effluent was routed into an Agilent 1100 MSD mass spectrometer operated with APCI in the positive mode in the range of *m/z* 200–2,000, with drying gas at 6.0 l/min, nebulizer pressure at 60 psi,

drying gas temperature at 350 °C, vaporizer gas temperature at 325 °C, capillary voltage of 4,000 V, corona current of 4.0  $\mu$ A, and fragmentor at 80 V. For HPLC-ESI-MS, the column effluent was routed into an Agilent 1100 MSD mass spectrometer operated with ESI in the positive mode in the range of  $m/z$  200–2,000, with the fragmentor at 5 V, drying gas at 6 l/min, nebulizing pressure at 50 psi, drying gas temperature at 300 °C, and a capillary voltage of 5,500 V.

#### Reverse-Phase HPLC and HPLC-ESI-MS Method for Lipid Class Analysis

For the reverse-phase (RP) analyses the HPLC, ELSD, and MS parameters were as described above. The column was a Prevail C18, 3 micron particle size ( $2.1 \times 150$  mm), from Alltech Associates, Northfield, IL. The binary gradient had a flow rate of 0.2 ml/min, with solvent A = methanol/water/ammonium formate (95:5:0.126, vol/vol/w), and solvent B = isopropanol. Gradient timetable: at 0 min, 100:0, by vol (%A/%B); at 5 min, 100:0, by vol; at 40 min, 60:40, by vol; at 45 min, 60:40, by vol; at 46 min, 100:0, by vol; and at 60 min, 100:0, by vol.

#### Lipid Nomenclature and Mass Description

Lipid molecular species are described as “X y:z”, where X indicates the class of galactolipid, y indicates the total number of carbon atoms in the fatty acyl moieties, and z

**Fig. 2** NP-HPLC-ELSD chromatogram of the classes of lipids in: **a** the oat total glycolipid fraction, **b** oat glycolipid subfraction 2, and **c** oat glycolipid subfraction 3

indicates the total number of carbon-carbon double bonds in the fatty acyl groups. For example, the DGDG mono-estolide previously reported [10] is abbreviated DGDG 54:6 because it is a DGDG with three 18-carbon fatty acids and a total of 6 double bonds. For clarification, nominal masses are provided in parentheses.

## Results and Discussion

#### Normal-Phase HPLC-ELSD Separation of the Oat Kernel Glycolipids Indicated the Presence of Multiple Lipid Classes

In our previous report on oat kernel lipids, the levels of DGDG and phospholipids were quantified using normal-phase HPLC with evaporative light scattering detection [2]. For the current study this HPLC method was modified by increasing the proportions of both isopropanol and water in the hexane/acetic acid/isopropanol/water system to

**Fig. 3** NP-HPLC-APCI-MS to identify classes of glycolipids in the oat total glycolipid fraction. **a** Total ion chromatogram (TIC) of the oat glycolipid fraction when separated in NP-HPLC-APCI-MS in the positive ion mode, **b** spectrum of the peak at 24.7 to 26.9 min in **a**, which has the same retention time as commercial DGDG, **c** spectrum of the peak at 23.3 to 24.7 min in **a**, which is tentatively identified as DGDG mono-estolide (Fig. 1), and **d** spectrum of the peak at 21.8 to 23.3 min in **a**, which is tentatively identified as DGDG di-estolide

**Fig. 4** Fragmentation of DGDG and neutral loss scans identifying digalactosyl acylglycerol species in the oat glycolipid SPE fraction. **a** Product ion spectrum of DGDG 36:4 [M + NH<sub>4</sub>]<sup>+</sup> ion at *m/z* 958 (nominal mass). **b–f** Scans of neutral loss of 341, showing **b** DGMG species, **c** DGDG species, **d** DGDG mono-estolide species, **e** DGDG di-estolide species, and **f** DGDG tri-estolide species

potentially permit the separation of very polar glycolipids (Fig. 2). As expected, DGDG (identified by co-chromatography with commercial DGDG standard) eluted at 20 min and was the major class of lipid detected in the total glycolipid fraction obtained by SPE (Fig. 2a). A smaller peak eluting at 19 min was proposed to be the DGDG mono-estolide previously reported [10]. A very small peak eluted at 18 min; its retention time suggested that it may be a DGDG di-estolide. Two other groups of peaks also appeared in the regions of 26–30 min and 35–39 min, and based on their retention times as compared with those

determined in previous analyses of more polar glycolipids in other plants [3–8], their structures were postulated to be TriGDG and TetraGDG, respectively. NP-HPLC-ELSD analyses of two glycolipid subfractions, also prepared by SPE, indicated that subfraction 2 contained higher levels of the 26–30 min series of peaks (Fig. 2b), and in subfraction 3, these unknown peaks in the region of 26–30 min were the major components (Fig. 2c). The small putative TetraGDG peaks in the region of 35–39 min in the total glycolipid fraction (Fig. 2a) were also present in glycolipid subfraction 2 (Fig. 2b) and subfraction 3 (Fig. 2c).

**Table 1** The fatty acyl combinations that make up the DGDG species were identified by multiple acyl precursor scanning in negative ion mode, in combination with neutral loss head group scanning in positive ion mode

DGDG species	% of total DGDG	Acyl species
DGDG 32:0	0.7	16:0/16:0
DGDG 34:3	3.2	16:0/18:3 (79%) > 16:1/18:2
DGDG 34:2	26.3	16:0/18:2 (99+%) > 16:1/18:1
DGDG 34:1	10.3	16:0/18:1 (99+%) > 16:1/18:0
DGDG 36:6	0.6	18:3/18:3
DGDG 36:5	4.8	18:3/18:2
DGDG 36:4	31.7	18:2/18:2 (94%) > 18:3/18:1 > 16:1/20:3
DGDG 36:3	9.6	18:2/18:1 (97%) > 16:0/20:3 > 18:3/18:0 > 16:1/20:2
DGDG 36:2	8.8	18:1/18:1 (79%) > 18:2/18:0 (21%) > 16:0/20:2
DGDG 36:1	0.8	18:1/18:0 (96%) > 16:0/20:1
DGDG 36:5-OH	0.1	18:3/18:2-OH (51%)
DGDG 36:4-OH	1.0	18:2/18:2-OH (97%)
DGDG 36:3-OH	0.2	18:1/18:2-OH (91%)

**Fig. 5** Product ion spectrum of DGDG 52:4,  $m/z$  1212 (nominal mass), a DGDG mono-estolide species containing the fatty acids 18:2, 16:0 and 18:2-OH

#### Identification of DGDG, DGDG Mono-Estolide and DGDG Di-Estolide Using Normal-Phase HPLC-APCI-MS

APCI-MS was employed previously for the structural characterization of DGDG and other glycolipids in red bell pepper [21]. In that study, the major ions observed were fragments attributed to loss of digalactose (i.e., protonated diacylglycerol (DAG)) and loss of digalactose and one fatty acid (i.e., protonated monoacylglycerol); the precursor DGDG ions were observed to be of low intensity. Using an NP-HPLC system similar to the one in the previous experiment, APCI-MS in the positive mode was used to obtain structural information about the three DGDG peaks identified in Fig. 2a. In this experiment (Fig. 3a), the HPLC conditions described in our previous report were used [2], and DGDG eluted at about 26 min, whereas it eluted at about 20 min under the conditions used in the analyses depicted in Fig. 2. The major peaks in the APCI-MS spectrum of the putative DGDG peak (Fig. 3b) were in the mass range consistent with DAG ions. The APCI-MS spectra of the putative mono-estolide (Fig. 3c) and di-estolide DGDG (Fig. 3d) species contained ions consistent

with loss of digalactose from each species, leaving fragments consistent with protonated DAG mono- and di-estolides, respectively. Thus, the APCI data (Fig. 3) support the tentative identifications of the three peaks (Fig. 2a), but stronger evidence was sought to confirm the identifications.

#### ESI-MS/MS Neutral Loss Scanning Reveals Digalactosyl Acylglycerol Molecular Species

Precursor or neutral loss scanning by ESI-MS/MS can be utilized to identify the lipid species within a lipid class [22]. ESI-MS/MS is the main tool employed in the new field of “lipidomics” and has been employed to characterize the “lipidome” of humans, other animals, and plants [20, 23–26]. Figure 4a shows that, in the positive mode, in solvent containing ammonium acetate, DGDG species underwent neutral loss of ammoniated digalactose minus  $H_2O$  (NL 341; the neutral fragment is  $C_{12}H_{23}O_{10}N$ ) or ammoniated digalactose (NL 359; the neutral fragment is  $C_{12}H_{25}O_{11}N$ ). Specifically, the ammoniated precursor ion of DGDG 36:4 at  $m/z$  958.6 (958) underwent neutral loss of 341 or 359 to produce the fragments observed at  $m/z$  617.7 (617) and  $m/z$  599.7 (599). (Loss of an “ammoniated digalactose minus  $H_2O$ ” is equivalent to the loss of the ammoniated digalactose with the bridging oxygen left behind as a glycerol hydroxyl group.) In this product ion spectrum, the peak at  $m/z$  337.4 (337) was a protonated 18:2 esterified to glycerol minus  $H_2O$  ( $C_{21}H_{37}O_3$ ), indicating that the major molecular species of DGDG 36:4 was DGDG 18:2/18:2. Small peaks at  $m/z$  335 (nominal) and  $m/z$  339 (nominal) correspond to analogous acylglycerol fragments, indicating that DGDG 36:4 contained a smaller amount of DGDG 18:3/18:1.

To elucidate the varied digalactosyl acylglycerol species in the glycolipid SPE extract, NL 341 scans were utilized

**Fig. 6** Proposed structures of ammoniated DGDG 52:4 mono-estolide,  $m/z$  1212 (nominal mass), and CID fragments at  $m/z$  615, 573, 591, and 597 (nominal mass), based on structures demonstrated for triacylglycerol and phosphatidylethanolamine [27, 28]. Please note that, although we have indicated the glycerol carbons by C<sub>1</sub>, C<sub>2</sub>, and C<sub>3</sub>, we have no information to indicate esterification to specific glycerol positions. We also do not know the position of carbon-carbon double bonds. **a** DGDG 52:4, with 16:0 and 18:2-OH/18:2 esterified

to glycerol. **b** DGDG 52:4, with 18:2 and 18:2-OH/16:0 esterified to glycerol. **c** Fragment resulting from loss of ammoniated digalactose and 16:0 from structure in **a**. **d** Fragment resulting from loss of ammoniated digalactose and 18:2 from structure in **a**. **e** Fragment resulting from loss of ammoniated digalactose and 18:2 from structure in **b**. **f** Fragment resulting from loss of ammoniated digalactose and 16:0 from structure in **b**

(Fig. 4b–f). These spectra depict the molecular species of DGDG and provide the total number of acyl carbons: total number of carbon-carbon double bonds. Figure 4b shows the NL 341 scan in the mass range corresponding to DGMG species; these peaks represent species with only one acyl moiety per molecule. To identify the individual acyl chains associated with the non-estolide DGDG class, as depicted in Fig. 4c, multiple acyl precursor scanning in

the negative ion mode [20], in combination with quantitative analysis of the DGDG class via the NL 341 scan in the positive mode, was carried out (Table 1). Hydrogenated DGDG species were used as internal standards. The data indicate that two DGDG species, 16:0/18:2 and 18:2/18:2 accounted for over half of the DGDG. A little over 1% of the DGDG (non-estolide) species contained 18:2-OH, consistent with the presence of 15(*R*)-hydroxylinoleic acid (avenoleic acid) [9, 10].

**Fig. 7** Product ion spectrum of DGDG 70:6,  $m/z$  1,490 (nominal mass), a DGDG di-estolide species containing the fatty acids 18:2, 16:0 and 2 18:2-OH species

Figure 4d–f shows that NL 341 scanning of the glycolipid SPE extract produced mass spectral peaks consistent with the identification of mono-, di-, and tri-estolides, respectively. Product ion spectra of specific mono-, di-, and tri-estolides of DGDG also were consistent with these identifications. The spectra suggest that some estolides are made up of multiple isomeric species. Figure 5 shows the product ion spectrum of the compound tentatively identified as DGDG 52:4, a DGDG mono-estolide species containing the fatty acids 18:2, 16:0 and 18:2-OH. The ammoniated DGDG 52:4  $[M + NH_4]^+$  ion at  $m/z$  1212 (nominal, not visible in figure) underwent neutral loss to

**Fig. 8** Product ion spectrum of DGDG 88:8,  $m/z$  1,768 (nominal mass), a DGDG tri-estolide species containing the fatty acids 18:2, 16:0 and 3 18:2-OH species

$m/z$  871.9 (871) or 853.8 (853). These species are likely to be due to loss of an ammoniated digalactose minus  $H_2O$  ( $C_{12}H_{23}O_{10}N$ ; 341 Da) or an ammoniated digalactose ( $C_{12}H_{25}O_{11}N$ ; 359 Da). The low abundance peak observed at  $m/z$  871.9 (871) is likely to represent a protonated diacylglycerol mono-estolide containing the fatty acids 18:2, 16:0, and 18:2-OH. The more abundant fragment at  $m/z$  853.8 (853) is likely to depict a conventional diacylglycerol-like fragment that lost the bridging oxygen during collision-induced dissociation (CID) [27, 28]. The peaks observed at  $m/z$  615.7 (615) and 597.7 (597) contain

**Fig. 9** Fragmentation of TriGDG and neutral loss scans identifying trigalactosyl acylglycerol species. **a** Product ion spectrum of TriGDG 36:4 [ $M + NH_4$ ] $^+$  ion at  $m/z$  1,120 (nominal mass). **b–e** Scans of neutral loss of 503, showing **b** TriGMG species, **c** TriGDG species, **d** TriGDG mono-estolide species, and **e** TriGDG di-estolide species

**Fig. 10** Neutral loss scans identifying tetralactosyldiacylglycerol species. TetraGDGs are identified in scans for neutral loss of an ammoniated tetralactose minus  $\text{H}_2\text{O}$  ( $\text{C}_{24}\text{H}_{43}\text{O}_{20}\text{N}$ ; 665 Da). Scans of neutral loss of 665, showing **a** TetraGDG species and **b** TetraGDG mono-estolide species

glycerol, one 18:2-OH, and one 18:2 fatty acid; the 16:0 fatty acid has been lost. These two peaks differ only in the amount of dehydration (1 dehydration for 615; 2 for 597). The peaks at  $m/z$  591.7 (591) and 573.8 (573) likely represent fragments with glycerol, one 18:2-OH, and one 16:0 fatty acid; the 18:2 fatty acid has been lost. Again, these two peaks differ only in the amount of dehydration (1 dehydration for 591; 2 for 573). These four peaks may depict fragments originating from two different isomers of the DGDG 52:4 mono-estolide species. Figure 6 shows two possible structures for DGDG 52:4, one with 16:0 and an 18:2-OH/18:2 linked moiety each esterified to the glycerol (Fig. 6a). Another possible structure has 18:2 and an 18:2-OH/16:0 linked moiety each esterified to the glycerol (Fig. 6b). When the ammoniated digalactose head group and one fatty acid are lost during CID, the resulting structures can be stabilized by cyclization, by analogy to the structures produced during CID of triacylglycerols and phosphatidylethanolamines [27, 28], resulting in different apparent amounts of dehydration (Fig. 6c–f). Loss of the 16:0 esterified to glycerol, along with the head group, from the structure in Fig. 6a, can produce the ion seen at  $m/z$  615.7 (615; Figs. 5, 6c). Loss of the 18:2 esterified to 18:2-OH, along with the head group, from the same structure (Fig. 6a) can produce the ion seen at  $m/z$  573.8 (573; Figs. 5, 6d). The DGDG 52:4 isomer shown in Fig. 6b can fragment during CID in the same manner. Loss of the glycerol-esterified fatty acid, 18:2, along with the head group, can produce the ion seen at  $m/z$  591.7 (591; Figs. 5, 6e). Loss of the 18:2-OH-esterified fatty acid, 16:0, along with the head group, can produce the ion seen at  $m/z$  597.7 (597; Figs. 5, 6f). In comparing Fig. 6c with 6f or 6e with 6d, loss of ammoniated digalactose + loss of a fatty acid from the glycerol backbone results in one apparent dehydration, whereas loss of ammoniated digalactose + loss of the same fatty acid from the 18:2-OH-esterified position results in two apparent dehydrations. The peak observed in Fig. 5 at  $m/z$  337.4 (337) is tentatively identified as

protonated 18:2 esterified to glycerol minus  $\text{H}_2\text{O}$  ( $\text{C}_{21}\text{H}_{37}\text{O}_3$ ). The peak observed at  $m/z$  335.4 (335) appears to correspond to protonated 18:2-OH esterified to glycerol minus 2  $\text{H}_2\text{O}$  ( $\text{C}_{21}\text{H}_{35}\text{O}_3$ ), while the peak at  $m/z$  313.4 (313) most likely represents protonated 16:0 esterified to glycerol minus  $\text{H}_2\text{O}$  ( $\text{C}_{19}\text{H}_{37}\text{O}_3$ ). Again, these products are likely to have been cyclized, by analogy to structures formed in phosphatidylethanolamine fragmentation [28]. The presence in the spectrum of peaks representing each of the three fatty acids esterified to the glycerol is also consistent with DGDG 52:4 being a mixture of DGDG 16:0/18:2-O-18:2 (Fig. 6a) and DGDG 18:2/18:2-O-16:0 (Fig. 6b). The larger size of the peak at  $m/z$  313.4 (313; acylglycerol 16:0 minus  $\text{H}_2\text{O}$ ) as compared to the peak at  $m/z$  337.4 (337; acylglycerol 18:2 minus  $\text{H}_2\text{O}$ ) suggests that DGDG 16:0/18:2-O-18:2 was likely the more abundant species.

Figure 7 shows the product ion spectrum of putative DGDG 70:6, a DGDG di-estolide species containing the fatty acids 18:2, 16:0 and two 18:2-OH species. The ammoniated 70:6 DGDG  $[\text{M} + \text{NH}_4]^+$  ion observed at  $m/z$  1,491.1 (1,490) underwent neutral loss of 341 or 359 Da, like the mono-estolide, to yield the small peak at  $m/z$  1,149 (nominal) and the larger peak observed at  $m/z$  1,132.1 (1,131). The  $m/z$  1,149 (nominal) peak represents loss of an ammoniated digalactose minus  $\text{H}_2\text{O}$  ( $\text{C}_{12}\text{H}_{23}\text{O}_{10}\text{N}$ ; 341 Da), leaving a protonated diacylglycerol di-estolide. Loss of the intact digalactosyl moiety (NL 359) formed a conventional diacylglycerol-like fragment ion at  $m/z$  1,132.1 (1,131) [27, 28]. The peak observed at  $m/z$  893.8 (893), by analogy to the proposed structures for DGDG 52:4 detailed above in Fig. 6, most likely represents a protonated mono-acylglycerol di-estolide, with two 18:2-OH groups and one 18:2 minus 1  $\text{H}_2\text{O}$ ; 16:0, along with the head group, was lost from the glycerol backbone. The peak at  $m/z$  875.9 (875) probably represents its isomer, a protonated diacylglycerol mono-estolide. The 16:0 fatty acid was most likely lost from an 18:2-OH linkage, resulting in an additional

**Fig. 11** NP-HPLC chromatograms of the oat total glycolipid SPE fraction. **a** NP-HPLC-ELSD chromatogram, **b** positive ESI TIC,  $m/z$  200–2,000, **c** EIC of  $m/z$  958.6, a major DGDG non-estolide, DGDG 36:4, **d** EIC of  $m/z$  1,236.9, a major DGDG mono-estolide, DGDG 54:6, **e** EIC of  $m/z$  1,515.1, a major DGDG di-estolide, DGDG 72:8, **f** EIC of  $m/z$  1,793.4, a major DGDG tri-estolide, DGDG 90:10 (The arrow indicates the possible location of this very small peak), **g** EIC of  $m/z$  1,120.8, a major TriGDG non-estolide, TriGDG 36:4, and **h** EIC of  $m/z$  1,399.1, a major TriGDG mono-estolide, TriGDG 54:6

dehydration. Likewise, the peaks at  $m/z$  869.9 (869) and 851.9 (851) are likely to represent separate isomers of protonated glycerol esterified with two 18:2-OH and one 16:0, with one or two dehydrations, respectively. The peaks in the range  $m/z$  573 to 615 represent additional acyl losses. The peaks at  $m/z$  615.6 (615) and 597 (nominal) are consistent with protonated 18:2 and 18:2-OH esterified to glycerol, with the higher mass ion representing a protonated monoacylglycerol mono-estolide minus 1  $H_2O$  and the lower mass ion representing a protonated diacylglycerol minus 2  $H_2O$ . The peaks at  $m/z$  613.6 (613) and 595 (nominal) are likely to represent protonated fragments with two 18:2-OH fatty acids esterified to glycerol with 2 or 3 dehydrations. The peaks at  $m/z$  591.7 (591) and 573.7 (573) are tentatively identified as protonated 16:0 and 18:2-OH esterified to glycerol minus 1 and 2  $H_2O$ , respectively. On the other hand, the peak at  $m/z$  559.7 (559) may represent a free fatty acid protonated mono-estolide made up of 18:2-OH and 18:2. The peak at  $m/z$  337 is likely to correspond to protonated 18:2 esterified to glycerol minus  $H_2O$  ( $C_{21}H_{37}O_3$ ). The peak at  $m/z$  335 may represent protonated 18:2-OH esterified to glycerol minus 2  $H_2O$  ( $C_{21}H_{35}O_3$ ), while the peak at  $m/z$  313 is probably protonated 16:0 esterified to glycerol minus  $H_2O$  ( $C_{19}H_{37}O_3$ ). These data indicate that DGDG 70:6 most likely was a mixture of

**Table 2** Identification of the major galactolipids and estolides in oats and their abbreviations and ammoniated ion masses

Galactolipid molecular species	Abbreviation	$m/z$ of $[M + NH_4]^+$
DGDG	DGDG 34:2	934.6

**Fig. 12** RP-HPLC chromatograms of the oat total glycolipid SPE fraction. **a** RP-HPLC-ELSD chromatogram, **b** positive ESI TIC,  $m/z$  200–2,000, **c** EIC of  $m/z$  958.6, a major DGDG non-estolide, DGDG 36:4, **d** EIC of  $m/z$  934.6, a major DGDG non-estolide, DGDG 34:2, **e** EIC of  $m/z$  936.6, a major DGDG non-estolide, DGDG 34:1, **f** EIC of  $m/z$  974.6, a major DGDG non-estolide with a free hydroxyl group, DGDG 36:4-OH (The peaks marked by the arrows are both candidates for authentic DGDG 36:4-OH; the identity of the lipids in the large broad peak at 40–55 min is unknown.), **g** EIC of  $m/z$  1,236.9, a major DGDG mono-estolide, DGDG 54:6, **h** EIC of  $m/z$  1,515.1, a major DGDG di-estolide, DGDG 72:8, and **i** EIC of  $m/z$  1,793.4, a major DGDG tri-estolide, DGDG 90:10

isomers, including DGDG 16:0/18:2-O-18:2-O-18:2 and DGDG 18:2/18:2-O-18:2-O-16:0. The presence of additional arrangements of the fatty acids, such as 18:2-O-18:2/18:2-O-16:0, cannot be ruled out by these data.

Similarly, Fig. 8 shows the product ion spectrum of the peak tentatively assigned as DGDG 88:8, a DGDG tri-estolide species containing the fatty acids 18:2, 16:0 and three 18:2-OH species. The ammoniated DGDG 88:8  $[M + NH_4]^+$  ion at  $m/z$  1,769.4 (1,768) underwent neutral loss to the peaks observed at  $m/z$  1,410.3 (1,409) and 1,427 (nominal). These probably represent loss of an ammoniated digalactose (NL 359) and an ammoniated digalactose minus  $H_2O$  (NL 341). Thus, the peak at 1,410.3 (1,409) lost the bridging glycerol-galactose oxygen and is probably a conventional diacylglycerol-like fragment [27, 28]. The peaks at  $m/z$  1,171.6 (1,171) and 1,153.8 (1,153) are likely to represent a protonated monoacylglycerol tri-estolide with one dehydration and a protonated diacylglycerol di-estolide with two dehydrations, respectively, with three 18:2-OH groups and one 18:2 each, by analogy to the proposed structures for DGDG 52:4 in Fig. 6. The peaks observed at  $m/z$  1,147 (nominal) and 1,130.2 (1,129) probably reflect protonated glycerol esterified with three 18:2-OH and one 16:0 minus 1 or 2  $H_2O$ . The peaks in the range  $m/z$  851.7 (851) to 893 (nominal) represent additional acyl losses. The small peak at  $m/z$  893 (nominal) represents a protonated fragment with two 18:2-OH and one 18:2 esterified to glycerol minus  $H_2O$ . The peaks at  $m/z$  891.8 (891) and 873 (nominal) are likely to represent a protonated fragment with three 18:2-OH esterified to glycerol with either 2 or 3 dehydrations. The peaks observed at  $m/z$  869.9 (869) and 851.7 (851) probably are protonated 16:0 and two 18:2-OH esterified to glycerol minus 1 or 2  $H_2O$ . On the other hand, the peak at  $m/z$  837.9 (837) may represent a free fatty acid protonated di-estolide species made up of two 18:2-OH and 18:2. The peaks in the range  $m/z$  573.5 (573) to 615.7 (615) represent further acyl losses leading to species with two acyl chains. The peaks at  $m/z$  615.7 (615) and 597 (nominal) probably represent protonated 18:2 and 18:2-OH esterified to glycerol, either a protonated monoacylglycerol mono-estolide with one dehydration or a protonated diacylglycerol with two

dehydrations, respectively. The peaks at  $m/z$  613.6 (613) and 595 (nominal) are consistent with a protonated fragment with two 18:2-OH esterified to glycerol with 2 or 3

**Fig. 13** RP-HPLC chromatograms of the oat total glycolipid SPE subfraction 2, enriched in DGDG and TriGDG. **a** RP-HPLC-ELSD chromatogram, **b** positive ESI TIC,  $m/z$  200–2,000 (The retention times of the three major non-estolide DGDG peaks previously identified in Fig. 12c–e were labeled with arrows), **c** EIC of  $m/z$  1,120.8, a major TriGDG non-estolide, TriGDG 36:4, **d** EIC of  $m/z$  1,096.7, a major TriGDG non-estolide, TriGDG 34:2, **e** EIC of  $m/z$  1,136.7, a major TriGDG non-estolide with a free hydroxyl group, TriGDG 36:4-OH, **f** EIC of  $m/z$  1,399.1, a major TriGDG mono-estolide, TriGDG 54:6, **g** EIC of  $m/z$  1,677.4, a major TriGDG di-estolide, TriGDG 72:8, and **h** EIC of  $m/z$  1,282.9, a major TetraGDG non-estolide, TetraGDG 36:4

peak at  $m/z$  335 is protonated 18:2-OH esterified to glycerol minus 2  $H_2O$  ( $C_{21}H_{35}O_3$ ), while the peak at  $m/z$  313 is probably protonated 16:0 esterified to glycerol minus  $H_2O$  ( $C_{19}H_{37}O_3$ ). These data imply that the tentatively assigned DGDG 88:8 was a mixture of isomers, including DGDG 16:0/18:2-O-18:2-O-18:2-O-18:2 and DGDG 18:2/18:2-O-18:2-O-18:2-O-16:0. Again, the presence of additional arrangements of the fatty acids, such as 18:2-O-18:2/18:2-O-18:2-O-16:0, cannot be ruled out by these data.

#### ESI-MS/MS of Trigalactosyldiacylglycerol and Tetragalactosyldiacylglycerol Species

The product ion spectrum shown in Fig. 9a indicates that, in the positive mode, in solvent containing ammonium acetate, putative TriGDG species underwent a neutral loss of ammoniated trigalactose minus  $H_2O$  (NL 503). Specifically, the ammoniated precursor ion of TriGDG 36:4 at  $m/z$  1,120.6 (1,120) underwent neutral loss to  $m/z$  617.7 (617). The observed fragment is consistent with loss of an ammoniated trigalactose minus  $H_2O$  ( $C_{18}H_{33}O_{15}N$ ; 503 Da). The peak observed at  $m/z$  337.4 (337) is a protonated 18:2 esterified to glycerol minus  $H_2O$  ( $C_{21}H_{37}O_3$ ), indicating that the major molecular species of TriGDG 36:4 was TriGDG 18:2/18:2. Peaks at  $m/z$  335 (nominal) and 339 (nominal) correspond to analogous acylglycerol fragments indicating that TriGDG 36:4 contains a smaller amount of TriGDG 18:3/18:1. Scanning for NL 503 (Fig. 9b–e) can be used to identify TriGMGs, TriGDGs, TriGDG mono-estolides, and TriGDG di-estolides, respectively. Similarly, in the positive mode, in solvent containing ammonium acetate, TetraGDGs underwent a neutral loss of ammoniated tetragalactose minus  $H_2O$  (NL 665), and scanning for NL 665 displays species of TetraGDG and TetraGDG mono-estolide (Fig. 10a, b).

#### Normal-phase HPLC-ESI-MS Evidence for the Structural Identification of Glycolipids and their Estolides in the Oat Total Glycolipid Fraction

Based on the numerous glycolipids and estolides that were identified by ESI-MS/MS (Figs. 4, 5, 7, 8, 9, 10), we used

dehydrations. The peak at  $m/z$  591.7 (591) and that observed at  $m/z$  573.5 (573) are likely to show protonated 16:0 and 18:2-OH esterified to glycerol minus 1 or 2  $H_2O$ . The peak at  $m/z$  557.5 (557) may represent a free fatty acid protonated mono-estolide species made up of two 18:2-OH minus  $H_2O$ . The peak at  $m/z$  337 is likely to be protonated 18:2 esterified to glycerol minus  $H_2O$  ( $C_{21}H_{37}O_3$ ). The

NP-HPLC-ESI-MS to try to identify some of the same lipids. The HPLC-ELSD chromatogram is shown in Fig. 11a. To assist in this evaluation, the major  $[M + NH_4]^+$  ions identified in Figs. 4, 9, and 10 are listed in Table 2, and we searched for these “extracted ions” in the NP-HPLC-ESI-MS total ion chromatogram (TIC)

◀ **Fig. 14** RP-HPLC chromatograms of the oat total glycolipid SPE subfraction 3, enriched in TriGDG and TetraGDG. **a** RP-HPLC-ELSD chromatogram, **b** positive ESI TIC,  $m/z$  200–2,000, **c** EIC of  $m/z$  1,282.9, a major TetraGDG non-estolide, TetraGDG 36:4 (The probable retention time of authentic TetraGDG 36:4 was identified with an *arrow*; the identity of the lipids in the multiple peaks at 35–45 min is unknown.), **d** EIC of  $m/z$  1,120.8, a major TriGDG non-estolide, TriGDG 36:4, **e** EIC of  $m/z$  1,096.7, a major TriGDG non-estolide, TriGDG 34:2, **f** EIC of  $m/z$  1,136.7, a major TriGDG non-estolide with a free hydroxyl group, TriGDG 36:4-OH, **g** EIC of  $m/z$  1,399.1, a major TriGDG mono-estolide, TriGDG 54:6, and **h** EIC of  $m/z$  1,677.4, a major TriGDG di-estolide, TriGDG 72:8

(Fig. 11b); the results are plotted as “extracted ion chromatograms” (EIC) (Fig. 11c–h). Early attempts to employ ESI produced very few ions, and it was only after we added ammonium formate to the mobile phase that we started to obtain good ESI spectra. After we began routinely including ammonium formate in our mobile phase, the  $[M + NH_4]^+$  ions were present in the greatest abundance (we saw very little of the  $[M + H]^+$  and  $[M + Na]^+$  ions), so we focused our attention on  $[M + NH_4]^+$ . Even with ammonium formate, the TIC for the normal-phase separation contained a very high background (Fig. 11b). However, by examining the EICs, we were able to identify peaks that corresponded to the major  $[M + NH_4]^+$  ions of: non-estolide DGDG (DGDG 36:4) (Fig. 11c), DGDG mono-estolide (DGDG 54:6) (Fig. 11d), DGDG di-estolide (DGDG 72:8) (Fig. 11e), DGDG tri-estolide (DGDG 90:10) (Figure 11f, with an arrow indicating the possible location of this very small peak, which is consistent with the expected retention time for this hydrophobic DGDG estolide), non-estolide TriGDG (TriGDG 36:4) (Fig. 11g), and TriGDG mono-estolide (TriGDG 54:6) (Fig. 11h).

#### Reverse-Phase HPLC-ESI-MS Evidence for the Structural Identification of Glycolipids and their Estolides in the Oat Total Glycolipid Fraction

RP-HPLC-ESI-MS was also employed to identify the glycolipids and their estolides determined above by ESI-MS/MS. The HPLC-ELSD chromatogram is shown in Fig. 12a. The major difference that was observed when switching to the reverse phase HPLC method was that the reverse phase TIC (Fig. 12b) contained much less background noise than the comparable normal phase TIC (Fig. 11b). Examination of the EICs revealed several large sharp peaks that corresponded to the major  $[M + NH_4]^+$  ions of: four non-estolide DGDGs (DGDG 36:4, 34:2, 34:1, and 36:4-OH) (Fig. 12c–f), DGDG mono-estolide (DGDG 54:6) (Fig. 12g), DGDG di-estolide (DGDG 72:8) (Fig. 12h), and DGDG tri-estolide (DGDG 90:10) (Fig. 12i). The putative DGDG 34:1 EIC (Fig. 12e) likely shows both an A + 2 isotope peak of the more abundant DGDG 34:2 (coeluting with DGDG 34:2, Fig. 12d) and

**Fig. 15** Proposed structures of: **a** a DGDG di-estolide (DGDG 72:8) identified in this study by HPLC-MS and MS/MS. Exact mass ( $C_{87}H_{148}O_{19}$ ), 1,497.0615 Da;  $m/z$  of  $[M + NH_4]^+$  ( $C_{87}H_{152}O_{19}N$ ), 1,515.0953. **b** A DGDG tri-estolide (DGDG 90:10) identified in this study by HPLC-MS and MS/MS. Exact mass ( $C_{105}H_{178}O_{21}$ ), 1,775.2861 Da;  $m/z$  of  $[M + NH_4]^+$  ( $C_{105}H_{182}O_{21}N$ ), 1,793.3199. In these figures the estolide is shown esterified to the sn-2 position of glycerol, as suggested by Hamberg [10], but our data do not preclude the possibility that some or all of the estolides may be esterified at sn-1

DGDG 34:1, eluting slightly later. The EIC for DGDG 36:4-OH shows two sharp peaks (Fig. 12f). The location of the peaks is consistent with the notion that the presence of an extra OH would cause DGDG 36:4-OH to elute early in RP-HPLC, but it is not clear which peak is DGDG 36:4-OH, nor is the identity of the lipids in the large broad peak at 40–55 min in Fig. 12f known.

#### Reverse-Phase HPLC-ESI-MS Evidence for the Structural Identification of Glycolipids and their Estolides in the Oat Glycolipid Subfraction 2

As noted previously, oat glycolipid subfraction 2 contained high levels of DGDG and moderate levels of the putative TriGDG peaks (eluting at 26–30 min in Fig. 2). The RP-HPLC-ELSD chromatogram (Fig. 13a) and RP-HPLC-ESI-MS-TIC (Fig. 13b) revealed peaks at 10–20 min that appeared to correspond to non-estolides and peaks at about 20–40 min that corresponded to estolides. The retention times of the three major non-estolide DGDG peaks previously identified in Fig. 12c–e were labeled with arrows in

Fig. 13b. The EICs revealed peaks that were tentatively identified as the major  $[M + NH_4]^+$  ions of: non-estolide TriGDGs 36:4, 34:2, and 36:4-OH (Fig. 13c–e), TriGDG mono-estolide (TriGDG 54:6) (Fig. 13f), and TriGDG di-estolide (TriGDG 72:8) (Fig. 13g). It is unknown which early-eluting peak corresponds to TriGDG 36:4-OH in Fig. 13e. The EIC for  $m/z$  1,282.9, corresponding to TetraGDG 36:4 (Fig. 13h), revealed weak peaks at about 9 (marked) and 40–42 min; the peak at 9 min exhibits a slightly shorter elution time than TriGDG 36:4 (Fig. 13c), consistent with expected behavior for TetraGDG 36:4 on a reverse-phase column.

#### Reverse Phase HPLC-ESI-MS Evidence for the Structural Identification of Glycolipids and their Estolides in the Oat Glycolipid Subfraction 3

As noted previously, oat glycolipid subfraction 3 was enriched in the putative TriGDG peaks (eluting at 26–30 min in Fig. 2) and contained a small putative TetraGDG peak (eluting at about 36 min). When analyzed

via reverse-phase HPLC-ESI-MS (Fig. 14), the EICs revealed peaks that corresponded to the major  $[M + NH_4]^+$  ions of TriGDG non-estolide and estolide peaks as identified in Fig. 13. The EIC of TetraGDG 36:4 revealed weak peaks at about 9 and 35–45 min (Fig. 14c) that were slightly stronger than those observed above (Fig. 13h). Based on its early elution time and the polar structure of TetraGDG, we speculate that the peak at 9 min is probably authentic TetraGDG and the peaks of less polar compounds at 35–45 min probably correspond to estolides with the same mass.

#### Estimation of the Total Amount of Estolides in Oat Lipids

The main objective of the current study was to provide structural evidence for the occurrence of several galactolipids and their estolides in oat kernels. In a future study we plan to report a comprehensive quantitative analysis of the levels of galactolipids and their estolides in several cultivars of oat kernels. However, we believe that it is important to estimate their approximate levels in this report to demonstrate that they are present in more than trace amounts. Using direct infusion electrospray ionization mass spectrometry we estimate that the oat glycolipid fraction contains: 58 mol% DGDG non-estolides, 25 mol% DGDG estolides, 8 mol% TriGDG non-estolides, 4 mol% TriGDG estolides, 0.3 mol% TetraGDG non-estolides, and 0.1 mol% TetraGDG estolides. Estolides therefore comprise about 29% of the total glycolipid fraction and 10% of the total methanol-extractable lipid fraction (based on the SPE fractionation yields).

#### Conclusion

We have confirmed the presence of DGDG mono-estolide (Fig. 1) in oat kernels, as previously reported by Hamberg et al. [10], and we have demonstrated that it is the most abundant estolide in oat kernels, but it is not the only estolide. Two larger DGDG estolides (di- and tri-estolides) (Fig. 15), two TriGDG estolides (mono- and di-estolides), and one TetraGDG estolide (mono-estolide) were also tentatively identified. The amounts of various estolide species did not vary, regardless of whether the oats were steamed to inactivate lipases before extraction, as in this study, or whether the oats were extracted directly (data not shown). To our knowledge, this report is the first evidence of natural di- and tri-estolides of polar lipids.

**Abstract** Phytosterols occur in high concentration in canola (*Brassica napus* L.) and other vegetable oils such as from the borage plant Echium (*Echium plantagineum* L.). We investigated if Atlantic salmon (*Salmo salar*) digest and accumulate dietary phytosterols in significant amounts in muscle and liver. Phytosterols are lipid soluble, lower cholesterol and reduce the risk of coronary heart disease in humans. We aimed to determine if fatty fish, such as salmon, can be used as a delivery source of this functional food component. Three diets containing canola oil (CO), Echium oil (EO) and fish oil (FO) were fed to Atlantic salmon smolt over 9 weeks. The digestibility of natural abundances of phytosterols by Atlantic salmon was poor compared to cholesterol. However, phytosterols accumulated in liver and muscle of fish. Significantly increased concentrations of 24-methylenecholesterol, campesterol,  $\beta$ -sitosterol and total phytosterol occurred in livers of EO fed fish compared to FO fed fish. Campesterol concentrations increased in CO fed fish compared to the FO fed fish. We demonstrated that natural abundances of dietary phytosterols are digested by and accumulated in liver and white

muscle of Atlantic salmon smolt. However, phytosterol levels in salmon muscle will not be a major source of phytosterols in human diets and would not be expected to significantly effect human cardiovascular health.

## Introduction

Phytosterols, a general term applied to a large number of plant-derived sterols, are found in all tissues of higher plants and are often enriched in seeds and seed oils [1, 2]. Phytosterols are natural, organic compounds with a molecular nucleus of 17 carbon atoms and a characteristic three-dimensional arrangement of four rings. Phytosterols can act as a structural component in the plant cell membrane, a role played in mammalian cells by cholesterol [2]. Unlike cholesterol, which has an alkyl side chain of 8 carbon atoms, the side chain of phytosterols generally contains 9 or 10 carbon atoms with alkyl substitution at C<sub>24</sub>. Phytosterols have wide bioactivity in humans, and in particular are considered an efficacious cholesterol-lowering agent and consequently may have a preventive role against cardiovascular disease [2, 3]. Phytosterols may also have a role in cancer prevention [2, 4]. Consequently, some margarines, butters, spreads and breakfast cereals are enriched with phytosterols and promoted as “functional foods” [5, 6].

Due to increasing demand and prices, reduced availability, the possibility of organic contaminants (such as dioxins and polychlorinated biphenyls (PCB)), and increased knowledge about fishing impacts, fish oil is being replaced in part with plant oils such as canola and soy in formulated/commercial feeds for aquaculture species [7]. Replacement oil diets have become an industry priority and over the last 20 years there has been increased scientific activity focused on the effects of substituting fish oil with plant oils, including effects on fish growth and health and on flesh quality. Limited research has been performed examining phytosterols in farmed Atlantic salmon (*Salmo salar*). The replacement of fish oil with plant oils in aquafeeds will increase dietary amounts of phytosterols. However, it has yet to be evaluated to what extent Atlantic salmon digest and accumulate phytosterols from dietary plant oils.

Pulp and paper mill effluent has been shown to affect reproductive and endocrine function in fish and this is thought to be due to the large amount of phytosterols, in particular  $\beta$ -sitosterol. In vivo and in vitro studies suggest that large amounts of  $\beta$ -sitosterol can affect fish endocrine activity and reproduction via many mechanisms/actions on numerous pathways [8].

The digestibility of phytosterols is poor in humans, and to our knowledge has yet to be evaluated in Atlantic salmon or in any other fish species. With the increased use of plant oils and meal in aquafeeds, minor components such

as phytosterols will be increasingly introduced into aquaculture diets and it is necessary to examine how they are digested by salmon. Phytosterols have been shown to have potential health benefits to the human consumer, in particular as a cholesterol-lowering agent. Therefore farmed Atlantic salmon fed a replacement plant oil diet may be a novel and further delivery source of phytosterols to humans. Assessment of how they are accumulated and concentrated in tissues such as liver and muscle of Atlantic salmon fed on replacement oil diets is needed to gauge any possible advantageous affect to the consumer. This study aims to assess digestibility and accumulation in white muscle and liver of phytosterols from two experimental plant oil diets (canola and Echium) compared with a traditional fish oil diet fed to Atlantic salmon smolt.

## Material and Methods

### Experimental Diets

Three diets were formulated to compare canola oil (CO), Echium oil (EO) and fish oil (FO) (Table 1). Fish meal was defatted three times using a 2:1 mixture of hexane and ethanol (400 ml/100g fish meal). Full fat soybean meal (Hamlet Protein A/S, Horsens, Denmark), casein (MP Biomedicals Australasia Pty Ltd, Seven Hills, NSW, Australia), wheat gluten (Starch Australasia, Lane Cove,

NSW, Australia) and BOIIC pre-gelatinised maize starch (Penford Australia Limited, Lane Cove, NSW, Australia) were used as ingredients. Echium oil was supplied as Crossential SA14 (Croda Chemicals, East Yorkshire, UK). Fish oil was from jack mackerel, *Trachurus symmetricus* L., (Skretting Australia, Cambridge, TAS, Australia) and a domestic refined source of pure canola oil was used (Steric Trading Pty Ltd, Villawood, NSW, Australia). Stay-C and Rovimid E50 were purchased from Roche Vitamins Australia (Frenchs Forest, NSW, Australia), and the remaining ingredients were purchased from Sigma-Aldrich (Castle Hill, NSW, Australia). Yttrium oxide was used as a digestibility marker. The diets were manufactured into 3 mm diameter pellets using a California Pellet Mill (CL-2), dried and stored at 5 °C [9].

### Growth Experiment

The experiment was conducted at the School of Aquaculture, University of Tasmania (Launceston, TAS, Australia). Atlantic salmon (*S. salar* L.) parr ( $\approx$ 87.9 g) were obtained from Springfield Fisheries hatchery (Scottsdale, TAS, Australia), acclimated for 14 days in 300 l tanks and fed a commercial feed (Skretting). Prior to the experiment the fish were slowly adapted to seawater over a 21 day period. The tanks were held at a constant temperature of 12.0 °C under a natural photoperiod. Water was treated through physical, UV and biofilters. Dissolved oxygen, pH, ammonia, nitrate, nitrite, and salinity were monitored daily to ensure water quality remained within parameters recommended for Atlantic salmon [10]. The fish were held in an average of 27.4  $\pm$  0.2 ppm saltwater. The experiment was conducted in accordance with the University of Tasmania Animal Ethics guidelines (Investigation A0008392).

At the start of the experiment fish (average weight 106.9 g) were anaesthetized (50 mg/l, benzocaine), their weight and length measured, and three fish were killed to measure initial lipid content and composition. Twenty-five fish were randomly re-allocated into each of twelve 300 l tanks, and 4 tanks were randomly allocated to each dietary treatment. The four diets were fed in triplicate at a ration of 1.8% body weight per day (% BW/d) in two equal feeds at 0900 and 1700 hours by automatic belt feeders. Every 7 days the total feed consumption (kg DM) was estimated from the amount of uneaten feed in Guelph-type sediment collectors [11, 12]. Every 3 weeks all fish were anaesthetized (50 mg/l, benzocaine) and batch-weighed. Fish were starved the day prior to weighing.

At the end of the experiment (day 84), fish were starved for 1 day prior to being anaesthetized (50 mg/l, benzocaine) and their weight and length measured. Three fish, which had doubled their initial weight, per tank were killed by a blow to the head after immersion in anaesthetic.

Samples of white muscle (approx 0.7 g), dissected from below the dorsal fin, and liver (average 2.7 g) were taken and frozen at  $-80^{\circ}\text{C}$  until analysis [7].

On days 86–90, faecal samples were collected from sediment collectors between 1100–1700 and 1900–0900 hours, freeze-dried and used in the analysis of digestibility [12]. The apparent digestibility coefficients (ADC) were calculated using the standard formula  $\text{ADC} (\%) = 100 - [100((Y_{\text{diet}}/Y_{\text{faeces}}) \times ((ST_{\text{faeces}}/ST_{\text{diet}})))]$ , where Y is percentage of yttrium oxide and ST is the % of particular sterols [13]. This calculation does not take into account possible dealkylation of phytosterols to cholesterol.

### Sterol Extraction and Isolation

All samples (tissue, faeces and diets) were freeze-dried and extracted overnight using a modified Bligh and Dyer protocol [14]. This involved a single phase extraction,  $\text{CHCl}_3/\text{MeOH}/\text{H}_2\text{O}$  (1:1:0.9, by vol), followed by phase separation to yield a total lipid extract (TLE).

Lipid classes were analysed using an Iatroscan MK V thin-layer chromatography-flame ionization detector (TLC-FID) analyser (Iatron Laboratories, Japan). Samples of the TLE were spotted onto silica gel SIII Chromarods (5  $\mu\text{m}$  particle size) and developed in a glass tank lined with pre-extracted filter paper. The solvent system used for the lipid separation was hexane:diethyl ether:acetic acid (60:17:0.1 v/v/v) [15]. After development for 25 min, the chromarods were oven-dried and analysed immediately to minimise adsorption of atmospheric contaminants. Lipid classes were quantified by DAPA software (Kalamunda, WA, Australia). The FID was calibrated for each compound class: phosphatidylcholine (retention factor 0.00), cholesterol (0.30), oleic acid (0.46); wax ester (derived from fish oil, 0.89) and triacylglycerol (derived from fish oil, 0.74).

An aliquot of the TLE was treated with 2 ml of 5% w/v KOH in 80:20 MeOH:H<sub>2</sub>O (60  $^{\circ}\text{C}$ , 3h, milli-Q water). Following the addition of water, sterols were extracted into hexane/chloroform (4:1 v/v,  $3 \times 1.5$  ml), transferred to vials, reduced under a stream of nitrogen and stored in chloroform. Samples were treated with *N,O*-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) to form trimethylsilyl (TMS) ether derivatives (of free sterols) prior to instrument analysis.

Concentrations of plant sterols were determined by gas chromatography. Samples were made up to a known volume with an internal injection standard containing methyl nonadecanate and analysed by gas chromatography (GC) using an Agilent Technologies 6890N GC (Palo Alto, CA, USA) equipped with an Equity<sup>TM</sup>-1 fused silica capillary column (15 m  $\times$  0.1 mm i.d., 0.1  $\mu\text{m}$  film thickness), an FID, a split/splitless injector and an Agilent Technologies 7683 Series autosampler. Helium was the carrier gas.

Samples were injected in splitless mode at an oven temperature of 120  $^{\circ}\text{C}$ . After 3 min, the oven temperature was raised to 270  $^{\circ}\text{C}$  at 10  $^{\circ}\text{C}$  per min and finally to 290  $^{\circ}\text{C}$  at 5  $^{\circ}\text{C}/\text{min}^{-1}$  holding at 290  $^{\circ}\text{C}$  for 5 min. Peaks were quantified with Agilent Technologies GC ChemStation software (Palo Alto, CA, USA).

Individual components were identified from mass spectral data and by comparing retention time data with those obtained for authentic and laboratory standards. GC-mass spectrometric (GC-MS) analyses were performed on a Finnigan Thermoquest GCQ GC-mass spectrometer fitted with an on-column injector and using Thermoquest Xcalibur software (Austin, TX, USA). The GC was equipped with an HP-5 cross-linked methyl silicone fused silica capillary column (50 m  $\times$  0.32 mm i.d.). Helium was used as the carrier gas, with operating conditions previously described [16]. Sterols were identified from comparison to known spectra and major ion fragments [17]. The stereochemistry was not determined for the C<sub>24</sub> position. The retention times for the major sterols were cholesterol 20.33 min, cholestanol 20.73 min, 24-methylenecholesterol 21.51 min, brassicasterol 20.85 min, campesterol 21.63 min, stigmasterol 22.17 min,  $\beta$ -sitosterol 22.77 min and isofucosterol 22.92 min.

### Statistical Analysis

Mean values are reported as plus or minus the standard error of the mean. Normality and homogeneity of variance were confirmed and percentage data were arcsin transformed prior to analysis. Comparison between means was by one-way analysis of variance (ANOVA) followed by multiple comparisons using Tukey–Kramer HSD. Significance was accepted at probabilities of 0.05 or less. Statistical analysis was performed using SPSS for Windows version 11.

## Results

### Growth Results

There was no significant difference in the final weight, final length or growth between fish fed the three experimental diets. Fish of an average weight (106.8 g) were grown on the three experimental diets for 12 weeks to an average sampled weight of 236.5 g.

### Sterol (ST) Composition

There was no significant difference in the sterol content in the white muscle between dietary treatments as determined by TLC-FID analysis (Table 2). There was significantly

**Table 2** Sterol and lipid content (wet weight) of white muscle and livers of Atlantic salmon smolt fed canola oil (CO), Echium oil (EO) and fish oil (FO) diets

Sterol content (mg/100g)	Initial ( $\pm$ SE)	CO ( $\pm$ SE)	EO ( $\pm$ SE)	FO ( $\pm$ SE)	<i>f</i>
White muscle	21.6 $\pm$ 4.8	15.0 $\pm$ 6.0	12.4 $\pm$ 6.5	13.9 $\pm$ 3.1	
Liver	139.9 $\pm$ 18.4 <sup>a</sup>	263.8 $\pm$ 34.3 <sup>b</sup>	144.7 $\pm$ 18.0 <sup>a</sup>	139.7 $\pm$ 11.8 <sup>a</sup>	7.9
Lipid content (mg/g)					
White muscle	17.9 $\pm$ 2.9	28.0 $\pm$ 3.4	30.1 $\pm$ 6.2	26.8 $\pm$ 4.9	
Liver	29.0 $\pm$ 2.2 <sup>a</sup>	49.1 $\pm$ 3.5 <sup>b</sup>	38.3 $\pm$ 2.4 <sup>a,b</sup>	35.8 $\pm$ 2.7 <sup>a</sup>	7.3

<sup>a, b</sup> Mean values across the row not sharing a common superscript were significantly different as determined by Tukey–Kramer HSD; *df* = 3,40, *P* < 0.01

higher total sterol content in the liver (263.8 mg/100 g) of the fish fed the CO diet. Cholesterol was the major sterol in all tissues, irrespective of diet, but the amounts of minor sterols varied. There were significantly (*P* < 0.01) higher concentrations of total phytosterols in the liver and white muscle in both the CO and EO fed fish compared to the FO or initial fish (Tables 3, 4). This equated to a fourfold increase in the white muscle and a twofold increase in the liver in total phytosterol concentrations in EO and CO fish compared to the FO fish. There were significant differences in the sterol composition of the liver (Table 4). There was a sevenfold significant (*P* < 0.01) increase in concentrations of campesterol (full chemical names for all sterols are contained in the footnote for Table 1) in the liver of both the CO and EO fish compared to the FO or initial fish. There were significant (*P* < 0.01) increases in concentrations of  $\beta$ -sitosterol and 24-methylenecholesterol in the liver of EO fish compared to that of the FO or initial fish. This equated to a sevenfold increase in  $\beta$ -sitosterol in the EO fish compared with the FO fish. There was a

significantly (*P* < 0.01) higher concentration of cholesterol in the initial fish compared to the CO and EO fish. There was a significant (*P* < 0.01) five to ninefold increase in the concentrations of other minor sterols including 24-ethyl-5 $\alpha$ -cholest-7-en-3 $\beta$ -ol, lanosterol, and other undetermined sterols in the liver of CO and EO fish.

There was no significant difference in the sterol composition (%) between the white muscle for fish fed the three diet treatments (Table 3). However, although not significant, the same trends in increased concentration of individual phytosterols that occurred in the liver were observed in the white muscle. There was a three to fivefold increase in the amount of  $\beta$ -sitosterol and a twofold increase in campesterol in the white muscle of fish fed EO and CO diets compared with the FO fish.

#### Digestibility of Phytosterols

There was no significant difference between the ADC of cholesterol between the three diet treatments (Table 5).

**Table 3** Sterol composition (mg/100g wet weight) of white muscle of Atlantic salmon smolt fed canola oil (CO), Echium oil (EO) and fish oil (FO) diets

<sup>a, b, c</sup> Mean values across the row not sharing a common superscript were significantly different as determined by Tukey–Kramer HSD;  $df = 3,36$ ,  $P < 0.01$

<sup>d</sup> Other minor sterols including 24-ethyl-5 $\alpha$ -cholest-7-en-3 $\beta$ -ol, lanosterol, and other undetermined sterols

<sup>e</sup> Includes all C<sub>28</sub> and C<sub>29</sub> sterols excluding 24-methylenecholesterol

There were no significant differences between the ADC of any phytosterol between the three diet treatments. Cholesterol has an ADC of 46.7–65.8% across the three diets. In general phytosterols had a lower ADC than cholesterol. Specifically, C<sub>28</sub> phytosterols such as brassicasterol and campesterol had a relative absorption of 9.2–18.1%, three to sixfold lower than that of cholesterol. 24-Methylenecholesterol was excluded from the calculation as it is a metabolite of cholesterol and is usually not associated with plant phytosterols. C<sub>29</sub> phytosterols including  $\beta$ -sitosterol, stigmasterol, and isofucosterol have a relative absorption of 1.1–7.1%, 7–60-fold lower than that of cholesterol.

**Table 5** Apparent digestibility coefficients (ADC) (%) for the different sterols in canola oil (CO), Echium oil (EO) and fish oil (FO) diets fed to Atlantic salmon

ADC (%)	CO ( $\pm$ SE)	EO ( $\pm$ SE)	FO ( $\pm$ SE)
Cholesterol	57.5 $\pm$ 4.4	46.7 $\pm$ 5.4	65.8 $\pm$ 7.2

## Discussion

Due to the decreasing availability and increasing price of fish oil, renewable land plant based oils have been increasingly incorporated into aquafeeds, and the replacement of fish oil has become an industry priority. Plant based oils contain phytosterols which are not part of the natural diet of Atlantic salmon. Therefore it is important to investigate how natural abundances of phytosterols in replacement oils are digested and incorporated in different tissues of salmon. We demonstrated that both the liver and the white muscle accumulated significantly increased amounts of total phytosterols with both plant oil diets (CO and EO) compared to FO fed fish. Differences in the absolute abundances and relative levels of individual phytosterols were demonstrated in the liver and white muscle of fish fed plant oil diets compared to the FO and initial fish. This study indicates that small amounts of phytosterols can be digested and accumulated in both the white muscle and liver of fish when fed replacement plant oil over a 12 week period.

### Digestibility of Phytosterols in Atlantic Salmon

Although cholesterol and phytosterols have similar structures, phytosterols have significantly reduced absorption compared to cholesterol and it has been shown that negligible amounts of phytosterol are absorbed by humans [18, 19]. There have been numerous studies looking at cholesterol and phytosterol adsorption in humans [20–23]. From these studies cholesterol has an absorption range of 33–60%, with phytosterols having reduced absorption, 2–10% for campesterol and 0.5–5% for  $\beta$ -sitosterol [20–23]. The

digestibility of sterols and phytosterols in Atlantic salmon show similar patterns to those in humans. Our study demonstrates that cholesterol has an ADC of 46.7–65.8%. A reduced digestibility was demonstrated with phytosterols. An ADC of 14–18.1% for campesterol and 1.1–7.1% for  $\beta$ -sitosterol was observed across the diets.  $C_{29}$  phytosterols, such as  $\beta$ -sitosterol and isofucoesterol, had reduced digestibility compared with that of  $C_{28}$  phytosterols such as 24-methylcholesterol. Phytosterols may be dealkylated to cholesterol which will reduce their ADC. Phytosterols and cholesterol are also likely to be metabolized by either internal and/or external microorganisms, or possibly by the smolt themselves. Both dealkylation and metabolism will also reduce the ADC, but the extent of these processes is yet to be assessed in Atlantic salmon. Phytosterols can be esterified with a mixture of fatty acids which are naturally occurring in small quantities in plants. The concentration of phytosterol esters can change rapidly in response to various types of stimuli. In this study, phytosterol esters were not detected in fish tissues by TLC–FID, however, small quantities occur in plant based replacement diets. It has been shown that in canola oil, 65% of the total phytosterols are present as free sterols and 35% as phytosterol esters [24]. Total phytosterols were measured in this trial and used in the calculation of digestibility. We have not defined the proportions of free phytosterols and phytosterol esters in the diets. However, the digestibility of total phytosterols was measured from saponified total solvent extract (TSE), which include both esters and free phytosterols. As no phytosterol esters were detected by TLC–FID in the fish muscle or liver this indicates that dietary phytosterol esters are hydrolyzed in the intestine or not digested [25]. Our study showed no difference in the digestibility of individual phytosterols across diets, which suggests that dietary concentration does not affect their digestibility by Atlantic salmon.

#### Accumulation of Phytosterols in Atlantic Salmon

We determined that 0.8–0.9 mg of total phytosterols per 100 g of tissue were accumulated in the white muscle and 6.1–7.5 mg/100 g in the liver of fish fed plant oil replacement diets over a 12 week period. Our experimental diets contained 100% replacement vegetable oil. This level of replacement would not be the case in commercial aquafeeds. Phytosterol accumulation is dependant on dietary concentration as they are unable to be in vivo biosynthesized. As phytosterols are lipid soluble, the higher the fat content of the fish or tissue will increase the amount of phytosterols it contains. The major phytosterols accumulated in the liver and white muscle were campesterol and  $\beta$ -sitosterol. Generally the relative concentrations of individual phytosterols in the liver and white muscle

reflected that of their diet. However,  $C_{29}$  phytosterols had a reduced digestibility compared with  $C_{28}$  phytosterols and therefore lower amounts accumulated in the liver or white muscle in both the CO and EO fish.

Phytosterols are very expensive ingredients and therefore it would not be economically feasible for these ingredients to be added to aquafeeds. However, replacement plant oils, such a canola, contain phytosterols as minor components. Canola is a prime candidate for fish oil replacement as it contains high levels of  $\omega$ 3 PUFA, largely as  $\alpha$ -linolenic acid (ALA, 18:3 $\omega$ 3) and is grown in sufficient quantities to meet future aquaculture demands. A recent study suggested that Echium oil also may be a candidate as it contains an unusual  $\omega$ 3 PUFA profile containing stearidonic acid (SDA, 18:4 $\omega$ 3), which was shown to maintain concentrations of important omega 3 long chain PUFA ( $\omega$ 3 LC-PUFA) in Atlantic salmon parr [7]. Both these plant oils have phytosterol compositions which are dependent on genotype, planting location and temperature [26–28].

In our study all the experimental diets had minor concentrations of phytosterols from the meal and oil sources. In the CO and EO diets the major source of phytosterols was the plant oil. All the diets contained plant based proteins, which consisted of soybean meal, casein and wheat gluten. As phytosterols occur in membranes and perhaps other parts of plant cells, the plant meals also will have residual concentrations of phytosterols. The FO diet contained 1.9 g/kg WW phytosterols, while the CO (6.8 g/kg WW) and the EO (5.6 g/kg WW) had 3.5 and 2.9 times the amount of total phytosterols (Table 1).

In the present study sterols represented only about 1% of the total lipid of salmon, and 92–99% of that 1% is present as cholesterol. Salmon smolt in this study had an average total white muscle lipid content of 28.3 and 39.6 mg/g in the liver. Therefore the amount of phytosterols in Atlantic salmon smolt compared to other lipids including cholesterol is relatively low. Phytosterols cannot be synthesized by humans or fish, therefore they are supplied in the diet. Phytosterols, due to their lipophilic nature, have been added to margarines and spreads which are known as “functional foods”. Oily fish, such as Atlantic salmon, may provide another possible delivery source. Phytosterols in combination with the high levels of omega 3 long chain ( $\geq C_{20}$ ) polyunsaturated fatty acids ( $\omega$ 3-LC PUFA) found in salmon may act in unison to deliver an enhanced benefit against coronary heart disease (CHD). Additionally and unlike  $\omega$ 3-LC PUFA, phytosterols are more stable compounds and are not as readily oxidised under severe conditions, such as deep frying.

Most human nutrition studies with phytosterols assessed an intake of 0.8–4.0 g of phytosterol as a daily dose which reduced the lower density lipoprotein (LDL) cholesterol

between 6 and 15% which reduces the risk of CHD [2, 29]. Dietary intake of phytosterols ranges from 150 to 400 mg/day, with a typical composition of 65%  $\beta$ -sitosterol, 30% campesterol and 5% stigmasterol [2, 19]. The content of phytosterol from this experiment in white muscle of Atlantic salmon smolt is 0.8–0.9 mg/100 g which is well below the concentration range of dietary phytosterol generally being supplied in functional foods for CHD prevention. This result will be elevated in larger commercial cultured fish, where oil content (7–20%) of white muscle is markedly higher than observed in the smolt (2–3%) examined here. Due to use of extrusion technologies commercial salmon aquafeeds have an oil content of 30–40%. Our study used an inclusion of 20% oil which will underestimate the phytosterol content compared to commercial diet. It was not possible for this experiment to obtain the high lipid content of commercial aquafeeds. However, even at this lower inclusion, it was possible to demonstrate that phytosterols significantly accumulated in the tissues of Atlantic salmon. Our experiment was for a 12 week period. It is plausible to suggest that over a life time of replacement oil diets that Atlantic salmon will accumulate considerably more phytosterols. However, at this point it is yet to be determined to what concentrations Atlantic salmon will accumulate phytosterols. The phytosterol concentrations in the white muscle (0.8–0.9 mg/100 g) of plant oil fed fish is several orders of magnitude less than the recommended daily serving size of functional foods such as spreads and margarines (phytosterols total  $\approx$  200 mg/day) [30]. However, in a balanced diet, this additional amount of phytosterols (we estimated to be  $\approx$  20–50 mg/serve in a large commercial size fish) is a 10–25% increase in the average adult human dietary intake of phytosterols.

#### Environmental Effects of Phytosterols

Several studies have shown that phytosterols in effluent, in particular  $\beta$ -sitosterol, produced estrogenic effects in maturing fish as well as a reduced cholesterol level [8, 31, 32]. Cholesterol is a precursor of steroid hormones and therefore the presence of structurally similar molecules or the reduction of cholesterol may effect maturation in fish. Phytosterols, in particular  $\beta$ -sitosterol, are present in pulp and paper mill effluents and have been associated with different reproductive responses in fish including reduction in gonad size, delayed sexual maturation, and reduced expression of secondary sexual characteristics [31, 33, 34]. A recent study strongly suggested that cholesterol in Atlantic cod (*Gadus morhua*) liver is lowered by phytosterol rich soy based diet and is possibly involved in changes observed in gonad development [32]. It has also been suggested that increased sterol-like compounds may

have contributed in the postponed spawning of Baltic cod in the Baltic Sea [32]. However, most farmed fish are harvested prior to maturation and a postponing of maturation may be advantageous to the aquaculture industry. Research has focused on the effect of phytosterols as a waterborne contaminant on fish health, reproduction and endocrine function [31, 33, 34]. The effects of dietary sources of phytosterols on fish have yet to be assessed, however, dietary concentrations are significantly lower than that of the effluent experiments.

There have been many well designed and executed experimental aquaculture trials with replacement oil, which have all shown no difference in growth, performance or health of fish [7, 35–40]. Further research looking at dietary phytosterol accumulation over a longer period and in particular reproductive and endocrine function such as the production of vitellogenin will provide insight on the accumulation and function of these ingredients. The use of vegetable oils in aquafeeds is now commonplace throughout the aquaculture industry and the small accumulation of phytosterols in Atlantic salmon that we have demonstrated will be advantageous to their continued use. However, Atlantic salmon require a dietary source of  $\omega$ 3 LC-PUFA which can presently only be provided by fish oil. Therefore, oil blends of plant and fish oils are commonly used throughout the aquaculture industry. While it has been shown that phytosterols in pulp mill effluent can be detrimental to fish health, low concentrations that occur in plant oils most likely will not affect health and performance of fish, and ultimately may provide health benefits to the consumer. Although the digestibility of phytosterols is low and their accumulation in fish of commercial size is likely to be at a level lower than used in functional food such as spreads and margarines, a small enhancement of dietary phytosterols along with the high content of  $\omega$ 3 LC-PUFA may give increased CHD protection to consumers.

**Abstract** To investigate the occurrence of positional isomers of unsaturated fatty acids (FA) in triacylglycerols (TAG) and polar lipids (PL) in the female gonads of a dominant limpet, *Cellana grata*, fatty acid methyl esters (FAME) were fractionated according to the degree of their unsaturation by argentation thin-layer chromatography. Their structures were elucidated by gas chromatography–mass spectrometry of a combination of their FAME and picolinyl esters. A total of 125 different FA ranging from 12 to 24 carbon atoms were identified, and 105 unsaturated FA, including 34 nonmethylene-interrupted FA as minor components, were recognized. Although the major FA 16:0 and 18:1n-7, which accounted for more than 20 and 10%, respectively, of total FA, were present in TAG and PL, higher amounts of 20:4n-6 and 20:5n-3 were present in PL. Unsaturated FA consisting of more than five different positional isomers were 17:1, 19:1, 18:2, 19:2, 20:2, 21:2, 22:2, 20:3, and 22:3, most of which were present in TAG. Furthermore, a larger variety of nonmethylene-interrupted

FA was found in TAG than in PL. This limpet gonad had a diverse assortment of unsaturated FA that comprised a wide range of unusual positional isomers with one to five double bonds.

**Keywords** *Cellana grata* · Limpet gonad · Nonmethylene-interrupted fatty acid · Positional isomer

## Abbreviations

ECL	Equivalent chain length
FA	Fatty acid(s)
FAME	Fatty acid methyl ester(s)
GC-MS	Gas chromatography–mass spectrometry
GLC	Gas–liquid chromatography
NMI FA	Nonmethylene-interrupted fatty acid(s)
PL	Polar lipids
TAG	Triacylglycerols
TLC	Thin-layer chromatography

## Introduction

Limpets, as intertidal gastropods, are abundant and familiar inhabitants of rocky shores and play an important role in littoral marine food webs [1–3]. Comparative biochemical research on the occurrence and distribution of FA in limpet gonads has been very limited, except for several studies examining the effects of environmental factors on FA composition of the gonads of limpet *Patella* species [4–6].

From the viewpoint of comparative biochemical interest, previous studies revealed that the significant differences between male and female gonads of two dominant limpet species, *Cellana grata* and *Collisella dorsuosa*, which are distributed in northern Japan, were characterized by their

proportions of 16:0, 20:4n-6, and 20:5n-3 [7, 8], and their composition and proportions of unusual nonmethylene-interrupted (NMI) FA, whose physiological role and function are not fully understood. Furthermore, the positional isomers of unusual minor polyenoic FA with 24 carbon atoms have been also found in triacylglycerols (TAG) of the female gonads of *C. grata*, one of the commonest species, from the Sanriku coast, northern Japan [9]. Although mainly major FA and their characterization in limpet gonads have been investigated, the occurrence and unique structures of the unknown minor FA including NMI FA have yet not been well clarified. Therefore, as part of our continuing intensive investigation of gonad lipids from dominant species of Japanese limpets, positional isomers of FA with one to five double bonds in the female gonads of *C. grata* have been more completely clarified by detailed analysis of the FA mass spectra. This paper describes the occurrence and characterization of unusual positional isomers of unsaturated FA between TAG, the most abundant lipid class, and polar lipids (PL) in the gonads. The present results may provide new insights for a comparative biochemical study of marine gastropods of their gonads and the effects of ecological factors on their FA composition.

## Materials and Methods

### Reagents

Reagents and most standards were purchased from Sigma-Aldrich Co. (St Louis, MO, USA).

### Sampling

The mean shell length of the limpet *C. grata* used for lipid and FA analysis was  $34.1 \pm 1.7$  mm ( $n = 25$ ). Limpets were collected from the coast waters of Miyako Bay, Iwate Prefecture, northern Japan, in July and August 2002. All individuals of *C. grata* were sexually mature. After sampling, all limpets were immediately frozen at  $-20$  °C. The sex was determined by microscopic examination, and the gonads were distinguished as female or male.

### Extraction and Fractionation of Lipids

Pooled female gonads (8.10 g wet weight,  $n = 25$ ) of *C. grata* were suspended in a chloroform–methanol mixture (2:1, v/v) and homogenized for 1 min at  $891 \times g$  using an IKA ULTRA-TURRAX T25 Basic (IKA Japan KK, Nara, Japan). Lipids were extracted using the method of Bligh and Dyer [10]. The extracted total lipids (488 mg) were fractionated into TAG (351 mg) and PL (103 mg) by preparative thin-layer chromatography (TLC) on Silica gel

60 (Merck KGaA., Darmstadt, Germany). The plates were developed with *n*-hexane/diethyl ether/acetic acid (80:30:1, v/v/v). The bands corresponding to TAG and PL were scraped off the plates and then extracted twice with a chloroform–methanol mixture (1:1, v/v). The solvent extracts were combined and dried under a gentle stream of nitrogen at room temperature. Each residue was dissolved in chloroform and stored at  $-20$  °C until derivation prior to gas–liquid chromatography (GLC) and gas chromatography–mass spectrometry (GC–MS) analyses.

### Preparation of FAME and Argentation TLC

Fatty acid methyl esters (FAME) were prepared with transesterification of TAG and PL with 14%  $\text{BF}_3$  in methanol (GL Science, Tokyo, Japan) [11]. Five milliliters of the reagent was added to the fractionated lipids (40–60 mg) and refluxed at 90 °C for 60 min. The reaction was terminated by the addition of 2 mL of saturated NaCl solution. The FAME were extracted twice with 5 mL of *n*-hexane. The organic layer was dried over anhydrous sodium sulfate, filtered, and analyzed by TLC. The FAME were purified by preparative TLC and developed with the same solvent system that was used for the fractionation of TAG and PL. These samples were used for GLC and GC–MS analyses.

Fractionation of FAME by their double bond numbers and configuration of double bonds was performed using TLC plates on 5% (w/w) silver-impregnated layers of Kieselgel 60. The plates were developed twice with *n*-hexane/diethyl ether (80:20, v/v) and visualized at 366 nm after spraying with a solution of 2',7'-dichlorofluorescein in ethanol (0.2%, w/v). The individual FAME bands corresponding to monoenoic, dienoic, trienoic, tetraenoic, and pentaenoic FA were separately scraped off and transferred to screw-capped tubes, and methanol (2 mL), *n*-hexane (2 mL), and an aqueous solution of NaCl (10% w/v, 1 mL) were successively added with thorough mixing after each addition. After standing for 1–2 min, the organic layer was withdrawn, and an aliquot of the solvent was evaporated to dryness under a gentle stream of nitrogen at room temperature. Then, the residues that were dissolved in dry dichloromethane were converted into picolinyl ester derivatives by the reaction with 3-potassiooxamethylpyridine, as a catalyst, as described below.

### Catalytic Hydrogenation of Unsaturated FAME and Picolinyl Ester Derivatives

As previously described [12], an aliquot of unsaturated FAME was hydrogenated by stirring at room pressure and temperature for 40 min in methanol (5 mL) with catalytic amounts of palladium black (Wako Pure Chemical

Industries, Ltd, Osaka, Japan). The resulting mixture was analyzed by GLC and GC–MS as described below.

To further determine the double bond positions and methyl branching positions in FA detected in this study, FAME samples were converted into their picolinyl ester derivatives as previously described [13]. Briefly, a solution of potassium *tert*-butoxide (0.15 mL, 1.0 M in tetrahydrofuran) was added to 3-hydroxymethylpyridine (0.2 mL). After homogenization, the FAME (20–30 mg), fractionated by preparative argentation TLC, in dry dichloromethane (1 mL) was mixed with the reagent, and the mixture was held at 40 °C for 50 min in screw-capped tubes. After cooling to room temperature, distilled water (2 mL) and *n*-hexane (3 mL) were added to the reaction mixture, and the organic layer was collected, dried over anhydrous sodium sulfate, filtered, and evaporated to dryness under a gentle stream of nitrogen at room temperature. The residues were dissolved in *n*-hexane prior to structural determination of FA by GC–MS analysis.

#### GLC and GC–MS Analyses

Fatty acid methyl esters were analyzed by GLC with a Shimadzu GC-8A chromatograph (Shimadzu Seisakusho Co., Kyoto, Japan) equipped with a flame ionization detector (FID) and a Supelcowax<sup>TM</sup>-10 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco Inc., Bellefonte, PA, USA). The column temperature was either isothermal at 200 °C for 30 min or programmed to increase from 180 to 250 °C at a rate of 3 °C/min and then hold at 250 °C for 10 min. The injector and detector temperatures were 260 and 270 °C, respectively. The carrier gas was helium, at a flow rate of 1.0 mL/min, and the injection split ratio was 1:50.

We identified the mass spectra of FAME and picolinyl ester derivatives by a Hewlett-Packard 6890 GC-5973N MSD. The GLC was equipped with an Omegawax<sup>TM</sup>-320 capillary column (30 m × 0.32 mm i.d., 0.25 μm film thickness; Supelco Inc.) and used helium as the carrier gas with a constant flow of 1.5 mL/min. The oven temperature was held at 200 °C for 2 min, programmed to rise from 200 to 250 °C at a rate of 2 °C/min and then held for 90 min. The GC–MS analysis of FAME and picolinyl ester derivatives was recorded at an ionization energy of 70 eV by the electron impact mode. The split injection was performed with a split ratio of either 1:15 or 1:25. A scan range of 50–500 *m/z* was used. Most FA were identified by comparison of their mass spectra with those of authentic standards and published data [8, 9, 14]. In the absence of suitable standards, assignments were based on mass spectral fragments and on equivalent chain length (ECL) values for structurally analogous FA. The ECL values were determined by the same GLC apparatus with an FID, used for GLC

analysis of FAME, using an Omegawax<sup>TM</sup>-320 and a SAC<sup>TM</sup>-5 (30 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco Inc.) capillary columns. The column temperatures for an Omegawax<sup>TM</sup>-320 and a SAC<sup>TM</sup>-5 columns were isothermal at 200 and 250 °C, respectively. Except for the column temperatures, the GLC operating conditions were the same as described in GLC analysis of FAME. Gas–liquid chromatography analyses were performed in duplicate, and then mean values are reported here.

## Results and Discussion

### FA Composition of TAG and PL

The pooled female gonads of the limpet *C. grata* yielded 6.0% total lipids. The proportions of TAG, the most abundant lipid class, and PL were 72 and 21%, respectively. Among 53 different FA, accounting for more than 0.1% of total FA, including nine branched-chain FA and 2-hydroxyhexadecanoic acid, as shown in Table 1, the major FA 16:0 and 18:1n-7 each accounted for more than 20 and 10%, respectively, of total FA present in the TAG and PL of female gonads from *C. grata*. Both these fractions showed significantly higher amounts of 16:0 and 18:1n-7. Similar results of major FA have already been reported for those of the total lipids from female gonads of *C. grata* and *C. dorsuosa* [7]. More than 20 NMI FA were present as minor components in TAG rather than in PL. The present results were also shown to contain significantly higher amounts of 20:4n-6 and 20:5n-3 in PL, as compared with those in TAG. However, 22:6n-3, characteristic for marine lipids, was not detected in TAG and PL from the gonads.

To further clarify the characterization of the occurrence and detailed distribution of FA positional isomers with one to five double bonds between TAG and PL fractions in female gonads of *C. grata*, FAME were fractionated according to the degree of their unsaturation by preparative argentation TLC. Gas–liquid chromatography analyses of mono-, di-, tri-, tetra-, and pentanoic FAME fractions generally showed a range of unknown minor peaks, some of which did overlap with those of other FA shown in Table 1. The structures of these minor FA newly found were identified by capillary GC–MS of their FAME and picolinyl esters. The results of FA positional isomers including minor ones (accounting for less than 0.1% of total FA) are shown in Tables 2, 3, 4, and 5.

### Positional Isomers of Monoenoic FA

Table 2 lists the distribution of positional isomers of monoenoic FA. Among the 29 monoenoic FA identified, a

<sup>b</sup> Minor FA (<0.1%), identified, such as 16:1n-5, 18:1n-13, 18:2Δ5,9, 20:2Δ5,13, 20:2n-3, 20:4Δ5,11,14,17, 22:3Δ5,9,15, and 22:4n-3 were excluded from Table 1

<sup>c</sup> 4,8,12-Trimethyltridecanoic acid

number of unusual odd-numbered FA 17:1 and 19:1, which consisted of seven and six different positional isomers, respectively, were found in TAG, although 18:1n-7 and 18:1n-9 were present as the major monoenoic isomers. The isomer 15-methyl 16:1Δ9, together with other branched-chain FA, is present in mollusks, such as the marine sponges, *Aplysina fistularis* [15] *Hymeniacidon sanguinea* [16, 17], and *Plakortis halichondroides* [18], and the freshwater mussel, *Unio tumidus* [19], and also in the anaerobic sulfate bacterium of *Desulfovibrio* species [20]. However, the presence of 15-methyl 16:1Δ9 has not been reported in limpets and their gonads.

#### Positional Isomers of Dienoic FA

As shown in Table 3, a total of 42 dienoic FA with 16 and 18–24 carbon atoms were identified in this study, and the highly diverse NMI dienoic FA significantly differed between TAG and PL. The dienoic FA were 18:2, 19:2, 20:2, 21:2, and 22:2, which each consisted of more than five different positional isomers, and were mainly found in the TAG. Among these dienoic FA, the presence of both the odd-numbered FA 19:2 and 21:2 positional isomers including unusual NMI FA is very rare in living organisms.

As an interesting result of NMI dienoic FA, six different all-*cis*-Δ5,9-dienoic FA with 18 and 20–24 carbon atoms were identified by capillary GC–MS of their methyl ester (characteristic peaks at *m/z* 81 [parent ion], 109, 141, and [M-49]<sup>+</sup> for 5,9-double bonds) [14] and picolinyl ester (a characteristic abundant peak at *m/z* 219 for 5,9-double bonds) [14, 21] derivatives, whose mass spectral data were in agreement with literature data [14, 21–23]. (The mass spectra of picolinyl esters were also informative in identifying minor NMI polyenoic FA with a 5,9-double bond

system, such as 22:3Δ5,9,15, 24:3Δ5,9,15, 24:3Δ5,9,17, 24:4Δ5,9,15,18, and 24:5Δ5,9,15,18,21, as described previously [8,9].) These Δ5,9-dienoic FA, some of which are frequently present in marine sponges [12, 17, 22, 24], were mainly detected in the TAG in small amounts. Although all-*cis*-Δ5,9-dienoic FA with 18 and 20 to 23 carbon atoms have been found in whole bodies of the sea anemone *Stoichactis helianthus* [23], the detailed distribution of both even- and odd-numbered all-*cis*-Δ5,9-dienoic FA occurring in marine gastropods and their gonads is reported here for first time. The identified dienoic FA, together with other unusual NMI FA, may be incorporated from the limpet's diet or may be biosynthesized by some of the limpet's symbiotic organisms including microorganisms, but the reason remains unclear. Some Δ5,9-dienoic FA are known to arise from a symbiotic relationship of associated bacteria with host cells of marine invertebrates [25].

<sup>a</sup> Picolinyl ester, *m/z* (%): 92 (100), 164 (49), 220 (6), 246 (9), 302 (10), 328 (5), 356 (7), 382 (7), 425 (M<sup>+</sup>, 41)

<sup>b</sup> Picolinyl ester, *m/z* (%): 92 (100), 164 (66), 206 (10), 232 (4), 288 (4), 314 (34), 328 (9), 354 (10), 439 (M<sup>+</sup>, 37)

found in gonads of marine gastropods. Although basic knowledge of the physiological activities of all-*cis*-Δ5,9-dienoic FA and their derivatives is very limited [26, 27], very long chain Δ5,9-dienoic FA possessing a cyclopropylidene group and 30:3Δ5,9,21 isolated from an Australian sponge, *Amphimedon* sp., and the known 27:2Δ5,9 and 28:2Δ5,9 isolated from marine sponges inhibit human DNA topoisomerase I. These findings suggest that an essential factor of the inhibition is the location of the 5,9-double bonds rather than the presence of a cyclopropylidene moiety [26]. Furthermore, a 1:2 mixture of 23:2Δ5,9 and 24:2Δ5,9 isolated from the Turkish sponge *Agelas oroides* inhibits the activity of an enoyl-acyl carrier protein reductase, which catalyzes the last step in each cycle of FA elongation, a key enzyme of FA biosynthesis, in *Plasmodium falciparum*, which causes malaria in humans, and in *Escherichia coli* [27]. Therefore, among the six different Δ5,9-dienoic FA identified in this study, some of them may play roles in a physiological activity in limpet gonads. This will be studied in the future in the physiology of limpet gonads.

#### Positional Isomers of Trienoic FA

Table 4 lists the distribution of positional isomers of trienoic FA, some of which were unusual NMI polyenoic FA with 23 and 24 carbon atoms. In this study, 16:3n-4, 16:3n-3, 16:4n-3, and 16:4n-1 were not detected, although these FA were found in the limpet gonads and soft bodies of *P. depressa* [5]. This difference may be linked to the limpet's diet and environmental conditions.

Among NMI trienoic FA, small amounts of 20:3Δ5,11,14, together with 20:4Δ5,11,14,17, are frequently present in gastropods and plants, such as the bivalves *Meretrix lusoria*, *Tapes philippinarum*, *Corbicula japonica*, *Crassostrea gigas*, and *Mytilus coruscus* [28], the algae of Phaeophyta [29], and seeds of Gymnospermae [30]. The most abundant isomer 22:3Δ7,13,16 of positional isomers of 22:3 together with 22:3Δ8,14,18, which was tentatively identified by capillary GC-MS of its picolinyl ester derivative (Table 4), and 22:3Δ5,9,15, were present in TAG. A very small amount of 22:3Δ7,13,16, together other NMI FA, has been reported for some marine invertebrates, such as the bivalves *Unio tumidus* [19], *Crassostrea gigas* [31], *Megangulus zyonensis* [32], and *Ruditapes philippinarum* [33] and the sponge *Petrosia ficiformis* [34].

In this study, an unknown trienoic acid was detected in very small amounts in TAG. The methyl ester had an ECL of 23.71 on an Omegawax-320 column at 200 °C. The mass spectrum (MS) of this methyl ester showed a molecular ion peak at *m/z* 362 (relative intensity, 5%) and a characteristic ion peak at *m/z* 331 (relative intensity, 6%) due to a loss of OCH<sub>3</sub>, suggesting a tricosatrienoic acid. The structure was confirmed by the disappearance of the

**Fig. 1** Possible biosynthetic pathways for NMI trienoic FA

\* Not found in this sample

corresponding GLC peak upon catalytic hydrogenation and by a molecular ion peak at  $m/z$  368 for the corresponding methyl ester of *n*-tricosanoic acid. For further analysis of the double bond positions of this triene, the methyl tricosatrienoate was directly converted into its picolinyl ester derivative. The MS of the picolinyl ester gave a molecular ion at  $m/z$  439, and the characteristic ions of the double bond positions, shown in Table 4, were in good agreement with those of the picolinyl ester 22:3 $\Delta$ 7,13,16 [14]. On the basis of the results described above, the triene detected in this study was determined to be 23:3 $\Delta$ 7,13,16, which was presumed to have all *cis* double bonds by comparison of its ECL values with those of all-*cis*- $\Delta$ 7,13,16–22:3 using two different GLC columns, an Omegawax-320 and a SAC-5, and the same behavior of all-*cis*- $\Delta$ 7,13,16–22:3 using argentation TLC. To the best of our knowledge, this is the first report of tentative identification of all-*cis*- $\Delta$ 7,13,16–23:3 from living organisms. An interesting finding was the presence of a very unusual triene 23:3 $\Delta$ 7,13,16, together with 22:3 $\Delta$ 7,13,16, in the TAG of this species. However, compared with the even-numbered polyenoic FA occurring marine gastropods, which include bivalves, limpets, and their gonads, odd-numbered polyenoic FA with more than 21 carbon atoms, other than 21:5n-3, were not detected due to their very miniscule or small amounts. The biosynthesis of 23:3 $\Delta$ 7,13,16, like that of 22:3 $\Delta$ 7,13,16 as previously reported for marine bivalves [31, 35], may proceed by  $\Delta$ 5-desaturation followed by elongation (Fig. 1), but corroborating this hypothesis requires additional studies.

#### Positional Isomers of Tetraenoic and Pentaenoic FA

Table 5 lists the distribution of positional isomers of tetraenoic and pentaenoic FA. In this study, a total of 34 different NMI FA with 2–5 double bonds were identified, although the physiological role and function of these FA are unknown. Nonmethylene-interrupted fatty acids are present not only in invertebrates [36, 37] including marine gastropods and sponges, and also in plant seeds [30, 38], cellular slime mold [39], and fungus species [40].

As reported previously, positional isomers of unusual tri-, tetra-, and pentaenoic FA with 24 carbon atoms, 24:3 $\Delta$ 5,9,15, 24:3 $\Delta$ 5,9,17, 24:3 $\Delta$ ,9,15,18, 24:4 $\Delta$ 5,9,15,18, 24:5 $\Delta$ 5,9,15,18,21, 24:4n-6, and 24:5n-3, were present only in TAG in small amounts [9], but the reason is still

unclear. Among these FA with 24 carbon atoms, both 24:4n-6 and 24:5n-3, which each accounted for less than 0.1% of total FA, together with minor n-6 and n-3 polyunsaturated FA with 24, 26, 28, and 30 carbon atoms, have been identified in three crustacean species of the order of Bathynellacea [41]. Small amounts of 24:4n-6, together with five minor NMI FA, 20:2 $\Delta$ 5,11, 22:2 $\Delta$ 7,13, 22:2 $\Delta$ 7,15, 20:3 $\Delta$ 5,11,14, and 20:4 $\Delta$ 5,11,14,17, were found in marine and freshwater gastropod species from the littoral zone of the Red Sea, Mediterranean Sea, and Sea of Galilee, mostly comprising less than 1% of total FA [42]. In contrast, 24:5n-3, 21:5n-3, and 22:5n-3, less than 1% of total FA, together with considerable amounts of 20:5n-3, were found in gonads of the oyster *Ostrea edulis* [43]. The differences in the polyenoic FA compositions among marine gastropod species may be due to different environmental conditions and dietary habits.

This study, together with previous studies [8, 9], showed that a large diversity of unsaturated FA and their positional isomers was present in the female gonad lipids of *C. grata*, especially in TAG, the most abundant lipid class, which consisted of 29 monoenoic FA, 42 dienoic FA, and 20 trienoic FA with both odd- and even-numbered chain lengths. Furthermore, a wide range of NMI dienoic FA with double bonds at  $\Delta$ 5,9, together with  $\Delta$ 5,11,  $\Delta$ 5,13,  $\Delta$ 7,13,  $\Delta$ 7,15,  $\Delta$ 7,16,  $\Delta$ 7,17,  $\Delta$ 9,13,  $\Delta$ 9,15, and  $\Delta$ 9,17, and NMI polyenoic FA (22:3 $\Delta$ 5,9,15, 24:3 $\Delta$ 5,9,15, 24:3 $\Delta$ 5,9,17, 24:4 $\Delta$ 5,9,15,18, and 24:5 $\Delta$ 5,9,15,18,21) with a 5,9-double bond system, were characterized by capillary GC–MS of their FA derivatives, although most of these FA were minor components. Expansion of our knowledge of the occurrence and structure of unusual minor FA as well as major FA in the marine environment and organisms may be linked to the clarification of their physiological roles in marine organisms and their tissues. The present results may provide valuable information for comparative biochemical studies of the occurrence and distribution of unsaturated FA of positional isomers in marine invertebrate gonads. Further studies are needed to investigate whether the FA compositions of limpet gonads are the effects of environmental factors or are related to the reproductive cycle.

**Acknowledgments** We are grateful to Dr. S. Budge for her helpful comments of the manuscript. This study was done as a cooperative research program (No. 107) with the International Coastal Research Center, Ocean Research Institute, The University of Tokyo.

**Abstract** To understand the bilayer interaction with paclitaxel, fluorescence polarization, Fourier transform infrared spectroscopy (FT-IR) and 31-phosphorus nuclear magnetic resonance (31P-NMR) studies were performed on paclitaxel bearing liposomes. Fluorescence anisotropy of three probes namely, 1,6-diphenyl-1,3,5-hexatriene (DPH), 12-(9-anthroyloxy) stearic acid (12AS) and 8-anilino-1-naphthalene sulfonate (ANS) were monitored as a function of paclitaxel concentration in the unsaturated bilayers. The incorporation of paclitaxel decreased anisotropy of 12AS and ANS probes, while slightly increased anisotropy of DPH. Paclitaxel has a fluidizing effect in the upper region of the bilayer whereas the hydrophobic core is slightly rigidized. FT-IR spectroscopy showed an increase in the asymmetric and symmetric methylene stretching frequencies, splitting of methylene scissoring band and broadening of carbonyl stretching mode. These studies collectively ascertained that paclitaxel mainly occupies the cooperativity region and interact with the interfacial region of unsaturated bilayers and induces fluidity in the headgroup region of bilayer. At higher loadings (>3 mol%), paclitaxel might gradually tend to accumulate at the interface and eventually partition out of bilayer as a result of solute exclusion phenomenon, resulting in crystallization; seed non-bilayer phases, as revealed by 31P-NMR, thereby

destabilizing liposomal formulations. In general, any membrane component which has a rigidization effect will decrease, while that with a fluidizing effect will increase, with a bearing on headgroup interactions, partitioning of paclitaxel into bilayers and stability of the liposomes.

**Keywords** Paclitaxel · Bilayer · 31P-NMR · Fluorescence polarization · FT-IR · Interaction · Stability

## Abbreviations

12AS	12-(9-Anthroyloxy) stearic acid
ANS	8-Anilino-1-naphthalene sulfonate
DPH	1,6-Diphenyl-1,3,5-hexatriene
FT-IR	Fourier transform infrared spectroscopy
31P-NMR	31-Phosphorus nuclear magnetic resonance
PC	Phosphatidylcholine
PG	Phosphatidylglycerol

## Introduction

Paclitaxel has shown impressive performance in the clinic after its discovery due to its unique mechanism of action on microtubules and multiple pharmacological effects on rapidly dividing cells of tumor and its vasculature [1, 2]. In the clinic, paclitaxel is used for treatment of refractory breast and metastatic ovarian cancers, AIDS-related Kaposi's sarcoma, small and non-small cell lung, neck and colon cancers. This natural diterpenoid, a high molecular weight compound (854 Da) (Fig. 1), is extremely hydrophobic and has low aqueous solubility. After extensive formulation efforts, the final formulation selected for clinical use to deliver paclitaxel consisted of cremophor EL

and ethanol. However, the former excipient has been responsible for causing hypersensitivity reactions in patients which necessitates concomitant administration of anti-histamines and steroidal anti-inflammatory drugs. In order to overcome the current drawbacks and improve the delivery of this promising antineoplastic agent, huge number of efforts are being made to develop alternative formulations of paclitaxel such as, emulsions, liposomes, micelles, nanoparticles, prodrugs, conjugates, etc. [1]. Among various approaches listed above, there are several advantages associated with the use of liposomal formulations for which reason liposomes have been extensively studied as carriers for anticancer drugs. For instance, encapsulation of antineoplastic drugs in liposomes has proved promising to increase therapeutic ratio of chemotherapeutic agents as well as to combat multidrug resistance in cancer chemotherapy [3, 4]. In this regard, liposomal formulations of paclitaxel have been prepared to reduce toxicity of free drugs and tested in animals and humans [5, 6].

Keeping in view the significant developments in liposomal paclitaxel delivery, it is pertinent to understand the nature of the interaction of paclitaxel with the liposomal bilayer. A comprehension of the location and depth of penetration into the bilayer of the molecule would be of immense value for successful formulation and in vivo delivery. Since paclitaxel possess no charge, it is anticipated that the hydrophobic nature promotes partitioning and location within the bilayer. The interaction of paclitaxel with bilayers has been previously investigated with the help of fluorescence polarization, circular dichroism, DSC, and FT-IR techniques [7–9] which indicate both fluidizing and rigidization effects of paclitaxel. In order to better anchor the molecule in bilayers, different 2'-acyl prodrugs of paclitaxel were synthesized which varied with respect to the acyl chain length (C-6, 12, 16) [10]. Based on DSC studies, they showed that taxane prodrugs were solvated to a greater degree in dimyristoyl PC bilayers than dipalmitoyl PC, distearoyl PC bilayers and, the association of these prodrugs was better than paclitaxel itself which further

increased with the 2'-acyl chain length. In this work, it was also reported that the enthalpy of transition decreased with increasing amounts of paclitaxel within liposomes from which they related paclitaxel induced perturbation of bilayers to disruption of hydrogen bonding at lipid–water interface. Although a considerable number of reports point to the localization of paclitaxel at the membrane–water interface, to the best of our knowledge, so far, experimental evidence on the type of interaction and paclitaxel induced perturbation of interfacial region has not been substantial. In the present work, we make an attempt to further understand the interaction of paclitaxel with unsaturated lipid bilayers, and provide evidence for the interaction of paclitaxel with phospholipid headgroup region. Data acquired from spectroscopic studies comprising fluorescence anisotropy and FT-IR was useful in understanding the paclitaxel–bilayer interactions in terms of membrane dynamics and lipid acyl chain conformational changes. At the same time,  $^{31}\text{P}$ -NMR was employed as a more direct indicator of the effects induced in headgroup region as well as to detect type of perturbations imposed on the bilayer by paclitaxel.

## Experimental Procedures

### Materials

Paclitaxel was a sample donated by Dabur India Ltd. Soya phosphatidylcholine (PC) and phosphatidylglycerol (PG) *trans*-esterified from soya PC were kindly provided by Natterman Phospholipids (Germany). 1,6-Diphenyl-1,3,5-hexatriene (DPH), 12-(9-anthroyloxy) stearic acid (12AS) and 8-anilino-1-naphthalene sulfonate ammonium salt (ANS) were procured from Sigma-Aldrich (USA) and Fluka (Switzerland), respectively. Membrane filters were purchased from Millipore (USA). All other reagents were analytical or reagent grade. Water obtained from an ELGA purification unit (UK) was used throughout the study.

### Preparation of Paclitaxel Liposomes

Liposomal dispersions of paclitaxel were prepared by the film-hydration method [11]. Appropriate quantities of paclitaxel, PC and PG stock solutions in chloroform were placed in a round-bottomed flask and chloroform was removed under vacuum. In all cases the PC:PG mole ratio was 9:1. The drug–lipid mixture was re-dissolved in a cyclohexane-*tert*-butanol solvent system (0.5:1 v/v) and the organic phase was removed by rotary evaporation to obtain a drug–lipid film. The film was subjected to vacuum for an additional period of time in order to remove traces of

solvent before hydration using a 0.9% (w/v) sodium chloride medium. After hydration of the film, the multilamellar vesicles obtained were extruded through polycarbonate filters of 0.4  $\mu\text{m}$  pore size for further studies.

#### Analysis of Liposomal Components

The purity of the phospholipids used in the study was assessed by thin layer chromatography with two different mobile phases of different polarities and all samples exhibited a single spot. In addition, total lipid, PG in liposomal formulations were analyzed by the colorimetric methods described earlier [12, 13].

#### Steady-State Fluorescence Anisotropy Measurements

Both drug-containing and drug-devoid liposomes were prepared as mentioned in earlier section and labeled with fluorescent probes. The preparations contained lipids at 2  $\text{mg ml}^{-1}$  concentration while the concentration of the drug was varied from 0.5 to 10 mol% with respect to the lipid. All liposomal preparations had a PC:PG mole ratio of 9:1 and were extruded through 0.4  $\mu\text{m}$  membrane filters. The lipid to probe ratios of DPH, 12AS and ANS were 300:1, 200:1 and 100:1, respectively. Since the membrane probe concentrations are infinitesimally small, the lateral distributions of probes in liposomes primarily measure the dynamic component of membrane fluidity. DPH and 12AS stock solutions were prepared in tetrahydrofuran and added to extruded preparations while ANS was included in the medium for film hydration. After allowing a 2-h equilibration period in the dark, 75  $\mu\text{l}$  of each formulation containing DPH or 12AS probe and 200  $\mu\text{l}$  of formulation containing ANS were further diluted to 3 ml with saline for fluorescence anisotropy measurements. Fluorescence measurements were carried out on a Perkin Elmer LSB 50 spectrofluorimeter (UK) equipped with a circulating water bath and fluorescence anisotropy ( $r$ ) was calculated according to the following equation:

$$r = (I_p - I_v) / (I_p + 2I_v) \quad (1)$$

where  $I_p$  and  $I_v$  are the fluorescence intensities of the emitted light polarized parallel and perpendicular to the excited light, respectively. “G” factor = 1. The excitation and emission slit widths were 5 and 10 nm while the excitation and emission wavelengths in nanometers of DPH, 12AS and ANS were as follows: (1) 380 and 430, (2) 370 and 450, (3) 380 and 480. During measurements, the temperature of the sample was controlled with an accuracy of  $\pm 0.2$  °C of set temperature and, the phospholipid concentration was kept to  $< 1$   $\text{mg ml}^{-1}$  to minimize interference from light scattering.

#### Attenuated Total Reflectance FT-IR Studies

Infrared spectra were measured at room temperature on a Bruker Vector 22 attenuated total reflectance FT-IR spectrometer (Bruker Optik GmbH, Ettlingen, Germany). To obtain the FT-IR spectra, 100  $\mu\text{l}$  of liposome dispersions were placed on a germanium crystal and scanned in the range 600–3,000  $\text{cm}^{-1}$ . A total of 100 scans were collected and coadded with a spectral resolution of 2  $\text{cm}^{-1}$ . Background spectrum was always collected under identical conditions. The same liposomal preparations as described for NMR studies were used here.

#### $^{31}\text{P}$ -NMR Analysis

Liposomal formulations were prepared in a saline medium to obtain a final lipid concentration of 40  $\text{mg ml}^{-1}$ .  $^{31}\text{P}$ -NMR spectra were recorded (phosphoric acid standard) on a Bruker 300 spectrometer operating at 121.45 MHz in a 5-mm broad band probe at 25 °C as previously reported [14]. Each sample was suspended in 10%  $\text{D}_2\text{O}$  and 5,000–5,200 transients were accumulated with a pulse length of 14  $\mu\text{s}$  and 1 s relaxation delay. The free induction decays were processed using an exponential line broadening of 100 Hz prior to Fourier transformation.

#### Results

Liposomes containing paclitaxel were prepared at varying drug:lipid ratios at a fixed lipid composition (PC/PG:9/1) and the mean recoveries of total phospholipids and PG colorimetry were  $95(\pm 7.1)$  and  $96(\pm 5.5)$ , respectively. In view of crystallization problems, formulations were also analyzed for paclitaxel content by a radiochemical method of analysis after centrifugation at 5,000 rpm for 5 min to sediment precipitated drug/lipids. The encapsulation of paclitaxel was always greater than 90% which shows the presence of pre-determined drug:lipid ratios in formulations during the time-frame of characterization. Subsequently, the sort of perturbations caused in bilayer physical properties were investigated by spectroscopic techniques to elucidate the interaction of paclitaxel with these unsaturated phospholipid membranes. By using fluorescent probes, it was possible to determine fluidity/rigidity of the lipid membrane due to paclitaxel as a function of depth within the bilayer. Further, the non-perturbing FT-IR spectroscopy technique allowed us to consolidate the findings of fluorescence polarization and to clarify the dynamics both in hydrocarbon and head-group regions. Finally,  $^{31}\text{P}$ -NMR shed light on the taxane induced generation of a non-bilayer phase that co-exists with the regular bilayer phase.

## Steady-State Fluorescence Anisotropy Studies

For a given probe, the degree of fluorescence polarization depends on the rotation of the fluorophore relative to the direction of its emission transition moment [15]. The steady-state fluorescence anisotropy technique adopted here for examination of paclitaxel in the bilayer employed three probes, namely, DPH, 12AS and ANS which locate at different regions in the bilayer. Anisotropy measurements were done at 30 and 40 °C for liposomes at different paclitaxel loadings (Fig. 2). In general, anisotropy at 40 °C was observed to be lower when compared to 30 °C for all the probes at all drug loadings (as temperature is raised, more *gauche* rotamers are excited in the bilayer hydrocarbon) except for ANS where, the trend was reversed at greater than 3 mol% loadings (Fig. 2c). Barring this exception, anisotropy curves followed nearly identical trends for all probes at both temperatures.

**Fig. 2** The effect of paclitaxel on microviscosity of PC:PG = 9:1 (mol/mol) bilayers studied by steady-state fluorescence anisotropy ( $r$ ) using membrane probes **a** DPH, **b** 12AS and **c** ANS. The lipid to probe ratios used were 300:1, 200:1 and 100:1 for DPH, 12AS and ANS. Filled diamonds 30 °C, filled squares 40 °C

At a given temperature, when the effect of paclitaxel on fluorescence anisotropy of DPH in soya PC:PG (9:1) bilayers was studied, the incorporation of paclitaxel caused a slight increase in anisotropy (Fig. 2a). It was also evident from Fig. 2 that at fixed temperature, the changes brought about in fluorescence anisotropy of DPH due to varying concentrations of paclitaxel were of considerably smaller magnitude than for the other two probes. Anisotropy values for DPH located in the hydrophobic core of bilayer increased slightly up to 1 mol% of paclitaxel after which a first plateau was observed till 3 mol%. Further increase in anisotropy was also seen with increase in drug loading from 3 to 5 mol% following which a second plateau was attained. In order to draw further information on the location of paclitaxel, 12AS was selected to understand the effects in the acyl chain region just above center of bilayer. The AS probes (2AS, 7AS and 12AS) have a stearic acid backbone that is intercalated parallel to fatty acid chains of the phospholipids with its charged carboxylic group anchored at interfacial region of the bilayer and 12AS probes region from the 8–9th to the 15–16th carbon [16]. In case of 12AS, the presence of paclitaxel even at lowest concentrations studied (0.5 mol%) decreased anisotropy values (Fig. 2b) and this was followed by a moderate increase thereafter with increasing paclitaxel concentrations (beyond 3 mol%).

Following anisotropy studies in the bilayer using DPH and 12AS probes, an attempt was also made to understand the interfacial phenomena exploring ANS probe. Since ANS is an interface probe, its anisotropic behavior physically reflects changes more on the bilayer surface morphology than in the lipid bilayer core. With increasing paclitaxel concentration, trends similar to that of 12AS were also observed in the case of ANS at both temperatures (Fig. 2c); the only points of difference being that the initial fall in anisotropy was less steep and a sudden increase was observed after 3 mol% loading. At 3 mol% of paclitaxel, anisotropy values were 0.183, 0.15 and 0.11 for DPH, ANS and 12AS, respectively, at 30 °C. The highest anisotropy values attained for the three probes at 30 °C were in the following order: DPH > 12AS > ANS (0.204 > 0.177 > 0.175). Clearly, the anisotropy curves for all probes showed no change at paclitaxel loadings greater than 5 mol% suggesting that at higher than optimal paclitaxel–lipid concentrations, the excess amounts may no longer be associated with the membrane interiors [17].

## Attenuated Total Reflectance FT-IR Studies

FT-IR spectroscopy was employed to examine the effects of paclitaxel on the conformation of lipid acyl chains as well as headgroup and interfacial regions. Spectra of control and paclitaxel-loaded liposomes over the 3,000–800  $\text{cm}^{-1}$

range are shown in Fig. 3, and frequencies of selected absorption bands are listed in Table 1. Absorption bands considered to yield the most useful information on the analysis of FT-IR spectra are: methylene asymmetric and symmetric stretching, carbonyl stretching, phosphate asymmetric and symmetric stretching modes. In the hydrocarbon region, C–H stretching frequencies increase with increase in the number of *gauche* conformers while the bands broaden as a result of increasing motional freedom of methylene groups. In the spectral region of 3,000–2,800  $\text{cm}^{-1}$  for control liposomes, the acyl chain methylene C–H bond asymmetric stretching  $\nu_{\text{as}}(\text{CH}_2)$  and symmetric stretching  $\nu_{\text{s}}(\text{CH}_2)$  were observed at 2,925 and 2,852  $\text{cm}^{-1}$ , respectively. Due to paclitaxel,  $\nu_{\text{as}}(\text{CH}_2)$  stretch frequencies were unaltered while  $\nu_{\text{s}}(\text{CH}_2)$  frequency was  $\sim 2,854 \text{ cm}^{-1}$ . Though  $\nu_{\text{as}}(\text{CH}_2)$  was not affected due to paclitaxel, that of  $\nu_{\text{s}}(\text{CH}_2)$  stretch was substantially increased (2  $\text{cm}^{-1}$ ). Further, the methyl C–H bond asymmetric stretch  $\nu_{\text{as}}(\text{CH}_3)$  mode which was observed at 2,966  $\text{cm}^{-1}$  for control liposomes, was less apparent in paclitaxel liposomes due to broadening. These changes were also accompanied by significant increases in band widths of  $\nu_{\text{as}}(\text{CH}_2)$  and  $\nu_{\text{s}}(\text{CH}_2)$  stretch frequencies (Fig. 3, inset) indicating to alteration of lipid acyl chain dynamics [18].

The other most useful information regarding acyl chain packing and inter-chain interactions is derived from  $\text{CH}_2$  scissoring and wagging modes. For control liposomes a single sharp peak representing acyl  $\text{CH}_2$  scissoring mode was observed at 1,456  $\text{cm}^{-1}$  while for paclitaxel liposomes, it was observed with reduced intensity between 1,458 and 1,460  $\text{cm}^{-1}$ . On the other hand, the acyl  $\text{CH}_2$  wagging mode comprised multiple peaks in the spectra of

control liposomes at 1,317, 1,289 and 1,261  $\text{cm}^{-1}$  were not only shifted but also broadened by the incorporation of paclitaxel. The peak at 1,370  $\text{cm}^{-1}$  observed in control liposomes which is considered to originate from the terminal  $\delta_{\text{s}}(\text{CH}_3)$  symmetric bending mode, was found at 1,369–1,371  $\text{cm}^{-1}$  for paclitaxel liposomes whose intensity lowered as a function of loading. The other weak bands corresponding to that of  $\text{CH}_2$  scissoring adjacent to C=O group and terminal  $\delta_{\text{as}}(\text{CH}_3)$  asymmetric bending modes were found at 1,422 and 1,432  $\text{cm}^{-1}$ , respectively, in absence of paclitaxel. Upon incorporation of drug, these peaks merged into a single broad band and lacked sufficient resolution which did not allow assignment of frequencies to individual bands. Such characteristic changes in IR behavior of  $\text{CH}_2$  adjacent to C=O are possibly reflective of conformational changes in the interface of bilayer which is in line with the changes observed for the carbonyl stretching band, as discussed below.

In the spectral region of 1,700–1,800  $\text{cm}^{-1}$ , the phospholipid ester carbonyl stretching mode  $\nu(\text{C}=\text{O})$  was observed as a sharp and symmetric peak at 1,741  $\text{cm}^{-1}$  in the absence of paclitaxel in bilayers. However, there was a gradual broadening of the  $\nu(\text{C}=\text{O})$  band with an increasing concentration of paclitaxel and the intensity of the peak was lost to the developing shoulder on the low frequency side leading to peak asymmetry. The other important feature in spectra at the interfacial region of lipid membranes is that representative of C–O stretching, namely  $\nu(\text{OC}-\text{O})$  of esters of fatty acyl chains. This peak observed at 1,170  $\text{cm}^{-1}$  (0 mol%) was broadened with paclitaxel concentration (1–2 mol%) but reappeared at 3 mol% as a weak signal. These observations are not only suggestive of unique interactions of the C=O group at the interface but

<sup>a</sup> Peak assignments were done according to references [25–28, 32]

the reappearance of the C–O peak also indicates paclitaxel concentration being dependent on organizational differences of phospholipid molecules [19].

Besides the carbonyl group, the phosphate group is also sensitive to polarity changes in the headgroup region. When the effects of paclitaxel on the headgroup region were monitored via the asymmetric  $\nu_{\text{as}}$  (P=O) and symmetric  $\nu_{\text{s}}$  (P=O) stretch of phosphate, there were significant shifts in frequency of the former peak. In contrast to the usually observed single  $\nu_{\text{as}}$  (P=O) peak for a given species of phospholipid, IR spectra here showed two well resolved peaks at 1,226 and 1,212 cm<sup>-1</sup>; the former peak arising due to free phosphate and the latter from hydrogen bonded phosphate. This is considered as being possibly due to the presence of PG in the liposomes whose –OHs of glycerol moiety are known to form hydrogen bonds with phosphate thereby reducing the IR frequency [19, 20]. On this basis,  $\nu_{\text{as}}$  (P=O) at 1,226 cm<sup>-1</sup> for blank liposomes was assigned to free P=O, which was found to shift to 1,228, 1,232 and 1,234 cm<sup>-1</sup>, respectively, at 1, 2 and 3 mol% paclitaxel loadings. On the other hand,  $\nu_{\text{as}}$  (P=O) of hydrogen bonded phosphate moved in the opposite direction, i.e., from 1,212 cm<sup>-1</sup> (0 mol% drug) to 1,209 cm<sup>-1</sup> (1 mol%) and 1,204 cm<sup>-1</sup> (3 mol%) as a result of which the 2 peaks were clearly resolved. Though paclitaxel shifted both  $\nu_{\text{as}}$  (P=O) stretch of free and hydrogen bonded wavenumbers in liposomes,  $\nu_{\text{s}}$  (P=O) stretch wavenumber was only slightly altered (1,089–1,887 cm<sup>-1</sup>).

Other important changes include, a prominent shift in  $\nu$  (R–O–P–O–R') stretch band from 1,067 cm<sup>-1</sup> (control

liposomes) to 1,061, 1,055 and 1,049 cm<sup>-1</sup> for 1, 2 and 3 mol% paclitaxel loaded liposomes. Another peak distinctly observed in control liposomes but absent from paclitaxel liposomes was located at 1,019 cm<sup>-1</sup>, and this peak was a result of C–OP stretch in phosphate ester region. Further, in the headgroup region, N(CH<sub>3</sub>)<sub>3</sub> bending mode located at 1,489 cm<sup>-1</sup> and n (P–O) phosphate ester stretch at 810 cm<sup>-1</sup> were all considerably broadened upon incorporation of paclitaxel in liposomes. In addition to effect on  $\nu_{\text{as}}$  (P=O) vibration, concomitant changes recorded for the n (P–O) and n (C–OP) frequencies are also in support of paclitaxel mediated changes in the phosphate group. The broadening of  $\nu_{\text{s}}$  (P=O) and n (R–O–P–O–R') vibration bands indicating to greater mobility also is in agreement with increased fluidity due to paclitaxel in the headgroup region [20]. Further, in the headgroup region, broadening of the N(CH<sub>3</sub>)<sub>3</sub> bending mode and n (P–O) phosphate ester stretch might confirm findings with the ANS probe, namely, increased fluidity. A further examination of headgroup conformational changes was based on 31P-NMR spectroscopy.

### 31P-NMR Studies

31P-NMR measurements were carried out with paclitaxel-loaded and paclitaxel-free liposomes to find out whether the drug was interacting with the headgroups. In the concentration range studied (1–3 mol%), all formulations showed an intermediate-type powder spectrum with a high-field peak at approx. –7 ppm and a low-field

shoulder typical of bilayer arrangement of phospholipids within membrane (Fig. 4). The spectrum suggests that 400 nm sized vesicles undergo motional averaging due to a tumbling motion and the low intensity peak at 0 ppm superimposed on the main peak for control liposomes might be due to the presence of small vesicles [20, 21]. An important feature in the spectra following incorporation of paclitaxel is the emergence of a sharp isotropic signal at  $\sim 0$  ppm which increased in intensity with increasing drug concentration (Fig. 4). Also,  $^{31}\text{P}$ -peak positions were observed to slightly shift towards isotropic signal indicating to fluidization of bilayers [22] and shapes were altered due to paclitaxel at the peak crest (Fig. 5). A closer inspection of NMR spectra discloses that liposomes containing paclitaxel present a small but distinct increase in the low field shoulder at the base (Fig. 5). The relation of paclitaxel concentration in liposomes to the overall peak shape and isotropic signal intensity at 0 ppm implies concentration-dependent effects of the molecule on PC:PG lipid bilayers.

## Discussion

A number of reports exist in the literature dealing with the formulation of paclitaxel liposomes, which were shown to increase the biological half-life of drug [23] and retain anti-tumor properties of the molecule in cancer models [7]. In the clinical trials, liposomal paclitaxel was better tolerated than the cremophor formulation in the absence of standard

Note the gradually developing shoulder on low field with increasing paclitaxel concentration as indicated with broken-line arrow

premedication drugs even at higher doses [6]. Although paclitaxel is known to be located at the interface of the lipid bilayer, specific information about the nature of the interaction and the part of the phospholipid molecule involved is lacking. This information may help to better elucidate formulation aspects and the therapeutic efficacy of these delivery systems. Hence, in the current investigation an attempt was made to examine paclitaxel-bilayer interactions and results derived from fluorescence anisotropy, FT-IR and  $^{31}\text{P}$ -NMR techniques are presented.

In fluorescence anisotropy studies, a decrease in anisotropy is explained by the increased fluidity of the bilayers [17]. If it is assumed that anisotropy of DPH reflects the average extent of acyl chain motion within the bilayer core by virtue of its location, the incorporation of paclitaxel has a weak rigidizing effect in the core of bilayer (towards the terminal methyl end of the lipid acyl chain, Fig. 1a). In contrast, the effect of paclitaxel in liposomes was quite different on 12AS and ANS probes where anisotropy of 12AS and ANS decreased at 0.5–3 mol% loading. The decrease in anisotropy of the 12AS probe was more dramatic (Fig. 2b) and the trend reflects the fluidizing effect of paclitaxel in the vicinity of this probe below 3 mol% incorporation. Moreover, the anisotropy of ANS was also found to decrease with the incorporation of paclitaxel in the concentration range of 0.5–3 mol% (Fig. 2c) and this decrease in anisotropy may also be related to increased fluidity at the interface. The variation in membrane fluidity, that is the occurrence of fluidity gradient across the bilayer, was also previously demonstrated for local anesthetics [24]. At > 3 mol% drug loading, an increase in ANS anisotropy was observed which might be attributed to onset of typical aggregation behavior of the taxane, as pointed out elsewhere [8]. At higher loadings, the aggregation of paclitaxel monomers into micro-clusters might occur at the interface resulting in partitioning of the ANS probe into these structures where the molecules experience higher anisotropy. Since the magnitude of anisotropy changes were maximally recorded for 12AS and ANS probes, it is anticipated that paclitaxel is located within the vicinity of these probes. In accordance with this assumption, paclitaxel is mainly located in the cooperativity region (towards the interface) with some part of the molecule extending into the headgroup region of the bilayer, as shown previously [10].

Further detailed understanding of intra- and intermolecular interactions occurring within lipid membranes was gained by FT-IR as a non-perturbing physical technique and these interpretations are classified into spectral features originating from the nonpolar hydrocarbon acyl chains, interfacial and headgroup regions (Table 1). Considering the acyl chain spectral features, the increase in frequency of the vibration of the  $\nu_s$  ( $\text{CH}_2$ ) band caused by paclitaxel (Fig. 3) is a reflection of the change in conformation of the lipid acyl chain from the ordered *trans* C–C structure to the disordered *gauche* C–C structures [25]. Also the conformational disorder caused by paclitaxel was accompanied by bandwidth increases leading to augmentation of rotational mobility of acyl chains [18]. This fact was also reinforced by the broadened and decreased intensity of  $\text{CH}_2$  scissoring/wagging bands attributed to increased mobility and higher proportion of *gauche* conformers of methylene groups in acyl chains caused by

paclitaxel [20]. This effect, when put together with decreased fluorescence anisotropy of 12AS, it may be regarded that paclitaxel induces an increased degree of disorderliness in bilayers and leads to increased fluidity of bilayers [26].

An idea about molecular organization in the interfacial regions can be drawn by monitoring the spectral properties of carbonyl (C=O). The C=O band stretching is sensitive to changes in the polarity of the local environment and is influenced by hydrogen bonding or other interactions occurring in the presence of interfacially placed molecules. Also, any change in the contours of the  $\nu$  (C=O) band has often been understood in terms of structural and/or hydration changes at the bilayer interface [20]. In the present study, the typical alteration in the contour of the  $\nu$  (C=O) stretch peak (low field shoulder; Fig. 3) by paclitaxel may be interpreted as conformational changes along with an increased rate of motion. This is coincident with the distinct changes generated each in the  $\nu$  (OC–O) stretch mode and scissoring of  $\text{CH}_2$  (adjacent to C=O) mode. In addition to the above-mentioned conformational changes, the broadening might also indicate to the possibility of involvement in hydrogen bonding for the population of carbonyl along the shoulder, since  $\nu$  (C=O) stretch peak shoulder extended by about 10–20  $\text{cm}^{-1}$  from the principal peak in the presence of paclitaxel [20]. Hydrogen bonding of water molecules to  $\nu$  (C=O) group of phospholipid molecule was shown to shift the carbonyl stretch wavenumber to lower values resulting from a decrease in the double bond character [26–28]. In this regard, hydrogen bonding between the carbonyl of the phospholipids and the OH of water/paclitaxel is an immediate explanation in light of the decreased (C=O) bond strength. In order to arrive at a more plausible explanation in search of hitherto proposed hydrogen bonding, the incumbent evidence gathered from events occurring in headgroup region namely,  $\nu_{\text{as}}$  (P=O), will be considered.

In the headgroup region of lipid vesicles, the most widely studied spectral feature is the IR absorption band of the phosphate because wavenumber of P=O mode is particularly sensitive to hydration/dehydration state of phosphate. Generally,  $\nu_{\text{as}}$  (P=O) stretch mode is considered more sensitive and diagnostic of dehydration where, values around 1,220  $\text{cm}^{-1}$  are reported for hydrated state and 1,235–1,250  $\text{cm}^{-1}$  are observed for the dehydrated phosphate group [25]. In this context, an upward shift in the frequency of  $\nu_{\text{as}}$  (P=O) indicates distinct effects of paclitaxel in the interfacial region arising from dehydration of phosphate due to the removal of water, because hydrogen bonding to the oxygen atom would have an opposite effect, i.e., a decrease in frequency due to weakening of the vibrational force constant [19]. Since this comprehension is strongly supported by relevant

findings in literature and devoid of any ambiguity, it could be inferred that paclitaxel causes expulsion of water thereby decreasing the polarity in headgroup region, a condition favorable for association of hydrophobic taxane with bilayers at interface. A further extrapolation of this inference to C=O at interfacial region is that water is unavailable for hydrogen bonding with carbonyl of phospholipids thus indicating to the alternative possibility, i.e., the likely involvement of paclitaxel itself. In fact, previous studies claimed the location of paclitaxel in interfacial region of bilayer while the potential of 2'/7-OH groups of the molecule (Fig. 1) to engage in hydrogen bonding interactions was reported elsewhere [29]. From a consideration of structure of paclitaxel (Fig. 1), the involvement of 2'-OH in hydrogen bonding with phospholipid may be speculated based on geometrical and polarity constraints as this would obviate the need for placing the bulky taxane ring at the bilayer interface. There are other studies which indicate the existence of intermolecular interactions via C=O groups by means of hydrogen bonds in lipid membranes. Based on FTIR observations, it has been shown that melatonin interacts with dipalmitoyl PC through strong hydrogen bonding with (C=O) group [30]. Another publication reported on the extensive hydrogen bonding phenomenon between carbonyl ester of egg PC liposomes and OH of galactose moieties of digalactosyldiacylglycerol [31].

A special feature of PG-containing PC bilayers is the inter-molecular hydrogen bonding between headgroups [32] and the increased hydrophobicity of PC bilayers. Apart from interaction with the carbonyl, paclitaxel also seems to promote stronger hydrogen bonds between the hydroxyl of glycerol of PG and the phosphate of PC, i.e., following removal of water, the glycerol moiety of PG more closely interacts with P=O probably due to conformational changes in the headgroup region and steric factors. On extrapolating these properties of PG in lipid bilayers to paclitaxel liposomes, the simultaneous increase in hydrophobicity along with modification of bilayer headgroup with hydrogen bonding capacities could be held responsible for the observed favorable effects of PG, namely, promotion of formulation stability [3, 5].

<sup>31</sup>P-NMR spectroscopy provides valuable information on the organization of lipid bilayer vesicles due to sensitivity of the conformation and dynamics of the phosphate nucleus in the phospholipid headgroup to the surrounding environment. Differences in <sup>31</sup>P-NMR line shapes/widths have been understood in terms of orientation of phospholipid headgroups and the motions that cause the related residual chemical shift anisotropy. Boulanger et al. [33] reported 8% change in the <sup>31</sup>P-NMR basal line width in egg PC vesicles in the presence of charged tetracaine which preferably interacts with bilayers

towards the interfacial region while such changes were absent with the uncharged form due to localization in the core of lipid membrane. Similarly, the interfacially interacting taxane altered <sup>31</sup>P-NMR peak crest shapes (Fig. 5) because fluidity changes in bilayers could affect the motion of headgroups [20, 34]. To this end, the possibility of hydrogen bonding of paclitaxel with P=O of phosphate is ruled out since there is no distinct phosphorus peak associated with this event in <sup>31</sup>P-NMR spectra (Fig. 4). Importantly, in the NMR spectra of liposomes there have been two major events associated with the incorporation of paclitaxel which were concentration dependent: the appearance of (1) a low field weak shoulder (increased basal line width) and (2) an isotropic peak. The shoulder albeit small due to low drug loadings and liquid crystalline nature of bilayers (Fig. 5), indicate to perturbations introduced in bilayer by paclitaxel. These perturbations might result from increased hydrogen bonding of phosphate with glycerol and the presence of paclitaxel-rich domains. While the former of the two possibilities has already been speculated on from FT-IR data and can be explained by reduced mobility of the phosphate thereby increasing <sup>31</sup>P-NMR basal line widths, the latter event is based on non-homogeneous distribution of paclitaxel with lipids as a consequence of which such domains are formed and phase segregated from the rest of the membrane [8, 35]. These paclitaxel-rich domains, in contrast to the rest of the bilayer, would be featured with higher drug:lipid ratios with unique packing parameters.

An explanation for the isotropic peak is directed towards phospholipid molecules being present in non-bilayer phases (Fig. 5) within the lipid membrane and/or due to the formation of paclitaxel–phospholipid mixed micelles [36]. Owing to paclitaxel, a small fraction of lipid molecules participating in the bilayer phase are increasingly brought into the non-bilayer phase, for example, the hexagonal phase fostered by PG, whose phosphate headgroups are featured with rapid motion on the <sup>31</sup>P-NMR time scale, thus exhibiting an isotropic signal [22, 36]. As reported earlier, the propensity of phospholipids to form non-bilayer phases followed by accumulation of paclitaxel aggregates into them is also thermodynamically favorable in view of reduced perturbation caused on bilayers in the aggregated state at higher concentrations [8]. Elsewhere, the ability of amitriptyline to transform egg PC bilayers into mixed micelles has been described [37–39]. It is highly probable that with increased loading, paclitaxel is gradually expelled out of the bilayer into a new non-bilayer transient phase and; the non-bilayer structures are involved in a fusion process that would promote coalescence of smaller vesicles to produce larger liposomes and increase the dispersion size on the shelf [39, 40].

## Conclusion

The nature of the interaction of a guest molecule with the lipid bilayer depends not only on its hydrophobicity and conformation but also on the location of the molecule within the lipid membrane and the steric compatibility. Paclitaxel was predominantly observed to have a fluidizing effect on unsaturated phospholipid liposomal bilayers thereby influencing the acyl chain dynamics. However, the nature of paclitaxel interaction with the bilayer seems to be rather complex in that conformational changes are caused almost over the whole stretch of the membrane as a consequence of which, its influences are felt from the headgroup to the acyl chain terminal regions within the bilayer. Thus, it is considered that paclitaxel caused a significant alteration in the conformation of lipid acyl chains and the physical state of the bilayer. A further examination of these events by FT-IR spectroscopy revealed dehydrating effects of paclitaxel on phosphate groups as well its direct or mediated interaction with the carbonyl of the phospholipid. In addition, at higher concentrations of paclitaxel, phospholipid molecules tend to form non-bilayer structures and probably taxane-rich domains. Given these findings, the examination of molecular orientation of paclitaxel in bilayer and non-bilayer phases would be a subject of further interest.

**Abstract** 2-Chlorohexadecanal (2-CIHDA), a 16-carbon chain chlorinated fatty aldehyde that is produced by reactive chlorinating species attack of plasmalogens, is elevated in atherosclerotic plaques, infarcted myocardium, and activated leukocytes. We tested the hypothesis that 2-CIHDA and its metabolites, 2-chlorohexadecanoic acid (2-CIHA) and 2-chlorohexadecanol (2-CIHOH), induce COX-2 expression in human coronary artery endothelial cells (HCAEC). COX-2 protein expression increased in response to 2-CIHDA treatments at 8 and 20 h. 2-CIHA also increased COX-2 expression following an 8 h treatment. Quantitative PCR showed that 2-CIHDA treatment increased COX-2 mRNA over 8 h, while 2-CIHA treatment led to a modest increase by 1 h and those levels remained constant over 8 h. 2-CIHDA led to a significant increase in 6-keto-PGF<sub>1 $\alpha$</sub>  release (a measure of PGI<sub>2</sub> release) by HCAEC. These data suggest that 2-CIHDA and its metabolite 2-CIHA, which are produced during leukocyte activation, may alter vascular endothelial cell function by upregulation of COX-2 expression.

**Keywords** Myeloperoxidase ·  
Reactive chlorinating species (RCS) · Fatty acid ·  
Fatty alcohol · Plasmalogen · Prostacyclin

### Abbreviations

RCS	Reactive chlorinating species
2-CIHDA	2-Chlorohexadecanal
2-CIHA	2-Chlorohexadecanoic acid
2-CIHOH	2-Chlorohexadecanol
HDA	Hexadecanal
COX-2	Cyclooxygenase-2
NF- $\kappa$ b	Nuclear factor kappa B
TNF- $\alpha$	Tumor necrosis factor-alpha
HCAEC	Human coronary artery endothelial cells
MPO	Myeloperoxidase

### Introduction

The inducible form of cyclooxygenase (COX-2) is highly expressed in atherosclerotic lesions and nearly absent in normal arterial tissue [1]. Both COX-1, which is constitutively active, and COX-2 catalyze the production of prostaglandin H<sub>2</sub> (PGH<sub>2</sub>) from phospholipid-derived arachidonic acid [2, 3]. PGH<sub>2</sub> is subsequently converted by cell-specific isomerases into several structurally different eicosanoids. Activation of the coronary endothelium, leads to the production and release of PGI<sub>2</sub> [4, 5], which has vasodilatory and anti-atherogenic properties [6–8] that is partially mediated by upregulation of COX-2 [9].

Myeloperoxidase (MPO), highly expressed in atherosclerotic lesions [10], catalyzes the production of potent oxidants collectively termed reactive chlorinating species (RCS) [11]. The collateral damage caused by MPO-derived RCS to host tissue includes the formation of chlorinated tyrosine [12], cholesterol [12], and lipids [13–15]. Plasmalogens, a subclass of choline glycerophospholipids that contains a vinyl ether linkage between the *sn*-1 aliphatic chain and the glycerol backbone, are particularly abundant

in the heart vasculature [16–18]. We have shown that RCS attack the vinyl ether bond of plasmalogen, resulting in the release of 2-CIHDA (2-chlorohexadecanal) [19], which accumulates in activated neutrophils [14], monocytes [20, 21], ischemic/reperfused myocardium [22] and atherosclerotic aorta [21]. Thus far, 2-CIHDA has been shown to reduce eNOS (endothelial nitric oxide synthase) expression in endothelial cells [23] and elicit neutrophil chemoattraction [14].

2-CIHDA is oxidized and reduced to 2-chlorohexadecanoic acid (2-CIHA) and 2-chlorohexadecanol (2-CIHOH), respectively [24]. Little is known about the signaling properties of this unique class of chlorinated lipids resulting from MPO-mediated RCS attack of plasmalogens. In this study, we examined the effect of 2-CIHDA, 2-CIHA, and 2-CIHOH to induce COX-2 expression in HCAEC. The results suggest that 2-CIHDA and 2-CIHA, but not 2-CIHOH, induce COX-2 protein expression and PGI<sub>2</sub> release by increasing COX-2 gene expression.

## Experimental Procedures

### Lipid Preparation

2-CIHDA was prepared by treating 1-O-hexadec-1'-enylglycero-3-phosphocholine (100 mg) with freshly prepared hypochlorous acid (final concentration 1.5 mM) in phosphate buffer (pH 4) for 5 min at 37°C [24]. Reactions were terminated by lipid extraction and the chloroform layer was collected [25]. 2-CIHDA was purified by HPLC utilizing a Dynamax Si column (21.4 mm × 250 mm; 8 μm), and gradient elution over 3 h with hexane as the initial mobile phase and chloroform as the final mobile phase at a flow rate of 8 ml/min. Purity of synthetic 2-CIHDA was confirmed by GC-MS, and quantified by acid methanolysis and GC-FID (HP 5890A) using arachidic acid as an internal standard. 2-CIHA was synthesized and purified as previously described [24]. To synthesize 2-CIHOH, 2-CIHDA was resuspended in 2 ml radical free ethyl ether and 0.5 ml benzene and treated with Red Al<sup>TM</sup> reagent for 30 min at 37°C [24]. 2-CIHOH was purified by TLC (petroleum ether/ethyl ether/acetic acid (70/30/1 v/v/v) ( $R_F$  = 0.41).

### Cell Culture

HCAEC (Cell Applications, San Diego, CA) were seeded onto 60-mm<sup>2</sup> or 35-mm<sup>2</sup> 6-well polystyrene dishes and cultured in EGM-2-MV growth medium (Lonza, Walkersville, MD) at 37°C in a 5% CO<sub>2</sub> and 95% air atmosphere. Experiments were performed on confluent monolayers (~1 × 10<sup>6</sup> cells/60-mm<sup>2</sup> dish) between passages 5 and 9. HCAEC growth medium was replaced with growth medium

containing 2% FBS for 4–6 h prior to experiments. Lipids were dried under a stream of nitrogen and reconstituted in ethanol to inject into culture medium at a final ethanol concentration of 0.1%. Lipids were mixed with basal medium and added to each dish by pipette for a final concentration of 50 μM. TNF-α was mixed with basal medium containing 0.1% ethanol and added to dishes for a final concentration of 50 ng/ml. Control conditions included incubations with basal medium containing a final ethanol concentration of 0.1%.

### Western Blotting

Following each experimental condition, the medium was aspirated from the dishes and HCAEC monolayers were rinsed with PBS. Cells were scraped in SDS sample buffer, boiled, and protein was subjected to SDS-PAGE utilizing 10–12.5% polyacrylamide gels followed by transfer of proteins to polyvinylidene difluoride (PVDF)-plus membranes (GE Osmonics Inc., Trevose, PA) for Western blot analysis. Blots were probed with a monoclonal anti-COX-2 (1:1,000) (Zymed, San Francisco, CA) and an HRP-conjugated secondary antibody (1:7,000) (BioRad, Hercules, CA). Blots were stripped using 0.1 M glycine (pH 2.5) and, reprobed with a monoclonal anti-IκB (1:2,500) (BD Transduction Laboratories, San Jose, CA). Blots were stripped again and probed with a polyclonal β-Actin (1:5,000) (Abcam, Cambridge, MA) and probed with an HRP-conjugated goat-anti-rabbit (1:7,000) (Sigma, St. Louis, MO). Immunoreactive bands were visualized by exposure to autoradiographic film following incubation with enhanced chemiluminescence reagent (GE Healthcare, Piscataway, NJ). Densitometric analyses of immunoreactive bands were performed using ImageQuant software.

### RNA Extraction, Reverse Transcription, and Quantitative PCR

RNA was extracted and purified using an RNeasy Mini Kit (Qiagen, Valencia, CA) by following the manufacturer's instructions. Less than half of the mRNA elute was incubated with 0.5 μg Oligo (dT)<sub>12–18</sub> primer (Invitrogen, Carlsbad, CA) at 70°C for 10 min to yield cDNA. RNA and reaction mixture (200 units M-MLV H<sup>-</sup> reverse transcriptase (Promega, Madison, WI), buffer, dNTPs (Invitrogen, Carlsbad, CA), and 0.1 M DTT) were incubated at 42°C for 50 min and terminated at 70°C for 15 min. Reaction mix was incubated with 1U RNase H (Invitrogen, Carlsbad, CA) at 37°C for 20 min. Real-time PCR of the cDNA library was performed by mixing 1 μl cDNA, primers for COX-2 or GAPDH-1, dNTPs, TAQ polymerase, buffer, and SYBR Green fluorescence probe followed by quantitative RT-PCR (BioRad OpticonII) using the following parameters: 40 cycles of 95°C for 1 min, 56°C for 0.5 min, 72°C for 0.5 min, 87°C for 3 s. A

melt curve from 80–96°C was performed. The COX-2 primer pairs (SuperArray, Frederick, MD) and the primer sequences (5′–3′) for GAPDH-1 are GCATCTTC-TTT TGCGTCGCC (forward), and GTCATTGATGGCAA-CAATATCC (reverse) were used. Data were analyzed using BioRad Opticon II software and COX-2 levels were normalized to GAPDH-1 levels for each sample. Fidelity of the PCR reaction was determined by melting temperature analysis and visualization of products on a 2% agarose gel.

#### 6-keto-PGF<sub>1α</sub> Quantification

Following experimental conditions, the medium from each 60-mm<sup>2</sup> HCAEC monolayer dish was removed and centrifuged. The internal standard d<sub>4</sub>-6-keto-PGF<sub>1α</sub> at 10 pg was added to each sample followed by acidification with HCl to 2.5 pH for 30 min. C-18 SPE columns (Supelco, Bellefonte, PA) were washed with acetonitrile and equilibrated with water prior to addition of samples. Following sample loading, columns were sequentially washed with acidic water (2.5 pH) and water/ethanol (85:15 v/v) prior to elution of prostaglandins with ethyl acetate. Samples were dried under a stream of nitrogen and derivatized by treatment with O-methoxamine and PFB-Br followed by BSTFA as described previously [26]. Samples were reconstituted in ethyl acetate for GC-MS analysis. PGI<sub>2</sub> was measured as its stable hydrolytic product 6-keto-PGF<sub>1α</sub>. Samples were analyzed by selected ion monitoring on a Hewlett Packard 6890 GC coupled to a Hewlett Packard 5973 MS as described previously [27].

#### Cell Death

Following experimental conditions, cell medium was removed from 60-mm<sup>2</sup> dishes, centrifuged, and assayed for general cell death using a lactate dehydrogenase release assay (Sigma, St. Louis, MO) following the manufacturer's instructions.

#### Data Analysis

Statistical analyses of data were performed by one-way ANOVA followed by a Dunnett post hoc test, as appropriate.  $P \leq 0.05$  was considered statistically significant.

## Results

#### Effects of TNF- $\alpha$ , 2-CIHDA and 2-CIHA on COX-2 Protein Expression

COX-2 expression in vascular endothelial cells is induced in response to several cytokines such as TNF- $\alpha$  and IL-1 $\beta$

[9, 28, 29] suggesting that COX-2 may be involved in the pathophysiology of inflammation [30]. Induction of COX-2 in the endothelium leads to the production and release of PGI<sub>2</sub> [31], which has vasodilatory and anti-atherogenic properties. A time course analysis of TNF- $\alpha$ -treated HCAEC monolayers shows an increase in COX-2 protein expression by 8 h, reaching maximal expression at 20 h (Figs. 1, 2a). In comparison to TNF- $\alpha$  at 20 h, 50  $\mu$ M 2-CIHDA induced COX-2 expression to a lesser degree (Figs. 1, 2a). 2-CIHA increased COX-2 expression within 8 h, and returned to baseline by 20 h. 2-CIHDA, however, induced COX-2 expression above control at both 8 and 20 h (Figs. 1, 2a). Neither 2-CIHOH nor hexadecanal (HDA), the non-chlorinated aldehyde, induced COX-2 protein expression. Parallel experiments were performed showing that these chlorinated lipids did not cause significant cell death as determined by a lack of LDH release (Fig. 2b). Normal LDH concentrations fall between 100–350 U/ml, while elevated LDH concentrations occur above 500 U/ml. Treatment of 100  $\mu$ M 4-hydroxy-2-nonenal (HNE), known to induce cell death, was used as a positive control.

#### Effects of TNF- $\alpha$ , 2-CIHDA and 2-CIHA on COX-2 Gene Expression

Quantitative PCR was performed to explore the effects of HCAEC monolayers treated with TNF- $\alpha$ , 2-CIHDA, 2-CIHA, or vehicle on COX-2 gene expression. Treatment with TNF- $\alpha$  led to a rapid 2.5-fold increase in mRNA expression by 1 h and levels returned to control levels by 2 h (Fig. 3). COX-2 mRNA expression following 2-CIHDA treatment increased by  $\sim 3$  fold by 8 h. HCAEC treatment with 2-CIHA induced a 2-fold increase in COX-2 mRNA by 2 h and remained elevated by 8 h. In all treatment conditions, COX-2 mRNA levels returned to near control levels by 18 h (Fig. 3).

**Fig. 1** 2-Chlorohexadecanal and 2-chlorohexadecanoic acid induce COX-2 protein expression in HCAEC. Cell lysates were prepared from HCAEC treated with ethanol vehicle, 50 ng/ml TNF- $\alpha$ , or 50  $\mu$ M of hexadecanal (HDA), 2-chlorohexadecanal (2-CIHDA), 2-chlorohexadecanoic acid (2-CIHA), or 2-chlorohexadecanol (2-CIHOH) for 8 or 20 h as indicated. Samples were subjected to SDS-PAGE and western blotting for COX-2 expression

**Fig. 2** Time course of 2-chlorohexadecanal and 2-chlorohexadecanoic acid elicited COX-2 protein expression in HCAEC. Cell lysates were prepared from HCAEC treated with ethanol vehicle, 50 ng/ml TNF- $\alpha$ , or 50  $\mu$ M of hexadecanal (HDA), 2-chlorohexadecanal (2-CIHDA), 2-chlorohexadecanoic acid (2-CIHA), or 2-chlorohexadecanol (2-CIHOH) for 2 h (light grey bars), 8 h (black bars), and 20 h (striped bars). Samples were subjected to SDS-PAGE and western blotting for COX-2 expression and analyzed by densitometry of immunoreactive bands (a). Following COX-2 analysis, blots were subsequently stripped and then subjected to western blotting for  $\beta$ -actin, which was used to normalize each experimental analysis of COX-2 expression. Cell medium was assayed for general cell death using a lactate dehydrogenase release assay (b). Values (mean  $\pm$  SEM) are expressed as fold increase over control-treated cells for three independent determinations, \*\* represents  $P < 0.01$

### 2-CIHDA and 2-CIHA Elicit PGI<sub>2</sub> Release

The predominant COX-derived arachidonic acid product in coronary endothelial cells is PGI<sub>2</sub> [4, 5, 7]. 6-keto-PGF<sub>1 $\alpha$</sub> , the stable hydrolytic product of PGI<sub>2</sub>, was measured in cultured medium following solid phase extraction, derivatization, and GC-MS analysis [26, 27]. TNF- $\alpha$  treatment led to nearly a 2-fold increase in 6-keto-PGF<sub>1 $\alpha$</sub> , while 2-CIHDA, but not 2-CIHA at 20 h, led to lower but significant increases in 6-keto-PGF<sub>1 $\alpha$</sub> , (Fig. 4), analogous to the pattern seen in protein expression (Fig. 2a).

### NF- $\kappa$ B Signaling Pathways by TNF- $\alpha$ , 2-CIHDA

NF- $\kappa$ B is normally sequestered in the cytosol by I $\kappa$ B under non-inflammatory conditions. Upon stimulation of the NF- $\kappa$ B pathway, I $\kappa$ B is targeted for degradation and NF- $\kappa$ B is free to translocate to the nucleus where it binds to NF- $\kappa$ B DNA sites in the promoter of various genes. It has been shown in several cell types that treatment with TNF- $\alpha$  leads to NF- $\kappa$ B binding to the COX-2 promoter and reporter

gene expression [31–33]. In HCAEC, TNF- $\alpha$  and 2-CIHDA led to significant I $\kappa$ B protein disappearance at 20 h, while 2-CIHA or other tested lipids did not to lead to a significant decrease in I $\kappa$ B protein levels (Fig. 5a, b).

### Discussion

Oxidative attack of plasmalogens by RCS leads to the production of reactive lipid aldehydes, such as 2-CIHDA [19]. Little is known about the possible signaling roles these naturally occurring halogenated lipids play. Marsche et al. [23] discovered that HDL treated with hypochlorous acid, a component of RCS, led to a reduction in eNOS expression in endothelial cells and, upon further investigation, found that 2-CIHDA was responsible for the reduction in eNOS. An abundant non-chlorinated lipid aldehyde, HNE, has been shown to induce COX-2 expression in RAW264.7 macrophages [34, 35] and in human osteoarthritic chondrocytes [35]. In the present study, we show that TNF- $\alpha$ , 2-CIHDA, and 2-CIHA, but not 2-CIHOH, induce an increase in COX-2

**Fig. 3** 2-Chlorohexadecanal and 2-chlorohexadecanoic acid induce COX-2 mRNA expression. HCAEC were treated with either ethanol vehicle, 50 ng/ml TNF- $\alpha$  (light gray bars), or 50  $\mu$ M 2-chlorohexadecanal (2-CIHDA) (striped bars) or 50  $\mu$ M 2-chlorohexadecanoic acid (2-CIHA) (black bars) for the times indicated. Cells were scraped in lysis buffer, cDNA was prepared from purified mRNA, and samples were analyzed by quantitative PCR using primers for COX-2.

Values (mean  $\pm$  SEM) were normalized to GAPDH and expressed as fold increase over control-treated cells at each time point for three independent determinations. SEM of control values was less than 5% of the mean at all time points and there was no significant increase in control values over time, \* and \*\* represent  $P < 0.05$  and  $P < 0.01$ , respectively

**Fig. 4** 2-Chlorohexadecanal and 2-chlorohexadecanoic acid lead to PGI<sub>2</sub> release at 20 h. HCAEC were treated with ethanol vehicle, 50 ng/ml TNF $\alpha$ , 50  $\mu$ M 2-chlorohexadecanal (2-CIHDA), or 50  $\mu$ M 2-chlorohexadecanoic acid (2-CIHA) for 20 h ( $n = 4$  for each condition). Culture medium was removed and eicosanoids were purified by reverse SPE columns, converted to PFB esters, silylated using BSTFA, and analyzed by GC-MS, \*\* represents  $P < 0.01$

protein expression in human coronary artery endothelial cells. 2-CIHDA is produced by the production of RCS from phagocyte-derived myeloperoxidase [19]. 2-CIHDA concentrations range from 25–100  $\mu$ M in human neutrophils [14]. The concentration of 2-CIHDA used in these studies is

within the range that is physiologically produced from activated leukocytes. Although 2-CIHDA has been shown to have pro-atherogenic properties by decreasing eNOS [23] and increasing neutrophil chemotaxis [14], we show that 2-CIHDA increases COX-2 and PGI<sub>2</sub> levels (as determined by increases in 6-keto-PGF<sub>1 $\alpha$</sub>  levels). Interestingly comparisons of the time course of 2-CIHDA and 2-CIHA elicited COX-2 expression show that 2-CIHDA has a sustained impact on COX-2 expression. This may reflect disparate half-lives of these chlorinated lipids. In fact, 2-CIHDA is the precursor of 2-CIHA [24]. Thus, over time while 2-CIHDA levels decrease, the sustained COX-2 expression may be elicited by the product of 2-CIHDA metabolism, 2-CIHA.

The increase in COX-2 protein expression from TNF- $\alpha$ , 2-CIHDA, and 2-CIHA appears to occur by increased transcription of the COX-2 gene demonstrated by the results from quantitative PCR. The COX-2 gene contains 17 copies of the AUUUA motif in its 3'-UTR and can be regulated post-transcriptionally by elements that bind the AU-rich regions in its messenger RNA [36, 37]. Previous studies have indicated that shear stress stabilizes COX-2 mRNA levels in HUVECs [37]. In this study, although we have shown that 2-CIHDA and 2-CIHA induce gene expression, we cannot rule out that 2-CIHDA and/or 2-CIHA also lead to a stabilization of COX-2 mRNA.

The human COX-2 promoter includes the NF- $\kappa$ B, cyclic AMP response element (CRE), activator protein-2 (AP2),

**Fig. 5** 2-Chlorohexadecanal decreases I $\kappa$ B protein expression. Cell lysates were prepared from HCAEC treated with ethanol vehicle, 50 ng/ml TNF- $\alpha$ , or 50  $\mu$ M hexadecanal (HDA), 2-chlorohexadecanal (2-CIHDA), 2-chlorohexadecanoic acid (2-CIHA), 2-chlorohexadecanol (2-CIHOH) for 20 h. Samples were subjected to SDS-PAGE and western blotting for I $\kappa$ B expression (a) and analyzed by densitometry of immunoreactive bands (b). Values (mean  $\pm$  SEM) are expressed as fold increase over control treated cell at each time point, \*\* is  $P < 0.01$

signal transducers and activators of transcription (STAT3), SP1 and CCAAT/enhancer-binding protein (C/EBP $\beta$ ) [38–44]. The NF- $\kappa$ B pathway is considered to be a general inflammatory response pathway that can lead to gene transcription of various chemokines, adhesion molecules, and other pro-inflammatory molecules. In the present study we have shown that 2-chlorohexadecanal decreases I $\kappa$ B protein levels in HCAEC, suggesting that 2-CIHDA is signaling in part through the NF- $\kappa$ B pathway. Additionally it should be appreciated that COX-2 mRNA is elevated prior to I $\kappa$ B degradation in response to 2-chlorohexadecanal suggesting that additional pathways may play an important role in COX-2 expression in response to 2-chlorohexadecanal.

The release of 2-chloro fatty aldehydes from plasmalogens followed by its metabolism to 2-chloro fatty acids and 2-chloro fatty alcohols collectively suggest that a chlorinated lipidome is produced as a result of RCS attack of plasmalogens. It is now essential to determine the physiological role of these novel chlorinated lipids and their potential role in inflammation. The results herein demonstrate that 2-CIHA induces COX-2 expression and prostacyclin production in human coronary artery endothelial cells. Furthermore, the precursor of 2-CIHA, 2-CIHDA, also elicits COX-2 expression and prostacyclin production. It can be envisioned that the effect of these same chlorinated lipids on cells such as monocytes and neutrophils, which contain COX-2 associated isomerases that lead to pro-inflammatory eicosanoids, may have important roles in inflammation.

**Abstract** The formation of hydroxy radicals, hexanal, and 2,4-decadienal was demonstrated from the autocatalytic dimer peroxide which had been reported by us in autoxidizing linoleate (Morita and Tokita in *Lipids* 41:91–95, 2006). Then, autoxidizing linoleate containing eleostearate was investigated for new autocatalytic substances. The substances obtained were identified as peroxide-linked polymers consisting of both linoleate- and eleostearate-origin units with one hydroperoxy group, and also revealed activity of hydroxy-radical generation. The background of this study is as follows: the above paper reported this autocatalytic dimer peroxide as one of the real radical generators in linoleate autoxidation; this is a peroxide-linked dimer consisting of two linoleate moieties with two hydroperoxy groups, and was much more important than the main-product hydroperoxide in autocatalytic radical supply; its proposed decomposition mechanism has suggested the generation of hydroxy radicals, hexanal, and 2,4-decadienal; on the other hand, analogy to the formation mechanism of this dimer peroxide has predicted the formation of similar polymeric products from conjugated polyene components in lipids. In this study, these two predictions were successfully verified and a discussion is presented in connection with them.

**Keywords** Autocatalyst · Conjugated fatty acid · 2,4-Decadienal · Dimer · Eleostearate · Hexanal ·

Hydroxy radicals · Lipid autoxidation · Linoleate · Peroxide

## Abbreviations

AutCat	Autocatalytic dimer peroxide
MLOOH	Main-product hydroperoxide of methyl linoleate
oxML	Autoxidizing methyl linoleate
MLOH	Hydroxy derivative from the main-product hydroperoxide of methyl linoleate
DNPH	2,4-Dinitrophenylhydrazone
Azo	2,2'-Azobis(4-methoxy-2,4-
equiv	dimethylvaleronitrile) equivalent

## Introduction

The main product of lipid autoxidation is a type of hydroperoxide, and it has long been believed that the main-product hydroperoxide plays the main role both in autocatalytic supply of radicals and in forming aldehydes.

However, we have entertained a minority opinion [1–3] that this hypothesis is not necessarily valid, and as concerns aldehydes, we formerly obtained a clear result that they are not produced from the main-product hydroperoxide under usual mild conditions in linoleate autoxidation [4–5]. In our previous paper [6], the lack of autocatalytic activity was also clearly showed by using a highly rigorous and sensitive detecting method when the purified main-product hydroperoxide of methyl linoleate was examined under the usual storage conditions and at body temperature; in addition, a type of substance revealing potent autocatalytic activity was found in autoxidizing methyl linoleate.

The autocatalytic substances were isomeric mixtures possessing the structure of a peroxide-linked dimer with two hydroperoxy groups as shown in Scheme 1, which had been reported by Miyashita et al. [7–8] as oxidation products of both methyl linoleate and its main-product hydroperoxide.

**Scheme 1**

We assumed [6] that the mechanism of their homolytic decomposition and radical supply is an energetically favorable concerted one as depicted also in Scheme 1. The mechanism predicted the formation of hydroxy radicals and hexanal as direct products of the homolysis, and the formation of 2,4-decadienal via the  $\beta$ -scission route from linoleate-skeleton alkoxy radicals. In the present paper, the prediction was successfully verified.

On the other hand, it was inferred that the formation mechanism of the autocatalytic substances is an addition of linoleate peroxy radicals to the conjugated diene of the main-product hydroperoxide followed by the usual addition of oxygen to the resultant dimer radicals and hydrogen abstraction from an unoxidized linoleate molecule. We predicted [6] that an analogous mechanism may result in the formation of addition products with peroxy radicals from minor components containing conjugated double bonds in lipids such as conjugated fatty acids and carotenoids. The present paper also verifies the formation of such products in autoxidizing methyl linoleate containing eleostearate, and their activity of autocatalyst and hydroxy radical generation.

## Experimental Procedures

### Preparation of Tung Oil Methyl Ester

Tung oil of industrial use was converted to the methyl ester by the usual transesterification with 1 M methanolic sodium methoxide at room temperature. A polar-impurity-free material was prepared by passing it through a silicic acid column with hexane. The  $\alpha$ -eleostearate content was 83–85%.

### Preparation of Autocatalytic Dimer Peroxide (AutCat)

Methyl linoleate (Tokyo Kasei Kogyo Ltd., Tokyo, Japan) containing  $10^{-2}$  M 2,2'-azobis(4-methoxy-2,4-dimethylvaleronitrile) was allowed to stand at 20°C until the level of MLOOH reached 500–600  $\mu\text{mol/ml}$ . The autoxidizing material (1 ml) was diluted to 4–5 ml with methanol and applied to a  $1.35 \times 120$  cm Sephadex LH 20 column (Amersham Biosciences, Uppsala, Sweden) with methanol. Eluates were checked in TLC (Silicagel 60F<sub>254</sub>, Merck, Darmstadt, Germany) with hexane/diethyl ether 2:1 by vol by detection under UV light. The elution range corresponding to the dimer was 105–115 ml. The dimer-containing eluates from three to five runs were combined and rechromatographed. The resultant sample was further chromatographed on a  $1.35 \times 120$  cm Sephadex LH 20 column with chloroform. The eluates containing the main component group ranged from 108 to 135 ml. All the concentrated sample was then applied to a preparative HPLC on a  $7.6 \times 250$  mm Nucleosil® 100-5 column (Agilent, Palo Alto, CA, USA) with hexane/diethyl ether, 80:20 by vol, at a flow rate of 3 ml/min, monitored at 234 nm absorbance. Although AutCat was eluted as a widely spread zone, owing to large excess loading, at retention time from 14 to 35 min, the AutCat material thus prepared was not inferior to the material reported in the previous paper [6] in purity on HPLC. The present procedure was more efficient and facile than before.

### Preparation of oxML

One milliliter of methyl linoleate was spread on the bottom surface of a 300-ml beaker and was allowed to stand at 20°C until the level of MLOOH reached 500–600  $\mu\text{mol/ml}$ .

### Autoxidation of Linoleate Containing Tung Oil Methyl Ester and Separation of the Products

To methyl linoleate was added the methyl ester of tung oil and subjected to autoxidation at 20°C in the presence of  $10^{-2}$  M 2,2'-azobis-(4-methoxy-2,4-dimethylvaleronitrile). Sephadex LH 20 chromatography with methanol was carried out as above. A reversed phase HPLC was carried out on a  $7.6 \times 250$  mm Inertsil column (GL Science Inc., Tokyo, Japan) with methanol at a flow rate of 3 ml/min, monitored at 234 nm absorbance.

### Purification of MLOOH

Five microliters of oxML (600  $\mu\text{mol/ml}$ ) was applied to a  $7.6 \times 250$  mm Nucleosil® 100-5 column with hexane/diethyl ether 92:8 by vol at a flow rate of 3 ml/min. The hydroperoxide was monitored at 234 nm absorbance and

eluted from 9.4 to 12.5 min as a group of incompletely separated isomer peaks. The eluates were concentrated under reduced pressure below 30°C.

#### Analysis for Methyl $\alpha$ -Eleostearate

The concentration of  $\alpha$ -eleostearate was determined by HPLC on a 4.6  $\times$  150 mm Nucleosil<sup>®</sup> 100-5 column with hexane/diethyl ether 99.5:0.5 by vol at a flow rate of 1.5 ml/min, monitored at 270 nm absorbance.

#### Analysis for MLOOH

Main-product hydroperoxide of methyl linoleate was measured by HPLC on a 4.6  $\times$  150 mm Nucleosil<sup>®</sup> 100-5 column with hexane/diethyl ether 88:12 by vol at a flow rate of 1.5 ml/min, monitored at 234 nm absorbance. It was eluted as four isomer peaks at retention time from 5.3 to 6.6 min and its concentration was calculated using an  $\epsilon$  value of  $2.7 \times 10^{-4}$  as described [4].

#### Analysis for AutCat

AutCat was measured by HPLC on a 4.6  $\times$  150 mm Nucleosil<sup>®</sup> 100-5 column with hexane/diethyl ether 70:30 by vol at a flow rate of 1.5 ml/min. AutCat was monitored at 234 nm absorbance, was eluted from 4.3 to 7.5 min as shown in Fig. 1, and the concentration was expressed as MLOOH equivalent using an  $\epsilon$  value of  $2.7 \times 10^{-4}$ .

#### Analysis for Conjugated Diene

Molar quantity of conjugated diene in a product or a fraction was calculated tentatively on the assumption that the molar extinction at 234 nm was the same as that of main-product hydroperoxide of linoleate.

#### Autocatalytic Activity

Autocatalytic activity of samples was measured, and an expression for the activity, Azo equiv, was used according to the previous paper [6].

**Fig. 1** Elution pattern of AutCat in HPLC. On a 4.6  $\times$  150 mm Nucleosil<sup>®</sup>100-5 column using hexane/diethyl ether 70:30 by vol at a flow rate of 1.5 ml/min, monitored at 234 nm absorbance.

#### Analysis for Methyl Salicylate in the Presence of a Large Amount of Methyl Benzoate

Before analysis, the concentration of methyl benzoate was lowered below 0.5% by diluting samples with hexane. One hundred microliters of the hexane solution was applied to HPLC on a 4.6  $\times$  150 mm Nucleosil<sup>®</sup> 100-5 column with hexane/2-methanol 99.95:0.05 by vol at a flow rate of 1.5 ml/min. The retention time of methyl salicylate was 2.8 min and its concentration was calculated from 305 nm absorbance.

#### Analysis for Hexanal and 2,4-Decadienal

A column (1.35 cm inner diameter) was packed with silica gel 3 cm thick (Wakogel<sup>®</sup> C-100, Wako Pure Chemical Industries, Ltd., Osaka, Japan). On top of this, a 2-cm layer of silica gel impregnated with aqueous 10% sulfuric acid solution containing 0.3% 2,4-dinitrophenylhydrazine was placed. The column was washed with hexane/diethyl ether 4:1 by vol. A hexane solution containing aldehydes was poured into the column. The column was flushed with 20 ml hexane/diethyl ether 4:1 by vol. The eluate was concentrated under reduced pressure. All the concentrate was applied to a 4.6  $\times$  150 mm Nucleosil<sup>®</sup> 100-5 column with hexane/diethyl ether 70:30 by vol at a flow rate of 1.5 ml/min, monitored at 370 nm absorbance. A fraction (1.5–2.1 min) which could cover the elution region of both hexanal–DNPH and decadienal–DNPH was taken. The fraction was concentrated under reduced pressure and an aliquot of the concentrate was analyzed by HPLC on a 7.6  $\times$  250 mm Inertsil column with methanol/water 90:10 by vol at a flow rate of 3 ml/min. The retention times of hexanal–DNPH and decadienal–DNPH were 6.8–7.8 and 13.0–14.5 min, respectively. The amounts of hexanal–DNPH and decadienal–DNPH were calculated from 358 to 389 nm absorbance, respectively.

#### Activity Forming Hydroxy Radicals and Aldehydes

AutCat, pure MLOOH, and oxML each were mixed with methyl benzoate in ratio of 0.6  $\mu$ mol MLOOH (or MLOOH equivalent) to 1  $\mu$ l methyl benzoate. The samples containing 2–5  $\mu$ l methyl benzoate were treated at 50°C in Pyrex ampules sealed under a nitrogen atmosphere. After treatment, the contents of the ampules were diluted with hexane with a ratio of 1  $\mu$ l of methyl benzoate to 0.2 ml hexane, and subjected to analysis for methyl salicylate and aldehydes.

#### Identification Procedures of Separated Products

Separated products from autoxidizing linoleate containing eleostearate were converted with triphenylphosphine and

sodium borohydride, and by catalytic hydrogenation in a similar way to that for the autocatalytic substances reported [6].

### GC–MS

The methyl salicylate formed from AutCat was identified after HPLC isolation by GC–MS (JEOL JMS600) with a DB-1MS capillary column (length, 60 m; ID, 0.25 mm; film thickness, 0.25  $\mu\text{m}$ , J&W Scientific) at a flow rate of 1 ml/min from 50 to 300°C at a ramping rate of 16°C/min. GC–MS analysis of substances converted from the products of autoxidizing linoleate containing eleostearate was carried out as described [6].

**Table 1** Formation of hydroxy radicals and aldehydes from autoxidation products of linoleate

Analysis item	Material tested								
	AutCat			MLOOH		oxML

### Results

The autocatalytic dimer peroxide (AutCat) previously reported by us [6] was examined for the activity of hydroxy radical and aldehyde formation. Methyl benzoate can scavenge hydroxy radicals to form methyl salicylate and we examined the formation of methyl salicylate. The AutCat sample after treatment at 50°C under a nitrogen atmosphere gave a peak at the position of methyl salicylate in HPLC, and GC–MS confirmed that the eluate corresponding to the peak actually contained methyl salicylate. Table 1 describes the yield of methyl salicylate from the AutCat sample after 6 or 19 h treatment at 50°C, and no detectable formation of methyl salicylate in the MLOOH and oxML samples after 6 h.

Table 1 also shows that hexanal and decadienal in the AutCat samples markedly increased after 6 and 19 h treatment at 50°C. In the MLOOH and oxML samples, each amount of hexanal at 0 h was low, and no increase after 6 h treatment was observed. Decadienal could not be detected both in the MLOOH and oxML samples.

The concentration of AutCat in the AutCat sample was decreased as treatment time advanced. In the MLOOH sample, the concentration of MLOOH decreased to some extent after 6 h treatment.

Then, autoxidizing linoleate containing eleostearate was searched for autocatalytic substances. In an autoxidizing linoleate containing 10% tung oil methyl ester, considerable amounts of products were observed by monitoring at 234 nm absorbance besides the main-product hydroperoxide of linoleate. Table 2 shows distribution of

**Table 2** Autocatalytic activity of fractions from autoxidizing linoleate containing eleostearate

	Oxidation rate <sup>a</sup> ( $\mu\text{mol/ml h}$ )	Content <sup>b</sup> (%)	Retention time (min)	Component <sup>c</sup>
None	0.3

fr.6	1.3	25.0	23.0–28.0	

The autoxidizing sample was fractionated by reversed phase HPLC on a 7.6  $\times$  250 mm Inertsil column at a flow rate of 3 ml/min, monitored at 234 nm absorbance. After 14 min elution, the first solvent, methanol/water 85:15 by vol, was changed to methanol

<sup>a</sup> Autocatalytic activity was expressed as the formation rate of pentyl linoleate main-product hydroperoxide (oxidation rate) in autoxidation of pentyl linoleate in the presence of a sample to be tested for the activity [4]. Two microliters of pentyl linoleate with a sample of 0.13  $\mu\text{mol}$  as conjugated diene was oxidized at 20°C for 20 h

<sup>b</sup> The amounts of fractions were expressed as conjugated diene, and their contents were described as % of the sum of all fractions

<sup>e</sup> Methyl linoleate

<sup>f</sup> Methyl eleostearate

autoxidation–accelerating activity among fractions separated by a reversed phase HPLC from the sample autoxidizing at a 5–600  $\mu\text{mol/ml}$  level of main-product hydroperoxide. It was seen that the activity was widely spread over the fractions, although the intrinsic activity in fr.1 could not be evaluated owing to the residual Azo reagent.

A Sephadex LH20 gel filtration chromatography of the oxidized sample with methanol gave fractions eluted more rapidly than the main-product hydroperoxide of linoleate (Fig. 2). Frs.1, 2, and 3 in Fig. 2 each were further separated by reversed phase HPLC. Three main groups of components were obtained, P<sub>3</sub> from fr.1, P<sub>2</sub> from fr.2, and P<sub>1</sub> from fr.3. HPLC elution patterns of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> are shown in Fig. 3 and the designation of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> was based on the order of elution in the HPLC. P<sub>1</sub> was found in fr.5 in Table 2 and in fr.6 was contained P<sub>2</sub> and P<sub>3</sub>. Table 3 summarizes the

**Fig. 2** Elution patterns of autoxidizing methyl linoleate containing tung oil methyl esters in Sephadex LH20 gel filtration chromatography with methanol. The autoxidizing material (0.3 ml) was diluted to 2 ml with methanol and applied to a 1.35  $\times$  120 cm Sephadex LH 20 column. Eluates were separately collected in each 5 ml tube after 70 ml elution, and checked in TLC (Silicagel 60F<sub>254</sub>) with hexane/diethyl ether 2:1 by vol by detecting under UV light. chromatographic behavior of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub>, involving additionally that of related substances described in the later part. The elution position of P<sub>1</sub> in the Sephadex chromatography was similar to the previously reported dimer autocatalyst [6], which suggested that P<sub>1</sub> had a molecular size of a dimer. The sizes of P<sub>2</sub> and P<sub>3</sub> were, consequently, considered to be larger than a dimer size.

A 1 ml autoxidizing sample at a 500  $\mu\text{mol/ml}$  level of main-product hydroperoxide gave 46  $\mu\text{mol}$  of P<sub>1</sub>, 21  $\mu\text{mol}$  of P<sub>2</sub>, and 9  $\mu\text{mol}$  of P<sub>3</sub> as conjugated diene. The autoxidation–accelerating activities of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> were measured and expressed as Azo equiv of 3.7, 2.9, and 2.9  $\times 10^{-3}$ , respectively. On treatment of P<sub>1</sub> with methyl benzoate at 50°C for 19 h, hydroxy radicals from P<sub>1</sub> were detected as 0.58 mol% formation of methyl salicylate based on the starting amount of P<sub>1</sub>, where the decrease in P<sub>1</sub> was 23%. Treatment of P<sub>1</sub> at 50°C gave no observable amounts of hexanal and 2,4-decadienal.

The reduction with triphenylphosphine brought about no change in molecular sizes of  $P_1$ ,  $P_2$ , and  $P_3$  as shown from their behavior in Sephadex LH20 chromatography (Table 3). In every case of  $P_1$ ,  $P_2$ , and  $P_3$ , successive reduction with  $\text{NaBH}_4$  gave, besides MLOH, two major products of a monomer size,  $M_1$  and  $M_2$  (Fig. 4). Both of them seemed to be di-OH compounds because of their lower mobilities in normal-phase HPLC as shown in Table 3. The substances  $M_1$  and  $M_2$  showed an absorption at 229 and 231 nm (in methanol) respectively, which suggested that they contained conjugated diene. Each of  $P_1$ ,  $P_2$ , and  $P_3$  was considered to consist of MLOH and the di-OH compounds. Absorbance ratios,  $(M_1 + M_2)/\text{MLOH}$ , at 234 nm in the  $\text{NaBH}_4$  reduction products were increased in the order of 1.5 for  $P_1$ , 2.2 for  $P_2$ , and 3.3 for  $P_3$ . These ratios suggested that  $P_1$  was a dimer consisting of one MLOH unit and one di-OH unit,  $P_2$  was a trimer consisting of one MLOH unit and two di-OH units, and  $P_3$  was a tetramer consisting of one MLOH unit and three di-OH units. After hydrogenation with platinum black under an atmospheric hydrogen, the converted substances from  $M_1$  and  $M_2$  showed no UV absorption, and their  $R_f$  values (0.08) on TLC (silica gel with hexane/diethyl ether 1:3 by detecting on charring) roughly resembled those of intact  $M_1$  (0.14) and  $M_2$  (0.10), suggesting that they were also di-OH compounds.

After trimethylsilylation,  $M_1$ ,  $M_2$ , and their hydrogenated derivatives were subjected to GC-MS. The mass spectra of  $M_1$  and  $M_2$  were not distinguishable at all from each other, and the hydrogenated derivatives of  $M_1$  and  $M_2$  also gave indistinguishable spectra from each other. The lower spectrum in Fig. 5 was obtained from the hydrogenated derivatives, and its fragmentation was assigned undoubtedly to a structure of 9,14-dihydroxyoctadecanoic acid methyl ester, and in consideration of this result, the fragmentation of the upper spectrum indicated that  $M_1$  and  $M_2$  were 9,14-dihydroxy-10,12-octadecadienoic acid methyl ester, which had formerly reported by Hamberg [9] in a study on autoxidizing linoleic acid.  $M_1$  and  $M_2$  were probably two racemic pairs of diastereomeric isomers with 9- and 14-chiral centers.

**Fig. 4** Elution patterns of dihydroxy compounds,  $M_1$  and  $M_2$ , from a  $7.6 \times 250$  mm Inertsil column with methanol/water 80:20 by vol at a flow rate of 3 ml/min, monitored at 234 nm absorbance. MLOH also appears there

In the elution region of di-OH compounds, several minor peaks other than  $M_1$  and  $M_2$  were present as shown in Fig. 4, but the existence of 9,10- or 13,14-di-OH component was not recognized because the GC-MS of the hydrogenated products gave no component showing fragmentation characteristic of 9,10- or 13,14-di(trimethylsiloxy)octadecanoate.

## Discussion

As expected, AutCat proved to be the source of hydroxy radicals. On the other hand, hydroxy radicals were not formed in the case of the purified MLOOH sample, which supported the hitherto accepted view that hydroxy-radical formation from homolytic cleavage of simple hydroperoxide is energetically unfavorable [10]. It is well known that hydroxy radicals are generated by the reaction of hydrogen peroxide with transition metals, e.g., the Fenton's reaction, but such a reaction seems unlikely in the lipid autoxidation products. From this point of view, it is a very important findings that AutCat, one of the products of lipid autoxidation, showed a clear activity of generating hydroxy radicals in the absence of transition metals.

The concentration of AutCat in the present oxML sample was too low to reveal observable hydroxy-radical generating activity. In this situation, the lack of observable activity in this sample indicated that there were not other potent sources of hydroxy radicals largely excelling AutCat.

The AutCat sample showed clear increases in hexanal and decadienal after 6 and 19 h treatment, while the oxML and MLOOH samples did not. Our former paper [4] has shown that MLOOH did not generate hexanal and decadienal under mild conditions. The present experiments were carried out in methyl benzoate, and the increases in hexanal and decadienal were also not observed, although the conditions were so different from the former ones that a large amount of parent unoxidized linoleate was present. The lack of the precursor activity of the oxML sample indicated that other potent precursors of hexanal and decadienal largely excelling AutCat were not present as well as hydroxy-radical generating sources.

In the AutCat sample, the formation of hydroxy radicals, hexanal, and decadienal demonstrated the presence of homolytic decomposition. The yield of hexanal was about 9 mol% when about 90% AutCat in the AutCat sample was decomposed after 19 h treatment. Theoretical yield of hexanal ( $R_1\text{CHO}$ ) in Scheme 1 is expected to be 50 mol% of the amount of decomposed AutCat. So, a large part of AutCat seemed to disappear through other decomposition routes, probably being heterolytic ones, without giving radicals and aldehydes. The decrease in MLOOH observed

**Fig. 5** Mass spectra of  $M_1$  and  $M_2$  (upper) and of their hydrogenated derivatives (lower). They were analyzed after trimethylsilylation. Identified structures and assignment for fragment ions are described

in the present MLOOH sample is presumably caused also by heterolytic routes. A smaller formation of decadienal than that of hexanal in the AutCat sample suggests that  $\beta$ -scission plays a relatively minor role in the fate of linoleate-skeleton alkoxy radicals shown in Scheme 1. The yield of methyl salicylate was much smaller than that of hexanal in the AutCat sample, which may suggest low efficiency of methyl benzoate as a scavenger of hydroxy radicals under the present conditions.

Formerly, we reported [2] that a potent autocatalyst and potent precursors of hexanal and decadienal were present in a polar fraction of autoxidizing methyl linoleate and, thereafter, we demonstrated more strictly [5] that hexanal

and decadienal were formed through cumulative intermediates other than main-product hydroperoxide. The present AutCat is undoubtedly an important one of the substances suggested in these past papers.

To prove another prediction in our previous paper [6], attempts were made to search autoxidizing linoleate-containing conjugated polyene substances for other types of autocatalysts and hydroxy radical generators. In the present model experiments, we used an easily available material, tung oil, whose main constituent fatty acid is  $\alpha$ -eleostearic acid, *cis*-9, *trans*-11, *trans*-13-octadecatrienoic acid. We planned experiments of autoxidation accelerated with 2,2'-azobis-(4-methoxy-2,4-dimethylvaleronitrile) in order to

avoid the degradation of autocatalytic products during the long autoxidation time made necessary by the low oxidation rate.

In the case of 10% addition of tung oil methyl ester, the products of molecular sizes not less than dimer were found in considerably larger amounts than in the case of methyl linoleate alone. We could separate three groups of such products, P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub>, which each behaved as a single peak in reversed phase HPLC (Fig. 3). The derivatization and the following analyses of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> suggested the structures shown in Structure 1. The structure implies that each of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> consists of many isomers. Each of them was actually eluted as a set of incompletely separated peaks in normal phase HPLC (Fig. 3).

R<sup>1</sup>: CH<sub>3</sub>(CH<sub>2</sub>)<sub>4</sub>-

R<sup>2</sup>: CH<sub>3</sub>OOC(CH<sub>2</sub>)<sub>7</sub>-

R<sup>3</sup>: CH<sub>3</sub>(CH<sub>2</sub>)<sub>3</sub>-

n = 1: P<sub>1</sub>

2: P<sub>2</sub>

3: P<sub>3</sub>

#### Structure 1

The structures of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> suggest the following mechanism of formation: linoleate peroxy radicals are added to the conjugated triene of eleostearate followed by further addition of molecular oxygen as shown in Scheme 2; the fate of the resultant dimer peroxy radicals branches into two courses; one is the abstraction of hydrogen from linoleate giving P<sub>1</sub>, and the other is further addition to eleostearate giving trimer radicals; the trimer radicals have similarly two sorts of fate; one gives P<sub>2</sub> and the other gives tetramer radicals; the tetramer radicals can give P<sub>3</sub> and enter a further polymer-generating sequence.

ROO· : Linoleate Peroxy Radical, Dimer Peroxy Radical, Trimer Peroxy Radical, ………

#### Scheme 2

As shown in this mechanism, there are many sorts of peroxy radicals, linoleate, dimer, trimer, and so on, and each of them enters two reactions, hydrogen abstraction

from linoleate and addition to eleostearate, in a certain distribution ratio. If all the sorts of peroxy radicals have the same distribution ratio, the ratios of the formation rates for P<sub>2</sub> to P<sub>1</sub> and for P<sub>3</sub> to P<sub>2</sub> are expected to be equal. We can regard the yield ratio of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> as a rough estimate for the ratio of their formation rates. Then, we will see the yield ratios. The molar ratio of the observed yields of P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> was 23:7.7:2.3, which was given from the ratio of 46:23:9 at 234 nm absorbance and the number of conjugated diene chromophores a molecule, two for P<sub>1</sub>, three for P<sub>2</sub>, and four for P<sub>3</sub>. The yield ratio for P<sub>2</sub> to P<sub>1</sub> (7.7:23) approximated that for P<sub>3</sub> to P<sub>2</sub> (2.3:7.7). This agreement satisfactorily supports validity of the above argument.

In naturally occurring lipids, only such dimer products as P<sub>1</sub> are presumably important because low concentration of conjugated polyene compounds in general may lower the distribution of peroxy radicals to addition to such compounds, which is unfavorable to the formation of higher polymers than dimer.

Autocatalytic activity of autoxidizing linoleate containing eleostearate was not necessarily distributed only in higher-molecular-size fractions as shown in Table 2, but we focused the present survey on such higher-molecular-size products as P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub>. The autoxidation-accelerating activities as Azo equiv, 3.7 × 10<sup>-3</sup> for P<sub>1</sub>, 2.9 × 10<sup>-3</sup> for P<sub>2</sub>, and 2.9 × 10<sup>-3</sup> for P<sub>3</sub> were comparable to 1.8 × 10<sup>-3</sup> for the previously reported autocatalyst [6]. The hydroxy-radical-generating activity of P<sub>1</sub> (0.38 mol% yield of methyl salicylate) was also comparable to 0.3–0.6 mol% of this autocatalyst as shown in Table 1. These findings strongly suggested that conjugated polyene fatty acids which occur in lipid materials both as natural minor components and artificial products by heating, etc. can generate potent autocatalysts involving hydroxy radical generators such as the present substances. Activity generating hexanal and 2,4-decadienal was, however, not observed in P<sub>1</sub> unlike the previous autocatalyst. In the present investigation, we did not examine other aldehydes expected as products of eleostearate.

The previously reported autocatalytic substances have an α, β-diperoxy structure which is considered to undergo an energetically favorable concerted homolysis [6]. However, in the present system, polymeric products containing an α, β-diperoxy structure were not observed. The present substances, P<sub>1</sub>, P<sub>2</sub>, and P<sub>3</sub> possessed a 1,6-diperoxy-2,4-diene structure in which two peroxy groups are separated with conjugated diene, indicating that, after the addition of peroxy radicals to conjugated triene, the following addition of oxygen occurs only the remote position. It must be noted that, in autocatalytic activity and activity forming hydroxy radicals, the present substances are comparable to the previously reported autocatalysts in spite of different structural feature. On the other hand, the present substances

clearly contrast with the main-product hydroperoxide of linoleate. The hydroperoxide shows no activity of auto-catalysts [6] and forming hydroxy radicals as shown in Table 1, although its 1-peroxy-2,4-diene structure partly resembles the structure of the present substances. In consideration of these facts, it is suggested that the present substances are degraded through an unknown homolysis-assisting mechanism which may involve some interaction between two remote peroxy groups and may result in the cleavage to form radicals involving hydroxy radicals.

**Abstract** Autoxidation of conjugated linoleic acid (CLA) methyl ester follows at least partly Farmer's hydroperoxide theory. A mechanism for this hydroperoxide pathway has been proposed based on autoxidation of 9-*cis*,11-*trans*-CLA methyl ester. This investigation aims at confirming and further clarifying the mechanism by analyzing the hydroperoxides produced from 10-*trans*,12-*cis*-CLA methyl ester and by theoretical calculations. Five methyl hydroxyoctadecadienoates were isolated by HPLC and characterized by UV, GC-MS, and 1D- and 2D-NMR techniques. In addition, an HPLC method for the separation of the intact hydroperoxides was developed. The autoxidation of 10-*trans*,12-*cis*-CLA methyl ester in the presence of high amount of  $\alpha$ -tocopherol (20%) was diastereoselective in favor of one geometric isomer, namely Me

9-OOH-10*t*,12*c*, and produced new positional isomers 10- and 14-hydroperoxides (Me 10-OOH-11*t*,13*t*; Me 14-OOH-10*t*,12*c*; and Me 14-OOH-10*t*,12*t*). Importantly, one of these new isomers, which was characterized as an intact hydroperoxide, had an unusual *cis,trans* geometry where the *cis* double bond is adjacent to the hydroperoxyl-bearing methine carbon. Further insight to the mechanism was provided by calculating the relative energies for different conformations of the precursor lipid, the allylic carbon-hydrogen bond dissociation enthalpies, and the spin distributions on the intermediate pentadienyl radicals. As a result, a better understanding of the isomeric distribution of the product hydroperoxides was achieved and a modified mechanism that accounts for these calculations is presented.

## Introduction

Conjugated linoleic acid (CLA) is a generic name referring to a group of positional and geometric isomers of octadecadienoic acid with a 1,3-diene structure. Thus far, two CLA isomers, namely 9-*cis*,11-*trans*-CLA and 10-*trans*,12-*cis*-CLA, have been discovered to possess beneficial physiological properties [1]. The biochemical mechanisms of CLA action are unknown. These mechanisms, however, seem to include induction of fatty acid oxidation [2, 3]. Most oxidation studies on CLA are, despite the structure-specificity, performed with mixtures of isomers. Moreover, surprisingly little is known about the initial stages of CLA autoxidation. The early literature reported that CLA autoxidation differs from the autoxidation of linoleic acid (LA) and produces in the absence of antioxidants mainly relatively low molecular weight polymeric peroxides [4–7]. More recently, CLA has been proposed to autoxidize through two distinct pathways with unknown primary products [8] or speculated to yield products identical to those formed during singlet oxygen oxidation of CLA based on the analysis of secondary oxidation products [9, 10]. First in 2001, we discovered that hydroperoxides are one type of primary autoxidation product of CLA methyl ester formed in the presence and in the absence of  $\alpha$ -tocopherol [11]. The hydroperoxides produced during autoxidation of 9-*cis*,11-*trans*-CLA methyl ester (Me 9*c*,11*t*-CLA) in the presence of 20% of  $\alpha$ -tocopherol were isolated, reduced to the corresponding hydroxy derivatives, separated, and characterized [12]. This enabled us to propose a mechanism for the hydroperoxide pathway of CLA autoxidation, which occurs in agreement with kinetic data [5, 13] through an autocatalytic free radical chain reaction.

In continuation of our previous work [11, 12] we have now tested whether the mechanism proposed for the hydroperoxide pathway based on the autoxidation of Me 9*c*,11*t*-CLA correctly predicts the hydroperoxides and their isomeric distribution formed in the autoxidation of 10-*trans*,12-*cis*-CLA methyl ester (Me 10*t*,12*c*-CLA). To this end, Me 10*t*,12*c*-CLA was autoxidized under the same conditions as previously Me 9*c*,11*t*-CLA [12] in order to produce enough hydroperoxides for the characterization and to allow the comparison between the two studies. The hydroperoxides were isolated, reduced chemoselectively to hydroxy derivatives, and the separated hydroxy derivatives were characterized by UV, GC–MS, and 1D- and 2D-NMR

techniques. Due to unsatisfactory separation of certain methyl hydroxyoctadecadienoates, an HPLC method for the separation of the intact hydroperoxides was developed. In addition, theoretical calculations were carried out to provide further insight to the initial stages of CLA autoxidation and to the distribution of the product hydroperoxides. A scheme for the hydroperoxide pathway of CLA autoxidation consistent with these calculations is presented.

## Experimental Procedures

### Materials

Me 10*t*,12*c*-CLA was purchased from Matreya Inc. (Pleasant Gap, PA, USA) and the presence of only one isomer was confirmed by  $^{13}\text{C}$  NMR [14]. DL- $\alpha$ -Tocopherol was obtained from Calbiochem (Darmstadt, Germany). Isopropanol, heptane, and *tert*-butyl methyl ether (TBME) were from Rathburn Chemicals (Walkerburn, Scotland), bis(trimethylsilyl)-trifluoroacetamide and trimethylchlorosilane from Merck (Darmstadt, Germany), and calcium hydride, sodium borohydride, and platinum (IV) oxide from Fluka (Buchs, Switzerland). Isopropanol was dried by distillation over calcium hydride.

### Autoxidation

Me 10*t*,12*c*-CLA (0.4 g, 1.4 mmol) was autoxidized in a glass vial (20 mL,  $d = 2.0$  cm) for 16 days in the presence of  $\alpha$ -tocopherol (20% per weight) under atmospheric oxygen at 40 °C in the dark. The yield of hydroperoxides based on TLC analysis and on peroxide value (PV = 193 mequiv O<sub>2</sub>/kg) measured by the ferric thiocyanate method [15] was 6.3%. The hydroperoxides were isolated from the reaction mixture by SPE (2 g; Varian, Harbor City, CA, USA) using MTBE/heptane gradient (from 2.5 to 20%, v/v) as an eluent, and reduced to corresponding hydroxy derivatives using NaBH<sub>4</sub> in dry isopropanol at 0 °C according to the procedure reported previously [11]. The hydroperoxides and the hydroxy derivatives were stored as dilute heptane solutions at –20 °C under nitrogen.

### Isocratic Normal-phase HPLC

The separation of five hydroxy-CLA methyl esters and six hydroperoxy-CLA methyl esters was achieved using a semi-preparative Merck silica column (Supelcosil LC-SI Semi-Prep, 25.0 × 1.0 cm I.D., particle size 5  $\mu\text{m}$ ) and isopropanol/TBME/heptane (0.05/5/95, v/v/v) and isopropanol/heptane (0.65/100, v/v) as an eluent, respectively, at 2.0 mL/min flow rate. Approximately 1 mg of the mixture

of isomers was repeatedly injected. The fractions collected from non-baseline separated peaks were further purified using the semi-preparative column. The mixture and the separated isomers were analyzed by HPLC using a Supelco silica column (Supelcosil LC-SI, 25.0 cm × 2.1 mm I.D., particle size 5 μm) and isopropanol/TBME/heptane (0.05/4/95, v/v/v) or isopropanol/heptane (0.3/100, v/v) as an eluent at 0.4 mL/min flow rate. The columns were equipped with Waters 501 HPLC pump, Waters pump control module, Waters 717 plus autosampler, and Waters 996 photodiode array detector set at 234 nm.

### UV Spectroscopy

The separated isomers were quantified by UV spectroscopy at  $\lambda = 233$  nm for the *trans,trans* isomers and at  $\lambda = 236$  nm *cis,trans* isomers. UV spectra were recorded in ethanol solution on a Perkin Elmer UV/vis spectrometer Lambda Bio (Ueberlingen, Germany). Molar absorbance ( $\epsilon$ ) values used in calculations are from [16]. The concentration of the isomers for which no  $\epsilon$  value is available was approximated with the  $\epsilon$  value of the nearest positional isomer with the appropriate diene geometry.

### GC-MS

The hydroxy-CLA methyl esters were hydrogenated to hydroxystearates and derivatized to trimethylsilyl ethers according to the procedure described earlier [12]. The trimethylsilyl ethers were analyzed on an Agilent 5973 mass spectrometer (Palo Alto, CA, USA) connected to a Hewlett Packard gas chromatograph (HP 6890 Series GC System, Wilmington, DE, USA). GC was equipped with a Rtx-5MS (crossbond 5% diphenyl polysiloxane, 95% dimethyl polysiloxane) capillary column (60 m × 0.25 mm I.D., film thickness 0.1 μm, carrier gas: helium, 1.2 mL/min; Restek corporation, Bellefonte, PA, USA). Samples (0.1–1 μL) were injected using on-column injection. The column temperature program and other run parameters were as reported previously [12].

### NMR Spectroscopy

$^1\text{H}$ -,  $^{13}\text{C}$ -, and 2D-NMR spectra, including correlated spectroscopy (COSY), long-range COSY (LR-COSY), gradient heteronuclear multiple bond correlation (gHMBC), gradient heteronuclear single quantum coherence (gHSQC) and total correlation spectroscopy (TOCSY), were recorded in deuteriochloroform (contains 0.1% (v/v) tetramethylsilane, 99.8%  $^2\text{H}$ ; Aldrich, Milwaukee, WI, USA) on a Bruker DRX 500 spectrometer equipped with 5 mm broadband inverse probe with z-gradient (Fällanden, Switzerland) at 27 °C. Chemical shifts  $\delta$

are given in parts per million (ppm) relative to tetramethylsilane ( $\delta$  0.00).

The 1D- and 2D-NMR data of methyl 9-(*R,S*)-hydroxy-10-*trans*,12-*cis*-octadecadienoate (Me 9-OH-10*t*,12*c*<sup>1</sup>; 97.4%, 31 mM) and that of methyl 13-(*R,S*)-hydroxy-9-*cis*,11-*trans*-octadecadienoate (Me 13-OH-9*c*,11*t*; 98.5%, 17 mM) agreed with published data [12].

Methyl 10-(*R,S*)-hydroxy-11-*trans*,13-*trans*-octadecadienoate (Me 10-OH-11*t*,13*t*; 94.3%, 16 mM)  $^1\text{H}$  NMR  $\delta$  6.17 (*dd*, 1 H, H-12,  $^3J_{12,11} = 15.2$  Hz,  $^3J_{12,13} = 10.4$  Hz), 6.02 (*dddd*, 1 H, H-13,  $^3J_{13,14} = 15.1$  Hz,  $^4J_{13,15} \approx 1.4$  Hz,  $^4J_{13,11} \approx 0.9$  Hz), 5.70 (*dt*, 1 H, H-14,  $^3J_{14,15} = 7.0$  Hz), 5.57 (*dd*, 1 H, H-11,  $^3J_{11,10} = 7.0$  Hz), 4.10 (*dt*, 1 H, H-10,  $^3J_{10,9} \approx 6.5$  Hz), 3.66 (*s*, 3 H, OCH<sub>3</sub>), 2.30 (*t*, 2 H, H-2,  $^3J_{2,3} = 7.6$  Hz), 2.08 (*tdd*, 2 H, H-15,  $^3J_{15,16} \approx 7.3$  Hz), 1.61 (*quintet*, 2 H, H-3,  $^3J_{3,4} = 7.3$  Hz), 1.59–1.52 (*m*, 1 H, H-9), 1.52–1.45 (*m*, 1 H, H-9'), 1.45–1.26 (*m*, 15 H, H-4 to H-8, H-16, H-17, OH), 0.90 (*t*, 3 H, H-18,  $^3J_{18,17} = 7.2$  Hz).

### Theoretical Calculations

All calculations have been performed at the density functional theory (DFT) level employing the hybrid B3LYP functional [17, 18] as implemented in the TURBOMOLE program package [19] version 5.91. The structures were optimized using the polarized split-valence def2-SVP basis set [20]. The conformations of Me 10*t*,12*c*-CLA were confirmed to be local minima on the potential energy surface by ensuring that the lowest vibrational mode was non-imaginary. Furthermore, it was made sure that the geometries were comparable. In particular, in the peroxy radicals the O<sub>2</sub>-group was always oriented in a similar manner facing the methine hydrogen, since the other local minimum with the O<sub>2</sub>-group rotated to the opposite side of the chain lied ca. 0.8 kcal/mol higher in energy. Energies were evaluated using the larger, doubly polarized triple-zeta def-TZVPP basis set [20]. The environment was modeled using the COSMO continuum solvation model [21, 22] with a dielectric constant of methyl linoleate (3.4) which was considered as a typical value for this class of molecules [23]. Thermal enthalpy corrections at the autoxidation reaction temperature were calculated using the harmonic approximation via the (unscaled) vibrational frequencies calculated in gas-phase. An enthalpy correction of  $5/2 RT$  was used for the hydrogen atom. The gross spin densities of the radicals were calculated as outlined in Reference [24]. This level of theoretical treatment has been found to be suitable in previous work [25–28]. Although bond dissociation energies are known to be slightly underestimated at B3LYP level, the error is systematic and thus relative energies are comparable [29]. This was further confirmed by using the described level of theory for calculating the dissociation energies and enthalpies at 298 K for the monoallylic C–H bond in methyl oleate and for the bisallylic C–H bond in methyl linoleate. The difference between the calculated dissociation energy (enthalpy at 298 K) values of 86.2 (79.1) and 74.2 (67.5) kcal/mol for mono- and bisallylic C–H bonds, respectively, compare well with the literature values of 88 and 75 kcal/mol [30].

### Results and Discussion

The mechanism proposal developed for the hydroperoxide pathway of CLA autoxidation based on the autoxidation of Me 9*c*,11*t*-CLA [12] predicts that the autoxidation of Me 10*t*,12*c*-CLA is diastereoselective in favor of one geometric isomer, namely Me 9-OOH-10*t*,12*c*. In addition, the autoxidation should yield three types of geometric isomers and two new positional isomers *i.e.* 10- and 14-hydroperoxides. Importantly, one of these new positional isomers should have an unusual *cis,trans* geometry where the *cis* double bond is adjacent to the hydroperoxyl-bearing methine carbon. This type of geometric isomer is absent from the autoxidation of nonconjugated polyunsaturated fatty acids [31]. Analysis of the hydroperoxide mixture from autoxidation of Me 10*t*,12*c*-CLA confirmed that the mechanism predicts the formed isomers and the isomeric distribution correctly (see Scheme 1). The details of the mechanism, however, were altered based on the theoretical calculations.

### Autoxidation, HPLC Separation, and Characterization of the Products

The autoxidation of CLA methyl ester differs from that of its nonconjugated counterpart, methyl linoleate, and produces mainly polymeric products [4–7, 32]. Moreover, only small amounts of peroxides accumulate during the autoxidation of CLA methyl ester compared to the autoxidation of methyl linoleate [4]. Therefore, in order to direct the autoxidation of CLA methyl ester from autoxidative polymerization toward hydroperoxide formation the

**Scheme 1** Prediction of the hydroperoxide isomers and their isomeric distribution that will be formed during autoxidation of 10-*trans*,12-*cis*-CLA methyl ester based on autoxidation of 9-*cis*,11-*trans*-CLA methyl ester [12]

autoxidation must be performed in the presence of a good hydrogen atom donor [12]. Hence, Me 10*t*,12*c*-CLA was treated with 20% of  $\alpha$ -tocopherol under atmospheric oxygen at 40 °C in the dark. Under these conditions,  $\alpha$ -tocopherol does not exert its recognized antioxidant effect but allows the autoxidation to proceed quite rapidly to produce relatively good yield of monohydroperoxides. The separation and characterization of the Me 10*t*,12*c*-CLA hydroperoxides was attempted as their hydroxy derivatives. The separation of the hydroxy derivatives, however, proved to be more challenging than the separation of those from the autoxidation of Me 9*c*,11*t*-CLA. Indeed, only partial separation of the hydroxy derivatives was achieved when tested with mixtures of isopropanol/heptane, MTBE/heptane, and isopropanol/MTBE/heptane as an eluent. The best separation was obtained using isopropanol/MTBE/heptane (0.05/5/95, v/v/v) as an eluent and the elution order of five hydroxy derivatives was: Me 13-OH-9*c*,11*t*; Me 14-OH-10*t*,12*t*; Me 13-OH-9*t*,11*t*; Me 10-OH-11*t*,13*t*; and Me 9-OH-10*t*,12*c* (Fig. 1a). The separation of the intact Me

**Fig. 1** Semi-preparative HPLC separation of **a** hydroxy-CLA methyl esters and **b** hydroperoxy-CLA methyl esters using Supelco silica column (Supelcosil LC-SI, 25.0 cm  $\times$  2.1 mm i.d., particle size 5  $\mu$ m) and isopropanol/TBME/heptane (0.05/5/95, v/v/v) or isopropanol/heptane (0.35/100, v/v) as an eluent, respectively, at 2 mL/min flow rate with ultraviolet detection at 234 nm. For complete nomenclature of the compounds see Abbreviations. \*Unknown compound without a conjugated diene structure

10*t*,12*c*-CLA hydroperoxides was, however, more successful and it was achieved using isopropanol/heptane (0.35/100, v/v) as an eluent as depicted in Fig. 1b. HPLC analysis of the mixture at  $\lambda = 234$  nm gave the following elution order and area percentage composition for the hydroperoxides: Me 13-OOH-9*c*,11*t* (13%), Me 14-OOH-10*t*,12*c* (3%), Me 14-OOH-10*t*,12*t* (8%), Me 13-OOH-9*t*,11*t* (16%), Me 10-OOH-11*t*,13*t* (11%), and Me 9-OOH-10*t*,12*c* (49%). The 10- and 14-positional isomers were identified in the same manner as the hydroxy derivatives (*vide infra*) and the 9- and 13-hydroperoxides were identified by spiking the HPLC runs with pure hydroperoxides isolated from methyl linoleate autoxidation (i.e. Me 9-OOH-10*t*,12*c*; Me 9-OOH-10*t*,12*t*; Me 13-OOH-9*c*,11*t*; and Me 13-OOH-9*t*,11*t*). In particular, spiking with Me 9-OOH-10*t*,12*t* revealed that this isomer, which is the predicted seventh isomer that was not separated from the autoxidation mixture, was partly overlapping with the major product. This overlapping together with the expected small amount (<1%) explains why the separation of Me 9-OOH-10*t*,12*t* was not possible. Moreover, studies with methyl linoleate have established that this hydroperoxide isomer is formed through the  $\beta$ -scission pathway from Me 13-OOH-9*c*,11*t* and from Me 13-OOH-9*t*,11*t* [33–36] both of which were formed during the autoxidation of Me 10*t*,12*c*-CLA.

The separated isomers were analyzed by HPLC and UV spectra were recorded. In agreement with the findings of the autoxidation of Me 9*c*,11*t*-CLA, three different absorption maxima ( $\lambda_{\max}$ ) values for the three types of geometric isomers were obtained: 230.9 nm for the *trans,trans* isomers, 232.1 nm for the new type of *cis,trans* isomer where the allylic methine is adjacent to the *cis* double bond, and 234.4 nm for the *cis,trans* isomers where the allylic methine is adjacent to the *trans* double bond.

The position of the hydroperoxyl or the hydroxyl group in the individual isomers was determined by GC-MS using trimethylsilyl ethers of the corresponding hydroxystearates, which gave two characteristic fragment ions in mass spectra:  $m/z$  229, 259;  $m/z$  215, 273;  $m/z$  173, 315; and  $m/z$  159, 329 for 9-, 10-, 13- and 14-hydroxystearate, respectively.

The position of the 1,3-diene system within the alkyl chain, i.e., whether the double bonds lie between the hydroxyl and the ester group or between the hydroxyl and the methyl group, was determined by a TOCSY experiment by establishing which one of the allylic resonances is closest to the methyl group. The  $^{13}\text{C}$ -NMR spectra of the methyl hydroxyoctadecadienoates were assigned with the aid of the 2D-NMR spectra in a similar manner as described in detail previously [12, 37]. Because Me 10*t*,12*c*-CLA produces partly identical hydroperoxides with those from Me 9*c*,11*t*-CLA, only the unpublished

$^{13}\text{C}$ -NMR data are listed in Table 1. Characteristic and easily recognizable signals, in addition to the carbonyl, C-2, C-3, methoxy carbon, C-17, and terminal methyl carbon, are the allylic methine at  $\delta_{\text{C}}$  72.89–72.91, allylic methylene at  $\delta_{\text{C}}$  32.32–32.61, and the olefinic carbons at  $\delta_{\text{C}}$  129.43–135.57. The existence of the unusual *cis,trans* geometry was evident both from the  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR spectra of Me 14-OOH-10*t*,12*c*. In the  $^1\text{H}$ -NMR spectrum, which was assigned with the aid of  $^1\text{H}$ - $^1\text{H}$  COSY and TOCSY experiments, the methine proton allylic to a *cis* double bond resonated at  $\delta_{\text{H}}$  4.85 and is thus  $\sim 0.5$  ppm less shielded than those allylic to a *trans* double bond [11, 12]. In the  $^{13}\text{C}$ -NMR spectrum of Me 14-OOH-10*t*,12*c*, the methine carbon resonated at  $\delta_{\text{C}}$  81.44. Thus, this allylic methine carbon adjacent to a *cis* double bond is  $\sim 5.3$  ppm more shielded than those adjacent to a *trans* double bond. These findings agree with the  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR data on *cis* and *trans* monoene allylic hydroperoxides from methyl oleate autoxidation [38–40]. A more detailed investigation on the NMR properties of the conjugated diene allylic

monohydroperoxides produced from Me 10*t*,12*c*-CLA and also from Me 9*c*,11*t*-CLA including full assignments of the  $^{13}\text{C}$ -NMR spectra is reported elsewhere [41].

### Mechanism, Isomeric Distribution, and Theoretical Calculations

ESR studies have established that the first-formed pentadienyl radical in methyl linoleate autoxidation exists in the W-conformation [42] which is the most stable of the possible pentadienyl radical conformations. The W-conformation is also the only conformation detected at ambient temperature in the ESR studies with the pentadienyl radical itself [43, 44]. In our previous study [12], the most stable pentadienyl radicals were expected to be formed from the most extended conformation of Me 9*c*,11*t*-CLA and the proposed mechanism for the hydroperoxide pathway was drawn accordingly. In this study, the importance of the different conformations of the precursor lipid was estimated by calculating the energies for conformations A to D of Me 10*t*,12*c*-CLA (see Table 2). In these conformations, the allylic C–H bond that will undergo fragmentation in the hydrogen atom abstraction step is perpendicular or nearly so to the diene  $\pi$  system. This was considered important, because it enables the resonance stabilization to develop already in the transition state. The energy differences of the conformations with respect to conformation A together with the estimation of the distribution of these conformations using the Boltzmann equation are depicted in Table 2. The calculations agreed with our previous assumption that the extended conformation A is the most important contributor to the isomeric distribution of the product hydroperoxides. They also revealed that while the contribution of B is

significant, that of C and D may be disregarded. Because the hydroperoxides formed from conformation B could theoretically arise from A (one directly and the other by the  $\beta$ -fragmentation pathway) these calculations proved crucial to our understanding of the autoxidation mechanism; it is now apparent that the six products isolated from the autoxidation of Me 10*t*,12*c*-CLA are kinetic hydroperoxides. This is supported by the obtained product distribution and the absence of conjugated diene hydroperoxides that may be formed by the  $\beta$ -fragmentation pathway. In addition, this agrees with our previous observation that the hydroperoxide mixture was slightly more complex in the absence than in the presence of high amount of  $\alpha$ -tocopherol [11]. The experimental evidence also supported the result that conformations C and D are unimportant. For example, Me 10-OOH-11*t*,13*c*, a kinetic hydroperoxide that would theoretically arise from conformations C and D, was absent from the reaction mixture.

A modified mechanism for the hydroperoxide pathway of CLA methyl ester autoxidation in the presence of  $\alpha$ -tocopherol (TocOH) that accounts for the theoretical calculations performed in this study is presented in Scheme 2. It is noteworthy, that all hydroperoxides are formed as racemic mixtures of enantiomers, *i.e.* the chiral center is formed without stereoselection. In the first step, the abstraction of one of the four allylic hydrogen atoms from CLA methyl ester leads to a formation of three distinct pentadienyl radicals **2A**, **2B**, and **3** (=3A + 3B; Note: Radicals **3A** and **3B**, formed from conformations A and B by hydrogen atom abstraction from the allylic position adjacent to a *cis* double bond, are interconvertible conformations and thus, the subsequent steps are drawn only for **3A**). Peroxidation of the pentadienyl radicals followed by a fast hydrogen atom transfer from TocOH (ca.  $10^6 \text{ M}^{-1} \text{ s}^{-1}$ ; [45, 46]) explains the formation of five (**7**, **9**, **13**, **18**, and **21**) of the six conjugated diene allylic hydroperoxides isolated in this study. The most plausible pathway for the formation of the sixth hydroperoxide (**20**) is through rearrangement of the bisallylic peroxy radical **15** into the conjugated diene peroxy radical **17** followed by hydrogen atom abstraction.

In addition to conjugated diene hydroperoxides, the mechanism suggests the formation of three nonconjugated diene bisallylic hydroperoxides **8**, **12**, and **19**. These hydroperoxides are anticipated to be more unstable than the conjugated diene hydroperoxides based on the literature on products formed during singlet oxygen oxidation of conjugated dienes [47–49] and on kinetic studies with methyl linoleate [50, 51]. No attempts were made to isolate these hydroperoxides. HPLC analysis of the hydroperoxide mixture at  $\lambda = 205 \text{ nm}$  revealed, however, three additional minor peaks that may correspond to these hydroperoxides.

The formation of nonconjugated hydroperoxides during autoxidation of CLA has been suggested previously by Eulitz et al. [9] based on the analysis of secondary oxidation products. They speculate, however, that autoxidation and singlet oxygen oxidation of CLA would yield identical products and that the bisallylic hydroperoxides would form by way of a 1,3-addition reaction.

Scheme 2 illustrates that the key reactions governing the product distribution in the autoxidation of CLA in the presence of a good hydrogen atom donor are (1) the abstraction of one of the four allylic hydrogen atoms, (2) partitioning of oxygen on the resulted pentadienyl radicals, (3) hydrogen atom transfer from TocOH, and (4)  $\beta$ -fragmentation of the intermediate bisallylic peroxy radicals. Since experimental and theoretical data on the latter two have been published [26, 45, 46, 50, 51], the first two key reactions were addressed by theoretical calculations.

It is generally accepted that the rate constant for hydrogen atom abstraction depends primarily on the strength of the C–H bond being broken [26, 52, 53]. Therefore, the bond dissociation enthalpies (BDEs) for the allylic C–H bonds of the precursor lipid in conformations A and B were calculated and the results are listed in Table 3. The calculated C–H BDEs values range between 73.7 and 75.0 kcal/mol and thus fall in between the monoallylic C–H BDE (79.2 kcal/mol) and the bisallylic C–H BDE (67.5 kcal/mol) values that were calculated at the same temperature and level of theory. It is of interest to note that hydrogen atom abstraction from an allylic position seems to be easier when adjacent to a *trans* double bond than when adjacent to a *cis* double bond. Of the two pentadienyl radicals derived from conformation A, **2A** (W-conformation) was 1.3 kcal/mol lower in energy than **3A** (Z-conformation). This is in relatively good agreement with the experimental values on W- and Z-pentadienyl radicals derived from 1,4-pentadiene [54]. Moreover, based on the results, the direct interconversion of **2A** and **2B** may be discounted on energetic grounds and by analogy with the pentadienyl radical itself [42, 55].

It is reasonable to expect that the addition of oxygen to the intermediate pentadienyl radicals occurs preferentially at centers having the highest spin density [26, 51]. Therefore, the unpaired spin density distribution was calculated for the pentadienyl radicals formed from conformations A and B and the results are illustrated in Fig. 2. The spin density occupies *p*-type orbitals with the lobes perpendicular to the plane of the conjugated system. The degree of spin polarization of the radicals is high and the two carbon atoms (C-10 and C-12 in **2A** and **2B**; C-11 and C-13 in **3A** and **3B**) between the three main spin centers possess a notable spin density of opposite sign. The gross spin density *i.e.* the sum of unpaired  $\alpha$  and  $\beta$  spin amounts to ca. 1.6 electrons in the radicals studied. The spin contamination

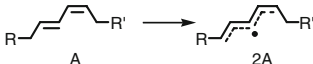

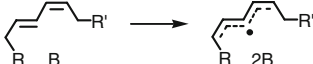

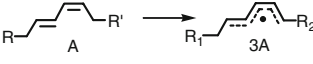

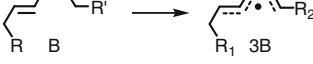

**Scheme 2** A proposed mechanism for the hydroperoxide pathway of CLA autoxidation in the presence of  $\alpha$ -tocopherol (TocOH)

was evaluated and found to be within acceptable limits; the  $\langle S^2 \rangle$ -expectation value, which serves as a useful diagnostic also within DFT [56], was 0.79 for all radicals compared to the ideal non-spin polarized value of 0.75.

By coincidence, radicals **2A** and **2B** are identical to those formed by abstraction of a bisallylic hydrogen atom

from Me 9*t*,12*c*-linoleate and from Me 9*c*,12*c*-linoleate, respectively. The calculated spin density values for **2A** and **2B** were slightly smaller than the experimental values obtained by ESR spectroscopy [42, 57] but comparable to those calculated by Pratt et al. for 1,5-dimethylpentadienyl radicals [26]. The calculations suggest that the central

**Table 3** Calculated allylic C-H BDEs of 10-*trans*,12-*cis*-CLA methyl ester in conformations A and B as electronic energies ( $\Delta E$ ) at 0 K and as enthalpies ( $\Delta H$ ) at 313 K (kcal/mol), and the relativeenthalpies  $\Delta H$  (kcal/mol) of the conformations (reactants) and the pentadienyl radicals (products) with respect to the most stable conformation and pentadienyl radical (A and 2A, respectively)

Entry	BDE $\Delta E$	BDE $\Delta H$	$\Delta H$ (reactant)	$\Delta H$ (product)
1. 	80.6	73.7	0	0
2. 	81.0	74.2	+0.8	+1.3
3. 	81.9	74.9	0	+1.3
4. 	82.0	75.0	+0.8	+2.2

$R_1 = (\text{CH}_2)_7\text{CO}_2\text{Me}$ ,  $R_2 = (\text{CH}_2)_3\text{CH}_3$

carbon atom of **2A** and **2B**, C-11, bears the highest spin density. Recent studies support this result; the bisallylic 11-hydroperoxides are the major oxidation products in the autoxidation of Me 9*t*,12*c*-linoleate and of Me 9*c*,12*c*-linoleate under kinetic conditions and at low conversion [50, 51].

According to the calculations there is a slightly higher spin density in **2A** at the *cisoid* end of the pentadienyl radical compared to the *transoid* end whereas in **2B** there is equal spin distribution at the two termini. The ESR measurements are consistent with this result [42, 57]. The calculations and the ESR both suggest that while the reaction of **2B** should lead to equal formation of **4'** and **11**, the *cisoid* end of **2A** should react faster with oxygen than the *transoid* end, leading to the preferential formation of peroxy radical **6** over **4**. Subsequent hydrogen atom transfer from TocOH to **6** and **4** should produce more hydroperoxide **9** than **7**. This contradicts with our experimental results. Since the observed isomeric distribution of hydroperoxides in the autoxidation of Me 9*t*,12*c*-linoleate [36, 51] also contradicts with the calculations and ESR data, it seems apparent that the unpaired spin density alone does not control the partitioning of oxygen in geometrically unsymmetrical pentadienyl radicals such as **2A**. Tallman et al. [51] have proposed that the biased product distribution in the autoxidation of Me 9*t*,12*c*-linoleate results from

**Fig. 2** Calculated relative Mulliken unpaired spin distribution in the pentadienyl radicals formed from conformations A and B of 10-*trans*,12-*cis*-CLA methyl ester (total Mulliken spin densities in parenthesis). Dark gray denotes excess  $\alpha$  spin density, light gray excess  $\beta$  spin density. The numbering of the radicals corresponds to Scheme 2

rearrangement of the bisallylic peroxy radicals into conjugated diene peroxy radicals via intermediate radical-dioxygen complexes similar to allylic radical-dioxygen

complexes in the isomerization of allylic hydroperoxides. This is a plausible explanation also in the case of CLA autoxidation. Hence, the rearrangement of the bisallylic peroxy radical **5** to conjugated diene peroxy radicals **4** and **6** would occur through two distinct isomeric radical-dioxygen complexes, **I** and **II**. The formation of **I** derives from the rearrangement across the *trans* double bond and that of **II** across the *cis* double bond. The low-energy conformation of **I** would be a five-membered ring envelope structure where the substituents are both at equatorial positions and thus, is expected to be favored over the formation of **II** where one of the substituents is at equatorial and the other at axial position. As a consequence, the formation of the peroxy radical **4** would be preferred over the peroxy radical **6**, and thereafter the formation of the hydroperoxide **7** in accordance with our observations.

For radicals **3A** and **3B**, the calculations predict an even higher spin density at the central carbon atom of the pentadienyl radical than in **2A** and **2B**. In addition, the spin distribution at the two termini of **3A** and of **3B** is unequal. No ESR data on fatty acid pentadienyl radicals with this geometry have been reported. However, the ESR data for the *Z*-conformation of the pentadienyl radical itself [43, 55] reveals that the central carbon atom bears the highest spin density and it is comparable to our calculated values. Consequently, the major product in the peroxidation of **3A** should be the bisallylic peroxy radical **15** that may rearrange through two distinct isomeric radical-dioxygen complexes, **V** and **VI**, to the conjugated diene peroxy radicals **14** and **17**, and thereafter to equal amounts of the hydroperoxides **18** and **20**. Moreover, oxygen should not partition equally at the two termini of **3A** (or of **3B**). More peroxy radical **16** than **14**, and thereafter more hydroperoxide **21** than **18** should be formed. Accordingly, slightly less hydroperoxide **21** was observed than what was expected. This might, however, result from the peroxy radical **16** being more prone to isomerization and/or decomposition than the other peroxy radicals because of its unusual *cis,trans* diene geometry.

As summarized in Scheme 2, the theoretical calculations provided an improved framework for understanding the formation of the isomeric distribution. The diastereoselectivity in favor of Me 9-OOH-10*t*,12*c* (**7**) may now be easily explained. Not only is this isomer formed in excess from **2A**, based on the analogy to the autoxidation of 9*t*,12*c*-methyl linoleate [51], but it is also formed from **2B**. Because the symmetrical radical **2B** is identical to that produced from 9*c*,12*c*-methyl linoleate [50], the reaction of **2B** leads to equal amounts of hydroperoxides **7** and **13** and thus, roughly one fourth of the main isomer **7** is formed through radical **2B**. Moreover, because the isolated products are kinetic products, it seems now apparent that  $\beta$ -fragmentations other than those of the bisallylic

hydroperoxides are not important contributors to the isomeric distribution under these reaction conditions. The formation of a small amount of Me 13-OOH-9*t*,11*t* in the autoxidation of Me 9*c*,11*t*-CLA (corresponds to 9-OOH-10*t*,12*t*, which was not isolated in this study) through the  $\beta$ -fragmentation of a conjugated diene peroxy radical is, however, highly plausible. In addition, as the isomerization of conjugated diene peroxy radicals is so well established [33–36], it is safe to assume that three additional conjugated diene hydroperoxides, *i.e.* altogether nine conjugated diene hydroperoxides, are formed during autoxidation of Me 10*t*,12*c*-CLA in the absence of  $\alpha$ -tocopherol. More research is needed to confirm the formation of the thermodynamic products.

The isomeric distribution of product hydroperoxides was expected to reflect the stability of the intermediate pentadienyl radicals. Calculations showed that **2A** was, as anticipated, the most stable (Table 3). Interestingly, the radicals **2B** and **3A** were of similar energy. Thus, more radicals **2A** + **2B** should be formed than radicals **3A** + **3B**. When only conformations A and B of the precursor lipid are considered significant, the ratio between radicals may be estimated based on the enthalpy differences ( $\Delta H$ s) via the Boltzmann distribution. The calculated enthalpy difference between conformations A and B, 0.84 kcal/mol, gives an initial ratio A/B of 3.9/1. Considering the BDEs for the formation of the pentadienyl radicals the estimated ratio (**2A** + **2B**)/(**3A** + **3B**) becomes 6.6/1. Experimentally this ratio was roughly 3.5/1 based on the ratio (9- and 13-hydroperoxides)/(10- and 14-hydroperoxides) determined by HPLC. The difference between the theoretical and experimental ratio may be partly explained by noting that radicals **2A** and **2B** with their lower BDEs are more stable and thus less prone to undergo reaction [58]. To explore this, the reaction energies were calculated for the peroxidation and they are, indeed, *ca.* 1 kcal/mol less negative for **2A** and **2B** than for **3A** and **3B**, which would shift the distribution towards products formed from the latter two radicals. It must be emphasized, however, that the theoretical ratio is based merely on the  $\Delta H$  values and it ignores all other factors such as reaction barriers and stereoelectronics that influence the course of the reactions.

## Conclusions

The hydroperoxide pathway is one of the reaction pathways of CLA autoxidation in the presence of a good hydrogen atom donor. The mechanistic proposal developed for this pathway based on our previous work [11, 12] and this study serves as means for predicting the hydroperoxides and their isomeric distribution formed during autoxidation of yet another CLA isomer and it facilitates

further investigations directed to a complete elucidation of the presented reaction mechanism. More research is required for example to establish the formation of the nonconjugated hydroperoxides as well as the details of the suggested isomerizations of the bisallylic peroxy radicals. Knowledge of these initial steps is crucial for understanding the subsequent steps in the CLA autoxidation. In particular, it allows us to predict the structures of the oligomeric products that can be envisioned to be formed by addition of the peroxy radicals to the double bond system of the oxidizing conjugated fatty acid ester. We anticipate that this addition reaction is the major pathway in the CLA autoxidation performed in the absence of a good hydrogen atom donor. However, in biological systems CLA is present only in small amounts and the likelihood of the autoxidative polymerization can be expected to be low. Therefore, the clarification of the reaction mechanism of the hydroperoxide formation can be considered to be of high importance when studying the biological significance of CLA isomers. This study offers now for the first time means of producing and separating intact CLA methyl ester hydroperoxides that may be used for evaluating their biological activity or for studying their secondary oxidation reactions.

**Abstract** Peroxisome proliferator-activated receptor  $\alpha$  (PPAR $\alpha$ ) belongs to the nuclear receptor superfamily that regulates multiple target genes involved in lipid metabolism. Cholesterol ester transfer protein (CETP) is a secreted glycoprotein that modifies high-density lipoprotein (HDL) particles. In humans, plasma CETP activity is inversely correlated with HDL cholesterol levels. We report here that PPAR $\alpha$  agonists increase CETP mRNA, protein and accordingly its activity. In a human CETP transgenic animal model harboring the natural flanking regions (Jiang et al. in *J Clin Investigat* 90:1290–1295, 1992), both fenofibrate and a specific synthetic PPAR $\alpha$  agonist LY970 elevated human CETP mRNA in liver, serum protein and CETP activity. In hamsters, the endogenous liver CETP mRNA level and the serum CETP activity were dose-dependently upregulated by fenofibrate. In addition Wy14643, a PPAR $\alpha$  agonist, also significantly elevated CETP mRNA and activity. In a carcinoma cell line of hepatic origin, HepG2 cells, overexpression of PPAR $\alpha$  resulted in increased CETP mRNA and agonist treatment further elevated CETP mRNA levels. We conclude that PPAR $\alpha$  agonists upregulate CETP expression and activity and may play an important role in PPAR $\alpha$  (agonist mediated HDL cholesterol homeostasis in humans.

## Introduction

Peroxisome proliferator-activated receptor  $\alpha$  (PPAR $\alpha$ ) together with PPAR $\gamma$  and PPAR $\delta$  form a subfamily of nuclear receptors that play a critical role in mediating lipid homeostasis, inflammation and metabolism. PPAR $\gamma$  plays a key role in adipocyte differentiation and is the molecular target of anti-diabetic thiazolidinediones (TZD) [1]. PPAR $\delta$  modulates lipid metabolism and inflammation in multiple tissues [2]. PPAR $\alpha$  primarily regulates fatty acid oxidation and also regulates many target genes such as apolipoprotein AI (ApoAI) [3], apolipoprotein CIII (ApoCIII) [4], apolipoprotein AV (ApoAV) [5], phospholipid transfer protein (PLTP) [6] and scavenger receptor class B, type I (SR-BI) in liver [7] that are intimately involved in lipoprotein metabolism.

Cholesterol ester transfer protein (CETP) is a 74 KDa glycoprotein that is primarily synthesized in liver [8]. The secreted protein is mainly associated with high-density lipoprotein (HDL) and catalyzes the neutral lipid exchange (cholesterol ester from HDL to triglyceride-rich lipoprotein particles and TG vice versa) among lipoprotein particles. Increased plasma CETP activity is inversely associated with HDL cholesterol levels [9]. While convincing epidemiological data strongly suggest the protective role of HDL cholesterol in cardiovascular diseases, the exact role of CETP in coronary artery diseases, however, remains controversial. In recent years, CETP has emerged as a major therapeutic target to modulate HDL cholesterol levels and cardiovascular diseases. CETP inhibitor CP-529,414 (torcetrapib) dose-dependently inhibited plasma CETP activity, elevated HDL cholesterol and reduced low-density lipoprotein (LDL) cholesterol levels in recent clinical studies [10–12]. However, the phase III study of torcetrapib was halted because of significantly increased cardiovascular and

total mortality [12]. While the exact reasons are being explored for the adverse mortality rate resulting from CETP inhibition using torcetrapib, torcetrapib was found to induce aldosterone levels and increase blood pressure in humans [12]. In addition, plasma electrolytes were also changed in patients treated with torcetrapib [12]. These observations on torcetrapib are believed to be off-target activity of torcetrapib, as other structurally divergent CETP inhibitors do not exhibit similar off-target activities [13, 14]. In addition, there have been no reports on blood pressure changes in human subjects with homozygous CETP deficiency.

To study the *in vivo* function of CETP, human CETP transgenic mice were generated using either metallothionein promoter [15] or its own genomic fragments (CETP minigene transgenic mice) [16]. The metallothionein promoter directed CETP transgenic mice did not have significant changes in HDL cholesterol although there was significant expression of human CETP under the basal condition. This was primarily due to the fact that CETP favors large HDL particles and in mice such HDL particles are relatively minor components of HDL [15]. The CETP minigene transgenic mice with its own natural flanking regions are responsive to diet-cholesterol, i.e. the increases in CETP transgene expression and its activity under hypercholesterolemic conditions [16]. A liver X receptor (LXR) basis was established recently for the observed cholesterol regulation of human CETP gene [17]. Synthetic LXR agonists thus regulate CETP expression in liver and possibly in adipose tissue as well [17].

Fatty acids are believed to be the natural ligands of PPAR $\alpha$ . Fenofibrate as a hypolipidemic drug is also believed to act as a weak PPAR $\alpha$  agonist [18]. In recent years, many potent synthetic pharmacological agonists have been made including LY970 that have demonstrated potent efficacy in reducing plasma triglyceride levels and elevating HDL cholesterol in an ApoAI transgenic animal model [19]. In humans, the fibrate class of drugs is known to effectively reduce plasma triglyceride levels but has only minimum to moderate effects in increasing HDL cholesterol levels [20, 21]. The modest change of HDL cholesterol mediated by PPAR $\alpha$  agonists is thus intriguing in light of the combined regulations of ApoAI, PLTP and SR-BI that are expected to dramatically elevate HDL cholesterol levels. Human ApoAI transgenic mice have significantly elevated plasma HDL cholesterol [22]. PLTP is an HDL remodeling protein that contributes to PPAR $\alpha$  agonist mediated HDL particle size increase [6] and SR-BI is an HDL receptor, reduced level of which leads to significantly elevated HDL cholesterol in mice [23].

We present evidence here in this report that PPAR $\alpha$  agonists upregulate CETP. Because of the pleiotropic effects of PPAR $\alpha$  agonists in regulating lipid homeostasis and also the limitation of the human CETP transgenic mice

in studying the CETP activity link to its HDL cholesterol effect, it is difficult to assess the exact impact on HDL cholesterol homeostasis in our studies directly. However, based on the well established link of plasma CETP activity and HDL cholesterol levels in humans, our results suggest that this regulation may result in the attenuation of HDL cholesterol elevation mediated by PPAR $\alpha$  agonists and thus may play a critical role in PPAR $\alpha$  agonist mediated HDL cholesterol homeostasis in CETP species.

## Methods

### Materials

Fenofibrate, Wy14643, triolein and salts were obtained from Sigma-Aldrich (St Louis, MO). Cholesterol Oleate and POPC were obtained from Avanti Polar Lipids (Alabaster, AL). BODIPY-CE analogue was obtained from Molecular Probes (Eugene, OR). Purified human VLDL was obtained from Intracel (Frederick, MD). LY970, 2-(4-{3-[1-(3,4-Dimethylbenzyl)-4-methyl-5-oxo-4,5-dihydro-1H-[1,2,4]triazol-3-yl]-propyl}-phenoxy)-2-methyl-propionic acid, was made at Lilly Research Laboratories as described [19].

### Animals

All experiments involving animals were approved by the Institutional Animal Care and Use Committee of Eli Lilly and Company, Indianapolis, Indiana. The human CETP minigene transgenic mice were described previously [16]. Seven-week old male CETP human transgenic mice under the control of the natural human promoter were obtained from The Jackson Laboratory (Bar Harbor, ME, Stock No. 003904) and acclimated for 2 weeks prior to the start of the studies. Each study used 4–6 mice per group and the mice were individually caged. Light was controlled on a 12 h on 12 h off light/dark cycle. The mice were provided Purina 5001 chow *ad libitum* and had free access to water throughout the experiments. Compounds were dosed daily by oral gavage in CMC/Tween80 (1.0%/0.25%) vehicle for 7 days. The animals were sacrificed by CO<sub>2</sub> asphyxiation 3 h after the last dose. Blood samples for serum preparation were collected by cardiac puncture and livers were collected and frozen in liquid nitrogen. Eight-week old male Syrian Golden Hamsters (six per group) were obtained from Harlan Sprague Dawley (Indianapolis, IN) and acclimated 2 weeks prior to the start of the study. The hamsters were housed 5 per cage. Light was controlled on a 12 h on 12 h off light/dark cycle. The hamsters were provided Purina 36315 chow *ad libitum* and had free access to water throughout the experiments. Compounds were dosed daily by oral gavage in CMC/Tween80 (1.0%/0.25%) vehicle for 14 days. The animals

were sacrificed by CO<sub>2</sub> asphyxiation 3 h after the last dose. Blood samples for serum preparation were collected by cardiac puncture and livers were collected and frozen in liquid nitrogen.

#### CETP Activity

A donor particle containing a fluorescent cholesterol ester analogue that self quenches its fluorescent signal was prepared similarly to what was described by Bisgaier et al. [24]. The particle contained 15 mol% BODIPY-CE analogue, 33 mol% cholesteryl oleate, 8 mol% triolein, and 44 mol% POPC. The donor particle was added to a Tris/NaCl buffer with an acceptor particle (purified human VLDL at final concentration of 25 µg/ml). Serum from the animals was added to the mixture and incubated 30 min at 37°C. Fluorescent signal at wavelengths 544 nm excitation, 595 nm emission with a 590 nm cutoff filter in a Gemini fluorescent plate reader (Molecular Devices, Sunnyvale, CA) represents CETP activity.

#### Plasma CETP Levels

An ELISA (Wako Diagnostics, Richmond, VA) was used to measure CETP protein concentration in mouse serum. The serum samples were serially diluted with PBS and the assay was performed as described according to the manufacturer's instructions.

#### Plasma Lipid Analysis

Serum triglyceride was measured in an automated clinical analyzer (Roche, Indianapolis, IN). Lipoproteins were analyzed by FPLC as described in Cao et al. [25].

#### mRNA Measurement

RNA was prepared with RNeasy Mini Kit (QIAGEN, Valencia, CA) or Total RNA Chemistry products for the ABI Prism 6100 Nucleic Acid PrepStation (PE Applied Biosystems, Foster City, CA, USA). Taqman real-time quantitative PCR (Q-PCR) was performed using an ABI Prism 7900 sequence detector (PE Applied Biosystems, Foster City, CA) with GAPDH as an internal control for HeG2 cells and 18S as an internal control for animal liver samples. Gene-specific primer probes were obtained from Applied Biosystems. Relative expression of the genes was determined by C<sub>t</sub> method and calculated to fold induction against the controls.

#### Cell Culture Studies

Full length human PPAR $\alpha$  cDNA was cloned from human liver and the sequence was confirmed by DNA sequencing.

It was then subcloned into the mammalian expression vector pcDNA3.1(+) with *KpnI* and *NotI* sites. The PPAR $\alpha$  expression vector was used to establish a HepG2 Stable cell line in which PPAR $\alpha$  was expressed at 80 fold (mRNA) over the basal expression level through standard Geneticin (G418, Invitrogen, Carlsbad, CA) selection procedure (800 µg/ml). HepG2 and HepG2 PPAR $\alpha$  stable cells were grown in 3/1 DME/F12 + 10% FBS and seeded in 24-well plates at the density of  $8 \times 10^4$  cells/well. Twenty-four hours later, the cells were treated with either DMSO or PPAR $\alpha$  agonists for 48 h. RNAs were then prepared and analyzed as described above.

#### Statistics

Values are given as mean  $\pm$  standard error of mean (SEM). Statistical differences, as defined as  $P < 0.05$ , from the vehicle control group were determined using Dunnett's test or *t* tests (JMP 5.1.1, SAS, Cary, NC).

## Results

To explore whether PPAR $\alpha$  agonists regulate CETP, we initially used a human CETP mini-gene transgenic mice. This mouse model utilized a DNA fragment containing the human CETP gene including coding regions, introns and flanking regulatory sequences to express the transgene product primarily in liver [16]. It has been shown previously that cholesterol rich diet induced hepatic CETP mRNA and activity in this model and the molecular basis for the observed regulation was traced to an LXR basis [16, 17]. We treated the animals ( $n = 4$ ) using fenofibrate for 7 days and 3 h after the last dose, we sacrificed the animals and analyzed the data. Serum triglyceride level was reduced by 38% (Fig. 1a), suggesting the activation of PPAR $\alpha$  in vivo. Serum CETP activity was assessed and demonstrated a significant increase (61%) (Fig. 1b). Measuring serum CETP protein levels using an ELISA indicated a 130% increase in serum CETP protein mass (Fig. 1c). A 2.7 fold increase in hepatic CETP mRNA was observed when liver samples were analyzed by the quantitative polymerase chain reaction (Fig. 1d). Next, we investigated specific PPAR $\alpha$  mechanism by using a potent specific synthetic PPAR $\alpha$  agonist LY970 that is structurally divergent from fenofibrate in the same model [19]. CETP mini-gene mice ( $n = 4-5$ ) were treated with 1 mg/kg dose of LY970 for seven days and the serum lipid, protein and hepatic mRNA levels were analyzed similarly. As expected, LY970 reduced serum triglyceride level dramatically (75%, Fig. 2a), suggesting a very potent PPAR $\alpha$  activation in this mouse model. Serum CETP activity was elevated 154% and the protein level increased 228% (Fig. 2b, c).

**Fig. 1** Regulation of CETP by fenofibrate in CETP minigene transgenic mice. Four animals per group were dosed orally at 500 mg/kg for 7 days. Plasma and tissue samples were prepared 3 h after the last dose and analyzed as described in “Methods”. **a** Fenofibrate reduced serum triglyceride levels. **b** Fenofibrate elevated CETP activity. Ex vivo CETP activity of serum samples was assessed with the assay described in “Methods”. **c** Fenofibrate increased serum CETP protein mass. Serum CETP protein levels were measured by an ELISA kit for human CETP as described in “Methods”. **d** Hepatic human CETP mRNA was increased upon PPAR $\alpha$  activation by fenofibrate. Liver RNA was prepared and CETP mRNA level was assessed by the quantitative PCR as described in “Methods”. \* $P < 0.05$  versus vehicle ( $t$  test)

Hepatic mRNA was upregulated three fold as well (Fig. 2d). Significant reduction of total cholesterol (23%) that was attributable primarily to reductions of VLDL and LDL was observed. HDL cholesterol was not changed (data not shown).

To explore whether endogenous CETP could be regulated by PPAR $\alpha$  agonists, we treated hamsters with increasing doses of fenofibrate or 10 mg/kg of Wy14634, a prototypic PPAR $\alpha$  agonist for fourteen days and analyzed lipids, CETP mRNA and its activity. As were shown in Fig. 3, fenofibrate at the highest dose trended towards a reduction of serum triglyceride levels (nonsignificant, Fig. 3a). Fenofibrate elicited a dose-dependent increase in plasma CETP activity that was 221% at the highest dose compared to the vehicle group (Fig. 3b). Hepatic CETP mRNA was also dose-dependently elevated with the highest elevation around 60% with the highest fenofibrate dose and close to 90% increase with Wy14643 treatment (Fig. 3c). There was no significant change in HDL cholesterol levels as assessed by FPLC analysis (data not shown). Taken together, these data indicated that PPAR $\alpha$  agonists upregulated CETP in vivo.

To explore the potential mechanisms of PPAR $\alpha$  agonist regulation of CETP, we used a human liver carcinoma cell line HepG2 cells as a model. HepG2 cells have low PPAR $\alpha$  expression [26] and not surprisingly, agonist treatment did not result in any significant change in CETP mRNA levels (Fig. 4b). We thus generated a stable cell line in which PPAR $\alpha$  was overexpressed. PPAR $\alpha$  overexpression led to an increase of more than 100% in CETP mRNA and a more than 5 fold elevation in carnitine palmitoyl transferase 1 (CPT1) mRNA as a control [27] (Fig. 4a). Treatment of the cells with PPAR $\alpha$  agonists resulted in a further but moderate elevation in CETP mRNA compared to DMSO as the vehicle (20–60%, Fig. 4b). As controls, liver X receptor (LXR) agonist T0901317 robustly elevated CETP mRNA in these cells [17]. Thus, PPAR $\alpha$  agonist regulation of CETP was direct on hepatocytes. In an attempt to map potential PPAR $\alpha$  responsive elements within the regulatory regions of human CETP gene, we searched the promoter and intron one of the human CETP gene for potential direct

**Fig. 2** Regulation of CETP by a specific synthetic PPAR $\alpha$  agonist LY970 in CETP minigene transgenic mice. Five animals in vehicle group and four animals in compound group were treated with either vehicle or LY970 at 1 mg/kg for 7 days. Serum and tissue samples were prepared and analyzed similarly to “Methods” in Fig. 1. **a** Significant reduction of serum triglyceride levels. **b** Significant elevation of serum CETP activity. **c** Significant increase in serum CETP mass. **d** Significant increase in hepatic CETP mRNA levels by LY970. \*  $P < 0.05$  versus vehicle ( $t$ -test)

repeat of hormone responsive element AGGTCA separated by one nucleotide (DR1) and did not find any obvious DR1 elements (data now shown). Accordingly a five kilobase promoter fragment subcloned into a luciferase reporter did not show any PPAR $\alpha$  agonist dependent increase in its reporter activity (data not shown). Thus, the molecular basis of PPAR $\alpha$  agonist regulation of CETP remains to be defined.

## Discussion

PPAR $\alpha$  is a nuclear receptor that plays an important role in lipid homeostasis. Besides its major role in regulating ApoCIII [3], apoAV [5] and fatty acid oxidation [18], it has been well recognized that PPAR $\alpha$  agonists regulate key molecular components involved in HDL cholesterol metabolism. Specifically, PPAR $\alpha$  agonists upregulate human ApoAI [3] and PLTP [6] and reduce expression of SR-BI [7]. ApoAI is the major structural component of HDL particles and the amount of ApoAI is closely associated with HDL cholesterol levels. PPAR $\alpha$  agonist treatment of human ApoAI transgenic mice resulted in dramatically elevated HDL cholesterol levels [3]. Although the role of PLTP in HDL metabolism is not entirely clear, it has been convincingly shown in rodent models that PLTP is essential for HDL biogenesis [28]. Further PPAR $\alpha$  regulation of PLTP is necessary for PPAR $\alpha$  agonist mediated HDL particle size increase in mice [6]. SR-BI is an HDL receptor, deficiency of which in mice leads to dramatically elevated plasma HDL cholesterol levels [23]. Despite the combined regulation of these important molecules involved in HDL cholesterol metabolism by PPAR $\alpha$  agonists that are expected to raise HDL cholesterol level, the effect on HDL cholesterol by PPAR $\alpha$  agonists in humans is minimum to modest [20, 21]. Although it has been suspected that potent synthetic PPAR $\alpha$  agonists may elevate HDL cholesterol more dramatically, it has not been proven clinically and it appears that induction of HDL cholesterol by PPAR $\alpha$  agonists may be bell-shaped [29]. A major missing link of PPAR $\alpha$  regulation of ApoAI, PLTP and SR-BI and the associated impact on HDL cholesterol in humans versus

**Fig. 3** Regulation of hamster CETP by PPAR $\alpha$  agonists. Five animals per group were treated with either various doses of fenofibrate or Wy14643 at 10 mg/kg for 14 days. Serum lipid and CETP activity was analyzed similarly to the studies with CETP minigene transgenic mice. **a** Serum a triglyceride analysis. **b** Dose dependent increase in ex vivo CETP activity by fenofibrate and 10 mg/kg Wy14643. **c** Hepatic mRNA analysis by quantitative PCR. \*  $P < 0.05$  versus vehicle (Dunnett's)

**Fig. 4** Regulation of cellular CETP by PPAR $\alpha$ . **a** Increased CETP expression by PPAR $\alpha$  overexpression in HepG2 cells. A HepG2 stable cell line was established through stable overexpression of human PPAR $\alpha$  driven by a CMV promoter. Relative CETP mRNA levels were assessed by quantitative PCR. **b** PPAR $\alpha$  agonist regulation of CETP in hepatic cells. HepG2 stable cells overexpressing PPAR $\alpha$  or the parental cell line were treated with different PPAR $\alpha$  agonists. 48 h later, cells were lysed and mRNA levels were analyzed by the quantitative PCR. T0901317 was used as a control for LXR agonist mediated CETP regulation

the studies in mice is the presence of CETP in humans. CETP catalyzes the transfer of cholesterol ester from HDL particles to ApoB-containing lipoproteins in exchange for triglyceride. It has been well documented through extensive genetic studies with CETP deficiency and polymorphisms in humans that plasma CETP levels are inversely correlated with HDL cholesterol levels. Subjects with either heterozygous or homozygous CETP deficiency not only have significantly elevated HDL cholesterol levels but also have a significant increase in HDL particle size [30]. CETP has been shown to significantly attenuate or abolish completely lecithin cholesterol acyl-CoA acyl-transferase (LCAT), or LXR $\alpha$  agonist mediated HDL

cholesterol and particle size increase [31, 32]. Significant attenuation of PPAR $\alpha$  agonist mediated HDL cholesterol increase by CETP in humans is thus conceivable and may at least partly explain the relative anemic elevation of HDL cholesterol induced by PPAR $\alpha$  agonists. Our data indicate that PPAR $\alpha$  agonists can increase CETP mRNA, serum proteins and activity and thus may provide a plausible explanation to the HDL cholesterol response clinically to PPAR $\alpha$  agonists. In our animal models, it has been impossible to study the direct effect of the changes of CETP level to the changes of HDL cholesterol because of pleiotropic effects of PPAR $\alpha$  agonists on HDL cholesterol homeostasis and the limitation of the human CETP transgenic mice [15]. Our attempt to study the clinical effect of PPAR $\alpha$  agonists on CETP levels, unfortunately, was inconclusive primarily because of the variations of the baseline plasma CETP levels and the extremely limited number of samples that were available for the study (data not shown). Thus, the exact pharmacological impact of PPAR $\alpha$  agonists on plasma CETP protein levels and its activity in humans awaits further investigation.

Our data are in stark contrast with van der Hoogt et al. [33], which reported a decrease in plasma CETP activity in CETP mini-gene transgenic mice with PPAR $\alpha$  activation by fenofibrate. At the moment, we do not know exactly the basis for the apparent opposite findings. In our studies we have used three different PPAR $\alpha$  agonists, each structurally divergent, to demonstrate the upregulation of CETP in mRNA, plasma protein and its activity. The experiment reported by van der Hoogt et al. was done with high fat diet in a hypercholesterolemic apoE3 Leiden transgenic background. Whether the presence of apoE3 Leiden transgene or the diet influenced the results they reported is not clear at the moment. Future studies will clarify the nature of the PPAR $\alpha$  regulation on CETP and its impact on HDL cholesterol.

**Acknowledgments** We would like to thank Dr. Shuyu Li for help with bioinformatics and Youyan Zhang for editorial support. We are indebted to Richard Tielking, Jack Cochran and Patrick Forler for excellent technical assistance. This work is supported by Lilly Research Laboratories.

**Abstract** Obesity is associated with impaired fatty acid (FA) oxidation and increased de novo hepatic lipogenesis that may contribute to the development of hypertriglyceridemia, an important risk factor for the development of cardiovascular disease. Strategies to improve hepatocyte FA metabolism, including dietary interventions, are therefore important for the prevention of obesity-associated comorbidities. Farnesol is consumed in the diet as a component of plant products. In the present study, we administered farnesol orally to rats for seven days and found significantly reduced serum triglyceride concentrations compared with controls. Potential mechanisms underlying the hypotriglyceridemic effect of farnesol were investigated using clone-9 cultured rat hepatocytes. Farnesol significantly upregulated expression of peroxisome proliferator-activated receptor alpha (PPAR $\alpha$ ) and the PPAR $\alpha$ -regulated genes fatty acyl-CoA oxidase and carnitine palmitoyl transferase 1a, suggesting that increased hepatic FA oxidation may contribute to serum triglyceride

lowering in rats. Farnesol did not change SREBP-1c mRNA levels, but significantly down-regulated fatty acid synthase (FAS) mRNA and protein levels and activity, indicating that attenuated lipogenesis may also contribute to hypotriglyceridemic effects of farnesol in vivo. Rescue experiments revealed that down-regulation of FAS by farnesol was not related to activation of PPAR $\alpha$ , but rather was caused by a 9-*cis* retinoic acid mediated mechanism that involved down-regulation of retinoid X receptor  $\beta$ . Diets rich in plant products are associated with a lower risk of cardiovascular disease. Our findings suggest that farnesol may contribute to this protective effect by lowering serum TG levels.

RXR $\beta$	Retinoid X receptor beta
SREBP-1c	Sterol regulatory element binding protein-1
TG	Triglycerides

## Introduction

Dyslipidemia, including elevated circulating levels of atherogenic triglyceride (TG)-rich lipoproteins, is increasing in prevalence in Western populations where rates of obesity have risen dramatically [1]. Hepatic production of TG-rich lipoproteins is primarily regulated by availability of fatty acids (FA) as substrates for TG synthesis [2]. Obesity is associated with reduced hepatic catabolism of FA through down-regulation of peroxisome proliferator-activated receptor alpha (PPAR $\alpha$ ) and genes of FA oxidation [3], and increased hepatic lipogenesis resulting from elevated blood insulin levels that stimulate expression of sterol regulatory element binding protein-1c (SREBP-1c) and fatty acid synthase (FAS) [4–6]. Dietary interventions that increase FA oxidation and decrease FA synthesis in hepatocytes may, therefore, provide a useful strategy to limit hepatic production of atherogenic lipoproteins and thereby decrease cardiovascular disease risk.

Farnesol is produced endogenously in cells from farnesyl pyrophosphate, the precursor of squalene in the cholesterol biosynthetic pathway [7]. It is also consumed in the diet as a component of plant products [8] including fruits and berries such as apricots, peaches, plums, blueberries, cranberries, raspberries and strawberries, vegetables such as tomatoes [9] and herbs such as chamomile [10]. A number of studies have shown that farnesol affects lipid metabolism in hepatocytes and other cells, and may be of benefit in regulating serum lipid levels. Dietary farnesol lowers serum cholesterol in rats [11], and a role for farnesol in the feedback control of cholesterol biosynthesis through down-regulation of HMG-CoA reductase is well characterized [12]. Farnesol has also been shown to inhibit phosphatidylcholine biosynthesis in human leukemia cells [13] and fatty acid synthesis in CaCo-2 colonic epithelial cells [14]. De novo synthesis of triglycerides (TG) in primary rat hepatocytes has been shown to be inhibited by farnesol [15], although mechanisms underlying this effect have not previously been investigated. Furthermore, the effect of farnesol on serum TG in rats had not been tested.

In the present study we showed that Sprague–Dawley rats administered farnesol had significantly lower levels of serum TG. We hypothesized that changes in regulation of hepatocyte FA metabolism may mediate this effect. Using clone-9 cultured rat hepatocytes we showed that farnesol up-regulated PPAR $\alpha$  and genes of FA oxidation. Although farnesol did not alter expression of the master lipogenic transcriptional regulator SREBP-1c, we showed for the first time that it significantly down-regulated FAS mRNA, protein, and activity levels, and that this was mediated by a 9-*cis* retinoic acid-dependent mechanism involving retinoid X receptor (RXR)  $\beta$ .

## Materials and Methods

### Materials

Unless otherwise indicated, all chemicals including *trans,trans*-farnesol were purchased from Sigma (Mississauga, ON, Canada).

### Animals

Rats were cared for in accordance with the recommendations of the Canadian Council on Animal Care and the University of Toronto Animal Care Policies and Guidelines. The experimental protocol utilized in the present study was reviewed and received ethical approval by the University of Toronto Animal Care Committee. Nine male Sprague–Dawley rats 7 weeks of age were purchased from Charles River Laboratories (Wilmington, MA, USA) and acclimatized for 1 week prior to study commencement on a standard AIN-93G diet (Dyets, Bethlehem, PA, USA) that was used throughout. Rats were randomized into two groups and were gavaged once daily with cottonseed oil (vehicle control) or farnesol (500 mg/kg body weight) dissolved in cottonseed oil for 7 days. Body weights were monitored to ensure that treatments were well tolerated, and did not change over the course of the study. On day 7, following an overnight fast, rats were euthanized by CO<sub>2</sub> asphyxia followed by cervical dislocation and samples of blood were taken by cardiac puncture. Serum TG were analyzed according to the manufacturer's protocol using Infinity triglyceride reagent (Thermo, Melbourne, Australia).

### Cell Culture

Clone-9 rat hepatocytes purchased from the American Type Cell Culture Collection (Manassas, VA, USA) were routinely cultured in DMEM in 150 dl flasks at 37 °C and 5% CO<sub>2</sub> in the presence of 1% penicillin/streptomycin with 10% fetal bovine serum (Hyclone, VWR, Mississauga, Canada). Farnesol and 9-*cis* RA were dissolved in DMSO immediately prior to use. Final concentrations of DMSO in both control and treatment medium were identical in all studies with a maximum level of 0.05%.

### Immunoblotting

Cells were washed repeatedly with ice cold PBS, then scraped into RIPA lysis buffer (1 $\times$  PBS, pH 7.4, 1% Nonidet P-40, 0.5% sodium deoxycholate, 0.1% SDS) containing 1% protease inhibitor cocktail and incubated on ice for 30 min with frequent vortexing then centrifuged for 20 min at 12,000 $\times$ g. Five to 40  $\mu$ g of protein in supernatants were mixed with 2 $\times$  Laemmli buffer, heated for 5 min at 95 °C,

electrophoresed in 10% SDS-polyacrylamide gels and transferred to polyvinylidene difluoride membranes. Blots were blocked for 1 h then probed overnight at 4 °C, first with antibodies to FAS (BD Biosciences, Mississauga, ON, Canada) or RXR $\beta$  (Upstate Biotechnology Inc., Charlottesville, VA, USA), then with horseradish peroxidase conjugated anti-mouse or anti-rabbit secondary antibodies (Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA). Signals were detected by enhanced chemiluminescence. Band densities were quantified in arbitrary units then expressed as relative density compared with untreated controls that were taken as 100%. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Abcam, Cambridge, MA, USA) was used as a loading control.

#### RNA Isolation, cDNA Synthesis, and PCR

Total RNA was isolated using TRI-Reagent. cDNA was synthesized from 5  $\mu$ g of total RNA by oligo(dT) priming using the SuperScript<sup>TM</sup> First-Strand Synthesis System for RT-PCR (Invitrogen, Burlington, ON, Canada). The cDNA was amplified under the following conditions: denaturation at 94°C for 5 min, followed by a pre-determined number of cycles of denaturation at 94 °C for 1 min, annealing at 62 °C for 1 min, and extension at 72 °C for 1 min, with the final extension at 72 °C for 10 min. The optimum cycle number for each primer set was determined so that the product was obtained during the exponential phase of the amplification (data not shown). Based on these preliminary studies cycle numbers, product size, and primer sets were used as outlined in Table 1. PCR products were electrophoresed on 1% agarose gels and stained with ethidium bromide. Band densities were measured and quantified by

densitometry in arbitrary units under UV light using an Alpha Innotech Fluorochem with AlphaEase image quantification software (San Leandro, CA, USA). Densities of amplified cDNA were normalized to the density of the corresponding 36B4 band, and relative densities were expressed as a percentage of control values.

#### FAS Assay

Cells were assayed for FAS activity as previously described [16]. Briefly, cells were washed with PBS, harvested by scraping into 500  $\mu$ l of PBS and pelleted by centrifugation for 5 min at 1,000 $\times$ g. Cell pellets were resuspended in 50  $\mu$ l of hypotonic buffer (20 mM Tris-HCl, 1 mM DTT, 1 mM EDTA, pH 7.5) for 15 min at room temperature and then centrifuged for 1 min at 12,000 $\times$ g. Supernatants containing 15  $\mu$ g of protein in 20  $\mu$ l of hypotonic buffer were added to 125  $\mu$ l of reaction buffer (100 mM potassium phosphate, 100 mM KCl, 0.5 mM NADPH, pH 7.0) and pre-warmed for 10 min at 37 °C. Reactions were started by the addition of 14  $\mu$ l of a substrate mixture containing 25 nmol of acetyl-CoA, 25 nmol of malonyl-CoA, and 0.05  $\mu$ Ci of [2-<sup>14</sup>C]malonyl-CoA (PerkinElmer Life Sciences, Boston, MA, USA). After 10 min, reactions were stopped by the addition of 1 ml of ice-cold 1 N HCl/methanol (6:4, v/v). Fatty acids were extracted with 1 ml of petroleum ether for 1 h and incorporation of radioactivity was measured by scintillation counting.

#### Statistical Analysis

All values shown are means  $\pm$  SEM. For Western immunoblots, values represent means from at least four

individual samples from two or more separate experiments with different cell preparations. Means for gene expression data were generated from five or more cell samples grown in three or more separate experiments. Differences between multiple treated groups and controls were analyzed by one-way ANOVA followed by Dunnett's post hoc test. Differences between treated and control FAS activity values were analyzed by Student's *t* test.

## Results and Discussion

We began the present study by treating 8-week-old male Sprague–Dawley rats with farnesol (500 mg/kg) by gavage for 7 days. This dose has previously been shown to elevate hepatic farnesol levels in rats [17] and to be well tolerated, resulting in no changes in body weights, food intakes, or liver weights after 28 days [10]. In agreement with those results, we found that farnesol did not change rat body weights (Fig. 1a), indicating an absence of overt toxicity or

malabsorption in treated animals. We found that serum TG concentration was reduced by ~40% in rats treated with farnesol compared with rats that received the vehicle control (Fig. 1b). To identify potential mechanisms underlying this effect, we next investigated the regulation of hepatocyte FA metabolism by farnesol using a rat hepatocyte cell line (clone-9 cells).

In rodents, diet-induced obesity causes reduced hepatic expression of PPAR $\alpha$  and genes of lipid oxidation [6]. Administration of PPAR $\alpha$  agonists has been shown to upregulate the expression of genes related to the oxidation of fatty acids [18], to lower serum TG concentrations, and to reverse hepatic lipotoxicity in diabetic mice [19]. A preliminary concentration-response study showed a significant effect of 30  $\mu$ M farnesol on expression of PPAR $\alpha$  by 24 h (data not shown). A time-course analysis showed that PPAR $\alpha$  was significantly induced by treatment with 30  $\mu$ M farnesol at both 24 and 48 h (Fig. 2a), indicating an autoregulatory activation of PPAR $\alpha$  transcription [20, 21] that has also been reported in HepG2 cells [22] and epidermal keratinocytes [23] treated with farnesol. PPAR $\alpha$  regulates the expression of genes involved in lipid homeostasis, stimulating fatty acid oxidation and improving lipoprotein metabolism [24]. We found that farnesol significantly induced expression of fatty acyl-CoA oxidase (ACOX) (Fig. 2B), a PPAR $\alpha$ -regulated gene involved in the peroxisomal beta-oxidation of very long chain FAs. Furthermore, farnesol stimulated expression of carnitine palmitoyl transferase 1a (CPT-1a), the rate-limiting enzyme in mitochondrial beta-oxidation of fatty acids (Fig. 2c). These results indicate that an increase in hepatic FA oxidation through activation of PPAR $\alpha$  by farnesol may have contributed to the reduction of serum TG concentration that was observed in rats.

Obesity and insulin resistance are also associated with elevated hepatic FA synthesis, in addition to reduced levels of lipid oxidation [4–6]. Increased circulating levels of glucose can act as a substrate for de novo hepatic lipogenesis, while elevated insulin stimulates expression of SREBP-1c [25] that transactivates the FAS promoter to induce hepatic FA biosynthesis [26]. Previous work has shown that farnesol decreases the de novo synthesis of FA from acetate in CaCo-2 colonic epithelial cells, and that inhibition of HMG-CoA reductase, causing depletion of farnesol as well as other downstream metabolites in this pathway, induces FAS mRNA expression [14]. A direct effect of farnesol on FAS mRNA and protein levels and activity, however, has not previously been reported. Here we show in concentration-response experiments that FAS protein levels were significantly down-regulated in clone-9 hepatocytes at 48 h in cells treated with 30  $\mu$ M farnesol (~40% reduction compared with controls) (Fig. 3a). A time-course analysis indicated that down-regulation of FAS

**Fig. 1** Farnesol has no effect on body weights and decreases serum TG concentrations. Male Sprague Dawley rats were treated with cottonseed oil (control) or farnesol (500 mg/kg) by oral gavage once daily for 7 days. Rat body weights (a) and serum TG concentrations (b). \**P* < 0.05 versus control

**Fig. 2** Farnesol induces PPAR $\alpha$  and genes of FA oxidation. Clone-9 rat hepatocytes were cultured with 30  $\mu$ M farnesol or DMSO (*control*) for the time periods indicated prior to harvest and analysis for gene expression by RT-PCR. Expression of PPAR $\alpha$  was significantly induced by farnesol (a), as was expression of the PPAR $\alpha$ -regulated genes ACOX (b) and CPT1a (c). \* $P < 0.05$ ; \*\* $P < 0.01$  versus control

protein was not evident before 48 h (Fig. 3b). FAS mRNA levels were also significantly decreased at 48 h in cells treated with 30  $\mu$ M farnesol (Fig. 3c). This decrease was evident by as early as 24 h (Fig. 3d), preceding the decrease in FAS protein and suggesting transcriptional regulation. Down-regulation of FAS protein by 30  $\mu$ M farnesol resulted in a >50% decrease in activity of the enzyme after 48 h of treatment (Fig. 3e). FAS protein levels also tended to be lower in livers of rats given farnesol (Fig. 3f), although this effect did not reach significance ( $P = 0.07$ ). These findings indicate that decreased hepatocyte FAS activity may contribute to hypotriglyceridemic effects of farnesol.

Interestingly, these findings may also explain several reports that the synthesis of fatty acids and triglycerides is modulated in response to changes in levels of metabolites derived from the cholesterol biosynthetic pathway [15, 27–30]. For example, statin drugs that deplete farnesol and other intermediates of the cholesterol biosynthetic pathway have been shown to increase TG synthesis in HepG2 hepatocarcinoma cells [29]. Conversely, squalene synthase inhibitors that increase cellular farnesol levels [31] have been shown to decrease the de novo synthesis of fatty acids and triglycerides in primary rat hepatocytes [15], and to lower serum triglyceride levels in several animal models [27, 28, 30]. Direct regulation of FAS by farnesol provides a unifying mechanism to explain these effects.

Mechanisms underlying the regulation of FAS expression by farnesol have not previously been investigated. Transcriptional regulation of the FAS promoter is complex. Multiple nuclear hormone receptors have been identified that can directly or indirectly modulate FAS transcription [26]. In an effort to understand the down-regulation of FAS by farnesol, we first tested whether farnesol caused any changes in expression of SREBP-1c, the major transcriptional regulator of lipogenesis [32]. SREBP-1c expression, however, did not change significantly in rat hepatocytes treated with farnesol (Fig. 4), in agreement with findings by Murthy et al. [14] who showed that SREBP-1c expression is not changed in CaCo-2 colonic epithelial cells treated with the farnesol precursor farnesyl-pyrophosphate. SREBP-1c is also regulated at the protein level by processing to an active form that translocates to the nucleus where it can regulate gene transcription [33]. While we did not measure protein levels of the nuclear form of SREBP-1c, we found no down-regulation of a number of genes that are controlled by this transcription factor (e.g., small heterodimer partner or ATP-binding cassette 1a (data not shown), or PPAR $\alpha$ ), indicating that a decrease in levels of the active form likely did not mediate down-regulation of FAS in the present study.

We next tested whether activation of PPAR $\alpha$  could have mediated the down-regulation of FAS that we observed in

**Fig. 3** Farnesol down-regulates FAS protein and mRNA expression and FAS activity in clone-9 cultured rat hepatocytes. **a** Representative immunoblot showing concentration-dependent effects of farnesol on FAS protein expression after 48 h. **b** Time-dependent effects of 30  $\mu\text{M}$  farnesol on FAS protein levels. clone-9 cells. However, when we treated cells with the potent PPAR $\alpha$  agonist fenofibrate, there was a trend towards increased FAS mRNA expression (data not shown), indicating that decreased FAS in the present study is not explained by PPAR $\alpha$  activation. We also treated cells with 9-*cis* retinoic acid (9-*cis* RA), a ligand activator of retinoid X receptors (RXRs) that heterodimerize with PPARs and other nuclear hormone receptors to form active complexes. Surprisingly, this compound alone completely restored FAS mRNA expression in the presence of farnesol (Fig. 5a). Ligand activation of RXRs by retinoids has previously been shown to induce FAS through a mechanism that does not appear to involve direct activation of a retinoic acid response element in the FAS promoter [34, 35]. Studies indicating induction of FAS by retinoids are normally performed under conditions in which the growth medium of cells has been treated to remove exogenous hormones and lipids from supplemental serum, or under

**Fig. 5** Farnesol down-regulates FAS in clone-9 cells through a 9-cis RA dependent mechanism that may involve regulation of RXRβ. Expression of FAS in cells treated with 30 μM farnesol was rescued by the addition of 1 μM 9-cis RA (a). Farnesol (30 μM) did not affect expression of RXRα (b), but significantly decreased mRNA expression of RXRβ (c). Levels of RXRβ protein were also significantly decreased by treatment with 30 μM farnesol (d). Numbers in parentheses are mean ±SEM for relative band density measured as a percentage of the density of the control band. \* $P < 0.05$ ; \*\* $P < 0.01$  versus control cells. <sup>ξ</sup> $P < 0.01$  versus cells treated with farnesol + RA

serum-free conditions [34, 35]. In the present study we utilized complete medium containing 10% untreated FBS and found no change in FAS mRNA levels in cells treated with 9-cis RA in the absence of farnesol, precluding a non-specific stimulation of gene transcription by this ligand. Farnesol significantly down-regulated RXRβ (Fig. 5c) but not RXRα (Fig. 5b). Western blotting indicated that RXRβ protein levels were also down-regulated by farnesol (Fig. 5d), suggesting that decreased expression and activity of this transcription factor may play a role in mediating effects of farnesol on FAS. The discovery that RXRβ is modulated by farnesol is novel and provides a new molecular pathway through, which farnesol may signal to regulate hepatocyte lipid metabolism.

In summary, we have shown that farnesol administered to rats significantly reduced serum TG concentration. Mechanisms that may mediate this effect include increased hepatocyte FA oxidation resulting from PPARα activation and subsequent upregulation of genes involved in peroxisomal and mitochondrial beta-oxidation as well as down-regulation of hepatocyte FA synthesis resulting from decreased mRNA and protein levels and activity of FAS. Rescue experiments showed that down-regulation of FAS by farnesol involved a 9-cis retinoic acid mediated mechanism that involves down-regulation of RXRβ. Diets rich in plant products, the principle source of farnesol, are generally associated with a reduced risk for the development of cardiovascular disease [36]. Our findings suggest that farnesol may contribute to this reduction in risk by not only helping to counter hypercholesterolemia, but also by lowering serum TG concentrations.

# Fatty Acid Profile of Sunshine Bass: I. Profile Change is Affected by Initial Composition and Differs Among Tissues

**Abstract** Fatty acid (FA) composition of fillet tissue can be tailored by transitioning fish from alternative lipid-based, low long-chain polyunsaturated fatty acid (LC-PUFA) grow-out feeds to high LC-PUFA “finishing” feeds. To address whether grow-out feed composition influences the responsiveness of fillet tissue to finishing, sunshine bass (SB, *Morone chrysops* × *M. saxatilis*) were reared to a submarketable size on grow-out feeds containing fish oil (FO) or a 50:50 blend of FO and coconut (CO), grapeseed (GO), linseed (LO), or poultry (PO) oil. For the final 8 weeks of the trial, fish were either maintained on assigned grow-out feeds or finished with the 100% FO feed. Production performance was unaffected by dietary lipid source, but fillet FA profile generally conformed to nutritional history. Regardless of grow-out regimen, finishing had a significant restorative effect on fillet FA composition; however, complete restoration of control levels of 20:5n-3, 22:6n-3, total LC-PUFA and n-3:n-6 FA ratio was achieved only among fish fed the CO-based grow-out feed. Saturated fatty acids (SFA) appear to be preferential catabolic substrates, whereas medium-chain and long-chain PUFA are selectively deposited in tissues. Provision of SFA in grow-out feeds appears to optimize selective FA metabolism and restoration of beneficial fillet FA profile during finishing.

MC-PUFA	Medium-chain polyunsaturated fatty acid(s)
MUFA	Monounsaturated fatty acid(s)
PO	Poultry oil
PUFA	Polyunsaturated fatty acid(s)
SB	Sunshine bass
SFA	Saturated fatty acid(s)

## Introduction

Seafood represents an increasingly important food source for the human population, particularly in developing regions—seafood comprises 20% of animal protein intake for more than half of the world population [1]. In addition, seafood is the predominant dietary source of long-chain polyunsaturated fatty acids (carbon atoms  $\geq 20$ , degree of unsaturation  $\geq 3$ , LC-PUFA), such as eicosapentaenoic (EPA, 20:5n-3) and docosahexaenoic acids (DHA, 22:6n-3), that are critical to human health [2]. These fatty acids (FA) impart benefits beyond basic nutritive value,

positively influencing neural, cardiac, vascular, immunological, reproductive, and oncogenetic health [3–8]. As a result, both nutritional and medical communities have recommended increasing human consumption of LC-PUFA to improve and maintain health of the American public [9].

With most traditional capture fisheries at sustainable harvest limits or in decline [10], seafood demand is increasingly met by aquaculture products. Currently, 45% of the fish consumed worldwide are cultured [1]. Assuming per capita seafood consumption is maintained, aquaculture production must double by 2030 to keep pace with human population growth over this time period [11]. Attendant to growth in the aquaculture sector is the further expansion of aquafeed manufacturing, an industry which relies on “reduction” fisheries for the production of fish meal and fish oil (FO) [12]. Recent peaks in the price of FO [13] reflect increasing competition for this resource among end-users and the inability of reduction fisheries to sustain further growth. In addition to economic and sustainability considerations, evidence linking FO in aquafeeds to elevated levels of environmental contaminants in cultured seafood [14–16] has motivated the aquaculture industry to identify alternatives to FO.

Fish oil replacement has been evaluated using a variety of plant- and animal-derived, alternative lipids in numerous aquaculture species, often with great success [17–20]. Although growth performance is typically unaffected by dietary lipid source, FA composition of fish tissues mirrors dietary content and is responsive to dietary change. Following a switch in dietary lipid source, fillet composition will change over time to more closely resemble the new dietary FA profile [21–24]. Thus, replacing FO with alternative lipid sources in aquafeeds results in the loss of nutritionally beneficial LC-PUFA within the resultant fillets and may, in turn, limit health benefits of cultured seafood to human consumers [25].

Based on the known plasticity of fillet composition, nutritionists have suggested the use of “finishing” feeds, high in LC-PUFA, to increase and/or restore high levels of these beneficial FA to the fillet prior to harvest. In this strategy, fish are raised on alternative lipid-based “grow-out” feeds for most of the production cycle and then transitioned to the finishing feed prior to harvest. Finishing feeds have been used to enhance fillet LC-PUFA content in a number of aquaculture species [26–34], however, the extent of LC-PUFA augmentation varies and complete restoration of FO-associated profile is infrequently reported [31, 34]. Fatty acid composition of the grow-out feed and pre-finishing fillet profile may contribute to differences in overall finishing success. Previous research suggested medium-chain polyunsaturated fatty acids (18 carbon, MC-PUFA) are resistant to “washout” or “dilution” during finishing [35], whereas saturated FA (SFA) are perhaps

more labile in fish tissues [33]. Most finishing strategies have employed MC-PUFA-rich plant oils during the grow-out phase, but high levels of MC-PUFA may render fillets comparatively unresponsive to finishing and LC-PUFA augmentation. To address this hypothesis, we evaluated alternative lipid sources with distinct FA profiles in sunshine bass (SB, *Morone chrysops* × *M. saxatilis*) grow-out feeds and subsequently assessed the responsiveness of fillet tissue to LC-PUFA augmentation during finishing.

## Methods and Materials

### Diet Preparation and Analyses

Five feeds were manufactured based on a practical, reduced fish meal feed our group previously developed for SB culture ([36], Table 1). As originally formulated, this feed contained 9.8% FO (dry matter basis; menhaden-derived; Virginia Gold<sup>TM</sup>, Omega Protein, Inc., Houston, TX, USA). In the present work, the original, FO-based formulation served as the control grow-out feed as well as the finishing feed. Four experimental grow-out feeds were derived from the basal formulation, with 50% of the FO replaced with poultry (PO, Tyson Foods, Inc., Robards, KY, USA), linseed (LO, Barlean's Organic Oils, Ferndale, WA, USA), grapeseed (GO, Kusha, Inc, Irvine, CA, USA), or coconut oil (CO, Spectrum Organic Products, Petaluma, CA, USA). These alternative lipids are predominantly comprised of a single FA class (monounsaturates [MUFA], n-3 MC-PUFA, n-6 MC-PUFA, and SFA, respectively) and were strategically chosen to generate distinct feed FA profiles for the purposes of hypothesis testing (Table 2). All feedstuffs were incorporated using a cutter–mixer (Model CM450, Hobart Corporation, Troy, OH, USA), pelleted using a food grinder, dried at room temperature to ~870 g kg<sup>-1</sup> dry matter, and stored frozen (–20°C) throughout the duration of the study. Proximate analyses of triplicate diet samples were conducted according to standard methods for analysis of animal feeds [37, 38] to confirm diet composition (Table 1). Reserved crude lipid samples were analyzed for FA composition (Table 2) according to the procedures described by Lane et al. [33].

### Experimental Design and Feeding Trial

Nine feeding regimens were developed to address influences of dietary lipid source and FA composition on production performance and subsequent finishing diet success in SB culture (Fig. 1). Eight experimental regimens represented feeding the grow-out feeds described above throughout the feeding trial (CO, LO, GO, and PO regimens) or with an 8-week finishing period (CO + Finish, LO + Finish, GO + Finish, and PO + Finish regimens). The control

regimen represented feeding the FO control/finishing feed throughout the duration of the feeding trial (FO Control regimen). Juvenile SB [46 ± 1 g, mean ± SE; age 1 (~ 10 months); Keo Fish Farm, Keo AR] were group-reared on the grow-out feeds described above, then stocked into a recirculation system consisting of 30, 270-l fiberglass tanks with associated mechanical and biological filtration units for the final 12 weeks of the production cycle. Each experimental regimen was randomly assigned to three replicate tanks ( $n = 3$ ), whereas the control regimen was assigned to six replicate tanks ( $n = 6$ ). For all regimens, each replicate tank was stocked with six fish from the appropriate dietary group. Eight weeks prior to harvest, a subsample of one fish per tank was collected to determine baseline tissue FA profile prior to finishing (tissues collected as described in “[Harvest, Sample Collection, and Production Performance](#)”). After baseline sampling, remaining fish were finished with the

100% FO feed for the remaining 8 weeks of the feeding trial (CO + Finish, LO + Finish, GO + Finish, and PO + Finish regimens) or maintained on assigned grow-out feeds (FO Control, CO, LO, GO, and PO regimens). Throughout the 7-month culture period, fish were fed assigned feeds once daily to apparent satiation.

Temperature (YSI Model 55 Oxygen Meter, Yellow Springs, OH, USA) was measured daily, whereas dissolved oxygen (YSI Model 55 Oxygen Meter, Yellow Springs, OH, USA), ammonia-, nitrite-, and nitrate–nitrogen as well as alkalinity were measured periodically throughout the study period (Hach DR/2010 spectrophotometer, Hach Company, Loveland, CO, USA). All water quality parameters were maintained within ranges suitable for SB culture [39]. All culture and husbandry methods, as well as euthanasia and sample collection procedures described below, were conducted under the direction and approval of the Southern

#### Harvest, Sample Collection, and Production Performance

After completion of the feeding trial, feed was withheld for 48 h prior to harvest. Fish within individual tanks were harvested and immediately anesthetized in an ice-water bath. Each anesthetized fish was individually weighed and euthanized by single cranial pithing prior to tissue sample collection. Boneless, skinless, J-cut (without belly flap) fillets were harvested by experienced filleters to calculate % dress-out [(weight of fillets/whole body weight) × 100]. Fillet subsamples were collected from a standardized dorso-anterior landmark (to isolate white muscle tissue),

packaged in sterile, polyethylene bags (Whirl-pak<sup>®</sup>, Nasco, Fort Atkinson, WI, USA), and stored frozen (−80°C) prior to proximate and FA analyses. Additional fillet subsamples were packaged similarly and held refrigerated for analysis of oxidative stability. Livers and intraperitoneal fat (IPF) masses were dissected from the viscera to calculate hepatosomatic index [HSI; (liver weight/whole body weight) × 100] and intraperitoneal fat ratio [IPFR; (IPF weight/whole body weight) × 100] indices. Subsamples of hepatic and IPF tissue were packaged and stored in the same manner as fillet tissue for FA analysis. Survival, percent weight gain [(average individual weight<sub>final</sub> − average individual weight<sub>initial</sub>)/average individual weight<sub>initial</sub> × 100], and food conversion ratio (FCR; average individual dry matter consumption/average individual gain) were calculated for each tank.

**Fig. 1** Schematic of experimental design and feeding trial. Groups of sunshine bass were group-reared on one of five grow-out feeds and then stocked into a recirculation system. Each grow-out group was assigned to six replicate tanks, each originally housing six fish. After 20 weeks of culture, baseline tissue samples were collected (1 fish per tank). Three replicate tanks within each grow-out group were transitioned to the FO-based finishing feed for the last 8 weeks of

the trial, whereas the other tanks were maintained on assigned grow-out feeds. At harvest, production performance was assessed and tissue samples were collected from all remaining fish (5 fish per tank). FO, 100% fish oil feed; PO, 50:50 poultry/fish oil feed; GO, 50:50 grapeseed/fish oil feed; LO, 50:50 linseed/fish oil feed; CO, 50:50 coconut/fish oil feed

### Tissue Composition

Fillet samples were analyzed according to standard methods [37, 38] for meat products to determine percent moisture, crude protein, crude lipid, and ash. All tissue samples were analyzed for FA composition in the same manner as diet samples (see “Diet Preparation and Analyses”).

### Peroxidative Stability

Short-term fillet oxidative stability was assessed at 24 h post-harvest by analyzing refrigerated fillet samples for the presence of peroxides and aldehydes using the Peroxy-safe™ and Aldesafe™ colorimetric assay kits (Saftest Incorporated, Tempe, AZ, USA).

### Statistical Analyses

Although multiple individual fish were sampled from each tank, replicate tanks served as the experimental units for all statistical analyses ( $n = 3$  for experimental regimens,  $n = 6$  for control regimen). All data were analyzed by one-way analysis of variance (ANOVA) within the General Linear Model framework of the Statistical Analysis System, version 9.1 (SAS Institute, Cary, NC, USA) to determine significance of differences among feeding regimens. Tissue FA data was further analyzed by two-way ANOVA within the Mixed Model framework of the Statistical Analysis System to test for independent and interactive effects of feeding regimen and tissue type. In all cases, differences were considered significant at  $P < 0.05$ .

## Results

Lipid source and FA profile of the grow-out feeds strongly influenced fillet FA profile and subsequent finishing success in SB culture. Feeding diets with different dietary lipid sources during the first 5 months of the feeding trial resulted in dramatic alterations of fillet FA composition, with baseline fillet profile (Table 3) generally mirroring dietary FA composition (Table 2). Expectedly, baseline fillet samples of fish fed the LO, GO, and PO feeds contained high levels of 18:3n-3, 18:2n-6, and total MUFA, respectively, whereas fillets of FO-fed fish were higher in LC-PUFA, particularly 20:5n-3 and 22:6n-3. However, baseline fillet samples of CO-fed fish did not reflect dietary prevalence of SFA or reduced LC-PUFA content, and prior to finishing, were largely equivalent to samples from the FO Control regimen.

Continued use of the alternative lipid-based grow-out feeds through harvest resulted in similar, though more pronounced deviations from the FO Control profile (Table 4). Nonetheless, in each of these unfinished regimens, fillet levels of LC-PUFA were exaggerated in comparison to dietary profile (Fig. 2). Finishing had a significant restorative effect on fillet FA profile, augmenting fillet levels of FO-associated FA, regardless of grow-out regimen (Table 4). However, complete restoration of FO Control levels of 20:5n-3, 22:6n-3, and LC-PUFA and n-3:n-6 FA ratio was achieved only in the CO + Finish group.

Liver and IPF FA composition were also significantly influenced by feeding regimen; however, comparison among fillet, liver, and IPF profiles revealed significant differences in how dietary FA were partitioned among the tissue types (Fig. 3). Saturated FA and MUFA were most abundant within the IPF, particularly when abundant in the feed. Conversely, levels of LC-PUFA, but not MC-PUFA, were consistently lower within the IPF compared to liver and fillet tissue ( $P_{\text{tissue type effect}} < 0.01$ ). Liver FA profile largely mirrored fillet composition, in that both tissue types typically contained lower levels of MUFA and higher levels of LC-PUFA compared to IPF tissue ( $P_{\text{tissue type effect}} < 0.01$ ). When tissue composition of the unfinished groups was standardized to dietary composition (Fig. 4), these distinctions were particularly apparent, indicating concentration of LC-PUFA within the liver and fillet tissues and concentration of MUFA within the IPF.

Fillet proximate composition did not vary, with the exception of fillet moisture content (Table 5), which showed slight, though significant, reductions for GO Control and PO + Finish treatments. Consumption, weight gain, FCR, HSI, and dress-out were unaffected by feeding regimen and acceptable in terms of production performance typically observed for SB (Table 6). LSI values

were significantly lower among fish fed the CO- and GO feeds (Table 6). LSI tended to be higher among finished groups relative to their unfinished counterparts, though significant differences were only observed within the GO-fed groups. No mortalities occurred during the course of the feeding trial. Peroxide and aldehyde concentrations were below detection limits for all samples analyzed (data not shown).

## Discussion

Although production performance and fillet crude lipid content were unaffected, feeding diets with different dietary lipid sources resulted in dramatic alterations of fillet total lipid FA composition. These findings are in agreement with previous investigations of CO [40], PO [41, 42], and LO [43], as well as the well-established paradigm of compositional plasticity of fish tissues with respect to FA profile. Finishing augments fillet nutritional quality among fishes raised on feeds containing FO alternatives [26–34]; however, complete restoration of FO-associated FA profile, specifically LC-PUFA content, is rarely observed [31–34]. For example, in Atlantic salmon *Salmo salar* fed linseed, palm, and/or rapeseed oil-based grow-out feeds, complete profile restoration was not observed after 20–24 weeks of finishing [27, 30, 32]. Similarly, 8–16 weeks of finishing were insufficient to completely restore the profile of Murray cod *Maccullochella peelii peelii* previously fed diets containing blends of linseed, olive, palm, sunflower, or rapeseed oils [34, 35]. Prior attempts to restore fillet LC-PUFA content of SB fed a corn-oil based, n-6 MC-PUFA-rich grow-out feed were unsuccessful after 12 weeks of finishing [33]. In the present work, restoration was incomplete among fish fed diets high in MC-PUFA. Fillet 20:5n-3, 22:6n-3, and LC-PUFA levels were considerably improved by finishing in the LO- and GO-fed fish, however, the magnitude of restoration was moderate compared to the CO- and PO-fed groups. Arguably, fillet profile could have been completely restored among the LO- and GO-fed fish, however, a longer finishing period would have been necessary to achieve complete FA profile restoration. Conversely, fish fed the CO feed needed little alteration to achieve the FO-associated composition, and fillet FA profile was successfully restored to control levels of LC-PUFA within 8 weeks of finishing.

Pre-finishing fillet FA profile influenced finishing success, and the inclusion of oils high in 18-carbon FA in grow-out feeds limited the effects of finishing feeds on SB fillet FA composition. Others have noted MC-PUFA, such as 18:2n-6 and 18:3n-3, deposited in the fillet are resistant to dietary modification and may be problematic in the context of LC-PUFA restoration during finishing. For

example, after finishing Murray cod raised on vegetable oil-based grow-out feeds, the most rapid and extensive restorative effects were observed in fish fed a low MC-PUFA grow-out feed compared to those fed a high MC-PUFA feed [35]. Menoyo et al. [43] indirectly evaluated the unresponsiveness of 18-carbon FA in Atlantic salmon

tissues by using sunflower oil to spare either FO or LO, and noted ability of dietary sunflower oil to alter fillet composition was attenuated in the LO-fed groups. These authors attributed the differential response to reduced digestibility of the FO-based diets relative to the LO feeds; however, based on our findings, we suspect selective

**Fig. 4** Fatty acid composition of tissue total lipid expressed as a fraction of dietary FA composition for unfinished feeding regimes. Values were calculated from relative fatty acid methyl ester composition (%FAME) as  $\%FAME_{\text{tissue}} \times FAME_{\text{feed}}^{-1}$ . Based on this calculation, a value of 1 represents equality between fillet and

dietary composition. All FA abbreviations are as reported in Table 3. Other abbreviations: FO, 100% fish oil feed; PO, 50:50 poultry/fish oil feed; GO, 50:50 grapeseed/fish oil feed; LO, 50:50 linseed/fish oil feed; CO, 50:50 coconut/fish oil feed

metabolism of certain FA may have been a contributing factor.

The process of FA profile change in fish tissues following a change in dietary lipid composition, often described as FA “dilution” or “washout”, is relatively well-described by an asymptotic, simple dilution curve [21–23]. The simple dilution curve predicts temporal changes in tissue FA profile based on the relative disparity between dietary and tissue FA composition and the change in overall body mass or adiposity over time. By its definition, the dilution model assumes no selective processes of FA metabolism. Therefore, deviations from the dilution model are often interpreted as indicative of selective partitioning of specific FA, or FA classes, or catabolism via  $\beta$ -oxidation. Our group previously tested the dilution model by comparing the model’s predictions to observed fillet FA profile of SB reared on corn-oil based feed after finishing [33]. This comparison revealed apparent selective retention of total n-3 FA, MC-PUFA, LC-PUFA, and n-3 LC-PUFA within fillet tissue. Conversely, total fillet SFA were significantly lower than the model’s predictions, suggesting selective catabolism or storage of these FA in other lipid depots. The present work demonstrates dietary SFA are not

proportionally reflected within fillet, liver, or IPF lipid of SB. Plausibly, consumed SFA may be elongated and/or desaturated to MUFA, for example, which are strongly partitioned into IPF lipid (Fig. 4). If this were the case, one would expect increased consumption of dietary SFA to result in increasing levels of MUFA within the tissues. However, given the lack of increasing levels of MUFA within any lipid depot of CO-fed fish (Fig. 3), and the generally poor ability of SB to biotransform FA in appreciable amounts [44], this scenario seems unlikely. Rather, levels of SFA were routinely lower than expected in all tissues analyzed, suggesting catabolism of these FA, not selective partitioning into storage lipid.

Evidence of selective FA metabolism has also been noted for Atlantic salmon [27, 45, 46], however, Bell and colleagues observed the FA composition of the dietary lipid seemed to influence the selective processes. Specifically, 22:6n-3 was selectively retained within fillet lipid in all three studies, illustrating the necessity of this FA for physiological function. Monounsaturated FA were selected against, indicating these FA are comparatively expendable, however, the strength of selective catabolism (magnitude of deviation from line of equality in tissue vs. dietary

regressions) decreased with increasing availability of SFA. When SFA were abundant, these FA were more strongly selected for catabolism, and MUFA, given a “catabolic reprieve”, were deposited to a greater extent in fillet tissue. Observations of selective FA metabolism in fish tissues are further supported by the preferential shunting of shorter chain FA into  $\beta$ -oxidation [47–50]. Oxidation of longer-chain and unsaturated FA appears to be a function of their relative abundance [51], and in the case of LC-PUFA, only substantial in vertebrates with a profusion of LC-PUFA stored in tissue [52].

Based on the various estimates of selective metabolism of FA in fishes, SFA appear to be the preferential catabolic substrate, whereas MC-PUFA and LC-PUFA are selectively deposited in tissues. Hence, attempts to spare LC-PUFA and optimize profile restoration during finishing may be enhanced by providing a largely saturated diet, with few MC-PUFA to compete with LC-PUFA for fillet deposition. Our work confirms this hypothesis in the context of SB culture. We demonstrated SB fillets with equivalent LC-PUFA content and associated nutritional value can be produced using a reduced FO grow-out feed followed by an 8-week finishing period. Using CO in the grow-out feed, the negative effects of FO replacement on SB fillet LC-PUFA content were rapidly reversed during finishing. The comprehensive profile restoration we observed among the CO-fed fish is unprecedented in SB culture. Low MC-PUFA feeds could be implemented in SB culture throughout a majority of grow-out, followed by implementation of an 8-week FO finishing period prior to harvest. Assuming the CO + Finish regimen and a conservative FCR (consumption/weight gain) of 2, fillets of equivalent LC-PUFA content and nutritional value could be produced with a 35% reduction in FO use over the course of the production cycle. This strategy offers a substantial reduction in marine-derived inputs to SB feeds and, potentially, a significant savings in feed cost. Furthermore, by restricting use of FO-rich feeds to the weeks immediately preceding harvest, cumulative dietary exposure of the livestock to FO-associated contaminants is reduced. We hypothesize other saturated lipids could be used to similar effect in SB and other cultured fishes. Compared to MC-PUFA-rich lipids, improved finishing success has been observed in Murray cod fed a blend of palm and olive oils, but after 16 weeks, LC-PUFA restoration was still incomplete [35]. Lack of comprehensive profile restoration may reflect a difference between Murray cod and SB as culture taxa (pure species vs. hybrid, marine vs. freshwater-reared euryhaline, medium-fat fleshed vs. lean-fleshed, etc.) or a difference between CO and palm and olive oils as lipid sources (mostly short-chain vs. medium-chain SFA and MUFA). Additional research will be necessary to resolve discrepancies in finishing success, and to identify

appropriate strategies for all species. Regardless, use of a saturated grow-out feed coupled with finishing is an effective strategy to produce high quality cultured SB fillets and represents a considerable step forward in judicious use of limited marine resources in aquaculture.

**Abstract** Fatty acid (FA) profile of fish tissue mirrors dietary FA profile and changes in a time-dependent manner following a change in dietary FA composition. To determine whether FA profile change varies among lipid classes, we evaluated the FA composition of fillet cholesteryl esters (CE), phospholipids (PL), and triacylglycerols (TAG) of sunshine bass (SB, *Morone chrysops* × *M. saxatilis*) raised on feeds containing fish oil or 50:50 blend of fish oil and coconut, grapeseed, linseed, or poultry oil, with or without implementation of a finishing period (100% FO feed) prior to harvest. Each lipid class was associated with a generalized FA signature, irrespective of nutritional history: fillet PL was comprised largely of saturated FA (SFA), long-chain polyunsaturated FA (LC-PUFA), and total n-3 FA; fillet TAG was higher in MC-PUFA and total n-6 FA; and fillet CE was highest in monounsaturated FA (MUFA). Neutral lipids reflected dietary composition in a near-direct fashion; conversely, PL showed evidence of selectivity for MC- and LC-PUFA. Shorter-chain SFA were not strongly reflected within any lipid fraction, even when dietary availability was high, suggesting catabolism of these FA. FA metabolism in SB is apparently characterized by a division between saturated and unsaturated FA, whereby LC-PUFA are preferentially incorporated into tissues and SFA are preferentially oxidized for energy production. We demonstrated provision of SFA in grow-out feeds for SB, instead MC-PUFA which compete for tissue deposition, meets energy demands and allows for maximum inclusion of LC-PUFA within fillet lipids.

### Introduction

Fish oil (FO) replacement has been investigated for a large number of aquaculture species, employing a variety of alternative lipid sources, such as corn, canola, soybean, linseed, and palm oils [1–4]. In general, these studies have demonstrated FO can be partially or completely replaced in aquafeeds without affecting growth performance of the livestock. We previously demonstrated canola, coconut, corn, grapeseed, linseed, and poultry oils are effective substitutes for FO in feeds for sunshine bass (SB, *Morone chrysops* × *M. saxatilis*) [3–5]. Unfortunately, FO replacement significantly alters the fatty acid (FA) composition of the resultant product and results in a corresponding decline in fillet long-chain polyunsaturated fatty acids (carbon atoms  $\geq 20$ , degree of unsaturation  $\geq 3$ , LC-PUFA), such as eicosapentaenoic (EPA, 20:5n-3) and docosahexaenoic acids (DHA, 22:6n-3). Fish tissues are plastic with respect to FA composition, and reflect recent nutritional history, that is, tissue FA profile mirrors dietary FA profile and changes in a time-dependent manner following modification of dietary composition [6–9]. Compared to FO, alternative oils are typically higher in monounsaturates (MUFA) and medium-chain polyunsaturated fatty acids (18 carbon, degree of unsaturation  $\geq 2$ , MC-PUFA), whereas LC-PUFA are low or lacking altogether. Accordingly, fillets of fish fed alternative oil-based feeds reflect these differences: replacing LC-PUFA-rich FO with MC-PUFA-rich canola oil, for example, increases fillet 18:2n-6 and 18:3n-3 content at the expense of 20:5n-3 and 22:6n-3 [3, 4]. Although cultured seafood produced

using alternative lipids sources are attractive from sustainability and production cost standpoints, they are also substantially less valuable in terms of providing beneficial LC-PUFA to human consumers.

The inherent conflict between production of fillets with the greatest nutritional value (FO-based feeds) and the lowest feed costs (alternative lipid-based feeds) may be overcome through the use of “finishing” feeds to augment fillet LC-PUFA content of fish raised on alternative feeds prior to harvest. As mentioned above, fillet FA composition changes following dietary modification to more closely reflect the profile of the new feed. Finishing strategies exploit this process by implementing high-LC-PUFA content feeds at the end of the production cycle to restore fillet LC-PUFA content immediately prior to harvest. Employing FO-based finishing feeds, fillet LC-PUFA content of fish raised on alternative lipid-based grow-out feeds was augmented [10–18]; however, complete profile restoration has been achieved in very few studies [17, 18]. The process of FA profile change appears to differ among lipid classes [12, 17], leading some to attribute variation in finishing success to differences in fillet lipid content and class composition. We previously assessed production performance and finishing success of SB raised on multiple alternative lipid sources [5]. The purpose of the present work was to determine whether FA profile change varied among fillet lipid classes.

## Methods and Materials

In the following sections, we describe our experimental design and provide a brief summary of the pertinent methods. Animal husbandry, sample collection, and analysis are described in detail in our previous paper [5]. All procedures were conducted under the direction and approval of the Southern Illinois University Institutional Animal Care and Use Committee, protocol #07-008.

### Experimental Feeds

Five feeds were manufactured based on a practical, reduced fish meal feed our group had previously developed for SB culture [5]. As originally formulated, this feed contained 9.8% FO (dry matter basis; menhaden-derived; Virginia Gold™, Omega Protein, Inc., Houston, TX, USA). In the present work, the original, FO-based formulation served as the control grow-out feed as well as the finishing feed. Four experimental grow-out feeds were derived from the basal formulation, with 50% of the FO replaced with poultry (PO, Tyson Foods, Inc., Robards, KY, USA), linseed (LO, Barlean's Organic Oils, Ferndale, WA, USA), grapeseed (GO, Kusha, Inc, Irvine, CA, USA), or coconut oil (CO,

Spectrum Organic Products, Petaluma, CA, USA). Dietary formulations and FA composition data are provided in Tables 1 and 2.

### Experimental Design and Feeding Trial

Nine feeding regimens were developed to address influences of dietary lipid source and FA composition on production performance and subsequent finishing diet success in SB culture. Eight experimental regimens represented feeding the grow-out feeds described above throughout the feeding trial (CO, LO, GO, and PO regimens) or with an 8-week finishing period (CO + Finish, LO + Finish, GO + Finish, and PO + Finish regimens). The control regimen represented feeding the FO control/finishing feed throughout the duration of the feeding trial (FO Control regimen). Juvenile SB [46 ± 1 g, mean ± SE; age 1 (~10 months); Keo, Fish Farm, Keo AR] were fed the grow-out feeds for 20 weeks until they reached a submarketable size (328 ± 16 g). After 20 weeks, subsamples of fish were harvested to determine baseline tissue FA profile prior to finishing. After baseline sampling, remaining fish were finished with the 100% FO feed for the remaining 8 weeks of the feeding trial (CO + Finish, LO + Finish, GO + Finish, and PO + Finish regimens) or maintained on assigned grow-out feeds (FO Control, CO, LO, GO, and PO regimens). After completion of the feeding trial, all remaining fish were harvested. Survival and production performance criteria were assessed, and muscle samples were collected to determine fillet FA composition.

### Lipid Class Separations and Fatty Acid Analysis

Total lipid was extracted from lyophilized fillet tissue as previously described [5]. Phospholipid (PL), cholesteryl ester (CE), and triacylglycerol (TAG) fractions were separated via solid-phase extraction according to Burdge et al. [19]. Briefly, ~75–100 mg of total lipid was suspended in chloroform and applied to amino-propyl silica columns (Supelclean™ LC-NH2 1 mL SPE columns, Supelco, Bellefonte, PA, USA) under gravity. The columns were washed with 2 mL of chloroform under a vacuum to elute a mixed TAG and CE fraction. The column was subsequently washed with 1 mL each of chloroform:methanol solution (3:2 v/v) and methanol to elute the phospholipid fraction. The mixed TAG and CE fraction was dried under nitrogen, resuspended in hexane, and applied to a fresh column (preconditioned with hexane). The column was washed with 2 mL of hexane followed by 2 mL of hexane:chloroform:ethyl acetate solution (100:5:5 v/v) to elute the CE and TAG fractions, respectively. Burdge et al. [19] also allows for separation of free fatty acids; however,

<sup>f</sup> Tate and Lyle, Decatur, IL, USA

<sup>g</sup> Formulated to contain: 7,000 mg kg<sup>-1</sup> copper, 70,000 mg kg<sup>-1</sup> iron, 100,000 mg kg<sup>-1</sup> manganese, 200,000 mg kg<sup>-1</sup> zinc, 0.24% iodine

<sup>h</sup> Formulated to contain: 99.8 mg kg<sup>-1</sup> selenium, 2,200 mg kg<sup>-1</sup> folic acid, 88,000 mg kg<sup>-1</sup> niacin, 35,200 mg kg<sup>-1</sup> pantothenic acid, 11,000 mg kg<sup>-1</sup> vitamin B6, 13,200 mg kg<sup>-1</sup> riboflavin, 11,000 mg kg<sup>-1</sup> thiamin, 11,000 mg kg<sup>-1</sup> vitamin B12, 66,000 mg kg<sup>-1</sup> vitamin E, 4,400 mg kg<sup>-1</sup> vitamin K, 4,400,000 IU kg<sup>-1</sup> vitamin A, 2,200,000 IU kg<sup>-1</sup> vitamin D, 100,000 mg kg<sup>-1</sup> vitamin C

amounts recovered from fillet total lipid were extremely small (0.1–0.2 mg) and insufficient for subsequent FA analysis. Once separated, each lipid class was evaporated to dryness under nitrogen and weighed to determine total tissue PL, CE, and TAG content. All lipid samples were then resuspended in toluene, subjected to acid-catalyzed trans-methylation, and analyzed for FA composition as described in our previous paper [5].

### Statistical Analysis

Although multiple individual fish were sampled from each tank, replicate tanks served as the experimental units for all statistical analyses ( $n = 3$  for experimental regimens,  $n = 6$  for control regimen). Lipid class data were analyzed by one-way analysis of variance (ANOVA) within the Mixed Model framework of the Statistical Analysis System,

version 9.1 (SAS Institute, Cary, NC, USA) to determine significance of differences among feeding regimens. In all cases, differences were considered significant at  $P < 0.05$ .

### Results

Across all lipid classes, FA profiles of unfinished groups generally reflected the FA composition of the grow-out feed (Tables 3, 4, 5). Increased levels of 12:0, 18:1n-9, 18:3n-3, and 18:2n-6 were associated with all lipid classes of the CO, PO, LO, and GO groups, respectively; however, the extent to which the tissue reflected the diet varied among individual lipid classes. Among unfinished groups, the TAG and CE fractions showed a strong correlation with dietary composition; whereas the PL fraction was less representative of dietary composition (Fig. 1). Comparing

**Table 2** Dietary composition with respect to FA and FA classes

Values represent least-square means of triplicate samples

<sup>1</sup> Saturated fatty acids—sum of all FA without double bonds

<sup>2</sup> Monounsaturated fatty acids—sum of all FA with a single double bond

<sup>3</sup> Polyunsaturated fatty acids—sum of all FA with  $\geq 2$  double bonds

<sup>4</sup> Long-chain PUFA—sum of all FA with chain length  $\geq 20$  carbon atoms and double bonds  $\geq 3$

<sup>5</sup> Medium-chain—sum of all PUFA with chain length of 18 carbon atoms; includes 18:3n-4 in addition to individually reported MC-PUFA

the CO regimen with the FO Control regimen, the difference between 12:0 levels was greatest within the neutral TAG and CE fractions (1.1 vs. 9.5% for TAG, 1.0 vs. 8.6% for CE Tables 4 and 5) and minor, though statistically significant within the polar PL fraction (0.0 vs. 0.5%; Table 3). Differences in 18:1n-9 content between the FO Control and PO regimens were similarly partitioned among the neutral and polar lipid classes, with differences of the greatest magnitude observed within the TAG and CE. Although 18:3n-3 and 18:2n-6 enrichment within the LO and GO regimens was also greatest within the neutral lipid, substantial increases in these FA were also observed within the PL fraction.

Implementation of the 8-week finishing period reversed grow-out related changes in fillet FA composition to varying degrees (Tables 3, 4, 5). Absolute levels of LC-PUFA were increased in all lipid classes by finishing;

however, differences between finished and unfinished groups were not statistically significant in all cases, particularly among the PL fraction (Tables 3, 4, 5). Among finished groups, increased levels of LC-PUFA were accompanied by decreased levels of MUFA and MC-PUFA. Reduced levels of MUFA and MC-PUFA in finished groups compared to unfinished groups were most noticeable among the PL fraction (Table 3).

Each lipid class was associated with a generalized FA signature, irrespective of nutritional history, which indicated differences in partitioning of dietary FA within the lipid classes. The PL fraction represented  $\sim 14\%$  of the total fillet lipid (Table 3) and was comprised largely of SFA (specifically 16:0 and 18:0), LC-PUFA (specifically 20:4n-6, 20:5n-3, and 22:6n-3), and n-3 FA (Table 6). Conversely, the TAG fraction ( $\sim 10\%$  of total lipid, Table 5) contained greater amounts of MC-PUFA

**Table 3** Fillet phospholipid fatty acid composition with respect to predominant (>1% fatty acid methyl esters, FAME) fatty acid (FA) and FA classes

8 The distribution of total fillet lipid among the lipid classes was somewhat surprising, specifically the high level of CE relative to PL and TAG. Previous research with SB has indicated CE contributes very little to total fillet lipid (<5% of total lipid) [37, 38]. However, each of these studies employed much smaller, juvenile fish (~30 g final weight), whose tissue composition is likely to differ from that of large (~500 g) fish nearing sexual maturity (well-developed gonadal tissue was observed in many of our fish at harvest). In this respect, one might expect the tissue composition of larger fish to be skewed toward increased levels of storage lipid, i.e., CE and TAG. Additionally, the previous studies by Gatlin and colleagues employed TLC-FID to quantify lipid classes, which may have underestimated CE content. Recovery of PL and TAG fractions with SPE methods is apparently equivalent to TLC; however, recovery of CE is significantly greater using SPE (19)

**Fig. 1** Relationship between mean fatty acid composition (as relative % of fatty acid methyl esters) of feeds and fillet lipid classes. All fatty acids listed in Tables 1, 2, 3 are depicted. Abbreviations: CE cholesteryl esters, TAG triacylglycerols, PL1 phospholipids, 16:0 20:4n-6, 20:5n-3, 22:6n-3, PL2 phospholipids, all other fatty acids. Solid lines represent best-fit linear regressions; equations and  $R^2$  values are provided for each regression

(specifically 18:2n-6, 18:3n-3, and 18:4n-3) and n-6 FA (Table 6). CE was the most predominant lipid class represented within the fillet total lipid ( $\sim 70\%$  of total lipid, Table 4), and was highest in MUFA (specifically 18:1n-7 and 18:1n-9, Table 6).

## Discussion

Fatty acid composition of fillet lipid classes was affected by feeding regimen, however, the extent to which tissue profile reflected dietary profile varied among lipid classes and feeding regimens. Fillet TAG and CE profiles of unfinished groups mirrored dietary FA composition in a direct relationship approaching unity (Fig. 1), indicating FA profile within these classes is plastic and suggests their composition is established via nonspecific processes. Accordingly, the neutral lipid classes were quite responsive to finishing, and overall, demonstrated a high level of finishing success, that is, restoration of the FO-associated FA profile. However, in terms of total LC-PUFA content within the CE, only the CO + Finish and the PO + Finish regimens were equivalent to the FO Control regimen. Of the experimental regimens, CO + Finish and PO + Finish were also the highest in LC-PUFA within the TAG

fraction; however, within this lipid class they remained statistically different from the FO Control regimen.

Fillet PL composition was less responsive to dietary manipulations than the neutral lipid fractions, that is, the difference between finished and unfinished profiles was generally less noticeable within the PL fraction compared to the CE and TAG fractions. Although dietary FA composition was largely reflected within the PL, the relationship was more or less direct depending on the individual FA. For 16:0, 20:4n-6, 20:5n-3, and 22:6n-3, the relationship between dietary composition and tissue composition was greater than 1:1, suggesting selective incorporation of these FA within the PL fraction (Fig. 1). Conversely, for all other FA, the relationship was less than 1:1, suggesting exclusion of these FA from the PL fraction.

In comparing the finished and unfinished groups, it is interesting to note the pattern of change which did occur within the PL fraction. In the case of the GO-fed fish, the GO group displays a high level of 18:2n-6 enrichment

within the PL, but the level of 18:2n-6 in the finished group is less than half that observed in the unfinished fish. In comparing the LO- and PO-fed regimens, we observe a similar PL enrichment in 18:3n-3 and 18:1n-9 among the LO and PO groups, respectively, and comparable reductions in these FA within the PL of the finished groups. Within the CO-fed fish, there is virtually no enrichment of 12:0 within the PL, and only a minor distinction between the final PL profiles of the CO and CO + Finish regimens. This suggests some level of plasticity within the PL fraction, but perhaps more importantly, a selectivity for certain FA which may drive profile change within this lipid class.

Phospholipids have been described as being less responsive to dietary manipulations than neutral lipids [6], but also as exhibiting more active FA turnover than neutral lipid [9, 20, 21]. The specificity of PL for FA of certain chain lengths and degrees of unsaturation has been documented [22], and may be responsible for the discrepancy between differing observations of unresponsiveness and active profile change within the PL fraction. Specificity of PL for certain FA moieties is thought to arise from FA selectivity occurring during two processes related to PL biosynthesis, specifically *de novo* phosphatidic acid synthesis and phospholipid FA remodeling. In terms of *de novo* phosphatidic acid synthesis, for example, mitochondrial glycerol-3-phosphate acyltransferase preferentially utilizes saturated FA acyl-coAs (acylated to the sn-1 position), whereas lysophosphatidic acid acyltransferase has a greater affinity for unsaturated FA acyl-coAs (acylated to the sn-2 position). Further, the FA binding proteins (FABP), which apparently direct this process via inhibitory/stimulatory effects on key enzymes and by regulating FA absorption and cellular uptake, also demonstrate FA selectivity. Fatty acid binding proteins, and their associated FA specificities, are also involved in the process of PL remodeling via deacylation-reacylation and transacylation reactions [22].

The FA composition of PL fractions in fishes may also be determined, in part, by the affinity of acyl transferases and/or FABPs for particular FA moieties. In fishes, the PL fraction is commonly associated with 16:0 and LC-PUFA, in a variety of tissues, including gametes [23, 24], and neural, optic, and immunocompetent cells [25], and our data are in agreement with these observations. In Atlantic salmon *Salmo salar* hepatocytes, 16:0, 20:4n-6, 20:5n-3, 22:6n-3 were preferentially incorporated into intra- and extracellular polar fractions relative to 18:1n-9, 18:2n-6, and 18:3n-3 [26]. Thus, the processes of FA incorporation and/or remodeling within the PL fraction of fish appear selective and similar to those observed in mammals. However, the prevalence of certain molecular “species” of PL is also influenced by FA availability, that is, dietary intake. Hvattum et al. [25] quantified the molecular species

of PL within head kidney macrophages of Atlantic salmon reared on diets containing FO, soybean oil, or a 50:50 blend of these two lipids. Among fish fed the soybean oil diet, increasing dietary abundance of 18:2n FA (the analytical methods used in this study do not allow position of double bonds to be assigned, but the presumption is that 18:2n represents 18:2n-6, 20:5n represents 20:5n-3, 22:6n represents 22:6n-3, etc.) was reflected within the PL. Although some C<sub>20</sub> and C<sub>22</sub>-containing species decreased with increasing dietary soybean oil (e.g., 14:0/22:6 and 16:0/20:5n PC, 16:0/22:6n and 16:0/20:5n-3 PE, 16:0/20:5n and 16:0/22:6n PI, 16:0/20:5n and 16:0/22:6n PS, etc.) others increased (18:2n/20:5n and 18:2n/22:6n PE, 18:2/22:6n PS, etc.). This suggests that, despite decreasing dietary availability, 20:5n-3 and 22:6n-3 were being actively retained in the polar lipid, but increasingly paired with abundant 18:2n-6. Bell et al. [25] also noted conservation of LC-PUFA within the PL of salmon head kidney macrophages, but similar to Hvattum et al. [27], these authors observed substantial enrichment of 18:3n-3 and 18:2n-6 when this FA was abundant in the feed. Interestingly, the magnitude of 18:3n-3 enrichment was lower than that of 18:2n-6 despite roughly equivalent dietary levels [25]. We also observed 18:2n-6 enrichment within the PL (18.3% in GO-fed fish vs. 32.40% in GO feed) to exceed that of 18:3n-3 relative to dietary content (6.2% in LO-fed fish vs. 22.56% in LO feed), suggesting selective process(es) in PL metabolism have a greater affinity for 18:2n-6 than 18:3n-3.

Generally, composition of the neutral lipid classes demonstrates less specificity for certain FA moieties. Although many of the same enzymes and proteins involved in PL metabolism are also associated with TAG synthesis and remodeling, apparently TAG fractions are not as strongly affected by FA selectivity [24]. FA specificity may occur within biosynthesis of CE; however, lecithin:cholesterol acyltransferase, the enzyme responsible for esterifying FA to cholesterol, shows a preference for C<sub>14</sub> and C<sub>16</sub> FA [28]. The data available for fishes supports extension of these mammalian paradigms to piscine models. Although Stubhaug et al. [26] noted significant differences in incorporation of certain FA within the intracellular neutral lipid of Atlantic salmon hepatocytes, in general, this fraction showed less specificity for individual FA than the polar fraction [26]. Specificity was noted within the extracellular neutral lipid, but in this case, selection was for 16:0 and 18:0 within the sterol esters and TAG, respectively. In general, we did not observe enrichment of FA within the neutral lipid beyond dietary composition, and thus our data do not support a hypothesis of positive selection for certain FA within the CE or TAG fractions. However, the shorter-chain SFA (8:0, 10:0, 12:0, and 14:0) content of the CE and TAG fractions of fish fed

the CO feed was lower than expected in all lipid classes, suggesting selection against deposition of these FA in fillet tissue.

High dietary levels of shorter-chain SFA in the CO feed were not proportionally reflected in fillet PL, TAG, or CE, or total lipid of other major lipid depots [5], which suggests either (1) impaired digestion/absorption or (2) catabolism of these FA. Lower digestibility of alternative lipids has been reported for cold-water marine species [29–32], and has been attributed to differences in melting points and PUFA content between the alternative lipid and FO. Reductions in growth are also observed in these cases, and dietary FA composition of poorly digested lipid is not reflected within the tissues [32]. Reduced digestibility of the CO feed seems an unlikely explanation for our results given the lack of growth differences and the limited, but significant, enrichment of CO-associated FA within the fillet and other tissues [5]. Sunshine bass can effectively utilize a wide-range of alternative lipids [3–5], as can other cool- and warm-water species, indicating lipid digestibility is primarily temperature-dependent, and issues of poor lipid digestion may be limited to cold-water species. Catabolism of shorter-chain SFA for energy production explains the low level of shorter-chain SFA enrichment observed in the CO-fed fish. Rates of  $\beta$ -oxidation have been determined for a variety of FA in several fish species, and these studies indicate SFA are preferred substrates for energy production [33–36].

The available data indicate selective processes govern the metabolic fate of FA in fishes. Although neutral lipids reflect dietary composition in a near-direct fashion, polar lipids show evidence of preference for certain FA. Medium-chain and LC-PUFA are preferred substrates for inclusion in polar lipid, whereas shorter-chain SFA are excluded. Although MC-PUFA appear to be somewhat inferior to LC-PUFA in terms of affinity, increased availability may overwhelm any enzymatic selectivity and result in high levels of incorporation of MC-PUFA within the PL fraction. Shorter-chain SFA are apparently poor substrates for the enzymes involved in PL synthesis and remodeling, and are not included within the PL fraction, even when availability is high. Conversely, SFA are preferentially used for energy production, whereas MC- and LC-PUFA are catabolized only when preferred substrates are absent. FA metabolism in fishes is characterized by a functional division between SFA and LC-PUFA, with MC-PUFA bridging the gap. Of the feeds we evaluated, the CO feed represented an ideal balance between providing preferred FA substrates for energy production (SFA) and tissue incorporation (LC-PUFA), and few MC-PUFA to compete within either process. We demonstrated provision of SFA in grow-out feeds for SB, instead of competing MC-PUFA, meets energy demands and allows

for maximum inclusion of LC-PUFA within fillet lipid classes.

# Hydrolysis of Acyl-Homogeneous and Fish Oil Triacylglycerols Using Desalted Midgut Extract from Atlantic Salmon, *Salmo salar*

A. S. Bøgevik · A. Oxley · R. E. Olsen

**Abstract** Despite several studies aimed at evaluating the positional and fatty acid specificity of fish triacylglycerol (TAG) digestive lipases, there is still much uncertainty regarding these issues. The aim of the present study was therefore to address these questions in Atlantic salmon (*Salmo salar* L.). Crude luminal midgut extracts were collected from fed salmon and the hydrolysis studied for various substrates including triolein (Tri-18:1), trilinolein (Tri-18:2), trilinolenin (Tri-18:3), triicosapentaenoic (Tri-20:5), tridocosahexaenoic (Tri-22:6) and natural fish oil TAG. Using Tri-18:1, in a time-curve model showed an initial high degree of *sn*-1 or *sn*-3 specificity where *sn*-1,2(2,3)-diacylglycerol (1,2(2,3)-DAG) and free fatty acid (FFA) were the main hydrolytic products up to 15 min. Lack of initial *sn*-2 specificity was confirmed by negligible *sn*-1,3-diacylglycerol (1,3-DAG) being produced. During the further hydrolysis of DAG, all positions appeared susceptible to attack causing a concomitantly small increase in *sn*-1(3)-monoacylglycerol (1(3)-MAG) and 2-MAG, but not at the level expected for an exclusively *sn*-1,3-specific lipase. Oleic acid (18:1n-9) and eicosapentaenoic acid (20:5n-3) were preferred substrates for hydrolysis using both fish oil and acyl-homogeneous TAGs with FFA as the main product of lipolysis. Hydrolysis of the natural fish oil TAG appeared slower yet produced proportionally more MAG and DAG after 5 min, and similar specificities, as for synthetic TAG substrates,

were exhibited with 18:1n-9 and 20:5n-3 accumulating in the FFA fraction after 30 min. Notably, 16:0 was particularly conserved in MAG. As TAG resynthesis of absorbed lipid in salmon enterocytes proceeds preferably with 2-MAG as templates, the absorption of 2-MAG, produced during initial stages of TAG hydrolysis, would need to occur rapidly to be effectively utilised via the MAG pathway.

**Keywords** Gastrointestinal tract · Lipid hydrolysis · Triacylglycerol hydrolysis · Bile salt-dependent lipase · Intestine

## Abbreviations

DAG	Diacylglycerol
FFA	Free fatty acid
FO	Fish oil
MAG	Monoacylglycerol
MGAT	Monoacylglycerol acyltransferase
Tri-18:1	Triolein
Tri-18:2	Trilinolein
Tri-18:3	Trilinolenin
Tri-20:5	Triicosapentaenoic
Tri-22:6	Tridocosahexaenoic
PUFA	Polyunsaturated fatty acid
TAG	Triacylglycerol
TLC	Thin-layer chromatography

## Introduction

In the pancreatic juice of mammals there are two major lipolytic enzymes responsible for neutral lipid digestion: pancreatic lipase (PL; E.C. 3.1.1.3.) and bile salt-dependent

lipase (BSDL; E.C. 3.1.1.1.). In the intestinal lumen, triacylglycerol (TAG) is mainly hydrolysed by PL. This enzyme has several distinctive characteristics. It possesses good activity towards lipid emulsions, yet is inhibited by the presence of bile salts and other amphipathic lipids. Inhibition is only overcome by the addition of colipase, which acts as an anchor for PL at the lipid droplet interface [1]. Furthermore, PL has a characteristic *sn*-1,3-specificity towards TAG producing free fatty acids (FFA) and *sn*-2-monoacylglycerols (2-MAG) for subsequent absorption.

In comparison, BSDL is dependent on bile salts for its hydrolytic activity towards TAG, cholesteryl esters, wax esters, vitamin esters, and phospholipids [2, 3]. BSDL is also less discriminatory, than PL, towards *sn*-fatty acyl position yielding mainly glycerol and FFA as hydrolytic products of TAG. Lower specificity is also apparent in that it has good activity towards all fatty acids including long chain polyunsaturated fatty acids (PUFA) that are not effectively hydrolysed by PL. Hence, intestinal BSDL is non-specific towards fatty acyl moiety and *sn*-position of TAG, displays a preference for micellar substrates, yet possesses 10–60 times less activity than PL in mammals. Thus, PL and BSDL appear to act sequentially where partial acylglycerols are released from lipid droplets by the PL-colipase complex for incorporation into mixed micelles and possible complete hydrolysis by BSDL [4, 5].

The advantage of producing 2-MAG during digestion, as is the case for PL, is that when absorbed into the enterocytes, resynthesis of TAG can proceed rapidly via the MAG pathway using 2-MAG as a template. This process is catalyzed by monoacylglycerol acyltransferase (MGAT) with relatively low expenditure of energy [6]. If TAG is completely hydrolysed to FFA and glycerol, TAG resynthesis in enterocytes must proceed through the slower and energy-consuming *de novo* glycerol-3-phosphate (G3P) pathway [7].

Dietary lipid for fish species in the marine environment is characteristically high in wax esters and TAG containing *n*-3 highly unsaturated fatty acids (HUFA) such as eicosapentaenoic (20:5*n*-3) and docosahexaenoic (22:6*n*-3) acids [8]. As PL does not possess wax ester hydrolytic activity and has low activity towards ester bonds containing pentaenoic and hexaenoic fatty acids, the predominant lipid-digesting enzyme in fish may be BSDL [2, 9]. This is furthermore evident in the failure to prove the existence of a PL-colipase system in fish [9, 10] and the cessation of all lipolytic activity upon removal of bile, that is subsequently restored by addition of bile salts in rainbow trout (*Oncorhynchus mykiss*), red sea bream (*Pagrus major*) and Atlantic salmon, *Salmo salar* [10–12].

Recent reports have however, shown the existence of MGAT in both Atlantic salmon [13, 14] and seabream, *Sparus aurata* [15], which is most likely required for a fast

and efficient transfer of absorbed intestinal lipid to the blood as lipoproteins. This again indicates that the hydrolysis of luminal TAG may proceed through *sn*-1,3-specificity. This possibility is strengthened by the observation of some *sn*-1,3-specificity of digestive lipases in cod, *Gadus morhua* [16, 17] and rainbow trout [10, 18]. Furthermore, Gjellesvik [16] showed evidence of BSDL with *sn*-1,3-specificity using partially-purified caecal tissue from cod. This opens for the possibility that BSDL in fish may actually possess *sn*-1,3-specific lipase capability.

As previous studies in fish have shown both *sn*-1,3-specificity and complete hydrolysis of different TAG substrates, the present study was conducted to elucidate possible discrepancies in luminal lipase specificity with regard to *sn*-acyl position and fatty acid species. Complete hydrolysis to FFA and glycerol has especially been noted in fish if the fatty acid in *sn*-2 of TAG is PUFA [18–21]. Thus, we hypothesised that the luminal formation of 2-MAG is dependent on the species of fatty acid present at *sn*-2 position of TAG. The present study utilised a crude intestinal lipase preparation from the midgut lumen of Atlantic salmon as a model for studying TAG hydrolase activity [10, 12]. As BSDL activity is dependent on bile salt concentration [10], intestinal extracts were desalted and known concentrations added in the assay to avoid concentration dependent errors. Utilising synthetic acyl-homogeneous TAG substrates in the assay allowed for the relative determination of lipase *sn*-positional specificity, with respect to fatty acid species, by quantifying the isomeric products released. Furthermore, fish oil was also used to represent a natural TAG substrate, with a more typical distribution of fatty acids that salmon intestinal lipases would encounter.

## Materials and Methods

### Chemicals

Triolein (Tri-18:1), trilinolein (Tri-18:2), trilinolenin (Tri-18:3), trieicosapentaenoic (Tri-20:5), tridocosahexaenoic (Tri-22:6) and TLC standard (>99%) were all purchased from Nu-Chek Prep Inc. (Minnesota, USA). Chloroform, methanol, hexane, sulphuric acid, ethanol, acetone, sodium taurocholate, boric acid, 2,7-dichlorofluorescein were purchased from Sigma–Aldrich (St Louis, USA).

### Substrate

The substrates of Tri-18:1, Tri-18:2, Tri-18:3, Tri-20:5 or Tri-22:6 were made to a concentration of 100 mg/mL in chloroform. Triacylglycerols from fish oil (Möllers Tran; MöllerCollett AS, Lysaker, Norway) were purified on TLC plates (20 × 20 cm × 0.5 mm, Merck 1.13894, Darmstadt,

Germany) using hexane: diethyl ether: acetic acid (80:20:2) as developing solvent. Lipid classes were visualized using 0.1% (w/v) 2,7-dichlorofluorescein in 95% methanol. The TAG band was extracted from the silica with hexane: diethyl ether (1:1), evaporated under a stream of nitrogen and stored at  $-80\text{ }^{\circ}\text{C}$  in chloroform. To prepare lipase substrates, 10 mg of the respective substrate was evaporated under a stream of nitrogen and the residue dissolved in 200  $\mu\text{L}$  taurocholate (400 mM,  $4\text{ }^{\circ}\text{C}$ ) and 1,800  $\mu\text{L}$  of 100 mM potassium phosphate buffer (pH 8) containing 1 mM EDTA (ethylene diamine tetraacetic acid), 1 mM DTT (1,4-dithiothreitol) and 1 mM benzamidine ( $4\text{ }^{\circ}\text{C}$ ). The substrate mixture was stirred for 5 min, sonicated in ice-cold water for 2 min and vortexed for 1 min before use.

### Enzyme

Atlantic salmon of 1,000 g, fed commercial diets (Biomar, Trondheim) 1 h twice a day, were anaesthetised in 4 g/kg benzocaine (Braine-L alleud, Belgium) 1 hour after the last meal and killed by a sharp blow to the head. Four fish were weighed, and the intestinal tract dissected. Luminal contents were collected from the midgut, defined as the section from the last pyloric caeca to the start of the distal intestine, as recognised by its larger diameter [22]. The enzyme preparation was made once from pooling the intestinal contents from the four salmon. The pooled content were further diluted twofold (w/v) in 100 mM potassium phosphate buffer (pH 8) containing 1 mM EDTA, 1 mM DTT and 1mM benzamidine. The suspension was centrifuged at  $3,220\times g$  for 10 min at  $4\text{ }^{\circ}\text{C}$ . The lipid layer was aspirated from the surface and the infranatant collected and designated "crude extract". To remove endogenous bile salts, the extract was transferred to Zeba<sup>TM</sup> Desalt Spin Columns (Pierce, Rockford, USA) and centrifuged at  $200\times g$  for 2 min at  $4\text{ }^{\circ}\text{C}$ . The protein contents of the desalted extract was analysed by the method of Lowry et al. [23] using an Ultrospec 4000 spectrophotometer (Pharmacia Biotech, Cambridge, England) and adjusted to 1.0 mg/mL. The enzyme preparation was then prepared in cryo tubes each containing materials for 1 day work and stored at  $-80\text{ }^{\circ}\text{C}$  prior to use, as preliminary tests had shown no loss of activity when stored under these conditions. By this procedure, all experiments were carried out on the same enzyme preparation.

### Incubation

The incubation assay was performed according to a modification of the method of Bogevik et al. [12]. In brief, 0.2 mL of the enzyme extract was added to 0.2 mL substrate suspension and incubated for 5–30 min at the ambient temperature of the fish ( $10\text{ }^{\circ}\text{C}$ ). The reaction was

terminated by the addition of 8 ml chloroform. The tubes were vortexed for 15 s and centrifuged for 2 min at  $300\times g$  after which the upper aqueous layer was aspirated off and the lower chloroform layer evaporated under a stream of nitrogen. The residue was resuspended in 30–50  $\mu\text{L}$  chloroform and applied to TLC plates ( $20\times 20\text{ cm}\times 0.25\text{ mm}$ , Merck 1.05721, Darmstadt, Germany) pre-impregnated with 2.3% boric acid in ethanol:water (1:1) and developed in 50 ml chloroform:acetone (96:4), according to Thomas [24]. Lipid spots were detected by spraying the plate with 0.1% 2,7-dichlorofluorescein in 95% methanol and visualized under UV light.

### Lipid Extraction

Two-hundred microlitres either of the pooled desalted midgut extract or the substrate suspension were added to 4 mL chloroform and extracted as above. The desalted midgut extract was separated into neutral lipid classes as described above.

### Quantification of Lipid Classes

The lipid class bands representing 1(3)-MAG, 2-MAG, FFA, 1,2(2,3)-DAG, 1,3-DAG, and TAG were scraped into tubes, added internal standard (19:0) and subjected to acid-catalyzed transesterification using 1% (v/v)  $\text{H}_2\text{SO}_4$  in methanol [25]. The resulting fatty acid methyl esters (FAME) were extracted and quantified by gas liquid chromatography using a HP 5890 gas chromatograph equipped with a J&N Scientific Inc. DB-23 fused silica column ( $30\text{ m}\times 0.25\text{ mm id}$ ). Hydrogen was used as carrier gas and temperature programming was from 50 to  $150\text{ }^{\circ}\text{C}$  at a rate of  $40\text{ }^{\circ}\text{C}/\text{min}$ , from 150 to  $195\text{ }^{\circ}\text{C}$  at  $1.5\text{ }^{\circ}\text{C}/\text{min}$ , and then to a final temperature of  $205\text{ }^{\circ}\text{C}$  at  $0.5\text{ }^{\circ}\text{C}/\text{min}$ . Individual components were identified by comparison with known standards.

### Calculation and Statistics

The amount of fatty acids in neutral lipid classes were converted to the amount of lipid by a correction factor which takes into account the amount of glycerol [25]. The amount of lipid were converted into moles for the respective lipid classes. From this, individual lipid classes were calculated as a percentage of total lipid classes recovered from each substrate. Data is given as  $\pm\text{SD}$  for replicate incubations. All statistical analysis was performed using STATISTICA 8.0 software for Windows (StatSoft. Inc., Tulsa, USA). The statistical significance of differences was tested using one-way ANOVA followed by the Tukey post hoc test for comparison of the different acyl-homogenous substrate in each lipid class after hydrolysis. Significance

was accepted at  $P < 0.05$ . The fish oil TAG substrate contained different levels of each fatty acid, and the fatty acid profile in each lipid class was therefore compared to the original TAG substrate after hydrolysis.

## Results

In order to test for possible interference from the lipid contained in the digesta, neutral lipid content of the desalted midgut extract was estimated. The distribution of lipid classes was: FFA (10  $\mu\text{g}$ ) > MAG (2  $\mu\text{g}$ ) > DAG (2  $\mu\text{g}$ ) > TAG (0.5  $\mu\text{g}$ ). The main fatty acids of the lipid classes were palmitic acid (16:0) in MAG (0.73  $\mu\text{g}/200 \mu\text{L}$ ), 1,2/2,3-DAG (0.40  $\mu\text{g}/200 \mu\text{L}$ ) and TAG (0.24  $\mu\text{g}/200 \mu\text{L}$ ), while 1,3-DAG had oleic acid, 18:1n-9 (0.79  $\mu\text{g}/200 \mu\text{L}$ ) and FFA had 20:5n-3 (2.84  $\mu\text{g}/200 \mu\text{L}$ ) as the major fatty acid (Table 1). However, the total amount of each of these fatty acids only accounted for a small fraction compared to the amount of substrate (1 mg) added in the incubation, and was subtracted from the fatty acids calculated in the lipid classes after hydrolysis.

The time course digestion of Tri-18:1 is shown in Fig. 1. The hydrolysis was very high over the first 5 min and then stabilized at a relative constant rate throughout. FFA was the major product reaching a 1:1 ratio of FFA and TAG after 20 min hydrolysis, and increased to account for almost 60% of the lipid classes at the termination of the study, showing a 10-times higher concentration than MAG and DAG. *Sn*-1,2(2,3)-DAG increased to a maximum of 14% of the lipid classes after 15 min followed by a reduction towards the termination of the study. Both 1(3)-MAG and 2-MAG increased slowly towards the end, but neither contributed to more than 9% of the lipids.

The hydrolysis of various acyl-homogeneous TAGs was assessed after 5 (Fig. 2) and 30 min of incubation (Fig. 3). After 5 min, hydrolysis of Tri-18:1 and Tri-20:5 proceeded at a higher rate than the other synthetic TAG substrates. The main products were in both cases increased levels of FFA compared to the other TAG substrates. The 1,2(2,3)-DAG

**Fig. 1** The mol% of total lipid class hydrolysis of 1 mg tri-18:1 with desalted midgut extract (118  $\mu\text{g}$ ) from Atlantic salmon in 100 mM sodium phosphate-buffer (pH 8.0) and 20 mM sodium taurocholate at 0, 5, 10, 15, 20 and 30 min. Mean  $n = 3$

were the second largest hydrolysis products, while 1,3-DAG and various MAG products were in minute amounts. There was also a notable but non-significant tendency of more 2-MAG to be produced using Tri-18:1 and Tri-20:5 as substrates. The tendency of Tri-18:1 as the best substrate for lipolysis was verified after 30 min incubation where more than 80% was hydrolysed compared to less than 70% for the other substrates. The lowest rate of hydrolysis was found with Tri-22:6, where less than 50% was hydrolysed, which was significantly lower than for the other synthetic substrates (Fig. 3). In each case, FFA was the main product of hydrolysis, but there was also an increase in 1,2(2,3)-DAG and MAG isomers, particularly 2-MAG that reached around 10% of the lipid classes. Very low amounts of 1,3-DAG was produced regardless of substrate.

The hydrolysis of fish oil TAG appeared to progress at a different rate than for the structured substrates. After 5 min of hydrolysis, only 40% of the TAG remained with the main hydrolysis products being 1,2(2,3)-DAG (25%), 1(3)-MAG (15%) and 2-MAG (15%). Only 3% was found in FFA (Fig. 2). After 30 min of incubation, the FFA content

had increased to 49% while the content of the different MAGs was notably decreased while the level of 1,2(2,3)-DAG was at 13% (Fig. 3).

The fish oil TAG contained oleic acid (18:1n-9, 29.0%) as the major fatty acid followed by palmitic acid (16:0, 21.5%), the fatty acids of the 20-carbon series (gadoleic acid (20:1n-9), 14.6%), eicosapentaenoic acid (20:5n-3, 14.6%) and docosahexaenoic acid (22:6n-3, 11.9%).

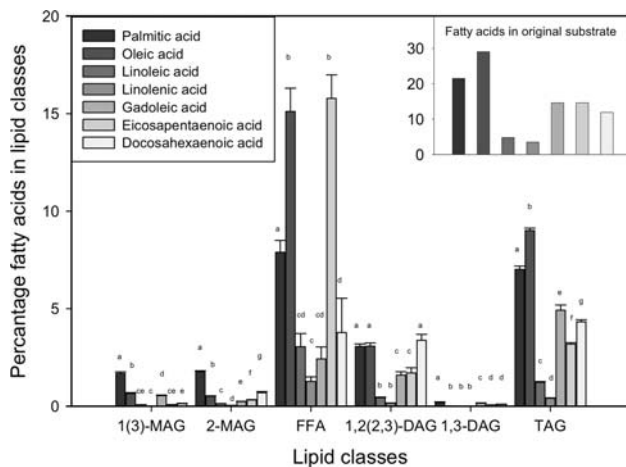

**Fig. 4** Total fatty acid composition of the substrate and fatty acid specificity within each lipid class after hydrolysis of 1 mg of fish oil TAG with desalted midgut extract (118  $\mu$ g) from Atlantic salmon in 100 mM sodium phosphate-buffer (pH 8.0) and 20 mM sodium taurocholate at 5 min (mol% fatty acid within each lipid class/1 mg TAG/118  $\mu$ g desalted midgut extract/5 min). Means,  $n = 6 \pm$  SD, values not having the same *superscript* letter are significantly different ( $P < 0.05$ ) as determined by one-way-ANOVA

Linoleic acid (18:2n-6, 4.8%) and linolenic acid (18:3n-3, 3.5%) were only found in small amounts (Fig. 4).

After 5 min of incubation, the pattern of fatty acids in the remaining TAG was very similar to that of the substrate with the exception that the level of 20:5n-3 appeared to be somewhat reduced (Fig. 4). The fatty acid pattern in 1,2(2,3)-DAG had many similarities to that of TAG but with some notable differences. Firstly, the content of 22:6n-3 was increased to 5% of the fatty acids. Secondly, the content of 20:5n-3 was reduced further in relation to TAG. All MAGs were significantly altered compared to the substrate where 1(3)-MAG and 2-MAG were enriched in 16:0 by circa 6%. Furthermore, there was also a notable retention of 18:3n-3 in all MAGs, while the levels of 18:2n-6 and 20:5n-3 were very low. Comparing the different MAGs showed that 22:6n-3 accumulated somewhat in 2-MAG while 18:1n-9 and 18:3n-3 were higher in 1(3)-MAG. Of the minor lipid classes, FFA appeared to be enriched in 18:3n-3 and 20:1n-9 while 1,3-DAG was enriched in 16:0, 18:3n-3 and 20:1n-9.

After 30 min, unreacted TAG still had many similarities to the original substrate except for a lower content of 20:5n-3 and a tendency to increased levels of 22:6n-3 and 20:1n-9 (Fig. 5). In the FFA fraction, 18:1n-9 and 20:5n-3 was significantly increased in relation to the substrate while 22:6n-3 was reduced. As shown after 5 min, all MAGs were enriched in 16:0. In 2-MAG, there was still a clear accumulation of 22:6n-3. Docosahexaenoic acid (22:6n-3) was significantly increased in 1,2(2,3)-DAG compared to the substrate while the content of 18:1n-9 was reduced (Fig. 5).

**Fig. 5** Total fatty acid composition of the substrate and fatty acid specificity within each lipid class after hydrolysis of 1 mg of fish oil TAG with desalted midgut extract (118  $\mu$ g) from Atlantic salmon in 100 mM sodium phosphate-buffer (pH 8.0) and 20 mM sodium taurocholate at 30 min (mol% fatty acid within each lipid class/1 mg TAG/118  $\mu$ g desalted midgut extract/30 min). Means,  $n = 6 \pm$  SD, values not having the same superscript letter are significantly different ( $P < 0.05$ ) as determined by one-way-ANOVA

## Discussion

Dietary lipid is well utilized in most fish species [9]. In order to accomplish this, fish require an efficient system for the intestinal digestion of TAG for absorption across the brush border membrane (BBM) and subsequent resynthesis of hydrolytic products in enterocytes for transportation. The MAG pathway has recently been established as the predominant pathway for TAG resynthesis in the intestine of Atlantic salmon [13, 14] and sea bream [15], which challenges the presence of a non-specific bile salt-dependent lipase (BSDL) as the major lipolytic enzyme of the luminal content in fish. There is a general assumption that BSDL does not discriminate towards *sn*-acyl position on the glycerol ‘backbone’ of TAG thus yielding glycerol and FFAs that must be resynthesized by the slower and more energetically-consuming glycerol-3-phosphate (G3P) pathway in enterocytes [6].

Therefore, there is some uncertainty as to which lipase system predominates in fish. Although several studies have attempted to verify the existence of a pancreatic *sn*-1,3-specific lipase, no such enzyme has ever been proven [9]. In most fish species studied so far, desalting appears to halt all lipolytic activity while it is regained by the addition of bile salts [10–12]. This clearly points to the prevalence of a bile salt dependent lipase (BSDL) in fish [9]. However, some studies have reported this lipase to be *sn*-1,3-specific [10, 16] which, concomitant with the presence of the MAG pathway in enterocytes, opens up the possibility that BSDL in fish may actually possess *sn*-1,3-specific hydrolytic activity. Furthermore, this specificity has especially been

reported for Tri-18:1n-9 [16] and in the presence of shorter chain fatty acyl esters or saturated fatty acids [26].

The present study showed that the lipase has a high degree of *sn*-1 or *sn*-3 specificity initially where *sn*-1,2(2,3)-DAG and FFA were the main hydrolytic products of Tri-18:1n-9 up to 15 min, while *sn*-1,3-DAG was produced in minute amounts showing low activity towards the *sn*-2 position in the intermediate hydrolysis. During further hydrolysis of DAG, all *sn*-positions appeared to be susceptible to hydrolytic attack causing a concomitant small increase in *sn*-1(3)-MAG and *sn*-2-MAG in roughly equimolar concentrations. However, the occurrence of 1(3)-MAG could be an isomerisation product from 2-MAG due to the instability of 2-MAG in biological systems having a reported half-life of 2–10 min dependent on protein content and pH [27]. This does suggest the possibility for the existence of a 1,3-specific lipase. However, the total level of MAG (including 2-MAG) never reached the concentrations that would be expected with a 1,3-specific lipase (see Mattson and Volpenhein [4] and Gjellesvik et al. [16]) indicating that a step-wise hydrolysis from TAG through DAG and MAG will eventually proceed to glycerol and FFA as final products. In this respect, our data appear to comply with in vivo feeding studies of Atlantic salmon that has suggested that FFA and glycerol are the main hydrolysis products [28].

There was also an interesting difference in the rate of hydrolysis of synthetic substrates and fish oil. While the digestion of the synthetic substrates was faster producing mainly FFA, the natural substrate had a slower rate producing more intermediate products of MAG and DAG after 5 min. The reason for this could be the fatty acid complexity of the natural oil, where the enzyme will most likely prefer certain fatty acids in a certain position over another, as seen previously where complete hydrolysis to FFA and glycerol has especially been noted if the fatty acid in *sn*-2 position is a monounsaturated fatty acid [2, 18] or PUFA [18–21].

If the high activity of the MAG pathway is to be effective in the resynthesis of TAG, it is essential that the 2-MAG being produced at an early stage of hydrolysis is absorbed rapidly. In this respect it is interesting to note that the hydrolysis of fish oil over the first 5 min actually did produce substantial amounts of MAG. So even if salmon lipase does not have the traditional *sn*-1,3-specificity, the MAG pathway would still have sufficient material providing that the absorption is rapid. This would not be the case for the synthetic substrates where the hydrolysis seems to proceed to FFA and glycerol. Fish fed on these diets would consequently rely on the G3P pathway for TAG synthesis, and would probably have lower growth rates. Glycerol-3-phosphate (G3P) is normally produced from amino acids/pyruvate through pathways of glyceroneogenesis, or

alternatively generated from glycerol via glycerol kinase, which has extremely low activity in mammalian intestine compared to adipose and has yet to be investigated in fish.

The salmon lipase in the present study also possessed some fatty acid specificity, at least during parts of the hydrolysis process. The most notable effect using synthetic substrates was the very rapid hydrolysis of Tri-18:1 and Tri-20:5n-3 over the first 5 min of incubation compared to the other substrates. This led to a significantly increase in FFA but not other acylglycerols. After 30 min of incubation all differences had evened out, and there was no significant difference between these substrates. This may indicate that FFA has a feedback inhibition on the lipase activity. The only notable effect after 30 min was the high level of Tri-22:6n-3 compared to the other substrates indicating low substrate specificity of the lipase. Fish oil was also very rapidly degraded over the first 5 min of incubation. But in this case, the main products were MAG and 1,2(2,3)-DAG with little occurring in FFA and 1,3-DAG. The build up of 22:6n-3 in 1,2(2,3)-DAG and 16:0 in the MAG fractions do however, show that these were difficult to digest by the lipase. At 30 min this tendency was maintained to some degree, although they were more hydrolysed to FFA, while the build up of 18:1n-9 and 20:5n-3 in the FFA fraction clearly demonstrates that these were preferred over the other fatty acids for hydrolysis.

These data do in some respects agree with previous results from fish. As in our study, Halldorsson et al. [29] showed that 16:0 accumulated in the DAG and MAG fractions while 20:5n-3 increased in the FFA fraction when caecal lipase was incubated with various fish oils. They did however, not observe a similar preference for 18:1n-9 as seen in the present study. Furthermore, they found a significant accumulation of 22:6n-3 in the FFA fraction that was not the case in the present study. Cod digestive lipase also seems to have many similarities with the salmon lipase in that there is a preference for unsaturated fatty acids, 20:5n-3 and a lower activity towards 22:6n-3 [17, 19, 25]. However, cod lipase also seems to have the same preference for shorter chain PUFA like 18:2n-6, which does not seem to be the case in salmon. It thus appears that although fish digestive lipases are similar with regard to preference for 20:5n-3, there are also notable differences. This may indicate some adaptations to natural habitats and the presence of different fatty acids in their natural diets.

However, it is also possible that some of the differences observed are due to variations in experimental conditions. In the present study for example, we used ambient temperature of the fish (10 °C) for incubations in order to mimic natural conditions. Other studies like that of Gjellesvik [26] and presumably Halldorsson et al. [29] used room temperature for their studies. As lipase specificity is known to change at higher temperatures, in cod lipase towards saturated fatty

acids [26] this may explain some of the differences observed. Furthermore, assay conditions may also affect the specificities. This was elegantly shown using cod lipase where there was a dramatic change in specificity when the substrates were added in alcoholic or taurocholate solutions [26]. In the present study, we solubilised the TAG substrate in a taurocholate solution before use.

In conclusion, Atlantic salmon lipase does possess some specificity towards *sn*-1 or *sn*-3 fatty acyl positions on TAG, at least with Tri-18:1n-9 due to initial increases in 1,2(2,3)-DAG but not 1,3-DAG. However, this specificity is not as pronounced as for mammalian pancreatic lipase or as suggested for BSDL in other fish species. The lack of MAG as a major product of hydrolysis poses a problem for the MAG pathway for reconstituting TAG in the enterocytes when utilising acyl-homogeneous TAG substrates. However, by using natural TAG substrates in the present study, fairly large amounts of MAG were produced during the early stages of digestion that is not seen using synthetic substrates. Provided that MAG is absorbed rapidly, fish enterocytes may still be supplied with sufficient 2-MAG for the MAG pathway to function effectively. Atlantic salmon digestive lipases also have a clear specificity towards certain fatty acids like 20:5n-3 and 18:1n-9, regardless of their positional distribution. This lipase has therefore similarities to that found in other fish species like cod and rainbow trout [19, 29] but there are also some differences that may indicate species adaptations to specialized feed habitats, or simply variations in the in vitro experimental setup.

**Abstract** The present study determined alpha-tocopherol mass transfer from an alpha-tocopherol-rich emulsion to LDL and HDL, and assessed the potential of different mechanisms to modulate alpha-tocopherol transfers. Emulsion particles rich in alpha-tocopherol were incubated in vitro with physiological concentrations of LDL or HDL. The influence of plasma proteins was assessed by adding human lipoprotein poor plasma (LPP) fraction with intact vs heat inactivated PLTP, or with a specific cholesteryl ester transfer protein (CETP) inhibitor, or by adding purified PLTP or pig LPP which lacks CETP activity. After 4 h incubation in absence of LPP, alpha-tocopherol content was increased by ~80% in LDL and ~160% in HDL. Addition of LPP markedly enhanced alpha-tocopherol transfer leading to 350–400% enrichment in LDL or HDL at 4 h. Higher (~10 fold) enrichment was achieved after 20 h incubation with LPP. Facilitation of alpha-tocopherol transfer was (i) more than 50% higher with human vs pig LPP (despite similar PLTP phospholipid transfer activity), (ii) reduced by specific

CETP activity inhibition, (iii) not fully suppressed by heat inactivation, and (iv) not restored by purified PLTP. In conclusion, alpha-tocopherol content in LDL and HDL can be markedly raised by rapid transfer from an alpha-tocopherol-rich emulsion. Our results indicate that alpha-tocopherol mass transfer between emulsion particles and lipoproteins is mediated by more than one single mechanism and that this transfer may be facilitated not only by PLTP but likely also by other plasma proteins such as CETP.

**Keywords** Vitamin E · Alpha-tocopherol mass transfer · Lipid emulsions · LDL · HDL · PLTP · CETP

## Abbreviations

CETP	Cholesteryl ester transfer protein
HDL	High density lipoproteins
LDL	Low density lipoproteins
LPP	Lipoprotein poor plasma
PLTP	Phospholipid transfer protein
TC	Total cholesterol
TG	Triglycerides
TGRP	Triglyceride-rich particles

## Introduction

Vitamin E is a group of eight lipid soluble molecules including alpha-, beta-, gamma-, and delta-tocopherol as well as alpha-, beta-, gamma-, and delta-tocotrienols (Fig. 1). Alpha-tocopherol is the most abundant form of vitamin E in man due to the selective recognition and retention of this isoform by a specific binding protein present in the liver. Alpha-tocopherol is transported by plasma lipoproteins and plays an important role not only in

**Fig. 1** The molecular structure of vitamin E is characterised by a chromanol ring substituted by an aliphatic side chain (C16), which is saturated for tocopherols and unsaturated for tocotrienols. The hydrophobic aliphatic side chain allows vitamin E to partition

preventing lipid peroxidation but also in modulating several cell functions such as cell signaling and gene expression [1, 2]. Epidemiological studies have shown a better protection against cardiovascular diseases for individuals in the higher ranges of vitamin E status [3, 4]. However, the results of some large-scale clinical trials using supplementation with mega-doses ( $\geq 400$  IU/day) vitamin E to general populations have not shown clear protection against cardiovascular diseases [5–8]. A recent meta-analysis even suggests that chronic supplementation with mega-doses of vitamin E may increase all-cause mortality [9]. Thus, many questions remain open notably with respect to potential indications, dosage as well as route of vitamin E supplementation for specific target populations.

Although alpha-tocopherol is transported by chylomicrons and very low density lipoproteins in the immediate and late postprandial phases, respectively, low density lipoproteins (LDL) and high density lipoproteins (HDL) are the main carriers of alpha-tocopherol in plasma and largely contribute to its delivery to cells and tissues [10]. Exchanges of alpha-tocopherol molecules occur between plasma lipoproteins and depend on the relative alpha-tocopherol content in each lipoprotein subpopulation [11, 12]. Alpha-tocopherol transfer between lipoproteins as well as between lipoproteins and cells may be facilitated by plasma proteins. Plasma phospholipid transfer protein (PLTP), member of the plasma lipid transfer protein family, has been reported to play a major role in the facilitation of alpha-tocopherol transfer between plasma lipoproteins as well as between lipoproteins and cells [13, 14], whereas the related cholesteryl ester transfer protein (CETP), has been reported not to facilitate alpha-tocopherol transfer [15].

Alpha-tocopherol exchanges may also occur, in both directions, between lipoproteins and intravenous lipid emulsion particles [16–18]. The relative importance of alpha-tocopherol net mass transfer from alpha-tocopherol rich lipid emulsion particles to LDL and HDL as well as the extent to which plasma factors facilitate these

between membrane and lipoprotein lipids while presenting the chromanol ring with the hydroxyl group towards the aqueous phase. The four forms of tocopherols and tocotrienols vary in the number and the position of methyl groups on the chromanol ring

transfers have not been investigated in depth. In the present study, an in vitro model was used in which particles isolated from an alpha-tocopherol-enriched emulsion were incubated with total plasma or physiological concentrations of LDL or HDL in presence of non-lipid plasma fractions or purified transfer proteins. The aims were to determine: (i) the kinetics of alpha-tocopherol transfer from emulsion particles to plasma lipoproteins; (ii) the amount of alpha-tocopherol that can be acquired by LDL and HDL; (iii) the influence of proteins present in non-lipid plasma fractions on such alpha-tocopherol exchanges. Our data indicate that multiple mechanisms are involved in alpha-tocopherol mass transfer from lipid emulsions to plasma lipoproteins.

## Material and Methods

### Lipid Emulsion

A lipid emulsion (100 g triglycerides/l) containing a mixture of medium-chain triglycerides and long-chain triglycerides (1:1; w:w) with an elevated alpha-tocopherol content ( $10.70 \pm 0.90$  g/l) was prepared by B. Braun (Melsungen, Germany) for the purpose of this in vitro study. Since lipid emulsions contain a mixture of triglyceride-rich particles (TGRP) together with other particles formed from the excess of phospholipid emulsifier, the TGRP fraction was isolated by flotation in saline solution (NaCl 0.9%, EDTA 0.01%) through  $3 \times 30$  min ultracentrifugation at  $70,000 \times g$  using a SW-41Ti rotor in a L8-55 ultracentrifuge (Beckman Instruments, Palo Alto, CA, USA). Approximately 90% of emulsion alpha-tocopherol content was recovered in the TGRP fraction. TGRP were stored overnight under nitrogen at 4 °C. In all incubation assays, TGRP were incubated at a triglyceride (TG) concentration of 100 mg/dL, a level commonly observed in the plasma of patients receiving parenteral nutrition with lipids [19].

## Separation of LDL, HDL and Lipoprotein Poor Plasma Fraction

Lipoproteins (LDL and HDL) were separated from pooled normolipidemic human plasma by sequential ultracentrifugation [20] using a 50-2Ti rotor (Beckman, Palo Alto, CA, USA) in a L8-55 ultracentrifuge (Beckman). Plasma density was adjusted by addition of solid KBr at density ranges 1.025–1.055 and 1.070–1.18 g/mL for LDL and HDL, respectively. Plasma was centrifuged at  $302,000 \times g$  (5 °C) for 20 h for LDL and for another 40 h for HDL separation. The isolated lipoprotein fractions were then extensively dialysed against a saline solution (NaCl 0.9%, EDTA 0.01%, glycerol 10%, pH 7.4) and stored under nitrogen at –70 °C until incubation assays. Glycerol present in LDL and HDL fractions was removed by filtration on PD10 Sephadex columns (Amersham Pharmacia, Uppsala, Sweden) prior to incubation.

The lipoprotein poor plasma (LPP) fraction, containing the majority of plasma proteins, was also separated by sequential ultracentrifugation. Plasma density was adjusted at  $d > 1.24$  g/mL and centrifuged during 40 h at  $302,000 \times g$  (5 °C) to remove all lipoproteins. After ultracentrifugation, the LPP fraction was extensively dialysed against a saline solution (NaCl 0.9%, EDTA 0.01%, pH 7.4) and stored under nitrogen at –20 °C until incubation assays.

## Incubation Protocols

### *Alpha-tocopherol Mass Transfer from Lipid Emulsion Particles to LDL and HDL*

To determine the kinetics of alpha-tocopherol net mass transfer from emulsion particles to plasma lipoproteins, TGRP (100 mg TG/dL) were incubated at 37 °C in presence of LDL (120 mg LDL-cholesterol/dL) or HDL (50 mg HDL-cholesterol/dL) over increasing time periods (0.5, 1, 2, 4 h) in a gently shaking water bath. Incubations were performed in absence or presence of human LPP (65 g protein/l). Furthermore, a few incubations were performed over 20 h in presence of LPP to determine the sub-maximal amount of alpha-tocopherol that can be acquired by LDL and HDL. Finally, TGRP were incubated in total plasma (with a LDL-cholesterol/HDL-cholesterol ratio of 1.2:1) to determine alpha-tocopherol partitioning between LDL and HDL. At the end of the incubation period, the TGRP fraction was isolated by flotation (ultracentrifugation of 45 min at  $80,000 \times g$  at 12 °C) from the infranatant containing the lipoproteins and LPP. After adjusting the density of the infranatant, individual lipoprotein fractions were isolated by sequential ultracentrifugation. Each collected fraction was stored

at 4 °C for lipid analyses and aliquots of 300 µl were stored under nitrogen at –70 °C for vitamin E analyses performed within 2 weeks. Vitamin E content in LDL and HDL was expressed relative to particle lipid (total cholesterol + TG) content. Net alpha-tocopherol enrichment in LDL and HDL was calculated by comparison to data from control incubations of lipoproteins over the same time periods but without TGRP. Alpha-tocopherol content in lipoproteins was not significantly modified after control incubations over 4 and 20 h, whether in absence or presence of LPP.

### *Influence of Non-lipid Plasma Components on Alpha-tocopherol Transfer*

To assess the influence of proteins present in the LPP plasma fraction on alpha-tocopherol exchanges, TGRP (100 mg TG/dL) were incubated at 37 °C with LDL (120 mg LDL-cholesterol/dL) or HDL (50 mg HDL-cholesterol/dL) for 2 h in the absence or presence of human LPP (65 g protein/l). To distinguish the effect of PLTP from that of CETP, experiments were carried out with LPP heated for 1 h at 58 °C to inactivate PLTP activity [13, 21, 22], or with addition of a potent CETP inhibitor (synthesised according to the patent application:WO2006013048; F. Hoffmann-La Roche, Basel, Switzerland) to LPP and to total plasma. CETP inhibitor was used at a concentration of 212 nM corresponding to four times the IC<sub>50</sub> for a complete inhibition of CETP activity in plasma samples (personal communication, Roche Basel). In parallel, experiments were carried out with LPP (65 g protein/l) isolated from pig plasma, the latter being largely devoid of CETP [23, 24] but not of PLTP activity [25]. Finally, incubations were also performed in absence of LPP but with albumin as the most abundant plasma protein (40 g/l fatty acid-free BSA, Sigma Aldrich, Steinheim, Germany), and with partially purified PLTP (5–10 µg/mL, Cardiovascular Targets Inc., NY, USA). After incubation, lipoproteins were isolated by ultracentrifugation and their alpha-tocopherol content analysed. The enhancing action of non-lipid plasma components upon alpha-tocopherol transfer from emulsion particles to LDL and HDL was obtained by subtracting spontaneous transfer measured in incubations with no proteins.

## Analytical Measurements

Total cholesterol (TC) and TG concentrations were measured in LDL and HDL fractions using enzymatic kits CHOD-PAP (Roche Diagnostics GmbH, Mannheim, Germany) and Triglycerides Glycerol blanked (Roche Diagnostics GmbH), respectively. For alpha-tocopherol measurements in LDL and HDL [26, 27], lipoproteins were

saponified at 70 °C with alcoholic KOH followed by alpha-tocopherol extraction with hexane. Hexane was dried and the extract was dissolved in methanol:water (95/5, w/w). Alpha-tocopherol content in the extract was then measured by reverse-phase HPLC (Merck-Hitachi Ltd, Tokyo, Japan) using a Lichrospher column 100 RP 18 (125 m<sup>2</sup> × 4 m<sup>3</sup>; LxID; Merck, Darmstadt, Germany) and a mobile phase of methanol:water (95/5, w/w) at a flow rate of 1.5 mL/min; alpha-tocopherol was monitored at 292 nm by a UV detector [28].

### Phospholipid Transfer Activity Assay

Phospholipid transfer activity was assessed by measuring the transfer of 1,2 di-[1-<sup>14</sup>C]palmitoyl phosphatidylcholine (100 mCi/mmol, Amersham Biosciences, Buckinghamshire, UK) from small unilamellar liposomes to HDL particles [29, 30]. In brief, labeled liposomes (125 nmol of phospholipids) were incubated with HDL (250 µg proteins) and LPP (10 µl) or partially purified PLTP (20 µg, Cardiovascular Targets Inc., NY, USA) in a final volume of 400 µl. The percentage of transferred radioactivity to HDL was calculated after correcting for background radioactivity. In this assay, partially purified PLTP induced a 19% transfer of total radiolabelled phospholipids, after correction for spontaneous transfer (7%).

### Statistical Analysis

Results are expressed as mean values ± SEM. Statistical analyses were made by using Student's *t* test. The statistical significance of differences between values was assessed by paired comparison of data recorded within each individual experiment.

## Results

### Alpha-tocopherol Mass Transfer from Lipid Emulsion Particles to LDL and HDL

Kinetics of alpha-tocopherol transfer from emulsion particles to plasma lipoproteins, were assessed by incubating LDL and HDL with TGRP over increasing time periods (0.5–4 h) (Fig. 2). In the absence of LPP fraction, spontaneous transfer of alpha-tocopherol from TGRP to LDL progressively increased LDL alpha-tocopherol content over time leading to an 80 ± 6% enrichment after 4 h (5.26 ± 0.63 vs 2.91 ± 0.27 µmol/mmol in control LDL; *p* < 0.001). Spontaneous alpha-tocopherol transfer also occurred from TGRP to HDL particles and induced a 163 ± 36% enrichment after 4 h incubation (15.34 ± 0.41 vs 6.22 ± 0.79 µmol/mmol in control HDL; *p* < 0.02).

**Fig. 2** The time course of alpha-tocopherol transfer over a 4 h incubation period from lipid emulsion particles to LDL (a) and HDL (b) in the absence and presence of human lipoprotein poor plasma fraction (LPP) was compatible with an exponential pattern according to the equation  $Y = Y_{\max}(1 - e^{-kx})$ . Equation in which *Y* represents the increment of alpha-tocopherol content compared to control conditions (lipoproteins incubated without TGRP), *Y*<sub>max</sub> the maximal increment, *k* the rate constant and *x* the time (expressed as hours). In control incubations the absence vs presence of LPP did not modify the alpha-tocopherol content of control LDL (2.91 ± 0.27 vs 2.96 ± 0.2, *p* > 0.8) and HDL (6.22 ± 0.79 vs 6.24 ± 0.62, *p* > 0.9). Each point represents the mean ± SEM of 4 separate experiments. Also indicated is the correlation coefficient (*r*) between the mean experimental values and those derived from the above equation

Addition of LPP markedly enhanced alpha-tocopherol transfer to LDL particles leading to an alpha-tocopherol enrichment of 359 ± 4% after 4 h (13.57 ± 0.83 vs 2.96 ± 0.20 µmol/mmol in control LDL; *p* < 0.0001). Addition of LPP fraction also enhanced alpha-tocopherol transfer to HDL particles leading to an alpha-tocopherol enrichment of 393 ± 20% after 4 h (30.38 ± 2.67 vs 6.24 ± 0.62 µmol/mmol in control HDL; *p* < 0.001). Therefore, some factor(s) contained in LPP stimulate alpha-tocopherol transfer to cholesterol-rich particles.

As shown in Fig. 2, increases of LDL and HDL alpha-tocopherol content could be fitted to a single exponential equation, according to  $Y = Y_{\max}(1 - e^{-kx})$ , whether in presence or absence of LPP. The rate constant of alpha-tocopherol transfer was higher with HDL than with LDL, both in absence (*k* = 0.48 vs 0.28) and in presence of LPP (*k* = 1.34 vs 0.70). However, the enhancing effect of LPP on alpha-tocopherol transfer was more marked with LDL than with HDL (4.09 ± 0.59 fold for LDL and 2.09 ± 0.25 fold for HDL after 4 h incubation, *n* = 16; *p* < 0.005). Alpha-tocopherol enrichment in both LDL and HDL plateaued after 4 h incubation in absence but not in presence of LPP. When the incubation period was prolonged to 20 h in

**Table 1** Alpha-tocopherol content of LDL and HDL after 20 h incubation

	Control ( $\mu\text{mol}/\text{mmol}$ )	20 h ( $\mu\text{mol}/\text{mmol}$ )
LDL + LPP	$3.18 \pm 0.21$	$27.53 \pm 0.68$
HDL + LPP	$6.72 \pm 0.28$	$47.37 \pm 2.69$

Alpha-tocopherol content of LDL and HDL particles after a 20 h incubation without (control) or with lipid emulsion particles and human lipoprotein poor plasma fraction (LPP). Alpha-tocopherol is expressed in relation to particles total cholesterol and triglyceride content ( $\mu\text{mol}/\text{mmol}$ ). Results are means  $\pm$  SEM of three separate experiments

presence of LPP, alpha-tocopherol content further increased and led to an enrichment of  $776 \pm 83\%$  in LDL and of  $611 \pm 73\%$  in HDL ( $p < 0.01$ ) (Table 1). In absolute values TGRP supplied  $209 \pm 9 \mu\text{mol}$  alpha-tocopherol in the incubation medium. After 4 h incubation in presence of LPP,  $\sim 15\%$  of exogenous alpha-tocopherol was acquired by LDL ( $31 \pm 3 \mu\text{mol}$ ) or HDL ( $26 \pm 2 \mu\text{mol}$ ). After 20 h incubation in presence of LPP, the amount acquired by LDL ( $113 \pm 16 \mu\text{mol}$ ) or HDL ( $89 \pm 7 \mu\text{mol}$ ) corresponded to  $\sim 50\%$  of exogenous alpha-tocopherol.

Finally, when TGRP were incubated in whole plasma for 4 h, a comparable alpha-tocopherol enrichment of  $\sim 75\%$  was observed in both LDL (from  $3.50 \pm 0.14$  to  $6.06 \pm 0.08 \mu\text{mol}/\text{mmol}$ ,  $n = 4$ ;  $p < 0.0001$ ) and HDL (from  $6.05 \pm 0.11$  to  $10.72 \pm 0.23 \mu\text{mol}/\text{mmol}$ ,  $n = 4$ ;  $p < 0.0001$ ).

#### Influence of Non-lipid Plasma Components on Alpha-tocopherol Transfer

Since substantial alpha-tocopherol transfers to plasma lipoproteins were observed within 2 h incubation (and since the residence time of TG-rich emulsion particles in the circulation does not exceed 2 h), further experiments to characterise the influence of LPP proteins on alpha-tocopherol transfer were performed over 2 h.

Addition of human albumin did not facilitate alpha-tocopherol transfer from emulsion particles to LDL and HDL compared to spontaneous transfer ( $p > 0.2$ ) (Table 2).

**Table 2** Influence of albumin on alpha-tocopherol transfer

	Control ( $\mu\text{mol}/\text{mmol}$ )	TGRP ( $\mu\text{mol}/\text{mmol}$ )	TGRP + albumin ( $\mu\text{mol}/\text{mmol}$ )	TGRP + LPP ( $\mu\text{mol}/\text{mmol}$ )
LDL	$3.44 \pm 0.14$	$5.30 \pm 0.27$	$5.63 \pm 0.19$	$12.20 \pm 0.15$
HDL	$7.29 \pm 0.07$	$13.94 \pm 0.20$	$11.19 \pm 1.32$	$18.80 \pm 0.70$

Alpha-tocopherol content of LDL and HDL particles incubated without (control) or with TGRP in presence of albumin or human lipoprotein poor plasma (LPP). Alpha-tocopherol is expressed in relation to particles total cholesterol and triglyceride content ( $\mu\text{mol}/\text{mmol}$ ). Results are means  $\pm$  SEM of three separate experiments

**Table 3** Phospholipid transfer activity

HDL + human LPP	$22.5 \pm 0.5$
HDL + heated human LPP	$5.3 \pm 0.4$
HDL + pig LPP	$26.1 \pm 0.2$
HDL + heated pig LPP	$20.7 \pm 0.2$

Lipoprotein poor plasma fraction (LPP) from human and pig plasma were compared for phospholipid transfer activity. Results are expressed as a percentage of total radiolabelled phospholipids (total count) which were transferred (after correcting for spontaneous transfer) from liposomes to HDL over a 30 min incubation period. Values are means  $\pm$  SEM of two separate experiments

Heating the human LPP fraction at  $58^\circ\text{C}$  for 1 h to inactivate PLTP activity almost completely abolished phospholipid-specific transfer activity as indicated by the transfer radioassay (Table 3). As shown in Fig. 2, alpha-tocopherol transfer from TGRP to LDL was lower in presence of heat-inactivated compared to normal LPP ( $6.20 \pm 0.41$  vs  $8.94 \pm 0.32 \mu\text{mol}/\text{mmol}$ ;  $n = 4$ ;  $p < 0.01$ ). This suggests that  $36 \pm 6\%$  of the enhancing action of human LPP on alpha-tocopherol transfer (calculated by subtracting spontaneous transfer from facilitated transfer) was due to heat sensitive factor(s), presumably PLTP. Alpha-tocopherol transfer from TGRP to HDL particles was also lower after heat inactivation of human LPP ( $11.35 \pm 0.32$  vs  $13.46 \pm 0.38 \mu\text{mol}/\text{mmol}$ ;  $n = 5$ ;  $p < 0.005$ ); indicating that  $27 \pm 3\%$  of the enhancing action of human LPP on alpha-tocopherol transfer to HDL was due to heat sensitive factor(s) (Fig. 3).

Addition of partially purified PLTP tended to increase alpha-tocopherol net transfer from TGRP to LDL ( $18.5 \pm 8.5\%$ ; NS) and HDL ( $7.3 \pm 2.8\%$ ; NS).

LPP fraction from pig plasma (devoid of functional CETP) induced comparable transfer of radiolabelled phospholipids as human LPP (Table 3); however, alpha-tocopherol mass transfer to LDL was lower with pig vs human LPP ( $5.29 \pm 0.55$  vs  $7.94 \pm 0.32 \mu\text{mol}/\text{mmol}$ ;  $n = 6$ ;  $p < 0.001$ ). Hence, the enhancing effect of pig LPP on alpha-tocopherol transfer to LDL represented  $55 \pm 10\%$  of that induced by human LPP. Surprisingly, heat inactivation had only a limited effect on reducing phospholipid specific transfer activity in pig LPP (Table 3). Consistently, prior heating of pig LPP did not significantly reduce alpha-tocopherol transfer ( $p > 0.6$  by comparison to non-heated

**Fig. 3** Influence of lipoprotein poor plasma fraction (LPP) on alpha-tocopherol transfer from emulsion particles (TGRP) to LDL (a) and HDL (b). LDL (120 mg/dL) and HDL (50 mg/dL) were incubated for 2 h at 37 °C in absence and presence of human or pig LPP (65 g protein/l). All available values collected in each set of experiments are expressed as means  $\pm$  SEM and represent the increment of alpha-tocopherol content compared to control conditions (lipoproteins incubated without TGRP). Compared to alpha-tocopherol facilitated transfer by human LPP substitution with heated human LPP ( $p < 0.01$  for LDL and  $p < 0.005$  for HDL), or with pig LPP ( $p < 0.001$  for LDL and  $p < 0.002$  for HDL), or with heated pig LPP ( $p < 0.002$  for LDL and  $p < 0.001$  for HDL) led to significantly reduced alpha-tocopherol transfer

pig LPP;  $n = 6$ ). In incubations of TGRP with HDL, alpha-tocopherol transfer was also much lower in presence of pig vs human LPP ( $6.44 \pm 0.64$  vs  $13.59 \pm 0.46$   $\mu\text{mol}/\text{mmol}$ ;  $n = 4$ ;  $p < 0.002$ ). A limited enhancing action of pig LPP on alpha-tocopherol transfer was observed in only 3 out of 4 individual experiments. Even in these 3 experiments, this represented only  $13.6 \pm 2.9\%$  of the facilitated transfer

**Fig. 4** Effect of a specific CETP inhibitor on alpha-tocopherol facilitated transfer from emulsion particles (TGRP) to LDL (a) and HDL (b). LDL (120 mg/dL) and HDL (50 mg/dL) were incubated for 2 h at 37 °C in absence or presence of human LPP (65 g protein/l) and CETP inhibitor (CETP inh. 212 nM). All available values collected in each set of experiments are expressed as means  $\pm$  SEM and represent the increment of alpha-tocopherol content compared to control conditions (lipoproteins incubated without TGRP). Compared to alpha-tocopherol facilitated transfer by human LPP addition of CETP inhibitor significantly reduced alpha-tocopherol transfer to LDL ( $p < 0.03$ ) or HDL ( $p < 0.03$ )

observed with human LPP within the same experiments ( $p < 0.005$ ). Prior heating suppressed the modest enhancing action of pig LPP on alpha-tocopherol transfer to HDL particles ( $p < 0.05$ ).

As shown in Fig. 4, addition of a specific CETP inhibitor to incubations of TGRP with LDL, reduced alpha-tocopherol facilitated transfer to LDL by  $\sim 11\%$  ( $4.18 \pm 0.30$  vs  $4.65 \pm 0.35$   $\mu\text{mol}/\text{mmol}$ ;  $n = 5$ ;  $p < 0.03$ ). In incubations with HDL, however, CETP inhibition markedly lowered

**Fig. 5** Effect of a specific CETP inhibitor on alpha-tocopherol transfer from emulsion particles (TGRP) to LDL and HDL in total plasma. Total plasma (C) was incubated for 2 h at 37 °C in absence or presence of CETP inhibitor (CETP inh. 212 nM). At the end of the incubation period, LDL and HDL were isolated from total plasma. All available values collected in each set of experiments are expressed as means  $\pm$  SEM and represent the increment of alpha-tocopherol content compared to control conditions (lipoproteins isolated from plasma that was incubated without TGRP). Addition of CETP inhibitor to total plasma significantly reduced alpha-tocopherol transfer to both LDL ( $p < 0.03$ ) and HDL ( $p < 0.04$ )

alpha-tocopherol facilitated transfer to HDL ( $5.21 \pm 0.30$  vs  $9.38 \pm 0.48$   $\mu\text{mol}/\text{mmol}$ ;  $n = 3$ ;  $p < 0.03$ ). Addition of CETP inhibitor to total plasma reduced by  $\sim 50\%$  the transfer of alpha-tocopherol from TGRP to LDL ( $0.96 \pm 0.05$  vs  $2.25 \pm 0.16$   $\mu\text{mol}/\text{mmol}$ ;  $n = 3$ ;  $p < 0.03$ ) and HDL ( $2.12 \pm 0.36$  vs  $3.52 \pm 0.16$   $\mu\text{mol}/\text{mmol}$ ;  $n = 3$ ;  $p < 0.04$ ) (Fig. 5).

## Discussion

Previous experiments studying alpha-tocopherol transfer between plasma lipoproteins have mainly used radiolabelled transfer assays and have generally focused on evaluating the effect of single mechanisms susceptible to facilitate alpha-tocopherol transfer [11, 13, 15]. The present study measures mass transfers of alpha-tocopherol from an artificial lipid emulsion to LDL and HDL and investigates the potential for several mechanisms to mediate such transfers. An *in vitro* model of incubation was used with an emulsion markedly enriched in alpha-tocopherol to avoid a rate-limiting availability of alpha-tocopherol when assessing mass transfers. In the different experiments, the emulsion lipid concentration was maintained at a relatively low level and lipoprotein concentration was comparable to that commonly found in the circulation. The range of

incubation periods generally covered the residence time of emulsion particles in plasma.

In the first part of this study, alpha-tocopherol mass transfer from emulsion particles to lipoproteins was measured over increasing time periods. Incubations of alpha-tocopherol-rich emulsion particles together with either LDL or HDL resulted in a rapid net mass transfer of alpha-tocopherol to both plasma lipoprotein fractions. In absence of non-lipid plasma components, spontaneous alpha-tocopherol transfer was already detected after  $\leq 1$  h incubation and led to sub-maximal alpha-tocopherol enrichment after 4 h in LDL ( $+ \sim 80\%$ ) and HDL ( $+ \sim 160\%$ ). The higher spontaneous transfer to HDL may be related to the larger surface to volume ratio of HDL compared to LDL particles, which increases the available accepting surface for alpha-tocopherol molecules. To our knowledge, this is the first study to report such significant spontaneous alpha-tocopherol mass transfer from lipid emulsions to plasma lipoproteins. These observations differ from previous data of Desrumaux et al. [14] who did not detect spontaneous mass transfer between lipoproteins. However, these authors used for their transfer experiments lipoproteins depleted of alpha-tocopherol by oxidation, a procedure that may considerably modify particle surface and capacity for accommodating extra-alpha-tocopherol. Kostner et al. [13] who reported spontaneous transfer of radiolabelled alpha-tocopherol between plasma lipoproteins, showed that the addition of LPP accelerated alpha-tocopherol transfer without a net increase in lipoprotein alpha-tocopherol enrichment over spontaneous transfer. In our experiments, addition of LPP fraction not only accelerated but also increased the maximal amount of alpha-tocopherol transferred to LDL and HDL. In this condition, enrichment was not sub-maximal after 4 h incubation and alpha-tocopherol content could be further increased to almost 10 fold in both lipoproteins when incubation period was prolonged to 20 h.

Incubations with total plasma (containing LDL and HDL at a 1.2:1 cholesterol ratio) led to a comparable enrichment ( $\sim 75\%$  after 4 h) in both lipoprotein fractions, suggesting a competition between LDL and HDL fractions for alpha-tocopherol acquisition. All together, this data indicates that, at a fixed concentration of alpha-tocopherol provided by emulsion particles, the limiting factor for alpha-tocopherol enrichment is not the capacity of plasma lipoproteins to accommodate extra-amounts of alpha-tocopherol but rather the facilitating effect of non-lipid plasma components on alpha-tocopherol transfer, the residence time of emulsion particles and possibly the competition between different acceptor particles.

In the second part of this study the influence of individual or groups of proteins was assessed in relation to facilitating alpha-tocopherol transfer. Results of experiments using

addition of heat inactivated LPP, of partially purified PLTP, of pig LPP and of CETP inhibitor suggest that the facilitating effect of LPP on alpha-tocopherol transfer from emulsion particles to plasma lipoproteins is not related to a single protein but rather to several non-lipid components present in the LPP fraction. This observation is at variance with previous papers suggesting an exclusive role for PLTP in enhancing vitamin E exchanges between plasma lipoproteins (together with surface phospholipids) [13], as well as between lipoproteins and cells [14]. Indeed, inactivation of PLTP activity by heating human LPP for 1 h at 58 °C reduced alpha-tocopherol transfer from emulsion particles by only ~40% in the case of LDL and ~30% in the case of HDL by comparison to experiments with non heated LPP. Moreover, addition to the incubation medium of partially purified PLTP (with maintained phospholipid-specific transfer activity) did not substantially increase alpha-tocopherol net mass transfer, although our model does not take into account alpha-tocopherol back transfers. Overall these results confirm a role for PLTP in alpha-tocopherol transfer facilitation but indicate that  $\geq 50\%$  of alpha-tocopherol transfer facilitation by human LPP is due to components other than heat-sensitive PLTP. This leads to question the role of heat-resistant lipid transfer proteins such as CETP. Granot et al. [15] who evaluated the role of purified CETP in alpha-tocopherol transfer between plasma lipoproteins did not report a facilitating effect of CETP. Nevertheless, this study used radiolabelled alpha-tocopherol which may not have distributed normally throughout the lipoprotein particles, did not assay for mass transfers and measured alpha-tocopherol transfer over relatively long incubation periods which would promote back transfers; these factors could explain the lack of effect of CETP. In our experiments using pig LPP with PLTP activity comparable to human LPP but deficient in CETP, alpha-tocopherol enrichment in LDL and HDL was much lower (~50%) than that facilitated by human LPP. This data again supports the point that alpha-tocopherol transfer from emulsion particles to plasma lipoproteins is facilitated not only by PLTP but also by other transfer proteins, and possibly CETP. Indeed, addition of a specific CETP inhibitor to incubation assays with LDL or HDL, or with total plasma, significantly reduced alpha-tocopherol transfer facilitated by human LPP. The reduction of alpha-tocopherol facilitated transfer was more marked for HDL when lipoproteins were incubated separately. However, addition of CETP inhibitor to total plasma, reduced by ~50% alpha-tocopherol transfer to both LDL and HDL particles. Hence, these experiments using a specific CETP inhibitor also support a role for CETP in alpha-tocopherol transfer from emulsion particles to plasma LDL and HDL. In addition to transfer proteins, lipoprotein lipase may facilitate alpha-tocopherol exchange between lipoproteins during the lipolytic process

[27, 31]. This was not tested in the in vitro model used in the present study.

The present study demonstrates a very high capacity of LDL and HDL to accommodate extra-amounts of alpha-tocopherol by rapid transfer from an alpha-tocopherol enriched emulsion. Such increased alpha-tocopherol content in LDL and HDL may facilitate subsequent alpha-tocopherol delivery to cells and tissues. The emulsion used in this study was prepared for these in vitro experiments and not as a component of parenteral nutrition. However, similar alpha-tocopherol enriched preparations could be developed in view of intravenous bolus injections in patients with increased alpha-tocopherol requirements associated to acute conditions. If supported by evidence-based data, intravenous administration of emulsions with extra-alpha-tocopherol may find an indication in critically ill patients (injury, trauma, sepsis, ischemia, or severe inflammation) who consistently show reduced numbers of circulating LDL and HDL particles and are at high risk of oxidative tissue injury [32]. Furthermore, using intravenous emulsions as suppliers of alpha-tocopherol allows to bypass intestinal absorption which may be a limiting factor for alpha-tocopherol supplementation particularly in critically ill patients [33–35].

In conclusion, the present study demonstrates rapid and substantial mass transfer of alpha-tocopherol from an alpha-tocopherol rich lipid emulsion to plasma lipoproteins. Our data further indicates that alpha-tocopherol mass transfer is mediated by multiple mechanisms and that this transfer is largely facilitated not only by PLTP but also by other non-lipid factors present in plasma.

**Abstract** Previous studies have shown that postprandial triglyceride-rich lipoproteins (TRLs) are enriched with apolipoprotein-C-I (apoC-I) in healthy individuals with increased intima-media thickness and in patients with coronary artery disease. The purpose of the present study was to determine apoC-I in TRL in persons with carotid atherosclerosis and its relation to plaque area. A population-based case ( $n = 42$ )-control ( $n = 39$ ) study was conducted in persons with carotid atherosclerosis, assessed by B-mode ultrasound, and healthy controls. VLDL (Sf 20–400) was isolated in the fasting state and 4 h after ingestion of a standard fat meal. In the fasting state, persons with carotid atherosclerosis had increased number of apoC-I per VLDL-particle compared to persons without carotid atherosclerosis ( $8.6 \pm 5.4$  vs.  $6.3 \pm 4.2$ ,  $P = 0.018$ ). Total plaque area increased linearly ( $P = 0.017$ ) across tertiles of apoC-I per

VLDL-particle. In the postprandial state, a similar increase in the number of apoC-I per VLDL-particle occurred in both cases and controls ( $P < 0.001$ ), but no significant difference was observed between groups. The number of apoC-I per VLDL-particle in the fasting state was accompanied by delayed clearance of TRL in the postprandial state, and associated with cholesterol enrichment of the VLDL-particles. Our findings support the concept that the number of apoC-I per VLDL-particle may be of importance for initiation and progression of atherosclerosis.

### Introduction

Elevated postprandial levels of triglyceride-rich lipoproteins (TRLs), i.e. chylomicrons (CM) and very low-density lipoproteins (VLDL) have been associated with both coronary [1] and carotid artery [2] atherosclerosis.

The metabolism of TRL particles is determined by their apolipoprotein (apo) and lipid composition, which affects their access to lipases and receptors [3, 4]. Hepatic removal of TRLs from the circulation is mediated by apoB100 and apoE [5], and lack of apoE leads to accumulation of chylomicron remnants [6]. Triglycerides in the core of TRL in circulating blood are hydrolyzed by the action of endothelial cell-bound lipoprotein lipase (LPL). Low LPL activity can be due to reduced mass or specific activity of LPL or its activator protein apoC-II. Low LPL activity, as encountered in patients with LPL deficiency, is associated with increased plasma levels of chylomicrons, [7] premature atherosclerosis and accelerated progression of atherogenesis [8].

Members of the apolipoprotein-C family are of major importance for the metabolism of postprandial TRLs. ApoE-mediated binding of TRLs to receptors is inhibited by apoC-I and apoC-III, [9] and experimental studies have shown that apoC-I displaces apoE from TRL and thereby delays their hepatic uptake [10, 11]. Furthermore, apoC-II promotes and apoC-III attenuates the hydrolysis of TRLs by lipoprotein lipase (LPL) [12]. Enrichment of TRLs with apoC-I is associated with a proatherogenic composition of the particles by increasing the cholesterol/triglyceride ratio due to prolonged half-life of TRL remnants in the circulation [13].

Postprandial TRL is enriched with apoC-I in patients with coronary artery disease, [14] in healthy individuals with increased intima-media thickness (IMT) [15] and is an independent predictor for IMT in normolipidemic healthy middle-aged men [13]. These findings do suggest that the apoC-I content of TRL is a novel risk factor for early atherosclerosis and CAD. The purpose of the present study was to investigate the apoC-I in TRL in persons with carotid atherosclerosis and to determine the associations of the apoC-I in TRL with plaque area and morphology.

## Material and Methods

### Study Participants

The participants of the study were recruited from a population health study (the fifth survey of The Tromsø Study in 2001), which included ultrasound examination of the right carotid artery. Persons were eligible for the plaque group if they were aged 56–80 years and had one plaque or more in the carotid bifurcation or internal carotid artery at the screening with a plaque thickness of  $\geq 2.5$  mm. Persons in the same age groups without plaques in their carotid arteries were used as controls. Persons who responded positive to our invitation letter to participate in the study were invited to a screening visit. At the screening visit, a complete medical history, physical examination and blood samples were taken with special emphasis on exclusion criteria. A detailed interview on the occurrence of cerebrovascular and cardiovascular events, defined as prior or present transient ischemic attacks (TIA), stroke, amaurosis fugax, angina pectoris, myocardial infarction, peripheral vascular disease, and diabetes, smoking habits and drugs was obtained. Exclusion criteria were any of the following conditions: regular use of lipid-lowering drugs (HMG-CoA reductase inhibitors, resins or nicotinic acid derivatives) or oral anticoagulants, cancer or other serious life-threatening medical conditions, hypothyroidism, renal, hepatic, or psychiatric disease, and current abuse of alcohol or drugs. Among eligible persons, 42 cases and 39 controls were

invited to a second visit in which, an ultrasound examination of both carotid arteries was performed, and the participants were subjected to a fat tolerance test. Informed written consent was obtained from the participants, and the regional ethical committee approved the study. The study was performed at the Clinical Research Unit at the University Hospital of North-Norway.

### Ultrasound Examination

At the population health screening, high-resolution B-mode and color Doppler/pulsed-wave Doppler ultrasonography of the right carotid artery was performed as described previously [16, 17]. A plaque was defined as a localized thickening of the vessel wall of more than 50% compared to the adjacent vessel wall thickness. As only the right carotid artery was examined at the screening, a new ultrasound examination of both carotid arteries was performed. These ultrasound examinations were performed by the same experienced examiner, and with the use of an Acuson Xp10 128 ART ultrasound scanner equipped with a linear array 5–7 MHz transducer.

Plaque morphology in terms of echogenicity was assessed by analysis of grey scale content of the plaques and calculation of grey scale median (GSM). Assessment of plaque size and morphology was made in all plaques present in the near and far walls of the common carotid, the bifurcation, and the internal carotid arteries on both sides (12 locations). All examinations and measurements of all plaques were recorded on videotapes. Stored B-mode images were subsequently transferred to a personal computer and digitized into frames of  $768 \times 576$  pixels of 256 grey levels each (0 black and 256 white) with the use of a commercially available video grabber card (meteor II/Matrox Intellicam). Measurements of plaque area were made with the use of the Adobe Photoshop image-processing program (version 7.0.1), by tracing around the perimeter of each plaque with a cursor. The grey-level distribution and GSM of each plaque was calculated. Standardization of GSM was performed as previously described [18]. A fixed area of the lumen of the carotid artery (300 pixels), the brightest area of the innermost adventitia adjacent to the plaque (150 pixels), and the plaque were marked. The plaque image was normalized by adjusting linearly their grey tonal range so that the lumen was assigned a GSM of 1 and the adventitia 200. After standardization, the GSM of the plaques were recalculated. In persons with more than one plaque, the standardized GSM of the total plaque area was estimated as a weighted mean of the GSM value of each single plaque. The area of each plaque was divided by the total area of the plaques in each person, and this fraction was multiplied with each plaques normalized GSM value. All scores were added to calculate the total normalized GSM score for each person.

## Fat Tolerance Test

A fat tolerance test was conducted using a test meal prepared from standard porridge cream containing 70% of calories from fat of which 66% saturated fat, 32% monounsaturated fat and 2% polyunsaturated fat. A weight-adjusted meal (1 g fat per kg body weight) was served at 8:00 a.m. and consumed over a 15 min period. The participants were allowed to drink 350 ml calorie-free beverages and eat an apple during the following 8 h. Blood samples for isolation of CM, VLDL, and serum- and plasma preparations were collected before the meal and every second hour during the next 8 h.

## Blood Collection, Isolation of Triglyceride-rich Lipoproteins and Storage

Blood was drawn from an antecubital vein in the morning at 7:45 a.m. after 12 h overnight fasting and 2, 4, 6, and 8 h after the meal, using a 19 gauge needle in a vacutainer system with minimal stasis. Serum was prepared by clotting whole blood in a glass tube at room temperature for 1 h and then centrifuged at 2,000g for 15 min at 22 °C. Aliquots of 1 ml were transferred into sterile cryovials (Greiner laboratechnik, Nürtingen, Germany), flushed with nitrogen, and frozen at –70 °C until further analysis.

CM were isolated by over layering 8 ml EDTA plasma with 5 ml of NaCl solution (density 1.006 kg/L NaCl solution with 0.02% sodium azide and 0.01% EDTA) in a cellulose nitrate tube (Beckman Instruments Inc, CA, USA) and centrifuged in a Beckman SW40 Ti swinging bucket rotor at 20,000 rpm for 1 h at 4 °C. The CM, with Svedberg flotation (Sf) rates >400, were carefully removed by aspiration from the top of the tube. The baseline and 4 h plasma samples were relayered with 5 ml 1.006 kg/L NaCl solution and subjected to centrifugation at 40,000 rpm for 20 h at 20 °C. VLDL, with Sf 20–400, was carefully removed by aspiration from the top of the tube. TRL fractions were divided into three aliquots in cryovials, flushed with nitrogen, and frozen at –70 °C until further analysis.

## Serum Lipid and Apolipoprotein Measurements

Serum lipids were analyzed on a Cobas Mira S (Roche Diagnostics, F. Hoffmann-La Roche Ltd, Basel, Switzerland) with reagents from ABX Diagnostics (Montpellier, France). Total cholesterol (CHOD-PAP) and triglycerides (GPO-PAP) were measured with enzymatic colorimetric methods. Low-density lipoprotein (LDL) and high-density lipoprotein cholesterol were measured by selective inhibition colorimetric assays (LDL cholesterol direct and HDL cholesterol direct, respectively, ABX Diagnostics). Serum apolipoprotein AI (apo-AI) and apolipoprotein-B (apo-B)

were analyzed by turbidimetry on Cobas Mira S with reagents from ABX Diagnostics. Serum apolipoprotein E (apo E) was measured by an enzyme-linked immunosorbent assay, Apo-Tek ApoE™ (PerImmune Inc., Rockville, MD, USA) and genotyping of Apo E was performed according to Hixson and Vernier [19] with slight modifications. An enzymatic immunoassay was used to measure apoC-I in isolated VLDL fractions [10].

## Calculations and Statistics

The number of apoC-I per VLDL-particle was calculated by dividing apolipoprotein concentrations in density fraction S<sub>f</sub> 20–400 by their respective molecular mass (apoB-100 = 549 kDa and apoC-I = 6.5 kDa). The fraction molarity of apoC-I was then divided by the corresponding molarity of apoB. Continuous variables were tested for normal distribution, and they were logarithmically transformed and expressed as geometric means if not normally distributed. Differences between the groups were analyzed by unpaired *t* test for continuous variables and  $\chi^2$  (Chi-square) tests for categorical variables. General linear models for univariate analysis of variance were used for adjustments. Pearson's correlation coefficients were used to examine correlations between continuous variables. Linear regression models were used to test linear trends. All analyses were performed using SPSS (SPSS Inc. Chicago, Illinois, USA) for windows software, version 14.0. Two-sided *P* values (<0.05) were considered statistically significant. Results are expressed as means  $\pm$  1 SD unless otherwise stated.

## Results

Characteristics of the participants are shown in Table 1. Persons with carotid atherosclerosis were older (*P* = 0.026) and had a higher frequency of diabetes mellitus (*P* = 0.006), whereas the healthy controls tended to have higher BMI (*P* = 0.075). Fasting levels of total cholesterol, HDL cholesterol, triglycerides and apolipoproteins were not significantly different between groups, but LDL cholesterol (*P* = 0.049) and apolipoprotein-B (*P* = 0.075) tended to be higher in persons with carotid atherosclerosis. The frequencies of smoking, hypertension, presence of cardiovascular and cerebrovascular diseases and prescription of cardiovascular drugs were similar between groups. The apoE-genotype did not differ between groups, where 58% of the participants had the E3/3 isoform, 30% E3/4, 10% E2/3, 1% E4/4, 1% E2/4 and none had the E2/2 isoform.

Changes in concentrations of total and chylomicron triglycerides after ingestion of the test meal are shown in Fig. 1. Ingestion of a standard high fat meal caused a significant

**Table 1** Baseline characteristics of persons with ( $n = 42$ ) and without carotid atherosclerosis ( $n = 39$ ) included in the study

increase in total and chylomicron triglycerides, which peaked 4 h after the meal and returned to baseline levels after 8 h. Persons with carotid atherosclerosis had delayed clearance of total and chylomicron triglycerides 6 h ( $162.6 \pm 89.1 \mu\text{mol/L}$  vs.  $109.2 \pm 83.7 \mu\text{mol/L}$ ,  $P = 0.028$ ) and 8 h ( $72.3 \pm 52.7 \mu\text{mol/L}$  vs.  $46.9 \pm 38.0 \mu\text{mol/L}$ ,  $P = 0.017$ ) after the meal compared to persons without carotid atherosclerosis.

Plasma VLDL-particles, Sf 20–400, were isolated by preparative ultracentrifugation before and 4 h after intake of a standardized fat-enriched meal and analyzed for triglycerides, total cholesterol, apolipoprotein B and CI (Table 2). The fasting number of apoC-I per VLDL-particle was significantly higher in persons with carotid atherosclerosis compared to controls ( $P = 0.013$ ). The difference between groups remained significant after adjustments for age, sex, BMI and diabetes mellitus ( $P = 0.018$ ). Ingestion of the standard fat meal caused a significant increase in VLDL triglycerides ( $P < 0.001$ ), VLDL cholesterol ( $P < 0.001$ ), apoC-I concentration ( $P < 0.001$ ) and the number of apoC-I molecules per VLDL-particle ( $P < 0.001$ ) without differences between groups (Table 2). The number of apoC-I molecules per VLDL-particle at baseline was strongly correlated to the number of apoC-I molecules per VLDL-particle isolated four hrs after

the meal both in persons with ( $r = 0.53$ ,  $P < 0.001$ ) and without ( $r = 0.74$ ,  $P < 0.001$ ) carotid atherosclerosis. Furthermore, significant correlations were found between the number of apoC-I molecules per VLDL-particle and VLDL cholesterol in the fasting state in persons with and without carotid atherosclerosis ( $r = 0.64$ ,  $P < 0.001$  and  $r = 0.45$ ,  $P = 0.006$ , respectively) and in the postprandial state ( $r = 0.41$ ,  $P = 0.01$  and  $r = 0.32$ ,  $P = 0.03$ , respectively). The levels of VLDL cholesterol and triglycerides at 4 h were not significantly different between groups.

Analyses of linear trends for change in total plaque area across tertiles of apoC-I per VLDL-particle showed that total plaque area ( $P = 0.017$ ) increased with increasing number of apoC-I molecules per VLDL-particle, and this association remained significant after adjustments for age, sex, and BMI ( $P = 0.012$ ) (Fig. 2). No relation was found between apoC-I per VLDL-particle and GSM.

## Discussion

In the present study we found that the number of apoC-I per VLDL-particle in the fasting state was increased in persons with carotid atherosclerosis compared to persons

**Fig. 1** Line graph showing postprandial concentrations of serum triglycerides (upper panel) and chylomicron triglycerides (lower panel) over time after a standard fat meal in persons with ( $n = 42$ ) and without ( $n = 39$ ) carotid atherosclerosis. Values are means  $\pm$  SEM

without carotid atherosclerosis. Furthermore, within the atherosclerosis group, total plaque area was associated with the number of apoC-I per VLDL-particle. To the best of our knowledge, this is the first report that shows a significant linear relation between the number of apoC-I per

**Fig. 2** Line graph showing the increase in total plaque area with increasing number of apoC-I per VLDL-particle under fasting condition in persons with ( $n = 42$ ) and without ( $n = 39$ ) carotid atherosclerosis. Values are means  $\pm$  SEM. The number of apoC-I per VLDL-particle is divided in tertiles (mean, range); T1 (4.6, 3.1–5.7), T2 (6.9, 5.8–8.4), and T3 (14.3, 8.7–27.2)

VLDL-particle and carotid atherosclerotic plaques. These associations remained significant after adjustments for traditional atherosclerotic risk factors and the apoE-genotype. Our findings support the concept that the number of apoC-I per VLDL-particle may serve as an independent marker of carotid atherosclerosis and even play a pivotal role for initiation and progression of atherosclerosis.

In the fasting state, apoC-I is mostly associated with high-density lipoprotein and transferred to TRLs during the postprandial state [20]. In healthy volunteers, Björkegren and coworkers demonstrated a 75–150% transient increase of the number of apoC-I molecules per VLDL-particle, but not in chylomicron remnants, in the postprandial state [11]. In agreement with most studies in healthy individuals [11, 15] and patients with coronary artery disease [14], but not all, [13] we observed a pronounced increase in the number of apoC-I per VLDL-particle from the fasting to the postprandial state (Table 2). Furthermore, we found that the

**Table 2** Composition of VLDL-particles isolated before and 4 h after intake of a standard high fat meal in persons with ( $n = 42$ ) and without ( $n = 39$ ) carotid atherosclerosis

Variables	Carotid atherosclerosis		Controls		Between groups ( <i>P</i> values)

number of apoC-I per VLDL-particle in the fasting state was strongly correlated with the number of apoC-I per VLDL-particle in the postprandial state for both persons with and without carotid atherosclerosis. The latter observation may suggest that the number of apoC-I per VLDL-particle in the fasting state reflects the capacity for apoC-I transfer from high-density lipoprotein to VLDL in the postprandial state.

ApoC-I is known to inhibit apoE-mediated binding of TRLs to receptors, [9] and experimental studies have shown that apoC-I displaces apoE from TRL and thereby delays their hepatic uptake [10, 11]. Thus, delayed clearance of postprandial TRL in the present study and previous studies in patients with coronary and carotid atherosclerosis [1, 2, 14] may in part be explained by apoC-I enrichment of VLDL-particles. Delayed clearance of TRL will increase the time where CETP-mediated cholesterol ester-triglyceride exchange with HDL occur, and may thereby explain the present and previous [13–15] observed relation between apoC-I and cholesterol enrichment in these TRL particles.

Previous studies have shown a non-significant increase in the number of apoC-I per VLDL-particle in the fasting state of healthy individuals with increased intima-media thickness (IMT) [15] and in patients with coronary artery disease, [14] whereas our study showed a significant increase in the number of apoC-I per VLDL-particle in the fasting state in persons with carotid atherosclerosis. The reason for this apparent difference is unknown, but may in part be explained by differences in statistical power. The difference in the number of apoC-I per VLDL-particle was of similar magnitude in our and previous studies, but only 28–30 persons were included in the previous studies compared to 81 persons in the present study.

The most consistent and prominent finding in previous studies was that postprandial TRL was enriched with apo-C-I in patients with coronary artery disease, [14] in healthy individuals with increased intima-media thickness (IMT) [15] and was an independent predictor for IMT in normolipidemic healthy middle-aged men [13]. In contrast, we found a significant enrichment of VLDL with apoC-I in the fasting state among persons with carotid atherosclerosis, but only a tendency to enrichment of VLDL with apoC-I in the postprandial state. However, the total plaque area in persons with carotid atherosclerosis increased linearly with the number of apoC-I molecules per VLDL-particle both in the fasting and the postprandial state.

Many potential confounders may contribute to the apparent differences between our and previous findings. First, we isolated VLDL-particles from plasma 4 h after the meal in contrast to 6 h after the meal in those studies who reported an association between enrichment of TRL with apoC-I and IMT in the postprandial state. As delayed clearance [21] rather than increased peak levels [1, 2] of

TRL are the most consistent finding in patients with atherosclerotic diseases in the postprandial state, isolation of VLDL-particles 4 h instead of 6 h after the meal may conceal potential differences between groups. Second, age, [22] BMI, [23] fasting triglycerides, [21, 23] apoE-genotype, [24] and severity of the atherosclerotic disease are all predictors for the increase in TRL in the postprandial state. We recruited participants with subclinical carotid plaques from a population-based survey in contrast to young myocardial infarction survivors and healthy individuals [13–15]. In the previous studies [13–15] middle-aged men 45–55 years of age and only healthy males with the apoE3/E3 genotype were included. We recruited persons from an older age strata without predefined apoE-genotype criteria for inclusion. Furthermore, the difference in the number of apoC-I per VLDL-particle between groups and the linear relation between the number of apoC-I per VLDL-particle and plaque area remained significant after adjustments for traditional atherosclerotic risk factors and the apoE-genotype.

In conclusion, our study provides evidence for a pivotal role for the number of apoC-I per VLDL-particle in initiation and progression of atherosclerosis. Further experimental and clinical studies are warranted to elucidate the mechanism(s) by which enrichment of VLDL-particles with apoC-I affect the atherosclerotic process.

**Abstract** Photolabeling and site-directed mutagenesis were performed on recombinant *Saccharomyces cerevisiae* 24-C-sterol methyltransferase (SMT) to elucidate the location and role of active site residues involved in AdoMet binding and catalysis. Bioinformatic analysis of the SMT revealed a ten amino acid segment, conserved between L124 and P133, associated with the Rossmann-like fold belonging to AdoMet-dependent methyltransferases. Irradiation of the SMT in the presence of [*methyl*-<sup>3</sup>H<sub>3</sub>]AdoMet directly photolabeled the protein. The specificity of photolabeling was demonstrated by inactivation experiments with structural analogs of AdoMet, including sinefungin. Trypsin digestion of the [*methyl*-<sup>3</sup>H<sub>3</sub>]AdoMet photolabeled Erg6p afforded a single radioactive band in SDS-PAGE gel of 4 kDa. HPLC purification of this material generated a single radioactive fraction. The corresponding <sup>3</sup>H-AdoMet-peptide adduct was subjected to Edman sequencing and the first fifteen residues gave a sequence Gly<sub>120</sub>-Asp-Leu-Val-Leu-Asp-Val-Gly-Cys-Gly-Val-Gly-Gly-Pro-Ala<sub>134</sub> that contained the predicted AdoMet binding site. Amino acid residues in the tryptic digest fragment considered to bind covalently with the AdoMet at Asp125, Cys128, Pro133 and Tyr153 were replaced with leucine and analyzed kinetically and by photolabeling inactivation experiments. The results indicate that one or both of Cys128 and Pro133 are covalently bound to AdoMet.

## Introduction

S-Adenosyl-L-methionine (AdoMet)-dependent methyltransferases (MTases) are a large family of proteins involved in diverse methyl transfer reactions, including *N*-, *O*- and *C*-methyl transfer reactions [1]. Recently, these catalysts have been grouped into five distinct families based on their 3D structures [2, 3]. Kagan and Clarke reported several conserved regions aligned in the same order on the polypeptide chains and separated by comparable intervals; one of them possesses a consensus sequence (V/I/L)(L/V)(D/E)(V/I)G(G/C)G(T/P)G referred to as Motif II diagnostic for the MTases methylating small molecules such as sterol acceptors [4, 5]. In several instances, radiolabeled AdoMet and 8-azido AdoMet were shown to specifically label the MTase using UV radiation [6–11]. In addition, trypsin digestion of AdoMet-bound

proteins followed by chromatography to establish the peptide/amino acid-AdoMet adduct and site-directed mutagenesis experiments of amino acid residues predicted to be associated with the AdoMet binding site demonstrated the requirement for one or more conserved residues (i.e., Tyr, Cys or Pro) or motifs in MTase specific activity [12–14].

A major group of AdoMet-dependent methyltransferases for which no three-dimensional structure exists, yet are essential to the evolution of life through their contribution to the phytosterol (24-alkyl sterol) pathway of microbes and plants [15], are the 24-C-sterol methyltransferases (SMT). The SMTs operate  $C_1$ - and  $C_2$ -transfer activities of different reaction times to form single or multiple biomethyl products [16]. In humans, the 24-alkyl sterol pathway appears to have been lost (a TBLASTIN search of the SMT genome sequence in humans yielded no match for a SMT ortholog), although, human nutrition benefits from dietary supplements of plant sterols [17]. Interestingly, in the course of co-evolution of animals with certain microbes ergosterol-dependent diseases appeared for which the fungal/protozoan SMT is now considered a target of rational drug design and in chemotherapy [18–21]. Studies with a number of SMTs responsible for the formation of phytosterols of the ergostane (C24-methyl) (Fig. 1) and stigmasterane (C24-ethyl) families have led to the formulation of a comprehensive proposal referred to as the steric-electric plug model for the stereochemical mechanism and substrate acceptability of SMT-catalyzed reactions [22].

Previous studies on SMT have focused on the biosynthetic function of the enzyme [15, 23–26] and, in particular, the substrate specificity and inhibitor potency of transition state analogs and mechanism-based inactivators designed to impair the SMT action involved with

disrupting carbon flux to the final 24-alkyl sterols [18]. SMTs can be classified according to their specificity for the sterol acceptor, referred to as SMT1 for  $\Delta^{24(25)}$ -sterols or SMT2 for  $\Delta^{24(28)}$ -sterols [27]; or further categorized by the nature of the substrate nucleus for cycloartenol (E.C. 2.1.1.142), 24(28)-methylene lophenol (E.C. 2.1.1.143) or zymosterol (E.C. 2.1.1.41) [15]. Identification of the sterol binding site was demonstrated through primary structure comparisons, chemical affinity labeling and site-directed mutagenesis studies of fungal, plant and protozoan SMTs [28–34]. These studies unmasked multiple signature motifs that occur in all SMTs referred to as Regions I and III that stretch between Y81 and H90 and Y192 and P201, respectively in the Erg6p; directed mutations of select amino acids in the conserved domains were shown to affect catalytic competency and promote enzyme promiscuity. In contradistinction, a conserved motif of ten amino acids at L124 to Pro133 was detected in the SMT centered toward the N-terminus sandwiched between the catalytic sites of Regions I and III [34], considered to be the AdoMet-binding site.

The ability of such a catalytically similar group of SMTs to utilize a shared methyl donor contrasts to the SMT recognition of different sterol acceptors involved with mono (fungi) and bifunctional (protozoa and plants) behavior [15]. On the one hand, these data suggest a common core that forms a structurally homologous active center of similar amino acids to contact the AdoMet and sterol in SMT1 and SMT2 isoforms. On the other hand, a sequence comparison of the relevant amino acids of the enzymes in the phytosterol pathway fail to reveal a motif or amino acid residue that reflects a common active site for sterol binding, nonetheless, in all cases these enzymes recognize similar sterol features, that is ca. 20 angstroms long, amphipathic and greasy. In related work, kinetic observations of AdoMet binding to the SMT support a single subsite [34], which is not the case for other enzymes that act on lipids where AdoMet can interact with multiple regions on the enzyme [12, 36]. Consequently, whether additional AdoMet binding region(s) exist in the SMT and the number and type of individual amino acids that contact the methyl donor in the active center remains enigmatic.

In this paper, we describe the further application of bioinformatics analysis with UV light-dependent photolinkage of [*methyl*- $^3H_3$ ]AdoMet to establish that a single motif corresponds to the conserved sequence considered to represent the AdoMet binding site of the SMT from *Saccharomyces cerevisiae*. The specificity of the photolinkage and essential nature of Cys128 and Pro133 contained in the covalently formed AdoMet-peptide adduct are demonstrated for the first time by a combination of sequence specific cleavage of the enzyme–ligand adduct with trypsin digestion followed by HPLC analysis of the trypsin digest

**Fig. 1** C-methylation reaction catalyzed by the wild-type yeast 24-C-sterol methyltransferase (SMT) and photolabeling reaction to yield a SMT-AdoMet adduct

fragments and site-directed mutagenesis experiments. The results reported here show close resemblance to motif-II of Class-I MTases with a typical sequence *GXGXG*, regarded as the hallmark of a nucleotide or AdoMet binding site [5]. In view of the high sequence similarity among several SMTs in this AdoMet binding region, the information generated in this study could potentially serve to reveal similar findings in the SMT family of proteins expressed in diverse species ranging from protozoa to fungi to plants.

## Experimental Procedures

### Materials

The sources and preparation of substrates of the wild-type yeast SMT catalyzed reaction are described in our earlier papers [28–34]: zymosterol, [ $3\text{-}^3\text{H}$ ]zymosterol (sp. act. 9  $\mu\text{Ci}/\mu\text{mol}$ ), AdoMet iodide salt, and [ $\text{methyl-}^3\text{H}_3$ ]AdoMet (NEN, diluted with AdoMet to a sp. act. of 10  $\mu\text{Ci}/\mu\text{mol}$ ). Sinefungin (SF), 5'-Deoxy-5'-(methylthio)adenosine (MTA), S-isobutyladenosine (SIBA) were from Sigma.  $\text{H}_2\text{O}_2$  solution (50%) was from HACH Co. Ames, Iowa. Trypsin (proteomics-grade) was purchased from Sigma. Quick Change site-directed mutagenesis kit was purchased from Stratagene. Custom oligonucleotides were synthesized by Texas Tech Biotech Core Facility. Isopropyl  $\beta$ -D-thiogalactoside (IPTG) was purchased from Research Products International Corp. Bradford protein assay kit and protein electrophoretic supplies were obtained from Bio-Rad. All other reagents and chemicals were from Sigma or Fisher unless otherwise noted.

### General Methods

General methods for cloning, expression of yeast-SMT (*ERG6*), and homogenate preparation were as described [32]. Protein concentration contained in the crude SMT enzyme was determined by Bradford method with bovine serum albumin (BSA) as the standard using commercial reagents from Bio-Rad. Otherwise, the determination of pure SMT concentration was measured at  $A_{280}$  using extinction coefficient of  $58,370\text{ cm}^{-1}\text{ M}^{-1}$  for the native SMT and considering the tetrameric composition of the native protein (ca.  $M_r$  172 kDa).

### SMT Activity Assays

The standard assay conditions for enzyme activity and kinetic analysis were as described [29–34]. To summarize, the standard assay for the wild-type or mutants of yeast-SMT enzyme was performed in 600  $\mu\text{L}$  total volume, with 1 mg/mL total protein (100,000 $\times$ g fraction) prepared by

cell lysis (using French press) with saturating levels of co-substrates, zymosterol and [ $\text{methyl-}^3\text{H}_3$ ]AdoMet. The reaction was quenched with an equal volume of methanolic KOH and methylated product was extracted with hexane (Fisher) three times and dried. The activity in each case was measured by liquid scintillation counting (Beckman) against a suitable blank. The initial velocity data was determined using Sigmaplot 2001 with the enzyme kinetics module software package. Data were fitted to the equation  $v = V_{\text{max}}S/(K_m + S)$  using a nonlinear least-squares approach. Kinetic constants  $\pm$  standard errors were never greater than 5% of the experimental measurement, and  $R^2$  values were between 0.90 and 0.99. For  $k_{\text{cat}}$  analysis, partially purified SMT protein preparations from Q-Sepharose anion exchange chromatography (ca. 80% pure SMT) was used. Generally, the activity assay contained 0.3  $\mu\text{M}$  SMT and varied amounts of zymosterol (5–100  $\mu\text{M}$ ) and a fixed [ $\text{methyl-}^3\text{H}_3$ ]AdoMet concentration of 100  $\mu\text{M}$  in buffer A (50 mM Tris-HCl, 2 mM  $\text{MgCl}_2$ , 2 mM 2-mercaptoethanol, and 20% (v/v) glycerol, pH 7.5). The assays were performed in triplicate with variation among the trials no greater than  $\pm$  5%. For reaction mixtures that generated activity, the experiment was repeated with saturating amounts of sterol and AdoMet and the product distribution examined by GC-MS according to the established protocol [29].

### Binding Assays and Immunoblotting

Binding assays for AdoMet and zymosterol were performed using the equilibrium dialysis and filter-binding method respectively, as previously reported [29]. Varied concentrations of ligands-[ $\text{methyl-}^3\text{H}_3$ ]AdoMet (0–40  $\mu\text{M}$ ); [ $3\text{-}^3\text{H}$ ]zymosterol (0–28  $\mu\text{M}$ ), were incubated separately with purified SMT protein preparations in buffer A, pH 7.5 at 35  $^\circ\text{C}$  for the desired time on a shaking water bath. Nonspecific binding was estimated using 100,000 $\times$ g supernatants of BL21(DE3) cells transformed with a pET(23a+) blank vector, the same expression system used in expressing SMT cDNA. In the case of the filter binding method, bound and free ligands were separated by filtration over Whatman GF/C filters (pretreated with 0.1% BSA) with ice cold buffer A. Binding parameters ( $K_d$ ,  $B_{\text{max}}$ ) were determined by nonlinear curve fitting for one-site ligand saturation. *Saccharomyces cerevisiae* SMT-specific antibody produced by Invitrogen<sup>®</sup> was purified using a Bio-Rad<sup>®</sup> IgG purification kit. For immunoblotting, Q-sepharose purified wild-type and mutant proteins resolved on a 12% SDS-PAGE gel were electrophoretically transferred on to a nitrocellulose membrane and SMT protein was detected using polyclonal anti-yeast SMT as a primary antibody (Invitrogen) and anti-Rabbit IgG-HRP conjugate as a secondary antibody with color development using a

HRP substrate kit (Bio-Rad) for appropriate time at room temperature.

#### AdoMet Photoaffinity Labeling

The wild-type yeast-SMT was semi-purified on a Q-Sepharose column previously equilibrated with HEPES Buffer [10 mM HEPES, 2 mM MgCl<sub>2</sub>, 1 mM EDTA and 5% glycerol(v/v), pH 7.5]. The procedure for Q-Sepharose anion exchange chromatography remained the same as the earlier protocol [34] except for the change in the buffer system. The change in the buffer system is reported due to the observation of enhanced AdoMet photolabeling and enzyme activity in the case of HEPES buffer compared to the Tris buffered system used earlier. About 0.3 mg of Q-Sepharose semi-purified wild-type yeast-SMT protein (~80% pure, equivalent to 1.74 nmol) was made up to a 2.5 mL solution in HEPES Buffer, pH 7.5 and kept on ice. [*methyl*-<sup>3</sup>H<sub>3</sub>]AdoMet (10 Ci/mmol, Perkin Elmer) equivalent to 27.5 μCi or 18.34 nmol was dried under a low stream of N<sub>2</sub> to remove the sulfuric acid content, resuspended in 500 μL of HEPES Buffer, pH 7.5 to ensure the optimal pH conditions and added to the wild-type SMT protein solution prepared above. The mixture was incubated at 35 °C for 45 min in a shaking water-bath to allow the AdoMet to bind to SMT under steady-state conditions. The ice-cooled reaction mixture was transferred to a pre-chilled 96-well titer plate (Whatman®) with 100 μL of the sample placed in each well and illuminated with a UV lamp at short wavelength (254 nm) placed 1 cm above the sample for 45 min. The samples were mixed intermittently every 5 min. The irradiated samples were pooled and dialyzed using Slide-A-Lyser cassettes (Pierce) with HEPES Buffer, pH 7.5 at 4 °C to remove the unbound AdoMet. The samples were concentrated using a 10-kDa cut off ultrafiltration centrifugal device (Centricon) and stored at -20 °C until further use.

#### Fluorography

The AdoMet-bound SMT samples were resolved on a 12% SDS-PAGE. After staining (Coomassie Blue) and destaining, the gels were soaked in Fluoroenhancer solution (Kodak™, Perkin Elmer) and gently agitated for 30 min and dried on a gel dryer for 3–4 h. Films were developed by placing the dried gel over a blue sensitive X-ray film (Kodak X-Omat AR) in a cassette and incubated at -80 °C for 3 weeks or until the bands were visible.

#### Time-Dependent Inactivation and Inhibition Studies

The protocol involved similar photoaffinity labeling conditions as described above. Aliquots of 50 μL of the photolabeled mixture were siphoned out at different time

intervals and assayed for enzyme activity at saturating concentrations of co-substrates, zymosterol and [*methyl*-<sup>3</sup>H<sub>3</sub>]AdoMet (100 μM each) under standard assay conditions. For data analysis, the dpm value obtained for the samples were transformed into % activity based on the sample at 0 min.

To test the AdoHcy analogs [Sinefungin (SF), 5'-Deoxy-5'-(methylthio)adenosine (MTA), *S*-isobutyladenosine (SIBA)] as inhibitors against AdoMet in a SMT catalyzed reaction, typical activity assays (in triplicates) were set up with varied [*methyl*-<sup>3</sup>H<sub>3</sub>]AdoMet concentration from 5 to 100 μM with a fixed zymosterol concentration of 100 μM and the inhibitor at a particular concentration (SF, 0.1–10 μM; MTA, 1–100 μM; SIBA, 1–100 μM), under standard assay conditions. The data were fitted into Michaelis–Menton equations for competitive [ $v = V_{\max}/\{1 + (K_m/S) \times (1 + I/K_i)\}$ ] or non-competitive [ $v = V_{\max}/\{(1 + I/K_i) \times (1 + K_m/S)\}$ ] or uncompetitive [ $v = V_{\max}/(1 + I/K_i + K_m/S)$ ] inhibition patterns to determine the most favorable kinetic pattern of inhibition for each inhibitor. Lineweaver-Burk plots were generated in each case using an enzyme kinetics module in Sigmaplot 2001 software. Minimal variation was detected in the experimentally determined kinetic constants with standard errors of 2–10% between the trials.

These inhibitors were also tested under AdoMet photolabeling to determine their effect on AdoMet photolabeling capabilities on the wild-type yeast-SMT enzyme. Under these conditions, the pre-incubated wild-type yeast-SMT samples with [*methyl*-<sup>3</sup>H<sub>3</sub>]AdoMet alone and AdoHcy analogs combined with [*methyl*-<sup>3</sup>H<sub>3</sub>]AdoMet were photo-irradiated for 45 min under the standardized conditions outlined above. The samples were dialyzed against HEPES Buffer, pH 7.5 to remove the unbound material and analyzed for radioactivity by liquid scintillation counting to establish the extent of binding in the presence and absence of each inhibitor.

#### H<sub>2</sub>O<sub>2</sub> Digestion

The specific activity of the AdoMet photolabeled wild-type SMT protein resolved on a 12%-SDS-PAGE gel was determined separately using the H<sub>2</sub>O<sub>2</sub> digestion procedure adapted from a previously reported protocol [9]. After staining and destaining, the bands corresponding to 43 kDa were excised from the gel, cut into 1 mm<sup>2</sup> pieces and transferred to a scintillation vial; 1 mL of chilled 50 % H<sub>2</sub>O<sub>2</sub> solution was added and incubated at 70 °C for 20 h in a water bath and 5 mL of scintillation cocktail (Optiphase HiSafe 3, Perkin Elmer) was added to the vials and analyzed by liquid scintillation counting. A control was set up using a blank piece of gel that contained no protein.

## Electroelution

The SMT bands corresponding to 43 kDa were electroeluted using Electro-Eluter Concentrator (C.B.S. Scientific Company, Inc. Del Mar, CA, USA) prior to trypsin digestion. The elution was carried out for a total duration of 15–20 h as per manufacturer's instruction. To determine the % recovery, an aliquot of electroeluted sample was counted for radioactivity. The yield was greater than 50% in the majority of the trials. The electroeluted SMT-AdoMet samples were pooled and concentrated using ultrafiltration centrifugal devices (Centricon, 10-kDa cut off membrane) and dialyzed with of 0.1 M  $\text{NH}_4\text{HCO}_3$  Buffer, pH 8.5 suitable for further trypsin digestion.

## Trypsin Digestion

The trypsin digestion of the enzyme–ligand adduct was initiated by addition of proteomics-grade trypsin (Sigma) solution (prepared in 1 mM HCl) to the electroeluted protein sample. The substrate to enzyme-S/E ratio for the tryptic digestion was 100–5 (w/w). The resulting reaction mixture was incubated for 8 h at 37 °C. A control was set up with trypsin in 0.1 M  $\text{NH}_4\text{HCO}_3$  Buffer, pH 8.5 and incubated under similar conditions as above. The tryptic digestion was quenched by the addition of 5  $\mu\text{L}$  of glacial acetic acid (HPLC grade) to the samples and rapid freezing of the reaction mixture in liquid  $\text{N}_2$  and stored at  $-20$  °C until use. The samples were resolved on a 20% SDS-PAGE gel and the radioactive peptides migrating in the gel identified either by fluorography and/or  $\text{H}_2\text{O}_2$  digestion.

## Radiolabeled Peptide Purification

As a primary step to get rid of most of the impurities, the trypsin-digested material was filtered using a 10-kDa cut off ultrafiltration centrifugal device (Sigma) to collect the pass through. The radiolabeled samples were resuspended in 0.1% Trifluoroacetic acid (TFA, HPLC grade, Biochemica) prior to HPLC purification. Preparative purification of the radiolabeled peptide was achieved by reverse-phase HPLC using  $\text{C}_{18}$  Vydac<sup>TM</sup> (4.6 mm  $\times$  250 mm) with a solvent system comprising of 0.1% TFA in both water (A) and acetonitrile (B). The peptides were eluted with a linear gradient of 0–99% B at a constant flow rate of 0.5 mL/min with the column temperature maintained at 15 °C. The eluant was monitored using a multiple-diode array detector at 210, 240 and 280 nm. The radioactive peak fractions were identified by liquid scintillation counting of fractions collected every minute. The radioactive peak fractions were re-chromatographed under similar conditions until they were pure for further analysis.

## MALDI-TOF Spectrometry

The samples were prepared by “dried-droplet” method. To obtain a better coverage of components in a mixture, spectra were acquired from the samples prepared with different matrix solution conditions [35]. The matrix solutions used were: 20 mg/mL  $\alpha$ -cyano-4-hydroxy-*trans*-cinnamic acid (Sigma) or 20 mg/mL 2,5-dihydrobenzoic acid [DHB, Sigma] in 0.1% TFA in 50% acetonitrile in water solution. The matrix additive-1 mg/mL 2-methoxybenzoic acid (Sigma) was added to the DHB solution for detection of peptides larger than 3 kDa. A mixture of 1  $\mu\text{L}$  each of matrix solution and peptide sample (1 pmol/ $\mu\text{L}$ ) was applied to the gold target and air dried. A control was set up by using synthetic peptides (Biosynthesis Inc, Lewisville, TX, USA) with known molecular weights. For these purposes, peptides corresponding to Regions I (L63-R93, 3.7 kDa), II (G120-R135, 1.48 kDa) and a typical tryptic fragment (L203-K212, 1.2 kDa) of yeast-SMT were used as reference specimens. The individual mass was analyzed using laser intensity between 2,500 and 3,000 units. Minimal variations of 1–2% were observed in the experimental data compared to the established mass for peptide standards.

## Site-Directed Mutagenesis of SMT

Site specific mutations at various positions along the pET23a(+)-*ERG6* template were carried out using the QuickChange<sup>TM</sup> (QC) site directed mutagenesis kit (Stratagene) as per manufacturers' instructions. The oligonucleotide primers used for mutagenesis are listed in Table 1. The relevant mutation was confirmed by automated sequencing at the Texas Tech Core facility. Routine screening of the mutants for activity assays are as previously described [34].

## AdoMet Photolabeling of the Synthetic Peptide

The synthetic peptide corresponding to the 3.9-kDa peptide fragment obtained in this study was subjected to purification by HPLC on a  $\text{C}_{18}$  Vydac<sup>TM</sup> (4.6 mm  $\times$  250 mm) instrument with a solvent system comprising of 0.1% TFA in both water (A) and acetonitrile (B). The peptide was eluted with a similar gradient system used for purification of radioactive peptide(s) mentioned before. The purified material was dried under  $\text{N}_2$  to remove the solvent and resuspended in HEPES buffer, 7.5. [*methyl*- $^3\text{H}$ ]AdoMet was added in a stoichiometric ratio of peptide: AdoMet of 1:10 and the mixture was photo-irradiated under similar conditions outlined for wild-type Erg6p. The photolabeled sample was analyzed by HPLC radio-counting to determine the amount of photolabeling. The samples were

finally resuspended in 0.1 M  $\text{NH}_4\text{HCO}_3$  buffer, pH 8.5 in case to be subjected for further tryptic digestion. A similar sample prepared with cold-AdoMet was subjected to further analysis by MALDI/MS and/or Edman degradation (Macro Core Facility, Penn State College of Medicine, Hershey, PA, USA) to determine the derivatized amino acids within the synthetic peptide.

## Results

### Photoaffinity Labeling of Yeast-SMT with AdoMet

Preliminary photolabeling experiments, performed with the purified SMT and [*methyl*- $^3\text{H}$ ]AdoMet generated a covalently labeled enzyme–ligand adduct detected by fluorography (Fig. 2). The specificity of photolabeling was further demonstrated by inactivation experiments. Heat-inactivated enzyme preparations were used as negative controls in all experiments (data not shown) since irradiation of denatured SMT in the presence of [*methyl*- $^3\text{H}$ ]AdoMet

did not generate any appreciable levels of photolabeling. During the course of our initial standardization procedures, we observed not only an increased specific activity for SMT catalysis but also AdoMet photolabeling efficiency by a factor of three when a buffer change was introduced to HEPES in our assays (data not shown). Therefore, we chose the HEPES buffer system for all the subsequent photoaffinity labeling treatments. The AdoMet photoaffinity labeled SMT from the Tris and HEPES buffered reaction mixtures resulted in similar outcomes in fluorography producing single radioactive band (data not shown).

In order to specify the optimal photo-irradiation time, we performed a time-dependent inactivation experiments with the wild-type yeast SMT. The photolabeled-SMT aliquoted under differing time periods was assayed in the presence of zymosterol using the standard assay conditions. Approximately 50% of the SMT activity was lost during the first 30 min of photo-irradiation and less than 10% of the activity was retained at the end of 60 min (Fig. 3). Based on these results, a 45 min of photo-irradiation time suited best for the routine-SMT photolabeling studies.

**Fig. 2** SDS-PAGE analysis (12%) of AdoMet photolabeling of wild-type yeast SMT. *Lane 1* electroeluted sample of wild-type SMT species bound to [*methyl*- $^3\text{H}$ ]AdoMet; *Lane 2* fluorography of the sample as in *lane 1* showing single radioactive band corresponding to 43 kDa; *Lane 3* low molecular-weight range protein marker. The respective M.Wt in kDa is indicated

**Fig. 3** Time-dependent inactivation of Wild-type Yeast-SMT against AdoMet photolabeling. The % activity values were normalized to the protein sample without AdoMet photolabeling (0 min of photolabeling). SMT activity in each reaction mixture was determined as per standard assay conditions using saturating concentrations (100  $\mu\text{M}$  each) of co-substrates, zymosterol and [*methyl*- $^3\text{H}$ ]AdoMet. Each data point represents an average of three independent determinations with standard errors under 10%

## Effect of AdoMet Analogs on Photolabeling

The AdoHcy analogs [SF, MTA, SIBA (Fig. 4)] were shown earlier to competitively inhibit the wild-type SMT [37]. Experiments were performed to determine the effect of these AdoMet analogs on photolabeling of the enzyme in the presence of AdoMet. Steady-state kinetic experiments revealed competitive-type inhibition kinetics against AdoMet with dissociation constants ( $K_i$  values) of 1.3  $\mu\text{M}$  (SF), 22  $\mu\text{M}$  (MTA) and 58  $\mu\text{M}$  (SIBA) (Fig. 5). These observations are consistent with the expected behavior of the AdoMet analogs to compete for the same binding site on the enzyme surface. A similar trend was observed during the AdoMet photolabeling of the SMT enzyme. With the addition of SF, MTA or SIBA to the photolabeling mixture of [*methyl*- $^3\text{H}$ ]*AdoMet* and SMT, the percentage of reduction in the AdoMet photolabeling of SMT ranged from 85 to 50 (Fig. 6). There was a direct correspondence between the change in binding constants and the photolabeling results of the AdoMet analogs. These results agree with the proposed competitive nature of AdoHcy analogs against AdoMet [10, 37].

## Limited Proteolysis of the SMT-AdoMet Adduct

In order to localize the AdoMet binding region in wild-type yeast-SMT, we subjected the electroeluted [*methyl*- $^3\text{H}$ ]*AdoMet* photolabeled samples of SMT protein to trypsin digestion to generate small peptide fragments that can be easily monitored on a 20% SDS-PAGE. For these studies, a procedure involving  $\text{H}_2\text{O}_2$  treatment of the excised SDS-PAGE gel slices was employed for the rapid detection of radioactivity associated with the peptide fragments. As shown in Fig. 7, more than 90% of the radioactivity applied to the SDS-PAGE gel electrophoresis was recovered and ca. 95% of the radioactivity migrates in a single zone at ca. 3.5–4 kDa. An independent experiment using fluorography confirmed that a single radioactive band migrates in the SDS-PAGE gel electrophoresis around 4 kDa (Fig. 7).

## Identification of the Labeled Adduct

Since we had established above that a single AdoMet-peptide adduct of 4 kDa was formed by the limited proteolysis, we initially chose ultrafiltration with a 10 kDa cut off membrane to remove undigested material and other potential impurities larger than 10 kDa. The resulting peptide mixture was injected into the reverse-phase-HPLC eluted with the combination of acetonitrile and water as described in the “[Experimental procedures](#)”. The radioactivity of individual fractions containing the peptide was determined, and the corresponding mass monitored by UV detection at 210 nm. Figure 8 (Panel A) shows a single radioactive peak fraction that elutes between 38 and 40 min, accounting for >80% of the total radioactivity injected into the HPLC. The elution profile remained consistent with several successive HPLC runs on the same column. A set of peptide standards were synthesized that ranged in size and corresponded to various segments of the SMT primary structure (Fig. 8, Panel B). A synthetic peptide was prepared that corresponded to the predicted composition of a yeast SMT peptide formed by limited trypsin digestion and that possesses a molecular weight of 3.9 kDa, close to the molecular weight of the adduct obtained from the 20% SDS-PAGE gel electrophoresis experiment. This synthetic peptide was photolabeled with AdoMet and the resulting adduct injected into the HPLC where the radioactive AdoMet-peptide adduct eluted at the same time as the synthetic peptide of 3.9 kDa (Fig. 8, Panel B).

To establish the exact mass of the radioactive AdoMet-peptide adduct, a separate experiment was performed to generate the non-radioactive adduct for MALDI-TOF analysis. Our initial MALDI-TOF analysis using  $\alpha$ -cyano-4-hydroxy-*trans*-cinnamic acid as the matrix material did not show any mass for the peptide. It was not clear whether the recognition of no mass was due to our limits of detection or due to the hydrophobic nature of the peptide. On the other hand, the synthetic peptides corresponding to

**Fig. 4** Structures of AdoMet analogs tested as inhibitors of the SMT

**Fig. 5** Lineweaver-Burk plots for the inhibition of yeast-SMT by AdoHcy analogs. **a** SF Sinefungin [0.1  $\mu\text{M}$  (filled circles), 0.5  $\mu\text{M}$  (open circles), 1  $\mu\text{M}$  (filled inverted triangles)]; **b** MTA 5'-Deoxy-5'-(methylthio)adenosine [1  $\mu\text{M}$  (filled circles), 10  $\mu\text{M}$  (open circles), 50  $\mu\text{M}$  (filled inverted triangles), 100  $\mu\text{M}$  (open inverted triangles)]; **c** SIBA S-isobutyladenosine [1  $\mu\text{M}$  (filled circles), 10  $\mu\text{M}$  (open circles), 50  $\mu\text{M}$  (filled inverted

triangles), 100  $\mu\text{M}$  (open inverted triangles)]. The kinetic pattern in all the cases was found to be competitive as determined by Sigma plot Enzyme kinetics module. Assays were performed as per standard conditions mentioned under "Experimental procedures" using fixed zymosterol of 100  $\mu\text{M}$  and varied [*methyl*- $^3\text{H}$ ]AdoMet (5, 10, 20, 50, 100  $\mu\text{M}$ ) concentrations. Each data point represents a mean of three independent determinations with standard errors under 10%

**Fig. 6** Effect of AdoHcy analogs on AdoMet photolabeling efficiency of wild-type yeast-SMT. The % photolabeling values are based on the wild-type SMT protein samples labeled to AdoMet under normal photoaffinity labeling conditions. The concentration of inhibitor used are as follows: Sinefungin (SF), 100  $\mu\text{M}$ ; 5'-Deoxy-5'-(methylthio)adenosine (MTA), 200  $\mu\text{M}$ ; S-isobutyladenosine (SIBA), 200  $\mu\text{M}$ . The values represent a mean of three independent determinations with standard errors between 4 and 12%

different tryptic fragments of wild-type Erg6p, when concurrently used as peptide standards, under the similar conditions and similar concentrations revealed mass with less than 1% errors when compared to the respective established mass. Owing to the hydrophobic nature of the peptide, we decided to use 2,5-dihydrobenzoic acid (DHB) with the additive 2-methoxybenzoic acid as the matrix material for further analysis. This procedure allowed us to predict a mass of 3.9 kDa for the radioactive peptide, which is consistent with the 20% SDS-PAGE analysis; and

**Fig. 7** SDS-PAGE analysis (20%) of AdoMet photolabeled tryptic digest fragments by  $\text{H}_2\text{O}_2$  digestion and autoradiography. Lane 1 polypeptide marker (kDa) in the order: 26.6, 16.9, 14.4, 6.5, 3.5 and 1.4; Lane 2 tryptic digest sample of AdoMet photolabeled wild-type yeast SMT; Lane 3 fluorography of the tryptic digested sample of SMT as in lane 2. The radioassay of gel samples by  $\text{H}_2\text{O}_2$  digestion are indicated by histogram in the figure. The values from  $\text{H}_2\text{O}_2$  digestion represent a mean of three independent determinations obtained from three successive SDS-PAGE runs with standard errors between 5 and 12%

for the synthetic peptide standards, the mass was identical to the previous determination, indicating similar level of accuracy (Supplementary Fig. 1).

Due to the large size of the AdoMet-peptide fragment adduct, Edman sequencing of the purified radioactive peak fraction was performed for the first fifteen cycles. This yielded a sequence  $\text{NH}_2\text{-Gly-Asp-Leu-Val-Leu-Asp-Val-Gly-Cys-Gly-Val-Gly-Gly-Pro-Ala}$ . When compared with the established primary and(or) cDNA sequence of Erg6p, the peptide sequence could be clearly assigned to residues

**Fig. 8** HPLC of the tryptic digest of AdoMet Photolabeled wild-type yeast-SMT (**a**). The UV detector response was monitored at 210 nm. The fractions collected every minute were radioassayed by liquid scintillation counting. The radioactivity associated with each fraction is shown as a line and scattered plot. **b** HPLC of synthetic peptides used as reference specimens. The operating conditions of the HPLC in **b** were the same as the conditions used in the run shown in **a**

120–134. Due to unanticipated shortcomings, the specific amino acid residues derivatized in this peptide could not be established by means of radioassay of PTH derivative obtained from each cycle of Edman degradation. Yet, during the sequencing of the adduct, there was a huge drop in the amino acid yield starting from the second cycle which could only be attributed to the fact that the peptide fragment was bound to AdoMet. We were able to account for only 1.3 kDa for the first fifteen residues from the total of 3.9 kDa determined by MALDI-TOF spectrometry. Therefore, to get a complete peptide fragment length and taking into consideration the trypsin recognition sites and the mass from the AdoMet, we screened the downstream region of Erg6p starting from the 134th residue. Extension of peptide length to incorporate three immediate trypsin cut sites, the size of the peptide fragment exactly matched to 3.92 kDa, however the mass of the AdoMet could not be

accounted for. One explanation for these results could be the elimination of AdoMet during the MALDI-TOF MS analysis. Based on these observations, the peptide fragment bound to AdoMet was determined to span the Erg6p from 120 to 157, a 38 residue segment with a highly conserved motif of L124 to P133 (Fig. 9).

#### Mutational Analysis of AdoMet Binding Region

Since Edman sequencing of the AdoMet-peptide adduct failed to establish the relevant amino acids covalently bound to AdoMet, we turned our efforts to site-directed mutagenesis of putative residues that might engage AdoMet during photolabeling. Sequence analysis of the Erg6p AdoMet binding domain compared with 17 different SMT species belonging to SMT1 and SMT2 type isoforms revealed several absolutely conserved amino acid residues

Species	Type	Mass of the tryptic fragment: 3.9 kDa		Total amino acids	% Identity

**Fig. 9** Partial sequence alignments of 18 fungal and plant SMTs. The alignments are based on the sequence obtained from the Edman degradation of the [methyl-<sup>3</sup>H<sub>3</sub>]AdoMet wild-type yeast SMT peptide adduct. The appropriate amino acid numbering for the wild-type yeast-SMT peptide fragment is indicated. The 18 SMTs, indicated by the number are as follows: 1 *Saccharomyces cerevisiae*, CAA52308; 2 *Candida albicans*, AAC26626; 3 *Schizosaccharomyces pombe*, CAB16897; 4 *Neurospora crassa*, CAB97289; 5 *Oryza sativa*, AAC34989; 6 *Glycine max*, AAB04057; 7 *Arabidopsis thaliana 1*, AAG28462; 8 *Ricinus communis*, AAB62812; 9 *Zea mays*,

AAC04265; 10 *Triticum aestivum*, AAB37769; 11 *Nicotiana tabacum 1*, AAC34951; 12 *Gibberella zeae*, EAA70778; 13 *Trypanosoma brucei*, AAZ40214; 14 *Oryza sativa sub sp. Japonica*, AAC34988; 15 *Nicotiana tabacum 2*, T03848; 16 *Arabidopsis thaliana 2-1*, CAA61966; 17 *Arabidopsis thaliana 2-2*, AAB62809; 18 *Pneumocystis carinii*, AAK54439. The type of each SMT, total length of the respective primary sequence and % identities within Region-II signature motif and in the 38 residue long partial fragment are indicated

(Fig. 9). Within the domain, a stretch of highly conserved residues is boxed and is referred to as Region-II to signify the similarities with GXGXG or GXG motif which is recognized as a hallmark of nucleotide (AdoMet) binding site in the Class-I type of AdoMet dependent methyltransferases superfamily of proteins [5]. The % identity within the Region-II motif ranged from 90 to 100% and 47–79% for the entire 3.9-kDa fragment relative to Erg6p sequence (Fig. 9). Overall, we were able to find 12 absolutely conserved amino acids within the 38 residue long Erg6p AdoMet binding segment. Thus, our plan was to determine which of the conserved residues in the adduct are directly involved with AdoMet binding. In other MTases, the AdoMet photoincorporation site has been established to be either a tyrosine, proline, aspartate (glutamate) or cysteine residue [6–12, 38], which are present in the radioactive tryptic fragment at Asp125, Cys128, Pro133, Asp152 and Tyr153. In this study, the relevant amino acids were replaced with leucine, phenylalanine or serine. The resulting proteins were expressed, partially purified and tested kinetically and via photo-incorporation.

Previously, through non-conservative mutagenesis experiments of conserved acidic residues in the SMT, the Asp125 and Asp152 were identified as key residues to AdoMet binding [34]. In similar fashion, to examine the role of Cys128 and Pro133, leucine, mutants were constructed and screened for SMT activity. These mutants exhibited no change either in protein purification process or

native molecular weights compared to the wild-type yeast-SMT enzyme (data not shown). However, both Cys128Leu and Pro133Leu mutants turned out to be inactive (Table 2). The lack of catalytic competence was investigated further through binding studies for the two substrates which either showed AdoMet binding to be poor (Cys128) or no binding even at the highest concentration of AdoMet tested at 40 μM (Pro133). On the other hand, both mutants continued to bind zymosterol within the margin of acceptable binding for catalytic behavior. A second mutation of Cys128 to Ser was made to determine the importance of the thiol group to catalysis. The Cys128Ser mutant retained nearly 50% of the SMT activity compared to the wild-type (Table 2), suggesting that the Cys128 sulfur group is not essential to activity. In the C-terminal of this peptide fragment, the absolutely conserved Tyr residue (Tyr153) was replaced with phenylalanine or leucine. In both of the mutants, catalytic activity was retained (Table 2). Earlier, the mutational analysis of conserved acidics in the yeast-SMT suggested a potential role of Asp152 residue towards AdoMet binding [34]. The new results suggest that Cys128 and Pro133 can be important to AdoMet binding and ruled out Tyr153 as essential to activity. In further support to this proposal, none of the active mutants exhibited a gain in function where the zymosterol substrate was converted to fecosterol, which in turn can be converted to multiple 24-ethyl sterol products (data not shown), as reported for mutants of Region 1 [29, 30]. In order to examine these

residues further as potential AdoMet photoincorporation site(s), we subjected the corresponding mutants to AdoMet photoaffinity labeling studies. Both Cys128Leu and Pro133Leu mutants failed to show any AdoMet labeling while the acidic mutants, Asp125Leu and Asp152Leu showed AdoMet photolabeling efficiencies of 30–40% and the Tyr153Phe mutant exhibited approximately 60% AdoMet photolabeling action compared to the native Erg6p (Table 2). These results indicate that one or both Cys128 and Pro133 can be covalently bound to the AdoMet during the photolabeling of the wild-type Erg6p.

## Discussion

The SMTs are highly conserved sterol catalysts and differ from other phytosterol biosynthetic enzymes in the type and timing of the chemical reaction employed and differ kinetically from other MTases with respect to substrate recognition of the acceptor molecule. To date, no structural data is available for the yeast sterol methyltransferase that shows the AdoMet binding pocket. However, by employing a highly specific photoaffinity labeling procedure in the presence and absence of AdoHcy analogs, we observed high specificity of photolabeling of AdoMet to Erg6p, indicating AdoMet is covalently bound to the enzyme. Our research findings also revealed the first fifteen residues of the AdoMet-Erg6p peptide adduct are associated with a highly conserved (90–100%) motif among phylogenetically diverse SMTs (i.e., Region II) linked to the GXGXX

motif of Class-I type MTases. From these observations, it would appear that the SMT is a Class-I type MTase with a AdoMet binding fold in the active site similar to related MTases [6–12, 38].

Although an exacting analysis of the peptide labeled species was not forthcoming from the initial work, subsequent functional analysis of key residues in the tryptic digest fragment by directed mutation indicated that two of them can interact with AdoMet after the photolabeling procedure. In a leucine scanning experiment, residues mutated at positions 125, 128, 133 and 152 and 153, considered as possible contact amino acids in the peptide, were found to generate different activities that ranged from none to 100%. For the Cys128Leu and Pro133Leu mutants, catalytic competence was lost in conjunction with lost photolabeling activity, suggesting these residues contact AdoMet in the active site. Conservative replacement of Cys128 with Ser resulted in 50% of SMT activity and a slightly lower binding affinity ( $K_d$ ) towards AdoMet relative to the native Erg6p, indicated that Cys128 interacts with AdoMet via hydrogen bonding interactions. On the other hand, the Tyr153 mutants behaved similarly to the wild-type Erg6p suggesting they are not in contact with AdoMet directly. The acidic residues mutated to leucine at Asp125 and Asp152 were inactive, yet reactive to photoaffinity labeling; they exhibited reduced photolabeling efficiency of 30–40% compared to the wild-type. Consequently, these residues are not likely attached to AdoMet upon photolabeling. Still unclear is which of these residues in the adduct bind AdoMet in covalent fashion. To resolve

these anomalies, future experiments to unmask the catalytic amino acids bound to AdoMet after the photoaffinity labeling experiments are warranted.

SMTs have clearly been shown to be essential to normal growth and maturation of microbes and plants as well as a target for rational drug design in ergosterol-dependent diseases. This suggests that the family of SMTs may have particular importance to human health. Because there are no known 24-alkyl sterols synthesized in mammals, we believe that a thorough study of the distribution and enzyme properties of the SMT, including testing dual action inhibitors designed to disrupt the active center for methyl donor and acceptor is warranted. This investigation has enabled us to determine the potential roles of active site amino acids specifically in the Region-II (Erg6p nomenclature) of the yeast SMT. It is only a matter of time to the discovery of similar findings in other SMT types due to the highly conserved nature of this signature motif relative to Erg6p sequence. Deeper insights into the kind of interaction of AdoMet with the SMT should be possible from the three-dimensional structural data captured from covalently bound AdoMet and through affinity labeling of a suicide substrate, such as 26,27-dehydrozymosterol, where the AdoMet is part of the sterol covalently bound to the yeast-SMT. These investigations are underway.

**Acknowledgments** This work has been made possible by the following grants awarded to W.D.N.: National Science Foundation (MCB 0417436) and the Welch Foundation (D-1276). We are grateful to Dr. Julie Marshall for the technical assistance and advice of photolabeling techniques during the initial part of this investigation.

**Abstract** The effects of four cornstarches containing various contents of resistant starch on serum and liver cholesterol levels in rats fed a high-cholesterol diet were investigated. Male Sprague Dawley rats (aged 4 weeks) were divided into four groups ( $n = 7$ ) and fed high-cholesterol diets containing 15% of cornstarch (CS), heat-moisture-treated CS (HCS), high-amylose CS (HA), or heat-moisture-treated HA (HHA) for 21 days. The results showed that the serum and hepatic level of total cholesterol, LDL-cholesterol, and triglyceride in rats of the HHA group and their arteriosclerosis index were significantly higher, suggesting that HHA increases the risk of arteriosclerosis under a high-cholesterol dietary condition. No significant between-group differences were noted in the levels of plasma mevalonic acid and hepatic HMG-CoA reductase mRNA, whereas fecal cholesterol excretion was significantly higher in the HHA group, indicating that the elevation of the serum and liver cholesterol levels was not due to the promotion of liver cholesterol synthesis and cholesterol absorption in the intestine.

## Introduction

Resistant starch (RS) is defined as “starch and partially degraded starch not absorbed by the healthy human small intestine” [1]. RS can be present in all starch-containing foods (grains, legumes and tubers) and is influenced by both botanical source and processing, and classified into three types: starch that cannot be physically exposed to digestive enzymes, raw starch not readily affected by digestive enzymes, and retrograded starch after cooking. In terms of such RS, there are many reports on the physiological functions. For instance, RS had a preventive effect against intestinal tumorigenesis due to the alteration of the colonic luminal environment by increasing the concentration of short chain fatty acid and lowering production of potentially harmful fermentation products [2]. In addition, RS has been shown to be fermented in the colon, and exhibit a dietary fiber-like effect [3]. Among the functions of RS, the noteworthy one is a hypocholesterolemic effect. The ingestion of RS contained in normal diets with no cholesterol loaded has been reported to decrease the serum cholesterol level, serum triglyceride level and epididymal fat weight [4–7]. In particular, HA and HHA, which have higher RS contents, are expected to exert the decreasing effect of serum cholesterol concentration. Liu et al. [8] showed that HA and HHA decreased the level of serum and liver cholesterol in ovariectomized rats. Vanhoof and Schrijver [9] have reported that the administration of retrograded high-amylose cornstarch (HA) to rats fed on a 1% cholesterol-containing diet decreased the serum cholesterol level. They have suggested that the promotion of coprostanol excretion

by RS contained in HA was involved in the serum cholesterol-lowering action. We also reported that HHA was decreased serum cholesterol level in rats fed a diet with 0.1% cholesterol, 0.1% cholic acid and 10% lard [10].

However, little information is available about the function of RS under the condition of a high-cholesterol diet. Modern diets have high-levels of animal fat and cholesterol. Therefore, the increase in the level of serum cholesterol is becoming a concern because of increasing the concentration of serum LDL-cholesterol by ingestion of animal fat [11]. Consequently, it is necessary to investigate the physiological function of RS under high-cholesterol dietary conditions.

In this study, we made our study focused on heat-moisture-treated HA (HHA) whose RS content is increased more. Rats were fed a high-cholesterol diet constituted with four types of cornstarch, including HHA, to investigate their effects on the serum and liver cholesterol levels.

## Materials and Methods

### Materials

Cornstarch (CS), heat-moisture-treated CS (HCS) (Delicastar 200), high-amylose CS (HA), and heat-moisture-treated HA (HHA) (Amylogel HB450) were obtained from SANWA CORNSTARCH Co., Ltd (Nara, Japan). Determinar TC 555 kit was purchased from Kyowa Medex Co., Ltd (Tokyo, Japan). Triglyceride E test Wako and total bile acid test Wako kits were obtained from Wako Pure Chemical Industries Ltd (Osaka, Japan). Resistant starch measurement kit was purchased from Megazym (Sydney, Australia).

### Resistant Starch Content of Various Types of Cornstarch

The RS content in samples was measured with a resistant starch measurement kit.

### Animals and Diets

Four-week-old male Sprague Dawley rats were purchased from Clea Japan Co. (Tokyo, Japan). The rats were individually housed in stainless cages, and maintained in an animal room controlled at 23–25 °C and 50–56% humidity under a 12-h lighting cycle (light-on 8:00–20:00). The animals were made free access to food and drinking water. After acclimatization with a normal diet based on AIN-76 feed composition [12] for 1 week, animals were divided into four groups ( $n = 7$ ): CS, HCS, HA, and HHA groups, and fed for 21 days on a high-cholesterol diet containing each of the starch samples. High-cholesterol diets containing each starch were prepared by replacing  $\beta$ -cornstarch with each cornstarch and adding 0.5% cholesterol, 0.25% cholic acid and 10% lard at the expense of sucrose (Table 1). The animals were dissected on the final day of experimental period under Nembutal anesthesia. Serum was prepared by centrifugation of the blood sample (3,000 rpm, 4 °C, 20 min), and used for the analysis of serum lipid and mevalonic acid. The liver was washed with physiological saline, rapidly frozen in liquid nitrogen, and then used for the analyses of liver lipids and HMG-CoA reductase mRNA. Feces were collected 3 days before dissection, weighed, and subjected to lipid analysis. Animal experiments in this study were performed in conformity to the guidelines for maintenance and handling of

### Lipid Analysis

The serum levels of total cholesterol (TC), HDL-cholesterol, LDL-cholesterol, triglyceride, and total lipid were measured using an automatic biochemical analyzer model 7450 (Hitachi Co., Tokyo, Japan). The arteriosclerosis index was calculated from the formula of  $(TC - HDL\text{-cholesterol})/HDL\text{-cholesterol}$ .

Liver sample solutions were prepared as follows: 1.000 g of the excised liver was homogenized in a chloroform-methanol mixture, 2:1 (v/v), kept in a dark room for 1 day, and then filtered. The liver TC and triglyceride were measured with Determinar TC 555 kit and a Triglyceride E Test Wako kit, respectively. The phospholipid level was measured by molybdcid acid colorimetry [13].

Fecal sample solutions were prepared as follows: freeze-dried feces were powdered, and 0.5 g of the powder was heat-extracted with a chloroform-methanol mixture, 2:1 (v/v), at 45 °C for 10 h. The fecal levels of TC and total bile acid were measured using a Determinar TC 555 kit and total bile acid test Wako kit, respectively. The RS level in feces was measured using a resistant starch measurement kit.

### Organic Acid Analysis for Cecal Contents

The organic acid level in the cecal contents was measured by HPLC [14]. The sample solution was prepared as follows: a sample of the cecal contents (300 mg) was dissolved with 2 ml of 10 mM sodium hydroxide solution and centrifuged at  $10,000 \times g$  for 15 min. Then, 1 ml of the supernatant was combined with 1 ml of chloroform and centrifuged. The supernatant was filtered through a 0.2- $\mu\text{m}$  membrane filter before subjecting to HPLC. For HPLC analysis, two Shim-pack SCR-102H columns (8 mm i.d.  $\times$  300 mm, Shimadzu, Kyoto, Japan) and an electroconductivity detector (CDD-6A, Shimadzu) were used. The mobile phase for separation was 5 mM *p*-toluenesulfonic acid aqueous solution, and that for detection was 20 mM bis-(2-hydroxyethyl) iminotris (hydroxymethyl) methane (Bis-Tris) aqueous solution containing 5 mM *p*-toluenesulfonic acid aqueous solution and 100  $\mu\text{M}$  EDTA. The HPLC was carried out at a flow rate of 0.8 ml/min and with a column temperature of 40 °C.

### Plasma Mevalonic Acid Analysis

The plasma mevalonic acid (MVA) level was measured by HPLC by SRL Inc. (Tokyo, Japan).

### RNA Extraction

RNA was extracted from the liver by the method reported by Chomczynski and Sacchi [15].

### First-Strand cDNA Synthesis

cDNA was prepared from 5  $\mu\text{g}$  of DNase I-treated total RNA using reverse transcriptase (Super-script III<sup>TM</sup>, Invitrogen, CA, USA) following the instructions of the manufacturer.

### Quantitative PCR

Quantitative PCR and hybridization primers were synthesized by Applied Biosystems (Foster, IN, USA). Oligonucleotide primers were designed to amplify rat HMG-CoA reductase nucleotide 1412–1503 (GenBank accession number NM013134) and  $\beta$ -actin nucleotide 2838–3041 (GenBank accession number V01217). The sequences of the primers are as follows: rat HMG-CoA reductase sense primer, 5'-AGA GAA AGG TGC GAA GTT CCT TAG T-3' and HMG-CoA reductase antisense primer, 5'-CCA TGA GGG TTT CCA GTT TGT AG-3'; and  $\beta$ -actin sense primer, 5'-CCC TGG CTC CTA GCA CCA T-3' and  $\beta$ -actin antisense primer, 5'-GAT AGA GCC ACC AAT CCA CAC A-3'.

The predicted PCR product sizes were 192 (rat HMG-CoA reductase) and 204 bp ( $\beta$ -actin). The amplification products obtained following the manufacturer's instructions were detected using a TaqMan universal PCR master mix core reagent kit (Applied Biosystems).

The rat HMG-CoA reductase hybridization probe was a nucleotide corresponding to 1452–1479, 5'-CAG TTG G TC AAT GCT AAG CAC ATC CCA G-3', and the 5' and 3' ends were labeled with 6-carboxyfluorescein (FAM) and *N,N,N',N'*-tetramethyl-6-carboxyrhodamine (TAMRA), respectively. The  $\beta$ -actin probe corresponded to 2865–2866 and 2991–3015 (2867–2990 corresponded to an intron), 5'-AGA TCA TTG CTC CTC CTG AGC GCA AGT-3', and the 5' and 3' ends were labeled with VIC<sup>TM</sup> and TAMRA, respectively. The mRNA level of HMG-CoA reductase was measured by quantitative PCR using an ABI Prism 7300 apparatus (Applied Biosystems), and presented as the relative value to the mRNA level of  $\beta$ -actin.

### Statistical Analysis

A statistical analysis was performed with software, SPSS 15.0J. The statistically significant differences of the means among four groups were evaluated by non-parametric statistical analysis (Kruskal–Wallis) and individual comparisons were made by Tukey's multiple comparison test.

A statistically significant difference of the means between two groups was evaluated by the Mann–Whitney test.

## Results

### Resistant Starch Content of Various Types of Cornstarch

Figure 1 shows the RS contents of the four cornstarch samples used in this study. The RS content was significantly higher in HA and HHA than in the other types.

### Food Intake and Body Weight

Table 2 shows the food intake and initial and final body weights in rats fed the high-cholesterol diets containing each of the starch samples. No significant between-group difference was found in terms of food intake. The final body weight was not significantly different between the CS and HCS groups or between the HA and HHA groups, but was significantly lowest in the HHA group whose RS content was higher than CS and HCS groups, showing that the high-RS diet was effective in reducing body weight.

**Fig. 1** Resistant starch contents in various types of cornstarch. Resistant starch contents in various types of cornstarch were measured with a resistant starch kit. CS cornstarch; HCS heat moisture treated cornstarch; HA high-amylose cornstarch; HHA heat-moisture-treated high-amylose cornstarch. Values are means  $\pm$  SE ( $n = 7$ ). Bars without a common letter represent significant differences at  $P < 0.05$

**Table 2** Effects of various types of cornstarch on food intake, and initial and final body weights in rats fed experimental diets

	CS	HCS	HA	HHA
Food intake (g/day)	20.6 $\pm$ 0.5	20.3 $\pm$ 0.4	21.1 $\pm$ 0.6	20.4 $\pm$ 0.6
Initial body weight (g)	147 $\pm$ 2	147 $\pm$ 2	149 $\pm$ 2	150 $\pm$ 2
Final body weight (g)	332 $\pm$ 7 <sup>b</sup>	321 $\pm$ 3 <sup>b</sup>	316 $\pm$ 2 <sup>ab</sup>	304 $\pm$ 2 <sup>a</sup>

Values are means  $\pm$  SE ( $n = 7$ ). Values within a row with different superscript letters denote that there are significant differences at  $P < 0.05$ . For abbreviations see Table 1

### Serum Lipid Levels

Table 3 shows the serum lipid levels in rats fed the high-cholesterol diets containing each starch. The serum TC level was significantly higher in the HHA group than in the CS and HCS groups. The LDL-cholesterol level was significantly increased in the HA and HHA groups compared to the CS and HCS groups. No significant differences were observed in the level of HDL-cholesterol or total lipid level among the groups. The triglyceride level and arteriosclerosis index were significantly higher in the HHA group than in the CS, HCS, and HA groups.

### Liver Tissue Weight and Liver Lipid Levels

Table 4 shows the liver weight and lipid levels in rats fed the high-cholesterol diets containing each starch. No significant difference was observed in the liver weight among the groups. The liver TC level was significantly higher in the HHA group than in the CS group. The levels of phospholipids and triglyceride in the test groups was similar to those in the control group.

### Fecal Dry Weight, RS Content, and Lipid Levels

Table 5 shows the fecal dry weight, RS content, and lipid levels in rats fed the high-cholesterol diets containing each starch. The fecal dry weight was significantly higher in the HA and HHA groups, and increased as the RS level increased. In the RS content in feces, the HHA group was the highest of all groups, followed by HA, HCS, and CS groups, depending on the RS content of the diet. The fecal TC level was significantly higher in the HHA group than in the HCS group, showing that the TC level increased with an elevation in the RS content of the diet. The level of fecal bile acid was significantly increased in the HA and HHA groups compared to the HCS group.

Values are means ± SE ( $n = 7$ ). Values within a row with different superscript letters denote that there are significant differences at  $P < 0.05$ . For abbreviations see Table 1

### Cecum Parameters

Table 6 shows the cecal tissue and content weights, pH, and organic acid level of the contents in rats fed the high-cholesterol diets containing each starch. The cecal tissue weight was significantly increased in the HHA group, compared to the CS group. No significant between-groups difference was found in the weight of cecal contents. The pH of the cecal contents was significantly lower in the HA and HHA groups. The maleic acid level of the cecal contents was significantly increased in the HA and HHA groups, compared to the CS and HCS groups. The level of succinic acid was higher in the HA and HHA groups than in the CS group. In the level of lactic acid and acetic acid, no significant difference was observed among the groups. The propionic acid and butyric acid levels were

significantly lower in the HHA group than in the CS and HCS group.

### Levels of Plasma Mevalonic Acid and Liver HMG-CoA Reductase mRNA

Figure 2 shows the plasma mevalonic acid and the liver mRNA levels of HMG-CoA reductase in rats fed the high-cholesterol diets containing each starch. The feeding of HHA did not change the plasma mevalonic acid level, an index of liver cholesterol synthesizing-enzyme activity, among the groups. The mRNA level of HMG-CoA reductase in the HHA group was similar to that in the CS group. The absence of significant differences in the mevalonic acid or mRNA level of HMG-CoA reductase in the liver was observed between the CS and HHA groups.

**Fig. 2** Effects of various types of cornstarch on the levels of serum mevalonic acid and liver HMG-CoA reductase mRNA in rats fed a high-cholesterol diet. Mevalonic acid in serum was quantified by HPLC. The mRNA level of HMG-CoA reductase in the rat liver was measured by quantitative PCR. The mRNA level of HMG-CoA

reductase was presented as the relative value to that of  $\beta$ -actin. CS cornstarch; HCS heat-moisture-treated cornstarch; HA high-amylose cornstarch; HHA heat-moisture-treated high-amylose cornstarch. Values are means ± SE ( $n = 7$ )

## Discussion

In this study, we investigated the effect of HA and HHA, which have a high content of RS, on serum cholesterol levels in rats given a high-cholesterol diet. As a high-cholesterol diet, the diet containing 0.5% cholesterol, 0.25% cholic acid and 10% lard was used because such a diet increased serum cholesterol level in rats [16]. As a result, HHA increased the level of total cholesterol and triglyceride in serum, arteriosclerosis index and the level of cholesterol in the liver under the high-cholesterol diet condition (Table 3), although there are some reports that HHA decreased serum cholesterol level under the normal diet condition [4–7]. Similar to our results of HHA, HA increased the serum level of LDL-cholesterol. These

increasing effects were not observed in rats fed a diet containing CS or HCS, suggesting that the high amylose content was a factor for the elevation of serum and liver cholesterol levels.

In this study, 0.5% cholesterol, 0.25% cholic acid and 10% lard in the high-cholesterol diet was added in order to increase the level of serum cholesterol. This diet condition was reported to lower the levels of HMG-CoA reductase activity and its mRNA level in the liver [17, 18]. In the present study, no significant differences were observed in the level of hepatic HMG-CoA reductase mRNA and the plasma level of mevalonic acid produced by hepatic HMG-CoA reductase [19] between the CS and HHA groups (Fig. 2). These results suggest that the promotion of cholesterol synthesis in the liver was not attributed to the

serum and liver cholesterol-elevating effect by HHA ingestion.

In contrast, the lowering effect of resistant starch on the serum cholesterol level has previously been reported to be related to the promotion of bile acid excretion [20]. In addition, there is a report that the promotion of cholesterol uptake into the liver was a factor for the decreasing effect of resistant starch on the serum cholesterol level [21]. In this present study, no significant increase in bile acid excretion was apparent in any group fed on the HHA diet. Therefore, the promotion of bile acid excretion is not probably related to the increasing level of serum and liver cholesterol by HHA ingestion.

No information is still available on the elevation of serum level of cholesterol and triglyceride by intake of HA or HHA under the condition of a normal diet. Vanhoof and Schrijver [9] reported that retrograded HA lowered the serum cholesterol level in rats fed on 1% cholesterol- and 0.1% cholic acid-loading diet. However, their study differs from our study in view of the use of lard-unloaded diet and resistant starch contents used. Verbeek et al. [20] reported that the retrograded amylose decreased the serum cholesterol level in rats fed a cholesterol- and lard-loading diet. However, their study differs from our study in view of the use of cholic acid-unloaded diet. We investigated the effect of HHA on serum cholesterol level in rats fed a diet with 0–0.1% cholesterol, 0.1% cholic acid and 10% lard, and showed that HHA decreased serum cholesterol level in the rats fed a diet with 0.1% cholesterol [10]. In addition, our preliminary experiment of 0.25% instead of 0.1% cholic acid showed that a HHA had a lowering effect on the serum cholesterol level in rats fed on a 0.5% cholesterol and 10% lard diet (data not shown). Therefore, these results suggest that the serum level of the cholesterol- and triglyceride-elevating effect of HHA was dependent on the diet conditions, and the effect is highly likely to be caused by 0.5% cholesterol, 0.25% cholic acid and 10% lard in the diet.

Shibata et al. [16] showed that the level of serum cholesterol markedly increased in rats fed a diet with 0.5% cholesterol, 0.25% cholic acid and 10% lard, but no change in the activity for hepatic HMG-CoA reductase and CYP7a1, and a decrease in the level of LDL receptor mRNA was observed. Stanley et al. [22] reported that myristic, lauric and palmitic acids which are abundant in animal fats increased the level of serum cholesterol because the saturated fatty acids decreased the expression of the gene coding for the LDL receptor and increased expression of the gene coding for the VLDL particles released. Given that the serum level of cholesterol and triglyceride was increased by intake of high-cholesterol diet, HHA increased the serum level of LDL-cholesterol

and triglyceride, a main lipid component in VLDL. This result suggests that intake of HHA affects factors involved in cholesterol metabolism.

However, it is unlikely that HHA itself increased the serum cholesterol and triglyceride levels, because HHA is not absorbed into the body due to being poorly digested. Thus, HHA may be indirectly involved in the serum cholesterol- and triglyceride-elevating effects. One of the possible reasons for the indirect action of HHA is organic acids in cecum contents. Hara et al. [23] have reported that a serum cholesterol-decreasing effect of feeding dietary fiber may be involved in the increased content of organic acids produced in the cecum of rats due to the inhibition of cholesterol synthesis in the liver. In this study, the concentration of maleic and succinic acids was elevated by HHA intake. There is a report that maleic acids decreased the level of serum cholesterol [24]. In addition, our preliminary experiment showed that the intake of maleic and succinic acids reduced the serum cholesterol-elevating effect using rats (data not shown). Therefore, maleic acid and succinic acid have little to do with the increase in the serum cholesterol level. In contrast, only propionic acid showed a significant decrease among organic acids in the cecum contents of HHA group. Interestingly, Chen et al. [25] have reported that the ingestion of propionate reduced the level of serum cholesterol in rats. Lin et al. [26] reported that propionate inhibited cholesterol and triglyceride synthesis in rat hepatocytes in a dose-dependent manner. It is possible that propionic acid produced by the intake of HHA caused the increase in serum cholesterol and triglyceride levels, due to low level of propionic acid in the cecum content.

In humans, although HA and HHA have been reported to lower the serum cholesterol level [27], no information is yet available about an increase in serum cholesterol level caused by ingestion of HHA. Our animal experiments showed that the intake of HHA in conjunction with a high-cholesterol/high-animal fat diet could increase serum cholesterol and triglyceride concentration in humans. However, since the metabolism of cholesterol and lipids in humans is different from that in rats, further studies on the effects of HHA in human and experimental animals will be required.

In conclusion, the intake of HHA elevated the serum and liver cholesterol levels and the arteriosclerosis index in association with a high-cholesterol diet. These results suggest that HHA, when consumed in conjunction with a high-cholesterol/high-animal fat diet, does not reduce serum cholesterol levels, but rather increases the risk of arteriosclerosis. Although the use of resistant starch has become popular in recent years, it is important to note that starch under severe conditions, such as in the case of heat-moisturing, has some undesirable effect on the target

function of the body. Further experimentation will be needed to learn more about the effect of HHA at biochemical and physiological levels.

**Abstract** Insulin resistance is characterized by increased metabolic uptake of fatty acids. Accordingly, techniques to examine in vivo shifts in fatty acid metabolism are of value in both clinical and experimental settings. Partially metabolizable long chain fatty acid (LCFA) tracers have been recently developed and employed for this purpose: [9,10- $^3$ H]-(*R*)-2-bromopalmitate ([ $^3$ H]-BROMO) and [ $^{125}$ I]-15-(*p*-iodophenyl)-3-*R,S*-methylpentadecanoic acid ([ $^{125}$ I]-BMIPP). These analogues are taken up like native fatty acids, but once inside the cell do not directly enter  $\beta$ -oxidation. Rather, they become trapped in the slower processes of  $\omega$  and  $\alpha$ -oxidation. Study aims were to (1) simultaneously assess and compare [ $^3$ H]-BROMO and [ $^{125}$ I]-BMIPP and (2) determine if tracer breakdown is affected by elevated metabolic demands. Catheters were implanted in a carotid artery and jugular vein of Sprague–

Dawley rats. Following 5 days recovery, fasted animals (5 h) underwent a rest ( $n = 8$ ) or exercise ( $n = 8$ ) (0.6 mi/h) protocol. An instantaneous bolus containing both [ $^3$ H]-BROMO and [ $^{125}$ I]-BMIPP was administered to determine LCFA uptake. No significant difference between [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO uptake was found in cardiac or skeletal muscle during rest or exercise. In liver, rates of uptake were more than doubled with [ $^3$ H]-BROMO compared to [ $^{125}$ I]-BMIPP. Analysis of tracer conversion by TLC demonstrated no difference at rest. Exercise resulted in greater metabolism and excretion of tracers with  $\sim 37\%$  and  $\sim 53\%$  of [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO present in conversion products at 40 min. In conclusion, [ $^3$ H]-BROMO and [ $^{125}$ I]-BMIPP are indistinguishable for the determination of tissue kinetics at rest in skeletal and cardiac muscle. Exercise preferentially exacerbates the breakdown of [ $^3$ H]-BROMO, making [ $^{125}$ I]-BMIPP the analogue of choice for prolonged ( $>30$  min) experimental protocols with elevated metabolic demands.

## Introduction

Abnormalities in lipid trafficking and uptake are a hallmark of numerous metabolic disease states including obesity, type 2 diabetes and atherosclerosis. To assess lipid kinetics in these states, partially metabolizable long chain fatty acid (LCFA) tracers have been developed for use in vivo [1–7]. Two such tracers are [9,10-<sup>3</sup>H]-(*R*)-2-bromopalmitate ([<sup>3</sup>H]-BROMO) and [<sup>125</sup>I]-15-(*ρ*-iodophenyl)-3-*R,S*-methylpentadecanoic acid ([<sup>125</sup>I]-BMIPP). Both analogues are taken up by tissues like native substrates however, once inside the cell, they become trapped in various stages of  $\omega$  or  $\alpha$ -oxidation. As a result, the analogues remain in the tissue allowing their quantification by specific activity.

Developed and extensively tested by Oakes et al. [8], [<sup>3</sup>H]-BROMO shows excellent retention in the majority of tissues examined. Studies employing this tracer were the first to effectively show increased efficiency of tissue LCFA uptake in a model of dietary induced insulin resistance [9]. BMIPP was developed by Knapp et al. [10–12] and has been primarily used for cardiac imaging with an [<sup>123</sup>I] label. Using single photon emission computed tomography (SPECT) defects in fatty acid uptake by the heart are imaged and are indicative of ischemia or tissue injury [5, 13–15]. Like [<sup>3</sup>H]-BROMO, the tracer has also proven to be a powerful tool in evaluating various pharmacological treatments on cardiac metabolism [16–19].

To date, numerous studies have individually assessed the metabolism of these fatty acid tracers in vivo and some comparisons between different tracers have been reported [1]. However, studies directly comparing [<sup>125</sup>I]-BMIPP and [<sup>3</sup>H]-BROMO in specific tissues under varied metabolic conditions have not been performed. Therefore, the aim of the present study was to assess and compare [<sup>125</sup>I]-BMIPP and [<sup>3</sup>H]-BROMO in vivo. The effects of enhanced LCFA metabolism due to exercise on tissue retention of these tracers was examined. Together, these studies will provide needed information on the use of [<sup>125</sup>I]-BMIPP and [<sup>3</sup>H]-BROMO, and their applicability to the study of metabolism.

## Experimental Methods

### Animals

Male Sprague–Dawley rats (Harlan Industries, Indianapolis, IN) were housed individually and maintained at 23°C on a 0600–1800 hours light cycle. Rats were fed standard chow ad libitum (Purina, Nestlé, St Louis, MI) and given free access to water. The rats were housed under these conditions for ~1 week, by which time their weights had

reached ~330 g. Following weight gain, rats were randomly divided into rest and exercise groups ( $n = 8$  per group). All procedures were approved by the Vanderbilt University Animal Care and Use Subcommittee and followed National Institutes of Health guidelines for the care and use of laboratory animals.

### Surgical Procedures

Surgical procedures were performed as previously described for arterial and venous catheterizations [20]. Briefly, animals were anaesthetized with a 50:5:1 vol/vol/vol mixture of ketamine, rompun, and acepromazine, and the left common carotid artery and right jugular vein were catheterized with PE50 catheters, which were exteriorized and secured at the back of the neck, filled with heparinized saline (150 U/ml), and sealed with a stainless steel plug. Immediately post-surgery, each animal received 75 mg/kg of ampicillin subcutaneously to prevent infection. After surgery, animal weights and food intake were monitored daily.

### Isotopic Analogues

(*ρ*-iodophenyl)-3-*R,S*-methylpentadecanoic acid was a kind gift from Oak Ridge International Laboratories (Oak Ridge, TN). Radioiodination was performed according to the manufacturer's suggested protocol. Briefly, (*ρ*-iodophenyl)-3-*R,S*-methylpentadecanoic acid was heated in the presence of Na[<sup>125</sup>I] solution (740 MBq/200  $\mu$ l), propionic acid, and copper (II) sulfate. Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> was then added and the organic phase ether extracted and sequentially back extracted with saturated NaHCO<sub>3</sub> and water. After evaporation, the [<sup>125</sup>I]-BMIPP was solubilized using sonication into ursodeoxycholic acid. The initial concentration of [<sup>125</sup>I]-BMIPP was 1.05  $\mu$ Ci/ $\mu$ l. However, due to the short half life of [<sup>125</sup>I]-BMIPP, the administered dose was volumetric. A dose of 100  $\mu$ l was administered and the activity of the tracer was determined for each individual animal and corrected for any decay. To limit tracer decay, all studies were performed within 30 days of synthesis.

[<sup>3</sup>H]-BROMO was prepared by American Radioactive Chemicals Co (St Louis, MO) from palmitic acid as previously described [8]. The final concentration was 1  $\mu$ Ci/ $\mu$ l. On the day of the experiment, 20  $\mu$ l of [<sup>3</sup>H]-BROMO was evaporated and reconstituted in 100  $\mu$ l of saline containing 0.35 mg/ml rat albumin (Sigma Chemical, St Louis, MO). This solution was added to 100  $\mu$ l of [<sup>125</sup>I]-BMIPP in ursodeoxycholic acid. In total, [<sup>3</sup>H]-BROMO, 19.5  $\mu$ Ci was administered to each animal. On the day of the experiment, 5  $\mu$ l of infusate was retained for normalization of radioactivity while the remaining 195  $\mu$ l was administered to the animal.

## Resting Studies

On the morning of the study, rats were fasted for 5 h in a clear Tupperware (2 l) container lined with bedding. Approximately 1 h prior to the experiment, catheters were flushed with heparinized saline (10 U/ml) and connected to PE50 and Silastic tubing for infusions and sampling. Rats were then placed in the Tupperware container until the commencement of the experimental protocol. Throughout the experimental protocol rats were conscious and unrestrained. In total the experimental protocol was 40 min in duration. Prior to tracer infusions, a basal blood sample were obtained (100  $\mu$ l) for the measurement of isotopic analogues, plasma glucose, insulin and nonesterified fatty acids (NEFA). To prevent declines in hematocrit, the erythrocytes taken prior to isotopic analogue infusion were washed in saline and re-infused shortly after each sample was taken. At 0 min, an instantaneous bolus of [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO was administered and additional plasma samples (200  $\mu$ l) were obtained at 2, 5, 10, 15, 25, and 40 min for the measurement of [ $^{125}$ I]-BMIPP, [ $^3$ H]-BROMO, NEFA and plasma glucose. Following the final blood sample, rats were anesthetized with pentobarbital sodium and skeletal muscle (gastrocnemius), liver, heart, brain and epididymal fat were rapidly excised, rinsed in saline to remove excess blood, freeze clamped in liquid nitrogen and frozen at  $-80^{\circ}\text{C}$  until further analysis.

## Exercise Studies

Two days prior to the protocol, rats in this treatment were acclimated by running on a motorized treadmill for 10 min at 0.6 mi/h. On the morning of the study, rats were fasted for 5 h in a clear Tupperware (2 l) container lined with bedding. Approximately 1 h prior to the experiment, catheters were flushed with heparinized saline (10 U/ml) and connected to PE50 and silastic tubing for infusions and sampling. Rats were then placed in the treadmill until the commencement of the experimental protocol. Following basal blood sampling, rats were run on the treadmill at 0.6 mi/h and samples were obtained as in the resting protocol. This exercise intensity is moderate for rats. At 40 min, rats were anesthetized and tissue samples were obtained as previously described.

## Plasma Analysis

Plasma NEFAs were measured spectrophotometrically by an enzymatic colorimetric assay (Wako NEFA C kit, Wako Chemicals Inc., Richmond, VA). Plasma glucose concentrations were measured by the glucose oxidase method using an automated glucose analyzer (Beckman Instruments, Fullerton, CA). [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO were

measured in the same plasma sample (15  $\mu$ l). Plasma was counted for [ $^{125}$ I]-BMIPP using a Beckman Gamma 5500 counter (Beckman Instruments, Fullerton, CA). Following this, 100  $\mu$ l of 50% ethanol was added to the sample and  $^3\text{H}$  radioactivity was counted after addition of fluor (10 ml; Ultimate Gold, Packard Bioscience, Boston, MA.) using a Packard Tri-Carb 2900TR Liquid Scintillation Analyzer (PerkinElmer, Boston, MA). In addition, plasma was also analyzed by thin layer chromatography (TLC) by methods that were derived from Kropp et al. [21]. Here, individual plasma time points were examined by TLC from a representative animal in each treatment group. TLC plates reflecting plasma samples were segmented into 1 cm sections and analyzed for tracer and tracer conversion products. Each plate was examined for radioactivity. Significant radioactivity appearing in minor lipid fractions over time was considered evidence of tracer breakdown, although the exact chemical nature of each product was not identified. Tracer conversion or breakdown was calculated as a ratio of total activity appearing on the plate for each time point.

## Tissue Analysis

Total [ $^{125}$ I] radioactivity in tissues was determined on sections of whole tissue ( $\sim 100$  mg) using a Beckman Gamma 5500 counter (Beckman Instruments, Fullerton, CA). Following this, total lipid was extracted from the tissue using a modified Folch–Lees extraction [22]. The [ $^{125}$ I] radioactivity in this fraction was then reassessed before 10 ml of flour was added to samples and then  $^3\text{H}$  radioactivity determined by liquid scintillation counting (Packard TRI-CARB 2900TR, Packard, Meriden, CT) with Ultima Gold (Packard) as scintillant. The relationship between gamma radioactivity and beta emissions using this specific process and counter has been previously established in our laboratory. This relationship was used to correct  $^3\text{H}$  radioactivity for beta-emissions originating from [ $^{125}$ I] radioactivity in both tissue and plasma samples [3]. In addition, lipid was extracted from a portion of each tissue ( $\sim 100$  mg) from four rats in both the resting and exercise protocols using a Folch–Lees extraction [22]. Lipid fractions were then separated by TLC [23]. Plate segments were subsequently separated and individually counted. Tissues plates were separated based on lipid fraction (phospholipid, mono-diglyceride, free fatty acids and triglyceride).

## Calculations

### *Plasma Kinetics*

Identical equations were used for the determination of [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO kinetics. Plasma tracer ( $p$ ) kinetics are based on the disappearance of tracer from the

plasma over time. Movement of the tracer out of the plasma pool into tissues is denoted by clearance ( $K_p$ , Eq. 1). When  $K_p$  is expressed in terms of tracee or mean LCFA concentration as measured by an enzymatic assay, the measure is termed uptake ( $R_p$ , Eq. 2). Finally, if  $K_p$  is expressed as a fraction of the original tracer dose administered ( $D$ ), the resultant expression is metabolic clearance rate or  $MCR_p$ . Equations 1–3 are calculated independently for [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO. Equations employed were defined as follows where  $\int_0^t$  represents integral over the time between 2 and 40 min.

$$K_p = \int_0^t \left[ [^{125}\text{I}]\text{-BMIPP or } [^3\text{H}]\text{-BROMO} \right] p dt \quad (1)$$

$$R_p = K_p [\text{LCFA}]_p \quad (2)$$

$$MCR_p = \frac{D}{\int_0^t \left[ [^{125}\text{I}]\text{-BMIPP or } [^3\text{H}]\text{-BROMO} \right] p dt} \quad (3)$$

#### Tissue Kinetics

Rates of tissue LCFA clearance ( $K_t$ , Eq. 4) and metabolic indices ( $R_t$ , Eq. 5) were calculated from the accumulation of [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO in tissues ( $t$ ) relative to the integral of the plasma ( $p$ ) concentration following the instantaneous bolus. These measurements follow from Eqs. 1–3 and have been previously described [3, 9].

$$K_t = \frac{\left[ [^{125}\text{I}]\text{-BMIPP or } [^3\text{H}]\text{-BROMO} \right]_t}{\int_0^t \left[ [^{125}\text{I}]\text{-BMIPP or } [^3\text{H}]\text{-BROMO} \right] p dt} \quad (4)$$

$$R_t = K_t [\text{LCFA}]_p \quad (5)$$

A one-way repeated measures analysis of variance (ANOVA) was performed to compare differences between [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO within specific tissues. To determine differences over time for blood glucose and NEFA, a two-way repeated measures ANOVA was performed. To establish differences within ANOVA, a Tukey post hoc test was used. Significance levels of  $p \leq 0.05$  were employed, and data are reported as means  $\pm$  standard error of the mean (SEM).

## Results

### Animal Characteristics

Baseline animal characteristics for both rest and exercise experiments are outlined in Table 1. Blood glucose remained stable in the rest group ( $7.7 \pm 0.3$  mM at 40 min) while it steadily increased in the exercise group to  $11.5 \pm 0.6$  mM at the end of the protocol ( $p < 0.05$ ). Plasma NEFA levels remained stable with average values of  $0.63 \pm 0.06$  mM and  $0.56 \pm 0.05$  mM for rest and exercise studies at the end of the experimental protocol ( $p > 0.05$ ). All animals in the exercise protocol were able to successfully complete the required 40 min of exercise.

### Metabolic Clearance and Uptake

Whole body metabolic clearance in the resting state was set to an arbitrary value of 1.0 for each tracer for comparison to the exercise treatment. Results show comparable increments in fatty acid clearance for each tracer with exercise (Fig. 1). Tissues (skeletal muscle, heart, liver, adipose tissue) were examined for rates of fatty acid uptake ( $R_t$ ,  $\mu\text{mol}/100$  g/min). Absolute values are shown in Fig. 2. No quantitative difference between [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO  $R_t$  values were noted during the resting protocol with the exception of the liver. In the liver, rates of  $R_t$  calculated using [ $^3$ H]-BROMO was more than double that calculated using [ $^{125}$ I]-BMIPP.

### Tracer Correlations

Correlations of tissue fatty acid uptake between [ $^{125}$ I]-BMIPP and [ $^3$ H]-BROMO are plotted in Fig. 3.  $R^2$  values for resting and exercise samples are plotted individually, and an aggregate value also presented. Results of individual muscle types for rest and exercise studies were at least moderately correlated, with aggregate  $R^2$  values of 0.39, 0.55, 0.26, and 0.56 for the soleus, vastus lateralis, gastrocnemius and heart respectively. In contrast, data from liver and adipose tissue are poorly correlated between tracers with both treatments.

**Table 1** Baseline characteristics of animals in the sedentary and exercise experiments

	<i>n</i>	Weight (g)	Recovery (days)	Glucose (mM)	NEFA (mM)	Hct 0 (%)	Hct 40 (%)
Rest	8	330 $\pm$ 10	7.8 $\pm$ 0.9	7.3 $\pm$ 0.2	0.76 $\pm$ 0.11	47 $\pm$ 1	43 $\pm$ 1
Exercise	8	340 $\pm$ 12	8.3 $\pm$ 0.4	7.5 $\pm$ 0.2	0.73 $\pm$ 0.11	46 $\pm$ 1	41 $\pm$ 1

Recovery (days) reflects the number of days between surgery and the experiment. Basal plasma glucose (glucose) and non-esterified fatty acids (NEFA) are shown along with starting and ending hematocrit (Hct) levels

**Fig. 1** Relative change in whole body LCFA clearance rates (MCR) for [<sup>3</sup>H]-BROMO (top panel) and [<sup>125</sup>I]-BMIPP (bottom panel) from rest to exercise. Calculations are based on the measurement of radioactivity in the plasma over time. As tracer moves from the plasma into tissues, the rate of decay for each tracer can be quantified. Resting values for each tracer were set to an arbitrary value of one. Values represent means  $\pm$  SEM

#### Plasma Analysis

Analysis of tracer distribution in resting animals by TLC demonstrated no observable differences between [<sup>125</sup>I]-BMIPP and [<sup>3</sup>H]-BROMO at rest. Each tracer showed the expected exponential decay pattern and similar rates of fractional conversion in this state (Table 2). Analysis of fractional conversion during exercise was comparatively greater than exercise at all time points analyzed. Furthermore, results show conversion of [<sup>3</sup>H]-BROMO to exceed that of [<sup>125</sup>I]-BMIPP in the latter stages (>20 min) of the experiment (Table 2).

#### Tracer Tissue Distribution

The intracellular fate of tracers were analyzed by TLC. Results demonstrated tracers to reside in three distinct

fractions (Table 3). The first fraction contained phospholipid, monoglyceride, and diglyceride (PL + MG + DG) while others analyzed free fatty acids (FFA), triglyceride (TG). Analysis showed the majority of radioactivity resided in the PL + MG + DG fraction followed by FFA and finally TG. Differences between tracer distributions were minimal. At rest, a lower fraction of [<sup>125</sup>I]-BMIPP was found in TG in cardiac muscle. During exercise, lower [<sup>125</sup>I]-BMIPP was found in cardiac FFA and skeletal muscle TG.

#### Discussion

The purpose of this study was to assess and compare [<sup>3</sup>H]-BROMO and [<sup>125</sup>I]-BMIPP during rest and a state of accelerated fatty acid metabolism (moderate exercise). Tracers were simultaneously administered so that direct comparisons of tissue fatty acid uptake could be made. Results show good agreement between [<sup>3</sup>H]-BROMO and [<sup>125</sup>I]-BMIPP for cardiac and skeletal muscle during rest and exercise. In contrast, liver and epididymal fat pads showed poor correlations under both conditions. At rest, rates of liver [<sup>3</sup>H]-BROMO uptake were more than double those of [<sup>125</sup>I]-BMIPP.

Conceptually, both agents are regarded as “generic” long chain fatty acid tracers. The close agreement between these tracers in muscle tissue is reassuring in terms of this usual simplification. There may be tissue specific differences related to precise molecular structure of both fatty acids and fatty acid tracers that are reflected in the differences in adipose and liver. An increase in hepatic extraction and breakdown of [<sup>3</sup>H]-BROMO compared to [<sup>125</sup>I]-BMIPP may also play a role. Evidence of increased hepatic [<sup>3</sup>H]-BROMO breakdown has been previously reported [8]. Intravenous administration of [<sup>3</sup>H]-BROMO to rodents found liver to have a retention rate of only 77% compared to skeletal muscle that retained over 90% of tracer during 16 min of infusion [8]. Given these and the present findings, it is reasonable to hypothesize that [<sup>125</sup>I]-BMIPP retention rates may most closely reflect actual liver LCFA uptake. For epididymal fat, we show absolute rates of fatty acid uptake to be similar between tracers. However, correlation of individual animals between [<sup>3</sup>H]-BROMO and [<sup>125</sup>I]-BMIPP for this tissue yielded poor results. This discrepancy is likely due to the low rate of fatty acid uptake and tracer detection in this tissue.

To examine fractional conversion of each tracer by tissue, detailed analysis of tracer distribution in plasma over time was conducted by TLC. A known conversion product for [<sup>3</sup>H]-BROMO is <sup>3</sup>H<sub>2</sub>O. Previous analysis of the tracer show conversion to be ~5% of the dose at 16 min in sedentary rats [8]. This value compares favorably with the

**Fig. 2** Tissue fatty acid uptake ( $\mu\text{mol}/100\text{ g}/\text{min}$ ) for [ $^{125}\text{I}$ ]-BMIPP (filled bars) and [ $^3\text{H}$ ]-BROMO (empty bars). Tissues were collected following 40 min of rest or moderate intensity exercise. \* Indicates a significant difference between [ $^3\text{H}$ ]-BROMO and [ $^{125}\text{I}$ ]-BMIPP within an experimental protocol. † Indicates a significant difference between rest and exercise for a given tracer. Values represent means  $\pm$  SEM

present study that estimates a conversion of  $\sim 4\%$  at 15 min at rest. Like [ $^3\text{H}$ ]-BROMO, [ $^{125}\text{I}$ ]-BMIPP becomes trapped in  $\alpha$ -oxidation [24]. End products of this reaction yield  $\text{CO}_2$ , a fatty acid shortened by one carbon and a methyl substitution at the second carbon, which in the case of [ $^{123}\text{I}$ ]-BMIPP and [ $^{131}\text{I}$ ]-BMIPP is 2-( $p$ -iodophenyl) acetic acid ( $\text{IPC}_2$ ) [21]. Previous analysis of fractional conversion of [ $^{123}\text{I}$ ]-BMIPP show  $\sim 11\%$  of injected dose is released at 60 min in humans while perfusion of isolated rat hearts have a conversion of  $\sim 12\%$  following 3 h. In the present study, we show conversion of BMIPP to be  $\sim 12\%$  of total radioactivity at 40 min. Comparison of [ $^{125}\text{I}$ ]-BMIPP and [ $^3\text{H}$ ]-BROMO during rest, show comparable levels of conversion over time. Given this, either tracer is suitable for resting studies.

Elevation of metabolic demands by moderate exercise resulted in increases fatty acid uptake in skeletal and cardiac muscle for both [ $^{125}\text{I}$ ]-BMIPP and [ $^3\text{H}$ ]-BROMO.

Generally, tissue extraction of fatty acids doubled with exercise. This finding confirms previous observations of Oakes and colleagues [8] who have shown [ $^3\text{H}$ ]-BROMO is not affected by metabolic (oxidative vs. nonoxidative) status in skeletal muscle. Of note, differences in liver fatty acid uptake at rest were not observed during exercise. This may be due to a diversion of blood flow away from this organ during exercise. In addition to increasing tracer tissue uptake, exercise also resulted in greater tissue excretion of tracers at all time points measured. At 40 min, 37 and 53% of the initial tracer dose were present in conversion products for [ $^{125}\text{I}$ ]-BMIPP and [ $^3\text{H}$ ]-BROMO respectively. This excretion is due to elevated  $\alpha$  and  $\omega$ -oxidation of fatty acids with exercise or simply back diffusion. However, despite increasing fractional conversion with exercise, we show good agreement between tracers in cardiac and skeletal muscle.

**Fig. 3** Comparison of fatty acid uptake rates between [ $^3\text{H}$ ]-BROMO (y axis) and [ $^{125}\text{I}$ ]-BMIPP (x axis) for individual tissue measurements. Values for resting (*open circles*) and exercise (*closed circles*) are shown along with their corresponding  $R^2$  values for rest, exercise and total aggregate are shown

**Table 2** Estimated fractional tracer conversion of [ $^3\text{H}$ ]-BROMO and [ $^{125}\text{I}$ ]-BMIPP in plasma over time during rest and exercise

	2 (%)	5 (%)	10 (%)	15 (%)	25 (%)	40 (%)
Rest						
[ $^{125}\text{I}$ ]-BMIPP	1.2	6.3	12.4	14.3	11.8	11.4
[ $^3\text{H}$ ]-BROMO	1.0	4.0	9.2	12.7	10.5	10.4
Exercise						
[ $^{125}\text{I}$ ]-BMIPP	4.6	10.4	14.6	17.3	24.7	37.0
[ $^3\text{H}$ ]-BROMO	5.3	10.6	21.2	40.4	53.5	52.9

Results represent the % of radioactivity in breakdown products versus [ $^3\text{H}$ ]-BROMO and [ $^{125}\text{I}$ ]-BMIPP as assessed by thin layer chromatography

From a technical perspective, [ $^3\text{H}$ ]-BROMO has advantages primarily related to the label-induced limitations of [ $^{125}\text{I}$ ]-BMIPP. These include its shorter half-life, elevated biological risk and synthesis. [ $^{125}\text{I}$ ]-BMIPP has a half life of 60 days compared to [ $^3\text{H}$ ]-BROMO which is 12 years. Given this, corrections for tracer decay with [ $^{125}\text{I}$ ]-BMIPP need to be considered, when studies extend over days to weeks. In the present study, a single batch of [ $^{125}\text{I}$ ]-BMIPP was employed and studies occurred over a 1-month period. All results were scaled to include corrections for tracer decay. Another consideration involves the biological risk involved with working these isotopes. [ $^{125}\text{I}$ ]-

BMIPP is a gamma and X-ray emitter and although used in low doses, still poses a greater hazard than [ $^3\text{H}$ ]-BROMO which is a lower energy beta emitter. Finally, the labelling for [ $^3\text{H}$ ]-BROMO is complex but the compound is currently commercially available, while [ $^{125}\text{I}$ ]-BMIPP is straightforward to label but requires specific precautions related to iodination, and currently must be performed in an institutional setting. Finally, in studies where multiple tracers are employed, there may be specific limitations related to other radioactive labeled compounds in concurrent use. These issues must be considered prior to commencing studies with either tracer.

In conclusion, this study directly compares isotopic analogs for the measurement of fatty acid kinetics in vivo. Results show both analogues are effective for the measurement of FFA uptake and clearance in plasma. We showed a high correlation between tracers for cardiac and skeletal muscle. However, in both the liver and adipose tissue, derived rates of uptake diverged depending on the specific tracer. As a result, studies employing these or other fatty acid tracers in these tissues must be interpreted with caution. Generally, technical considerations argue for [ $^3\text{H}$ ]-BROMO. However, when studies are prolonged (>20 min) and employ experimental manipulations requiring elevated metabolism, we show the preferable analog to be [ $^{125}\text{I}$ ]-BMIPP due to its lower rates of tissue excretion.

**Table 3** Incorporation of [<sup>125</sup>I]-BMIPP and [<sup>3</sup>H]-BROMO into various lipid fractions in tissues at rest (*n* = 5) and exercise (*n* = 5) as determined by thin layer chromatography

Tissue	Lipid fraction	[ <sup>3</sup> H]-BROMO	[ <sup>125</sup> I]-BMIPP
Rest

**Abstract** Total parenteral nutrition (TPN) studies in human babies of very-low-birth-weight suggest that the lipid emulsions currently available are not optimum for neonatal nutrition. Since fatty acid metabolism in human and pigs is very similar, the present study examines how lipid emulsions used in clinical TPN (i.e. ClinOleic, Intralipid, Lipofundin or Omegaven), with different fatty acid compositions, administered to neonatal piglets for 7 days, influenced their tissue fatty acid composition as compared to those enterally fed with a sow milk replacer. A positive linear relationship was found between the proportion of all individual fatty acids in the lipid emulsions or in the milk replacer versus those in plasma, skeletal muscle, subcutaneous fat, liver, heart, pancreas, stomach or intestine total lipids or in brain phospholipids, the latter showing the lowest correlation coefficient. With the exception of brain, the proportion of either oleic acid or  $\alpha$ -linolenic acid in the individual tissues was correlated with those present in the corresponding lipid emulsion or milk replacer, whereas the proportion of linoleic acid correlated significantly with all the tissues studied. With the exception of brain

phospholipids, both eicosapentaenoic and docosahexaenoic acids were higher in the tissues of piglets receiving Omegaven than in all other groups. In conclusion, with the exception of the brain, fatty acid composition of plasma and different tissues in piglets are strongly influenced by the fatty acid profile of TPN emulsions. Fatty acid composition of brain phospholipids are, however, much less influenced by dietary composition, indicating an active and efficient metabolism that ensures its appropriate composition at this key stage of development.

## Introduction

Total parenteral nutrition (TPN) has been used in routine nutritional care since the 1960s. The first lipid emulsion developed for TPN was a soybean oil-based lipid emulsion [1]. This lipid emulsion was marketed as Intralipid and is one of the most widely emulsions used in TPN administration [2]. Evidence has accumulated that, in addition to their nutritional role as energy source, lipid emulsions have numerous other biologic functions. In particular, it has been shown that the fatty acid composition of cell membranes is highly influenced by the fatty acid profile of dietary lipids [3], which may in turn affect their structural and regulatory properties [4]. Indeed, lipids can influence numerous physiological processes including some roles of the cellular membrane such as membrane permeability, receptor pathways and membrane-associated enzyme activities [5], and can also affect the immune function [6, 7].

Preterm infants often require a parenteral lipid emulsion in order to prevent essential fatty acid deficiency,

particularly if an adequate energy and lipid intake cannot be achieved by enteral feeding. The adequacy of soybean lipid emulsions for the nutritional needs of newborn and premature infants has been questioned [8]. Soybean-oil-based lipid emulsions contain only minor amounts of the long chain polyunsaturated fatty acids (LCPUFA). These long chain fatty acids, in particular arachidonic acid (AA) and docosahexaenoic acid (DHA), have essential functions for early visual and neural development [9–11]. In addition, AA is the main precursor for eicosanoids [12, 13] and is known to play a key role in neonatal growth [14, 15]. The endogenous synthesis of LCPUFA from precursor essential fatty acids (EFA), linoleic acid (LA) and  $\alpha$ -linolenic acid (ALA), involves  $\Delta 6$  and  $\Delta 5$  desaturases, constituting the n-6 and n-3 PUFA metabolic pathways, respectively [16, 17]. Although intake of PUFA is required to prevent any EFA deficiency, it is known that excessive intake has detrimental effects. Thus, excessive intake of LA may inhibit  $\Delta 6$  desaturase resulting in a decrease in the formation of DHA from ALA [18]. An excess of n-3 fatty acids has also been demonstrated to inhibit  $\Delta 6$  desaturase activity [19], which is responsible for a major decline in AA concentrations in rats fed a fish oil diet [20]. Desaturase activities are limited in preterm and term infants [21], and the large amounts of LA and ALA in soybean oil emulsions may further impair LCPUFA formation through substrate inhibition. Furthermore, the high supply of PUFA in soybean oil emulsions may enhance lipid peroxidation [22], which is of particular concern in preterm infants as it may for example cause liver damage [23]. The lipid content must be balanced to provide the correct fatty acids for brain development whilst avoiding the dangers of oxidative damage.

Total parenteral nutrition studies in human babies of very-low-birth-weight suggest that lipid emulsions currently available are not optimum for nutrition of the neonate [8]. The new lipid emulsions for clinical use are differentiated by their content in polyunsaturated (n-3 and n-6), monounsaturated, and saturated fatty acids. Due to similarities in the fatty acid metabolism in human and pigs [24], and for obvious ethical reasons, a piglet model of such treatments has been successfully developed in this study, and has enabled the effects of the treatments on tissue composition to be determined.

## Materials and Methods

Experimental protocols were carried out as defined by the regulations of the Animals (Scientific Procedures) Act 1986, under the appropriate Home Office Licence and all procedures were agreed by the local ethical review board.

## Experimental Design

Sixteen nulliparous sows (25% Meishan, 12.5% Duroc and 62.5% Large White X Landrace) were entered into the study. A routine caesarean section was carried out under anaesthesia at 113 days of gestation (term = 115 days). Anaesthesia was induced by administration of 2–5 mg/kg ketamine i.v. (Ketaset, Fort Dodge, Southampton, UK) and maintained using isoflurane 4–6 % (Schering-Plough Animal Health, Harefield, UK) oxygen (BOC, Manchester, UK). Following delivery, the piglets were given oxygen and an intramuscular injection of vitamin K (0.25 ml, Konaktion MM 10 mg ml<sup>-1</sup>, Roche Products Ltd, Lewes, UK) to assist blood clotting and allowed to recover from anaesthesia.

Piglets were selected so as to balance experimental groups for sex, body weight at birth and maternal influences. Practically, each experimental group contained piglets from at least three sows and within each litter, male and female piglets were ranked according to weight, and any outliers removed. Within each gender, piglets were matched for weight, and randomly allocated to one of five treatment groups and fed either enterally (E) with a commercially-available sow milk replacer (4.5 kJ ml<sup>-1</sup>, Primary Diets, Ripon, UK); or TPN solution (1,690 J/ml; 99.34 mg ml<sup>-1</sup> glucose; 17.89 mg ml<sup>-1</sup> amino acids; Portsmouth Hospital NHS Trust, Portsmouth, UK), plus one of the following commercially available lipid emulsions: Intralipid 20% (Fresenius Kabi Ltd., Runcorn, UK), ClinOleic 20% (Baxter Healthcare Ltd, Northampton, UK), Lipofundin 20% (Baxter Healthcare Ltd, Northampton, UK) or Omegaven 10% (Fresenius Kabi Ltd., Runcorn, UK). The fatty acid profile of the lipid emulsions is shown in Table 1. The TPN solution was formulated according to the prescription used by the local neonatal care centre (The William Harvey Hospital, Ashford, Kent). As humans and pigs have similar nutritional requirements [25] it is possible to provide adequate nutritional support in the pig using clinical TPN regimes, which is useful in establishing an animal model with clinical relevance [26].

At 2–4 h post-delivery, piglets of similar body weight were anaesthetized using isoflurane 0.5–2% (v:v; Schering-Plough Animal Health, Harefield, UK) and bilateral jugular catheters were inserted. One of these catheters was used for daily administration of TPN and the corresponding commercially available lipid emulsion, the other catheter was used to administer intravenous antibiotics, as required, and for blood sampling. The TPN solution was infused using a volumetric infusion pump (IVAC 598, Alaris medical, Basingstoke, UK) at 2.9 ml/h/kg. and lipid emulsion, via the same infusion line, using a syringe pump (IVAC P7000, Alaris medical, Basingstoke, UK) at 0.2 ml/h/kg for the

first 12 h. After 12 h the infusion rate of the TPN solution was increased to 5.8 ml/h/kg and lipid emulsion at 0.5 ml/h/kg and, after 24 h, piglets were receiving TPN solution at 5.8 ml/h/kg and lipid emulsion at 1.0 ml/h/kg. These rates were maintained throughout the remainder of the study. Other piglets, after recovering from surgery were fed enterally with a commercially-available sow milk replacer (Primary Diets, Ripon, UK). They were initially given 10 ml of milk replacer and subsequently supplied with 100 ml of milk at 4 h intervals, the volume of milk refused was recorded as a means of measuring intake. Piglets were weighed daily and given antibiotics i.v. (50 mg benzylpenicillin: Crystapen, Britannia Ltd., Redhill, UK) twice daily.

On the final day of treatment (a few animals were slaughtered prior to the end of the study due to the varying ability of individual piglets to tolerate parenteral feeding), piglets were humanely slaughtered using pentobarbitone sodium (Euthatal, Rhone Merieux, Harlow, UK) and blood and tissue samples were taken. All tissue samples were frozen in liquid nitrogen and were kept at  $-80^{\circ}\text{C}$  until analysis. Blood samples were taken into EDTA tubes (Teklab, Durham, UK) and centrifuged at 1,400 g in a bench centrifuge for 15 min at  $4^{\circ}\text{C}$  to produce plasma, which was stored at  $-20^{\circ}\text{C}$  for subsequent analysis.

## Processing of Samples

Fresh aliquots of each lipid emulsion as well as milk replacer, frozen plasma, liver, subcutaneous fat, brain, heart, pancreas, muscle, intestine and stomach were used for lipid extraction and purification [27]. To assess the fatty acid profile of the phospholipids in the brain, following the lipid extraction, lipids were separated by thin layer chromatography using Silicagel 60 F<sub>254</sub> plates (Merck, Darmstadt, Germany) with *n*-heptane/diisopropyl ether/acetic acid (70:30:1 v/v/v) as the solvent system. The bands were visualized with 2',7'-dichlorofluorescein (Supelco, Bellefonte, PA, USA) and the phospholipid fractions were eluted from the plate. Total lipid or phospholipid fatty acids were simultaneously saponified and methylated following the method of Lepage and Roy [28, 29]. Fatty acid methyl esters were separated and quantified on a Perkin-Elmer gas chromatograph (Autosystem; Norwalk, CT, USA) with a flame ionisation detector and a 30 m × 0.25 mm Omegawax capillary column. Nitrogen was used as carrier gas, and the fatty acid methyl esters were compared with purified standards (Sigma Chemical Co., St. Louise, MO, USA). Individual fatty acids are expressed as percent of total fatty acids in the sample. Although all the fatty acids from 10:0 to 22:6 (n-3) were analyzed in every sample and used in calculating the corresponding proportions, in the tables and figures just those that have any significance due to their particular presence in the analyzed sample or are of interest due to their respective endogenous metabolism are given.

## Statistical Analysis

Data are expressed as means ± SEM. Treatment effects (emulsions or enteral feeding) were analysed by one-way ANOVA with SPSS 12.0 for Windows. When treatment effects were significantly different ( $P < 0.05$ ), means were tested by a Student–Newman–Keuls test. Linear regressions were calculated by the least-squares method [30]. To test the potential interrelationship in fatty acid composition between the emulsions given and the different tissues, correlations of the proportion of fatty acids in the emulsions and the mean value of individual fatty acids in each tissue were calculated.

## Results

### Plasma

The fatty acid profile of the plasma (Table 2) shows that the proportions of saturated and monounsaturated fatty acids were very similar between the groups with the only

ND non detectable

exception being palmitic acid (16:0) which was the lowest in Lipofundin and highest in the Omegaven groups. The n-3 LCPUFA, eicosapentaenoic acid (EPA, 20:5 n-3) and also DHA (22:6 n-3) was higher in those animals given Omegaven compared to the other nutritional treatments (Table 2). AA (20:4 n-6) was almost non-detectable in the milk replacer and the lipid emulsions except for Omegaven (Table 1); however the plasma from all groups showed a considerable and similar proportion of AA (Table 2). There were no other changes observed in the PUFA between the groups, either in terms of the lipid of the nutrients supplied or in the plasma sampled from the animals.

### Skeletal Muscle

The fatty acid composition of the skeletal muscle of piglets maintained on TPN with different lipid emulsions or enterally with milk replacer (Fig. 1) closely corresponded to the fatty acid composition of the TPN lipid emulsions or the milk replacer received by each group (Table 1). Of the saturated fatty acids the greatest proportion in all groups was palmitic acid and as it would be expected, myristic acid (14:0) was higher in the skeletal muscle of enterally fed piglets than in the TPN groups. Oleic acid (18:1n-9) was the predominant monounsaturated fatty acid in all the groups, being highest in the ClinOleic group, followed by the enterally fed group. Among n-6 fatty acids, linoleic acid (18:2 n-6) reached the greatest proportion in the Intralipid group followed by Lipofundin (Fig. 1), which fits with its larger proportion in these specific lipid emulsions (Table 1). The proportion of AA was similar in all the groups with a tendency of being slightly although not significantly higher in the Omegaven group than in the others. The proportion of  $\alpha$ -linolenic acid (18:3n-3) in muscle, was greater in the Intralipid and Lipofundin groups than in the others (Fig. 1), in agreement with

**Fig. 1** Fatty acid profile (g/100 g fatty acids) of skeletal muscle in piglets maintained on total parenteral nutrition (TPN) for up to 7 days ( $n = 5\text{--}6/\text{group}$ ). Values are expressed as means ± SEM. Student–Newman–Keuls test was used to determine differences between groups after ANOVA. Different letters over each bar indicate significant differences ( $P < 0.05$ )

their higher proportion in the corresponding lipid emulsion. Concerning the long chain n-3 PUFA (EPA and DHA), their proportions in muscle were much higher in the Omegaven group than in any of the others.

### Subcutaneous Adipose Tissue

As shown in Table 3, the fatty acid profile of subcutaneous fat also mirrored that of the milk replacer given enterally or the lipid emulsion given during TPN and was markedly different between the groups. No differences among the groups were seen for the saturated fatty acids, whereas the proportion of oleic acid was higher in both the enterally fed and the ClinOleic groups than in the others. The proportions of both linoleic and  $\alpha$ -linolenic acids in subcutaneous adipose tissue were higher in the Intralipid and Lipofundin groups whereas no differences among the groups were

found for AA. Here again, the proportion of both EPA and DHA was greater in the Omegaven group than in any of the others.

#### Liver

In liver, the composition of the fatty acids differ from the other tissues (Fig. 2). The proportion of saturated fatty acid was similar among the groups except for stearic acid (18:0) that was higher in the enterally fed group than in any of the others. Oleic acid reached the largest proportion in liver of the ClinOleic group, which fits with being the lipid emulsion containing the highest proportion of this fatty acid. The proportion of linoleic acid was highest in the Intralipid and the lowest in the Omegaven group. The proportion of  $\alpha$ -linolenic acid in liver was higher in the Intralipid and Lipofundin groups than in any of the others. With AA, its highest proportion was reached by the enterally fed piglets,

**Fig. 2** Fatty acid profile (g/100 g fatty acids) of liver in piglets maintained on TPN for up to 7 days ( $n = 5\text{--}11/\text{group}$ ). Values are expressed as means ± SEM. whereas the rest of the groups showed a similar proportion including the Omegaven group, which on the other hand showed the greatest proportion of n-3 LCPUFA, EPA and DHA (Fig. 2).

#### Heart, Pancreas, Stomach and Intestine

Similar fatty acid profiles were found in heart (Table 4), pancreas (Table 5), and stomach (Table 6) and could be considered together: No major differences were detected for the saturated fatty acids, although values for stearic acid appeared lower in enterally fed and ClinOleic treated piglets than in the other groups in pancreas and stomach. Oleic acid tended to be higher in these tissues in the piglets receiving milk replacer enterally or the ClinOleic emulsion intravenously, than in the other groups. Both linoleic and  $\alpha$ -linolenic acids were higher in these tissues in the groups given Intralipid and Lipofundin. AA showed a considerable proportion in these tissues in all the groups even though its proportion in the administered emulsions or enteral diet was very low, except for Omegaven. Piglets receiving the Omegaven emulsion showed the highest proportion of both EPA and DHA in these three tissues (Tables 4, 5, 6).

In the intestine there were some differences between the enterally fed piglets and those on TPN that require highlighting (Table 7). Higher proportions of lauric (12:0), myristic and oleic acid were found in the enterally fed group compared to any of the other groups. In contrast, proportions of stearic and AA were lower in the enterally fed piglets than in any of the other groups (Table 7). The Omegaven group also showed some differences in the intestine fatty acid profile compared to the other groups, with a lower proportion of both LA and ALA and a higher proportion of both EPA and DHA, all of which coincide with the relative proportions in the profile of the emulsion (Table 1).

## Brain

In relation to the fatty acid composition of brain phospholipids in piglets fed enterally or maintained on TPN

(Fig. 3), it can be seen that there were no statistical differences in the proportions of the main saturated fatty acids (palmitic and stearic acids) between the different treatments. It is also interesting to notice that the proportion of

stearic acid seen in brain phospholipids of all the groups is higher than that present in plasma or in any of the other tissues studied. The proportion of oleic acid (18:1n-9) was also similar in all the groups despite the differences in the proportion of this fatty acid in the emulsions used. In relation with PUFA, linoleic acid proportions in all the groups were lower than in any of the other tissues studied, and values were higher in the Intralipid group, followed by Lipofundin, which may be related to the high proportion of this fatty acid in the emulsion's composition. The proportion of  $\alpha$ -linolenic acid was practically undetectable in brain phospholipids from all the groups, despite its significant proportion in the corresponding emulsions. Despite major differences in the proportions of LCPUFA in the emulsions or milk replacer, the brain phospholipids showed similar proportions across the different groups, with the exception of DHA, which showed a large proportion in all the groups, although the Omegaven group showed its greatest proportion (Fig. 3).

#### Relationship Between Emulsions and Tissues

There were positive significant linear correlations between the proportion of the fatty acids in the emulsions and the proportions of the same fatty acids in each of the tissues studied, with brain phospholipids showing the lowest correlation coefficient (data not shown). Besides, by calculating the relationship of individual fatty acids for each tissue vs. their proportion in the milk replacer or lipid emulsions or even in plasma, it was found that in case of the saturated fatty acids the correlations did not reach statistical significance whereas the proportions of oleic acid, linoleic acid,  $\alpha$ -linolenic acid, EPA or DHA were significantly correlated in case of skeletal muscle, subcutaneous fat, liver, heart, pancreas,

**Fig. 3** Fatty acid profile (g/100 g fatty acids) of brain phospholipids in piglets maintained on TPN for up to 7 days ( $n = 4\text{--}11/\text{group}$ ). Values are expressed as means ± SEM. stomach or intestine, but not in brain phospholipids (data not shown).

#### Discussion

##### Tissue Fatty Acid Profiles in Piglets on TPN Emulsions with Different FA Compositions

The present study shows that the fatty acid composition of the skeletal muscle and subcutaneous adipose tissue from piglets enterally fed a milk replacer or intravenously administered ClinOleic, Intralipid, Lipofundin or Omegaven emulsions—having different fatty acids composition—for 7 days from birth, is clearly influenced by the dietary fatty acid composition, and it is consistent with a previous report that indicates that fatty acid composition of adipose tissue and muscle of 7-day-old pigs reflects milk

fatty acid composition [31]. This fits with the high lipoprotein lipase (LPL) activity that has been found in adipose tissue of these animals [31, 32], and although in muscle the LPL activity is lower, it has been found that there is no release of NEFA from skeletal muscle during high rates of LPL action, suggesting that in muscle LPL-derived fatty acids are effectively trapped in the tissue [33], which is in accordance with our results. Nevertheless, previous observations support the hypothesis that lipogenesis may be significant in adipose tissue of the neonatal pig [31, 34] and in our study the lack of difference in the proportion of palmitic acid in adipose tissue between the different groups studied, despite the fact that milk replacer contained nearly twofold the proportion of palmitic acid in the TPN emulsions, also supports this hypothesis.

In liver, the fatty acid composition must be modulated by *in situ* metabolism of fatty acids and the influx of fatty acids from the diet and/or from the *de novo* synthesis in the adipose tissue. Although it has been reported that the rate of lipogenesis in the liver of newborn piglets is low [35], a high rate of desaturase activities is found in the liver of piglets [19, 36]. As a result of this, and even though Omegaven emulsion is the only one that contains AA in its composition, all the groups produce high proportions of AA in liver. It is known that high proportions of long-chain n-3 fatty acids decrease  $\Delta$ -6 desaturase activity [37, 38], the main enzyme responsible for the synthesis of AA from linoleic acid, but this effect could be compensated for by the presence of AA in the Omegaven emulsion, causing the Omegaven group to have a similar amount of AA in liver in comparison with the rest of the TPN fed groups. Moreover, it is important to point out that the highest proportion of AA in liver is observed in the enterally fed group, and the lower AA proportion in the TPN treated groups could be the result of lower rates of desaturation that have been already reported in other studies as a consequence of TPN treatments [39]. This lower proportion of AA following TPN occurs even after treatment with Intralipid, which contains the highest proportion of linoleic acid as compared to other emulsions and more than eight times higher than the milk replacer. It could well be that the high dietary intake of linoleic acid in this group inhibits AA synthesis or competes with AA for acylation, as it has been previously proposed [40]. Fatty acid composition of liver is also influenced by its LPL activity, allowing circulating triacylglycerols to be hydrolyzed and fatty acids to be taken up by the tissue. In contrast to what occurs in adults, the liver of the newborn in different species expresses LPL [41, 42] and the pig is not an exception [32]. In fact, we have previously shown that the piglets receiving TPN develop fatty liver, the effect being probably mediated by the action of LPL contributing to the tissue uptake of circulating fatty acids [32].

The fatty acid proportion in plasma must be the result of the influx of fatty acids from the emulsions, plus those from the metabolic changes taking place in liver and/or adipose tissue. The fact that no differences were found between the groups in oleic, linoleic, ALA and even AA in plasma, despite major differences in their respective proportion in the different lipid emulsions or milk replacers, would indicate that they represent a combination of these different sources. These metabolic changes also influence the fatty acid composition of other tissues such as heart, pancreas, stomach and intestine. Among them, the one that follows most closely the differences found in the lipid emulsions or milk replacer fatty acid composition is the heart, which has been reported not to exhibit desaturase activities [19, 43].

#### Relationship Between the Fatty Acid Profiles of the TPN Emulsions and in Different Tissues

In order to obtain an approximation of the influence of administered fatty acids, with the different emulsions or milk replacer, on the tissue fatty acid composition, linear correlations were made. Strong linear correlations were found between the fatty acids in the TPN emulsion given and the fatty acid composition of plasma and several tissues of piglets, the lowest correlation being found for brain phospholipids. In an attempt to analyze in more detail the influence that each fatty acid present in the emulsion has in its corresponding proportion in the different tissues, correlations were performed and it was found that the proportions of palmitic and stearic fatty acids, the main saturated fatty acids, did not correlate with their proportion in the TPN or in the milk replacer. This finding is consistent with the results found in other studies where it is observed that lipogenesis is significant in adipose tissue and muscle of neonatal pigs [31] and in developing brain [44, 45]. However, different to other tissues, oleic acid in brain phospholipids did not correlate with this fatty acid in the TPN emulsions or milk replacer, and its precursor, stearic acid shows the highest proportion in brain phospholipids than in any of the other tissues studied. Although we have not measured the actual rate of lipogenesis, these findings indicate an active elongase process in brain allowing the efficient conversion of palmitic acid into stearic acid, and the efficient  $\Delta$ 6 desaturation of the later, all of which agree with the active lipid metabolism known to take place in brain [46], and with the high stearyl-CoA desaturase present in brain during the perinatal period [47]. The correlation between the proportion of tissue fatty acids and those present in the TPN emulsions and milk replacer were particularly significant for the PUFA, which agrees with similar previously described findings in adipose tissue [48]. EFA cannot be synthesized endogenously. The proportion of LA in the emulsions or milk replacer is strongly

correlated with the proportion found in each of the tissues studied, including brain phospholipids. However, the LA derivative, AA, reach a proportion in different tissues that is independent of its presence (or absence) in the diets. This indicates an active endogenous synthesis of AA in all the studied tissues, including brain, where it has been described that is active during development [49]. Concerning the n-3 LCPUFA, present findings indicate that with exception of brain phospholipids, the presence of both EPA and DHA in the different tissues is very much dependent on their presence in the corresponding emulsion or milk replacer, since despite of the presence of their precursor in the diets and tissues both fatty acids reached significant proportions only in the tissues of the TPN-Omegaven group, indicating that their endogenous synthesis in the neonatal pig is relatively low. This situation completely differs in brain phospholipids, where the proportion of EPA did not differ in the piglets receiving Omegaven compared to any of the other groups and in case of DHA, its comparative proportion in brain of animals on Omegaven versus the rest of the groups is much smaller than for any of the other studied tissues. This occurs despite the brain having the lowest proportion of ALA in all the groups, suggesting a rapid and efficient conversion to their LCPUFA derivatives, EPA and DHA.

#### Final Considerations

It is not possible to directly compare present findings to the condition present in premature human neonates on TPN. However, the premature piglet has previously been used as a model for the premature infant [50–52], and by using an experimental design similar to that previously used, we have recently found that during TPN, the piglets show typical responses previously reported in human infants [32]. Thus, with the appropriate caution, the findings here reported can be used to understand some of the responses to TPN in human premature neonates.

In conclusion, with the exception of the brain, the fatty acid composition of plasma and of different tissues of piglets are strongly influenced by the fatty acid profile of TPN emulsions. However, fatty acid composition in brain phospholipids is much less dependent on dietary composition, indicating an active and efficient metabolism that ensures the appropriate composition in this key stage of its development. It is proposed that an appropriate availability of essential fatty acids, rather than synthesized LCPUFA is needed to ensure an appropriate fatty acid profile in the brain during its developmental stage.

**Abstract** The aim of the present study was to assess the plasma fatty acid composition of the total plasma lipids and lipid fractions in obese prepubertal children with and without metabolic syndrome (MS). Thirty-four obese prepubertal children were recruited: 17 who met MS criteria and 17 who did not; and twenty prepubertal children of normal weight. MS characteristics, insulin resistance (by homeostasis model assessment [HOMA-IR]), and plasma adiponectin (by radioimmunoassay) were recorded. Separation of lipid fractions was performed by liquid chromatography and the concentration of fatty acids in total plasma lipids and fractions was determined by gas-liquid chromatography. Concentrations of 16:1n-7, 16:1n-9, 18:3n-3, 22:6n-3, and n-3 PUFA in total plasma lipids ( $P < 0.05$ ) and of 16:0, 16:1n-7, 18:1n-9, 18:2n-6, and n-6 PUFA in triacylglycerols (TG) ( $P < 0.05$ ) were significantly higher in obese MS versus normal-weight children. Increased risk of MS was positively associated with plasma concentration of 16:1n-7 and negatively associated with proportion of 20:4n-6 (OR 2.76;  $P = 0.004$ ; OR 0.56,  $P = 0.030$ , respectively). Saturated FA in TG were

associated with HOMA-IR ( $R = 0.349$ ,  $P = 0.017$ ) and 22:5n-6 with adiponectin ( $R = 0.336$ ,  $P = 0.05$ ). In conclusion, increased concentrations of 16:1n-7 and decreased proportions of 20:4n-6 and 22:5n-6 in plasma lipids appear to be early markers of MS in children at prepubertal age.

### Abbreviations

HOMA	Homeostatic assessment model
IR	Insulin resistance
FSH	Follicle-stimulating hormone
LC-PUFA	Long-chain polyunsaturated fatty acids
LH	Lutein hormone
MS	Metabolic syndrome
MUFA	Monounsaturated fatty acids
NEFA	Non-esterified fatty acids
NMS	Non-metabolic syndrome
SCD1	Stearoyl-coenzyme A desaturase 1
SFA	Saturated fatty acids
TG	Triacylglycerols
TFA	Total FA

### Introduction

The prevalence of obesity in infancy has dramatically increased over the last few decades in both developed and developing countries [1]. Obese patients typically show a cluster of clinical and metabolic abnormalities known as metabolic syndrome (MS), characterised by insulin resistance (IR), hyperglycemia, high VLDL triacylglycerols

(TG), low HDL-cholesterol, and hypertension [2]. Changes in plasma concentrations of some hormones and adipokines, e.g., adiponectin, are also associated with MS [3]. Evidence is accumulating that IR induced by excess of fat may be a common link among clinical manifestations of MS [4–6]. MS has a high prevalence among children and adolescents, increases with worsening obesity, and is associated with an increased risk of cardiovascular disease [4, 7].

Very little research has been published on the association between childhood obesity or MS and possible changes in fatty acid profiles of plasma and its lipid fractions. Alterations in the proportions of saturated fatty acids (SFA) and some long-chain polyunsaturated fatty acids (LC-PUFA), mainly arachidonic acid (20:4n-6) have been reported in pubescent children with MS [8, 9]. More recently, plasma fatty acid composition was shown to be associated with MS and low-grade inflammation in overweight adolescents [10]. A search of the literature yielded no data on changes in plasma fatty acid composition related to obesity or MS in prepubertal children. The study of fatty acid composition in plasma of prepubertal children with and without MS may contribute to a better knowledge of the mechanisms involved in alterations of lipid metabolism related to early onset and development of obesity and MS. Therefore, the aim of the present study was to quantify and compare the plasma fatty acid composition of total plasma lipids and plasma lipid fractions PL, CE, TG and non-esterified fatty acids (NEFA) in obese prepubertal children with and without MS and in prepubertal children of normal weight.

## Experimental Procedures

### Subjects

Fifty-four Caucasian children aged 6–12 years, comprising 34 obese and 20 normal-weight children at prepubertal age (Tanner I) were selected, the clinical stage being confirmed with the determination of sexual hormones (FSH, LH, estradiol and testosterone). Children with Tanner II or III did not enter into the study and Tanner I with elevated levels of hormones that indicated starting puberty, were excluded. Most of the children that were 12 years old were boys.

Two recent papers by our group on the postprandial response of *trans* and other plasma fatty acids in the prepubertal obese children are based on the same population of the present report [11, 12]. The study was approved by the Human Investigation and Ethics Committees of the University of Granada and the Reina Sofia University Hospital of Cordoba (Spain). Written informed consent

was obtained from parents and verbal approval from children.

### Classification of Obese Children by Presence/Absence of Metabolic Syndrome

Although a new worldwide definition for the MS has been reported for adults [2], there has been no equivalent international agreement on the criteria for MS in childhood. Therefore, our classification of the obese children as non-MS (NMS) or MS was a modification of criteria established by the World Health Organisation [13] and the Adult Treatment Panel of the Cholesterol Education Program [14]. MS was diagnosed if three or more of the following criteria were met in relation to the age and sex of the child: BMI  $z$  score  $\geq 2.0$ ; plasma TG concentration  $>95$ th percentile; plasma HDL-cholesterol concentration  $<5$ th percentile; systolic or diastolic pressure  $>95$ th percentile; and impaired glucose tolerance, defined as a fasting plasma glucose concentration  $>6.1$  mmol/L [15].

### Dietary Assessment

Children and parents were interviewed on an individual basis to obtain information on lifestyle and dietary habits. Dietary intake was estimated by means of a food-frequency questionnaire and 72-h dietary survey, using a database of the composition of Spanish foods [16].

### Anthropometric, Blood Pressure, and Sex Maturity Measurements

An initial examination was conducted by trained pediatric endocrinologists according to standardised methods. Measurements were taken of height, weight, tricipital and subscapular skinfolds, and waist and hip circumferences and the BMI (weight-[kg]/height<sup>2</sup> [m<sup>2</sup>]) and waist-to-hip ratio were calculated. The BMI  $z$  score was calculated based on the averages and standard deviations of BMI for the Spanish children population, considering sex and age as published by Hernández et al. [17]. Blood systolic and diastolic pressures were measured using a standardised mercury sphygmomanometer and an adapted cuff size. Self-assessed Tanner stages and concentrations of plasma follicle-stimulating hormone (FSH), lutein hormone (LH), estradiol, and testosterone were recorded and used to estimate the sexual maturity of the children.

### Blood sampling

Baseline blood samples were obtained from children at 9 a.m. after a 12-h overnight fast, using an indwelling venous line for the measurement of plasma glucose, insulin, sex

hormones, lipids, total fatty acids, and fatty acid composition of lipid fractions. All samples were processed within 2 h of sampling, and were divided into aliquots for immediate processing or for long-term storage at  $-80^{\circ}\text{C}$  until their analysis.

### Biochemical Analysis

Sex hormones, blood glucose, plasma insulin, adiponectin and lipids, as well as isolation, separation and quantitation of fatty acids in total plasma lipids and plasma lipid fractions were analysed as previously reported [3]. In brief, sex hormones (FSH: CV 3.6%; LH: CV 3.1%; testosterone: CV 2%; estradiol: CV 1.8%) were measured by chemiluminescence using an automatic analyser (Architet I4000, Abbott Laboratories Chicago, IL, USA). Glucose was analysed using the glucose oxidase method in an automatic analyser (CV 1%) (Roche-Hitachi Modular PyD Autoanalyser, Roche Laboratory Systems, Mannheim, Germany), and plasma insulin was analysed by radioimmunoassay (CV 2.6%) using an automatic analyser for microparticles (Axsym, Abbott Laboratories, Chicago, IL, USA). Insulin resistance was calculated by means of the homeostatic assessment model (HOMA-IR), as defined by the equation  $\text{HOMA-IR} = \text{fasting glucose (G0) (mM)} \times \text{fasting insulin (I0) } (\mu\text{U/mL})/22.5$  [18].

Plasma TG (CV 1.5%) and HDL-cholesterol (CV 0.8%) were measured using an automatic analyser (Roche-Hitachi Modular PyD Autoanalyser, Roche Laboratory Systems, Mannheim, Germany). Plasma adiponectin was measured by radioimmunoassay (Human adiponectin RIA kit, Cat.#HADP-61HK, Linco Research Inc., St. Charles, MO, USA).

### Statistical Analysis

The minimum sample size to detect an effect due to the presence of MS in obese children was estimated as 16 children per group; this figure allows a type I error  $\alpha = 0.05$  and a type II error  $\beta = 0.1$  (power 90%) for an estimated difference of 20% between groups in the mean value of major plasma fatty acids (oleic and linoleic acids), considering the variances obtained previously in plasma fatty acid analyses of children measured by gas–liquid chromatography [19].

All data for continuous variables are expressed as means  $\pm$  SEM. Variables not following a normal distribution (insulin, HOMA, TG and fatty acid percentages) were logarithmically transformed before analysis. Comparisons of continuous variables among groups, with adjustments for age and sex, were assessed by general linear models of variance and post hoc Bonferroni tests. The association of fatty acid variables with variables

considered in the definition of MS was analysed for the obese children by multivariable linear regression models. Logistic regression models were performed to identify fatty acids significantly related to the likelihood of having MS. All statistical analyses were performed with SPSS version 14.1 software (Statistical Package for Social Sciences, SPSS Inc. Chicago, IL, USA).

## Results

### Anthropometric, Metabolic, and Dietary Evaluation

Table 1 shows sex frequencies, age, and anthropometric and metabolic data adjusted for sex and age in the normal-weight, and NMS and MS obese prepubertal groups. Anthropometric and metabolic data, with the exception of the waist-to-hip ratio and glucose values, were significantly different in obese individuals than in controls, but did not differ between NMS and MS groups. However, insulin, HOMA-IR, and TG values were significantly higher, and adiponectin and cHDL significantly lower, in MS than in NMS groups. All anthropometric variables except for the waist-to-hip ratio were positively associated with MS. Blood pressure, insulin, HOMA-IR, and TG were also positively associated with MS whereas HDL-cholesterol was negatively associated with MS; fasting glucose was not associated with MS.

We previously reported that this group of obese children had a significant higher absolute daily intake of energy and all major nutrients compared with normal-weight children but the intake of energy and macronutrients to BMI ratios were significantly lower in the obese group [11]. No differences in the daily intake of energy and macronutrients as well as saturated, monounsaturated and polyunsaturated fat, were observed between the obese NMS and MS groups (Table 2).

### Plasma Fatty Acids

Figure 1 shows the fasting plasma fatty acid concentrations of 16:1n-7, 16:1n-9, 18:3n-3, and 22:6n-3 by weight and MS status with significance adjusted for age, sex and BMI z score. Compared with the normal-weight group, obese MS children had significant higher concentrations of these fatty acids. 20:2n-6 and n-3 PUFA showed a trend to be significantly higher in the obese groups (20:2n-6 control:  $5.4 \pm 0.5$ , obese NMS:  $7.3 \pm 0.6$  and obese MS:  $7.0 \pm 0.6$ ,  $P = 0.064$ ) (n-3 PUFA control:  $80.5 \pm 8.6$ , obese NMS:  $88.3 \pm 9.3$  and obese MS:  $118.1 \pm 9.5$ ,  $P = 0.061$ ), and lower concentration of 22:5n-6 (control:  $7.1 \pm 0.6$ , obese NMS:  $5.1 \pm 0.5$  and obese MS:  $5.7 \pm 0.6$ ,  $P = 0.086$ ).

Table 3 shows the proportions of fatty acids in total plasma lipids by weight and MS status adjusted for age, sex and BMI *z* score. The proportion of 16:1n-7 was significantly higher in obese MS children compared with

controls. In contrast, the proportion of 22:5n-6 was significantly lower in obese MS children than in controls. 16:1n-7 was significantly correlated with the carbohydrate dietary intake (16:1n-7 (mg/l), *r* = 0.311, *P* = 0.042;

**Fig. 1** Concentrations of selected fatty acid for total plasma lipids in prepubertal control children ( $n = 20$ ) and obese children with ( $n = 17$ ) and without metabolic syndrome ( $n = 17$ ). *NMS* non-metabolic syndrome, *MS* metabolic syndrome. All values were expressed as means  $\pm$  SEM adjusted for age and sex. Statistical analyses were done using general linear models of variance with adjustments for age, sex and BMI  $z$  score with post hoc Bonferroni tests. Values with different superscript letters are significantly different ( $P < 0.05$ )

16:1n-7(%),  $r = 0.432$ ,  $P = 0.004$ ). However, we did not find any association between plasma 20:5n-3 and 22:6n-3 and the estimated n-3 PUFA intake.

#### Fatty Acid Composition of Lipid Fractions

SFA, MUFA, and PUFA concentrations were higher in obese MS than in control children in plasma TG, but not in CE and PL; TFA and SFA concentrations in NEFA, were lower in NMS than in MS or control children (Fig. 2). 16:0, 16:1n-7, 18:1n-9, 18:2n-6 and n-6 PUFA were elevated in TG of obese children compared with controls; 16:1n-7 was higher in CE of obese MS than in normal weight children; 16:0 and 18:0 concentrations in NEFA were lower in obese NMS, but not in obese MS, compared with control children (Table 4).

#### Relationships Between Plasma Fatty Acid Concentrations and Metabolic Syndrome Features

Table 5 shows the multiple linear regression analysis of some plasma fatty acids and MS in obese prepubertal children. TFA, SFA and MUFA were associated with MS; particularly 16:0, 16:1n-9 and 22:5n-6 concentrations were highly associated to MS. As 16:1n-7 was correlated to the carbohydrate dietary intake we included this last variable as an additional exposure variable in the multivariate regression analysis for this fatty acid. Plasma 16:1n-7 both in concentration and percentage was positively associated

with the MS. Particularly, for the plasma concentration of 22:5n-6 the partial correlation with adiponectin was significantly high ( $\beta = 0.375$ ,  $P = 0.009$ ). HOMA-IR and adiponectin were included among the risk factors associated with the MS in obese children because they were related to the risk of MS in the multiple logistic regression analysis (HOMA-IR: OR 2.28; 95% CI, 1.17–4.42;  $P = 0.015$ ; Adiponectin: OR 0.593; 95% CI, 0.429–0.820;  $P = 0.002$ ). Otherwise, after adjustment for sex and age, each unit increase in the concentration of total plasma 16:1n-7 was positively associated with a significant increase in the risk of MS (OR 2.76; 95% CI, 1.39–5.46,  $P = 0.004$ ). Similarly, each 1.5 unit increase in the concentration of 16:1n-7 in TG was positively associated with a significant increase in the risk of MS (OR 4.70; 95% CI, 1.45–5.18,  $P = 0.014$ ). Likewise, each half-unit decrease in the proportion of 20:4n-6 in plasma lipids was associated with a significant increase in the risk of MS (OR 0.56; 95% CI, 0.32–0.94,  $P = 0.030$ ).

A significant negative association was found between presence of MS and the concentration of MUFA in PL fraction after adjustment for age and sex ( $r = -0.307$ ,  $P = 0.038$ ). In contrast, a positive association with MS presence was found for TFA ( $r = 0.470$ ,  $P = 0.003$ ), SFA ( $r = 0.411$ ,  $P = 0.011$ ), MUFA ( $r = 0.402$ ,  $P = 0.339$ ), PUFA ( $r = 0.442$ ,  $P = 0.006$ ), 16:0 ( $r = 0.456$ ,  $P = 0.014$ ), 16:1n-7 ( $r = 0.339$ ,  $P = 0.040$ ), 18:1n-9 ( $r = 0.418$ ,  $P = 0.010$ ), and 18:2n-6 ( $r = 0.477$ ,  $P = 0.003$ ) in plasma TG.

## Discussion

The prevalence of MS in some studies that use several definitions, with moderate to substantial agreement between them, including that of Weiss et al. [4], ranges 25.7–57.4%. In a recent work to examine the prevalence of the MS using different pediatric definitions reported in the literature, regardless of the MS criteria used, its prevalence in obese Caucasian children and adolescents between 8 and 19 years was 51% [20]. The average prevalence of MS in children and adolescents aged 7–16 years with Weiss criteria is around 38.5% [21, 22], although there are no specific studies of prevalence in prepubertal children. In the present study, using the Weiss criteria, prepubertal obese children had a prevalence of MS about 50%. This high percentage may be due to the fact that our obese children were referred from primary health care centres to our specialised pediatric endocrinology unit because of the grade of obesity and suspicious of metabolic alterations.

The present study demonstrates that obese MS prepubertal children have higher concentrations of specific plasma fatty acids in comparison with prepubertal children of normal weight, related to the increased plasma TG in the former. Although studies in animal models of obesity [23] and in obese adult humans [24–29] have reported changes

in fatty acid proportions in plasma lipid fractions and in adipose and hepatic tissue lipids, studies of plasma fatty acids in obese children have yielded controversial results [8, 10, 30–32].

Most studies of plasma fatty acids and obesity have been based on mixed populations of children and adolescents [9, 31–33] or preteen adolescents [10]. It has been proposed that puberty-related alterations should be investigated in homogeneous groups of children [32], and only prepubertal children were selected for the present investigation.

In contrast to most of previous reports, in the present study the concentrations of fatty acids were determined in total plasma lipids and in TG, PL, CE, and NEFA. This methodology was previously used in adults and children and, in comparison with measurement of proportions, provided a superior evaluation of metabolic and dietary changes related to effects of dietary long-chain PUFA supplementation in preterm infants [18] and related to certain diseases in adults e.g., liver cirrhosis [33] and inflammatory bowel disease [34].

Obesity and MS severely affects lipoprotein metabolism and especially TG synthesis and peripheral tissue utilisation, which are mediated by impaired insulin sensitivity [4, 35]. In the present study, the altered concentrations of some fatty acids in total plasma lipids of obese MS children are

**Fig. 2** Indices of fatty acid concentrations for plasma lipid fractions in prepubertal control children ( $n = 20$ ) and obese children with ( $n = 17$ ) and without metabolic syndrome ( $n = 17$ ). *NSM* non-metabolic syndrome, *MS* metabolic syndrome, *TFA* total fatty acids, *SFA* saturated fatty acids, *MUFA* monounsaturated fatty acids, *PUFA* polyunsaturated fatty acids. All values were expressed as means  $\pm$  SEM adjusted for age and sex. Statistical analyses were done using of variance with adjustments for age, sex and BMI  $z$  score with post hoc Bonferroni tests. Values with different superscript letters are significantly different ( $P < 0.05$ )

explained by the elevated concentrations of 16:0, 16:1n-7, 18:1n-9 and 18:2n-6 in TG compared with normal-weight children. SFA, and 16:0 were associated with MS, as also reported in obese adults [25, 29].

Palmitoleic acid (16:1n-7) and oleic acid (18:1n-9) are products of 16:0 and 18:0 $\Delta$ -9 desaturation, respectively. Whereas oleic acid is present in most dietary fats, especially olive oil, 16:1n-7 is unusual in the human diet, but it is readily produced in humans by the enzyme stearoyl-CoA desaturase-1 (also called  $\Delta$ -9 desaturase) [36]. Palmitoleic acid is a good marker for endogenous lipogenesis from carbohydrates and obese animals showed a significantly higher activity of liver stearoyl-coenzyme A desaturase 1 (SCD1) versus non-obese animals [37]. In addition, mice with targeted disruption of the *SCD1* gene were found to have decreased expression of lipogenesis genes and increased expression of lipid oxidative genes [38]. In the present study we have also documented a significant relationship between carbohydrate intake and plasma levels of 16:1n-7. Regardless of this fact, 16:1n-7 was highly associated with MS.

Significantly higher proportions of 16:1n-7 were reported in PL and CE of obese adolescents with MS compared with those without MS [9, 10]. The present study also found a higher concentration of this fatty acid in total

plasma lipids and TG of the obese children with MS in comparison with the normal-weight children. However, no differences were found in its concentrations in PL, suggesting that 16:1n-7 is still not incorporated in this fraction during early stages of obesity. A study of 14 pairs of obese female monozygotic twins found that 16:1n-7 was present in adipose and serum TG and was associated with the BMI [27], as found in our study. Based on these findings, we hypothesise that this fatty acid is an early marker of lipid metabolic changes associated with obesity and MS.

Below-normal proportions of PL 20:4n-6 have been reported in serum from obese humans [24] and in liver from obese Zucker rats [39], suggesting an abnormality in  $\Delta$ -6 desaturase activity or in the catabolism or distribution of 20:4n-6. A low proportion of 18:2n-6 has been described in obesity associated with insulin resistant states [24], and a reduced content of 18:2n-6 in TG, CE, and PL has been reported in obese adult patients [25]. However, a mixed population of children and adolescents showed a higher proportion of 20:4n-6 in the PL and CE of those with marked obesity, while no differences were found in 18:2n-6 [8, 30]. In a similar mixed population, the same group reported a lower proportion of 18:2n-6 in PL, and a higher proportion of 18:3n-6 and 20:3 n-6 in PL, TG and CE, in obese children with and without MS than in normal-weight

<sup>a</sup> General multiple linear regression models with adjustments for MS features (BMI *z* score, arterial systolic blood pressure, triacylglycerols, HDL-cholesterol, homeostasis model assessment of insulin resistance and adiponectin) For 16:1n-7 we also included carbohydrate dietary intake as a variable in the regression analysis due to the fact that both concentration and percentage of this FA were correlated with the carbohydrate intake

TFA total plasma fatty acids, SFA saturated fatty acids, MUFA monounsaturated fatty acids

children [9]. In contrast to these findings by Decsi and coworkers, other authors found that obese children with MS had higher proportions of SFA and lower proportions of 22:6n-3 in plasma PL and CE and a lower proportion of 18:2n-6 in PL compared with children without MS [10]. The present series of prepubertal children with MS from Southern Spain showed higher concentrations of 22:6n-3 in total plasma lipids compared with those without MS and controls. This might be explained by a higher intake of n-3 PUFA. However, we did not find any difference in the estimated intake of n-3 PUFA between MS and NMS children. In addition, no correlation was found between n-3 PUFA intake and plasma 20:5n-3 and 22:6n-3. Nevertheless, the estimated ratio for the intake of n-3 to n-6 PUFA in our children was close to 10, which is considered an optimal figure to maintain an adequate status of n-3 PUFA in the body [40]. Although the low variance of fatty acids in GLC analysis allowed for a high statistical power in establishing differences between plasma fatty acid values for control and obese children, in the present study, the sample size (only 34 obese) is a limitation particularly when estimating the dietary intake. In addition, it was unfeasible to estimate the dietary intake of single fatty acids and then to evaluate the correlations between plasma fatty acid values and dietary fatty acid intakes.

No significant differences were found between obese and normal-weight children in concentrations or proportions of 18:2n-6, 20:4n-6 and 22:6n-3 in PL and CE. Therefore, it cannot be assumed that there is an enhanced activity of  $\Delta$ -6 fatty acid desaturase in child obesity, as suggested by some authors [9], or a limitation of this

activity, as proposed by others in adult obesity [38]. However, an inverse association was found between the proportion of 20:4n-6 in total plasma lipids and the risk of MS. In addition, lower levels of 22:5n-6, a metabolite of 20:4n-6, were associated with MS, and particularly with adiponectin. An association between circulating adiponectin, a component of the MS, and plasma fatty acid profile was recently reported in adults [41]. Indeed, the present results confirm that this adipokine appears to be an important feature of MS and is related to metabolic abnormalities that occur in obesity during the prepubertal period.

In conclusion, our findings suggest an altered plasma fatty acid profile in childhood obesity during the prepubertal period that is related to the main features of the MS. Elevated concentrations of 16:1n-7 and reduced proportions of 20:4n-6 and 22:5n-6 in plasma lipids appear to be early markers of MS in prepubertal children.

**Abstract** Hei Yi Zhuang is an isolated subgroup of the Zhuang minority in China. This study was designed to compare the difference in the hepatic lipase gene (*LIPC*) –514C/T polymorphism and its association with lipid profiles between the Guangxi Hei Yi Zhuang and Han populations. Genotyping of the *LIPC* –514C/T was performed in 873 subjects of Hei Yi Zhuang and 867 participants of Han Chinese. The frequency of –514T allele was 43.47% in Hei Yi Zhuang, and 36.10% in Han ( $P < 0.001$ ). The frequencies of *CC*, *CT* and *TT* genotypes were 30.01, 53.04 and 16.95% in Hei Yi Zhuang, and 40.95, 45.91 and 13.14% in Han ( $P < 0.001$ ); respectively.

Serum high-density lipoprotein cholesterol (HDL-C) and apolipoprotein B levels in both ethnic groups were higher in *LIPC* –514T carriers than in *C* carriers. In addition, serum triglyceride levels in Han were higher in *TT* genotype individuals than in *CC* genotype subjects ( $P < 0.05$ ). Serum HDL-C levels were positively correlated with age, alcohol consumption and *LIPC* –514C/T genotypes, and negatively associated with hypertension and cigarette smoking in Hei Yi Zhuang ( $P < 0.05$ – $0.01$ ), whereas HDL-C levels were positively correlated with age, alcohol consumption and *LIPC* –514C/T genotypes, and negatively associated with body mass index and cigarette smoking in Han ( $P < 0.05$ – $0.001$ ). The differences in serum HDL-C levels between the two ethnic groups might partially attribute to the differences in the *LIPC* –514C/T polymorphism.

### Abbreviations

ANCOVA	Analysis of covariance
Apo	Apolipoprotein
BMI	Body mass index
CHD	Coronary heart disease
DNA	Deoxyribonucleic acid
HDL-C	High-density lipoprotein cholesterol
HL	Hepatic lipase
LDL-C	Low-density lipoprotein cholesterol
<i>LIPC</i>	Hepatic lipase gene
PCR	Polymerase chain reaction
SNP	Single nucleotide polymorphisms
TC	Total cholesterol
TG	Triglyceride

## Introduction

Epidemiological studies have shown that a low plasma concentration of high-density lipoprotein cholesterol (HDL-C) is associated with an increased risk of developing coronary heart disease (CHD) [1]. Plasma HDL-C concentration is modulated by both environmental and genetic factors. Family and twin studies have shown that genetic polymorphism could account for up to 60% of the interindividual variation in plasma HDL-C concentrations [2–4]. The polymorphism at the hepatic lipase gene (*LIPC*) –514C/T has been suggested to be a major cause of genetically determined variation in plasma HDL-C levels [4–6]. It can account for up to 25% of the variability in plasma HDL-C concentrations [4, 6]. Observational studies in the United States have demonstrated that CHD risk increases by 2–4% for every 1 mg/dL decrease in HDL-C levels [1].

Hepatic lipase (HL) is a lipolytic protein that catalyzes the hydrolysis of triglycerides (TG) and phospholipids in low-density lipoprotein cholesterol (LDL-C) and HDL particles and may also act as a ligand between these particles and receptors [7–9]. HL activity contributes to plasma HDL levels, as it promotes the conversion of large, buoyant HDL<sub>2</sub> to small, dense HDL<sub>3</sub> [10]. Increased HL activity is associated with reduced plasma HDL levels and reduced large, buoyant HDL<sub>2</sub> particles, thought to be the more anti-atherogenic subspecies of total HDL [11, 12].

The human *LIPC*, located on chromosome 15q21-q23 and composed of nine exons, is expressed in the liver. It spans more than 120 kb of deoxyribonucleic acid (DNA) and encodes a protein of 449 amino acids [13, 14]. Numerous common single nucleotide polymorphisms (SNPs) in the promoter region or in the coding region of the *LIPC* have been described [5, 15–17]. Four different promoter polymorphisms of the *LIPC* have been identified (*G*-250A, *C*-514T, *T*-710C, and *A*-763G), which are in complete linkage disequilibrium [16]. On a population level, the *LIPC* promoter polymorphism is quite common, but with different allele frequencies in diverse ethnic groups [5, 6, 18–20].

There are 56 ethnic groups in China. Han is the largest group, and Zhuang is the largest minority. Hei Yi (means black-worship and black dressing) Zhuang is the most conservative subgroup of the Zhuang minority. The population size is 51,655. Because of isolation from the other ethnic groups, the special customs and cultures including their clothing, intra-ethnic marriages, and dietary habits are still completely conserved to the present day. In a previous epidemiologic study, we showed that serum HDL-C concentrations were higher in Hei Yi Zhuang than in Han Chinese from the same region [21]. This ethnic difference in serum HDL-C concentrations cannot be accounted for by environmental factors. Although the genetic differences

between the two ethnic groups are still not well known, we hypothesized that there may be significant differences in some gene polymorphisms between the two ethnic groups. Therefore, the aim of the present study was to determine the *LIPC* –514C/T polymorphism and its association with serum lipid profiles in the Guangxi Hei Yi Zhuang and Han populations.

## Materials and Methods

### Subjects

A total of 873 subjects of Hei Yi Zhuang residing in seven villages in Napo County, Guangxi Zhuang Autonomous Region were surveyed by a stratified randomized cluster sampling. The age of the subjects ranged from 16 to 80 years, with an average age of  $46.15 \pm 16.06$  years. There were 452 men (51.78%) and 421 women (48.22%). All of them were peasants. During the same period, a total of 867 subjects of Han Chinese who lived in nine villages in Napo County were also surveyed by the same method. The mean age of the subjects was  $45.58 \pm 15.57$  years (range 16–82). There were 449 males (51.79%) and 418 females (48.21%). All of them were also peasants. All study subjects were essentially healthy and had no evidence of any chronic illness, including hepatic, renal, thyroid, diabetes or CHD. None of them had been treated with  $\beta$ -adrenergic blocking agents and lipid-lowering drugs such as statins or fibrates. The present study was approved by the Ethics Committee of the First Affiliated Hospital, Guangxi Medical University. Informed consent was obtained from all subjects after they received a full explanation of the study.

### Epidemiological Survey

The survey was carried out using internationally standardized methods, following a common protocol. Information on demographics, socioeconomic status, and lifestyle factors was collected with standardized questionnaires. Smoking status was categorized into groups of cigarettes per day: <10, 10–19, 20–39, and  $\geq 40$ . Alcohol consumption was categorized into groups of grams of alcohol per day: <25, 25–49, 50–99, and  $\geq 100$ . The physical examination included blood pressure, body height, and body weight etc., and body mass index (BMI) was calculated as weight (kg) divided by height (m) squared. Sitting blood pressure was measured three times with the use of a mercury sphygmomanometer after the subject rested for 5 min, and the average of the three measurements was used for the level of blood pressure. Systolic blood

pressure was determined by the first Korotkoff sound, and diastolic blood pressure by the fifth Korotkoff sound.

#### Measurements of Lipids and Apolipoproteins

A venous blood sample of 8 mL was obtained from all subjects between 8 and 11 AM, after at least 12 h of fasting, from a forearm vein after venous occlusion for few seconds in a sitting position. 3 mL was collected into glass tubes and allowed to clot at room temperature, and used to determine serum lipid and apolipoprotein (apo) levels, and the remaining 5 mL was transferred to tubes with anticoagulant solution (4.80 g/L citric acid, 14.70 g/L glucose, and 13.20 g/L tri-sodium citrate) and used to extract DNA. Immediately following clotting serum was separated by centrifugation for 15 min at 3,000 rpm. The levels of total cholesterol (TC), TG, HDL-C, and LDL-C in samples were determined by enzymatic methods with commercially available kits, Tcho-1, TG-LH (RANDOX Laboratories Ltd., Ardmore, Diamond Road, Cruclin Co. Antrim, United Kingdom, BT29 4QY), Cholestest N HDL, and Cholestest LDL (Daiichi Pure Chemicals Co., Ltd., Tokyo, Japan), respectively. Serum apoA-I and apoB levels were detected by the immunoturbidimetric immunoassay using a commercial kit (RANDOX Laboratories Ltd.). All determinations were performed with an autoanalyzer (Type 7170A; Hitachi Ltd., Tokyo, Japan) in the Clinical Science Experiment Center of the First Affiliated Hospital, Guangxi Medical University [21].

#### Genotyping

Genomic DNA was isolated from peripheral blood leukocytes by the phenol-chloroform method as described in our previous reports [22]. Genotyping of the *LIPC* –514C/T was performed as described by Couture et al. [15]. A 285-bp sequence of the *LIPC* was amplified by polymerase chain reaction (PCR) by using oligonucleotide primers 5'-TCTAGGATCACCTCTCAATGGGTCA-3' and 5'-GGTGGCTTCCACGTGG-CTGCCTAAG-3'. DNA templates were denatured at 95 °C for 3 min, and then each PCR was subjected to 35 cycles, each consisting of 1 min of denaturation at 95 °C, 0.5 min of annealing at 63 °C, and 0.5 min of extension at 72 °C. The PCR products were digested with 10 U of *Nla*III and the fragments separated by electrophoresis on a 1.5% agarose gel. After electrophoresis, the gel was treated with ethidium bromide for 20 min, and DNA fragments were visualized by UV illumination. The resulting fragments are 215 and 70 bp for the *T* allele and 285 bp for the uncut *C* allele. Genotypes were scored by an experienced reader blinded to epidemiological and lipid results.

#### Diagnostic Criteria

The normal values of serum TC, TG, HDL-C, LDL-C, apoA-I, apoB, and the ratio of apoA-I to apoB in our Clinical Science Experiment Center were 3.10–5.17, 0.56–1.70, 0.91–1.81, 1.70–3.20 mmol/L, 1.00–1.76, 0.63–1.14 g/L, and 1.00–2.50, respectively. The individuals with TC > 5.17 mmol/L and/or TG > 1.70 mmol/L were defined as hyperlipidemic [21]. Hypertension was defined as a systolic pressure of 140 mmHg or higher and/or a diastolic pressure of 90 mmHg or higher [23]. Overweight and obesity were defined according to the diagnostic criteria of the Cooperative Meta-analysis Group of China Obesity Task Force. Normal weight, overweight and obesity were defined as a BMI < 24, 24–28, and > 28 kg/m<sup>2</sup>, respectively [24].

#### Statistical Analysis

Epidemiologic data were recorded on a pre-designed form and managed with Excel software. Levels of the quantitative variables are presented as mean ± standard deviation (SD). The difference of general characteristics between Hei Yi Zhuang and Han was tested by the Student's unpaired *t* test. The allelic and genotypic frequencies of *LIPC* –514C/T were estimated by counting alleles and genotypes and calculating sample proportions; the statistical significance of differences in frequencies between groups was compared by  $\chi^2$  test. The distribution of *LIPC* –514C/T polymorphism was tested for Hardy–Weinberg equilibrium using  $\chi^2$  goodness-of-fit test. The association of *LIPC* genotypes with lipid variables was tested by analysis of covariance (ANCOVA). The co-variables include sex, age, BMI, hypertension, alcohol consumption and cigarette smoking. In order to evaluate the association of HDL-C levels with ethnic group (Han Chinese = 0; Hei Yi Zhuang = 1), sex (male = 0; female = 1), age (year), BMI (kg/m<sup>2</sup>), blood pressure (normotensives = 0; hypertensives = 1), alcohol consumption (nondrinkers = 0; <25 g/day = 1; 25–49 g/day = 2; 50–99 g/day = 3; ≥100 g/day = 4), cigarette smoking (nonsmokers = 0; <10 cigarettes/day = 1; 10–19 cigarettes/day = 2; 20–39 cigarettes/day = 3; ≥40 cigarettes/day = 4), or *LIPC* –514C/T genotype (*CC* = 1; *CT* = 2; *TT* = 3), unconditional logistic regression analysis was also performed in combined population of Hei Yi Zhuang and Han, Hei Yi Zhuang, and Han; respectively. The backward multiple logistic regression method was used to select the risk factors significantly associated with serum HDL-C levels. All statistical analyses were done with the statistical software package SPSS 11.5 (SPSS Inc., Chicago, Illinois). A *P* value of less than 0.05 was considered significant.

## Results

### General Characteristics and Serum Lipid Levels

Table 1 gives the general characteristics between the Hei Yi Zhuang and Han populations. Systolic blood pressure and pulse pressure levels were higher in Hei Yi Zhuang than in Han ( $P < 0.001$  for each), whereas BMI was higher in Han than in Hei Yi Zhuang ( $P < 0.001$ ). There were no significant differences in diastolic blood pressure levels, age structure, the percentages of subjects who consumed alcohol or smoked cigarettes, or the ratio of male to female between the two ethnic groups ( $P > 0.05$ ). Serum TC, TG, LDL-C, and apoB levels were lower in Hei Yi Zhuang than in Han ( $P < 0.01$ – $0.001$ ), whereas HDL-C levels and the ratio of apoA-I to apoB were higher in Hei Yi Zhuang than in Han ( $P < 0.001$ ). There were no significant differences in apoA-I levels between the two ethnic groups ( $P > 0.05$ ).

**Table 1** Comparison of general characteristics, serum lipid levels, and genotypic and allelic frequencies between the Hei Yi Zhuang and Han populations

HDL-C high-density lipoprotein cholesterol; LDL-C low-density lipoprotein cholesterol

\*  $P < 0.05$ , \*\*  $P < 0.01$  and

\*\*\*  $P < 0.001$  in comparison with the same subgroup of Hei Yi Zhuang

### Genotypic and Allelic Frequencies

The frequencies of the *LIPC* –514C/T alleles and genotypes are also shown in Table 1. The frequencies of C and T alleles were 56.53 and 43.47% in Hei Yi Zhuang, and 63.90 and 36.10% in Han ( $P < 0.001$ ); respectively. The frequencies of CC, CT and TT genotypes were 30.01, 53.04 and 16.95% in Hei Yi Zhuang, and 40.95, 45.91 and 13.14% in Han ( $P < 0.001$ ), respectively. There were no significant differences in the genotypic and allelic frequencies between males and females in the two ethnic groups ( $P > 0.05$ , Table 2).

### The *LIPC* –514C/T Genotypes and Serum Lipid Levels

As shown in Table 3, there were significant differences in the serum HDL-C and apoB levels among three genotypes in the both ethnic groups after adjustment for all the covariates. Serum HDL-C and apoB levels were higher in

TC total cholesterol; TG triglycerides; HDL-C high-density lipoprotein cholesterol; LDL-C low-density lipoprotein cholesterol; apoA-I apolipoprotein A-I; apoB apolipoprotein B; apoA-I/apoB the ratio of apolipoprotein A-I to apolipoprotein B

\*  $P < 0.05$ , \*\*  $P < 0.01$  and \*\*\*  $P < 0.001$  in comparison with the same subgroup of Hei Yi Zhuang

<sup>a</sup>  $P < 0.05$  in comparison with the CC genotype of the same ethnic group

<sup>b</sup>  $P < 0.01$  in comparison with the CC genotype of the same ethnic group

<sup>c</sup>  $P < 0.05$  in comparison with CT genotype of the same ethnic group

<sup>d</sup>  $P < 0.01$  in comparison with CT genotype of the same ethnic group

<sup>e</sup> Analyses of covariate analysis, adjusted for sex, age, body mass index, hypertension, alcohol consumption and cigarette smoking

TT or CT genotype subjects than in CC genotype individuals. In addition, serum TG levels in Han were higher in TT genotype than in CC genotype subjects ( $P < 0.05$ ). There were no significant differences in TC, LDL-C, apoA-I levels and the ratio of apoA-I to apoB among the three genotypes in the both ethnic groups ( $P > 0.05$ ).

#### Correlative Factors for the HDL-C Levels

Multivariate logistic regression analysis showed that serum HDL-C levels were positively correlated with ethnic group (Hei Yi Zhuang), age, alcohol consumption, and the *LIPC* –514C/T genotypes, and negatively associated with BMI, hypertension and cigarette smoking in combined population of Hei Yi Zhuang and Han ( $P < 0.05$ –0.001). Serum HDL-C levels were positively correlated with age, alcohol consumption and *LIPC* –514C/T genotypes, and negatively associated with hypertension and cigarette smoking in Hei Yi Zhuang ( $P < 0.05$ –0.01). Serum HDL-C levels were positively correlated with age, alcohol consumption

and *LIPC* –514C/T genotypes, and negatively associated with BMI and cigarette smoking in Han ( $P < 0.05$ –0.001). No association was found between serum HDL-C levels and sex in both ethnic groups ( $P > 0.05$ , Table 4).

#### Discussion

The present study shows that serum TC, TG, LDL-C and apoB levels were lower in Hei Yi Zhuang than in Han, whereas HDL-C levels and the ratio of apoA-I to apoB were higher in Hei Yi Zhuang than in Han. These findings are consistent with those of our previous studies in a large population [21]. It is well known that dyslipidemia is a complex trait caused by the interactions of multiple environmental and genetic factors. Hei Yi Zhuang is an isolated subgroups of the Zhuang minority in China. Strict intra-ethnic marriages have been performed in this population from time immemorial. But consanguineous marriages are forbidden in this ethnic subgroup. No one can marry to the

direct descendant blood kin or the collateral branch blood kin in seven generations. Therefore, we hypothesized that the hereditary characteristic and genotypes of some lipid metabolism-related genes in this population may be different from those in Han Chinese.

In the present study, we show that the frequency of the *LIPC* −514T allele was higher in Hei Yi Zhuang than in Han. The frequencies *CT* and *TT* genotypes were also higher in Hei Yi Zhuang than in Han. There were no differences in the genotypic and allelic frequencies between males and females in both ethnic groups. The frequencies of the *LIPC* −514T allele and *TT* genotypes in Hei Yi Zhuang were also higher than those of previous studies in Chinese from America (Taiwanese-Chinese, *T* allele 37.5%) [20], Singapore (*TT* genotype 12.7%) [25], Taiwan (*TT* genotype 12.6%) [26], and Hong Kong (*TT* genotype 12.8–14.8%) [27]. Studies on the *LIPC* −514C/T polymorphism in several populations have demonstrated that the frequency of both −514C/T alleles varies highly among different ethnic populations [19, 27, 28]. The −514C allele is the most common allele in Caucasians, whereas the −514T allele is the major allele in black Americans. Asians have an intermediate frequency. The frequency of the −514T allele was 0.15–0.21, 0.45–0.53, and about 0.47 in Caucasians, African Americans, and Japanese Americans [5, 6, 17, 29], respectively. These variations in genotypic and allelic frequencies between the two ethnic groups may

partially explain the observed higher HDL-C levels seen in the Hei Yi Zhuang populations. Several studies have shown that the −514T allele of the *LIPC* promoter appears to be associated with decreased HL activity, and increased HDL-C [6, 18].

The potential relationship between the *LIPC* −514C/T polymorphism and plasma or serum HDL-C levels in humans has been evaluated in a large number of studies. However, previous findings on the association of this polymorphism with the changes in plasma HDL-C levels are inconsistent. Jansen et al. [5], Couture et al. [15], and Murtomaki et al. [17] reported significant association between the *LIPC* polymorphisms and HDL-C levels, whereas Zambon et al. [18], Tahvanainen et al. [29], Hegele et al. [30], and Shohet et al. [31] failed to find a significant genetic effect on HDL-C concentrations. Zambon et al. [18] first reported that the promoter polymorphism significantly influenced HDL<sub>2</sub>-C but not HDL-C levels, which is consistent with the previous report that HL activity is primarily associated with HDL<sub>2</sub>-C but not with HDL<sub>3</sub>-C [32, 33]. This result was also replicated on the basis of the data from the Framingham Offspring study [15]. However, only a few studies have reported an association between this polymorphism and plasma TG [14, 34]. In one study, carried out by Jansen et al. [34] in the European Atherosclerosis Research Study II, the *T* allele was associated with higher concentrations of plasma

TG, HDL-C, apoA-I and apoB. The effects of *LIPC* polymorphism on LDL-C and apoB are inconsistent; one study reported significantly higher LDL-C levels and borderline higher apoB levels in *TT* patients than in those with the *CC* genotype [35], whereas in other studies there were no differences in LDL-C and apoB levels with genotype [15, 29]. In the present study, we show that HDL-C and apoB levels in both ethnic groups were higher in *LIPC* –514T carriers than in noncarriers. In addition, serum TG levels in Han were higher in *TT* genotype individuals than in *CC* genotype subjects. These results suggest that there was an association between the *LIPC* –514C/T polymorphism and serum HDL-C and apoB levels.

In addition to the genetic factors, environmental factors such as obesity [36], physical inactivity [37], alcohol consumption [38], cigarette smoking [38, 39], diet [40], and hypertension [41] also influence plasma HDL-C levels. For example, heavy smokers have, on average, 9% lower HDL-C levels than matched nonsmokers [39]. Obesity is one of the most important factors in reducing HDL-C levels [36, 42]. In the present study, we also show that serum HDL-C levels were positively correlated with age and alcohol consumption, and negatively associated with hypertension and cigarette smoking in Hei Yi Zhuang. Serum HDL-C levels were also positively correlated with age and alcohol consumption, and negatively associated with BMI and cigarette smoking in Han. These findings suggest that environmental factors or the interactions of environmental and genetic factors may be involved in determining the difference in serum HDL-C concentrations between the two ethnic groups.

In conclusion, the results of the present study show that there were significant differences in genotypic and allelic frequencies of the *LIPC* –514C/T between the Hei Yi Zhuang and Han populations. An association between the *LIPC* –514C/T polymorphism and serum HDL-C and apoB levels was observed in both ethnic groups. Higher serum HDL-C and apoB levels were found in *LIPC* –514T carriers than in noncarriers. Serum HDL-C levels were positively correlated with *LIPC* –514C/T genotypes in both ethnic groups. The differences in serum HDL-C levels between the Hei Yi Zhuang and Han populations might partially attribute to the differences in the *LIPC* –514C/T genotypic and allelic frequencies.

**Abstract** We succeeded in purifying a major glycolipid fraction from a green vegetable, spinach. This fraction consists mainly of three glycolipids: monogalactosyl diacylglycerol (MGDG), digalactosyl diacylglycerol (DGDG), and sulfoquinovosyl diacylglycerol (SQDG). In a previous study, we found that the glycolipid fraction inhibited DNA polymerase activity, cancer cell growth and tumor growth with subcutaneous injection. We aimed to clarify oral administration of the glycolipid fraction, suppressing colon adenocarcinoma (colon-26) tumor growth in mice. A tumor graft study showed that oral administration of 20 mg/kg glycolipid fraction for 2 weeks induced a 56.1% decrease in the solid tumor volume ( $P < 0.05$ ) without any side-effects, such as loss of body weight or major organ failure, in mice. The glycolipid fraction induced the suppression of colon-26 tumor growth with

inhibition of angiogenesis and the expression of cell proliferation marker proteins such as Ki-67, proliferating cell nuclear antigen (PCNA), and Cyclin E in the tumor tissue. These results suggest that the orally administered glycolipid fraction from spinach could suppress colon tumor growth in mice by inhibiting the activities of neovascularization and cancer cellular proliferation in tumor tissue.

## Introduction

We have been screening for inhibitors of eukaryotic DNA polymerase for more than 10 years, and we and other researchers have reported previously that major plant glycolipids [1] such as monogalactosyl diacylglycerol (MGDG), digalactosyl diacylglycerol (DGDG), and sulfoquinovosyl diacylglycerol (SQDG) have potential anti-cancer functions as follows: DNA polymerase inhibition [2–7], suppression of cancer cell proliferation [4–6, 8, 9], anti-angiogenesis [10], and anti-tumor promotion [11, 12]. In animals, glycolipids are contained in a minute amount in the brain [13] and in sea urchin [14, 15]. Comparing various vegetables, we found that glycolipids were highest in spinach, which is especially rich in SQDG [16]. In our previous study, we developed a method to purify a glycolipid fraction from spinach and found that this fraction had anti-tumor activity in a subcutaneous solid tumor model [17, 18].

We eat vegetables, grains, and so on every day; however, the anti-cancer effect of orally administered glycolipids has not been ascertained, and the functional role of glycolipids is not well understood. In addition, a few studies have suggested that some of these glycolipids are digested and not absorbed in an *in vivo* rat model [19, 20], *in vitro* human pancreatic lipolytic enzyme, and duodenal contents model [21].

We investigated the orally administered glycolipid fraction of spinach for anti-tumor function in a colon solid tumor mouse model, and then evaluated anti-angiogenesis and anti-proliferation effects in tumor tissue using histopathological analysis.

## Experimental Procedure

### Materials

Spinach (*Spinacia oleracea* L.) was purchased from a supermarket (Co-operation Union Co., Kobe, Hyogo prefecture, Japan). Rabbit polyclonal antibodies of anti-Ki-67 (NB500-170), Cyclin E (ab7959) and von Willebrand Factor (vWF, AB7356) were obtained from Novus Biologicals, Inc. (CO, USA), Abcam, Inc. (MA, USA) and Chemicon International, Inc. (CA, USA), respectively. Mouse anti-proliferating cell nuclear antigen (PCNA)

monoclonal antibody (sc-56) was purchased from Santa Cruz Biotechnology, Inc. (CA, USA). Peroxidase-conjugated forms of goat anti-rabbit or anti-mouse IgGs (i.e., secondary antibodies) were obtained from Nichirei Biosciences Inc. (Tokyo, Japan). All reagents were analytical grade and were purchased from Merck Ltd (Tokyo, Japan).

### Purification Methods of the Glycolipid Fraction from Spinach

Water-soluble substances were extracted from dried spinach (20 g) with 1,000 mL of water at 60 °C. The tissue cake was added to 1,000 mL of 100% ethanol at 60 °C, and substances containing glycolipids were extracted. The 100% ethanol extract was diluted to a 70% ethanol solution with water. The solution was subjected to Diaion HP-20 (Mitsubishi Chemical Inc., Tokyo, Japan) column chromatography, hydrophobic-type chromatography, washed with 1,000 mL of 70% ethanol, and then eluted using 95% ethanol. The 95% ethanol-eluted solution was the glycolipid fraction (1.3 g). This fraction was stored at –20 °C until used for an experiment and contained the three major glycolipids: MGDG, DGDG, and SQDG [6], the chemical structures of which are shown in Fig. 1. By fatty acid analysis of each spinach glycolipid by gas chromatography,

**Fig. 1** Chemical structures of the major glycolipids in the fraction from spinach. **a** Monogalactosyl diacylglycerol (MGDG). **b** Digalactosyl diacylglycerol (DGDG). **c** Sulfoquinovosyl diacylglycerol (SQDG).  $R_1$ – $R_6$  = in these structures are fatty acids

the major fatty acids of MGDG were stearic acid (18:0) and oleic acid (18:1), DGDG contained mostly palmitic acid (16:0) and oleic acid (18:1), and SQDG mostly consisted of palmitic acid (16:0) and linolenic acid (18:3) [6].

#### Cell Culture and Cell Growth Inhibition Assay

The mouse colon adenocarcinoma cell line, colon-26 [22] was provided by the Cell Resource Center for Biomedical Research (Tohoku University, Sendai, Japan), and human cancer cell lines, A549 (lung cancer), BALL-1 (B cell acute lymphoblastoid leukemia), HeLa (cervical cancer), Molt-4 (T cell acute lymphoblastic leukemia), and NUGC-3 (stomach cancer), were obtained from the Health Science Research Bank (Osaka, Japan). These cancer cells were cultured in RPMI 1640 (Nissui Pharmaceutical Co., Ltd, Tokyo, Japan) supplemented with 10% fetal bovine serum (Equitech-Bio, Inc., Texas, USA), penicillin (100 units/mL), and streptomycin (100 µg/mL). The cells were cultured under an atmosphere of 95% air and 5% CO<sub>2</sub> at 37 °C. The cancer cells ( $5 \times 10^3$ ) were seeded onto a 96-well plate ( $n = 5$ ) and allowed to adhere overnight. The culture was then washed and added to the medium or to the medium containing different concentrations (0–100 µg/mL) of the glycolipid fraction of spinach dissolved in each medium. After 24 h, cell-growth activity was determined by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2H-tetrazolium bromide (MTT) assay [23].

#### Animals

Specific pathogen-free female BALB/c mice (5 weeks of age, 14–19 g) were purchased from Japan SLC, Inc. (Shizuoka, Japan). The laboratory standard diet for mice (code: MF) was purchased from Oriental Yeasts Co., Ltd (Osaka, Japan). The mice were housed and acclimated in the animal research facilities for a least 1 week before being used in the present study. They were kept in isolation rooms at a controlled temperature and had free access to laboratory standard diet (contents by weight %: water-soluble non-nitrogen compounds 52.3%, protein 24.6%, water 8%, ash 6.4%, fat 5.6%, and fiber 3.1%) and water. All animal studies were approved by the Kobe-Gakuin University Animal Committee, according to the guidelines for the “Care and Use of Laboratory Animals” of the University.

#### Implantation of Mouse Cancer Cells and Anti-Tumor Growth Assay

For anti-tumor experiments *in vivo*, colon-26 cells [ $1 \times 10^6$  cells/mouse in 100 µL of phosphate-buffered saline (PBS)] were subcutaneously inoculated into BALB/c

mice (18–21 g). Five days after the start of inoculation, we observed the engraftment of tumor cells, which reached a volume of 20–30 mm<sup>3</sup>; tumors were measured with a caliper at each administration, and tumor volumes were calculated using the formula: volume =  $a \times b \times b/2$ , where  $a$  and  $b$  are the length and width diameters. The mice were divided randomly into three groups: a control group ( $n = 5$ ) with orally administered PBS alone, and two experimental groups (each  $n = 5$ ) with the orally administered glycolipid fraction dissolved in PBS. All mice were orally administered 100 µL of the fraction dissolved in PBS at dose of 10, 20 mg/kg or PBS only every day using a gastric feeding needle, and tumor volume was measured from the beginning of administration for 2 weeks (total of 15 administrations). After the anti-tumor assay (i.e., 19 days after implantation), the mice were killed and the histopathological features of the tumors were observed with gross diagnosis of major organs, the lung, heart, spleen, stomach, liver, pancreas, kidney, intestine, and brain.

#### Preparation of Mouse Tissue Samples

In the significantly decreased tumor volume group, we evaluated the tumor tissue. For hematoxylin and eosin (H&E) staining and immunohistochemical procedures, tumor tissues from killed mice were fixed with 10% formalin in PBS (pH 7.2) and processed for paraffin embedding. The sections, 3 µm thick, were stained with H&E or appropriate antigens for immunohistochemistry. For immunohistochemical staining, all antibodies were reacted with deparaffinized antigen-retrieved sections.

#### Histopathological and Immunohistochemical Analysis of Cell Proliferation in Tumor Tissues

The sections were histopathologically analyzed using the mitotic index [number of mitoses/high power field (HPF)] of five to eight random non-necrotic areas by H&E stain at 400× magnification. The expressions of cell proliferation marker proteins such as Ki-67, PCNA, and Cyclin E [24–26] were determined by immunohistochemistry. The sections were incubated overnight at 4 °C with the primary antibodies such as 1:50 dilution of anti-Ki-67, 1:500 dilution of anti-PCNA, or 1:1,000 of anti-Cyclin E. The sections were then rinsed three times with PBS and incubated for 10 or 30 min with the peroxidase-conjugated secondary antibody at room temperature. The positive reaction was visualized by incubating the sections with 3,3'-diaminobenzidine (DAB) for 5–10 min. The sections were then washed with water and counterstained with hematoxylin. To assess the average proteins of proliferation markers in entire tumor sections, four to six

areas, were chosen from the stained section in each tumor, and high expression spots at 400× magnification were counted.

#### Vessel Count within Tumor Tissue

Deparaffinized sections were incubated overnight with 1:1,000 dilution of anti-vWF at 4 °C. The sections were rinsed three times with PBS and incubated for 30 min with the peroxidase-conjugated secondary antibody at room temperature. The positive reaction was visualized by incubating the sections with DAB for 5–10 min. The sections were then washed with water and counterstained with hematoxylin. Vessel counts were based on the criteria of Weidner et al. [27] and were performed at 200× magnification (0.785 mm<sup>2</sup> per field). To assess average vascularization in entire tumor sections, three areas were chosen from the stained section of each tumor, and the number of vessel markers with a high expression in the field was counted.

#### Statistical Analysis

Statistical analyses were performed using the Steel–Dwass test for in vitro experiments and the Mann–Whitney *U* test for in vivo experiments, using the software package KyPlot 5.0 (Kyens Lab., Inc., Tokyo, Japan) for Windows.

**Fig. 2** Dose–response curve of the glycolipid fraction for cancer cell growth inhibition. Colon-26 cells (mouse colon adenocarcinoma) were incubated with 0–100 µg/mL of the glycolipid fraction of spinach for 24 h. The rate of cultured cell growth inhibition was determined by MTT assay [23]. Bars indicate the mean ± SEM of five independent experiments. \*Different from the control,  $P < 0.05$

## Results

### Inhibitory Effect of the Glycolipid Fraction on Cancer Cell growth

The glycolipid fraction from spinach was incubated with mouse colon-26 cell lines for 24 h, and cellular proliferation was inhibited in a dose-dependent manner, with an IC<sub>50</sub> value of 74.5 µg/mL (Fig. 2). At 100 µg/mL, the growth inhibition rate of colon-26 cells decreased to 75.7% compared with the control ( $P < 0.05$ ).

We also investigated whether this fraction could inhibit the growth of other cancer cell lines from humans, and the IC<sub>50</sub> values are shown in Table 1. The glycolipid fraction also suppressed the growth of all human cancer cell lines by 24 h incubation, and the range of IC<sub>50</sub> values were 58.5–81.7 µg/mL. The inhibitory effect of 48 h culture was as strong as with 24 h incubation (data not shown). The cancer cell line from mice (i.e., colon-26) showed almost the same cell growth inhibitory results as cancer cell lines from humans; therefore, we used mouse colon-26 cells in the latter part of this study.

### Suppression of Tumor Growth in BALB/c Mice

Five days after cancer cell implantation, daily oral administration of the glycolipid fraction at 20 mg/kg significantly suppressed the growth of colon-26 solid tumor in mice ( $n = 5$ ), and treatment with the glycolipid fraction resulted in a 56.1% inhibition of tumor growth compared with the control group ( $P < 0.05$ ) on the final day (i.e., 19 days after implantation) (Fig. 3). However, oral administration of 10 mg/kg glycolipid fraction did not

**Table 1** Inhibitory effect of the glycolipid fraction from spinach on cultured cancer cell growth

Cell line	Type of cancer	IC <sub>50</sub> values (µg/mL)
Colon-26	Mouse colon	74.5 ± 9.0
A549	Human lung cancer	81.7 ± 9.9
BALL-1	Human B cell acute lymphoblastoid leukemia	59.0 ± 7.1
HeLa	Human cervix cancer	57.2 ± 6.9
Molt-4	Human T cell acute lymphoblastic leukemia	58.5 ± 7.1
NUGC-3	Human stomach cancer	79.8 ± 9.6

Mouse cancer cells, such as colon-26, and human cancer cells, such as A549, BALL-1, HeLa, Molt-4 and NUGC-3, were incubated with the glycolipid fraction for 24 h. The rate of cell growth inhibition was determined by MTT assay [23]. Data are expressed as the mean ± SEM of five independent experiments

**Fig. 3** Effect of the glycolipid fraction on tumor growth in mice. Mice with solid tumors were orally administered 100  $\mu$ L of PBS as a control group ( $n = 5$ ) (open circles) and the glycolipid fraction in 100  $\mu$ L of PBS at dose of 10 mg/kg ( $n = 5$ , closed diamonds) and 20 mg/kg ( $n = 5$ , closed triangles) as experimental groups. All data are shown as the means  $\pm$  SEM of five independent animals. \*Different from the control,  $P < 0.05$

significantly decrease the solid tumor volume on the final day compared with the control group ( $P = 0.42$ ). The body and major organ weights in the experimental group with the orally administered glycolipid fraction were almost the same as in the control group with orally administered PBS, and there was no drug-related animal death.

#### Suppression of the Expression of Mitosis and Cell Proliferation Marker Proteins in Tumor Tissues

After the tumor formation experiment in mice ( $n = 3-5$ ), paraffin sections of tumor tissues were made for H&E staining and immunohistochemical staining of cell proliferation marker proteins such as Ki-67, PCNA, and Cyclin E. The results of histopathological analysis for the proliferation of tumor cells are shown in Table 2. First, the

mitotic index, which indicates the rate of cell division, of the administered glycolipid fraction was approximately 1.8-fold lower than that of the control mitotic index. Second, the immunohistochemical assay showed that the number of high expression spots in positive cells treated with the glycolipid fraction in tumor tissues decreased compared with the control, and the reduction rates of Ki-67, PCNA, and Cyclin E were 18.7, 17.6, and 14.4%, respectively. These results suggest that the glycolipid fraction could inhibit cell proliferation in tumor tissue.

#### Inhibition of Anti-Angiogenic Activity in Tumor Tissues

As shown in Fig. 4a and b, daily oral administration of 20 mg/kg glycolipid fraction decreased the number of microvessels compared with the control. Microvessel density (MVD) was measured by positive staining of vessels with vWF antibody per 1  $\text{mm}^2$ . Mice ( $n = 4-5$ ) treated with the glycolipid fraction ( $11.3 \pm 1.8$ ) induced 56.4% inhibition of vessel formation compared with the control ( $25.8 \pm 5.3$ ,  $P < 0.05$ , Fig. 4c). These results suggest that the glycolipid fraction of spinach could lead to a significant decrease of MVD, and this phenomenon must increase necrosis of colon-26 tumors (Fig. 5). Since the value of MVD is closely related to angiogenesis formation, the glycolipid fraction could be considered as having anti-angiogenic activity.

#### Discussion

We prepared the glycolipid fraction of spinach, and showed that it has anti-tumor activity with oral administration. This fraction consists of three glycolipids: MGDG, DGDG, and SQDG, but it is too difficult to purify each glycolipid separately from the fraction. We consider that the fraction containing glycolipids, which is easy to purify from spinach, could be a functional foodstuff with anti-cancer effects.

We found that oral administration of 20 mg/kg glycolipid fraction of spinach suppressed the formation of colon tumor in mice with no adverse drug reaction (Fig. 3). The

**Table 2** Histopathological analysis of the sections of colon-26 cells in mouse tumor tissue

	Mitosis (/HPF)	Ki-67 (%)	PCNA (%)	Cyclin E (%)
Control	$16.6 \pm 1.3$	$86.7 \pm 4.7$	$78.6 \pm 1.4$	$57.1 \pm 2.0$
Spinach glycolipid fraction	$9.4 \pm 1.7^*$	$70.5 \pm 3.0^*$	$64.8 \pm 1.3^*$	$48.9 \pm 1.0^*$

Mice were orally administered PBS (control) or the glycolipid fraction from spinach in PBS at a dose of 20 mg/kg. Mitotic index and immunohistochemical proliferative analysis were calculated at a high magnification field ( $400\times$ ). Data are shown as the means  $\pm$  SEM of four to six areas per mouse ( $n = 3-5$ )

\* Different from the control,  $P < 0.05$

content (weight %) of fat in the laboratory standard diet of mice is 81.0% triglycerides, 17.4% phospholipids and 1.6% cholesterol. This diet hardly consists of glycolipids; therefore, glycolipids must be important for anti-tumor activity. Generally, tumor growth depends on angiogenesis [28, 29], and oral administration of the glycolipid fraction inhibited angiogenesis in tumor tissues (Fig. 4). The formation of tumors treated with the glycolipid fraction decreased MVD to 56.5% (Fig. 4c). These results showed that the inhibition of angiogenesis might cause tumor shrinkage and widespread necrosis (Fig. 5). In addition, since MVD relates to tumor development, malignancy, and metastasis [30–32], the glycolipid fraction could influence these phenomena.

The spinach glycolipid fraction induced a significant decrease of the expression of cell proliferation marker proteins such as Ki-67, PCNA, Cyclin E, and the index of tumor mitosis in tumor tissues (Table 2). The expression of Ki-67 occurs continuously in all cycling cells of  $G_1$ , S,  $G_2$ , and M phases, but not in resting cells in the  $G_0$  phase. PCNA and Cyclin E are positive in the nuclear cell cycle of  $G_1$  and S phases. Therefore, this fraction could arrest the cell cycle, and reduce the cell proliferation in the tumor cells. In addition, these cell proliferation marker proteins have negative effects on other indicators such as tumor prognosis, malignancy and metastasis [31, 33–35]. We have observed that glycolipids inhibited the activity of DNA polymerases [2–7]. Tumors have high DNA polymerase

activity; therefore, the dual activities of anti-proliferation of cancer cells and inhibition of DNA polymerases must suppress the turnover and division of tumor cells.

On the other hand, a rat intake study and human duodenal contents study shows that glycolipids are digested or not absorbed [19–21]; however, the present study indicated that glycolipids might be absorbed and affect anti-tumor activity, similar to previous studies [7, 17]. Glycolipids, especially MGDG and SQDG, are hydrolyzed and yield monogalactosyl monoacylglycerol (MGMG) and sulfoquinovosyl monoacylglycerol (SQMG), respectively, and MGMG and SQMG increased the inhibition of DNA polymerase activity, anti-proliferation of cancer cells [36] and tumor suppression more than MGDG and SQDG [17].

In conclusion, this study shows that 20 mg/day of the orally administered spinach glycolipid fraction can effectively suppress mouse colon tumor growth, influenced by the anti-angiogenesis and anti-proliferation of tumor cells without side-effects. The glycolipid fraction suppressed the growth of cancer cells from humans and mice (Table 1; Fig. 2); therefore, glycolipids are suggested as preventing human cancer disease, and this spinach fraction could become a functional foodstuff with anti-cancer effects.

**Abstract** Modern diets are often deficient in  $\omega$ -3 fatty acids and additional dietary sources of  $\omega$ -3 fatty acids are useful. In order to investigate the molecular basis of the high accumulation of the  $\omega$ -3 fatty acid,  $\alpha$ -linolenic acid (18:3), in three different plants, flax (*Linum usitatissimum*), *Dracocephalum moldavica*, and *Perilla frutescens*  $\omega$ -3 desaturase activity, transcript levels, and 18:3 in-vivo synthesis were examined. The 18:3 content was found to be higher at the later developmental stage of *D. moldavica* (68%) compared with *P. frutescens* (59%) and flax (45%) cotyledons. The 18:3 and 18:2 contents in both PC and TAG were determined during various stages of seed development for all three plants in addition to soybean (*Glycine max*). Northern blot analysis data of three different stages of *D. moldavica*, flax, and *P. frutescens* compared with moderately low 18:3 producers, soybean (*Glycine max*), and *Arabidopsis thaliana* and *Brassica napus*, (8–10% 18:3) at a stage of zygotic embryo development of high triglyceride synthesis showed that  $\omega$ -3 desaturase mRNA levels were higher in all three high 18:3 producers, flax, *D. moldavica* and *P. frutescens*. This indicates that the high level of  $\alpha$ -linolenic acid in TAG may be largely controlled by the level of  $\omega$ -3 desaturase gene expression. However, the PC versus TAG fatty acid composition data suggested that along with  $\omega$ -3 desaturase

other enzymes also play a role in 18:3 accumulation in TAG, and the high accumulators have a selective transfer of  $\alpha$ -linolenic acid into TAG.

**Keywords** Fatty acid · Lipids · Omega-3 · Flax · Perilla

### Abbreviations

ACP	acyl carrier protein
ALA	$\alpha$ -linolenic acid
DAG	diacylglycerol
DGAT	diacylglycerol acyl transferase
DHA	docosohexaenoic acid
EFA, EPA	eicosapentaenoic acid
ER	endoplasmic reticulum
FFAP, PC	phosphatidylcholine
PUFA	polyunsaturated fatty acid
TAG	triacylglycerol

### Introduction

The diets of people in some countries come close to the apparent  $\omega$ -3/ $\omega$ -6 fatty acid ratio of diet during human evolution: such as the traditional diets of Greece and Japan. In both countries the rate of death due to cardiovascular disease is among the lowest. It is now recognized that there is a need to return  $\omega$ -3 fatty acids into the food supply, both for normal growth and development and for the prevention and management of chronic diseases [1]. Human beings evolved on a diet in which the ratio of omega-6/omega-3 EFA was about 1, whereas in the western diets the ratio is 15/1 to 16.7/1. Increased use of certain plant oils and modern day agriculture has led to a decrease in omega-3

fatty acids and increases in omega-6 fatty acids [2–4]. Linoleic acid and  $\alpha$ -linolenic acid are not interconvertible in animals and compete for the rate limiting delta-6 desaturase in the synthesis of long chain PUFA. Among the cardiovascular benefits of increased omega-3 fatty acids in the diet is the prevention of cardiac arrhythmias [4]. Already eggs high in omega-3 fatty acids are available on the market [5]. All these factors increase proportionally with an increase in the omega-3 fatty acid intake, including either ALA or EPA, but especially DHA.

Seed oils are composed primarily of triacylglycerols (TAGs), which are glycerol esters of fatty acids. The primary fatty acids in the TAGs of oilseed crops are 16–18 carbons in length and contain 0–3 double bonds. Palmitic acid (16:0), oleic acid (18:1), linoleic acid (18:2), and linolenic acid (18:3) predominate. In this study we used soybean (*G. max*) as a moderate linolenic acid producer and three different high linolenic acid producers: flax (*Linum usitatissimum*) which has a high content of linolenic acid in the triacylglycerol (TAG), normally more than 45% of the total fatty acid content [6–8], *Perilla frutescens* oil contains 50–64% of 18:3 [9–11], and *Dracocephalum moldavica* contains 59–68% 18:3 [9, 12, 13].

Flax (*L. usitatissimum*) oil content ranges from 40 to 52% and 40 to 64% of this oil is linolenic acid depending on the flax variety [6–8]. *D. moldavica* contains 25–30% oil and 59–68% of it is 18:3 [9, 12, 13]. The oil content of *P. frutescens* is 35–45%, and contains 50–64% of 18:3 [9–11]. It is known that  $\omega$ -3 fatty acids are synthesized from  $\omega$ -6 fatty acid precursor membrane lipids in plastids and the ER by  $\omega$ -3 desaturases [14].

The objective of this study was to investigate the biochemical basis of  $\alpha$ -linolenic acid accumulation in developing seeds of flax (*L. usitatissimum*), *D. moldavica* and *P. frutescens* as high linolenate accumulators compared to the moderate accumulators soybeans and canola.

## Materials and Methods

### Plant Materials

Soybean (*G. max*) cv. 'Jack', *Brassica napus* cv. 'Westar', flax (*L. usitatissimum*) cv. 'NorLin', *P. frutescens* and *D. moldavica* plants were grown in the greenhouse at the University of Kentucky, Lexington. Dicot embryogenesis is divided into five general stages: globular, heart, cotyledon, maturation, and dormancy. By the end of the cotyledon stage and during maturation primary storage products including lipids accumulate in preparation for seed germination later [15]. In this study we focused on cotyledon to maturation stages and classified them to six different stages based on seed size, color, and weight. Seed

coats were carefully removed; embryo length and fresh weight were measured. Samples were frozen in liquid N<sub>2</sub>, lyophilized and the dry weight was measured.

### Fatty Acid and Lipid Analysis

The overall fatty acid composition of seed tissues of different cotyledon developmental stages of the investigated plants were analyzed by modifications of the procedure of [16]. About 1–10 mg lyophilized seed samples with added heptadecanoic acid (17:0) were placed into 2 mL of 2% (v/v) H<sub>2</sub>SO<sub>4</sub> in methanol. The samples were ground finely, and then heated at 80 °C until the volume was reduced to approximately 0.5 mL (2 h). One and one-half milliliters of hexane containing 0.001% butylated hydroxytoluene (BHT) were added and the mixture was vortexed vigorously. The fatty acid methyl esters in the hexane layer were separated by gas chromatography on a Hewlett-Packard 0.25 mm I.D. × 0.33 mm × 10 m FFAP column and quantified using a flame ionization detector. A Hewlett-Packard 5890A gas chromatograph was programmed for an initial temperature of 140 °C for 1 min followed by increases of 12 °C/min to 210 °C and to 235 °C. The final temperature was maintained for 8 min. The injector and detector temperatures were 220 and 250 °C, respectively. Helium was used as the carrier gas with a flow rate of 10 mL/min. Total lipids were extracted from seed tissue as described by [17]. Individual lipids were separated by one-dimensional thin layer chromatography 20 × 20 cm TLC plate (LK60 silica gel 60 A°, Whatman) by the method of [18]. TLC plates were developed in two solvent systems. Phospholipids and glycolipids were separated in chloroform:methanol:water (65:25:4, v/v). Neutral lipids were separated in hexane:diethyl ether:acetic acid (100:100:2, v/v) [17, 19]. Lipids were located by spraying the plates with a solution of 0.005% primulin in 80% acetone, followed by visualization under UV light. In order to determine the fatty acid composition of individual lipids, ten µg of 19:0 was added to the silica gel of each lipid band before scraping, transferred to a tube containing 2 mL of 2% (v/v) H<sub>2</sub>SO<sub>4</sub> in methanol, and fatty acid methyl esters were prepared and analyzed as described above. Radiolabeled 18:2 CoA was synthesized using <sup>14</sup>C linoleic acid and co-enzyme A by the method described by [20]. The labeled <sup>14</sup>C 18:2-CoA was fed to the embryos on a µL (0.0028 µCi/µL) per gram fresh weight basis and incubated for 90 min in light as described by [8]. After incubation the embryos were washed to remove unabsorbed radioactivity and crushed in chloroform/methanol (2:1) to extract lipids. Reverse phase chromatography was used to separate the 18:2 from 18:3. The free fatty acids were methylated by diazomethane and the esterified fatty acids by sodium methoxide. The samples along with the standards were

loaded on to a KV18 silica gel plate and ran in a solvent system consisting of acetonitrile/acetic acid/water (70:10:10). The image was developed in a phosphorimager. The standards were identified and thus used to identify the location of the radioactivity, by placing the plate into an iodine chamber.

### RNA Isolation

RNA was isolated using the Trizol Reagent (Life Technologies, GibcoBrl). 50–100 mg seed tissues of different cotyledon developmental stages of tested plants were frozen in liquid N<sub>2</sub>, homogenized in 1 mL Trizol reagent, transferred into microcentrifuge tubes and incubated for 5 min at room temperature. 0.2 mL chloroform per 1 mL of Trizol was added; tubes were vigorously shaken for 15 s and incubated at room temperature for 3 min. Samples were centrifuged at 12,000×g for 15 min at 2–8 °C. The upper aqueous phase containing RNA was collected in fresh tubes; RNA was precipitated with 0.5 mL of isopropyl alcohol and samples incubated at room temperature for 10 min. Samples were centrifuged at 12,000×g for 10 min, and the RNA pellet was washed once with 1 mL of 75% ethanol. Samples were vortexed and centrifuged at 7,500×g for 5 min. The RNA pellet was air-dried, then dissolved in RNase-free water and incubated for 10 min at 60 °C. The concentration of RNA was estimated by reading the absorbance at 260 nm. The 260/280 ratio of the RNA was 1.9–2.0. The quality of RNA was checked using 1.2% agarose gels. Samples were stored at –80 °C until used.

### Northern Blotting

RNA samples (30 µg) were prepared by adding 2.0 µL of 5× formaldehyde gel-running buffer, 3.5 µL 12.3 M formaldehyde, 10 µL formamide, and incubated 15 min at 65 °C. The samples were chilled in ice for 3 min. Samples were immediately loaded on a pre-run denaturing 1% agarose-formaldehyde gel, the electrophoresis was carried out in the presence of 1× formaldehyde gel-running buffer. The gel was washed with 0.05 N NaOH for 20 min, rinsed with RNase-free water, followed by 10× SSC for 45 min. Blotting and transfer of RNA onto the 6× SSC pre-soaked nylon membrane was carried out according to the standard procedure [21]. RNA was fixed to the Zeta-probe nylon membrane by UV cross-linking (UV stratalinker 1800, Stratagene). The *B. napus* ω-3 desaturase probe was labeled with [ $\alpha$ -<sup>32</sup>P] dCTP using the random priming method. Pre-hybridization and hybridization were carried out at 42 °C following the instructions for using the Zeta-Probe Membrane (Bio-Rad) as outlined by the manufacturer. After hybridization a PhosphorImager system

(Molecular Dynamis, 445 SI) was used to visualize the bands obtained. The radioactive probes were stripped by washing the blots three times with 0.1% SDS in 2× SSC at 95 °C, 10 min each.

## Results

### Fatty Acid Composition in Different Oil Seeds of Moderate and High Linolenate Accumulators During Maturation

The percentage of total fatty acids in flax seeds at different cotyledon developmental stages were analyzed (Fig. 1). Linolenic acid (18:3) accumulated during seed

**Fig. 1** Accumulation of fatty acids in developing flax seeds (a), *P. frutescens* seeds (b), *D. moldavica* seeds (c). µmol of fatty acid/mg seed dry weight were calculated during different stages of cotyledon development. Data points are the means of six replications ± standard errors

development and reached 46% by the end of maturation, oleic acid increased during maturation until stage IV at 40% and then become steady until the end of the maturation. 18:2 was found to be 45% at the first stage and dropped dramatically during the rest of the developmental stages to reach 10% by the end of the maturation process. Also 16:0 dropped from 25% at the beginning of the cotyledon maturation stage to 10% by the end of seed maturation.

The synthesis of 18:3 takes place rapidly at the beginning of cotyledon development in *P. frutescens*. The level of 18:2 declines with the increase in 18:3 while the 18:1 content slightly increased during seed maturation but its level remained relatively lower than the case of flax seed. This suggests that  $\Delta$ -12 desaturase is more efficient in desaturating 18:1–18:2 in *P. frutescens* than in flax. *P. frutescens* seed has a high content of  $\alpha$ -linolenate (57%) [10, 22, 23] and other fatty acid contents were also similar to reported values. The percentage ratio for both 18:2 and 18:3 in *P. frutescens* seed during maturation indicates that  $\omega$ -3 desaturase is very active at the beginning of cotyledon development. However, the 18:3 content reached a steady state at the third stage and remained constant thereafter until the end of seed maturation (Fig. 1). The amount of 18:3 ( $\mu\text{mol}/\text{mg}$  dry weight) increased during cotyledon developmental stages to reach 1.15  $\mu\text{mol}/\text{mg}$  dry weight at the maturation stage.

The accumulation of 18:3 in *D. moldavica* increased gradually to 68% by the end of seed maturation (Fig. 1). The 18:2 and 18:1 levels are lower at maturity. This suggests that both  $\Delta$ 12 and  $\Delta$ 15 ( $\omega$ -3) desaturases are very active in desaturation of 18:1 and 18:2 and are largely responsible for the high level of 18:3 in *D. moldavica*. The accumulation of other FA including 18:1 is minimal as in *P. frutescens* unlike the accumulation of 18:1 in flax during seed maturation. In all high 18:3 accumulators, the linolenic acid content starts at a moderate level. The percentage of 18:3 is higher at a very early cotyledon developmental stage (first stage) of *P. frutescens* (35%) compared with flax (25%) and *D. moldavica* (15%).  $\alpha$ -Linolenic acid gradually accumulated in developing cotyledons of all three plants. However, 18:3 content was found to be higher at the late mature developmental stage of *D. moldavica* (68%) compared with *P. frutescens* (59%) and flax (45%) cotyledons under our greenhouse growth conditions (Fig. 1).

The ratio of 18:2 and 18:3 in TAG in developing soybean seeds is the opposite to that in the three high 18:3 accumulators previously mentioned, which suggests that the level of desaturation of 18:2 into 18:3 decreases in soybean as the seeds mature (Fig. 2). The unsaturated fatty acid levels in PC remain almost constant throughout seed maturation. The increase in lipid content in soybean seed is

**Fig. 2** Linoleic and linolenic acids in PC versus TAG in developing soybean seeds (a), Flax seeds (b), *P. frutescens* seeds (c)

accompanied by a shift in lipid composition from PC (membrane lipids) to TAG accumulation (storage lipids) during seed maturation [24, 25]. Figure 2 shows the amount of 18:3 in flax seed increases during cotyledon maturation stages in TAG in comparison to the 18:3 content in PC.

The level of 18:3 in *P. frutescens* TAG is much higher than in PC, also compared with flax (Fig. 2) the 18:2 levels in *P. frutescens* is lower in PC, which agree with the fact that 18:3 level in TAG of *P. frutescens* seed (Fig. 2) is much higher.

A slightly higher 18:3 amount was found in PC of flax seed in the first three stages of cotyledon development compared to the amount of 18:3 in PC of *P. frutescens* seeds (Fig. 2). However, the percentage of 18:3 in *P. frutescens* PC was slightly higher (6%) in the first two stages compared to the first two stages in flax PC (0.9–3%). Unlike TAG, the 18:3 content was low in PC throughout seed development in flax and *P. frutescens* (Fig. 2). An

increase in 18:3 content was observed in TAG of developing seeds in both flax and *P. frutescens*, however, flax seeds showed a gradual increase of 18:3 in TAG throughout all stages of development, while on the other hand a dramatic increase of 18:3 in TAG of *P. frutescens* seeds was observed during the later stages of development (from 0.15  $\mu\text{mol}/\text{mg}$  seed at the second stage up to 0.9  $\mu\text{mol}/\text{mg}$  seed at seed maturation). It was found that the second stage of cotyledon development is the optimum stage for monitoring  $\omega$ -3 desaturase activity so this stage was used for northern blots.

The 18:3 levels are much higher in TAG compared to its level in PC in *D. moldavica* developing cotyledons while the level of 18:2 is lower in TAG but in PC the amount of 18:2 ( $\mu\text{mol}/\text{mg}$  seed) is relatively higher during second to third stages of cotyledon development (data not shown). The 18:2 level in PC dropped by the end of maturation of the seed.

#### $\omega$ -3 Desaturase Activity

To investigate whether higher  $\omega$ -3 desaturase activity is responsible for the higher synthesis of 18:3 fatty acid, which in turn is incorporated in to TAG in higher amounts, the  $\omega$ -3 desaturase of flax and two moderate accumulators *Arabidopsis* and soybean were assayed. Feeding studies with  $^{14}\text{C}$  labeled 18:2-CoA showed that developing embryos of flax have higher  $\omega$ -3 desaturase activity compared to *Arabidopsis* and soybean (Fig. 3). Stage II flax seeds have much higher activity compared to the stage V flax seeds. During stage II 18:3 accumulation is linear and in stage V embryos 18:3 reaches a plateau (Fig. 1).

#### Microsomal $\omega$ -3 Desaturase Transcript Levels

The  $\omega$ -3 desaturase transcripts levels in stage II flax embryos are much higher compared to soybean embryos of both stages and stage V flax embryos (Fig. 4). These results were also in line with 18:3 fatty acid accumulation in flax seeds (Fig. 1) and also indicated by the  $\omega$ -3 desaturase

**Fig. 3**  $\omega$ -3 desaturase assays:  $^{14}\text{C}$ -18:2 CoA was fed to developing embryos of high 18:3 accumulating flax and moderate 18:3 accumulators soybean and *Arabidopsis*. Lipids were extracted, methylated, and separated on a reverse phase C18 TLC plate and then read on a phosphorimager

**Fig. 4** Northern blot analyses of  $\omega$ -3 desaturase expression in developing embryos of flax and soybean. RNA was extracted from: *B. napus* (Br), the second and fifth developmental stage of flax cotyledons (F1, F5) and the second and fifth developmental stage of soybean cotyledons (S2, S5). (Above) *B. napus*  $\omega$ -3 desaturase (FAD3) cDNA was used as a probe to check the expression of FAD3 gene (Below) to confirm the amount of RNAs loaded were equal 18S ribosomal DNA was used as probe to measure 18S rRNA expression. Equal RNA loading was also confirmed by measuring RNA concentration spectroscopically at 260 nm

activity assay (Fig. 3). The activity assay results show that stage II flax embryos had much higher activity than both stages of soybean embryos and stage V flax. Northern blot analysis data also show developing embryos of *P. frutescens* have much higher  $\omega$ -3 desaturase transcript levels than soybean and *Arabidopsis* (Fig. 5). When three different stages of *D. moldavica*, *P. frutescens* and flax, were compared with the moderately low 18:3 producers (8–10%), soybean and *Arabidopsis*, and *B. napus*,  $\omega$ -3 desaturase mRNA levels were also higher in all three high 18:3 producers, flax, *D. moldavica* and *P. frutescens* compared with the moderately low 18:3 producers (figure not shown for *D. moldavica*). However among high 18:3 producer plants, the  $\omega$ -3 desaturase transcript level was found to be much higher in *D. moldavica* than in *P. frutescens*, which in turn has a higher transcription level than flax (Fig. 5).

**Fig. 5** Northern blot analyses of  $\omega$ -3 desaturase gene expression in developing embryos of *B. napus*, *Arabidopsis*, soybean and *P. frutescens*. RNA was extracted from *B. napus* (Br), *Arabidopsis* seed (Ar), soybean seed cotyledon developmental stages 5–6 mm (S1), 7–9 mm (S2), 9–11 mm (S3), Pr1, Pr2, Pr3, are *P. frutescens* cotyledon at developmental stages (based on size, color, and seed weight) 1, 2 and 3?. (Above) RNAs were blotted on a nylon membrane and probed with *B. napus*  $\omega$ -3 desaturase cDNA to check the  $\omega$ -3 desaturase gene expression (Below) To confirm the amount of RNAs loaded were equal 18S ribosomal DNA was used as probe to measure 18S rRNA expression. Equal RNA loading was also confirmed by measuring RNA concentration spectroscopically at 260 nm

The lipid content and compositions of soybean seeds changes considerably as the embryo progress from the early stages of development to the maturation stage [26]. In soybean the level of 18:3 is higher at the beginning of the cotyledon maturation stage and begins to decline toward the late maturation stages while the 18:2 concentration increases. The opposite is found in all high 18:3 accumulators, with levels of 18:3 increasing during the maturation stages while the 18:2 levels decreased.

In flax (Fig. 3),  $\omega$ -3 desaturase is highly active in converting 18:2-CoA to 18:3 compared to *Arabidopsis* and soybean.

## Discussion

During the first three stages of cotyledon development, in all high 18:3 producers, linear increases in 18:3 levels were found. This suggests that these stages have the highest  $\omega$ -3 desaturase activity. The 18:1 levels in both flax and *P. frutescens* (Fig. 1 and 2) suggests that  $\Delta$ -12 desaturase is more active in desaturating 18:1–18:2 in *P. frutescens* than in flax. In *D. moldavica* 18:3 levels was very high compared with other fatty acids levels suggesting that lipid metabolism in this plant is optimally adjusted for 18:3 accumulation. The level of 18:3 in *P. frutescens* TAG is much higher than in PC, also compared with flax (Fig. 2) the 18:2 levels in *P. frutescens* is lower in PC, which is consistent with the high 18:3 level in TAG of *P. frutescens* seed (Fig. 2). This suggests that desaturation of 18:2–18:3 by  $\omega$ -3 desaturase is more efficient in *P. frutescens* than in flax, which in turn is much higher than in soybean.

The changes in lipid concentration are accompanied by a shift in lipid composition from polar lipids to storage lipids [24]. In soybean the 18:2 levels in TG increase while 18:3 levels decrease. Acyltransferase enzymes catalyze the incorporation of fatty acids into the glycerol backbone to produce different glycerolipids classes including PC and TG [25, 27–29], so that from our data (e.g., Fig. 2) and the selective accumulation of 18:2 in TG of soybeans we can suggest that acyltransferases are selective with 18:2 over 18:3 in soybean seed. However, the absolute amount ( $\mu$  mol/mg seed) of 18:3 in high producing plants suggests that the incorporation rate into TG is very high which in turn indicates that acyltransferases may selectively incorporate 18:3 into storage lipids.

Northern blot data shows that the  $\omega$ -3 desaturase gene expression level is higher in high 18:3 producing plants compared to low producers. This indicates that the level of  $\omega$ -3 desaturase gene expression may largely control the level of  $\alpha$ -linolenic acid in TAG, although as mentioned above acyltransferases also appear to be involved. High accumulation of 18:3 correlates with  $\omega$ -3 desaturase

mRNA levels which suggests transcriptional control of fatty acid desaturase genes [30, 31]. However, the PC versus TAG fatty acid composition data suggest that  $\omega$ -3 desaturase is not the only factor in 18:3 accumulation in TAG, and the high accumulators appear to have a selective transfer of  $\alpha$ -linolenic acid into TAG which in turn suggested that certain acyltransferases or transacylases may play an important role in 18:3 accumulation in triacylglycerols. Another possible factor is the speed of flux from phospholipid to TAG as this can compete with 18:2–18:3 desaturation. It was shown in flax cultivars AC Emerson and Vimy that diacylglycerol acyltransferase (DGAT) prefers 18:3-CoA as substrate [32]. The data from both lipid analysis and Northern blot highly suggest that the reduced linolenic acid content in soybean compared with high 18:3 accumulators is mainly due to the lower transcript level of  $\omega$ -3 desaturase. Byrum et al. [33] found that the reduced 18:3 concentration in the soybean genotype A5 was at least partially the result of a microsomal  $\omega$ -3 desaturase gene with a reduced activity. Collectively, these results indicate that one can obtain *B. napus*, soybeans or other oilseed crops that accumulate high  $\omega$ -3 fatty acid levels simply by increasing expression of the  $\omega$ -3 desaturase gene by use of a strong promoter or trans-activation. Acyltransferases with specificity for 18:3 are likely to be needed for very high  $\omega$ -3 fatty acid accumulation, for example, >80%.

**Abstract** Liquid chromatography–ion trap mass spectrometry (LC/ITMS) was employed for a metabolic kinetics study of *tert*-butylhydroquinone (TBHQ) and its metabolites in rat serum after oral administration. The mean serum concentration–time data of TBHQ and its four metabolites (M1–M4) in both male and female rats after oral administration of TBHQ at dosages of 7, 350 and 700 mg/kg were all best-fitted by a two-compartment model with first-order absorption. TBHQ was rapidly absorbed, distributed and metabolized. The metabolites were also distributed rapidly except M2, but eliminated more slowly than TBHQ. At the doses of 350 and 700 mg/kg, the total concentrations of TBHQ and its metabolites in serum were much higher for male than female rats during the metabolic process ( $P < 0.01$ ). In addition, the serum concentrations of M1, M3 and M4 were all much higher for males than for females ( $P < 0.01$ ) during the metabolic process, while no significant differences between male and female rats were found ( $P > 0.05$ ) for TBHQ and M2,

at the doses of 350 and 700 mg/kg. The exploratory assessment of dose proportionality for TBHQ and its metabolites by the power model indicated that the TBHQ exposure increased in a more-than-dose-proportional manner, but the exposures of the metabolites M1–M4 increased in a less-than-dose-proportional manner, across the dose of 7–700 mg/kg.

**Keywords** *tert*-Butylhydroquinone (TBHQ) · Liquid chromatography–ion trap mass spectrometry (LC/ITMS) · Metabolic kinetics

### Introduction

Prevention of lipid peroxidation has long become an important issue, since oils and fats, essential to our diets, tend to encounter problems of oxidation and rancidity, which affect food quality and may endanger our health [1]. Among various modern methods for preventing lipid peroxidation, the addition of antioxidants is preferentially considered [2, 3]. Most of the commonly used antioxidants are synthetic compounds such as tertiary butylhydroquinone (TBHQ) because of its chemical stability, low cost and availability. However, the safety of the antioxidant was questioned due to its potential risk [4–7]. In order to evaluate the safety of TBHQ, several methods have been carried out to measure TBHQ in body fluids as well as foods [8–10]. Most methods require long analysis time and laborious techniques for the treatment of samples which also have low resolution. Meanwhile, it is found that they are limited in study of biological samples, such as analyses of metabolites, which is very important to study the pharmacokinetics and toxicology of TBHQ. HPLC coupled with mass spectrometry is a currently developed unique

technique for monitoring antioxidant content and studying compound structure [11]. In particular, MS/MS triple quadrupole mass spectrometry in the multiple reaction monitoring modes (MRM) provides surpassing speed, sensitivity and selectivity. But, there is very little information regarding the metabolites of TBHQ and its metabolic kinetics using liquid chromatography–ion trap mass spectrometry (LC/ITM).

In our previous study, we established a rapid, sensitive, precise and accurate quantitative method for the measurement of TBHQ in commercial edible oil as well the determination of TBHQ and its metabolites in rat serum after oral administration by liquid chromatography/tandem mass spectrometry (LC/MS/MS) [12, 13]. Mass spectral analysis of TBHQ and its metabolites peaks in rat serum indicated four major ionic parent masses  $[M-H]^-$  at  $m/z$  245 (M1),  $m/z$  305 (M2),  $m/z$  327 (M3) and  $m/z$  341 (M4) [13]. M1 and M4 were found to be a TBHQ-sulfate (3-*tert*-butyl-4-hydroxyphenyl hydrogen sulfate) and a TBHQ-glucuronide [6-(3-*tert*-butyl-4-hydroxyphenoxy)-3,4,5-trihydroxytetrahydro-2H-pyran-2-carboxylic acid] and two TBHQ-sulfate-derived substances named M2 and M3 in further identifying work) by LC/MS/MS [13]. In this study, the LC/MS/MS method was applied to metabolic kinetics studies of TBHQ and its metabolites in rat serum following oral administration of TBHQ at three different dosage levels.

## Experimental Procedure

### Reagents

The purity of TBHQ (IUPAC compliant name: 2-(1,1-dimethylethyl)-1,4-benzenediol, CAS No.: 1948-33-0) from J & K chemica, Augsburg, Germany was better than 98%. Methanol and acetonitrile (Fisher Scientific, Pittsburgh, PA) were of HPLC grade. Absolute ethyl alcohol, aqua ammonia and acetic acid (Beijing Chemical Reagent Co., Beijing, China) were of analytic grade. Water was purified using a Milli-Q gradient system (Millipore Corporation, Genay Cedex, France).

### Animals

Adult Sprague–Dawley (SD) rats, weighing  $160 \pm 10$  g, were obtained from Department of Laboratory Animal Science of Peking University (Beijing, China). The animals in this study received humane care according to the guidelines set forth in the principles of the care and use of laboratory animals formulated by the General Administration of National Quality Supervision, Inspection and Quarantine of the People's Republic of China (GB14923-2001).

### Animal Handling and Sample Collection

The procedures for animal handling and sample collection were described in the previous paper [10, 13]. On the study of metabolic kinetics, SD rats used were divided into four groups (six male and six female rats/group). Rats in group 1, as control group, were assigned to receive corn oil at a gavage dose of 1 mL, respectively. Rats in Group 2, 3 and 4 were given TBHQ dissolved in corn oil at gavage doses of 7, 350 and 700 mg/kg, respectively. Blood samples from rat tail vein were collected in EP (epoxy epoxide) tubes (0.25 mL of blood sample/rat) at times of 0.08, 0.25, 0.5, 1, 2, 3, 5, 7, 9, 12, 24 and 48 h after oral administration and following centrifugation of the blood samples at 13,225 g-force for 20 min, each serum sample was collected and stored at  $-20$  °C until analyzed [13].

### Quantitative Analyses of TBHQ and Its Metabolites

The procedures for quantitative analysis of TBHQ and its metabolites in rat serum were described in the previous paper [13]. TBHQ's  $MS^2$  characteristic product ion and its  $MS^1$  product ions based on extracted ion chromatograms (EICs) were employed for quantitation of free TBHQ and semi-quantitation of its metabolites in rat serum.

The concentration of TBHQ in rat serum was quantified using an external standard prepared in a blank matrix. The calibration curve was obtained by plotting the peak area of EIC  $m/z$  149 ( $MS^2$ ) against the concentration of TBHQ. The calibration curve ( $Y = 401.22X + 39958.87$ ) showed good linearity over the concentration range of 49–5,030  $\mu\text{g/L}$  with the coefficient ( $r^2$ ) of 0.99. The detection limit of TBHQ for serum sample was 14  $\mu\text{g/L}$  ( $S/N = 3$ ). To evaluate accuracy and precision, six serum samples, where each contains three different concentrations of TBHQ (328, 998, 1,969  $\mu\text{g/L}$ ), were prepared and analyzed. The recoveries of TBHQ in serum ( $n = 6$ ) were  $96.08 \pm 11.85$ ,  $93.43 \pm 6.65$  and  $95.50 \pm 9.44\%$ . The intra-day relative standard deviations (RSDs) ( $n = 6$ ) were 14.82, 10.31 and 7.74% and the inter-day RSDs over three consecutive days were 20.60, 14.39 and 8.26%. The results show that the method could be used for quantifying TBHQ in rat serum.

Under the adopted LC/ITMS conditions, peaks of TBHQ and its metabolites appear with retention times of 5.3 and 3–4 min, respectively. The nearness of their chromatographic retention times suggests that the polarities of TBHQ and its metabolites are quite similar. The  $MS^1$  response of a compound is decided by its polarity to some extent. So, using TBHQ standards, the semi-quantification of its metabolites was acceptable for metabolic kinetics study. In the research, the  $MS^1$  responses of per unit concentration were defined to be equivalent for TBHQ and its

metabolites; the calibration curve was obtained by plotting the peak area of EIC  $m/z$  165 against the concentration of TBHQ. The coefficient ( $r^2$ ) of the calibration curve ( $Y = 817.23X - 74268.46$ ) was 0.98, suggesting that the curve could work well for semi-quantifying the metabolites of TBHQ in rat serum.

### Metabolic Kinetics Analysis

The most common method of evaluating the metabolic kinetics of a chemical is to assume that the chemical concentration–time data can be described by one of several compartment models. The model was selected on the basis of the residual sum of squares and minimum Akaike's information criterion (AIC) value [14, 15]. AIC is a criterion for selecting the best model among a number of candidate models, and the model that yields the smallest value of AIC is considered the best. The Practical Pharmacokinetic Program was usually used for metabolic kinetics analysis [16–19]. In our study, the metabolic kinetics parameters were calculated using Practical Pharmacokinetic Program-Version 97 (3P97) published by the Chinese Pharmacological Association (Beijing, China). The metabolic kinetics parameters include those such as the hybrid rate constant for the distribution phase ( $\alpha$ ), the hybrid rate constant for the elimination terminal phase ( $\beta$ ), the first-order absorption rate constant ( $k_a$ ), absorption half-life ( $T_{1/2k_a}$ ), half-life of  $\alpha$  phase ( $T_{1/2\alpha}$ ), half-life of  $\beta$  phase ( $T_{1/2\beta}$ ), distribution rate constant for transfer of the chemical from the central to the peripheral compartment and from the peripheral to the central compartment ( $K_{12}$  and  $K_{21}$ ), the elimination rate constant ( $K_{10}$ ), area under the curve from time zero to last time of sampling ( $AUC_{0-t}$ ), area under the curve from time zero to infinity ( $AUC_{0-\infty}$ ), maximum chemical concentration after oral administration ( $C_{max}$ ), and the interval (time) from oral administration until  $C_{max}$  were obtained ( $T_{max}$ ).

### Statistical Analysis

Data are presented as means  $\pm$  SD. The results were statistically analyzed by analysis of variance (ANOVA) followed by Fisher's test. Differences were considered significant at  $P < 0.01$ .

## Results and Discussion

The mean serum concentration–time courses of TBHQ and its four metabolites (M1–M4) after oral gavage of TBHQ at dosages of 7, 350 or 700 mg/kg were investigated in previous research [13]. According to AIC value, the mean serum concentration–time data of TBHQ and its metabolites M1–M4 could all best-fitted by a two-compartment model

with first-order absorption as serum concentration  $C = Ae^{at} + Be^{bt} - (A + B)e^{-k_d t}$ . The metabolic kinetics parameters based on the serum concentration–time data of TBHQ and its metabolites M1–M4 were automatically simulated with the aid of Practical Pharmacokinetic Program 3P97. The metabolic kinetics parameters were listed in Tables 1, 2, 3.

After oral administration, TBHQ was rapidly absorbed with a mean  $T_{max}$  between 0.12 and 0.23 h (male, ♂), 0.16–0.27 h (female, ♀). A rapid distribution phase and a slower elimination phase were also observed, with a half-life of distribution  $\alpha$  phase ( $T_{1/2\alpha}$ ) of 0.12–0.35 h (♂), 0.21–0.48 h (♀) and a half-life of elimination  $\beta$  phase ( $T_{1/2\beta}$ ) of 10.27–14.39 h (♂), 3.51–10.73 h (♀). When administered orally, TBHQ was rapidly metabolized to M1, M3 and M4, with a mean  $T_{max}$  of 0.17–0.57 h (♂) and 0.18–0.61 h (♀) for M1, 0.30–0.60 h (♂) and 0.22–0.66 h (♀) for M3, 0.29–0.74 h (♂) and 0.23–0.46 h (♀) for M4, respectively. However, the metabolic reaction from TBHQ to M2 was a bit slower, with a mean  $T_{max}$  of 5.29–8.95 h (♂) and 4.50–9.74 h (♀) for M2. The distribution half-lives ( $T_{1/2\alpha}$ ) of the metabolites were very short, like TBHQ, 0.35–0.63 h (♂) and 0.32–1.11 h (♀) for M1, 0.10–0.28 h (♂) and 0.27–0.51 h (♀) for M2, 0.38–0.77 h (♂) and 0.98–1.62 h (♀) for M3, 0.26–2.60 h (♂) and 1.07–1.66 h (♀) for M4, respectively. But the elimination half-lives ( $T_{1/2\beta}$ ) of the metabolites were longer than TBHQ, 12.69–45.57 h (♂) and 11.75–24.54 h (♀) for M1, 7.75–17.64 h (♂) and 8.96–28.62 h (♀) for M2, 43.61–66.71 h (♂) and 29.82–68.38 h (♀) for M3, 9.94–65.78 h (♂) and 21.98–36.00 h (♀) for M4, respectively. This reveals that the metabolites of TBHQ are transported to tissues or organs from blood almost as rapidly as TBHQ, but cleared more slowly from blood than TBHQ, which is consistent with the results reported by Ikeda et al. [10] to a certain extent. Ikeda et al. [10] found that the distribution of [ $^{14}C$ ] TBHQ in various tissues was biphasic, consisting of a rapid component and a slower component.

The plots of  $C_{max}$  versus dose are presented in Fig. 1. In previous study, it was found that the concentration of free TBHQ in the serum samples at the dose of 7 mg/kg was lower than the limit of detection [13], therefore,  $C_{max}$  of free TBHQ at the dose is regarded as 0  $\mu\text{mol/L}$  (Fig. 1a). With TBHQ across a dosage range of 7–700 mg/kg, significant increases of  $C_{max}$  were found for TBHQ (both ♂ and ♀), M1 (♂) and M4 (both ♂ and ♀). For M1 (♂) and M3 (both ♂ and ♀),  $C_{max}$  increased when the dosage of TBHQ was raised, but apparent saturations in  $C_{max}$  were observed at doses higher than 350 mg/kg. An almost sustained  $C_{max}$  value was observed for M2 (both ♂ and ♀). Furthermore, the exploratory assessment of dose proportionalities for TBHQ and its metabolites was performed by fitting the power model:  $\ln C_{max} = a + b \ln \text{dose}$ , where the slope  $b = 1$  indicates dose-proportionality. The *dose*-proportionality constant for

A and B: mathematical coefficients. ♂ denotes male rat and ♀ denotes female rat. Data represent mean ± s.d. for six rats

C<sub>max</sub> is estimated as 1.19 (♂) and 1.25 (♀) for TBHQ, 0.83 (♂) and 0.78 (♀) for M1, 0.21 (♂) and -0.04 (♀) for M2, 0.44 (♂) and 0.33 (♀) for M3, 0.64 (♂) and 0.51 (♀) for M4, respectively. The dose-proportionality constants for C<sub>max</sub> are in the order of TBHQ > 1 > M1 > M4 > M3 > M2. The results of power model show that as determined by C<sub>max</sub>, TBHQ exposure increases in a more-than-dose-proportional manner, but the exposures of the metabolites M1–M4 increase in a less-than-dose-proportional manner, across the dose of 7–700 mg/kg. It seems that the metabolic reactions from TBHQ to M1–M4 are likely to be restricted by enzymes or substrates connecting with those reactions to different extents, and metabolic saturations would occur at TBHQ doses higher than 350 mg/kg.

The serum concentrations of M1, M3 and M4 were all much higher for males than for females (P < 0.01) during the metabolic process, while no significant differences between male and female rats were found (P > 0.05) for TBHQ and M2, at the doses of 350 and 700 mg/kg. The sex difference in the metabolism of TBHQ and its metabolites might be attributed to differences in the expressed levels of cytochrome P-450 (CYP-450) and other metabolizing enzymes [20–22]. A differentiated pattern of hormone release in females and males [23] contributes to different levels of CYP-450 expression, influencing their metabolic capability [24], which could result in differences of metabolic kinetics between TBHQ and its metabolites.

In this work, the LC/ITMS was used for investigating the metabolic kinetics of TBHQ and its metabolites in rat serum after oral doses of 7, 350 and 700 mg/kg. It was found that the TBHQ exposure increases in a more-than-dose-proportional manner, but the exposures of the metabolites M1–M4 increase in a less-than-dose-proportional manner, across the dose of 7–700 mg/kg. TBHQ were rapidly absorbed, distributed and metabolized. The metabolites except M2 appear to be rapidly absorbed and distributed as TBHQ, but they were observed to be eliminated more slowly than TBHQ. Moreover, apparent sex difference in the metabolism of TBHQ was found. After oral administration, TBHQ seems to be more completely absorbed and biotransformed by males than females and the serum concentrations of M1, M3 and M4 also appear significantly higher for males than females. The results suggest that TBHQ may result in higher acute oral toxicity for males than for females. The sex differences of metabolic kinetics and the toxicities of TBHQ and its metabolites, which might be resulted from the differences of expressed levels of CYP-450 and other metabolizing enzymes between male and female, should be further investigated. These findings suggest that although rat is a useful animal model for clarifying the mechanisms underlying TBHQ adverse actions after oral administration and to optimize its usages, sex differences should be

**Fig. 1** Plots of peak serum concentration ( $C_{max}$ ) of TBHQ and its metabolites versus dose after oral administration. **a** for TBHQ, **b** for M1, **c** for M2, **d** for M3, and **e** for M4

carefully considered especially when extrapolating metabolic kinetic profile and the safety results of TBHQ from rat to human. The research is not only favorable for enhancing the understanding of the metabolic mechanism of TBHQ, but also for facilitating finding additional targets such as its metabolites for evaluation of TBHQ safety.

**Abstract**  $\alpha,\beta$ -unsaturated aldehydes are toxic products of lipid peroxidation. Detection and characterization of these aldehydes is important in many human disease states as well as in the food industry. Our study shows that electron ionization-mass spectrometry (EI-MS) and positive-ion chemical ionization-mass spectrometry (PICI-MS), but not electron capture negative ionization-mass spectrometry (ECNI-MS), can be used to detect the C4-hydroxylation state of  $\alpha,\beta$ -unsaturated aldehydes derivatized with pentafluorobenzyl hydroxylamine alone. EI-MS and PICI-MS spectra of 4-hydroxy-2-alkenals contained a fragment with  $m/z$  252, whereas spectra of 2-alkenals contained a fragment with  $m/z$  250. These fragments are consistent with fragmentation between C3 and C4 with transfer of two hydrogens from C4 and the C4 hydroxyl group in the case of 4-hydroxy-2-alkenals. In addition, EI-MS and PICI-MS were able to distinguish 4-hydroxy-2-alkenals and 2-alkenals from 4-keto-2-alkenals and 4-hydroxyalkenals. On the other hand, ECNI-MS provided complex spectra regarding C4-hydroxylation state. Furthermore, the *syn*- and *anti*-configurations of PFB-oximes had different resultant spectra using ECNI-MS, but not with EI-MS or PICI-MS. These data indicate that EI-MS and PICI-MS are more amenable for structural analysis of  $\alpha,\beta$ -unsaturated aldehydes than ECNI-MS.

## Introduction

Lipid peroxidation is important in the food industry [1] and is implicated in many disease states such as Alzheimer's disease [2], atherosclerosis [3], and amyotrophic lateral sclerosis [4]. Lipid peroxidation of n-3 and n-6 fatty acids leads to the formation of multiple keto and aldehyde species, including  $\alpha,\beta$ -unsaturated aldehydes. These  $\alpha,\beta$ -unsaturated aldehydes include *trans*-4-hydroxy-2-alkenals, such as *trans*-4-hydroxy-2-nonenal (HNE), *trans*-4-

hydroxy-2-hexenal (HHE), *trans*-4-oxo-2-alkenals such as *trans*-4-oxo-2-nonenal (4-ONE) and *trans*-4-oxo-2-hexenal, and 2-alkenals, such as *trans*-2-hexenal [5–9].

Structural and quantitative analyses of  $\alpha,\beta$ -unsaturated aldehydes are performed using gas chromatography (GC) coupled to various forms of ionization methods, such as electron ionization-mass spectrometry (EI-MS) and electron capture negative ionization-mass spectrometry (ECNI-MS). Typically, samples are derivatized with O-(2,3,4,5,6-pentafluorobenzyl)-hydroxylamine (PFBHA) [10–12]. PFB-derived aldehydes containing hydroxyl groups may be further derivatized using *N,O*-bis(trimethylsilyl) acetamide [5, 6].

During development of an analytical method for quantifying  $\alpha,\beta$ -unsaturated aldehydes using GC/EI-MS, we observed mass spectral differences between 4-hydroxy-2-

alkenals and 2-alkenals when derivatized with PFBHA alone. 4-Hydroxy-2-alkenal spectra contained an abundant  $m/z$  252 fragment whereas spectra of 2-alkenals contained an abundant  $m/z$  250 fragment (Fig. 1).

Based on these initial data, the goals of this study are to determine the mechanism by which these fragments are produced and determine if other ionization methods produce results similar to those seen using GC/EI-MS. Our results demonstrate that hydrogen transfer is involved in the fragmentation difference observed between C4-hydroxylated and unsubstituted 2-alkenals using GC/EI-MS. The fragmentation pattern observed for 4-hydroxy-2-alkenals requires both a 4-hydroxyl group and a C2, C3 double bond. GC/positive-ion chemical ionization-mass spectrometry (PICI-MS) yielded results similar to those of EI-MS, and provided the  $[M + H]^+$  ion in the case of 2-alkenals and the

**Fig. 1** EI-MS spectra of PFB-HNE (a) and PFB-nonenal contain fragments with  $m/z$  252 and  $m/z$  250, respectively. In addition, both contain  $m/z$  181, characteristic of PFB-oximes. The PICI-MS spectrum of PFB-HNE (c) contains a fragment with  $m/z$  334 corresponding to  $[M + H - H_2O]^+$ , in addition to fragments with  $m/z$  181 and 252. The PICI-MS spectrum of PFB-Nonenal (d) contains a fragment with  $m/z$  336 corresponding to  $[M + H]^+$ , in addition to fragments with  $m/z$  181 and 250. The ECNI-MS spectrum of PFB-HNE contains a complex mixture of spectra, which include  $m/z$  192, specific to 4-hydroxy-2-alkenals, and  $m/z$  301 which corresponds to  $[M - CF_2]^-$ . The ECNI-MS spectrum of PFB-nonenal include  $m/z$  197, specific to 2-alkenals, and  $m/z$  285, which corresponds to  $[M - CF_2]^-$

$[M + H - H_2O]^+$  ion for 4-hydroxy-2-alkenals. However, ECNI-MS yielded less clear structural information in regards to  $\alpha,\beta$ -unsaturated aldehydes. Despite the different information provided by each ionization method, our results also demonstrate that these techniques can be used for complementary characterization and identification of  $\alpha,\beta$ -unsaturated aldehydes.

## Materials and Methods

### Materials

HNE was purchased from Cayman Chemical Company (Ann Arbor, MI). *O*-(2,3,4,5,6-pentafluorobenzyl) hydroxylamine (PFBHA) was purchased from Alpha Aesar (Ward Hill, MA). Sodium borodeuteride ( $NaBD_4$ ) and 1,1,3,3-tetra-methoxypropane were purchased from Sigma (St Louis, MO). *trans*-4-Hydroxy-2-nonenal-5,5,6,6,7,7,8,8,9,9,9- $d_{11}$  ( $d_{11}$ -HNE) dimethyl acetal (stated isotopic purity >99%) was purchased from CDN Isotopes (Pointe-Claire, QC, Canada). *trans*-2-Nonenal was purchased from Aldrich (Milwaukee, WI). *trans*-2-Hexenal and diisobutyl aluminum hydride (DIBAL-H) were purchased from Acros Organics (NJ, USA). Docosahexaenoic acid and arachidonic acid were purchased from Nu-Chek Prep, Inc. (Elysian, MN). HNE and HNE dimethyl acetal were synthesized in our laboratory [13, 14].

### Methods

#### *Synthesis of 4-Hydroxynonanal (HNA)*

HNA was synthesized from  $\gamma$ -nonalactone via a method similar to that of Bloch and Gilbert [15]. Six grams of  $\gamma$ -nonalactone was added to 400 mL toluene and cooled to  $-78^\circ\text{C}$  under argon. 60 mL of 1 M DIBAL-H was added dropwise for 1 h. The reaction was stirred for 3.5 h at  $-78^\circ\text{C}$ . Excess DIBAL-H was destroyed by addition of 30 mL isopropyl alcohol (2 M) in toluene. One milliliter of water was added, followed by 100 mL tetrahydrofuran, then 15 g of silica gel with 30 g magnesium sulfate, with 30 min between each addition. This reaction was filtered, and the residue was washed with 100 mL THF and 100 mL dichloromethane. The filtrate and washes were combined and dried twice over magnesium sulfate. HNA was purified from the filtrate via flash chromatography with silica solid phase and 70:30 hexane:isopropanol mobile phase, dried, weighed and suspended in hexane. The structure of HNA was confirmed using ESI-MS (positive mode) as evidenced by a peak with  $m/z$  159 corresponding to  $[M + H]^+$ . Also present were peaks corresponding to  $[M-17]^+$  which corresponds to addition of a hydrogen followed by loss of water, and  $[M + 23]^+$ , which corresponds to the sodium

adduct. ESI-MS/MS was done using a Perkin-Elmer/Sciex API 3000 triple quadrupole mass spectrometer (Concord, ON, Canada). We also compared HNA to HNE and 4-ONE via HPLC-UV analysis and determined that HNA did not coelute with HNE or 4-ONE (data not shown). The yield from this reaction was 17.4 mg HNA.

$^1\text{H-NMR}$  spectra of HNA were recorded in  $CDCl_3$  using TMS as an internal standard on an Avance 500 Bruker spectrometer.  $^1\text{H-NMR}$  spectrum (500 MHz,  $CDCl_3$ ,  $\delta$ ): 0.89 t (3H,  $J = 6.6$  Hz,  $CH_3$ ), 1.25–2.17 m (12H, six  $CH_2$  groups), 2.97 and 3.06 two d (1H,  $J = 2.5$  Hz, OH), 3.97 and 4.20 two m [1H, H(4)], 5.47 and 5.55 two m [1H, H(1)]. According to the  $^1\text{H-NMR}$  spectrum of HNA in  $CDCl_3$ , the compound exists in the solution as a cyclic hemiacetal. The ratio of the integration curves for the trace signal at  $\delta$  9.80 ppm [assigned to the H(1) of the linear form] and two signals at 5.47 and 5.55 ppm (assigned to the H(1) of the cyclic form), suggests that the amount of the linear form in the solution does not exceed 1%. As expected, some signals [e.g., the OH, CH(4), and CH(1) signals] assigned to the hemiacetal, are doubled due to the presence of two chiral centers.  $^1\text{H-NMR}$  spectra showed no evidence of a carbon-carbon double bond.

#### *Synthesis of trans-4-Hydroxy-2-nonenal-4- $d_1$ ( $d_1$ -HNE)*

$d_1$ -HNE was synthesized according to the method for synthesis of  $^3\text{H-HNE}$  by Chandra and Srivastava [13]. Two hundred and thirty-seven milligrams of pyridinium chlorochromate, 265 mg sodium acetate and 7.3 mL  $CH_2Cl_2$  were mixed together and stirred. To this mixture, 112 mg HNE-dimethylacetal was added and stirred for 30 min. This reaction was monitored by TLC. Forty millilitres of ether was added to the mixture, decanted, filtered, and evaporated, resulting in 4-ONE dimethylacetal. Ten milligrams of 4-ONE dimethylacetal was added to 5 mL ethanol with 8 mg  $NaBD_4$  and stirred for 2 h. This resulted in the reduction of the 4-keto group yielding a C4 deuterium and a C4-hydroxyl group. The reaction was evaporated and added to 50 mL water acidified to pH 2 with phosphoric acid to remove the protecting groups. The reaction was then extracted three times into  $CH_2Cl_2$ , evaporated, weighed, and raised in hexane. The product coeluted with non-deuterated HNE during HPLC-UV analysis using a Waters Spherisorb ODS2 reverse phase column. The solvent system was 65:35 water:acetonitrile with a flow rate of 1.5 mL/min. Absorbance was monitored using a photodiode array detector scanning from 200 to 300 nm. The absorbance maximum for HNE and  $d_1$ -HNE was 223 nm (data not shown). No other compounds were detected. The yield of this reaction was 3.54 mg.

ESI-MS analysis (in positive mode) of the resulting  $d_1$ -HNE resulted in four main  $m/z$  peaks at 157 (relative

percentage of 20.7%), 158 (70.5%), 159 (8.2%), and 160 (0.6%). The  $m/z$  157 corresponds to the  $[M + H]^+$  of non-deuterated HNE. The  $m/z$  158 corresponds to the  $[M + H]^+$  of  $d_1$ -HNE. Given the natural abundance of  $^{13}\text{C}$  (1.1%), the  $m/z$  159 and  $m/z$  160 likely correspond to the  $[M + H]^+$  of  $d_1$ -HNE containing one and two atoms of  $^{13}\text{C}$ , respectively. Taking into consideration the abundance of  $^{13}\text{C}$ , approximately 2% of the  $m/z$  159 is non-deuterated HNE. From these data, we conclude that the isotopic purity of  $d_1$ -HNE is 77%.

Comparison of  $^1\text{H-NMR}$  spectra of the resulting  $d_1$ -HNE and non-deuterated HNE was used to confirm the C4 deuterium of  $d_1$ -HNE. For non-deuterated HNE,  $^1\text{H NMR}$  ( $\text{CDCl}_3$ ,  $\delta$ , ppm): 0.90 t (3H,  $^3J = 7.0$  Hz,  $\text{CH}_3$ ), 1.30–1.70 m (6H, three  $\text{CH}_2$  groups), 1.81 m (1H, OH), 4.43 m (1H, HC(4)O), 6.31 ddd (1H,  $^4J_1 = 6.3$ ,  $^3J_2 = 7.8$ ,  $^3J_3 = 15.6$  Hz, HC(2)), 6.82 dd (1H,  $^3J_1 = 4.7$ ,  $^3J_2 = 15.6$  Hz, HC(3)), 9.59 d (1H,  $J = 7.8$  Hz, H–C=O). The  $^1\text{H-NMR}$  spectra of both  $d_1$ -HNE and non-deuterated HNE in  $\text{CDCl}_3$  have the signals of the C(3)H=C(2)H–HC(1)=O and  $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2$  fragments. However, in the spectrum of  $d_1$ -HNE, the signal at d 4.43 ppm, assigned to the hydrogen bonded to the C4 OH group in the spectrum of the non-deuterated HNE, is greatly reduced. These data confirm that the deuterium of  $d_1$ -HNE is localized to C4, and that there is some non-deuterated HNE present.

#### Synthesis of 4-oxo-2-nonenal (4-ONE)

Seventy-five milligrams of 4-ONE dimethyl acetal was deprotected in 50 mL pH 2 water acidified with phosphoric acid to form 4-ONE. The product was confirmed as 4-ONE via comparison during synthesis by TLC to 4-ONE standard purchased from Cayman Chemical Company (Ann Arbor, MI) with a solvent system of 80:20 hexane:ethyl acetate. The standard and the reaction product were both reactive towards dinitrophenylhydrazine and chromatographed identically. The product and the standard had the same  $\lambda_{\text{max}}$  of 228 nm in ethanol. The product had a mass consistent with a bis-PFBHA oxime derivative of 4-ONE by GC-MS (see Table 2). The yield of this reaction was approximately 65 mg of 4-ONE.

#### Preparation of $d_{11}$ -HNE

$d_{11}$ -HNE dimethyl acetal was added to 50 mL water acidified to pH 2 with phosphoric acid to yield  $d_{11}$ -HNE. The reaction was extracted three times into  $\text{CH}_2\text{Cl}_2$ , evaporated, weighed, and raised in hexane. Molecular mass was confirmed by ESI-MS/MS. The yields of this reaction were typically over 90%.

#### Synthesis of Malondialdehyde

Malondialdehyde (MDA) was synthesized by deprotection of 1,1,3,3-tetramethoxypropane in 1 M HCl according to the method of Hjelle and Petersen [16]. This reaction consisted of 1 mL of 1 M HCl containing 567 mM 1,1,3,3-tetramethoxypropane. The reaction was allowed to proceed for 2 h at 37 °C. After incubation, the reaction mixture was diluted to approximately 10 mL final volume with 50 mM sodium phosphate buffer set to pH 7.4. The final stock was set to pH 7.4 using 1 M NaOH. The final concentration was determined using spectrophotometric analysis at  $\lambda_{\text{max}}$  265 nm using  $\epsilon = 31,800 \text{ M}^{-1} \text{ cm}^{-1}$ .

#### Preparation of PFB-Oximes

Aldehydes at 10  $\mu\text{M}$  concentrations were added to an equal volume of 50 mM PFBHA in 50 mM sodium acetate buffer at pH 5.0 for 30 min. Following derivatization, reaction mixtures were acidified using sulfuric acid to precipitate unreacted PFBHA·HCl. Previous work by Luo et al. [17] shows that acidification aided in the removal of excess PFBHA. Samples were extracted three times into methylene chloride and dried over sodium sulfate and evaporated under nitrogen. The samples were then raised to their original volume (1 mL) in methylene chloride.

#### Gas Chromatography/Mass Spectrometry

GC/MS analyses were performed using a ThermoElectron Corp (Waltham, MA) GC/MS with a Trace GC, a PolarisQ ion trap mass spectrometer and an AS3000 autosampler. This system was coupled to a Dell PC and data was analyzed using Xcalibur version 1.3 software. We used a J&W Scientific 30 m DB5-MS capillary column. Our method used a 1  $\mu\text{L}$  splitless injection. The inlet temperature was held at 250 °C. The oven temperature was held at 50 °C for 1 min followed by an increase of 20 °C/min up to 320 °C, which was held for 10 min. The transfer line temperature was 300 °C and the ion source temperature was maintained at 250 °C for all analyses. Total ion current was measured from 5 to 24 min using a 70 eV ionization energy for EI analyses. Chemical ionization analyses used the same method as above with the addition of methane reagent gas (3.0 mL/min). Samples were analyzed using both PICI-MS and ECNI-MS using total ion current.

#### Oxidation of Docosahexaenoic Acid and Arachidonic Acid

DHA and arachidonic acid oxidation reactions were prepared separately at concentrations of 10 mM in 10 mL of 50 mM sodium phosphate buffer at pH 7.4 in the presence

of 1 mM ascorbic acid and 50  $\mu$ M iron(II) chloride [18]. The reaction mixtures were heated to 37 °C for 6 h. After incubation, 1 mL of the reaction mixtures was taken and added to 1 mL 50 mM PFBHA derivatization solution for 1 h. After derivatization, derivatives were extracted three times with dichloromethane and dried under nitrogen. Samples were then reconstituted in 1 mL of dichloromethane and subjected to GC/MS analysis.

### Statistical Analyses

Linear regression was performed using Prism 4 software (Graphpad Software, Inc., San Diego, CA).

## Results

As shown in Fig. 1, derivatization of  $\alpha,\beta$ -unsaturated aldehydes with PFBHA followed by analysis using GC/EI-MS produced clear spectra that distinguished the C4-hydroxylation state of  $\alpha,\beta$ -unsaturated aldehydes. Spectra of all aldehydes contained fragments with  $m/z$  181 corresponding to  $[C_6H_2F_5]^+$ , a common indicator of PFB-oximes produced by EI-MS [15]. In addition to  $m/z$  181, spectra of 4-hydroxy-2-alkenals (HNE and HHE) contained fragments with  $m/z$  252 (Fig. 1; Table 1) whereas unsubstituted 2-alkenals (*trans*-2-nonenal and *trans*-2-hexenal) contained fragments with  $m/z$  250 (Fig. 1; Table 1). Both of these fragments are consistent with fragmentation

between C3 and C4 with the 2 mass unit difference resulting from hydrogen transfer to the charged fragment.

In order to determine the origin of the hydrogens transferred during analysis of 4-hydroxy-2-alkenals, we employed  $d_{11}$ -HNE, deuterated on C5–C9. Our EI-MS spectrum of PFB-derivatized  $d_{11}$ -HNE contained a fragment with  $m/z$  252, showing that the deuteria remained on the deuterocarbon tail during fragmentation (Table 1). We synthesized  $d_1$ -HNE, which contained a C4 deuterium to determine if one of these hydrogens originated from C4. The EI-MS spectrum of PFB- $d_1$ -HNE contained a fragment with  $m/z$  253 (Table 1). These data indicate that the transfer of a hydrogen from C4 accounts in part for the  $m/z$  252 fragment observed with the 4-hydroxy-2-alkenals.

To determine the necessity of the C2, C3 double bond to produce  $m/z$  252 or 250 using EI-MS, we synthesized HNA, a known metabolite of HNE, and derivatized it with PFBHA [19]. Spectra of PFB-HNA contained  $m/z$  181 and  $m/z$  251 fragments, resulting from fragmentation at the C3–C4 bond with a subsequent loss of a proton (Table 1). This result indicates that the  $m/z$  252 fragment seen in 4-hydroxy-2-alkenal spectra requires a C2–C3 double bond.

In order to determine if the fragmentation differences seen using EI-MS are a property of general C4-substitution or specific to C4-hydroxylation we analyzed PFB-4-ONE to determine if an aldehyde with a 4-keto group would produce the same fragmentation pattern as those of PFB-HNE and PFB-HHE. This resulted in different fragmentation as

**Table 1** EI-MS fragmentation of PFBHA-derived aldehydes

PFBHA-Derived Aldehydes	Fragments ( $m/z$ )
<p>HNE/HHE            HHE: R=C<sub>2</sub>H<sub>5</sub> (MW 309 g/mol)            HNE: R=C<sub>5</sub>H<sub>11</sub> (MW 351 g/mol)            d<sub>11</sub>-HNE: R=C<sub>5</sub>d<sub>11</sub> (MW 362 g/mol)</p>	181 252
<p><i>trans</i>-2-nonenal/<i>trans</i>-2-hexenal            Hexenal: R=C<sub>2</sub>H<sub>5</sub> (MW 293 g/mol)            Nonenal: R=C<sub>5</sub>H<sub>11</sub> (MW 335 g/mol)</p>	181 250
<p>4-ONE (MW 544 g/mol)</p>	181 332 347 363
<p>HNA (MW 353 g/mol)</p>	181 236 251
<p>d<sub>1</sub>-HNE (MW 353 g/mol)</p>	181 253

4-ONE formed a bis-PFB-oxime at the aldehyde and ketone moieties. The characteristic  $m/z$  181 fragment was accompanied by  $m/z$  363  $[M-C_7H_2F_5]^+$ ,  $m/z$  347  $[M-C_7H_2F_5O]^+$ , and  $m/z$  332  $[M-C_8H_5F_5O]^+$  (Table 1). This pattern was different from EI-MS fragments of both 4-hydroxy-2-alkenals and 2-alkenals, thus differentiating these aldehydes from 4-keto- $\alpha,\beta$ -unsaturated aldehydes.

Chemical ionization is also widely used for characterization and quantification of  $\alpha,\beta$ -unsaturated aldehydes. Analysis of PFB-oximes via PICI-MS yielded results similar to those seen using EI-MS. A fragment corresponding to  $m/z$  181 was seen for all aldehydes and the  $m/z$  252 versus  $m/z$  250 distinction was preserved (Fig. 1; Table 2). PICI-MS also provided information about molecular mass and hydroxylation state in the form of  $[M + H]^+$  fragments for 2-alkenals and  $[M + H - H_2O]^+$  for 4-hydroxy-2-alkenals (Fig. 1; Table 2).

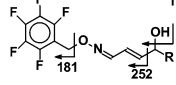

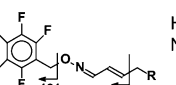

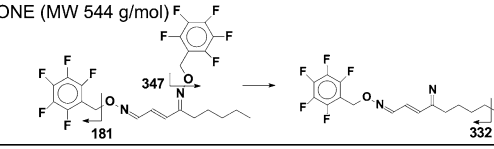

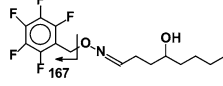

PICI-MS spectra of PFB-4-ONE were similar to EI-MS spectra of PFB-4-ONE with two exceptions: (1) the  $m/z$  363 peak seen using EI-MS was absent and (2) a  $[M + H]^+$  ( $m/z$  545) peak was detected (Table 2). These data show that the fragmentation patterns of PFB-HNE and PFB-HHE using PICI-MS were specific to the presence of a C4-hydroxyl group. In contrast, the fragmentation pattern seen for 4-HNA was different with PICI-MS than EI-MS. The characteristic  $m/z$  181 peak was present, but the  $m/z$  251 peak was absent. The other prominent peak observed at  $m/z$  350 is presumably associated with  $[M + CH_5 - H_2 - H_2O]^+$  (Table 2).

ECNI-MS of  $\alpha,\beta$ -unsaturated aldehydes yielded spectra different than EI-MS and PICI-MS. ECNI-MS produced two spectra associated with either *syn*-PFB-oximes or *anti*-PFB-

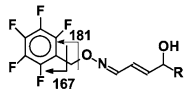

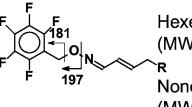

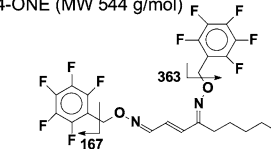

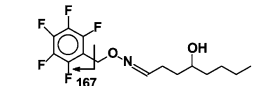

oximes that are separated chromatographically [10]. Spectra of *anti*-PFB-oximes provided information regarding structural characteristics; 4-hydroxy-2-alkenals contained a fragment with  $m/z$  192 corresponding to  $[C_7H_2F_4NO]^-$  and 2-alkenals contained a fragment  $m/z$  197 corresponding to  $[C_7H_2F_5O]^-$  (Fig. 1; Table 3). These fragments were not found in spectra of PFB-4-ONE or PFB-HNA (Fig. 1; Table 3), suggesting that they are specific to 4-hydroxy-2-alkenals and 2-alkenals, respectively. In addition, spectra of *anti*-PFB-4-hydroxy-2-alkenals contained fragments with  $m/z$  167  $[C_6F_5]^-$ , 179, 181  $[C_6H_2F_3]^-$ , 201,  $[M-C_2H_7FO]^-$ , and  $[M-CF_2]^-$ . Spectra of *anti*-PFB-2-alkenals contained fragments with  $m/z$  178, 181, and  $[M-CF_2]^-$  in addition to the aforementioned  $m/z$  197. Spectra of *syn*-PFB-oximes did not provide specific structural information regarding C4-hydroxylation state of  $\alpha,\beta$ -unsaturated aldehydes, as fragments with  $m/z$  197, in the case of 2-alkenals, and  $m/z$  192, in the case of 4-hydroxy-2-alkenals, were not present. The fragments observed are shown in Fig. 1d, e and listed in Table 3. Spectra of *syn*-PFB-HNE are similar to previously described results [10].

Comparison of limits of quantitation of  $\alpha,\beta$ -unsaturated aldehydes for each ionization method is essential for the determination of their utility in analyses of complex mixtures. Limits of quantitation for PFB-derivatives of  $\alpha,\beta$ -unsaturated aldehydes were determined for each ionization method using  $d_{11}$ -HNE as an internal standard. EI-MS yielded limits of quantitation below 100 fmol for 2-alkenals and 250 fmol for 4-hydroxy-2-alkenals using  $m/z$  250 and  $m/z$  252 for quantitation, respectively (Fig. 2a, b). Calibration curves were linear from 100 fmol to 2.5 pmol with an  $r^2$  value of 0.992 for 2-alkenals and from 250 fmol to 2.5 pmol

with an  $r^2$  value of 0.998 for 4-hydroxy-2-alkenals. PICI-MS yielded limits of quantitation below 250 fmol for 2-alkenals and 500 fmol for 4-hydroxy-2-alkenals, using  $[M + H]^+$  and  $[M + H - H_2O]^+$  for quantitation, respectively (Fig. 2c, d). Calibration curves were linear from 250 fmol to 2.5 pmol for 2-alkenals with an  $r^2$  value of 0.995 and from 500 fmol to 10 pmol for 4-hydroxy-2-alkenals with an  $r^2$  value of 0.997. Fragments with  $m/z$  250 or 252 were not used for quantitation in PICI-MS analyses because they were not suitable for quantitation below 2.5 pmol. ECNI-MS yielded limits of quantitation below 100 fmol for 2-alkenals and 250 fmol for 4-hydroxy-2-alkenals using  $[M - CF_2]^-$  for both classes of  $\alpha,\beta$ -unsaturated aldehydes (Fig. 2e, f). Calibration curves were linear from 100 fmol to 10 pmol for 2-alkenals with an  $r^2$  value of 0.999 and from 250 fmol to 10 pmol for 4-hydroxy-2-alkenals with an  $r^2$  value of 1.00.

In order to show the role of each ionization method for characterization of  $\alpha,\beta$ -unsaturated aldehydes in complex mixtures, we oxidized DHA and arachidonic acid. Using reconstructed ion chromatograms (RIC) of EI-MS spectra using  $m/z$  250 or  $m/z$  252 we were able to determine the presence of 4-substituted and unsubstituted  $\alpha,\beta$ -unsaturated aldehydes. RIC of DHA and arachidonic acid oxidations using  $m/z$  250 showed peaks corresponding to acrolein (RT 6.53 min) and MDA (RT 11.00 and 11.14 min) (Fig. 3a, b).

The identity of these peaks was confirmed by comparison to pure standards. In addition, RIC of arachidonic acid with  $m/z$  250 also showed peaks that likely correspond to *trans*-2-heptenal (RT 9.01 and 9.07) and *trans*-2-octenal (RT 9.48 and 9.64), the latter of which was identified as a product of arachidonic acid by Mlakar and Spiteller [20] (Fig. 3b, inset). The identity of these analytes was deduced using the  $[M + H]^+$  ion ( $m/z$  308 for *trans*-2-heptenal and  $m/z$  322 for *trans*-2-octenal) provided by PICI-MS analysis and the  $[M - CF_2]^-$  ion ( $m/z$  257 for *trans*-2-heptenal and  $m/z$  271 for *trans*-2-octenal) provided by ECNI-MS analysis. RIC of arachidonic acid oxidations using  $m/z$  252 contained one major peak corresponding to PFB-HNE (RT 11.06 and 11.17), consistent with previous evidence that HNE is the major 4-hydroxy-2-alkenal product of n-6 fatty acid oxidation [9]. RIC of DHA oxidations produced similar results in that the major peak represented by  $m/z$  252 corresponded to PFB-HHE (RT 9.59 and 9.64) (Fig. 3c, d). However, there was an additional peak present in the DHA RIC that corresponded to the PFB-derivative of 4-hydroxy-2,6-nonadienal (RT 11.01 and 11.13), a product of DHA oxidation previously identified by Beckman et al. [5]. The structure of this analyte was deduced using the  $[M + H - H_2O]^+$  ( $m/z$  338) ion provided by PICI-MS and the  $[M - CF_2]^-$  ( $m/z$  303) ion provided by ECNI-MS.

**Fig. 2** Plots of linear regression analyses show the linear range in fmol for EI-MS, PICI-MS, and ECNI-MS. Linear ranges for EI-MS PFB-nonenal using  $m/z$  250 and PFB-HNE using  $m/z$  252 are represented by (a) and (b), respectively. Linear ranges for PICI-MS of PFB-nonenal using  $m/z$  336 and PFB-HNE using  $m/z$  334 are represented by (c) and (d), respectively. Linear ranges for ECNI-MS of PFB-nonenal using  $m/z$  285 and PFB-HNE using  $m/z$  301 are represented by (e) and (f), respectively

## Discussion

Previous studies have catalogued the utility of derivatization with PFBHA for detection and quantification of biologically relevant molecules such as  $\alpha,\beta$ -unsaturated aldehydes [10, 17]. In studies examining 4-hydroxylated aldehydes, PFBHA derivatization is often followed by trimethylsilylation. However, one study demonstrated that PFBHA derivatization alone can be used to detect and quantify known 4-hydroxy-2-alkenals in biological samples in the absence of trimethylsilylation using GC/ECNI-MS [10].

Our study demonstrates that EI-MS and PICI-MS produce simple and clear information regarding the C4-hydroxylation state of  $\alpha,\beta$ -unsaturated aldehydes. In the case of 4-hydroxylated or unsubstituted  $\alpha,\beta$ -unsaturated aldehydes, spectra contain either a  $m/z$  252 or  $m/z$  250 fragment, respectively. These fragments are the result of cleavage of the C3, C4 bond. The  $m/z$  252 fragment is consistent with the transfer of two hydrogens during the

fragmentation process. As fragmentation occurred between C3 and C4 with the PFB-containing fragment becoming positively charged, the hydrogens likely originate from either the C4/C4-hydroxyl moiety or from the C5–C9 hydrocarbon tail. As spectra of PFB-d<sub>11</sub>-HNE, which is deuterated at the C5–C9 tail, contained a fragment with  $m/z$  252 we concluded that deuteria were not transferred from this moiety. A possible origin of the hydrogens transferred during fragmentation are C4 and the C4-hydroxyl group. Analysis of the PFB-oxime of d<sub>1</sub>-HNE resulted in a fragment with  $m/z$  253 and indicates that the C4 deuterium along with another hydrogen of undefined origin were transferred to the charged fragment.

ECNI-MS is often used for the analysis of  $\alpha,\beta$ -unsaturated aldehydes. However, ECNI-MS spectra of PFBHA-derived  $\alpha,\beta$ -unsaturated aldehydes are complex in that they contain a number of peaks that are not easily related to structure of the analyte in question. Furthermore, ECNI-MS analysis is complicated by differences in the *syn*- and *anti*-configuration spectra [10]. These differences in

**Fig. 3** A reconstructed ion chromatogram (RIC) of EI-MS analysis of an oxidation reaction of DHA using  $m/z$  250 (a) resulted in two major peaks corresponding to PFB-acrolein and bis-PFB-malondialdehyde. RIC of EI-MS analysis of an oxidation reaction of arachidonic acid (AA) using  $m/z$  250 (b) resulted in four peaks corresponding to PFB-acrolein, *trans*-2-heptenal (inset), *trans*-2-octenal (inset), and bis-PFB-MDA. RIC of EI-MS analysis of an oxidation reaction of DHA using  $m/z$  252 (c) resulted in peaks corresponding to PFB-HHE and PFB-4-hydroxy-2,6-nonadienal. RIC of an EI-MS analysis of an oxidation reaction of arachidonic acid (AA) using  $m/z$  252 (d) resulted in one peak corresponding to PFB-HNE

*syn*- and *anti*-spectra were not present when using EI-MS or PICI-MS. This complexity makes ECNI-MS a difficult method to utilize for structural characterization of unknown  $\alpha,\beta$ -unsaturated aldehydes in complex biological mixtures.

Using pure standards, we were able to show that the three ionization methods used in this study were comparable in terms of sensitivity. ECNI-MS and EI-MS were equally sensitive, with PICI-MS being slightly less sensitive. Due to this similarity in sensitivity, these methods can be used in combination for characterization and identification of  $\alpha,\beta$ -unsaturated aldehydes. The EI-MS spectra are useful because of the abundance of the  $m/z$  250 and 252 fragments, which allows for characterization of 4-hydroxyl-substitution. PICI-MS is useful for determination of the molecular ion in the case of 2-alkenals, and the ion corresponding to addition of hydrogen and loss of water for 4-hydroxy-2-alkenals. Finally, ECNI-MS can be used to confirm the results obtained by EI-MS and PICI-MS using the  $[M-CF_2]^-$  ion.

Each ionization technique utilized in our work can be used for quantitation of a known analyte as determined by comparison to pure standard. However, in the case of an unknown, none of these methods alone is sufficient for identification without corroboration from another source. We show that combinations of EI-MS, PICI-MS, and ECNI-MS can effectively be used to characterize and

identify unknown  $\alpha,\beta$ -unsaturated aldehydes produced by oxidation of DHA and arachidonic acid in the absence of pure standard. These results highlight the potential application of this combination of analyses to characterization and identification of  $\alpha,\beta$ -unsaturated aldehydes in foods, supplements, and biological samples (Figs. 2, 3).

**Acknowledgments** This study was made possible by NIH grant P20 RR17699-01 COBRE from the NCCR. We thank Dr. Alena Kubatova for her training in the use of gas chromatography/mass spectrometry instrumentation. We thank Dr. Mikhail Golovko of the UND Mass Spectrometry Core Facility for performing the ESI-MS analyses.

**Abstract** We have previously reported that the majority of phospholipase A<sub>2</sub> (PLA<sub>2</sub>) activity in rabbit ventricular myocytes is membrane-associated, calcium-independent (iPLA<sub>2</sub>), selective for arachidonylated plasmalogen phospholipids and inhibited by the iPLA<sub>2</sub>-selective inhibitor bromoenol lactone (BEL). Here, we identified the presence of iPLA<sub>2</sub> in rabbit ventricular myocytes, determined the full length sequences for rabbit iPLA<sub>2</sub> $\beta$  and iPLA<sub>2</sub> $\gamma$  and compared their homology to the human isoforms. Rabbit iPLA<sub>2</sub> $\beta$  encoded a protein with a predicated molecular mass of 74 kDa that is 91% identical to the human iPLA<sub>2</sub> $\beta$  short isoform. Full length iPLA<sub>2</sub> $\gamma$  protein has a predicated molecular mass of 88 kDa and is 88% identical to the human isoform. Immunoblot analysis of iPLA<sub>2</sub> $\beta$  and  $\gamma$  in membrane and cytosolic fractions from rabbit and human cardiac myocytes demonstrated a similar pattern of distribution with both isoforms present in the membrane fraction, but no detectable protein in the cytosol. Membrane-associated iPLA<sub>2</sub> activity was inhibited preferentially by the R enantiomer of bromoenol lactone [(R)-BEL], indicating that the majority of activity is due to iPLA<sub>2</sub> $\gamma$ .

**Keywords** Bromoenol lactone · Phospholipase A<sub>2</sub> · Myocardium · Plasmalogens · Arachidonic acid

## Abbreviations

BEL Bromoenol lactone  
iPLA<sub>2</sub> Calcium-independent phospholipase A<sub>2</sub>

MAFP Methyl arachidonyl fluorophosphonate  
PKC Protein kinase C  
PLA<sub>2</sub> Phospholipase A<sub>2</sub>

## Introduction

Phospholipase A<sub>2</sub> (PLA<sub>2</sub>) catalyzes the hydrolysis of the fatty acid at the *sn*-2 position of membrane phospholipids, resulting in the generation of multiple biologically-active, membrane phospholipid-derived metabolites (for review, see [1]). The family of PLA<sub>2</sub> enzymes has been classified into 15 groups and several subgroups based on the catalytic mechanism, functional and structural features, and sequence homology [1].

We reported previously that the majority of PLA<sub>2</sub> activity in rabbit ventricular myocytes is membrane-associated, calcium-independent (iPLA<sub>2</sub>) and selective for arachidonylated plasmalogen phospholipids [2]. Activation of this membrane-associated iPLA<sub>2</sub> occurs when ventricular myocytes are incubated with phorbol 12-myristate 13-acetate, suggesting that activation of iPLA<sub>2</sub> is regulated by protein kinase C [3]. We have also demonstrated that rabbit ventricular myocyte membrane-associated iPLA<sub>2</sub> is activated in response to either thrombin stimulation [4] or the presence of hypoxia [5]. Multiple types of iPLA<sub>2</sub> have been identified in cytosolic, microsomal and mitochondrial fractions from mammalian myocardium [6, 7], but to date there is no data concerning the specific iPLA<sub>2</sub> isoform that may be present and activated in rabbit ventricular myocytes. Our previous data indicate that rabbit ventricular myocyte iPLA<sub>2</sub> activity is inhibited by bromoenol lactone (BEL) but not by methyl arachidonyl fluorophosphonate (MAFP) [2], suggesting that it is either iPLA<sub>2</sub> $\beta$  or iPLA<sub>2</sub> $\gamma$ .

The iPLA<sub>2</sub> $\beta$  isoform is predominantly a cytosolic isoform and highly homologous cDNAs have been cloned from the hamster, mouse, rat and human (approximately 95% identity). In addition, several splice variants of human iPLA<sub>2</sub> $\beta$  have been identified [8]. However, in COS-7 cells overexpressing iPLA<sub>2</sub> $\beta$ , Larsson Forsell et al demonstrated a 5.5-fold increase in membrane-associated iPLA<sub>2</sub> activity [8], and membrane-associated iPLA<sub>2</sub> $\beta$  has also been found in rat vascular smooth muscle cells [9].

More recently, a novel membrane associated iPLA<sub>2</sub> (iPLA<sub>2</sub> $\gamma$ ) has been identified [7] which possesses several of the properties demonstrated in our previous studies using rabbit ventricular myocytes, including the optimum pH for activity, sensitivity to BEL and a tight association with the membrane fraction. Homology between iPLA<sub>2</sub> $\beta$  and iPLA<sub>2</sub> $\gamma$  is confined to the ATP binding motif, the serine lipase site and a region of nine amino acids for which, as yet, there is no known functional significance [7]. The human iPLA<sub>2</sub> $\gamma$  gene contains 4 possible translation codons that result in proteins of 63, 74, 77 and 88 kDa [10]. When first described, iPLA<sub>2</sub> $\gamma$  was proposed to be localized to peroxisomes due to the presence of a C-terminal SKL signal sequence and recent studies have confirmed that the peroxisomal iPLA<sub>2</sub> $\gamma$  is the 63-kDa protein [11]. More recent studies have demonstrated higher molecular weight isoforms of iPLA<sub>2</sub> $\gamma$  in mitochondria and endoplasmic reticulum [6].

This study was designed to identify the presence of iPLA<sub>2</sub> $\beta$  and iPLA<sub>2</sub> $\gamma$  in rabbit ventricular myocytes and to determine the similarity of these isoforms to those identified previously.

## Experimental Procedures

### Rabbit Ventricular Myocyte Isolation and Culture

Adult rabbits of either sex weighing 2–3 kg were anesthetized with intravenous pentobarbitone sodium (50 mg/kg) and the heart rapidly removed. The heart was mounted on a Langendorff perfusion apparatus and perfused for 5 min with a Tyrode solution containing (mmol/l) NaCl 118, KCl 4.8, CaCl<sub>2</sub> 1.2, MgCl<sub>2</sub> 1.2, NaHCO<sub>3</sub> 24, KH<sub>2</sub>PO<sub>4</sub> 1.2 and glucose 11; the Tyrode solution was saturated with 95% O<sub>2</sub>/5% CO<sub>2</sub> to yield a pH of 7.4. This was followed by a 4-min perfusion with a Ca-free Tyrode solution containing EGTA (100  $\mu$ M) and a final perfusion for 20 min with the Tyrode solution containing 100  $\mu$ M Ca and 0.033% collagenase. The heart was removed from the perfusion apparatus, the atria were removed and the remaining ventricles were cut into small pieces and incubated in fresh 0.033% collagenase solution at 37 °C in a shaking water bath for 4 successive harvests of 20 min.

Individual myocytes were washed with a HEPES buffer containing (mmol/l): NaCl 133.5, KCl 4.8, MgCl<sub>2</sub> 1.2, CaCl<sub>2</sub> 0.3, KH<sub>2</sub>PO<sub>4</sub> 1.2, glucose 10 and HEPES 10 (pH 7.4). Extracellular Ca was increased to 1.2 mM in three stages at intervals of 20 min. Myocytes were incubated overnight in M199 medium with 10% fetal calf serum at 37 °C and then washed three times with 1.2 mM Ca HEPES solution.

### Culture of Human Cardiac Myocytes

Human adult cardiac myocytes (Sciencell, San Diego, CA) were cultured in cardiac myocyte medium consisting of 500 ml of basal medium, 25 ml of fetal bovine serum, 5 ml of cardiac myocyte growth supplement and 5 ml of penicillin/streptomycin solution (Sciencell, San Diego, CA).

### Generation of iPLA<sub>2</sub> Clones

Total RNA for use in all cloning steps was isolated with the Versagene Cell Kit (Gentra Systems, Minneapolis, MN); 5' and 3' end sequences of rabbit ventricular myocyte iPLA<sub>2</sub> were obtained by rapid amplification of cDNA ends following the manufacturer's instructions for the GeneRacer Kit from Invitrogen (Carlsbad, CA). Briefly, total RNA was dephosphorylated, decapped and ligated to the GeneRacer RNA Oligo to form template for first strand RACE-ready cDNA synthesis. Following cDNA amplification with the appropriate GeneRacer Oligo and gene specific Oligo, 5' and 3' end PCR fragments were cloned into the pCR4-TOPO vector and sequenced by automated DNA sequencing with BigDye chemistry. This sequence was conceptually translated and Oligos were designed to yield a full-length amplicon corresponding to the longest open reading frame for each isoform. Oligo dT primed first strand cDNA was generated from total RNA using the Thermoscript RT-PCR System (Invitrogen) and used as template for PCR amplification of full-length iPLA<sub>2</sub> clones. These products were cloned into the pCR-XL-TOPO vector and five independent clones of each isoform,  $\beta$  and  $\gamma$ , were sequenced. Sequence analysis and assembly was performed using the Vector NTI Suite 9.0.0 (Invitrogen) and the BLAST server at NCBI. Sequence assembly was performed using the ContigExpress program (Invitrogen) and the full-length cDNA sequences were deposited into Genbank (iPLA<sub>2</sub> $\beta$ —Accession # AY744674, iPLA<sub>2</sub> $\gamma$ —Accession # AY738591).

### Production of iPLA<sub>2</sub> $\gamma$ Antibody

A custom-made chicken antibody was obtained from Aves Labs, Inc. (Tigard, OR). Hens were injected four times with a KLH conjugate of the peptide CZSKYIERNEHKMK

KVAK and immune eggs were collected for 10–15 days after the final injection. The IgY fractions were purified and passed over an affinity column, the column washed and antibody eluted. The final concentration of affinity-purified antibody in the eluant was 0.6 mg/ml.

#### HPLC Separation of (*R*)- and (*S*)-Enantiomers of BEL

(*R*)- and (*S*)-enantiomers of BEL were isolated from racemic BEL (Calbiochem) using a chirex 3,5-dinitrobenzoyl-(*R*)-phenylglycine chiral HPLC column (Phenomenex Inc., Torrance, CA) and previously published methods [17]. The column was equilibrated with hexane/dichloroethane/ethanol (150:15:1, by vol) and the optical enantiomers eluted isocratically at 2 ml/min. Elution of (*R*)- and (*S*)-BEL was monitored by UV absorbance at 280 nm. Under these conditions the retention times ( $R_t$ ) for (*R*)- and (*S*)-BEL differ by almost 1 min with the  $R_t$  for (*S*)-BEL being 11.1 min and 12.2 min for (*R*)-BEL [12]. Peaks corresponding to these  $R_t$  were collected, dried under  $N_2$ , and stored at  $-20^\circ C$ . The concentration of each enantiomer was determined spectrophotometrically based on its UV absorbance [12].

#### Immunoblot Analysis of iPLA<sub>2</sub> Isoforms

Myocytes were suspended in lysis buffer containing (mmol/l) HEPES 20 (pH 7.6), sucrose 250, dithiothreitol 2, EDTA 2, EGTA 2,  $\beta$ -glycerophosphate 10, sodium orthovanadate 1, phenylmethylsulfonyl fluoride 2, leupeptin 20  $\mu$ g/ml, aprotinin 10  $\mu$ g/ml and pepstatin A 5  $\mu$ g/ml (buffer 2). Cells were sonicated on ice for 6 bursts of 10 s and centrifuged at  $10,000\times g$  at  $4^\circ C$  for 20 min to remove cellular debris and nuclei. Cytosolic and membrane fractions were separated by centrifuging the supernatant at  $100,000\times g$  for 60 min. The pellet was resuspended in lysis buffer and the suspension centrifuged at  $100,000\times g$  for 60 min twice to minimize contamination of the membrane fraction with cytosolic protein. The final pellet was resuspended in lysis buffer containing 0.1% Triton X-100. Protein (cytosol or membrane) was mixed with an equal volume of SDS sample buffer and heated at  $95^\circ C$  for 5 min prior to loading onto a 10% polyacrylamide gel. Protein was separated by SDS/PAGE at 200 V for 35 min and electrophoretically transferred to PVDF membranes (Bio-Rad, Richmond, CA) at 100 V for 1 h. Non-specific sites were blocked with Tris buffered solution containing 0.05% (v/v) Tween-20 (TBST) and 5% (w/v) nonfat milk for 1 h at room temperature. The blocked PVDF membrane was incubated with primary antibodies to iPLA<sub>2</sub> $\beta$  (1 in 1,000 dilution, Cayman Chemical Company, Ann Arbor, MI) or iPLA<sub>2</sub> $\gamma$  (1 in 1,000 dilution, Aves Labs Inc., Tigard, OR), followed by horseradish peroxidase-conjugated secondary antibodies. Regions of antibody binding were

detected using enhanced chemiluminescence (Amersham, Arlington Heights, IL) after exposure to film (Hyperfilm, Amersham). Multiple exposures of film to the blots were developed.

#### Phospholipase A<sub>2</sub> Activity

Myocytes were suspended in 1 ml buffer containing (mmol/l): Sucrose 250, KCl 10, imidazole 10, EDTA 5, dithiothreitol (DTT) 2 with 10% glycerol, pH 7.8 (buffer 1). The suspension was sonicated on ice six times for 10 s (using a microtip probe at 20% power output, 500 Sonic Dismembrator, Fisher Scientific) and the sonicate centrifuged at  $20,000\times g$  for 20 min to remove cellular debris and nuclei. The supernatant was then centrifuged at  $100,000\times g$  for 60 min to separate the membrane fraction (pellet) from the cytosolic fraction (supernatant). The pellet was washed twice to minimize contamination of the membrane fraction with cytosolic protein by resuspending in buffer 1, and centrifuging at  $100,000\times g$  for 60 min. The final pellet was resuspended in buffer 1. PLA<sub>2</sub> activity in cytosolic and membrane fractions was assessed by incubating enzyme (8  $\mu$ g membrane protein) with 100  $\mu$ M (16:0, [<sup>3</sup>H]18:1) plasmenylcholine substrate in assay buffer containing (mmol/l): Tris 10, EGTA 4, 10% glycerol, pH 7.0 at  $37^\circ C$  for 5 min in a total volume of 200  $\mu$ l. The radiolabeled phospholipid substrate was introduced into the incubation mixture by injection in 5  $\mu$ l ethanol to initiate the assay. Reactions were terminated by the addition of 100  $\mu$ l butanol and released radiolabeled fatty acid was isolated by application of 25  $\mu$ l of the butanol phase to channeled Silica Gel G plates, development in petroleum ether/diethyl ether/acetic acid (70/30/1, v/v) and subsequent quantification by liquid scintillation spectrometry. Protein content of each sample was determined by the Lowry method utilizing freeze dried bovine serum albumin as the protein standard. Radiolabeled (16:0, [<sup>3</sup>H]18:1) plasmenylcholine was synthesized using [9,10-<sup>3</sup>H] oleic acid and lysoplasmenylcholine as described in detail previously [4].

#### Statistical Analysis

Statistical comparison of values was performed by Student's *t* test. All results are expressed as mean  $\pm$  SEM. Statistical significance was considered to be  $P < 0.05$ .

#### Results

iPLA<sub>2</sub> $\beta$  cDNA was amplified, cloned and sequenced from freshly isolated rabbit ventricular myocytes, (GenBank accession No. 744674), and the amino acid sequence was

determined (Fig. 1). The longest open reading frame of iPLA<sub>2</sub> $\beta$  was found to encode a protein of 665 amino acids in length with a predicted molecular mass of 74 kDa that a BLAST analysis of the non-redundant protein database reveals is 91% identical to the human short isoform. The

sequences are highly conserved except for a divergent segment at the N-terminus which is 128 amino acids long in the human and 42 amino acids in the rabbit. Immunoblot analysis of cytosolic and membrane fractions isolated from rabbit and human cardiac myocytes demonstrated an

**Fig. 1** Full-length rabbit iPLA<sub>2</sub> $\beta$  cDNA sequence. Underlines indicate the conserved ATP-binding and lipase active sites. Potential transmembrane domains were predicted using the TMpred server and are indicated with boldface type. Potential PKC-phosphorylation sites were predicted using the NetPhosK 1.0 Server and are boxed

iPLA<sub>2</sub> $\beta$  immunoreactive band that ran just below the 80-kDa molecular mass marker (Fig. 3a). The human and rabbit immunoreactive bands ran at a similar molecular weight and were present in the membrane fraction only. No immunoreactive band was detected with iPLA<sub>2</sub> $\beta$  antibody in the cytosolic fraction of human or rabbit myocytes (Fig. 3a).

Rabbit ventricular myocyte iPLA<sub>2</sub> $\gamma$  was also cloned and sequenced, and is predicted to encode a full-length protein of 786 amino acids (Fig. 2) with a molecular mass of 88 kDa that was found by BLAST analysis to be 88% identical to the human form. It has been reported previously that the human iPLA<sub>2</sub> $\gamma$  sequence contains multiple alternative start sites for translation, which correspond to protein products of 88, 77, 74 and 63 kDa [10]. We analyzed the amino acid sequence for iPLA<sub>2</sub> $\gamma$  in rabbit ventricular myocytes and identified 6 methionine residues upstream of the active site which could encode functional

PLA<sub>2</sub>. In addition to the 88-, 77-, 74-, and 63-kDa isoforms found in the human isoform, we also identified two single amino acid substitutions which could encode alternative start sites for 58 and 49 kDa proteins. Immunoblot analysis of rabbit ventricular myocytes detected immunoreactive bands corresponding to the 88- and 73-kDa isoenzymes in the membrane fraction of isolated rabbit ventricular myocytes. Immunoblot analysis of human cardiac myocytes revealed a single band corresponding to the 73-kDa isoform of iPLA<sub>2</sub> $\gamma$  in the membrane fraction (Fig. 3b). No bands were detected in the cytosolic fractions from either rabbit or human myocytes (Fig. 3b).

Since we detected both iPLA<sub>2</sub> $\beta$  and  $\gamma$  in isolated rabbit ventricular myocytes and the majority of iPLA<sub>2</sub> activity is membrane-associated, we incubated isolated membrane fractions with (*R*)-BEL, (*S*)-BEL or racemic BEL. Previous studies have indicated that (*S*)-BEL is approximately an order of magnitude more selective for iPLA<sub>2</sub> $\beta$  in

**Fig. 2** Full-length rabbit iPLA<sub>2</sub> $\gamma$  cDNA sequence. Underlines indicate the conserved ATP-binding and lipase active sites. Potential PKC-phosphorylation sites were predicted using the NetPhosK 1.0 Server and are boxed

**Fig. 3** Immunoblot analysis of the localization of iPLA<sub>2</sub>β (Panel A) and iPLA<sub>2</sub>γ (Panel B) in the cytosolic (C) and membrane (M) subcellular fractions isolated from rabbit and human cardiac myocytes. Proteins were separated by SDS-PAGE and transferred to polyvinylidene difluoride membranes. Membranes were probed with anti-iPLA<sub>2</sub>β or anti-iPLA<sub>2</sub>γ antibodies (1:1,000 dilution) and incubated with horseradish peroxidase-linked secondary antibody (1:50,000 dilution). Immunoblots were detected with enhanced chemiluminescence and exposure to film

comparison to iPLA<sub>2</sub>γ [12]. Conversely, (R)-BEL is approximately an order of magnitude more selective for iPLA<sub>2</sub>γ in comparison to iPLA<sub>2</sub>β [12]. After pretreatment with BEL for 10 min, membrane-associated iPLA<sub>2</sub> activity was significantly decreased with concentrations of (R)-BEL greater than 0.1 μM (Fig. 4). At 10 μM, (R)-BEL inhibited iPLA<sub>2</sub> activity by 90%, whereas (S)-BEL inhibited iPLA<sub>2</sub> activity by approximately 50% (Fig. 4).

## Discussion

Myocardial iPLA<sub>2</sub> activity in the rabbit was first described by Ford et al. [13]. They described a tenfold increase in microsomal, plasmalogen-selective iPLA<sub>2</sub> activity during myocardial ischemia [13]. We have demonstrated increases in membrane-associated, plasmalogen-selective iPLA<sub>2</sub> activity in isolated rabbit ventricular myocytes in response to thrombin [14] and hypoxia [5]. The activation of iPLA<sub>2</sub> and accelerated plasmalogen phospholipid hydrolysis lead to the production of lysoplasmalogen choline [5, 14], an amphipathic metabolite that can have direct effects on the function of integral membrane proteins. We have shown that lysoplasmalogen choline produces action potential derangements in cardiac myocytes at much lower concentrations than that previously demonstrated for lysoplasmalogen choline [5]. The action potential derangements caused by lysoplasmalogen choline occur as a result of its action on multiple membrane currents [15].

Although several studies have described iPLA<sub>2</sub> activation in rabbit ventricular myocytes, this is the first study to sequence iPLA<sub>2</sub>β and iPLA<sub>2</sub>γ and to demonstrate that

**Fig. 4** Membrane-associated iPLA<sub>2</sub> activity measured in the absence or presence of bromoenol lactone (BEL). Isolated membrane fractions were incubated with increasing concentrations of (R)-BEL (open circles), (S)-BEL (X) or racemic BEL (filled squares) for 10 min prior to assay of PLA<sub>2</sub> activity. PLA<sub>2</sub> activity was measured using 100 μM (16:0, [<sup>3</sup>H]18:1) plasmalogen choline (PlsCho) in the absence of Ca (4 mM EGTA). Values are mean ± SEM for independent results from six separate animals. \*P < 0.05, \*\*P < 0.01 when compared to activity in the absence of BEL

iPLA<sub>2</sub>γ is the major isoform in the rabbit myocardium. Our immunoblot analysis data suggest that the vast majority of iPLA<sub>2</sub> is membrane-associated, and this agrees with our previous data measuring iPLA<sub>2</sub> activity [2]. In previously reported studies, iPLA<sub>2</sub>β has been demonstrated to be primarily cytosolic. It was originally purified from the cytosol of the mouse macrophage cell line P388D<sub>1</sub> [16] and its cDNA was later identified in P388D<sub>1</sub> and Chinese hamster ovary cells [17] and human B lymphocytes [18]. In humans the difference between the membrane-associated and cytosolic isoforms is the presence of 54 amino acid residues that may lead to a membrane-associated protein [8]. While we did not identify a similar sequence in the rabbit isoform, TMPred analysis suggests that rabbit iPLA<sub>2</sub>β contains a potential transmembrane domain (indicated by the boldface type in Fig. 1).

In a previous study, we have identified the presence of multiple iPLA<sub>2</sub> isoforms in several tissues and species [6]. The role of myocardial iPLA<sub>2</sub> isoforms has been investigated in several recent studies using mouse models. iPLA<sub>2</sub> activity in murine heart is less than 5% of that in human myocardium, suggesting that the mouse could be a species-specific knockdown model of human ischemia-induced arrhythmogenesis [19]. Accordingly, Mancuso et al. [19] generated transgenic mice that expressed amounts of

iPLA<sub>2</sub>β activity comparable to that present in human myocardium and demonstrated malignant ventricular arrhythmias, increased fatty acid release in venous effluents and increased lysophospholipid content in the ischemic zone in response to ischemia. These data demonstrate the role of myocardial iPLA<sub>2</sub>β in the hydrolysis of membrane phospholipids and arrhythmogenesis in response to ischemia. Transgenic mice expressing iPLA<sub>2</sub>γ in cardiac myocytes demonstrated a marked loss of mitochondrial phospholipids accompanied by mitochondrial dysfunction [20]. In a subsequent study, mice null for iPLA<sub>2</sub>γ displayed growth retardation, cold intolerance, reduced exercise endurance and abnormal mitochondrial function [21]. In particular, iPLA<sub>2</sub>γ knockout mice were more susceptible to sudden death following transverse aortic constriction, indicating the importance of iPLA<sub>2</sub>γ in the ability of the myocardium to respond to stress [21].

We have previously reported that incubation of isolated membrane fractions from rabbit ventricular myocytes demonstrate increased iPLA<sub>2</sub> activity when incubated with phorbol 12-myristate 13-acetate in the absence of Ca [3]. These data suggests that a membrane-associated novel PKC isoform modulates iPLA<sub>2</sub> activity. Increased iPLA<sub>2</sub> activity required the presence of ATP, suggesting that the enzyme is phosphorylated by PKC [3]. Sequence analysis of rabbit ventricular myocyte iPLA<sub>2</sub>β and γ isoforms reveals the presence of several predicted PKC phosphorylation sites that are indicated by the boxes in Figs. 1 and 3.

In conclusion, we have identified and sequenced iPLA<sub>2</sub>β and iPLA<sub>2</sub>γ from isolated rabbit ventricular myocytes. These isoforms possess a high degree of sequence homology between rabbit and human and there is a similar protein expression pattern when comparing rabbit and human cardiac myocytes. Both isoforms have several putative PKC phosphorylation sites and our previous studies suggest that membrane-associated iPLA<sub>2</sub> is activated directly by a membrane-associated novel PKC isoform [3]. Finally, our data obtained using (*R*)- and (*S*)-enantiomers of the iPLA<sub>2</sub>-selective inhibitor BEL, suggest that the majority of membrane-associated iPLA<sub>2</sub> activity is iPLA<sub>2</sub>γ.

**Acknowledgments** This research was supported in part by National Heart, Lung and Blood Institute Grant HL 68588 (JM). The authors would like to thank Dr. Brian Cummings for the separation of (*R*)- and (*S*)-enantiomers of BEL.

**Abstract** Conjugated linoleic acid (CLA) is anti-proliferative and anti-inflammatory in the Han:SPRD-*cy* rat model of kidney disease. We used different doses of CLA and examined effects on renal histological benefit, the renal PPAR $\gamma$  system and hepatic and renal levels of CLA isomers. Male and female offspring of Han:SPRD-*cy* heterozygotes were fed diets with 0, 1 or 2% CLA isomer mixture for 12 weeks before dual-energy X-ray absorptiometry, harvest of renal and hepatic tissue for histologic and lipid analysis. Both CLA diets reduced body fat content in both genders but did not change lean body mass. CLA produced a dose dependent reduction in female renal cystic change. CLA reduced fibrosis, but this reduction was significantly less with higher dose in males. CLA reduced macrophage infiltration, tissue oxidized LDL content and proliferation of epithelial cells. Serum creatinine rose significantly in female animals fed CLA diets. CLA treatment did not change PPAR $\gamma$  activation. A significant negative correlation with renal content of the 18:2 c9,t11 isomer and

the sum of histologic effects was identified. CLA reduces histologic renal injury in the Han:SPRD-*cy* rat model probably inversely proportionate to c9,t11 renal content. Possible functional CLA toxicity at high dose in female animals warrants further exploration.

## Introduction

Conjugated linoleic acid (CLA) refers to a group of positional and geometric isomers of linoleic acid produced by bacterial action in the gastrointestinal tract of ruminants [1, 2] that are significant dietary components in humans on

hunter-gatherer or primitive agrarian diets, but exposure is much lower in modern urban diets [3]. CLA has been shown to have a dose dependent effect on tumor development or growth in skin, prostate, mammary and colonic tumors [2, 4, 5]. CLA feeding has demonstrated beneficial effects in a murine model of lupus nephritis [6]. CLA produces tissue specific alteration in production of eicosanoids [7, 8], and decreases release of arachidonic acid (ARA) or prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) in different tissue types or cell lines [9–12]. CLA has been associated with improved outcome in experimental porcine colitis [13], and is capable of exerting an anti-inflammatory effect without compromising resistance to infection [14]. CLA has been identified as a ligand for PPAR $\alpha$ , through which effects on lipid and carbohydrate metabolism may be modified [15], and PPAR $\gamma$ , through which anti-inflammatory and anti-proliferative effects may be modulated [16].

In a previous study, we demonstrated that dietary supplementation with a mixture of CLA isomers was effective in reducing histologic injury and renal PGE<sub>2</sub> production in male animals with the Han:SPRD-*cy* form of polycystic kidney disease [11]. The Han:SPRD-*cy* model of polycystic kidney disease (PKD), characterized by autosomal dominant inheritance with marked sexual dimorphism in expression, has proved an excellent system in which to explore the modification of chronic renal injury, including by dietary means. Epithelial proliferation and progressive dilatation of nephrons, marked interstitial inflammation and fibrosis characterize the disease [17]. Oxidant injury has been implicated in its pathogenesis [18]. It can be ameliorated with methylprednisolone [19], angiotensin blockade or converting enzyme inhibition [20, 21], and lovastatin [22]. Amelioration occurs with dietary soy protein substitution [23], protein restriction [21], flaxseed, flax oil or flax lignans [24–28] and citrate supplementation [29].

Although this model is amenable to dietary modification, a recent study we performed with flax derivatives demonstrated that gender influenced the extent of the dietary benefit [27], with female animals with an earlier stage of the disease demonstrating greater beneficial changes in renal histology. This study was therefore undertaken to explore if the observed benefits of CLA supplementation could be increased with a higher level of supplementation and as well as whether this response was influenced by animal gender. As secondary objectives, we explored if histologic benefits were associated with reduction in renal PPAR $\gamma$  activation and whether benefit could be correlated with tissue level changes in specific CLA isomers. We also explored previously reported effects of CLA on body composition to see if they are reproduced in animals with renal disease, and if these showed any relationship to renal histologic and functional change.

## Methods

### Animals

All animal procedures and care were approved by the University of Manitoba Committee on Animal Use and were within the guidelines of the Canadian Council on Animal Care. Surviving offspring of known Han:SPRD-*cy* heterozygotes from our own breeding colony were randomly assigned to groups fed 7% by weight corn oil as the lipid source alone, 6% corn oil and 1% CLA concentrate, or 5% corn oil and 2% CLA concentrate ad libitum at weaning at 3 weeks of age. CLA concentrate was a gift of Bioriginal, Saskatoon, Canada, and was diluted into the oil fraction of the diet to achieve the target concentrations. Animals were killed after 12 weeks on the diet and kidney, liver and serum collected for analysis. Animals found not to have PKD at necropsy, approximately one-third of the total, were excluded from further analysis. Diets were based on the formula from prior studies [11, 27] using casein as the protein source (20% by weight) supplemented with 0.3% methionine, corn starch (52% by weight) and dextrose (13% by weight) as the carbohydrate sources and lipid sources as described. The detailed analysis of the dietary fatty acid content is summarized in Table 1. The animals were fed ad libitum, as our prior studies have not found differences in intake related to disease status in animals in the earlier stages of disease progression [11, 23, 28, 30].

**Table 1** Lipid analysis of CLA diets

Lipid	Control	1% CLA	2% CLA
C13:0	ND	1.9	2.5

## DXA Scanning

Animals were anesthetized after 12 weeks of study using sodium pentobarbital (65 mg/kg, i.p.), followed by measurement of whole body weight and body composition including bone mass using dual-energy X-ray absorptiometry and the small animal software (QDR 4500A, Hologic Inc, Waltham, MA). This technology has been validated for use in rodents [31].

## Histology and Immunohistochemistry

Tissue from the left kidney was processed using our previously described methods [11, 26] for histologic and immunohistochemical analysis. These studies included hematoxylin and eosin, Sirius red staining for fibrosis, PCNA (M 0879, Dako A/S, Glostrup, Denmark) and macrophages (MAB1435, Chemicon International, Temecula, CA). Oxidized LDL (ox-LDL) staining was used as a marker of oxidant injury [27, 32], using a polyclonal antibody (AB3230, Chemicon, Temecula, CA). Animals were classified as affected by one of two experienced observers (N.B.C., M.R.O.), blinded to dietary intervention on the basis of the characteristic cystic and inflammatory pathology of this disease.

## Image Analysis

Image analysis procedures were performed with a system consisting of a Spot Junior CCD camera mounted on an Olympus BX60 microscope. The captured images from random stage movement through the sections were subsequently analyzed using Image Pro version 4.5 Package (Media Cybernetics, Silver Spring, MD). The observer was blinded to dietary treatment, although disease status is obvious upon microscopic examination. Raw analysis data were processed as previously described [23] to give objective measures of cystic change, fibrosis, interstitial macrophage infiltration and extent of ox-LDL staining. Measurements of fibrosis and cellular markers were corrected to solid-tissue areas of sections so that the presence of empty cystic areas on the section did not lead to an underestimation of these parameters.

## Chemistry

Biochemical measurements were performed by an observer blinded to disease status and dietary intervention (E.N.). Serum and urine creatinine, and serum cholesterol were determined by spectrophotometric methods using Sigma kits (Sigma Chemical Co., St Louis, MO). Urine protein was measured by the brilliant Coomassie Blue method of Bradford.

## Gas Chromatography

Lipids were extracted for gas chromatographic analysis using a modified Folch extraction procedure, as we have previously described [23, 26, 33]. Liver tissue was examined in addition to kidney as our previous studies have shown this tissue to be a more sensitive and consistent marker to confirm absorption and incorporation of the ingested PUFA. Prior to analysis, samples were redissolved in 1 ml of dry toluene, mixed with 2.0 ml of 0.5 M sodium methoxide and heated to 50 °C for 10 min, then mixed with 0.1 ml of glacial acetic acid, 5 ml of distilled H<sub>2</sub>O, and 5 ml of hexane. This method was selected as being reliable for the methylation of the CLA isomers which were primary interest in tissue analysis in this study [34]. After vortexing, the mixture was centrifuged at 2,500×g for 10 min and the hexane fraction removed. Fresh hexane is added to the remaining solution and the previous steps repeated. The hexane fractions were dried under anhydrous sodium sulfate, evaporated under nitrogen and the lipid esters redissolved in 1 ml hexane. Gas chromatography (GC) was performed on a Varian Chrompack 3800 instrument, using a Varian CP-Sil 88 100 meter column (Varian, Walnut Creek, CA). Total  $\omega$ 6: $\omega$ 3 ratio was calculated from the sum of proportions of linoleic acid (LNA, 18:2 c9,c12),  $\gamma$ -linolenic acid (GLA), 20:3  $\omega$ 6 and ARA divided by the sum of  $\alpha$ -linolenic acid (ALA), 20:3  $\omega$ 3, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). The ratio of ARA:LNA was calculated as an indicator of  $\Delta$ -6 desaturase activity. The ratio of 18:1 c9 (oleic acid) to 18:0 (stearic acid) was calculated as an indicator of  $\Delta$ -9 desaturase activity.

## PPAR $\gamma$ Activation

PPAR $\gamma$  activation was measured using a commercial ELISA assay (Panomics EK1211, Fremont, CA) of in-vitro binding to a specific DNA promoter sequence, after extraction of nuclear material according the manufacturer's specifications. Results were expressed as percentage of activity of a positive control standard provided by the manufacturer.

## Statistical Analysis

Results were analyzed using two-way and three-way analyses of variance (ANOVA) with Tukey's post hoc comparisons, using SAS version 9.1 software packages as appropriate. The model detected differences between main effects by diet, and sex as applicable. The model also reported interaction effects between diet and sex which were considered significant at  $P < 0.05$ . Log and square root transformations were done for the variables which were not

distributed in a Gaussian fashion. To measure the degree of relationship between histology measures with renal contents of specific fatty acids, canonical correlation analysis was performed using the SAS version 9.1 software package.

## Results

A total of 54 female and 47 male animals who were found to be Han:SPRD-*cy* heterozygotes were included in the analysis. Animal weight was found to be significantly influenced by gender, but not by diet, with females being smaller as expected (Fig. 1). Serum creatinine, as a marker of renal function, was also significantly influenced by gender, again consistent with the known slower progression of the disease in female animals (Fig. 2), but serum creatinine actually increased significantly with increasing dose of CLA in female animals.

**Fig. 1** Animal weight at conclusion of feeding period (g). A main effect of gender only is significant ( $P < 0.001$ )

**Fig. 2** Serum creatinine at conclusion of study ( $\mu\text{mol/l}$ ). A significant major dietary effect was seen. *a* Significant difference from control diet, same gender in post hoc testing. *b* Significant difference between 1% and 2% CLA, same gender in post hoc testing

When results of all densitometric indices of histologic injury are considered, diet ( $P < 0.01$ ) and gender ( $P < 0.001$ ) had significant effect on reducing relative cyst area which was found to be dose dependent for diet, although in post hoc analysis, significant differences between dietary groups in female animals accounted for the observed effect (Fig. 3a). As gender difference is inherent to the model, post hoc comparisons between genders, which were significant for all histologic outcome measures

**Fig. 3** Densitometric analysis of renal cystic change (a) fibrosis (b) and Ox-LDL (c) (fraction image area, fibrosis and ox-LDL are corrected to solid-tissue area). A significant major dietary effect was seen for all histologic measures. *a* Significant difference from control diet, same gender in post hoc testing. *b* Significant difference between 1% and 2% CLA, same gender in post hoc testing

and serum creatinine, are not further reported here. A similar dose dependent effect of diet ( $P < 0.001$ ) and effect of gender ( $P < 0.001$ ) was observed with fibrosis (Fig. 3b) Diet also had dose dependent effects on ox-LDL measurement ( $P < 0.001$ , Fig. 3c) with marginal gender interactions manifest as lower values in female animals (diet  $\times$  gender,  $P = 0.05$ ). Major diet effects were also observed upon macrophage content and PCNA count ( $P < 0.001$ , Fig. 4) due entirely to highly significant differences between control and both dietary interventions in post hoc testing. The small differences between the 1 and 2% CLA dietary groups within genders did not achieve significance in post hoc testing for these parameters.

Neither diet nor gender had a statistically significant effect on PPAR $\gamma$  activation (Fig. 5).

Diet significantly elevated renal levels of all detected CLA isomers in kidney and liver as expected and decreased

**Fig. 4** Cell count analysis of renal macrophages and PCNA positive renal epithelial cells (cells per high power field, corrected to solid-tissue area). A significant major dietary effect was seen, *a* significant difference from control diet, same gender in post hoc testing

**Fig. 5** PPAR $\gamma$  activation in renal tissue homogenates expressed as a ratio to the manufacturer's positive control

levels of LNA in both organs. The levels found in both organs, however, were in different proportions to the diet (Table 2). Both diet and gender were likely to influence fatty acid composition of liver more than that of kidney. Levels of 18:1 c9 were significantly lower in liver but not kidney tissue in both genders, as was  $\Delta$ -9 desaturase activity. ARA content did not differ with diet in renal and hepatic tissue and  $\Delta$ -6 desaturase activity was significantly increased in liver from animals of both genders (Table 2). Female animals demonstrated higher hepatic content of the anti-inflammatory PUFA, DHA. Canonical correlation between renal content of CLA isomers and a total histologic score pooled across both genders derived by addition of the numeric values of all histologic variables revealed a significant negative correlation only between the renal content of 18:2 c9, t11 and histologic indices (standardized canonical coefficient =  $-0.63$ ,  $P < 0.001$ ). There was no significant correlation between the renal level of any CLA isomer and serum creatinine in the whole group; however, if the analysis was restricted to only female animals with PKD, the correlation between serum creatinine and the renal levels of the t10, t12 isomer approached significance ( $r^2 = 0.27$ ,  $P = 0.067$ ).

Gender was associated with expected changes in bone mineral content, body fat and lean body mass (Table 3). Diet only had a significant effect in reducing % body fat in both genders compared to controls of the same gender in post hoc testing. Increases in lean body mass in animals receiving CLA diets did not achieve significance. Lean body mass did not correlate with serum creatinine in either gender (males  $r^2 = -0.139$ , females  $r^2 = 0.299$ ,  $P = ns$ ).

## Discussion

The results reported here reinforce the findings of our previous studies with respect to a possible therapeutic role for CLA in inflammatory renal disease [11]. This study, however, is the first to explore the role of animal gender in the response to CLA in this context, and, as with our recent study with flax derivatives, gender does influence the outcome of this type of dietary intervention. Indeed, we have not been able to identify any prior study exploring gender differences in CLA response in any system.

CLA isomers may compete with linoleic acid at the level of desaturases and elongases, thus influencing ARA content [35]. CLA reduces the expression of the gene for stearyl-CoA reductase, the initial  $\Delta$ 9-desaturase step in the formation of monoenoic fatty acids [36], a finding confirmed by our results.  $\Delta$ 6-desaturase inhibition by CLA has been reported in a transfected yeast system [37], and by the t10, c12 isomer specifically in human hepatoma cells [38], whereas our study found no such effect in kidney and possibly the opposite

effect in liver. In a prior study using a soy protein based diet, we found an association between inhibition of Δ6-desaturase and histologic improvement in this model [23], but this is

clearly not the mechanism here. Although found to have benefits in the areas of carbohydrate metabolism, cholesterol metabolism and atherosclerosis [39], the major health related

interest in CLA has been as an anti-carcinogen [2]. CLA enhances lymphocyte proliferative responses to phytohemagglutinin, but not to LPS or concanavalin A [40], implying a positive or negative immunomodulatory role under differing circumstances. Our results demonstrating decreased macrophage infiltration and fibrosis might be interpreted as a specific effect on the inflammatory response or may be a non-specific response based on inhibition of cell proliferation.

Most CLA preparations are a mixture of isomers, with the precise mix a function of both the substrate oil and the manufacturing process [41]. Our statistical association of benefit with the renal concentration of the c9-t11 isomer, while a novel approach to the issue of identifying the active lipid, is supported by studies using pure isomers. Jensen et al. [4] have associated antiproliferative effects of CLA with the c9-c11 isomer. Yang and Cook [42] have demonstrated that the release of anti-inflammatory cytokines essential to the innate immune response is inhibited by the c9-t11 isomer. Conversely, the t10-t12 isomer has been associated with pro-inflammatory effects [43], may have adverse effects on lipid metabolism [44], and may play a larger prostaglandin inhibition mediated effects of CLA [38].

Our finding of a different distribution of CLA isomers in tissue compared to the diet and differing proportions in differing organs is consistent with previous reports. Kramer et al. [45] have reported similar findings in a piglet model and speculate that the cause is related to differing metabolism of different isomers, which is supported by Tsuzuki et al. [46] who failed to demonstrate differences in absorption as a basis for such differences in a rat model. The basis for the observed differences remains to be elucidated. In this inflammatory model, the content and role of fatty acids in the inflammatory cell population that may migrate into the kidney from a circulating pool would be extremely difficult to measure and yet may be extremely important in elucidating the precise relationships between this nutritional intervention and histologic change and toxicity.

The role of CLA as a ligand for the PPAR $\gamma$  system suggests a direct pathway that might mediate the observed effects [15]. This pathway has been specifically implicated in the regulation of inflammatory response [16]. Our results do not demonstrate a dietary effect on PPAR $\gamma$  activation, thus cannot at this stage support this as the relevant pathway. It is, however, possible, that as we based our measurements upon whole tissue homogenates, we would not have had sufficient sensitivity to detect activation that is specific to individual cell types such as macrophages and fibroblasts. In-vitro studies of separated cells may offer insight into this question.

The new finding of a rise in serum creatinine in female animals is a serious concern. CLA has been associated

with an increase in lean body mass [47–49], which may increase serum creatinine without change in renal function [50]. In this study, however, very small changes in lean body mass that did not achieve significance and were proportionately much less than the change in serum creatinine were observed. In a previous study, we demonstrated that a 1% CLA diet reduced renal PGE<sub>2</sub> production [11]. It is plausible that at even higher doses, a more generalized effect of prostaglandin inhibition on glomerular tubular balance, combined with the loss of urinary concentrating ability that is an early clinical feature of this disease may result in disturbed renal function in a manner analogous to the adverse effects of non-steroidal anti-inflammatory drugs [51]. Sullivan et al. [52] have described gender dimorphism with higher expression of prostaglandin synthase and renal production of prostaglandins in female spontaneously hypertensive rats, but the relationship of this observation to renal functional homeostasis is not known. It is possible that their observation implies that more prostaglandin synthesis is required for homeostasis in females; inhibition of the pathway would therefore create a larger functional disturbance. Our finding of a diminution of the antifibrotic effect at higher doses of the CLA mixture in males may also be cautionary and could reflect a shift in the balance of beneficial versus harmful effects of the two predominant isomers [43]. As with an earlier study with flax oil and lignan [27], we did detect relatively subtle qualitative differences in the profile of histologic effects between genders. The magnitude of these differences may not be of clinical significance but the finding underlines the importance of considering gender as a variable in functional food studies.

Proportions of CLA in plasma, adipose tissue and red blood cell membranes are low in adult patients with chronic renal failure managed without dialysis, but increase in dialysis patients [53]. It is likely that changes in dietary intake, with severe restriction of dairy products mandated to maintain serum phosphate in an acceptable range, are a major factor. Our study suggests that CLA, and in particular the c9-t11 isomer, may warrant further exploration as an anti-inflammatory functional food that may influence renal injury. Our results, however, also caution that the unconditional recommendation of CLA supplements of variable composition and quality in this high risk population is not only premature but carries a credible risk of harm.

**Acknowledgments** This work was supported by a grant from Dairy Farmers of Canada and performed in facilities of the Manitoba Institute of Child Health, a division of the Children's Hospital Foundation of Manitoba, Inc. The assistance of Dr Rasheda Rabbani with the statistical analysis and of Heather Kovacs with the DXA scanning is gratefully acknowledged.

**Abstract** HDL is able to displace cell surface-bound hepatic lipase (HL) and stimulate vascular triglyceride (TG) hydrolysis, much like heparin. Displacement appears to be a result of a high-affinity association of HL and apoA-I. HDL varies in its ability to displace HL, and therefore experiments were undertaken to evaluate the impact of HDL composition and structure on HL displacement from cell surface proteoglycans. HDL apolipoprotein and lipid composition directly affect HL displacement. ApoA-II and apoC-I significantly increase HL displacement from the cell surface. While changes in HDL cholesteryl ester and fatty acid content have no effect on HL displacement, increases in HDL phospholipid and TG content significantly inhibit HL displacement. HDL fractions from hyperlipidemic patients are unable to displace HL from the cell surface. These results indicate that the structure and composition of HDL particles in plasma are central to regulation of HL displacement and the hydrolytic activity of HL.

## Abbreviations

apoA-I Apolipoprotein A-I  
apoA-II Apolipoprotein A-II  
apoE Apolipoprotein E  
DPPC Dipalmitoyl phosphatidylcholine

HL Hepatic lipase  
CETP Cholesteryl ester transfer protein  
CHD Coronary heart disease  
HSPG Heparan sulfate proteoglycan  
LPL Lipoprotein lipase  
LCAT Lecithin:cholesterol acyl transferase  
PLA<sub>2</sub> Phospholipase A  
PC Phosphatidylcholine  
PA Phosphatidic acid  
PS Phosphatidylserine  
PI Phosphatidylinositol  
rHDL Reconstituted HDL  
TG Triacylglyceride  
VLDL Very low-density lipoprotein

## Introduction

Heparin promotes the displacement of hepatic lipase (HL) and lipoprotein lipase (LPL) from the liver and vascular endothelium and stimulates lipolytic activity and plasma triglyceride (TG) clearance [3, 28, 46]. The enzymatic activity of HL is undetectable in the plasma, and activity is usually measurable only after intravenous injection of heparin (post-heparin HL activity). Increased post-heparin HL activity is associated with low HDL-cholesterol (HDL-C) levels [22, 27, 35] and an abundance of small, dense LDL particles in the plasma [6, 11, 49]. A number of clinical studies show that these conditions are concomitant with increased coronary heart disease (CHD) risk in the patients. Lower HDL-C levels in postmenopausal women and similarly aged men, and a higher incidence of CHD in these groups compared to the premenopausal women, are related to higher post-heparin HL activity [14]. Similarly,

conditions related to the higher risk of heart disease, such as smoking [19], visceral obesity [16], and sedentary lifestyle [31], are known to be associated with elevated post-heparin HL activity. In addition, combined familial hyperlipidemic [39] and type 2 diabetic patients [47], who are at a higher risk for CHD, have elevated levels of post-heparin HL activity and an atherogenic lipoprotein profile (small dense LDL particles, decreased HDL-C, and increased TG levels) [1, 4, 5].

Accumulating evidence suggests that an increase in post-heparin HL lipolytic activity may be representative of an increased inactive pool of cell-associated HL in the liver. In vitro experiments have shown that proteoglycan-bound HL is inactive [37]. Displacement of HL from the cell surface increases hydrolytic activity and stimulates TG hydrolysis. In vivo experiments [10] have confirmed that an increase in circulating HL increases plasma HL lipolytic activity. In the mouse model, expression of a mutant human HL, which is unable to bind liver cells, elevates pre-heparin HL activity and leads to enhanced lipid hydrolysis and lipoprotein catabolism. An increased post-heparin HL activity may therefore be indicative of a reduced ability of liver-bound HL to be displaced and activated. As such, a high post-heparin HL activity would be expected to result in decreased vascular lipolysis and may be related to increased plasma TG levels.

Similar to heparin, both apoA-I and HDL stimulate HL displacement from the cell surface proteoglycans of CHO and HepG2 cells [36, 37]. Specific subclasses of HDL have different effects on HL displacement. The larger and more buoyant HDL<sub>2</sub> causes more HL to be displaced from the cell surface, while the smaller dense HDL<sub>3</sub> is unable to displace HL [36, 37]. The differential ability of HDL particles to liberate lipases from cell surface proteoglycans appears to influence lipid hydrolysis and clearance. Abnormalities in HDL structure and lipase displacement ability may therefore be related to perturbations in TG metabolism.

In this study, the relationship between HDL structure and HL displacement was evaluated. It was shown that both the lipid and protein components of HDL affect HL displacement. The results provide new insights into the regulation of HL metabolism and demonstrate how the lipid and protein composition of HDL controls HL displacement. Evidence suggests that HDL isolated from hyperlipidemic patients may have an impaired ability to promote HL displacement. Perturbations in HL displacement may therefore be partly causative of the abnormal clearance of plasma TG.

## Materials

TG diagnostic kits were purchased from Roche Diagnostics (Laval, PQ, Canada). Anti-mouse IgG horseradish

peroxidase (HRP)-linked whole antibody (isolated from goat), broad-range molecular weight markers, protein-G Sepharose 4 Fast Flow beads, HiTrap heparin HP columns, and native gradient Phast gels were purchased from Amersham Biosciences (Baie d'Urfé, PQ, Canada). Super Signal West Pico Chemiluminescent Substrate was purchased from Pierce Chemical Co. (Rockford, IL). Agarose Paragon® lipogels and the lipid stains were obtained from Beckman Coulter Inc. (Fullerton, CA). Novex polyacrylamide mini-gels, Ham's F12 medium, Dulbecco's modified Eagle's medium (DMEM), Geneticin® Selective Antibiotic (G418 sulfate), L-glutamine, and penicillin/streptomycin (pen/strep) were obtained from Invitrogen (Burlington, ON, Canada). Fetal bovine serum (FBS) and heparin (from porcine intestine) were purchased from Sigma Chemical Co. (St. Louis, MO). 1-Palmitoyl-2-oleoylphosphatidylcholine (POPC) was purchased from Avanti Polar Lipids (Alabaster, AL). CHO and HepG2 cell lines were obtained from ATCC (Manassas, VA). The polyclonal anti-human apolipoprotein A-I antibody from rabbit was purchased from Calbiochem Biosciences Inc. (La Jolla, CA). The monoclonal anti-human HL XHL3-6a antibody from mouse and monoclonal anti-human apoA-I (5F6 and 4H1) antibody from mouse were obtained from Drs. Bensadoun and Marcel, respectively. The polyclonal anti-human HL antibody from rabbit was obtained from Santa Cruz (Santa Cruz, CA). All other reagents were of analytical grade.

## Methods

### Isolation of Lipoproteins by Sequential Ultracentrifugation

Blood was donated from human subjects with informed consent of the participants and approval from the University of Ottawa Heart Institute Research Ethics Board. Blood samples from fasting normolipidemic and hyperlipidemic subjects were collected in Vacuette® tubes. VLDL, LDL, and HDL fractions were isolated from the plasma by sequential ultracentrifugation within the density ranges of  $\rho < 1.006$  g/ml,  $\rho = 1.019$ – $1.063$  g/ml, and  $\rho = 1.063$ – $1.21$  g/ml, respectively, as previously described [23]. The isolated lipoprotein fractions were dialyzed extensively against PBS (50 mM sodium phosphate, 150 mM NaCl, pH 7.2) at 4 °C. Protein concentrations of lipoproteins were determined by the modified Markwell Lowry method [30]. Cholesterol and TG concentrations were measured enzymatically, using the commercial diagnostic kits (Roche Diagnostics, Laval, PQ). The homogeneity of the lipoprotein fractions was determined by agarose gel electrophoresis using pre-made Paragon® Lipogels.

## HL Purification

HL was purified from post-heparin human plasma by heparin affinity chromatography as previously described [17, 36, 37]. Post-heparin human plasma was collected from normolipidemic subjects, and a 20% TG emulsion (Intralipid 20%, Pharmacia & Upjohn Inc., Mississauga, ON, Canada) was added to the plasma. Lipid cakes were harvested centrifugally and delipidated. The resuspended aqueous solution of crude HL was loaded onto a heparin-Sepharose CL-6B column and eluted with linear salt gradient of 0.15–1.5 M NaCl in 5 mM sodium barbital, pH 7.4, 20% glycerol, and the pooled fractions stored at  $-80^{\circ}\text{C}$  until use. HL activity was characterized using a TG emulsion and quantified into units of enzyme activity (where 1 unit = 1  $\mu\text{mol}$  of fatty acid hydrolyzed/h). The protein concentration of the purified HL was 0.114 mg/ml, and the specific activity was determined to be 19,455 units/mg protein. SDS-PAGE and immunochemical analysis using the HL monoclonal antibody, XHL3-6a, showed a single band with an apparent molecular mass of 66 kDa.

## Preparation of reconstituted HDL (rHDL) Particles

Purified apoA-I, apoA-II, and apoC-I were isolated from delipidated HDL by anion exchange chromatography [43]. Apolipoproteins were resolubilized in a 6 M guanidine

HCl, 10 mM Tris (pH 7.2) solution, and dialyzed extensively against PBS (pH 7.2). Reconstituted HDL complexes were prepared by sonicating POPC with a mixture of apolipoproteins (apoA-I, A-II, C-I) with or without additional amounts of TG (triolein), FFA (oleic acid), or CE (cholesteryl oleate) (molar ratio of 1 mol protein: 60 mol lipids) as previously described [8]. The molar concentration of apolipoproteins in rHDL was determined by chemical crosslinking with dimethylsuberimidate [8] (Tables 1, 2). Briefly, POPC (3.2 mg) and other lipids in chloroform were dried under nitrogen in a  $12 \times 75\text{-mm}$  test tube, and 800  $\mu\text{l}$  of PBS, pH 7.4 was added. The lipid-buffer solution was initially sonicated for 1 min in a  $15^{\circ}\text{C}$  water bath using a Branson 450 sonicator. The suspension was then incubated in a sealed tube for 30 min at  $37^{\circ}\text{C}$  and sonicated again for 5 min using a 95% duty cycle. ApoA-I (3 mg of a 1.8 mg protein/ml PBS, pH 7.4) or other apolipoproteins were added to the lipid suspension, and the protein–lipid mixture was sonicated for  $4 \times 1$  min punctuated by 1-min cooling periods. All rHDL complexes were filtered through a 0.22- $\mu\text{m}$  syringe tip filter. The size and homogeneity of rHDL complexes were estimated by non-denaturing gel electrophoresis on precast 8–25% acrylamide Phastgels (Amersham Biosciences) after protein staining. The protein concentration was determined by the modified Markwell Lowry method.

**Table 1** Reconstituted HDL apolipoprotein composition

rHDL particle <sup>a</sup>	POPC (mol)	apoA-I (mol)	apoA-II (mol)	apoC-I (mol)	apoHDL (mol)	rHDL protein:lipid <sup>b</sup> (mol:mol:mol)
ApoA-I/POPC	60	1.0	0.0	0.0	0.0	2:120
ApoA-I/A-II/POPC	60	0.33	0.66	0.0	0.0	1:2:120
ApoA-I/C-I/POPC	60	0.33	0.0	0.66	0.0	1:2:120
ApoHDL <sup>c</sup> /POPC	60	0.0	0.0	0.0	1.0	Nd

<sup>a</sup> rHDL particles were prepared by cosonication with the indicated compositions as described

<sup>b</sup> rHDL prepared from apoA-I alone contained 2 mol of apoA-I/particle, while those prepared with apolipoprotein mixtures contained 1 mol of apoA-I, and 2 mol of the test apolipoprotein

<sup>c</sup> apoHDL was prepared from delipidated HDL and contained apoA-I, apoA-II, apoC-I, apoC-II, and apoC-III

**Table 2** Reconstituted HDL lipid composition

rHDL particle <sup>a</sup>	ApoA-I (mol)	POPC (mol)	CE (mol)	TG (mol)	FFA (mol)	rHDL protein:lipid <sup>b</sup> (mol:mol:mol)
ApoA-I/POPC	1.0	60.0	0.0	0.0	0.0	2:120
ApoA-I/POPC/CE	1.0	60.0	15.0	0.0	0.0	2:120:30
ApoA-I/POPC/TG	1.0	60.0	0.0	15.0	0.0	2:120:30
ApoA-I/POPC/FFA	1.0	60.0	0.0	0.0	15.0	2:120:30

<sup>a</sup> rHDL particles were prepared by cosonication with the indicated compositions as described

<sup>b</sup> rHDL particles contain 2 mol of apoA-I/particle

### Preparation of Lipid-enriched HDL

Phosphatidylinositol (PI) and phosphatidylcholine (PC) vesicles were prepared by sonication in PBS and then incubated with native HDL. Briefly, 3 mg of each lipid in chloroform was dried under nitrogen. PBS (1 ml) was added, and the lipid-PBS mixture was sonicated for 1 min at constant duty cycle in a 15 °C water bath and incubated at 37 °C for 15 min. The mixture was then sonicated for 5 min at 95% duty cycle. The lipid vesicles (0.2 mg) were incubated per 1 mg fresh HDL protein for 48 h at 4 °C. Under these conditions, essentially the entire exogenous lipid was assimilated into the HDL particles. HDL charge was determined by electrophoretic mobilities on 0.6% agarose Paragon lipogels (Beckman, Coulter) as previously described [42].

### Preparation of Apolipoprotein-enriched HDL

Freshly isolated HDL (1 ml; 5.8 mg protein/ml) from a fasting normolipidemic subject was incubated with 1.35 ml of purified and dialyzed apoA-II (2.4 mg protein/ml) for 30 min at room temperature with constant stirring. At the end of the incubation, the free apoA-I and apoA-II were separated from HDL by ultracentrifugation. The apoA-I/apoA-II mass ratio of HDL was estimated by SDS-PAGE on 12% precast Novex minigels followed by silver staining. The apoA-II content of HDL was also approximated by subtraction of apoA-I concentration from total protein. The apoA-I protein concentration of HDL was determined by ELISA (enzyme-linked immunosorbent assay) and calculated relative to an apoA-I standard curve. The ratio of apoA-I/apoA-II was similar using both measurements.

### HL Displacement Assay in CHO and HepG2 Cells

CHO cells stably transfected with human HL (CHO-hHL) were plated in Ham's F12 medium containing 10% FBS, 500 µg/ml G418, 1% glutamine, and 1% penicillin/streptomycin in six-well plates. HepG2 cells were plated and grown to confluency in DMEM medium containing 10% FBS, 1% glutamine, and 1% penicillin/streptomycin in six-well plates. Once confluent, cells were washed with PBS and incubated with fresh medium in the absence of FBS overnight. The next day, the medium was aspirated, and the cells were washed 2× with FBS-free medium. Following the washes, the cells were incubated with FBS-free medium containing HDL or rHDL samples at a concentration of 150 µg/ml for 30 min at 37 °C. The media was collected into microcentrifuge tubes and stored at −80 °C. Cell lysates were prepared by washing the cells twice with PBS and incubation with 100 µl of sample buffer (62.5 mM Tris-HCl, pH 6.8, 20% glycerol, 2% SDS, 0.5% (w/v)

bromophenol blue) for 30 min at 37 °C. The cell lysates were transferred into microcentrifuge tubes, heated for 10 min at 90 °C, and kept at −20 °C until it was electrophoresed. The frozen medium was lyophilized overnight, resolubilized in 200 µl of sample buffer, and heated at 90 °C for 10 min.

### SDS-PAGE and Immunochemical Analysis

The cell lysate and media samples were electrophoresed on 8% polyacrylamide gels under denaturing conditions and transferred onto a nitrocellulose membrane. The membrane was incubated with blocking solution (PBS containing 1% BSA and 0.2% Tween-20) at room temperature for 1 h and then with the monoclonal anti-human HL XHL3-6a antibody from mouse (1:5,000) in blocking solution containing 0.02% NaN<sub>3</sub> at 4 °C overnight. Following three washes in PBS-0.2% Tween-20, a goat anti-mouse IgG HRP-linked whole antibody was used as the secondary antibody. After 1 h incubation with secondary antibody, the membrane was washed in PBS-0.2% Tween-20 and visualized by chemiluminescence following a 5-min incubation with the Pierce Super Signal West Pico substrate. The membrane was exposed to film, and the molecular mass of the cell surface-associated HL as well as the HL liberated into the medium was determined using broad-range molecular weight markers as a reference. The film was subsequently scanned, and the mass of HL that had been displaced into the media, by various types of HDL, was determined relative to standard rHDL by densitometry.

### Non-denaturing Gradient Gel Electrophoresis Analysis

Conditioned media samples were electrophoresed using 4–20% Tris-Glycine precast gels under non-denaturing conditions overnight for 2000Vh at 4 °C. The gel was then incubated in a 0.1% SDS solution for 15 min to ensure the proteins had enough negative charge to transfer unidirectionally toward the anode. The gel was transferred for 4 h at 125 V at 4 °C (Tris-Glycine transfer buffer with 20% methanol) onto a PVDF membrane. The membrane was cut in half, and each half was incubated with either an HL blocking solution (TBS containing 1% BSA and 0.2% Tween-20) or an apoA-I blocking solution (TBS containing 5% skim milk and 0.2% Tween-20) overnight at 4 °C. The membranes were then incubated with either the monoclonal anti-human HL XHL3-6a antibody from mouse (1:5,000) or the monoclonal anti-human apoA-I 4H1 (2–8) and 5F6 (118–141) antibody from mouse (1:5,000) in blocking solution. Following three washes in TBS-0.2% Tween-20, both membranes were incubated for 1 h with a goat anti-mouse IgG HRP-linked whole antibody as the secondary antibody. The membranes were washed in TBS-0.2% Tween-20 and visualized by chemiluminescence

following a 5-min incubation with the Pierce Super Signal West Dura substrate. The molecular weight and the densitometry profiles were generated using AlphaEase© software (AlphaInnotech Corp., San Leandro, CA).

### HL Immunoprecipitation

Purified HDL (100 µg) from human plasma was mixed with 20 µl of purified HL (114 µg protein/ml) and 10 µl of polyclonal anti-human HL antibody and incubated overnight at 4 °C on a rotating wheel. A 10% protein-G Sepharose bead suspension (200 µl) (2% BSA in PBS) was added to the samples and incubated at 4 °C on a rotating wheel for 2 h. The samples were centrifuged at maximum speed in a microcentrifuge for 3 min. The supernatant was discarded, and following two gentle washes with PBS, SDS sample buffer was added to remove proteins from the beads with heating. The samples were either electrophoresed on a 12% polyacrylamide gel and probed for human apoA-I or electrophoresed on a 8% gel and probed for human HL.

### Statistical Analyses

The significance of the difference between group mean values was calculated by the Student's *t*-test or one-way ANOVA and Dunnett post-test analysis using SigmaStat® Software (Version 3.0) (Systat Software Inc., San Jose, CA).

## Results

### Displacement of HL by Heparin and HDL in CHO-hHL Cells

Experiments show that HDL and heparin affect the cell surface association of HL and release it into the media of the human HL transfected CHO (CHO-hHL) cells (Fig. 1). There is very little HL normally released into the media when the cells are cultured in FBS-free medium alone, but similar to heparin, HDL readily displaces HL. Displacement of HL by heparin or HDL is time and dose dependent, and the maximal HL displacement into the incubation media occurs with 200 IU of heparin/ml or 150 µg of HDL protein/ml of media (Fig. 1). Both HDL and heparin increased the displacement of HL over the 2 h time course (data not shown). The molecular weight of HL released into the media (HSPG-bound HL) is estimated to be 66 kDa, which is similar to that for purified human HL (Fig. 2) [37].

### Displacement of Cell Surface-Bound HL by HDL in HepG2 Cells

To compare the effect of HDL on HL displacement in transfected CHO-hHL cells and cells that express HL

**Fig. 1** Concentration-dependent displacement of cell surface-bound HL in CHO-hHL cells by HDL and heparin: CHO-hHL cells were grown to confluency and incubated with increasing concentrations of HDL protein or heparin for 30 min at 37 °C. The media was collected and analyzed by Western blots to determine the amount of HL released. HL release into medium was calculated relative to control incubations with apoA-I and normalized to total cell protein. These values are the mean  $\pm$  SD of triplicate determinations from one assay and are representative of two separate experiments

**Fig. 2** Displacement of cell surface-bound HL from CHO-hHL (panel a and b) and HepG2 cells (panel c and d): CHO-hHL and HepG2 cells were grown to confluency and incubated with FBS-free media (control), heparin, and HDL for 30 min at 37 °C. The incubating media was collected, lyophilized, and resolubilized in SDS sample buffer. The cells were washed twice with PBS and solubilized in SDS sample buffer. Immunochemical analysis followed to detect the amounts of HL associated with the cells (CHO-hHL cells: panel a, HepG2 cells: panel c) and released into the medium (CHO-hHL cells: panel b, HepG2 cells: panel d). The duplicate images are from one analysis and are representative of three separate experiments for each cell line

endogenously (HepG2), both cell lines were grown and treated with HDL, heparin, or FBS-free medium alone for 30 min. The results of immunochemical analysis by anti-HL mAb show two distinctive bands in the total extract of the CHO cells corresponding to the intra- and extra-cellular forms of overexpressed HL (Fig. 2a) [36]. Addition of HDL or heparin to the incubation medium results in the appearance of a 66 kDa HL band in the incubation media of CHO and HepG2 cells (Fig. 2b, d).

## Association of HDL and HL In Vitro

In order to evaluate whether a direct interaction occurs between HDL and HL, both non-denaturing electrophoretic Western blots and co-immunoprecipitation studies were undertaken. Non-denaturing gradient gel electrophoresis (NGGE) was performed on normolipidemic HDL samples that had been incubated with CHO-hHL cells. The proteins were transferred to PVDF membrane and probed for both apoA-I and HL (Fig. 3). NGGE probed for apoA-I showed the expected profile for a normolipidemic HDL, with the large, 11-nm HDL<sub>2</sub> class and smaller 8.0-nm HDL<sub>3</sub> class. NGGE probed for HL had almost an identical profile as shown for apoA-I (Fig. 3). HL appears to be associated with all classes of apoA-I containing HDL particles. Similar results were observed for HDL preparations from three different subjects. In co-immunoprecipitation studies, mixtures of pure HL and HDL were immunoprecipitated with a polyclonal anti-human HL Ab. The immunoprecipitate was electrophoresed and analyzed by Western blots to detect both apoA-I and HL. Blots probed for human apoA-I showed that HDL particles are immunoprecipitated when pure human HL is added to the HDL preparation (data not shown). These results confirm our earlier chromatographic work [8, 9], which showed that HL tightly interacts with HDL particles in solution.

**Fig. 3** Non-denaturing gradient gel electrophoresis of HL displaced from CHO-hHL cells by HDL: CHO-hHL cells were grown to confluency and incubated with 150 µg/ml of HDL for 30 min at 37 °C. The cell medium was collected and analyzed by non-denaturing gradient gel electrophoresis on 4–20% polyacrylamide gels. Proteins were transferred to PVDF and immunoblotted with anti-apoA-I and anti-HL antibodies. Densitometric profiles of apoA-I and HL blots are shown. The profiles are from one experiment undertaken with HDL from a single normolipidemic subject. Profiles are similar to that observed from separate experiments with HDL isolated from three different subjects

## Displacement of Cell Surface-Bound HL by Synthetic HDL

The ability of native and synthetic HDL particles to displace HL was determined by incubating CHO-hHL cells with native HDL from normolipidemic subjects, rHDL (apoA-I and POPC), heparin, and FBS-free medium. rHDL displaces HL similar to heparin, while the ability of HDL is variable (60–90%) and dependent on the batch/donor of HDL (data not shown). This is consistent with previous work showing that pure apoA-I is more effective at displacing cell surface-associated HL than HDL [36].

## HL Displacement by HDL Enriched with apoA-II

Normolipidemic HDL was enriched with pure apoA-II and ultracentrifuged to separate free apolipoproteins from the mixture. The apoA-I and apoA-II content of HDL was determined from silver-stained PAGE gels. The mass ratio of apoA-I to apoA-II decreased by 50% in apoA-II-enriched HDL.

HL displacement from CHO-hHL cells by HDL or HDL-apoA-II is shown in Fig. 4. Percent HL displacement was calculated relative to that for a control rHDL (apoA-I:POPC) particle. Incorporation of apoA-II into HDL causes a 2.5-fold increase in HL displacement from the cell surface. These data suggest that apoA-II is a structural component of HDL that plays a significant role in displacing cell surface-bound HL. The work appears

**Fig. 4** HL displacement in CHO-hHL cells by HDL and apoA-II-enriched HDL: CHO-hHL cells were grown to confluency and incubated with 150 µg/ml of HDL or apoA-II-enriched HDL for 30 min at 37 °C. The cell medium was collected and analyzed to determine the mass of liberated HL by HDL or HDL-apoA-II relative to a control rHDL (apoA-I/POPC) particle. The concentration of HL in the media is mean value ± SD of triplicate determinations from one assay and is representative of two separate displacement experiments. (The significance of difference relative to control HDL was determined by Student's *t*-test, \*\*\**p* < 0.0001.)

consistent with previous work showing that apoA-II enhances association of HL with HDL particles [8].

#### HL Displacement by rHDL Particles Enriched with Apolipoproteins

To confirm that apoA-II has a specific impact on HL displacement and to estimate the role of other structural apolipoproteins of HDL in HL displacement, various HDL particles were reconstituted with different apolipoprotein mixtures. Purified apolipoproteins apoA-I, A-II, and C-I were isolated from delipidated HDL by anion exchange chromatography and used to generate rHDL complexes. rHDLs were also prepared from a full compliment of HDL apolipoproteins (apoHDL) that was prepared by delipidation of HDL. The molar ratio of the lipid and protein components of each particle is shown in Table 1.

Figure 5 presents the percent HL release into the media by various kinds of rHDL particles and heparin, relative to the standard rHDL particle (apoA-I/POPC). The figure indicates that apoA-I/apoA-II/POPC particles increase HL displacement by more than twofold relative to control rHDL. This confirms the results of the previous experiment with apoA-II-enriched native HDL. ApoA-I/apoC-I/POPC particles also increase HL displacement by 1.5-fold compared to the control. This suggests that both apoC-I and apoA-II are able to stimulate HL displacement. HDL

**Fig. 5** HL displacement by rHDL particles containing various apolipoproteins: CHO-hHL cells were grown to confluency and incubated with 150  $\mu\text{g}/\text{ml}$  of various synthetic rHDL particles: apoA-I/POPC, apoA-I/apoA-II/POPC, apoA-I/apoC-I/POPC, and apoHDL/POPC, for 30 min at 37  $^{\circ}\text{C}$ . The incubating media was analyzed by Western blots to determine the mass of HL released into the media. HL mass in the media was calculated relative to the control rHDL (apoA-I/POPC). The values of HL are mean  $\pm$  SD of triplicate determinations from one assay and represent three displacement experiments. (The significance of difference relative to heparin was determined by one-way ANOVA, \*\* $p < 0.001$ , \* $p < 0.01$ )

apolipoproteins (apoHDL) were resolubilized after HDL extraction and shown to contain primarily apoA-I, apoA-II, apoC-I, apoC-II, and apoC-III. ApoHDL/POPC particles were less able to promote HL displacement (25% of control rHDL).

#### HL Displacement by HDL Enriched with Phospholipids

Normolipidemic HDL was enriched with various phospholipid vesicles (PI and POPC), and the impact of the increased phospholipid content of HDL on HL displacement was studied. Agarose gel electrophoresis of HDL-PI showed that PI enrichment of HDL increases lipoprotein net negative charge, while PC had the opposite effect (data not shown). HL displacement with native HDL, HDL-PI, and HDL-POPC, followed by immunoblotting of the incubation media, reveals that both phospholipids decrease HL displacement relative to native HDL or heparin ( $\sim 50\%$  that of control rHDL) (Fig. 6).

#### HL Displacement by rHDL Particles Enriched with Specific Lipids

Different kinds of rHDL particles were prepared enriched in cholesterol ester (CE), TG, and free fatty acid (FFA) to evaluate the impact of HDL lipid composition on HL displacement. These particles contained apoA-I, POPC, and

**Fig. 6** HL displacement by phospholipid-enriched HDL: HDL obtained from normolipidemic subjects was enriched with phosphatidylcholine (PC) or phosphatidylinositol (PI) as described. CHO-hHL cells were grown to confluency and incubated with 100 IU/ml of heparin or 150  $\mu\text{g}/\text{ml}$  of HDL, HDL/PC, or HDL/PI for 30 min at 37  $^{\circ}\text{C}$ . The incubating media was analyzed by Western blots to determine the mass of HL released into the media. The values of HL in the medium were calculated relative to the control rHDL particle (apoA-I/POPC). These values are mean  $\pm$  SD of triplicate determinations from one assay and are representative of three different experiments. (The significance of difference relative to heparin was determined by one-way ANOVA, \* $p < 0.01$ )

the test lipid (starting ratios are shown in Table 2). HL displacement from CHO-hHL cells (Fig. 7) demonstrates that CE-enriched particles slightly increase HL displacement (1.2-fold), whereas rHDL enriched with FFA has a modest inhibitory effect in HL displacement. Enrichment with TG significantly decreases HL displacement to 25% of the control. These results suggest that the TG component of HDL is an important inhibitor of HL displacement from the cell surface.

#### HL Displacement by HDL Fractions from Hypercholesterolemic Patients

To determine whether HDL from hypercholesterolemic patients has an altered ability to displace cell surface HL, displacement experiments were performed with HDL isolated from hypercholesterolemic patient plasma and normolipidemic plasma. The plasma sample from the hypercholesterolemic patient had a total cholesterol of 5.9 mM, a TG of 1.22 mM, and an HDL cholesterol of 1.33 mM. The HDL-TG levels were significantly higher in the hypercholesterolemic than the normolipidemic subject. The HDL<sub>2</sub> and HDL<sub>3</sub> fractions were isolated from plasma samples ultracentrifugally ( $d = 1.063$ – $1.125$  g/ml and  $1.125$ – $1.21$  g/ml, respectively). HL levels were low and barely detectable in isolated HDL fractions. CHO-hHL cells were treated with total HDL, HDL<sub>2</sub>, and HDL<sub>3</sub>

fractions and the incubation media analyzed for HL content. The Western blots of the cell media (Fig. 8, upper blot) reveal that HDL from the normolipidemic subject was able to displace HL into the media. As previously shown [36, 37], the HDL<sub>2</sub> fraction (lanes 8 and 9) was more effective at displacing HL than the HDL<sub>3</sub> fraction (lanes 5, 6, and 7). In contrast, none of the HDL fractions from the hypercholesterolemic patient (lower blot) were able to displace cell surface HL. Similar observations have been made with HDL isolated from three other hypercholesterolemic patients, with similar lipid profiles (data not shown).

#### Discussion

Previous work has shown that HDL and apoA-I can displace HL from purified HSPG [37] and cell surface proteoglycans [36] and increase VLDL-TG hydrolysis. HL displacement by infused heparin and the consequent increase in plasma HL activity (post-heparin HL activity) was demonstrated as early as 1972 [28]. Intravenous injection of heparin to both humans [26] and animal models [2] results in the displacement of HL from the hepatic endothelium and increases HL activity in the bloodstream. The data cumulatively suggest that hepatic-bound HL is inactive and HL displacement is required for

**Fig. 7** HL displacement by rHDL particles prepared with different lipids: Confluent CHO-hHL cells were incubated with 100 IU/ml of heparin or 150  $\mu$ g/ml of different rHDL particles: apoA-I/POPC, apoA-I/POPC/CE, apoA-I/POPC/TG, and apoA-I/POPC/FFA, for 30 min at 37 °C. The incubating media was then analyzed immunochemically to determine the mass of HL released into the media. The values of HL in the media were calculated relative to the control rHDL particle (apoA-I/POPC). These values are mean  $\pm$  SD of triplicate determinations from one set of particles and are representative of three different experiments. (The significance of difference relative to heparin was determined by one-way ANOVA, \*\* $p < 0.001$ )

**Fig. 8** HL displacement by normal and hyperlipidemic HDL: HDL subfractions from a normolipidemic and a hyperlipidemic subject were incubated (150  $\mu$ g/ml) with confluent CHO-hHL cells for 30 min at 37 °C. The incubating medium was then analyzed by Western blots to determine the mass of HL released into the medium. The images are from one analysis and are similar to that observed from separate experiments with HDL isolated from three different hyperlipidemic patients

TG hydrolytic activity [37]. In vivo evidence that supports this view [10] also comes from mice expressing a mutant human HL that had decreased binding to liver HSPG. While wild-type human HL transfected animals had no increase in plasma activity and no overt phenotype, the animals expressing the mutant HL had elevated pre-heparin HL activity and decreased plasma lipid and apolipoprotein levels. The increase in lipid hydrolysis and clearance resulting from increased circulating HL activity suggests that hepatic-bound HL is minimally active and activity is linked to displacement. Therefore, a high post-heparin HL activity may reflect the size of the storage/inactive pool of HL in the liver.

Post-heparin HL activity in familial low HDL patients is higher than in normal subjects [40]. This supports the view that plasma HDL plays a role in displacement and activation of HL. Cell culture studies have shown that the larger, more buoyant subfractions of HDL have the greatest ability to displace cell surface-bound HL [36]. This suggests that composition and structural properties of HDL may be important regulatory factors in HL displacement. Interestingly, related studies have demonstrated that both the apolipoprotein and lipid components of HDL also directly regulate HL activity and VLDL–TG hydrolysis by directly affecting HL association with HDL [8, 9]. These data suggest that plasma HDL regulates HL at two stages: (1) displacement of cell surface-bound HL and (2) modulation of the activity of displaced HL by binding to it and inhibiting VLDL–TG hydrolysis. Activity and displacement are regulated independently. Tight associations with HDL appear critical to inhibiting the activity of circulating HL. The activity of HL is activated by lipoprotein electrostatic properties [9], but HL displacement is controlled by lipid and protein composition of HDL particles.

Heparin has a well-documented role in displacing HL and LPL. Tagashira et al. [48] reported that heparin may act through protein kinase-dependent signaling pathways to stimulate the release of HL. However, it is generally thought that heparin directly interacts with the lipase or competes with it to bind to the binding sites on the cell surface HSPG [2]. It has been suggested that the interaction of heparin with lipases or other biological molecules such as antithrombin-III is due to the association of charged groups of heparin with unique sequences of amino acid residues that are potentially involved in heparin binding [2, 12]. Endogenous heparin levels may impact lipid metabolism. Individuals with lower endogenous circulating heparin activity have more serum lipid abnormalities and are more susceptible to atherosclerosis [20].

Low HDL levels are also associated with an increased post-heparin plasma HL activity, aberrant TG metabolism, and increased atherosclerotic risk [13, 15, 21, 38]. HDL may regulate HL displacement, and evidence suggests that

HDL may displace cell surface HL by directly binding to the enzyme. HL binds to HDL with a high affinity interaction, and studies show that HL is primarily found in the plasma compartment associated with HDL particles [8, 9, 33]. Co-immunoprecipitation studies confirm the association of HL with HDL and Western blots of NGGE show that HL is associated with all classes of HDL containing apoA-I. NGGE densitometric profiles for apoA-I and HL were almost identical (Fig. 3). In contrast, NGGE probed for other apoproteins (i.e., apoA-II) showed completely different profiles from that shown for HL (data not shown).

HDL composition directly affects HL displacement, and HDL apolipoproteins play an important role. The effect of apoA-II on apoA-I conformation and HDL structure has been described previously [8]. ApoA-II significantly increases the binding of HL with HDL particles [8, 33]. Thus, one may conclude that HDL structural alterations caused by apoA-II directly enhance HDL and HL association. Previous work, however, has shown that apoA-II also inhibits VLDL–TG hydrolysis by HL [8]. The increased binding of HL to HDL may therefore increase HL displacement but decrease activity by blocking the ability of HL to shuttle between the lipoprotein substrates and hydrolyze them. HDL<sub>2</sub> has a greater capacity to displace HL, while HDL<sub>3</sub> is poor at displacing HL from the cell surface [36]. This observation is consistent with the inverse relationship reported between plasma HDL<sub>2</sub> levels and magnitude of post-prandial lipemia [34]. However, HDL<sub>2</sub> contains lower relative amounts of apoA-II [23], and therefore apoA-II content cannot directly account for the increased displacement ability of HDL<sub>2</sub>.

ApoC-I also increases HL displacement, but to a lesser extent than apoA-II. Since this apolipoprotein is readily exchangeable between VLDL and HDL (more than apoA-II) [18], it is conceivable that apolipoprotein exchanges during a post-prandial response render HDL more able to displace cell surface HL (Fig. 9, Steps 1 and 2). HDL is known to lose other apoC proteins post-prandially [18], and since apoHDL containing rHDL was poor at displacing HL, it is also conceivable that a loss of apoC-II and apoC-III from HDL could directly enhance HL displacement.

The HDL lipid components also regulate HL displacement. Phospholipid-enrichment of HDL particles blocks the displacement of HL from the CHO-hHL cells. The electrostatic charge of the HDL particle does not appear to directly affect HL displacement, as opposite changes in charge (HDL–PI = negative, HDL–PC = positive) both inhibit HL displacement. This suggests that phospholipid components of HDL affect its structure and function in a manner independent of charge modifications. Phospholipids have also been shown to increase the hydrolytic activity of HL by reducing the binding affinity of HL for HDL [9]. It is known that during a post-prandial response, remnant

**Fig. 9** Proposed model of HL displacement and activation by HDL: Alterations in HDL composition may control the displacement and activation of HL. Apolipoprotein exchange between HDL and chylomicron/VLDL particles occurs during a post-prandial response (Step 1). Assimilation or loss of apolipoprotein molecules from/to HDL stimulates HL displacement by promoting a direct binding of HL to HDL (Step 2). Enrichment of HDL with remnant PL and TG causes HL to dissociate from HDL (Step 3). Dissociation of HL from HDL activates HL-mediated lipid hydrolysis

phospholipids are absorbed into the HDL pool. This may have the function to block additional HL displacement and liberate HL from HDL for increased VLDL hydrolysis.

The TG content of HDL is also an inhibitor of HL displacement. While the free fatty acid and cholesteryl ester contents of HDL have only modest effects on HL displacement, small changes in TG content block HL displacement. Modifications in the neutral lipid content of HDL give rise to unique changes in the structure of apoA-I and stability of the particle. A decrease in CE/TG ratios in reconstituted HDL particles decreases the integrity of the particle and stability of apoA-I  $\alpha$ -helical segments [43]. This kind of alteration in the composition and structure of HDL has been observed in the plasma of hyperlipidemic subjects [18, 45]. Abnormalities in HDL composition directly affect the physiological functions of HDL by altering the interaction of HDL with LCAT [44], CETP [32], and cell surfaces [24]. An increase in the TG content of HDL would be expected to disrupt the stability of the complex, which may directly impact HL displacement. Conversely, apoA-II increases HDL structural stability [8] and enhances HL displacement. It is believed that the core TG enrichment and CE depletion of HDL associated with conformational changes of apoA-I may be related to acceleration of atherosclerosis in metabolic diseases [25]. Thus, an increased CE/TG content of HDL seems to be essential for proper function of HDL. This perspective appears to be consistent with enhancement of HL displacement by larger classes of HDL, which contain increased CE/TG in their core [7].

HDL from dyslipidemic patients appears unable to displace HL. This may support the view that the TG content of HDL plays a role in regulation of HL displacement. This

could be a normal phenomenon during a post-prandial response that has negative consequences in dyslipidemic subjects. Several hours after a meal, plasma TG levels reach a peak, the magnitude and duration of which is dependent on TG hydrolytic rates. During this period, the exchange of core lipids and apolipoproteins between circulating lipoproteins is increased [29]. Lipemia is prolonged in hyperlipidemic conditions and results in TG enrichment of LDL and HDL particles [29]. The expected consequence would be less HL displacement and higher post-heparin HL activity. Elevated post-heparin HL activity is common in hyperlipidemia and therefore suggests that abnormal HL displacement may result in high blood TG levels.

Figure 9 summarizes the view that HL displacement and activation are regulated by structural modifications of HDL during a post-prandial response. Apolipoprotein exchanges between HDL and the apoB lipoproteins may act to initiate HL displacement (Step 1). An increase in HDL apoC-I, apoA-II, and/or loss of apoC-II, apoC-III may act to promote HL displacement from the liver (Step 2). High-affinity association of HL with HDL inhibits lipolytic activity [8, 9], and therefore the displaced circulating HL would be initially inactive. As VLDL and chylomicrons are degraded by LPL, remnant fatty acids and PL are transferred to HDL, which act to liberate HL and stimulate HL-mediated lipolysis (Step 3). HL can then return to its storage location in the liver. Chronic hypertriglyceridemia would be expected to give rise to alterations in HDL structure and block Steps 1 and 2, which would leave higher levels of cell-associated HL in the liver. Elevated post-heparin HL activities in hyperlipidemic patients are in fact a hallmark of perturbations in TG clearance and are directly associated with increased CHD risk [41].

**Acknowledgments** This work was supported by a grant from the Heart and Stroke Foundation of Canada. We would also like to thank Dr. A. Bensadoun and Dr. Y. Marcel for the monoclonal anti-HL and the anti-apoA-I antibodies, respectively.

**Abstract** A plant source of omega-3 fatty acid (FA) that can raise tissue eicosapentaenoic acid (EPA) and/or docosahexaenoic acid (DHA) is needed. A soybean oil (SBO) containing approximately 20% stearidonic acid [SDA; the delta-6 desaturase product of alpha-linolenic acid (ALA)] derived from genetically modified soybeans is under development. This study compared the effects of EPA to SDA-SBO on erythrocyte EPA + DHA levels (the omega-3 index). Overweight healthy volunteers ( $n = 45$ ) were randomized to SDA-SBO (24 ml/day providing  $\sim 3.7$  g SDA) or to regular SBO (control group) without or with EPA ethyl esters ( $\sim 1$  g/day) for 16 weeks. Serum lipids, blood pressure, heart rate, platelet function and safety laboratory tests were measured along with the omega-3 index. A per-protocol analysis was conducted on 33 subjects (11 per group). Compared to baseline, average omega-3 index levels increased 19.5% in the SDA group and 25.4% in the EPA group ( $p < 0.05$  for both, vs. control). DHA did not change in any group. Relative to EPA, SDA increased RBC EPA with about 17% efficiency. No other clinical endpoints were affected by SDA or EPA treatment (vs. control). In conclusion, SDA-enriched SBO significantly raised the omega-3 index. Since EPA supplementation has been shown to

raise the omega-3 index and to lower risk for cardiac events, SDA-SBO may be a viable plant-based alternative for providing meaningful intakes of cardioprotective omega-3 FAs.

### Introduction

Evidence from large clinical trials confirms that diets enriched with long-chain omega-3 (n-3) fatty acids (eicosapentaenoic acid, EPA, or C20:5n-3 and docosahexaenoic acid, DHA, or C22:6n-3) are advantageous to cardiovascular health [1]. Although most studies have been done with both EPA and DHA (provided as fish oils), the largest clinical trial with major coronary heart disease (CHD) endpoints, the Japan EPA lipid intervention study [2], was done with EPA alone and was shown to reduce the risk of these events by 19%. EPA supplementation raises membrane phospholipid EPA content, and elevated omega-3 fatty acid (FA) membrane levels alter cellular metabolism in a number of ways beneficial to cardiovascular health [3]; therefore, it is reasonable to conclude that raising tissue levels of EPA can reduce the risk for CHD. A new marker for tissue omega-3 content is the “omega-3 index,” which is the sum of EPA and DHA in erythrocyte membranes [4]. This metric has been shown to reflect human myocardial EPA and DHA content [5, 6], and has been proposed as a novel risk factor for death from CHD [7].

The American Heart Association has recommended that all adults strive to consume at least two servings of fish (preferably oily) per week to reduce the risk for CHD [8]. Western diets are typically low in EPA and DHA because

the primary source of these FAs is oily fish (such as salmon, mackerel, albacore tuna, and sardines), and consumption of these is minimal [9]. If such advice were actually heeded, there is serious doubt that the world's oceans could support such a shift in dietary consumption patterns [10]. Accordingly, a new and sustainable source of long-chain omega-3 FAs is needed. Currently, land-based sources of omega-3 FAs include flaxseed, canola, and soybean oils, which contain alpha-linolenic acid (C18:3n-3, ALA). ALA can be converted in vivo via desaturation and elongation pathways to EPA [11]. However, this conversion has a very low efficiency, converting somewhere between 0.01 and 8% of ALA to EPA and less to DHA [11, 12]. The rate-limiting step in the conversion of ALA to EPA is the delta-6 desaturase, and the product of this reaction is stearidonic acid (C18:4n-3, SDA). SDA is more readily converted to EPA than is ALA [13]. Hence, another strategy for raising tissue EPA levels with a plant-based omega-3 FA is to consume foods containing SDA. SDA is found in low concentrations (up to 4% w/w of total fatty acids) in fish oils (which also provide EPA and DHA), but also in some plant oils that are consumed as dietary supplements (e.g., echium). Recently, soybean plants have been genetically modified to produce oil containing a substantial amount of SDA (15–30% w/w of total fatty acids) [14]. This study was designed to test the hypothesis that increased SDA intake would favorably impact the omega-3 index.

## Subjects and Methods

### Study Participants

Healthy male or female adult volunteers between the ages of 21 and 70 with a body mass index (BMI) of 25–40 kg/m<sup>2</sup>, an initial omega-3 index of  $\leq 5\%$ , and with an average resting heart rate  $>69$  bpm were recruited. Individuals who were pregnant or lactating, current smokers, or had a history of significant cardiac, renal, hepatic, gastrointestinal, pulmonary, biliary or endocrine disorder, as well as any persons with diagnosed cancer, psychiatric disorders, diabetes mellitus, peripheral arterial disease, symptomatic coronary artery disease, a history of stroke or transient ischemic attack were excluded. Persons on specific medications or supplements that affected heart rate, blood pressure, serum lipids or platelet function were also excluded, as were those on weight-loss medications. Individuals taking dietary supplements that could alter tissue omega-3 fatty acids, such as fish oil, flaxseed or flaxseed oils, were excluded. Finally, persons with untreated hypertension, those who had taken any investigational agent in the prior 30 days and premenopausal females not on an effective birth control regimen were excluded.

### Design

This was a randomized, double-blind, placebo-controlled study, conducted between January and October 2007. Subjects were randomized into one of three treatment groups. The control group was given packets and capsules containing regular SBO; the EPA group was given regular SBO packets plus capsules of EPA ethyl esters ( $2 \times 500$  mg); the SDA group was given packets of SBO derived from plants genetically modified to produce SDA (SDA-SBO; 16.6% SDA) plus SBO capsules. The fatty acid composition of the test oils is given in Table 1. In addition to SDA, SDA-SBO also contains 5% gamma-linolenic acid (GLA, which is not found in regular SBO) and somewhat higher amounts of ALA. The oils were provided in single-use, tear-open packets, and subjects were instructed to keep their packets in the refrigerator at home. They were instructed to consume the contents of three 8-ml packets (total dispensed oil averaged 7.4 g/packet) daily by pouring them onto foods and to take two 500-mg capsules per day. The total daily intake of SDA was  $\sim 3.66$  g/day in the SDA group, and the intake of EPA was 0.98 g/day in the EPA group. ALA intake from the test oils was 1.7 g/day in the control and EPA groups, and 2.42 g/day in the SDA group. The study lasted for 16 weeks. All participants were instructed to maintain a

consistent lifestyle (diet, exercise, alcohol intake, sleep habits, etc.) and to avoid intake of fatty fish (including salmon, mackerel, albacore tuna, herring and sardines) for the duration of the study. Compliance with the treatment regimen was measured by counting unused oil packets and capsules. Non-compliance was defined as consumption of less than 80% of the experimental oils and/or capsules. The study was approved by the Copernicus Group Institutional Review Board, and all subjects gave informed consent prior to participation.

#### Laboratory Methods

The primary endpoint of the study was EPA + DHA as a percent of total red blood cell (RBC) FAs (the omega-3 index). Secondary endpoints were EPA, DHA and SDA alone (all as a percent of total RBC FAs), fasting lipids (cholesterol, triglycerides, LDL and HDL cholesterol), whole blood platelet aggregation, blood pressure and heart rate.

#### *Omega-3 Index*

Fasting venous blood samples were collected into ethylenediaminetetraacetic acid-containing vacutainer tubes. After centrifugation for 5 min at 10 g, plasma and buffy coats were removed, and an aliquot of the RBC pellet was stored at  $-80^{\circ}\text{C}$  until analyzed. RBC samples were thawed and placed in a reaction vial containing 14% boron trifluoride ( $\text{BF}_3$ ) in methanol (one part RBC to ten parts methanol) and heated at  $100^{\circ}\text{C}$  for 10 min. After cooling, hexane and distilled water (same volumes as  $\text{BF}_3$  methanol) were added, and the tube was shaken and centrifuged to separate layers. An aliquot of the hexane supernatant was analyzed by flame ionization gas chromatography using a GC2010 (Shimadzu Corporation, Columbia, MD) equipped with a 100-m capillary column (SP-2560, Supelco, Bellefonte, PA). FAs were identified and response factors adjusted (assuming palmitic acid = 1.0) using a standard FA mixture (GLC-727, Nuchek Prep, Elysian, MN). FAs are reported as a percent of total identified FAs in the RBC sample.

#### *Platelet Aggregation Analysis*

Fresh venous blood was collected into 3.8% (w/v) citrated vacutainer tubes and analyzed using a Chronolog 4 Channel Whole Blood Aggregometer (Model 590-4D) within 30–60 min as described by Riess et al. [15]. Whole blood was mixed 1:1 with isotonic saline, placed in a cuvette and stirred prior to the addition of agonists. Collagen (5  $\mu\text{g}$ ) or ADP (1  $\mu\text{g}$ ) was added to separate aliquots to stimulate aggregation. The change in impedance as platelets

adhered to the electrode was recorded over the subsequent 5–8 min, and the peak impedance was recorded.

#### *Lipid Analysis and Serum Chemistry*

Blood samples were collected after a 12-h fast into serum separator tubes and assayed for total cholesterol (C), high density lipoprotein (HDL)-C and low density lipoprotein (LDL)-C, and triacylglycerol using enzymatic methodologies in the clinical laboratory at Sanford USD Medical Center. Standard serum safety tests were performed at baseline and study end.

#### *Other Measurements*

Body weight was measured at each visit, and subjects who gained weight between visits were offered additional dietetic counseling to reinforce calorie substitution advice. Heart rate and blood pressure were measured at each study visit by averaging multiple values taken after the subjects had rested quietly for at least 5 min.

#### Statistical Analysis

Data were analyzed for both intention-to-treat (ITT) and per-protocol (PP) populations. The ITT analysis utilized the missing-at-random method to account for missing values. Analysis of covariance (ANCOVA) was used for each of the efficacy endpoints to examine the treatment effect after 16 weeks. This method takes into account group differences in baseline measurements and demographics (age, sex and BMI). ANCOVA results represent an estimate of what the mean values at the end of the study would have been if all groups had had the same baseline values and demographic profiles. To control type I error, Holm's step-down Bonferroni method was used to adjust *p*-values for comparisons among treatment groups. Fisher's exact test was used to test for differences between treatments for number of adverse events by body system category and by severity. For all analyses, a two-tailed *p*-value of  $<0.05$  was required for statistical significance.

#### Results

Of the 64 subjects who were screened and gave informed consent, 45 were enrolled and 33 completed the study. Reasons for early discontinuation are described below under "[Adverse events and safety](#)". The ITT analysis was conducted on all 45 subjects and the PP analysis on 33. As there were no differences between the two, only the PP efficacy results are presented. There were no significant differences between treatment groups at baseline with

**Table 2** Baseline characteristics for per-protocol subjects

respect to demographics or laboratory or clinical metrics (Tables 2, 3, 4).

### Omega-3 Index and Other RBC Fatty Acids

The omega-3 index was increased (relative to the control group) in the EPA ( $p = 0.026$ ) and the SDA ( $p = 0.042$ ) groups (Table 3). There was no difference between the omega-3 index in the EPA and SDA groups ( $p = 0.69$ ). The %EPA in RBCs was significantly increased by EPA ( $p < 0.0001$ ) and SDA ( $p = 0.0005$ ), relative to the control group, but there was no difference between the two omega-3 groups ( $p = 0.07$ ). There were no effects on DHA. SDA increased RBC EPA with about 17% of the efficacy of EPA, whereas the efficiency of the additional ALA provided in the control SBO group was about 0.1% (Table 5). Low endogenous levels of SDA were detected in RBCs in all treatment groups at baseline. The %SDA in RBCs was increased by SDA treatment ( $p = 0.0002$ ), but final levels remained less than 0.05%.

<sup>a</sup> Actual means, not ANCOVA estimates

the ITT population. There were no significant associations between the category or the severity of adverse events and treatments. Likewise, there were no clinically significant changes in laboratory safety tests (all adverse event and clinical laboratory safety data are provided in Tables 1, 2, 3 in the Online Supplement). Non-serious adverse events related to gastrointestinal distress (e.g., diarrhea, abdominal cramps) were evenly distributed across all three groups and contributed to early study discontinuation in four subjects. Other reasons for discontinuation from the study included abscess (1), acid reflux (1), throat swelling (1), fatigue (1), asthma exacerbation (1), mouth sores (1), use of excluded medication (1) and change in family circumstances (1).

## Discussion

SDA-enriched SBO significantly increased the omega-3 index in overweight subjects. On a mass basis, six parts of SDA raised RBC EPA levels to the same extent as one part of EPA. The efficiency of conversion (relative to EPA) of SDA in this study (about 17%) was less than the 27% seen by James et al. [16] when calculated based on changes in RBC EPA levels. This discrepancy may relate to the different chemical forms of SDA used (triglyceride vs. ethyl ester), the differences in study duration (16 vs. 6 weeks) or the types of subjects included (BMIs were 31 vs. 26 kg/m<sup>2</sup>). Although there were differences in background linoleic acid intakes (about 7% of total energy in James and about 10% in the present study, data not shown), this is not a likely explanation for the difference in response because linoleic acid would not be expected to impair the conversion of SDA to EPA like it would inhibit the more upstream conversion of ALA to SDA (by competing for delta-6-desaturase).

Based on the lack of any change in RBC EPA in the control group that received an additional 1.7 g of ALA per day, it is not possible to calculate a percent conversion

and can only estimate that, under these conditions, it would take over 1,000 parts of ALA to produce the same effect. The lack of change in RBC EPA in the control group in this study indicates that none of the rise in RBC EPA seen in the SDA group can be attributed to the ALA contained in the SDA-enriched SBO. The virtual lack of conversion of ALA to EPA seen in this study has been reported by others using different methods. Pawlosky et al. used stable isotope tracers and multi-compartmental modeling to track ALA conversion to EPA and reported a conversion of 0.2% [17]. On the other hand, Goyens and colleagues used a similar approach and found approximately 8% conversion [18]. Neither of these studies calculated conversion relative to that produced by EPA or based on RBC fatty acid pattern changes; hence, their results cannot be directly compared with the present study. Both of those studies did, however, confirm the fact that ALA conversion to EPA is significantly reduced by higher background dietary linoleic acid levels, presumably because these two essential fatty acids compete for the delta-6 desaturase [12].

Higher omega-3 indexes have been associated with a reduction in risk for sudden cardiac death both prospectively and cross-sectionally [19, 20], and the EPA and DHA content of RBC membranes is highly correlated with that of the human heart [5]. Further, there is evidence that a 1% change in the omega-3 index (e.g., from 4 to 5%) could have a significant impact on risk for sudden cardiac death [21]. Thus, if SDA consumption could materially raise RBC and heart EPA content, as suggested in this study, the impact is likely to be clinically significant.

Increasing the omega-3 index can be easily accomplished by eating oily fish species [22] or fish oil [4], but many populations around the world are not significant fish consumers (e.g. the USA and UK), and changing population taste preferences is typically difficult. In addition, over-fishing is depleting stocks of some species [10], intensifying the need for new sources. Thus, alternative, readily available dietary sources of omega-3 fatty acids are

needed. Currently available plant sources, such as soybean, canola and flax seed oils, contain ALA. Although epidemiological data support the hypothesis that ALA favorably affects heart health [23–25], few randomized trials with clinically important endpoints have been conducted with ALA. In those that have been done, clear conclusions have been difficult to reach, but overall consensus at this time is that ALA does not have a demonstrated benefit on cardiovascular disease outcomes [1, 26].

The western diet contains very little SDA, but there are natural sources, notably fish oils, which contain up to 4% SDA (w/w of total fatty acids) [14]. Oil derived from *Echium plantagineum*, a plant that grows wild in Australia, contains about 8–12% SDA [27]. Echium oil raised the EPA content of peripheral blood mononuclear cell phospholipids [28, 29], and, when fed at 15 g/day for 4 weeks, significantly increased EPA and DPA, but not DHA, in plasma and neutrophils in 11 hypertriglyceridemic humans [30]. In the same trial, echium was reported to lower serum triglyceride concentrations by 21%, but these findings need to be confirmed in randomized, blinded and placebo-controlled trials. Compared to canola or soybean oil, which are in large-scale commercial production and approved for human consumption, echium oil is very limited in abundance, and its use is currently limited to dietary supplements in the USA. Other minor sources of SDA are also limited in availability (e.g., evening primrose, borage and black currant seed oils). The genetically enhanced SBO used in this study contained about 17% SDA [14], but other cultivars can approach 30% and hence could provide a substantial amount of omega-3 fatty acids in the human diet.

The Japan EPA lipid intervention study (JELIS) provided strong evidence for cardioprotective effects of EPA alone [2]. In this randomized clinical trial, over 18,000 statin-treated patients were assigned to either 1.8 g of EPA ethyl esters/day in their diet or to usual care, and followed for major adverse cardiac events for 4.5 years. Although EPA treatment reduced overall risk by 19% ( $p = 0.01$ ), the interpretation and extrapolation of these results to the context of the western diets is complicated by the relatively high usual intake of EPA and DHA (about 1 g/day) in this Japanese population [31]. Median intakes of EPA and DHA in the USA are about 100–150 mg/day [3]. Nevertheless, the results of the JELIS trial indicate that increasing already high tissue levels of omega-3 FA with additional EPA confers additional protection against cardiovascular disease and that these benefits can be achieved in patients on statin therapy.

In conclusion, a marker of omega-3 biostatus, the omega-3 index, was increased by feeding SDA-enriched SBO for 16 weeks. The impact of dose and duration of SDA intake on the omega-3 index and the degree to which

such alterations in the omega-3 index affect risk for CHD and other chronic diseases need to be further defined.

**Acknowledgments** The authors express their appreciation to Karla Reilly, RN, for study coordination and to Andrew Christianson and Brenda Collison-Schmidt for the RBC analyses. In addition, we wish to thank our research volunteers, without whom this study would not have been possible. This study was funded by Monsanto Company.

**Abstract** Atlantic salmon (*Salmo salar*) (90 g) were fed four different diets for 21 weeks (final weight 344 g). The levels of n-3 highly unsaturated fatty acids (HUFA) ranged from 11% of the total fatty acids (FA) in the low n-3 diet to 21% in the intermediate n-3 diet, to 55 and 58% in the high n-3 diets. The high n-3 diets were enriched with either docosahexaenoic acid (DHA) or eicosapentaenoic acid (EPA). Increasing dietary levels of n-3 HUFA led to increasing percentages (from 31 to 52%) of these FA in liver lipids. The group fed the highest level of DHA had higher expressions of peroxisome proliferator-activated receptor (PPAR)  $\beta$  and the FA  $\beta$ -oxidation genes acyl-CoA oxidase (ACO) and carnitine palmitoyltransferase (CPT)-II, compared to the low n-3 groups. The high n-3 groups had reduced activity of mitochondrial cytochrome c oxidase and  $\beta$ -oxidation capacity, together with increased activities of superoxide dismutase (SOD) and caspase-3 activities. In the group fed the highest level of n-3 HUFA, decreased percentages of major phospholipids (PL) in the mitochondrial and microsomal membranes of the liver were also apparent. The percentage of mitochondrial cardiolipin (Ptd<sub>2</sub>Gro) was 3.1 in the highest n-3 group compared to 6.6 in the intermediate group. These data

clearly show an increased incidence of oxidative stress in the liver of fish fed the high n-3 diets.

## Abbreviations

ACO	Acyl-CoA oxidase
BSA	Bovine serum albumin
CoA	Coenzyme A
CPT	Carnitine palmitoyltransferase
DHA	Docosahexaenoic acid
DTT	Dithiothreitol
EDTA	Ethylene diamine tetra-acetic acid
EF1- $\alpha$ $\beta$	Elongation factor 1- $\alpha$ beta isoform
EGTA	Ethylene glycol tetra-acetic acid
EPA	Eicosapentaenoic acid
FA	Fatty acid
FAD	Flavin adenine dinucleotide
FBS	Fetal bovine serum
FO	Fish oil
HPTLC	High-performance thin-layer chromatography
HUFA	Highly unsaturated fatty acid
L-15	Leibowitz-15 medium
NAD	Nicotinamide adenine dinucleotide
PBS	Phosphate-buffered saline
PL	Phospholipid
PPAR	Peroxisome proliferator-activated receptor
PtdCho	Phosphatidyl-choline
PtdEtn	Phosphatidyl-ethanolamine
Ptd <sub>2</sub> Gro	Cardiolipin
PtdIns	Phosphatidyl-inositol
RO	Rapeseed oil
ROS	Reactive oxygen species

## Introduction

Atlantic salmon (*Salmo salar*) have traditionally been fed diets rich in fish oil (FO) containing relatively high levels of the essential highly unsaturated fatty acids (HUFA) eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). Dietary n-3 HUFA play a prominent role in fish nutrition, providing essential FA that are vital constituents of cell membranes, being necessary for the normal membrane structure and function [1]. However, recent trends in the fish industry include replacing these FO in the diet by more available vegetable oils, having lower n-3 HUFA levels. This change in dietary regimes has resulted in a major research focus on how this reduction in the essential FA affect FA metabolism. The tissues capacity of  $\beta$ -oxidation may be affected by changes in dietary FA, as demonstrated by decreased liver  $\beta$ -oxidation capacity when salmon were fed dietary vegetable oils [2–4]. In addition, both high dietary EPA and an increase in the n-3/n-6 ratio of FA in the diet induce mitochondrial proliferation [5–8]. Furthermore, Jordal et al. [9] found that dietary rapeseed oil (RO), which has a lower level of n-3 HUFA, induced a significant down-regulation of several mitochondrial genes in Atlantic salmon liver. In addition, salmonids fed a diet scarce in n-3 FA generally have higher activities of  $\Delta$ 5- and  $\Delta$ 6-desaturases than fish fed an n-3 FA rich diet [10–13]. They also express higher mRNA levels of the gene for  $\Delta$ 5-desaturase [9, 14].

There has been much focus on the effects of reduced levels of n-3 HUFA, however, less is known about the effects of n-3 HUFA levels above those normally obtained when salmon are fed commercial cod liver oil diets. The South American FO for instance, is generally a rich source of these n-3 HUFA. The HUFA are highly susceptible to peroxidation due to their high number of double bonds [15]. Peroxidation products may influence the HUFA in membrane phospholipids (PL), and thereby impair cell and organelle membrane structure and functions [1]. HUFA taken into the body are mostly delivered to liver cells in mammals [16]. The liver is thus one of the principal targets of HUFA peroxidative effects. Lipid peroxidation generally results in a decrease in membrane fluidity, an increase in the permeability of the membrane, and inactivation of membrane-bound enzymes [17, 18]. These effects can eventually lead to a complete loss of membrane integrity and cause apoptosis. The proteins cytochrome c and cytochrome c oxidase located in the mitochondrial membrane of healthy mammalian cells, function in the

respiratory chain interacting with the membrane PL cardiolipin (Ptd<sub>2</sub>Gro) [19]. Decline in cytochrome c oxidase activity can be ascribed to a loss in Ptd<sub>2</sub>Gro content [20]. Further, both cytochrome c and Ptd<sub>2</sub>Gro decrease in mitochondria has been shown as an initial step in the pathway of apoptosis in mammals [21, 22]. Whether these mechanisms are the same in fish or not remains to be studied.

The present study had two primary goals; firstly to study how the mitochondrial and peroxisomal FA  $\beta$ -oxidation and its regulatory genes were affected by increasing levels of n-3 HUFA in the diet. Secondly to determine whether increasing dietary levels of n-3 HUFA affect the composition of membrane PL—both in cells and their organelles, cell morphology, intracellular oxidative stress and apoptosis.

## Materials and Methods

### Materials

Metacain (MS-222) was obtained from Norsk Medisinaldepot (Oslo, Norway). The radioactive isotope [1-<sup>14</sup>C]-palmitoyl coenzyme A, (40–60 mCi/mmol) was obtained from American Radiolabeled Chemicals, Inc. (St. Louis, MO, USA). Sodium chloride, sulfuric acid, perchloric acid, diethyl ether, methyl acetate, hexane, copper acetate, phosphoric acid and benzene were purchased from Merck (Darmstadt, Germany). Ethylene glycol tetra-acetic acid (EGTA) was bought from AppliChem (Darmstadt, Germany). Cell flasks and cell scrapers were obtained from Nalge Nunc International (Rochester, NY, USA). Glutaraldehyde, Epon resin, copper grids, uranyl acetate, osmium tetroxide, sodium cacodylate and lead citrate were supplied by Electron Microscopy Science (Fort Washington, PA, USA). RNeasy Mini Kit and QIAshredder columns were purchased from Qiagen (Valencia, CA, USA). The TaqMan<sup>®</sup> Gold RT-PCR kit and the ABI Prism 7000 sequence detection system were bought from Applied Biosystems (Foster City, CA, USA). Insta gel II plus was obtained from Packard Instruments (Downers Grove, IL, USA). Chloroform, methanol and acetic acid were obtained from VWR International (West Chester, PA, USA). Total protein kit, cytochrome c oxidase (EC 1.9.3.1) assay kit, acid phosphatase (EC 3.1.3.2) assay kit, Leibowitz-15 medium (L-15), phosphate-buffered saline (PBS), fetal bovine serum (FBS), bovine serum albumin (BSA), sucrose, ethylene diamine tetra-acetic acid (EDTA), antibiotics, HEPES, L-glutamine, collagenase type 1 (EC 3.4.24.3), trypsin, sodium bicarbonate solution, trypan blue, laminin, potassium ferrocyanide, NaOH, nicotinamide adenine dinucleotide (NAD), dithiothreitol (DTT), flavin adenine dinucleotide (FAD), Triton-X 100, L-Carnitine, Coenzyme

A (CoA), Imidazole buffer, Palmitoyl CoA, Tris base, Peroxidase type II (EC 1.11.1.7), HCl, 2,2-dimethoxypropane, 2',7'-dichlorofluorescein and silica gel 60 glass-backed TLC plates were all supplied by Sigma-Aldrich (St. Louis, MO, USA). Primers for the real-time PCR analysis were ordered from Invitrogen Ltd (Paisley, UK). The superoxide dismutase (SOD, EC 1.15.1.1) assay kit was purchased from Cayman Chemicals (Ann Arbor, MI, USA) and the Caspase-3 (EC 3.4.22.56) colorimetric assay kit was from R&D Systems, Inc. (Minneapolis, MN, USA). Hydrogen peroxide and titanium oxysulfate were obtained from Riedel-de Haën (Seelze, Germany). *O*-Nitrophenyl acetate was purchased from MP Biomedicals (Solon, OH, USA). Ethanol and isopropanol were obtained from Arcus (Oslo, Norway). 2',7'-dichlorofluorescein was bought from Eastman Kodak Company (Rochester, NY, USA).

### Feeding Trial and Sampling

The feeding trial was carried out at Nofima's research station, Sunndalsøra, Norway. Four diets with approximately 50% (of dry matter, by weight) crude protein and 23% (of dry matter, by weight) crude lipid contained 13.5% (g/100 g feed) oils with increasing levels of n-3 HUFA (Table 1). The diets contained 11, 21, 55 and 58% n-3 HUFA (of total FA), and they were named low n-3 diet, intermediate n-3 diet, high n-3 DHA diet and high n-3 EPA diet, respectively. The high n-3 EPA diet and high n-3

DHA diet were both characterized by high percentages of n-3 HUFA and low percentages of n-6 FA (Table 2). In contrast, the low n-3 diet contained almost four times more n-6 FA than the intermediate n-3 diet, and 2.5 times more n-6 FA than the high n-3 EPA and high n-3 DHA diets. Four groups of post-smolt Atlantic salmon (*Salmo salar*), with an initial average weight of 90 g were distributed into three cylinder-conical tanks (flow through system, 0.85 m diameter) per diet, and fed one of the four diets for 21 weeks. The fish were not fasted prior to the final sampling. The average fish weight was 344 g at the end of the growth period, with no significant differences in the growth (total weight) between the dietary groups.

### Isolation of Hepatocytes

Five fish per diet (randomly taken from the three tanks) were used for the isolation of hepatocytes at the end of the growth period. The fish were anaesthetized with metacain (MS-222) and their individual weights and lengths determined. The abdominal cavity was exposed and the vena portae cannulated. The liver was perfused following a two-step collagenase procedure developed by Seglen [23] and modified by Dannevig and Berg [24], in order to isolate hepatocytes. The hepatocytes were isolated after collagenase digestion by gentle shaking of the digested liver in L-15 medium. The suspension of parenchymal cells was filtered through a 100 µm mesh nylon filter. Hepatocytes

were washed three times in L-15 medium and sedimented by spinning for 2 min at 50×g. The hepatocytes were resuspended in L-15 culture medium containing 10% FBS, 1% bicarbonate, 1% L-glutamine, 1% penicillin-streptomycin solution and 5 mM HEPES. Cell viability was assessed by staining with Trypan Blue (0.4%). Approximately  $1 \times 10^7$  hepatocytes were plated onto 25 cm<sup>2</sup> cell flasks coated with laminin, and left to attach overnight at 12 °C. Two hepatocyte flasks per fish were used for transmission electron microscopy and one flask for the isolation of RNA.

#### Preparation of Hepatocytes for Transmission Electron Microscopy

The cells were washed in PBS and harvested in 1.5 ml of fixative solution (2% glutaraldehyde in 0.1 M cacodylate buffer, pH = 7.4). Then, the cells were washed twice in 0.1 M cacodylate buffer, and post-fixed for 1 h in 0.1 M

cacodylate buffer containing 2% osmium tetroxide and 1.5% potassium ferrocyanide. The specimens were stained for 30 min in 1.5% uranyl acetate, dehydrated in a series of ethanol solutions (70, 90, 96 and 100%), and embedded in epon resin. The resin was polymerized at 60 °C for at least 12 h. Ultra-thin sections were prepared and stained with lead citrate. EM specimens were examined using a Philips CM100 transmission electron microscope (80 V) (FEI, Acht, The Netherlands).

#### Liver Homogenization

A further three fish per diet (one from each tank) were used for liver homogenization. The fish were anaesthetized with metacain (MS-222) and their weights and lengths determined. They were killed by a blow to the head, and the livers were dissected out and weighed. The hepato-somatic indexes (HSI: liver weight/body weight × 100) were  $1.00 \pm 0.11$ ,  $1.06 \pm 0.08$ ,  $0.88 \pm 0.04$  and  $0.88 \pm 0.03$

for low n-3, intermediate n-3, high n-3 DHA and high n-3 EPA dietary groups, respectively, with no significant differences between the groups. The tissue was homogenized in a sucrose buffer (0.25 mM sucrose, 15 mM HEPES, 1 mM EDTA and 1 mM EGTA) by using a glass Dounce homogenizer powered by a drill.

#### Analysis of Fatty Acid Composition

Liver homogenate from three fish in each dietary group (one from each tank) was used for the analysis of FA composition. The total FA profiles in the diets (Table 2) and the livers (Table 4) were determined. Lipids were extracted using the Folch method [25]. The chloroform phase was dried under N<sub>2</sub> and the residual lipid extract was redissolved in benzene, and then transmethylated overnight with 2,2-dimethoxypropane and methanolic HCl at room temperature, as described by Mason and Waller [26] and by Hoshi et al. [27]. The methyl esters of FA thus formed were separated in a gas chromatograph (Hewlett Packard 6890) with a split injector, SGE BPX70 capillary column (length 60 m, internal diameter 0.25 mm and thickness of the film 0.25 µm) flame ionization detector and the results analysed using HP Chem Station software. The carrier gas was helium. The injector and detector temperatures were 280 °C. The oven temperature was raised from 50 °C to 180 °C at the rate of 10 °C/min, and then raised to 240 °C at the rate of 0.7 °C/min. The relative quantity of each FA present was determined by measuring the area under the peak corresponding to that FA.

#### Lipid Class Analysis

The lipid class compositions in different liver fractions (total homogenate, mitochondria and microsomes) were quantified using high-performance thin-layer chromatography (HPTLC). Ten microgram total lipid was applied using an automatic sample applicator (ATS4, CAMAG, Muttenz, Switzerland) onto a 10 × 20 cm HPTLC plate that had been pre-run in hexane/diethyl ether (1:1, by vol.) and activated at 110 °C for 30 min. The plates were developed for the first 5.5 cm in methyl acetate/isopropanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol.) to separate PL classes with neutral lipids running at the solvent front [28] using an automatic developing chamber (AMD2, CAMAG, Muttenz, Switzerland). After drying, the plates were developed fully in hexane/diethyl ether/acetic acid (80:20:2, by vol.) to separate neutral lipids and cholesterol. Lipid classes were visualized by charring at 160 °C for 15 min after dipping the plate into a glass tank with 3% copper acetate (w/v) in 8% (v/v) phosphoric acid. The lipid classes were identified by comparison with commercially available standards, and quantified by scanning

densitometry using a CAMAG TLC Scanner 3. Scan lines were analysed using an integrator (WinCATS-Planar Chromatography, Version 1.3.3). Further, the weight of each lipid class per gram of tissue was determined by establishing standard equations for each lipid class within a linear area, and a standard mix of all the lipid classes was included on each HPTLC plate to correct for between plate variations.

#### Subcellular Fractionation

Subcellular fractions were separated by differential centrifugation first described by de Duve [29]. The homogenate was centrifuged at 1,000×g for 10 min to separate out the nuclear fraction. The pelleted nucleus was re-homogenized in 1 ml of homogenization buffer. Mitochondria and peroxisomes were then isolated by two differential centrifugation steps for 10 min at 2,000×g and 25,000×g, respectively, in a fixed-angle rotor 70-Ti (Beckman). Each mitochondrial and peroxisomal pellet recovered was resuspended in 1.5 and 1 ml of the buffer, respectively. The remaining supernatant was the microsomal fraction. The different organelles in the fractions were identified by measuring the activities of subcellular marker enzymes in the diluted pellets and supernatant.

The presence of mitochondria was assessed by a Sigma kit based on the method of Storrie and Madden [30]. The amounts of mitochondria were determined by measuring the activity of cytochrome c oxidase. Total cytochrome c oxidase activity was measured by observing the decrease in absorbance at 550 nm of Fe<sup>2+</sup>-cytochrome c caused by its oxidation to Fe<sup>3+</sup>-cytochrome c by cytochrome c oxidase in mitochondria (measured at room temperature for 3 min). Further, the cytochrome c oxidase assay allowed us to measure the integrity of the outer mitochondrial membrane, by measuring the cytochrome c oxidase activity in the presence and in the absence of the detergent *n*-dodecyl β-D-maltoside. This detergent allows the maintenance of the cytochrome c oxidase dimer in solution. Absorbance was measured in a GBC UV/VIS 918 spectrophotometer (GBC Scientific Equipment, Victoria, Australia).

The presence of peroxisomes was assessed by the activity of catalase (EC 1.11.1.6), using a method based on that of Baudhuin et al. [31]. The substrate hydrogen peroxide, produced in peroxisomes, is broken down by catalase to oxygen and water. This reaction is stopped by the addition of a saturated solution (0.45%) of titanium oxysulfate in 2 N sulfuric acid. Titanium oxysulfate reacts with the amount of hydrogen peroxide that remains to give a yellow solution of peroxy titanium sulfate. The amount of the product was measured spectrophotometrically at 405 nm in a Victor 3 1420 Multilabel counter spectrophotometer (PerkinElmer, CT, USA).

Acid phosphatase is an acid hydrolase that normally resides in lysosomes. This enzyme was assayed as described by Bergmeyer [32], using an acid phosphatase assay kit to identify the lysosomes. The measurement was based on the hydrolysis of 4-nitrophenyl phosphate by acid phosphatase. The samples were mixed with 4-nitrophenyl phosphate and citrate buffer solution (0.09 M, pH 4.8), and incubated for 20 min at room temperature. The reaction was stopped by NaOH (0.5 N). The color formed was measured spectrophotometrically at 405 nm in a Victor 3 1420 Multilabel counter spectrophotometer (PerkinElmer, CT, USA).

Esterase (EC 3.1.1.1) was first assayed by Beaufay et al. [33]. Esterase is a marker enzyme for microsomes, and catalyzes the production of *o*-nitrophenol from *o*-nitrophenyl acetate. To 2.7 ml of medium containing 20 mM potassium phosphate buffer (pH 7.4), 1 mM EDTA, 0.1% Triton X-100 and 0.25 ml of sample were added. The changes in absorbance were measured at 420 nm for 3 min in a GBC UV/VIS 918 spectrophotometer (GBC Scientific Equipment, VIC, Australia).

#### Beta-Oxidation Assay

Mitochondrial  $\beta$ -oxidation was measured in freshly isolated mitochondria by the method of Lazarow [34]. This assay determines the amounts of acid-soluble products in mitochondrial fractions. Acid-insoluble  $^{14}\text{C}$ -palmitoyl-CoA is converted to acid soluble  $^{14}\text{C}$ -acetyl-CoA. Incubation media contained 50 mM Tris-HCl (pH 8.0), 20 mM NAD, 0.33 M DTT, 1.5% BSA, 10 mM CoA, 1 mM FAD, 5 mM palmitoyl-CoA and  $^{14}\text{C}$ -palmitoyl-CoA (60 Ci/mol, 20  $\mu\text{Ci/ml}$ ), 0.25 M sucrose and 1 mM L-carnitine. The samples were incubated for 30 min at room temperature. Reactions were stopped by adding ice-cold 6% perchloric acid. A zero-time control was used in which perchloric acid was added to the reaction mixture before the addition of organelle. This control established the acid stability of  $^{14}\text{C}$ -palmitoyl-CoA, as virtually all unchanged substrate was precipitated by acid. The radioactivity in 500  $\mu\text{l}$  of the supernatant was determined by liquid scintillation spectrometry.

#### Acyl-CoA Oxidase Assay

Acyl-CoA oxidase (ACO, EC 1.3.3.6) activity was assayed in peroxisomes by determining the rate at which hydrogen peroxide was produced, coupled to the oxidation of 2',7'-dichlorofluorescein, essentially as described by Small et al. [35]. The oxidation of 2',7'-dichlorofluorescein by hydrogen peroxide to 2',7'-dichlorofluorescein was followed spectrophotometrically at 502 nm in a GBC UV/VIS 918 spectrophotometer (GBC Scientific Equipment). The reac-

tion mixture contained 0.1 M Tris-HCl (pH 8.5), 0.05 M 2',7'-dichlorofluorescein, 50  $\mu\text{M}$  horseradish peroxidase type II, 0.015 mM FAD, 60 mg/ml BSA and 0.02% Triton-X 100, and was started with 60  $\mu\text{M}$  palmitoyl-CoA. All concentrations are given as final values. The reaction mixture contained 30–85  $\mu\text{g}$  of protein in a total volume of 1 ml at 20 °C. The ACO activity was calculated as total activity per gram liver.

#### Protein Measurements

Protein concentrations were determined using a total protein kit (Micro Lowry/Peterson's modification) based on the method of Lowry [36] and modified by Peterson [37]. Standards (BSA) were prepared by diluting 400  $\mu\text{g/ml}$  of BSA in water. Sodium chloride (final concentration of 0.1 M) was added in order to reduce ampholyte interference. Proteins were precipitated by adding 0.1% trichloroacetic acid in the presence of 0.15% deoxycholate. Color was measured at 500 nm in a Wallac 1420 VICTOR<sup>3</sup>™ Multi-label counter spectrophotometer (PerkinElmer, CT, USA).

#### Superoxide Dismutase Assay

The SOD catalyzes the reduction of superoxide to oxygen and hydrogen peroxide. A cell that has a high level of SOD has probably increased production of this enzyme in order to deal with high levels of superoxide. The kit uses a tetrazolium salt to detect superoxide radicals generated by xantine oxidase and hypoxanthine. One unit of SOD is defined as the amount of enzyme needed to achieve 50% dismutation of the superoxide radical. Color was measured at 405 nm in a Titertek Multiskan PLUS MKII (Labsystems, Helsinki, Finland) plate reader.

#### Caspase-3 Assay

Caspases are a group of cysteine proteases that exist as proenzymes, becoming activated during the cascade of events associated with apoptosis. The caspase-3 colorimetric assay kit detects the increased enzymatic activities of the caspase-3 classes of proteases in apoptotic cells by a colorimetric reaction. Cells are first lysed to release their intracellular contents. The cell lysate can then be tested for protease activity by the addition of a caspase-specific peptide that conjugates to a color reporter molecule, *p*-nitroaniline. The cleavage of the peptide by the caspase releases the chromophore *p*-nitroaniline, which can be quantified spectrophotometrically. Color was measured at 405 nm in a Titertek Multiskan PLUS MKII (Labsystems, Helsinki, Finland) plate reader.

## RNA Isolation

Total RNA was isolated from hepatocytes from three fish in each dietary group using an RNeasy<sup>®</sup> Mini Kit. Samples were first lysed in RNeasy lysis buffer and then homogenized using QIAshredder columns. Ethanol was added to the lysate to provide ideal binding conditions. The lysate was then loaded onto the RNeasy silica-gel membrane. The RNA bound to the membrane, while all contaminants were efficiently washed away. Pure, concentrated RNA was eluted in water. Residual amounts of remaining DNA were removed using an RNase-Free DNase set during the RNeasy procedure. The total RNA concentrations were determined by spectrophotometry.

## Sequence Information, Primer Design and Real-Time PCR

The designs of the PCR primers and TaqManMGB probes were based on published sequences from Atlantic salmon or comparative species. The forward and reverse primers and probes are listed in Table 3. RT-PCR efficiency was monitored using two-fold dilution curves of RNA. Four concentrations were used for the two-fold dilution curve (starting at 250 ng total RNA). For analysis of gene expression (separate 96 well plates) three parallels were used at a total RNA concentration of 125 ng ( $\pm$  5%). The following conditions were used for the amplification of cDNA: 2 min at 50 °C, followed by denaturation for 10 min at 95 °C, followed by 50 cycles of 15 s at 95 °C and finally 1 min at the annealing temperature listed in Table 3. Thermal cycling and fluorescence detection was done using an ABI Prism 7000 sequence detection system.

## Data Analysis and Statistical Analysis of Gene Expression Data

Each assay was tested on different samples from the same plate to determine how reproducible the results were. QGene was used to normalize and calculate relative expression data [38]. QGene takes into account the PCR efficacy, calculated on the basis of two-fold dilution curves, and obtains, in this way, normalized expression data. The gene expression levels were normalized against a reference gene. Two different reference genes,  $\beta$ -actin and elongation factor 1-alpha beta isoform (EF1- $\alpha\beta$ ) [39], were measured for all dietary treatments. Results based on the use of  $\beta$ -actin as reference gene had a higher variation between replicates of hepatocytes, and thus EF1- $\alpha\beta$  was used for the final calculations of relative gene expression in hepatocytes. Gene expressions from fish in the intermediate n-3 dietary group were set to 1, and the expression of each target gene for the experimental groups low n-3, high n-3

EPA and high n-3 DHA was expressed relative to this. Significant differences ( $P \leq 0.05$ ) in normalized gene expression levels between dietary treatments were detected by one-way analysis of variance (ANOVA) (Statistica, version 6.1; Statsoft, Tulsa, USA).

## Statistical Analysis

All data, except for gene expression data, were subjected to one-way ANOVA for the factor “diet”, and differences were ranked by Duncan’s multiple range test. We used the software package UNISTAT (London, England). The significance level was set to  $P \leq 0.05$ .

## Results

### Fatty Acid Composition

The percentages of n-3 HUFA in the fish livers increased with increasing level of n-3 HUFA in the diet, while the percentages of n-6 FA decreased (Table 4). The main contributor to n-3 FA in the intermediate n-3 and high n-3 DHA dietary groups was 22:6n-3, while 20:5n-3 and 22:5n-3 also contributed in the high n-3 EPA dietary group. In contrast, the livers from fish fed the low n-3 diet contained more than twice as much n-6 FA as those from the other three dietary groups, with 18:2n-6 being the dominating n-6 FA. In addition, the low n-3 group contained approximately 20% 18:1n-9, whereas the intermediate n-3, high n-3 EPA and high n-3 DHA dietary groups all contained less than 8% of this FA. The percentage of 22:6n-3 in the liver lipids was the same in fish fed the low n-3 diet as in the fish fed the high n-3 EPA diet, despite a threefold higher 22:6n-3 level in the latter diet. The percentage of the elongation product 22:5n-3 was significantly higher in livers from the high n-3 EPA group.

### Lipid Classes

There were between 33 and 53% polar lipids in the total liver homogenate, and between 47 and 66% neutral lipids (Table 5). TAG was the major lipid class followed by phosphatidyl-choline (PtdCho) and then cholesterol and phosphatidyl-ethanolamine (PtdEtn) in the total liver homogenate. The fraction of polar lipids was significantly lower in the high n-3 EPA group than in the other groups, and the fraction of neutral lipids higher. Ptd<sub>2</sub>Gro was present almost exclusively in mitochondria. Fish from the high n-3 EPA dietary group contained less Ptd<sub>2</sub>Gro than fish from the intermediate n-3 group. The amount of PtdCho in microsomes was slightly higher than in the mitochondria. Phosphatidyl-inositol (PtdIns) was present in

all tissue fractions, but the highest percentage was found in microsomes.

#### Fatty Acid $\beta$ -Oxidation

The  $\beta$ -oxidation capacity in the high n-3 EPA and high n-3 DHA dietary groups were significantly lower than the capacity in the intermediate n-3 and low n-3 dietary groups (Fig. 1). There were no significant differences between the intermediate n-3 and the low n-3 groups. There were no significant differences in the total liver ACO activity between the dietary groups. However, a tendency toward higher ACO activity in the high n-3 DHA group was evident (Fig. 2).

#### Gene Expression

The relative expressions of genes involved in lipid metabolism are shown in Fig. 3. Fish fed the low n-3 diet had significantly higher expression of both  $\Delta 5$ -desaturase and  $\Delta 6$ -desaturase genes than fish fed the high n-3 DHA diet. The relative expressions of genes involved in peroxisomal  $\beta$ -oxidation (ACO), mitochondrial  $\beta$ -oxidation [carnitine palmitoyltransferase (CPT) II, acyl-CoA dehydrogenase

(ACAD)] and the transcription factor PPAR $\beta$  were all up-regulated in livers from fish fed the high n-3 DHA diet. These genes showed the lowest expression levels in livers from fish fed the lowest n-3 HUFA diet.

#### Oxidative Stress Markers

Cytochrome c oxidase measurements showed that its activity was greatly reduced in the mitochondrial membranes, by a factor of 2–3, in the high n-3 EPA and high n-3 DHA dietary groups than in the group with the lowest level of n-3 HUFA (Fig. 4). Caspase-3 activity, an apoptosis marker, was also significantly different between the dietary groups (Fig. 5a). Caspase activity was significantly higher in the high n-3 EPA group than in all other groups, increasing by 100–200%. The activity of SOD, as well, was significantly different between the dietary groups (Fig. 5b). The activities were lowest in fish fed low n-3 and intermediate n-3 diets, and significantly higher in fish from the two high n-3 groups. EM pictures of representative cells from the low n-3 HUFA dietary group (6a), and the high n-3 EPA group (6b) are shown in Fig. 6. Cells from fish given high n-3 EPA diet had an abnormal morphology. The nuclear chromatin in these

The lipid class composition was measured in total homogenate, microsomes and mitochondria in liver from fish fed four different diets. The quantity of each lipid class is given as the percentage of total lipids. The values given are means ± SEM ( $n = 3$ ). Different letters indicate significant differences ( $P \leq 0.05$ ) between the different dietary treatments within each lipid class, within each fraction

LPC lyso-phosphatidyl-choline, SM sphingomyelin, PtdCho phosphatidyl-choline, PtdSer phosphatidyl-serine, PtdIns phosphatidyl-inositol, Ptd<sub>2</sub>Gro cardiolipin, PtdEm phosphatidyl-ethanolamine, DAG diacylglycerol, CHOL cholesterol, FFA free fatty acids, TAG triacylglycerol, PL polar lipids, NL neutral lipids

**Fig. 1** Mitochondrial  $\beta$ -oxidation activity.  $\beta$ -oxidation was measured in the mitochondrial fraction. Data are means  $\pm$  SEM ( $n = 3$ ). Different letters indicate significant differences ( $P \leq 0.05$ )

**Fig. 2** ACO enzyme activity. ACO activity was measured in the peroxisomal fractions, and is displayed here as the total activity per gram liver tissue. Data are means  $\pm$  SEM ( $n = 3$ ). Different letters indicate significant differences ( $P \leq 0.05$ )

cells was condensed, and the cellular contents seemed to be released.

## Discussion

Feeding Atlantic salmon diets having major differences in the n-3 HUFA content affected the FA composition of the liver. N-3 HUFA in the liver increased with increasing dietary level of these FA. However, even though the level of 22:6n-3 in the low n-3 diet was less than half of the 22:6n-3 level in the high n-3 EPA diet, the percentages of 22:6n-3 recovered in the liver lipids were the same in these two dietary groups. One explanation for this relatively low percentage of 22:6n-3 recovered in liver of fish

fed the high n-3 EPA diet may be explained by a lower capacity to produce 22:6n-3 than in those fed a diet with low levels of n-3 HUFA. In addition, the livers of the fish fed the high n-3 EPA diet had significantly higher percentages of 22:5n-3, indicating that the further conversion of 22:5n-3 to 22:6n-3, which involves a  $\Delta 6$ -desaturation step, is inhibited. These findings are further supported by the lower expression of genes for both  $\Delta 5$ -desaturase and  $\Delta 6$ -desaturase in the liver tissue from fish fed the two high-level n-3 HUFA diets. It has previously been shown that Atlantic salmon fed diets containing plant oils have significantly higher desaturation enzyme activity [10–13] and higher expressions of hepatic  $\Delta 5$ -desaturase and  $\Delta 6$ -desaturase genes than those fed FO diets [9, 14]. An alternative explanation to the relatively high 22:6n-3 level in the tissue of fish fed low n-3 diet could be selective utilization of shorter chain, less unsaturated FA, and a more highly conservation of 22:6n-3 in the liver PL of fish fed low n-3 HUFA levels. This is in agreement with what was found in fish fed an essential FA free diet [40]. We have recently shown that feeding salmon diets rich in EPA increases the number of mitochondria in the liver [8]. We know that the shorter chained FA are mainly oxidized within mitochondria [41], and that the longer chained FA, like 22:6n-3, are very poor substrates for mitochondrial FA  $\beta$ -oxidation [42]. The finding that several mitochondrial and peroxisomal genes, involved in FA  $\beta$ -oxidation, were up-regulated in fish fed high levels of dietary 22:6n-3 may then support the last explanation. An unexpected result was therefore that the mitochondrial  $\beta$ -oxidation capacities were dramatically lower in isolated liver mitochondria from fish fed the diets with the high levels of n-3 HUFA, than they were in liver mitochondria from fish fed low n-3 and intermediate n-3 diets. Though not well studied in fish, the mitochondrial membrane is found to be a very sensitive target for lipid peroxidation in mammals [43]. The low FA  $\beta$ -oxidation capacity in our study, seen in livers of fish fed the high n-3 HUFA diets may be the result of an extensive lipid peroxidation of the mitochondrial membranes. This assumption is further supported by the loss of cytochrome c oxidase activity and mitochondrial membrane PL found in livers of fish fed high levels on n-3 HUFA. The higher SOD levels found in both high n-3 EPA and high n-3 DHA dietary groups compared to the two groups with lower level of n-3 HUFA further support the theory that the mitochondrial function has been damaged due to oxidative stress. The decreased percentages of PL, especially Ptd<sub>2</sub>Gro, in the high n-3 EPA mitochondrial membranes may also be consistent with a higher level of apoptosis in this group. It has been suggested in mammalian studies that Ptd<sub>2</sub>Gro is required for the activity of cytochrome c oxidase [19], and that the Ptd<sub>2</sub>Gro content in mitochondria decreases during

**Fig. 3** Relative gene expressions of lipid-related genes. **3a** Gene expressions were measured using isolated mRNA from hepatocytes. Genes involved in gene regulation (PPARs), peroxisomal  $\beta$ -oxidation (ACO) and mitochondrial  $\beta$ -oxidation (ACAD, CPTI, CPTII) were measured. **3b**  $\Delta 6$ -desaturase and  $\Delta 5$ -desaturase activity. Data are presented as means  $\pm$  SD ( $n = 3$ ). Different letters indicate

significant differences between dietary groups within each gene. Significance level is set at  $P \leq 0.05$ . PPAR peroxisome proliferator-activated receptor, ACO acyl-CoA oxidase, ACAD acyl-CoA dehydrogenase, CPT I, II carnitine palmitoyltransferase I, II, D6D delta 6 desaturase, D5D delta 5 desaturase

**Fig. 4** Cytochrome c oxidase activity. The activity of cytochrome c oxidase was measured in mitochondrial fractions with and without dodecyl. The difference in activity between preparations with and without dodecyl measured in the low n-3 HUFA group was set to 1, and the differences in the other dietary groups are expressed relative to this. Data are means  $\pm$  SEM ( $n = 3$ ). Different letters indicate significant differences ( $P \leq 0.05$ )

**Fig. 5** Enzyme activities. Caspase-3 (5a) and SOD (5b) activity was measured in total homogenates. Data are means  $\pm$  SEM ( $n = 3$ ). Different letters indicate significant differences ( $P \leq 0.05$ )

apoptosis [44]. Oxidative stress in mitochondria is known to mediate the apoptotic signalling pathway in mammals [45], and caspases, in particular caspase-3, play a central role. The activity of caspase-3 increased in the high n-3 EPA dietary group. These results are further confirmed by our EM pictures showing abnormal morphology of hepatocytes from fish fed the high n-3 EPA diet. Nuclear chromatin was more highly condensed in these cells, and cellular contents were released [46]. Although not studied in such detail, similar results were found in grass carp (*Ctenopharyngodon idella*), which show decreased growth performance, increased blood lipid peroxidation, altered lipoprotein synthesis and impaired FA  $\beta$ -oxidation capacity when fed a diet with high lipid level, especially high HUFA levels [47, 48]. These results led us to yet another possible explanation for the lower level of 22:6n-3 found in the high n-3 EPA dietary group relative to the level found in the low n-3 HUFA group. The cause could be increased breakdown of 22:6n-3 due to peroxidation.

**Fig. 6** Electron micrographs of hepatocytes. The images shown are representative cells for fish fed the low n-3 diet (a) and fish fed the high n-3 EPA diet (b). Bars 5  $\mu$ m

In the present study we fed fish with diets containing high levels (55% of total FA) of n-3 HUFA, and these high values of n-3 rich lipids clearly led to oxidative stress in the liver. In our study, cases of damage were apparent despite of added antioxidants (160 ppm Vitamin E and 150 ppm BHT). This shows the importance of protecting high n-3 HUFA feed with proper antioxidants and proper storage in order to minimize the peroxidation of FAs both prior to feeding and in fish after feeding. Stephan et al. [49] demonstrated that a FO-enriched diet fed to turbot (*Scophthalmus maximus*), increased the susceptibility to FA peroxidation. They found that increased levels of dietary and tissue HUFA require increased dietary supplementation with antioxidants to prevent the occurrence of oxidative damage. A correlation between increased dietary HUFA and antioxidant requirement has been found in other fish species as well [50–52], including Atlantic salmon [53]. More research is needed in order to increase the knowledge about suitable antioxidants and concentrations of these in fish diets, in order to protect FA from oxidative damages both in the feed and in the fish.

In this study, we have shown that the expressions of genes encoding proteins involved in lipid metabolism differ between the low n-3 HUFA group and the groups with the highest n-3 HUFA levels. We do not know whether it is peroxidative damage due to the increased level of HUFA, or the HUFA themselves that are involved in the regulation of these genes. Some studies have suggested that the inhibitory effect of HUFA on lipogenic genes is linked to cytotoxic effects, due to the peroxidative mechanism [54, 55]. On the other hand, other studies have shown that lipid-related genes are altered due to the direct transcriptional effect of HUFA themselves, not to peroxidative damage [56, 57].

In conclusion, we have shown that the expressions of several genes related to hepatic lipid metabolism in Atlantic salmon change in response to changes in dietary HUFA. These genes include those for  $\Delta 5$ -desaturase and  $\Delta 6$ -desaturase and several genes whose gene products are

involved in mitochondrial functions such as FA  $\beta$ -oxidation. The observed increased production of SOD and caspases, and loss of cytochrome c oxidase and Ptd<sub>2</sub>Gro in the membranes of fish fed high levels of n-3 HUFA may be a result of increased dietary HUFA levels in the membranes, and subsequent increased oxidative breakdown of FA rich in double bonds. Clearly, the presence of lipids vulnerable to oxidation may be involved in oxidation processes that can have toxic consequences for fish, whether they arise from dietary input or from deficiencies in essential antioxidant nutrients. These results reveal new elements in favor of greater sensitivity of n-3 FAs to peroxidation in fish. Nevertheless, it is important to appreciate that n-3 FA have both adverse and beneficial effects, to adequately evaluate the consequences of membrane enrichment with these lipids.

**Abstract** Black Sea molluscs and gastropods are the most studied organisms from the Romanian littoral zone. In particular, those from the Mytilidae species are of great interest because biochemical investigations have shown that they can be sources of biological active substances which can have different applications (e.g. food additives). We report here the extraction of lipids from two different species of molluscs (*Mytilus galloprovincialis* L., Mediterranean mussel) and gastropods (*Rapana venosa*, hard-shell clam). The extracts were evaluated in terms of antioxidant and composition properties and their healing properties were tested on skin burns in Wistar rats. Our studies proved that the two lipid extracts contained a relatively complex distribution of compounds, in terms of characteristic indices, polyunsaturated fatty acids (PUFA) and vitamins E and D. The presence of such compounds rendered the extracts very efficient in healing induced skin burns in Wistar rats. The histological analysis showed a

reduction in the time of healing (12–13 and 13–15 days for the *Mytilus galloprovincialis* (L.) *Rapana venosa* extracts, respectively) compared to 20–22 for untreated animals, based on results from tissues and blood samples. Our investigations have been proved to be promising in terms of future potential applications of the extracts as skin-care products, cosmetics and/or pharmaceutical preparations owing to their dermorestitutive properties.

**Keywords** Lipid extracts · *Mytilus galloprovincialis* (L.) · *Rapana venosa* · Neopreol · Wound healing

## Introduction

Prospecting marine resources for biotechnological use, particularly in drug discovery, is a relatively recent activity.

The ocean is a rich source of biological and chemical diversity. It covers more than 70% of the earth's surface and hosts more than 300,000 described species of plants and animals to date [<http://blacksea.orlyonok.ru/e2-1.shtml>]. This diversity has been the source of unique chemical compounds with potential for industrial development as pharmaceuticals, cosmetics, nutritional supplements, molecular probes, enzymes, and agrochemicals [1–4].

Focussing on the Black Sea, molluscs are very important species [<http://blacksea.orlyonok.ru/e2-1.shtml>]. These marine resources have not been industrially exploited in any form so far, with a few exceptions in the food industry [5].

Many compounds can potentially be obtained from marine organisms such as *Mytilus galloprovincialis* (L.) (Mediterranean mussel) and *Rapana venosa* (hard-shell clam) including polyunsaturated omega 3 ( $\omega$ -3) and omega 6 ( $\omega$ -6) fatty acids (FA) and liposoluble vitamins (A, D and E) [6–10]. However, few reports dealing with applications of these lipid extracts can be found (apart from supplements in nutrition) mainly due to the low efficiency (in terms of quantities) in their extraction and unknown effects that did not encourage further investigations of these useful and promising extracts [11–14].

Long chain  $\omega$ -3 and  $\omega$ -6 polyunsaturated fatty acids (PUFA) including eicosapentaenoic (EPA, 20:5n-3), docosahexenoic (DHA, 22:6n-3) and arachidonic acids (AA, 20:4n-6) have been recognised as effective compounds in human health and nutrition, especially in the prevention of cardiovascular diseases [15–17] and to alleviate various inflammation conditions [18–23].

In addition to the reported anti-inflammatory effects of  $\omega$ -3 and  $\omega$ -6, these compounds have been shown to have immune enhancing benefits, improving resistance to infection, inhibiting platelet function and reducing thrombosis [24–26]. However, how these substances can affect cutaneous wound healing is still under debate [27–29].

In the present work, the physico-chemical characterisation of two lipid extracts from *Mytilus galloprovincialis* (L.) and *Rapana venosa* was carried out. The two species were especially chosen as they have a trophic relationship, being the gastropod *Rapana venosa* a common predator of the mollusc *Mytilus galloprovincialis* (L.).

Based on the rich polyunsaturated fatty acids content (in particular  $\omega$ -3 and  $\omega$ -6) that is expected to be found on the lipid extracts [8, 30, 31], this study aimed to investigate their wound healing properties on skin burns and comparing them to those of a commercially available ointment (Neopreol, Iasi Medicals) with fish oil as a bioactive substance as the control sample.

## Materials and Characterisation

### Samples Characterisation

The samples (from different sizes ranging from 2 to 5 cm) were collected from the Baia Mamaia zone–Park (Latitude, 44°10'N, Longitude 28°41'E, Romanian sector of the Black Sea), from Constanza. We are aware of the variabilities due to the sampling season as reported by other authors [8, 30, 31]. In this regard, molluscs were collected in May (2006 and 2007) as spring is ideal due to the accumulation of bioactive (lipids) and structural compounds (proteins) as the marine organisms prepare for reproduction as well as to the maximum concentrations of organic substances in plankton [30, 32].

The two *Mytilus galloprovincialis* (L.) and *Rapana venosa* lipid extracts were obtained according to the Christie method [33]. Total organ lipid content [13, 14] and total body fatty acid contents [33] were determined. The tissue was dried at 50 °C, homogenised and the samples subsequently extracted in chloroform: methanol 1:2 (v/v). The mixture was then filtered off and the organic phase was kept. The final extract was concentrated on a rotary evaporator under vacuum at room temperature and lyophilised (–20 °C) to avoid any oxidation due to thermal treatment.

Several physico-chemical properties of the lipid extracts [34, 35] were investigated including the relative density, refractive index, acidity, iodine, saponification indexes and unsaponified substances [36]. Olive oil was also investigated and analysed for comparison purposes following the Reg CEE 796/2002 directive.

The relative density of the samples was determined using a picnometer, and 1 mL of extract.

The refractive index was obtained using an ABBE Refractometer (Carl Zeiss, Jena, 389820 type) from the Physico-optics laboratory (Ovidius University of Constanza). The extracts were solubilised in ethanol (0.25 mg/25 mL ethanol) and then the refractive index was measured.

The acidity index was measured by titration of the lipid extracts with KOH, after their solubilisation in ethanol/ether mixture 1:2 (v/v).

The iodine index was determined as follows: 0.11 g sample (*Mytilus galloprovincialis* (L.), *Rapana venosa* lipid extracts and olive oil) were dissolved in 10 mL CHCl<sub>3</sub> and subsequently stirred in 25 mL of Hannus solution [IBr in acetic acid], keeping the mixture in a dark place for 1 h at room temperature. Then, 20 mL of a KI solution in 100 mL water was added and 6 mL Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub> in the presence of 1 mL starch solution until disappearance of the blue colour. Blank samples were analysed in parallel using the same quantities and procedure.

The saponification index was also determined. A 2 g sample were stirred in 25 mL KOH and the excess of the mixture was then titrated with a HCl 0.5 N solution using phenolphthalein as indicator.

The unsaponified substances were also analysed. 5 g lipid extract, 2.5 g KOH and 40 mL ethanol were heated under reflux for 2 h. The ethanol was then distilled and the residue was extracted twice in a separating funnel with 50 mL hot water (25 + 25 mL). Then, the organic substances were extracted with 50 mL ether (twice) and after separation of the organic phase, the extract was concentrated in a rotary evaporator and subsequently dried. The quantity of the unsaponified substances was reported for 100 g [27].

The extracts were characterised using different techniques including Infrared (FTIR), UV-Vis spectroscopy and Gas Chromatography-Mass Spectrometry (GC-MS).

FTIR spectra were recorded on a BRUKER-VEKTOR 33 instrument equipped with a liquid N<sub>2</sub> cooled MCT detector. Attenuation Total Reflectance (ATR) spectra were obtained using a methodology devised by the Romanian Spectroteam and Arena Group from Bucharest. 1 g extract was dissolved in *n*-hexane 1:2 (v/v) and then the measurement was performed. The spectra were collected in the 3,900–450 cm<sup>-1</sup> range.

UV-Vis absorption measurements were performed on a GBC CINTRA 5 Spectrophotometer, using a few drops of sample diluted in *n*-hexane to a 1:2 (v/v), in 10 mm quartz cells.

Lipid extracts were analysed by GC-MS using an Agilent GC 6890N model (1 µL sample injected, split 1:50 column flow 1.6 mL/min., program temp. 100–290 °C (rate 10 °C/min) coupled with a quadrupole MS 5973. Samples were injected after derivatisation for the complete identification of all existing compounds in the lipid extracts. The derivatisation of the extracts to investigate the total body fatty acid content was carried out by methylation. Bis-(trimethylsilyl)-trifluoroacetamide (BSFTA) was employed as derivatising agent to determine the quantities of sterols present in the extracts.

The methylation comprises several steps: 1 g extract (*Mytilus galloprovincialis* (L.), *Rapana venosa* lipid extracts or olive oil) dissolved in 10 mL MeOH (0.2 ml KOH were also added to the mixture) was heated under reflux for 15 min, cooled down and extracted with 5 mL heptane and 10 mL saturated NaCl solution. The organic phase was dried on Na<sub>2</sub>SO<sub>4</sub> and subsequently analysed by GC and GC-MS.

The derivatisation using BSFTA was carried out as follows: 0.5 mL BSFTA (per 0.055 g sample) after heating the mixture of the sample and the BSFTA in heptane (5 mL) at 90 °C for 1 h. The resulting solution was allowed to cool down and subsequently analysed by GC and GC-MS.

## Animals and Experimental Design

The study was carried out on adult male Wistar rats, weighing 250 ± 10 g. The animals were individually housed in thermostated (22 ± 2 °C) windowless plexiglass cages with constant humidity and controlled lighting conditions (12 h of light and 12 h of darkness per day) as well as with free access to tap water. They were fed under standard laboratory conditions.

The experiment was carried out in accordance with the Helsinki Declaration and guidelines of the Ethics Committee of the International Association for The Study of Pain. They were approved by the Animal Care Committee of the Faculty of Natural and Agricultural Sciences, “Ovidius” University, Romania.

Each animal was firstly anaesthetised with an intraperitoneal (IP) injection of 5% ketamine (Narkamon inj., Leciva, Czech Republic) in a dose of 90 mg/kg. The hair of the dorsum (around 2.5 cm diameter skin area) was deeply shaved with an electric razor and the wound was subsequently induced with hot water (90 °C, 5 s) on the shaved area, resulting in a clearly distinguished burn.

Fifteen male Wistar rats were randomly divided into five groups, according to the treatment, as follows:

*Group 1 (control)*, (*n* = 3): Rats with an induced skin burn without any treatment.

*Group 2* (*n* = 3): Rats with an induced skin burn treated with the *Mytilus galloprovincialis* (L.) lipid extract, (0.2 mg/kg, twice a day).

*Group 3* (*n* = 3): Rats with an induced skin burn treated with the *Rapana venosa* lipid extract (0.2 mg/kg, twice a day).

*Group 4* (*n* = 3): Rats with an induced skin burn treated with a mixture of the *Mytilus galloprovincialis* (L.): *Rapana venosa* lipid extracts (1:1 ratio, w/w) (0.2 mg/kg, twice a day).

*Group 5* (*n* = 3): Rats with an induced skin burn treated with the specific ointment Neopreol (Iasi Medicals, Romania), (0.2 mg/kg, twice a day).

Experiments were terminated after 22 days, after achieving comparable healed wounds between the untreated animals (control) and the animals treated with both *Mytilus galloprovincialis* (L.) and *Rapana venosa* lipid extract, as observed from the histological results and established through different scores.

## Sample Preparation

Samples were periodically taken from tissues and blood to be analysed. The animals were anaesthetised using IP injections of 90 mg/kg ketamine and 15 mg/kg xylazine

(Rometa inj., Leciva, Czech Republic) and blood and tissue samples from the wounded area were taken.

Tissue samples were homogenised in 10% formaldehyde solution and lyophilised at  $-20\text{ }^{\circ}\text{C}$ . Blood samples were taken by aorta puncture and collected into tubes containing ethylenediamine tetraacetic acid (EDTA), subsequently frozen and stored  $-25\text{ }^{\circ}\text{C}$  until analysis.

The microscope employed in the samples analysis was a Leica DM L 32 and the visualisation was with  $20 \times 10$  for the tissues and  $10 \times 100$  for the blood.

Tissue sections ( $5\text{ }\mu\text{m}$ ) were stained with a Mayer haematoxylin solution in ethanol (15 min) and an eosin solution in ethanol (10 s) (H&E) for general histology [37]. After subsequent washing with ethanol and distilled water, the tissues were eventually mounted in Canada balsam.

The blood was stained according to the May Grunwald Giemsa protocol: the sections were covered with a certain quantity of May Grunwald solution and subsequently washed with distilled water for 1 min. The mixture was then removed without washing and the sections were immersed in a Giemsa solution ex tempore (20–30 min). The sections were eventually washed with water and mounted in Canada balsam [38].

#### Statistical Analysis

Statistical comparisons were performed by one-way analysis of variance (ANOVA). In the case of the identification of statistical differences using ANOVA, the Student Newman-Keuls test was used to compare the groups. Probability values  $<0.05$  were considered to indicate significant difference. Data in Fig. 7 are presented as mean values  $\pm$  standard deviation (SD, error bar depicted in the figure).

## Results and Discussion

### Physico-Chemical Properties of the Extracts

The results of the physico-chemical characteristics of the lipid extracts of *Mytilus galloprovincialis* (L.) (dark brown

colour) and *Rapana venosa* (orangish colour), compared to those of olive oil, are summarised in Table 1.

Several interesting differences could be found between the extracts. The two extracts had similar values of relative density, refractive index and unsaponified substances compared to olive oil, which demonstrates the purity of the obtained extracts. Moreover, a significant difference was showed for unsaponified substances (Table 1, entry 6) when the olive oil was compared to *Mytilus galloprovincialis* (L.) lipid extract ( $P = 0.005$ ). It is worth mentioning at this stage that the olive oil employed in all measurements was commercially refined oil.

Interestingly, there were differences in density between the two extracts, being the *Mytilus galloprovincialis* (L.) more dense compared to *Rapana venosa*. This interesting fact led us to think that there will be differences between the two extracts in terms of compounds present in the mixture, as we will see later on. The refractive index of the lipid extracts were also within the XRF and EECC limits established for food and pharmaceutical oils.

A remarkable difference was found in acidity index in the lipid extracts compared to olive oil (Table 1, entry 3). The molluscs' extracts were close to 20 times higher in acidity than olive oil. This suggested the presence of important quantities of free fatty acids in the mixtures. Nevertheless, the 5 mL KOH/g difference between the *Mytilus galloprovincialis* (L.) and *Rapana venosa* extracts suggested that there may not be major differences between the two species in terms of quantities of free fatty acids present in the extracts. A significant difference was observed when olive oil was compared with *Rapana venosa* lipid extract ( $P = 0.005$ ).

The iodine index (Table 1, entry 4) is characteristic of the content of (poly)unsaturated lipids/fatty acids [39] and it is also an indicative of the physiological condition of the marine organisms. The value of the iodine index is also greatly influenced by the position of the double bond(s) with respect to the carboxylic group. Interesting differences were also found for the two lipid extracts compared to olive oil. The higher iodine index in the *Mytilus galloprovincialis* (L.) and *Rapana venosa* extracts (83 and 87 mL  $\text{Na}_2\text{S}_2\text{O}_3/\text{g}$ , respectively) compared to olive oil (66 mL

**Table 1** Physico-chemical characteristics of the *Mytilus galloprovincialis* (L.) and *Rapana venosa* lipid extracts compared to olive oil

Entry	Physical-chemical characteristics	<i>Mytilus galloprovincialis</i> (L.)	<i>Rapana venosa</i>	Olive oil
1	Relative density ( $d_{20}^{20}$ , g/mL)	1.03	0.83	0.91
2	Refraction index ( $n_{20}^{20}\text{D}$ )	1.48	1.49	1.47
3	Acidity index (mL KOH/g)	44	39	2
4	Iodine index (mL $\text{Na}_2\text{S}_2\text{O}_3/\text{g}$ )	83	87	66
5	Saponification index (mL HCl/g)	281	140	112
6	Unsaponification substances (%g)	2.77	2.44	2.00

$\text{Na}_2\text{S}_2\text{O}_3/\text{g}$ ) suggested a higher content of (poly)unsaturated lipids in our extracts, which is extremely important in terms of nutritive value. Also, significant differences were found when olive oil was compared with both lipid extracts ( $P = 0.007$  and  $0.004$  for *Mytilus galloprovincialis* (L.) and *Rapana venosa*, respectively). The presence of these unsaturated compounds is slightly higher in the *Rapana venosa* species compared to *Mytilus galloprovincialis* (L.).

The saponification index (Table 1, entry 5) indicates the average molecular weight of the fatty acids in fats/lipids, which are related to their organoleptic properties (firmness, taste and flavour) [39]. The measurements provided extremely interesting results in the particular case of the *Mytilus galloprovincialis* (L.) lipid extract which showed a remarkably high saponification index (281 mL HCl/g) compared to *Rapana venosa* (140 mL HCl/g, respectively). This suggested the presence of a higher content of low molecular weight fatty acids in the *Mytilus galloprovincialis* (L.) extract compared to *Rapana venosa*. A significant difference could also be observed when olive oil was compared to the lipid extract from *Rapana venosa* ( $P = 0.0007$ ).

All values obtained for our lipid extracts were within the allowed minimum-maximum range as established in the XRF and EEC regulations (EEC/2568/91 and EEC/2472/97) of the European Union Commission.

#### Identification of the Different Compounds Present in the Extracts

##### UV-VIS Absorption Measurements

The UV-Vis spectra of the *Mytilus galloprovincialis* (L.) and *Rapana venosa* lipids extracts compared to olive oil are included in Fig. 1. The experiments were run after dilution of the extracts in *n*-hexane. The most relevant data that can be extracted from the UV-spectra is summarised in Table 2.

The *Mytilus galloprovincialis* (L.) diluted extract UV-spectra showed 4 significant bands at 271, 281, 412 and 670 nm. The bands were attributed to the presence of different compounds as detailed in Table 2. The most interesting chromophore in the mixture was the E-vitamin ( $\alpha$ -tocopherol), which was identified by its characteristic absorption bands at 223 and 292 nm [40, 41]. Peaks at 223 and 292 nm, were found only in the concentrated extract (UV-spectra not shown), although a slight shoulder could be observed for the diluted spectra (Fig. 1). This shoulder was also present (in a significantly higher concentration) in the olive oil sample.

The UV-spectra of the *Rapana venosa* diluted extract exhibited a similar profile to that of the *Mytilus galloprovincialis* (L.) but various distinctive bands were present in

**Fig. 1** UV-VIS spectra of *Mytilus galloprovincialis* (L.) (solid line) and *Rapana Venosa* (dashed line) lipid extract compared to olive oil (dotted line)

the spectra. The 200–350 nm range was pretty similar to both species and may be attributed to the absorption of unsaturated fatty acids in the extracts. The 400–600 nm range (missing in the olive oil spectra) was significantly different. In particular, the absence of the broad absorption band at 400–450 nm was correlated to the absence of various chromophores. The UV-Vis spectra of the *Rapana venosa* concentrated extract (not showed) also revealed the presence of an absorption band at 264 nm, characteristic of different components/complexes of vitamin D and another interesting band at ca. 1,100 nm that could be attributed to *trans*- $\text{C}_6\text{H}_5-(\text{CH}=\text{CH})_n-\text{C}_6\text{H}_5$  poly-enes and/or carboxylic organic compounds that absorbed at higher wavelengths. In any case, UV results provided enough data to demonstrate the presence of different characteristic chromophores.

##### IR Experiments

Figure 2 includes the IR spectra of the *Mytilus galloprovincialis* (L.) (a) and *Rapana venosa* (b) lipid extracts compared to olive oil (c). Interesting differences were found in the spectra. The three mixtures showed a similar IR profile in the  $3,500\text{--}2,000\text{ cm}^{-1}$  range, that is, bands below  $3,000\text{ cm}^{-1}$  that are attributed to the saturated part from the compounds and a small peak over  $3,000\text{ cm}^{-1}$ , due to unsaturations. No alkyne bands were found at  $3,300\text{--}3,500\text{ cm}^{-1}$ . However, the *Rapana venosa* extract had a very broad peak in the  $3,400\text{--}3,600\text{ cm}^{-1}$  range that

**Table 2** Relevant UV-data of the two diluted lipid extracts (1:2 dilution in hexane) from *Mytilus galloprovincialis* (L.) and *Rapana venosa* lipid extracts compared to olive oil

<i>Mytilus galloprovincialis</i> (L.)		<i>Rapana venosa</i>		Olive oil	
$\lambda$ (wavelength)	Chromophore	$\lambda$ (wavelength)	Chromophore	$\lambda$ (wavelength)	Chromophore
271	Poly-enes/sterol derivatives	270.5	Poly-enes	271	Poly-enes/sterol derivatives
281	E-vitamin ( $\alpha$ -tocopherol)	281	E-vitamin ( $\alpha$ -tocopherol)	281	E-vitamin ( $\alpha$ -tocopherol)
412	$C_6H_5(CH=CH)_5-C_6H_5$ - <i>trans</i>	412	$C_6H_5(CH=CH)_5-C_6H_5$ - <i>trans</i>		
670	$(CH_3)_3C-NO$ , $n-\pi$	608	$R-NO$ , $n-\pi$		
		668	$(CH_3)_3C-NO$ , $n-\pi$		
		Around 1,100	Organic acids $C_6H_5-(CH=CH)n-C_6H_5$ <i>trans</i>		

**Fig. 2** IR spectra of **a** *Mytilus galloprovincialis* (L.), **b** *Rapana venosa* and **c** Olive oil

could be attributed to OH groups coming from alcohol groups presumably from the fatty acids in the mixture and/or water traces in the extract. The most interesting part of the spectra is probably the  $1,800-1,000\text{ cm}^{-1}$  range.

A very intense and sharp peak at ca.  $1,744\text{ cm}^{-1}$  was found for the *Mytilus galloprovincialis* (L.) sample whereas there was no peak at  $1,744\text{ cm}^{-1}$  in the *Rapana venosa* extract. This peak is likely to be due to C=O bands arising from  $\alpha,\beta$ -unsaturated carboxylic acids. Only a small peak at ca.  $1,728\text{ cm}^{-1}$  was found for the *Rapana venosa* extract, implying a significant difference in nature of the fatty acids and compounds with C=O present in the sample. Moreover, a peak at  $1,646$  and  $1,656\text{ cm}^{-1}$  was found for the *Mytilus galloprovincialis* (L.) and the *Rapana venosa* extracts, respectively. These are likely to be due to C=O bands in aromatic acids and/or compounds in which intermolecular interactions are present. Peaks at  $1,500-1,300\text{ cm}^{-1}$  were attributed to  $CH_3-CH_2$ -alkyl chains and were present in all samples. Moreover, the peaks at  $971$  and  $973\text{ cm}^{-1}$  for the *Mytilus galloprovincialis* (L.) and the *Rapana venosa* extracts have been attributed to specific  $\gamma$ -CH *trans* vibrational modes as they were not present in olive oil.

Interestingly, a peak due to monosubstituted aromatics (C–H bending,  $828\text{ cm}^{-1}$ , only one band) was found for the *Rapana venosa* lipid extract, in good agreement with the UV-Vis results that were indicating the potential presence of monosubstituted aromatics in the extract.

#### Gas Chromatography–Mass Spectrometry (GC/MS) Analysis

Qualitative and quantitative GC/MS analysis of the lipid extracts were performed in order to identify the different compounds in the extracts following a similar methodology to that reported by Christie [42]. Some examples of the chromatograms are shown in Figs. 3 and 4, respectively.

**Fig. 3** GC-MS product distribution of the fatty acids from *Rapana venosa* (top) and *Mytilus galloprovincialis* Lmk. (middle) lipid extracts compared to olive oil (bottom) using the derivatisation by methylation

Several products were identified and quantified. The relative proportions of the components in the extract were obtained for both fatty acids (Table 3) and sterols (Table 4) after derivatisations by methylation and using BSFTA, respectively, as method of analysis. Cholesterol was found to account for over 50% weight of the extracts. Data included in Table 3 were recalculated removing such 50% cholesterol contribution to further clarify future discussions about the application of the lipid extracts.

Various saturated, mono-, di and polyunsaturated fatty acids were present in the extracts. Saturated fatty acids including 14:0, 16:0, 18:0 were found in different quantities in the lipid extracts but accounting for a similar saturated fatty acid content (around 35% of the total FA content). Similarly, monounsaturated acids (16:1n-7, 18:1n-9 and n-10, 20:1n-9) content was also analogous (around 30% of the total FA content) for both marine species.

Nevertheless, the differences between samples in terms of content and distribution of PUFA were significant. Thus, the *Mytilus galloprovincialis* (L.) extract had up to a 31% (of the total FA content) by weight of PUFA with a 2:1 EPA:DHA ratio (Table 3, entries 13 and 14). The *Rapana venosa* extract had a striking 40% by weight of PUFA including a 17 and 20 wt% of  $\omega$ -3 and  $\omega$ -6 FA, respectively (Table 3, entries 12–14). Interestingly, no  $\omega$ -6 FA were found in the *Mytilus galloprovincialis* (L.) extract. The unsaturated/saturated FA ratio in our extracts was close to 2:1 in good agreement with reported results for *Mytilus galloprovincialis* (L.) [8, 30, 31] and *Rapana venosa* [9]. Furthermore, the sum of quantities of EPA and DHA was similar to that of AA [9]. EPA and DHA inhibit competitively the utilisation of AA [43].

Further investigations were performed to identify the sterols distribution in the lipid extracts through derivatisation using BSFTA. Various sterols have been identified in various species from marine invertebrates [9, 44, 45]. Up to five different compounds in different quantities were clearly identified in the lipid extracts (Table 4, entries 2–6), accounting for about 30–35% in *Mytilus galloprovincialis* (L.) and *Rapana venosa*, in agreement with previous reports of identified sterols in molluscs [9, 45]. The difference to 100 corresponds to other compounds including 7 and 8-dehydrocholesterols, cholesterolene and related substances [9, 45].

$\alpha$ -tocopherol ( $14 \mu\text{g mL}^{-1}$  extract) and D-vitamin (40 U.I) were also found and quantified in the concentrated samples.

#### Studies of Regenerative Properties of the Extracts

The potential healing activity of the lipid extracts was then investigated in their application to induced skin burns in rats. Table 5 summarises the main scoring employed for the histological features of the wound tissue samples. A summary of the main results is presented in Figs. 5, 6 and 7 and Table 6.

A summary of the microscopic properties of the different blood and tissue samples extracted from the wounds are presented in Figs. 6 and 7. Blood samples for treated rats presented the normal constituents including leucocytes, lymphocytes and so on (Fig. 5c–f, groups 2 to 5).

**Fig. 4** GC–MS product distribution of the sterols identified from *Rapana venosa* (top) and *Mytilus galloprovincialis* Lmk. (bottom) lipid extracts using BSFTA as derivatising agent

**Table 3** GC–MS product distribution and relative proportions (wt% of total fatty acids) of the fatty acids from *Mytilus galloprovincialis* (L.) and *Rapana venosa* lipid extracts compared to olive oil (in wt % dry weight lipid extract) using methylation as derivatisation method

Entry	Fatty acid	<i>Mytilus galloprovincialis</i> (L.)	<i>Rapana venosa</i>	Olive oil
1	10:0 (4,8,12-trimethyldecanoic acid)	1.30	–	–
2	14:0 (myristic acid)	5.57	4.40	–
3	16:0 (palmitic acid)	22.71	16.45	9.84
4	16:1n-7 (palmitoleic acid)	17.9	4.57	0.88
5	17:0 iso 16-methyl (16-methyl-heptadecanoic acid)	–	1.71	–
6	18:0 (stearic acid)	6.23	12.33	1.93
7	18:1n-9 (oleic acid)	5.28	10.98	60.12
8	18:1n-10 (10-octadecenoic acid)	7.00	–	–
9	18:2n-6 (linoleic acid)	2.04	–	8.10
10	20:0 (arachidic acid)	–	–	18.81
11	20:1n-9 ( <i>cis</i> -11-eicosenoic acid)	–	13.51	–
12	20:4n-6 (arachidonic acid)	–	18.90	–
13	20:5n-3 (all- <i>cis</i> -5,8,11,14,17-eicosapentaenoic acid, EPA)	20.65	8.19	–
14	22:6n-3 (all- <i>cis</i> -4,7,10,13,16,19-docosahexaenoic acid, DHA)	11.18	8.90	–
15	Others	0.14	0.06	0.32

Untreated animals exhibited a leucocyte afflux with increasing quantities of constituents (leucocytes, lymphocytes, eosinophyles and monocytes) compared to normal blood (Fig. 5a, Group 1).

Microscope examination of the tissues of treated mice disclosed moderate to complete re-epithelialisation, minimal intercellular or subepithelial oedema, without crusting

(++ to +++ scoring, Table 6, Fig. 6). In general, granulation tissue was characterised by dense collagen matrix deposition, slight oedema, and few scattered inflammatory infiltrates mainly confined in deep dermis and to the wound margins. The capillaries were significantly bigger than those found in untreated Wistar rats with no evidence of fibrin deposition, haemorrhage or vascular congestion.

**Table 4** GC–MS product distribution and relative proportions (wt% of total sterol content) of the sterols identified from *Mytilus galloprovincialis* (L.) and *Rapana venosa* dry weight lipid extracts

Entry	Sterols	<i>Mytilus galloprovincialis</i> (L.)	<i>Rapana venosa</i>
1	Cholesterol	51.87	71.52
2	(22E)-24-norcholesta-5, 22-dien-3 $\beta$ -ol	7.89	6.11
3	(22E)-5 $\alpha$ -ergosta-7,22-dien-3 $\beta$ -ol	11.12	7.75
4	25-hydroxy-24-methylcholesterol	12.93	5.20
5	5 $\alpha$ -cholesta-8, 24-dien-3 $\beta$ -ol (zymosterol)	–	3.77
6	5 $\alpha$ -ergosta-7,24-dien-3 $\beta$ -ol	–	4.29
7	Others (7 and 8 dehydrocholesterols, cholesterolene)	16.19	1.36

**Table 5** Criterion to evaluate the histological features of the tissue samples

Score	Epidermal and dermal regeneration	Granulation tissue thickness	Angiogenesis
+	Little epidermal and dermal regeneration	Thin granular layer	High degree of oedema, haemorrhage and occasionally congestion and thrombosis
++	Moderate epidermal and dermal regeneration	Moderate granulation layer	Moderate degree of oedema and haemorrhage. Few newly formed capillary vessels
+++	Complete regeneration of epidermis and dermis	Thick granulation layer	Moderate degree of perivascular and interstitial oedema, absence of haemorrhage, newly formed capillary vessels
		Very thick granulation layer	Well-structured capillary vessels at the wound margins. Low degree of oedema

Skeletal muscle cells form a border zone between normal and wounded tissue, notably in Groups 3 and 5 (Fig. 6d, f). However, some scar tissue was still visible for groups 3, 4 and 5. In the particular case of the use of neopreol, the epidermis was indeed not completely recovered (Fig. 6f).

Compared to most treated animals, those treated with the lipid extracts from *Mytilus galloprovincialis* (L.) and the mixture *Mytilus galloprovincialis* (L.)/*Rapana venosa* exhibited an almost complete regenerated skin including epidermis, dermis and hypodermis (Fig. 6c and e, Groups 2 and 4, +++ scoring). New epithelium was being laid down and newly formed vessels, collagen fibres, and basal membrane could be visualised in provisional fibrin matrix. The inner epithelial layer was almost completely remodelled by day 12 and granulation tissue thickened close to the base of the wound (Fig. 6c, e).

In contrast, untreated animals presented only a partially recovered skin (Fig. 6b, Group 1) with abundant scar tissue, oedematous and inflamed granulation tissue with little epithelial covering (Fig. 6b, right side of the image). Few newly and immature formed vessels along with fibrin deposition, haemorrhage, interstitial oedema and evidence of generalised vascular congestion were also observed. Undeveloped collagenous connective tissue stroma and moderate granulation tissue accumulation with minimal adipose tissue substitution could also be seen.

The results pointed out the untreated wounds required a time to heal of approximately 3 weeks (20–22 days) to

achieve a ++ score (Fig. 7, Table 6). The use of the lipid extracts was found to remarkably reduce such time of healing to 12–13 days (with a daily treatment with the *Mytilus galloprovincialis* (L.) extract) and 13–15 days (daily treatment with the *Rapana venosa* extract) to achieve +++ and ++ score, respectively. Interestingly, the mixture of the two lipid extracts did not significantly improve the time of healing (14–15 days, Fig. 7, group 4), although a better score was awarded due to the almost complete regeneration of the skin (Table 6). The commercial ointment neopreol also gave very similar results (Fig. 7, group 5, Table 6).

#### Discussion Along the Wound Healing Properties of the Extracts

Wound healing is a complex and continuous sequence of cellular and molecular processes including inflammation, cell migration, angiogenesis, synthesis of provisional matrix, collagen deposition and re-epithelialisation [27, 29, 46]. Nevertheless, the initial inflammatory phase has been reported as the most critical [27]. In this regard, the proven anti-inflammatory and immunomodulatory benefits of  $\omega$ -3 and  $\omega$ -6 FA seemed to have a positive effect on the wound healing as demonstrated in Fig. 7. Our results are in conflict with those reported by Cardoso et al. that reported the topical administration of  $\omega$ -3 and  $\omega$ -6 essential FA significantly delayed the wound closure process [47], in a

**Fig. 5** Microscopy images ( $10 \times 100$ , MGG) of the blood sections of **a** healthy rats; **b** untreated rats with skin burns after 21 days (Group 1); **c** rats with skin burns treated with the *Mytilus galloprovincialis* (L.) lipid extract after 12 days (Group 2); **d** rats with skin burns treated with *Rapana venosa* lipid extract after 14 days (Group 3); **e** rats with skin burns treated with *Mytilus galloprovincialis* Lmk.:*Rapana venosa* lipid extracts after 13 days (Group 4); **f** rats with skin burns treated with Neoprenol after 14 days (Group 5)

similar way to results reported by Albina et al. that suggested the use of a  $\omega$ -3 enriched diet might negatively affect the wound healing process by altering the fibroblastic or maturational phases [48].

Despite our controversial findings, other authors have observed that both  $\omega$ -3 and  $\omega$ -6 do not seem to have a harmful effect on wound healing in mice [9].

With regards to the potentially active compounds involved in the healing process, we believe the  $\omega$ -3 (EPA and DHA) and  $\omega$ -6 (AA) essential FA actively take part possibly via reduction of the initial inflammatory phase and consequent facilitation of the subsequent wound healing steps through stimulation of dermal and epidermal regeneration, proliferation of fibroblasts and formation of new well-structured capillary vessels. Furthermore, the higher content of  $\omega$ -3 (EPA and DHA) essential FA and improved healing properties of the *Mytilus galloprovincialis* (L.) and mixture *Mytilus galloprovincialis* (L.)/*Rapana venosa* extracts

compared to those of *Rapana venosa* led us to infer the direct involvement of EPA and DHA in the wound healing process.

In conclusion, we have investigated two different lipid extracts from two molluscs species from the Black Sea. The mixtures analysed were found to be very complex, containing overall a high cholesterol content and interesting quantities of several saturated and PUFA including  $\omega$ -3 (EPA and DHA) and  $\omega$ -6 (AA).

The activities of the lipid extracts were then investigated on induced cutaneous burns in Wistar rats.

The extracts were found to accelerate the time of healing in the wounds from 20–22 days (untreated animals) to 12–16 days (treated animals), showing some improvements with respect to results obtained using neoprenol. We believe the AA and, in particular, the EPA and DHA essential FA are directly involved in the healing process, reducing the initial inflammatory phase and promoting the recovery of the damaged tissue.

**Fig. 6** Microscopy images (20 × 10, HE) of the tissue sections of **a** healthy rats before the skin burn was induced; **b** untreated rats with skin burns after 21 days (Group 1); **c** rats with skin burns treated with the *Mytilus galloprovincialis* (L.) lipid extract after 12 days (Group 2); **d** rats skin burns treated with *Rapana venosa* lipid extract after 14 days (Group 3); **e** rats skin burns treated with *Mytilus galloprovincialis* Lmk.: *Rapana venosa* = 1:1 lipid extract after 13 days; **f** rats with skin burns treated with Neoprenol after 14 days (Group 5)

**Fig. 7** Healing time (days) of the skin burns for the five groups of Wistar rats: 1 untreated animals; 2 treated with *Mytilus galloprovincialis* (L.); 3 treated with *Rapana venosa*; 4 treated with a *Mytilus galloprovincialis* (L.):*Rapana venosa* 1:1 mixture; 5 treated with neoprenol

**Table 6** The histological score of the five groups of Wistar rats

Groups	Histological score
1 (Control)	++
2	+++
3	++
4	+++
5	++

These results pointed out the lipid extracts have an outstanding potential to be used as active compounds in ointments and skin-care products with potential benefits on burns, inflammations etc.

**Abstract** A previously unreported series of di- and trimethylated fatty acids, as well as saturated and monounsaturated diacids were identified in polar lipids isolated from environmental subsurface sediment samples. Mechanisms are proposed for their formation, but their origin and role in cell membranes remains unknown.

**Keywords** Branched fatty acids · Lipid analysis · Environmental samples

## Introduction

Polar lipid fatty acid (PLFA) analysis is a powerful method in microbial ecology, providing information on the biomass, community structure, and metabolic status of the viable microbial community [1, 2]. To extract the maximum information from environmental samples, it is important to identify unusual PLFA, which may be of low abundance, and for which there are often no standards available.

As part of a study on biological immobilization of uranium by reduction from soluble  $U^{6+}$  to insoluble  $U^{4+}$  [3, 4], sediment samples were analyzed for their PLFA content. An unusually large number of unknown fatty acid methyl esters were detected by gas chromatography–mass spectroscopy, a few of which had been seen previously in samples from other environments. Their mass spectra were those of saturated fatty acid methyl esters (74 and 87, or 88 and 101 for 2-methyl, or 74 and 101 for 3-methyl fatty acid methyl esters, M+, M-31, and the alkyl loss series), but their retention times were too early for straight-chain or singly branched fatty acids. The pattern of their appearance in other samples sets had been suggestive of some component of the microbial community, but could not be proven not to be a new contaminant. Their number and abundance in this sample set presented the opportunity for their identification, but the samples had already been analyzed and the chance to use the more informative picolinyl or DMOX derivatives was past. Using mass spectral and equivalent chain length analyses, and relying heavily on the lipid literature, 21 multiply branched saturated fatty acids, 4 diacids, and 3 monounsaturated diacids were identified as their methyl esters.

## Materials and Methods

### Study Site

The Old Rifle site is a former uranium processing facility near Rifle, CO, USA. Within the sampling area and near the time of sampling, groundwater analysis found  $U^{6+}$  from 0.5 to 1.3  $\mu\text{M}$ , nitrate 0.1–0.3 mM,  $Fe^{2+}$  0.03–0.05  $\mu\text{M}$ , sulfate 5.3–6.8 mM, sulfide 6–33  $\mu\text{g/L}$ , pH 6.7–7.0, and oxygen from 0.2 to 0.5 mg/L. Sediment samples were collected from the saturated zone of the aquifer, between 4 and 5.2 m below land surface. Subsurface sediment samples were collected aseptically using a roto-sonic drilling rig (Boart Longyear, Environmental Drilling Division, Little Falls, MN, USA) and were kept frozen until analysis, as described [4]. As part of the overall experiment,  $^{13}\text{C}$ -labeled acetate was injected into the aquifer, but only control samples collected before  $^{13}\text{C}$ -labeled acetate injection were used for the identification of unknowns.

### Polar Lipid Fatty Acid Analysis

The total lipid was extracted from subsurface sediment samples by the method of Bligh and Dyer [5] as modified [6] utilizing a single-phase mixture of chloroform, methanol, and phosphate buffer. The polar lipid fraction was separated from neutral lipids and glycolipids by silicic acid column chromatography, and transesterified to fatty acid methyl esters by a mild alkaline methanolysis [7]. Gas chromatography–mass spectroscopy was performed on an Agilent 6890 series gas chromatograph with a 50 m HP-1 nonpolar column (0.2 mm I.D., 0.11  $\mu\text{m}$  film thickness), and a temperature program of 100  $^{\circ}\text{C}$  initial temperature, 10  $^{\circ}\text{C}/\text{min}$  to 150  $^{\circ}\text{C}$ , hold for a minute, 3  $^{\circ}\text{C}/\text{min}$  to 282  $^{\circ}\text{C}$ , and hold for 5 min. The injector and detector temperatures were 270 and 290  $^{\circ}\text{C}$ , respectively. The carrier gas was hydrogen. Peak quantitation and mass spectral acquisition was by an Agilent 5973 mass-selective detector.

### Equivalent Chain Length Analysis

Equivalent chain lengths (ECL) of fatty acid methyl esters were calculated by linear interpolation between the normal saturates, rather than the more commonly used linear or non-linear regression across the entire chromatogram. The untransformed retention times were regressed against carbon number for the 12 normal saturates, in order to test for outlier retention times. Pearson's  $R^2$  for the regression was generally greater than 0.95. The high abundance of 16:0 gave non-ideal behavior in some samples. Due to the

method used, the ECLs of the normal saturates are by definition equal to their chain lengths (Table 1).

Equivalent chain lengths for the multiply branched fatty acid methyl esters identified by mass spectroscopy were estimated by considering them as isomers of a normal saturate, each methyl branch lowering the ECL by some fraction, depending upon position and chain length (Fig. 1 of the Electronic Supplementary Material). This is expected to give reasonable estimates of the ECLs when the methyls are well-separated on the carbon chain, so that interaction between the methyl groups is not significant. The fractional ECL for a fatty acid methyl ester  $X$ ,  $f(\text{ECL})_X$ , was calculated by

$$f(\text{ECL})_X = \text{ECL}_X - \text{ECL}_1 + 1$$

where  $\text{ECL}_1$  is the ECL of the isomeric normal saturate. Since a methyl branch nearer the carboxylate end of the molecule affects the retention time more than one further away, the calculated ECL is based on the ECL of the isomeric mono-methyl FAME at the first position, and then adjusted for the methyl closer to the aliphatic end. Using the equation

$$\text{ECL} = \text{ECL}_{n,1} + f(\text{ECL})_{n,2} - 1$$

where  $n$  is the carbon number of the dimethyl fatty acid and 1 and 2 represent the methyl positions closer to and further from the carboxylate, respectively. If the  $f(\text{ECL})$  of the second methyl branch varies strongly with chain length, the following equation is more accurate.

$$\text{ECL} = \text{ECL}_{n,1} + f(\text{ECL})_{n-1,2} + \left\{ f(\text{ECL})_{n,1} \times \left[ f(\text{ECL})_{n-1,2} - f(\text{ECL})_{n,2} \right] \right\} - 1$$

## Results

Table 1 lists 86 polar lipid fatty acid methyl esters detected in this microaerophilic microbial community and Fig. 1 gives some of the structures. The 12 normal saturates detected from 14:0 to 26:0 showed a strong even carbon number dominance and a bimodal distribution centered on 16:0 and 22:0. The 6 terminally branched fatty acids had the even- and odd-numbered *iso*-branched and odd-numbered *anteiso*-branched fatty acids expected of bacterial lipids [8]. Both the 15- and 17-carbon terminally branched fatty acids had more of the *anteiso*- than *iso*-branched isomer, as is often found in actinomycetes [9–11]. The ECLs of the terminally branched fatty acids were consistent internally and with published values [12].

The three 2-methyl fatty acid methyl esters (2Me16:0, 2Me17:0, and 2Me18:0) had fragments at  $m/z = 88, 101, M+,$  and  $M - 31$ . They showed the alkyl loss series (101, 115, ...  $M - 15$ ) similar to normal saturates but with lower

*MW* molecular weight of the methyl ester, *ECL* equivalent chain length, and *Percent* average mole percent

and more equal abundance [13]. The ECLs of all three are consistent with 2Me fatty acids [12, 14]. Two 3-methyl fatty acids were detected (3Me14:0 and 3Me16:0), with major fragments at  $m/z = 74$  and 101, and mass spectra otherwise similar to 2-methyl fatty acids [13].

**Fig. 1** Some novel polar lipid fatty acids

The 12 mid-chain branched fatty acid methyl esters identified (Table 1) showed the expected order of elution times  $2\text{Me} < 3\text{Me} < 8\text{Me} < 10\text{Me} < 11\text{Me} < 12\text{Me} < \textit{iso}$ -branched  $< \textit{anteiso}$ -branched [15], and the expected decrease in fractional ECL with increasing carbon number. Saturated mid-chain branched fatty acid methyl esters were identified by comparison with the isomeric normal saturate (Fig. 2), which is characterized by fragments at  $m/z = 74, 87, M+, M-31$ , the alkyl loss series (87, 101, 115, ...  $M-15$ ) [13]. A mid-chain branched fatty acid methyl ester always has a retention time earlier than its *iso*-branched isomer. Single mid-chain methyl groups were located by the absence or lower abundance of the alkyl loss fragment at the methyl position, and the enhanced alkyl loss fragments from cleavage at either side of the methyl branch (Fig. 2). Other characteristic fragments with much lower abundance are the loss of methanol (loss of 32) from the alkyl loss fragments at either side of the branch and methanol + water (loss of 50) from the longer fragment [13] (Fig. 2). Their ECLs were also consistent with earlier work in this laboratory and with literature values [15, 16].

There were 21 multiply methyl-branched saturated fatty acid methyl esters identified in these samples with fragmentograms as described above for 2-methyl, 3-methyl, or mid-chain branched fatty acids, but ECLs less than the isomeric 2-methyl fatty acid methyl esters (Table 2). Nineteen of these were dimethyl fatty acids, and two had three methyl groups.

Five fatty acids with mid-chain and terminal branches were identified by the fragmentations typical of mid-chain branched fatty acids (above),  $M-29 > M-31$  for *anteiso*-branched fatty acids, ECLs much lower than possible for a

single methyl branch, and by eliminating all other possibilities. The estimated ECLs were correct to within  $\pm 4\%$  of a methylene unit.

There were eight dimethyl fatty acids with a mid-chain branch and the other methyl group on the second or third carbon identified (Table 2).

Two trimethyl fatty acids were also identified in these samples—10,12diMe-i18:0 and 2,10diMe-i17:0. There were other multiply branched fatty acids seen in these samples which could not be completely identified including 3Me-br14:0, ECL = 14.03; 8Me-br14:0, 14.09; 3Me-br17:0, 17.03; 2Me-br19:0, 18.79; br20:0, 19.16; 2Me-br21:0, 20.71; 2Me-br22:0, 21.02; 2Me-br23:0, 22.68; and 2Me-br24:0, 22.97.

Four long chain diacids and 3 monounsaturated diacids were identified in these samples by their mass spectra (NBS75K library, Hewlett-Packard, Palo Alto, CA, USA) and retention times. An  $n$ -carbon saturated diacid dimethyl ester elutes soon after the  $(n+3)$ -carbon normal saturate methyl ester [17]. For example, 16:0dioic elutes soon after 19:0 at an ECL of 19.10. The monounsaturated diacid dimethyl esters eluted about as much earlier than the corresponding saturate as an  $\omega 7c$  monounsaturated methyl ester eluted earlier than its corresponding normal saturate.

## Discussion

### Mass Spectral and Equivalent Chain Length Analyses

The multiply branched fatty acids identified in this work had mass spectra typical of saturated fatty acid methyl

Bold value indicates that it is the exception to the high accuracy of the ECL calculation, due the methyl groups being close to each other on the carbon chain

% mole percent, ECL equivalent chain length, Est. estimated ECL, Err. Est.–ECL, Grp. fatty acid biosynthetic group (e even, ei even iso, oi odd iso, a anteiso), and IUPAC fatty acid name according to the rules of the International Union of Pure and Applied Chemists

esters, as illustrated with the mass spectra of the isomers 16:0, 12Me15:0, and 10Me-i15:0 (Fig. 2). The two most abundant peaks are at 74 and 87, or 88 and 101 for 2-methyl fatty acids, or 74 and 101 for 3-methyl fatty acids. The molecular ion, M<sup>+</sup>, and M – 32 (loss of methanol) are usually apparent, though M – 32 may not be seen in longer-chain fatty acid methyl esters. Consideration of the major ions and molecular weight eliminated unsaturated, hydroxylated, keto, or methoxyl fatty acids, as well as various possible nitrogen, sulfur, or halogen substitutions. Ethyl-branches would give rise to an M – 28 ion [18], which was not observed. By similar arguments, larger alkyl branches or cyclic saturates were eliminated as possibilities.

The effect of methyl substitution on the mass spectrum of a fatty acid methyl ester is greatest at the two position, and decreases as the position of the substitution proceeds down the carbon chain, to the *iso*-branched fatty acid which can rarely be distinguished from the normal saturate isomer by its mass spectrum [13]. In multiply methyl branched saturated fatty acid methyl esters, the methyl nearer the carboxyl end of the molecule somewhat

suppresses ions due to the methyl further away. Identification of these minor fatty acids by subtle differences in their mass spectra required analysis of multiple chromatograms and extensive use of background subtraction and extracted ion chromatograms.

ECL analysis can support a proposed structure, but is not proof. The great power of ECL analysis is in eliminating a proposed structure. Once a structure was deduced from the mass spectral analysis, it was tested by ECL analysis. All structures reported here were supported by both methods.

#### Elimination of Known Multi-Methyl Fatty Acid Methyl Esters

The mass spectra and ECLs of several other types of multiply branched fatty acids were compared with these multi-methyl branched fatty acids, but did not match. The mycocerosates found in *Mycobacteria* have methyl groups at the even-numbered carbons near the carboxyl terminus. Examples include (with ECLs) 2,4diMe14:0 (14.56),

**Fig. 2** Mass spectra of the isomers 16:0, 12Me15:0, and 10Me-i15:0

2,4diMe16:0 (16.59), 2,4diMe20:0 (20.67), 2,4,6triMe22:0 (22.82), 2,4diMe24:0 (24.67) [14, 15]. None of these compounds were found. Their retention times are earlier than the multiply branched fatty acids found in this study with the same molecular weight and degree of methylation due to the crowding of their methyl groups near the carboxy-terminus. Their mass spectra are characterized by major fragments at  $m/z = 88$  and 101 (due to the 2-methyl), and 129 (due to the 4-methyl) [19–21], which do not match any compounds found in these samples. Certain 2-hydroxy-alkanes found in the membrane lipids of *Mycobacteria* were also not found in these samples—2-hydroxy-octadecane and 2-hydroxy-eicosane [14].

Another source of multiply branched fatty acids is the degradation of isoprenoids from chlorophyll or archaeobacterial ether lipids. However, the multiply branched saturated FAME's found in these samples do not appear at

the published retention times for these products, nor do the mass spectra match [22–24]. For some of the isoprenoid fatty acids, multiple ECLs were reported for a single structure, which is most likely due to variation in the stereochemistry of the methyl groups [25]. These include 3,7diMe-i13:0 (ECL = 13.44), 4,8diMe-i14:0 (14.16, 14.53), 5,9diMe-i15:0 (15.49), 2,6,10triMe-i16:0 (15.80, 16.61), 3,7,11triMe-i17:0 (17.04, 17.29, 17.72), and 4,8,12triMe-i18:0 (18.34) [25–31].

Another possibility is sub-terminal carboxylation (addition of carboxylic acid to the second carbon of an alkane to produce a 2-methyl fatty acid) which has been seen in some anaerobic bacteria [32, 33]. However, for this mechanism to be relevant requires abundant alkanes, which were not reported in this environment. Also, the typical distribution of alkanes from industrial or natural sources would produce a large envelope of small overlapping

peaks, which was not seen. And further, most of the multiply branched fatty acids found were *iso*- or *anteiso*-branched, which would require unusually high levels of *iso*- and *anteiso*-branched alkanes as substrate.

A similar series of multiply methyl branched fatty acids have been found in a halophilic *Bacillus*, including 4,11diMe12:0, 4,10diMe12:0, 2,13diMe14:0, 2,12diMe14:0, and 4,13diMe14:0 [34]. While the 4-methyl branched fatty acids from this *Bacillus* were not found in these sediments, 2,12diMe14:0 is a shorter chain homolog of 2,12diMe16:0 and 2,12diMe18:0 which were found in these sediments.

#### Are These Membrane Fatty Acids?

There are several lines of evidence that these multiply branched and dioic fatty acids are membrane fatty acids produced by some organism, probably a bacterium, living in these subsurface sediments.

When  $^{13}\text{C}$ -acetate was injected into the subsurface sediment (as part of a test of a bioremediation program), the label appeared in several of the multiply branched fatty acids (A. D. Peacock et al. in preparation). This is very strong support for biosynthesis of multiply branched fatty acids in the subsurface environment.

Second, this is a well-studied site with an active program of experimental bioremediation [3, 4; and references therein], but there is no mention of organic contaminants at this site which might be the source for these compounds.

Third, the total viable microbial biomass over these samples averaged 238 pmol/g with a standard deviation of 102 pmol/g ( $n = 11$ ), and the percent of multiply branched fatty acids averaged 7.3% of the total with a standard deviation of 1.3%, similar to other fatty acid groups. If these compounds were independent of microbial biomass, their percentage would be expected to be more variable than the other fatty acid groups. Rather the amount of multiply branched fatty acids closely followed the amount of total PLFA. A similar pattern was seen for the diacids.

Fourth, some of these multiply methyl branched fatty acids have been detected but not identified before in PLFA from environmental samples, but not in procedural blanks. However, due to their very low abundance and lack of identification, they were not reported.

Fifth, the multiply branched fatty acids were detected as methyl esters and the diacids as dimethyl esters. The mild alkaline methanolysis used transesterified ester-bound carboxylic acids, but does not efficiently form methyl esters from free fatty acids. Therefore, these compounds were ester-linked in some complex polar lipid in the sample. Complex polar lipids are essential components of all cellular membranes, but polar lipid anthropogenic contaminants are very rare.

Sixth, while an extensive literature search revealed no previous report of several of these compounds, this is probably due to them not being recognized as authentic membrane components. These multiply branched fatty acids and diacids were minor components in these samples, but more abundant in these samples than any others in our experience. 2-Methyl or 3-methyl fatty acid methyl esters might not be recognized if they were not expected, and if the compounds were very minor components, because they do not have the signature  $m/z = 74$  and  $87$  typical of fatty acid methyl esters. The mass spectra of diacid dimethyl esters are similar to those of fatty acid methyl esters, and may have been confused with the normal saturates or a hydrocarbon contaminant series which elute near them. Alternatively, the increasing background noise due to the chromatographic temperature program could have obscured the diacid peaks, or the temperature program might not have been run long enough to elute the diacids.

And finally, seventh, these multiply branched fatty acids and diacids could be synthesized by extension of known microbial lipid biosynthetic pathways. For most of the multiply branched fatty acids found, there are fatty acids in this sample with a single methyl group at each of those positions. A fatty acid can be converted into a diacid by the same oxidation mechanisms that convert alkanes to acids [35, 36].

#### The Origin of Multiply Branched Fatty Acids

While a strong argument can be made that these are biosynthesized membrane lipids, the organism(s) responsible for their synthesis and their role in the cell are unknown. The three main mechanisms for methyl group addition to bacterial fatty acids are (1) *iso*- and *anteiso*-branched fatty acids synthesized by using a branched volatile fatty acid as the primer in fatty acid biosynthesis in place of acetate [8], (2) mid-chain branched fatty acids formed by addition of a methyl group from *S*-adenosyl-methionine to an unsaturation [37, 38], and (3) 2-methyl fatty acids and mycocerosates are made by *Mycobacteria* by substituting methyl malonyl-CoA for acetate in chain elongation [39]. The multiply branched fatty acids found in these samples could have been formed by the successive action of these 3 methylation mechanisms, but the 2- and 3-methyl fatty acids found in these samples do not match to those produced by *Mycobacteria*.

#### Dioic Fatty Acids

In this sample set, 4 diacids and 3 monounsaturated diacids of chain length from 16 to 22 carbons were found in the polar lipid fraction (Table 1). The only example in the literature of a long-chain diacid in membrane lipids is

diabolic acid, found in a few eubacterial extremophiles [40]. But diabolic acid has 30 carbons including 2 methyl groups near the center of the molecule, while the diacids found in this work were shorter and unbranched. Dembitsky found several dioics in methanolysates of total lipids from a red alga [41], but they were only from 7 to 11 carbons long, and they could have been neutral or complex lipids.

Diacids are major components of plant waxes such as cutin. For example, diacids from 14 to 22 carbons long, including a monounsaturated diacid, were found in samples of pine, fig, and oak bark [42]. Diacids from 20 to 28 were found in whole soil methanolysates, which probably originated from plant waxes [43]. While the diacids found in this sample were most similar to plant wax diacids, there is no source of plant waxes in this subsurface environment. Furthermore, plant waxes would not appear in the polar lipid fraction.

These multiply branched and dioic fatty acids are biologically reasonable in terms of known lipid biosynthetic pathways, and are unlikely to be anthropogenic contaminants esterified in the polar lipid fraction. They probably have been unreported from earlier PLFA analyses of environmental samples because they were unexpected, minor components.

These multiply branched fatty acids are similar in degree of methylation to fatty acids from bird preen gland lipids [12, 18], and the dioics are like plant wax lipids in chain-length distribution and the presence of a monounsaturations [42]. Bird preen gland lipids and plant waxes are both protective hydrophobic barriers. Perhaps these unusual membrane lipids are a defense against aqueous toxins, such as sulfide and metals found at this site.

**Abstract** Four groups of eight New Zealand hybrid rabbits were fattened with ad libitum access to the following pelleted experimental diets: ryegrass meal or alfalfa meal fed either alone or with oats meal in a ratio of 1:1. After 25 weeks they were slaughtered and dissected. Fatty acid (FA) profiles of caecotrophs (re-ingested fermentation products of the caecum), perirenal adipose tissue and intramuscular fat in the *Musculus quadriceps* were determined. With high proportions of branched-chain FA (BFA) and *trans* FA, and increased proportions of saturated FA relative to the diets, the caecotroph FA profile showed a clear fingerprint of anaerobe microbial lipid metabolism including biohydrogenation. By contrast, the FA profiles of adipose and lean tissue comprised high proportions of polyunsaturated FA (PUFA), whilst BFA and *trans* FA occurred in much lower proportions compared to the caecotrophs. Thus, coprophagy did not substantially modify the FA composition of the tissues investigated. Use of forage-only diets, compared to the oats supplemented diets, led to extraordinary high proportions of n-3 PUFA (including 18:3 and long-chain n-3) in the fat of adipose (21.3 vs. 6.7%) and lean tissue (15.4 vs. 5.7%). The forage type diet (grass vs. alfalfa) had smaller effects on the FA profiles. Indications of diet effects on endogenous desaturation, chain elongation and differential distribution of

functional FA between the two tissues investigated were found.

BFA	Branched chain fatty acids
CLA	Conjugated linoleic acids
FA	Fatty acids
FAME	Fatty acid methyl ester
MUFA	Monounsaturated fatty acids
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
TVA	<i>trans</i> -Vaccenic acid 11 <i>trans</i> -18:1

### Introduction

The significance of microbial lipid digestion in rabbits and other small herbivores with significant microbial fermentation in the hindgut (caecum) [1], is not yet well known. Information on the effect of the microbial influence on lipids in the digestive tract mostly comes from ruminant animals with their large forestomach [2, 3]. The microbial fermentation of the ingested feed is associated with biohydrogenation and isomerisation of unsaturated FA. This results in the production of considerable amounts of several *trans*-FA, conjugated linolenic acids (CLA) and stearic acid [2, 4]. Another particularity of ruminal digestion is the de novo synthesis of branched-chain FA [3]. Therefore, microbial digestion results in characteristic FA profiles in

the tissues of ruminants, which were subject to extensive research work aimed to improve the nutritional quality of animal products [2, 4–8]. In rabbits, digestive fermentation takes place in the hindgut, namely the caecum. Ingesta undigested so far—predominantly plant cell walls—are fermented and relevant nutrients including B vitamins and protein are anaerobically synthesised by the hindgut microbes [1, 9]. Because nutrient absorption from the hindgut is limited, these animals produce a particular kind of soft feces in the caecum, the caecotrophs, which are re-ingested [9, 10]. In wild living rabbits, the main part of the unabsorbed ingesta is recycled by this way [9].

Lipids produced by bacteria in the caecum should share the typical microbial FA profile as described for the foregut of ruminants. Potentially, such lipids could reach the duodenum and the blood via coprophagial re-ingestion. High amounts of *trans*-FA and branched-chain FA (BFA), as found in the tissues of beavers [11, 12], could be explained by this behavior. However, in-depth research on the FA profile of caecotrophs and an evaluation of its influence on the endogenous FA metabolism of such animals has not yet been performed. This could be useful in comparative physiological research on wild animals in order to develop a marker for coprophagy [10]. It could also elucidate the significance of coprophagy for the endogenous metabolism of the animal and, consequently, for the use of rodents and rabbits, as animal models in lipid metabolism research. These species could, by coprophagy alone, ingest an uncontrolled amount of these FA in experimental studies, which may cause particular metabolic responses [13], thus partially questioning their use to simulate potential effects of *trans* FA and BFA in humans. Finally, coprophagy could influence the nutritional value of rabbit meat if the ingested hindgut microbe-derived FA result in a substantial modification of the tissue lipids. This context has not yet been investigated.

Another important question is how the diets fed to rabbits interact with the microbial metabolism in the caecum resulting in a specific pattern of FA supply. In comparison, *n*-3 PUFA and 9*c*,11*t*-18:2 CLA in meat and milk from ruminants increase when animals are fed diets containing high proportions of forage and only low proportions of cereal or legume grain crops [6–8], i.e. diets which are relatively close to the natural feeding behavior of these species. A similar situation might be found in rabbits which are grazing animals as well [14]. Accordingly, in the tissues of wild rabbits, concentrations of ALA and long-chain *n*-3 PUFA were found [15] to be clearly higher than those reported from rabbits fattened on farm [16]. Rabbits in agricultural production systems are commonly fed diets which largely differ from that of wild rabbits because they contain high cereal proportions [17–19]. The question remains whether the nutritional quality

of the rabbit meat lipids could be increased with high-forage diets which are closer to the natural diets, and to which extent an interaction with coprophagy is relevant. Although a number of publications on the fat quality of rabbit meat exist [15–17, 19–23], no reports on controlled studies of the effects of high-forage diets are available. Diet type, especially the proportion of concentrate, was shown to influence the amount of caecotroph formation [18, 24] and, thus, indirectly the ingestion of microbially modified FA. Finally, the forage type might be important in this respect. From ruminant research, there are indications that legumes such as alfalfa, although having lower ALA proportions in the lipids than ryegrass [25], could inhibit microbial biohydrogenation [2, 5] and thus could increase supply with ALA. In case caecotrophy substantially influences FA intake, such an effect could be important in rabbits, too.

The hypotheses to be tested by an experiment with growing rabbits included: (1) that the profile of long-chain FA in rabbit's caecotrophs closely resembles the FA profile of ruminant digesta, (2) that traces or larger amounts of those FA which are typical for microbial fermentation can be recovered in the body tissue of rabbits, (3) that high-forage diets have a direct (more ALA) or caecotrophy-mediated (more 9*c*,11*t*-18:2 CLA and TVA) influence on tissue FA composition, and (4) that a leguminous forage type has a significant influence in this respect.

## Experimental Procedure

Four groups of eight New Zealand hybrid type rabbits were fattened on different diets for 25 weeks. The four diets were pelleted, consisting either of pure ryegrass meal (G), pure alfalfa meal (A), grass meal and oats meal 1:1 (GO) or alfalfa meal and oats meal 1:1 (AO). The composition of the main dietary nutrients as analyzed according to Naumann and Bassler [26] is given in Table 1, and their FA profile in Table 2. The rabbits originated from one breeding facility for meat rabbits. At the beginning of treatment feeding, they were between 5 and 6 weeks old with a body mass between 1,124 and 1,930 g. Groups proportionately consisted of female and castrated male animals, and allocation to treatment was balanced with respect to the average of and variation in initial body mass. Animals of each group were kept together on woodchips in enclosures of 5.4 m<sup>2</sup>, fitted with a sleeping box of 0.59 m<sup>2</sup>. Feed and water was provided with ad libitum access. Daily intake was recorded as the average per group. Feed consumption of the groups was monitored daily by weighing the feed refusals before filling the troughs for the next day. No measures were taken to prevent coprophagy in the animals. The animals were also weighed before slaughter.

**Table 1** Nutrient composition of the experimental diets as well as food intake and body masses development in the experimental groups (means)

<sup>e</sup> Body mass minus feet, head, skin, internal organs, and discrete adipose tissue

Immediately after slaughter, the animals were dissected, and samples of abdominal (perirenal) fat and of the central quadriceps muscle of the left hind leg were taken. Additionally, the gastrointestinal tract was dissected, opened, and controlled for the presence of caecotrophs. In the colon, caecotrophs can be differentiated from hard faeces based on their smaller size, and softer and moister consistency [1]. Due to a tough mucoprotein membrane, which resists digestion in the stomach for several hours [9], re-ingested caecotrophs can be identified from shape, form and consistency. Therefore, we assumed that caecotrophs in the stomach that still were not disintegrated were equal in composition to caecotrophs from the caecum and colon. No caecotrophs were collected from the small intestine. Samples of adipose and muscle tissue and caecotrophs were immediately sealed in plastic bags and stored at –20°C until analysis.

#### Lipid Extraction from the Samples

Lipids from feeds and caecotrophs were extracted by accelerated solvent extraction (ASE 200; Dionex Corp., Sunnyvale CA) using hexane/isopropanol (2:1 vol/vol) and transformed into FA methyl esters (FAME) according to Wettstein et al. [27]. The FAME were dissolved in hexane and purified on a silica gel column.

Lipid extraction from lean and adipose tissue was performed after homogenisation of the samples. Lipids from *M. quadriceps* were extracted by dissolving 1 g of homogenisate in 5 ml hexane-isopropanol (3:2). The lipids from adipose tissue were extracted from 0.2 g homogenisate with 12 ml hexane. Both solvents contained triundecanin and phosphatidylcholin (Fluka Chemie,

Buchs, Switzerland) as internal standards. Subsequently, the fatty acids in the extracts were converted to methyl esters according to the official IUPAC method [28] with slight modifications (2 ml 0.5 M methanolic NaOH boiled for 3 min in a reaction tube, 3 ml 1.3 M boron trifluoride boiled for 4 min). A cleaning step was carried out to prevent artifacts caused by cholesterol when analyzing the *trans*-FA isomers. The FAME were sprayed onto a thin layer chromatography glass plate coated with silica gel 60 *F*<sub>254</sub> (Merck KGaA, Darmstadt, Germany). Subsequently, the plates were run in a chamber saturated with a solution of hexane, diethylether and acetic acid in a ratio of 85:15:0.2 for 30 min until the solvent had reached the upper border of the plate. The FAME were identified and marked in UV light (440 nm) after having sprayed the plate with a fluorescent dye (2',7'-Dichlorofluorescein, Fluka, Sigma-Aldrich Chemie GmbH, Buchs, Switzerland). The identified zone was scratched off, dissolved with a 1:1 mixture of chloroform and hexane and filtered through a silica gel column.

#### Fatty Acid Analysis

All samples were analyzed for individual FAME on a gas chromatograph (HP 6890, Agilent Technologies Inc., Wilmington, DE) equipped with an FID detector and a Supelcowax<sup>TM</sup> 10 capillary column (30 m × 0.32 mm, 0.25 µm film thickness; Supelco, Bellefonte, PA). An amount of 1 µl was injected by split injection (1:30, split temperature 260°C). Hydrogen was used as a carrier gas at a flow rate of 2.2 ml/min and a pressure of 55.8 kPa. The initial oven temperature was 160°C for 0.5 min. The temperature program was as follows; increase of 20°C/min up

**Table 2** Total amount and individual proportions of FAME (g/100 g FAME) in the experimental diets (means of duplicate analyses; deviation always below 0.05)

to 190°C; increase of 7°C/min up to 230°C; isotherm at 230°C for 5.3 min; increase of 20°C/min up to 250°C; isotherm for 6 min. The detector temperature was 270°C. For a clearer separation of *trans* and *cis*18:1 isomers, extracts from caecotrophs, adipose and lean tissue were further analyzed on a 200 m × 0.25 mm size CP7421 capillary column (Varian Inc., CA, USA). An amount of 1 µl was split injected (1:50; split temperature 270°C). Again hydrogen was used as a carrier gas, and gas flow was 1.7 ml/min for 59 min and, subsequently, 1.3 ml/min for 42 min. The initial temperature was 181°C for 60 min. Subsequently the temperature was increased by 5°C/min up to 230°C; isotherm for 32 min, then increase by 5°C/min up to 250°C, then kept isothermic for 12 min. The detector temperature was 300°C.

## Statistical Evaluation

Linear multivariate ANOVA was carried out with the SPSS<sup>®</sup> 14.0 software. Fixed factors were oats supplementation (– vs. + oats) and forage type (ryegrass vs. alfalfa), and the model included the interaction of both factors.

## Results

Alfalfa contained less lipids than the ryegrass. The SFA were higher and MUFA were lower in alfalfa compared to ryegrass. The PUFA proportions were similar in both forages. (Tables 1, 2). By contrast, the addition of oats increased the ether extract content of the diets and massively shifted the FA profile from ALA to monounsaturated FA. BFA occurred for all diets only at the detection threshold in feed and are therefore not given in Table 2. *trans*18:1 FA occurred at a low level. Due to the higher energy density (less fibre) in the oats supplemented diets, voluntary food intake was lower while gains and dressing percentage (48.2% on average) remained similar. Differences found in body mass at slaughter between the groups were mostly due to variations of discrete adipose tissue. Caecotrophs were found with similar frequency in all groups (in 4, 4, 4 and 3 animals of groups G, A, GO and AO, respectively).

### Fatty Acid Profile of the Caecotrophs and Effects of Diet

In the caecotrophs, the saturated FA (SFA) represented the most abundant group of FA, followed by monounsaturated FA (MUFA) and PUFA (Table 3). The proportion of the branched-chain saturated FA (BFA) was also rather high, ranging from 7 to 13 g/100 g FAME on average. The FA 15:0a (*anteiso*) and 16:0i (*iso*) contributed clearly more than half of all BFA. Oats supplementation had significant effects on proportions of various FA in the caecotrophs. With diets GO and AO, total SFA were significantly higher compared to diets G and A, due to higher proportions of 18:0, while BFA, *trans*18:1 FA and n-3 PUFA were lower. Overall total MUFA, PUFA and n-6 PUFA were not affected ( $P > 0.05$ ) by dietary oats. Among the two most abundant 18:1 FA, 9c-18:1 was higher, while *trans*-vacenic acid (11t-18:1; TVA) was lower ( $P < 0.05$ ) when feeding oats. With diets GO and AO, the proportion of 9c,11t-CLA in the caecotroph FAME was reduced to below 0.1 g/100 g. The largest proportionate reduction with oats was found in 18:3n-3 leading to a significant increase of the n-6/n-3 ratio from about one to 2–4. The use of alfalfa instead of grass meal led to significantly lower proportions of 18:0 both in diets with and without oats. Most of the

<sup>d</sup> These fatty acids are co-eluting

<sup>e</sup> Sum of two peaks containing unidentified 18:2 isomers

BFA and some minor SFA were significantly higher with the pure alfalfa diet, but this was reversed for the SFA in the presence of the oats (O × F interaction,  $P < 0.01$ ). Interactions among the two dietary factors were also found for total MUFA and PUFA with the result that no clear overall forage type effect remained. Alfalfa resulted in a lower 18:3n-3 proportion than the grass ( $P < 0.05$ ), but only in the non supplemented diets.

#### Fatty Acid Profile of the Body Tissues and Effects of Diet

In the perirenal adipose tissue, total SFA, MUFA and PUFA occurred at relatively similar levels. BFA, TVA and CLA, indicative for microbial lipid sources, occurred at very low proportions (Table 4). Most of the FA were significantly influenced by oats supplementation. For the SFA, this effect was marginal, while MUFA were clearly elevated by oats. This resulted mainly from higher values of the 9*c*-18:1/15*t*-18:1 peak ( $P < 0.001$ ); but also 16:1n-7 was considerably higher ( $P < 0.01$ ) with the oats diets. Total PUFA declined with diets GO and AO compared to G and A, exclusively resulting from a highly significant drop in n-3 PUFA. Thus, the average n-6/n-3 ratio increased from 0.7 with G and O to 2.7 with GO and AO ( $P < 0.001$ ). The proportions of total and individual BFA were lower by about half with oats diets ( $P < 0.001$ ). Total SFA significantly increased and total MUFA and PUFA significantly declined with the alfalfa compared to the grass diet, but this effect occurred mainly in the diets without

oats. Total and some individual BFA were significantly higher in proportion with alfalfa instead of the grass, while 18:3n-3 was lower ( $P < 0.01$ ). Alfalfa significantly increased long chain n-3 PUFA; this, however, at a low level.

The FA profile of the intramuscular fat and its variation with diet were relatively similar in nature to those found in the adipose tissue (Table 5). However, particularly for individual PUFA, the effects of oats addition were not as distinct, and significant effects of alfalfa were absent. Intramuscular lipids proportion of 18:3n-3 was considerably lower, and the long-chain PUFA (>3 double bonds) occurred with five- to ten-fold higher proportions than in the FAME of the adipose tissue. Particularly arachidonic acid (20:4n-6) and docosapentaenoic acid (22:5n-3) made up a considerable proportion of total PUFA in intramuscular fat, which was not the case in perirenal adipose tissue.

#### Differences in Fatty Acid Profiles of Food, Caecotrophs and Body Tissues

In contrast to the body tissue lipids, caecotroph lipids contained comparably high proportions of BFA and *trans*-18:1 FA. These FA occurred only in traces or low amounts in feeds and body tissues. Although the diet effects on BFA were similar in direction in the caecotrophs and in the body tissues, the relative proportions between the individual BFA in caecotrophs differed. The relative proportions of 17:0*i* and 17:0*a* within BFA were clearly higher in the body tissues than in the caecotrophs. A second property,

characterising the caecotrophs vs. the tissue lipids, was the high proportion of SFA (including most individual SFA). The proportion of SFA in total FAME was clearly above 50 g/100 g for caecotrophs and below 40 g/100 g for the perirenal adipose and intramuscular fat. Complementary, PUFA were distinctly higher in the investigated tissues than in the caecotrophs.

## Discussion

### Characteristics of the Caecotroph Fatty Acid Profile, and Effects of Diet Type

In general, comparing the FA profiles of the caecotroph lipids with those of the corresponding feeds indicated an active anaerobe microbial lipid metabolism. A first crude indicator was the ratio of SFA, in particular 18:0, to PUFA, being higher in caecotrophs than in the diets. As described for the forestomach of ruminant animals [2], 18:0 is the terminal product of microbial biohydrogenation of dietary 18:3 and 18:2. A second indicator was the high concentration of *trans* FA, mainly 11*trans*18:1, found in the caecotrophs. These FA are also the result of microbial lipid metabolism in the digestive tract [2, 29]. Finally, the substantial proportions of BFA and odd-chain FA found in the caecotroph lipids support the same conclusion [3].

High proportions of forages in the diet are known to increase BFA formation in ruminant digestion [3]. In the caecotrophs, the same effect was indicated by the elevated proportions of BFA and odd-chain FA found in the rabbits receiving the forage-only diets (G and A). Alfalfa diets obviously did not have the inhibitory effect on ALA biohydrogenation anticipated from replacing grass by legumes [2, 5]. By contrast, when feeding the pure alfalfa diet the reduction of the ALA proportion was even more

pronounced than with the ryegrass diet, suggesting increased biohydrogenation and isomerisation. Higher BFA proportions with the alfalfa diets suggest increased microbial activity, too, contrasting to what is known from ruminants [5, 30].

However, an increased biohydrogenation should not only reduce ALA or linoleic acid proportions, but also increase CLA, octadecanoic MUFA and 18:0 [2]. In this respect, the results on the caecotroph FA profiles were apparently inconsistent because neither 18:1 nor 18:0 were higher with diet A compared to G. A confounding between discriminating absorption in the duodenum and biohydrogenation in the caecum cannot be excluded. The interactions of the two dietary factors give no clear picture for SFA, MUFA and PUFA in the caecotrophs, either. Significant interactions of the sums of FA groups have no corresponding counterpart in interactions in all single FA. They appear rather to be artifacts. Thus, the clearest information about diet effects on microbial activity in the caecum apparently may be obtained from BFA which are synthesised *de novo*. This is reflected by the fact that the diet effects on all FA of this group were almost parallel.

### Signature of the Caecotroph FA Profile as Found in the Body Tissues

FA profiles typical for microbial fermentation are found in both ruminating and non-ruminating foregut-fermenting herbivores, e.g. kangaroos [2, 31–33]. By contrast, mono-gastric herbivores have no forestomach with microbial fermentation; instead, microbial digestion occurs in the caecum and the colon of such species. In most aspects, the bacterial fermentation in the hindgut is comparable to that in the rumen [34] and similar effects of microbial lipid metabolism were demonstrated in the hindgut and the faeces, as e.g. by Hartman et al. [31] for horse faeces.

However, as these processes in monogastric animals occur after the digesta has passed the duodenum, the major site of absorption for lipids, they do not have a major influence on the lipid composition of body tissues. This is reflected by higher proportions of PUFA in the tissues of horses, pigs and other hindgut fermenters as compared to ruminants and non-ruminant foregut fermenters [35–38].

Due to this dichotomy—absorption of ‘ruminant-specific’ FA in foregut fermenters, no absorption of such FA in hindgut fermenters—the endogenous presence of ‘ruminant specific’ FA has been considered as an indicator of foregut fermentation [39]. Thus, Käkela et al. [11] interpreted the endogenous presence of BFA and *trans* FA in tissue lipids of beavers (*Castor canadensis*) as an indication of a ‘ruminant-like’ bacterial fermentation in the gastrointestinal tract. However, the same research group [12] described PUFA levels in beaver tissues exceeding those found in ruminants by far. The beaver, therefore, shares similarities with ruminants with respect to BFA and *trans* FA and with hindgut-only fermenters concerning PUFA. This phenomenon could be explained by the digestive strategy of coprophagy of rodents and other small herbivores [9]. Coprophagy has been studied particularly well in rabbits [18, 24, 40, 41]. Hirakawa [9] describes that wild rabbits recycle almost the entire undigested matter in the form of caecotrophs. Based on the values published by Belenguer et al. [24], coprophagy could have made up approximately 10% of nutrient intake in our study. The proportion of total lipid absorption covered by coprophagy is not clear from the literature.

One central question of the present study was to which extent coprophagy can alter rabbit tissue FA composition. If the microbial lipids contain functional FA like CLA, even a proportion of 10% of the absorbed FA would be

valuable in terms of the nutritional quality of the meat. If, on the other hand, with a more natural feeding strategy, coprophagy would be intensified [9, 24], the related increase of SFA might counterbalance such positive effects. The results show that both were only marginally the case. With its extraordinary high proportions of PUFA, the rabbits’ tissues had nothing in common with those of ruminants, which consistently comprise much lower proportions of PUFA [4, 6–8, 29, 30]. It seems likely that a high proportion of dietary FA was absorbed in the small intestine before any biohydrogenation processes could take place in caecum and colon. This is consistent with the reduction found in total FAME from diets to caecotrophs, which was in the magnitude of 2/3. In this respect, the rabbits of this experiment were not only able to corroborate some previous findings on tissue PUFA content in rabbits [15, 19], but also the observations of the high PUFA content in beaver tissues [12].

However, certain amounts of BFA, odd-chain FA and *trans*18:1 FA were still found in the rabbits’ tissues. Although endogenous BFA synthesis cannot be excluded, this is expected to take place to a low extent [3]. It seems reasonable to assume that the majority of BFA found in the tissues are of caecotroph origin. Compared to that reported for sheep [42], the BFA content of intramuscular fat was only approximately three times lower. Considering the high impact of ruminal processes on the endogenous FA metabolism in sheep [2], the amounts of BFA in the rabbits’ tissues indicate that the contribution of microbially modified lipids to the total dietary lipids was not negligible. The considerably higher BFA proportions in tissues of the groups fed without oats are obviously a reflection of the diet effects on caecotrophs. With increasing dietary fibre proportions, the caecal microbial fermentation in rabbits

and their intake of microbially fermented matter increases [18, 24]. Based on what is known from ruminant digestion [3], it seems likely that the increased BFA proportions in the tissues are an indicator of increased coprophagial activity by the rabbits fed forage-only diets. In this context, the increase in SFA in the tissues of the forage-only groups compared to the oats-groups could be explained by an enhanced intake of caecotrophs as these contained proportionately more SFA than the diets. By contrast, the low and insignificant amounts of *trans*-FA found in the tissues do not allow the same conclusion.

We conclude that, although on a low level, FA originating from the caecotrophs are traceable in the rabbits' metabolism, but to a different degree for individual FA. Provided these results are confirmed with other diets and under different conditions, markers for the occurrence of coprophagy in wild animals could be developed on the basis of certain BFA and *trans* FA. Under free-ranging conditions, on a less consistent supply of high-quality forage, coprophagy might contribute even more to the animal's nutrient intake. This would lead to higher tissue proportions of the discussed FA. For example, the higher proportions of *trans* FA in free-ranging beavers [12], as compared to the rabbits of the present study, could indicate a higher proportionate intake of caecotrophs.

#### Influence of Excluding Concentrate on the FA Profile of the Body Tissues

Feeding the forage-oats diets resulted in a recovery of the characteristically high MUFA content of oats. It also led to high concentrations of n-3 PUFA, particularly of 18:3n-3, in the lipids of perirenal adipose and muscle tissue. These concentrations were in the upper range of data reported in the majority of other studies about rabbit meat quality [16, 17, 21–23]. By feeding a high n-3 oil supplement, Dal Bosco et al. [43] achieved n-3 PUFA concentrations in the range found in the present study with the oats diets. Cobos et al. [15] found such values in wild rabbits and hares from central Spain. For long chain n-3 PUFA in intramuscular lipids, comparable or higher values were described by Forrester-Anderson et al. [19] for grazing rabbits consuming an unknown amount of additional concentrate. Comparably high n-3 FA proportions in the rabbit meat had never been achieved in the other studies reviewed. Those studies always used dietary forage proportions of less than 50%, the lowest value applied in the present investigation.

When increasing the forage proportion from 50 to 100% in the present study, the 18:3n-3 proportions were significantly higher and amounted to 15.4 and 21.3% of the intramuscular and the adipose fat of the rabbits, respectively. This reflects the favorably high 18:3n-3/18:2n-6

ratio in diets G and A, and illustrates the limited role coprophagy played for the FA composition of the rabbits' tissues. Positive effects of the forage-only diets were also noted on the proportions of the long-chain n-3 PUFA, particularly in the intramuscular lipids. This indicates considerable chain elongation processes, converting ingested 18:3n-3 into long-chain n-3 PUFA. Elongation of 18:2n-6 and 18:3n-3 competes for the same enzymes and depends on the respective concentration of both substrates [44]. Thus, the effects of diets G and A on n-3 PUFA confirmed our anticipation. The expected decrease of 20:4n-6, however, was lacking. The efficiency of endogenous elongation is crucial for the estimation of health effects of dietary 18:3n-3 in human diets [45], and the findings are controversial in this respect [46, 47]. The present data show that the endogenous concentrations of long-chain n-3 PUFA may depend considerably on the intake of 18:3n-3, at least in rabbits. An open question is whether the source of dietary 18:3n-3, other dietary factors or both have a confounding influence on the elongation processes.

In a broad range of animal species, body tissues were found to have higher proportions of n-3 PUFA under free-ranging conditions as compared to animals kept in captivity [48]. Our data, as well as data for cattle [8, 29], suggest that this 'wilderness effect' can be mimicked in domesticated herbivore species by high-forage diets. Overall, the present data show that a forage-only diet increases the sum of n-3 PUFA in rabbit meat to a level similarly high as that found in free-ranging conspecifics [15]. Compared to domesticated animals, including ruminants [36], free-range grazing pigs [49] and the horse [36], the enhancement of total of n-3 PUFA by a forage-only diet was particularly high in the rabbits of the present study. Even under extensive organic feeding conditions neither pork [49, 50] nor beef [8] reached these concentrations. Provided these results can be generalised for various rabbit rearing conditions, meat from forage-only fed rabbits could represent a particularly healthy food. Although feed conversion efficiency is lower with forage-only diets due to the high contents of indigestible fibre [24], the economic success of forage-only feeding systems could be substantial, if the nutritional value of such a high n-3 meat is paid for.

Another significant effect of the forage-only compared to the oats-supplemented diets was the lower proportion of 9c-16:1. Since this MUFA only occurred in traces in feeds and caecotrophs, it is likely that the high tissue level was caused by endogenous  $\delta$ -9-desaturation [51]. This would imply that forage-only diets might reduce tissue desaturase activity. One explanation for this phenomenon could be the higher exogenous intake of dietary PUFA making endogenous desaturation less important.

## Influence of the Forage Type on the FA Profile of the Body Tissues

The comparison of alfalfa versus grass as dietary forages did not reveal substantial effects on tissue FA profiles. Besides the influence on BFA, which was discussed above, the most obvious effect of dietary alfalfa compared to ryegrass was a small but significant reduction in 18:3n-3 and an increase in long-chain n-3 PUFA. This suggests a positive effect of alfalfa on the endogenous chain elongation. This effect only occurred in adipose tissue. The distribution of n-3 PUFA across the entire organism depends on several factors as described for other small herbivores [46], pigs [47], and humans [45]. Thus, any explanation for the alfalfa effect on adipose n-3 PUFA remains speculative. It is, however, interesting to note that total n-3 PUFA did not differ much between grass- and alfalfa-fed rabbits although total lipid and, accordingly, total n-3 content of the alfalfa-containing diets was lower by a factor of two than with the grass.

## Conclusion

1. The FA profiles of caecotroph lipids of rabbits showed typical properties of an anaerobic microbial lipid metabolism comparable to that occurring during ruminal digestion.
2. Small amounts of BFA and *trans*-FA from caecotrophs are obviously ingested and metabolised. This could have significance for the evaluation of FA digestion and metabolism with small herbivore animal models. It seems possible to develop markers for the occurrence of significant levels of coprophagy in non-ruminant herbivores particularly on the basis of BFA and *trans*18:1 FA.
3. Considering the nutritive value of rabbit meat, the contribution of coprophagy to the tissue FA profiles appears to be marginal. This holds true for SFA concentrations, which are more similar to horse meat than to beef, as well as for CLA, which were nearly absent in the tissues of the rabbits in the present study.
4. The endogenous FA metabolism, with respect to chain elongation, desaturation and distribution between different tissues, to some extent depends on dietary factors such as proportions and type of forage.
5. The effect of high dietary forage proportions on the n-3 contents of rabbit meat is so substantial that it seems worthwhile confirming these data with various forages and developing forage-based feeding strategies for rabbit meat production.

**Abstract** Previously we have shown that an alkylating agent *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) can induce receptor clustering and the activation of a downstream signal molecule NF- $\kappa$ B, and that the receptor clustering is associated with changes in sphingolipids metabolism. On the other hand, the polyene antibiotic nystatin can block MNNG-induced receptor clustering. In this study, using a lipidomic approach, we further evaluated whether nystatin influenced the effects of MNNG on sphingolipids metabolism. It was found that nystatin itself induced changes in the sphingolipids profile in human amnion FL cells to a certain extent, including an increase or decrease of some sphingolipid species. Interestingly, nystatin can block, at least partially, the changes of sphingolipids-induced by MNNG. In addition, nystatin can also partially inhibit the activation of NF- $\kappa$ B induced by MNNG. Neither MNNG nor nystatin affects the mRNA levels of serine palmitoyltransferase, acid sphingomyelinase (ASM), and sphingomyelin synthase, key enzymes in the sphingolipids biosynthesis pathway. However, MNNG can activate ASM and neutral sphingomyelinase, while

nystatin preincubation inhibits the activation. Taken together, these data suggested that nystatin interferes with the effects of MNNG, and might elicit its function through altered sphingolipids metabolism.

## Introduction

Besides serving as structural materials to provide a physical barrier for cells and providing a platform (the so-called lipid raft) for membrane protein–protein interaction, many lipids also have distinct cellular functions. Sphingolipids are the second largest group of membrane lipids as well as the major components of the lipid raft. In the sphingolipid metabolism pathway, ceramide is on the center stage; it can be generated from simple molecules by a de novo synthesis pathway, or from the hydrolysis of more complex sphingolipids (Fig. 1) [1, 2]. Now it is clear that sphingolipids and their metabolites are involved in many important signal transduction pathways which regulate many cellular events such as cell cycle arrest or apoptosis, proliferation, calcium homeostasis, cancer development, multidrug resistance, or even viral or bacterial infection processes [1, 3]. Clearly, the importance of this group of lipids should not be underestimated.

However, the study of lipids goes far behind those of genes and proteins, and the major problem is the lack of high-throughput technologies for lipid analysis. Only after the coming of “lipidomics”, in which the individual lipid components can be analyzed by the mass spectrometric (MS) technique, have vast amounts of information been generated regarding the changes of lipid metabolism under

various conditions [3–5]. Compared with traditional methods, such as thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC), MS analysis is more accurate, less labor-intensive and can identify the molecular species of each class of lipids [6, 7].

For lipid studies, the ability to perturb lipid metabolism is essential to understanding the metabolic pathways of lipids. Nystatin is a polyene antibiotic that is routinely used to interfere with cellular lipid rafts, by depleting cholesterol from lipid rafts thus leading to their disruption [8–10]. Previously, we have found that an alkylating agent *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) can induce the clustering of membrane receptors, including epidermal growth factor receptor (EGFR) and tumor necrosis factor  $\alpha$  receptor (TNFR), as well as the activation of the downstream signal molecule NF- $\kappa$ B [11, 12]. By using TLC and matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) MS techniques, it was further shown that MNNG affected sphingolipid metabolism, including changes in ceramide and sphingomyelin species, and that sphingolipids are involved in MNNG-induced receptor clustering [13–15]. On the other hand, nystatin can block MNNG-induced receptor clustering [13]. Although the disruption of the lipid raft by nystatin could contribute to the inhibition of receptor clustering, however, it was not clear whether nystatin had any other influence on MNNG-induced changes in cells, such as altered sphingolipids metabolism and the activation of NF- $\kappa$ B. Therefore, in the present study, using the lipidomic approach, the effects of nystatin on MNNG-induced sphingolipid changes were evaluated. In addition, the effects of various treatments on

the activation of NF- $\kappa$ B and the expression of key enzymes in sphingolipids metabolism were examined.

## Experimental Procedures

### Cellular Culture, Reagents, and Treatment

Human amnion FL cells were cultured in Eagle's Minimum essential medium (EMEM, Invitrogen, Carlsbad, CA) containing 10% fetal bovine serum, and supplemented with 100 U/ml penicillin, 100 U/ml streptomycin and 0.03% L-glutamine in a humidified incubator at 37 °C with 5% CO<sub>2</sub>. MNNG (Sigma, St Louis, MO) was dissolved in dimethylsulfoxide (DMSO) as a 10 mM stock. Nystatin (Sigma) was also dissolved in DMSO as a 1 mg/ml stock. To evaluate the effects of nystatin on MNNG, cells were pre-incubated with 100  $\mu$ g/ml nystatin for 30 min, and then treated with 0.2  $\mu$ M MNNG for another 8 h. C<sub>2</sub>-ceramide was purchased from Sigma, and cells were treated with 100  $\mu$ g/ml for 8 h as positive control.

### Sphingolipid Extraction and MALDI-TOF MS

Sphingolipids were extracted as described before [2]. In short, approximately  $4 \times 10^7$  cells were dissolved in 500  $\mu$ l chloroform:methanol (2:1, V/V). One milliliter H<sub>2</sub>O was then added to each sample. The mixed samples were centrifuged at  $4,770 \times g$  for 15 min, and the lower phase was dried by vacuum centrifugation in a centrifugal evaporator (Speed-Vac, Thermo Savant, Holbrook, NY). Then, 500  $\mu$ l of methanol containing 0.1 M NaOH was added into each tube and held at 55 °C for 1 h to decompose glycerophospholipids. After neutralization with 100  $\mu$ l methanol containing 1 M HCl, 500  $\mu$ l hexane and one drop of water were added to each sample. The mixture was then centrifuged again at  $4,770 \times g$  for 15 min, and the lower phase was dried in a centrifugal evaporator after the upper phase was removed. The residue was mixed with 0.8 ml theoretical lower phase (chloroform:methanol:water, 86:14:1, V/V) and 0.2 ml theoretical upper phase (chloroform:methanol:water, 3:48:47, V/V) for Folch partition, and centrifuged in a centrifugal evaporator after removing the upper phase to discard the salt. The residual crude sphingomyelin was stored at  $-70$  °C.

For MALDI-TOF MS analysis, each sample was dissolved in 5  $\mu$ l chloroform:methanol (2:1, V/V), followed by the addition of 5  $\mu$ l matrix solution (ethyl acetate containing 0.5 M 2,5-dihydroxyl-benzoic acid (2,5-DHB, Sigma) and 0.1% TFA) in a 0.5 ml Eppendorf tube. The tube was agitated vigorously on a vortex mixer then centrifuged in a microcentrifuge for 1 min. One microliter of mixture was directly applied to the sample plate and

rapidly dried under a moderately warm stream of air in order to remove the organic solvent within seconds.

All samples were analyzed using a Voyager-DE STR MALDI-TOF mass spectrometer (ABI Applied Biosystem, Framingham, MA) with a 337 nm N<sub>2</sub> UV laser. The mass spectra of the sample were obtained in positive ion mode. Mass/charge (*m/z*) ratios were measured in the reflector/delayed extraction mode with an accelerating voltage of 20 kV, grid voltage of 67% and delay time of 100 ns. C<sub>2</sub>-dihydroceramide (MW 343.6) was used to calibrate the instrument. All sample lipid spectra were acquired using a low-mass gate at 400 Da. For each sample 7 spectra were obtained.

#### Establishment of Reference Mass Spectrum and Relative Quantification

For analyzing sphingolipids, the “reference mass spectrum” (RMS) method established in this laboratory was applied to deal with the problem of intra-sample variation, as well as the problem associated with the poor quantification capability of MALDI-TOF-MS [2]. The basic principle is that only those peaks present in at least 5 mass spectra collected from the same sample were chosen for entry into the RMS. By doing so, the intra-sample variation could be minimized. Since it is difficult to quantify the amount of each sphingolipid species using MALDI-TOF-MS, a relative quantification method was also created by comparing the ratio of different sphingolipid species instead of the absolute amount of each species. It was found in all the mass spectra obtained, peak 506.9, was always given the relative intensity of 100%. Thus, the relative intensities of other peaks were calculated by comparing to peak 506.9. Then the mean and standard deviation of the relative intensity of each peak was computed for each sample. Combining these data, a final RMS was established for these samples, and the particular lipid giving rise to the peak was identified by comparing their validated masses in our database (<http://lipid.zju.edu.cn>). All the comparisons were then conducted using the RMS.

#### NF- $\kappa$ B p65 Activity Analysis

Nuclear protein was extracted using the Nuclear Extract Kit (Active Motif, Carlsbad, CA) following the manufacturer’s instructions. Briefly, cells in a 75 cm<sup>2</sup> flask were washed with ice-cold PBS, then scraped off the flask into 10 ml of ice-cold PBS and transferred into a pre-chilled 15 ml tube and spun at 300×*g* for 5 min at 4 °C. The pellet was resuspended in 1 ml of ice-cold hypotonic buffer by gentle pipetting and then transferred into a pre-chilled 1.5 ml tube. After swelling on ice for 15 min, 50  $\mu$ l 10% Nonidet P-40 was added and mixed by gentle pipetting.

The homogenate was centrifuged for 30 s at 4 °C in a microcentrifuge. The nuclear pellet was resuspended in 50  $\mu$ l complete lysis buffer and gently rocked on ice for 30 min on a shaking platform. The mixture was centrifuged for 10 min at 14,000×*g* at 4 °C, and the supernatant (nuclear cell extract) was then stored at –80 °C for further analysis. The protein concentration was determined by using the Bradford assay.

NF- $\kappa$ B activity was measured using the TransAM NF- $\kappa$ B p65 Kit (Active Motif). In short, 30  $\mu$ l of complete binding buffer was added to each well of the 96-well plate provided by the kit, and then 20  $\mu$ l of the nuclear protein extracts were added. After 1 h incubation at room temperature, the wells were washed with buffer for three times, and 100  $\mu$ l NF- $\kappa$ B antibody (1:1,000) was added for another 1 h incubation at room temperature. The plate was then washed for three times, and HRP-conjugated secondary antibody (1:10,000) was added and incubated for another 1 h. Finally, the chemiluminescent working solution was added, and chemiluminescence was read at 450 nm by the Infinite 200 multifunctional microplate reader (Tecan, Austria).

#### RNA Isolation and RT-PCR

The mRNA levels of three enzymes, e.g., serine palmitoyltransferase (SPT), acid sphingomyelinase (ASM), and sphingomyelin synthase (SMS), were analyzed by RT-PCR following various treatments. Total RNA was prepared using TRIzol reagents (Invitrogen) according to the manufacturer’s instruction. RNA samples were dissolved with diethylpyrocarbonate (DEPC)-treated water and stored at –80 °C. For reverse transcription, the complementary DNA (cDNA) was generated using 5  $\mu$ g of total RNA, N6 primer, and RevertAid<sup>TM</sup> M-MuLV Reverse transcriptase (Fermentas, Glen Burnie, MD) following the manufacturer’s instructions. The subsequent PCR was carried out in a 20- $\mu$ l mixture containing 1  $\mu$ l cDNA, 2  $\mu$ l 10× PCR buffer [100 mM Tris–HCl (pH 8.3), 500 mM KCl, 15 mM MgCl<sub>2</sub>], 0.5  $\mu$ l of 2.5 mM of each dNTPs, 0.5  $\mu$ l of each primer (20 mM), and 2.5 U Taq DNA polymerase (Takara Biotech. Inc., Dalian, China). The following primers were used in the PCR reaction:

1. SPT: sense 5′-GGGCT TCATC ATCTA TGG-3′ and anti-sense 5′-TCAGT AGCTG AGGCA ATGTC-3′;
2. ASM: sense 5′-CTCTG TCTGA CTCTC GGGTT C-3′ and anti-sense 5′-GCTTC GGCAC AGTAG GC-3′;
3. SMS: sense 5′-GTAAA CCCAA GAGCT TATCCA-3′ and anti-sense 5′-GCCCA TTTCA CCCTA TCA-3′;
4.  $\beta$ -Actin: sense 5′-CATGT ACGTT GCTAT CCAGG C-3′ and anti-sense 5′-CTCCT TAATG TCACC CACGAT-3′.

Amplification was performed with an initial denaturation step at 94 °C for 5 min followed by 30 cycles of denaturation for 30 s, annealing at optimum temperature (ASM and SMS at 60 °C, SPT at 55 °C) for 30 s and extension at 72 °C for 45 s. A final extension was carried out at 72 °C for 8 min. PCR amplification was performed in an automated heat block thermal cycler (GeneAmp PCR System 9700, ABI). The products were run on a 1% agarose gel and stained with ethidium bromide. The gels were then scanned with GelDoc-It™ Imaging System (UVP Inc., Upland, CA) and quantified using VisionWorksLS Image Acquisition and Analysis Software (UVP). The percentage of surface area under the peak of each band was normalized to that of the corresponding  $\beta$ -actin band.

### Sphingomyelinase Activity Measurement

Sphingomyelinase activity was measured by Amplex Red sphingomyelinase assay kit (Molecular Probe, Invitrogen, UK). In short,  $10^6$  cells were collected and resuspended in 40  $\mu$ l ice-cold buffer (150 mM NaCl, 5 mM EGTA, 10 mM Tris-HCl, pH 7.5, for neutral sphingomyelinase (NSM); 50 mM sodium acetate, 5 mM EGTA, pH 5.0, for ASM) containing 1% Triton X-100 and 100  $\mu$ g/ml phenylmethylsulfonyl fluoride. After shaking on ice for 30 min, cells were frozen and thawed three times with liquid nitrogen. Cellular debris was removed by centrifugation at 14,000 rpm for 30 min. Then the supernatant was diluted with reaction buffer (pH 7.4, 100 mM Tris-HCl for NSM and pH 5.0 NaAc for ASM), and the SMase activity was measured according to the manufacturer's instruction. The samples were read in an Infinite M200 multifunctional microplate reader (Tecan, Austria) with the excitation and emission wavelength set at 530 and 585 nm, respectively.

### Statistical Analysis

Each experiment was conducted at least three times. Statistical analysis was performed Student's *t*-test. A probability level of  $P < 0.05$  was considered significant. Data are presented as mean  $\pm$  SD.

## Results

### Nystatin Inhibits MNNG-induced Changes in Sphingolipid Profiles

Previously, we have shown that MNNG can induce dramatic changes in ceramide and sphingomyelin [13, 14]. On the other hand, although nystatin is routinely used to interfere with the cellular lipid metabolism, little is known about its effect on sphingolipids. Therefore, we first

analyzed the sphingolipid profile using MALDI-TOF MS in cells treated with nystatin (Fig. 2). To establish the RMS, peak 506.9 was chosen as the internal standard and assigned a relative intensity of 100%. The final RMS obtained was shown in Fig. 3, and the ions characterized, as well as the values of their relative intensities, are listed in Table 1.

As shown in Figs. 2 and 3, it was found that nystatin could induce changes in sphingolipid profile, such as the decrease of intensities of ions  $m/z$  701.5 and 831.2, while the intensity of  $m/z$  617.7 was significantly increased. On the other hand, nystatin had little effect on ceramide-mono-hexoside (CMH). In contrast, the effects of MNNG were more profound, including the generation of many new sphingolipid species.

However, when cells were first incubated with nystatin and then treated with MNNG, it was found that most of the effects of MNNG on sphingolipids were suppressed. For example, for ceramides, the intensity of  $m/z$  645.6 was returned to basal levels, while  $m/z$  589.2 and 683.9 disappeared again as in controls. Similarly, MNNG-induced increase of sphingomyelin and CMH were also inhibited. Together, these data indicated that nystatin can reverse the effects of MNNG on sphingolipid metabolism.

### Nystatin Partially Inhibits the Activation of NF- $\kappa$ B by MNNG

Previously, we have shown that MNNG can induce the activation of NF- $\kappa$ B [11, 12], which is a downstream molecule effector in both EGFR- and TNFR-mediated signaling pathway [16, 17]. Since nystatin can influence the effects of MNNG on sphingolipids, it was also of interest to know whether nystatin can affect the activation of NF- $\kappa$ B by MNNG. Therefore, cells were preincubated with nystatin, followed by MNNG treatment, and the activation of NF- $\kappa$ B was measured using the NF- $\kappa$ B activity kit. As shown in Fig. 4, nystatin preincubation indeed, although not completely, inhibited the MNNG-induced NF- $\kappa$ B activation.

### Neither Nystatin nor MNNG Affect the Expression of mRNA of Key Enzymes in the Sphingolipid Metabolism Pathway

Sphingolipid metabolism is regulated by various enzymes. For example, serine palmitoyltransferase (SPT) is the rate-limiting enzyme in the de novo synthesis pathway for ceramide, while acid sphingomyelinase (ASM) and sphingomyelin synthase (SMS) control the balance between ceramide and sphingomyelin (Fig. 1). Since nystatin and MNNG can both induce changes in sphingolipid profile, we were interested to know whether these agents affected the

**Fig. 2** Representative MALDI-TOF mass spectra of FL cells following different treatments. DMSO was used as solvent control. *M+N* cells were pretreated with nystatin (100  $\mu\text{g/ml}$ ) for 30 min followed by MNNG (0.2  $\mu\text{M}$ ) treatment for 8 h

**Fig. 3** Reference mass spectra of sphingolipids in cells following different treatments. *M+N* MNNG with nystatin preincubation. \*  $P < 0.05$ , compared to blank; #  $P < 0.05$ , compared to MNNG, student's *t*-test

transcription of genes of these key enzymes. Therefore, mRNA from cells with different treatments was extracted and subjected to RT-PCR to examine transcription of SPT, ASM, and SMS genes, with  $\beta$ -actin as an internal standard. As shown in Fig. 5, neither nystatin or MNNG treatment alone, nor nystatin plus MNNG treatment significantly affects the expression of mRNA of these three enzymes.

#### MNNG Activates both ASM and NSM while Preincubation with Nystatin Inhibits such Activation

Since neither MNNG nor nystatin affected the mRNA levels of these enzymes, we were interested to know if they can affect their activities. Thus, the activities of both ASM and NSM were examined after different treatments. As shown in Fig. 6, it was found that MNNG indeed can increase the activities of both ASM and NSM. In contrast, nystatin did not induce the activation of neither ASM nor NSM. On the other hand, 30 min preincubation with nystatin almost completely inhibited the activation of NSM, but only partially inhibited the activation of ASM.

## Discussion

In our laboratory MNNG is used as a model chemical to investigate characteristics of DNA damage by environmental toxins. However, during the study some phenomena independent of nuclear DNA damage were also observed, and one such phenomenon was the clustering of cell surface receptors EGFR and TNFR that occur on lipid rafts [12, 13]. Further analysis revealed that sphingolipids are involved in this process, and that MNNG can induce

profound changes in sphingolipid metabolism [13, 14]. It has also been demonstrated that nystatin, which can disrupt lipid rafts, also inhibits receptor clustering [13].

The polyene antibiotics including nystatin and filipin have long been used to interfere with lipid rafts due to their ability to interact with cholesterol [10, 18]. However, to date there had been no information regarding their effects on another important class of lipid raft components, the sphingolipids. Here for the first time, using a lipidomic approach, we have shown that nystatin also influences sphingolipid metabolism, although the effects were less profound than those of MNNG (Table 1). More importantly, it is shown that nystatin could partially inhibit the effects of MNNG. Therefore, we postulated that nystatin might also inhibit MNNG-induced, lipid raft-mediated receptor clustering through perturbation of sphingolipid metabolism.

Once receptor clustering is disrupted, it likely follows that the downstream signaling would also be disrupted. Thus, we further evaluated the activation of NF- $\kappa$ B, a known downstream signaling molecule of both EGFR and TNFR [16, 17]. Although nystatin itself did not affect the activation status of NF- $\kappa$ B, it can inhibit the activation of NF- $\kappa$ B by MNNG (Fig. 4). Hence, based on these data, it is suggested that nystatin could target lipid raft, presumably through the combined action of cholesterol depletion and altered sphingolipid metabolism, and at least partially, interfere with the function of MNNG (Fig. 7).

Sphingolipid metabolism is a very complex process, involving the regulation of many enzymes (Fig. 1). As nystatin and MNNG can both alter the sphingolipid profile, we also examined the expression levels of some key metabolic enzymes in the sphingolipid synthesis pathway, which might be responsible for the sphingolipid changes

induced by these treatments. However, our results demonstrated that the various treatments did not affect the expression of these enzymes at the mRNA level (Fig. 5). Therefore, it is more likely that changes in enzyme activity rather than changes in enzyme quantity might be the reason for altered sphingolipid metabolism. Indeed, our results showed that MNNG can activate both ASM and NSM, while nystatin can inhibit the effects of MNNG (Fig. 6).

Lipidomics is a fast growing research area, which has already been applied in biomarker discovery, drug

development, signaling pathway analysis, as well as disease mechanistic studies [19–23]. MS has been adopted as the instrumental platform of choice to investigate lipidomics by the lipid metabolites and pathways strategy (LIPID MAPS) initiative [24]. Our study, in particular, has utilized MALDI-TOF MS. Although MALDI-TOF MS has its own advantages, however, compared to other types of MS such as liquid chromatography-electrospray ionization-tandem MS (LC-ESI-MS/MS), it suffers from the poor quantification. To overcome this problem, we had developed the

RMS method to quantify the sphingolipids relative to a single, commonplace sphingolipid and, thus to facilitate comparisons among separate experiments [2]. In this study,

**Fig. 7** Illustration of proposed action of nystatin to interfere with the effects of MNNG

RMS was also established for the sphingolipid profile of human FL cells, although the defined internal reference ( $m/z$  506.0) was not the same as that for mice brain tissues ( $m/z$  753.6) [2]. This could be the result of different sphingolipid composition of different species. Nonetheless, this poses a problem when comparing results from different samples/experiments, especially across species. Recently, Fujiwaki et al. [25] used sphingosylphosphorylcholine (SPC) as an internal standard to quantitatively evaluate sphingolipids in human patients. As SPC is physiologically nonexistent in normal human tissues or body fluids except as an artifact [25], it is believed that SPC might be a better choice as externally added standard for quantification purpose.

There are also problems faced by the lipidomic study. For example, during the extraction of sphingolipids, there is the possibility of potential degradation of sphingolipids and artifact during base methanolysis, which should be recognized. Also, the assignments for sphingolipid molecule solely based on the mass determined by MALDI-TOF/MS may not be accurate, and only by further MS/MS analysis could the definite molecular structures be assigned. Still, in the present study, we first demonstrated that the polyene antibiotic nystatin can affect sphingolipid metabolism. In addition, it can inhibit the biological effects of MNNG (such as the activation of NF- $\kappa$ B), probably through the altered sphingolipid metabolism.

**Abstract** Ozone treatment of commercially available vegetable oils gives rise to the formation of chemical species that are responsible for the therapeutic properties of ozonated oil derivatives in dermatological diseases. In the last years, these products have been successfully used as a topical disinfectant in a number of serious skin affections. The medical application of empirically prepared ozonated oil has yielded striking improvements with unexpected and rapid healing, compelling us to begin a long-range study aiming first to define the main characteristics of the most common ozonated vegetable oils, about which there is usually no medical consensus because of the lack of standardization of their technological parameters. Sesame oil was selected because of its great amount of polyunsaturated acyl groups, as well as natural antioxidants. Moreover, we have determined the kinetics and optimal conditions of ozonation (e.g., ozone concentrations, time of exposure, temperature) for obtaining an ozonated oil characterized by well-established technological and physico-chemical properties, namely an accurate peroxide value determination. On the basis of the results, we have gained an understanding of the modifications of the vegetable oils during the ozonation process.

OE	Ozonation efficiency
PUFAs	Polyunsaturated fatty acids
SO	Sesame oil
TAG	Triacylglycerides

## Introduction

From many years the medical use of ozone has represented a challenging topic [1–5]. The parenteral autohemotherapy—namely the method of exposing *ex vivo* human blood to oxygen–ozone for a few minutes in an ozone-resistant glass bottle and successive, prompt reinfusion in the donor patient—is still the object of controversial findings [6]. It has been reported that ozonotherapy is very useful in many pathologies, such as chronic osteomyelitis, pleural empyema, abscesses with intractable fistulae, infected wounds, bed sores, chronic ulcers and initial gangrene, necrotizing fasciitis, diabetic foot, skin, mouth, vaginal and rectal bacterial as well as viral infections and burns [7], especially when in combination with topical therapy by ozonated oils [8, 9]. Rapid healing is attributable to the disinfectant properties of ozone and to an enhanced cell proliferation allowed by an improved oxygenation and metabolism [10]. Thus, the antimicrobial properties of ozone derivatives like ozonated oils represent an interesting pharmaceutical approach to the management of a variety of dermatological pathologies [10, 11]. Unsaturated vegetable oils react with ozone at the level of

double bonds to form ozonoid compounds that have sustained germicidal actions, as well as retaining the properties of stimulating tissue regeneration and repair.

The chemical reactions of ozone when bubbled into an oil are very complex. The analyses of these reactions provide information on the functional group changes during ozonation as well as the identification of the products without prior separation techniques, according to the well-known Criegee mechanism regarding the formation of ozonides from alkenes and ozone [12]. The peroxidic species are one of the most important products formed. This group includes hydroperoxides, hydrogen peroxides, polymeric peroxides, and other organic peroxides [13–15]. The yield of ozonated derivatives from unsaturated oils depends on reaction conditions (e.g., temperature, time, ozone generator, reactor type, stirring conditions, applied ozone dose). Therefore, an understanding of the physico-chemical properties of ozonated vegetable oils has great importance for their characterization and identification. For determining the quality of ozonated products, analytical methods such as peroxide, acidity, and iodine values are usually carried out [10, 13, 15].

Referring to ozonation of vegetable raw materials, theobroma fats [16] as well as olive, soybean and sunflower oils have been the most investigated [17–19]. The aim of the present study was to extend knowledge of pharmaceutical interest to other vegetable oil products, with particular emphasis on sesame oil (SO). It is expressed from the seeds of *Sesamum indicum*. SO is used in the pharmaceutical, cosmetic, and food industries. The major use of SO in pharmaceutical formulations is as a solvent in the preparation of sustained-release intramuscular or subcutaneous injections [20, 21] as well as an auxiliary substance in the preparation of oral capsules, disperse systems, and topical ointments [22, 23]. SO has been selected for our investigation because it is a convenient starting material, with a high concentration of olefinic double bonds. SO is composed principally of triacylglycerides (TAG). The predominant unsaturated fatty acids in SO are oleic acid (45.4%) and linoleic acid (40.4%). However, these acyl groups are not distributed randomly across the glycerol positions. The saturated acyl groups are almost exclusively in the 1 and 3 positions, and unsaturated acyl groups are predominantly in the 2 position [24]. Furthermore, SO presents significant proportions of natural antioxidants, which protect it against natural oxidation [25, 26] and could play a significant role during the ozonation process. Our goal is to investigate the doses of ozone, which, at appropriate experimental conditions, can react with oils leading to biologically active derivatives without any deleterious effect in terms of toxicity and stability. Moreover, attention should be paid to a

correct quantification of the peroxide value, because of the great number and stability properties of the various peroxidic species generated during ozone treatment [14] as well as the underestimated values obtained using official methodology.

We consider our results useful to determine technological aspects that are necessary for the optimization of ozonated oil quality.

## Experimental Procedure

### Materials

Chemicals were purchased from Sigma-Aldrich and used without further purification. In particular, the SO was obtained from the seeds of *S. indicum* (batch number S3547). 4-Hydroxynonenal (4-HNE) was obtained from Cayman Chemical Co. and stored at  $-80^{\circ}\text{C}$ .

### Ozonation Method

Ozone was generated by the  $\text{O}_3$  generator (Model Ozonosan PM 100 K, Hansler GmbH, Iffezheim, Germany) from medical-grade oxygen ( $\text{O}_2$ ) as feed gas using electrical corona arc discharge. The gas flow rate and  $\text{O}_3$  concentration have been controlled in real time by both photometric and iodometric determinations, as recommended by the Standardization Committee of the International  $\text{O}_3$  Association. The  $\text{O}_3$  flow rate was kept constant at 1.5 l/min in all experiments, and ozone concentration was 55 mg/l. The ozone/oxygen mixture was bubbled in Drechsel bottles containing 40 ml of SO for different times comprising between 15 and 120 min (SO15, SO30, SO60, SO90 and SO120), and corresponding to about 1,240, 2,480, 4,950, 7,450 and 9,900 mg of  $\text{O}_3$  dose, respectively. Gas inlet was performed by using a Drechsel bottle with a sintered filter at the bottom (porosity 145–174  $\mu\text{m}$ ), unless otherwise stated. Furthermore, we have carried out blank tests under the same conditions bubbling only oxygen for the same time (see above).

### FT-IR Spectroscopy

Ozonated SO samples were used for FT-IR spectroscopy measurement (Perkin-Elmer Spectrum BX). About 2  $\mu\text{l}$  of sample were deposited between two disks of KBr, avoiding air bubble formation [27], then the transmittance % was measured in the range 4,000–800  $\text{cm}^{-1}$ . Spectra were obtained using a 16-scan summation at a minimal resolution of 4  $\text{cm}^{-1}$ .

## NMR Spectroscopy

$^1\text{H}$  and  $^{13}\text{C}$  NMR spectroscopy was performed on a Bruker Avance 400-MHz Spectrometer; 100  $\mu\text{l}$  of each sample was placed into 5-mm tubes and dissolved in  $\text{CDCl}_3$  (750  $\mu\text{l}$ ). To obtain information on the production of toxic aldehydes like 4-HNE as by-products of ozonation, a neat SO sample was cured with 5  $\mu\text{l}$  of 4-HNE, and the  $^1\text{H}$  NMR was recorded.

## Iodine Value

The iodine value (IV) is a measure of the total number of double bonds present in the sample. It represents the quantity of iodine (in grams) that will react with the double bonds in 100 g of sample. IV was determined according to the European Pharmacopoeia [28]. The IV was calculated by means of the following equation:

$$\text{IV} = \frac{1.269 \times (n_1 - n_2)}{m} \quad (1)$$

where  $n_1$  is the volume in ml of thiosulphate solution used for carry out a blank test,  $n_2$  is the volume in ml of thiosulphate solution used for the titration, and  $m$  the quantity, in grams, of substance.

## Acid Value

The acid value (AV) is the number that expresses, in mg, the quantity of potassium hydroxide required to neutralize the free acids present in 1 g of the substance [29]. The AV was calculated by means of the following equation:

$$\text{AV} = \frac{5.610 \times n}{m} \quad (2)$$

where  $n$  is the volume in ml of titrant and  $m$  the quantity, in grams, of substance.

## Peroxide Value and Method Evaluation

The peroxide value (PV) represents the quantity of peroxide expressing in milliequivalents of active oxygen contained in 1,000 g of the sample.

PV was determined introducing changes, unless otherwise stated, into the method described in the official monograph [30], as recently evidenced by some authors in the case of materials characterized by a high peroxide content and slow iodide reactivity with dialkylperoxides [14, 31]. In particular, we are able to obtain reproducible and/or realistic results only by modifying both the temperature and the reaction time with respect to the monograph conditions. Briefly, 2 g of SO were weighed in a 250-ml conical flask, and 30 ml of chloroform/glacial

acetic acid (2:3) were added. Then, 3.0 ml of saturated potassium iodide solution was added. The flask was stirred at reflux temperature (60° C) for various times (0–180 min). After this time, the solution was cooled, and 25 ml of water was added. Solutions of sodium thiosulphate at the appropriate concentration (0.0001–0.1 M) were used for the titration. The PV was calculated by means of the following equation:

$$\text{PV} = \frac{1,000 \times (V_1 - V_0) \times c}{m} \quad (3)$$

where  $V_1$  is the volume in ml of thiosulphate solution used for the titration,  $V_0$  is the volume in ml of thiosulphate solution used for carry out a blank,  $c$  the thiosulphate concentration, and  $m$  the quantity of substance.

All samples carried out by peroxide value titration were treated in order to evaluate the reaction process. Briefly, the organic layer of titrated mixture was dried over sodium sulfate and evaporated under reduced pressure to give a yellow oil, which was analyzed by both FT-IR and  $^1\text{H}$ -NMR spectroscopies (see above).

Moreover, the ozonation efficiency (OE%) was calculated. It represents the % ratio of the amount of peroxidation due to the ozonation process, as estimated by PV value, to the amount of total ozone applied to the system.

## Viscosity Measurements

Viscosity measurements were carried out with an innovative torsional-oscillation viscometer [32] (Viscomate VM-10AL, CBC Europe). Briefly, this instrument measures viscosity by sensing a change in oscillation amplitude of a liquid-immersed detector, based on constant input voltage. The detector oscillation amplitude with no resistance is 1  $\mu\text{m}$ . Angular acceleration of the detector is measured and reported as dynamic viscosity with a declared range of 0.400–1,000 mPa s and a precision equal to  $\pm 5\%$ . All the determinations were conducted in polystyrene Technicon® sample cups (Kartell, nominal capacity 2 ml). Temperature control was accurately monitored during the experiments ( $22.0 \pm 0.1$  or  $35.0 \pm 0.1$  C). Viscosity values were recorded until equilibrium (data collection every 5 s) by PC connection through a RS-232 port.

In the present study all the physico-chemical characterizations were repeated at least three times.

## Results

### FT-IR Spectroscopy

For the IR spectroscopy of SO we have focused our attention on the wave numbers characterizing the double bond, C=C

stretching ( $1,654\text{ cm}^{-1}$ ) and  $\text{=C-H}$  stretching ( $3,009\text{ cm}^{-1}$ ) [33], as well as the ozonide CO stretching (the  $1,105\text{ cm}^{-1}$ ) by unsaturated fatty acid moieties [34, 35]. As expected, the intensity of the bands corresponding to the double bond decreases and the band identifying the formation of the ozonide increases with respect to time of ozone treatment (Fig. 1). Apparently, when we have the maximum ozone dose, all double bond signals disappeared. As can be seen, the peaks reported above reveal the chemical changes occurring in the fatty acid chain during the reaction.

### NMR Spectroscopy

The  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR assignment to principal peaks of SO are listed in Table 1. The proton and carbon resonances were assigned according with literature data, as obtained for similar vegetable oils [25, 34]. The  $^1\text{H}$  NMR spectrum of SO is shown in Fig. 2, top. NMR analyses confirmed the structural changes undergone by oil during the ozonation (Fig. 2, bottom). The new signals found in ozonated oil are summarized in Table 2. In  $^1\text{H}$  NMR spectra of ozonated SO, new signal at 5.15 ppm appears, attributed to the ring proton of 1,2,4-trioxolane. Such evidence was confirmed by the appearance of signal in  $^{13}\text{C}$  NMR spectra at 104.33 ppm assigned by Wu et al. [36] as the ring carbon in the same structure. Moreover, the decrease of multiplet at 5.20–5.38 ppm and of signals at

128.06–130.16 ppm was observed in the  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra, respectively, due to olefinic moiety. Furthermore, a new signal at 5.56 ppm, assigned as protons directly bonded to  $\text{sp}^2$ -hybridized carbons, appeared at the early stage of ozonation (until 60 min) to gradually decrease, in agreement with previous results obtained for transesterified sunflower oil [34].

The protons of the methylene group  $\alpha$  to the  $\text{sp}^2$ -hybridized carbons resonated at 2.00 and 2.71 ppm before the ozonation and shifted to 1.36 and 1.65 ppm after formation of 1,2,4-trioxolane [37].  $^1\text{H}$  NMR spectra of ozonated SO showed peaks at 9.69 and 2.42 ppm attributable to the aldehydic proton and the methylene proton  $\alpha$  to the carbonyl carbon, respectively. In  $^{13}\text{C}$  NMR, the carbonyl carbon, and the carbon  $\alpha$  to it, resonated at 202.58 and 44.02 ppm, respectively.

### Iodine, Acid and Peroxide Values

In Table 3 the IV, AV, PV as well as the ozonation efficiency are reported. As far as IV is concerned, it decreases as the insufflated ozone dose increases, leaving from the value of 113.65 (according to certificate of analysis limits, 103–116) to 13.39 with the greater ozone dose used (9,900 mg). Such a value is indicative that about all of the unsaturated group in SO reacted with ozone, according to the double bond disappearance.

**Fig. 1** FT-IR spectroscopy of the samples after exposure to progressively increasing ozone amounts

**Table 1**  $^1\text{H}$  and  $^{13}\text{C}$  NMR assignments of neat sesame oil (SO)

Chemical shift (ppm)		Functional group
$^1\text{H}$	$^{13}\text{C}$	
0.83	14.28	$-\text{CH}_3$
1.27	29.15–31.89	$-(\text{CH}_2)_n-$
1.60	24.84	$-\text{CH}_2-\text{CH}_2-\text{OCO}-$
2.00	27.18	$-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2-$
2.30	34.08	$-\text{CH}_2-\text{OCO}-$
2.71	25.62	$-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-$
4.05–4.35	173.07	$-\text{CH}_2-\text{OCOR}$
5.20–5.26	172.73	$>\text{CH}-\text{OCOR}$
5.20–5.38	128.06–130.16	$-\text{CH}_2-\text{CH}=\text{CH}-\text{CH}_2-$
–	172.98	$-\text{OCO}-$

An increase in both acidity and peroxidation values was observed. In detail, about 18- and 34-fold grow-up with respect to the initial value and ozonation time was obtained,

**Fig. 2**  $^1\text{H}$  NMR spectra: neat sesame oil (before ozone treatment) and ozonated sesame oil (after ozone treatment, 90 min)

respectively (see Table 3). In the first ozonation phase (SO30, 2,480 mg of ozone) the increase was fast, followed by a decrease in rate, until the plateau of about 3,800 was obtained in terms of peroxide value (SO120, 9,900 mg of ozone). These results were expected because, in preliminary experiments, we noted only a partial reaction of ozone in the oil compartment, as evidenced by an increased amount of ozone recovered in a suitable iodide trap that was posed after the vessel. Such a phenomenon is justified if we consider that a substantial portion of the unsaturation became slow reacting with time, because of probabilistic and steric conditions [38]. This behavior might be due to formation of polymeric peroxides, which are responsible for viscous mass achieved after massive ozonation.

In Table 3, ozonation efficiency was also reported. It represents an estimation of the amount of ozonated compound, evaluated by PV, to the amount of the applied ozone. As expected, the reaction yield decreases because of the double bond disappearance with time.

### Method Evaluation of the Peroxide Value

The PV determination according to the European Pharmacopoeia [30] leads to an underestimation of  $O_3$  reacting with unsaturated substrates. In fact, these values are very low with regard to the  $O_3$  dose insufflated ( $PV < 350$ , see Fig. 3). The difference between values among the various treatment times is minimal, even if statistically significant ( $P < 0.001$ ), in all cases except between SO90 and SO120.

**Table 2**  $^1H$  and  $^{13}C$  NMR new signals of ozonated sesame oil

Chemical shift (ppm)		Functional group
$^1H$	$^{13}C$	
5.15	104.33	1,2,4-trioxolane
1.36	–	– $CH_2-CH=CH-CH_2-$
1.65	–	– $CH=CH-CH_2-CH=CH-$
2.42	44.02	$\alpha$ -Methylene group

FT-IR spectra of titrated samples confirm this assumption: ozonide CO stretching ( $1,105\text{ cm}^{-1}$ ) was unchanged between the control sample and the sample titrated according to Pharmacopoeia (Fig. 4). Such a result was also validated by the signal at 5.15 ppm in NMR spectra (data not shown).

The behavior is different if the sample was stirred at reflux temperature: PV considerably increases already after 10 min (about 2,800 for SO120), corresponding to a decrease in the CO stretching band. The full titration was carried out for 180 min at reflux. The plateau, defined as the absence of statistically significant differences between two successive points, was reached after 120 min for SO15, SO30, and SO60, whereas the samples SO90 and SO120 required minor reflux times (30 min).

The data were confirmed by NMR spectroscopy analysis carried out on oil recovered from the titration, where the 5.15 ppm signal disappears.

It should be noted that the heat treatment does not change the FT-IR transmittance band of the SO control sample (Fig. 4, left side).

**Table 3** Iodine value (IV), acid value (AV) and peroxide value (PV) of the samples after exposure to progressively increasing ozone amounts

Sample	Ozone dose (mg)	IV (g/100 g)	AV (mg KOH/g)	PV (mEq/1,000 g)	OE (%)
SO	0	113.65 ( $\pm 1.50$ )	0.70 ( $\pm 0.01$ )	104 ( $\pm 3$ )	–
SO15	1,240	92.20 ( $\pm 1.60$ )	2.30 ( $\pm 0.08$ )	1,480 ( $\pm 70$ )	96
SO30	2,480	79.65 ( $\pm 4.80$ )	3.19 ( $\pm 0.08$ )	2,503 ( $\pm 101$ )	84
SO60	4,950	52.65 ( $\pm 1.10$ )	7.40 ( $\pm 0.18$ )	3,100 ( $\pm 93$ )	52
SO90	7,425	37.10 ( $\pm 1.00$ )	9.80 ( $\pm 0.30$ )	3,440 ( $\pm 89$ )	38
SO120	9,900	13.90 ( $\pm 0.50$ )	12.6 ( $\pm 0.35$ )	3,800 ( $\pm 179$ )	31

**Fig. 3** Peroxide values at the different conditions adopted (see text for explanation)

**Fig. 4** FT-IR spectroscopy of titration samples (SO, SO30 and SO60): **a** control, **b** titration in agreement with the European Pharmacopoeia monograph, **c** reflux time 10 min, **d** reflux time 60 min

**Fig. 5** Viscosity measurements of the samples after exposure to progressively increasing ozone amounts: open circle and solid circle refer to 35 °C and room temperature, respectively

As expected, the OE% is almost quantitative (>96%) and anyhow high (>80%) for SO15 and SO30, respectively. After this time, it is possible to observe a reduction in the ozone yield (until 31%, SO120) due to a lack in the number of available double bonds for the reaction (Table 3).

#### Viscosity Measurement

An increase of the ozonation time leads to an exponential trend in the increase of the sample viscosity, as shown in Fig. 5. Ozonated SO reached viscosity values up to 900 and 400 mPa s, depending to the temperature of determination (22 and 35 °C, respectively).

It is noteworthy that when ozone inlet was performed by using a Drechsel bottle with Drechsel bottle heads in the absence or in the presence of a sintered filter disk,

analogous results in terms of IV, PV NMR and FT–IR characterization as well as viscosity determination were always obtained. Moreover, when oxygen inlet instead of ozone was performed as control, no differences were observed with respect to the native SO characteristics.

Eventually, the stability of the ozonated oil was monitored over a period of at least 1 year. No appreciable changes in the physico-chemical profile of the derivatives was observed if they were stored at room temperature in the dark.

## Discussion

SO represents a valuable matrix to obtain derivatives useful in treating dermatological affections. SO was selected because this vegetable product is often used in pharmaceutical formulations, but it was never characterized in terms of its reactivity with ozonation processes. Our proposed accurate methods to check the oxidative processes and status are important factors in terms of sample stability.

Specific bibliographic information on the spectroscopic characterization (FT–IR and NMR) of SO derivatives generated by ozonation is absent. Ozone concentration and time of reaction are important for the ozonation reaction. The appreciable change in the FT–IR spectra between 3,300 and 3,600  $\text{cm}^{-1}$  broad peak, indicating the presence of hydroxyl groups in the ozonated oil different from SO [35], was not evidenced in our study.

The extent of ozonation had very little effect on the aldehyde-to-ozonide ratio obtained from NMR spectra. These results indicate that, as expected, also for SO the NMR spectroscopy can provide valuable information about the amount of reaction compounds during ozone treatment.  $^1\text{H}$ -NMR spectra of neat oil samples and ozone-treated oil showed peaks due to methyl protons from fatty acids. It was also evidenced from NMR spectra that the double bond peak decreased in intensity after ozonation. Moreover, the appearance of new peaks at 2.42 and 9.69 ppm for the ozonated oils is comparable with analogous derivatives obtained for similar substances (2.50 and 9.75 ppm). These results can be explained by the decomposition of all the peroxidic compounds present in the different equilibriums into the same reaction system. One example of these is the formation of carboxylic acid from peroxidic compounds. Besides, SO has a high proportion of unsaturated fatty acid, leading to a very complex ozonated system where the peroxidic compound decomposition to acid is very high.

As far as formation of several secondary oxidation products is concerned, aldehydes are of peculiar concern in terms of their cytotoxic and genotoxic potentiality [39]. In particular, among the reactive species produced upon lipid

peroxidation, 4-HNE is one of the most abundant aldehydes when ozone reacts with olefins in the presence of water [40]. In the overall spectra, it was observed that the specific region of this compound (9.57–9.59 ppm) was free of signals, leading us to conclude that 4-HNE is not a secondary product of SO ozonation.

During ozonation reaction, ozone reacted with the vegetable oils that have high levels of polyunsaturated fatty acids (PUFAs). This aspect was evidenced by the IV decrease in relation to applied ozone dosage, representing a measure of the residual double bonds. Almost all unsaturated groups reacted with ozone, even if the condensation of peroxides led to a thickening of the system that could limit the whole double bond accessibility [19, 24].

The reaction of ozone with PUFAs present in SO, as well as in other unsaturated substrates, produces different types of peroxidic compounds as described by the Criegee mechanism, and the peroxide value represents the method generally employed to determine total peroxidic compounds formed. However, the official monographs report standard methods based on iodometric characterization with a reaction time of 1 min to analyze the samples. It should be observed that these assays apply well only to samples at low content of peroxidic compounds. In fact, ozonated SO as well as other unsaturated oils contains a great amount and diversity of peroxides. For these reason, different conditions could be necessary to determine its correct peroxide content. In particular, the prescribed reaction time of 1 min is insufficient for determining all kinds of long-chain peroxides [14, 31].

Acids are directly formed both during ozonation and because of peroxide decomposition. However, at these conditions, a high acidity value does not directly indicate that the oil quality has diminished and is at risk of becoming rancid.

Viscosity represents an evaluation of the peroxides species that are generated during the SO ozonation process, giving information about: (1) the increase of the van der Waals interactions due to the disappearance of the double bonds, indicating that the double bonds in the oil molecules reacted with ozone to form a more bulky molecule; (2) the modification of the unsaturated acyl chains ozonation kinetic, affecting the mobility and the reactivity of the species involved in the reaction. This aspect is of particular importance in terms of product characterization and evaluation of the ozonation reaction. Furthermore, our proposed method represents a useful online instrumentation that doesn't require periodic recalibration or frequent maintenance while providing continuous data logging during both ozonation reaction and storage time.

It could be considered that, when ozone inlet was performed by using the Drechsel bottle with Drechsel bottle heads in the absence or in the presence of sintered filter

disk, a large vortex is always formed, resulting in significant mixing of the liquid phase and high ozone dispersion and reactivity, leading to a high efficiency of the various systems.

In conclusion, these results suggest that physico-chemical properties can provide valuable information about the ozonation level of SO and its potential applicability in dermatological infective pathologies. The evaluation of the oxygenated compound derived by ozonation processes is necessary in order to deepen the mechanism of action of these products. The future objectives will be the ongoing preclinic studies of both their antimicrobial properties and in vivo assessment of nontoxicity/allergenicity as well as the therapeutic activity of ozonated SO at different concentrations in a variety of chronic skin ulcers of patients with peripheral obstructive arterial diseases.

**Abstract** The present review is focused on the metabolism and the emerging roles of oleoylethanolamide (OEA) with emphasis on its effects on food intake control and lipid metabolism. The biological mechanism of action, including a non-genomic effect mediated through peroxisome proliferator-activated receptor alpha (PPAR- $\alpha$ ) and transient receptor potential vanilloid type 1 (TRPV1) receptor, is discussed. The research related to fatty acid ethanolamides has been focused until recently on anandamide and its interaction with cannabinoid receptor subtype 1. The roles of other *N*-acyl ethanolamine fatty acid derivatives have been neglected until it was demonstrated that OEA can modulate food intake control through interaction with PPAR- $\alpha$ . Further investigations demonstrated that OEA modulates lipid and glucose metabolism, and recent study confirmed that OEA is an antagonist of TRPV1. It has been demonstrated that OEA has beneficial effects on health by inducing food intake control, lipid

$\beta$ -oxidation, body weight loss and analgesic effects. The investigation of the mechanism of action revealed that OEA activates PPAR- $\alpha$  and stimulates the vagal nerve through the capsaicin receptor TRPV1. Pre-clinical studies showed that OEA remains active when administered orally.

### Introduction

Fatty acid ethanolamides belong to a family of lipids naturally found in both plant and animal tissues. These fatty acid derivatives appear to have biological properties. Indeed, palmitoylethanolamide (PEA, derived from palmitic acid) has anti-nociceptive and anti-inflammatory properties [1]. Within this family, anandamide (derived from arachidonic acid) has been of great interest. In the last decade, it was discovered that anandamide is an endogenous ligand for cannabinoid receptor subtype 1 (CB1). Activating CB1, anandamide increases food intake. Another interesting fatty acid amide is oleoylethanolamide (OEA), formed from oleic acid and phosphatidylethanolamine. Biological functions of OEA, such as anorexigenic or body fat loss properties, have been extensively studied over the past decade. This molecule is naturally present at low concentrations in food products, such as cocoa powder (up to 2  $\mu$ g/g), oatmeal or nuts [2, 3]. Biologically, the OEA function is to regulate food intake via a synthesis/degradation balance, which occurs mainly in the enterocytes (brush border). The present review is focused on these recently discovered biological functions of OEA, its metabolism and analysis.

## Biological Functions of Oleoylethanolamide

### Effect of Oleoylethanolamide on Food Intake Control

Oleoylethanolamide is synthesized in the small intestine of various vertebrate species, where its level decreases during food deprivation and increases upon re-feeding [2, 4, 5]. The increased level of plasmatic OEA after feeding could be due to the presence of OEA in food [2, 3], but OEA concentrations in food products are really low (under 2 µg/g of food), suggesting that one part of the increased level of OEA is linked to an activated endogenous synthesis. Indeed, food intake may stimulate *N*-acyltransferase (NAT) activity, and biosynthesized OEA can trigger satiety signals [2, 4, 5]. In brain, the anandamide concentration significantly increases upon severe food restriction. The level of this endocannabinoid is modulated in the brain structures according to the feeding status and depending on specific localization in the brain. Anandamide levels do not change in the hypothalamus, but increase in the limbic forebrain [6]. Anandamide and OEA were shown to be active through two distinct pathways. Thus, anandamide activates cannabinoid receptor CB1 mainly in the mesolimbic system [6], leading to an increase of food intake, whereas intestinal OEA induces a satiety signal, leading to a decrease of food intake. Similarly to anandamide, the natural levels of OEA change with respect to the nutritional status, leading to a precise control of food intake. This control is central to induce food intake and peripheral to induce satiety [5].

Pharmacological studies have been performed to better understand how a very simple fatty acid derivative can control food intake. A significant decrease of food intake was observed for 4 h after intraperitoneal (ip) injection of OEA at 5 mg/kg of body weight and for all of the 9 days of the experiment in rats [7]. The same treatment also lowered the body weight gain compared to the control [7]. Intracerebroventricular administration of OEA did not induce any effects underlying the peripheral action of OEA [4]. Various OEA doses have been tested with ip administration from 5 to 20 mg/kg of body weight, always leading to a dose-dependent decrease of food intake. Compared to the control (animals injected with vehicles), the percentages of food intake decrease were 32, 24 and 14%, respectively, for 20, 10 and 5 mg of OEA/kg bw on the 24 h following the injection [8, 9]. These measures were performed in a 24-h experiment. The effects of OEA on food intake were reproducible for 14 days. Indeed, subchronic intraperitoneal administration of 5 mg OEA/kg bw induced a global diminution of food consumption. Cumulative food intake was significantly decreased over the 14 days of the experiment, but the daily food intake was not significantly lower compared to controls among these experimental

periods. Nevertheless, the subchronic OEA administration, with a daily injection of 5 mg OEA/kg bw, induced a 3% significant decrease of body weight for all of the experiment [10].

Further studies looking at the oral administration effect of OEA confirmed that OEA acts peripherally [11]. When OEA was administrated by gavage at different concentrations, a significant decrease of food intake on 24 h was observed at 200 mg/kg of oral OEA [11]. When OEA was administrated in pH-protective capsules (releasing OEA at pH 6), a similar effect was observed at a fourfold lower level (50 mg/kg bw) [12]. The effects of OEA capsules were significantly different from controls 5 h after administration, which corresponds to the time for the capsules to go from the stomach to the small intestine. All together, these results suggest that OEA reduces food intake by acting at a local site within the small intestine [12]. Several meal parameters have also been monitored and demonstrated that OEA induced a delay of the first meal, a decrease of the size of the first meal and an increase of the post-meal intervals [12]. It has been shown that ethanolamine and oleic acid, the degradation products of OEA, did not have any influence on food intake when administrated orally [11]. A bioavailability study, using radiolabeled OEA administrated to rats by gavage (10 mg/kg of body weight), has been performed to assess OEA degradation in the gastrointestinal tract [11]. This treatment increased the OEA level to about 11 times in intestinal tissue. However, only 0.48% of the given dose was found unchanged in the tissue. The ratio of intact OEA to hydrolyzed OEA decreased along the gastrointestinal tract, showing that OEA is progressively catabolized [11].

In parallel, studies have been performed to establish whether OEA has any influence on the synthesis of satiety signaling biomarkers, such as glucagon-like peptide-1 (GLP-1), cholecystokinin (CCK) and peptide YY (PYY), which have satietogenic effects, and ghrelin, which stimulates appetite. These molecules act along the gastrointestinal tract and are secreted separately depending on the nutritional status. The satietogenic peptides GLP-1, CCK and PYY are released during the post-prandial period, whereas the ghrelin plasma level is increased under starvation. The alternative release of these different biomarkers contributes strongly to food consumption regulation. Intraperitoneal injection of OEA was shown to reduce the ghrelin level, but not the GLP-1 concentration in rats [13], whereas CCK and PYY remained unaffected [8]. The anorectic effects of OEA do not imply the modulation of the secretion of satiety signals [8, 13].

Satiatogenic properties of OEA can also be partially explained by its action on the gastrointestinal tract itself. Indeed, OEA delays gastric emptying [14] and slows down intestinal motility [15]. The delay of these parameters has a

strong influence on nutrient absorption and thus on food intake control. All together, these results suggest that OEA plays a role in the peripheral control of food intake that has to be integrated with the nervous and hormonal control of satiety. Nevertheless, more studies are necessary to confirm that OEA properties that were observed in *in vitro* studies or in animal models are applicable to humans for therapeutic metabolic health.

#### Effects of Oleoylethanolamide on Lipid Metabolism

The modulation of lipid metabolism by OEA was initially demonstrated by Rodriguez de Fonseca et al. [4]. Indeed, OEA treatment induced a higher reduction of body weight gain than the one observed in the pair-fed group, demonstrating that the effect on body weight is not only due to the decrease of food intake, but also to a direct effect on lipid metabolism [4]. Intraperitoneal administration of 5 mg/kg of OEA in rats increased the expression of FAT/CD36 (fatty acid translocase) in adipose tissues [4]. Following this observation, the OEA effect was tested on cell cultures of enterocytes and adipocytes. In adipocytes, OEA induced an increase of the FAT/CD36 expression and of the fatty acid release, suggesting an increased lipolysis [7]; it is also an agonist of the capsaicin receptor transient receptor potential vanilloid type 1 (TRPV1) that is expressed in preadipocytes. Once activated, this receptor inhibits differentiation of preadipocytes and adipogenesis [16]. In enterocytes, an increase of FAT/CD36 expression and of fatty acid uptake was demonstrated after OEA treatment [7]. These observations suggest that the increased fatty acid uptake in enterocytes is due to the decreased food intake and body weight gain. OEA would enhance the utilization of nutrients in the small intestine. These findings support the fact that OEA would play an important role in lipid metabolism by increasing the lipolysis in adipocytes and, simultaneously, increasing fatty acid uptake in the intestine, partially implicating the modulation of FAT/CD36 expression [7]. These results on lipolysis were previously demonstrated *in vivo*, suggesting a role of peroxisome proliferator-activated receptor alpha (PPAR- $\alpha$ ) in fatty acid  $\beta$ -oxidation in muscle through a study performed on PPAR- $\alpha$  null mice [17], but also in obese rats, as OEA treatment can reduce the accumulation of lipid droplets in the liver and significantly decrease plasma cholesterol and triglyceride levels [10].

These results suggest that OEA has lipolytic properties through the inhibition of adipogenesis in adipose tissue [16] and the activation of lipid  $\beta$ -oxidation in muscle [17]. Nevertheless, OEA concentration was not decreased during preadipocyte differentiation after the negative control of leptin or PPAR- $\gamma$ , contrary to the level of its anti-inflammatory analogue PEA [16]. These last findings do not favor

the local action of OEA on preadipocyte differentiation through the activation of TRPV1 [18]. Consequently, the major action of OEA on lipid metabolism would be essentially an increased lipid  $\beta$ -oxidation in muscle and a better fat utilization through a higher lipolysis in mature adipocytes. These results would have to be confirmed in humans through clinical trials.

#### Oleoylethanolamide Acts Peripherally

It has been demonstrated that in some of the OEAs observed, peripheral anorexic effects [4] are mediated by the activation of peroxisome proliferator-activated receptor alpha (PPAR- $\alpha$ ) [19] with a relatively high affinity ( $K_d = 37.4$  nM) compared to other potential endogenous ligands of PPAR- $\alpha$  present in partially digested food, such as free fatty acids [20]. A study has been performed in wild-type and PPAR- $\alpha$  knock-out mice to understand how OEA, which is a potent endogenous PPAR- $\alpha$  agonist, can regulate food intake and body weight gain [10]. This study showed that OEA reduces food intake, inhibits body-weight gain and lowers plasma cholesterol levels in wild-type mice, whereas it does not have such effects in PPAR- $\alpha$  mutant mice [10]. This implication of PPAR- $\alpha$  in the OEA mechanism of action has also been confirmed with some *in vitro* gene reporter assays on cell cultures [21].

In addition to its interaction with PPAR- $\alpha$ , OEA has been shown to be an agonist of TRPV1. At submicromolar concentrations, OEA activates native TRPV1 in rodents on perivascular sensory nerves and elicits whole cell currents and fluorometric calcium response in human cell lines expressing TRPV1 [22]. TRPV1 activation leads to the excitation of peripheral vagal sensory nerves involved in the nervous control of food intake [23]. TRPV1 is expressed in both nociceptive neurons, where it is involved in the detection of noxious chemicals and thermal stimuli, and in visceral sensory neurons and brain, where it could have a role on food intake control. OEA was shown to indirectly regulate the activity of TRPV1 and the excitation of sensory nerves expressing TRPV1. Indeed, if TRPV1 is phosphorylated by the protein kinase C, it becomes more sensitive to OEA activation [23]. To confirm TRPV1 involvement in OEA effects on food intake, normal mice and TRPV1-null mice were injected with OEA (12.5 mg/kg bw). Short-term feeding was significantly reduced in the control group, but not in the TRPV1-null group, showing the role of this receptor in feeding regulation [22, 24]. Another study was performed *in vivo* and *in vitro* to establish the relationship between the rat TRPV1 receptor and OEA, employing measurement of  $^{45}\text{Ca}^{2+}$  uptake in TRPV1 receptor-transfected cells. OEA showed agonist properties on TRPV1 receptor by stopping  $^{45}\text{Ca}^{2+}$  uptake in cells expressing TRPV1 [25]. The mechanism of action of OEA on TRPV1

is linked to a  $\text{Ca}^{2+}$  concentration modulation inside the cell, inducing an effect on vagal sensory nerves and, consequently, on food intake regulation.

Furthermore, a protein-G coupled receptor (GPR119) having affinity with OEA (OEA activates GPR119 with an  $\text{EC}_{50}$  superior to  $30 \mu\text{M}$ ) has been recently identified in intestinal and pancreatic cells [26, 27]. This receptor is mainly expressed in the gastrointestinal tract and in the pancreas. A specific agonist of GPR119, named PSN632408, has been identified. The satietogenic efficiency of PSN632408 was investigated in vivo through intraperitoneal administration ( $100 \text{ mg/kg bw}$ ). It induced a 30% decrease of food intake, strongly associated to GPR119 activation. As GPR119 is activated by OEA, it could partially participate in OEA satietogenic effects [26]. However, although the implication of GPR119 in food intake regulation has been demonstrated, it is still uncertain whether it can be activated in vivo by OEA [28].

In Fig. 1, a tentative mechanism of action of OEA on the control of food intake is proposed. Fatty acids and derivatives such as OEA are PPAR- $\alpha$  ligands ( $\text{Kd} = 37.4 \text{ nM}$  for OEA) [19, 29]. OEA can activate intestinal PPAR- $\alpha$ , inducing the activation of other nuclear receptors such as RXR. Indeed, PPAR- $\alpha$  and RXR can form a heterodimer that can bind to response elements, leading to the activation of target gene transcription [29, 30]. These expression modulations would be involved in food intake and lipid metabolism regulation. In addition to this intestinal effect, circulating OEA could block TRPV1 receptors on neuronal cells. This mechanism would modify the electrical status of the  $\text{Ca}^{2+}$  channel, inducing small depolarization [24]. Thus, the vagal sensory nerves would be excited, directly influencing food intake regulation.

**Fig. 1** Mechanism of action of oleoylethanolamide. PPAR- $\alpha$  and TRPV1 stand respectively for peroxisome proliferator-activated receptor  $\alpha$  and transient receptor potential vanilloid 1

## Effects of Oleoylethanolamide on Glucose Metabolism

Rats, intraperitoneally treated with OEA, showed a glucose intolerance compared to control without decreasing the insulin level [31]. The effects of OEA on the plasma glucose management were tested in vivo by performing glucose tolerance tests [31]. OEA-treated animals had significantly higher plasma glucose after 30 min of glucose load, but no other significant differences in any other time points have been noticed, indicating an impairing effect on glucose tolerance in the short term rather than a diabetogenic effect [31].

Some experiments performed on isolated adipocytes showed that OEA induces a 30% inhibition of insulin-stimulated glucose uptake and inhibits insulin action [31]. These observations cannot totally explain the glucose intolerance observed in rats in vivo [31], because, on one hand, the glucose transport inhibition due to OEA in adipocytes is really low, and, on the other hand, only part of the glucose clearance from the blood happens in adipocytes; the liver and the skeletal muscles strongly contribute to this phenomenon. Moreover, in another study, OEA administration did not induce modification of blood glucose levels at any time point [10], and it has been reported that OEA can trigger phosphorylation of the glucose transporter GLUT4, which could counterbalance the observed OEA inhibition of insulin-stimulated glucose transport [31]. Indeed, glucose transport activity has been reported to be mediated by phosphorylation and dephosphorylation of transporters such as GLUT4.

Oleoylethanolamide effects on glucose metabolism seem to depend on the tissue; further studies need to be performed, including a glucose tolerance test on hepatic cells.

## Metabolism of Oleoylethanolamide in Animals

In mammalian tissue, the synthesis/degradation of OEA occurs mainly in specific cells, such as enterocytes (brush border) [32–40]; nevertheless, OEA biosynthesis has also been observed in adipose tissue and in insulinoma  $\beta$ -cells [41]. OEA biosynthesis involves two steps, which are catalyzed by two different enzymes called NAT and *N*-acyl-phosphatidylethanolamine phospholipase D (NAPE-PLD) (Fig. 2) [42, 43]. The first step, catalyzed by NAT, consists of the *N*-acylation of an oleic acid residue from membrane phosphatidylcholine (PC) to a phosphatidylethanolamine (PE). Different pathways have been proposed for the formation of *N*-acyl-phosphatidylethanolamine (NAPE) by inter- or intra-molecular *N*-acylation from PE, PC, lyso-PC or cardiolipin (Fig. 3) [43]. OEA, together with a phosphatidic acid molecule, is released from the

**Fig. 2** Metabolism of oleylethanolamide (adapted from LoVerme et al. [42] and Schmid [43])

NAPE formed by NAPE-PLD-catalyzed hydrolysis. Alternatively, hydrolysis can be catalyzed by phosphodiesterase. OEA can be broken down into oleic acid and ethanolamine by two different hydrolases: fatty acid amide hydrolase (FAAH) or *N*-acylsphingosine amidohydrolase-

like protein (ASAH like-protein) [44]. FAAH is specific for fatty acid amides and mainly responsible of OEA degradation according to high levels of plasma OEA in FAAH-null mice [15], and ASAH like-protein is a more ubiquitous amidase (Fig. 4) [42].

**Fig. 3** Inter- and intra-molecular N-acylation of PE from PC (adapted from Schmid [43])

**Fig. 4** Catabolism of oleoylethanolamide, adapted from LoVerme et al. [42]

Moreover, the link between OEA and food intake regulation has been shown by Fu et al. [45]; indeed, feeding stimulates OEA mobilization in the mucosal layer of rat duodenum and jejunum by increasing NAPE-PLD activity and expression and by decreasing amido-hydrolase (FAAH) activity and expression. Nutrient availability regulates OEA mobilization in the mucosa of the proximal intestine through a concerted regulation of OEA biosynthesis and degradation [45].

Astarita et al. [2] examined whether feeding-induced OEA mobilization can be observed in Burmese pythons (*Python molurus*), which consume huge meals after months of fasting. Their way of feeding seems to depend on changes in gastrointestinal hormonal release and gut morphology. A nearly 300-fold increase in OEA levels in the small intestine of fed compared to fasted animals has been observed [2]. NAPE species increase simultaneously with OEA in situ; therefore, NAPEs can be considered as potential biosynthetic precursors for OEA.

OEA synthesis in the intestinal mucosa has been extensively studied; less is known about the regulation of OEA synthesis in other tissues. In adipocytes, OEA levels do not vary during differentiation, contrary to PEA levels [41], whereas in insulinoma  $\beta$ -cells, OEA levels are decreased under “high glucose” conditions [41]. In “high glucose” conditions, OEA biosynthesis is activated by glucose and insulin [41]. In addition, diabetes type II patients are characterized by a higher OEA level in their plasma after food consumption [41]. All together, these results suggest that OEA biosynthesis is downregulated under transient hyperglycemia [41].

## Conclusion and Perspectives

Oleoylethanolamide is a very promising molecule; the simple derivative of oleic acid is a transient endogenous signaling lipid formed from PE and PC through the actions of NAT and NAPE-PLD. After ingestion, OEA has a short lifetime and is cleaved into acid oleic and ethanolamine by the FAAH or the ASAH-like protein in many tissues, including the gastrointestinal tract. The core biological functions of OEA are (1) to control food intake through activation of peripheral PPAR- $\alpha$ , (2) to promote lipid utilization and (3) to modulate lipid storage in liver and

circulating plasma lipids (triglycerides and cholesterol). However, the effects of chronic oral administration of OEA on lipid metabolism and satiety have not been extensively studied to date. The gap between the science and the potential applications in weight management is important, and studies evaluating long-term effects and safety are necessary.

# Substrate Preferences of a Lysophosphatidylcholine Acyltransferase Highlight Its Role in Phospholipid Remodeling

**Abstract** An important enzyme involved in phospholipid turnover is the acyl-CoA: lysophosphatidylcholine acyltransferase (LPCAT). Here, we report characterization of a newly discovered human LPCAT (LPCAT3), which has distinct substrate preferences strikingly consistent with a role in phosphatidylcholine (PtdCho) remodeling and modulating fatty acid composition of PtdCho. LPCAT3 prefers lysophosphatidylcholine (lysoPtdCho) with saturated fatty acid at the *sn*-1 position and exhibits acyl donor preference towards linoleoyl-CoA and arachidonoyl-CoA. Furthermore, LPCAT3 is active in mediating 1-*O*-alkyl-*sn*-glycero-3-phosphocholine acylation with long chain fatty acyl-CoAs to generate 1-*O*-alkyl-phosphatidylcholine, another very important constitute of mammalian membrane systems. These properties are precisely the known attributes of LPCAT previously ascribed to the isoform involved in Lands' cycle, and thus strongly suggest that LPCAT3 is involved in phospholipids remodeling to achieve appropriate membrane lipid fatty acid composition.

## Introduction

Phosphatidylcholine (PtdCho) is one type of glycerolipid molecule that is present in almost all cellular membrane systems. An important aspect of PtdCho metabolism first discovered by Lands almost a half century ago was that PtdCho synthesized through the *de novo* pathways undergoes extensive remodeling [1–4]. The remodeling process, which concerns the turnover of about half of the PtdCho molecules, involves the deacylation of PtdCho

to lysophosphatidylcholine (lysoPtdCho), followed by reacylation of lysoPtdCho to PtdCho. It has since become apparent that the process of PtdCho remodeling concerns a wide range of cellular activities because fatty acids derived from PtdCho can be precursors for the biosynthesis of other lipid-related molecules, and that any change in the balance of the deacylation/reacylation processes may have a direct consequence to membrane lipid composition. One key enzymatic component involved in PtdCho remodeling is acyl-CoA: lysophosphatidylcholine acyltransferase (LPCAT), which is detected in many different types of mammalian cells [4].

Fatty acyltransferases are integral membrane proteins recalcitrant to purification, and often exhibit promiscuity in regards to substrate specificity. Recently, identifications of several LPCAT enzymes have been reported; they all mediate the *sn*-2 acylation of lysoPtdCho, but also have their own distinct functionalities. For example, LPCAT1 identified from lung alveolar type II cells was responsible for lung surfactant PtdCho production [5, 6]. An isoform with lyso-platelet-activating factor (lysoPAF) and lysoPtdCho dual substrate acyltransferase was reported as involved in inflammatory process in inflammatory cells [7]. Another isoform particularly important for PtdCho biosynthesis in human red blood cells was also identified [8]. With regard to structure, all these enzymes exhibit high sequence similarity to the previously identified *sn*-2 lysophosphatidic acid acyltransferase family, which is characterized by four highly conserved motifs [9].

We and others have recently reported a new lysophosphatidylcholine acyltransferase (LCA1) from yeast that is predominant in mediating lysoPtdCho acylation [2, 10–13]. Structurally, the yeast LPCAT is closely related to the membrane-bound *O*-acyltransferase (MBOAT) family and does not possess the conserved motifs of the previously studied *sn*-2 acyltransferases [9]. The present study was conducted to examine the biochemical function of LCA1 close homologs from mammals. Data presented in this report extend the latest reports from Zhao et al. [14] and Hishikawa et al. [15] on the LPCAT activity of this class of enzyme, but we conducted our study through heterologous expression in a yeast LPCAT knockout mutant that had a very low LPCAT background, and hence ideal for substrate specificity characterization. Our results serve to emphasize the properties that draw attention to its role in PtdCho remodeling and modulating the fatty acid compositions of PtdCho. We also show that, in addition to acylating lysoPtdCho, this enzyme is active in mediating 1-*O*-alkyl-*sn*-glycero-3-phosphocholine (also known as lyso-platelet-activating factor, lysoPAF) acylation to generate 1-*O*-alkyl-phosphatidylcholine. Its distinct substrate preferences and wide distribution of transcript strongly suggest that this isoform is a key

component of the Land's cycle, and hence important in modulating the fatty acid composition of membrane lipids.

## Materials and Methods

### Strains and Reagents

Yeast strains: BY4741 (WT, *MATa hisΔ1 leuΔ0 metΔ0 uraΔ0*) and Y02431 (*lca1Δ, MATa his3Δ1 leu2Δ0 met15Δ0 ura3Δ0 YOR175c::KanX4*) were purchased from European *Saccharomyces cerevisiae* archive for functional analysis (EUROSCARF). Various lysophospholipids and acyl-CoAs were obtained from Avanti Polar Lipids (Alabaster, AL). [<sup>14</sup>C] oleoyl-CoA, [<sup>14</sup>C] palmitoyl-CoA, [<sup>14</sup>C] arachidonoyl-CoA, [<sup>14</sup>C] palmitoyl lysoPtdCho were purchased from American Radiolabeled Chemicals Inc. and Moravsek Biochemicals, Inc. Yeast extract, Yeast Nitrogen Base, Bacto-peptone, and Bacto-agar were purchased from Difco™, D-glucose, D-galactose and D-raffinose were from Sigma. SC minimal medium and plates was prepared according to Invitrogen's recipe described for the pYES2.1 TOPO TA Cloning Kit.

### Gene Expression Vector Construction and Yeast Transformation

Full-length cDNAs of human genes (NM\_005768, NM\_024298) and mouse genes (NM\_145130, NM\_029934) were purchased from Openbiosystem (Huntsville, USA). The cDNAs were PCR amplified with primer pairs listed in Table 1 and cloned into yeast expression vector pYES2.1 using pYES2.1TOPO TA Expression Kit. Correctly-oriented plasmids were identified by mini-prep and further verified through DNA sequencing. The plasmid was subsequently introduced into yeast strain Y02431, of which the MBOAT lysophosphatidylcholine acyltransferase-encoding gene *LCA1* was disrupted.

### Microsomal Preparation

Yeast strains were first grown in 15 ml of SC-Ura medium containing 2% glucose. Protein expression induction was carried out as described in the manufacturer manual (Invitrogen). After 24 h of growth in SC + 2% galactose + 1% raffinose, the cells were washed sequentially with distilled water and homogenization buffer [50 mM Tris-HCl, 1 mM EDTA, 0.6 M sorbitol, pH 7.4, 1 mM dithiothreitol (DTT)]. After centrifugation at 4,000 rpm (Eppendorf centrifuge 5145C), the cells were resuspended in 1 ml homogenization buffer containing 10 μl yeast protease cocktail (Sigma), and shaken vigorously

(1 min  $\times$  2 times) in the presence of acid-washed glass beads (diameter 0.5 mm). The resultant homogenate was centrifuged at 12,000 rpm for 10 min at 4 °C. The decanted supernatant was further centrifuged at 100,000 $\times$ g for 90–120 min at 4 °C. The supernatant was discarded, and the pellet was resuspended in homogenization buffer containing 20% glycerol and frozen at –80 °C until use. Protein concentration was measured using a Bio-Rad Protein Assay Kit for final enzyme activity calculation.

#### In Vitro Assay of LPCAT Activity

LPCAT substrate specificity was determined by measuring incorporation of [<sup>14</sup>C] lysoPtdCho or [<sup>14</sup>C] Acyl-CoA into PtdCho. All assays were performed at least twice. In order to reduce the influence of endogenous acyl-CoAs two different concentrations of microsomal proteins were used. For lysophospholipid substrate specificity assessment, 1.0 ml HEPES (pH 7.4, 0.1 M) buffer contained 0.5  $\mu$ g microsomal protein, 5.6  $\mu$ M of lysophospholipid substrates and 13.5  $\mu$ M [<sup>14</sup>C] arachidonoyl-CoA (20 nCi/nmol). For acyl-CoA substrate selectivity analysis, 1.0 ml HEPES reaction buffer (pH 7.4, 0.1 M) contained 20  $\mu$ g microsomal proteins, 11.25  $\mu$ M acyl-CoA and 5.6  $\mu$ M [<sup>14</sup>C] palmitoyl lysoPtdCho (1.35 nCi/nmol). Reaction was allowed to proceed for 10 min at 30 °C with 100 rpm shaking. For determination of  $K_m$  and  $V_{max}$ , 20  $\mu$ g microsomal protein was used in a 0.8 ml HEPES reaction buffer (pH 7.4, 0.1 M) with different concentrations of acyl-CoA and 5.6  $\mu$ M [<sup>14</sup>C] palmitoyl-lysoPtdCho (1.35 nCi/nmol). All reactions were linear in 1 h range. The reaction products were extracted with chloroform/methanol (2/1, v/v) and separated with Merck silica G60 TLC plates. Spots corresponding to different phospholipid species products were scraped off and <sup>14</sup>C incorporation were scintillation counted.

#### 1-*O*-Alkyl-*sn*-Glycero-3-Phosphocholine Sensitivity

Yeast strains Y02431 expressing NM\_005768 cDNA or harboring empty vector were first grown in 15 ml of SC-Ura medium containing 2% glucose then transferred to SC-Ura + 2% galactose and 1% raffinose. After 12 h gene expression induction, the culture was diluted to correspond to OD<sub>600</sub> value of 0.5, 1, 2 and 4. A measure of 5  $\mu$ l of each

dilution was spotted to YPD plate supplemented with varying concentrations of 1-hexadecyl-*sn*-glycero-3-phosphocholine. The plates were incubated at 28 °C for 2 days.

#### Northern Blot

The premade human Northern blot (Cat.#:HN-MT-1) was purchased from ZYAGEN laboratories. A 1.5 kb fragment of *LPCAT3* (NM\_005768) cDNA was PCR amplified with primer pairs described in Table 1 and purified for probe preparation. The <sup>32</sup>P-labeled probe was purified with NICK column (Amersham), denatured by incubation at 100 °C for 5 min and then added to the hybridization tube containing 25 ml hybridization solution (0.5 M Sodium Phosphate buffer pH 7.5, 7% SDS, 1 mM EDTA, 1% BSA). After overnight hybridization at 60 °C, the membrane was washed twice using 40 mM sodium phosphate buffer and 1% SDS and exposed to X-ray film in Saran wrap for 1 week.

## Results

#### Identification of LPCAT3

We previously established that the yeast MBOAT protein YOR175cp (LCA1) is a LPCAT and plays a significant role in PtdCho turnover. A BLAST [16] search using YOR175cp identified several homologs from human (MBOAT1 NP\_001073949, XP\_001131044, MBOAT2 NP\_620154, MBOAT4 XP\_001125855, MBOAT5 NP\_005759, MBOAT7, NP\_077274) and mouse (MBOAT1 NP\_705774, XP\_134120, MBOAT2 isoform b NP\_001076810, MBOAT2 isoform a NP\_080313, MBOAT5 NP\_660112, MBOAT7 NP\_084210). Sequence alignment indicated that human proteins NP\_077274, NP\_005759, and mouse proteins NP\_660112, NP\_084210 had the highest sequence similarity to YOR175p (Fig. 1). Consequently, these four proteins were selected as human and mouse LPCAT candidates in this study.

The cDNAs of the four candidate genes were cloned into the yeast expression vector pYES2.1 and subsequently introduced into the yeast host strain *lcalΔ*. The *lcalΔ* strain has a very low LPCAT background activity, and thus functionality of LPCAT orthologs can be readily tested in

**Fig. 1** Unrooted phylogenetic tree based on yeast LPCAT (YOR175cp) and its related proteins in human and mouse. An alignment analysis of all the selected protein sequences was performed with ClustalW of Molecular Evolutionary Genetics Analysis software (Mega 4) with default parameters: gap opening penalty = 10; gap extension penalty = 0.2. The phylogenetic tree was constructed by neighbor-joining method using default settings

this host strain. The calculation of the enzyme activity was based on the difference between the *lca1Δ* strain harboring the human cDNAs and that of an empty vector. Preliminary enzyme assays using microsomal fractions with palmitoyl-lysoPtdCho as acyl acceptor, and either oleoyl-CoA (18:1) or arachidonoyl-CoA (20:4) as acyl donor, showed that *lca1Δ* expressing NP\_005759 and NP\_660112 displayed LPCAT activity (Fig. 2). But repeated assays failed to detect significant increase of LPCAT enzyme activity in *lca1Δ* strains expressing the other two closely related homologs, NP\_077274 and NP\_084210. NP\_077274 was recently shown to have LPIAT activity [17]. Since both

**Fig. 2** LPCAT activity of selected human and mouse LPCAT orthologs. Assays were performed with 5.6  $\mu\text{M}$  [ $^{14}\text{C}$ ] palmitoyl-lysoPtdCho (1.35 nCi/nmol), 11.25  $\mu\text{M}$  acyl-CoA (18:1/20:4) and 20  $\mu\text{g}$  microsomal protein prepared from *lca1Δ* strains expressing human proteins NP\_077274, NP\_005759, mouse proteins NP\_660112 and NP\_084210. Empty vector transformant (EV) was used as control. The enzyme reactions were allowed to proceed for 15 min at 30  $^{\circ}\text{C}$ . The results were presented as means  $\pm$  SD of differences between empty vector and LPCAT3 transformants

NP\_005759 and NP\_660112 appeared to have similar enzyme property, we subsequently conducted detailed biochemical characterization on the human protein NP\_005759. We followed the nomenclature proposed by Zhao et al. [14], and designated this enzyme as LPCAT3.

### LPCAT3 Displays Acyl-Acceptor Preference Towards 18:0-lysoPtdCho

In light of observations that acyltransferases are often promiscuous in substrate specificity [5, 7, 18], we performed acyltransferase assays with various lysophospholipid substrates to assess acyl acceptor preference of LPCAT3. Based on previous reports that selective acylation of lysophospholipids tends to occur only at very low concentration of substrates [19] and enzyme activity could be inhibited by high levels of acyl acceptors [3], the concentration of lysophospholipid substrate in our assays was provided at 5.6  $\mu\text{M}$ . Based on existing literature showing that PC in many tissues was predominant by 20:4 at the *sn*-2 position [20], we used [ $^{14}\text{C}$ ] arachidonoyl-CoA (20:4-CoA) as acyl donor at 11.25–13.5  $\mu\text{M}$ , a concentration much lower than reported level (50–130  $\mu\text{M}$ ) of long chain acyl-CoA known to be present in human tissue [19]. As shown in Fig. 3, the yeast strain expressing *LPCAT3* exhibited a dramatic increase in acylation activity with lysoPtdCho. Efficient LysoPtdEtn acylation was also evident. But no significant activity of acylation was detected when 16:0-lysoPtdGro was used as substrate. Acylation rate for lysoPA was less than 1% of the LPCAT activity. Thus, similar to the yeast LCA1[2] LPCAT3 exhibited the highest activity with lysoPtdCho.

**Fig. 3** LysoPtdCho substrate preference assessment of LPCAT3. Assay mixture contained 13.5  $\mu\text{M}$  [ $^{14}\text{C}$ ] arachidonoyl-CoA (20 nCi/nmol), 5.6  $\mu\text{M}$  lysophospholipid and 0.5  $\mu\text{g}$  microsomal protein extracted from *lca1Δ* harbouring empty vector or expressing *LPCAT3*. The reaction mixture was incubated for 1 h at 25  $^{\circ}\text{C}$ . The results were presented as means  $\pm$  SD of differences between empty vector and LPCAT3 transformants

To investigate if the *sn-1* fatty acid species of the lyso-phospholipid acceptor affected LPCAT3 activity, assays were also performed using 1-palmitoyl-lysoPtdCho (16:0-lysoPtdCho), 1-stearoyl-lysoPtdCho (18:0-lysoPtdCho), 1-oleoyl-lysoPtdCho (18:1-lysoPtdCho), 1-arachidonyl-lysoPtdCho (20:0-lysoPtdCho), as well as the ether-linked lysoPtdCho analog of 1-hexadecyl-*sn*-glycero-3-phosphocholine, arachidonoyl-CoA (20:4-CoA) was provided as acyl donor. The LPCAT3 could efficiently use 16:0-lysoPtdCho, 18:0-lysoPtdCho and 20:0-lysoPtdCho, but apparently not the 18:1-lysoPtdCho (Fig. 3). LPCAT3 could also efficiently mediate 16:0-lysoPAF acylation. Based on our assay using arachidonoyl-CoA as acyl donor, LPCAT3 exhibited substrate preferences in the order of 18:0-lysoPtdCho > 20:0-lysoPtdCho  $\approx$  16:0-lyso-PAF > 16:0-lysoPtdCho. It must be noted, however, as we show later in Fig. 4 that 18:2-CoA is the most preferable acyl donor, the question of whether 18:2-CoA would affect the order of acyl acceptor preferences requires future investigation.

#### LPCAT3 is Most Active in Utilizing 18:2-CoA as Acyl Donor

To characterize LPCAT3 acyl-CoA substrate preference, we incubated yeast microsomal fraction with 16:0-lysoPtdCho and acyl-CoAs of different chain length and various degrees of unsaturation (Fig. 4). LPCAT3 exhibited activity with all acyl-CoAs tested. However, the activity with linoleoyl-CoA (18:2) at a concentration of 11.25  $\mu$ M was several folds higher than that with other acyl-CoAs. The degree of unsaturation seemed not to be the only determinant of lysoPtdCho acylation activity, since the utilization rate of other acyl-CoAs was found in the order of 16:0-CoA  $\approx$  20:4-CoA > 18:1-CoA > 18:0-CoA. The effect of increasing concentrations of two acyl

**Fig. 4** Acyl-CoA substrate preference assessment of LPCAT3. Assays were performed with 5.6  $\mu$ M [ $^{14}$ C] palmitoyl-lysoPtdCho (1.35 nCi/nmol), 11.25  $\mu$ M acyl-CoA as indicated and 20  $\mu$ g microsomal protein from *lca1 $\Delta$*  yeast cells harbouring empty vector or expressing LPCAT3. The reaction mixtures were incubated for 10 min at 30  $^{\circ}$ C. Results were presented as means  $\pm$  SD of differences between empty vector and LPCAT3 transformants

**Fig. 5** LPCAT3 activity dependence on acyl-CoA concentration. Assays were performed with 5.6  $\mu$ M [ $^{14}$ C] palmitoyl-lysoPtdCho (1.35 nCi/nmol), 18:1-CoA or 20:4-CoA of various concentrations, 20  $\mu$ g microsomal proteins prepared from *lca1 $\Delta$*  yeast cells harbouring empty vector or expressing LPCAT3. The enzyme reaction was allowed to proceed for 10 min at 30  $^{\circ}$ C

donors, 18:1-CoA and 20:4-CoA, on LPCAT activity is shown in Fig. 5. At lower acyl-CoA concentrations the enzyme was more active with 18:1-CoA. However, at concentrations higher than 3  $\mu$ M, the enzyme was more active with 20:4-CoA. The  $V_{\max}$  was calculated as 7.4 pmol/min/ $\mu$ g protein for 18:1-CoA and 12.4 pmol/min/ $\mu$ g protein for 20:4-CoA. The apparent  $K_m$  was  $0.45 \pm 0.01$   $\mu$ M and  $5.1 \pm 1.2$   $\mu$ M for 18:1-CoA and 20:4-CoA, respectively. Since the reported physiological acyl-CoA concentration was 5–160  $\mu$ M [21, 22], our results suggest that under physiological conditions the LPCAT3 could effectively acylate lysoPtdCho into PtdCho, especially using 20:4-CoA as acyl donor.

#### LPCAT3 Acylates 1-*O*-Alkyl-*sn*-Glycero-3-Phosphocholine with Arachidonyl-CoA but not Acetyl-CoA

Since LPCAT3 could efficiently acylate 1-*O*-alkyl-*sn*-glycero-3-phosphocholine with long chain fatty acid, particularly 20:4-CoA (Fig. 4), we then tested if LPCAT3 could acylate this ether lipid with acetyl-CoA, which would generate the platelet-activating factor (PAF). Our result showed that acetylation of 1-*O*-alkyl-*sn*-glycero-3-phosphocholine was negligible (Fig. 6). It is known that 1-*O*-alkyl-*sn*-glycero-3-phosphocholine can be effectively taken up and reacylated by yeast [23], and that the *lca1 $\Delta$*  yeast strain was hypersensitive to 1-*O*-alkyl-*sn*-glycero-3-phosphocholine [2], likely caused by the detergent effect of this ether lipid when it is not reacylated. To examine if LPCAT3 could detoxify 1-*O*-alkyl-*sn*-glycero-3-phosphocholine when expressed in yeast, the LPCAT3 transformant and vector-only transformant of *lca1 $\Delta$*  yeast strain were spotted onto media supplemented with varying concentration of 1-*O*-alkyl-*sn*-glycero-3-phosphocholine. Both strains could grow reasonably well with 5  $\mu$ g/ml 1-*O*-alkyl-*sn*-glycero-3-phosphocholine but failed to grow at a concentration beyond 20  $\mu$ g/ml. However, when transferred to

**Fig. 6** Comparative assessment of LPCAT3 substrate preference towards lysoPtdCho and lyso-PAF. Assays were performed with 5.6  $\mu$ M lysophospholipids, 13.5  $\mu$ M [ $^{14}$ C] radiolabeled acyl-CoA (20 nCi/nmol) and 0.5  $\mu$ g microsomal protein extracted from *lca1Δ* harbouring empty vector or expressing *LPCAT3*. The reaction mixture was incubated for 1 h at 25 °C. Results were presented as means  $\pm$  SD of differences between empty vector and LPCAT3 transformants

media supplemented with 10  $\mu$ g/ml 1-*O*-alkyl-*sn*-glycero-3-phosphocholine, *LPCAT3* transformant evidently grew better as compared with the vector-only transformant (Fig. 7). This result further corroborated our in vitro assay data that LPCAT3 possessed the ability to transfer an acyl group to *sn*-2 position of 1-*O*-alkyl-*sn*-glycero-3-phosphocholine.

#### Transcript of LPCAT3 Is Widely Distributed

We examined the *LPCAT3* gene expression profile in different human tissues through Northern blot hybridization. *LPCAT3* was highly expressed in lung and thymus but also expressed at a significant level in testis, heart, kidney and pancreas (Fig. 8a). Since Northern blot analysis would not

**Fig. 7** 1-*O*-alkyl-*sn*-glycero-3-phosphocholine sensitivity test of *lca1Δ* harbouring empty vector and *lca1Δ* strain expressing *LPCAT3*. Cells were grown first in SC-Ura + 2% glucose media overnight then in protein expression induction media for 6 h. Cultures were diluted to OD<sub>600</sub> = 0.5, 1, 2, 4, respectively. A measure of 5  $\mu$ l of each dilution was inoculated (from left to right) onto YPD plate containing 16:0-lysoPtdCho and 1-hexadecyl-*sn*-glycero-3-phosphocholine of varying concentration. The plates were incubated at 28 °C for 36 h

**Fig. 8** *LPCAT3* expression profile in different human tissues **a** Northern blot hybridization **b** relative expression in different cells and tissues based on Genevestigator human gene expression data

allow an accurate quantitative assessment of the transcript level, we also retrieved *LPCAT3* expression pattern from Genevestigator (<https://www.genevestigator.ethz.ch>), which contained *LPCAT3* expression data from many tissues and cell cultures not included in our northern blot. A considerable high expression level was detected in adipocyte cell (Fig. 8b). Taken together, these results indicated a wide distribution of *LPCAT3* transcript in human tissues.

#### Discussion

There is usually an asymmetric distribution of acyl groups in phospholipids, with saturated fatty acids esterified at the *sn*-1 position of the glycerol backbone, whereas the unsaturated fatty acids are normally found at the *sn*-2 position. It has been accepted as truism that the appropriate fatty acid composition in membrane systems is achieved through extensive PtdCho remodeling after de novo synthesis [3, 4], and that the Lands cycle represents a major route through which “tailoring” of the PtdCho takes place. However, understanding of the mechanistic details has been hindered by the lack of a molecular handle.

Upon testing different lysoPtdCho substrates we found that LPCAT3 had a lysoPtdCho species preference in the order of 18:0-lysoPtdCho > 20:0-lysoPtdCho > 16:0-lysoPtdCho. Strikingly, lysoPtdCho with unsaturated fatty acid residue (18:1-lysoPtdCho) was not able to sustain

detectable acylation by this enzyme. Such an acyl acceptor preference is remarkably consistent with the stereo-specific distribution of fatty acids in PtdCho because 18:0 and 16:0 fatty acyl moieties occupy the *sn-1* position in more than 80% of PtdCho molecules in most tissues [24–26]. In this respect, this mammalian LPCAT is different from that reported for a plant LPCAT, which was shown to display equal utilization rate to 16:0, 18:0 and 18:1-lysoPtdCho [27]. With regard to acyl donors, LPCAT3 is very active in incorporating unsaturated 18:2-CoA. Indeed, in animal cells, the most prevalent fatty acid found at the *sn-2* position of the PtdCho is 18:2 [24–26]. LPCAT in Lands' cycle is also believed to play a role in mediating the replacement of the fatty acid at the *sn-2* position of PtdCho with arachidonic acid, which is stored until it is required for the generation of signal molecules including prostaglandins, prostacyclins, thromboxanes and leucotrienes. Depending on tissues, PtdCho containing an arachidonoyl moiety at the *sn-2* position represents as much as a third of total PtdCho. Interestingly, we found that LPCAT3 was very efficient in incorporating 20:4 into PtdCho. Taken together, these substrate preferences, presumably reflecting its properties in vivo, strongly suggest that LPCAT3 is a key enzymatic agent controlling the fatty acid composition of PtdCho in membrane systems [28].

It was also significant that LPCAT3 was capable of acylating 1-*O*-alkyl-*sn*-glycero-3-phosphocholine. The substrate specificity of this LPCAT leads to the expectation that it is a *sn*-1-lysophosphocholine acyltransferase that does not distinguish the type of bond at the *sn-1* position of phospholipids. A minimal interpretation of these results is that LPCAT3 may play a role in generating 1-*O*-alkyl-phosphatidylcholine, which, depending on tissues, can represent a significant portion of membrane lipid constituent. However, different from the recently identified lysoPtdCho/lysoPAF dual substrate enzyme [15], it is clear that LPCAT3 is not directly involved in PAF biosynthesis because LPCAT3 did not display any activity in mediating acetylation of lyso-PAF with acetyl-CoA to generate PAF [29] (Fig. 6).

It must be noted that it is enzyme substrate specificity and supply of acyl donor substrates that collectively account for the phospholipid profiles of membrane systems. Concentrations of different fatty acyl-CoAs under physiological condition are at about 5–150  $\mu\text{M}$  in a variety of the tissues [21, 22]. Moreover, different tissues may have variable intracellular acyl-CoA concentrations that can be fluctuating within a wide range [30]. The  $K_m$  of LPCAT3 for acyl-CoAs was found to be well below physiological levels. Thus, LPCAT3 may mediate a metabolic step that allows changes in acyl-CoA pool size to influence PtdCho composition. Another aspect of LPCAT3 being able to potentially exert regulatory input to PtdCho

composition is the observation that higher 18:1-CoA concentration could in fact inhibit its acylation activity. The curve of the substrate dependence for 18:1-CoA exhibited a typical shape of an enzymatic reaction with substrate inhibition. It is unclear if this inhibitory effect has any significance in vivo, but clearly it was not caused by micelle formation since micelle formation would typically require fatty acyl-CoAs in a range of 10–30  $\mu\text{M}$  [31, 32]. Intriguingly, 20:4-CoA did not appear to exert inhibitory effects to LPCAT3.

Our assessment on the transcript distribution from both RNA blot analysis and the public available microarray data indicated that *LPCAT3* was widely distributed in different tissues. This finding is somewhat different from the results of a previous report in which LPCAT3 was shown to be primarily expressed in metabolic active tissues [14]. We are unable to explain this apparent discrepancy, but tissue conditions and/or physiological conditions may have contributed to this. It should be noted that the mouse *mLPCAT3* was also found in a wide range of tissues.

## Conclusions

The turnover of phospholipids and the remodeling of fatty acid composition have direct effects on membrane structure and intracellular trafficking in the secretory and endocytic pathways. The different kinetics mechanisms, substrate selectivity of LPCAT3 for both acyl acceptors (lysoPtdCho species) and acyl donors (acyl-CoAs) may play an important role in modulating the fatty acid composition of PtdCho in mammalian membrane systems. Our results also show that LPCAT3 is sensitive to acyl-CoA level and thus this enzyme provide a basis for metabolic variables to influence fatty acid compositions of PtdCho. That the *LPCAT3* gene is widely expressed in different tissues offers the prospect of it being a novel platform for studying Lands' cycle and PtdCho remodeling.

**Abstract** Production of dairy products with increased amounts of nutraceutical FA such as conjugated linoleic acid (CLA) represents a recent approach for dairy producers and processors to increase the value of their products. The effect of CLA and other FA on the expression of *diacylglycerol acyltransferase-1 (DGAT-1)* and *DGAT-2*, and DGAT activity were investigated in bovine mammary gland epithelial (MAC-T) cells. DGAT gene expression analyses were also conducted using bovine mammary gland tissue from dairy cows. In the studies with MAC-T cells, there were no significant effects of CLA isomers or other FA on *DGAT1* expression, whereas all FA tested showed enhanced *DGAT2* expression ( $P < 0.05$  to  $P < 0.001$ ), with  $\alpha$ -linolenic acid ( $\alpha$ -18:3) having the greatest effect. Additionally, *DGAT2* expression was coordinated with expression of *lysophosphatidic acid acyltransferase (LPAAT)*, an observation that was also apparent in mammary gland from lactating dairy cows. In contrast, treatment of MAC-T cells with *trans*-10, *cis*-12 18:2 or  $\alpha$ -18:3 resulted in a significant ( $P < 0.05$ ) decrease in overall DGAT enzyme activity, although the mechanisms resulting in these effects are unclear. Competition assays using microsomes from bovine mammary gland tissue and 1-[ $^{14}$ C]oleoyl-CoA suggested that DGAT activity was

more selective for oleoyl (*cis*-9 18:1)-CoA than *cis*-9, *trans*-11 18:2-, *trans*-10, *cis*-12 18:2- or *cis*-9, *cis*-12 18:2-CoA. Collectively, the results suggest the relationship between *trans*-10, *cis*-12 18:2 and reduced TAG production in bovine milk is not linked to the production of DGAT1 or DGAT2 transcripts, but probably involves effects of this CLA isomer at events beyond transcription, such as post-translational and/or enzyme activity effects.

### Introduction

Conjugated linoleic acid (CLA) is a naturally abundant component in ruminant milk fat. These positional and geometric isomers of octadecadienoic acid occur as intermediates during the biohydrogenation of dietary fatty acids (i.e., linoleic and linolenic acid) by rumen microbes. Several isomers, most notably *cis*-9, *trans*-11 18:2 and *trans*-10, *cis*-12 18:2, have demonstrated nutraceutical properties,

including decreased cancer incidence [1] and body weight [2]. Endogenous synthesis in the mammary gland is estimated to account for up to 78% of *cis*-9, *trans*-11 18:2 in milk from cows on total mixed ration diets [3, 4] and for up to 91% of milk CLA from pasture-fed cows [5].

Dairy producers wish to market products enriched in CLA so that consumers may benefit from these properties. The content of CLA isomers can be readily increased in milk fat by supplementing cattle diets with oilseeds or plant oils enriched in linoleic acid (*cis*-9, *cis*-12 18:2) [6, 7]. Another strategy is to supplement cattle with synthetic mixtures of CLA isomers protected from the rumen microflora by abomasal infusion [8]. The ionophore monensin may also be supplemented to the diet to prevent CLA isomers from being altered through rumen biohydrogenation [9].

In many cases, strategies resulting in elevated milk CLA content have also been shown to result in net milk fat depression (MFD). *Trans*-10, *cis*-12 18:2 has been suggested as the isomer responsible for this phenomenon [10, 11]. Cattle fed diets resulting in increased milk *trans*-10, *cis*-12 18:2 content coinciding with MFD also had decreased mRNA levels representing lipogenic genes, including those encoding *sn*-glycerol-3-phosphate acyltransferase (GPAT, EC 2.3.1.15), and lysophosphatidic acid acyltransferase (LPAAT, EC 2.3.1.51) [12]. GPAT and LPAAT catalyze the first and second acyl-CoA-dependent acylations of the glycerol backbone, respectively, in the Kennedy pathway leading to TAG [13].

Diacylglycerol acyltransferase (DGAT, EC 2.3.1.20) catalyzes the transfer of an acyl moiety from acyl-CoA to *sn*-1,2 diacylglycerol to form triacylglycerol (TAG) [13]. cDNAs encoding two isoforms of this enzyme (DGAT1 and DGAT2), which do not share amino acid sequence, have been isolated [14, 15]. An early study suggested that the level of DGAT activity in fat-forming tissues may have a substantial effect on the flow of carbon into TAG [16]. Indeed, over-expression of *DGAT1* and *DGAT2* in mouse liver has been shown to result in a 2.0- and 2.4-fold increase, respectively, in tissue TAG content [17]. In contrast, female mice with an inactivated *DGAT1* gene (*DGAT*<sup>-/-</sup>) are unable to lactate [18] and have impaired mammary gland development [19]. Additionally, a missense mutation in *DGAT1* has been shown to result in decreased milk fat content in dairy cows [20]. Hamsters supplemented with CLA isomers in the diet have been shown to display decreased intestinal acyl-CoA: cholesterol acyltransferase (ACAT EC 2.3.1.26) activity [21], suggesting that CLA may act to down regulate ACAT activity. Since *DGAT1* shares some sequence homology with ACAT [14], CLA might regulate both enzymes in a similar fashion. In another study, murine primary preadipocyte cultures (3T3-L1) treated with arachidonic acid

(all-*cis*-5,8,11,14 20:4) has been shown to result in repressed DGAT activity [22]. In addition, rats fed mixtures of CLA have been shown to display decreased hepatic DGAT activity compared with control rats fed the same amount of FA [22]. Earlier studies had found no difference in DGAT activity in rats fed similar amounts of *cis*-9 18:1 versus 18:0 [23].

Given the association of *trans*-10, *cis*-12 18:2 with MFD, we hypothesized that *DGAT* expression and/or DGAT activity might be affected by this CLA isomer. The effect of CLA isomers, including *cis*-9, *trans*-11 18:2 and *trans*-10, *cis*-12 18:2, and other FA, on *DGAT1*, *DGAT2*, and *LPAAT* expression levels, and DGAT activity were examined in cultured bovine mammary gland epithelial cells (MAC-T cells). Other FAs tested included *trans*-11 18:1, a substrate of mammalian  $\Delta$ -9 desaturase, and FA commonly found in dietary plant oils ingested by dairy cattle. In addition, expression of *DGAT1*, *DGAT2*, and *LPAAT* were examined in mammary gland tissue from lactating dairy cows. Furthermore, the direct effects of CLA isomers on DGAT activity were investigated using microsomes prepared from bovine mammary gland tissue.

## Materials and Methods

### Animals

All procedures involving the use of animals were approved by the University of Alberta Animal Policy and Welfare Committee. Cows were housed in tie-stalls with water available at all times. The diets were fed once per day at 09:00 as total mixed rations consisting of 60% (w/w) forage and 40% (w/w) concentrate. Feed intake was recorded daily and adjusted to maintain 5–10%orts (feed remaining). Diets for the primiparous and multiparous lactating Holstein cows are described elsewhere [24]. Samples of mammary gland tissue were taken from six cows supplemented with safflower oil and monensin and six cows not receiving this treatment using a method adapted from Knight et al. [25]. The animals were sedated by administration of xylazine hydrochloride (10 mg/50 kg body weight) and ketamine (2 mg/kg body weight) via jugular catheter. The animals were maintained in a state of sedation with an intravenous drip of glycerol guaiacolate and ketamine [50 g glycerol guaiacolate, 1,000 mg ketamine, 1,000 ml 50% (w/v) dextrose and 900 ml sterile water]. The drip rate was set at 20 ml/min and maintained during surgery. The udder was shaved around the biopsy site and swabbed with iodine and 70% (v/v) ethanol. A region of the basal portion of the udder free of major subcutaneous blood vessels was chosen for the biopsy site. The area was

anesthetized locally by injection of lidocaine (10–30 ml of 2% v/v lidocaine with epinephrine). An 8-cm incision was made in the skin; a 5–10-g piece of mammary gland tissue was excised using a scalpel and snap frozen in liquid nitrogen and then stored at  $-80^{\circ}\text{C}$ .

## Chemicals

Both *cis*-9, *trans*-11 18:2 and *trans*-10, *cis*-12 18:2 were obtained from Matreya (Pleasant Gap, PA). [ $1-^{14}\text{C}$ ] *cis*-9 18:1 was from GE Healthcare (Baie d'Urfé, Quebec, Canada). Fatty acyl-CoA was prepared from the above FA as described by Taylor et al. [26]. Silica gel 60 H was from VWR Canlab (Mississauga, Ontario, Canada). Solvents (HPLC grade) were from Fisher Scientific (Ottawa, Ontario, Canada). Ecolite(+) biodegradable scintillation cocktail was from ICN Biomedicals (Irvine, CA). *sn*-1,2 Diolein was from Nu Chek Prep Inc. (Elysian, MN). Dulbecco's Modified Eagle Media (DMEM), fetal bovine serum (FBS), TRIzol<sup>®</sup> reagent, M-MLV reverse transcriptase, oligo (dT)<sub>12–18</sub> primer, Rnase OUT Rnase inhibitor, dNTPs, 5X first strand buffer, and custom primers were from Invitrogen (Burlington, Ontario, Canada). rDNase, 10X buffer, and DNase inactivation agent were included in the Ambion DNA-free<sup>™</sup> kit (catalog no. 1906, Austin, TX). FAM and VIC labeled probes and TaqMan<sup>®</sup> Universal PCR Mastermix were from Applied Biosystems (Foster City, CA). All other chemicals were from Sigma (Oakville, Ontario, Canada).

## Maintenance and Treatment of Cultured Mammary Gland Epithelial Cell Line

MAC-T cells were originally established by Huynh et al. [27] and were kindly provided by Nicholas Lemee of Nexia Biotechnologies, Inc. (Montreal, Quebec, Canada). Cells were maintained essentially as described by Keating et al. [28]. The cells were cultured in high glucose (4.5 g/l) DMEM containing L-glutamine, sodium pyruvate, and pyroxidine-HCl and supplemented with 10% (v/v) FBS and 5  $\mu\text{g}$  bovine insulin/ml. FAs used to treat MAC-T cells were complexed to BSA as potassium salts. Twelve milligrams of FA was treated with 1 ml of 0.1 M KOH. The solution was vortexed and incubated at  $50^{\circ}\text{C}$ , and then added dropwise to 9 ml of 7.5% (w/v) BSA. The resulting FA-BSA stock solution was incubated at room temperature for 3 h and then overnight at  $4^{\circ}\text{C}$ , and finally stored in small aliquots at  $-20^{\circ}\text{C}$ . FA-BSA stock solution was added to DMEM to produce the final FA concentration used in FA treatment experiments. Cells were maintained in a humidified incubator at  $37^{\circ}\text{C}$  and 5%  $\text{CO}_2$ .

## RNA Isolation, Reverse Transcription, and Quantitative Real-Time Polymerase Chain Reaction (QRT-PCR)

Total RNA was extracted from confluent MAC-T cells treated for 24 h with various exogenous FA and from the mammary gland tissue using TRIzol<sup>®</sup> reagent as described in the manufacturer's protocol. The total RNA was then treated with DNAase using the DNA-free<sup>™</sup> kit from Ambion. cDNA was synthesized from 1  $\mu\text{g}$  of total RNA in a 20- $\mu\text{l}$  reaction volume with a final concentration of 0.5 mM dNTP mix, 0.5  $\mu\text{g}$  Oligo (dT)<sub>12–18</sub>, 5  $\mu\text{M}$  DTT, 4  $\mu\text{l}$  5X first strand buffer, 40 U RNase out RNase inhibitor, and 200 U of M-MLV reverse transcriptase. The reaction mixture was incubated at  $37^{\circ}\text{C}$  for 60 min and then at  $70^{\circ}\text{C}$  for 15 min.

QRT-PCR was performed using the ABI Prism<sup>®</sup> 7900HT FAST QRT-PCR system with 9600 Emulation (Applied Biosystems) in a total volume of 25  $\mu\text{l}$  reaction mixture following the manufacturer's protocol, using TaqMan<sup>®</sup> 2X Universal PCR Mastermix, 0.1  $\mu\text{M}$  each of forward and reverse primer, and 0.2  $\mu\text{M}$  of probe. Primers and TaqMan-MGB probes were designed against mRNA sequences specific for *DGAT1* (GenBank NM\_174693), *DGAT2* (NM\_205793), *LPAAT* (NM\_177518), and *glyceraldehyde-3-phosphate dehydrogenase (GAPDH)* (NM\_001034034) from *Bos taurus* using Primer Express<sup>®</sup> 3.0 Software (Applied Biosystems; Table 1).

Relative gene expression for *DGAT1*, *DGAT2*, or *LPAAT* was normalized to a calibrator that was chosen to be the basal condition (BSA control) for each treatment. Results were calculated with the  $2^{-\Delta\Delta C_T}$  method [29] where  $\Delta\Delta C_T = (C_{T, \text{Target}} - C_{T, \text{GAPDH}})_{\text{Time } x} - (C_{T, \text{Target}} - C_{T, \text{GAPDH}})_{\text{Time } 0}$  and expressed as n-fold differences in gene expression relative to GAPDH mRNA and calibrator (BSA). Standard errors of the average  $C_{T, \text{Target}}$  and average  $C_{T, \text{GAPDH}}$  were pooled.  $C_T$  is defined as the number of cycles required until the specific dye-reporter emission reached the defined intensity threshold.

## Extraction of Lipid from MAC-T Cells and Analysis of FA Composition

MAC-T cells were grown in 75-cm<sup>2</sup> flasks in DMEM containing 20  $\mu\text{M}$  FA-BSA and incubated at  $37^{\circ}\text{C}$ . Upon confluence, cells were treated with trypsin-EDTA and harvested and transferred to acid-washed glass tubes. The vials were centrifuged at 1,500 $\times g$ . The supernatant was removed, and the cells were resuspended in 1 ml phosphate buffered saline. The resuspended cells were probe sonicated for 30 s, and a sample was removed for protein determination. Lipids were extracted using a modified Folch [30] protocol. The following were added in sequence to the cell suspension, mixing by vortex for 30 s after each

**Table 1** Primer and probe sequences for real-time polymerase chain reaction

addition: 0.1 M KCl to bring suspension to total volume of 1.6 ml, 0.8 ml methanol, 2 ml chloroform/methanol (1:1, v/v), 2.7 ml chloroform, and 2.5 ml chloroform/methanol (2:1, v/v). The samples were incubated overnight at 4°C. Phase separation was achieved by centrifugation, and the chloroform layer was transferred to a glass vial and dried under N<sub>2</sub> (g). Prior to extraction, 100 µg of tritricosanoin (tri-23:0) was added to the cell suspension as an internal standard.

Production and GC analysis of FAME was based on methods described by Cruz-Hernandez et al. [31]. To the dried extract was added 100 µg of trionadecanoin (tri-19:0), 1.7 ml of hexane, 40 µl of methyl acetate, and 100 µl of NaOCH<sub>3</sub> (0.5 M in methanol) followed by mixing for 2 min and incubation at room temperature for 20 min. The vial was then cooled at -20°C for 20 min, and 60 µl of oxalic acid (saturated in diethyl ether) was added. The vials were centrifuged to collect the oxalate precipitate, and the supernatant was spotted to a TLC plate. The plate was developed in one ascension of hexane/diethyl ether (80:20, v/v) using methyl-oleate as a standard. The plates were then visualized by spraying with 0.2% (w/v) 2,7' dichlorofluorescein. The area corresponding to methyl-oleate was scraped and transferred to a column containing sodium sulfate. The FAMES were eluted using 2 ml of chloroform, and 50 µg of methyl-hexacosanoate (methyl-26:0) was added.

FAMES were analyzed by GC with a Varian 3800 GC (Varian Inc., Mississauga, Ontario, Canada), equipped with splitless injection port flushed after 0.3 s, a flame ionization detector (FID), autosampler (Model 8200, Varian Inc.), 100-m CP-Sil 88 fused capillary column (Varian Inc.), and a Hewlett-Packard ChemStation software system (version A.07). Operating conditions included: injector and detector temperatures both at 250°C; H<sub>2</sub> as carrier gas (1 ml/min) and for the FID (40 ml/min), N<sub>2</sub> (g) as makeup gas (100 ml/min), and purified air (250 ml/min). The initial

temperature of 45°C was held for 4 min, increased at a rate 13°C/min to 175°C, and held for 27 min, and finally increased at a rate 4°C/min to 215°C and held for 35 min. FAMES were identified by comparison with a reference standard.

#### Assay of DGAT Activity in MAC-T Cells

DGAT activity was measured in MAC-T cells based on the protocol described by Geelen [32]. MAC-T cells were grown in DMEM containing 20 µM FA-BSA. Confluent cells were treated with trypsin-EDTA and centrifuged for 10 min at 1,500 × g. The pelleted cells were incubated in 96 mM MES (pH 6.5) containing 9.6 mM EDTA, 1.9 mM DTT, 125 mM NaCl, 15 µM [1-<sup>14</sup>C] *cis*-9 18:1-CoA, 30 µg BSA, and 18 µg of digitonin for 10 min at 37°C. The reaction was quenched with 10 µl of 12.4 M HCl, and lipids were extracted as described by Bligh and Dyer [33]. Lipids were spotted to silica gel 60 H TLC plates, which were developed with a single ascension of hexane/diethyl ether (80:20, v/v) using triolein as a standard. Standards were visualized using iodine vapor, and corresponding areas were scraped into vials followed by the addition of scintillant and the determination of [1-<sup>14</sup>C] *cis*-9 18:1 incorporated into TAG. The protein content of sonically disrupted cells was determined using the Bio-Rad protein microassay based on the method of Bradford [34] using BSA as a standard.

#### Assay of DGAT Activity in Microsomes from Mammary Gland Tissue

Microsomes were prepared from bovine mammary gland tissue as previously described for muscle and adipose tissue [35], and DGAT was assayed as described in Lozeman et al. [36] with a final concentration of 15 µM [1-<sup>14</sup>C] *cis*-9 18:1-CoA (56 Ci/mol) in the reaction mixture. Reactions

were allowed to proceed for 10 min at 30°C in the presence of increasing concentrations (0–20  $\mu$ M) of unlabeled *cis*-9, *trans*-11 18:2-; *trans*-10, *cis*-12 18:2-; *cis*-9, *cis*-12 18:2- or *cis*-9 18:1-CoA.

### Statistical Analysis

For effect of exogenous FA treatment on expression of genes encoding lipogenic enzymes in cultured MAC-T cells, statistical analysis was performed using the mixed procedure in SAS (version 9.1), with variance components covariance structure and Kenward-Roger adjustment for the denominator degrees of freedom. The statistics are based on duplicates from three independent trials. Gene and FA treatments were considered fixed effects, and the trial was considered as a random effect in the mixed model analysis. For the effect of various FA treatments on the mole percentages of various FA in the acyl lipid of MAC-T cells, the mixed procedure (SAS) was used, with FA treatment as fixed effect. Spearman's rho correlation coefficients (JMP<sup>®</sup> IN statistical software, version 4, Duxbury Press, Toronto, ON, Canada) were generated for *DGAT1*, *DGAT2*, and *LPAAT* expression data for mammary gland tissue obtained from lactating Holstein cows. For the experiment measuring the effect of increasing concentrations of various unlabeled acyl-CoA species on the incorporation of radiolabeled-18:1 (from radiolabeled-18:1-CoA) into TAG using bovine mammary gland microsomes, statistical analysis was performed using the mixed procedure in SAS using a diagonal covariance structure and residual degrees of freedom method, considering substrate and substrate concentration as fixed effects in the model.

## Results

### Effect of Exogenous FA on Expression of Genes Encoding Lipogenic Enzymes in MAC-T Cells

Results from QT-PCR of *DGAT1*, *DGAT2*, and *LPAAT* expression are shown in Fig. 1. None of the FA isomers had a substantial effect on *DGAT1* expression relative to the control, and none resulted in significant change in the expression of *DGAT1*. Treatment with oleic acid (*cis*-9 18:1), vaccenic acid (*trans*-11 18:1); linoleic acid (*cis*-9, *cis*-12 18:2); *cis*-9, *trans*-11 18:2; *trans*-10, *cis*-12 18:2; or  $\alpha$ -linolenic acid ( $\alpha$ -18:3), however, resulted in increases in *DGAT2* expression ( $P < 0.01$ ,  $P < 0.001$ ,  $P < 0.01$ ,  $P < 0.05$ ,  $P < 0.05$ , and  $P < 0.001$ , respectively). CLA isomers, *cis*-9, *trans*-11 18:2 and *trans*-10, *cis*-12 18:2 did not have a differential effect on *DGAT1* versus *DGAT2* expression, but *trans*-11 18:1 treatment resulted in more

**Fig. 1** Expression of genes encoding lipogenic enzymes in MAC-T cells treated with exogenous FA. Data points were calculated using the  $2^{-\Delta\Delta CT}$  method [30]. Duplicates from three separate trials were used. Error bars represent upper and lower intervals. \*, \*\*, \*\*\* represent significant differences between treatment and control (\* $P < 0.05$ ), \*\*( $P < 0.01$ ), \*\*\*( $P < 0.001$ )

enhanced *DGAT2* expression ( $P < 0.05$ ) than for treatment with *cis*-9, *trans*-11 18:2. All FA tested for enhanced *LPAAT* expression ( $P < 0.001$ ) in the MAC-T cells.

### Expression of Genes Encoding Lipogenic Enzymes in Mammary Gland

Spearman rho coefficients for *DGAT1*, *DGAT2*, and *LPAAT* expression in mammary gland samples from 12 lactating cows are shown in Table 2. Expression of *DGAT2* demonstrated significant positive correlation to that of *LPAAT*.

### Effect of Exogenous FA on Lipid Accumulation and DGAT Activity in MAC-T Cells

None of the exogenous FA tested affected lipid accumulation in MAC-T cells (Fig. 2). The FA composition of lipid extracted from treated MAC-T cells is shown in Table 3. SFA, MUFA, and PUFA proportions are shown

**Table 2** Spearman  $\rho$  coefficients for expression<sup>a</sup> of genes encoding lipogenic enzymes from mammary gland tissue of lactating Holstein cows ( $n = 12$ )

Exogenous fatty acid species in growth media (20  $\mu$ M complexed to BSA)

**Fig. 2** Acyl lipid content of MAC-T cells treated with exogenous FA. Esterified lipid (fatty acyl lipid) content was obtained from the FA composition. Mean values are presented for the results of two experiments

along with specific proportions for C18 FA. In each case, there was an enhanced incorporation of exogenous FA into the cellular lipid. Treatment of the cells with *trans*-10, *cis*-12 18:2 resulted in increased proportions of saturated FA and stearic acid (18:0) ( $P < 0.01$ ) and a decreased proportion of *cis*-9 18:1.

The effect of exogenous FA on DGAT-specific activity in MAC-T cells is shown in Fig. 3. Compared to control cells (treated only with BSA), the DGAT-specific activities of cells treated with *trans*-10, *cis*-12 18:2, and  $\alpha$ -18:3 were decreased ( $P < 0.05$ ).

#### Competition Assays of DGAT Activity Using Mammary Gland Microsomes

The effect of increasing concentrations of unlabeled molecular species of acyl-CoA on the incorporation of [ $^{14}$ C] *cis*-9 18:1 from radiolabeled *cis*-9 18:1-CoA is shown in Fig. 4. Incorporation of [ $^{14}$ C]18:1 into TAG was decreased at all concentrations of *cis*-9, *trans*-11 18:2-; *trans*-10, *cis*-12 18:2- or *cis*-9, *cis*-12 18:2-CoA into TAG was decreased ( $P < 0.001$ ) compared to *cis*-9 18:1-CoA.

## Discussion

In an early study, Hansen and Knudsen [37] found that the addition of long chain FA, namely 18:0 and *cis-9, cis-12 18:2*, inhibited the incorporation of FA into the TAG of mammary gland epithelial cells. Peterson et al. [12] reported that treating MAC-T cells with *trans-10, cis-12 18:2* resulted in reduced lipid synthesis. In the current study, this CLA isomer had no effect on lipid accumulation in cultured MAC-T cells (Fig. 2). Peterson et al. [12], however, measured lipid synthesis by monitoring the incorporation of  $[^{14}\text{C}]$  acetate into total lipid and noted inhibition of lipid accumulation at increasing concentrations of *trans-10, cis-12 18:2*. The effects of other isomers of CLA were not investigated. Our studies of lipid accumulation in MAC-T cells were based on the methods used in the recent report by Keating et al. [28] to study bovine mammary cell growth, apoptosis, and stearoyl-CoA (SCD) gene expression. In this recent report, various concentrations of CLA and other FA were applied to MAC-T-cells for 48 h. CLA (*cis-9, trans-11 18:2* and *trans-10, cis-12 18:2*) concentrations of 30  $\mu\text{M}$  or greater resulted in MAC-T-cell apoptosis. Twenty micromolar CLA was the highest concentration that could be applied before the cells began to do poorly. In the current study, a 20- $\mu\text{M}$  FA treatment for 24 h was used to minimize the chances of apoptosis. The MAC-T cell line presents limitations for the study of a functioning mammary gland as it has abnormal characteristics in vitro. The in vitro data of Keating et al. [28], however, may help to clarify the effect of relatively high doses of fatty acids in vivo on the mammary gland. Eventually these investigations could be extended to evaluate the effects of CLA on differentiated mammary

gland cells in vitro, such as the bovine mammary epithelial cell collagen cell culture system [38].

In the current study, treatment of MAC-T-cells with *trans-10, cis-12 18:2* resulted in an increased proportion of 18:0 and decreased proportion of *cis-9, 18:1* in total lipid compared to the control treatment (Fig. 3). This is consistent with evidence that this CLA isomer results in decreased expression and activity of SCD [39]. The decreased production of *cis-9 18:1* and ultimately *cis-9 18:1*-CoA, a readily utilized substrate of DGAT, might be a factor in the MFD effect. The ability of DGAT to effectively utilize *cis-9 18:1*-CoA is confirmed in our competition studies using mammary gland microsomes where radiolabeled *cis-9 18:1*-CoA was incubated separately with unlabeled *cis-9 18:1*-; *cis-9, trans-11 18:2*-; *trans-10, cis-12 18:2*- or *cis-9, cis-12 18:2*-CoA (Fig. 4).

Degrace et al. [40] have reported that feeding *trans-10, cis-12 18:2* to mice increases the abundance of hepatic DGAT1 mRNA. All mice received control diet for 1 week and then control versus CLA isomer diets for 4 weeks. In the current study, treating of MAC-T-cells with various FA, however, had no effect on the expression of *DGAT1*. Peterson et al. [12] reported that cattle fed a MFD-inducing diet (i.e., high concentrate/low forage) resulted in decreased expression of *LPAAT*, whereas our data indicate that that *trans-10, cis-12 18:2* increased expression of this gene to the same extent as any other FA tested. In the current study, incubation of MAC-T cells with *trans-10, cis-12 18:2* or  $\alpha$ -18:3 resulted in decreases ( $P < 0.05$ ) in DGAT activity. In the competitive assay, however, the addition of *cis-9 18:1*-CoA decreased the incorporation of radiolabeled  $[1-^{14}\text{C}]$  *cis-9 18:1* into TAG more than for other acyl-CoA tested. Although *cis-9 18:1* may be preferentially used by DGAT, it is possible that one or more of the other molecular species of acyl-CoA tested is inhibitory. For example, *trans-10, cis-12 18:2* might inhibit microsomal DGAT activity and not serve as an effective substrate for the enzyme. Berge et al. [41] incubated rat liver microsomes in the presence of various acyl-CoA derivatives, including *cis-9, cis-12 18:2*-CoA in the presence of 20  $\mu\text{M}$  *cis-9 18:1*-CoA, and demonstrated that TAG synthesis was decreased. Eicosapentaenoyl-CoA (all *cis-5,8,11,14,17 20:5*-CoA) has also been shown to cause a substantial decrease in hepatic DGAT activity, but other acyl-CoAs tested were not inhibitory [42].

Although DGAT activity was decreased in the MAC-T cells as a result of incubation with *trans-10, cis-12 18:2* or  $\alpha$ -18:3, it is unclear how DGAT production may have been affected. Application of all FA types led to increased expression of *DGAT2* (Fig. 1), suggesting that the effect of *trans-10, cis-12* and  $\alpha$ -18:3 in decreasing DGAT activity production was post-transcriptional in nature. Exogenous application of  $\alpha$ -18:3 did not influence lipid accumulation

in the MAC-T cells (Fig. 1), even though treatment of the cells with this FA appeared to have the greatest effect on enhancing *DGAT2* expression (Fig. 2).

Furthermore, treatment with  $\alpha$ -18:3 resulted in a decrease in microsomal DGAT-specific activity (Fig. 3). A number of studies have shown that dietary  $\alpha$ -18:3 leads to enhanced  $\beta$ -oxidation and reduced fat accumulation [43–46]. The increased *DGAT2* expression brought about by treatment of MAC-T cells with  $\alpha$ -18:3 and other FAs suggests that *DGAT2* mRNA levels probably do not reflect the activity of this isoenzyme of DGAT in promoting fat accumulation in this system. The occurrence of *DGAT2* transcript in the bovine mammary gland, however, is consistent with the previous discovery of this transcript in human mammary gland [15]. CLA may not directly affect the activity of DGAT, but rather the apparent *trans*-10, *cis*-12 18:2-mediated decrease in DGAT activity may be the result of the action of this isomer on other lipogenic enzymes that generate substrates for DGAT. Cattle treated by abomasal infusion of purified *trans*-10, *cis*-12 18:2 emulsified in skim milk have been shown to exhibit a decrease in the expression of *SCD* [47]. In *SCD*<sup>-/-</sup> mice, decreased *SCD* activity has been shown to result in the accumulation of saturated FA, which had an inhibitory effect on acetyl-CoA carboxylase [48]. In turn, decreased acetyl-CoA carboxylase activity has been shown to result in a decrease in the production of malonyl-CoA, and ultimately a decrease in FA synthesis would result in less acyl-CoA available for DGAT. In cattle fed a MFD-inducing diet (i.e., high concentrate/low forage), Peterson et al. [12] also noted a decrease in the abundance of mRNA encoding FA binding protein. In another study, Brown et al. [49] have shown that treatment of human primary preadipocytes with *trans*-10, *cis*-12 18:2 results in a decrease in the expression of acyl-CoA binding protein. Thus, a decrease in the cellular content of these proteins might affect the availability of substrate for DGAT.

It is also possible that *trans*-10, *cis*-12 18:2 may influence the splicing of *DGAT* mRNA. Indeed, Grisart et al. [50] have shown using a baculovirus expression system that a K232A mutation in *DGAT1* increases the occurrence of an alternative splicing variant of *DGAT1* that produces a *DGAT1* isoform that is devoid of DGAT activity.

In addition, *trans*-10, *cis*-12 may have caused alterations in the phospholipid composition of the ER of the MAC-T cells leading to changes in the physical properties of the membrane. Ma et al. [51] have shown that *trans*-10, *cis*-12 18:2 is rapidly incorporated into the membrane phospholipid of MDA-MB-123 cells. Changes in *SCD* activity induced by *trans*-10, *cis*-12 18:2 also resulted in altered membrane composition. Since DGAT is membrane-bound, changes in the membrane environment may affect the

activity of the enzyme. Indeed, Mathur et al. have shown that varying the phospholipid composition in incubations of rat liver microsomes alters ACAT activity [52].

In the present study, the fact that *DGAT2* and *LPAAT* showed similar expression patterns in response to the application of various exogenous FAs (Fig. 1) suggests that the two acyltransferases may be coordinated at the transcriptional level. As well, the expression of *DGAT2* and *LPAAT* showed a significant positive correlation in mammary gland tissue obtained from 12 dairy cows (Table 2). A similar association was observed by Kazala et al. [53] who previously reported a significant positive correlation between microsomal DGAT and *LPAAT* activity in bovine *pars costalis diaphragmitis* muscle tissue. The results reported here suggest this relationship is also reflected at the transcript level. Although Cases et al. [15] were able to differentiate between the activity of murine *DGAT1* and *DGAT2* by altering the concentration of MgCl<sub>2</sub> in the reaction mixture, we were unable to replicate this technique using MAC-T cells or bovine mammary gland tissue. At this point, it remains unclear to which extent *DGAT2* contributes to the overall DGAT activity.

In conclusion, *trans*-10, *cis*-12 18:2 does not appear to mediate MFD by decreasing the expression of either *DGAT1* or *DGAT2*. Instead, the results of this study suggest that, upon exposure to *trans*-10, *cis*-12 18:2 or  $\alpha$ -18:3, DGAT activity in MAC-T-cells is decreased, but the mechanism is unclear. *Trans*-10, *cis*-12 18:2 may inhibit DGAT activity either directly or indirectly as a result of altered substrate pools that in turn are a result of the action of *trans*-10, *cis*-12 18:2 on enzymes that are located upstream of DGAT in the lipid biosynthetic pathway. MFD caused by the *trans*-10, *cis*-12 CLA isomer probably affects a number of lipogenic enzymes including possible effects on DGAT production and/or activity.

**Abstract** Synthetic activators of peroxisome proliferator-activated receptors (PPAR)- $\alpha$  and - $\gamma$  are capable of reducing macrophage foam cell cholesterol accumulation through the activation of genes involved in cholesterol homeostasis. Since conjugated linoleic acids (CLA) were also demonstrated to activate PPAR $\alpha$  and PPAR $\gamma$  in vivo and in vitro, we tested the hypothesis that CLA are also capable of reducing macrophage foam cell cholesterol accumulation. Thus, mouse RAW264.7 macrophage-derived foam cells were treated with CLA isomers, *c9t11*-CLA and *t10c12*-CLA, and linoleic acid (LA), as reference fatty acid, and analyzed for the concentrations of free and esterified cholesterol, cholesterol efflux and expression of genes involved in cholesterol homeostasis (CD36, ABCA1, LXR $\alpha$ , NPC-1, and NPC-2). Treatment with *c9t11*-CLA and *t10c12*-CLA, but not LA, lowered cholesterol accumulation, stimulated acceptor-dependent cholesterol efflux, and increased relative mRNA concentrations of CD36, ABCA1, LXR $\alpha$ , NPC-1, and NPC-2 ( $P < 0.05$ ). In conclusion, the present study showed that CLA isomers reduce cholesterol accumulation in RAW264.7 macrophage-derived foam cells presumably by enhancing lipid acceptor-dependent cholesterol efflux.

**Keywords** Conjugated linoleic acid · Peroxisome proliferator-activated receptors · Cholesterol accumulation · Cholesterol efflux · Macrophage foam cell · Atherosclerosis

## Abbreviations

ABCA1	ATP-binding cassette transporter A1
AcLDL	Acetylated LDL
CLA	Conjugated linoleic acid
HDL	High-density lipoprotein
LA	Linoleic acid
LDL	Low-density lipoprotein
LXR $\alpha$	Liver X receptor $\alpha$
NPC	Niemann Pick type C
PPAR	Peroxisome proliferator-activated receptor

## Introduction

Atherosclerosis, the principle cause of coronary heart disease and stroke, is responsible for more than 40% of all deaths in Europe and the US [1]. Macrophages are centrally involved in the initiation and progression of atherosclerosis and are the predominant cellular component of atherosclerotic lesions [2]. When concentrations of low-density lipoprotein (LDL) are elevated, macrophages accumulate lots of LDL-derived cholesterol through scavenger receptor-dependent pathways, and, then transform into cholesterol-enriched foam cells. Development of macrophage-derived foam cells is considered to be a critical step in atherogenesis, since foam cells account for the development of fatty streaks which represent the initial stage of atherosclerosis [3].

Recent in-vitro studies indicated that synthetic activators of PPAR $\alpha$  and PPAR $\gamma$  induce cholesterol removal from macrophage foam cells through the induction of genes involved in cholesterol homeostasis [4, 5]. Although PPAR $\gamma$  ligands increase expression of CD36 scavenger receptors [6, 7], which mediate uptake of modified LDL,

concomitant induction by PPAR $\alpha$  and PPAR $\gamma$  ligands of liver X receptor  $\alpha$  (LXR $\alpha$ ) and cholesterol exporters of the ATP-binding cassette (ABC) family, ABCA1 and ABCG1, results in a net increase in cholesterol efflux from macrophage foam cells [4, 5, 8, 9]. ABCA1 in particular plays a key role in cellular cholesterol efflux from macrophages to apo-AI, the first step in reverse cholesterol transport. This has been demonstrated in patients with a mutated ABCA1 gene, where cholesterol efflux and reverse cholesterol transport are impaired and development of atherosclerosis is accelerated [10–12]. Recent studies also demonstrated that PPAR $\alpha$  activators up-regulate proteins involved in intracellular cholesterol trafficking, namely Niemann Pick type C (NPC) proteins-1 and -2 [13], which mediate cholesterol transport from the lysosome to the plasma membrane [14, 15]. Increased expression of NPC-1 and NPC-2 by PPAR $\alpha$  activators increases cholesterol content of the plasma membrane, and, the efflux of cholesterol to extracellular acceptors such as apo-AI [13]. These in vitro effects of PPARs also explain, at least partially, that treatment with PPAR $\alpha$  and PPAR $\gamma$  ligands exerts anti-atherogenic effects in vivo [16, 17]. Similarly to synthetic agents, conjugated linoleic acids (CLA), a group of positional and geometric isomers of linoleic acid naturally occurring in food derived from ruminants such as milk and milk products, were also demonstrated to activate PPAR $\alpha$  and PPAR $\gamma$  [18–20], and inhibited atherosclerosis in animal feeding experiments [21–23]. Although the effects of CLA on plasma lipid concentrations as a surrogate marker of atherosclerosis in human studies are very inconsistent [24], there is at least some evidence that specific CLA isomers exert beneficial effects on plasma lipids in humans as well [25]. This suggests that CLA might stimulate cholesterol removal from macrophage foam cells through activation of PPAR $\alpha$  and PPAR $\gamma$ , but a recent study by Weldon et al. [26] revealed no effects of CLA on molecular markers of cholesterol homeostasis in human THP-1 macrophage-derived foam cells. Although the lack of effect might be explained by the relatively poor accumulation of CLA isomers in THP-1 cells [26] when compared to other cell types [27–29], cell type-specific actions of CLA, e.g. on PPAR $\gamma$  expression [30, 31], might also account for this.

Thus, in the present study we aimed to test the hypothesis that CLA isomers have an impact on cholesterol homeostasis in RAW264.7 macrophage-derived foam cells. These cells have been reported to show pronounced biological activities, partially mediated by a PPAR $\gamma$ -dependent mechanism, in response to treatment with CLA [19, 28]. Moreover, these cells are a widely used model to study macrophage foam cell cholesterol homeostasis [32]. RAW264.7 macrophages were transformed to foam cells by treatment with acetylated LDL (acLDL). AcLDL is a well-recognized ligand for multiple scavenger receptors

(SR) including CD36 and SR-A [33–36], and causes excessive uptake of lipoprotein-associated cholesterol in an unregulated fashion, leading to foam cell formation in vitro [37]. Kunjathoor et al. [36] have demonstrated that CD36 and SR-A account for 75–90% of the total amount of acLDL degraded by macrophages. Cholesterol loading by acLDL is further increased because acLDL dramatically increases CD36 expression in macrophages [38, 39]. In contrast, other SR involved in the uptake of acLDL such as SREC-I play only a minor role for acLDL uptake in both non-stimulated as well as stimulated macrophages [40]; according to [40] the contribution of SREC-I to the overall uptake and degradation of acLDL is only 5% in the non-stimulated and 6% in the stimulated condition. As parameters of cholesterol homeostasis, we considered the concentrations of free and esterified cellular cholesterol, and mRNA and/or protein expression levels of PPAR $\alpha$  and PPAR $\gamma$  as well as important genes involved in the regulation of cholesterol homeostasis (CD36, ABCA1, LXR $\alpha$ , NPC-1, and NPC-2) in acLDL-induced macrophage foam cells. Cholesterol removal from macrophage foam cells was estimated by measurement of high-density lipoprotein (HDL)-dependent cholesterol efflux. As isomers *cis*-9, *trans*-11 (*c9t11*)-CLA, which contributes to more than 90% of total CLA in natural foods such as milk, dairy products, and meat of ruminants [41], and *trans*-10, *cis*-12 (*t10c12*)-CLA, which is a minor isomer in natural foods but one of the main isomers in chemically produced CLA mixtures, were used. Linoleic acid (LA) was used as reference fatty acid.

## Experimental Procedure

### Materials and Reagents

The CLA isomers *c9t11*-CLA ( $\geq 96\%$  pure) and *t10c12*-CLA ( $\geq 98\%$  pure) were purchased from Cayman Chemicals (Ann Arbor, MI). LA ( $\geq 99\%$  pure) was obtained from Sigma-Aldrich (Taufkirchen, Germany).

### Cell Culture and Treatments

Mouse RAW264.7 cells, obtained from LGC Promochem (Wesel, Germany), were grown in DMEM medium (Gibco/Invitrogen, Karlsruhe, Germany) supplemented with 10% fetal calf serum, 4 mmol/L L-glutamine, 4.5 g/L glucose, 1 mmol/L sodium pyruvate, 1.5 g/L sodium bicarbonate and 0.5% gentamicin. For experiments RAW264.7 cells were plated in 24-well plates at a density of  $2 \times 10^5$ /well. After reaching 80% confluence, cells were treated with 50  $\mu$ mol/L of either *c9t11*-CLA, *t10c12*-CLA or LA for 24 h. To induce foam cell transformation, cells were

incubated with fatty acids and 50  $\mu\text{g}/\text{mL}$  human acLDL for an additional 24 h, as established in the literature [42]. Cells treated without additional fatty acids but with the vehicle (ethanol) were used as controls. Incubation media containing fatty acids were prepared by diluting the fatty acid stock solutions (100 mmol/L fatty acid in ethanol) with DMEM medium to the concentration indicated. Incubation media of control cells contained the same vehicle (ethanol) concentration of 0.05% (v/v). Preliminary experiments revealed no differences between vehicle controls and non-vehicle controls (data not shown). Experiments were performed between passages 5 and 20.

#### Cell Viability

The viability of cells after treatment with fatty acids was examined by the MTT assay [43].

#### Fatty Acid Analysis of Cell Total Lipids

After treatment of cells as indicated above, cells were washed with PBS and total lipids were extracted with hexane/isopropanol (3:2 v/v). Aliquots of the lipid extracts were dried under nitrogen, and total lipids of the extracts were transmethylated with trimethylsulfonium hydroxide as recently described in detail [44]. In brief, fatty acid methyl esters (FAME) were separated by gas chromatography using a gas chromatographic system (Hp 5890; Hewlett Packard, Waldbronn, Germany) fitted with an automatic split injection system, a flame ionization detector and a FFAP fused silica capillary column (30 m  $\times$  0.53 mm i.d.; Macherey and Nagel, Düren, Germany). FAME were identified by comparing their retention times with those of individual purified standards.

#### Isolation and Acetylation of LDL

LDL was isolated from fresh human serum by sequential gradient ultracentrifugation [45]. Afterwards LDL was dialyzed for 24 h at 4 °C against a buffer containing 0.15 mol/L NaCl and 0.3 mmol/L EDTA, pH 7.4. Acetylation of LDL was performed according to the method of Fraenkel-Conrad [46]. In brief, 1 mL of 0.15 mol/L NaCl containing 3 mg LDL protein was added to 1 mL of a saturated sodium acetate solution, and stirred in an ice water bath. Acetic anhydride (Sigma) was added slowly in small aliquots (2  $\mu\text{L}/2$  min) equal to 1.5 times the mass of LDL protein, and the mixture was stirred for an additional 30 min. Subsequently, the acLDL was dialyzed for 24 h at 4 °C against a buffer containing 0.15 mol/L NaCl and 0.3 mmol/L EDTA, pH 7.4, filter-sterilized, and stored at 4 °C.

#### Cholesterol Analysis

After treatment of cells as indicated above, cells were washed twice with PBS, cellular lipids extracted with a mixture of hexane and isopropanol (3:2 v/v), and lipid extracts dried under a stream of nitrogen. Total cholesterol and free cholesterol concentrations were determined using enzymatic assays (Wako Chemicals GmbH, Germany). The concentration of esterified cholesterol was determined by subtraction of the concentration of free cholesterol from that of total cholesterol. Cholesterol concentrations were related to cellular protein as determined by the BCA protein assay kit (Pierce, Rockford, IL). Cellular protein was obtained by lysis of cells in 0.2 mol/L NaOH after extraction of cellular lipids. Results are expressed as lipids/mg cellular protein.

#### RNA Isolation and Real-Time RT-PCR

After treatment of cells as indicated above, total RNA of the cells was extracted using Trizol reagent (Invitrogen, Karlsruhe, Germany) according to the manufacturer's instructions. RNA concentration and purity were estimated from the optical density at 260 and 280 nm, respectively. cDNA synthesis and real-time RT-PCR were performed as described recently in detail [47]. Mouse-specific primer sequences were as follows (forward, reverse):  $\beta$ -Actin (5'-ACG GCC AGG TCA TCA CTA TTG-3', 5'-CAC AGG ATT CCA TAC CCA AGA AG-3'), CD36 (5'-GAA CCT ATT GAA GGC TTA CAT CC-3', 5'-CCC AGT CAC TTG TGT TTT GAA C-3'), PPAR $\alpha$  (5'-CGG CCC CAT ACA GGA GAG CAG-3', 5'-GGG TGG CAG GAA GGG AAC AGA C-3'), PPAR $\gamma$  (5'-GGC GAG GGC GAT CTT GAC AG-3', 5'-GGG CTT CCG CAG GTT TTT GAG-3'), ABCA1 (5'-TGC CAG CAA GAC GAA ACA GAC G-3', 5'-GAC CAG GGC AAT GCA AAC AAA GAC-3'), LXR $\alpha$  (5'-GTA CAA CCC CGG CAG TGA GAG C-3', 5'-GCA GGC GAA GGG CAA ACA C-3'), NPC-1 (5'-GGG GCA TCA GTT ACA ATG CT-3', 5'-AAA CAC CGC ACT TCC CAT AG-3'), NPC-2 (5'-GAA ATC AGA CCC GAA ATG GA-3', 5'-CAT CCT GTC TGG TGG AAC CT-3').

#### Western Blot Analysis

After treatment of cells as indicated above, cells were lysed with RIPA lysis buffer (50 mmol/L Tris pH 7.5, 150 mmol/L NaCl, 1 mmol/L EDTA, 1% Triton X-100, 1% sodium deoxycholate, 0.1% SDS) containing protease inhibitor cocktail (Sigma), and protein concentrations of lysates determined by the BCA assay. Equal amounts of protein were electrophoresed by 7.5% SDS-PAGE for ABCA1 and 10% SDS-PAGE for LXR $\alpha$ , PPAR $\gamma$ , and

$\beta$ -Actin, and transferred to a nitrocellulose membrane. The membranes were blocked overnight at 4 °C in blocking solution (5% skim milk in Tris buffered saline with Tween-20 [TBS-T]: 50 mmol/L Tris, 150 mmol/L NaCl, pH 7.5, 0.1% Tween-20), and then incubated with primary antibodies against PPAR $\gamma$  (1:1,000, Upstate), ABCA1 (1:1,000, Novus Biologicals), LXR $\alpha$  (1:500, Affinity Bioreagents), and  $\beta$ -Actin (1:1,000, Novus Biologicals) for 1.5 h at room temperature. The membranes were washed with TBS-T, and incubated with a horseradish peroxidase conjugated secondary anti-mouse IgG antibody (1:2,000, Amersham Biosciences) or anti-rabbit IgG antibody (1:10,000, Amersham Biosciences) for 1.5 h at room temperature. Afterwards blots were developed using ECL Plus (Amersham Biosciences). The signal intensities of specific bands were detected with a Bio-Imaging system (Biostep) and quantified using TotalLab TL100-Quick Start analysis software (nonlinear dynamics).

#### Cholesterol Efflux Measurement

Cholesterol efflux assays were performed as described with minor modifications [32]. Twenty-four hours after plating, RAW264.7 macrophages were pre-treated with medium containing 10% low density lipoprotein-deficient serum for 24 h. Subsequently, RAW264.7 cells were incubated with fatty acids in the absence or presence of acLDL (50  $\mu$ g/mL) and 1  $\mu$ Ci  $^3$ H-cholesterol (Amersham-Biosciences) per well in a medium containing 0.2% bovine serum albumin for 24 h. After incubation, the medium was aspirated, cells were washed two times with PBS, and incubated with fatty acids in a medium containing 0.2% bovine serum albumin for a further 8 h. Cells were washed again with PBS, and incubated in the presence or absence of 50  $\mu$ g/mL HDL as cholesterol acceptor for 4 h. After incubation, the medium was collected and cells were lysed using 0.2 M NaOH, and the medium and lysates were checked for  $^3$ H-activity. Cholesterol efflux was calculated as the percentage of  $^3$ H-activity in the medium from the total  $^3$ H-activity in the medium and lysate as described in [48].

#### Statistical Analysis

Data were subjected to one-way ANOVA using the Minitab Statistical Software (Minitab, State College, PA, USA). For statistically significant *F* values, individual means of the treatment groups were compared by Fisher's multiple range. Means were considered significantly different for *P* < 0.05. Significant effects are denoted with superscript letters. Bars marked with different superscript letters significantly differ.

## Results

### Effects of Treatment on Viability of RAW264.7 Macrophage-Derived Foam Cells

Treatment with 50  $\mu$ mol/L of either *c9t11*-CLA, *t10c12*-CLA or LA had no effect on the viability of RAW264.7 cells compared to vehicle control treatment; cell viabilities after treatment with *c9t11*-CLA, *t10c12*-CLA or LA were in the range between 97 and 103% relative to vehicle controls (=100%).

### Effects of Treatment on Fatty Acid Composition of RAW264.7 Macrophage Total Lipids

Incubation of RAW264.7 macrophages with 50  $\mu$ mol/L of either *c9t11*-CLA, *t10c12*-CLA or LA resulted in a marked incorporation of the respective fatty acids into the total cell lipids compared to vehicle controls (Table 1). However, the increase in the proportion of C18:2*c9t11* after treatment with *c9t11*-CLA was less pronounced than the increase in the proportions of C18:2*t10c12* and C18:2(n-6) after treatment with *t10c12*-CLA and LA, respectively. The incorporation of the respective fatty acids was accompanied by a concomitant marked decrease in the proportions of C16:1 and C18:1 when compared to vehicle controls. Other major fatty acids such as C16:0 and C18:0 were similar between treatment groups. The proportion of C14:0 was slightly increased by treatment with *c9t11*-CLA and *t10c12*-CLA relative to vehicle controls. Moreover, the proportion of C22:6(n-3) was decreased by treatment with *c9t11*-CLA and *t10c12*-CLA, whereas the

C22:4(n-6)	0.5 $\pm$ 0.1	0.7 $\pm$ 0.1	0.7 $\pm$ 0.1	3.1 $\pm$ 0.1
C22:6(n-3)	2.8 $\pm$ 0.1	2.3 $\pm$ 0.1	2.3 $\pm$ 0.1	2.4 $\pm$ 0.1

<sup>a</sup> Values are mean  $\pm$  SEM of two independent experiments (*n* = 2). Data were not subjected to statistical analysis due to the low amount of experiments

proportion of C20:5(n-3) was only decreased by treatment with *c9t11*-CLA compared to vehicle controls. Treatment with LA increased the proportions of C20:4(n-6) and C22:4(n-6) when compared to vehicle controls.

#### Effects of Treatment on Cholesterol Concentrations in RAW264.7 Macrophage-Derived Foam Cells

Treatment of acLDL-induced RAW264.7 macrophage-derived foam cells with either *c9t11*-CLA or *t10c12*-CLA lowered concentrations of esterified cholesterol but not of free cholesterol compared to vehicle control cells ( $P < 0.05$ ; Fig. 1). Treatment with LA had no effect on the concentrations of free or esterified cholesterol in acLDL-induced RAW264.7 macrophage-derived foam cells when compared to vehicle controls. However, the effect of CLA isomers on the concentration of esterified cholesterol did not differ from that of LA.

#### Effects of Treatment on Relative mRNA Concentrations of Genes Involved in Cholesterol Homeostasis in RAW264.7 Macrophage-Derived Foam Cells

Relative mRNA concentrations of CD36, ABCA1, and LXR $\alpha$  were significantly increased by both *c9t11*-CLA and *t10c12*-CLA compared to vehicle control cells and LA ( $P < 0.05$ ; Fig. 2), whereas those of NPC-1 and NPC-2 were only increased by *t10c12*-CLA compared to vehicle

**Fig. 1** Effect of treatment with 50  $\mu\text{mol/L}$  of either *c9t11*-CLA, *t10c12*-CLA or LA on free and esterified cholesterol concentrations in acLDL-induced RAW264.7 macrophage-derived foam cells. Cells treated without fatty acids were used as controls. Data represent mean  $\pm$  SEM of at least three independent experiments ( $n \geq 3$ ). Results from statistical analysis (one-way ANOVA followed by Fisher's test) are indicated: Significant effects are denoted with superscript letters. Bars marked without a common superscript letter significantly differ ( $P < 0.05$ )

control cells and LA ( $P < 0.05$ ). Treatment of RAW264.7 macrophage-derived foam cells with LA did not alter mRNA concentrations of the genes investigated compared to vehicle controls ( $P < 0.05$ ). Relative mRNA concentration of PPAR $\alpha$  in RAW264.7 macrophage-derived foam cells was not altered by treatment with either fatty acid. Relative mRNA concentration of PPAR $\gamma$  in RAW264.7 macrophage-derived foam cells was significantly elevated by incubation with *c9t11*-CLA compared to vehicle controls and LA ( $P < 0.05$ ). Incubation with *t10c12*-CLA or LA had no effect on the relative mRNA concentration of PPAR $\gamma$  in RAW264.7 macrophage-derived foam cells compared to vehicle controls.

#### Effects of Treatment on Relative Protein Concentrations of ABCA1, LXR $\alpha$ and PPAR $\gamma$ in RAW264.7 Macrophage-Derived Foam Cells

Since mRNA data indicated an induction of genes involved in cholesterol efflux by CLA we also determined relative protein concentrations of ABCA1 and its transcriptional activator LXR $\alpha$  in western blot experiments. PPAR $\gamma$  protein was also considered because of the marked effect of *c9t11*-CLA on its mRNA concentration. Our western blot experiments revealed that the protein concentration of ABCA1 was significantly increased by *t10c12*-CLA compared to vehicle controls and LA ( $P < 0.05$ ; Fig. 3a, b), whereas *c9t11*-CLA tended to increase the protein concentration of ABCA1. Relative protein concentration of LXR $\alpha$  was not altered by treatment with either CLA isomers or LA. The relative protein concentration of PPAR $\gamma$  was significantly increased by *c9t11*-CLA compared to vehicle controls and LA ( $P < 0.05$ ). Treatment with LA even decreased the relative protein concentration of PPAR $\gamma$  compared to vehicle controls ( $P < 0.05$ ).

#### Effects of Treatment on Cholesterol Efflux from RAW264.7 Macrophage-Derived Foam Cells

In the presence of HDL, cholesterol efflux from acLDL-induced RAW264.7 macrophage-derived foam cells was significantly increased by *c9t11*-CLA and *t10c12*-CLA compared to vehicle control treatment ( $P < 0.05$ ; Fig. 4), but not by LA. The effect of *c9t11*-CLA and *t10c12*-CLA, however, did not differ from that of LA. In the absence of HDL, cholesterol efflux was not different between vehicle control cells and cells treated with fatty acids.

## Discussion

Pharmacological PPAR $\alpha$  and PPAR $\gamma$  ligands have been demonstrated to induce cholesterol removal from

**Fig. 2** Effect of treatment with 50  $\mu\text{mol/L}$  of either *c9t11*-CLA, *t10c12*-CLA or LA on relative mRNA concentrations of genes involved in cholesterol homeostasis in acLDL-induced RAW264.7 macrophage-derived foam cells. Cells treated without fatty acids were used as controls. Data represent mean  $\pm$  SEM of at least three independent experiments ( $n \geq 3$ ) and are expressed as percentage of mRNA abundance of controls ( $=100 \pm 0\%$ ). Results from statistical analysis (one-way ANOVA followed by Fisher's test) are indicated: Significant effects are denoted with superscript letters. Bars marked without a common superscript letter significantly differ ( $P < 0.05$ )

macrophage foam cells through alterations in the expression of genes involved in cholesterol homeostasis [4, 5, 8, 9, 13]. Since CLA are also well-known activators of PPAR $\alpha$  and PPAR $\gamma$  [18–20], the present study aimed to test the hypothesis that CLA isomers have an impact on cholesterol homeostasis in RAW264.7 macrophage-derived foam cells. For the incubation experiments, we used concentrations of CLA of 50  $\mu\text{mol/L}$ . This concentration is similar to what has been typically used in cell culture studies dealing with CLA's mechanisms of action [20, 26–31]. However, based on the observation that incubating RAW264.7 cells with 50  $\mu\text{mol/L}$  of CLA resulted in concentrations of CLA in cell lipids of up to 13 g/100 g of total fatty acids, this concentration of CLA must be considered as rather high. In contrast, humans supplemented with 3 g per day of a CLA mixture for 6 weeks had plasma concentrations of *c9t11*-CLA of only about 0.8 g/100 g total fatty acids [49]. Nevertheless, our study shows that the concentration of CLA isomers in macrophage cells can be extremely elevated as also observed in several other cell lines [20, 29] while the cells still have normal morphological appearance and growth characteristics. This opens up the possibility of studying the influence of high concentrations of CLA on diverse functional properties of cells and of addressing mechanistic questions. This cell culture study, thus, must be considered as a model study that cannot be directly extrapolated to humans. As expected, the incorporation of the CLA isomers into macrophage total lipids was accompanied by concomitant changes in the

proportions of other fatty acids. Most important, the proportions of C16:1 and C18:1 were markedly reduced by treatment with CLA isomers, and the proportions of polyunsaturated fatty acids (PUFA) like C22:6(n-3) and C20:5(n-3) were slightly decreased by CLA isomers. This indicates that the effects observed in the present study cannot solely be ascribed to the incorporation of CLA isomers but also, at least partially, to changes in fatty acid composition. However, since the proportions of PUFA, which are known PPAR ligands [50], were even decreased by treatment with CLA isomers, we are confident that activation of PPARs in response to CLA treatment was primarily caused by the added CLA isomers.

The present study clearly demonstrated that *c9t11*-CLA and *t10c12*-CLA lowered concentrations of esterified cholesterol, the storage form of cholesterol in macrophage-foam cells, and stimulated HDL-dependent cholesterol efflux in mouse RAW264.7 macrophage-derived foam cells when compared to control cells treated without additional fatty acids. The reduction of cholesterol accumulation by CLA isomers in RAW264.7 macrophage-derived foam cells was evidenced by a decline in the concentration of esterified cholesterol. Thus, the finding that lowering of macrophage cholesterol accumulation and induction of HDL-dependent cholesterol removal could be observed with CLA isomers, which has also been reported in response to pharmacological PPAR ligands [4, 5, 8, 9, 13], strengthens our hypothesis that CLA isomers are capable of affecting macrophage foam cell cholesterol

**Fig. 3** Effect of treatment with 50  $\mu\text{mol/L}$  of either *c9t11*-CLA, *t10c12*-CLA or LA on relative protein concentrations of ABCA1, LXR $\alpha$ , and PPAR $\gamma$  in acLDL-induced RAW264.7 macrophage-derived foam cells. Cells treated without fatty acids were used as controls. **a** Representative immunoblots specific to ABCA1, LXR $\alpha$ , PPAR $\gamma$ , and  $\beta$ -Actin which was used for normalization are shown. **b** Graphs represent data from densitometric analysis and represent mean  $\pm$  SEM of at least three independent experiments ( $n \geq 3$ ). Data are expressed as percentage of protein concentration of controls ( $=100 \pm 0\%$ ). Results from statistical analysis (one-way ANOVA followed by Fisher's test) are indicated: significant effects are denoted with superscript letters. Bars marked without a common superscript letter significantly differ ( $P < 0.05$ )

homeostasis through their potential to activate PPARs. In connection with recent findings that treatment with CLA isomers failed to reduce cholesterol accumulation in human THP-1 macrophage-derived foam cells [26], the results from the present study may indicate that the effect of CLA on macrophage cholesterol accumulation is cell type- or species-specific. The reason for these divergent effects of CLA cannot be definitely ruled out, but differences in the cellular uptake and incorporation of CLA isomers between RAW264.7 and THP-1 cells might be causative. Whereas in THP-1 macrophages only a poor incorporation of CLA isomers in total cell lipids after treatment with CLA isomers has been reported [26], treatment of RAW264.7 macrophage foam cells with CLA isomers in the present study resulted in a marked incorporation of CLA isomers. However, since up-regulation of CD36 by CLA isomers has been observed in that recent report [26] other reasons such as differences in the expression pattern of PPAR-subtypes between these two cell lines might also apply [18, 51]. Nevertheless, to resolve these contradictory results between RAW264.7 and THP-1 cells with certainty further research is required.

On the molecular level, reduction of cholesterol accumulation in cultured macrophages by PPAR $\alpha$  and PPAR $\gamma$  activators has been explained by increased expression of LXR $\alpha$ , which in turn activates expression of LXR $\alpha$  target genes such as macrophage cholesterol exporters, namely ABCA1 and ABCG1, and, thereby, stimulates cholesterol efflux to extracellular acceptors for reverse cholesterol transport [4, 5, 8, 9]. A recent study further demonstrated that PPAR $\alpha$  activation stimulates postlysosomal mobilization of cholesterol by induction of gene expression of NPC-1 and NPC-2 [13]. Both proteins control intracellular trafficking of cholesterol from the late endosomal compartment and lysosome, respectively, to the plasma membrane [14, 15]. It has been suggested [13] that this results in an enrichment of cholesterol in the plasma membrane and an enhanced availability of cholesterol at the cell membrane, which also contributes to increased macrophage cholesterol efflux and reverse cholesterol transport by PPAR $\alpha$  activators. Hence, the increased

mRNA abundance of ABCA1, LXR $\alpha$ , NPC-1, and NPC-2 in response to CLA isomers as observed in the present study is associated with the reduced cholesterol accumulation in RAW264.7 macrophage-derived foam cells. The induction of ABCA1 by CLA isomers could also be observed at the protein level although this effect was only significant for *t10c12*-CLA whereas *c9t11*-CLA only showed a tendency towards an increased ABCA1 protein concentration. However, this observation is in the line

**Fig. 4** Effect of treatment with 50  $\mu\text{mol/L}$  of either *c9t11*-CLA, *t10c12*-CLA or LA on cholesterol efflux in acLDL-induced RAW264.7 macrophage-derived foam cells in the presence and absence of HDL. Cells treated without fatty acids were used as controls. Efflux is expressed as counts media/(counts media + counts lysate)  $\times 100$ . Data represent mean  $\pm$  SEM of at least three independent experiments ( $n \geq 3$ ). Results from statistical analysis (one-way ANOVA followed by Fisher's test) are indicated: significant effects are denoted with superscript letters. Bars marked without a common superscript letter significantly differ ( $P < 0.05$ )

with the more pronounced effect of *t10c12*-CLA on the elevation of ABCA1 mRNA concentration compared with *c9t11*-CLA. We have no explanation for the slightly stronger effect of *t10c12*-CLA on ABCA1 mRNA concentration compared with *c9t11*-CLA. However, this might be related to the slightly higher incorporation of *t10c12*-CLA into the macrophage total lipids when compared to *c9t11*-CLA, which in turn resulted in an increased PPAR ligand availability, thereby, causing a stronger LXR $\alpha$  and ABCA1 induction. Surprisingly, we could not detect an increased protein concentration of LXR $\alpha$  in response to *t10c12*-CLA or *c9t11*-CLA although both CLA isomers elevated the mRNA concentration of this transcription factor. Although we do not know the exact reason for this discrepancy it has to be considered that the elevation of LXR $\alpha$  mRNA concentration by CLA isomers was only about 50%, a degree that can hardly be demonstrated in western blot experiments. In addition, it should be kept in mind that CLA isomers might have also stimulated LXR $\alpha$  transactivation without influencing protein levels of this transcription factor. This, however, has to be elucidated in further studies. Nevertheless, collectively the present data suggest that reverse cholesterol transport is presumably stimulated by natural PPAR ligands deriving from food like CLA. The observation from a recent study that plasma HDL cholesterol concentrations and ABCA1 gene expression were increased in the aorta of hamsters fed *c9t11*-CLA is indeed indicative

of the potential of CLA to increase the capacity for reverse cholesterol transport [52].

We cannot exclude the possibility that CLA isomers might also had an effect on genes regulating cholesterol esterification in macrophage-derived foam cells such as acyl-CoA:cholesterol acyltransferase (ACAT), which catalyzes cholesteryl ester formation from cholesterol and fatty acyl-CoA, and cholesteryl ester hydrolase (CEH), which is responsible for hydrolysis of stored cholesterol esters in macrophage foam cells and release of free cholesterol for high-density lipoprotein-mediated efflux. Indeed, Hirakata et al. [53] have demonstrated that reduction of cholesteryl ester accumulation by pharmacological PPAR $\gamma$  ligands in THP-1 macrophages was accompanied by enhanced CEH mRNA expression and inhibited ACAT-1 mRNA expression. Since free cholesterol mobilized from hydrolysis of cholesteryl esters by increased expression of CEH is also partially diffusing through the plasma membrane as shown by the cholesterol efflux observed in the absence of added HDL, we suggest that this stimulation of "passive" cholesterol efflux is at least in part responsible for the reduced cholesteryl ester levels observed during incubation without extracellular cholesterol acceptors (Fig. 1). Therefore, downregulation of ACAT-1 and upregulation of CEH by CLA isomers might have also contributed to the reduced cholesteryl ester concentrations as observed in the present study. However, this deserves further investigation.

The present study revealed that the inhibitory effect of CLA isomers on macrophage foam cell cholesterol accumulation was only significant when compared to vehicle control cells treated without additional fatty acids. However, when compared to LA, a frequently used reference fatty acid when studying the effects of CLA [26, 54], the inhibitory effect of CLA isomers on cholesterol accumulation was not significant. In part, this might be due to the fact that the standard variation of measured values in the LA group (e.g. esterified cholesterol) was quite high whereas that in the vehicle control group was comparatively low, therefore, explaining that the effect of CLA was not different from LA. Since the present study further shows that treatment with LA had no effect on mRNA abundance of genes involved in cholesterol homeostasis in RAW264.7 macrophage-derived foam cells, we suggest that LA had no effect on macrophage foam cell cholesterol accumulation and, thus, clearly differs from CLA in its action on the parameters investigated herein. This indicates that the inhibitory effect of CLA isomers on macrophage foam cell cholesterol accumulation is dependent on the specific conjugated dienoic structure of CLA. In part the lack of effect of LA might be explained by the fact that LA is a weaker PPAR $\alpha$  and PPAR $\gamma$  activator than *c9t11*-CLA or *t10c12*-CLA [18]. Consistent with this finding is the

observation that LA, in contrast to *c9t11*-CLA or *t10c12*-CLA, did not induce the PPAR $\gamma$  target gene CD36 in RAW264.7 and THP-1 macrophage-derived foam cells [26]. Similar observations have been reported from Yu et al. [19] using RAW264.7 macrophages.

In conclusion, the present study shows that *c9t11*-CLA and *t10c12*-CLA reduce cholesterol accumulation in RAW264.7 macrophage-derived foam cells probably by stimulating HDL-dependent cholesterol efflux. The CLA-induced increase in cholesterol efflux from macrophage foam cells is presumably explained by the up-regulation of ABCA1, which operates on cholesterol export to extracellular acceptors such as apo-AI/HDL. Up-regulation of NPC-1 and NPC-2 as evidenced by increased transcript levels of NPC-1 and NPC-2 in response to treatment with CLA isomers probably also contributes to the observed lowering of cholesterol accumulation in RAW264.7 cells, since both proteins mediate intracellular cholesterol transport to the plasma membrane and increase the availability of cholesterol for efflux through extracellular acceptors. Since treatment with CLA isomers also caused an increase in the transcript levels of CD36, which mediates cholesterol uptake from modified LDL particles [55], we suggest that the concomitant up-regulation of ABCA1, which mediates cholesterol removal from cells, was probably more pronounced leading to a net efflux of cholesterol. Because extensive accumulation of cholesterol by macrophage foam cells in the arterial wall leads to atherosclerosis, the present findings in connection with other beneficial effects of CLA in macrophages [19, 26, 56, 57] might in part explain the anti-atherogenic actions of CLA as observed in animal models of experimental atherosclerosis [21–23].

# Women and Smokers Have Elevated Urinary F<sub>2</sub>-Isoprostane Metabolites: A Novel Extraction and LC–MS Methodology

Alan W. Taylor · Richard S. Bruno ·

**Abstract** F<sub>2</sub>-Isoprostanes (F<sub>2</sub>-IsoPs), regio- and stereoisomers of prostaglandin F<sub>2 $\alpha$</sub>  (PGF<sub>2 $\alpha$</sub> ), and urinary F<sub>2</sub>-IsoP metabolites including 2,3-dinor-5,6-dihydro-8-*iso*-PGF<sub>2 $\alpha$</sub>  [2,3-dinor-8-*iso*-PGF<sub>1 $\alpha$</sub>  (2,3-dinor-F1)] and 2,3 dinor-8-*iso*-PGF<sub>2 $\alpha$</sub>  (2,3-dinor-F2), have all been used as biomarkers of oxidative stress. A novel method was developed to measure these biomarkers using a single solid phase extraction (SPE) cartridge, separation by HPLC, and detection by negative mode selected reaction monitoring (SRM) mass spectrometry (MS), using authentic standards of PGF<sub>2 $\alpha$</sub> ; 8-*iso*-PGF<sub>2 $\alpha$</sub> ; 2,3-dinor-F1 and 2,3-dinor-F2 to identify specific chromatographic peaks. The method was validated in a population of healthy, college-aged nonsmokers ( $n = 6$  M/8F) and smokers ( $n = 6$  M/5F). Urinary F<sub>2</sub>-IsoP concentrations were  $\sim 0.2$ – $1.5$   $\mu\text{g/g}$  creatinine, 2,3-dinor-F1 was  $\sim 1$ – $3$   $\mu\text{g/g}$  and 2,3-dinor-F2 was  $\sim 3$ – $5$   $\mu\text{g/g}$ . Additional F<sub>2</sub>-IsoPs metabolites were identified using SRM. The sum of all urinary F<sub>2</sub>-IsoP metabolites was 50–100  $\mu\text{g/g}$  creatinine indicating their greater abundance than F<sub>2</sub>-IsoPs. Women had higher F<sub>2</sub>-IsoP metabolite concentrations than did men (MANOVA, main effect  $P = 0.003$ ); cigarette smokers had higher concentrations than did nonsmokers (main effect  $P = 0.036$ ). For men or women, respectively, smokers had higher metabolite concentrations than did nonsmokers ( $P < 0.05$ ). Thus, our method simultaneously allows

measurement of urinary F<sub>2</sub>-IsoPs and their metabolites for the determination of oxidative stress.

## Introduction

F<sub>2</sub>-Isoprostanes (F<sub>2</sub>-IsoPs, Fig. 1) are regio- and stereoisomers of prostaglandin F<sub>2 $\alpha$</sub>  (PGF<sub>2 $\alpha$</sub> ) formed by the free radical-mediated oxidation of arachidonic acid [1]. Thus, F<sub>2</sub>-IsoPs, particularly the 15-series regioisomer, 8-*iso*-PGF<sub>2 $\alpha$</sub> , are often used as biomarkers of oxidative stress [2, 3], and have been measured using well-established GC–MS and ELISA methods [4]. Recent advances in LC–MS methods have allowed faster and simpler sample preparation [4, 5].

Plasma or tissue F<sub>2</sub>-IsoPs concentrations provide a “snap-shot” assessment of oxidative stress. However, concerns have arisen due to the potential for artifacts

**Fig. 1** Structures of F<sub>2</sub>-Isoprostanes (F<sub>2</sub>-isoPs) and metabolites

arising from *in vitro* lipid oxidation changes during sample preparation [6]. Thus, measurement of urinary F<sub>2</sub>-IsoPs was proposed to be more reliable and less prone to artifactual increases in measured products thereby allowing for the more reliable assessment of oxidative stress *in vivo*. [6]. Urine also contains appreciable levels of F<sub>2</sub>-IsoP metabolites [4, 6, 7], which could be measured simultaneously to bolster urinary F<sub>2</sub>-IsoP results. Additionally, urine can be collected non-invasively from humans. Thus, urinary F<sub>2</sub>-IsoPs may provide a better assessment of oxidative stress than samples from other biological materials, such as plasma.

Potentially, urinary F<sub>2</sub>-IsoP metabolites may be better biomarkers of oxidative stress [4, 6, 7]. Roberts et al. [6] determined that 2,3-dinor-5,6-dihydro-8-*iso*-PGF<sub>2 $\alpha$</sub>  (2,3-dinor-F1, Fig. 1) was the major metabolite of 8-*iso*-PGF<sub>2 $\alpha$</sub> . Chiabrando et al. [4] also identified 2,3-dinor-8-*iso*-PGF<sub>2 $\alpha$</sub>  (2,3-dinor-F2) as an additional urinary 8-*iso*-PGF<sub>2 $\alpha$</sub>  metabolite. Interestingly, both 2,3-dinor-F1 and -F2 were present in similar urinary concentrations. Although both groups developed GC–MS procedures for the identification of these compounds [4, 8], the GC–MS methodology described by Nourooz-Zadeh et al. [7] facilitated the

simultaneous measurement of these metabolites along with the parent compound, 8-*iso*-PGF<sub>2 $\alpha$</sub> . Importantly, there is consensus among these investigators that the F<sub>2</sub>-IsoPs metabolites, 2,3-dinor-F1 and -F2, are present in significantly greater urinary concentrations than is 8-*iso*-PGF<sub>2 $\alpha$</sub> , suggesting that the metabolites may be more easily measured biomarkers. Moreover, F<sub>2</sub>-IsoP metabolism may be important in decreasing adverse consequences of oxidative stress and increasing removal of oxidatively damaged lipids [9].

LC–MS methodologies for the determination of these metabolites have been developed [5, 10]. These methods stressed high sample throughput by using short HPLC columns (e.g. rocket method) and reported a single value for the F<sub>2</sub>-IsoP metabolites. However, the metabolites from the 64 possible isomers of F<sub>2</sub>-IsoPs are likely to be numerous. Moreover, it is unlikely that all species from a biological sample having the same molecular-ion-to-product-ion reaction are derived from a single parent compound. Thus, the evaluation of F<sub>2</sub>-IsoP metabolites resolved by prolonged HPLC separation, as we described for plasma F<sub>2</sub>-IsoPs [11], may be more advantageous than existing rocket methods because quantitation of specific biomarkers could potentially provide information concerning metabolism of specific precursors.

To this end, we developed a method that uses one solid phase extraction (SPE) cartridge, followed by prolonged gradient HPLC–MS–MS, to identify and quantitate urinary F<sub>2</sub>-IsoPs and their metabolites, specifically including 2,3-dinor-F1 and -F2. Additionally, we have identified several other potential F<sub>2</sub>-IsoP metabolites using selected reaction monitoring (SRM). The procedure was validated by assessing urinary F<sub>2</sub>-IsoPs and their metabolites from a cohort of otherwise healthy nonsmokers and smokers, described previously [12]. Free F<sub>2</sub>-IsoPs were measured previously in the plasma from these individuals [12], as were total (free + esterified) 15-series F<sub>2</sub>-IsoPs [11]. While mean F<sub>2</sub>-IsoP concentrations were numerically higher among smokers compared to nonsmokers, the differences were not statistically significant for any measured analyte due to large within-group variation. Thus, the simultaneous quantitation of urinary F<sub>2</sub>-IsoPs and their metabolites from this same cohort will assess the utility of measuring F<sub>2</sub>-IsoPs in urine versus plasma as well as measuring F<sub>2</sub>-IsoP metabolites versus parent F<sub>2</sub>-IsoPs in urine.

## Experimental Procedures

### Materials

HPLC grade solvents and reagents were obtained from VWR (West Chester, PA). Purified water was obtained

from a Millipore Milli-Q apparatus (Billerica, MA). Authentic samples of 8-*iso*-prostaglandin F<sub>2α</sub> (8-*iso*-PGF<sub>2α</sub>), PGF<sub>2α</sub>, PGE<sub>2</sub>, 2,3-dinor-8-*iso*-PGF<sub>1α</sub>, and 2,3-dinor-8-*iso*-PGF<sub>2α</sub>, and the deuterated internal standards 8-*iso*-PGF<sub>2α</sub>-d<sub>4</sub> and PGE<sub>2</sub>-d<sub>4</sub> were obtained commercially (Cayman Chemical; Ann Arbor, MI).

#### Study Design and Sample Collection

The study protocol for assessing vitamin E pharmacokinetics and oxidative stress markers in smokers and nonsmokers was reported previously [12]. The protocol was approved by the Institutional Review Board for the protection of human subjects at Oregon State University. At the time of the study, participants consented to the use of archived specimens for the continued assessment of oxidative stress biomarkers.

In brief, healthy, 18–35-year old male and female nonsmokers ( $n = 6$  M/8F) and smokers ( $n = 6$  M/5F; 10–20 cigarettes/day) were recruited from the university area [12]. Participants were not nutritional supplement users (>6-months) and they maintained normal exercise patterns (<7 h/week aerobic exercise). The study was designed as a randomized, double-blind, placebo-controlled vitamin C intervention study in which participants received vitamin C (500 mg; twice daily) or matching placebo for 17 days. On day 14, participants received an equimolar mixture of deuterium-labeled  $\alpha$ - and  $\gamma$ -tocopherols (~50 mg each d<sub>6</sub>- $\alpha$ - and d<sub>7</sub>- $\gamma$ -tocopheryl acetates) on a single occasion and blood was collected in regular intervals from 0 to 72 h following labeled-tocopherol administration. Urine was collected in 8-h intervals from 0 to 24 h, aliquoted, and subsequently stored at –20 °C. The last 8 h collection (16–24 h) contained the first void on the second day of the trial.

At the completion of the trial, all participants underwent a 3-month washout period, and subsequently returned to the study center to complete the alternate arm of the study as described. During each supplementation period, participants were instructed to follow a low ascorbic acid diet; plasma ascorbic acid was reported previously [12].

Plasma unesterified F<sub>2</sub>-IsoPs were measured previously using GC–MS [12]. Plasma samples were analyzed previously for total (free + esterified) F<sub>2</sub>-IsoPs by HPLC–MS–MS [11]. The data reported herein from 24 h urine collections are limited to those participants who completed the vitamin C intervention and respective placebo trial and provided complete urine samples from each 8 h collection period. Thus, the present investigation is limited to nonsmokers ( $n = 6$  M/8F) and smokers ( $n = 6$  M/5F). Smokers had lower body mass indexes (BMI) than nonsmokers and higher cotinine concentrations; women had higher high density lipoprotein (HDL) cholesterol concentrations (Table 1). Otherwise, there were no major differences between genders or smoking status groups.

#### Sample Preparation

Urine was thawed at room temperature, mixed by inversion, and centrifuged (200g, 5 min). The supernatant (600  $\mu$ l) was mixed with 500  $\mu$ l methanol, internal standards (IS, 12 ng 8-*iso*-PGF<sub>2α</sub>-d<sub>4</sub> and 3 ng PGE<sub>2</sub>-d<sub>4</sub> in 24  $\mu$ l 1:1 methanol:water) added, followed by addition of buffer (2.0 ml 0.02 M bis-tris-HCl) with mixing at each step. The diluted sample pH was then adjusted using H<sub>3</sub>PO<sub>4</sub> or KOH to pH 6.0 ± 0.05.

Strata X-AW cartridges (100 mg/3 ml, Phenomenex, Torrance, CA) were each pre-conditioned with 2 ml 98:2 methanol:formic acid (v:v) and subsequently equilibrated

with 2 ml water. Diluted urine samples were loaded, the cartridges washed with 2 ml water, followed by 4 ml 25% methanol, 2 ml acetonitrile, and cartridges dried under a gentle vacuum ( $\sim 5$  mm Hg, 30 s). Cartridges were then eluted 3-times with 1 ml methanol, and the eluants from each cartridge pooled and collected into glass tubes. Samples were dried under nitrogen gas, reconstituted in 200  $\mu$ l methanol containing 0.1% formic acid (v:v), and injected onto the LC–MS–MS.

### Chromatography and Mass Spectrometry

Separation was carried out using a Shimadzu HPLC system (Columbia, MD) consisting of two LC-10ADvp pumps, a DGU-14A degasser, a SIL-HTc autosampler-system controller maintained at 10 °C, and a CTO-10Avp column oven (35 °C) with a Synergi Hydro-RP column (250  $\times$  2 mm i.d., 4  $\mu$ m) equipped with a SecurityGuard C<sub>18</sub> guard cartridge (4  $\times$  2 mm; both from Phenomenex; Torrance, CA). Mobile phases A (water) and B (methanol) contained 0.01% acetic acid (v/v) and were delivered at a total flow of 200  $\mu$ l/min using the following gradient scheme: 5 min equilibration at 30% B prior to injection, 30% B from 0–0.5 min, followed by a linear gradient over 1 min to 58% B, a linear gradient over 13.5 min to 66% B, a linear gradient over 7 min to 69% B, then to 100% B over 2 min which was held until the completion of the run at 32 min.

The HPLC system was coupled to a triple quadrupole mass spectrometer with TurboIon Spray source operated with both mass analyzers set at unit resolution in negative mode (Applied Biosystems/MDS Sciex API 3000, Foster City, CA). Nebulizer, curtain, and collision (CAD) gas parameters were set at 12, 10, and 7, respectively. Heater gas was supplied at 6 l/min at 425 °C. All gases were high purity nitrogen supplied by a custom liquid nitrogen system (Polar Cryogenics, Portland, OR). The ionizing voltage was  $-4,000$  V, and the declustering, focusing, entrance, and exit potentials were  $-50$ ,  $-250$ ,  $-8$ ,  $-35$ , and  $-11$  V, respectively.

To identify chromatographic peaks, product ion spectra of authentic standards of 8-*iso*-PGF<sub>2 $\alpha$</sub> , PGF<sub>2 $\alpha$</sub> , 2,3-dinor-F1, and 2,3-dinor-F2 were acquired at collision energies (CE, see below) that produced a molecular ion intensity of 30–80% of the most abundant fragment ion. Then, each standard was analyzed by gradient HPLC and detected by selected reaction monitoring (SRM) experimentation based on the major fragment ions in the corresponding product ion spectrum, thereby creating a multi-trace profile for each compound. Next, a human urine sample was analyzed similarly to identify corresponding chromatographic peaks eliciting identical SRM characteristics to each specific standard.

Analytes were detected and quantified using SRM of seven reactions:

15-series PGFs,  $m/z$  353–193, CE  $-35$  V.

8-*iso*-PGF<sub>2 $\alpha$</sub> -d<sub>4</sub> internal standard,  $m/z$  357–197, CE  $-35$  V.

PGE<sub>2</sub>,  $m/z$  351–189, CE  $-27$  V; PGE<sub>2</sub>-d<sub>4</sub>,  $m/z$  355–193, CE  $-27$  V.

2,3-dinor-F1,  $m/z$  327–283, CE  $-28$  V.

2,3-dinor-F2,  $m/z$  325–237, CE  $-22$  V.

Standard curves were constructed at 8 concentrations for 8-*iso*-PGF<sub>2 $\alpha$</sub> , PGF<sub>2 $\alpha$</sub> , PGE<sub>2</sub> (100–4,000 pg/ml), 2,3-dinor-F1 (1,250–50,000 pg/ml), and 2,3-dinor-F2 (2,500–100,000 pg/ml). 8-*iso*-PGF<sub>2 $\alpha$</sub> -d<sub>4</sub> was used as the IS for all analytes with the exception that PGE<sub>2</sub>-d<sub>4</sub> was used for PGE<sub>2</sub>. Quantitation was performed using the Analyst 1.41 software (Applied Biosystems/MDS Sciex). The Analyst software calculated signal to noise (S/N) ratios for 2,3-dinor-F1 ( $m/z$  327–283) ranging from 6 to 50 (15–20 as the mode values), when a representative, non-zero background region of a urine sample chromatogram (at 4–6 min) was chosen as the reference background.

### Accuracy and Precision

Assay accuracy was evaluated by standard addition experiments conducted in urine and methanol. Known quantities of 8-*iso*-PGF<sub>2 $\alpha$</sub> , PGF<sub>2 $\alpha$</sub> , PGE<sub>2</sub>, 2,3-dinor-F1, and 2,3-dinor-F2 were spiked, in duplicate, into urine or methanol. Spiked urine was extracted as described above and spiked methanol was analyzed by LC–MS without prior extraction. Intra-day- and between-day precision was determined by analyzing five aliquots of urine on five separate occasions throughout a month.

### Statistical Analysis

Data are expressed as mean  $\pm$  SE. Repeated measures MANOVA was performed using JMP Statistical Discovery Software (SAS Institute, Cary, NC) to evaluate effects attributed to smoking status, gender, and with-in subject vitamin C treatment effects and time effects from urine samples collected in three 8-h intervals over 24 h (0–8, 8–16, and 16–24 h). For the analysis of repeated measures (multiple samples from the same subject), the natural logarithm of the dependent variables (urine concentration at the three time points in each study period, or vitamin C treatment) was used to minimize the correlation between the mean and variance of the data. Results were considered to be statistically significant at  $P < 0.05$ . Vitamin C had no effect on the oxidative stress parameters studied, as has been observed previously [13], so data from time points were averaged, as indicated. Similarly, when other parameters did not reach statistical significance, the values from each subject were averaged and the statistical analysis

was repeated using matched pairs or MANOVA with repeated measures, as appropriate. It should be noted that as the numbers of data points decreased the statistical power decreased.

## Results

### Precision and Accuracy of the SPE Extraction and LC–MS Analyses

The intra-day and inter-day precision of the SPE extraction and LC–MS analyses were evaluated from five aliquots of a single urine specimen analyzed over one month on five separate occasions. For the five analytes for which standards are available (8-*iso*-PGF<sub>2α</sub>; PGF<sub>2α</sub>; PGE<sub>2</sub>; 2,3-dinor-F1 and 2,3-dinor-F2), the intra-day coefficients of variation (CV) for each of the standards ranged from 6 to 9%, while the inter-day CVs for each ranged from 10 to 14%.

Assay accuracy was determined by comparing the ratio of the slopes of the line determined from measured amounts recovered from spiked human urine samples (standard addition) with the slope generated from spiked methanol. Standard addition experiments indicated that the accuracy of the assay was 101% for 8-*iso*-PGF<sub>2α</sub>, 104% for PGF<sub>2α</sub>, 102% for PGE<sub>2</sub>, 59% for 2,3-dinor-F1, and 86% for 2,3-dinor-F2. Because the measured concentrations of 2,3-dinor-F1 and F2 were within the quantitative range of the standard curves, the lower accuracy for these analytes was apparently the result of lower extraction recoveries. Therefore, the extraction protocol was optimized for maximum recovery of 2,3-dinor-F1 and -F2.

The standard addition regression estimates were linear in the range of 0, 20, 50, and 100% of standard mix added (equivalent to a urinary concentration of 8-*iso*-PGF<sub>2α</sub>, 1,000 pg/ml; PGF<sub>2α</sub> and PGE<sub>2</sub>, 2,000 pg/ml; 2,3-dinor-F1, 5,000 pg/ml, and 2,3-dinor-F2 10,000 pg/ml at 100%). The standard curves used for quantitation were linear from 0 to 4,000 pg/ml for 8-*iso*-PGF<sub>2α</sub>, PGF<sub>2α</sub>, and PGE<sub>2</sub>; 0–40 ng/ml for 2,3-dinor-F1; and 0–80 ng/ml for 2,3-dinor-F2.

### Identification of Metabolites with SRM Patterns Similar to 2,3-dinor-F1 and 2,3-dinor-F2

Identification of biomarkers of lipid peroxidation is difficult due to the variety of lipid oxidation products, which potentially may be metabolized to an even greater variety of products. In addition, few authentic standards are available commercially. To circumvent these potential limitations, we used a prolonged HPLC gradient to separate multiple peaks from human urine samples and identified those peaks with product ion spectra matching those of available standards.

F<sub>2</sub>-IsoPs in human urine were identified tentatively as 8-*iso*-15(*R*)-PGF<sub>2α</sub>, 8-*iso*-PGF<sub>2α</sub>, and PGF<sub>2α</sub> because they had retention times identical to those of the standards and they had SRM profiles matching the authentic standards, 8-*iso*-PGF<sub>2α</sub> and PGF<sub>2α</sub> (data not shown).

Product ion spectra of the 2,3-dinor-F1 and -F2 standards (Figs. 2A, 3A, respectively) were similar to those reported previously by others [5, 10]. The retention times shown from the HPLC–SRM tracings of the 2,3-dinor-F1 and -F2 standards were 11.7 and 11.9 min, respectively (Figs. 2B, 3B, respectively). However, when urine sample extracts were analyzed, additional, sometimes larger, peaks had the same SRM profiles as these standards. Three peaks (identified as 2, 3 and 4 in Fig. 2C), had SRM profiles that matched 2,3-dinor-F1 (Fig. 2B, identified as 1 in Fig. 2C). Similarly, three peaks (identified as 1, 3 and 4 in Fig. 3C) had SRM profiles that matched 2,3-dinor-F2 (Fig. 3B, identified as 2 in Fig. 3C).

Peaks are named according to their metabolite class and retention time (e.g. F1-12 from a 2,3-dinor-F1 SRM match eluting at 12 min).

### F<sub>2</sub>-IsoPs in Urine from Smokers and Nonsmokers

The method described herein allows the simultaneous measurement of both F<sub>2</sub>-IsoPs and F<sub>2</sub>-IsoP metabolites in a single extraction and LC/MS separation. Urinary F<sub>2</sub>-IsoPs (Fig. 4), specifically 8-*iso*-PGF<sub>2α</sub>, 8-*iso*-15(*R*)-PGF<sub>2α</sub> and PGF<sub>2α</sub>, were measured in three separate urine specimens collected in 8 h intervals over 24 h from smokers and nonsmokers who completed placebo and vitamin C supplementation trials [12]. Thus, six samples were analyzed for each subject. Remarkably, neither the time of day, nor vitamin C supplementation had any effect on the urinary excretion of any of the three F<sub>2</sub>-IsoPs measured ( $P > 0.05$ , MANOVA). The consistency of the methodology described herein is readily apparent in that the urinary concentrations for each of the subjects did not vary widely for any of the three F<sub>2</sub>-IsoPs measured (Fig. 4).

In contrast to our expectation that cigarette smoking would increase all of the urinary F<sub>2</sub>-IsoPs identified, we found that only 8-*iso*-PGF<sub>2α</sub> concentrations were significantly increased in smokers ( $P = 0.012$ , MANOVA, main effect of smoking). However, women compared with men (MANOVA, main effect of gender) excreted significantly greater 8-*iso*-PGF<sub>2α</sub> ( $P = 0.02$ ), 8-*iso*-15(*R*)-PGF<sub>2α</sub> ( $P = 0.04$ ), and PGF<sub>2α</sub> ( $P = 0.015$ ) concentrations.

Given the lack of statistical significance in the F<sub>2</sub>-IsoP concentrations between time points, or with vitamin C supplementation, the concentrations for each of the six samples were then averaged for each subject (three collections for each of the two supplements) and the statistical analyses repeated. Nonsmoking men had the lowest

**Fig. 2** LC-MS identification of 2,3-dinor-PGF<sub>1x</sub>. **A** Fragmentation pattern of 2,3-dinor-PGF<sub>1x</sub> standard, *m/z* 327–283 (a), 265 (b), 183 (c), 193 (d) or 221 (e). **B** LC-MS chromatogram of 2,3-dinor-PGF<sub>1x</sub> standard showing tracings of each of the fragments (a–e) identified in **A**. **C** LC-MS chromatogram of a urine extract with tracings of peaks identified with SRM profiles showing each of the fragments (a–e, identified in **A**) that matched those of 2,3-dinor-PGF<sub>1x</sub> (2,3-dinor-F1, retention time same as the standard, labeled 1; F1-12, labeled 2; F1-13, labeled 3, and F1-14 labeled 4)

F<sub>2</sub>-IsoP concentrations, while women smokers had the highest concentrations (Table 2). In general, urinary PGF<sub>2x</sub> concentrations were approximately double those of either 8-*iso*-PGF<sub>2x</sub> or 8-*iso*-15(*R*)-PGF<sub>2x</sub>. Although PGF<sub>2x</sub> is the largest of the 15-series peaks in our samples, it is likely a mixture of PGF<sub>2x</sub> and *ent*-PGF<sub>2x</sub> that we cannot resolve, based on the findings by Yin et al. [14], who used a chiral column and showed that the major portion of PGF<sub>2x</sub> in human urine is the enantiomer (*ent*) form of PGF<sub>2x</sub>. Thus, this peak is called PGF<sub>2x</sub> + *ent*-PGF<sub>2x</sub>.

**Fig. 3** LC-MS identification of 2,3-dinor-PGF<sub>2x</sub>. **A** Fragmentation pattern of 2,3-dinor-PGF<sub>2x</sub> standard, *m/z* 325–237 (a), 137 (b), 183 (c), 219 (d) or 145 (e). **B** LC-MS chromatogram of 2,3-dinor-PGF<sub>2x</sub> standard showing tracings of each of the fragments (a–e) identified in **A**. **C** LC-MS chromatogram of a urine extract with tracings of peaks identified with SRM profiles showing each of the fragments (a–e, identified in **A**) that matched those of 2,3-dinor-PGF<sub>2x</sub> (2,3-dinor-F2, retention time same as the standard, labeled 2; F2-12, labeled 1; F2-13, labeled 3, and F2-15 labeled 4)

#### 2,3-dinor-F1 and 2,3-dinor-F2 in Urine from Smokers and Nonsmokers

The urinary F<sub>2</sub>-IsoPs metabolites, 2,3-dinor-F1 and -F2, were measured in the same extract and during the same HPLC analyses as described above for the urinary F<sub>2</sub>-IsoPs. Similar to the F<sub>2</sub>-IsoPs data, no significant effects of vitamin C supplementation on urinary 2,3-dinor-F1 or -F2 concentrations were observed (data not shown). The consistency of the 2,3-dinor-F1 and 2,3-dinor-F2 measurements is readily apparent in the concentrations (averages for each time point

**Fig. 4** Urinary  $F_2$ -isoPs determined over 24 h in smokers and nonsmokers. The urinary  $F_2$ -isoPs: 8-iso-PGF $_{2\alpha}$ , 8-iso-15(R)-PGF $_{2\alpha}$  and PGF $_{2\alpha}$ , were quantified both during placebo and vitamin C supplementation in smokers and nonsmokers from three separate urine collections (0–8, 8–16, and 16–24 h after taking deuterated  $\alpha$ -tocopherol during a vitamin E kinetics study [12]). Neither the time of day, nor the supplementation with vitamin C had any effect on the urinary excretion of each of the three  $F_2$ -isoPs measured ( $P > 0.05$ , MANOVA). 8-iso-PGF $_{2\alpha}$  concentrations were significantly increased in smokers ( $P = 0.012$ , MANOVA, main effect of smoking). Women compared with men excreted significantly (MANOVA, main effect of gender) higher concentrations of 8-iso-PGF $_{2\alpha}$  ( $P = 0.02$ ), 8-iso-15(R)-PGF $_{2\alpha}$  ( $P = 0.04$ ), and PGF $_{2\alpha}$  + ent-PGF $_{2\alpha}$  ( $P = 0.015$ )

obtained during the vitamin C and placebo trials) shown for the three time points for each group (Fig. 5a, b).

Women excreted more 2,3-dinor-F1 than did men (MANOVA, main effect of gender,  $P = 0.025$ ); cigarette smokers also excreted more 2,3-dinor-F1 than did non-smokers (main effect of smoking  $P = 0.039$ , Fig. 5a). When 2,3-dinor-F1 concentrations were averaged over the six time points for each subject, women smokers had significantly higher concentrations ( $P < 0.05$ ,  $2.3 \pm 0.3 \mu\text{g/g}$  creatinine) than did nonsmokers (women  $1.6 \pm 0.3$ , or men  $1.2 \pm 0.1$ ), or male smokers ( $1.5 \pm 0.3$ ).

Women also excreted more 2,3-dinor-F2 than did men (MANOVA, main effect of gender  $P = 0.0012$ ). Similarly, cigarette smokers excreted more 2,3-dinor-F2 than did nonsmokers (main effect of smoking  $P = 0.013$ , Fig. 5b). However, 2,3-dinor-F2 concentrations varied with time (main effect,  $P = 0.006$ ). When the 2,3-dinor-F2 data were analyzed separately for men and women, interesting differences were apparent. Women smokers excreted more 2,3-dinor-F2 ( $4.6 \pm 0.5 \mu\text{g/g}$  creatinine) than did non-smokers ( $3.2 \pm 0.4 \mu\text{g/g}$ ,  $P = 0.036$ ), but concentrations did not vary significantly with the time of day. In contrast, cigarette smoking had no significant effect on the 2,3-dinor-F2 excretion in men. However, men excreted greater 2,3-dinor-F2 concentrations ( $3.0 \pm 0.3 \mu\text{g/g}$  creatinine) during the overnight collection (16–24 h) compared with 8–16 h ( $2.3 \pm 0.2$ ,  $P = 0.001$ ). The collections taken during the day 0–8 h ( $2.6 \pm 0.3 \mu\text{g/g}$  creatinine) were also greater than during 8–16 h ( $P = 0.03$ ). These latter data suggest that men may have increased  $F_2$ -IsoPs metabolism and excretion overnight into morning.

#### Additional Urinary $F_2$ -IsoPs Metabolites in Smokers and Nonsmokers

In addition to 2,3-dinor-F1 and -F2, we identified using SRM several other potential urinary  $F_2$ -IsoP metabolites (Figs. 2, 3, respectively). Pair-wise correlations between all data ( $n = 144$ ) showed that F1-12 and F1-13 concentrations were correlated with 2,3-dinor-F1 ( $r > 0.9$ ,  $P < 0.0000$ ); F2-12, F2-13 and F2-15 concentrations were correlated with 2,3-dinor-F2 ( $r = 0.7–0.9$ ,  $P < 0.0000$ ); while F1-14 had lower correlation coefficients with concentrations of either 2,3-dinor-F1 or -F2 ( $r < 0.4$ , Table 3). Of particular interest, F1-14 was not correlated ( $P > 0.05$ ) with 8-iso-15(R)-PGF $_{2\alpha}$  suggesting that it has a different precursor than do the other metabolites.

Given that all of the “identified” urinary  $F_2$ -IsoPs metabolite concentrations (except F1-14) were correlated, the concentrations calculated for each metabolite were summed for each subject at each time point and then

**Table 2** Urinary F<sub>2</sub>-isoprostanes in smokers and nonsmokers

Gender	Group	8-iso-PGF <sub>2x</sub> (μg/g creatinine)	8-iso-15(R)-PGF <sub>2x</sub> (μg/g creatinine)	PGF <sub>2x</sub> + ent-PGF <sub>2x</sub> (μg/g creatinine)
Women	Nonsmoker	0.43 ± 0.06 <sup>a</sup>	0.61 ± 0.09 <sup>a,b</sup>	1.27 ± 0.16 <sup>a</sup>

Statistical summary (MANOVA)		P-value		
Gender		0.019		0.04
Smoking		0.012		NS
Interaction		NS		NS

No significant differences were observed for vitamin C supplementation or for each 8-h collection interval; therefore, urinary F<sub>2</sub>-IsoPs were averaged within each participant over time and vitamin C supplementation. Urinary F<sub>2</sub>-IsoPs were analyzed using MANOVA and Tukey's post hoc where appropriate for pair-wise comparisons. Main effects are listed in the table and pair-wise comparisons within a column not sharing the same superscript are significantly different ( $P < 0.05$ )

averaged for the six time points within each subject. Women had higher F<sub>2</sub>-IsoPs metabolite concentrations than did men (MANOVA, main effect  $P = 0.0033$ ), while cigarette smokers had higher concentrations than did nonsmokers (main effect  $P = 0.036$ , Fig. 6). Women smokers had higher metabolite concentrations than did men ( $P < 0.05$ ); nonsmoking men had lower concentrations than did women ( $P < 0.05$ ).

Although F1-14 concentrations were not used in the above estimation of F<sub>2</sub>-IsoPs metabolites, the SRM characteristics of the peaks were consistent with the F<sub>2</sub>-IsoPs metabolite standards, 2,3-dinor-F1 and -F2. F1-14 concentrations (averaged over the six time points for each subject) showed that smokers had higher F1-14 concentrations than did nonsmokers ( $P = 0.025$ , Fig. 7). Unlike all of the other biomarkers of lipid peroxidation that were evaluated and reported herein, there was no statistically significant effect of gender on F1-14 concentrations even when all six data points per subject (rather than averages) were evaluated.

## Discussion

The strategy used in the current study was to identify multiple biomarkers of oxidative stress in human urine. Rather than using a rapid passage through the HPLC column to obtain a single peak containing various F<sub>2</sub>-IsoPs or their metabolites, the separation was prolonged to resolve individual peaks of interest. Our hypothesis was that some biomarkers may be more sensitive to oxidative stress than others. Our strategy has been effective in that significant differences in urinary F<sub>2</sub>-IsoPs were detected between women and men, nonsmokers and smokers (~10 cigarettes/day); differences that our plasma F<sub>2</sub>-IsoP assay was unable to detect in these same subjects [11]. Perhaps more

**Fig. 5** Urinary isoprostane metabolites excreted by smokers and nonsmokers. Urinary 2,3 dinor F1 (a) and 2,3 dinor F2 (b) concentrations, respectively, were averaged for the vitamin C and placebo supplementation trials at each of the three time points. **a** Women excreted higher 2,3-dinor-F1 concentrations than did men (MANOVA, main effect of gender  $P = 0.025$ ); cigarette smokers excreted higher concentrations than did non-smokers (main effect of smoking  $P = 0.039$ ). **b** Women excreted more 2,3-dinor-F2 than did men (MANOVA, main effect of gender  $P = 0.0012$ ); cigarette smokers excreted higher concentrations than did non-smokers (main effects of smoking  $P = 0.013$ ). 2,3-dinor-F2 concentrations also varied with time (main effect,  $P = 0.006$ )

All pair-wise correlations are statistically significant ( $P < 0.0001$ ) with the exception of the correlation of F1-14 with 8-iso-PGF<sub>2x</sub> ( $P = 0.0037$ ), 8-iso-15(R)-PGF<sub>2x</sub> (not significant), PGF<sub>2x</sub> + ent-PGF<sub>2x</sub> ( $P = 0.0002$ ), 2,3-dinor-F2 ( $P = 0.0004$ ), F2-12 ( $P = 0.0014$ ), and F2-13 ( $P = 0.0047$ )

**Fig. 6** Urinary total isoprostane metabolites excreted by men and women smokers and nonsmokers. Urinary F<sub>2</sub>-isoP metabolite concentrations (identified as shown in Figs. 2 and 3, except F1-14) were individually calculated, summed for each subject at each time point and then averaged for the six time points for each subject. Women had higher F<sub>2</sub>-isoP metabolite concentrations than did men (MANOVA, main effect  $P = 0.0033$ ), while cigarette smokers had higher concentrations than did nonsmokers (main effect  $P = 0.036$ ). Bars not sharing the same letter are significantly different by Tukey's pairwise comparisons ( $P < 0.05$ )

importantly, we have identified a series of metabolites that have mass spectral characteristics of the relatively low abundance 2,3-dinor-F1 and -F2, but when summed together, these apparent metabolites are excreted in quantities 50–100 times greater than the two metabolites for which we have commercially available standards. The urinary F<sub>2</sub>-IsoPs were found at concentrations of about 0.2–1.5 µg/g creatinine (Fig. 4), while urinary 2,3-dinor-F1 was about 1–3 µg/g and 2,3-dinor-F2 was about 3–5 µg/g (Fig. 5). In contrast, the sum of the various F<sub>2</sub>-IsoP metabolites was in the range of 50–100 µg/g (Fig. 6). Thus, these urinary F<sub>2</sub>-IsoPs metabolite concentrations are supportive of rapid F<sub>2</sub>-IsoP metabolism [15] and the excretion of the metabolites

**Fig. 7** Urinary F1-14 excreted by smokers and nonsmokers. F1-14 (identified in Fig. 2C) concentrations were averaged over the six time points for each subject. Smokers had higher F1-14 concentrations than did nonsmokers ( $P = 0.025$ ). There were no significant effects of gender on F1-14 concentrations

as potentially important in ameliorating the adverse effects of oxidative stress.

To identify F<sub>2</sub>-IsoPs and F<sub>2</sub>-IsoPs metabolites, we first acquired product ion spectra of the individual standards. We then used these results to design an SRM program for each class of analyte. For example, authentic 2,3-dinor-F1 had a molecular ion of  $m/z$  327 (negative mode), and major products ions, in order of abundance, of  $m/z$  283, 265, 209, 183, 193, and 221 (Fig. 2). The SRM program detected these ions as  $m/z$  327 products during an HPLC separation of authentic 2,3-dinor-F1 and also during analysis of a human urine extract. The peaks in the urine extract chromatogram that had SRM profiles resembling those of authentic 2,3-dinor-F1, were likely to have a similar chemical structure, but perhaps with stereochemical differences. Once specific peaks were identified based on SRM profiles as likely members of a particular analyte

type, we integrated only those peaks. Note that that Figs. 2C and 3C also show peaks in the urine extract that did not have the appropriate SRM profile, thus, were not included in our analyses.

Previous methods have utilized mass spectrometry to identify and quantify components with the same single molecular ion-to-product ion reaction as that of available standards with minimal HPLC separation. We found that human urine chromatograms contained a peak, F1-14, with a product ion spectrum similar to that of 2,3-dinor-F1; however, the amounts were not correlated with F<sub>2</sub>-IsoP concentrations (Table 3). These findings suggest that peak F1-14 is not derived from the F<sub>2</sub>-IsoPs that we quantitated. Moreover, analyses based solely on tandem MS detection with minimal or no HPLC separation may not provide accurate results. Importantly, unlike every other F<sub>2</sub>-IsoP and metabolite we detected, there was no gender effect, just increased F1-14 concentrations in smokers (Fig. 7). Without the prolonged HPLC separation we used, this very interesting biomarker would have escaped discovery. F1-14 likely has a molecular structure similar to that of 2,3-dinor-F1, but with perhaps different stereochemistry. Clearly, further investigation is needed to characterize this molecule(s).

The SPE method described is a new innovation compared with previously published methods by others. We sought to extend our LC-MS-MS assay for plasma 15-series F<sub>2</sub>-IsoPs [11] for use with urine samples and to simultaneously measure urinary F<sub>2</sub>-IsoPs metabolites. However, our initial efforts using liquid-liquid extraction or published SPE protocols [5, 10] yielded poor recoveries (~25–50% of spiked internal standard) from urine samples. A generic anion exchange SPE protocol (including a methanol wash, then elution with acidified methanol) using mixed-mode weak anion exchange-reverse phase cartridges gave satisfactory recovery of the internal standard, 8-*iso*-PGF<sub>2 $\alpha$</sub> -d<sub>4</sub>, when added to water, but not when added to urine. Moreover, when the internal standard was added to an extracted urine sample, only half the expected increase in peak area was observed, suggesting a matrix effect, possibly ion suppression in the mass spectrometer. In the course of developing a new F<sub>2</sub>-IsoP extraction method, we observed that when urine samples were loaded on mixed-mode reverse phase-weak anion exchange cartridges at ~1 pH unit above the typical carboxylic acid pK<sub>a</sub> (e. g., *n*-butyric, pH 4.81), the protic solvent, methanol (but not acetonitrile) was capable of eluting F<sub>2</sub>-IsoPs and F<sub>2</sub>-IsoP metabolites, indicating ionic forces still contributed to F<sub>2</sub>-IsoP binding to the cartridge at the lower pH. Acetonitrile could then be used to wash any neutral, nonpolar compounds from the cartridge, as well as any residual water. Good recoveries of F<sub>2</sub>-IsoPs and F<sub>2</sub>-IsoP metabolites were achieved with neutral methanol elution, while agents that

caused ion suppression in the MS were eluted with acidified solvents. These findings explain the low recoveries of urinary F<sub>2</sub>-IsoPs and F<sub>2</sub>-IsoP metabolites when we used conventional anion exchange methods, in which samples are usually loaded at greater than or equal to 2 pH units higher than the pK<sub>a</sub> of the analyte of interest, which in turn, is eluted with acidified solvents.

Intra- and inter-day precision of the final assay compare satisfactorily with previously published methods, and the accuracy of measurements of the F<sub>2</sub>-IsoPs was nearly 100%. However, the accuracies of 2,3-dinor-F1 and -F2 were lower. We believe the lower accuracy is due to lower rates of recovery of these analytes from urine. The SPE procedure was more robust for variations in the loading pH and elution volumes when determining recoveries of 8-*iso*-PGF<sub>2 $\alpha$</sub> , PGF<sub>2 $\alpha$</sub> , and PGE<sub>2</sub> than for 2,3-dinor-F1 and -F2. As a consequence, attention was focused on achieving as good recovery as possible of the latter without compromising the recovery of the F<sub>2</sub>-IsoPs. Our accuracy of 59% for 2,3-dinor-F1 and 86% for 2,3-dinor-F2 is not as high as the 80% reported for the former [5] or the 98–99% reported for the latter [10]. Nevertheless, the recoveries were reproducible and were linear over a large range, allowing the use of our protocol in analyzing a set of samples collected from college-age subjects, some of them light smokers and others nonsmokers. Bohnstedt et al. [16] previously reported that reverse phase SPE was unsatisfactory for urine sample preparation; they then developed a liquid-liquid extraction method for F<sub>2</sub>-IsoPs. Herein we report a SPE procedure using a different stationary phase chemistry that was satisfactory for both F<sub>2</sub>-IsoPs and their metabolites. Bohnstadt et al. [16] reported urinary concentrations of iPF2a from control subjects (216 pg/mg creatinine) that were similar to those we observed of 8-*iso*-PGF<sub>2 $\alpha$</sub>  (the same compound) from nonsmoking male subjects (280 pg/mg creatinine), while we report higher concentrations in female smokers (530 pg/mg creatinine). Welsh et al. [17] also report satisfactory recoveries of F<sub>2</sub>-IsoPs and their metabolites using SPE technology.

In the present study, we observed that smokers had greater urinary 8-*iso*-PGF<sub>2 $\alpha$</sub>  concentrations than did nonsmokers, but cigarette smoking did not significantly increase urinary 8-*iso*-15(R)-PGF<sub>2 $\alpha$</sub>  or PGF<sub>2 $\alpha$</sub>  concentrations. We previously reported plasma F<sub>2</sub>-IsoPs measured from a similar cohort of otherwise healthy college-aged nonsmokers and smokers. Utilizing GC-MS [12] or LC-MS [11] approaches, smokers had numerically higher plasma F<sub>2</sub>-IsoPs but without statistical significance between the groups. In a separate study, plasma F<sub>2</sub>-IsoPs were significantly higher among smokers, but their smoking history and frequency (>30 cigarettes/day) were substantially greater than observed in the participants from the present study [18, 19]. Also, proposed biomarkers of

oxidative stress are often tested with a strong stress such as  $\text{CCl}_4$  poisoning [20]. Thus, significantly greater urinary 8-*iso*-PGF<sub>2 $\alpha$</sub>  in smokers supports the well-established literature indicating that smoking enhances oxidative stress [21, 22] and supports the hypothesis of the present work that specific F<sub>2</sub>-IsoPs may be more sensitive biomarkers of oxidative stress in vivo. The latter is important for studies conducted in populations that are otherwise healthy, young, and with a limited history (<5 years) and frequency (~10 cigarettes/day) of smoking, that is, subjects with a relatively low magnitude of oxidative stress, where decreased variability in the methodology would allow increased sensitivity to detect differences between subjects.

It should be noted that our method also allows quantitation of PGE<sub>2</sub>. In general, PGE<sub>2</sub> is formed enzymatically [23], but there is evidence that non-enzymatic generation can also occur [24]. Given our interest in oxidative stress markers, and the non-specific origin of PGE<sub>2</sub>, this molecule was not quantitated for smokers and non-smokers.

Of particular interest is that plasma F<sub>2</sub>-IsoP turnover is rapid [15]; therefore, blood levels may vary widely over time with transient oxidative stress. Thus, urinary F<sub>2</sub>-IsoPs and their metabolite concentration would be expected to provide a more reliable index of systemic oxidative stress with less variability than that of circulating concentrations. Indeed, our measurements confirmed this notion (Table 2) and demonstrated the significance of measuring these biomarkers in urine.

Consistent with the notion of enhanced oxidative stress in smokers, we observed significantly higher urinary 2,3-dinor-F1 and -F2 concentrations in smokers compared with nonsmokers (Fig. 5), as were urinary total F<sub>2</sub>-IsoP metabolites (Fig. 6). However, to our surprise, we observed that women compared with men had higher urinary concentrations of all F<sub>2</sub>-IsoPs measured (Table 2; Fig. 4), as well as urinary F<sub>2</sub>-IsoP metabolites (Figs. 5, 6) despite men and women having similar characteristics (Table 1). Gender effects on lipid peroxidation or oxidative stress biomarkers have been addressed in clinical studies only to a limited extent and the results have been equivocal. Men had higher urinary F<sub>2</sub>-IsoPs and plasma thiobarbituric acid-reactive substances (TBARS) than did women [25], as well as higher plasma malondialdehyde (MDA) [26]. However, in a study with nearly 300 men and women, Block et al. [27] demonstrated that women had significantly higher plasma MDA and F<sub>2</sub>-IsoPs than did men. Moreover, the gender effect was maintained despite efforts to adjust for BMI which would potentially control for differences in adiposity. In the present study, F<sub>2</sub>-IsoPs and F<sub>2</sub>-IsoP metabolite concentrations were not correlated with any parameter shown in Table 1, including BMI (data not shown). Coudray et al. [28] also observed significantly greater

evidence of lipid peroxidation in women compared with men in a cohort of nearly 1,400 participants. Clearly, additional study is needed to further characterize gender differences on oxidative stress as well as to potentially unravel the mechanism leading to such effect.

**Abstract** Glucose-sensitive liposomes were prepared by incorporating hydrophobically modified glucose oxidase (EC 1.1.3.4.) into the liposomal bilayer of dioleoylphosphatidylethanolamine and cholesteryl hemisuccinate. For the release test, calcein, a fluorescence marker, was entrapped in the liposomes. The liposomes were stable under neutral conditions in terms of calcein release but an extensive release was observed under acidic conditions. In the experiment of glucose concentration-dependent calcein release, no release was observed for 180 min when the suspension of liposome was free of glucose. With a glucose concentration of 50 mg/dL, no appreciable amount of calcein was released for the first 20 min, and then the release rate was accelerated. At 200 mg/dL glucose concentration which is diagnostic and indicative for insulin-dependent diabetes, the lag time of calcein release became shorter and a faster response was obtained. When glucose concentration further increased to 400 mg/dL, the calcein release rate and the degree of release in 180 min were almost the same as the values when the glucose concentration was 200 mg/dL. The glucose concentration-dependent release is due to pH change, since the suspension of liposomes became acidic during the release experiments.

## Introduction

Much attention has been paid to stimuli-sensitive drug delivery systems, since they can control drug release in response to environmental stimuli such as change in pH [1, 2], temperature [3–8] and biochemical concentration [9]. One of extensive research areas is glucose-sensitive systems for the treatment of type I diabetes. Glucose-sensitive polymer membranes were prepared using immobilized glucose oxidase (GOD; EC 1.1.3.4.) in pH-sensitive polymers [10–15]. Glucose was converted to gluconic acid and hydrogen peroxide by the enzymatic reaction of GOD. In turn, the pH of release medium decreased with time, since the concentration of gluconic acid increases as the enzymatic reaction progresses. Accordingly, release is triggered by the swelling and the deswelling of the pH-sensitive hydrogels. Other glucose-sensitive systems were based on the competitive binding of glycosylated insulin and free glucose to concanavalin A (Con A). One example is that glycosylated insulin bound to Con A was immobilized either in polymer beads or in membranes [16–21]. When the concentration of free glucose is abnormally high, glycosylated insulin is detached from Con A and is released from the beads or the membranes. Another example takes advantage of the competitive binding of glucose attached to a polymer and free glucose to Con A [16–21]. Depending on the concentration of glucose, a sol–gel transition of the polymer system occurs and the insulin release is controlled. In previous studies, synthetic polymers were used for insulin carriers. However, the synthetic polymers are, in general, toxic and not tolerated in the human body. In this study, liposomes were designed as a glucose-sensitive carries. A liposome is defined as a phospholipid bilayer vesicle and it is known to be non-toxic and non-immunogenic in human body [22]. Liposomes can be

functionalized by modifying the surface with environment-responsive molecules. The specific functions of liposomes are induced by direct interaction with targets sites [23, 24], environmental pH [1, 2] and temperature changes [3–8]. Target-sensitive liposomes were proposed by modifying the surface of dioleoylphosphatidylethanolamine (DOPE) liposomes with an antibody [23, 24]. Specific interaction between a ligand immobilized on the liposomal membrane and a receptor on a target cell leads to the destabilization of DOPE liposomes. On the other hand, pH-sensitive liposomes were prepared by combining DOPE with *N*-succinyl-1,2-phosphatidylethanolamine, cholesteryl hemisuccinate (CHEMS), fatty acid and its derivatives, and palmitoyl homocysteine [26, 27]. Since the molecule of DOPE is conical and its packing parameter is greater than one, the phospholipids tend to form a non-bilayer structure in a physiological condition [26, 27]. In order to form a bilayer, it needs complementary molecules which fill the space among the head groups of DOPE [25–27]. It is a weakly acidic amphiphile and could stabilize DOPE bilayers at neutral pH. Among pH-sensitive complementary molecules, CHEMS has been the most frequently used [28–33]. It is also a weakly acidic amphiphilic molecule and could stabilize DOPE bilayers at physiological pH.

In this study, a novel glucose-sensitive liposome was developed by modifying the surface of pH-sensitive liposomes with hydrophobically modified glucose oxidase (HmGOD). As the concentration of glucose increases, the pH of the liposomal suspension decreases due to the increased amount of gluconic acid, which is produced by the enzymatic reaction. Accordingly, release is triggered by pH change of the liposomal suspension. Our idea was to develop a glucose-sensitive liposome. DOPE and CHEMS were used as the lipid components of the pH-sensitive liposome. To immobilize GOD onto the surface of the liposome, GOD was hydrophobically modified by covalently attaching alkyl chains to the amino groups of the enzyme. The DOPE/CHEMS liposome incorporating HmGOD was prepared by a detergent removal method and the glucose-sensitive release of the liposome was investigated.

## Experimental

### Materials and Methods

DOPE was purchased from Fluka (Buchs, Switzerland). Deoxycholate (DOC), CHEMS, GOD from *Aspergillus niger* Type X, palmitic acid *N*-hydroxysuccinimide ester, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), calcein, sodium phosphate, sodium acetate trihydrate, sodium citrate, citric acid, horseradish peroxidase,

$\beta$ -D-glucose, *o*-dianisidine dihydrochloride, sodium lauryl sulfate (SLS), Bradford reagent and amino acid standard were purchased from Sigma Chemical Co (St. Louis, MO, USA). Trinitrobenzene sulfonic acid (TNBS, 5% methanol solution) was provided by PIERCE (Rockford, IL, USA). All other reagents were of analytical grade.

### Modification of GOD

GOD was hydrophobically modified as described in a previous report [34]. First of all, 0.24 g of DOC was dissolved in 12 mL of phosphate buffer (pH 8.8, 0.16 M) and then, 0.081 g of GOD was added to the solution. In parallel, 0.0228 g of palmitic acid *N*-hydroxysuccinimide ester was dissolved in 2 mL of dry dioxane. The 0.4 mL of ester solution was added to the GOD solution by adding one of four portions of 0.1 mL every 2 h. Therefore, the molar ratio of GOD to the palmitic acid ester was 1:40. The reaction was done at 30 °C for 10 h with gently stirring. To remove insoluble byproducts, the reaction mixture was filtered through a syringe filter (0.45  $\mu$ m) and then, the filtrate was dialyzed against 1 L of phosphate buffer (pH 8.0, 0.02 M) for 12 h with four exchanges of the buffer. Further dialysis was performed for 12 h with two exchanges of phosphate buffered saline (pH 7.4, 0.15 M). Finally, the dialyzed solution was filtered through a syringe filter (0.22  $\mu$ m) and lyophilized for 3 days.

### Determination of the Number of Palmitic Acid Residues Conjugated to GOD

The number of palmitic acid residues conjugated to GOD was determined by the TNBS method [34, 35]. A measure of 0.025 g of SLS was dissolved in 50 mL of phosphate buffer (pH 8.9, 0.01 M). A TNBS solution (0.03%) was prepared by adding 0.5 mL of TNBS to 83 mL of the SLS solution. One milliliter of each SLS and TNBS solution were mixed with 0.5 mL of HmGOD solution (3.55 mg/mL) in a 10 mL vial and the reaction was carried out at 50 °C for 1 h. Then, 1.9 mL of HCl solution (0.21 M) was added to the reaction mixture and the vial was kept at room temperature for 30 min. Finally the absorbance of the reaction was measured at 335 nm. A standard curve was prepared following the same procedure as described above except various concentrations of amino acid standard solutions were used instead of HmGOD. The number of palmitic acid residues conjugated to GOD was determined by comparing the absorbance of enzyme solutions with the standard curve.

### Determination of Enzymatic Activity

A measure of 0.173 mL of 10% glucose solution in HEPES buffer (pH 7.5, 10 mM HEPES and 150 mM sodium

chloride) and 0.827 mL of *o*-dianisidine dihydrochloride solution (0.21 mM) in HEPES buffer were mixed together. And then, 0.033 mL of horseradish peroxidase solution in HEPES buffer (0.33 mg/mL, 60 purpurogallin units/mL) was added to the solution. Finally, 0.1 mL of enzyme solution in distilled water (0.0488 mg/mL) was added to the previous solution. The concentration of the enzyme was determined using Bradford method [36]. The products of the enzymatic reaction are gluconic acid and hydrogen peroxide. Hydrogen peroxide oxidizes *o*-dianisidine dihydrochloride to the oxidized form with the aid of the catalytic action of horseradish peroxidase. The characteristic wavelength of the oxidized form is around 500 nm. Thus, the absorbance is a measure of the enzymatic activity. Since the amount of hydrogen peroxide increases with reaction time, the absorbance was proportional to time elapse. The absorbance value was converted to units/mg enzyme by using the millimolar extinction coefficient of oxidized *o*-dianisidine dihydrochloride at 500 nm. HEPES buffer of free enzyme was used as a control.

#### Preparation of DOPE/CHEMS Liposome Incorporating HmGOD

DOPE (10 mg/mL) and CHEMS (6.53 mg/mL) solutions in chloroform were put into a 50 mL round bottom flask so that the molar ratio of DOPE to CHEMS is 7:3 and the total amount of lipids is 18 mg. The solvent was evaporated in a rotary evaporator at reduced pressure to obtain a mixed dry film of DOPE and CHEMS. The dry film was dispersed into 2 mL of HEPES buffer (pH 8.2) containing calcein (50 mM), and DOC (0.09%). HmGOD was added to the dispersion so that the molar ratio of lipid to HmGOD is 10,000:1. The mixture was sonicated for 20 min with a bath-type sonicator (Ultrasonic processor, VCX 500, SONIX, USA). The liposomal suspensions were allowed to stand at room temperature for 4–5 h. DOC, untrapped calcein and unbound enzyme were removed by gel permeation chromatography using a Sephadex G-75 column (1.6 cm × 40 cm). The final concentrations of lipids were adjusted to 2 mg/mL.

#### pH-Dependent Calcein Release

The calcein-containing liposome suspensions of 0.1 mL, 2 mg lipid/mL in HEPES (pH 8.2), were injected into a fluorescence cell containing 2.9 mL of HEPES buffer or sodium citrate buffer, pre-adjusted to pH ranging from 5.0 to 8.0. The change in fluorescence was monitored at 524 nm with excitation at 494 nm. The percentage release of calcein was determined as follows.

$$\% \text{ Release} = (F_t - F_i)/(F_f - F_i) \times 100$$

where  $F_t$  is the intensity of fluorescence at a given pH and  $F_i$  is the initial intensity at pH 8.2.  $F_f$  is the total fluorescence after adding DOC so that the final concentration is 0.2%. The fluorescence intensity at various pHs should be converted to the intensity at pH 8.2, since the release experiment was performed at various pHs, which is different from the pH of liposome preparation (pH 8.2). The calibration curves of calcein fluorescence were obtained at various pHs, where the degree of release was observed. The slope of each curve decreased with decreasing pH. It means that the intensity of fluorescence is suppressed at acidic pHs. Using these curves, fluorescence intensities were corrected.

#### Glucose-Dependent Calcein Release and Change in pH by Enzymatic Reaction

The 1.724 mL of liposome suspension was put into 50 mL of glucose solution in isotonic saline (adjusted to pH 7.5 with 0.001 M NaOH). The final concentrations of glucose were 0, 50, 200 and 400 mg/dL. The percent release of calcein was determined as described in the section of pH-dependent calcein release. In parallel, the change in pH of the liposomal suspensions containing varying amounts of glucose was measured during the release experiment.

## Results and Discussion

#### Determination of Number of Palmitic Acid Residue Conjugated to GOD

The amino acid standard curve was expressed as  $A_{335} = 0.572 M + 0.0062$  ( $R^2 = 0.9994$ ), where  $A_{335}$  is absorbance at 335 nm and  $M$  is  $\mu\text{mol}$  of amino acids. Since the TNBS method detects reactive amino groups, the absorbance of enzyme solutions is directly related to the number of reactive lysine residues of the enzymes. Under our experimental conditions, the absorbance of native GOD was 0.165, corresponding to 25.02 reactive amino groups per native GOD molecule. On the other hand, the absorbance of HmGOD was 0.127, calculated to be 19.03 reactive amino groups per the modified GOD molecule. This means that six palmitic acids were covalently attached to one GOD molecule by amide bonds formation with reactive lysine residues. In a previous report where GOD from *Aspergillus niger* (Type VII-S) was hydrophobized using palmitic acid *N*-hydroxysuccinimide ester, the number of reactive amino groups in native GOD was reported to be around 24 and the average number of covalently attached alkyl chains per GOD molecule was around  $5 \pm 1$  [34].

**Fig. 1** Activity of native GOD **a**, HmGOD **b**, and HmGOD incorporated into liposomal membrane **c**

#### Determination of Enzymatic Activity

Figure 1 shows the enzymatic activities of native GOD, HmGOD and HmGOD incorporated into liposomal membranes. According to the data, the activity of HmGOD was 60–65% of that of native GOD. The covalent attachment of alkyl chains to lysine residues has a great effect on the enzymatic activity, possibly because of the enzyme deformation caused by the modification. In addition, HmGOD is likely to aggregate since it has six alkyl chains attached. In this circumstance, active sites could be sequestered, resulting in an attenuated enzymatic activity. In the case of HmGOD immobilized in the liposomal membrane, the activity is slightly less than that of free HmGOD. The mobility of HmGOD immobilized in liposomal membranes would be less than that of free HmGOD. Accordingly, the formation of a substrate/enzyme complex would be somewhat restricted, resulting in reduced activity. Another reason is that some of HmGOD would be entrapped in the inner aqueous phase of liposome and the amount of HmGOD available for the enzymatic reaction might decrease.

#### pH-Dependent Calcein Release

Figure 2a shows the pH-dependent calcein release from the liposome composed of DOPE/CHEMS/HmGOD (7/3/0.0007 in molar ratio). There was no significant release in 60 s at pH 8.2 and pH 7.0 whereas, the release became extensive at pH 5.6 and pH 6.0, and the degrees of release in 60 s were 51 and 73%, respectively. Almost 100% of release was observed at pH 5.0. Several studies have been done on the pH-dependent fluorescent dye release from DOPE/CHEMS (6/4–7/3 in molar ratio) [33, 37–39]. According to their results, no significant release was observed in neutral pH range, whereas almost 100% of release was observed around pH 4.5–5.0. These previous

**Fig. 2** pH-Dependent calcein release (panel *a*) and glucose-triggered calcein release (panel *b*) from liposome composed of DOPE/CHEMS/HmGOD. Inset in panel *a* is pH-dependent calcein release for 10 s labels for panel *a* : pH 5.0 **a**, pH 5.6 **b**, pH 6.0 **c**, pH 7.0 **d**, pH 8.2 **e** labels for panel *b* : 0 mg glucose/dL **a**, 50 mg glucose/dL **b**, 200 mg glucose/dL **c** and 400 mg glucose/dL **d**

results are in a good agreement with results obtained in this study. Since the  $pK$  value of carboxylic acid of CHEMS is 5.8, the carboxylic acid would be ionized above the pH, such as pH 7.0 and 8.2, so that the head group was large enough to stabilize DOPE bilayers. On the other hand, when pHs were below the  $pK$  value, such as pH 5 and pH 5.6, carboxylic acid would be deionized and the size of head group of CHEMS could decrease. Accordingly, the DOPE bilayer would be destabilized into non-bilayer structures, giving a rise to a higher release. At pH 5.6 and 6.0, a fast release was observed for the first 5 s and then subsequently a slow release. Those pHs are the values around  $pK$  and accordingly the deionization of CHEMS would occur gradually at those pHs. This may account for the slow release at the latter stage. At pH 5.0, the initial rate of release was faster [see initial slope of plot (a)], so the release was completed in 5 s. Because pH 5.0 was less than  $pK$ , CHEMS could be deionized at a burst. This may explain the earlier completion of the release at pH 5.0.

### Glucose-Triggered Calcein Release and Change in pH Caused by the Enzymatic Reaction

Figure 2b shows glucose-triggered calcein release from liposomes incorporating HmGOD. In case of the suspension of liposome without glucose, there was no release observed for 180 min. When the concentration of glucose was 50 mg/dL, no appreciable amount of calcein released for the first 20 min, and then the release rate accelerated for the next 70 min. Thereafter, the rate of acceleration was reduced and the degree of release was approximately 80% in 180 min. Glucose is converted to gluconic acid and hydrogen peroxide by the enzymatic reaction of HmGOD. Thus, the pH of liposomal suspension would decrease with time because the concentration of gluconic acid increases as the enzymatic reaction goes on. Thus, it is believed that the release was triggered by the pH change of liposomal suspension. When the concentration of glucose was 50 mg/dL, the concentration of gluconic acid was thought not to be high enough to trigger the release for the first 20 min. That is, the lag time of 20 min is possibly due to the lower concentration of glucose and gluconic acid. When the concentration of glucose increased to 200 mg/dL, which is diagnostic and indicative for insulin-dependent diabetes, the release pattern was similar to that of 50 mg/dL. But the lag time became shorter, and a faster response was obtained. This is because higher concentration of glucose produces more gluconic acid. In addition, the rate of release was higher and the degree of release within 180 min was more extensive (about 95%). When glucose concentration further increased to 400 mg/dL, the release rate for the first 40 min and the degree of release within 180 min were almost the same as the values when the glucose concentration was 200 mg/dL. The release was, however, completed in 60 min and the completion of release was earlier than in case of 200 mg/dL. On the other hand, liposomes without HmGOD exhibited only 2% of release over 180 min even at a glucose concentration of 400 mg/dL. Therefore, the calcein release from liposomes incorporating HmGOD was not due to osmotic pressure but due to the acidification caused by the enzymatic reaction. To investigate whether the glucose-dependent release is triggered by pH change or not, the pH of liposomal suspension was measured with time (Fig. 3). When glucose was not added, the pH remained almost constant. When the glucose concentration was 50 mg/dL, pH decreased steadily for the first 60 min and the decreasing rate of pH was accelerated for the next 30 min. Thereafter, the rate of the decrease in pH was reduced. The pH of the liposomal suspension was around 4.3 after 180 min had elapsed.

When the glucose concentration was 50 mg/dL, it took about 20 min to reach pH 7 (Fig. 3). In 20 min when pH was 7, there was no appreciable amount of calcein released at the same concentration of glucose (Fig. 2b). At pH 7, no

**Fig. 3** Change in pH of the suspensions of liposomes incorporating HmGOD over time. The concentrations of glucose in liposomal suspensions were 0 mg/dL **a**, 50 mg/dL **b**, 200 mg/dL **c** and 400 mg/dL **d**

appreciable amount was released (Fig. 2a). For another example, when the glucose concentration was 50 mg/dL, it took about 70 min to reach pH 6 (Fig. 3). In 70 min when pH was 6, the degree of release was about 45% at the same concentration of glucose (Fig. 2b). At pH 6, the degree of completed release was about 50% (Fig. 2a), not significantly different from 45%. In similar manner, the comparisons of Figs. 2a, b and 3 were also applicable when the glucose concentrations are 200 and 400 mg/dL. Therefore, it is reasonable that the release could be caused by pH change, which is due to the conversion of glucose to gluconic acid.

Insulin might be encapsulated in the liposomes incorporating HmGOD for the treatment of type I diabetes. Unfortunately, the release from liposomes occurred when the glucose concentration was less than the indicative concentration for diabetes. That is one of the handicaps to be overcome. In order to use the liposome as an insulin carrier for diabetes, the carrier should retain its content when glucose concentration is in the normal range (80–140 mg/dL) and it should release timely when the glucose concentration is more than 200 mg/dL. In addition, calcein release from the liposome in this study was achieved in distilled water. Hence, the glucose-induced release of calcein would be irrelevant in a pH-buffered medium. However, the pH near the location of the enzyme immobilization on the liposome surface could be changed for an instant even in a pH-buffered medium. Hence, the glucose-induced release would also occur even in buffer solution. In fact, Traitel and his coworkers prepared glucose-sensitive hydrogel using GOD and poly(2-hydroxyethyl methacrylate-*co*-*N,N*-dimethylaminoethyl methacrylate), and they investigated the release of insulin in phosphate-buffered saline (pH 7.4) at glucose concentrations of 0, 100, and 500 mg/dL [40]. According to their results, a significant

insulin release occurred at the concentration of 500 mg/dL. Although the concentration triggering the release was higher than in the present study, the results obviously showed a possibility that the glucose-sensitive system would work in a buffered milieu. On the other hand, an on-off type of release could hardly be observed under our experimental conditions. It might be obtained by varying the amounts of CHEMS and HmGOD in the liposomal membrane. However, it would be hard to avoid the leakage at normal glucose concentrations (80–140 mg/dL) because the amount of deionized CHEMS at those concentrations might be already enough to destabilize DOPE bilayers. One of more practical approaches to suppress the undesirable release is to shift the triggering glucose concentration. For that purpose, other complement molecules could be used instead of CHEMS. Their titratable groups pK values should be quite different from that of carboxylic acid of CHEMS. The most important thing for practical use is that compounds involved in the glucose-sensitive liposomes should be non-toxic in the human body. CHEMS is believed to increase immunogenicity of tumor cells and no toxicity profiles about CHEMS have been reported [41]. GOD is known to be antibiotic because hydrogen peroxide, produced by the enzymatic reaction of GOD, exhibits antibacterial activity [42]. Hydrogen peroxide causes oxidative stress in the human body. As a result, degeneration of DNA, membrane lipid and protein, and enzyme may occur, leading to various pathological conditions [43]. To circumvent the side effect of hydrogen peroxide, catalase has been frequently used when GOD is included in glucose-sensitive insulin delivery systems [44].

## Conclusion

Glucose-sensitive release was obtained by incorporating hydrophobically modified GOD into the membrane of pH-sensitive liposomes. Although a clear-cut release pattern could hardly be obtained, the degree and the rate of release from DOPE/CHEMS liposomes incorporating HmGOD were strongly dependent on the concentration of glucose. The liposome is thought to have a potential as a carrier for diabetes treatment.

**Abstract** Lectin-like oxidized-low-density lipoprotein receptor-1 (LOX-1) is increasingly linked to atherosclerotic plaque formation and the soluble form of this receptor may reflect activities of disease. We investigated the associations among levels of sLOX-1, oxidized-low-density lipoprotein (ox-LDL), cytokines and the extension of atherosclerosis in patients with coronary artery disease (CAD). Lipid, TNF- $\alpha$ , IL-6, C reactive protein (CRP), ox-LDL, peroxy radical and sLOX-1 levels were measured in 29 controls and 60 patients with CAD, 30 of which with one or two vessels involved (group 1), and 30 patients with three or four vessels involved (group 2). The serum levels of sLOX-1 were significantly and progressively higher in group 1 [611 (346–1,313) pg/ml, median (interquartile range)] and in group 2 [2,143 (824–3,201) pg/ml] than in control subjects [268 (111–767) pg/ml]. LOX-1 levels positively correlated with IL-6 ( $r = 0.38$ ,  $P = 0.0042$ ), TNF- $\alpha$  ( $r = 0.38$ ,  $P = 0.0037$ ), CRP levels ( $r = 0.32$ ,  $P = 0.027$ ) and age ( $r = 0.25$ ,  $P = 0.048$ ). In the multivariate analysis TNF- $\alpha$  resulted the only independent determinant of LOX-1 serum levels ( $\beta$ -value = 0.304,  $P = 0.017$ ). These findings suggest that sLOX-1 levels are up-regulated during CAD progression and are associated with inflammatory markers. The measurement of the circulating soluble form of this receptor may be potentially useful in predicting CAD progression in humans.

## Introduction

Lectin-like oxidized-low-density lipoprotein receptor-1 (LOX-1) was initially identified as the major receptor for ox-LDL (oxidized low-density lipoprotein) in endothelial cells and was later found also to have an inducible expression in macrophages and smooth muscle cell [1, 2]. Besides ox-LDL, LOX-1 can recognize apoptotic/aged cells, activated platelets, and bacteria, implying versatile physiological functions as a “scavenger” receptor. LOX-1 activation by ox-LDL binding stimulates intracellular signalling, gene expression and production of superoxide radicals [3, 4]. In vivo, its expression is enhanced in pro-atherogenic settings including, hypertension, hyperlipidemia, diabetes, and atherosclerosis. Transgenic mouse models for LOX-1 overexpression or gene knockout suggests that LOX-1 contributes to atherosclerotic plaque formation and progression [5, 6]. Besides being involved in the activation of endothelial cells, LOX-1 is also involved in the transformation of smooth muscle cells, and accumulation of lipids in macrophages, resulting in cell injury that facilitates the development of atherosclerosis.

Like many cell-surface receptors with a single transmembrane domain, LOX-1 can be cleaved at the juxtamembrane region, most likely by serine proteases, and secreted in a soluble form [7]. Since elevated levels of soluble receptors in plasma may reflect increased expression of membrane-bound receptors and disease activities, circulating soluble LOX-1 (sLOX-1) is increasingly viewed as a vascular disease biomarker and

V. Lubrano · S. Del Turco · G. Nicolini · P. Di Cecco ·

foundation, Via Moruzzi, 1, 56124 Pisa, Italy  
e-mail: lapina@ifc.cnr.it

a potential therapeutic target in heart attack and stroke prevention [8].

Serum sLOX-1 have been shown to be increased early in patients with acute coronary syndrome, suggesting that it may reflect vulnerable unstable atherosclerotic plaques with enhanced proinflammatory and protease activities [9]. Recently, it has been shown that sLOX-1 correlated with oxidative stress markers in stable coronary artery disease [10]. However, the association of circulating sLOX-1 with the extension of CAD and inflammatory markers has not been properly addressed. We therefore attempted to clarify the link between sLOX-1 with plasma ox-LDL, cytokines and the extension of coronary atherosclerosis in patients affected by CAD.

## Methods

The study included 60 patients admitted to our Institute because of documented or suspected ischemic heart disease and who, after undergoing coronary angiography, were diagnosed as being affected by coronary artery disease (CAD). Our controls were 29 healthy subjects who had not undergone coronary angiography. Physical examination and routine laboratory tests excluded the presence of other major disease (e.g. diabetes, hypertension, renal or liver diseases, infectious, chronic inflammatory or immunologic diseases, or malignancies). Exclusion criteria were any acute cardiovascular events during the last 3 months before hospitalization, and assumption of statins, other hypolipemic therapy, vitamins or antioxidant dietary supplements. Prior to drawing blood, patients were taken off antianginal medication, while sublingual nitrates were allowed only in the case chest pain were to persist for more than 3 minutes. Of the initial patients, 4 required sublingual nitrates and were therefore excluded from the study. All other medication, except antiplatelets, was suspended 7 days before taking the blood sample.

All subjects gave written informed consent for their participation in the study which was approved by the local ethics committee and conforms to the principles outlined in the Declaration of Helsinki.

Of the 60 patients enrolled, 17 had a reduced lumen diameter in one coronary artery, 14 patients had two arteries involved, 15 patients had three arteries involved and 14 patients had four arteries involved; in each case the mean reduction lumen was at least about 50%.

## Analytical Methods

All blood samples were collected at 4 °C the day before the cardiac catheterization and were immediately centrifuged. Plasma or serum samples were stably stored at –80 °C for

no more than 15 days. Plasma concentrations of TC, HDL and Triglycerides (Tg) were determined by standard laboratory methods. The concentration of LDL was calculated using the Friedewald equation.

To measure the generation of peroxy radicals—the initial products of the reaction between free radicals and oxygen—a colorimetric method (D-Roms test, Diacron international, Italy) was used as previously described [11]. This test is based on the ability of transition metals to catalyze in the presence of peroxides with the generation of free radicals that are trapped by an alchilamine whose reaction yields a colored radical detectable at 505 nm. The results are expressed as Carratelli Units (UC) (1 UC = 0.08 mg H<sub>2</sub>O<sub>2</sub>/dl).

High sensitivity (hs)-IL-6 and hs-TNF $\alpha$  were quantified using sandwich ELISA kits (Biosource International, CA) according to the manufactures' instructions. Inter-assay coefficients of variation was 7.8%.

High sensitivity C reactive protein (hs-CRP) was measured by the Immulite System (Diagnostic Products Corporation, CA).

Ox-LDL was assessed by a sandwich ELISA kit (Mercordia AB, Sweden) according to the manufactures' instructions. The inter-assay coefficient of variation was 4.7%.

Serum LOX-1 levels were measured by an in-house double-sandwich ELISA kits. Briefly, 96-well microplates (Nunc-Immuno Plates Maxisorp, Nunk, Roskilde, Denmark) were coated with monoclonal anti-human LOX-1 antibody (R & D systems, Minneapolis, MN) (0.25  $\mu$ g/ml) in coating buffer (10 mmol/l PBS, pH 7.2) and incubated overnight at room temperature (RT). The serum specimens were initially inactivated at 56 °C for 30 min to block non-specific protein binding sites. Four rinses with washing buffer (PBS containing 0.05% Tween 20, PBST) followed each incubation step. After blocking with reagent buffer (1% BSA in PBS) at RT for 1 h, 100  $\mu$ l of heat-inactivated sample (diluted 1:2 in reagent diluent) was added, and incubated at RT for 2 h. Recombinant human LOX-1 (R & D systems) was used as the standard in a concentration range of 100–10,000 pg/ml. Then, 100  $\mu$ l of polyclonal goat anti-human LOX-1 antibody (R & D systems) (0.25  $\mu$ g/ml) was added and incubated at RT for 2 h. Next, 100  $\mu$ l of rabbit antigoat-HRP antibody (Santa Cruz Biotechnology, Inc., CA) (diluted 1:400) was added and incubated for 1 h at RT. Finally, 100  $\mu$ l of tetramethylbenzidine substrate (Sigma-Aldrich, St. Louis, MO) was added. After 5–15 min, 50  $\mu$ l of 2 mol/l sulphuric acid was added to stop the reaction, and optical density at 450 nm determined by an ELISA plate reader. The inter-assay coefficient of variation value was 7.2%. The lower limit of detection for LOX-1 was 30 pg/ml.

## Statistical Analysis

Data are given as the mean  $\pm$  SD. Variables with a skewed distribution are expressed as median and interquartile range. Appropriate variable transformations were made to reduce the skewness of the data, such as natural logarithmic transformation for sLOX-1, TNF- $\alpha$ , IL-6 etc. Differences among different groups of patients and controls were evaluated by one-way ANOVA followed by Bonferroni post hoc test for continuous variables and by  $X^2$  test for noncontinuous variables. Relationships between serum sLOX-1 and other factors were assessed by Pearson correlation analysis. In order to evaluate the factors affecting sLOX-1 levels, all variables significantly associated with sLOX-1 were included in the multiple regression analysis, plus gender and BMI as confounding factors. A  $P$  value lower than 0.05 was considered statistically significant.

## Results

To determine whether the circulating parameters varied with the severity of the disease, we divided the patients into two groups. Patients with one or two vessels involved were clustered in group 1, while patients with three or four vessels involved were clustered in group 2. Table 1 summarizes age, gender and lipid profiles in each group of patients and controls. Controls and patients were comparable for sex, age, BMI, pressure, glycemia and triglycerides, while HDL values were more elevated in controls than in patients. Instead, total cholesterol and LDL values resulted significantly lower in the group 2 compared to the controls (Table 1).

Circulating sLOX-1, as well as peroxy radical, CRP, TNF- $\alpha$ , IL-6 levels resulted significantly higher in patients than controls and tended to increase with the severity of CAD (values of group 2 were higher than values of group 1) (Table 2). Instead, ox-LDL values were significantly higher in group 1, while those of the group 2 resulted comparable to control values (Table 2).

As shown in the Fig. 1a–d, LOX-1 serum levels positively correlated with TNF- $\alpha$  ( $r = 0.38$ ,  $P = 0.0037$ ), IL-6 ( $r = 0.38$ ,  $P = 0.0042$ ), CRP levels ( $r = 0.32$ ,  $P = 0.027$ ) and age ( $r = 0.25$ ,  $P = 0.048$ ), and did not correlate with peroxy radicals, ox-LDL, and with all the other parameters reported in Table 1. The multivariate analysis revealed that, after correction for confounding factors, TNF- $\alpha$  was the only determinant of LOX-1 levels ( $\beta$ -value = 0.304,  $P = 0.017$ ).

## Discussion

Atherosclerosis is associated with oxidative stress, inflammation, and upregulation of LOX-1. We found that sLOX-1 is significantly more elevated in patients affected by CAD than in controls and that this increase correlated with the number of affected vessels.

This increase raises the question of the cell source and the triggers for this soluble receptor. Although we do not know whether the measured sLOX-1 levels in serum are related to tissue LOX-1 values, some studies have highlighted that circulating concentrations of this receptor are indicative of endothelial-surface bound receptor levels [9, 12]. In vitro, the cell-surface expression of LOX-1 is induced by many inflammatory cytokines, oxidative stress,

**Fig. 1** Correlations between serum sLOX-1 concentrations and TNF- $\alpha$  (a), IL-6 (b), CRP (c) and age (d) in all subjects of the study

hemodynamic stimuli [13, 14]. Expression of LOX-1 can be induced after macrophage-like differentiation in vitro in human peripheral blood monocytes [15]. In endothelial cells activated by TNF- $\alpha$ , the cell-surface expression of LOX-1 precedes soluble LOX-1 production [7], suggesting that the regulation of LOX-1 cleavage is correlated to LOX-1 cell expression. Our present study clearly shows a positive correlation between circulating sLOX-1 and TNF- $\alpha$  plasma concentrations, indicating this latter as independent determinant and possible trigger of the s-LOX-1 increase. Likewise, CRP and IL-6 enhance, in a dose- and time-dependent manner, endothelial LOX-1 mRNA and protein expression [14]. In line with this finding, we found a significant relationship between circulating sLOX-1 and CRP or IL-6. However, our results do not agree with those

of other authors [9, 10] who have reported no correlation between sLOX-1 and CRP or IL-6. This discrepancy with our results probably stems from a difference in the selection of patients. Contrary to them, we excluded patients with diabetes, hypertension, and/or under the respective therapy that could influence the results. Another explanation for this discrepancy could be the higher sensitivity of our method (10-fold more sensible) that is able to reveal correlations with the other parameters which could have remained hidden with the less sensitive methodology used in the above-mentioned studies.

Similarly to other studies [16, 17], our data confirm the link between CAD and elevated plasma concentrations of peroxy radicals, cytokines, and CRP, and between their levels and the severity of the disease.

However in our study, contrary to expectations, ox-LDL plasma levels were higher in less severe patients (group 1) and lower in more severe patients (group 2).

We can assume that, the reduced levels of ox-LDL in more severely affected patients, could be due to increased uptake of ox-LDL by sLOX-1 which are present in high levels in this group. In support to this hypothesis, some studies have shown that soluble membrane receptors can modulate disease activity by binding to its ligand and preventing ligand uptake by the receptor at the cell-surface [18–20]. For instance, the soluble TNF receptors, whose shedding is induced by TNF itself as well as other cytokines [18], have extracellular regulatory functions affecting local or systemic TNF bioavailability. Circulating sLOX-1 could hence be an important regulator of plasma ox-LDL levels. To explore whether the antibodies used in our ELISA could bind the complex ox-LDL ↔ sLOX-1 in serum as well, we performed a sLOX-1 assay in the presence of exogenously added high levels of ox-LDL; no interference of this ligand was observed in sLOX-1 detection (data not shown). Alternatively, we performed an ox-LDL assay in the presence of high levels of sLOX-1. Also in this case, the adding of sLOX-1 did not interfere with the assay (data not shown). Thus, we can speculate that, cytokines, ox-LDL and the soluble form of its receptor constitute a complex network, which interactively influence the development of the atherosclerotic vascular lesion. However, unlike the inflammatory cytokines and ox-LDL that have a clear pathogenetic role in the atherosclerotic process, little is known about the regulation of sLOX-1 shedding, the biological mechanisms underlying the kinetics of sLOX-1 production and removal and the complex interaction between the soluble receptor and its ligands in health and disease states.

## Conclusion

The measurement of sLOX-1 in serum may be potentially useful in predicting atherosclerotic disease progression in humans. Nevertheless, in order to have a clear picture of the pathophysiological roles of sLOX-1 and establish the diagnostic value of sLOX-1 in atherogenesis and vascular diseases, further studies are required.

**Abstract** Alterations in mitochondrial function have long been considered a hallmark of cancer. We compared the lipidome and electron transport chain activities of non-synaptic brain mitochondria in two inbred mouse strains, the C57BL/6J (B6) and the VM/Dk (VM). The VM strain is unique in expressing a high incidence of spontaneous brain tumors (1.5%) that are mostly gliomas. The incidence of gliomas is about 210-fold greater in VM mice than in B6 mice. Using shotgun lipidomics, we found that the mitochondrial content of ethanolamine glycerophospholipid, phosphatidylserine, and ceramide was higher, whereas the content of total choline glycerophospholipid was lower in the VM mice than in B6 mice. Total cardiolipin content was similar in the VM and the B6 mice, but the distribution of cardiolipin molecular species differed markedly between the strains. B6 non-synaptic mitochondria contained 95 molecular species of cardiolipin that were symmetrically distributed over 7 major groups based on mass charge. In contrast, VM non-synaptic mitochondria contained only 42 molecular species that were distributed asymmetrically. The activities of Complex I, I/III, and II/III enzymes were

lower, whereas the activity of complex IV was higher in the mitochondria of VM mice than in B6 mice. The high glioma incidence and alterations in electron transport chain activities in VM mice compared to B6 mice could be related to the unusual composition of mitochondrial lipids in the VM mouse brain.

## Introduction

Mitochondria are necessary for the maintenance of brain metabolism supporting neurological function. Alterations in brain mitochondria can impair bioenergetic efficiency resulting in disease pathology or neurological impairment [1–3]. Although such alterations can exist at the DNA or protein level, little attention has been focused on the role of mitochondrial lipids in neurological function. Mitochondrial membrane lipids can regulate numerous functions to include electron transport chain (ETC) activities, membrane fluidity, mitochondrial protein import, and ATP synthesis [4–8]. Non-synaptic (NS) brain mitochondria are derived from the cell bodies of neurons and glia and represent the predominant mitochondrial population in brain [9]. Alterations in the NS mitochondrial lipid composition could influence ETC activities resulting in a change in neural cell metabolism.

Shotgun lipidomics, using electrospray ionization mass spectrometry (ESI/MS), can now determine the total content and composition mitochondrial lipids (the lipidome) [10]. Using this approach, we recently characterized the lipid composition of mouse brain mitochondria [11]. The mitochondrial specific lipid cardiolipin (1,3-diphosphatidyl-*sn*-glycerol, Ptd<sub>2</sub>Gro), contains nearly 100 different molecular species in the C57BL/6J (B6) mouse brain [11].

Moreover, these molecular species are symmetrically distributed in seven major groups when arranged according to mass to charge ratios [11]. This distribution in B6 mice is similar to that in several other mammalian species and reflects a conserved cardiolipin remodeling process for brain [12].

Our objective was to compare and contrast the lipidome of NS mitochondria and ETC activities in mice of the B6 and the VM/Dk (VM) strains. B6 mice are often used as a control strain for many existing neurological mutations that alter CNS function [13, 14]. VM mice are unique in expressing a relatively high incidence (1.5%) of spontaneous brain tumors, which occur over a broad age range between 4 and 18 months [15]. Most of these brain tumors were characterized as astrocytomas, but microgliomas and neural stem tumors also occur [15–17]. Indeed, the incidence of spontaneous brain tumor formation is about 210-fold greater in VM mice than in B6 mice. Although altered mitochondrial energy metabolism has long been connected to tumorigenesis (Warburg theory) [18–21], the role of mitochondrial lipids in this connection remains unclear. Ours is the first comparative analysis of the NS brain mitochondria lipidome in two mouse strains that differ in susceptibility to spontaneous gliomas.

## Experimental Procedures

### Animals

The VM mice were obtained from Professor H. Fraser, University of Edinburgh. The B6 mice were obtained from the Jackson Laboratory (Bar Harbor, ME). Mice of both strains were matched for age (4 months) and sex (males) and were propagated under similar conditions at the Boston College Animal Facility. Mice were housed in plastic cages with filter tops containing Sani-Chip bedding (P.J. Murphy Forest Products Corp., Montville, NJ, USA). The room was maintained at 22 °C on a 12 h light/dark cycle. Food (Prolab RMH 3000; PMI LabDiet, Richmond, IN, USA) and water were provided ad libitum. This study was conducted with the National Institutes of Health Guide for the Care and Use of Laboratory Animals and was approved by the Institutional Animal Care Committee.

### Non-synaptic Brain Mitochondrial Isolation

We recently described an improved procedure for isolation and purification of NS mitochondria from mouse brain for the purpose of lipid analysis and biochemical analysis of ETC activities [11]. Briefly, the B6 and VM mice were sacrificed by cervical dislocation and the cerebral cortex was dissected. Mitochondria were isolated in a cold room

(4 °C) and all reagents were kept on ice. The isolation procedure employed a combination of gradients and strategies as previously described [22–28] (Fig. 1). The cerebral cortexes (a pool of 6/sample) were diced on an ice cold metal plate and then placed in 12 mL of mitochondria isolation buffer [MIB; 0.32 M sucrose, 10 mM Tris–HCl, and 1 mM EDTA-K (pH 7.4)]. The pooled cerebral cortexes were homogenized using a Potter Elvehjem homogenizer with a Teflon coated pestle attached to a hand-held drill. Samples were homogenized using 15 up and down strokes at 500 rpm. The homogenate was centrifuged at 1,000×g for 5 min. The supernatant was collected and the pellet was washed twice by centrifugation, collecting the supernatants each time. The supernatants were pooled and centrifuged at 1,000×g for 5 min. The collected supernatant was then spun at 14,000×g for 15 min. The supernatant was discarded and the pellet, which contained primarily NS mitochondria, synaptosomes and myelin, was resuspended in 12 mL MIB and was layered on a 7.5/12% discontinuous Ficoll gradient. Each Ficoll gradient layer contained 12 mL for a total volume of 36 mL. The Ficoll gradients were made from a 20% Ficoll stock with MIB. The gradient was centrifuged at 73,000×g for 36 min (4 °C) in a Sorvall SW 28 rotor with slow acceleration and deceleration (Optima L-90K Ultracentrifuge). The centrifugation time used permitted sufficient acceleration and deceleration to achieve maximum g force and to prevent synaptosomal contamination of the mitochondrial fraction below the 12% Ficoll layer [27]. Crude myelin collected at the MIB/7.5% Ficoll interface was discarded. The Ficoll gradient purified NS mitochondria (FM) were collected as a pellet below the 12% Ficoll.

The FM pellet, containing NS mitochondria, was resuspended in MIB containing 0.5 mg/mL bovine serum albumin (BSA) and was centrifuged at 12,000×g for 15 min. The resulting pellet was collected and resuspended in 6 mL of MIB. The resuspended FM pellet was layered on a discontinuous sucrose gradient containing 0.8/1.0/1.3/1.6 M sucrose. The volumes for the sucrose gradient were 6/6/10/8 mL, respectively. The gradients were made from a 1.6 M sucrose stock containing 1 mM EDTA-K and 10 mM Tris–HCl (pH 7.4). The discontinuous sucrose gradient was centrifuged at 50,000×g for 2 h (4 °C) in a Sorvall SW 28 rotor using slow acceleration and deceleration to prevent disruption of the gradient. Purified NS mitochondria were collected at the interface of 1.3 and 1.6 M sucrose. NS mitochondria were collected and resuspended in (1:3, v/v) TE buffer (1 mM EDTA-K and 10 mM Tris–HCl, pH 7.4) containing 0.5 mg/mL BSA and centrifuged at 18,000×g for 15 min. The pellet was then resuspended in MIB and centrifuged at 12,000×g for 10 min. The pellet was again resuspended in MIB and centrifuged at 8,200×g for 10 min.

**Fig 1** Procedure used for the isolation and purification of NS mitochondria from mouse cerebral cortex

#### Materials for Mass Spectrometry

Synthetic phospholipids including 1,2-dimyristoleoyl-*sn*-glycero-3-phosphocholine (14:1-14:1 PtdCho), 1,2-dipalmitoleoyl-*sn*-glycero-3-phosphoethanolamine (16:1-16:1

PtdEtn), 1,2-dipentadecanoyl-*sn*-glycero-3-phosphoglycerol (15:0-15:0 PtdGro), 1,2-dimyristoyl-*sn*-glycero-3-phosphoserine (14:0-14:0 PtdSer), *N*-lauroryl sphingomyelin (N12:0 CerPCho), 1,1',2,2'-tetramyristoyl cardiolipin (T14:0 Ptd<sub>2</sub>Gro), heptadecanoyl ceramide (N17:0 Cer), 1-heptadecanoyl-2-hydroxy-*sn*-Glycero-3-phosphocholine (17:0 LysoPtdCho) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL, USA). It should be noted that the prefix “N” denotes the amide-linked acyl chain. All the solvents were obtained from Burdick and Jackson (Honeywell International Inc., Burdick and Jackson, Muskegon, MI, USA). All other chemicals were purchased from Sigma-Aldrich (St. Louis, MO, USA).

#### Sample Preparation for Mass Spectrometric Analysis

An aliquot of the mitochondrial preparation was transferred to a disposable culture borosilicate glass tube (16 × 100 mm). Internal standards were added based on protein concentration and included 16:1-16:1 PtdEtn (100 nmol/mg protein), 14:1-14:1 PtdCho (45 nmol/mg protein), T14:0 Ptd<sub>2</sub>Gro (3 nmol/mg protein), 15:0-15:0 PtdGro (7.5 nmol/mg protein), 14:0-14:0 PtdSer (20 nmol/mg protein), 17:0 LysoPtdCho (1.5 nmol/mg protein), N12:0 CerPCho (20 nmol/mg protein), N17:0 Cer (5 nmol/mg protein). This allowed the final quantified lipid content to be normalized to the protein content and eliminated potential loss from the incomplete recovery. The molecular species of internal standards were selected because they represent <0.1% of the endogenous cellular lipid mass as demonstrated by ESI/MS lipid analysis.

A modified Bligh and Dyer procedure was used to extract lipids from each mitochondrial preparation as previously described [29]. Each lipid extract was reconstituted with a volume of 500 μL/mg protein (which was based on the original protein content of the samples as determined from protein measurement) in CHCl<sub>3</sub>/MeOH (1:1, v/v). The lipid extracts were flushed with nitrogen, capped, and stored at −20 °C for ESI/MS analysis. Each lipid solution was diluted approximately 50-fold immediately prior to infusion and lipid analysis.

#### Instrumentation and Mass Spectrometry

A triple-quadrupole mass spectrometer (Thermo Scientific TSQ Quantum Ultra, Plus, San Jose, CA, USA), equipped with an electrospray ion source and Xcalibur system software, was utilized as previously described [30]. The first and third quadrupoles serve as independent mass analyzers using a mass resolution setting of peak width 0.7 Th while the second quadrupole serves as a collision cell for tandem MS. The diluted lipid extract was directly infused into the ESI source at a flow rate of 4 μL/min with a syringe pump.

Typically, a 2-min period of signal averaging in the profile mode was employed for each mass spectrum. For tandem MS, a collision gas pressure was set at 1.0 mTorr, but the collision energy varied with the classes of lipids as described previously [10, 30]. Typically, a 2- to 5-min period of signal averaging in the profile mode was employed for each tandem MS spectrum. All the mass spectra and tandem MS spectra were automatically acquired by a customized sequence subroutine operated under Xcalibur software. Data processing of 2D MS analyses including ion peak selection, data transferring, peak intensity comparison, and quantitation was conducted using self-programmed Microsoft Excel macros [30].

### Electron Transport Chain Enzyme Activities

Purified mitochondrial samples were freeze–thawed three times before use in enzyme analysis to give substrate access to the inner mitochondrial membrane. All assays were performed on a temperature controlled SpectraMax M5 plate reader (Molecular Devices) and were done in triplicate. Specific enzyme activities were calculated using ETC complex inhibitors in order to subtract background activities.

Complex I (NADH-ubiquinone oxidoreductase) activity was determined by measuring the decrease in the concentration of NADH at 340 nm as previously described [31, 32]. The assay was performed in buffer containing 50 mM potassium phosphate (pH 7.4), 2 mM KCN, 5 mM MgCl<sub>2</sub>, 2.5 mg/mL BSA, 2 μM antimycin, 100 μM decylubiquinone, and 0.3 mM K<sub>2</sub>NADH. The reaction was initiated by adding purified mitochondria (20 μg). The enzyme activity was measured for 5 min and values were recorded 30 s after the initiation of the reaction. Specific activities were determined by calculating the slope of the reaction in the linear range in the presence or absence of 1 μM rotenone (Complex I inhibitor).

Complex II (succinate decylubiquinone DCIP oxidoreductase) activity was determined by measuring the reduction of 2,6-dichloroindophenol (DCIP) at 600 nm as previously described [32, 33]. The Complex II assay was performed in buffer containing 25 mM potassium phosphate (pH 7.4), 20 mM succinate, 2 mM KCN, 50 μM DCIP, 2 μg/mL rotenone, and 2 μg/mL antimycin. Purified mitochondria (10 μg) were added prior to initiation of the reaction. The reaction was initiated by adding 56 μM decylubiquinone. Specific activities were determined by calculating the slope of the reaction in the linear range in the presence or absence of 0.5 mM Thenoyltrifluoroacetone (Complex II inhibitor).

Complex III (ubiquinol cytochrome *c* reductase) activity was determined by measuring the reduction of oxidized cytochrome *c* at 550 nm. The Complex III assay was performed in buffer containing (25 mM potassium phosphate (pH 7.4), 1 mM EDTA, 1 mM KCN, 0.6 mM dodecyl

maltoside, 32 μM oxidized cytochrome *c*) using purified mitochondria (2.5 μg). The reaction was initiated by adding 35 μM decylubiquinol. The reaction was measured following the linear slope for 1 min in the presence or absence of 2 μM antimycin (Complex III inhibitor). Decylubiquinol was made by dissolving decylubiquinone (10 mg) in 2 mL acidified ethanol (pH 2) and using sodium dithionite as a reducing agent. Decylubiquinol was further purified by cyclohexane [31, 32, 34].

Complex IV (cytochrome *c* oxidase) activity was determined by measuring the oxidation of reduced ferrocytochrome *c* at 550 nm. The Complex IV assay was performed in buffer containing [10 mM Tris–HCl and 120 mM KCl (pH 7.0)] using purified mitochondria (5 μg). The reaction was initiated by adding 11 μM reduced ferrocytochrome *c* and monitoring the slope for 30 s in the presence or absence of 2.2 mM KCN (Complex IV inhibitor) [32, 35].

Complex I/III (NADH cytochrome *c* reductase) activity was determined by measuring the reduction of oxidized cytochrome *c* at 550 nm. The Complex I/III assay was performed in buffer [50 mM potassium phosphate (pH 7.4), 1 mM EDTA, 2 mM KCN, 32 μM oxidized cytochrome *c*, and 105 μM K<sub>2</sub>NADH] and was initiated by adding purified mitochondria (10 μg). The reaction was measured for 30 s with a linear slope in the presence or absence of 1 μM rotenone and 2 μM antimycin (Complex I and III inhibitors) [31, 32, 34].

Complex II/III (succinate cytochrome *c* reductase) activity was measured following the reduction of oxidized cytochrome *c* at 550 nm. The Complex II/III assay was performed in buffer [25 mM potassium phosphate (pH 7.4), 20 mM succinate, 2 mM KCN, 2 μg/mL rotenone] using purified mitochondria (10 μg). The reaction was initiated by adding 40 μM oxidized cytochrome *c* in the presence or absence of 2 μM antimycin (Complex III inhibitor) [31, 32].

## Results

### Lipid Composition of B6 and VM NS Brain Mitochondria

The differences between the B6 and VM mice for the content NS mitochondrial lipids are shown in Table 1. The lipid classes were listed according to their relative abundance. The mass content of phosphatidylinositol (PtdIns), phosphatidylserine (PtdSer), and ceramide (Cer) was higher, whereas the content of total choline glycerophospholipids (ChoGpl), in particular phosphatidylcholine (PtdCho), was lower in VM mice than in B6 mice. Plasmalogen, PlsEtn) was significantly higher in VM mice than in B6 mice. Plasmalogen (PlsEtn) was detected

only in the NS mitochondria of VM mice and not in B6 mitochondria. No differences were found between the strains for the mass content of phosphatidylethanolamine (PtdEtn), Ptd<sub>2</sub>Gro, sphingomyelin (CerPCho), plasmenylcholine (PlsCho), or plasmanylcholine (PakCho). Previously, it was reported that the ratios of ChoGpl/EtnGpl and CerPCho/EtnGpl were accurate indicators of a change in mitochondrial membrane fluidity. Bangur et al. [36] showed that differences in these ratios were correlated with changes in membrane fluidity as determined by fluorescence polarization. The ratio of ChoGpl to EtnGpl in the B6 and VM mice was 0.693 and 0.333, respectively, whereas the ratio of CerPCho to EtnGpl in these strains was 0.028 and 0.010, respectively. Myelin-enriched lipids, sulfatides and cerebrosides, were not detected in B6 or VM NS mitochondria (data not shown). Our previous findings also showed that gangliosides are not present in NS mitochondria from B6 mice [11]. Corresponding lipid molecular species mass content can be found in Supplementary Tables 4, 5, 6, 7, 8, 9, 10, 11 and 12.

#### Cardiolipin Molecular Species Distribution in B6 and VM NS Brain Mitochondria

B6 mice contained 95 molecular species of cardiolipin, whereas VM mice contained only 45 molecular species

(Supplementary Table 6). In addition, some cardiolipin molecular species found in the VM mice (18:1-16:1-16:1-16:1, 18:1-16:1-16:1-16:0, 18:1-16:1-16:0-16:0, 18:2-18:1-16:1-16:1) were not found in the B6 mice. The cardiolipin species found in VM mice may represent newly synthesized forms based on chain lengths and degree of unsaturation [11]. These fatty acids were also similar to those found in PtdGro, the precursor of cardiolipin (Supplementary Table 8). When expressed as mole percentages of mass charge values, the cardiolipin molecular species in B6 NS mitochondria formed a unique pattern consisting of seven major groups (Fig. 2). Group I had the shortest fatty acid chain lengths and the least degree unsaturation, whereas group VII had the longest chain lengths and the greatest unsaturation [11]. The cardiolipin pattern found for VM mice differed markedly from that of B6 mice (Fig. 2; Supplementary Table 6). Cardiolipin in VM mice had elevated amounts of short chain fatty acids and lacked the molecular species found in groups IV, V, and VII. These groups are enriched in 20:4 and 22:6 fatty acids in the B6 brain cardiolipin. These fatty acids were reduced in VM cardiolipin molecular species likely due to the loss of these cardiolipin groups (Table 2). The content of the 16:0, 16:1, 16:2, and 18:1 in brain cardiolipin molecular species was higher in the mitochondria of VM mice than in B6 mice (Table 2). More variation in the distribution of mitochondrial EtnGpl fatty acids was found in the VM mice than in the B6 mice. The content of 22:6 fatty acids in brain ChoGpl was lower in VM mitochondria than in the B6 mitochondria.

#### ETC Activities in NS Mitochondria of B6 and VM Mice

The activities of the unlinked ETC complexes (Complex I, II, III, and IV) as well as those of the linked enzyme complexes (Complex I/III and II/III) are shown in (Table 3). The activities of Complex I, I/III, and II/III were 22, 51, and 25% lower and Complex IV was 22% higher in VM mitochondria than in B6 mitochondria (Table 3).

#### Discussion

We found that the NS mitochondrial lipidome differed markedly between the B6 and VM mice. Mitochondrial membrane lipids are known to influence membrane fluidity/permeability, ETC activities, membrane fusion, calcium homeostasis, and ATP synthesis [4, 6, 37, 38]. EtnGpl and ChoGpl were the most abundant phospholipids in the NS mitochondria of both mouse strains. Previous studies showed that changes in the ChoGpl/EtnGpl ratio and the CerPCho/EtnGpl ratio could significantly influence mitochondrial membrane fluidity [36]. We found that these lipid

**Fig 2** Distribution of brain cardioliplipin molecular species in B6 NS (*black bar*) and VM NS (*gray bar*) mitochondria. Cardioliplipin molecular species were arranged according to mass to charge ratios. Corresponding molecular species mass content can be found in Supplementary Table 6. Molecular species can be arranged into seven groups (I–VII) based on chain length and degree of unsaturation

ratios were markedly lower in the VM NS mitochondria than in the B6 mitochondria indicating that mitochondrial membrane fluidity is greater in VM mice than in B6 mice.

The most remarkable difference in NS mitochondrial lipid composition found between the strains was for the distribution of cardioliplipin molecular species. While B6 mice expressed 95 cardioliplipin molecular species that were

symmetrically distributed over 7 major groups based on mass charge, the VM mice expressed only 45 cardioliplipin molecular species that were asymmetrically distributed with three major groups missing. The distribution of brain cardioliplipin molecular species in B6 NS mitochondria was similar to that in the brains of other mammalian species indicating that the distribution in B6 mitochondria is

conserved [12]. It is also important to mention that the distribution of cardiolipin molecular species in brain differs significantly from the distribution in non-neural tissues, which contain predominantly tetralinoleic cardiolipin (18:2-18:2-18:2-18:2) [39]. Newly synthesized cardiolipin is extensively remodeled using donor fatty acyl groups from the *sn*-2 position of ChoGpl and EtnGpl to form mature cardiolipin (Fig. 3) [40]. The unusual cardiolipin distribution in VM brain mitochondria could result from a strain difference in the activities or specificities of phospholipases and/or acyltransferases, which regulate cardiolipin remodeling. This would alter the normal remodeling process involving random incorporation of fatty acids as occurs in B6 mice [11]. We propose that the asymmetrical distribution of cardiolipin molecular species in VM mice arises in part through abnormalities in the remodeling process.

**Fig 3** Cardiolipin synthesis and remodeling. Cardiolipin is synthesized by the condensation of phosphatidylglycerol (PtdGro) and CDP-DAG to form immature cardiolipin. Immature cardiolipin is then deacylated to form monolysocardiolipin, which uses the deacylated *sn*-2 position fatty acid tails of choline (ChoGpl) and ethanolamine (EtnGpl) glycerophospholipids for the reacylation of monolysocardiolipin. This remodeling process forms mature cardiolipin with specific fatty acid molecular species

The lipid differences in NS mitochondria found between the strains would lead to differences in mitochondrial function. Support for this comes from finding significant differences in the ETC enzyme activities between the strains. Changes in cardiolipin molecular speciation can influence the activity of complex I and may affect the mitochondrial membrane environment influencing linked enzyme activities (I/III and II/III) or supercomplex formation [5, 41–44]. Alterations in supercomplex formation would result in a decrease in efficiency of respiration [43, 45]. Increased docosahexaenoic (DHA) containing cardiolipin results in decreased complex IV activity [46–48]. A loss of DHA containing cardiolipin might therefore produce increased Complex IV activity as we found in the VM strain. Previous studies suggest that cardiolipin does not significantly influence Complex II activity [41]. This is interesting since we found that Complex II activity was similar in the B6 and VM mitochondria. As mitochondrial membrane lipids can influence ETC activities [4, 5, 42, 49], it is likely that the differences in lipid composition underlie the differences in ETC activities.

Alterations in brain mitochondrial lipid composition should affect mitochondrial energy production and neurological function. Additionally, disturbances in the brain mitochondrial lipidome could produce a bioenergetic state conducive to brain tumorigenesis. Warburg indicated that respiratory damage was the cause of most tumors [19]. However, the type of respiratory damage was not specified. It is possible that the lipidomic abnormalities expressed in the VM brain mitochondria could contribute to a respiratory defect that enhances the incidence of spontaneous brain tumors. Further studies will be needed to determine if the differences in brain mitochondrial lipid composition between the B6 and VM mouse strains are related to the differences between these strains for the incidence of spontaneous brain tumors.

**Abstract** Thirty-five species of marine mollusk bivalves were analyzed for their fatty acid (FA) composition of cardiolipin (Ptd<sub>2</sub>Gro). All species showed a Ptd<sub>2</sub>Gro with strong selectivity for only a few polyunsaturated fatty acids, but three characteristic FA profiles emerged, with clear parallels to bivalve phylogeny. A first group of 12 species belonging to the Eupteriomorphia subgroup (Filibranchia) was characterized by a Ptd<sub>2</sub>Gro almost exclusively composed of 22:6n-3, whereas in the four Filibranchia Pteriomorph species analyzed, this FA was combined with substantial proportions of 18:2n-6 and 18:3n-3. Finally, a third group of 20 species, all belonging to the Heterodonta subclass, possessed Ptd<sub>2</sub>Gro containing predominantly both 22:6n-3 and 20:5n-3. Polyunsaturated FA moieties and arrangements in the Ptd<sub>2</sub>Gro of some marine species investigated in other classes of the mollusk phylum (Gastropoda, Polyplacophora) were found to be different. The present results suggest that the specific Ptd<sub>2</sub>Gro FA compositions in bivalves are likely to be controlled and conserved in species of the same phylogenetic group. Functional significances of the evolution of this mitochondrial lipid structure in bivalves are discussed.

## Introduction

Cardiolipin (Ptd<sub>2</sub>Gro) is an anionic phospholipid with a unique dimeric phosphatidyl lipid moiety. This phospholipid is predominantly distributed in bacterial plasma membranes and in eukaryotic mitochondrial inner membranes [1]. Ptd<sub>2</sub>Gro has been shown to be a key factor in the control of major mitochondrial membrane protein activity, such as ADP–ATP and pyruvate carriers, but also of the large complexes involved in oxidative phosphorylation, including complex I (NADH–CoQ reductase), III (ubiquinol:cytochrome *c* oxydoreductase), complex IV (cytochrome *c* oxidase), and V (F<sub>0</sub>F<sub>1</sub>-ATP synthase) [2–6]. Ptd<sub>2</sub>Gro plays a central role in higher order organization of complexes III and IV of the respiratory chain in mitochondria [7–9], as well as in optimal coupling of oxidative phosphorylation [10]. There is also evidence that Ptd<sub>2</sub>Gro regulates membrane binding of the mitochondrial peripheral membrane protein cytochrome *c* [11] and is a critical component in the apoptotic cell-death program [12].

One of the intriguing aspects of eukaryotic Ptd<sub>2</sub>Gro is the unique acyl composition of its four FA residues [2, 13, 14]. Only C<sub>16</sub>–C<sub>18</sub> monounsaturated or diunsaturated fatty acyl chains are usually selected for the assembly of Ptd<sub>2</sub>Gro [14, 15]. For instance, in many mammalian tissues, Ptd<sub>2</sub>Gro has a strong preference for 18:2n-6, constituting up to 85 mol% of the total FA of Ptd<sub>2</sub>Gro [4, 6]. This specific hydrophobic part appears to be an important structural requirement for the high binding affinity of Ptd<sub>2</sub>Gro with proteins, and appropriate molecular composition of Ptd<sub>2</sub>Gro may be critical for optimum mitochondrial respiratory performance [16]. Indeed, in mammals, dietary manipulations affecting 18:2n-6 levels in Ptd<sub>2</sub>Gro (corresponding to a Ptd<sub>2</sub>Gro enriched in 22:6n-3) is associated with a decrease of the O<sub>2</sub> consumption rate of mitochondria isolated from rat heart, a

decrease of the activity of cytochrome *c* oxidase [17–20], but an increase of the activity of  $F_1F_0$ -ATPase [17]. Selection of a limited number of molecular species also appears to be an important feature for Ptd<sub>2</sub>Gro protein interactions influencing enzymatic activities [16]. This common feature was found among Ptd<sub>2</sub>Gro from diverse eukaryotic organisms having different FA compositions [14]. This led to structural uniformity and to a high proportion of molecules with symmetric FA distribution [14]. It is argued that tafazzin (TAZ gene product), a phospholipid acyltransferase, is involved in this acyl-specific modeling of Ptd<sub>2</sub>Gro [16, 21].

Recently, we characterized a Ptd<sub>2</sub>Gro containing more than 80 mol% of 22:6n-3 in three commercial marine bivalve species, the scallop *Pecten maximus*, the oyster *Crassostrea gigas*, and the mussel *Mytilus edulis* [22]. Thereafter, a new highly unsaturated Ptd<sub>2</sub>Gro was discovered in the Manila clam, *Ruditapes philippinarum*, which had two main FA (20:5n-3 and 22:6n-3) found in approximately equal proportions [23]. In this study, we reported a symmetrical structure with 20:5n-3 and 22:6n-3 predominating at *sn*-1 and *sn*-2 positions, respectively. Interestingly, 22:6n-3-enriched Ptd<sub>2</sub>Gro and 20:5n-3/22:6n-3-enriched Ptd<sub>2</sub>Gro, respectively, in scallops, oysters, mussels, and Manila clams are conserved between organs [23]. The replacement of the 22:6n-3 chain in *sn*-1 positions by the 20:5n-3 for the Manila clams, when compared to mussel, oyster, and scallop, is puzzling. It appeared that these characteristic Ptd<sub>2</sub>Gro FA compositions were species specific rather than dietary dependent for the analyzed bivalve species, and it was speculated that these structures could be essential for optimal energy and respiratory metabolisms of mitochondria between bivalve species. These observations raised the questions of the importance and significance of such highly unsaturated long-chain FA and composition specificities in bivalve Ptd<sub>2</sub>Gro.

To begin to address these questions, we investigated the FA composition of Ptd<sub>2</sub>Gro in 35 different species of marine mollusk bivalves belonging to the three most important subclasses in terms of number of species: Filibranchia Pteriomorpha, Filibranchia Eupteriomorpha, and Eulamellibranch Heterodonta (including Anomalodesmata). Investigated species covered 17 of the 94 existing families (20% of family diversity) and 8 of the 13 orders. Ptd<sub>2</sub>Gro FA compositions of some marine species in other classes of the mollusk phylum (Gastropoda, Polyplacophora) were also investigated. Specific objectives were: (1) to assess whether 22:6n-3/20:5n-3-enriched Ptd<sub>2</sub>Gro and 22:6n-3-dominant Ptd<sub>2</sub>Gro are the most representative patterns in bivalves, or whether other FA patterns of Ptd<sub>2</sub>Gro exist, and (2) to determine if

chemotaxonomic relationships exist between Ptd<sub>2</sub>Gro FA composition and bivalve phylogeny. The possible functional implications of the FA patterns found in Ptd<sub>2</sub>Gro also were considered.

## Materials and Methods

### Reagents

Boron trifluoride [BF<sub>3</sub>, 10% (by wt) in methanol] was obtained from Supelco (St. Quentin Fallavier, France). Other reagents and solvents were purchased from Merck (Darmstadt, Germany).

### Bivalve Species

The locations and sampling date of the bivalves species studied are presented in Table 1. For the purpose of the present table, bivalve species are listed according to the taxonomic subclass to which they belong. We followed a recent combined morphological, anatomical, and molecular study in a total evidence framework that resumed a clear pattern of bivalve phylogeny [24]. This classification also includes the two subgroups in the subclass Filibranchia: the Pteriomorpha and the Eupteriomorpha [25].

### Sample Preparation and Lipid Extraction

For all the species analyzed, the digestive tract was removed before whole animals were pooled and homogenized with a Danguomeau homogenizer at  $-180^{\circ}\text{C}$ . Lipids were extracted from tissue homogenates according to the method described by Folch et al. [26]. To ensure complete extraction of tissue lipids, a solvent-to-tissue ratio of 70:1 was used as described by Nelson [27]. After removing the organic phase, the residue was washed with a mixture of CHCl<sub>3</sub>/MeOH (2:1, *v/v*) to avoid any solvent retention. The final extract was stored at  $-20^{\circ}\text{C}$  under nitrogen atmosphere with 0.01wt% BHT (antioxidant).

### Separation of Polar Lipids by Silica Gel Microcolumn

An aliquot of the lipid extracts was evaporated to dryness, and lipids were recovered with three washings of 500  $\mu\text{l}$  of CHCl<sub>3</sub>/MeOH (98/2, *v/v*) and deposited at the top of a silica gel micro-column (30  $\times$  5 mm ID, packed with Kieselgel 60 70-230 mesh previously heated at  $450^{\circ}\text{C}$  and deactivated with 5 wt% H<sub>2</sub>O) [28]. Neutral lipids were eluted with 10 ml of CHCl<sub>3</sub>/MeOH (98/2 *v/v*). The polar lipid fraction was recovered with 15 ml of MeOH and

The list includes 35 species. Number of individuals pooled for analysis is given within brackets

B Brittany/Bay of Brest, MI Madeleine Islands, BC Baja California, M Marenne-Oléron, D Brittany/Bay of Douarnenez

stored at  $-20^{\circ}\text{C}$  for later phospholipid class separation by HPLC and FA composition analysis by GC.

#### Separation of Phospholipid Classes and Ptd<sub>2</sub>Gro—Fatty Acid Analysis

Separation of the phospholipid classes followed a method previously described [23], using a Waters (Milford, MA,

USA) HPLC system (UV detection at 206 nm). The Ptd<sub>2</sub>Gro fraction as well as the other glycerophospholipid classes were identified (i.e., phosphatidylethanolamine, phosphatidylcholine, phosphatidylserine, phosphatidylinositol, ceramide aminoethylphosphonate, and natural lysophosphatidylcholine), collected, and analyzed for FA composition using GC after transesterification (MeOH/BF<sub>3</sub>) [29]. Phosphatidylglycerol (PtdGro) was not detected in the

analyzed species and is likely to be absent or only present in trace amounts in marine bivalve tissues [22].

### Statistics

A hierarchical cluster analysis using the Bray–Curtis similarity index values was accomplished on Ptd<sub>2</sub>Gro FA

composition of the 35 bivalve species using Arcsinus transformation of the percentage data (“R” software). Simple linear regressions between neutral lipid (NL) and Ptd<sub>2</sub>Gro FA compositions were carried out using Stat-Graphics Plus 5.1 (Sigma Plus Inc., Toulouse, France). FA for which results are shown were considered significantly correlated when  $P \leq 0.05$ .

Only predominant PUFA are depicted (saturated FA and monounsaturated FA were always found lower than 15 and 10%, respectively). Results are expressed in mol% of the total FA of the class

## Results

### Taxonomic Sampling

The two most important recognized subclasses of the class Bivalvia were well represented with 20 species belonging to the subclass Heterodonta (+Anomalodesmata) and 15 to the Filibranchia. Two subgroups were distinguished in the subclass of Filibranchia: Pteriomorph (4 species) and Eupteriomorph (11 species) (Table 1). Species investigated covered 17 of the 94 existing families (20% of family diversity) and 8 of the 13 orders of mollusk bivalves.

### FA Composition of Ptd<sub>2</sub>Gro

Tissues of all bivalve species tested were dominated by only a few polyunsaturated FA (PUFA) (22:6n-3, 20:5n-3, 20:4n-6, 18:3n-3, and 18:2n-6), representing 76–96% of the total FA of Ptd<sub>2</sub>Gro, while saturated FA (16:0 and 18:0) (<15%), and monounsaturated FA (mainly 18:1n-9 and 18:1n-7) (<10%) were always found in low proportions.

Table 2 reports the proportions of the five main PUFA found in the Ptd<sub>2</sub>Gro of the 35 bivalve species. Three “types” of FA composition were characterized. In 12 species, Ptd<sub>2</sub>Gro was dominated by 22:6n-3, representing 73.2–87.1% of total FA (cardiolipin type 1). The other PUFA, 20:5n-3 and 20:4n-6, were minor components (<6% individually). In three other species, *Arca lactea*, *Glycymeris glycymeris*, and *Modiolus barbuatus*, 22:6n-3 represented 38.0–40.3% of total FA, and 18:2n-6 and 18:3n-3 were found in fairly high proportions in the Ptd<sub>2</sub>Gro of these species. This specificity was considered as a second type of Ptd<sub>2</sub>Gro (cardiolipin type 2). The other

PUFA, 20:5n-3 and 20:4n-6, were also found in low proportions in these species (<6.2%). In the last 20 species, 22:6n-3 (ranging from 17 to 54.5%) and 20:5n-3 (ranging from 30 to 60.4%) were found to be the two predominant PUFA in Ptd<sub>2</sub>Gro, defining a third type of Ptd<sub>2</sub>Gro (cardiolipin type 3). In these species, although 20:4n-6 was still a minor component, there is an evident trend that this FA reached higher levels than in species having Ptd<sub>2</sub>Gro of type 1 or type 2. The 18:2n-6 and 18:3n-3 FA were always lower than 3.2% in type 3 species.

To investigate if the FA compositions found in bivalves are representative of FA in Ptd<sub>2</sub>Gro from the mollusk phylum in general, FA compositions of Ptd<sub>2</sub>Gro from species belonging to other classes of mollusk were investigated. In the three gastropods and one polyplacophora species analyzed, Ptd<sub>2</sub>Gro revealed neither the same type of FA moieties nor the same arrangements (Table 3). Ptd<sub>2</sub>Gro had a mixed FA pattern with three or more kinds of FA. Nevertheless, as in bivalves, saturated FA (16:0 and 18:0) were found in small proportions (<15%) in these species.

Total FA compositions of Ptd<sub>2</sub>Gro of the 35 bivalve species were submitted to statistical analysis based upon Bray–Curtis similarity index values (Fig. 1). The hierarchical cluster dendrogram obtained clearly shows three main groups corresponding to the three types of Ptd<sub>2</sub>Gro FA composition described above. The overall similarity between type 1 and type 3 and between type 2 and type 3 is less than 40%, while it is close to 50% for types 1 and 2. Comparison between the cluster results and bivalve phylogeny [24, 25] enabled establishing a strong correlation between the three different types of Ptd<sub>2</sub>Gro FA composition and marine bivalves subclass and subgroup belonging. Indeed, all species in group 1 (12 species),

**Table 3** FA composition of cardiolipin (Ptd<sub>2</sub>Gro) in four species belonging to non-bivalve marine mollusk classes (Gastropoda and Polyplacophora)

which have 22:6n-3-enriched Ptd<sub>2</sub>Gro (type 1), belong to the Eupteriomorphia (Filibranchia) group. Species in group 3 (20 species) having Ptd<sub>2</sub>Gro with a strong preference for both 22:6n-3 and 20:5n-3 (type 3) were members of the Heterodonta and Anomalodesmata subclasses. In the second group (three species, type 2), species are all Filibranchia Pteriomorph. One exception is observed for *M. edulis*, which associated with Ptd<sub>2</sub>Gro of type 1, and thus the Filibranchia Eupteriomorph cluster, although this species is considered to be phylogenetically related to Filibranchia Pteriomorph. Nevertheless, the 18:2n-6 and 18:3n-3 proportions found in *M. edulis* (1.7 and 5.9%, respectively) were much higher than in the Ptd<sub>2</sub>Gro of all the other “true” Filibranchia Eupteriomorph species. This discrepancy between *M. edulis* phylogenetic position and its Eupteriomorph Filibranchia Ptd<sub>2</sub>Gro FA composition was confirmed by the Bray–Curtis analysis, which partitioned *M. edulis* into an isolated subcluster within the type 1 cluster.

### FA Composition of Neutral Lipids

To check for the possible dietary effect on FA in Ptd<sub>2</sub>Gro, FA composition of the neutral lipid fraction (NL), which carries a strong imprint of dietary FA in bivalves, was analyzed in 20 species among the 35 sampled species. Seven species were representatives of Ptd<sub>2</sub>Gro of type 1, three of type 2, and ten of type 3. These data showed a constant abundance of both 20:5n-3 and 22:6n-3 FA in NL of all species analyzed (Table 4). Linear correlations were tested between NL and Ptd<sub>2</sub>Gro for the major PUFA of Ptd<sub>2</sub>Gro (18:2n-6, 18:3n-3, 20:4n-6, 20:5n-3, 22:6n-3). From these statistical analyses, it clearly appeared that 18:2n-6, 18:3n-3, and 20:5n-3 contents in Ptd<sub>2</sub>Gro were independent of those FA in the NL as no significant correlation could be established between these two lipid fractions for any of these FA. 20:4n-6 and 20:5n-3 showed lower *P* values (*P* < 0.1). Nevertheless, only a weak correlation could be noted for both FA with their content in

## Discussion

FA compositions of Ptd<sub>2</sub>Gro were characterized in 35 marine bivalve species and were found to be related to the 3 major bivalve subclasses/subgroups: Filibranchia Pteriomorphia, Filibranchia Eupteriomorphia, and Heterodonta + Anomalodesmata. Ptd<sub>2</sub>Gro of Filibranchia Eupteriomorphia species was almost exclusively composed of 22:6n-3. For the species belonging to the Heterodonta subclasses, Ptd<sub>2</sub>Gro was characterized by the predominance of 20:5n-3 and 22:6n-3, even though inter-species variability in their proportions could be observed. The only species analyzed thus far in the Anomalodesmata subclass (*Thracia phaseolina*) has a Ptd<sub>2</sub>Gro FA composition very similar to those found in Heterodonta species. Interestingly, this corroborates the recent inclusion of this subclass within Heterodonta [24]. In addition to these two Ptd<sub>2</sub>Gro FA patterns described previously in *P. maximus*, *C. gigas*, and *M. edulis* for Filibranchia Eupteriomorph species [22]

and in *R. philippinarum* for Heterodonts [23], a new FA composition was found for Ptd<sub>2</sub>Gro of Filibranchia Pteriomorph. Indeed, also predominated by 22:6n-3 as the Ptd<sub>2</sub>Gro of Filibranchia Eupteriomorph bivalves, this FA is combined in this subgroup with substantial proportions of 18:2n-6 and 18:3n-3.

Ptd<sub>2</sub>Gro analysis of some marine species in other mollusk classes (Gastropoda, Polyplacophora) revealed neither the same unsaturated FA nor the same arrangements. The characteristic Ptd<sub>2</sub>Gro FA compositions within bivalve classes and groups may therefore be considered as an interesting chemotaxonomic marker. In addition, the uniformity of FA patterns observed across Pteriomorph, Eupteriomorph, and Heterodont + Anomalodesmatan bivalves suggests that FA composition of Ptd<sub>2</sub>Gro is possibly associated with genotypic evolution in these phylogenetic groups. Nevertheless, before one can definitively associate a specific FA composition of Ptd<sub>2</sub>Gro with evolutionary patterns, the possible role played by environmental conditions in the modeling of Ptd<sub>2</sub>Gro FA composition must be considered. Among environmental factors, the diet is generally supposed to have a profound effect on the FA composition of the lipids in bivalves [30–

35]. Bivalves have low, limited, or no ability for synthesis of  $C_{20}$ – $C_{22}$  PUFA with more than three double bonds. Thus, bivalves must acquire these from diets [36–38] rich in  $C_{20}$ – $C_{22}$  PUFA, including particularly 20:5n-3 and 22:6n-3 [39]. In other words, one can argue that the 22:6n-3-enriched Ptd<sub>2</sub>Gro of Filibranchia Eupteriomorph, jointly with 18:2n-6 and 18:3n-3 for Pteriomorph and 22:6n-3 + 20:5n-3-enriched Ptd<sub>2</sub>Gro of Heterodonta (+Anomalodesmatan), can reflect dietary differences in the availability of certain FA between these bivalve groups. For Ptd<sub>2</sub>Gro, dietary modification is known to affect FA composition significantly in mammals [4, 18, 40]. In contrast, even though there is not as much knowledge concerning the FA composition sensitivity of Ptd<sub>2</sub>Gro in marine animals, a relatively consistent 22:6n-3 content in Ptd<sub>2</sub>Gro was found in both female and male gonads of scallops *P. maximus* (Filibranchia Eupteriomorph) despite large differences in 22:6n-3 and 20:5n-3 contents in their diets [33, 34]. Another argument that refutes the possibility of a FA dietary imbalance between groups of bivalves is the examination of the FA compositions of NL (storage lipids) in bivalves. NL containing FA (mainly triacylglycerols) provides a good signature of dietary quality, in terms of FA [39, 41]. It appeared that there was no correlation for 22:6n-3 and 20:5n-3 contents between Ptd<sub>2</sub>Gro and NL of the bivalve species analyzed. Similarly, levels of 18:2n-6 and 18:3n-3 in Ptd<sub>2</sub>Gro were independent of those FA in NL. A clear example is the high proportions of 18:2n-6 and 18:3n-3 found in Ptd<sub>2</sub>Gro of Filibranchia Pteriomorph bivalves that could not be related to enrichment in their diets, as NL of these species contained as low levels of these FA as those found in the Filibranchia Eupteriomorph and Heterodont species.

Environmental factors such as temperature or salinity are also known to influence the FA composition of membrane lipids of ectotherms in order to defend membrane function from the effects of their fluctuations [42–45]. Whether Ptd<sub>2</sub>Gro FA compositions could show phenotypic or genotypic modifications in response to differences in these environmental factors is still unresolved for bivalves. Nevertheless, when considering that phylogenetically close species (Pectinids) such as *Nodipecten subnodosus*, *P. maximus* [origin France or Norway/south of Bergen (data not shown)], and *Placopecten magellanicus* inhabiting, respectively, sub-tropical, temperate, and sub-Antarctic regions, possess a Ptd<sub>2</sub>Gro fairly uniform in terms of FA composition, it is unlikely for FA composition of Ptd<sub>2</sub>Gro to be markedly influenced by latitudinal adaptations, i.e., different thermal environments. In addition, clear differences of composition between 22:6n-3-enriched Ptd<sub>2</sub>Gro of Filibranchia Eupteriomorph, 18:2n-6- and 18:3n-3-enriched Ptd<sub>2</sub>Gro of Pteriomorph, and 22:6n-3 + 20:5n-3 enriched Ptd<sub>2</sub>Gro of Heterodont (+Anomalodesmatan)

were found among species growing in similar habitats and sampled at the same period of the year. One exception concerned the peppery furrow shell, *Scrobicularia plana* (da Costa), which is commonly found in estuarine conditions with low salinities [46]. Nevertheless, a similar Ptd<sub>2</sub>Gro FA composition was found in this Heterodont species in comparison to the other “truly” marine species. Obviously, taking these observations into account, these specific FA patterns in Ptd<sub>2</sub>Gro of bivalves are likely to be related to different evolutionary positions rather than to environmental factors. This supports the above hypothesis that Ptd<sub>2</sub>Gro FA patterns should be genetically controlled.

The high proportion of PUFA found in bivalve Ptd<sub>2</sub>Gro is a unique, but common feature for most eukaryotic species [6, 14]. To date, in eukaryotes only one or two FA were usually reported for the assembly of Ptd<sub>2</sub>Gro, particularly  $C_{16}$ – $C_{18}$  monounsaturated or diunsaturated acyl chains [14, 15]. For instance, in many mammalian tissues, Ptd<sub>2</sub>Gro has a strong preference for 18:2n-6, constituting up to 90 mol% of total FA of Ptd<sub>2</sub>Gro in heart tissue [4, 6]. The fact that bivalve Ptd<sub>2</sub>Gro shows selective incorporation of a very small number of PUFA may reflect an ancestral characteristic of this intriguing structural aspect of eukaryote Ptd<sub>2</sub>Gro. Interestingly, we previously showed that molecular symmetry occurs in the Ptd<sub>2</sub>Gro of the Heterodont species *R. philippinarum* (20:5n-3 and 22:6n-3 predominating at *sn*-1 and *sn*-2 positions, respectively) [23] and obviously in the Ptd<sub>2</sub>Gro of the Eupteriomorph species, *P. maximus*, *M. edule*, and *C. gigas*, as this group contains only a single type of FA (22:6n-3) [22]. Then, although the type of FA in Ptd<sub>2</sub>Gro varied according to phyla and within the bivalve phylum, a high proportion of molecules with structural uniformity and symmetric FA distribution may also emerge as a common feature, as recently suggested for Ptd<sub>2</sub>Gro of various eukaryotes and organs in mammals [14]. Several acyltransferases, such as Tafazzin (TAZ gene product), acyl-CoA:monolysocardiolipin acyltransferase, and acyl-CoA:dilysocardiolipin acyltransferase (ALCAT gene product), as well as other enzymes, such as scramblase-3, are argued to be involved in this acyl-specific remodeling of Ptd<sub>2</sub>Gro [16, 47–50]. Homologs of these acyltransferases have been reported in the genomes of diverse eukaryotes [16]. Molecular mechanisms and existence of genes that encode for these enzymes remain to be established in bivalves. But from the present and previous data, the differences in FA specificity found in Ptd<sub>2</sub>Gro may be attributable to the existence of multiple and different remodeling acyltransferases, or gene isoforms, between Eupteriomorph, Pteriomorph and Heterodont + Anomalodesmatan species.

The functional significance of such specificity of Ptd<sub>2</sub>Gro FA composition among Eupteriomorph, Pteriomorph, and Heterodont + Anomalodesmatan species has

yet to be addressed. However, Ptd<sub>2</sub>Gro is now clearly recognized to play several key roles in mitochondria related to energy metabolism [5, 6, 21, 51], membrane integrity [3, 9, 52], but also apoptosis [12, 53] and ROS-induced damaging processes [54]. In mammals, as well as in ectotherms, the specific hydrophobic part (i.e., the fatty acid) of the Ptd<sub>2</sub>Gro appeared to be structurally important for the lipid–protein interactions with proteins involved in oxidative metabolism, such as the cytochrome *c* oxidase [19, 20, 55, 56] and F<sub>0</sub>F<sub>1</sub>-ATPase [17], but also complex I and III [6, 54]. An appropriate molecular symmetry of Ptd<sub>2</sub>Gro species may also be critical for optimal mitochondrial respiratory performance [14]. This notion was supported recently by the discovery that Barth syndrome (BTHS), an X-linked human disease, is associated with striking abnormalities in Ptd<sub>2</sub>Gro molecular species leading to changes in mitochondrial architecture and function [21, 57–59]. Thus far, there is no evidence of altered mitochondrial functionality among bivalve phylogenetic groups. However, taking into account all these observations, it may be considered that the specialized Ptd<sub>2</sub>Gro FA compositions found in these groups could be required for optimal functional activation of inner mitochondrial membrane proteins involved in oxidative phosphorylation.

## Conclusion

This work utilized marine bivalve phylogeny to explore the distribution, structure, and evolution of Ptd<sub>2</sub>Gro FA composition in 35 different species. The emerging picture suggests a parallel between FA composition and bivalve taxons. The consequences to mitochondrial function and mechanisms that underlie such unusual Ptd<sub>2</sub>Gro FA compositions remain to be explained. However, in the light of functions associated to the FA moieties of Ptd<sub>2</sub>Gro in mitochondria, we hypothesize that genotypic changes in Ptd<sub>2</sub>Gro FA composition during evolution could constitute an adaptive “strategy” of mitochondrial oxidative phosphorylation processes linked to prevailing conditions in different environmental habitats. Indeed, it is intriguing to note that bivalve species belonging to Eulamellibranch (Heterodonta subclass) containing 20:5n-3 with 22:6n-3 in Ptd<sub>2</sub>Gro are all burrowing bivalves, while those belonging to Filibranch (Pteriomorph and Eupteriomorph subclass), which have very low levels of 20:5n-3 in their Ptd<sub>2</sub>Gro, are epifaunal animals (lying on the surface of the sea bed).

Many questions remain unanswered, but the bivalve Ptd<sub>2</sub>Gro model could be an interesting field of study for the understanding of some of the intriguing aspects of the atypical Ptd<sub>2</sub>Gro acyl composition in eukaryotes.

**Abstract** Herein we report an improved method to separate cardiolipin (Ptd<sub>2</sub>Gro) from tissue total lipid extracts using a biphasic solvent system combined with high performance liquid chromatography. This method uses a normal phase silica column and two mobile phases: mobile phase A that was *n*-hexane:2-propanol (3:2 by vol) and mobile phase B that was *n*-hexane:2-propanol:water (56.7:37.8:5.5 by vol). The initial solvent conditions were 95% A and 5% B, with a flow rate of 1.5 mL/min. The samples were from non-derivatized aliquots of liver, heart, or brain lipid extracts. The peak corresponding to Ptd<sub>2</sub>Gro appeared at 31 min, was well defined and did not overlap with neighboring peaks. The adjacent peak corresponded to ethanolamine glycerophospholipids and the remaining phospholipids were eluted in a single peak. The identity of the phospholipids separated by this method was verified by thin layer chromatography (TLC) and fatty acid analysis, which confirmed that the Ptd<sub>2</sub>Gro was well resolved from other phospholipids. This method is useful to separate and quantify Ptd<sub>2</sub>Gro from small tissue samples thereby avoiding the variability associated with TLC methods.

**Keywords** High Performance liquid Chromatography · Cardiolipin · Phospholipids · Brain · Liver · Heart · Separation

## Abbreviations

ARA	Arachidonic acid
DHA	Docosahexaenoic acid
EtnGpl	Ethanolamine glycerophospholipids
FAME	Fatty acid methyl esters
GLC	Gas liquid chromatography
HPLC	High performance liquid chromatography
TLC	Thin layer chromatography
Ptd <sub>2</sub> Gro	Cardiolipin

## Introduction

Cardiolipin (Ptd<sub>2</sub>Gro) is a unique phospholipid that contains three glycerol molecules, two phosphate groups, and four fatty acids. Ptd<sub>2</sub>Gro is synthesized in mitochondria where it represents 12% of the total mitochondrial phospholipids [1]. In rat heart and liver, it represents approximately 7% of total phospholipids, while the brain contains substantially less Ptd<sub>2</sub>Gro, where it represents only 2.5% of the total brain phospholipids [2]. While Ptd<sub>2</sub>Gro is found in bacteria, in mammals it is found almost exclusively in the inner mitochondrial membrane and at intermembrane contact sites [3, 4]. Ptd<sub>2</sub>Gro is essential for the optimal function of numerous mitochondrial enzymes involved in energy metabolism, such as cytochrome *c* oxidase. It binds tightly to the cytochrome *c* oxidase complex and this interaction is required for efficient electron transport activity [5]. In addition, alterations in the content or structure of Ptd<sub>2</sub>Gro have been observed in aging [6, 7] and in a variety of diseases as, for example,

Barth's syndrome, a rare genetic disorder in which the synthesis of Ptd<sub>2</sub>Gro is deficient and mitochondrial function is impaired [8]. Although these observations imply a critical function for Ptd<sub>2</sub>Gro, the exact role in mitochondria is still not clear.

There are different techniques available for isolating and analyzing Ptd<sub>2</sub>Gro content (for review see [9]). It can be separated using one- or two-dimensional thin layer chromatography (TLC) [10–12], by column chromatography [13] or by high performance liquid chromatography (HPLC) [14]. However, separations using TLC are subject to variability in resolution based upon humidity and the fatty acids are subject to oxidation, both of which are minimized using an HPLC separation. In addition, Ptd<sub>2</sub>Gro can be measured spectrofluorimetrically using a Ptd<sub>2</sub>Gro specific dye *n*-nonyl acridine orange (NOA) [15]. Because there are concerns regarding the specificity of NOA to Ptd<sub>2</sub>Gro [16] and its dependency on membrane potential [17, 18], the reliability of this dye to be used to quantify Ptd<sub>2</sub>Gro is questionable. While this technique is not sufficient to analyze Ptd<sub>2</sub>Gro molecular species, such analysis can be achieved by GC–MS, but this method involves several derivatization steps. In order to avoid sample manipulation and any chromatographic separation using GC–MS, shotgun lipidomics has been used to analyze Ptd<sub>2</sub>Gro molecular species and mass using an approach utilizing multidimensional mass spectroscopy [19].

Here we have developed a HPLC method to isolate Ptd<sub>2</sub>Gro from total lipid extracts using a solvent system and column matrix that we routinely use to separate major phospholipids. The reason for improving our current method was that although it is able to separate minor phospholipids such as lysophosphatidylethanolamine and lysophosphatidylcholine, it does not separate Ptd<sub>2</sub>Gro [20]. Although we have used TLC methods in the past [21, 22], we found these separations to be highly dependent on environmental conditions and required multiple runs per sample to verify values, with the need for such repetition being the driving force for the development of our new HPLC based method. This new method allows a clear separation of Ptd<sub>2</sub>Gro from the rest of phospholipids even from tissues with low Ptd<sub>2</sub>Gro content, such as brain.

## Methods

### Animals

Male mice (25–30 g) 9-months old were maintained on standard laboratory chow diet and water ad libitum. All mice used in this study were killed by head-focused microwave irradiation (2.8 kW, 1.35 s; Cober Electronics, Inc., Norwalk, CT, USA). This study was conducted in accordance

with the National Institutes of Health Guidelines for Care and Use of Laboratory Animals (NIH Publication 80-23) and under an animal protocol approved by the IACUC at the University of North Dakota (Protocol 0110-1).

### Lipid Extraction

Livers, hearts, and brains were rapidly removed from mice post-mortem, the tissue immediately frozen in liquid nitrogen, and then pulverized under liquid nitrogen temperatures to a fine homogeneous powder. Lipids were extracted using *n*-hexane/2-propanol (3:2 vol/vol) from approximately 100 mg of frozen tissue [23, 24]. Tissue extracts were centrifuged at 1,000×*g* to pellet debris. The lipid-containing liquid phase was decanted, placed in a screw top test tube, overlaid with a nitrogen atmosphere, and stored at –80 °C until analysis.

### Thin Layer Chromatography

Individual phospholipid classes were separated by TLC using Whatman silica gel-60 plates (20 cm × 20 cm, 250 μm) that were heat-activated at 110 °C for 1 h. Samples streaked onto plates and the phospholipids were separated using chloroform:methanol:acetic acid:water (55:37.5:3:2 by vol) [10]. This method separates all major phospholipids, including Ptd<sub>2</sub>Gro, phosphatidic acid, and phosphatidylglycerol. Ptd<sub>2</sub>Gro was identified using bovine heart Ptd<sub>2</sub>Gro (catalog number 99054; Avanti Polar Lipids, Alabaster, AL, USA) as a standard. Mass was determined by assaying for the lipid phosphorus content [25] and converted to moles of using a standard curve. Moles of Ptd<sub>2</sub>Gro were calculated by dividing the total moles of lipid phosphorus by 2.

### Fatty Acid Analysis

The liver, heart, and brain Ptd<sub>2</sub>Gro and EtnGpl fractions collected from the HPLC separation were subjected to base-catalyzed transesterification, converting the phospholipid acyl chains to fatty acid methyl esters (FAME). To each fraction, 2 mL of 0.5 M KOH dissolved in anhydrous methanol were added [26]. FAME were extracted from the methanol using 2 mL of *n*-hexane and the *n*-hexane phase containing the FAME was removed. The lower phase was re-extracted two more times with 3 mL of *n*-hexane and these washes were combined with the original aliquot.

Individual fatty acids were separated by gas liquid chromatography (GLC) using an SP-2330 column (0.32 mm ID × 30 m length) and a Trace GLC (ThermoElectron, Austin, TX, USA) equipped with dual autosamplers and dual flame ionization detectors. Fatty acids were quantified using a standard curve from commercially purchased

standards (NuChek Prep, Elysian, MN) and 17:0 was used as the internal standard.

### HPLC Method

Prior to phospholipid analysis, the lipid extracts were dried under nitrogen and redissolved in a known volume of *n*-hexane/2-propanol/water (56.7:37.8:5.5, by vol). The separation method for Ptd<sub>2</sub>Gro used a biphasic solvent system with a step gradient and a Selectosil column (4.6 × 250 mm, 5 μm, Phenomenex, Torrance, CA, USA). Solvents used were HPLC grade *n*-hexane and 2-propanol from EMD and purchased from VWR (Chicago, IL, USA). The HPLC system consisted of a Beckman 126 pump and a 166 UV/Vis detector, the eluant was monitored at 205 nm.

The solvent system consisted of a combination of two mobile phases: Mobile phase A was *n*-hexane:2-propanol (3:2 by vol) and mobile phase B was *n*-hexane:2-propanol:water (56.7:37.8:5.5 by vol). The step gradient was as follows (1) initial conditions mobile phase A was 95%; (2) at 5 min mobile phase A was decreased to 90% and maintained for 5 more minutes; (3) at 10 min mobile phase A was decreased to 85% and maintained for 10 min; and (4) at 20 min mobile phase decrease to 0% A maintained for 30 min. The final step ensured that all possible phospholipids remaining on the column were removed. To return the column to stable starting conditions, mobile phase A was increased to 95% and maintained for 5 min. The method program is summarized in Table 1. The total run time was 55 min and the flow rate was 1.5 mL/min.

## Results

### Separation of Ptd<sub>2</sub>Gro by HPLC

Total lipids were extracted by *n*-hexane:2-propanol (3:2, by vol) from 100 mg of liver, heart, or brain tissue. An aliquot of each tissue extract corresponding to 5% of heart and liver lipid extract and 10% of brain lipid extract, was injected onto the HPLC column. Our previous experience

**Table 1** Step gradient of the new HPLC method for Ptd<sub>2</sub>Gro separation

Time (min)	Mobile phase A (%)	Mobile phase B (%)
0	95	5
5	90	10
10	85	15
20	0	100
50	95	5

Mobile phase A was *n*-hexane:2-propanol (3:2 by vol); mobile phase B was *n*-hexane:2-propanol:water (56.7:37.8:5.5 by vol)

for using TLC to separate phospholipid have indicated that brain Ptd<sub>2</sub>Gro is present in a lower concentration compared to heart and liver Ptd<sub>2</sub>Gro, necessitating injecting twice the amount of brain total lipid in order to approximate the amount used in the analysis of heart and liver lipid extracts. The elution profile shows three major peaks for each tissue analyzed (Fig. 1). We collected the first two peaks for analysis by TLC and fatty acid composition analysis by GLC. The first peak (*peak 1*), which we hypothesized was Ptd<sub>2</sub>Gro, eluted at 31 min, while the second peak (*peak 2*), which we hypothesized could correspond mainly to EtnGpl, eluted at 33 min. Note that the peak corresponding to Ptd<sub>2</sub>Gro was a well defined peak that did not overlap

**Fig. 1** High performance liquid chromatography elution profile of liver, heart, and brain total lipids. *Peak 1* corresponds to Ptd<sub>2</sub>Gro while *peak 2* contains mainly EtnGpl

with neighboring peaks. *Peak 1* appears clearly in all tissues, even in brain where Ptd<sub>2</sub>Gro level is low compared to liver and heart.

#### Analysis of the Ptd<sub>2</sub>Gro Fraction by TLC

To verify that the fraction named as *peak 1* was indeed Ptd<sub>2</sub>Gro, we applied this peak to a TLC plate and resolved it via the solvent system described previously [10]. *Peak 1* or the putative Ptd<sub>2</sub>Gro fraction (F) collected from each of the tissues was spotted next to its corresponding total lipid extract (T) (Fig. 2). In Fig. 2, it is clear that only one phospholipid was detected in the lane corresponding to *peak 1* after visualization with iodine. In addition, this phospholipid ran to the same height as the Ptd<sub>2</sub>Gro of the total lipid extract and as the Ptd<sub>2</sub>Gro standard (st). Visualization with 6-*p*-toluidino-2-naphthalenesulfonic acid, a very sensitive fluorescent indicator dye [27], also demonstrated no contamination of the Ptd<sub>2</sub>Gro with other phospholipids or neutral lipids, e.g., triacylglycerols, cholesteryl esters (data not shown). Thus, the apparent baseline separation of *peak 1* from *peak 2*, was confirmed by TLC and the identity of *peak 1* was Ptd<sub>2</sub>Gro as compared to authentic standards.

**Fig. 2** Thin layer chromatography (TLC) separation of isolated *peak 1* from the HPLC separation. Ptd<sub>2</sub>Gro fractions (F) obtained by the new HPLC method (labelled as *Peak 1*) and total lipid extracts (E) from liver, heart and brain were separated by one-dimensional TLC as described in materials and methods. *St* commercial Ptd<sub>2</sub>Gro standard. Phospholipid fractions were visualized by exposing the plate to iodine vapors. Other bands on the TLC plate correspond to, beginning at bottom of the plate, sphingomyelin, choline glycerophospholipid, phosphatidylserine, phosphatidylinositol, and ethanolamine glycerophospholipid (EtnGpl)

#### Fatty Acid Analysis of the Ptd<sub>2</sub>Gro Fraction

The main fatty acid in liver Ptd<sub>2</sub>Gro is linoleic acid (LNA, 18:2n-6) representing 70% of total Ptd<sub>2</sub>Gro fatty acids [28] while in bovine heart, Ptd<sub>2</sub>Gro contains about 80–90% LNA [29]. We took advantage of this characteristic fatty acid composition, to verify that *peak 1* corresponded to Ptd<sub>2</sub>Gro. Thus, we analyzed both *peak 1* and *peak 2* fatty acid composition by gas chromatography (Table 1). The fraction corresponding to liver and heart Ptd<sub>2</sub>Gro contained a very high percentage of LNA, 65 and 87%, respectively, confirming that the peak was indeed Ptd<sub>2</sub>Gro. Interestingly, brain Ptd<sub>2</sub>Gro fatty acid composition differed considerably, containing oleic acid (18:1n-9) as the predominant fatty acid (34.4%) and a much lower level of LNA (9%), results that agree with published data [30, 31]. In addition, brain Ptd<sub>2</sub>Gro contained higher amounts of longer and more unsaturated fatty acids such as arachidonic acid (ARA, 20:4n-6, 18.6%) and docosahexaenoic acid (DHA, 22:6n-3, 11.1%), consistent with previously published data [22]. In addition, brain The fatty acid composition of *peak 2* was clearly different as compared to *peak 1*, being highly enriched in ARA and DHA, a composition which is characteristic of the EtnGpl [2]. The lack of high amounts of ARA and DHA in the liver Ptd<sub>2</sub>Gro, adds additional evidence that the Ptd<sub>2</sub>Gro separated by HPLC was indeed well separated from *peak 2*, which was EtnGpl.

#### Intersample Variability

We compared mouse brain Ptd<sub>2</sub>Gro mass obtained by TLC and by HPLC from the same seven mice. While mass of Ptd<sub>2</sub>Gro separated by TLC was 573 ± 88 nmol/g ww (*n* = 7), mass of Ptd<sub>2</sub>Gro separated by HPLC was 739 ± 97 nmol/g ww (*n* = 7). While the relative standard deviation between these two methods was similar 15.3 and 13.1%, there was a significant difference between the mass (*p* = 0.0057, two-way, unpaired Student's *t*-test), indicating that some Ptd<sub>2</sub>Gro was lost when brain lipids are separated by TLC (see Sect. 'Discussion').

#### Discussion

In mammals, as in other eukaryotes, Ptd<sub>2</sub>Gro is a minor phospholipid present only in mitochondrial membranes [3, 4], with levels corresponding to the amount of mitochondria found in any given tissue. Thus, in mitochondria rich tissues such as heart and liver, Ptd<sub>2</sub>Gro is found at higher levels as compared with brain [2, 21, 22]. While we routinely use TLC to separate brain phospholipids, when brain lipids are separated using this method, Ptd<sub>2</sub>Gro appears as a disperse and blurry band, mainly due to its diverse fatty acid

composition (Table 2) [22]. For this reason we sought an alternative method to separate and isolate Ptd<sub>2</sub>Gro, modifying a previous HPLC method designed to separate major phospholipids and minor phospholipids as lysophosphatidylcholine and lysophosphatidylethanolamine [20].

This new method is based on the combination of two mobile phases. Mobile phase A is formed by *n*-hexane:2-propanol (3:2 by vol), while mobile phase B is formed by *n*-hexane:2-propanol:water (56.7:37.8:5.5 by vol) where water was added to increase the polarity of the solvent system. As observed in the HPLC eluting profile (Fig. 1) and in the TLC separation (Fig. 2), our new method allowed a clear separation of Ptd<sub>2</sub>Gro and the resolution was not sensitive to different concentrations of total lipid extracts commonly used for such analysis (Fig. 3). We spotted the eluted *peak 1* on a TLC plate (F lane) and it clearly ran to the same position as the Ptd<sub>2</sub>Gro standard (Fig. 2). F lane did not present with any additional spots and consequently we considered that this was a first demonstration that the eluted *peak 1* contained only Ptd<sub>2</sub>Gro. In addition, we developed the TLC plate with a fluorescent dye (6-*p*-toluidino-2-naphthalenesulfonic acid), which is more sensitive than iodine [27]. Even under these conditions, no additional bands appeared F lanes.

For further confirmation, we analyzed the fatty acid composition of *peak 1* and *peak 2* (Fig. 1). The results of these analysis confirmed that the peak eluting at 31 min was

**Table 2** Liver, heart, and brain fatty acid composition of *peak 1* and *peak 2* separated by the new HPLC method

FAME	Liver		Heart		Brain

Values are expressed as percentage of total fatty acid (mol%). Values are *n* = 1 for each tissue

ND non detected fatty acid

**Fig. 3** The effect of total lipid concentration on the resolution of Ptd<sub>2</sub>Gro and EtnGpl was determined. We injected 100 nmol of total heart phospholipids containing approximately 10 nmol of Ptd<sub>2</sub>Gro (continuous line), 200 nmol of total heart phospholipids containing approximately 20 nmol of Ptd<sub>2</sub>Gro (dashed line), and 300 nmol of total heart phospholipids containing approximately 30 nmol of Ptd<sub>2</sub>Gro (dotted line)

Ptd<sub>2</sub>Gro (Table 2). Heart and liver Ptd<sub>2</sub>Gro fatty acid composition was highly enriched in LNA [32, 33], while brain Ptd<sub>2</sub>Gro fatty acid composition differ from previous tissues [22]. This different fatty acid composition is consistent with the fact that brain contains extremely low concentrations of LNA [2, 34]. The role that the unique brain Ptd<sub>2</sub>Gro fatty acid composition has with regard to function remains elusive, although recent evidence indicates that changes in these fatty acids alters the membrane environment in a manner that can alter mitochondrial function [22].

Because the main problem in our studies was to adequately separate and isolate brain Ptd<sub>2</sub>Gro, we compared the mass of brain Ptd<sub>2</sub>Gro in the same cohort of seven mice separated by either TLC ( $573 \pm 88$  nmol/g ww, *n* = 7) or by HPLC ( $739 \pm 97$  nmol/g ww, *n* = 7). The results clearly showed that we obtained 1.3-fold more Ptd<sub>2</sub>Gro when we separated total lipids by HPLC, although the relative standard deviation was similar. One explanation accounting for this difference is the diffuse nature of the brain Ptd<sub>2</sub>Gro band (Fig. 2), more than likely due to the diverse fatty acid composition of brain Ptd<sub>2</sub>Gro. This diffuse nature could lead to the inadequate removal of the band from the TLC plate.

Using the same solvent system of Dugan et al. [20] is an advantage because it permits the separation all the phospholipids with no need to change systems, but would require modifying the step gradient program after the elution of the Ptd<sub>2</sub>Gro. An additional advantage of this method is that Ptd<sub>2</sub>Gro is separated directly from the total lipid extract with no need for derivatization. In conclusion, this new HPLC method is a simple method which allows a good separation of Ptd<sub>2</sub>Gro with no need of derivatization, previous separation of neutral lipids, is compatible with

different tissues, and it is highly compatible with a HPLC method that can be used to separate the remaining phospholipid classes.

## Introduction

The abundance of linoleic acid (C18.2 $\omega$ 6) and linolenic acid (C18.3 $\omega$ 3) in higher plants coincides with the occurrence of multiple lipoxygenase (LOX) enzymes that specifically oxygenate these polyunsaturated fatty acids. Linoleic acid has only two available positions for LOX-catalyzed oxygenation, at C-9 or C-13, and all LOX activities in plants target one position or the other, or both. Although LOX activities abound in plant tissues, and LOX-encoding genes have been identified in dozens of plant species, the positional specificity of the vast majority of plant LOX genes remains to be determined [1]. One issue addressed here concerns the identification of a specific 9-LOX gene in *Arabidopsis* (AtLOX1) and tomato (LOXA). An accompanying manuscript by Andreou et al. [2] details a 9-LOX characterization from potato.

Currently there is no direct evidence showing how LOX enzymes catalyze their specific oxygenations [3]. The amino acid sequences in the gene family are well conserved, indicating that in general terms the arrangement of the catalytic machinery is conserved. A single atom of non-heme iron is held in place by well-conserved amino acid ligands comprised mainly of histidines and the carboxyl group of the C-terminal amino acid, usually an isoleucine. Within this conserved structural framework, individual LOX enzymes are known to oxygenate at specific positions on the fatty acid and in either the *R* or *S* stereoconfiguration. To accommodate all the known activities within the well conserved enzyme structures, one of the variables proposed in individual enzymes is a change in the head-to-tail orientation of the bound fatty acid substrate. This was proposed originally in 1972 as the logical explanation for how corn 9*S*-LOX and soybean 13*S*-LOX abstract the 11*R* and 11*S* hydrogen respectively from linoleic acid in forming their 9*S*-HPODE and 13*S*-HPODE products (Fig. 1a) [4]. Other lines of circumstantial evidence point to 13*S* oxygenation being associated with the “tail-first” mode of fatty acid binding. For example, 13-LOX can oxygenate very large esters such as linoleoylphosphatidylcholine in the same way as free linoleic acid (e.g., ref. [5]). This suggests that 13*S* oxygenation involves tail-first entry of the fatty acid into the active site, as it is hard to imagine a carboxyl esterified to phosphatidylcholine entering the LOX active site.

Substrate binding orientation in 9*S*-LOX has been deduced in different ways in the literature. In contrast to the earlier conclusion of carboxyl-first substrate binding (Fig. 1a) [4], two separate observations lead logically to a contrary conclusion [6, 7]. The first relates to a known activity of several plant 9-LOX, namely that the main product of arachidonic acid oxygenation is the 5*S*-hydroperoxide. van Zadelhoff et al. [6] reported that when arachidonate ethanolamide (anandamide) is metabolized by

**Fig. 1** Stereochemistry of linoleic acid oxygenation. *Panel a:* Stereospecific hydrogen abstraction and specific oxygenation of linoleic acid retain the same spatial relationship in corn 9-LOX and soybean 13-LOX if the substrates adopt reversed orientations in the respective enzyme active sites. Adapted from ref. [35]. *Panel b:* A drawing in perspective illustrating potential oxygenation of linoleic acid at each end of the pentadiene. Note that 9*S* and 13*R* oxygenations are on the same face of the molecule, and 9*R*/13*S* on the other face. Adapted from ref. [3]

purified barley or tomato 9-LOX, the main specific oxygenation produces the 11*S*-hydroperoxide. This suggests that the carbon chain has slipped into a different alignment in the active site, and given the presence of the bulky anandamide moiety at the carboxyl end, it is hard to see why this would force the fatty acid deeper into the active site. Therefore, the investigators drew the opposite conclusion, that the fatty acid binds tail-first in 9-LOX [6]. Butovich and Reddy observed that 1-linoleoyl-glycerol is metabolized similarly to linoleic acid by potato 9-LOX (to the 9-hydroperoxide), and as this would seem to be incompatible with carboxyl end-first binding, they also came to the logical conclusion that the fatty acid substrate binds tail-first in 9-LOX.

Herein we address the issue of substrate binding in 9-LOX by testing a model that predicts reaction specificity and the formation of *R* or *S* configuration products in LOX enzymes [8]. A single active site amino acid was found to exert a major influence over *R* or *S* oxygenation [9]. This key determinant is conserved as an Ala in *S* lipoxygenases and a Gly in *R* lipoxygenases. An Ala allows oxygenation deep in the active site cavity and gives *S*-hydroperoxides while a change to Gly switches the position of oxygenation across the face of the reacting pentadiene and gives *R*-hydroperoxide stereochemistry. The model predicts that linoleic acid 9*S*-LOX (which naturally have Ala in the key position), should switch to forming 13*R*-hydroperoxide after the appropriate Ala-to-Gly mutation (see Fig. 1b).

Given that the model fits with many different LOX enzymes with different predicted orientations of fatty acid binding, the model is also only compatible with the carboxyl end-first substrate orientation in plant 9-LOX.

## Experimental Procedures

### Materials

Fatty acids were purchased from NuChek Prep Inc. (Elysian, MN). [1-<sup>14</sup>C]linoleic, and [1-<sup>14</sup>C]arachidonic acids were purchased from Perkin Elmer Life Sciences. Standards of racemic HPODEs and HODEs were prepared by vitamin E-controlled autoxidation [10]. 9S-H(P)ODE was prepared using the 9-LOX activity in potato tuber extracts, and 13S-H(P)ODE using soybean lipoxygenase (Sigma type V) [11]. 1-Palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphatidylcholine (C<sub>16</sub>/LA-PC) and 1-palmitoyl-2-arachidonoyl-*sn*-glycero-3-phosphatidylcholine (C<sub>16</sub>/AA-PC) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL).

### Construction of Expression Vectors

A full-length *AtLOX1* cDNA [12] as kindly provided by Dr. Kaye Peterman (Wellesley College). A PCR-based strategy was used to construct an expression vector for production of AtLOX1 with an N-terminal (His)<sub>6</sub>-tag. Forward and reverse primers that amplify the cDNA contained *NdeI* and *XhoI* restriction sites, respectively. The sequence of the forward primer was 5'-GGAATTCATA TGTTCCGGAGAACTTAG-3' and that of the reverse primer 5'-CCGCTCGAGTCAGATAGAGACGCTATTT-3'. PCR amplification of *AtLOX1* yielded a 2.7-kb product that was subsequently cut with *NdeI* and *XhoI* and subcloned into the same sites of the expression vector pET-14b (Novagen, Madison, WI). The resulting construct produced a (His)<sub>6</sub>-tagged AtLOX1 protein in which 20 amino acids (MGSSHHHHHHSSGLVPRGSH) were added to the initiator Met of the LOX1 enzyme. This construct was introduced into *E. coli* host strain BL21 (DE3) for protein expression.

The tomato (*Solanum lycopersicum*) *LOXA* cDNA was obtained by RT-PCR using an Enhanced Avian RT-PCR kit (Sigma Aldrich). The reverse transcription reaction contained 2 µg of total RNA isolated from 9-day-old tomato seedlings (cv. Castlemart) and an oligo (dT)<sub>23</sub> primer. The PCR reaction was performed with *LOXA*-specific primers 5'-CGGGATCCATGTTAGGTGAACCTGTGGG TG-3' and 5'-CCGAGCTCATGTGTACTCAAACCTC TTC-3', which included *BamHI* and *SacI* restriction sites, respectively. The resulting PCR product was cloned into *BamHI* and *SacI* sites of pBlueScript. The nucleotide

sequence of this tomato cDNA exactly matched the tomato *LOXA* sequence (GenBank accession number U09026) reported by Ferrie et al. [13].

A PCR-based strategy was used to construct an expression vector for production of an N-terminally (His)<sub>6</sub>-tagged LOXA enzyme. Following amplification with primers 5'-CGGGATCCGGTGGGTGGATTAATTGGTG-3' and 5'-CGGGATCCCTATATTGACACACTGTTT-3', this PCR fragment was cloned into the *BamHI* site of pET14b. The N-terminal amino acid sequence of the resulting (His)<sub>6</sub>-tagged LOXA enzyme is MGSSHHHH HHSSGLVPRGSHLEDPVGGL. The subcloning procedure resulted in a three amino acid change (GLD → EDP, underlined) in the N terminus of the native LOXA protein.

### Expression of Recombinant LOX in *E. coli*

Wild-type and mutant LOX were expressed in *E. coli* BL21 (DE3) as (His)<sub>6</sub>-tagged proteins using the protocol described for coral 8R-LOX [14] with the following modifications. The expressed proteins were recovered using Bugbuster (Novagen) with added 1 µl/ml Benzonase (Novagen) and 1 mM PMSF. The supernatants were purified on Ni-NTA agarose (Qiagen) according to manufacturer instructions. Fractions collected from the affinity column were assayed by SDS/PAGE and fractions containing recombinant lipoxygenases were dialyzed against 50 mM phosphate pH 7.0, 150 mM NaCl buffer containing 20% glycerol.

Fractions of 0.5 ml were collected from the affinity column and 10 µl aliquots analyzed using SDS-PAGE. Protein was determined using the Bio-Rad protein assay with bovine serum albumin as standard. Fractions containing the highest concentrations of protein were pooled and dialyzed against a buffer of 50 mM Tris (pH 7.5), 300 mM NaCl to remove imidazole.

### Quantitation of LOX Protein

The LOX proteins were quantified using a specific in-gel assay in which the LOX band on a stained SDS-PAGE gel is compared in intensity to the protein bands in a series of quantified albumin standards run in other lanes. Aliquots of the dialyzed protein from the Ni-NTA column were run on a 20–4% SDS-PAGE gel, and a second gel was run with aliquots of bovine albumin in concentrations ranging from 0.25 to 15 µg. The gels were stained with Bio-Safe Coomassie stain (Bio-Rad) and rinsed repeatedly with water. The protein bands at ~97 kDa representing the LOX protein were then quantified with the Odyssey Infrared Imaging System (Li-Cor Biosciences, Lincoln, NE), using the known amount of protein in the BSA bands to generate a standard curve.

## Site Directed Mutagenesis

Site directed mutagenesis of AtLOX1 and LOXA was performed using the QuikChange<sup>®</sup> site directed mutagenesis kit (Stratagene) using overlapping mismatching oligonucleotides as primers designed according to the manufacturer's instructions. The His-tagged Arabidopsis AtLOX1 and tomato LOXA in the pET14b expression vector were used as templates. The primer sequences (55-mers) were, for Arabidopsis LOX1, 5'-GTGATACGA TGAATATCAATGCACTTGGTAGGCAAATCTTGATC AATGGTGGTGG, and 5'-CCACCACCATTGATCAAG ATTTGCCTACCAAGTGCATTGATATTCATCGTATC AC, and for tomato LOXA, 5'-GGGACACAATGAATA TTAATGCTTTGGGAAGACAGATCCTAATCAATGCT GGTGG, and 5'-CCACCAGCATTGATTAGGATCTGT CTTCCCAAAGCATTAAATATTCATTGTGTCCC. PCR reactions and transformation of *Escherichia coli* XL1-Blue cells were performed according to the manufacturer's instructions (Stratagene). Correctly mutated clones were identified by DNA sequencing.

## Enzyme Reactions, Incubation and Extraction

Enzymatic activity of the Nickel column-purified enzymes was determined by monitoring the increase of the signal at 235 nm using a Perkin-Elmer Lambda-35 UV-Vis spectrophotometer. Rates of reaction were calculated from the initial linear part of the curve. Rates at varying pH values were compared using 50  $\mu$ M linoleic acid with phosphate buffers (pH 5.0, 6.0, 7.0 and 8.0) and borate buffer (pH 9.0). Products from reaction at pH 6 were extracted without pH change into dichloromethane or using a 1 ml Oasis HLB cartridge (Waters).

Incubations with anandamide were conducted in 1 ml of 100 mM sodium phosphate (pH 6) using 2  $\mu$ g of LOX protein; anandamide (50  $\mu$ M final concentration) was added in 5  $\mu$ l ethanol. After a 5 min incubation at room temperature, the reactions were extracted using a 1-ml Oasis HLB cartridge (Waters).

Incubations with C<sub>16</sub>/C<sub>18,2</sub>-phosphatidylcholine were conducted at pH 7.5 in the presence of sodium deoxycholate (final concentration, 4 mM) to help solubilize the substrate. The reactions were extracted using the Bligh and Dyer procedure [15] then transesterified using sodium methoxide [5] and the methyl esters subsequently analyzed by normal phase HPLC.

## HPLC Analysis

Reaction products of the two LOX enzymes and mutants with [1-<sup>14</sup>C]linoleic acid or [1-<sup>14</sup>C]arachidonic acid were analyzed on an Agilent 1100 HPLC equipped with a diode

array detector connected online to a Radiomatic FLO-ONE A-100 radioactive detector. Straight-phase HPLC analysis used a Beckman Ultrasphere silica column (25  $\times$  0.46 cm) eluted at a flow rate of 1 ml/min with hexane/isopropanol/acetic acid (100/2/0.1, v/v/v) with UV detection at 205, 220, 235 and 270 nm. Reversed-phase HPLC used a Waters Symmetry C18 5- $\mu$ m column eluted at 1 ml/min with a solvent of methanol/water/acetic acid (80/20/0.01, v/v/v), and finally with methanol to elute unreacted substrate. Chiral analysis was performed on HODE methyl esters using a Daicel Chiralpak AD column (25  $\times$  0.46 cm) eluted with hexane/methanol (100/2, v/v) at a flow rate of 1 ml/min, with UV detection at 235 nm [16].

## Results

### Expression and Purification

The cDNAs in the bacterial expression vector were prepared with an added N-terminal (His)<sub>6</sub>-tag as described in Methods. The two LOX enzymes expressed well in *E. coli* (2–5 mg LOX protein per 100 ml culture) and were partially purified by nickel affinity chromatography (Fig. 2). The *Arabidopsis* Ala562Gly mutant expressed at lower levels, although sufficient for evaluation of its activity and for analysis of products. In other SDS-PAGE analyses in which the LOX protein band was not overloaded (in contrast to Fig. 2), each LOX protein band at  $\sim$ 97 kDa was quantified by in-gel assay (Odyssey Imaging Systems, see "Methods"), and this specifically quantified LOX protein was used in the calculation of activity turnover numbers.

### Catalytic Activity and pH-Activity Profile

The pH dependence of AtLOX1 reacting with linoleic acid as substrate showed very similar rates over the pH range of 5–9, maximal at pH 6 (310 turnovers/s). For tomato LOXA activity was optimal around pH 6 (390 turnovers/s) and

**Fig. 2** SDS-PAGE gel analysis of LOX enzymes expressed in *E. coli*. The mutants refer to the AtLOX1 Ala562Gly and tomato LOXA Ala564Gly mutants. The three lanes for each sample represent aliquots (10  $\mu$ l) from the first three 0.5 ml fractions collected from the nickel NTS column purification. Proteins were detected using Coomassie staining. MW molecular weight

was maintained at least 30 and 15% of this optimal activity at pH 8 and pH 9, respectively. SP-HPLC analysis of the products from linoleic acid at pH 6 showed that 9*S*-HPODE accounted for over 95% of the products of both enzymes (Table 1; Figs. 3a, 4c).  $\alpha$ -Linolenic acid reacted at similar rates and similarly formed almost exclusively the 9-hydroperoxide. For comparison to the reactions at the optimal pH 6, the distribution of products from a reaction with linoleic acid conducted at pH 9 was also analyzed by SP-HPLC. Remarkably, the product pattern was indistinguishable from the reaction products at pH 6, i.e., 9*S*-HPODE accounted for >95% of the products (data not shown). This is in contrast to the properties of soybean LOX-1, which is specific for 13*S* oxygenation at its optimal pH 9–10, but changes at lower pH (pH 6 or 7) to producing a mixture of 9- and 13-hydroperoxide products with both *trans-trans* and *cis-trans* conjugated dienes [17].

#### Effects of Active Site Ala–Gly Mutation

By alignment with other LOX enzymes, the residue equivalent to the Ala that has a major influence on reaction stereospecificity [9] is Ala562 in *Arabidopsis* 9-LOX and Ala564 in tomato 9-LOX. This Ala was changed to Gly by site-directed mutagenesis and the expressed enzymes were reacted with linoleic acid. Following reduction of the hydroperoxides, two similar-sized peaks of hydroxy product were obtained by normal phase HPLC (Fig. 3b), identified as 13-HODE and 9-HODE by co-chromatography with standards and by their characteristic identical UV spectra with lambda max 234 nm (cf. ref. [18]). Chiral analysis showed the two products were almost purely the 13*R*-HODE and 9*S*-HODE enantiomers, respectively (Fig. 4d, e).

**Table 1** Linoleic acid products formed by *A. thaliana* AtLOX1 and tomato LOXA

Enzyme	9-HPODE (%)	13-HPODE (%)
<i>A. thaliana</i> WT	98.8	1.2
<i>A. thaliana</i> A562G	68.9	31.1
Tomato WT	99.1	0.9
Tomato A564G	59.9	40.1

	Chiral analysis (%)			
	9 <i>R</i>	9 <i>S</i>	13 <i>R</i>	13 <i>S</i>
<i>A. thaliana</i> WT	0.4	99.6	71.7 <sup>a</sup>	28.3
<i>A. thaliana</i> A562G	0.7	99.3	98.4	1.6
Tomato WT	0.3	99.7	67.7 <sup>a</sup>	32.3
Tomato A564G	0.9	99.1	98.6	1.4

<sup>a</sup> Note that, as shown above, WT produces 13-HPODE as only ~1% of products

A Beckman Ultrasphere silica column (5  $\mu$ m, 25  $\times$  0.46 cm) was eluted at 1 ml/min with hexane/isopropanol/glacial acetic acid (100/2/0.1, v/v/v) with UV detection at 235 nm. TPP triphenylphosphine

#### Arachidonic Acid Metabolism

Plant 9-LOX tend to form a mixture of chiral hydroperoxides when arachidonic acid (an unnatural substrate for a plant) is used as substrate (e.g., ref. [19, 20]). 9-LOX purified from potato tubers and one of the recombinant potato LOX isoforms give 5*S*-HPETE as the major hydroperoxide [21, 22]. Some other plant 9-LOX are reported to give 11*S*-HPETE as the major product [23]. As measured by the radioactive products formed from [<sup>14</sup>C]arachidonic acid (after NaBH<sub>4</sub> reduction of the HPETEs to HETEs), we found that AtLOX1 formed 11-HETE as the major product (accounting for 47% of the total HETEs), together with half as much 5-HETE (23%), and in order of abundance also 9-HETE (11%), 12-HETE (9%), and 8-HETE and 15-HETE (4.5% each). Tomato LOXA formed 11-HETE and 5-HETE in essentially equal amounts (38–39% each), and also 8-HETE (11%), 12-HETE (4%), 15-HETE (3%) and 9-HETE (2%). The

**Fig. 4** Chiral phase HPLC analysis of HODE methyl ester derivatives. Panels a and b: resolution of 9*RS*-HODE and 13*RS*-HODE, respectively. Panel c: 9-HODE from wild-type tomato LOXA. Panel d: 9-HODE from tomato LOXA Ala564Gly. Panel e: 13-HODE from tomato LOXA Ala564Gly. A Diacel Chiralpak AD column (5  $\mu$ m, 25  $\times$  0.46 cm) was eluted at 1 ml/min with hexane/methanol (100/2, v/v) with UV detection at 235 nm

pattern of hydroperoxide products for the tomato LOXA is similar to that illustrated previously for a 9-LOX purified from tomato [6]. We also found that the product profiles for each wild-type 9-LOX with arachidonic acid as substrate were essentially the same at pH 7 and 9; this contrasts with the results shown for a recombinant rice 9-LOX isozyme in which the 5-HPETE product almost disappeared at high pH [24].

#### Catalytic Activity with Other Substrates

Our results using arachidonate ethanolamide (anandamide) as substrate with the two recombinant 9-LOX enzymes are summarized in Table 2. The chiral analyses were performed after reduction to the hydroxy form, HANA, on a reversed-phase Chiralpak AD-RH column in which H(P)ETEs and their methyl ester derivatives are known to run with the *R* enantiomer eluting before the *S* enantiomer [25]. The same appeared to be true for anandamide derivatives, as confirmed using an authentic standard of 15*S*-HPANA prepared using soybean LOX-1, and from the fact that 11*S*-HPANA is the known product of purified 9-LOX from barley and tomato [6]. The most significant

findings were that wild-type AtLOX1 converted anandamide mainly to 11*S*-HPANA (99.4% 11*S*, and accounting for 91% of the total HPANA products). The AtLOX1 Ala562Gly mutant formed 11*S*-HPANA (98.3% 11*S*) plus an additional prominent product, 15*R*-HPANA (93% 15*R*) in a 3:2 ratio in favor of 11-HPANA. Wild-type tomato LOXA also formed mainly 11*S*-HPANA (99.0% 11*S*, accounting for 71% of total HPANA products) plus 16% 5*S*-HPANA (89% 5*S*). The tomato LOXA Ala564Gly mutant formed two additional prominent products, 15*R*-HPANA (93% 15*R*, accounting for 34% of HPANA products) and 9-HPANA (19% of products). On chiral analysis the 9-HANA product chromatographed as one main peak with no definite minor enantiomer, so it was not possible to determine order of elution and infer chirality.

We also tested 1-palmitoyl-2-linoleoylphosphatidylcholine as a potential substrate for AtLOX1 using the bile salt deoxycholate as detergent, a condition that achieves reaction with plant 13-LOX [26], coral 8*R*-LOX [9], as well as several mammalian arachidonate 12-LOX and 15-LOX [27–30]. However, we could detect no reaction with the recombinant 9-LOX, in agreement with a result reported for a purified tomato 9-LOX [20].

**Table 2** Distribution of 9-LOX products from anandamide (2A) and the chirality of selected products (2B)

2A						
Enzyme	H(P)ANA products (% of total)					
	15	11	12	8	9	5

## Discussion

The *Arabidopsis* genome contains six *LOX* genes (Table 3) and there are at least five *LOX* genes in tomato (Table 4). Although tomato has long been used as a source of 9-LOX [31], to our knowledge, the positional specificity, as determined by direct characterization of LOX reaction products, has not been reported for any recombinant *Arabidopsis* or tomato LOX. Our experimental analysis of purified recombinant AtLOX1 and tomato LOXA showed that both proteins function as specific linoleate 9-LOX.

This finding is consistent with phylogenetic analysis showing that AtLOX1 and tomato LOXA are closely related members of the plant LOX family (Fig. 5), and further predicts that other members of this subgroup are 9-LOX as well. In an accompanying paper, Andreou et al. [2] characterize the activity of a related sequence from potato also as a linoleate 9-LOX.

The notion that AtLOX1 and tomato LOXA are homologous proteins is supported by similarities in their expression pattern. Both genes, for example, are expressed to relatively high levels in germinating seedlings [13, 32]. Our results thus support the hypothesis that 9-LOX activity plays a physiological role during the early stages of seedling growth. Plant 9-LOX has been implicated in a variety of developmental and stress-related processes [1, 33]. Recently, oxylipins derived from the 9-LOX pathway were shown to play a role in lateral root development and pathogen defense in *Arabidopsis* [34]. Our data are in agreement with the proposal by Velloso and co-workers that 9-LOX activity in *Arabidopsis* roots can be attributed to LOX1/LOX5 [34].

Using the AtLOX1 and tomato LOXA we re-examined the debated issue of the mode of substrate binding orientation in the active site of 9-LOX, and how this relates to formation of specific chiral products. According to the model we outlined in the Introduction [35], linoleic acid should bind with a carboxyl end-first orientation in the active site of linoleate 9S-LOX, the same conclusion as originally inferred from the hydrogen abstraction results of 1972 with corn 9S-LOX (cf. Fig. 1a) [4]. The model predicts that the Ala-to-Gly switch in 9S-LOX should produce a new product, 13R-HPODE, formed on the same face of the molecule as 9S-HPODE (cf. Fig. 1b). This is exactly what was observed (Figs. 3, 4; Table 1).

We also re-examined the 9-LOX metabolism of anandamide, and also the consequences of the Ala-to-Gly

**Fig. 5** Phylogenetic tree of selected plant LOX enzymes. The enzymes include the six LOX in the *Arabidopsis*, the current five reported for tomato, ten soybean enzymes, and five sequences from potato. The enzymes studied in the present paper are shown in **bold** type. The *asterisk* marks a potato LOX studied in an accompanying paper [2]. GenBank accession numbers are shown

mutation on the distribution of products. As noted in the Introduction, purified barley and tomato 9-LOX were reported to convert anandamide mainly to 11S-HPANA (11S-hydroperoxyanandamide), in contrast to their products with arachidonic acid, which were largely 5-HPETE for barley 9-LOX and 5-HPETE/11-HPETE mixtures for tomato 9-LOX. And, because it appears that the additional functional moiety at the carboxyl end has pushed oxygenation further down the carbon chain, these observations were used to infer that the substrate binding orientation in plant 9-LOX is tail end-first [6]. Although this is a reasonable conclusion, we offer a different interpretation. Whereas van Zadelhoff et al. [6] placed an emphasis on the conversion of arachidonic acid to 5S-HPETE by the linoleate 9-LOX, we note that formation 11S-HPETE is equally common with several of the wild-type enzymes (cf. refs. [6, 20, 23] and the “Results” section above). With anandamide, the balance of oxygenation products tips in favor of 11S-HPANA and in some cases 5S-HPANA remains prominent. Significantly, the Ala-to-Gly mutation induces the formation of 15R-HPANA along with the 11S-HPANA, and 9-HPANA along with 5-HPANA

(“Results”, Table 3). These new findings fit perfectly with the orientation model that predicts carboxyl end-first binding of the substrate. Admittedly, this will require the “extra” ethanolamide moiety at C-1 to be accommodated in the 9-LOX active site, but our surmise is that this is the most straightforward interpretation of the available data.

Butovich and Reddy used the observation that linoleate 9-LOX can metabolize 1-linoleoyl-glycerol to the 9-hydroperoxide to propose the tail-first binding orientation [7]. As an extension of this conjecture, we tested 1-palmitoyl-2-linoleoyl-phosphatidylcholine and could find no reaction. While caution is warranted in interpretation of negative results, this lack of reaction classifies the linoleate 9-LOX along with other LOX enzymes that are predicted to exhibit carboxyl end-first binding and that show no reaction with very large phospholipid esters (arachidonate 8S-LOX and 5S-LOX) [9, 28]. (By contrast, all the LOX enzymes that have predicted tail-first substrate binding do react specifically with phospholipid ester substrates [5, 9, 26–30]). Again, our interpretation is that the 9S-LOX active site can accommodate substrates with C-1 appendages of the size of ethanolamide or glycerol, and that overall, the carboxyl end-first binding is the most satisfactory model for oxygenations by linoleate 9S-LOX enzymes.

**Acknowledgments** We thank Kaye Peterman (Wellesley College) for kindly proving the *AtLOX1* cDNA. This work was supported by NIH grants GM-53638 and GM-074888 (to ARB) and by the US Department of Energy Grant DE-FG02-91ER20021 (to GAH).

## Introduction

Sesamin is a known lipid modulator well investigated in mammalian systems [1–3]. To our knowledge it has never been investigated in fish. As lipid modulation can be of importance to improve the value of vegetable oil in fish diets in relation to aquaculture, we wanted to explore the physiological effects of sesamin in fish. The demand for fish oil for the aquaculture industry from natural pelagic fish populations is expected to outstrip current supply within the next decade [4, 5]. Partial replacement of marine oils with vegetable oils in fish feed is possible and is practiced. This requires new insights that consider the effects of a wide range of bioactive minor lipid components naturally present in the vegetable oils [6]. So far, studies have mostly focused on the production yield when fish are grown on feeds with a partial replacement of fish oil with vegetable oils, e.g. soybean and rapeseed oils. It was shown that up to 50% replacement of fish oils with a number of vegetable oils does not alter fish growth [7]. Thus, feeds with a replacement of 10–25% of fish oil by soybean and rapeseed oil are frequently commercialized [8]. A natural drawback of feeding vegetable oils to fish is decreased amounts of the highly unsaturated fatty acids (HUFA) eicosapentaenoic acid (20:5n-3, EPA), docosapentaenoic acid (22:5n-3, DPA), docosahexaenoic acid (22:6n-3, DHA) and to some extent arachidonic acid (20:4n-6, ARA) and increased amounts of the n-6 fatty acids, mainly linoleic acid (18:2n-6, LA), in the fish muscle. Depending on species, fish have different capabilities to elongate and desaturate fatty acids. In rainbow trout (*Oncorhynchus mykiss*) and salmon (*Salmo salar*), the steps in the elongation and desaturation from alpha-linolenic acid (18:3n-3, ALA) to DHA are well described [9–11]. Thus, new strategies leading to increased levels of n-3 HUFA in fish farmed with feed containing vegetable oils are needed. The increased levels of n-3 HUFA in farmed fish will contribute to positive health effects of the fish and also provide marketing advantages of farmed fish [12].

Sesamin, a minor component of sesame oil, is known to affect fatty acid desaturation and significantly increases the activity of enzymes involved in  $\beta$ -oxidation and expression of these enzymes in rats [2, 3]. Even though confirmation still is required, Ashakumary et al. [2] suggested, that the

underlying mechanism include the expression of peroxisome proliferator-activated receptors (*PPARs*).

Sesamin inhibits cholesterol absorption and synthesis, and tocopherol hydroxylation and urinary excretion by Cytochrome P450 in rats and humans [1, 13–15]. The methylenedioxyphenyl group of sesamin is known to affect cytochrome P450-dependent drug oxidation [16]. Cytochrome P450 (CYP) enzymes are known to play a central role in the oxidative metabolism and biotransformation of a wide range of endogenous and exogenous compounds [17]. Among the numerous CYP families identified, primarily CYP 1-3 are involved in biotransformation of xenobiotics. The CYP 1A subfamily is reported to be expressed in the liver of both mammals and fish [16, 18]. Due to the role of CYP1A isoenzymes in the metabolism and bioactivation of foreign compounds, alteration of the expression of hepatic CYP1A may affect the potential risk of xenobiotics [19]. CYP1A is readily inducible by aryl hydrocarbon (Ah) receptor agonist, thus the activity of CYP1A, measured as ethoxyresorufin O-deethylase (EROD) activity, is used as a biomarker for exposure to xenobiotic compounds in fish.

This study designed to investigate the physiological response of fish to sesamin in combination with vegetable oils with particular emphasis on n-3 HUFA and the n-3 desaturation index. We were especially interested in the physiological effects of sesamin at different n-6/n-3 ratios in the diet provided by either a mixture of linseed and sunflower oil or linseed oil solely. Further, we studied the expression of *PPARs* in liver, and sesamin content in liver and muscle lipid as well as response of total CYP content and CYP1A catalytic activity in liver.

## Materials and Methods

### Chemicals and Reagents

The sesamin/episesamin mixture (1:1, w/w) was a kind gift from Takemoto Oil and Fat Co., Ltd. (Gamagori Aichi, Japan). Fatty acid peaks were identified by comparison with the standard mixture GLC-68 A (Nu-check Prep, Inc, Elysian, MO). All solvents and other chemicals used for analysis were purchased from Merck and were used without further purification. All reagents and other chemicals for total CYP and EROD analysis were purchased from the Sigma Chemical Co. (St. Louis, MO).

### Animals and Diets

Rainbow trout (*Oncorhynchus mykiss*) were fed four different experimental diets. Prior to the study the fish were fed a commercial feed (Nutra Parr, Skretting AB, Västra

**Table 1** The lipid content and relative fatty acid composition (%) in the experimental diets

	MO	MO + S	LO	LO + S
Lipid content	16.3	16.7	17.4	19.8

SAFA saturated fatty acids (14:0, 16:0, 18:0, 20:0, 22:0, 24:0); MUFA monounsaturated fatty acids (16:1, 18:1n-9, 18:1n-7, 20:1, 22:1, 24:1); PUFA polyunsaturated fatty acids; MO mixed oil; MO + S mixed oil + sesamin; LO linseed oil; LO + S linseed oil + sesamin

Frölunda, Sweden). Experimental diets were prepared according to the method of Sanchez-Vazquez et al. [20] and contained casein (18.6%), calcium sulphate (4%), gelatine (3.1%), defatted fish meal (TripleNine, Esbjerg, Denmark) (21.8%), dextrin (9.8%), vegetable oil (21.8%), vitamin and mineral mixture (0.3%), starch (15%) and sodium alginate (4%). An equi-mixture of (+)-sesamin and (–)-episesamin was added at 0.58 g 100 g<sup>-1</sup> feed, in this paper we will refer to this equi-mixture as sesamin. The level of added sesamin was decided from the natural concentration of lignan in sesame oil, i.e. up to 2.5%. In a diet containing 20% sesame oil, this corresponds to 0.58 g 100 g<sup>-1</sup> feed. The four experimental diets used were: (1) mixed oil (linseed oil:sunflower oil, 6:4, by vol) (MO), (2) MO with sesamin addition (MO + S), (3) linseed oil (LO), and (4) LO with sesamin addition (LO + S). The fatty acid compositions of the experimental diets are shown in Table 1. Eight juvenile rainbow trout in each group (initial weight 34 g) were kept in tanks with a water temperature of 10 °C and fed ad libitum for 35 days. This number of fish was used as replicates to study the physiological response of pure sesamin in fish diet, as sesamin has been shown to have individual physiological response in rats (see above). At harvest (average fish weight 53 g), tissues from all fish were dissected, frozen in liquid nitrogen and stored at –80 °C until analyzed.

### Lipid Analysis

Tissues and diets were extracted following the method of Hara and Radin [21]. Total lipids of tissues were separated into phospholipids and triacylglycerols according to Pickova et al. [22]. Total lipids in the diets, and the phospholipids and triacylglycerols of tissues were methylated following the procedure of Appelqvist [23] and the fatty acids were analyzed with a gas chromatograph CP3800 (Varian AB, Stockholm, Sweden) equipped with

flame ionisation detector (FID) and split injector and fitted with a fused silica capillary column BPX 70 (SGE, Austin, Tex.), length 50 m. id. 0.22 mm, 0.25 µm film thickness. The column temperature was programmed to start at 158 °C held 5 min and then increased by 2 °C/min up to 220 °C where it remained for 8 min. The carrier gas was helium (0.8 ml/min) and the make up gas was nitrogen. The injector and detector temperatures were 230 and 250 °C respectively. Fatty acids were identified by comparison with the standard fatty acid mixture GLC-68 and retention times. Peak areas were integrated using Star chromatography workstation software version 5.5 (Varian AB, Stockholm, Sweden). For each group six samples were analyzed in duplicate.

### Sesamin and Episesamin Analyses

For the analysis of sesamin and episesamin, the lipid extracts of tissues and feed were dissolved in hexane and analysed with high performance liquid chromatography (HPLC) [15]. The mobile phase used was hexane/1,4-dioxane (94:4, by vol). The HPLC system was equipped with a Bischoff HPLC pump (Bischoff Analysentechnik und Geräte GmbH, Leonberg, Germany), and an Agilent 1100 series fluorescence detector (Agilent Technologies, Waldbronn, Germany). The HPLC column was Alltech SI 5U silica column (4.6 × 250 mm; Alltech Associates Inc., Deerfield, IL). The fluorescence detector was operated at an excitation wavelength of 296 nm and an emission wavelength of 324 nm. Identification and quantification was achieved by comparison to external standards. For each group six samples were analyzed in duplicate.

### Total Content of CYP and EROD Activity in Liver

For the analysis of total CYP content and EROD activity, only a few samples were available and therefore we choose to only compare the physiological response of sesamin regardless if the oil was MO or LO. For the total CYP analysis, samples also had to be pooled due to technical reasons in the analytical steps (insufficient amount of microsome suspension). For the CYP analysis, three samples from the control group and two from the sesamin group were analyzed. For the EROD analysis six samples from the control group and four from the sesamin group were analyzed.

The liver tissue was homogenized in ice-cold homogenization buffer (0.25 M sucrose and 0.1 mM EDTA in 0.01 M TRIS buffer, pH 7.4) using a Potter-Elvehjem homogeniser. The homogenate was centrifuged for 15 min at 10,000g (4 °C) and the resulting supernatant was spun down for 1 h at 105,000g (4 °C). The microsomal pellets were resuspended in the homogenization buffer and stored

at  $-80\text{ }^{\circ}\text{C}$  until used. The total CYP content was determined spectrophotometrically by the Co- and dithionite difference method (Shimadzu UV-1601PC, Columbia, USA) according to Omura and Sato [24].

Hepatic EROD activity was determined according to a modified method by Jönsson et al. [17]. Standard solutions of resorufin (0–50  $\mu\text{M}$ ) and protein (BSA; 1 mg BSA  $\text{ml}^{-1}$ ) were prepared in HEPES-Cortland (HC) buffer pH 8. The HC buffer was prepared by dissolving 0.38 g KCl, 7.74 g NaCl, 0.23 g  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ , 0.23 g  $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ , 0.41 g  $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ , 1.43 g HEPES, and 1 g glucose in 1 l of distilled water. Microsome suspensions were further diluted in the same buffer (1:5 and 1:10). Aliquots of the microsome suspensions (50  $\mu\text{l}$ ) and of the standard solutions (40  $\mu\text{l}$  of resorufin and 10  $\mu\text{l}$  of BSA) were added in duplicate wells in 96-well plate. A 160  $\mu\text{l}$  aliquot of 7-ethoxyresorufin (12.7  $\mu\text{M}$ ) and NADPH (2.1 mM) in HC buffer was rapidly added to all wells. The plate was then immediately placed in a microplate reader (Wallac 1420 VICTOR<sup>2</sup>, Turku, Finland) and the resorufin fluorescence was monitored for 10 min by repeated measurements at 544 nm (ex) and 590 nm (em). EROD activity was calculated and expressed as pmol of resorufin formed per mg protein per minute. The protein contents of the microsomes were assayed by the method of Smith et al. [25], adapted for microplate readers.

### RNA Analysis

Total RNA was purified from three livers from each group and analyzed in duplicate, using Trizol<sup>®</sup> (Invitrogen), followed by DNase treatment (TURBO DNA-free, Ambion). All protocols were according to the manufacturer's instructions. RNA quality and quantity were determined spectrophotometrically ( $A_{260/280}$ ) by using NanoDrop<sup>®</sup> (ND-1000 Spectrophotometer, NanoDrop Technologies, Wilmington, DE). Samples were stored in RNase-free water at  $-80\text{ }^{\circ}\text{C}$ .

The cDNA was synthesized following a modified protocol from the Taq Man Reverse Transcription Reagents kit (Applied Biosystems). The Oligo d(T)<sub>16</sub> primers were used. The reaction was performed by incubating the samples at 25  $^{\circ}\text{C}$  for 10 min, 48  $^{\circ}\text{C}$  for 6 min, 95  $^{\circ}\text{C}$  for 50 min and was terminated by reducing the temperature to 10  $^{\circ}\text{C}$ . Primers for Real-Time PCR analysis (Table 2) were designed using the Primer Express<sup>®</sup> software based on

available salmon sequences in the GenBank<sup>®</sup> and purchased from Invitrogen (CA, USA). Real-Time PCR was performed in a Prism<sup>®</sup> 7000 system by using gene-specific primers. A 2 $\times$  SYBR<sup>®</sup> Green PCR Mastermix (ABI) was used in the PCR reaction mix of 25  $\mu\text{l}$  with 1  $\mu\text{l}$  primers (final concentration of 0.5  $\mu\text{M}$ ), and 5  $\mu\text{l}$  cDNA. All samples were analyzed in duplicate with a non-template control on each plate. The reference gene used was elongation factor 1 $\alpha$  (EF1A). The reaction was performed by incubating the samples at 50  $^{\circ}\text{C}$  for 2 min, 95  $^{\circ}\text{C}$  10 min and 50 cycles of 95  $^{\circ}\text{C}$  for 10 s and 60  $^{\circ}\text{C}$  for 15 s. Standard curves were made for each primer pair and efficiencies (E) were calculated  $E = 10^{(-1/\text{slope})}$ .

### Data Analysis

Fatty acids, and sesamin and episesamin data are presented as mean values  $\pm$  standard deviation (SD). The General Linear Model (GLM) of SAS (SAS Institute Inc., Cary, NC, version 8.2) was used to compare the physiological responses of the different diets. The model included the fixed effect of treatment and random effect of individual. Relative expression of the different genes, in relation to housekeeping genes were determined using the Relative Expression Software Tool (REST-384<sup>®</sup>-version 1).

## Results

### Growth Measures

No mortality occurred during the experiment. There was no difference in starting weight, final weight or daily growth coefficient (DGC) among the four fish groups (Table 3). The DGC were calculated as:  $\text{DGC} = 100 \times (W_2^{1/3} - W_1^{1/3}) D^{-1}$  with  $W_2$  being final weight,  $W_1$  the starting weight and  $D$  the number of days [26]. The fat contents of the muscle tissues and liver were also similar among treatments (Table 3).

### Fatty Acid Composition

Some of the white muscle fatty acids were significantly affected by the presence of sesamin in the feed (Table 4). The presence of sesamin in the feed increased the

proportion of DHA ( $P = 0.02$ ) in the MO + S group and decreased that of 18:3n-3 ( $P = 0.05$ ) in the LO + S group (Fig. 1; Table 4) with a tendency to increase the desaturation index (n-3 HUFA/18:3n-3) ( $P = 0.06$ ) in MO + S group (Table 4). Sesamin addition also decreased the

proportion of 18:2n-6 in the MO + S group ( $P < 0.01$ ). The total percentage of polyunsaturated fatty acids (PUFA) was significantly decreased in triacylglycerols of MO + S group. The content of DHA was significantly increased ( $P < 0.02$ ) in phospholipid fraction in both MO + S and LO + S group. The proportions of EPA ( $P = 0.04$ ) and total n-3 fatty acids ( $P < 0.01$ ) were significantly increased and that of 18:3n-3 ( $P = 0.02$ ) decreased in the LO + S group phospholipid fraction. The fatty acid composition of the liver and red muscle was not significantly altered by the addition of sesamin in the diet (data not shown).

#### Sesamin and Episesamin

The mixture of sesamin fed to fish was found in white and red muscle and liver with the episesamin levels being higher than the sesamin levels (Table 5). A significantly higher level of sesamin and episesamin in red muscle ( $P = 0.04$ ) and of sesamin in liver ( $P = 0.05$ ) was found in the in the LO + S fed group compared to the MO + S group. The sesamin/episesamin ratio did not differ between the oils within the tissues, but the ratio was significantly

#### Gene Expression

The expression of *PPAR $\alpha$*  was significantly down regulated in liver of fish fed MO + S diet (Fig. 2). In fish fed LO + S diet, *PPAR $\alpha$*  was also reduced, albeit not

**Fig. 2** Relative expression of PPARs in liver of mix oil based diets (a) and of linseed based oil diets (b). Asterisk denotes significant difference from vegetable oil diet without sesamin ( $P < 0.05$ ),  $n = 3$ . *PPAR $\alpha$* ,  $\beta$ ,  $\gamma$  peroxisome proliferator-activated receptor alpha, beta, gamma

significantly. Expression of *PPAR $\beta$*  and *PPAR $\gamma$*  was not significantly affected by the inclusion of sesamin (Fig. 2).

#### Total Content of CYP and EROD Activity

The total amount of cytochrome P450 (CYP) was significantly higher ( $P < 0.01$ ) in the experimental group MO + S (0.117 nmol mg<sup>-1</sup> protein) when compared with mean level of CYP in the experimental group MO (0.086 nmol mg<sup>-1</sup> protein) (Fig. 3). Further, hepatic EROD activity was also higher ( $P < 0.01$ ) in MO + S experimental group (535.8 pmol mg<sup>-1</sup> protein min<sup>-1</sup>), when compared with experimental group MO (535.8 pmol mg<sup>-1</sup> protein min<sup>-1</sup>). Total CYP content and EROD activity were increased by the factors 1.4 and 8 in sesamin fed fish, respectively (Fig. 3).

#### Discussion

This study aimed to investigate the physiological effects of sesamin on fatty acid composition in rainbow trout fed vegetable oils. We were interested to study the effects of sesamin in diets containing different n-6/n-3 fatty acid ratio and different amount of 18:3n-3 substrate for elongation

**Fig. 3** Total amount of CYP,  $n = 6$  for control group and  $n = 4$  for sesamin group (a) and EROD activity,  $n = 3$  for control group and  $n = 2$  for sesamin group (b) in liver. Asterisk denotes significant difference from vegetable oil diet without sesamin ( $P < 0.01$ )

and desaturation. Therefore, we used linseed oil diet (LO) with the n-3/n-6 fatty acid ratio 3.6 and a mixed linseed oil/sunflower oil diet (MO) with the n-3/n-6 fatty acid ratio 1.0. In general, sesamin had the greatest physiological

effect when it was fed in combination with the MO diet, having the higher n-6/n-3 ratio of these two diets. Also in combination with the MO diet, lower levels of sesamin were found in the tissues.

Previously, sesamin has been reported to increase the rate of both peroxisomal and mitochondrial  $\beta$ -oxidation in rats [2, 14]. Even if the  $\beta$ -oxidation rate is low in the white muscle of fish, it is important as the white muscle contributes a larger part of the total body weight [27]. Peroxisomal  $\beta$ -oxidation is involved in the shortening of long-chain fatty acids (including synthesis of DHA from 24:6n-3) [28], in contrast to mitochondrial  $\beta$ -oxidation where saturated fatty acids are preferred substrates [29]. Thus increased  $\beta$ -oxidation at both mitochondria and peroxisomes by sesamin may explain the lower proportion of total PUFA and the increased percentage of DHA in the white muscle triacylglycerol fraction. This is in agreement with results from our in vitro study [30].

The increase in DHA corresponds well to decreased percentages of 18:3n-3 (Fig. 1; Table 4) and increased desaturation index (n-3 HUFA/18:3n-3) (Table 4). The addition of sesamin also significantly decreased the proportion of 18:2n-6 in the MO + S group phospholipid and triacylglycerol fraction (Table 4). In rats, it has been shown that sesamin has effects on the fatty acid composition with especially increased proportions of n-6 fatty acids [13]. The results from this study show more effects on the n-3 fatty acids in fish. An important difference between fish and rat diets is the higher lipid content and also content of 18:3n-3 in the fish diet [13]. One could argue that the amount of substrate (18:3n-3) is one of the reasons for the results obtained in this study. Another possibility is the difference in capacity for elongation and desaturation between species [9].

A slightly higher (non significant) percentage of DHA in phospholipids was found in the MO-fed fish than in the LO-fed fish, which could be due to the higher percentage of 18:3n-3 in the LO diet, in agreement with the suggestion by Tocher et al. [31] that linseed oil results in lower amounts of DHA than rapeseed oil. However in contradiction, in the triacylglycerol fraction DHA is higher in the LO group than in the MO group (non significant). In the white muscle, approximately 75% of the lipids belong to the triacylglycerol fraction (compared to fish of similar stage as in [32]). The triacylglycerol fraction of the white muscle, which is the fraction mostly affected in this study, is the important fraction in terms of the fatty acid composition of fish muscle as human food. The possibility that sesamin can be added to feeds containing vegetable oils with eighteen carbon polyunsaturated fatty acids (e.g. rapeseed oil and linseed oil) to improve their elongation and desaturation in fish towards HUFA, especially DHA, is beneficial in relation to nutrition of both fish and human. It might increase the efficacy of alternate vegetable oil partial

replacement to the fish oil needed in aquaculture production. The fact that the fatty acid composition of the livers was unchanged may be positive in terms of fish welfare.

In fish fed the mixture of sesamin/episesamin, these lignans were found in all tissues analyzed (Table 5) in contrast to rats [33] and humans where mostly the catechol metabolites are found [15]. The ratio sesamin/episesamin was similar in the fish tissues but was lower than in the feed. This finding is in agreement with a study in rats, showing twice as high level of episesamin than sesamin, even though the sesamin/episesamin ratio was one in the diet [34]. This could be caused by different absorption or by different rate of catabolism between the two isomers. The higher sesamin/episesamin ratio in the liver and white muscle compared to red muscle could indicate that sesamin is metabolized and deposited at different rates in the tissues, assuming that the tissues were exposed to the same ratio of sesamin/episesamin. To our knowledge, there are no studies on how fish metabolize sesamin and related compounds. The *in vivo* administrations of sesamin like compounds (methylenedioxyphenyl compounds) to rats and mammals exhibits a biphasic effect on CYP and microsomal oxidation activity that consist of a transient inhibitory phase and a subsequent phase of induction [16]. The level of total CYP and the EROD activity elevation in MO + S fish, indicates induction of cytochrome system in sesamin exposed fish. This indicates that sesamin in fish is recognized as a xenobiotic compound, however the pooled samples and the low power of statistics make it difficult to make any clear conclusions. No other toxic responses by the fish were recognized. In contrast, *in vitro* studies in humans show that sesamin inhibits cytochromes P450 [35].

Many studies in rats have shown effects of sesamin on the target genes or enzymes regulated by *PPARs* [2, 3]. In this study we demonstrate a relative down regulation of *PPAR $\alpha$*  in liver of the MO + S group ( $P = 0.04$ ) and a non significant down regulation in the LO + S group. This effect on gene expression indicates a different response in fish compared to rats. In rats, it has been shown that sesamin stimulates up regulation of genes involved in  $\beta$ -oxidation and metabolism of xenobiotic substances [36]. Similar to sesamin, expression of *PPAR $\alpha$*  has been reported to be down regulated in salmon fed 3-thia fatty acids [37], compounds that have also been associated with up regulation of *PPARs* in mammals [38, 39]. The effects of sesamin on gene expression are further investigated in an *in vitro* study on Atlantic salmon hepatocytes [30].

## Conclusion

The addition of sesamin/episesamin to vegetable oil-based diets increased the amount of DHA in the muscle of

rainbow trout. Both sesamin and episesamin were found in the analyzed muscle and liver and were present at higher levels in fish fed linseed oil than the mixed oil. The addition of sesamin to the diet of fish fed vegetable oils may enhance the nutritional value of the fish muscle, in particular the fatty acid quality. Studies in large scale, with market-sized fish and sesamin of feed grade would be interesting to do in order to evaluate the commercial use of sesamin in aquaculture production. Dose-response studies in larger scale are needed in order to achieve information of the economical viability of sesamin in aquaculture feeds. Sesamin could play an important role in enhancing the fatty acid quality in fish fed vegetable oils to complement the limited amounts of fish raw materials.

## Introduction

Due to a shortage of fish oil and an expected increase in aquaculture production, research is focussing on replacement of aqua feeds with increasing amounts of vegetable oils [1, 2]. It is well known that substitution of fish oil with vegetable oils decreases the content of n-3 long chain polyunsaturated fatty acids (LCPUFA) in the fish tissues [3]. In terms of the consumer's health, it would be beneficial to maintain as high as possible amounts of n-3 LCPUFA in fish muscle [4]. In a previous study from our group, we have shown that sesamin in vegetable oil based fish feed increased the percentage of DHA in the white muscle of rainbow trout (*Oncorhynchus mykiss*). This result indicates that vegetable-based ingredients may have beneficial effects in preserving the healthy fatty acid profile of fish muscle [5].

Sesamin is the main lignan in sesame seed and has been associated with several effects on lipid metabolism in mammals [6]. Although very little is known for fish, sesamin was shown to increase  $\beta$ -oxidation [7, 8] and affect elongation and desaturation of fatty acids in rats [9]. Sesamin was also shown to lower serum levels of triacylglycerols (TAG) and cholesterol in rats and humans [7, 10, 11]. A wide range of enzymes involved in the desaturation and  $\beta$ -oxidation of fatty acids are affected by sesamin, both at activity and mRNA levels (e.g., acyl-CoA oxidase and carnitin palmitoyl transferase) [6, 7, 10]. Many of these effects are presumed to be caused through the activation of peroxisome proliferator-activated receptors (PPARs) and inhibition of sterol regulatory element-binding protein-1 (SREBP-1) [8, 12].

In this study, we aimed to investigate the metabolic effects of sesamin on  $\beta$ -oxidation, elongation, desaturation, fatty acid profile and the expression of some lipid-related genes in hepatocytes isolated from Atlantic salmon (*Salmo salar* L.).

## Materials and Methods

### Chemicals and Reagents

The radiolabelled fatty acid [ $1\text{-}^{14}\text{C}$ ] 18:3n-3 (specific radioactivity 50 mCi/mmol) was obtained from American Radiolabeled Chemicals (St. Louis, MO, USA). The non-

labelled 18:3n-3, essential fatty acid free bovine serum albumin (BSA), fetal bovine serum (FBS), Leibovitz-15 (L-15), 2',7'-dichlorfluorescein, 2',7'-dichlorfluorescein and collagenase, Phosphate buffer saline (PBS), phenylethylamine and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), ethylenediaminetetraacetic acid (EDTA), sodium bicarbonate solution, L-glutamine, were obtained from Sigma Chemical Co. (St. Louis, MO, USA) and metacain MS-222 from Norsk Medisinaldepot (Norway). Sesamin (sesamin/episesamin mixture, 1:1, w/w) was a kind gift from Takemoto Oil and Fat Co., Ltd. (Gamagori Aichi, Japan). Fatty acid peaks were identified by comparison with the standard mixture GLC-68 A (Nu-check Prep, Inc, Elysian, Minnesota, USA). Ammonium dihydrogenphosphate, perchloric acid (HClO<sub>4</sub>), thin-layer chromatography (TLC)-plates, all solvents and other chemicals for fatty acid and sesamin analysis were purchase from Merck (Darmstadt, Germany).

### General Description

Hepatocytes isolated from Atlantic salmon were incubated with radiolabelled and non-radiolabelled  $\alpha$ -linolenic acid (18:3n-3) in the presence and absence of sesamin. For the experiment with non-radiolabelled fatty acid fatty acid composition and expression of some lipid related genes were measured. The radiolabelled 18:3n-3 was used to measure changes in fatty acid metabolism, desaturation and  $\beta$ -oxidation. The details of the different methodological and analytical steps are described below.

### Isolation of Hepatocytes

Atlantic salmon of approximately 800 g (NIVAs Research Station, Drøbak, Norway) were kept in seawater at 10 °C and fed on a commercial diet prior to isolation of hepatocytes. Hepatocytes were isolated from three fish at three different time points and used for three experiments: (1) Effects of sesamin (0.05 mM) on fatty acid  $\beta$ -oxidation, elongation, desaturation and fatty acid profile, (2) dose response study (0, 0.005, 0.05, 0.075 and 0.11 mM sesamin final concentration in the medium) on the effect on gene expression, (3) time course study over a 72 h time period and the effect of gene expression. The livers were perfused following the two-step collagenase procedure developed by Seglen [13] and modified by Dannevig and Berg [14] and conducted as per Kjær et al. [15]. At each time point, the hepatocytes were pooled from three livers and incubated as described below.

### Incubation of Hepatocytes with Linolenic Acid 18:3n-3

The isolated hepatocytes were incubated with 35 nmol, 2.5  $\mu\text{Ci}$  of [ $1\text{-}^{14}\text{C}$ ] 18:3n-3 as well as non radiolabelled

18:3n-3, final fatty acid concentration of 7  $\mu$ M, in 5 ml of L-15 culture medium without FBS. The radiolabelled fatty acid was added to the medium as potassium salt bound to BSA. To each experimental flask (four radiolabelled and seven with non-radiolabelled 18:3n-3), dimethyl sulfoxide (7.4  $\mu$ l/5 ml) without or with sesamin (final concentration 0.05 mM) was added and to control and treatment flasks (each four radiolabelled and seven with non-radiolabelled 18:3n-3) and in other two flasks sesamin but no fatty acid was added. The cells were incubated at 12 °C for 48 h. The radiolabelled experiment flasks with and without sesamin (four each) were washed and harvested in PBS for further analysis of  $\beta$ -oxidation, radiolabelled lipid classes and radiolabelled cellular fatty acids. The cells in the two flasks with no fatty acid substrate added were denatured after the incubation and thereafter added radiolabelled substrate in order to be used as a negative control for the acid soluble products (ASP) measurements and high pressure liquid chromatography analyses. In the non-labelled study, control and sesamin flask (four each) were washed in PBS prior to isolation of mRNA according to the protocol RNeasy<sup>®</sup> Mini Kit for gene expression analysis and three flasks of each control and sesamin were washed and harvested in PSB for fatty acid and sesamin analysis.

#### Incubation of Hepatocytes for Dose Response and Time Course Study

The cells for the dose response study were washed in PBS 24 h after seeding and incubated in L-15 culture medium with 10% FBS (the fatty acid composition of L-15 + FBS was: 14:0 = 8.4%; 14:1 = 0.6%; 15:0 = 2.3%; 16:0 = 31.7%; 16:1 = 4.1%; 18:0 = 31.7%; 18:1 n-9 = 14.9%; 18:1n-7 = 2.7%; 18:2n-6 = 3.7%; 18:3n-3 = 1.0%; 20:3 n-6 = 0.8%; 20:4n-6 = 2.4%; 20:5n-3 = 0.5%; 22:5n-3 = 0.9%; 22:6n-3 = 1.2%) and with five different concentrations of sesamin. Sesamin dissolved in dimethyl sulfoxide (7.4  $\mu$ l/5 ml medium) was added at final concentrations of 0.005 mM, 0.05 mM, 0.075 mM and 0.11 mM to duplicate flasks of cells in a regression design and incubated for 42 h at 12 °C. For the time course study, a final concentration of 0.05 mM sesamin in culture medium was added to the hepatocytes in duplicate flasks. The cells were incubated for 0, 18, 24, 42, 48, 66 and 72 h. As a control in both the dose response study and the time course study, dimethyl sulfoxide (7.4  $\mu$ l/5 ml medium) was added to the cells without sesamin. After incubation, the cells were washed in PBS prior to isolation of mRNA according to the protocol RNeasy<sup>®</sup> Mini Kit for gene expression analysis.

#### Analysis of Lipids in Cells and Medium

Lipids from cells and medium incubated with [1-<sup>14</sup>C] 18:3n-3 were extracted according to Folch et al. [16] and the fatty acid composition of the cells was determined by reversed phase high pressure liquid chromatography as described by Narce et al. [17]. The mobile phase was acetonitrile:water (85:15 v/v) at a flow rate of 1 ml/min and a temperature of 30 °C. The column used was a symmetry 3.5  $\mu$ m C<sub>18</sub> column and the fatty acids were detected with a radioactive detector A-100 (Radiomatic Instrument & Chemicals, Tampa, FL, USA). The fatty acids were identified by comparison of their retention times with those of external standards. The lipids extracted from the medium were separated on TLC-plates into various classes using a mixture of petroleum ether, diethyl ether and acetic acid (113:20:2 v/v/v). The separated lipid classes, phospholipids (PL), monoglycerides (MG) free fatty acids (FFA) and triacylglycerols (TAG) were visualised by spraying with 0.2% 2',7'-dichlorofluorescein in methanol and identified by comparison to standards under UV-light. The lipid classes were scraped off and dissolved in scintillation fluid for scintillation counting (TRI-CARB 1900 TR, Packard Instruments). The esterified fatty acids, PL, MG and TAG fractions within the media will be denoted as secreted fatty acids.

Lipids from the non-radioactive cells and the medium used for the dose response and the time course studies were extracted by using hexane:isopropanol (3:2 v/v) [18]. Total lipids were converted to fatty acid methyl esters by using 20% boron trifluoride–methanol complex according to Appelqvist [19] and analysed with Gas Chromatograph CP3800 (Varian AB, Stockholm, Sweden) according to Fredriksson et al. [20].

#### Measurements of $\beta$ -Oxidation

The capacity of  $\beta$ -oxidation was measured by determination of the <sup>14</sup>C-containing oxidation products, ASP and CO<sub>2</sub> as described by Christiansen et al. [21]. <sup>14</sup>C-CO<sub>2</sub> produced during the incubation of the cells was measured by transferring 1.5 ml of the medium to glass vials sealed with a rubber stop and a central well containing a Whatman filter paper with 0.3 ml phenylethylamine/methanol (1:1 v/v). The medium were acidified with 0.3 ml 1 M HClO<sub>4</sub> and <sup>14</sup>C-CO<sub>2</sub> was trapped for 1 h. Then the filter papers were placed in vials and dissolved in 8 ml of scintillation fluid for scintillation counting (Radiomatic Instrument & Chemicals, Tampa, FL, USA). The amount of <sup>14</sup>C-ASP was determined by adding 0.5 ml ice cold 2 M HClO<sub>4</sub> to the incubation medium and incubated at 4 °C for 1 h, then

the samples were centrifuged at  $17,950\times g$  for 10 min at 10 °C and 200  $\mu$ l of the supernatant was collected for scintillation counting (Radiomatic Instrument & Chemicals, Tampa, FL, USA). The remaining supernatant was neutralised with NaOH and the different ASPs were detected by using high pressure liquid chromatography equipped with a ChromSep Inertsil C8-3 column (250  $\times$  4.6 mm stainless steel), an UV-detector at 210 nm and radioactive detector A-100 (Radiomatic Instrument & Chemicals, Tampa, FL, USA) coupled to the UV detector. The mobile phase was 0.1 M ammonium dihydrogenphosphate adjusted with phosphoric acid to pH 2.5, the flow rate was 1 ml/min. The components were identified by comparison to external standards and retention times.

#### Protein Determination and Acyl-CoA Oxidase (ACO) Activity

The protein content of the cells was determined by using the total protein kit (Micro Lowry/Peterson's modification) [22, 23] and measured at 540 nm in a 96 well plate reader Titertek, Multiscan (Labsystem, Finland). The ACO activity was determined according to Small et al. [24]. The oxidation of 2,7 dichlorofluorescein (LDCF) was measured with a GBC UV/VIS 98 spectrophotometer (502 nm; GBC Scientific equipment, PTY, LTD, Melbourne, Victoria, Australia) during 3 min. The assay mixture contained 10  $\mu$ l LDCF, 50  $\mu$ l peroxidase type II in 0.1 M Tris, 10  $\mu$ l BSA (60 mg/ml), 10  $\mu$ l FAD, 0.15 mg protein and H<sub>2</sub>O up to 1 ml. The reaction was started with 10  $\mu$ l PalmCoA (6 mg/ml 0.1 M TRIS).

#### Total RNA Extraction, cDNA Synthesis and Real Time PCR

Total RNA was isolated from the cells using the RNeasy<sup>®</sup> Mini Kit with on-column Rnase free DNase set (Qiagen,

MD, USA). All protocols were according to the manufacture's instructions. Purity and density were measured by optical density (NanoDrop<sup>®</sup> ND-1000 Spectrophotometer, NanoDrop Technologies, Wilmington, Delaware, USA) and samples were stored in RNase-free water (Eppendorf, Hamburg, Germany) at  $-70$  °C.

The cDNA was synthesised following a modified protocol from the Taq Man Reverse Transcription Reagents kit (Applied Biosystems). The Oligo d(T)<sub>16</sub> primers were used. The reaction was performed by incubating the samples at 25 °C for 10 min, 48 °C for 6 min, 95 °C for 50 min and was terminated by reducing temperature to 10 °C.

Primers for Real-Time PCR analysis (Table 1) were designed based on available salmon sequences in the GenBank<sup>®</sup> using the Primer Express<sup>®</sup> software and ordered from Invitrogen (CA, USA). Real-Time PCR for the dose response study was performed in a Prism<sup>®</sup> 7000 system with gene-specific primers for scavenger receptor type B (SRB-I), PPAR $\alpha$ ,  $\beta$ ,  $\gamma$  and cluster of differentiation 36 (cd36) (Table 1). A 2 $\times$  SYBR<sup>®</sup> Green PCR Mastermix (ABI) was used in the PCR reaction mix of 25  $\mu$ l with 1  $\mu$ l primers (final concentration of 0.5  $\mu$ M), and 5  $\mu$ l cDNA. All samples were analyzed in duplicate with non-template control on each plate. Elongation factor 1 $\alpha$  (EF1A) and RNA polymerase II polypeptide (RPL2) were used as reference genes. The reaction was performed by incubating the samples at 50 °C for 2 min, 95 °C 10 min and 50 cycles of 95 °C for 10 s and 60 °C for 15 s. Standard curves were made for each primer pair and primer efficiency ( $E$ ) calculated [ $E = 10^{(-1/\text{slope})}$ ]. The Real-Time PCR for the time study and the cells incubated with non radiolabelled 18:3n-3 was performed in a LightCycler<sup>®</sup> 480 system using SYBR<sup>®</sup> Green PCR Mastermix (Roche, Oslo, Norway) and gene-specific primers for SRB-I,  $\Delta 5$  desaturase,  $\Delta 6$  desaturase, PPAR $\alpha$ ,  $\beta$ ,  $\gamma$ , cd36, acyl-CoA

**Table 1** Sequence of primers

oxidase (ACO) and carnitine palmitoyl transferase I (CPT1) (Table 1). The PCR reaction mix (10  $\mu$ l) consisted of 1  $\mu$ l forward and reverse primer (final concentration of 0.5  $\mu$ M), 4  $\mu$ l cDNA and 5  $\mu$ l mastermix. All samples were analysed in duplicate with non-template control on each plate and for each gene. RPL2 was used as a reference gene. The reaction was incubated at 95 °C for 5 min, 45 cycles of 95 °C for 10 s, 60 °C for 15 s and 72 °C for 15 s. Standard curves were made and the primer efficiency ( $E$ ) was calculated for each primer pair using the LightCycler® 480 software.

### Statistical Analysis

Relative expressions of the different genes, in relation to housekeeping genes, were determined using the Relative Expression Software Tool (REST-384®-version 1). For all other data, the student t-test in Microsoft Office Excel 2003 was used. The number of experimental replicates was three for the non-radiolabelled experiment [except the dose response and the time course study ( $n = 2$ )] and was four for the radiolabelled experiment. Differences were considered as significant at  $P < 0.05$ .

## Results

### Lipid Content and Fatty Acid Profiles in Hepatocytes Incubated with 18:3n-3

The total mean lipid content of the control cells (1.7 mg = 1.3%) was not different from that of cells incubated with sesamin (1.4 mg = 1.0%). Table 2 shows the fatty acid profiles of the hepatocytes incubated with non-radiolabelled 18:3n-3 in the absence and presence of sesamin. The addition of sesamin significantly reduced saturated fatty acids (SAFA,  $P < 0.01$ ) and monounsaturated fatty acids (MUFA,  $P < 0.02$ ) and elevated n-3 polyunsaturated fatty acids (n-3 PUFA,  $P < 0.01$ ). Especially, the proportion of DHA was significantly increased in the sesamin-incubated hepatocytes, from 27.2 to 36.0% ( $P < 0.01$ ) while the proportion of eicosapentaenoic acid (20:5n-3, EPA) did not change. The desaturation index (n-3 LCPUFA/18:3n-3) was increased from 27.0 to 33.8 in the presence of sesamin ( $P < 0.05$ ).

The proportions of radioactive fatty acids in the hepatocytes incubated with  $^{14}\text{C}$  18:3n-3 in the presence or absence of sesamin are shown in Table 3. The percentage of  $^{14}\text{C}$  DHA was significantly higher in the sesamin treated group than in the control group, 20.2 versus 10.5%, respectively ( $P < 0.001$ ). Sesamin also increased the percentage of  $^{14}\text{C}$  18:4n-3 ( $P = 0.04$ ) and the total amount of  $^{14}\text{C}$  LCPUFA ( $P = 0.01$ ). Notably, the percentage of  $^{14}\text{C}$

EPA was higher in the control than in the sesamin group, 12.3 versus 7.5%, respectively ( $P < 0.01$ ). As with the non-labelled 18:3n-3 experiment, the desaturation index ( $^{14}\text{C}$  LCPUFA/18:3n-3) was significantly higher in the sesamin group ( $P = 0.03$ ).

Distribution of radioactive products from  $^{14}\text{C}$  18:3n-3 substrate in cellular and secreted lipids, lipid classes and  $\beta$ -oxidation products.

The total amount of  $^{14}\text{C}$  18:3n-3 in cells and medium and the distribution of radiolabelled fatty acids in cellular, secreted lipids (i.e., all esterified lipid classes including phospholipids (PL), monoglyceride (MG), triacylglycerol (TAG) and free fatty acids), as well as the amount of radiolabelled fatty acids in the  $\beta$ -oxidation products (ASP,  $\text{CO}_2$  and total  $\beta$ -oxidation products = ASP +  $\text{CO}_2$ ) are shown in Table 4. Significantly more  $^{14}\text{C}$  18:3n-3 have been taken up into the sesamin-incubated hepatocytes than into the control hepatocytes, 3.2 and 2.8 nmol fatty acids mg protein $^{-1}$ , respectively ( $P < 0.01$ ). In contrast, the

amount of secreted lipids (PL + TAG + MG) tended to be lower in sesamin treated cells than the control cells ( $0.10 \pm 0.02$  and  $0.20 \pm 0.07$ , respectively,  $P = 0.09$ ), mainly the TAG content decreased in the medium (Table 4). The addition of sesamin increased the total  $\beta$ -oxidation (ASP +  $\text{CO}_2$ ), ( $P < 0.01$ ) of 18:3n-3 and especially the amount of ASP increased from  $0.03 \pm 0.02$  to  $0.08 \pm 0.02$  ( $P < 0.01$ ). The compound increased by sesamin in the ASP fraction was acetate representing 53.5% of ASP in the control group and 72.6% of ASP in the sesamin group ( $P < 0.01$ ). Oxaloacetate and malate decreased correspondingly (Fig. 1). No significant differences in the enzymatic activity of acyl-CoA oxidase between the groups were found. The acyl-CoA oxidase activity was  $0.35 \pm 0.08$  and  $0.39 \pm 0.02$  m unit mg protein $^{-1}$  in control and sesamin cells, respectively.

### Gene Expression

In the dose response experiment the relative expression of SRB-I, PPAR $\alpha$ , PPAR $\gamma$  and cd36 were significantly ( $P < 0.05$ ) downregulated at 0.05 mM sesamin and were downregulated at all concentrations of sesamin above

(Fig. 2). In the cells incubated with sesamin (0.05 mM) and 18:3n-3, the expression of CTP1 was significantly upregulated by a factor 3.8 ( $P < 0.01$ ) and expression of PPAR $\gamma$  was down-regulated by a factor 2.2 ( $P < 0.01$ , Fig. 3). In the time study, significant effects ( $P < 0.05$ ) of sesamin (0.05 mM) on the relative expression of  $\Delta 6$  and  $\Delta 5$  desaturases were found after 24 and 42 h incubation, respectively (Fig. 4). Both  $\Delta 6$  and  $\Delta 5$  desaturases followed the same pattern of relative expression.

### Discussion

In this study, we demonstrated clear effects of sesamin on fatty acid metabolism in salmon hepatocytes. An overview of the findings from this study is presented in Fig. 5. In the hepatocytes incubated with nonradioactive 18:3n-3 and sesamin, the percentage of DHA ( $P < 0.01$ ) and PUFA ( $P = 0.01$ ) and the desaturation index (LCPUFA/18:3n-3) ( $P = 0.04$ ) were significantly increased, and the percentage of 16:0 was significantly decreased ( $P < 0.01$ ). In both the sesamin and the control cells incubated with  $^{14}\text{C}$  18:3n-3, elongation and desaturation occurred. Strikingly 18:4n-3 and DHA increased while 18:3n-3 and EPA decreased in cells incubated with sesamin. This can be explained by the increase in activity of  $\Delta 6$  desaturase and  $\beta$ -oxidation by sesamin leading to increased conversion of 18:3n-3 to DHA. In addition, as the level of DHA in the liver cells has not reached the levels found before [15], it is unlikely that DHA would be  $\beta$ -oxidised to EPA.

The proportion of acetate in the acid soluble product (ASP) fraction increased by sesamin addition (Fig. 1,  $P < 0.01$ ). Previously, sesamin has been reported to increase the rate of both peroxisomal and mitochondrial  $\beta$ -oxidation in rats [7, 8]. In rat hepatocytes, acetate has been defined as the main product of peroxisomal  $\beta$ -oxidation [25]. However, we do not know if this is the case in salmon. The analysis of enzymatic activity of acyl-CoA oxidase did not show any significant differences between

the groups, but a slight increase in the sesamin group. The peroxisomal acyl-CoA oxidase activity in rat liver was significantly increased by dietary sesamin [7, 8, 12]. The peroxisomal  $\beta$ -oxidation is also involved in the synthesis of DHA (shortening of 24:6n-3 to 22:6n-3) [26]. Therefore, the increased DHA levels in this study and the previous study [5] could also result from increased peroxisomal  $\beta$ -oxidation. On the other hand, the increased gene expression of CPT1 indicates that mitochondrial  $\beta$ -oxidation is also influenced by sesamin addition. Since sesamin increased the production of radio labelled acetate and not oxaloacetate and malate  $\beta$ -oxidation, one can suggest that 18:3n-3 and its elongated and desaturated products were mainly oxidised in the peroxisomes and that  $\beta$ -oxidation of other fatty acids mainly occurs in the mitochondria as evidenced by the increase expression of CPT1. Kiessling et al. [27] showed that SAFA are the preferred substrate for selective  $\beta$ -oxidation in mitochondria in rainbow trout. In the sesamin treated cells incubated with non-radiolabelled 18:3n-3, lower percentage of 16:0 was found, a possible result of increased mitochondrial  $\beta$ -oxidation.

Sesamin tended to decrease the amount of secreted lipids in the medium by  $\sim 50\%$  from 0.20 to 0.10 nmol mg protein $^{-1}$ , the most decreased lipid class was TAG. This suggests lower levels of very low-density lipoprotein (VLDL) secreted from the liver. This result is in agreement with studies on rats, which show that sesamin lowers the levels of VLDL and TAG in plasma and serum [7, 10, 11, 28]. Increased levels of n-3 fatty acids are also shown to decrease the secretion of TAG in salmon [15, 29]. The reduced TAG level can also be an effect of the increased content of n-3 LCPUFA in this study.

**Fig. 2** Relative expression of SRB-I, cd36, PPAR $\alpha$ , $\beta$ , $\gamma$  in the four concentrations 0.005, 0.05, 0.075, 0.11 mM compared to the control group incubated with out sesamin, significant differences between the groups at the different concentrations are denoted with Asterisk ( $n = 2$ )

Kushiro et al. [10] suggests that the serum lipid lowering effects of sesamin are primary a response to decreased activity of lipogenic enzymes. In this study, we showed a

downregulation of *PPAR $\gamma$* , which may indicate a reduced lipid synthesis. *PPAR $\gamma$*  is highly expressed in adipose tissue in rodents, humans and Atlantic salmon where it, among other functions, is involved in lipid synthesis [30–33]. The expression of *cd36*, a gene involved in lipid storage and

uptake is regulated by *PPAR $\gamma$*  [34] and was also down-regulated in the dose-response study at 0.05 and 0.075 mM sesamin. This may also affect the content of TAG in secreted lipids.

The relative expression of both  $\Delta 5$  and  $\Delta 6$  desaturases was significantly downregulated by sesamin at several time points. Our first expectation was that the expression of these desaturase would be upregulated. However, at all time points from 42 to 72 h the relative expression of  $\Delta 5$  and  $\Delta 6$  desaturase was lower in the sesamin cells compared to the control cells (Fig. 4). One could speculate that the lower levels of mRNA are due to increased translation at a higher rate than the transcription rate. Interestingly, the curve for both  $\Delta 5$  and  $\Delta 6$  desaturases in the sesamin cells follow the same pattern over time and is different compared to the control cells. At this stage, we can not explain exactly how sesamin is affecting the expression of  $\Delta 5$  and  $\Delta 6$  desaturase. We know that there is a clear effect on the expression of  $\Delta 5$  and  $\Delta 6$  desaturase and that sesamin significantly increases the desaturation and elongation from 18:3n-3 to DHA. However, the present study can not explain whether that is due to increased transcription or translation or whether there are other mechanisms involved.

This study provides strong evidence that sesamin is a potent modulator of fatty acid metabolism in Atlantic salmon hepatocytes. In agreement with the results of our in vivo study [5] sesamin increased desaturation and

elongation of 18:3n-3 towards DHA. The  $\beta$ -oxidation of lipids was clearly increased as well as the expression of CPT1, a gene involved in  $\beta$ -oxidation. Furthermore, sesamin has an effect on several lipid related genes such as genes for  $\Delta 5$  and  $\Delta 6$  desaturase. It decreases secretion of lipid from hepatocytes, affecting in particular the TAG-levels. This knowledge can be of interest within aquaculture production in order to improve fish muscle quality by increasing its DHA levels.

various ray fish liver oils to the Pacific white shrimp *Litopenaeus vannamei*, the species of greatest commercial importance in the Americas.

## Experimental Procedure

### Source of Shrimp

Postlarvae at PL18 stage were obtained from the shrimp larviculture laboratory ‘Syaqua-Mexico S.A. de C.V.’, Coast of Hermosillo, Sonora, Mexico. They were transported to the Kino Bay Experiment Station (KBES), University of Sonora at Kino Bay, Sonora, Mexico, and maintained in an outdoor 6-m<sup>3</sup> circular (2.9-m diameter) fiberglass tank filled with seawater. Animals were maintained here for approximately one month and fed a commercial feed (Camaronina, Agribands Purina<sup>®</sup>, Ciudad Obregon, Sonora, Mexico) with a protein content of 40% until initiation of the experiment, at an overall mean ( $\pm$ SD) wet body weight of  $1.01 \pm 0.04$  g.

### Experimental Systems

The experiment was conducted at the Wet Laboratory of Aquaculture Nutrition and Biotechnology of the KBES, using two identical recirculating experimental culture systems, each system composed of 50 30-cm diameter circular polyethylene tanks (bottom area of 0.07 m<sup>2</sup> and 19-L capacity), a 1,100-L sump tank, a biofilter, a 19" sand filter (Jacuzzi, Model L-190-7, Little Rock, AR, USA), a 1.5-HP pump (Jacuzzi, Model 150MF-T, Little Rock, AR, USA), a 20- $\mu$ m pore size cartridge filter (Pentek, Model Big Blue PL5010BB, Sheboygan, WI, USA), a 120-W ultraviolet light chamber (Rainbow Lifeguard, Model UV97, El Monte, CA, USA), a 1,500-W in-line heater (Aquatic Ecosystems, Model DE-6115, Apopka, FL, USA), and a 1/2 HP in-line chiller (Aquatic Ecosystems, Model AE62B, Apopka, FL, USA). Aeration for both culture systems was provided by a 1.0-HP blower (Fuji, Model VFC40, Saddle Brook, NJ, USA). Seawater recirculation rate in each tank was 1.9 L/min (14,400% exchange in 24 h), and 5–10% daily replacement with fresh-filtered seawater was applied. The culture systems were interconnected with each other, i.e., they shared the same water quality. Shrimp were stocked into tanks at a rate of four individuals/tank (56 shrimp/m<sup>2</sup>).

### Extraction of Ray Fish Liver Oil

Livers were obtained from four different ray fish species, two from the Gulf of California, stingray (*Dasyatis brevis*) and golden cownose ray (*Rhinoptera steindachneri*), and two from the Gulf of Mexico, spotted ray (*Aetobatus*

*narinari*) and cownose ray (*R. bonasus*). Livers were removed from the fishes immediately after landing, frozen and transported to the Nutrition laboratory at the University of Sonora's main campus, Hermosillo, Sonora, Mexico, to perform oil extraction. Livers were homogenized for 2 min and incubated for 1 h in a water bath at 35 °C. Anhydrous sodium sulfate was added (30%, w/w) and the homogenate was mixed for 3 min and then centrifuged at  $1,150 \times g$  for 20 min at 25 °C [11].

### Experimental Treatments

Four feeds were prepared according to a basal experimental feed formulation (Table 1). Each dietary treatment was prepared with a different ray fish liver oil. A fifth experimental feed, included as a control treatment, was prepared with Menhaden fish oil (MP Biomedicals Inc., Solon, OH, USA). Feeds were prepared by cold extrusion using a Hobart mixer (Model A-200, Hobart, Troy, OH, USA). They were dried overnight at 40 °C, ground to appropriate size and stored frozen until use. Shrimp were fed to slight excess, with the daily ration divided into two equal amounts, one feed at 0800 and one at 1700. Faeces, exuviae and excess feed were siphoned out of all tanks each morning. Treatments were assigned randomly to at least 16 replicate tanks.

### Water Quality

A multi-function oxygen meter (YSI, Model Y85, Yellow Springs, OH, USA) was employed to measure water temperature, dissolved oxygen, and salinity each day. Weekly measurements of the concentrations of ammonia, nitrite, and nitrate were performed according to standard chemical procedures [12, 13].

### Proximate Composition of Feeds and Fatty Acid Analysis

Proximate composition of feeds was determined according to standard procedures (procedures 984.13, 920.85, 925.09, and 923.03 for protein, crude fat, moisture, and ash, respectively) [14]. For fatty acid analysis, lipids were extracted from feeds and abdominal shrimp muscle [15]. Quantification was performed by a gravimetric method after drying an aliquot under nitrogen. Fatty acids (FA) were transesterified using boron trifluoride (14% boron trifluoride in methanol, Sigma, St Louis, MO, USA). Fatty acid methyl esters (FAME) were analyzed with a gas chromatograph (Varian, Model CP 3800, Walnut Creek, CA, USA) equipped with a 30 m  $\times$  0.25 mm fused silica capillary column (Model CP WAX 52CB, Varian Inc., Palo Alto, CA, USA), and a flame-ionization detector [16]. They were identified by comparison of retention times to those of known standards

and quantified using heptadecanoic acid (17:0) as an internal standard [17]. Triplicate composite muscle samples were processed for fatty acid analysis, each composite sample consisted of tissue from the last abdominal segment of four individuals at intermolt stage taken from different tanks.

#### Statistical Analysis

Growth, survival (arcsine-transformed, untransformed data are shown), and shrimp muscle fatty acid content data were

analyzed by one-way ANOVA with a significance level of  $P \leq 0.05$ . Mean separation was applied using Tukey's Honestly Significant Difference (HSD) method. All statistical analyses were performed using Statistical Analysis System software (SAS Institute Inc. 1999-2000, Software Release 8.1, Cary, NC, USA).

## Results

### Water Quality

Mean values ( $\pm$ SD) for water temperature, dissolved oxygen, salinity, pH, ammonia, nitrite, and nitrate were  $31.7 \pm 0.18$  °C,  $5.87 \pm 0.12$  mg/L,  $38.7 \pm 2.25\%$ ,  $8.0 \pm 0.0$ ,  $0.12 \pm 0.03$  mg NH<sub>4</sub>-N/L,  $0.04 \pm 0.01$  mg NO<sub>2</sub>-N/L, and  $3.16 \pm 0.53$  mg NO<sub>3</sub>-N/L, respectively.

### Proximate Composition of Feeds

Proximate composition of the various feeds was characterized by homogeneous mean values for protein, crude fat, moisture and ash content (Table 2).

### Shrimp Growth and Survival

No significant differences in growth or survival of shrimp were observed among treatments at the end of the experiment (Table 3).

### Fatty Acid Analysis of Oils and Feeds

PUFA and HUFA represented the largest proportion of identified FAME of all ray fish liver oils, as well as of Menhaden fish oil and their respective feeds, ranging from 293.73 to 375.61 mg/g oil and from 8.4 to 14.52 mg/g feed (Tables 4, 5). Spotted ray liver oil and the feed prepared with it contained the highest amount of saturated fatty acids (197.86 mg/g oil and 11.02 mg/g feed, respectively). Monounsaturated fatty acids were more abundant in Menhaden fish oil and feed (174.47 mg/g oil and 8.35 mg/g feed) (Tables 4, 5). In the case of specific fatty acids, the content of arachidonic acid (ARA) was highest in spotted ray liver oil and feed. Spotted ray liver oil also contained the greatest amount of linoleic acid (LOA) and linolenic acid (LNA) (Table 4), but, in the feeds, the greatest content of these fatty acids corresponded to that prepared with Menhaden fish oil (Table 5). Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) were more abundant in Menhaden fish oil and in its respective feed (Tables 4, 5).

#### Total Lipid and Fatty Acid Analysis of Shrimp Muscle Tissue

Total lipid in shrimp muscle tissue ranged from 1.03 to 1.37% of wet weight, with no significant differences among treatments at the end of the feeding trial (Table 6).

Similarly to what was observed for oils and feeds, fatty acids of shrimp muscle tissue were mainly composed of PUFA and HUFA (Table 6). LOA, LNA, EPA, and DHA, more abundant in the feed containing Menhaden fish oil, were also more abundant in muscle tissue of shrimp receiving this dietary treatment. Specifically, the

<sup>a–e</sup> See footnotes of Table 4 for explanation

concentration of EPA in muscle tissue of shrimp fed the diet with Menhaden fish oil (5.93 mg/g muscle wet weight) was significantly greater than those of shrimp receiving feeds prepared with stingray, golden cownose ray, and spotted ray oil (3.47, 4.43, and 4.02 mg/g muscle wet weight, respectively), but not significantly greater than that of shrimp fed the diet with cownose liver oil (5.05 mg/g muscle wet weight). In the case of DHA, muscle tissue of

shrimp fed the treatment with Menhaden fish oil (3.45 mg/g muscle wet weight) was significantly more concentrated than those of shrimp fed diets with stingray and spotted ray liver oil (2.01 and 2.52 mg/g muscle wet weight, respectively), but not statistically more concentrated than those of the treatments with cownose ray and golden cownose ray liver oil (3.13 and 2.78 mg/g muscle wet weight, respectively) (Table 6).

## Discussion

### Water Quality

Adequate water quality was maintained throughout the study, for all physico-chemical parameters and levels of nitrogenous wastes were always kept within levels considered optimal for shrimp culture [18–21].

### Proximate Composition of Feeds

The homogeneity and small variability in the proximate composition of protein, crude fat, moisture and ash of the various feeds confirmed their isolipidic and isoproteic nature, and thus, their adequate preparation.

### Shrimp Growth and Survival

The lack of significant differences in final weight, weight gain or survival of shrimp revealed that the four ray fish liver oils evaluated were as efficient in promoting growth and survival of *L. vannamei* as Menhaden fish oil, an ingredient known for its adequate nutritional value to shrimp and fish [5]. These results effectively illustrate a practical application of a locally available resource that is currently being wasted. In this respect, it would be of interest to explore the use of the other parts of the ray fish body, i.e., the complete head and trunk with all other viscera, which like the liver, are discarded on shore or directly into the sea. On the other hand, the incorporation of ray fish liver oils into shrimp feeds represents only one of the many possible applications that, as other fish oils, they may have. For example, the preparation of the “so-called” omega-3-rich supplements for human consumption, their use in food products like baked goods and baking mixes, meat products, gravies, and sauces, among others [22].

### Fatty Acid Analysis of Oils and Feeds

Although added at a moderate level (5% of feed dry weight), the fatty acid composition of the oils undoubtedly influenced that of the resulting feeds, as illustrated by the higher levels of ARA found in spotted ray liver oil (52.16 mg/g oil) and its respective feed (1.85 mg/g feed), as well as by the greater levels of EPA and DHA of Menhaden fish oil (99.64 and 108.09 mg/g oil, respectively), also greater in the feed prepared with it (3.57 and 3.59 mg/g feed, respectively) (Tables 4, 5).

In the same way as Menhaden fish oil, used as a control treatment, the most prominent aspect of the ray fish liver oils evaluated was their high content of HUFA. In fact, all four liver oils were higher in ARA (ranging from 19.28 to 52.16 mg ARA/g oil) than Menhaden fish oil (8.33 mg

ARA/g oil) (Table 4). Menhaden fish oil had the highest concentration of EPA and DHA (99.64 and 108.09 mg/g oil, respectively) (Table 4), results that were consistent with previous data for this oil. For example, an EPA and a DHA content of 140 and 80 mg/g oil, respectively [22] or an EPA and a DHA content of 11.0 and 9.1% of total fatty acids [23] versus 14.7 and 15.9% of total fatty acids in this study. These fatty acids also were found in considerable concentrations in cownose ray, golden cownose and stingray liver oil (an EPA content ranging from 61.53 to 64.67 mg/g oil and a DHA content from 64.91 to 101.64 mg/g oil, respectively) but in moderately low concentrations in spotted ray liver oil (16.82 and 9.45 mg/g oil, respectively) (Table 4). However, spotted ray liver oil had a particularly high concentration of ARA (52.16 mg ARA/g oil), more than six times greater than that of Menhaden fish oil. Regardless of the family they belong to (n-3 or n-6 family), *L. vannamei* is reported to have a nutritional requirement for HUFA and not for PUFA [24, 25]. In this context, the fatty acid profile of the ray fish liver oils evaluated seems to adequately satisfy such requirement, and at the same time, explains their growth-promoting effect on *L. vannamei*, comparable to that of world renowned Menhaden fish oil.

Few other studies of the fatty acid profile of ray fish liver are available. EPA and DHA concentrations of 48.4 and 55.7 mg/g oil, respectively, have been reported for liver oil from golden cownose ray [11], as compared to 62.87 and 81.01 mg/g oil, respectively, for the same species in this study (Table 4). In liver oil of stingray, an EPA content of 53 mg/g oil and a DHA content of 48 mg/g oil have been reported [26], while in the present study this species had 61.53 and 64.91 mg/g oil, respectively (Table 4). EPA and DHA contents of 59.0 and 100.0 mg/g oil, respectively, were reported in *Gymnura marmorata* [26]. Levels of EPA and DHA in liver of the ray fishes *R. marginata*, *D. marmorata*, and *Rhinobatos cemiculus* have been reported to range from 1.88 to 5.01% and from 5.64 to 13.4% of total fatty acids, respectively [9]. In this study, the levels of these fatty acids varied from 2.8 to 11.08% and 1.57 to 13.49% of total fatty acids, respectively. In general, results of previous studies and of the present investigation are comparable not only in terms of PUFA and HUFA comprising the major fraction of identified fatty acids, but also in terms of the relatively high concentration of HUFA like EPA and DHA [9, 27].

### Total Lipid and Fatty Acid Analysis of Shrimp Muscle Tissue

Total lipid found in shrimp muscle tissue varied from 1.03 to 1.37% of wet weight, agreeing with data reported for *L. vannamei* (ranging from 0.71 to 2.10% of wet weight) [28, 29]. Although dietary lipid level is known to influence

muscle total lipid [30], the lack of significant differences among treatments in this study can be explained by the isolipidic nature of the feeds.

To a large extent, fatty acids of shrimp muscle tissue reflected the dietary fatty acid profile. The direct influence of dietary fatty acids on the fatty acid profile of shrimp tissues has been demonstrated a number of times in the past [28–35]. In this study, differences in dietary fatty acids elicited significant differences in the fatty acid content of muscle tissue among some dietary treatments, e.g., muscle tissue of shrimp fed the diet with Menhaden fish oil was significantly higher in EPA than muscle of shrimp fed diets with stingray, golden cownose ray or spotted ray liver oil. Shrimp fed Menhaden fish oil had a muscle tissue concentration of DHA statistically greater than muscle of shrimp fed stingray or spotted ray liver oil (Tables 5, 6). However, these differences were not reflected in shrimp growth or survival, supporting the earlier observation that the four ray fish liver oils evaluated seem to satisfy the dietary fatty acid requirements of *L. vannamei*.

In conclusion, PUFA and HUFA content of liver oils of the ray fishes evaluated were of comparable magnitude to that of Menhaden fish oil, an ingredient known for its adequate nutritional quality to shrimp and fish. When incorporated into shrimp feeds, the oils evaluated were as efficient as Menhaden fish oil in promoting growth and survival of *L. vannamei* and demonstrated one of the many possible applications of a locally available resource that is currently being wasted.

2005 the fish export earnings had replaced the traditional coffee as the leading export [3].

Lipids and fatty acids (FAs) have been studied in tissues of freshwater fish from all parts of the world [4]. This has led to the recognition of a so-called freshwater pattern, in contrast to a marine pattern, where the freshwater fish are able to convert the essential FAs 18:2n-6 and 18:3n-3 to longer FAs and physiologically important, highly unsaturated FAs [4, 5]. In this manner algae and plants with low nutritional value as food for herbivore fish will be converted into food with higher nutritional value. It is established that lipid and FA contents vary both within and between species [4], apparently more in tropical freshwater fish than in fish from colder waters [6]. Many factors may be responsible for the variation, i.e. internal factors like genetic variation, age, sex, condition, starvation, reproductive cycle, and external factors like diet, season, temperature.

A plethora of feeding experiments, particularly on salmon (*Salmo salar*) and Nile tilapia, two of the most common species in fish farming, have been conducted to study the influence of the diet on the FA composition of the edible tissue of the fish. Heavy impact of the FA composition of the diet on the FA composition of the fish tissue is evident, e.g. in salmon [7] and in Nile tilapia [8]. In line with this, studies on freshwater tropical fish in the wild have indicated the importance of the diet for the FA composition of the fish tissue [6, 9]. However, recently investigations reluctant to the heavy dietary control of the tissue FA composition and leaning more towards genetic control have surfaced [10, 11]. Indeed, tissue FA composition has been used for identification of stocks of marine fish [12].

Only two of the many species of fish inhabiting the lakes Victoria and Kyoga, Nile tilapia and Nile perch, have been investigated for tissue FAs [11]. Differences in the FA compositions were found between these two species and populations. The differences were even greater compared with Nile tilapia from other African lakes [13], and compared with this species collected in other parts of the world. It was of general interest to determine the tissue FA composition of other fish species used for consumption from lakes Victoria and Kyoga, and also to study if the pattern of species and population differences were of the same magnitude as in Nile tilapia and Nile perch. The heart tissue was chosen since it has been extensively used in identification of fish stocks [12]. It is a well defined tissue, easy to subsample, and the lipids are dominated by phospholipids.

In the present investigation tropical freshwater fish from seven different species were collected from three different sites, one at Lake Victoria and two at Lake Kyoga. The objectives were to detect how the FA composition/profiles

of the lipids in white muscle and heart tissue varied with species and populations, to explore the importance of diet and genetics for the tissue FA composition, and to report on the nutritional value of the muscle tissue.

## Materials and Methods

### Sample Collection

Specimens of Nile perch (*L. niloticus*), Nile tilapia (*O. niloticus*), marbled lungfish (*P. aethiopicus*), African catfish (*C. gariepinus*), Lake Victoria squeaker (*S. victoriae*), *B. docmas*, and *T. zilli* were caught in Bukungu on Lake Kyoga in October 2005, in Lwampanga on Lake Kyoga in December 2005, and in Napoleon Gulf in Lake Victoria in November 2005 (Fig. 1; Table 1). Three fleets of graded multifilament gillnets of mesh size 1–7 inches at an interval of 0.5 inches were set every evening and retrieved in the morning the following day. At each landing site a fleet would be located inshore, mid-shore and offshore, about 100, 100–200 and 200–300 m from the shore, respectively, at a water depth of 10 m or less. Fish specimen were identified according to Greenwood [20] and only mature specimen with a total length greater than: 28 cm for *O. niloticus*, 60 cm for *L. niloticus*, 73 cm for *P. aethiopicus*, 50 cm for *C. gariepinus*, 35 cm for *B. docmas*, 13 cm for *S. victoriae* and 13 cm for *T. Zilli* were selected. The fish

**Fig. 1** The fish were collected in Napoleon Gulf (V) in Lake Victoria, and Bukungu (B) and Lwampanga (L) at Lake Kyoga

**Table 1** Food groups and major food items of the seven investigated species

Species	Feeding habit/life stage	Major food items	References
<i>Oreochromis niloticus</i> (Nile tilapia)	<5 cm	Zooplankton	[14]
	TL > 10 cm	Bivalves, <i>C. nilotica</i> or oligochaetes.	[15, 16]
	All size groups	Algae, fish and plant material phytoplankton and bottom detritus, rarely/occasionally ingest crustaceans, insect larvae and zooplankton	
<i>Lates niloticus</i> (Nile perch)	<20 cm	Mainly on invertebrates, especially the prawn <i>Caridina nilotica</i> , zooplankton, chironomids.	[17]
	Adult Nile perch	Shifts to a fish diet with increasing size, like <i>Rastrineobola argentea</i> , Tilapinnes and juvenile Nile perch.	
<i>Protopterus aethiopicus</i> (marbled lungfish)	Omnivorous	Detritus, algae, Odonata, molluscs and small fish especially haplochromines.	[1] [18]
<i>Synodontis victoriae</i> (Lake Victoria squeaker)	Omnivorous	Chronomid larvae, Ostracods, Odonata, fish remains, Povilla, insect remains and higher plant material.	[18]
	Matures 13–21 cm		
<i>Clarias gariepinus</i> (African catfish)	Omnivorous	Small fishes, insects' larvae (Chironomid larvae and pupae), molluscs and plants (zooplankton).	[1] [19]
<i>Bagrus docmas</i>	Carnivorous	Mainly insect larvae (Odonata and terrestrial insects (cricket), crustaceans and small fishes especially haplochromines.	[18]
<i>Tilapia zilli</i>	Omnivorous	Higher plants and ingest bottom deposits	[1]
	Matures 13–15 cm		

were brought to the laboratory on ice and immediately deep frozen at  $-20^{\circ}\text{C}$  until analysis after 2–4 weeks.

#### Laboratory Methods

The FAs were determined in sub-samples of the tissues, weighing approximately 30–50 mg. The heart was carefully washed in water to remove blood and dried on filter paper, and the subsample was cut from the tip. From the white dorsal muscle the subsample was cut from the side about 2/5 of the distance from snout to tail, carefully avoiding red muscle, skin and bone. The subsamples were transferred to 15-mL thick-walled glass tubes containing an accurately determined amount of internal standard (19:0). After addition of 1 mL of anhydrous methanol containing 2 M HCl and exchange of the atmosphere in the tubes with nitrogen gas, the tubes were securely closed with Teflon-lined screw caps and placed in an oven for 2 h at  $90^{\circ}\text{C}$  for complete methanolysis.

After cooling to room temperature, the tubes were opened and the methanol evaporated down to about 0.5 mL by a stream of nitrogen gas and 0.5 mL distilled water was added to reduce the solubility of the formed FA methyl esters (FAME) which were extracted with  $2 \times 1$  mL hexane.

One microliter of the combined hexane extracts were injected splitless (the split was opened after 4 min), and chromatographed on a 25 m  $\times$  0.25 mm (i.d.) fused silica column with polyethylene-glycol (PEG) as stationary

phase, with a thickness of 0.2  $\mu\text{m}$  (CP-WAX 52CB Chrompack) and helium at 20 psi as mobile phase. The column was mounted in Hewlett-Packard 5890A gas chromatograph equipped with a Hewlett-Packard 7673A autosampler and a flame-ionisation detector (FID). The injector temperature was set at  $260^{\circ}\text{C}$  and the detector temperature at  $330^{\circ}\text{C}$ . The oven was programmed as follows:  $90^{\circ}\text{C}$  for 4 min,  $30^{\circ}\text{C}/\text{min}$  to  $165^{\circ}\text{C}$ , then  $3^{\circ}\text{C}/\text{min}$  to  $225^{\circ}\text{C}$ , where it was left isothermally for 10.5 min before cooling for the next run. The FID signal was A/D converted, recorded, stored and treated in Chromeleon 6.60 software.

The chromatographic peaks were identified by comparison with a chromatogram of a standard mixture of 20 FAME, GLC reference standard 68D from Nu-Chek-Prep (Elysian, Minn., USA), and by chromatographing selected samples under identical conditions with mass-spectrometric detection on Fison 800 GC-MS.

To monitor the performance of the column in the gas chromatograph, the standard mixture of FAME was chromatographed at regular intervals for each tenth sample. Empirical response factors relative to 18:0 were computed for the 20 FAME present in known amounts in the standard mixture. The response factors for each of the FAME not present in the standard mixture were estimated by comparison with the standard FAME which resembled them most closely in terms of chain length and number of double bonds. The areas of the FAME peaks were corrected with the response factors, and the relative amount of each FA in

a sample was expressed as a percentage of the sum of all FAs in the sample. The total amount of FAs in the tissue was determined by relating the total area of all FAME peaks to the area of the peak of the internal standard, 19:0.

A response factor for determination of the level of cholesterol from the sum of the areas of two peaks representing degradation products of cholesterol was obtained from calibration curves based on four different concentrations of cholesterol and cholesteryl stearate, respectively, together with known amounts of the internal standard 19:0, carried through methanolysis and gas chromatography. The response factor was found to be  $0.27 \pm 0.02$  relative to 19:0.

In the area of the chromatograms between 14:0 and 18:0 two peaks of methyl alkenyl ethers, i.e. *cis* and *trans* derived from plasmalogen with 18:0 side chain, and five peaks of dimethyl acetals derived from plasmalogens with 16:0, 17:0, 18:0, 18:1n-9 and 18:1n-7 side chains, respectively, were identified by mass spectrometry. The areas of these peaks were summed up. An average molecular weight of these seven components of 310 and an average weight of the parent plasmalogens of 750 gave a response factor of 0.4.

#### Statistical Methods

Corrected areas of chromatographic peaks were subjected to multivariate statistics using principal component analysis (PCA) available in the SIRIUS 7.0 software package [21]. The relative values (i.e. percentage of the sum) of the FAs were logarithmically transformed, thereby leveling out the quantitative differences among FAs. With each sample positioned in the multi-dimensional space described by the log-transformed variables (FA), new coordinates (principal components, PCs) in the directions of the largest and second largest variance among the samples were computed using SIRIUS [21]. In this manner the relationship between the samples could be described in much fewer dimensions than the original, retaining the systematic variation among the samples. The relative positions of the samples were displayed by projecting them on a plane defined by two new coordinates, i.e. PC1 and PC2, resulting in PC-plots.

The PC-plots are only qualitative displays of the relationship among the samples, they do not cover the total variation among them. Quantitative measures of the difference among the samples were obtained in two ways. Based on the average values for the fish from each species and location for the 14 most abundant FAs the five first PCs covered 91% of the total variance among the samples, as calculated from the normalized and log-transformed values. A hierarchical cluster analysis was then performed on the Euclidean distances between the samples in the 5D space based on the five PCs.

The other method for quantifying, Soft Independent Modeling of Class Analogy (SIMCA) [22] available in the software package SIRIUS [21], was used to determine the differences between the seven species. This computation was based on the 35 most abundant FAs. The normalized values were standardized within each species, i.e. by dividing the values for each FA by the standard deviation of that FA within each species. PCs were then fitted to the samples of each species and cross validation analysis [23] was done to get the best PC(s) that adequately describe the species. Space-filling models were then constructed around the PC(s) with an outer 95% confidence limit,  $RSD_{max}$ . The distance to the model, RSD, of each fish was determined. A fish belongs to a species when its RSD is lower than the  $RSD_{max}$  of the model.

#### Results

Regardless of tissue, species, population (site) the most abundant saturated FA (SAFA) was palmitic acid (16:0) followed by stearic acid (18:0) (Tables 2 and 3). Odd number SAFA pentadecanoic acid (15:0) and margaric acid (17:0) were present in small levels.

The dominating monounsaturated FA (MUFA) was oleic acid (18:1n-9) in all species except in *P. aethiopicus* (lungfish), where it was exceeded by vaccenic acid (18:1n-7). The level of 18:1n-9 was higher in the muscle tissue (4–18%) than in the heart tissue (4–13%)

Among the polyunsaturated FAs (PUFA) docosahexaenoic acid (DHA) 22:6n-3 and arachidonic acid (AA) 20:4n-6 were dominating in both muscle and heart tissue. PUFA was the dominating group, with MUFA the group present in the lowest levels, i.e. PUFA > SAFA > MUFA. The ratio  $n - 3/n - 6$  was 0.5–3 in the muscle and 0.4–1.6 in the heart tissue. In the heart tissue the n-6 PUFA was generally present in higher amounts than in the muscle tissue. The rather high standard deviations indicate large individual differences within each species.

Two components with longer retention times than that of 24:1n-9 appeared in higher amounts in the heart tissue than in the muscle tissue. The two components were identified by GC-MS as two isomeric degradation products of cholesterol,  $m/z = 368$ , cholesta-3,5-diene and cholesta-2,5-diene [24, 25]. It has turned out that the decomposition of cholesterol is reproducible, and these two peaks were used to determine the level of cholesterol in the tissue sample. The muscle tissue contained around 50 mg cholesterol per 100 g tissue, and the heart tissue contained from three to ten times as much, Tables 2 and 3.

The total amount of dimethylacetals and methyl alkenyl ethers amounted to 0.09–0.60 mg/g in the muscle tissue and 0.42–2.66 mg/g in the heart tissue.

A univariate approach, i.e. evaluating one FA in Tables 2 and 3 at a time, makes it impossible to compare all the seven species sampled at the three different sites/locations. To extract the total information from the average values of the 14 most abundant FAs in the seven species collected at the three sites, we employed multivariate principal component analyses. The FA composition of the lungfish is distinct from those of the other species for both muscle and heart tissue (Fig. 2a, c). Since all samples in these PC-plots influence the position of each other, the lungfish samples, being the most distinct, are squeezing the other samples together. Recalculation without the lungfish samples reveals that the other six species also have distinct, species specific FA compositions of the tissues (Fig. 2b, d).

Separate PCA on each of the seven species, including each fish, shows that the FA composition in both tissues is distinctly different between the three landing sites (Fig. 3).

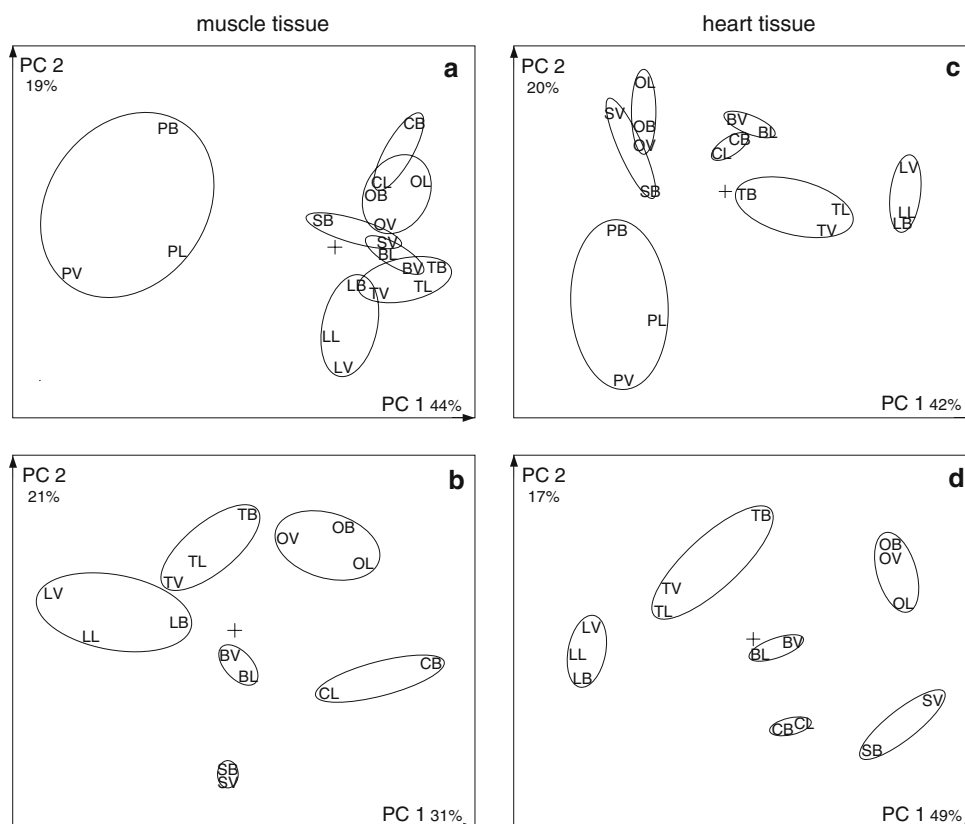

The PC-plots in Figs. 2 and 3 are, however, only a qualitative display of the differences, and cover only parts of the total variation among the samples. To obtain a quantitative measure where the total variation is taken into account, space filling models for each species, pooling the samples from the three (two) landing sites, were carried out using SIMCA [22] available in software package SIRIUS [21] based on 35 most abundant FAs. The average

distances expressed as RSD of all fish to the seven models for each of the heart and muscle tissues were calculated, Table 4. The vast majority of the fish were correctly allocated to their own species with only 15% not classified. No fish were wrongly classified. For the heart tissue, one fish (*O. niloticus*), and for the muscle tissue, four fish (*O. niloticus* and *T. Zilli*) were allocated to another species in addition to their own.

## Discussion

The results are characterized by large variations in the FA composition. A large individual variation is obvious from the large SD of the FA values, Tables 2 and 3. In spite of this, there is a systematic difference within each species between fish from the three locations, Figs. 3 and 4. Furthermore, differences between the species were even greater than the differences within the species, Fig. 2. Variations, both within and between species have been a commonplace observation for fresh water fish [11, 26]. Various factors such as diet, genetic variation, temperature, age, size and season are responsible for variability in FA composition of the tissues of fresh water fish [4]. Of these factors, diet is supposed to be dominating [27, 28]. Zenebe et al. [6] found a remarkably large variation in the lipid and

**Fig. 2** PC-plots of the average samples of fish from the respective species and locations based on the 14 most abundant FAs. The first letter in the code indicates the species: *L L. niloticus*, *O O. niloticus*, *P P. aethiopicus*, *C C. gariepinus*, *S S. victoriae*, *B B. docmas*, *T T. zilli*. The second letter indicates the location where they were caught: *V* Napoleon Gulf in Lake Victoria, *B* Bukungu at Lake Kyoga, *L* Lwampanga at Lake Kyoga. **a** muscle tissue with all species, **b** muscle tissue without *P. aethiopicus*, **c** heart tissue with all species, **d** heart tissue without *P. aethiopicus*. The percentage of the total variation among the samples along each of the two PC's is given

**Fig. 3** PC-plots based on 35 FAs of samples of muscle tissue and heart tissue from each fish from each location: *triangles* Lwampanga at Lake Kyoga, *circles* Napoleon Gulf in Lake Victoria, *squares*

Bukungu at Lake Kyoga. The percentage of the total variation among the samples along each of the two PC's is given

FA contents of the herbivorous *O. niloticus* in five Ethiopian lakes. They concluded that the FA content reflects the food quality of the fish feed, indicating that the statement “You are what you eat” applies particularly well to herbivores. They maintained that a species specific FA pattern can hardly be detected.

However, some doubts about how important the diet is for the composition of the FAs in the tissues have recently been expressed. Bahurmiz and Ng [29] state that the deposition of FAs in the fillet of red hybrid tilapia was influenced primarily by the FA composition of the experimental diets. Still, they found that the concentrations of 16:0 were generally high in the fillet regardless of dietary treatments, and that total MUFA were maintained somewhat constant at 33–37%. Ng et al. [30] have found a relatively uniform concentration of 16:0 in Nile tilapia despite being fed diets with a difference of about 20% in the level of this FA. They also found high levels of DHA even with low levels in the experimental diet, i.e. 20% vs. 5%. Ng et al. [31] fed tilapia palm oil-based diets with 47% and 76%, respectively, of SAFA but did not detect a

significant increase in the deposition of SAFA in fish muscle compared to fish fed a cod-liver oil based diet with 16% SAFA. Other researchers have also found that dietary SAFA tend to be incorporated into fish fillets within narrowly defined physiological levels. Francis et al. [32] found no correlation between the amount of SAFA in the diet and the SAFA in the fillet of Murray cod. Olsen et al. [33] have shown that tilapias have the ability to bio-convert C18 FA to highly unsaturated FA. The FA content of the food had slightly influenced the FA content of the dorsal muscle tissue of Nile tilapia [10]. The dominance of long-chained PUFA in the fish tissue, particularly DHA which was absent in both the algal and commercial diets (the control), indicated that the elongation and desaturation enzymes were very effective in the herbivorous *O. niloticus*. The temperature had little influence on the PUFA content of *O. niloticus*. These researchers, contrary to their earlier anticipations [8, 13], now state that *Oreochromis* seems to have a rather great capacity to modify FA, found in algal food, into their own species specific FA pattern.

**Table 4** The average relative distance of the fish from each species from all sites expressed as residual standard deviations (RSD) to the respective statistical models

Maximum allowed distances of the models based on 95% confidence limits, are given as RSD<sub>max</sub>. Averages which fall within a model are shown in bold. The first number in parentheses after the total number of fish for each species indicates the number of fish which do not fall into their own model, i.e. nonclassified. The second number in the parentheses indicates the number of fish which fall into both their own model and into another model, i.e. biclassified

The seven species we have studied belong to six families (Fig. 4) with 270 genera and more than two thousand species and numerous undescribed forms. A fast emergence of morphological changes and new species has been observed in Lake Victoria [34]. These fish are also rather stationary, e.g. *Tilapia spp.* movements in Lake Victoria were typically short (<1 km), and there were no systematic shifts in centres of gravity of populations [35]. The East African lakes contain closely spaced patches of habitat [36]. This may lead to different patterns of gene expression, i.e. differences in the transcriptomes, among the various populations [37], resulting in differences in the FA composition of the membrane lipids.

There is poor correlation between feeding habits of the fish species and FA composition of their tissues. This may infer that there is a low dietary effect on the FA composition. For example *T. zilli*, feeding on higher plants and bottom deposits and *L. niloticus* feeding primarily on fish, Table 1, have the smallest difference in FA composition (Fig. 5). *O. niloticus*, with algal and plant material as the major food items, is grouped together with *C. gariepinus*,

which are omnivorous, feeding mostly on insects and small fishes (Fig. 5).

The marbled lungfish, *P. aethiopicus*, belongs, according to the traditional morphologically based classification, to a different class than all the six other species (Fig. 4). The classification based on FA composition of the white muscle tissue shows the same distinction (Fig. 5). The further classification of three catfish species in one order, Siluriformes, and the three others in a different order, namely Perciformes, (Fig. 4) is, however, not paralleled by the FA classification (Fig. 5). Here the cichlid Nile tilapia is grouped together with the two catfish species *S. victoriae* and *C. gariepinus*, and the catfish *B. docmas* is grouped together with the two Perciformes *T. zilli* and *L. niloticus*. As discussed above, this deviation from the traditional classification cannot be explained by differences/similarities in diet.

The fish species studied here are very lean having between 2 and 6 mg total FAs per gram of muscle tissue, average 3.4 mg/g. This means that there are only small amounts of storage lipids and then mostly membrane lipids

**Fig. 4** Classification of the seven species according to Greenwood [20] and Okaromon et al. [57]. The numbers of genera and species are obtained from Wikipedia

**Fig. 5** Hierarchical cluster analysis of average samples of fish from the respective species and locations. The clustering is based on the 14 FAs present at the highest levels in the muscle samples. Five principal components were determined, describing 91% of the total variation among the samples, and the Euclidean distances between the samples positioned in the 5D space was the basis for the cluster analysis. The codes are explained in Fig. 2

in the cells. The general assumption is that the FA composition of the neutral, storage lipids reflect trophic influences much better than the physiologically more important phospholipids [38]. The formation of the phospholipids of the membranes are subjected to genetic control [39]. This suggests that the species differences in FA composition (Fig. 4) are genetically determined.

Furthermore, it suggests that the observed differences within the species among fish from the different locations (Fig. 3) are also of genetic character and not results of differences in foraging strategy.

The lipid level in the heart tissue is about five times higher than in the muscle tissue, i.e. with an average content of total FAs of 15.5 mg/g tissue, spanning from 7 to 29 mg/g

(Tables 2 and 3). There is no correlation between the total FA content of the muscle and heart tissues from fishes from the various species/locations. The cells in the heart tissue do not contain storage lipids. They are much smaller than the cells in white muscle tissue, about one fifth in diameter, and contain many more mitochondria than the muscle cells [40]. Therefore there are much larger amounts of membrane lipids on a tissue weight basis in the heart. This explains the higher levels of total FAs.

There is also a qualitative difference between the lipids in the heart and white muscle cells, with a different FA composition, i.e. lower levels of SAFA and higher levels of MUFA, but about the same levels of PUFA. Within the PUFA there are less n-3 and more n-6 FAs in the heart tissue, giving an average n-3/n-6 ratio of  $1.0 \pm 0.4$ , that is significantly,  $P < 0.01$  (student's *t*), lower than the ratio in the muscles,  $1.7 \pm 0.7$ . The large difference in FA composition between the polar lipids of the heart and white muscles emphasizes the low importance of the dietary lipids on the composition of the FA in the tissues.

The n-3/n-6 ratios are typical for freshwater fish, where the ratio lies in the interval 0.5–3.8, compared to the interval 4.7–14.4 for marine fish [4]. From a nutritional point of view the ratio is close to the recommended ideal value of between 0.5 and 1 [41]. However, these species are so lean that it will be impossible to cover the daily recommended intake of 500 mg 20:5n-3 and 22:6n-3 by eating fish alone [42].

## Cholesterol

As a natural component of membranes, regulating their fluidity, cholesterol is found in all tissues. The method of direct methanolysis of tissue samples used in the present investigation allows for quantitative determination of cholesterol since the cholestadiene derivatives that are formed during workup and chromatographic procedure are detected in the gas chromatograph [25]. We found between 30 and 60 mg cholesterol per 100 g muscle tissue with an average of 46 mg/100 g. The few data available on freshwater fish show approximately the same values: Three Brazilian farmed freshwater species were reported by Moreira et al. [43] to contain approximately 50 mg/100 g. Francis et al. [44] found approximately 60 mg/100 g, and Siddhuraju and Becker [45] approximately 70 mg/100 g cholesterol in Nile tilapia in feeding experiments. Piironen et al. [46] found cholesterol contents in the range 50–100 mg/100 g of the edible parts of fish from Finnish waters. Mathew et al. [47] found between 22 and 148 mg/100 g cholesterol in 97 species of Indian fish with the majority between 45 and 65 mg/100 g. In the freshwater species the cholesterol content was found to be lower than in their marine counter-parts. This is in contrast to

Oehlenschläger [48], who reported that the cholesterol content of the edible part of freshwater fish was found to be generally higher than the cholesterol content of marine fish species. Our results tend to support the finding of a lower level of cholesterol in freshwater fish.

Being largely of interest from a nutritional viewpoint, most cholesterol determinations have been carried out on the edible tissue of fish, and also in liver samples caused by studies of cholesterol synthesis. The present investigation is probably the first report on quantitative determination of cholesterol in fish hearts. It showed about five times higher levels in the heart tissue than in the muscle tissue, i.e. an average of 46 mg/100 g in the muscle tissue and 230 mg/100 g in the heart tissue.

Oehlenschläger [48] showed that the cholesterol content decreased the fatter the fish was. This was explained by the fact that cholesterol is a component of the phospholipids of cell membranes and not of depot fat within the cells, and the number of cells does not increase with an increase in the amount of depot fat. Francis et al. [49], on the other hand, suggested that higher muscle cholesterol content can be related to higher carcass lipid content. Both cholesterol and FA levels are five times higher in the heart than in the muscle tissue in the present case. This shows that the lipids in these tissues are predominantly phospholipids. In the heart tissue, where the levels are highest, the correlation between cholesterol and total FAs was fair, i.e.  $R^2 = 0.75$ ,  $P = 7 \times 10^{-6}$ , but in the muscle tissue the correlation was poorer,  $R^2 = 0.29$ ,  $P = 0.025$ .

Cholesterol has earlier been qualitatively determined in heart tissue from cod, where it was important for the discrimination between two populations [24]. It therefore appears that the tissue level of cholesterol may be genetically controlled. Genetic control of the cholesterol content was also suggested by Mathew et al. [47] who found significant differences among families of Indian fish. The variations detected here may therefore be species and population dependent.

## Plasmalogens

The phospholipids in membranes normally have two FAs esterified to the glycerol molecule with the phosphoric acid moiety esterified in the third position. However, a substantial portion of the phospholipids have an alkyl chain with 16 or 18 carbons bound by a vinyl ether bond to the first position of the glycerol backbone. These alkenyl-acyl-phospholipids are called plasmalogens and are present in all tissues [51]. They were first detected in marine organisms in 1960 [53].

The plasmalogens are unstable towards acid [51]. Under the conditions we use for methanolysis of the tissue lipids, the vinyl ether group is cleaved to give an aldehyde which

is methanolysed to a dimethyl acetal. They are gas chromatographed together with the FAMES, although some loss of methanol occurs in the injector, giving methyl alkenyl ethers, which also give nice peaks in the chromatogram [52]. The plasmalogens make out 7–8% of the amount of total FAs (Tables 2 and 3), with about five times as much in the heart tissue as in the muscle tissue. The higher amount in heart tissue correlates with the higher amount of phospholipids, measured as total FAs.

There are few reports on plasmalogens in freshwater fish. They have been studied in carp, *Cyprinus carpio*, and rainbow trout, *Oncorhynchus mykiss* [55, 56]. They are structural components of cell membranes, reducing their fluidity, and may have a number of other functions. When the environmental temperature is increased membrane permeability can be expected to increase and the plasmalogens can be raised to regulate this phenomenon. Kraffe et al. [54] found that total plasmalogen increased in warm acclimated rainbow trout, which might explain the relatively high values in fish from the tropical waters of lakes Victoria and Kyoga.

In the present investigation we have found large differences in FA composition of muscle and heart tissue among seven tropical freshwater fish species. We have demonstrated that the FA compositions are species specific and appear to be independent of the dietary intake, thus questioning the traditional view on the important dietary impact. The fish appear to belong to local populations as manifested by systematic differences in the tissue FA composition. We have shown how cholesterol and plasmalogens can be determined simultaneously with the FA by our analytical method of acid catalysed transesterification followed by gas chromatography.

## Introduction

The diagnosis of juvenile bipolar disorder (JBD) in children and adolescents is becoming increasingly well accepted in research literature and by clinicians [1, 2]. The lifetime prevalence of JBD is approximately 1% during adolescence and 2% during young adulthood [3, 4], similar to that found in adults [5]. On average there is a 10–15 year delay between the time that patients report having symptoms of JBD until their diagnosis and treatment which suggests that patients with JBD may have had the disease for many years, when they were children or adolescents, prior to treatment [6].

There is growing evidence that a deficiency in long-chain omega-3 polyunsaturated fatty acids (LCn-3PUFA) may be involved in the aetiology of bipolar disorder (BD) and major depressive disorder (MDD). The rate of fish consumption in western diets is negatively related to the occurrence of BD [7] and MDD [8]. Red blood cell (RBC) membrane concentrations of docosahexaenoic acid (DHA) are reportedly lower in adults with BD [9] and plasma eicosapentaenoic acid (EPA) [10] and DHA [11] lower in adults with MDD compared with normal controls. Although lower concentrations of LCn-3PUFA have been reported in adults, no past studies have examined blood concentrations of LCn-3PUFA in JBD.

One of the main criticisms of studies examining blood concentrations of LCn-3PUFA has been a lack of control for LCn-3PUFA intake [12]. Intake of LCn-3PUFA is closely related to blood concentrations of LCn-3PUFA, with plasma phospholipid concentrations representing intake over the last 1–2 weeks [13] and RBC concentrations reflecting intake in the previous 14–120 days [14].

The present study is the first to assess LCn-3PUFA intake and blood concentrations in children and adolescents with JBD compared with healthy controls. It was predicted that blood concentrations of LCn-3PUFA would be significantly lower in children and adolescents diagnosed with JBD compared with healthy controls after controlling for family socio-economic status (SES) and LCn-3PUFA intake.

## Materials and Methods

All experimental procedures were approved by the Hunter New England Area Health Service Research Ethics Committee and the University of Newcastle Human Research Ethics Committee. The study was conducted with cognisance of the following principles and guidelines: the Declaration of Helsinki [15, 16]; the National Statement on Ethical Conduct in Research Involving Humans [17] and the International Committee of Harmonisation Good Clinical Practice (GCP) guidelines [18]. All participants' parents/guardians gave written informed consent and participants gave informed assent prior to inclusion in the study. The study was also registered with the Australian Clinical Trials Registry (<http://www.actr.org.au>) ACTRN: ACTRN012606000440527.

### Participants

Participants with JBD were referred to The Bipolar Program (Hunter New England Area Health Service) and assessed prior to study admission through a clinical interview by a clinical psychologist and child and adolescent psychiatrist and during a structured interview using the Washington University at St Louis Schedule for Affective Disorders and Schizophrenia (WASH-U-K-SADS) [19]. One of the authors (TH) had been trained to administer and interpret this instrument. Psychological histories were obtained from the young person as well as their parent or carer.

Participants with JBD were included in the study if they satisfied the following criteria: met diagnostic criteria for either BD I, BD II or BD Not Otherwise Specified (BD NOS) as specified in the DSM-IV-TR [20]; had an episode of mania, hypomania, mixed mania or major depression in the preceding 6 months; were currently being prescribed a mood stabiliser, an atypical antipsychotic or a combination of both medications and were stabilised for at least 4 weeks prior to the study; and were aged between 8 and 18 years. Participants were excluded if they had a primary medical or neurological cause of their mood disorder or had a comorbid diagnosis of Autistic Spectrum Disorder or clinically evident mental retardation.

Participants were not excluded if they had a co-morbid substance abuse, as comorbidity can be up to 17.6% [21]. Substance induced hypomania was not an exclusion criteria [22], as this disorder was automatically excluded when a diagnosis of JBD was confirmed. Inclusion and exclusion criteria took into account previous guidelines [10, 23].

Healthy age and sex-matched controls were recruited from the general community and were excluded if they fulfilled any of the following criteria: had previously been diagnosed with any DSM-IV disorder or JBD according to

the WASH-U-K-SADS; had a family history of mental illness in first degree relatives; had ever been prescribed psychotropic medication or had a history of substance abuse.

In addition, participants with JBD or healthy controls were excluded from the study if they satisfied any of the following common criteria: had a diagnosis of a significant medical disorder, such as active hepatic or renal disease, dementia, serious head injury or active cancer, Non-Insulin Dependent Diabetes Mellitus (NIDDM)—type 2 diabetes, cardiovascular, haematological or gastrointestinal disease; had taken fish oil (LCn-3PUFA) as supplements within the previous 6 weeks; were taking medication affecting lipid metabolism, such as HMG-CoA inhibitors or high-dose niacin; were pregnant; had a body mass index (BMI) less than 16 or greater than 30; or finally, were actively consuming a low fat diet.

### Measurements

Fasting blood samples were collected on one occasion for analysis of fatty acids. Following collection and separation of plasma by centrifugation, RBC membranes were washed with saline [24] and centrifuged again prior to being frozen at  $-80^{\circ}\text{C}$  pending further analysis. LCn-3PUFA intake was assessed using a Food Frequency Questionnaire (FFQ). Development and preliminary validation of the FFQ will be reported separately.

SES was assessed in all participants by asking parents/guardians about their occupation, highest education level achieved and income [25, 26]. Parental occupation was rated according to the ANU3\_2 occupational status scale [27].

### Psychological and Behavioural Tests and Observations in Participants with JBD

Psychological measures assessed at the time of blood collection included clinician reported mania (Young Mania Rating Scale, YMRS [4, 28]) parent reported mania (P-YMRS, and clinician reported depression (Hamilton Depression Rating Scale, HAM-D [29]). Overall severity of symptoms (mania and depression) was assessed using the Clinical Global Impressions scale (CGI [30, 31]). Higher scores on these measures represent a higher severity of illness. Global functioning was assessed using the Global Assessment Scale for Children (C-GAS [32]), where a higher score represents a higher level of functioning. The Child Behaviour Checklist (CBCL [33]) was completed by parents or guardians and participant behaviour was self-assessed using The Beck Youth Inventories (BYI [34]). Higher scores on these measures also reflect more severe illness.

Average mood was rated by patients and clinicians on the Tripartite Mood Rating Scale (Client Version [35]), which incorporates a 3-pronged Likert scale for the moods depression, euphoric mania and dysphoric mania (anger), with higher scores representing a worsening of mood.

### Fatty Acid Analysis

Total fatty acids were determined in plasma and RBC using the method established by Lepage and Roy [36] and validated for RBC [37]. Briefly, following extraction and methylation of fatty acids using methanol:toluene and acetyl chloride, fatty acids were quantified using a Hewlett Packard Series Gas Chromatograph with a flame ionization detector in comparison to a standard mixture of genuine fatty acid methyl esters (Nu Chek Prep, Elysian, MN USA). Details of the methods have been described previously [38].

### Statistical Analysis

Prior to analysis, data were assessed for homoscedasticity and normality assumptions using the Scatterplot and Explore options of the Statistical Package for Social Sciences (SPSS) version 14.0 for Windows [39]. Differences in RBC fatty acid concentrations between groups were analysed using the MIXED Model procedure in the SAS program [40, 41] with subject pair as the individual experimental unit and pair within gender as a random effect. Data were analysed for main effects of group and gender as well as the interaction between main effects. SES and intake of LCn-3PUFA were analysed as co-variables and, where significant, were included in the final model. Psychological test score in participants with JBD were also correlated with plasma and RBC concentrations of LCn3PUFA by Pearson correlation using SPSS.

### Results

Fifteen participants with JBD (9 female, mean age =  $15.0 \pm 0.95$  year; 6 male, mean age =  $13.6 \pm 1.29$  year) and fifteen age and sex-matched controls (female mean age =  $14.7 \pm 1.12$  year; male mean age =  $13.8 \pm 1.30$  year) were enrolled in the study. Participants with JBD were diagnosed with BD I ( $n = 7$ ), BD II ( $n = 3$ ) or BD NOS ( $n = 5$ ) and were all receiving mood stabilising medication. No participants had taken LCn-3PUFA supplements within 12 weeks prior to the study.

The reported intake of LCn-3PUFA was significantly lower for participants with JBD compared with healthy controls (Table 1). Prior to adjusting for intake, RBC concentrations of EPA and DHA were significantly lower in participants with JBD compared with healthy controls

**Table 1** Mean reported daily intakes of LCn-3PUFA in children and adolescents in Australia diagnosed with JBD compared with healthy controls

LCn-3PUFA <sup>b</sup>	Fatty acid intake (mg/day) <sup>a</sup>		<i>P</i> -values
	Control	Bipolar	
EPA	39 (±3)	19 (±3)	<0.001
DPA	31 (±4)	23 (±4)	0.152
DHA	70 (±6)	28 (±7)	<0.001
LCn-3PUFA	139 (±11)	69 (±11)	<0.001

<sup>a</sup> Values are least squares means ± standard error of the least squares mean for 15 age and sex-matched pairs, *n* = 6 males (mean age = 13.6 years) and *n* = 9 females (mean age = 15.0 years)

<sup>b</sup> EPA eicosapentaenoic acid (C20:5n-3), DPA docosapentaenoic acid (C22:5n-3), DHA docosahexaenoic acid (C22:6n-3)

(Table 2). However RBC EPA ( $r(30) = 0.65$ ,  $P < 0.001$ ) and DHA ( $r(30) = 0.63$ ,  $P < 0.001$ ) were significantly correlated to EPA and DHA intake, respectively and, after controlling for LCn-3PUFA intake as a co-variate in the analysis, RBC concentrations of EPA and DHA were not significantly different between participant groups.

RBC DHA concentration was negatively related to clinician ratings of depression using the CGI ( $r(15) = -0.55$ ,  $P = 0.044$ ) and participant ratings of aggression using the BYI ( $r(15) = -0.55$ ,  $P = 0.043$ ). Plasma EPA (% of total fatty acids) was significantly positively associated with symptoms of mania and externalising and disruptive behaviour (Table 3).

RBC EPA ( $2.83 \pm 0.38$  versus  $3.17 \pm 0.44$ ,  $P = 0.584$ ), DHA ( $15.67 \pm 2.82$  versus  $23.08 \pm 3.28$ ,  $P = 0.123$ ) and arachidonic acid (AA;  $70.15 \pm 9.82$  versus  $82.53 \pm 12.03$ ,  $P = 0.440$ ) were not significantly different between participants with JBD receiving either lithium or valproate as their primary mood stabilising medication. Similarly, RBC concentrations of LCn-3PUFA were not significantly related to smoking, alcohol consumption or BMI.

## Discussion

Red blood cell membrane concentrations of EPA and DHA were significantly lower in children and adolescents diagnosed with JBD compared with healthy controls. However, reported intakes of EPA and DHA were also lower in participants with JBD and significantly related to RBC concentrations. Therefore, after controlling for reported intakes of EPA and DHA, RBC concentrations of EPA and DHA were not significantly different between participants with JBD compared with controls. This is the first study to report RBC concentrations of LCn-3PUFA in JBD compared with healthy controls and one of the first to report RBC LCn-3PUFA in mental illness after adequately controlling for intake in the statistical analysis.

A genetically determined metabolic abnormality of LCn-3PUFA metabolism such as a specific deficiency of fatty acid CoA ligase 4 and/or Type IV phospholipase A<sub>2</sub>, resulting in reduced incorporation of LCn-3PUFA into phospholipids and lower concentrations of LCn-3PUFA in RBC, in particular, is proposed in patients with BD and MDD [42, 43]. However, LCn-3PUFA intake was not assessed in several studies linking reduced LCn-3PUFA with BD [9] or MDD [10, 11, 23], so differences between the effects of intake and metabolism cannot be determined.

In addition, intakes of fish or LCn-3PUFA were reported in several studies, but inadequate design and statistical methods mean that their results cannot be easily interpreted. For example, RBC membrane EPA and DHA were significantly lower in adults with MDD compared with healthy controls [44]. Although intake of LCn-3PUFA was estimated using a 7-day weighed food record, differences in blood LCn-3PUFA were analysed using a 2-sample (non-paired) *t*-test, meaning intake could not be included as a co-variate in the analysis. As the correlation between

**Table 2** Red blood cell LCn-3PUFA concentration (µg/mL) in children and adolescents diagnosed with JBD compared with healthy controls

LCn-3PUFA <sup>b</sup>	RBC concentration (µg/mL) <sup>a</sup>		<i>P</i> -values	
	Control	JBD	Co-variate	No co-variate

reported intake and RBC % LCn-3PUFA were significant [44], it is likely that intake would have been significant as co-variate in the analysis and this may have significantly altered the outcome. In addition, it is unlikely that 14 controls and 10 patients with MDD could be matched on all criteria specified in the study. Similar problems matching criteria with control participants and not using intake as a co-variate in statistical analyses also occurred in other studies of attempted suicide [45] and ADHD [46].

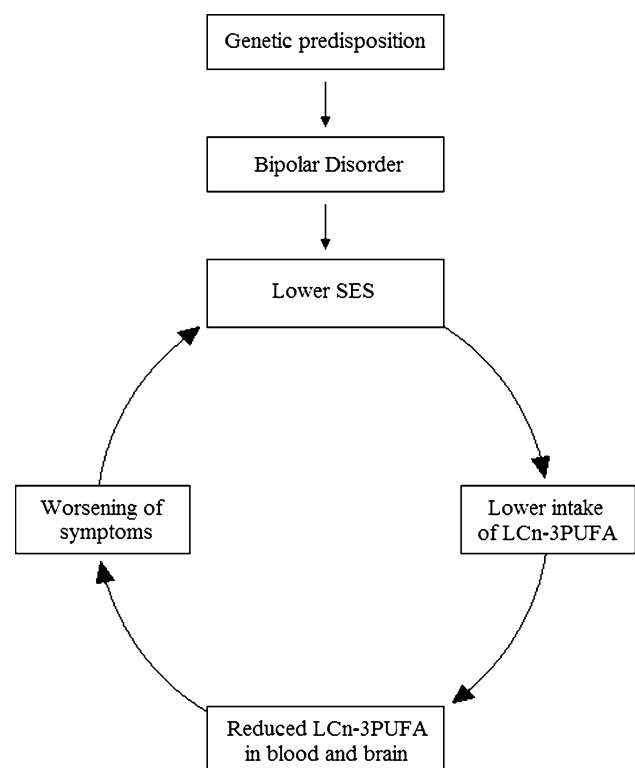

As blood concentrations were related to LCn-3PUFA intake and not significantly different between participants with JBD and controls after controlling for intake, data from the current study suggest that there was not a genetic abnormality in LCn-3PUFA incorporation into RBC in participants with JBD. However, there are still several possible hypotheses linking LCn-3PUFA intake and JBD incidence.

Firstly, as there is a strong genetic component to BD, participants with JBD are more likely to be from families with a higher incidence of BD and, subsequently, lower SES. Participants with JBD in the current study had a strong family history of depression and BD and family SES was lower for these participants than controls (data to be presented in more detail separately). These results agree with previous research linking lower SES to increased incidence of mental illness [47–49]. Therefore, a secondary effect from having JBD may be reduced SES, reduced family capacity to purchase food containing high concentrations of LCn-3PUFA (such as fresh oily fish which is expensive) and, therefore, RBC concentrations merely reflect lower intake. SES is significantly positively associated with fish consumption [50, 51] and serum phospholipid EPA % [26].

Secondly, lower intakes of LCn-3PUFA may precede the onset of JBD and lower blood concentrations may be involved in the aetiology of JBD through several mechanisms previously reviewed [52]. Finally, it is possible there is a combination of effects, if participants with JBD are from a lower SES, they consume less LCn-3PUFA, blood concentrations are lower and this contributes to an additive

decline in brain functioning and a worsening of symptoms (Fig. 1).

Increasing the consumption of LCn-3PUFA through fish or seafood high in LCn-3PUFA or by using supplements may break this negative cycle and lead to an improvement of symptoms separate to other pharmacological treatment. This strengthens the hypothesis to include LCn-3PUFA supplements as an adjunct to normal pharmacological treatment. Symptoms of JBD may be improved without altering pharmaceutical doses or similar symptom control

**Fig. 1** Theoretical cycle linking SES, intake of LCn-3PUFA and symptom severity in JBD

may be achieved with lower doses of pharmaceuticals and, therefore, lower unwanted side-effects.

RBC concentrations of DHA in the current study were negatively related to clinician ratings of depression and participant ratings of aggression. Lower LCn-3PUFA is related to increased depression and aggression in rats [53] and supplementation with DHA reduces aggression induced by stress [54]. Plasma EPA%, which reflects recent intake [55], was positively related to clinician ratings of mania, parent ratings of externalising symptoms and participant ratings of disruptive behaviour, while RBC EPA was not significantly related to any psychological measures. Future research should further distinguish differences between short-term intake and blood concentrations and long-term intake with state and trait measures of mood and behaviour. LCn-3PUFA supplementation is proposed to be more effective for depression than mania [56, 57] and DHA may be the preferred target treatment for depression and aggression.

The omega-3 index (RBC EPA + DHA%) [58] was not significantly different between groups. However, the omega-3 index of all participants was in the range considered to be a “Medium Risk” for cardiovascular disease (0–4% High Risk, 4–8% Medium Risk, >8% Low risk), indicating that all the participants in the current study had relatively low RBC EPA and DHA compared with recommended levels.

Although the effect of mood stabilising medication on RBC membrane LCn-3PUFA concentrations has not previously been studied, lithium [59, 60] and sodium valproate [61] are associated with decreased arachidonic acid (AA) turnover in the brain of rats without altering the turnover of DHA. In the current study, RBC concentrations of EPA and DHA (after controlling for intake) and AA were not significantly different between participants with JBD who were prescribed lithium compared with those prescribed sodium valproate. Antidepressants [11], haloperidol and diazepam [62] do not alter RBC LCn-3PUFA levels, so it seems unlikely that pharmaceutical treatment would explain further variation in blood concentrations. Therefore, LCn-3PUFA supplements could be effective in addition to standard pharmacotherapy for the treatment of JBD. Previous research has indicated that adjunct supplementation may be beneficial in the treatment of BD in adults [63–65]. Future clinical studies should monitor the interaction between medications and blood LCn-3PUFA.

There are obvious limitations to conducting a study with small numbers of participants. The results should be treated with caution and require replication. However, given the significant relationship between intake and RBC membrane concentrations of LCn-3PUFA, the methods used in the current study appear to be valid.

## Conclusions

Red blood cell membrane concentrations of EPA and DHA were not significantly different in participants with JBD compared with healthy controls after controlling for intake. However, lower intakes and subsequent blood concentrations in participants with JBD may contribute to worsening of symptoms, as RBC concentrations of DHA were negatively related to symptoms of depression. Therefore, supplementation with LCn-3PUFA to break the cycle of lower intake and to increase blood concentrations may be of benefit in alleviating symptoms of JBD.

**Acknowledgments** We thank the expert technical assistance of Robert Blake for advice on LCn-3PUFA analysis and Melinda Phang for assistance in conducting analyses. We also thank staff from the Hunter Area Pathology Service for assistance with blood collection and Dr Trent Watson for advice on the preparation of this manuscript. This study was conducted without dedicated external funding. This study was supported from in-kind donations from the Nutraceuticals Research Group and Hunter New England Area Health Service. Dr Clayton, Dr Hanstock, Mr Hirneth, Dr Kable, Professor Garg and Professor Hazell have previously received in-kind donations of omega-3 capsules from NuMega Ingredients Pty Ltd. The authors do not have any other financial interests or potential conflicts of interest in connection with this manuscript.

Typical changes in the insulin resistant state are an increased fat mass due to adipocyte hyperplasia and hypertrophy [1–4], liver steatosis and triacylglycerol (TAG) accumulation in skeletal muscle [5–8], as well as fasting and postprandial hyperlipidemia [9–11]. Previous studies have provided convincing evidence that an excessive amount of fatty acids is an important etiological factor in the development of these pathologies. Systemic insulin resistance can be induced in humans and in animal models by high fat diets (HFDs) [12–14] or by systemic elevation of fatty acids through lipid infusion [6, 15–17]. Alteration of fatty acid fluxes by transgenic intervention or by pharmacological means were demonstrated to modulate insulin sensitivity in disease models [18–22], adding further evidence to the notion that an excess of fatty acids causes insulin resistance.

In addition to overall fatty acid quantities, composition of tissue fatty acid pools is an important aspect of metabolic disease. Observational studies established that certain fatty acids are frequently associated with insulin resistance, suggesting that they may have a pathogenic role. For example, in human plasma, palmitate (C16:0), palmitoleate (C16:1), oleate (C18:1) and dihomo- $\gamma$ -linolenate (C20:3n-6) were found to be increased in insulin resistant subjects, while linoleate (C18:2) negatively correlated with metabolic disease in many cross-sectional and prospective studies (see [23] for review). Direct evidence that some fatty acid species or classes are more pathogenic than others was generated in dietary intervention studies. Diets enriched in SFA and MUFA were shown to induce insulin resistance in rodents [13, 24–26] while n-6 PUFA showed more variable effects [13, 27] and dietary fats enriched in n-3 PUFA unequivocally showed strong weight-reducing and insulin sensitizing effect in diet-induced obesity rodent models [24, 25]. In humans, a diet enriched in SFA but not one enriched in MUFA induced insulin resistance in healthy subjects [14]. In contrast to rodents, dietary intervention studies in humans using fish oils rich in n-3 PUFA found no positive effect on insulin action [14, 28–31], although muscle phospholipid n-3 PUFA content was found to correlate with insulin sensitivity [32, 33].

The fatty acid composition in the body is determined not only by dietary intake but also by fatty acid synthesis and processing of dietary fatty acids. One important pathway is the synthesis of SFA and MUFA including de novo synthesis of C16:0 by fatty acid synthase (FAS), elongation by fatty acid elongases (ELOVL1–6) and  $\Delta$ 9-desaturation by stearoyl-CoA desaturase (SCD), enzymes highly expressed in the major lipogenic tissues liver and adipose tissue. Among the lipogenic enzymes SCD1 is an especially well studied example. Its activity is essential for induction of other lipogenic genes, liver steatosis and weight gain after HFD feeding of mice [34]. Genetic deficiency of SCD1 and

long-term knockdown using antisense RNA technology led to protection from insulin resistance and obesity [35, 36]. Importantly, short-term inhibition of SCD1 improved insulin signaling, however, was not accompanied by reduced obesity or liver steatosis, suggesting a direct insulin sensitizing effect on liver [37]. SCD1 activity has also been implicated in human obesity and insulin resistance.  $\Delta$ 9-desaturase ( $\Delta$ 9D) indices, calculated from products and precursors of the SCD1 reaction, were frequently increased in obesity, insulin resistance and other parameters of metabolic disease suggesting that SCD1 is also an important mediator of human insulin resistance [23, 38, 39].

Fatty acid profiling in humans revealed that insulin resistance is also frequently associated with alterations in activity indices of  $\Delta$ 6-desaturase (FADS2) and  $\Delta$ 5-desaturase (FADS1), which are essential for synthesis of PUFA from essential fatty acids. Apparent activity of FADS2 is typically increased in metabolic disease while FADS1 is decreased [23]. In rodent models of obesity and insulin resistance alterations of FADS1 and FADS2 has been studied only in a few insulin resistant models [40, 41]. Compared to SCD1, less is known about causal links to metabolic disease. Even less is known about the role of fatty acid elongases in insulin resistance. Interestingly, the isoform ELOVL6, using fatty acids with chain length below C<sub>18</sub> as substrate, was recently shown to promote liver insulin resistance [42].

HFD-induced obesity in the C57Bl/6 mouse [12] is one of the most widely used mouse models of insulin resistance exhibiting many aspects of the metabolic syndrome in humans such as impaired glucose tolerance, hypertension, diminished immune function and a propensity for atherosclerosis [43]. The strain is susceptible to diet-induced obesity on different HFDs with the exception of diets rich in n-3 PUFA [25]. Despite the frequent use, especially for genetic studies, alterations in fatty acid profiles in relation to insulin resistance have not been studied extensively in this model. Therefore, we set out to perform a comprehensive lipid profiling experiment using a lard-based HFD to induce different degrees of insulin resistance. We observed profound changes in fatty acid content and composition. Some of these changes occurred even in a very early insulin resistant state while others were only apparent in fully developed insulin resistance.

## Materials and Methods

### Animal Diet Regimens and Necropsy

Age-matched male C57Bl/6 mice (Taconic, Germantown, NY) on distinct diets were used as models of insulin

resistance and as the respective controls. Healthy control mice were fed a normal chow diet (Chow, Purina 5001). Insulin resistance was induced by a lard-based, diabetogenic HFD (Bio-Serv S3282; proximate nutrient profile by weight: 35.5% lard, 20% casein, 14% sucrose, 18.6% maltose dextrin). As shown in Supplemental Figure 1, one group was made profoundly insulin resistant by feeding the HFD for a period of 16 weeks starting at weaning (16w-HFD). Another group was designed to be mildly insulin resistant and received the HFD only 1 week before necropsy (1w-HFD), after randomization at 19 weeks of age with the Chow-fed controls for fasting plasma insulin and glucose. At 20 weeks of age, blood and organs were collected from the mice for metabolic profiling. Before necropsy each feeding group was divided into two subgroups, mice fasted overnight for 16 h (Fasted) and mice fasted overnight with subsequent access to the HFD for 4 h (Refed).

The animals were anesthetized with isoflurane and cardiac stick was performed to collect blood as EDTA plasma (Li-heparin for NMR) from the right ventricle of the heart. After bleeding, the animals were perfused (10 U/L heparinized saline) through the right ventricle of the heart, allowing the blood to exit through a cut in the caudal vena cava. Organs and blood were taken and snap frozen in liquid nitrogen for storage at  $-80^{\circ}\text{C}$ .

Animals were maintained on a 12-h light, 12-h dark cycle and received tap water ad libitum. All animals were maintained in accordance with the Institutional Animal Use and Care Committee of Eli Lilly and Company and the NIH Guide for the Use and Care of Laboratory Animals.

#### Plasma Parameters

Plasma insulin was determined using Rat/Mouse Insulin Assay kit (Mesoscale Discovery, Gaithersburg, MD) and Mouse Endocrine Lincoplex kit (Millipore, St. Charles, MO) for randomization and final study, respectively. Glucose was measured using a Hitachi 912 clinical chemistry analyzer (Roche, Indianapolis, IN). Adiponectin was determined using an ELISA from R&D Systems (Minneapolis, MN). Blood lipid measurements including FPLC analysis were performed as described [44].

#### Metabolite Quantification by NMR

Li-heparin plasma samples were transferred into 1-mm NMR sample tubes and stored for a maximum duration of 2 h at  $4^{\circ}\text{C}$  prior to NMR data acquisition. T2-filtered  $^1\text{H}$ -NMR spectra were recorded at 300 K on a Bruker 600 MHz AVANCE spectrometer using a 1-mm TXI micro probe head equipped with  $z$ -gradient system. A standard 1D CPMG (Carr–Purcell–Meiboom–Gill) pulse

sequence [45] with 2 s presaturation delay ( $\gamma B_1 = 50$  Hz) and 80 echo cycles of 800  $\mu\text{s}$  duration resulting in a total echo time of 64 ms was employed. 256 scans of 32,768 data points covering 12019 Hz were recorded and zero filled to 65,536 points. An exponential window function with a line-broadening factor of 2.0 Hz was applied prior to Fourier transformation. All spectra were manually phased and baseline corrected and referenced to the  $\text{CH}_3$  signal of lactate (1.33 ppm). The relative 3-hydroxybutyrate, acetone and glycerol concentrations were determined by manual deconvolution of the spectra using reference data of the corresponding compounds recorded at 4 mM concentration in 0.067 M phosphate buffer (pH 7.4). Reference data were recorded using the first time increment of the 2D NOESY experiment [46] with presaturation ( $\gamma B_1 = 50$  Hz) during 2 s relaxation delay and 100 ms mixing time, respectively. Other parameters were as above except 64 scans were accumulated and data were referenced according to internal TSP at a concentration of 0.4 mM. The determined relative concentrations are given in relative units since the values were not corrected for attenuation of the signals caused by relaxation during the T2 filter delay and rapid pulsing saturation effects.

#### Liver Total Lipid Quantification

In homogenized liver samples, basal lipid values are high enough to measure efficiently and specifically total lipid content by standard colorimetric assays without any extraction. For lipid quantification, 50-mg pieces of frozen liver were homogenized in lysis buffer (2 mM  $\text{CaCl}_2$ , 80 mM NaCl, 1% TritonX-100, 50 mM Tris/HCl, pH 8.0). TAG and cholesterol were determined using commercial kits (Roche/Hitachi, Mannheim, Germany). Protein concentrations were measured by a Lowry method, which was modified for lipid containing samples by addition of 0.1% SDS.

#### Western Blot Analysis

Liver lysates were generated by homogenizing tissue in lysis buffer (50 mM Tris, 250 mM mannitol, 1 mM EDTA, 1 mM EGTA, 20 mM  $\text{Na}_4\text{P}_2\text{O}_7$ , 2 mM  $\text{Na}_3\text{VO}_4$ , 1 mM DTT, 50 mM NaF, protease inhibitors (COMPLETE, Roche, Mannheim, Germany), phosphatase inhibitor cocktail (Sigma, Munich, Germany), 1% Triton X-100) with subsequent clarification by centrifugation at 13,000 rpm for 30 min. Protein concentrations were determined using the BCA protein assay (Perbio, Bonn, Germany). Proteins were separated by SDS-polyacrylamide gel electrophoresis (4–12% acrylamide, NuPAGE system, Invitrogen, Karlsruhe, Germany) under denaturing conditions and transferred to Protran nitrocellulose

membranes. Immunodetection was performed with antibodies against IRS1 (Upstate, Schwalbach, Germany) and IRS2 (Santa Cruz, Heidelberg, Germany) using standard procedures. The signals were quantified by normalization to beta-tubulin using an antibody from Sigma (Munich, Germany).

#### Total RNA Extraction and Real-time Quantitative PCR

Total RNA from frozen liver samples was extracted using the TissueLyser and RNeasy system (Qiagen, Hilden, Germany) according to the manufacturer's instructions. DNA contaminants were removed via column DNase treatment (RNase-Free DNase set; Qiagen). 1 µg of RNA was reverse transcribed in 50 µl reaction mixture using the High Capacity cDNA Archive Kit (Applied Biosystems, Darmstadt, Germany) according to the manufacturer's instructions. Real-time RT-PCR was performed as described previously [47].

For all other genes Assay-on-Demand primer/probe sets supplied by Applied Biosystems were used (Assay IDs are available upon request). Relative expression was calculated by normalization to selected housekeeper mRNA (TBP) by  $\Delta\Delta\text{Ct}$  method [48]. Data are reported as copy number relative to housekeeper.

#### Fatty Acid Analysis

All chemicals were of analytical grade. Fatty acid methyl ester standards were obtained from Restek, (Bad Homburg, Germany), Cayman (IBL, Hamburg) and Supelco (Sigma). Total lipids from liver, subcutaneous adipose tissue and skeletal muscle were extracted essentially as described by Folch et al. [49]. Briefly, 250 µl of butylhydroxytoluene (0.1 mol/l in methanol) and 6 ml of chloroform/methanol (2:1) were added to 50 mg of tissue. After homogenization using an Ultraturrax homogenizer the samples were heated to 50 °C for 30 min and centrifuged (1800 g, 5 min). Lipid class separation of liver tissue was performed according to the method of Hamilton and Comai [50] using prepacked silica columns (Separtis, Grenzach-Wyhlen, Germany). Separated lipid fractions were evaporated and redissolved in methanol/toluene (4:1). Fatty acid methyl esters were prepared based on the method of Lepage and Roy [51] except that toluene was used instead of benzene. Briefly, 10 µl of plasma (or 100 µl of tissue extract), 2 ml methanol/toluene (4:1), 50 µl heptadecanoic acid (200 µg/ml in methanol/toluene, 4:1) and 200 µl acetyl chloride were heated in a capped tube for 1 h at 100°C. After cooling to room temperature 5 ml of 6% sodium carbonate was added. The mixture was centrifuged (1800 g 5 min.) and 150–200 µl of the upper layer were transferred to auto sampler vials. For liver extracts dilutions were made by

adding 1.6 ml of toluene preliminarily to the sodium carbonate. Gas chromatography analyses were performed using an HP 5890 gas chromatograph (Hewlett Packard) equipped with flame ionization detectors (Stationary phase: DB-225 30 m × 0.25 mm id., film thickness 0.25 µm; Agilent, Böblingen, Germany). Peak identification and quantification was performed by comparing retention times and peak areas, respectively, to standard chromatograms. All calculations are based on fatty acid methyl esters values. Composite  $\Delta 9\text{D}$  index was calculated as the sum of the fractional contents of all MUFA divided by the sum of the fractional contents of both MUFA and SFA.

#### Statistical Analysis

Unless indicated otherwise two-tailed Student's *t*-test was used to assess statistical significance between groups. Pearson's correlation test was used to evaluate the degree and the significance of association between plasma lipids and obesity or insulin resistance parameters.

## Results

### Short- and Long-Term Feeding of High Fat Diet Results in Progressive Insulin Resistance

Insulin sensitivity and metabolic status of the HFD-fed mice and control mice was determined by measuring plasma concentrations of glucose and insulin, as well as adipokines and lipids in the fasted and in the refed state (Supplemental Table 1). Feeding the HFD for 1 week resulted in a mild but significant insulin resistance as shown by higher fasting glucose and insulin in 1w-HFD mice vs. Chow mice (Fig. 1). Also, a significant rise in body weight and plasma leptin (Supplemental Table 1, Figure 1) was observed. As expected, 16 weeks HFD led to more pronounced overweight and insulin resistance compared to 1w-HFD mice, as reflected by fasting glucose, insulin and leptin levels. Fasting plasma adiponectin was decreased by HFD feeding, however, only in the 16w-HFD group (Fig. 1).

In the refed state, plasma glucose and insulin were elevated compared to fasted state in each dietary group, as expected. While in the refed state, glucose was still significantly higher in the 1w-HFD group vs. control mice, refed insulin levels were equal in both groups (Fig. 1). Consistent with the observation that leptin secretion is stimulated by high metabolic fuel availability [52, 53], plasma leptin was profoundly increased in the refed vs. the fasted state in controls and the 1w-HFD group. In the 16w-HFD group this regulation was lost and leptin was actually lower in refed vs. fasted animals. Interestingly, adiponectin

**Fig. 1** Plasma parameters related to insulin resistance. Plasma glucose **a** insulin **b** leptin **c** and adiponectin **d** levels in mice fed either control diet (Chow), control diet for 15 weeks and HFD for 1 week (1w-HFD), and HFD for 16 weeks (16w-HFD), respectively. Bar graphs are presented as mean  $\pm$  SEM. Closed bars, fasted state; open bars, refed state. T-Test HFD vs. Chow: \*  $p < 0.05$ ; \*\*  $p < 0.001$ ; T-Test 16w-HFD vs. 1w-HFD: *a*:  $p < 0.05$ ; *b*:  $p < 0.001$ . Mann–Whitney U-Test was used for insulin since most fasted Chow values were below detection limit (bld, 56 pmol/l)

levels in the refed state were no longer different between the feeding groups (Fig. 1).

#### High Fat Diet Induces Plasma Hyperlipidemia while Reducing Ketone Bodies

HFD feeding increased levels of plasma lipids, as expected (Supplemental Table 1). The lipid levels correlated positively with measures of obesity and insulin resistance, cholesterol having the highest scores (Pearson correlation coefficients for fasting plasma cholesterol: insulin,  $r = 0.899$ ; glucose,  $r = 0.823$ ; leptin,  $r = 0.854$ ;  $p < 0.001$ ). In order to characterize the observed hyperlipidemia in more detail we assessed the lipoprotein profiles of the insulin resistant mice by FPLC. The size of the HDL peak (fractions 22–28) increased moderately after 1 week of HFD feeding and increased further after 16 weeks of HFD (Fig. 2), as observed previously in mice [54]. A more dramatic change upon HFD feeding was observed for a peak eluting before HDL (fractions 15–20). This peak contained apolipoproteins B, E and C (data not shown) and, therefore, probably corresponded to LDL and/or apoE-containing HDL. The peak correlated with the degree of insulin resistance and was barely detectable in the Chow controls (Fig. 2). TAG-rich lipoproteins (fractions 7–11) were increased in both

the 1w-HFD and 16w-HFD group in the fasted state, whereas no increase compared to the control group was present in the refed insulin resistant animals. Similar levels of free glycerol (fractions 36–40) were measured in all experimental groups in the fasted state, as could be confirmed independently by NMR quantification (Supplemental Table 1). As expected, upon refeeding, the peak was strongly suppressed in Chow controls, presumably reflecting suppression of adipocyte lipolysis by insulin. Interestingly, this regulation was completely lost in the 16w-HFD group, indicating strong adipose tissue insulin resistance. In the 1w-HFD group, the suppression was partially lost, suggesting that adipocyte insulin signaling was already impaired at this early stage of the disease.

We quantified plasma ketone bodies as measures of liver ketone synthesis and, indirectly, of fatty acid oxidation. 3-hydroxybutyrate and acetone, the degradation product of the ketone body acetoacetate, were detectable by NMR. As expected, the ketones were much higher in fasted compared to refed animals, reflecting higher flux of fatty acids from adipose tissue to the liver. In agreement with previous reports describing reduction of ketone bodies in non-diabetic insulin resistant states [55–57], fasted ketones were significantly lower (60%) in the 16w-HFD group relative to Chow controls (Supplemental Table 1), while in the 1w-

**Fig. 2** Plasma lipoprotein profiles. Lipoprotein profiles of individual mice were determined by FPLC using samples from **a, c** fasted and **b, d** refed animals. **a, b** Cholesterol and **c, d** TAG in each fraction were

determined using standard enzymatic lipid measurements. The means of eight animals per group are shown. Peaks corresponding to HDL, TAG-rich lipoproteins (TRL) and free glycerol are marked

HFD group acetone but not 3-hydroxybutyrate was significantly decreased.

#### HFD-Induced Changes in Fatty Acid Composition Correspond to $\Delta 9$ -Desaturase Indices and Liver Lipid Concentration

We determined fasting state plasma and liver fatty acid profiles by gas chromatography to correlate alterations in fatty acid metabolism with insulin resistance after short-term and chronic HFD feeding.

As shown in Fig. 3, profound alterations in fatty acid profiles were observed, among others for the major C16 and C18 fatty acid species. The fractional content of C16:1 was decreased in the HFD-fed animals in plasma and liver already after 1 week HFD (Fig. 3). More moderate changes were observed for C16:0, most noteworthy a small increase in liver after 16 weeks of HFD feeding, as opposed to a decrease in plasma (Fig. 3).

A divergent pattern was observed for stearate (C18:0) and C18:1. The plasma content of C18:0 had significantly increased and that of C18:1 had decreased in both insulin resistant groups compared to Chow controls. In liver there was a profound rise in C18:0 and a complementary drop in

C18:1 after 1 week HFD while the opposite pattern was present after 16 weeks of HFD (Fig. 3).

The observed divergent regulation of C16 and C18 SFA and MUFA suggested liver regulation of SCD1, the  $\Delta 9$ D important for metabolic control in humans and mice. Therefore, we calculated  $\Delta 9$ D activity indices using substrate/product ratios (Fig. 4). Surprisingly, the product vs. substrate ratios of the two predominant  $\Delta 9$ D reactions, the C16:1/C16:0 ratio and the C18:1/C18:0 ratio, showed a converse pattern. Whereas the C16:1/C16:0 ratio showed a progressive decrease in liver and plasma, the C18:1/C18:0 ratio showed a distinct temporal pattern in liver, namely a drop in the 1w-HFD group and a subsequent increase, resulting in a higher ratio compared to Chow controls (Fig. 4). In plasma the C18:1/C18:0 ratio was equally decreased compared to Chow in the 1w-HFD and the 16w-HFD group. Calculation of a composite  $\Delta 9$ D index taking into account the sums of all MUFA and SFA (see “Materials and Methods”) resulted in a pattern similar to the C18:1/C18:0 ratio in liver (Fig. 4). The composite  $\Delta 9$ D index as well as the C18:1/C18:0 ratio in liver correlated with the expression of *Scd1*, which showed a non-significant dip after 1w-HFD and a significant increase after 16w-HFD (Fig. 4). Since increased  $\Delta 9$ D activity and SCD1

**Fig. 3** Changes in plasma and liver fatty acids. Changes in fractional content of fatty acids representing selected synthesis pathways. Total lipid fatty acids were determined in plasma and liver of fasted animals. Data are presented as percent change (mean  $\pm$  SEM) in 1w-HFD and 16w-HFD groups compared to Chow controls. T-Test HFD vs. Chow: \*  $p < 0.05$ ; \*\*  $p < 0.001$ ; T-Test 16w-HFD vs. 1w-HFD: *a*:  $p < 0.05$ ; *b*  $p < 0.001$

expression is typically associated with liver steatosis, we measured TAG and cholesterol content of the liver. After 1 week of HFD there was a strong decrease in fasted liver TAG content while after 16 weeks HFD liver TAG was significantly increased compared to Chow (Fig. 5). For liver cholesterol a similar, however less pronounced, pattern was observed (Fig. 5). To investigate whether decreased liver lipid content is associated with a corresponding increase in peripheral organs, we measured total fatty acid content in plasma, liver, skeletal muscle and subcutaneous adipose tissue (Fig. 5). Fatty acid content in the liver was decreased after 1 week HFD whereas in plasma, muscle and subcutaneous adipose tissue fatty acid levels per tissue wet weight was increased. In addition, the total weight of subcutaneous fat pads was profoundly increased already after 1 week HFD (Chow:  $97 \pm 26$  mg; 1w-HFD:  $506 \pm 77$  mg and 16w-HFD:  $1325 \pm 52$  mg;  $p < 0.001$ ). Despite the lower total liver lipid levels in the

1w-HFD group, mechanisms related to hepatic insulin resistance may already have been initiated at this stage, as suggested by decreased protein levels of the insulin receptor substrate (IRS) isoforms. The protein content of IRS1 and IRS2 were further diminished in the 16w-HFD group (Fig. 5).

Taken together, the C18:1/C18:0 ratio as well as the composite  $\Delta 9D$  index correlated with liver SCD-1 mRNA and with liver TAG content, however, not with early insulin resistance after 1w-HFD feeding.

#### HFD Increases Plasma and Hepatic Arachidonate

Arachidonate (C20:4) as the precursor of eicosanoids plays an important part in inflammation and may, therefore, be important for insulin resistance. For this reason we analyzed the content of C20:4 in plasma and liver. In plasma, a progressive increase in C20:4 was observed upon HFD

**Fig. 4**  $\Delta 9$ D activity indices and Scd1 expression.  $\Delta 9$ D indices **a**, **b**, **c** calculated from fatty acid fractional contents in plasma and liver of fasted HFD-fed and control mice. Data are presented as mean  $\pm$  SEM. T-Test HFD vs. Chow: \*  $p < 0.05$ ; \*\*  $p < 0.001$ ; T-Test 16w-HFD vs. 1w-HFD: *a*  $p < 0.05$ ; *b*  $p < 0.001$

feeding while at the same time the precursor C18:2 did not rise, actually decreased after 16 weeks of HFD (Fig. 3). In liver a similar pattern was present in the 1w-HFD group, however, after 16 weeks HFD feeding the hepatic C20:4 content returned to Chow level (Fig. 3).

C20:4, like other PUFA, is enriched in PL and exerts its most important biological functions from that lipid pool. In order to further characterize the changes in C20:4 content in liver we separated liver lipids into TAG, cholesteryl esters (CE), PL and free fatty acids (FFA), and determined

total fatty acid content as well as fractional content of C20:4 and other fatty acids in these subclasses (Fig. 6). As expected, C20:4 in the TAG and CE fractions, which are the most abundant lipids in liver showed a pattern similar to that found with total liver lipids (Fig. 3). In contrast, the PL and FFA fractions exhibited a significant increase in C20:4 after 1 week HFD feeding which did not further increase in the 16w-HFD group (Fig. 6, Supplemental Table 2).

#### Docosahexaenoate is Preserved in Plasma and Liver Phospholipid of Insulin Resistant Mice

Reduction of the final product of the n-3 PUFA synthesis pathway, docosahexaenoate (C22:6), has been mechanistically implicated in insulin resistance [13]. Therefore, we quantified C22:6 as well as its precursors. C22:6 showed little change in plasma, while it was profoundly down-regulated in the liver of 16w-HFD but not 1w-HFD mice (Fig. 3). Interestingly, when C22:6 was quantified in liver lipid subclasses, it became apparent that the decrease in total C22:6 was due to a decrease in the CE and TAG compartment while in PL, the compartment most important for PUFA function, C22:6 was preserved and the fractional content was actually increased in the 16w-HFD group

(Fig. 6, Supplemental Table 2). A different scenario was found for the precursors of C22:6. The first molecule in the n-3 synthesis pathway, the essential fatty acids  $\alpha$ -linolenate (C18:3n-3), and the n-3 intermediates eicosapentaenoate (C20:5) and docosapentaenoate (22:5), were reduced in insulin resistant mice in both plasma and liver (Fig. 3).

#### Hepatic Expression of Genes Regulating Fatty Acid Synthesis

The profound alterations in fatty acid profiles and liver lipid contents prompted us to look for potential mechanisms involving expression of key genes of lipogenesis and fatty acid metabolism in liver (Table 1). Genes important for lipogenesis (*Acc1*, *Fas*, *Gpat1*, *Dgat2*) were increased in the 16w-HFD group but not in the 1w-HFD group, consistent with the observed increase in liver TAG content in 16w-HFD mice. To understand the increase of C20:4 and C22:6 content in liver we quantified the key genes of PUFA synthesis. The expression of the two elongases important for PUFA elongation, *Elovl5* and *Elovl2*, was moderately decreased in the 16w-HFD group. In contrast, an increase in the expression of the two desaturases essential for PUFA synthesis, *Fads1* and *Fads2*, was observed already after 1 week of HFD, indicating that up-

regulation of these enzymes may be a cause for the observed increase in C20:4 and preservation of C22:6 in liver phospholipids and plasma.

## Discussion

The approach of this study was to generate detailed lipid and fatty acid profiles in mice made insulin resistant by means of a HFD. Mild and profound insulin resistance were induced in the mice by feeding HFD for 1 and 16 weeks, respectively. Subsequently, the observed metabolic alterations compared to chow-fed controls were related to the degree of insulin resistance in order to identify novel causative processes and biomarkers. As shown in Fig. 1 and Supplemental Table 1, fasting plasma levels of glucose and insulin were already increased after feeding the HFD for 1 week and were further increased in the chronically HFD-fed group, as expected. Body weight, plasma leptin and plasma total lipids were also significantly increased in the 1w-HFD group compared to the chow-fed controls, and further increased in the 16w-HFD group. Thus, the experimental groups used in this study displayed distinct degrees of insulin resistance, obesity and dyslipidemia and could be used for correlation with multiple lipid parameters.

In order to identify novel lipid markers and mechanisms in diet-induced insulin resistance, we determined fatty acid

profiles in plasma and in liver. One striking observation was profound quantitative changes of the most abundant C16 and C18 fatty acids. Surprisingly, the fractional content of C16:1 was decreased in plasma and liver of both HFD-fed groups (Fig. 3) despite higher content of this fatty acid in the diet (Supplemental Table 3). C16:0 content was also decreased, however, only in plasma of the 16w-HFD group (Fig. 3). This observation is in strong contrast to previous human studies, but also to rat experiments, which almost unequivocally found an increase in the fractional content of both C16:0 and C16:1 in insulin resistant states [23, 58]. The reason for this difference is not clear. The mechanisms proposed for humans, namely increased dietary intake of C16:0 and increased Δ9D activity (see below), were also present in our study. Therefore, alternative explanations must be chosen, such as increased conversion to longer fatty acids by fatty acid elongases. Intriguingly, a very recent paper using *Elovl6* knockout mice found that this elongase isoform is rate-limiting for elongation of C16 fatty acids as revealed by accumulation of C16 fatty acids in knockout liver. Furthermore, the knockout conferred protection from HFD-induced liver insulin resistance [42]. In our study we observed the opposite, namely a decrease of fatty acid substrates of ELOVL6 (C12-C16 fatty acids) in plasma and liver (data not shown). Therefore, although liver *Elovl6* mRNA expression was not altered in our study (Table 1) it is possible that flux through *Elovl6* or a related elongase was increased in the HFD-fed mice and did contribute to insulin resistance. Quantitative flux studies in metabolic disease models and humans as well as elongase gain of function studies will be needed to clarify the role of *Elovl6* and other elongases in the development of insulin resistance.

In the analysis of the fatty acid profiles we also addressed the potential involvement of SCD1, the predominant Δ9D converting SFA to MUFA by calculating a composite Δ9D activity index. The Δ9D index, like the C18:1/C18:0 ratio, exhibited an early and persistent decline in plasma, whereas in liver a transient drop in the 1w-HFD group and a subsequent increase was observed (Fig. 4). Unlike reported in many human studies [23], the C16:1/C16:0 ratio in our study decreased progressively with insulin resistance. The mechanism underlying the decreased ratio is not clear. It may be related to the reduced content of both C16 fatty acids, possibly caused by increased elongation of C16 fatty acids, as discussed above. More studies, taking into account de novo synthesis, elongation and desaturation of C16:0 are warranted to understand why the C16:1/C16:0 ratio behaves differently in mice and humans, and how this is related to insulin resistance.

Given the known strong link between SCD1 activity and lipogenesis, the Δ9D results in liver suggested that

lipogenesis was suppressed in the 1w-HFD group and elevated in the 16w-HFD group. Indeed, we found that total TAG and cholesterol content in liver was suppressed after 1 week of HFD feeding and elevated after 16 weeks of HFD feeding (Fig. 5). Surprisingly, despite the suppression of liver lipids after 1 week of HFD, protein levels of IRS1 and IRS2 were already significantly reduced (Fig. 5) suggesting but not proving that liver insulin resistance mechanisms were initiated at this stage. The mechanism underlying these dynamic TAG changes is unclear. Although we observed a downward trend for *Scd1* expression in the 1w-HFD group, correlating with the  $\Delta 9D$  index, other lipogenic genes were not down-regulated in the 1w-HFD group. This could mean that lipogenesis is suppressed through posttranscriptional mechanisms. Alternatively, increased, compensatory VLDL secretion could take place in the 1w-HFD group, triggered for example by increased leptin signaling which is likely to be present in the 1w-HFD animals (Fig. 1, [59–61]). Clearly, additional experiments are needed in order to identify the mechanisms causing the drop in liver lipids after short-term HFD feeding and also, to assess their relationship with the initiation of insulin resistance.

The plasma fatty acid profiling in our study revealed profound changes in PUFA content. Fractional content of C20:4, the end product of the n-6 fatty acid synthesis pathway, was increased by about 50% after 1 week of HFD, and doubled after 16 weeks of HFD (Fig. 3). In liver there was an early and persistent increase of C20:4 in PL (Fig. 6, Supplemental Table 2). As a potential mechanism for the C20:4 elevation in liver we identified induction of the two fatty acid desaturases participating in PUFA synthesis, *Fads1* and *Fads2*, which were increased already after 1 week of HFD (Table 1). Elevated C20:4 content and induction of *Fads1* or *Fads2* in liver has been observed in a few previous studies using insulin resistant rats and mice [40, 41, 54]. However, it is unclear if induction of the C20:4 synthesis pathway does occur in insulin resistance in general, as other animal and human metabolic disease studies have yielded variable results regarding C20:4 content [23, 58]. On the other hand, in most human insulin resistance studies decreased plasma content of the n-6 pathway precursor C18:2 and increased plasma content of the intermediate C20:3 was reported [23], suggesting increased flux through the PUFA synthesis pathway. In any event, our data indicate that n-6 fatty acid synthesis is induced in liver leading to progressively increased C20:4 efflux from liver on the HFD feeding regimen while in liver PL, C20:4 content reaches saturation level at an earlier time point.

The accumulation of C20:4 may have a functional impact on insulin resistance through several mechanisms. For instance, increased availability of C20:4 as a precursor

of leukotrienes and other pro-inflammatory eicosanoids may support chronic inflammation, which is known to be one of the causes of insulin resistance [62]. In support of this notion, we observed up-regulation of several inflammatory markers in both liver and adipose tissue already after 1 week of HFD feeding [63]. Alternatively, increased availability of C20:4 may affect insulin signaling directly, for example through activating PKC as shown in a rat liver cell line [64]. On the other hand, low PUFA content in phospholipids has been proposed as an insulin resistance mechanism (see below). Therefore, the induction of C20:4 could also be a mechanism counteracting insulin resistance. Intervention studies using inhibitors of desaturases critical for PUFA synthesis [65] or genetic knockdown studies would be suitable to address the role of C20:4 in the development of insulin resistance.

With respect to n-3 PUFA we found a decrease of C18:3n-3, C20:5 and C22:5 in plasma and liver. Interestingly, in liver the final product of the pathway, C22:6, was markedly reduced in the storage lipid classes (TAG and CE) but not in the PL compartment where it was actually increased after HFD feeding (Fig. 6). Because in plasma, C22:6 was also increased it is reasonable to assume that C22:6 was also not decreased in the PL membranes of the peripheral tissues, for example in skeletal muscle. These findings demonstrate the physiological capability of selectively preserving PUFA in PL membranes. Also, it is in conflict with several studies concluding that in insulin resistance there is a reduction in PUFA content in insulin target tissues and that this does contribute to impaired insulin signaling [13, 32, 33]. At least in the HFD-fed mouse model this does not appear to be the case.

In summary, we performed a comprehensive lipid profiling experiment in HFD-fed mice and confirmed previous reports showing a close correlation of plasma lipids with the degree of insulin resistance and hyperglycemia. Surprisingly, in liver, the 1w-HFD group had lower apparent  $\Delta 9D$  activity as well as markedly reduced TAG and cholesterol content, despite significant insulin resistance. This may indicate a compensatory mechanism directing excessive fat away from liver and into adipose tissue and muscle after short-term HFD feeding. Furthermore, we observed an early induction of desaturases important for PUFA synthesis accompanied by increased C20:4 content, which may play a role in the initiation of insulin resistance. The content of C22:6 was also increased in liver PL and in plasma. These findings indicate that lack of PUFA in cell membranes seems not to be responsible for the induction of insulin resistance in HFD-fed mice, as it has been postulated for other animal models.

## Introduction

*Bdellovibrios* (*Bdellovibrio* and like organisms; BALO) are fast swimming, small, comma- or crescent-shaped delta-proteobacteria that prey on larger Gram-negative bacteria [1–6]. After collision and attachment to the surface the predator penetrates the host cell then proliferates in the intraperiplasmic space of the prey producing large, rounded bdelloplasts [7, 8]. The parasitic phase is characterized by degradation of host macromolecules and uptake of the products into *Bdellovibrio*, which grows as a filament [9–13]. The filament forms septa and individual progeny cells are released during lysis of the host cell. BALO are ubiquitous and live in a wide range of water and soil habitats [2, 14, 15]. Because of their predatory and parasitic life style, it has been suggested that these bacteria might prove useful in treating environmental pollution, purifying drinking water systems, disrupting biofilms, and serving as potential agents for clearing bacterial infections [14, 16–18].

*Bdellovibrio bacteriovorus* is the major experimental system for studying predatory and parasitic bacteria [4, 14] and the genome of this bacterium has been sequenced [3]. Previous radiotracer studies showed that this bacterium mainly utilizes host fatty acids during intraperiplasmic growth but that it also has the capacity to synthesize some of its own [19–21]. However, details such as the identification of the bacterium's phospholipid classes are lacking. In contrast, much more is known about the lipids of the facultative predatory strain UKi2 of *Bacteriovorus stolpii* [22] (formerly also referred to as *Bdellovibrio bacteriovorus* [6, 23] and *Bdellovibrio stolpii* UKi2 [23]), which can be grown axenically. Once thought to be closely related, *Bdellovibrio* and *Bacteriovorus* were designated as separate genera in 2000 and various species were re-assigned after genotyping data showed these organisms represented distant phylogenetic backgrounds [23, 24]. In 1973, Steiner et al. [22] reported that *B. stolpii* UKi2 contained several sphingophosphonolipids (SPNL). More recently, the structural identities of 18 molecular species of *B. stolpii* UKi2 SPNL were elucidated by mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy techniques [25, 26].

Host-independent (HID) *B. bacteriovorus* strains are readily derived from host-dependent (HD) strains [27–30] and these facultative predators grow in axenic cultures. Since the biochemical makeup of axenically grown HID bacteria would not be complicated by the presence of compounds scavenged by parasitizing prey cells, such organisms can be analyzed and compared to the lipids of axenically grown *B. stolpii* UKi2. In the present study the major glycerophospholipids and fatty acids were identified in *Bdellovibrio bacteriovorus* strain HID5 providing new

data on the biochemical nature of this important predatory and parasitic bacterium.

## Experimental Procedures

### Organisms

*Bdellovibrio bacteriovorus* host-independent strain (HID5) was obtained from Carey Lambert and Elizabeth Sockett (University of Nottingham, UK), which was fully capable of predatory behavior and exhibited parasitic growth at the time of these studies. Cultures were grown in axenically in PY medium (1% yeast extract and 0.3% peptone) for four days at 29 °C in a shaker at 200 rpm. 50-ml cultures in 250 ml Erlenmeyer flasks or 500-ml in Fernbach flasks were grown for analyses. Organisms were harvested by centrifugation at 10,000g for 10 min at 4 °C. The supernatant was discarded and the pellet was washed three times with double-distilled water (ddH<sub>2</sub>O) and the final pellet was extracted for lipids.

Strain HD100 cultures, the parental strain of HID5, were maintained in liquid or agar plate cultures with *Escherichia coli* (K12). For mass cultures, an overnight culture of *E. coli* was grown at 37 °C in a shaking incubator at 200 rpm in YT medium (1.6% tryptone, 1% yeast extract, 0.5% NaCl). HD100 and *E. coli* cells were washed in a buffered solution containing 20 mM HEPES and 2.5 mM CaCl<sub>2</sub>, pH 7.4 (Ca/HEPES buffer) then combined. The mixed cell suspension was incubated at 29 °C on a shaker at 200 rpm for 1–2 days and aliquots were microscopically monitored for complete lysis of the *E. coli* cells by *B. bacteriovorus* HD100.

### Lipid Extraction and Analysis

All organic solvents were redistilled before use. Butylated hydroxytoluene (BHT, Shell Chemical Co., NY, USA) was added to all solvents at a final concentration of 8 µg/ml and dried lipid samples were stored under N<sub>2</sub> atmosphere to prevent oxidation of the lipids. BHT was excluded from solvents during the preparation of fatty acid methyl esters (FAME) for gas-liquid chromatographic (GLC) analysis.

The cell pellet was extracted for total lipids with CHCl<sub>3</sub>:methanol (MeOH):ddH<sub>2</sub>O (1:2:0.75, v/v/v) [31] for 24 h at room temperature. The lipids were purified by biphasic partitioning [32] then fractionated by adsorption column chromatography (Unisil, Clarkson Chromatography Products Inc., South Williamsport, PA, USA). The neutral lipid fraction was eluted with CHCl<sub>3</sub>, and polar lipids were eluted with MeOH. Sample volumes were reduced on a rotary evaporator, redissolved in CHCl<sub>3</sub>:MeOH (2:1, v/v), transferred into 4 dram screw-capped shell vials and were

dried down under a stream of N<sub>2</sub> and quantified gravimetrically.

### Thin-Layer Chromatography

The polar lipids were separated into individual phospholipid classes by thin-layer chromatography (TLC). Lipids on TLC plates were initially identified by the stain formulated by Dittmer and Lester [33] for phospholipids, Dragendorff for choline [34], ninhydrin for primary amines [34]. Iodine vapor, H<sub>2</sub>O and UV illumination were non-destructive methods used for visualizing the separated lipid classes. Authentic phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylinositol (PI), cardiolipin (CL) (all from Avanti Polar Lipids, Inc., Alabaster, AL) and phosphatidylglycerol (PG) (Sigma Chemical Co, St Louis, MO, USA) served as standards.

Preparative 1-D TLC for isolating individual lipids was performed on 500 µm-thick Silica H plates (Analtech, Newark, DE, USA) using CHCl<sub>3</sub>:MeOH:acetic acid:water (170:25:25:6, v/v/v/v; SS #1). This system separated lipids into three distinct bands (from the origin to the solvent front), band 1 (PG); band 2 (PS and PE); and band 3 [CL and *N*-acylphosphatidylethanolamine (NAPE)]. After recovering material in band 2, PE and PS were resolved on Silica 60 HPTLC plates (Merck KGaA, Darmstadt, Germany) developed in *n*-propanol:*n*-propylamine:ddH<sub>2</sub>O (80:15:5, v/v/v; SS #2) [25, 26]. Similarly, CL and NAPE recovered from band 3 by 1-D TLC were also separated using SS #2.

Analytical 2-D HPTLC Silica 60 plates were used to quantify individual phospholipids using CHCl<sub>3</sub>:MeOH:H<sub>2</sub>O (65:35:8, v/v/v; SS#3) in the first dimension. After the plate was dried, it was redeveloped in the same direction using CHCl<sub>3</sub>:MeOH:acetic acid (90:2:8, v/v/v; SS#4). After drying overnight, the plate was developed in the second dimension using SS #2 and stained for phosphorus [33]. Stained plates were scanned at 200 dpi (HP Scanjet 5590, Hewlett-Packard, L.P.) and quantified by image analysis (Metamorph2, Universal Imaging Corp., West Chester, PA, USA).

### Analysis for Sphingolipids

To test whether sphingophosphonolipids were present in *B. bacteriovorus*, the total polar lipid fraction and individual TLC-purified phospholipid classes were subjected to mild alkaline hydrolysis [35]. The products were recovered and analyzed by TLC in SS#1 and stained for phosphorus [33].

### Fatty Acids

Individual TLC-purified phospholipid classes were subjected to mild alkaline methanolysis to produce fatty acid

methyl esters (FAME). Alternatively, fatty acids were hydrolyzed then subjected to online derivatization in the GLC injection port according to the micro-method of MacGee and Allen [36]. Briefly, lipid components separated by TLC were saponified in 0.5 ml of 15% KOH–MeOH, phosphoric acid was added then the fatty acids were extracted into hexane. Fatty acids were then extracted from the hexane and concentrated into 10 µl of Meth-Prep I (Alltech Associates Inc, Deerfield, IL, USA) and injected with methylpropionate:methanol (1:2, v/v) into the gas chromatograph.

### Gas-Liquid Chromatography

FAME were separated and quantified using a Hewlett-Packard 5890 gas chromatograph equipped with a 30 m × 0.32 mm DB-1 fused silica capillary column (J&W Scientific, Folsom, CA, USA). The instrument was operated isothermally with 180 °C oven temperature. Injection port was set at 225 °C and the flame ionization detector (FID) temperature was set at 290 °C. Helium was the carrier gas at a flow rate of 1 ml/min. Initial identification of the fatty acids were made by comparing retention times with those of authentic standards (various mixtures from Matreya, Pleasant Gap, PA, USA, and Alltech) and confirmed by GC–MS. Peaks on chromatograms that did not correspond to available authentic standards were identified by GC–MS.

### Dimethyl Disulfide Derivatization and GC/MS

Dimethyl disulfide derivatives of the *B. bacteriovorus* FAME were prepared by adding 200 µl of dimethyl disulfide to the FAME samples [37]. A small iodine crystal of iodine was added and the solution was heated to 50 °C for 2 h. After cooling, 800 µl of a sodium thiosulfate solution (0.9541 g Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>·5H<sub>2</sub>O in 10 ml of water) was added. The derivatization procedure adds dimethyl disulfide across double bonds resulting in dithiomethoxy derivatives. The dithiomethoxy methyl esters were extracted with 600 µl of hexane. Nitrogen gas was used to concentrate the methyl esters by evaporating the hexane.

After dimethyl disulfide derivatization, analyses of the methyl esters derived from the phospholipids were performed using a Waters Micromass GCT<sup>TM</sup> GC/MS mass spectrometer. The gas chromatographic portion of the GCT<sup>TM</sup> was an Agilent Technologies model 6890 N gas chromatograph. Separation was performed using a J&W Scientific DB-XLB column (length: 30 m; ID 0.25 mm; film: 0.25 µm). Samples were injected under splitless conditions at 290 °C with helium as the carrier gas. The temperature was held at 120 °C for 1 min and increased at 10 °C/min to 290 °C and held for the remainder of the

**Fig. 1** Two-dimensional HPTLC separations of *B. bacteriovorus* strain HID5 (a) and strain HD100 (b) phospholipids stained for phosphorus. PE phosphatidylethanolamine, CL cardiolipin, PG phosphatidylglycerol, PS phosphatidylserine, NAPE *N*-acylphosphatidylethanolamine. These same major phospholipid classes were present in both strains

45-min analysis. Electron ionization (EI) mass spectrometry was performed using 70 eV electrons with a 200  $\mu$ A trap current. The mass spectrometer's source was held at 180 °C.

#### Nanospray Mass Spectrometry

Analyses of the separated phospholipids were performed in a Thermo Finnigan LTQ-FT<sup>TM</sup> MS using the static nanospray source. New Objective PicoTip<sup>TM</sup> emitters (2  $\mu$ m tip) were used for sample introduction. Nanospray solutions were prepared by dissolving the dried samples in  $\text{CHCl}_3$  followed by adding an equal volume of either MeOH or MeOH with 0.1 N  $\text{NH}_4\text{OH}$ . The source voltage was held at 1.70 kV with a capillary temperature of 175 °C. Capillary, tube lens, and other voltages varied and were optimized prior to data collection. High mass accuracy measurements of both the nanosprayed ions and product ions arising from collisional-induced dissociation, was performed in the Fourier transform ion cyclotron resonance (FT-ICR) portion of the LTQ-FT<sup>TM</sup>. FT-ICR data were acquired with the resolution set at 100,000. Collision-induced dissociation ( $\text{MS}^n$ ) was performed in the linear ion trap portion of the LTQ-FT<sup>TM</sup> with a normalized collision energy of 25. Automatic gain control (AGC) was used during data acquisition with the following settings: LTQ full scan 3e4; LTQ Selective Ion Monitoring (SIM) 1e4; LTQ  $\text{MS}^n$  1e4; FT full scan 5e5; FT SIM 5e5; FT  $\text{MS}^n$  1e5.

#### Results

Total extractable lipids and phospholipid composition of *B. bacteriovorus* HID5. Stationary phase cultures (500 ml) yielded 27 mg total extractable lipids ( $\pm 2$  SEM,  $n = 3$ ). The neutral and polar lipid fractions accounted for 17 and 83%, respectively, of the total lipids (97% recovery).

Approximately 8–10 phosphorus-positive spots were resolved and detected by 2-D HPTLC in the polar lipid fraction (Fig. 1). Five major components were tentatively identified by TLC migrations and staining properties compared to those of authentic standards. PE, PS and NAPE were phosphorus- and ninhydrin-positive; no spot stained with the Dragendorff reagent hence choline lipids were not detected. The relative percentages of the five identified phospholipid classes quantified by 2-D HPTLC separations and visualized by staining for phosphorus indicated the relative abundance of the phospholipid classes was  $\text{PE} > \text{PS} = \text{PG} = \text{CL} \gg \text{NAPE}$  (Table 1). However, as the lipids were stained for phosphorus and since CL contains two atoms of phosphorus, the moles of CL would be approximately half and the estimated moles of CL present in both strains were less than those estimated for PS and PG (Table 1).

After saponification, no detectable phosphorus-positive components were detected by 1-D HPTLC using SS #1 and by 2-D HPTLC using the same solvent systems described above. Thus alkaline-stable sphingolipids were not detectable among the phospholipids of *B. bacteriovorus* under the experimental conditions and analytical methods used in the present study. These analyses did not rule out the possible presence of free ceramides in the bacterium.

*Mass spectrometric identification of B. bacteriovorus HID5 phospholipids.* The identities of the five major phospholipid components in *B. bacteriovorus* HID5 were determined by accurate mass (Fig. 2; Table 2) and tandem MS procedures. The dominant phospholipid was PE and PS, PG and CL were also readily detected and identified. We were able to identify a minor phospholipid class in *B. bacteriovorus* by MS as the relatively rare phospholipid NAPE.

FT-ICR provided exceptional mass accuracy, typically less than 500 ppb, resulting in confident assignments of elemental composition (Fig. 2; Table 2). Ions were

to separate isobaric species including complications arising from isotopic contributions. While the FT-ICR data assigned elemental compositions, tandem mass spectrometry or  $MS^n$  data from the linear ion trap, provided structural information.

Multiple stages of tandem  $MS$  up to  $MS^4$ , were used to characterize the phospholipids. Negative ion  $MS/MS$  clearly identified the fatty acid components of phospholipids by product ions resulting from ketene loss, carboxylic acid loss, or directly as illustrated by the observed carboxylate anions. The observed product ions for the PG anions corresponded well with the literature [38]. Transferring the  $MS/MS$  product ions to the FT-ICR portion of the

<sup>a</sup> Minor components may also be present but are not shown in this table; e.g. PE *m/z* 702 has C15:0/C18:1

<sup>b</sup> Indicates that ions were too low in abundance or spectra too complex due to isotopic or multiple species

<sup>c</sup> GC/MS analysis indicated that C17:1 and C19:1 may be present as cyclopropyl fatty acids

<sup>d</sup> Unsaturated fatty acid with “+O” indicates an oxidized fatty acid possibly as an epoxide

<sup>e</sup> Both (C16:1 + O)/C18:1 and C16:1/(C18:1 + O) were observed

<sup>f</sup> Both (C17:1 + O)/C18:1 and C17:1/(C18:1 + O) were observed

<sup>g</sup> Overlapped with another phospholipid ion

instrument allowed for accurate mass assignments for the product ions. For example, as illustrated in Fig. 3, the deprotonated C16:0/C18:1 PG anion at *m/z* 747.5 produced the following products ions including their elemental composition, mass error from the theoretical mass, and ion structural description: 509.28832 (C<sub>24</sub>H<sub>46</sub>O<sub>9</sub>P<sup>-</sup>, –344 ppb, ketene loss from the C16:0 group), 491.27774 (C<sub>24</sub>H<sub>44</sub>O<sub>8</sub>P<sup>-</sup>, –388 ppb, fatty acid loss from the C16:0 group), 483.27265 (C<sub>22</sub>H<sub>44</sub>O<sub>9</sub>P<sup>-</sup>, –404 ppb, ketene loss

**Fig. 3** MS/MS of PG  $m/z$  747 on the LTQ-FT. Linear trap detection (a); FT-ICR detection (b)

from the C18:1 group), 465.26209 ( $C_{22}H_{42}O_8P^-$ , -410 ppb, fatty acid loss from the C18:1 group), 417.24093 ( $C_{21}H_{38}O_6P^-$ , -530 ppb; see Fig. 3), 391.22531 ( $C_{19}H_{36}O_6P^-$ , -489 ppb, see Fig. 3), 281.24844 ( $C_{18}H_{33}O_2^-$ , -583 ppb, C18:1 carboxylate anion), and 255.23284 ( $C_{16}H_{31}O_2^-$ , -447 ppb, carboxylate anion). Relative ion intensities show a preference for the C18:1 ketene and acid losses and the C18:1 carboxylate formation, which favors the C18:1 group in the *sn*-2 position and the C16:0 group in the *sn*-1

position [38]. While it may be difficult with many isobaric species being analyzed simultaneously (e.g.,  $m/z$  719 is predominantly C16:0/C16:1 but also has significant C14:0/C18:1), it appears that the *sn*-2 position favors the unsaturated group. It has been shown in the literature that the relative intensity of the loss corresponds more to position and not degree of unsaturation [38].

Oxidized phospholipids were also observed and characterized. While every effort was made to avoid oxidizing

the phospholipid samples (see “[Experimental Procedures](#)”), the possibility must be considered. Nonetheless, identification of these species is possible. Some of these species have been identified as containing epoxy-fatty acids. An example of an oxidized PG is the deprotonated anion at  $m/z$  763. Collision-induced dissociation of  $m/z$  763 coupled with FT-ICR mass accuracy measurements yielded an MS/MS product ion of  $m/z$  297.24356 and an elemental composition of  $C_{18}H_{33}O_3^-$  (−164 ppb mass error). Further dissociation of the  $m/z$  297 product ion or  $MS^3$  and accurate mass measurements, resulted in two subsequent product ions at  $m/z$  199.13393 ( $C_{11}H_{19}O_3^-$ , −192 ppb) and  $m/z$  183.13905 ( $C_{11}H_{19}O_2^-$ , −19 ppb); these ions are indicative of an epoxy group primarily at the  $\Delta^{11}$  position.  $MS^2$  results on  $m/z$  297 from an epoxy acid standard further supported the identification.

### Fatty Acids

The total cellular fatty acid composition of *B. bacteriovorus* HID5, was dominated by 16:0 (Table 3). No polyunsaturated acids were detected and only monounsaturated acids

with either 16, 17 or 18 carbons were present. However, several isomers with different double bond positions were identified among these monounsaturated fatty acids. The double bond position, determined by the addition of dimethyl disulfide across the double bond of unsaturated fatty acids and separation of the different isomers by GLC of their methyl ester derivatives. Electron ionization spectra for these derivatized compounds clearly indicated the location of the double bond prior to dimethyl disulfide derivatization [37].

The methyl ester of the cyclopropane fatty acid 9,10-Mt C16:0 (cyC17:0) was identified by MS. This component had a mass identical to the methyl ester of a 17:1 fatty acid and it did not react with dimethyl disulfide. Incomplete derivatization of 17:1 was ruled out as underivatized 16:1 and 18:1, which are fatty acids that are present at higher concentration, were not detected. Furthermore, the spectrum of the *B. bacteriovorus* cyC17:0 is the same as those of two entries in the National Institute of Standards and Technology registry of mass spectra (NIST 13093 and NIST 111346) reported for authentic standards of this fatty acid (cyclopropaneoctanoic acid, 2-hexyl-, methyl ester) (Fig. 4).

**Table 3** Fatty acid composition of *B. bacteriovorus* strain HID5 total lipids and its major glycerophospholipids and the total lipid fatty acid composition of *B. bacteriovorus* HD100 and *E. coli* prey cells

Total extracted lipids of strain HID5 and its major phospholipid classes and total extracted lipids of strain HD100 and its prey *E. coli* (percent of total ± SEM;  $n = 3$ ). Fatty acids were identified and quantified by a combination of GLC analyses of FAME and by GC/MS (TIC) of DMDS derivatives. Fatty acids of *N*-acylphosphatidylethanolamine and other minor unidentified phospholipid components were not analyzed in this study

<sup>a</sup> Number of carbons:number of double bonds

<sup>b</sup> Includes iso-branched and normal acids

<sup>c</sup> 16:1<sup>Δ9</sup> was the only isomer detected by MS in PS

<sup>d</sup> 16:1<sup>Δ7</sup> represented 4.3%, 16:1<sup>Δ9</sup> was 92.8%, and 16:1<sup>Δ11</sup> comprised 2.9% of the total 16:1 fatty acids in PG as determined by MS analysis

<sup>e</sup> 9,10 Indicates location of ring in the chain; Mt, methano; C16:0, cyclopropane fatty acid with 16 carbons in the straight portion of the chain (also designated as cyC17:0)

<sup>f</sup> 18:1<sup>Δ11</sup> was the only isomer detected in PS by MS

<sup>g</sup> 18:1<sup>Δ9</sup> comprised 1.0%, 18:1<sup>Δ11</sup> was 30.9%, and 18:1<sup>Δ13</sup> was 1.0% of the total 18:1 fatty acids in PG as determined by MS

<sup>h</sup> Unsaturation index (% total unsaturated fatty acids/% total saturated fatty acids)

<sup>i</sup> Lipid bilayer fluidity index (% total unsaturated + cyclopropane fatty acids/% total normal saturated fatty acids)

**Fig. 4** Electron ionization (EI) GC/MS of the major cyclopropane fatty acid in *B. bacteriovorus* HID5 identified as 9,10-Mt C16:0. The mass spectrum of *B. bacteriovorus* 9,10-Mt C16:0 (a); mass spectrum library entry for 9,10-Mt C16:0 (b). Some differences in ion intensities are the result of background subtraction which was required to remove the contribution of the perfluorinated tributylamine standard. This standard was continuously introduced during the chromatographic run to provide a “lock mass” that enhanced mass accuracy

Analyses of individually isolated phospholipid classes of *B. bacteriovorus* strain HID5 indicated that there were similarities in the fatty acid profiles between PE and PS and between PG and CL. PE and PS had high percentages of cyC17:0 compared to PG and CL whereas PG and CL were enriched in the monounsaturated acids 16:1 and 18:1.

There was insufficient amount of *B. bacteriovorus* NAPE isolated in the present study and only few of the major acids were detectable by GLC. Therefore, quantitative analysis of the fatty acid composition of this phospholipid class was not performed.

## Discussion

This is the first report on the glycerophospholipids of the predatory and parasitic delta-protobacterium *Bdellovibrio bacteriovorus*. With respect to general lipid classes, PE, PS, CL, and PG identified in HID5 were those commonly found among most organisms. Preliminary studies on the parental host-dependent *B. bacteriovorus* strain HD100 cultured with prey *E. coli* indicated that the same major

glycerophospholipid classes were also present in this strain (Table 1).

Although the glycerophospholipid NAPE is usually found as minor membrane components of plant and animal cells [39–41] and is developmentally regulated in the cellular slime mold *Dictyostelium discoideum* [42], these are very rare among prokaryotes. This lipid was detected in another bacterium, the anaerobic ovine rumen bacterium *Butyrivibrio fibrisolvens* [43]. The present study suggests the possibility that NAPEs might also be more commonly distributed among prokaryotes than previously thought. These lipids might not have been identified because NAPEs might represent only minor lipid components of bacterial cells as they are in eukaryotic cells. The property of having an additional fatty acid in NAPE is expected to enhance insertion of the amphipathic phospholipid molecule into membrane lipid bilayers.

Although there is evidence suggesting that a transacylation reaction between two PE molecules produces NAPE and lysoPE in *Butyrivibrio*, it remains unclear whether *O*-linked fatty acyl groups of PE or other lipids can be deacylated and used in transacylation reactions to produce the *N*-acylation of PE [43]. Studies on the biosynthesis of NAPE or any glycerophospholipid in *Bdellovibrio* are lacking. In a study of *Bacteriovorus stolpii* UKi2, cells metabolically radiolabeled with serine indicated PS, PE and a spot in TLC plates corresponding to the migration of NAPE were radioactive [44]. Whether this minor lipid component in *B. stolpii* UKi2 is NAPE remains to be determined by additional experiments.

As many organisms, especially parasites, scavenge lipids and other molecules from their environment (in the environment, culture medium or host cytoplasm) *B. bacteriovorus* was shown to gain most of its fatty acids from the host cell during intraperiplasmic growth [19]. However, the present analysis of *B. bacteriovorus* HID5 grown axenically in the absence of prey host cells demonstrates it has the ability to synthesize de novo its own fatty acids producing its distinct fatty acid profile. Like *B. bacteriovorus*, the culture medium is enriched in 16:0 but other components in the bacterium such as cyclopropane fatty acids are not found in the medium [25] and hence must be synthesized by the bacterium. The fatty acid composition of *E. coli* strain K12 identified in the present study was similar to those recently reported by Oursel et al. [45] on the lipids of strain LM3118. These workers employed liquid chromatography and tandem MS/MS with electrospray ionization that are comparable state of art techniques used in the present study. The total lipid fatty acid compositions of strains HD100 and HID5 might differ (Table 3) qualitatively (e.g. 18:0) and in the proportions of individual components. However, definitive conclusions on HD100 fatty acid compositions cannot yet be made. In this initial

analysis of HD100 cells, elimination of *E. coli* cell debris by extensive purification procedures were not included to prevent starvation conditions and other physiological and potentially biochemical changes in the *B. bacteriovorus* HD100 cells. Hence some *E. coli* cell debris might have been included in the HD100 cell preparations analyzed. Nonetheless, the major fatty acids in HD100, *E. coli* and axenically grown HID5 were 16:0, cy17:0 (not detected in the culture medium), 18:1, and 16:1 (Table 3).

Initial studies earlier reported on the total ester-linked fatty acids in *B. stolpii* UKi2 grown in a peptone and yeast extract medium indicated that the major components were those with 15 carbons (iso-branch, monounsaturated, or saturated); no cyclopropane fatty acids were detected [22]. The fatty acids in isolated glycerophospholipids of *B. stolpii* were not analyzed in that study. In contrast, the present study on *B. bacteriovorus* clearly demonstrated that this bacterium has ester-linked fatty acid distinct from that of *B. stolpii* UKi2 and that fatty acid synthesis in *B. stolpii* UKi2 and *B. bacteriovorus* are quite different. Fifteen-carbon acids in *B. bacteriovorus* total glycerolipids and in each isolated phospholipid class analyzed were only present in low proportions. The dominant fatty acid was 16:0 as previously reported [19]. Analysis of individual glycerophospholipids demonstrated that the monounsaturated acids 16:1 and 18:1 were found high in PG and CL and low in PE and PS whereas the cyclopropane fatty acid cyC17:0 was high in PE and PS and low in PG and CL. These data suggest that CL is produced from two PG molecules and PE from the decarboxylation of the PS headgroup.

Unsaturation index comparing unsaturated to saturated fatty acids is commonly examined as an indication of membrane bilayer fluidity (Table 3). However, both double bonds and the bulk of the cyclopropane ring contribute to loosening of lipid bilayer packing. If only double bonds are considered to contribute to fluidity, it would then appear that *B. bacteriovorus* HID5 membrane bilayers are tightly packed but when combining unsaturated and cyclopropane fatty acids and then comparing those values to normal saturated fatty acids, the unsaturation index values are close to 1. Since *B. bacteriovorus* is ubiquitous in nature and grows in a broad range of temperatures [2, 4, 15, 46] it should have the ability to alter membrane bilayer packing like other poikilothermic organisms. Thus, it is expected that the fatty acid composition would differ from that reported here if the bacterium is grown at a temperature different from that used in this study.

Sphingophosphonolipids were not detected in *B. bacteriovorus* and the presence in its genome of the gene coding for serine:fatty acyl transferase is not apparent. Therefore the correlation previously made between the presence of these lipids and predation in *B. stolpii* UKi2 (and their absence in non-predatory UKi1 and other strains) does not

appear applicable to *B. bacteriovorus*. Furthermore, it was recently shown that myriocin-treated *B. stolpii* UKi2 can exhibit predation and parasitism in the absence of sphingophosphonolipids albeit their locomotory behavior was affected [44]. On the other hand, the presence of sphingolipids in *B. bacteriovorus* cannot yet be ruled out; they might be present in concentrations not detectable by protocols used in the present study. While we have identified PG and CL in the present study, only the gene coding for cardiolipin synthase in the *B. bacteriovorus* HD100 was identified (National Center for Biotechnology Information, NCBI, #2735852); annotation for most genes coding for enzyme proteins in phospholipid synthesis is not yet available. This initial study on the extractable lipids of *B. bacteriovorus* indicate that there are other minor lipids present in this bacterium. Hence it would be good if future studies were conducted to identify the other lipid components present in *B. bacteriovorus*. Nonetheless the differences found so far between the lipids of these two predatory bacteria *Bdellovibrio bacteriovorus* and *Bacteriovorus stolpii* are consistent with the assignment of them to separate genera.

dioxygenases. Lipoxygenases catalyse the addition of molecular oxygen to polyunsaturated fatty acids with a (*cis,cis*)-1-4-pentadiene system to give an unsaturated fatty acid hydroperoxide [10]. However, an oxygenation of monounsaturated fatty acids such as oleic [11–14] and octadec-*cis*-12-enoic [14] acids by such enzymes has also been reported. These reactions produce mainly hydroxy, hydroperoxy or oxoacids. Lipoxygenases are widely distributed in plants, fungi and animals [15]; however, these enzymes have also been detected in bacteria [12, 16]. The fungal heme enzyme linoleate 8-dioxygenase abstracts allylic hydrogen and introduces molecular oxygen in an antarafacial way at C-8 leading to the formation of 8*R*-hydroperoxylinoleic acid [17, 18]. It is interesting to note that the allylic oxygenation induced by this enzyme, which also oxygenates oleic,  $\alpha$ -linolenic and ricinoleic acids [17], presents some analogies with the regiospecific allylic oxygenation of *cis*-vaccenic acid at C-10 previously observed [8, 9].

In the present work, we intended to re-examine the strain *Erythrobacter* sp. MG3 in order to try to determine the growth conditions favouring this peroxidation of *cis*-vaccenic acid and to elucidate the behaviour of the 10-hydroperoxyoctadec-11(*cis*)-enoic acid thus formed.

## Experimental Procedures

### Organism

*Erythrobacter* sp. strain MG3 was isolated in December 2000 from the surface of SE Atlantic/W Indian Ocean (41°06'N, 72°27'W). The strain is phylogenetically related to *Erythrobacter longus* and exhibits the typical features of members of the *Erythrobacter* genus [2]. The cultures were grown in Erlenmeyer flasks on a rotary shaker at 23 °C. The illumination was provided by a bank of luminescent tubes giving  $\sim 200 \mu\text{mol quanta m}^{-2} \text{s}^{-1}$  with a 12:12 h light/dark cycle. Generally the cells were grown in an enriched seawater medium supplemented by 0.5 g peptone and 0.1 g yeast extract per litre [2]. For nutrient limitation studies the cultures were grown on artificial seawater media as described in [2] and supplemented by glucose as the sole source of carbon. The carbon limited medium contained 1 mM glucose, 2.5 mM ammonium sulfate and 0.3 mM phosphate. For the phosphorus limitation condition, the medium was supplemented by 10 mM glucose and the phosphate content was reduced to 0.03 mM. In the case of nitrogen limitation, the ammonium sulfate content was reduced to 0.1 mM and supplemented by 10 mM glucose and 0.3 mM phosphate. The cultures were harvested in steady-state phase by centrifugation (10,000  $\times$  g).

### Alkaline Hydrolysis

Saponification was carried out on both reduced and non-reduced cells. After reduction, 25 ml of water and 2.8 g of potassium hydroxide were added and the mixture was directly saponified by refluxing for 2 h. In the case of non-reduced samples, an additional 25 ml of methanol was added before saponification. After cooling, the contents of the flask were extracted three times with *n*-hexane. The combined *n*-hexane extracts were dried over anhydrous  $\text{Na}_2\text{SO}_4$ , filtered and concentrated to give the unsaponified fraction. The aqueous phase was then acidified with hydrochloric acid (pH 1) and subsequently extracted three times with dichloromethane. Treatment of the combined dichloromethane extracts as described above gave the saponified fraction.

### Reduction

Hydroperoxides were reduced to the corresponding alcohols in methanol (25 ml) by excess  $\text{NaBH}_4$  or  $\text{NaBD}_4$  (10 mg/mg of extract) using magnetic stirring (15 min at 0 °C). During this treatment, ketones are also reduced and the possibility of some ester cleavage cannot be excluded. After reduction, a saturated solution of  $\text{NH}_4\text{Cl}$  (10 ml) was added cautiously to destroy the excess reagent, the pH was adjusted to 1 with dilute HCl (2 N) and the mixture was shaken and extracted with hexane: $\text{CHCl}_3$  (4:1, v/v;  $\times 3$ ). The combined extracts were dried as described above and evaporated to dryness under a stream of nitrogen.

### Catalytic Hydrogenation

Lipid extracts were hydrogenated overnight under magnetic stirring in methanol with  $\text{Pd/CaCO}_3$  (10–20 mg/mg of extract) (Aldrich) as a catalyst. After hydrogenation, the catalyst was removed by filtration and the filtrate was concentrated by rotary evaporation.

### Osmium Tetroxide Oxidation

Lipid extracts and  $\text{OsO}_4$  (1:2, w:w) were added to a pyridine-dioxane mixture (1:8, v/v; 5 ml) and incubated for 1 h at room temperature. Then, 6 ml of  $\text{Na}_2\text{SO}_3$  suspension (16%  $\text{Na}_2\text{SO}_3$  in water-methanol, 8.5:2.5, v/v) was added and the mixture was again incubated for 1.5 h. The resulting mixture was gently acidified (pH 3) with HCl and extracted three times with dichloromethane (5 ml). The combined dichloromethane extracts were subsequently dried over anhydrous  $\text{Na}_2\text{SO}_4$ , filtered and concentrated.

## Methylation

Lipid extracts were taken up in 2 ml of  $\text{BF}_3$ /methanol (14%) and heated at 80 °C for 1 h. After cooling, an excess of water was added and methyl esters were extracted three times with hexane, dried over anhydrous  $\text{Na}_2\text{SO}_4$ , filtered and concentrated using rotary evaporation.

## Silylation

After evaporation of the solvent, each residue was taken up in 300  $\mu\text{l}$  of a mixture of anhydrous pyridine and BSTFA (Supelco) (2:1, v/v) and silylated for 1 h at 50 °C. After evaporation to dryness under nitrogen, the residue was redissolved in ethyl acetate (2 ml/mg) and BSTFA (0.1 ml) (in order to avoid desilylation of fatty acids) and then analysed by GC–EIMS.

## Gas Chromatography–Electron Impact Mass Spectrometry (GC–EIMS)

GC–EIMS analyses were carried out with an Agilent 6890 gas chromatograph connected to an Agilent 5973 Inert mass spectrometer. The following conditions were employed: 30 m  $\times$  0.25 mm (i.d.) fused silica capillary column coated with SOLGEL-1 (SGE; 0.25  $\mu\text{m}$  film thickness); oven temperature programmed from 70 to 130 °C at 20 °C  $\text{min}^{-1}$ , from 130 to 250 °C at 5 °C  $\text{min}^{-1}$  and then from 250 to 300 °C at 3 °C  $\text{min}^{-1}$ ; carrier gas (He) maintained at 0.69 bar until the end of the temperature program and then programmed from 0.69 to 1.49 bar at 0.04 bar  $\text{min}^{-1}$ ; injector (on column with retention gap) temperature, 50 °C; electron energy, 70 eV; source temperature, 190 °C; cycle time, 1.99 cycles  $\text{s}^{-1}$ , scan range, 50–800.

Structural assignments were based on the interpretation of mass spectrometric fragmentations and confirmed by comparison of retention times and mass spectra with those of authentic compounds, when these were available.

## Standard Compounds

Classical fatty acids and 2-hydroxy acids were purchased from Sigma (St. Quentin Fallavier, France).  $\text{Fe}^{++}$ /ascorbate induced autoxidation [19] of *cis*-vaccenic acid produced a mixture of allylic hydroperoxides containing significant amounts of *cis*- and *trans*-10-hydroperoxyoctadec-11-enoic and 12-hydroperoxyoctadec-10-enoic acids [20]. Subsequent reduction of these different allylic hydroperoxides in methanol with excess  $\text{NaBH}_4$  afforded the corresponding hydroxy acids. Oxoacids were obtained by dehydration of the corresponding hydroperoxides in a mixture of pyridine and acetic anhydride [20].

Hydrogenation of hydroxy acids and oxoacids was carried out in methanol with  $\text{Pd}/\text{CaCO}_3$  as catalyst [20].

## Results and Discussion

### Characterisation of the Main Lipidic Components of *Erythrobacter sp.* strain MG3

The unsaponified lipidic fraction obtained after alkaline hydrolysis of cells of *Erythrobacter sp.* strain MG3 is dominated by a single component, assigned by GC/EIMS as phytol. This isoprenoid alcohol arises from the hydrolysis of bacteriochlorophyll-a, which constitutes with erythroxanthin sulfate the major pigments of this phototrophic bacterium [2]. Though present in large amounts in this fraction, erythroxanthin sulfate was non-amenable to gas chromatography with the operating conditions used.

As previously described [8], the corresponding saponified fraction obtained after  $\text{NaBH}_4$  reduction is dominated by *cis*-vaccenic acid and also contain  $\text{C}_{12:0}$ ,  $\text{C}_{14:0}$ ,  $\text{C}_{15:0}$ ,  $\text{C}_{16:1\omega7}$ ,  $\text{C}_{16:0}$ ,  $\text{C}_{18:2\omega7,13}$ ,  $\text{C}_{18:0}$ , 11-methyl $\text{C}_{18:1\omega6}$  fatty acids and some 2-hydroxy acids, which are classical components of sphingolipids of *Erythrobacter*-related strains. As expected, we detected *cis* and *trans* 10-hydroxyoctadec-11-enoic acid trimethylsilyl derivatives (Table 1). These two isomers exhibit exactly similar mass spectra [9] and their identification is based on comparison of their retention times with standards. Deuterium labelling allowed previously to prove that these compounds resulted from the reduction during the treatment of a mixture of the corresponding hydroperoxyacids, oxoacids and hydroxy acids [8]. Surprisingly, the proportion of 10-hydroxyoctadec-11(*cis*)-enoic acid after reduction, which constituted previously only 1% of the parent *cis*-vaccenic acid during the stationary phase of growth [8], is now of 48 % (Table 1). We also detected small amounts of *trans* 12-hydroxyoctadec-10-enoic acid deriving from allylic rearrangement of the 10-hydroperoxyoctadec-11-enoic acid. In addition to all these previously described compounds, we observed the production of five new interesting compounds (7,10-epoxyoctadec-11-enoic, 11-hydroxyoctadecanoic, 12-hydroxyoctadecanoic, 10-hydroxyoctadecanoic and 10-hydroxyoctadeca-5,11-enoic acids) (Table 1).

Mass spectra of the methyl and trimethylsilyl esters of 7,10-epoxyoctadec-11-enoic acid appeared to be poorly informative (Fig. 1). The position of the tetrahydrofuran (THF) ring of this compound was determined after hydrogenation of the corresponding methyl ester (in the presence of Pd as catalyst) and subsequent GC–EIMS analysis (Fig. 2b). The mass spectrum thus obtained exhibits a molecular peak at  $m/z$  312 (instead of  $m/z$  310 for the non-hydrogenated methyl ester) (Fig. 1a) and two

**Table 1** Fatty acid composition (relative percentage) of *Erythrobacter* sp. strain MG3 cells collected at different phases of growth

prominent ions at  $m/z$  183 and 199 corresponding to the two strongly favoured  $\alpha$ -cleavages relative to the ionised oxygen of the THF ring. These two fragments then undergo losses of water or methanol affording ions at  $m/z$  149, 165, 167 and 181. The presence of the fragment ion at  $m/z$  172 resulting from a THF-specific cleavage initiated by an initial hydrogen transfer from the carbon 7 to the ester group [21] also confirms the position of the THF ring relative to the ester group. The position of the double bond was determined after  $\text{OsO}_4$  oxidation of the methyl ester and subsequent silylation. The mass spectrum of the bis-trimethylsilyloxy derivative thus obtained (Fig. 2a) exhibited two fragment ions at  $m/z$  187 and 301 resulting from the cleavage of the bond between the two carbon atoms bearing the trimethylsilyloxy groups. Due to the involvement of subsequent loss of methanol ( $m/z$  269) and different cleavages induced by the THF ring or the ester group, the fragment ion at  $m/z$  301 is weaker than this at  $m/z$  187. The useful ion at  $m/z$  374 resulting from trimethylsilyl transfer towards the ester group [22, 23] (and this at  $m/z$  284 formed after an additional loss of trimethylsilanol) confirmed that the fragment ion at  $m/z$  301 contains the ester group. This proved the presence of a double bond in position 11 in the parent fatty acid and allowed us to identify this compound as 7,10-epoxyoctadec-11-enoic acid. If the presence of furan fatty acids in several marine bacteria [24, 25] and crayfish [26] was previously described; to our knowledge, this is the first report of a natural fatty acid containing a THF cycle.

Reduction with  $\text{NaBD}_4$  instead of  $\text{NaBH}_4$  allowed to show that the 11-hydroxyoctadecanoic and 12-

hydroxyoctadecanoic acids detected arise from the reduction of 11,12-epoxyoctadecanoic acid during the treatment (Fig. 3a, b). The presence of this epoxide could be confirmed in non-reduced samples. Deuterium labelling also allowed us to demonstrate that the 10-hydroxyoctadecanoic acid detected results from the reduction of the corresponding oxoacid during the treatment.

The mass spectrum of the silylated derivative of 10-hydroxyoctadeca-5,11-enoic acid is given in Fig. 3c. It exhibits a molecular peak at  $m/z$  440 (instead of  $m/z$  442 in the case of the silylated 10-hydroxyoctadec-11-enoic acid) [9] and a strong fragment ion at  $m/z$  213 corresponding to the cleavage at the carbon bearing,  $\text{OSiMe}_3$  group. The presence of this compound is very interesting. Indeed, it shows that the regiospecific enzymatic peroxidation of the allylic position 10 is not restricted to *cis*-vaccenic acid but seems to act on all the fatty acids possessing a double bond at the position 11.

#### Behaviour of 10-Hydroperoxyoctadec-11-enoic Acid in Cells of *Erythrobacter* sp. strain MG3

Hydroperoxides are extremely cytotoxic and cause damage to membranes and proteins in particular [27]. Several enzymatic processes causing further reactions of the hydroperoxides and avoiding their accumulation have been previously described. These processes involve: (1) reduction to the corresponding hydroxy acids [27], (2) homolytic cleavage of the O-O bond resulting in the formation of oxoacids [15], (3) dehydration to allene oxides and subsequent hydrolysis of these unstable intermediates [28], and (4) direct cleavage of the hydroperoxides to aldehydes

**Fig. 1** EI mass spectra of 7,10-epoxyoctadec-11-enoic acid methyl (a) and trimethylsilyl (b) esters

and oxoacids [29]. Only the two first processes seem to act in strain MG3. The reduction of hydroperoxyacids to the corresponding hydroxy acids is generally attributed to dioxygenases themselves [27]. However, the presence of 11,12-epoxyoctadecanoic acid in strain MG3 (see above) allowed us to attribute the reduction of 10-hydroperoxyoctadec-11-enoic acid to the corresponding alcohol to the involvement of a peroxygenase. Indeed, this enzyme catalyses an intermolecular transfer of oxygen from hydroperoxides to the double bonds of fatty acids yielding alcohols and epoxides (Fig. 4) [30, 31]. Conversion of hydroperoxyacids to oxoacids is induced by lipohydroperoxidases [32].

Allylic hydroperoxides are not stable and may also undergo highly stereoselective free radical allylic rearrangement [33]. These processes, which can act on both *cis* and *trans* allylic hydroperoxides, affords only *trans* configurations [33]. Allylic rearrangement of 10-hydroperoxyoctadec-11(*cis*)-enoic acid results to the formation

of 10-hydroperoxyoctadec-11(*trans*)-enoic and 12-hydroperoxyoctadec-10(*trans*)-enoic acids; these isomeric hydroperoxyacids being then also converted to the corresponding hydroxyacids and oxoacids (Fig. 4).

The *cis* and *trans* 10-oxooctadec-11-enoic acids formed undergoes subsequent saturation to 10-oxooctadecanoic acid (Fig. 4). The saturation of unsaturated fatty acids in the gut of some animals has been long recognised [34]. This biohydrogenation is brought about by the mixed culture of rumen bacteria and involves several enzyme catalysed steps. It was previously demonstrated that anaerobic incubation of oleic and elaidic acids with strained rumen contents lead to their saturated counterpart (stearic acid) and to a lesser extent to the isomerisation of each monounsaturated fatty acid to its geometric isomer [35]. Consequently, the formation of 10-oxooctadec-*trans*-11-enoic acid may be also attributed to the isomerisation of its geometrical isomer during the biohydrogenation (Fig. 4).

**Fig. 2** EI mass spectra of the silylated OsO<sub>4</sub> (a) and hydrogenated (b) derivatives of 7,10-epoxyoctadec-11(*cis*)-enoic acid methyl ester

In parallel to enzymatic conversion, hydroperoxides may also undergo chemical decomposition under mild conditions. The majority of these decomposition reactions involve free radicals and are promoted by heat, photolysis, metal ions and metalloproteins. The very distinct proportions of hydroperoxyacids, hydroxy acids and oxoacids observed in the case of the *cis* and *trans* isomers [8] allowed us to exclude the involvement of such abiotic

processes during the degradation of *cis* and *trans* 10-hydroperoxyoctadec-11-enoic acid to the corresponding hydroxyacids and oxoacids. In contrast, we proposed the abiotic formation pathways described in Fig. 5 for the formation of 7,10-epoxyoctadec-11-enoic acid. These pathways involve the cyclisation of the alkoxy radical deriving from homolytic cleavage of 10-hydroperoxyoctadec-11-enoic acid. A similar cyclisation process (involving

**Fig. 3** EI mass spectra of (11-D<sub>1</sub>)-12-hydroxy-octadecanoic (a), (12-D<sub>1</sub>)-11-hydroxyoctadecanoic (b) and 10-hydroxyoctadeca-5,11-dienoic (c) acid trimethylsilyl derivatives

the passing through alkoxy radicals) was previously proposed to explain the formation of THF rings during the treatment of monohydroxyalcohols with lead tetraacetate

[36]. The strong increase of the ratio 7,10-epoxyoctadec-11-enoic acid / 10-hydroxyoctadec-11(*cis*)-enoic acid observed during the growth (Table 1) well supports a

**Fig. 6** Partial total ion chromatogram showing the presence of diastereoisomeric 7,10-epoxyoctadecanoic acids after catalytic hydrogenation of methylated lipid extracts obtained from *Erythrobacter* sp. strain MG3 (steady-state phase)

peroxidation appeared to be strongly enhanced in all the cultures grown at low (7 °C) temperature (Table 2).

Re-examination of the fatty acid content of *Erythrobacter* sp. strain MG3 cells (dominated by *cis*-vaccenic acid) allowed us to confirm the involvement of an unusual regiospecific enzymatic peroxidation of the allylic carbon 10 of *cis*-vaccenic acid, which seems to be a characteristic of aerobic and anaerobic phototrophic bacteria. A peroxidation of the allylic carbon 10 of octadeca-5,11-dienoic acid, which is also present in this strain [4], could also be observed showing that this enzymatic attack is not restricted to *cis*-vaccenic acid but can act on all the acids possessing a double bond at the position 11. Enzymatic degradation of 10-hydroperoxyoctadec-11(*cis*)-enoic acid resulting from the peroxidation of *cis*-vaccenic acid mainly

**Table 2** Percentage (relative to residual *cis*-vaccenic acid) of compounds resulting from the enzymatic attack of the allylic position 10 (Sum of 7,10-epoxyoctadec-11-enoic, 10-hydroxyoctadec-11(*cis*)-enoic, 10-hydroxyoctadec-11(*trans*)-enoic, 12-hydroxyoctadec-10-enoic, 10-hydroxyoctadecanoic, 11-hydroxyoctadecanoic and 12-hydroxyoctadecanoic acids) in *Erythrobacter* sp. strain MG3 cultivated at different growth conditions

Growth conditions	Percentage
C-limited 22 °C light/dark	7.1

N-limited 7 °C dark	36.5

involves reduction to the corresponding hydroxy acid (probably catalysed by peroxygenases) and cleavage to the corresponding oxoacid, which is then biohydrogenated. In parallel to these enzymatic processes, 10-hydroperoxyoctadec-11(*cis*)-enoic acid also undergoes abiotic allylic rearrangement to 10-hydroperoxyoctadec-11(*trans*)-enoic and 12-hydroperoxyoctadec-10(*trans*)-enoic acids and cyclisation to the very unusual 7,10-epoxyoctadec-11-enoic acid. The proportion of products resulting from this enzymatic peroxidation strongly increases at low temperature and in carbon limited steady-state cultures.

domain and sheds a soluble form [3, 4]. CXCL16 promotes interactions between macrophages/DC and CD8 T cells and guides effector T cell trafficking in lymphoid organs and some nonlymphoid tissues [3, 5, 6]. The membrane bound CXCL16 also mediates the firm adhesion of CXCR6-expressing T cells [6]. Recent reports indicated that the elevated CXCL16 mediated a unique pathogenic role in chronic inflammatory diseases such as rheumatoid arthritis, cardiac vascular atherosclerosis, and cancers [7–9]. CXCL16 is not exclusively expressed on the cell surface. It is also found as a soluble molecule that is constitutively generated by proteolytic cleavage of its transmembrane variant, a process called shedding [10].

LysoPtdOH is a serum-borne lysophospholipid that signals through the cognate G protein-coupled receptors to evoke a great variety of responses in numerous cell types. In addition to stimulating cell proliferation and survival, lysoPtdOH might regulate the trafficking, cytokine production, and T cell-activating functions of DC [11–13]. Reports have indicated that lysoPtdOH receptors might also appear on the human macrophage surface, however, influences of lysoPtdOH on cytokines/chemokines production in macrophages/DC have been controversial [14–16]. The effect of lysoPtdOH on CXCL16 expression in macrophages/DC has never been explored. Using monocyte-derived macrophages/DC (MoDC), we investigated how lysoPtdOH regulate CXCL16 production and shedding. The increased production of CXCL16 stimulated by lysoPtdOH in macrophages/MoDC may involve multiple signaling transduction pathways including  $G_{i/o}$ , Rho, and NF- $\kappa$ B, which would affect the chemotactic activity of macrophages/MoDC as well.

## Materials and Methods

### Reagents

The endotoxin content of the sodium salt of 18:1 lysoPtdOH (1-oleoyl-2-hydroxy-*sn*-glycero-3-phosphate; Avanti Polar Lipids) in working solution was <50 pg/ml. Pertussis toxin (PTx), lipopolysaccharide (LPS), and pyrrolidine dithiocarbamate (PDTC) were purchased from Sigma (St Louis, MO). The C3 exoenzyme (exoC3) was purchased from Cytoskeleton (Denver, CO). Anti-lysoPtdOH receptor antibodies, anti-CXCL16 antibody, and isotype-matched control were from BD Pharmingen (San Diego, CA).

### Cell Source and Culture

CD14<sup>+</sup> monocytes were purified from heparinized peripheral blood mononuclear cells (PBMC), which were

either purchased from BRT Laboratory (Baltimore, MD) or healthy donors using immunomagnetic selection according to the manufacturer's instructions (Miltenyi Biotec, Auburn, CA). All donors (both male and female, 20–50 year old) provided written informed consent according to federal, state and institutional guidelines. Monocyte-derived macrophages were obtained by culturing CD14<sup>+</sup> monocytes ( $0.5 \times 10^6$  cells/ml) in complete RPMI-1640 (Invitrogen, Carlsbad, CA) with 10% human serum (Sigma, MO) in the presence of GM-CSF (50 ng/ml, R&D Systems, Minneapolis, MN) for 6 days. MoDC were generated by supplementing with GM-CSF and IL-4 (50 ng/ml, each) for over 6 days. Macrophages/MoDC were washed and incubated with LPS (100 ng/ml, Sigma Chemicals) for 24 h to induce cytokine secretion. To determine whether lysoPtdOH affect macrophages/MoDC activation or modulate the effects of LPS, macrophages/MoDC were incubated with and without lysoPtdOH or LPS.

### Flow Cytometry Analysis

Cells were counted ( $2 \times 10^6$ ) and stained with fluorescence-labeled antibodies against lysoPtdOH receptors and CXCL16 for 30 min, washed and analyzed by flow cytometry (FACS, Becton Dickinson Immunocytometry Systems, San Jose, CA). Gated on live cells, expression of LPA1, LPA2, LPA3, and CXCL16 was analyzed in comparison with isotype-match controls. Mean fluorescence intensities (MFI) were analyzed with CellQuest software (Becton Dickinson Immunocytometry Systems).

### Qualitative RT-PCR

Cells were lysed using TRIzol Reagents. Total RNA was precipitated from the aqueous phase using isopropyl alcohol after separation by chloroform. After DNase I treatment, cDNA was synthesized from 1  $\mu$ g total RNA using MLV-Reverse Transcriptase (Invitrogen, Carlsbad, CA) according to the manufacturer's directions. RT-PCR profiled as followed: 48 °C for 45 min, 94 °C for 2 min, 30 cycles (94 °C for 30 s, 60 °C for 1 min, 68 °C for 2 min), 68 °C for 5 min. Primer sequences used in RT-PCR were 5'-CGGAGACTGACTGTCAGCAC-3' and 5'-GGTCCAGAACTATGCCGAGA-3' for LPA1 mRNA; 5'-TGGCCTA CCTTCTCCTCATGTTCCA-3', 5'-GGGTCCAGCACAC CACAAATGCC-3' for LPA2 mRNA; 5'-GGACACCCAT GAAGCTAAT-3' and 5'-TCTGGGTTCTCCTGAGAG AA-3' for LPA3 mRNA [17, 18].  $\beta$ -actin primer sequences were described previously [19]. To analyze the reactions, 10  $\mu$ l of each reaction was subjected to electrophoresis on a 1% agarose gel and DNA was detected by ethidium bromide staining.

## ELISA

CXCL16 concentrations in the spent culture supernatant were measured by ELISA kits purchased from R&D Systems (Minneapolis, MN). Briefly, the capture antibody in the working concentration was diluted and coated in a 96-well microplate overnight at 4 °C. After washing and blocking, 100 µl of the sample or standard in appropriate diluents were added and incubated for 2 h at room temperature following the manufacturer's protocol. The detection antibody conjugated with biotin in the working concentration was added after washing for 2 h, then streptavidin conjugated with HRP was incubated for 1 h. Color was developed by adding substrates for 20 min and the optical density of each well was determined using a microplate reader set to 650 nm. CXCL16 concentrations were calculated according to the standard controls.

## Real-time PCR

Cells were lysed, total RNA was purified and cDNA was synthesized as above. RT-PCR was set up in a 96-well plate using a TaqMan® Universal PCR Master Mix kit from Applied Biosystems (Foster City, CA). The reactions were run on an ABI PRISM® 7300 Sequence Detection System and compared to the actin control. Pre-validated primers and probes specific for CXCL16 (Hs00222859\_m1) and  $\beta$ -actin (Hs00194811\_m1) were purchased from Applied Biosystems. After normalization RNA amplified from different cells was exported as TIFF files.

## T cells Activation and Migration Assay

CD3<sup>+</sup> T cells were purified from normal donor PBMC as above by positive selection (Miltenyi Biotec, Auburn, CA). Purified CD3<sup>+</sup> T cells were stimulated with anti-CD3/CD28 coated beads for 5 days before analysis or migration assay [20]. Activated CD3<sup>+</sup> cells were loaded into the top chamber of a trans-well (5.0 µm pore size, Costar, New York, NY). In the bottom well, a total of 500 µl spent culture supernatant or fresh media as control were plated. Anti-CXCL16 blocking antibody was purchased from R&D Systems. Migration was allowed to proceed for 2 h. Then cells that had migrated to the bottom wells were counted and the absolute numbers of migrated cells were calculated. Some macrophages were pretreated with different inhibitors PTx (1 µg/ml), exoC3 (1 µg/ml), or PDTC (200 µM), then treated with lysoPtdOH/LPS, spent culture supernatant were collected and plated in the bottom wells [13, 21].

## Statistics

One-way ANOVA with Dunnett's post test was performed using GraphPad InStat version 3.05 to compare the averages of different experiment groups.  $P < 0.05$  was accepted as being significant.

## Results

### Macrophages and MoDC Express LysoPtdOH Receptors

Macrophages and MoDC were derived from CD14<sup>+</sup> monocytes from normal donor PBMC without age or gender discrimination. FACS confirmed the cell surface expression of LPA1 and LPA2, but not LPA3 on macrophages/MoDC, as well as their precursors CD14<sup>+</sup> monocytes (Fig. 1a). Similar results were observed when analyzing mRNA expression of lysoPtdOH receptors by qualitative RT-PCR, where expression of both LPA1 and LPA2 mRNA was readily detectable (Fig. 1b).

### Macrophages and MoDC Express and Secrete CXCL16

FACS confirmed macrophages and MoDC expressed CXCL16 on the cell surface. A few monocytes expressed CXCL16 on their cell surface, almost all macrophages acquired CXCL16 after differentiation, MoDC expressed CXCL16 with the highest intensity on the cell surface (Fig. 2a). ELISA showed both macrophages and MoDC secreted soluble CXCL16, while macrophages released more CXCL16 into their spent culture supernatants (Fig. 2b).

### LysoPtdOH Stimulates CXCL16 Production from Macrophages

To examine the effect of lysoPtdOH on CXCL16 expression, we cultured macrophages, stimulated them with LPS to trigger chemokine release. We observed that lysoPtdOH at 10 µM significantly increased the production and release of CXCL16 from macrophages by more than twofold as detected by ELISA (Fig. 3a). LysoPtdOH did not affect CXCL16 cell surface presentation shown by FACS (Fig. 3b). Quantitative real-time PCR showed lysoPtdOH upregulated CXCL16 mRNA expression in macrophages also (Fig. 3c). Control macrophages had basal CXCL16 mRNA (detectable at cycle 35), lysoPtdOH increased CXCL16 mRNA (detectable at cycle 32), LPS induced CXCL16 mRNA (detectable at cycle 28), however, lysoPtdOH and LPS synergized in CXCL16 mRNA transcription (detectable at cycle 22). By calculating the cycle

**Fig. 1 a** Expression of lysoPtdOH receptors on the cell surface of macrophages and MoDC. Macrophages and MoDC were derived from CD14<sup>+</sup> monocytes by culturing with GM-CSF or GM-CSF+IL-4 for 6 days. Cells were harvested and stained with PE labeled anti-LPA antibodies. Cells were washed and analyzed by FACS. *Filled curves* show results from cells stained with isotype-matched control mAbs. *Curves with just lines* show results from cells stained with specific antibodies. The *numbers* shown in each histogram represent MFI of LPA, LPA<sub>2</sub> or LPA<sub>3</sub> over control. *Graphs* shown are representative of three independent experiments. **b** RT-PCR analysis of mRNAs encoding lysoPtdOH receptors in macrophages and MoDC

threshold (CT) values of each sample and  $\Delta$ CT, we found that lysoPtdOH enhanced CXCL16 mRNA transcription by 64-fold.

#### Signaling Pathways Regulating CXCL16 Production Enhanced by LysoPtdOH

By binding to specific LPA receptors, lysoPtdOH activates complex cell signaling including PTx sensitive and insensitive G proteins depending on cell types, triggering tyrosine phosphorylation and regulating rho-dependent actin reorganization [19, 22]. PTx, a specific inhibitor of G<sub>i/o</sub> proteins, which has been shown to inhibit G<sub>i/o</sub>-dependent lysoPtdOH effects in different cell systems. Pretreatment of macrophages with 10 ng/ml of PTx for 16 h before lysoPtdOH

suppressed CXCL16 protein production stimulated by LPS. In addition, pretreatment with 1 μg/ml of exoC3, a specific inhibitor of Rho and 200 μM of PDTC, an inhibitor of the NF-κB-dependent pathway significantly decreased lysoPtdOH enhanced CXCL16 protein production from macrophages, suggesting that the enhancement of lysoPtdOH on CXCL16 production are G<sub>i/o</sub>, Rho, and NF-κB dependent (Fig. 4). Similar results were also observed at the RNA level as detected by RT-PCR.

#### LysoPtdOH Enhances Chemotactic Activity of Macrophages

Macrophages play an important role in immune cell trafficking into inflammation and tumor sites. To investigate

**Fig. 2 a** Macrophages and MoDC express CXCL16 on the cell surface. Macrophages and MoDC were cultured as above and stained with anti-CXCL16-PE and analyzed by FACS. Filled curves represent cells stained with isotype-matched control mAb. Curves consisting of lines alone were from cells stained with anti-CXCL16. The numbers shown in each histogram were MFI of CXCL16 over control. The data shown are representative of five repeated experiments. **b** Macrophages and MoDC secrete soluble CXCL16. Cells

were washed on day 5, resuspended at  $5 \times 10^5/\text{ml}$  and cultured. The spent culture supernatants were harvested after 24 h. The concentrations of CXCL16 were measured by ELISA. Data shown are means  $\pm$  SE of three experiments with duplicates. Compare to the media control, monocytes secrete basal level CXCL16 ( $*P < 0.06$ ); macrophages give the highest level of CXCL16 ( $**P < 0.01$ ); while MoDC shed the median level of CXCL16 ( $\dagger P < 0.05$ )

CXCL16 production stimulated by lysoPtdOH would functionally attract more T lymphocyte migration, chemotactic activity of spent culture supernatant collected from lysoPtdOH/LPS treated macrophages was tested in a trans-well system. Results showed that spent culture supernatant from lysoPtdOH/LPS stimulated macrophages significantly increased  $\text{CD}3^+$  T cells migration, and pre-incubation the spent culture supernatant with 10  $\mu\text{g}/\text{ml}$  blocking antibody against human CXCL16 significantly blocked  $\text{CD}3^+$  cells migration. In contrast, normal mouse IgG (10  $\mu\text{g}/\text{ml}$ ) had no effects on  $\text{CD}3^+$  cell migration, implying the enhanced chemotactic activity of macrophages stimulated by lysoPtdOH was mediated through the increased production of soluble CXCL16 (Fig. 5a). Consistent with the ELISA results of CXCL16 production regulated by lysoPtdOH through several signaling transduction pathways above, the chemotactic activity of macrophages was also mediated through  $G_{i/o}$ -, Rho-, and NF- $\kappa$ B-dependent pathways, since  $\text{CD}3^+$  cells migration toward to spent culture supernatant collected from macrophages were blocked by pretreatment macrophages with

PTx, exoC3, or PDTC (Fig. 5b). LysoPtdOH and LPS alone did no significantly enhance  $\text{CD}3^+$  cells migration.

## Discussion

Chemokines play an important role as paracrine and autocrine mediators in healthy and diseased skin. They have been implicated in wound healing, inflammatory processes and tumors [23, 24]. CXCL16 has been linked with different biological activities. As a surface-expressed molecule CXCL16 functions as a scavenger receptor for oxidized low-density lipoprotein [25], binds to CXCR6 expressed on leukocytes and establishes firm cell to cell contact [5]. The constitutively proteolytic soluble form CXCL16 functions as a chemoattractant for CXCR6-expressing cells such as T cells [26–28]. CXCL16 has been detected in wound fluids, acute and chronic inflammation sites and tumor tissues, implicating its important roles in broad physiological and pathological situations [10, 24].

**Fig. 3** **a** LysoPtdOH increases CXCL16 production and shedding in macrophages. Macrophages were prepared as above. Cells were treated with LPS, lysoPtdOH or lysoPtdOH plus LPS for 16 h, levels of CXCL16 in spent culture supernatant were measured by ELISA. Data presented as the mean  $\pm$  SE of five experiments with similar results. Compare to macrophage control supernatant, LPS induced CXCL16 release from macrophage ( $*P < 0.01$ ); LysoPtdOH increased CXCL16 production and shedding from macrophage stimulated by LPS ( $**P < 0.05$ ); while lysoPtdOH alone had no effect on CXCL16 secretion ( $\dagger P > 0.05$ ). **b** LysoPtdOH lead to undetectable change on CXCL16 cell surface presentation in macrophages. Above macrophages were stained with anti-CXCL16-PE and

analyzed by FACS. *Black filled curve* represent cells stained with isotype-matched control mAb. *Gray filled curve* was for cells stained with anti-CXCL16 after lysoPtdOH stimulation. *Broken line curve* was for cells stained with anti-CXCL16 after LPS activation. *Solid line curve* was for cells stained with anti-CXCL16 after lysoPtdOH and LPS treatment. Data shown are representative of three repeatable experiments. **c** LysoPtdOH upregulated CXCL16 mRNA expressions in macrophages shown by real-time PCR. The same number of cells treated as above were lysed, RNA was purified, cDNA was synthesized and the same amount of cDNA was used for RT-PCR

Lipids have long since been recognized as signaling molecules that have the capacity to control important cellular processes, including cell proliferation, apoptosis, metabolism and migration and trigger profound physiological responses [29]. The same signaling lipid can provoke different cellular responses, depending on the precise cell type and underlying signaling network present in the target cell. LysoPtdOH, a natural occurring water-soluble phospholipid was originally identified as a key molecule in lipid biosynthesis. It is stored within the cell at concentrations up to 60  $\mu$ M and may accumulate in extracellular fluids such as in the inflammatory exudate at concentrations as high as 10  $\mu$ M [22]. Both lysoPtdOH and

CXCL16 have been detected in the wound fluid in multiple tissues upon injury with the similar kinetics [24, 30–32], which may allow the coordinated skin repair with subsequent cell infiltrations [33, 34]. The instrumental role of disintegrin-like metalloproteinase ADAM10 on CXCL16's proteolytic shedding has been introduced recently [10, 24], and lysoPtdOH has been reported to affect the production and shedding of several transmembrane proteins [35, 36], here we have shown that lysoPtdOH treatment significantly increased the production and shedding of CXCL16 stimulated by LPS as well, supporting the important roles of lysoPtdOH in multiple cellular systems by regulating macrophages/MoDC's chemotactic activity toward to T

**Fig. 4** Signaling transductions regulating CXCL16 shedding stimulated by LysoPtdOH. Macrophages prepared as above were pretreated with different inhibitors for 16 h before lysoPtdOH and/or LPS stimulations, concentrations of CXCL16 in spent culture supernatant were measured by ELISA. Data were presented as the mean  $\pm$  SE from three experiments with similar results. Compare to spent supernatant from lysoPtdOH/LPS treated macrophages, CXCL16 secretion in supernatant collected from PTx, exoC3, or PDTC pretreated macrophages were significantly inhibited ( $*P < 0.01$ ;  $**P < 0.05$ ;  $\dagger P < 0.01$ )

cells. The correlated expression of CXCL16 and its protease ADAM-10 within the synovium and cultured macrophages has been reported recently [37], which may explain why the change of cell surface presentation of CXCL16 affected by lysoPtdOH was undetectable by FACS in our culture system.

Playing an important role in innate immunity, macrophages detect the invading pathogens through Toll-like receptors (TLR). LPS, a major cell wall component of gram-negative bacteria, binds to mainly TLR4 and other cell surface molecules such as HSP70, HSP90, chemokine receptor 4 (CXCR4), and growth differentiation factor 5, as well as some cytoplasm molecules then lead to mainly activation of NF- $\kappa$ B [38–42]. Therefore, whether the involvement of NF- $\kappa$ B in lysoPtdOH-enhanced CXCL16 production stimulated by LPS was solely induced by lysoPtdOH from LPS cannot be decided in this experimental setting. Meanwhile activation of  $G_{i/o}$ -, Rho- in lysoPtdOH and LPS stimulated macrophages is more likely through LPA receptors binding and signaling [19, 43–45].

LysoPtdOH has been indicated as promoting early T cell migration to tissue sites of immune responses and regulating T cell proliferation and secretion of numerous cytokines [46, 47]. LysoPtdOH has also been reported to regulate the differentiation and activation of monocytes/macrophages and their further interactions with endothelial cells [48, 49]. However, this is the first demonstration that lysoPtdOH increases CXCL16 production and shedding in addition to other inflammatory cytokines [21, 50, 51],

**Fig. 5 a** LysoPtdOH increased chemotactic activity of macrophages. Spent culture supernatant was put in the bottom well of a trans-well system and activated  $CD3^+$  T cells were loaded into the top chambers of the trans-well system. Migration was allowed for 2 h, and cells that had migrated to the bottom wells were collected and counted. Data are presented as the mean  $\pm$  SE of five experiments with similar results. Compared to the supernatant from control macrophages, supernatant collected from LPS treated cells slightly induced  $CD3^+$  T cells migration ( $*P < 0.05$ ); supernatant collected from LPA/LPS treated cells macrophages attracted more  $CD3^+$  T cells migration ( $**P < 0.01$ ), which was significantly blocked by preincubation supernatant with anti-CXCL16 blocking antibody ( $\dagger P < 0.01$ ); non-specific mIgG antibody had no effect on the chemotactic activity of supernatant collected from LPA/LPS treated macrophages ( $\ddagger P > 0.05$ ). **b** Signaling pathways regulating chemotactic activity of macrophages. Spent culture supernatant collected from macrophages treated with different inhibitors was also placed in the bottom wells of a trans-well system and migration of  $CD3^+$  T cells was calculated. Data presented as the mean  $\pm$  SE of three experiments with similar results. Compare to spent supernatant from LPA/LPS treated macrophages, migration of  $CD3^+$  T cells toward supernatant collected from PTx, exoC3, or PDTC pretreated macrophages were significantly blocked ( $*P < 0.01$ ;  $**P < 0.01$ ;  $\dagger P < 0.01$ )

therefore directing more activated T cells to the inflammation and tumor sites to develop functional immune responses [13, 52]. Since most of CXCL16 binding CXCR6 expressing cells in blood are IFN-secreting helper T cells, cytotoxic T cells, or CD56<sup>+</sup> T cells that are enriched for effector functions, thus upregulation of CXCL16 by lysoPtdOH in macrophages and MoDC most likely leads to the (T helper 1) Th1 and cytotoxic effector function in inflammation and tumor sites. The direct effect of lysoPtdOH on MoDC maturation and the ability of DC to influence Th1 cell polarization has been investigated [16], this study elucidated its role in CXCL16 production in macrophages as a focus. We hope this mechanic link between lysoPtdOH and chemokines advances our knowledge of lipid mediated immune responses.

**Acknowledgments** We thank all the healthy blood donors provided written informed consent according to federal, state and institutional guidelines. The authors declare no conflicting and commercial interest.

eicosapentaenoic acid (20:5 $\omega$ 3; EPA) and DHA, as well as the principal ‘competing’  $\omega$ 6 fatty acid—arachidonic acid (20:4 $\omega$ 6; ARA) [4]. Because the level of ‘free’ (non-esterified) plasma DHA and ARA is thought to be important for their uptake by the brain [5], those data are provided as both percentages and concentrations.

## Methods

All procedures reported here were approved by the Human Ethics Research Committee of the Health and Social Sciences Center—Sherbrooke University Geriatrics Institute, which is the committee mandated to oversee human experimentation at our institution.

### Compliance Methodology

In addition to capsule counts and a checklist completed by the subjects, we independently verified compliance by adding a small amount of carbon-13-labeled glucose ( $^{13}\text{C}$ ; Cambridge Isotopes Limited, Andover, USA) to the  $\omega$ 3 fatty acid capsules used in the metabolic study. This was done only during the third week of the study. With 10 mg/capsule of  $^{13}\text{C}$ -glucose, we established in preliminary tests that if breath  $^{13}\text{C}$  value during the supplementation period did not exceed 2.5 times the baseline  $^{13}\text{C}$  value, the subject was non-compliant on that day. Non-compliance on more than one day/week led to exclusion of the subject’s data from the final analysis.

### $\omega$ 3 Fatty Acid Supplementation

Following informed written consent, the participants’ medical histories were taken by a registered nurse and 12 h fasting blood chemistries were assessed. Inclusion criteria were: 18–29 years old or 70–79 years old, thyroid stimulating hormone (0.35–7.0 mIU/L), glucose (3.3–6.1 mmol/L), cholesterol (3.3–4.6 mmol/L in the young and 3.3–6.2 mmol/L in the elderly), triglycerides (0.6–2.3 mmol/L), and hemoglobin A<sub>1c</sub> (4.0–6.0 mmol/L). Exclusion criteria were: smokers, pregnancy/lactation, <18 years old or between 30 and 70 years old or >70 years old, or use of medication for diabetes, liver disease, renal disease, hypertension, anemia or low serum albumin or other evidence of malnutrition. An upper limit of 3.0% DHA in plasma total lipids was set to exclude those individuals who were probably already consuming  $\omega$ 3 fatty acid supplements or relatively high amounts of fish.

A dose of  $\omega$ 3 fatty acids (EPA and DHA) was provided that was calculated to be four to five times the average intake in Quebec of  $\omega$ 3 fatty acids from fish or seafood [6].

One lot of an encapsulated commercially available brand of fish oil was purchased in sufficient quantity to supply all the participants for the duration of the study (Genuine Health, O3mega + Think, Toronto, Canada). According to our measurements, two capsules/day provided 1,070 mg of  $\omega$ 3 fatty acids: 3 mg  $\alpha$ -linolenic acid (18:3 $\omega$ 3), 64 mg docosapentaenoic acid (22:5 $\omega$ 3), 323 mg of eicosapentaenoic acid (20:5 $\omega$ 3; EPA) and 680 mg of DHA (Table 1). Participants consumed the two capsules each morning for 3 week, followed by a 2 week wash-out during which no capsules were consumed. Participants were told to take the capsules in the morning at breakfast and to take duplicate breath samples not less than 2 and not more than 4 h later. Fasting blood samples were collected once weekly between 7–8 a.m. They were anti-coagulated in EDTA and the plasma removed by centrifugation and stored at  $-20\text{ }^{\circ}\text{C}$ .

### Analytical Methodology

For fatty acid analysis, total lipids from 0.5 ml plasma was extracted into chloroform-methanol, internal standards added, the lipid classes separated by neutral lipid thin layer chromatography, and fatty acid methyl esters prepared and analyzed as previously described [7]. Glucose, triglycerides, total cholesterol, and free fatty acids were measured by an automated analyzer (Xpand, Dade-Behring, Mississauga, ON).

**Table 1** Baseline characteristics of the two groups

Group	Young ( $n = 9$ )	Elderly ( $n = 10$ )
Age	24 $\pm$ 2	74 $\pm$ 4*

## Statistics

Using DHA values in plasma total lipids analyzed in our laboratory as a benchmark, power analysis showed that 9–10 subjects/group would be sufficient to demonstrate a significant effect of the supplement. Data are shown as means  $\pm$  SD. Fatty acid values were not normally distributed so the non-parametric Mann-Whitney test was used (SPSS; Chicago, IL, USA) with the cut-off for statistical significance set at  $P < 0.05$ . Freidman's test was used to verify whether the young and elderly groups differed when there was no effect of the supplement.

## Results

### Compliance

Based on the rise in  $^{13}\text{C}$  in breath  $\text{CO}_2$  from the  $^{13}\text{C}$ -glucose on the capsules, we observed that one young participant was non-compliant on two occasions and another was non-compliant on six of the seven days tested, leaving  $n = 9$  in the young group. Lack of change in plasma  $\omega_3$  fatty acids in the least compliant participant supported the  $^{13}\text{C}$  compliance data. All 10 elderly participants who started the supplementation study were included in the final analyses.

### $\omega_3$ Fatty Acid Supplementation

DHA in plasma total lipids was not different between the two groups at baseline. After 3 week supplementation, in the elderly, plasma DHA stabilized 46% higher than baseline ( $P < 0.05$ ), a rise that was 42% higher than in the young group. During the wash-out, plasma DHA declined to a similar value in both groups (Fig. 1). After the supplementation, EPA in plasma total lipids rose similarly in both groups. In both groups, whereas % DHA rose in plasma phospholipids during the supplementation period, EPA was largely unaffected in phospholipids, and neither changed significantly in plasma triglycerides (data not shown). Other  $\omega_3$  fatty acids ( $\alpha$ -linolenic acid,  $\omega_3$  docosapentaenoic acid) remained statistically unchanged during supplementation and did not differ between the two groups.

Expressed as percentage of the plasma free (non-esterified) fatty acid pool, free DHA did not differ between the two groups and also did not change significantly during either the supplementation or the wash-out phase of the study. The plasma concentration of free DHA also did not change during fish oil supplementation, but owing to the higher concentration of plasma total free fatty acids in the elderly, the plasma concentration of free DHA averaged over both phases of the study was 82% higher in the elderly

**Fig. 1** Docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA) and arachidonic acid (ARA) in plasma total lipids (%) during 3 weeks supplementation and 2 weeks follow up in nine young and ten elderly subjects. Black squares young adults, White squares elderly adults: mean  $\pm$  SD, \* $P < 0.05$

(data not shown). EPA was largely undetectable in plasma free fatty acids so the few values that were recorded could not be compiled and are not reported here.

In the elderly, plasma total ARA started and remained about 20% higher throughout the supplementation and wash-out periods ( $P < 0.00004$ ; Fig. 1).

The higher percentage of ARA in plasma of the elderly seen both at baseline and throughout the study was a function of higher ARA in both phospholipids and triglycerides but not free fatty acids (data not shown). When expressed as a percentage of the total free fatty acid pool, free ARA did not differ between the two groups at any time point. When expressed as a concentration (mg/dL), free ARA differed between the two groups at a couple of time points but not overall (data not shown).

There was no treatment effect on the plasma concentration of the main plasma lipid classes during the supplementation period or during the wash-out. Hence, during the overall study period, the elderly averaged 9%

higher phospholipids, 19% higher triglycerides, and 64% higher free fatty acids; all  $P < 0.05$ ). The significant difference in plasma total cholesterol between the two groups seen at baseline was unaffected during the supplementation and wash-out periods (data not shown).

## Discussion

This study shows that compared to young adults, healthy, free-living elderly from our region of Québec have a somewhat higher response of plasma DHA to a short-term daily fish oil supplement. This result contradicts our initial hypothesis that the plasma response to a fish oil supplement would be significantly dampened in the healthy elderly. Higher baseline plasma EPA in our elderly group (Table 1) confirms observations reported previously for plasma EPA [8, 9] and red cell  $\omega$ 3 PUFA [10, 11]. In 30-year old women, plasma EPA tends to rise more quickly than DHA during short term supplementation with fish oil and fall more quickly after the supplementation period [12].

Despite raising DHA intake by four to five fold compared to average intake in Quebec [6] and approximately doubling plasma total DHA during the supplementation period, in neither group did plasma *free* DHA rise significantly during the supplementation period nor fall during the wash-out (whether expressed as percentage or as mg/dL). The higher concentration of free plasma DHA in our elderly subjects was clearly a function of a larger plasma free fatty acid pool and not due to higher percentage DHA in plasma free fatty acids. No change in % DHA in plasma free fatty acids has previously been reported during a 3 week supplementation with 750 mg/day of DHA but no EPA [13]. However, in that study, plasma free DHA did rise significantly after the 6th week of supplementation or when a 1,500 mg daily dose of DHA was given. We focused on plasma free DHA because of its purported role as a precursor to brain DHA [5]. Given the emerging though still controversial link between low DHA status and increased risk of cognitive decline in the elderly [3], it was therefore not anticipated that the pool of plasma free DHA would be higher in the elderly than in our young subjects. If, as proposed by Lagarde's group, a lysophosphatidylcholine form of DHA is the carrier of DHA to the brain [14], then the larger pool of plasma free DHA in the elderly would have no direct bearing on their susceptibility to cognitive decline.

In all plasma lipid classes we evaluated, ARA was statistically unaffected by an intake of about 1,000 mg/day of  $\omega$ 3 fatty acids, given mostly as EPA and DHA. Higher baseline ARA in our elderly group contrasts somewhat with the results of Rees et al. [9] but their elderly group

was 15 years younger than ours. Rees et al. [9] also used a higher dose of EPA and DHA and for a longer period but otherwise both our studies agree that raising EPA and DHA intake by up to tenfold does not seem to significantly affect plasma ARA.

Incomplete compliance is one potential confounder that was not a factor in the results of the present study. Our stable isotope-based method was relatively non-invasive and well tolerated. It was a good independent measure of compliance but because of cost, labor-intensiveness and the need for specialized equipment to analyze  $^{13}\text{C}$  in breath  $\text{CO}_2$ , it perhaps not widely applicable.

We conclude that during short-term supplementation with fish oil capsules, healthy aging is associated with significantly higher DHA incorporation into plasma lipids. This result contributes to the emerging literature suggesting that subtle but potentially important changes in  $\omega$ 3 PUFA metabolism occur during healthy aging. The possible relevance of these aging-related changes in  $\omega$ 3 PUFA metabolism to risk of chronic disease, particularly cognitive decline, remains to be established.

**Acknowledgments** Financial assistance was provided by the Canadian Institutes for Health Research, Natural Sciences and Engineering Research Council of Canada, the Canada Research Chairs (SCC), the Canadian Foundation for Innovation, and FORMSAV (MV). Excellent technical assistance was provided by Mary Ann Ryan, Julie Desgagné and Martine Fisch.

Since 1970, AOCS has been a regular host to the sterol symposia. Table 1 summarizes the history of the AOCS Sterol Symposium Series. The pioneers who established the AOCS Sterol Symposium during its first decade include Dr. Henry W. Kircher (University of Arizona, an expert on natural product chemistry and insect-sterol ecology), Dr. James W. Hendrix (University of Kentucky, an expert on fungal sterols), Dr. John L. Laseter (University of New Orleans, an expert on the analysis of sterols by gas chromatography), Dr. William R. Nes (Drexel University, a bioorganic chemist and an expert on the structure, function and evolution of sterols, and whose research accomplishments were commemorated in *Steroids* 53:261–648, 1989),

and Dr. Erich Heftmann (Western Regional Research Center, USDA, ARS, a biochemist and an expert on the chromatography and biosynthesis of plant sterols, and whose research accomplishments were commemorated in *J Chromatogr A* 452, 1–634, 1988). Throughout the years the sterol symposia have focused on current research in the areas of sterol structure, biosynthesis, chemistry, regulation, and function.

The 2008 Sterol Symposium, “Recent Advances in Sterol Research,” was held at the AOCS Annual Meeting in Seattle, Washington. This year the symposium held special significance, for it hosted the presentation of the fourth G. J. Schroepfer Jr. Award for sterol research. The Award was established to honor the memory of Dr. George J. Schroepfer Jr., a prominent sterol biochemist and chemist who made major and lasting contributions to the sterol field. Much of his research dealt with the biosynthesis of cholesterol and its regulation. In addition, he maintained a strong organic synthesis program to support his biochemical studies. A biography describing many of Dr. Schroepfer’s contributions can be found in this journal (Wilson, W. K. *Lipids* 35, 242, 2000). Dr. Schroepfer was scheduled to be the keynote speaker at the sterol symposium in Orlando, Florida, in 1999, but unfortunately, he passed away on 11 December 1998. The three previous recipients of the Schroepfer Award were Professor Geofrey Gibbons (2002), Professor Jan Sjövall (2004) and Professor Ingemar Björkhem (2006).

The fourth recipient of the G. J. Schroepfer Jr. Award for sterol research was Professor Michel Rohmer from the Institute of Chemistry at the University Louis Pasteur/CNRS in Strasbourg, France. Professor Rohmer, a member of the French Academy of Sciences, has made major contributions to the sterol field and we were pleased when we learned that he had been chosen to receive this

prestigious award. Professor Rohmer is well known for research on the discovery of bacterial hopanoids and on the elucidation of the mevalonate-independent methylerythritol phosphate (MEP) biosynthetic pathway (sometimes called the non-mevalonate pathway), a second pathway for the biosynthesis of terpenes. Although it was previously thought that all terpenes were synthesized via the mevalonate (MVA) pathway, the research of Professor Rohmer and his collaborators established that terpenoids are synthesized by the alternative MEP route in most bacteria (e.g. triterpenes of the hopane series, the prenyl chains of ubiquinone), in unicellular green algae (all terpenoids including the sterols), as well as in the chloroplasts in plants (carotenoids, the phytol portion of

chlorophyll, the prenyl chain of plastoquinone). The same pathway was shown to be involved in the formation of other terpene series in plant plastids (hemi-, mono- and diterpenes), whereas the cytoplasmic MVA pathway is involved in the biosynthesis of sterols and the prenyl chain of ubiquinone. Professor Rohmer's research accomplishments are described in detail in the first paper in this issue and were also summarized in a recent article that he has authored (Rohmer, M. Nonprogrammed research: discovery of the mevalonate-independent methylerythritol phosphate pathway for the formation of isoprene units in bacteria and plants. *Inform* 19, 482–485, 2008).

**Professor Michel Rohmer**

In this year's Sterol Symposium, Professor Michael Waterman from Vanderbilt University was also honored for his long and productive career and for his significant contributions to the field of steroid biochemistry, especially for his pioneering research into the role of various cytochrome P450 enzymes in the steroid biosynthetic pathway. Several of Professor Waterman's colleagues (students, postdocs, and other collaborators) were invited to present seminars describing their individual accomplishments and the positive influence that Professor Waterman had on their careers. The colleagues included I. Pikuleva (Case Western Reserve University), M. Sewer (Georgia Institute of Technology), R. Bernhardt (Universität des Saarlandes), S. K. Kelley (Swansea University), R. Peters (Iowa State University), J. Noel (The Salk Institute) and G. Lepesheva (Vanderbilt University).

**Professor Michael Waterman**

As with past sterol symposia, we are indebted to our corporate partners who helped make the symposium a success. This year, Forbes Medi-Tech generously supported our symposium. We appreciate their contribution and look forward to their continued support of our symposium series. We also appreciate the support of the Biotechnology Division of AOCS for their long commitment to support the AOCS Sterol Symposium. We are looking forward to the next sterol symposium which will be held at the 101st Annual Meeting and Expo of the American Oil Chemists' Society, 16–19 May 2010, in Phoenix, Arizona.

## Bacterial Biohopanoids

Geohopanoids probably represent the most abundant natural products on earth. This pentacyclic triterpenoid series is found in the organic matter of all sediments, independent of their age, origin or nature [11]. They represent the molecular fossils of a long overlooked family of bacterial metabolites. Triterpenes of the hopane series are rarely found in plants. They are more common in lichens, mosses and especially ferns. In contrast to the higher plant hopanoids, which are derived from the cyclization of oxidosqualene and possess an oxygenated function at C-3, hopanoids from lower eukaryotes are mostly derived from the direct cyclization of squalene and are accordingly devoid of such an oxygen function. Diploptene **2** (Fig. 1), a simple C<sub>30</sub> hopanoid, was the first triterpene found in bacteria in the early 1970s. The major triterpenoids in all bacteria producing hopanoids were, however, always the C<sub>35</sub> bacteriohopane derivatives (e.g. **3a**, **3b**, Fig. 1) [12]. Their discovery was rather fortuitous, by looking at the compounds responsible for the alignment of the cellulose microfibrils secreted by *Acetobacter xylinum* [13, 14]. This family of natural products, proved to be first precursors for the ubiquitous geohopanoids, presented an unique feature in natural product chemistry: an additional polyfunctionalized C<sub>5</sub> *n*-alkyl side-chain is linked by a carbon/carbon bond to one of the methyl group of isopropyl group of the hopane skeleton [15]. A huge structural diversity characterizes the bacterial biohopanoids. Modifications of

the triterpene hopane skeleton include the introduction of double-bonds at C-6 and/or C-11 [16, 17], of an additional methyl group at C2 $\beta$ , C-2 $\alpha$  or C-3 $\beta$  [18–21] or the presence of the two diastereomers at C-22 [15]. The side chains may differ by the number of the hydroxy groups, the replacement by the terminal C-35 hydroxy group by an amino group, the presence of polar moieties linked to the terminal hydroxy group (hexose derivatives linked via a glycosidic bond or carbapseudopentose linked via an ether bond) or to the terminal amino group (amino-acids or fatty acids via a peptide bond) [22]. Usually hopanoids are present in eubacterial cells in concentrations similar to those found for sterols in eukaryotes [12] and suitable for <sup>13</sup>C-NMR biosynthetic studies.

Like cholesterol **1a** (Fig. 1), biohopanoids are amphiphilic molecules with a flat, rigid skeleton due to the all *trans* ring junctions of the pentacyclic triterpene ring system and a length corresponding to the half of the thickness of a phospholipid bilayer. Such structural similarities suggested similar physiological roles. Indeed, in membrane models, hopanoids behave much like sterols, modulating the fluidity and the permeability of phospholipid mono and bilayers [23, 24]. This interpretation is corroborated by in vivo data. The hopanoid concentration increases with temperature in the thermoacidophile *Alicyclobacillus acidocaldarius*, counterbalancing the destabilizing effect of temperature [25]. In *Zymomonas mobilis*, a bacterium that can tolerate high ethanol concentrations up to 13% in its culture medium [26], the extremely high hopanoid concentrations (30 mg/g,

dry weight) has been proposed as being involved in the membrane stabilization in the presence of the solvent. Other roles may be assigned to hopanoids. In the cyst cells of the nitrogen-fixing *Frankia* sp., the high hopanoid concentrations may protect the sensitive nitrogenase from degradation by atmospheric oxygen [27]. In *Streptomyces coelicolor*, hopanoid biosynthesis is strongly linked to aerial growth and sporulation, these triterpenoids being nearly undetectable under vegetative growth conditions in submerged cultures [28].

The chemistry and biochemistry of the bacterial hopanoids turned out to be a rich topic. Hopanoid biosynthesis is a mine of yet undisclosed enzyme reactions involved in the linkage of the side-chain to the triterpene moiety and in the methylation of the A ring. The most surprising consequence was however, the non-programmed and non-programmable discovery of a novel pathway for the formation of the isoprene units.

The biosynthesis of isopentenyl diphosphate (IPP **18**, Fig. 2) and dimethylallyl diphosphate (DMAPP **19**), the universal precursors of isoprene units had already been elucidated in the 1950s, essentially using systems prepared from liver and from yeast, and resulted in the description of the mevalonate (MVA **15**) pathway (Fig. 2b). This pathway is also involved in the formation of plant triterpenoids, including sterols. MVA was believed to be the universal precursor of isoprene units despite many contradictory observations in the field of the biosynthesis of the isoprenoids from bacteria and especially plants (e.g. the biosynthesis of mono and diterpenes, carotenoids) [29].

### Hopanoid Biosynthesis: First $^{13}\text{C}$ -Labeling Experiments and Discovery of the Methylerythritol Phosphate (MEP) Pathway

The first incorporations of  $^{13}\text{C}$ -labeled precursors into bacterial hopanoids were designed in order to determine the origin of the  $\text{C}_5$  side-chain linked to the triterpenes moiety [30]. For this purpose, selected bacteria were grown on a synthetic mineral medium with acetate as the sole carbon and energy source. These growth conditions differed from those of most former experiments where the labeled carbon source was usually administered in a complex medium in the presence of many other sources of carbon. Under such growth conditions, there is no competition for the utilization of different carbon sources. The cells are obliged to use the labeled substrate via known probable metabolic routes. Starting from the  $^{13}\text{C}$ -labeled position and their isotope abundance, a retro-biosynthetic scheme, we expected to be able to deduce the enzyme reactions involved in the metabolism of the carbon source. Such experiments were first made on bacteria capable of utilizing acetate as the sole

carbon and energy source: *Rhodospseudomonas palustris*, which is characterized by very simple hopanoid content, synthesizing only aminobacteriohopanetriol **3b** (Fig. 1), and *Methylobacterium organophilum*, which produces bacteriohopanetetrol **3a** (Fig. 1) derivatives and has a better versatility in the utilization of carbon sources, a feature which later proved interesting.

These first experiments showed that the bacteriohopane side-chain is indeed a D-pentose, derived from the non-oxidative pentose phosphate pathway and linked via its C-5 carbon atom to the hopane isopropyl group [30, 31]. The most striking result was, however, found on the triterpene moiety. The labeling pattern of the hopane isoprene units (Fig. 3) was not in accordance with the expected one from the MVA pathway. At the time of these early investigations, there was no reason to reject the universally accepted MVA pathway. Results were interpreted in the frame of this metabolic route, expecting that MVA had to be formed from two distinct acetyl-CoA pools, although a completely different pathway could not be excluded [30].

### Incorporation of $^{13}\text{C}$ -Labeled Glucose Isotopomers into the Hopanoids of *Zymomonas mobilis*: The Origin of the Carbon Atoms of Isoprene Units in the MEP Pathway

*Zymomonas mobilis* is a good hopanoid producer [32] and possesses minimal enzymatic equipment, utilizing only hexoses (mainly glucose) as a carbon and energy source and having no complete tricarboxylic acid cycle. These properties made this bacterium an interesting target for the further investigations that we performed in collaboration with the group of Hermann Sahm (Forschungszentrum Jülich, Germany). Incorporation of  $^{13}\text{C}$ -labeled D-glucose isotopomers into the hopanoids of the bacterium *Zymomonas mobilis* (with labeling either at C-1, C-2, C-3, C-5 or C-6) gave the first insights into an alternative metabolic route for the formation of isoprene units [33]. The carbon atoms of IPP **18** (for IPP skeleton numbering, cf. Fig. 2c) could be divided into two subgroups. C-3 and C-5 had a dual origin, being respectively equally derived from C-2 or C-5 of glucose for the former and C-3 and C-6 of glucose for the second one, whereas C-1, C-2 and C-4 of IPP had a single origin, being respectively derived from C-6, C-5 and C-4 of glucose. This labeling pattern characterizes the glucose catabolism via the Entner–Doudoroff pathway in *Z. mobilis*. The first subgroup corresponds to the C-2 and C-3 carbon atoms of pyruvate **11**, and the second one to the complete carbon skeleton of D-glyceraldehyde-3-phosphate **10** (Fig. 2). This interpretation requires a rearrangement allowing the insertion of the two-carbon subunit derived from pyruvate (by decarboxylation) between the carbon atoms from D-glyceraldehyde-3-phosphate derived from

**Fig. 2** Biosynthesis of isoprene units. **a** Labeling from [1-<sup>13</sup>C] glucose of glyceraldehyde phosphate **10** and pyruvate **11**, the precursors of the methylerythritol phosphate (MEP) pathway, and of acetyl-CoA **12**, the precursor of the mevalonate (MVA) pathway. **b** Mevalonate pathway. **12** acetyl-CoA, **13** acetoacetyl-CoA, **14** hydroxymethylglutaryl-CoA, **15** MVA, **16** phosphoMVA, **17** diphosphoMVA, **18** IPP, **19** DMAPP. **c** Methylerythritol phosphate pathway. **10** D-glyceraldehyde 3-phosphate, **11** pyruvate, **20** 1-deoxy-D-xylulose 5-phosphate, **21** 2-C-methyl-D-erythritol 4-phosphate, **22** 4-diphosphocytidyl-2-C-methyl-D-erythritol, **23** 4-diphosphocytidyl-2-C-methyl-D-erythritol 2-phosphate, **24** 2-C-methyl-D-erythritol 2,4-cyclodiphosphate, **25** (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate, **18** IPP, **19** DMAPP. Adapted from reference [117]

C-4 and C-5 of glucose. Incorporation of doubly labeled [4,5-<sup>13</sup>C<sub>2</sub>] glucose showed in the isoprene units of the bacteriohopanetetrol derivatives and of 2 $\beta$ -methylidiplopterol characteristic <sup>2</sup>J<sup>13</sup>C/<sup>13</sup>C coupling constants, indicating that C-4 and C-5 from glucose are introduced into the isoprene units via a single precursor molecule and representing the signature of the previously described rearrangement. Confirmation of the role of pyruvate and D-glyceraldehyde-3-phosphate was obtained after incorporation of uniformly labeled [U-<sup>13</sup>C<sub>6</sub>] glucose into the hopanoids of *Z. mobilis* and the incorporation of [1-<sup>13</sup>C]

glucose into the prenyl chain of ubiquinone in *E. coli* mutants, each lacking an enzyme of the triose phosphate metabolism inter converting glycerol and pyruvate [34]. Evidence for an alternative biosynthetic route was later obtained for other bacterial isoprenoid series. In *Escherichia coli*, which do not synthesize hopanoids, the same labeling pattern was obtained in the isoprene units of the prenyl chain of ubiquinone upon feeding with <sup>13</sup>C-labeled acetate as in the hopanoids from *R. palustris* and *M. organophilum*. Upon feeding with [1-<sup>13</sup>C] glucose, the labeling distribution could be analyzed in the same way as

**Fig. 3** Incorporation of [1-<sup>13</sup>C] acetate for isoprene unit biosynthesis into the MVA pathway (**A**) or via the tricarboxylic acids and the glyoxylate cycles into the MEP pathway (**B**). For the sake of

simplicity, cofactors have been omitted in the tricarboxylic acids and glyoxylate cycles. Only the carbon skeletons of the metabolites have been represented

those obtained for the formation of isoprene units in *Z. mobilis*, but in the frame of the glycolysis, which is utilized by *E. coli* for glucose catabolism [33].

All these features are inconsistent with the MVA pathway and a novel biosynthetic route had to be imagined [33, 34]. This was proposed by analogy with known enzymatic and chemical reactions. The pyruvate-derived two-carbon subunit is obtained from pyruvate decarboxylation by a thiamine diphosphate enzyme, much like the reactions catalyzed by pyruvate decarboxylase or pyruvate dehydrogenase, yielding (hydroxyethylidene) thiamine diphosphate. The later intermediate is a nucleophile that can be added onto the carbonyl group of glyceraldehyde-3-phosphate in a reaction resembling the reaction catalyzed by a transketolase and yielding a 1-deoxypentulose phosphate identified as 1-deoxy-D-xylulose 5-phosphate (DXP, **20**, Fig. 2c). A further step is the intramolecular rearrangement mentioned above, followed by the concomitant reduction of the resulting aldehyde intermediate. It was thought to be an acid-catalyzed rearrangement of a  $\alpha$ -ketol resembling the rearrangement involved in the formation of the carbon skeleton of the branched amino-acids, but was later characterized by analysis of the isotope effects induced by the presence of a deuterium atom either at C-3 or at C-4 in the substrate as a retro-aldol/aldol reaction [35]. The reaction product is 2-C-methyl-D-erythritol 4-phosphate (MEP, **22**, Fig. 2C), a tetrol already presenting the branched isoprene skeleton. In contrast with DXP, which is also in *E. coli* a precursor of thiamine diphosphate and pyridoxal phosphate, no other function than that of an

isoprenoid precursor is known for MEP. Accordingly, the pathway was proposed to be named after this intermediate.

The first two candidates for the C<sub>5</sub> precursors of this novel MVA-independent pathway are the phosphates of already known natural products. 1-Deoxy-D-xylulose (DX, **26**, Fig. 4) was previously isolated from the fermentation broth of a *Streptomyces* sp. and was known as a precursor of pyridoxal phosphate thiamine diphosphate in *E. coli*, and 2-C-methyl-D-erythritol (ME, **27**, Fig. 4) is accumulated in many plants, often in stress conditions [29, 36]. Incorporation of deuterium-labeled isotopomers of 1-deoxy-D-xylulose by the group of Duilio Arigoni [37] and of 2-C-methyl-D-erythritol [38–40] by our group into the prenyl chain of ubiquinone **4** and menaquinone **5** (Fig. 1) from *Escherichia coli* confirmed that these compounds are involved in an isoprenoid biosynthetic pathway.

The odd labeling patterns obtained with the first <sup>13</sup>C-labeled acetate incorporations [30] can now be easily interpreted. One has only to find out how glyceraldehyde-3-phosphate **10** and pyruvate **11** are synthesized from acetate via the tricarboxylic acid and the glyoxylate cycles, which are utilized by bacteria when acetate is the only carbon and energy source (Fig. 3).

### Isoprenoid Biosynthesis in Plant Plastids

While we were carrying out our investigations on the biosynthesis of bacterial hopanoids, the group of Duilio Arigoni (ETH, Zürich, Switzerland) was investigating

**Fig. 4** IPP **18** and DMAPP **19** as precursors of isoprene units in the MEP pathway. Tracing the origin of the isoprene units by incubation of [4-<sup>2</sup>H]DX **26** or [3-<sup>2</sup>H]ME **27**. Adapted from reference [98] and reproduced with permission

independently and nearly simultaneously the biosynthesis of diterpenoids of the ginkgolide series **7** (Fig. 1) in *Ginkgo biloba* embryos [41, 42]. In this study, and again in contrast with former work on plant isoprenoid biosynthesis where <sup>13</sup>C-labeled acetate was utilized, labeling experiments were performed with <sup>13</sup>C-labeled glucose. Results were straightforward. Labeling patterns determined in the diterpenoid isoprene units did not correspond to those expected from the MVA pathway. They corresponded to those described for the bacterial MEP pathway. Isoprene units were synthesized from pyruvate and GAP, both derived from labeled glucose via glycolysis [41].

Interestingly, this study on ginkgo embryos showed for the first time the dichotomy characterizing isoprenoid biosynthesis in plants: sitosterol **1b** (Fig. 1) is synthesized in the cytoplasm as expected via the MVA pathway whereas diterpenoids, which are plastid isoprenoids, are derived from the alternative MEP route [41, 42].

We later extended this observation in collaboration with the group of Hartmut K. Lichtenthaler (University of Karlsruhe, Germany) to algae [43–46] and to other plants and to the normal isoprenoid constituents of the photosynthetic apparatus. Incubation of barley seedlings, an axenic duckweed culture or a carrot tissue culture with [1-<sup>13</sup>C] glucose all showed the same dichotomy: the cytoplasmic phytosterols are synthesized via the MVA pathway and phytol **8** (Fig. 1) from chlorophyll, carotenoids **9** and the prenyl chain of plastoquinone **6** via the MEP route [47]. Confirmation of such a compartmentation was obtained for many other systems. The key to the success for all these experiments was the utilization of <sup>13</sup>C-labeled glucose for in vivo incubation in the place of labeled acetate. Hemiterpenes (such as isoprene and 2-methylbut-3-en-2-ol) [48, 49], monoterpenes [50, 51],

diterpenes [52–54] and carotenoids [47, 55], are mainly synthesized in the plastids and derived from MEP pathway. This intracellular localization of the MEP pathway was later corroborated by the presence of a plastid targeting sequence for all enzymes involved in this metabolic route [56, 57].

### Molecular Biology: The Key for the Full Elucidation of the MEP Pathway

When the MEP pathway was discovered, no bacterial genome was completely sequenced. The formation of DXP was thought to be catalyzed by a thiamine diphosphate enzyme with a transketolase resembling mechanism. Indeed, deoxyxylulose phosphate synthase shares sequence similarities with transketolases and was thus rapidly identified in the genomes of *E. coli* [58, 59] and peppermint [60]. Once ME was shown to be incorporated into the isoprenoids of *E. coli*, the search for auxotrophic mutants requiring this tetrol for growth led to the identification of the DXP reductoisomerase [61, 62], an enzyme which catalyzes as expected the reversible rearrangement of DXP into 2-C-methyl-D-erythrose phosphate [63] and the concomitant NADPH-dependent reduction of the latter aldehyde into MEP.

In the meantime, more and more bacterial genomes were sequenced facilitating the search for the MEP pathway genes among unannotated genes. The next genes were detected by genome mining. Incubation of <sup>3</sup>H-labeled MEP with crude cell-free extracts from *E. coli* led to the isolation of a radioactive compound when the reaction mixture contained ATP. Yields were improved in the presence of CTP, and radioactivity was incorporated from [ $\alpha$ -<sup>32</sup>P]CTP,

but not from [ $\gamma$ - $^{32}\text{P}$ ]CTP, suggesting that the detected product is a MEP adduct to a nucleoside derivative. This compound could not be further purified and characterized by chemical methods. The search for the gene of an enzyme catalyzing the coupling of a polyol phosphate to a nucleotide triphosphate resulted in the finding of the recently described *acs1* gene from *Haemophilus influenzae* encoding a bifunctional enzyme, which catalyzes the conversion of ribulose 5-phosphate into ribitol 5-phosphate and the further coupling of ribitol 1-phosphate to CTP yielding the CDP adduct of ribitol [64]. This *acs1* *H. influenzae* gene presents homologies with the unannotated *ygbP* gene from *E. coli*, and the cognate protein catalyzes the conversion of MEP into 4-diphosphocytidyl-2-*C*-methyl-D-erythritol **22** (Fig. 2c) in the presence of CTP [65]. The next two genes belong, with the former one, to a small cluster in the *E. coli* genome. They were consecutively identified, and the corresponding enzymes characterized. The unannotated *ychB* and *ygbB* genes of *E. coli* were revealed by bacterial genomics. Their distribution in bacterial genomes was identical with that of the already known genes of the MEP pathway, and the corresponding recombinant proteins catalyzed the next steps: the phosphorylation of the tertiary hydroxy group yielding 4-diphosphocytidyl-2-*C*-methyl-D-erythritol 2-phosphate **23** [66], followed by the elimination of UMP yielding 2-*C*-methyl-D-erythritol 2,4-cyclodiphosphate (MEcPP) **24** [67] (Fig. 2c). The two latter compounds were incorporated into carotenoids by isolated *Capsicum annuum* chromoplast and were thus established as intermediates of the MEP pathway. Sequence homologies led to the identification of the corresponding genes in *Arabidopsis thaliana* and tomato [68, 69].

Isoprenoid biosynthesis is an essential metabolic pathway. Any deletion of a MEP pathway gene is therefore lethal. Another approach for the identification of MEP pathway genes was the deletion of genes in an *E. coli* construct capable of utilizing exogenous MVA as isoprenoid precursor after the insertion of all genes required for the conversion of MVA into IPP (MVA kinase, phosphoMVA kinase and diphosphoMVA decarboxylase, Fig. 2a) [70, 71]. Growth after deletion of a MEP pathway gene is thus restored by addition of exogenous MVA to the culture medium. This approach was independently utilized for the characterization of the genes encoding the three enzymes responsible for the conversion of MEP into MEcPP **24** [70, 72, 73].

The last steps correspond to the reduction of a tetrol derivative, MEcPP **24**, into a primary allylic (DMAPP, **19**) and/or homoallylic (IPP, **18**) alcohol diphosphate (Fig. 2c). This implies unprecedented elimination as well as reduction steps, i.e. the involvement of an associated reduction system. The genes corresponding to these last steps were

found by bacterial genome mining. The search for the genes accompanying the already known MEP pathway genes led to the identification of two unannotated genes in *E. coli* *gcpE* and *lytB*. Their involvement in isoprenoid biosynthesis was shown using the *E. coli* mutants capable of utilizing MVA described above: the lethal deletion of *gcpE* or *lytB* was rescued by the addition of exogenous MVA [74, 75]. In vivo incorporation of [U- $^{13}\text{C}_6$ ]DX by *E. coli* constructs overexpressing MEP pathway genes followed by  $^{13}\text{C}$ -NMR analysis of the resulting crude cell extracts afforded interesting clues about the respective role of the GcpE and LytB proteins [76, 77]. Overexpression of all genes upstream of GcpE was followed by the accumulation of MEcPP **24** (Fig. 2c). Additional overexpression of *gcpE* resulted in the accumulation of (*E*)-4-hydroxy-3-methylbut-2-enyl diphosphate (HMBPP, **25**, Fig. 2), and of *gcpE* and *lytB* in the accumulation of IPP **18** as well as DMAPP **19** in a ca. 5:1 ratio, identifying MEcPP and HMBPP as substrates of respectively GcpE and LytB, and HMBPP and IPP as well as DMAPP as the reaction products of the same enzymes.

Characterization of the corresponding enzymatic activities was rather tricky. The first hints of the role of GcpE were obtained in vivo with an *E. coli* strain with a deleted *dxr* gene, engineered for the utilization of exogenous MVA and overexpressing *gcpE*: in the presence of a cocktail of cofactors (including those required for reduction reactions),  $^3\text{H}$ -labeled ME was converted into MEcPP **24** (Fig. 2c), suggesting that the cyclodiphosphate is the substrate of GcpE [78]. Further, a crude cell free-system from an *E. coli* strain overexpressing *gcpE* converted MEcPP into (*E*)-methylbut-2-ene-1,4-diol in the presence of a phosphatase [79] or into HMBPP **25** (Fig. 2c) in the presence of fluoride as phosphatase inhibitor [80]. In contrast, in a MVA utilizing and *lytB*-deficient *E. coli* strain HMBPP **25** was accumulated in sufficient amounts for direct spectroscopic characterization, indicating that this allylic diol diphosphate is most probably the substrate of LytB [81].

Improvements in the enzyme assay methods were only possible once the real nature of the GcpE and LytB proteins was recognized. GcpE and LytB share with [4Fe-4S] cluster enzymes three conserved cysteines serving as anchors for such a cluster [79, 80, 82]. Most of these enzymes are quite oxygen sensitive, losing their prosthetic group and consequently their activity in the presence of air. They usually require handling under an inert atmosphere in a glove box as well as reconstitution of their prosthetic group in the presence of  $\text{Fe}^{3+}$ , sulfide and dithiothreitol. This observation opened up new possibilities for the investigations on the last two steps of the MEP pathway. When bacterial [4Fe-4S] cluster enzymes are involved in a reducing process, they are associated in vivo to flavodoxin/flavodoxin reductase/NADPH for the regeneration of the

reduced state of the prosthetic group. The former biological system can be replaced in an enzyme assay by the semi-quinone radical obtained by photoreduction of deazaflavin. This approach proved fruitful. Reconstituted recombinant GcpE enzyme from *E. coli* [83] or the native as-isolated protein [84] converted in the presence of the biological or of the chemical reducing system MEcPP **24** into HMBPP **25** (Fig. 2c). Even dithionite was an effective reducing agent with the *Thermus thermophilus* GcpE [85]. Binding of intermediates to the cluster was suggested by EPR for the GcpE from *E. coli* [86].

Similarly, the last enzyme encoded by the *lytB* gene was also found to be a [4Fe–4S] enzyme converting HMBPP **25** (Fig. 4) into either IPP **18** or DMAPP **19** in a ca. 1:5 ratio [82] in the presence of the same associated biological reducing systems for the *E. coli* enzyme [87], and even in the presence of dithionite in the case of the *Aquifex aeolicus* enzyme [88]. Protonation of an allylic anion intermediate **28** (Fig. 4) is the most likely final step of the LytB catalyzed reaction (Fig. 4) [89].

Characterization of the cluster was performed by EPR spectroscopy of the LytB enzyme from *E. coli* with the cluster in its reduced [4Fe–4S]<sup>1+</sup> form from *E. coli* obtained upon dithionite reduction [87]. The as-isolated enzyme presented the signal of a [3Fe–4S]<sup>2+</sup> cluster, which represented about 10% of the protein and was most likely derived from the degradation by oxygen [87]. The same signal was also reported from the spectrum of LytB isolated under an inert atmosphere [90]. Mössbauer spectroscopy allowed the characterization of the GcpE/IspG from *E. coli* and *Arabidopsis thaliana* in the oxidized [4Fe–4S]<sup>2+</sup> form upon reconstitution with <sup>57</sup>Fe [91].

In plants and other organisms phylogenetically related to phototrophic phyla, the MEP pathway is localized in the plastids where flavodoxin is absent. GcpE interacts with ferredoxin in the cyanobacterium *Thermosynechococcus elongatus* [92] and in the malaria parasite *Plasmodium falciparum* [93], and activity was characterized in the presence of the associated reducing system ferredoxin/ferredoxin reductase/NADPH. In higher plants, the electrons required for the reduction converting MEcPP **24** into HMBPP **25** are derived also from ferredoxin. Indeed, a preparation containing *Arabidopsis thaliana* GcpE and purified spinach thylakoids afforded upon illumination, and in the absence of any reducing cofactor, HMBPP **25** from MEcPP **24** (Fig. 2c) [94], showing that the electron flow derived from the photo-oxidation of water can be directly diverted via photosystems I and II towards isoprenoid biosynthesis. In the dark (or in roots), the electron flow must come from catabolic processes, and ferredoxin is

associated with the NADPH-dependent ferredoxin reductase under these conditions [94].

## Conclusion: Further Developments

The MEP pathway for the biosynthesis of isoprene units in bacteria and plant plastids is now completely elucidated. All genes and enzymes are known. Many structural features of the enzymes as well as mechanistic aspects of the catalyzed reactions have, however, still to be deciphered. The discovery of this new metabolic pathway opened additional unexplored fields in plant and bacterial metabolism.

### IPP and/or DMAPP as Precursor of the Isoprene Units?

The origin of the hydrogen atoms found in the isoprene units derived from MEP pathway was followed by incorporation of <sup>2</sup>H-labeled DX or ME. If the hydrogen atoms corresponding to those located at C-1, C-4 and C-5 of MEP are integrally retained in the isoprene units, quite striking observations were made on the retention or the loss of the hydrogen atom at C-4 of DXP corresponding to the hydrogen atom at C-3 of MEP. Three labeling patterns were described for isoprene units upon feeding of DX **26** or ME **27** (Fig. 4) with <sup>2</sup>H labeling at C-4 or C-3 respectively: (i) quantitative loss in all isoprene units wherever they are derived from IPP or from DMAPP as found in the carotenoids and phytol from a plant cell culture of *Catharanthus roseus* [95], (ii) quantitative retention in the DMAPP derived unit and quantitative loss in those derived from IPP in the prenyl chains of ubiquinone and menaquinone from the bacterium *Escherichia coli* [40, 96] or significant retention in the DMAPP derived unit and nearly complete loss in that derived from IPP in the monoterpene cineol from *Eucalyptus globulus* [97] and finally (iii) retention of deuterium in all isoprene units derived either from IPP or from DMAPP as observed for phytoene and the prenyl chain of plastoquinone from a tissue culture of tobacco BY-2 [98] (Fig. 4). Such apparently contradictory observations may in fact be explained, keeping in mind that IspH/LytB, the last enzyme of the MEP pathway, affords two reaction products, IPP **18** or alternatively DMAPP **19**. Taking into account the stereoselectivity of the introduction of the proton on the allylic anionic intermediate and of the elimination of the pro-*R* proton of IPP by the IPP isomerase and the *trans*-prenyl transferase, each labeling pattern reflects the origin of the isoprene units, the presence of deuterium representing the signature of a DMAPP origin, and its absence the signature of an IPP origin [36, 98] (Fig. 4).

## Cross-Talk Between Cytoplasmic and Plastidial Compartments in Plant Cells

In plant cells, two pathways contribute to isoprenoid biosynthesis: the MVA pathway localized in the cytoplasm and the MEP pathway found in the plastids. The origin of the isoprene unit precursors, IPP and/or DMAPP is, however, scrambled by exchanges of intermediates between these two cell compartments. This aspect is well illustrated by the labeling patterns observed after incorporation of [1-<sup>13</sup>C] glucose into plant isoprenoids, and was already clearly documented in the first study on ginkgolide biosynthesis. From the labeling pattern observed in the diterpenes skeleton of ginkgolides, it was deduced that most of the geranylgeranyl diphosphate (ca. 98%) was made from isoprene units uniquely derived from the MEP pathway. A small but significant part of the C<sub>20</sub> skeleton has a composite origin: a C<sub>15</sub> farnesyl diphosphate chain synthesized from isoprene units derived from the MVA pathway is completed by a fourth unit solely derived from the MEP pathway [41]. This shows that an acyclic C<sub>15</sub> precursor, most probably farnesyl diphosphate, is carried from the cytoplasm to the plastids. Similar observations describing a dual origin for isoprene units were later reported for many other systems from higher plants [41, 55, 99–101], liverwort [102] and hornwort [103], illustrating the possibility of exchanges of C<sub>5</sub>, C<sub>10</sub> and C<sub>15</sub> intermediates between cytoplasm and plastids. A striking example is given by the tobacco BY-2 cell culture where MEP and MVA pathways can complement each other [104]. Upon inhibition of the MVA pathway by a sublethal dose of mevinolin, phytosterol in the cytoplasm are synthesized via the MEP pathway from exogenous DX. Similarly, upon inhibition of the MEP pathway by fosmidomycin, the prenyl chain of the plastidial plastoquinone is synthesized from MVA, like the isoprene units of sterols [104].

The simultaneous presence of two independent pathways opens new understanding of plant physiology at the level of the regulation of isoprenoid biosynthesis. For instance, the emission of volatile plant defense terpenoid is dependent on both pathways: sesquiterpenoids being preferentially derived from the MVA route whereas monoterpenoids are synthesized via the MEP pathway [105, 106]. In addition, a nycthemeral rhythm (corresponding to the succession of day and night) has been pointed out for the MEP pathway in snapdragon flowers. Emission of volatile terpenoid synthesized via the MEP pathway occurs essentially during the day and is controlled by the circadian clock. Both plastidial monoterpenes and the cytosolic sesquiterpene nerolidol are derived from MEP pathway, suggesting a unidirectional trafficking of precursor(s) from plastids towards the cytoplasm [107].

## MEP Pathway Enzymes as Targets for Antibacterial Drugs

The MEP pathway is the major metabolic route for isoprenoid biosynthesis in eubacteria. It is present in most bacterial taxa, including many obligate pathogens as well as opportunistic pathogens responsible for hospital-acquired diseases [108, 109]. In addition, some eukaryotes phylogenetically related to photosynthetic phyla, possess the MEP pathway, among them the *Plasmodium* spp. responsible for malaria [110].

The MEP pathway is absent in humans and animals, and isoprenoid biosynthesis is an essential metabolic route in all living organisms. Inhibition of any enzyme of this pathway has lethal consequences. This means that all enzymes of the MEP represent unexplored targets for the design of antibacterial or antiparasitic drugs [109–111]. This aspect is particularly interesting to overcome the widespread resistance towards most current commercial antibiotics. The concept has already been validated. Indeed, despite poor pharmacokinetic properties, a rapid elimination in urine [112] and the fast appearance of bacterial resistance, fosmidomycin, a natural antibiotic and a potent inhibitor of the second enzyme of the MEP pathway, the DXP reducto-isomerase [113], is quite effective against bacterial growth [112, 114] or against simple *Plasmodium* infections in rodents and in man [110, 115, 116].

aspects of the factors that control hormone production are unknown. For example, steroid hormone biosynthesis is a step-wise process that requires several enzymes that are compartmentalized in mitochondria and the endoplasmic reticulum (ER) (Fig. 1). However, the molecular mechanisms underlying inter-organelle substrate delivery are largely unexplored. Research carried out over the past several decades have provided evidence for a key role of the cytoskeleton in mediating steroidogenesis. The goal of this review is to provide a brief summary of studies investigating the role of components of the cytoskeleton in controlling steroidogenic capacity.

## The Cytoskeleton

The cytoskeleton plays a key role in varied cellular processes, including motility and migration, organelle and vesicular transport, cell–cell communication and gap junction formation, mitosis and meiosis, and maintenance of cellular morphology. In eukaryotic cells there are three major cytoskeleton components: microfilaments, intermediate filaments, and microtubules. Microfilaments are comprised of polymerized actin and are integral in the formation of cleavage furrows during cytokinesis and in cytoplasmic streaming. Intermediate filaments are larger in diameter than microfilaments and serve to maintain

cellular structural architecture and spatial distribution of organelles. Intermediate filaments are comprised of lamins (form the nuclear envelope), keratin, and vimentins. Microtubules are formed when tubulin polymerizes and the dynamic assembly and disassembly of these fibers is largely regulated by the hydrolysis of GTP. Consistent with the role of GTP in microtubule function, these polymers are typically associated with motor proteins such as kinesin and dynein. Microtubules play a well-established role in the formation of cilia and flagella and are gaining much attention for their role in the intracellular transport of vesicles and organelles, particularly mitochondria in neurons.

Due to the multifaceted roles of cytoskeletal proteins in general cellular processes, it is not difficult to ascribe functions for these proteins in the biosynthesis of steroid hormones in the adrenal cortex and gonads. In fact, four decades ago observations made on Y1 mouse adrenal cells that underwent morphological changes in response to adrenocorticotropin (ACTH) provided clues into the role of the cytoskeleton architecture in controlling the response of steroidogenic cells to trophic hormone stimulation [3, 4]. These marked changes in steroidogenic cell morphology have been confirmed by several researchers [5–7] and have been subsequently attributed to cAMP-dependent rapid dephosphorylation of the focal adhesion protein paxillin [8, 9].

**Fig. 1** Steroidogenic biosynthetic pathways

## Cholesterol Trafficking

The first and rate-limiting step in steroid hormone biosynthesis is the delivery of the substrate cholesterol to the inner mitochondrial membrane, the site of the first enzymatic reaction. Efficient delivery of cholesterol requires the coordination of several steps. First, two receptors, low-density lipoprotein receptor (LDLR) and scavenger receptor BI (SR-BI), import lipoprotein particles containing esterified cholesterol molecules into steroidogenic cells. In humans, the primary source of cholesterol for steroid hormone production is LDL, which is imported via LDLR. However, SR-BI has been shown to be a major provider of cholesterol for hormone biosynthesis, particularly in the rodent [10, 11]. Unlike lipoproteins imported by SR-BI, both LDL and LDLR are internalized and transported to lysosomes for processing.

Studies carried out by Crivello and Jefcoate three decades ago indicated a role for cytoskeletal proteins in adrenocortical steroidogenesis [12]. Various chemical inhibitors of microfilament and microtubule formation have been shown to inhibit corticosterone biosynthesis in rat adrenal glands [12]. Notably, these studies also found that inhibitors of microtubule and microfilament polymerization decreased the delivery of cholesterol to P450 side chain cleavage enzyme (P450<sub>scc</sub>), suggesting that cytoskeleton proteins regulate steroidogenesis by facilitating the trafficking of substrate to mitochondria. A role for microtubules in steroidogenesis was also shown by Rajan and Menon where lipoprotein-stimulated progesterone synthesis was found to be inhibited by the tubulin polymerization inhibitors colchicine and nocodazole [13]. Significantly, the authors demonstrated that microtubule polymerization inhibitors decreased the degradation of radiolabeled LDL and high density lipoprotein (HDL) in cultured rat luteal cells. The role of the cytoskeleton in facilitating the uptake of HDL for steroidogenesis was also demonstrated in studies using cytochalasin B, an inhibitor of actin polymerization [14] and also in experiments using the endonuclease DNase I [15].

In a series of elegant experiments employing laser scanning coherent anti-Stokes Raman scattering (CARS) microscopy it was recently shown that lipid droplets move along microtubule tracts in Y1 mouse adrenal cells [16]. Interestingly, when CARS and two-photon fluorescence microscopy were simultaneously used to image lipid droplets and mitochondria, the investigators found that the mitochondria interacted with lipid droplets that were highly motile. In contrast to these studies establishing a role for microtubules in cholesterol transport in steroidogenic cells, it has also been found that while colchicine disrupts both lipid droplet capsules and microtubules, it stimulates corticosterone biosynthesis in rat adrenocortical cells [17].

Colchicine has also been found to stimulate corticosterone secretion from wild type Y1 protein kinase A (PKA) deficient kin-8 mouse adrenal cell lines [18], suggesting that preventing microtubule polymerization promotes steroidogenesis in a cAMP/PKA-independent manner. These studies also showed that taxol, an agent that stabilizes microtubules, inhibits ACTH- and colchicine-stimulated corticosterone biosynthesis [18].

A role for actin polymerization into microfilaments has also been demonstrated in Y1 murine adrenal cells. Treatment of Y1 cells with acrylamide to disrupt microfilaments stimulates corticosterone production in a cAMP-independent manner [19]. The stimulatory effect of acrylamide on adrenal steroidogenesis was shown to be mediated at a step prior to the conversion of cholesterol to pregnenolone [19], thus implicating the cytoskeleton in assuring efficient substrate delivery.

After lipoproteins are processed, cholesterol movement out of lysosomes is facilitated by Niemann-Pick type C1 (NPC). NPC1 is localized in late endosomes along with the lipid transfer proteins MLN64 and NPC2 that travel along microtubules tracks [20, 21]. Thus, the cytoskeleton plays a key role in directing the positioning of cholesterol in steroidogenic cells. The processing of stored cholesterol esters is mediated by hormone sensitive lipase (HSL), a neutral cholesterol ester hydrolase that cleaves the ester bonds to form free cholesterol substrate [22]. While HSL trafficking has not been studied in steroidogenic cells, the lipase is rapidly translocated to the surface of lipid droplets in 3T3-L1 adipocytes upon treatment with the beta-adrenergic receptor agonist isoproterenol [23]. This translocation, however, is not dependent on microtubules and microfilaments [23]. Collectively, these studies demonstrate the pivotal role that the cytoskeleton plays in assuring efficient uptake, processing, and transport of cholesterol in steroidogenic cells.

## Steroid Hormone Biosynthesis

As mentioned above, upon delivery of cholesterol to the inner mitochondrial membrane of human adrenocortical cells, this substrate is subjected to the sequential actions of several steroid hydroxylases (cytochrome P450s) and 3 $\beta$ -hydroxysteroid dehydrogenase (3 $\beta$ HSD) leading to the production of steroid hormones (Fig. 1). In the human adrenal cortex, production of these steroid hormones occurs in specific zones, where aldosterone is formed in the outermost zone (glomerulosa), cortisol in the zona fasciculata (middle zone), and adrenal androgens in the zona reticularis (inner zone). As shown in Fig. 1, three P450s are localized in mitochondria (P450<sub>scc</sub>, P450 11 $\beta$ , P450<sub>aldo</sub>), while P450<sub>c17</sub>, P450<sub>c21</sub>, and P450<sub>c19</sub> are expressed in the ER, and 3 $\beta$ HSD expressed in both organelles.

In the first enzymatic process, P450<sub>scc</sub> (encoded by CYP11A1) catalyzes the conversion of 27-carbon cholesterol to a 21-carbon pregnenolone. Once pregnenolone is formed, it enters the ER where it can be hydroxylated on carbon-17 by P450<sub>c17</sub> (encoded by CYP17) to form 17-hydroxy pregnenolone or converted to progesterone by 3 $\beta$ HSD (Fig. 1). Importantly, optimal steroid hormone production requires the movement of pregnenolone out of mitochondria and into the ER. However, the factors that regulate inter-organelle delivery of pregnenolone to the ER are largely unexplored.

In the ER P450<sub>c17</sub> also catalyzes a 17,20 lyase reaction to form the adrenal androgens dehydroepiandrosterone (DHEA) and androstenedione. Also, both progesterone and 17-hydroxy progesterone can be hydroxylated at the 21-carbon by P450<sub>c21</sub> to yield deoxycorticosterone and 11-deoxycortisol, respectively (Fig. 1). The final reactions in adrenocortical steroid hormone biosynthesis occur in mitochondria, where 11-deoxycortisol and deoxycorticosterone are converted to cortisol and corticosterone, respectively, by P450 11 $\beta$  hydroxylase (encoded by CYP11B1). As is the case for the movement of pregnenolone into the ER, regulated transport of deoxycorticosterone and 11-deoxycortisol is also required for glucocorticoid and mineralocorticoid biosynthesis. While inter-organelle trafficking of metabolites produced in the ER back to mitochondria plays a key role in the biosynthesis of glucocorticoids and mineralocorticoids, adrenal androgens only depend on the movement of pregnenolone out of mitochondria and to ER. In the human adrenal cortex, expression of P450<sub>aldo</sub> (encoded by CYP11B2) in the zona glomerulosa allows for the conversion of corticosterone to aldosterone in a series of hydroxylation steps. In the gonads, all reactions except the initial conversion of cholesterol to pregnenolone, which takes place in the inner mitochondrial membrane, occur in the ER (Fig. 1).

### Regulation of Steroid Hormone Production by the Cytoskeleton

The relationship between steroidogenesis and the cytoskeleton has been studied in several laboratories that have used microtubule depolymerization agents to demonstrate that steroid hormone production is impaired [13, 18, 24–28]. Immunostaining of microtubules in sheep follicles has revealed decreases in the amount of polymerized tubulin prior to ovulation followed by subsequent increases in microtubule formation as progesterone biosynthesis increases [29]. Moreover, colchicine prevents increased progesterone production in these follicular cells [29], providing support for the importance of dynamic changes in

microtubule structure in response to changing demands for steroid hormone production. In contrast to the inhibitory effect of colchicine on progesterone production in sheep [29], this microtubule polymerization inhibitor has been shown to stimulate progesterone biosynthesis in porcine luteal cells [30]. Stabilization of microtubules in porcine granulosa cells using taxol suppresses both basal and human choriogonadotropin-stimulated progesterone and 17 $\beta$ -estradiol [31].

In human adrenocortical slices, preventing microtubule polymerization has been shown to reduce ACTH-stimulated cortisol biosynthesis [32]. However, Benis and Mattson have also found that stabilizing microtubules inhibits ACTH-stimulated steroidogenesis in cultured murine adrenocortical cells [27, 28]. While collectively the studies described have demonstrated an integral role for cytoskeletal proteins in controlling hormone biosynthesis, the use of chemical inhibitors to manipulate cytoskeletal protein polymer formation has resulted in conflicting results being found with regard to the specific role of these proteins. Although it is likely that many of these inconsistencies can be attributed to species and cell specific differences, further investigation is needed to resolve these conflicting findings. Additionally, more detailed interrogation of each of the steps involved in steroidogenesis is warranted to determine if the cytoskeleton also regulates processes in hormone production that occur after cholesterol uptake and transport.

### Regulation of Organelle Positioning by the Cytoskeleton

As discussed earlier, components of the cytoskeleton function in a wide variety of cellular processes. Extensive research has provided compelling evidence for the critical roles of microtubules and microfilaments in cholesterol transport and steroid hormone secretion [33, 34], however, less is known about the role of cytoskeletal proteins in the transport of substrates (pregnenolone, deoxycorticosterone, and 11-deoxycortisol) between mitochondria and the ER or increasing the proximity of mitochondria and ER.

Given the well-established role of mitochondrial transport in neurons [35–38], we sought to characterize the role of dynamic mitochondrial movements in steroidogenesis. Mitochondria have been visualized in association with microfilaments [35], microtubules [39, 40], and intermediate filaments [41, 42] in various cell types. Further, mitochondria-bound motor proteins, such as kinesins, facilitate the movement of these organelles along cytoskeletal fibers [43–47].

We postulated that components of the cytoskeleton facilitate steroidogenesis by promoting inter-organelle

substrate delivery. We envisioned that agents that induce steroid hormone biosynthesis might regulate a discrete set of factors that act to promote the transport of substrates between mitochondria and the ER. To begin examining these processes, we employed time-lapsed video microscopy of H295R human adrenocortical cells. H295R cells were plated onto cover slips, labeled with MitoTracker Red, and mounted into a chamber for microscopic analysis. Cells were then treated with the bioactive lipid sphingosine-1-phosphate (S1P). S1P was used because we have previously demonstrated that S1P increases CYP17 gene expression and steroidogenesis in H295R human adrenocortical cells [48]. Several other laboratories have also shown that S1P stimulates hormone secretion from various steroidogenic cell types [49–52]. Further, S1P is a well-established inducer of cell migration [53–57] and chemotaxis [58, 59].

As shown in Fig. 2a, administration of S1P to H295R cells resulted in a 3-fold increase in the rate of mitochondrial movement. The increase in S1P-stimulated mitochondrial movement was attenuated when cells were pre-treated with

**Fig. 2** S1P stimulates mitochondrial movement and cell migration. **a** H295R cells were cultured on cover slips, incubated with MitoTracker Red (Invitrogen), and then placed in a chamber for time lapsed video microscopy. Cells were treated with S1P (1  $\mu$ M) and/or 1  $\mu$ M colchicine (colc.) and data was collected for 1 h using an LSM510 confocal microscope system (Carl Zeiss Inc., Thornwood, NY) equipped with a krypton-equipped with a helium-neon Coherent laser with an excitation wavelength of 543 nm MitoTracker Red. Emissions were collected with a C-apochromast 40 1.3 NA oil immersion objective (Zeiss) using a 560-nm long pass filter. **b** Cells expressing GFP-labeled tubulin were monitored by time lapsed video microscopy. Shown are frames during time course after exposure to 1  $\mu$ M S1P

**Fig. 3** Colchicine alters the ratio of cortisol and DHEA secreted in response to S1P. Media was collected from cells treated with S1P (1  $\mu$ M) and/or colc. (1  $\mu$ M) and cortisol and DHEA released determined in triplicate against standards made up in DME/F12 medium using a 96-well plate enzyme-linked immune assay (Diagnostic Systems Corporation, Houston, TX). Results are expressed as nanomoles per milligram cellular protein

colchicine, indicating that microtubule polymerization is required for S1P-dependent mitochondrial trafficking. In addition to an increase in the rate of mitochondrial trafficking, S1P also promoted cell migration (Fig. 2b).

We also determined the effect of S1P and colchicine on the secretion of cortisol and DHEA into the cell culture media. S1P increased the amounts of cortisol and DHEA produced by the H295R cells while colchicine prevented this increase (Fig. 3). Interestingly, colchicine did not decrease the amount of DHEA secreted into the media, suggesting that the increase in the rate of mitochondrial trafficking evoked by S1P is dependent on microtubule polymerization and required for S1P-induced cortisol secretion. Studies are underway to determine the effect of ACTH and other agents known to stimulate adrenocortical steroidogenesis on the positioning of mitochondria in adrenal cells. Ongoing experiments are also aimed at defining the precise molecular mechanism by which S1P (and other inducers of steroidogenesis) promote mitochondrial trafficking and at identifying the factors involved in controlling the microtubule-dependent mitochondrial movement.

## Conclusions and Future Directions

Significant advances have been made in understanding the complex and multi-faceted mechanisms used to control steroid hormone biosynthesis. Further, the use of chemical

agents that perturb the polymerization of cytoskeletal proteins has shed light on a key role for microfilaments and microtubules in regulating the uptake and transport of cholesterol in steroidogenic cells. Our data presented herein describing that SIP induces rapid increases in the trafficking of mitochondria in a manner that is dependent on microtubules suggests that the cytoskeleton is also involved in steroid hormone production at steps subsequent to cholesterol delivery to mitochondria. It is tempting to speculate that the increased rate of mitochondrial movement in response to SIP promotes cortisol biosynthesis by bringing mitochondria in close proximity to the ER, thereby maximizing the delivery of 11-deoxycortisol to mitochondria for the final step of steroidogenesis. However, further studies are required to elucidate the precise role of mitochondrial trafficking in steroidogenesis. Additionally, it is equally likely that a macromolecular complex containing an unidentified 11-deoxycortisol binding transport protein may mediate this response. The use of approaches such as RNA interference, mass spectrometry, and time-lapsed video microscopy are likely to provide insight into the precise molecular parameters that underlie the role cytoskeletal proteins play in steroid hormone biosynthesis.

sterol biosynthetic pathway exists in all eukaryotic kingdoms and is even found in some bacteria [6]. At the stage of squalene 2,3-epoxide cyclase the pathway bifurcates into two branches (Fig. 1a). The cycloartenol route is typical for photosynthetic organisms, while nonphotosynthetic progenitors and their descendants possess a lanosterol-based pathway [7]. Further conversions of sterol precursors include C14 and C4 demethylations, introduction of double bond(s) into the B ring and, in plants, fungi and protists, modification of the side chain to form cholesterol (animals), ergosterol (fungi) and a variety of 24 alkylated and olefinated products in plants and protists. Sterols stabilize the membranes, determine their fluidity and permeability and also serve as precursors for biologically active molecules essential for regulation of growth and development.

In view that humans consume cholesterol from the diet thereby downregulating sterol biosynthesis, the microbial ergosterol biosynthetic pathway can serve as a potential selective target for the treatment of human infections with ergosterol biosynthetic inhibitors such as itraconazole. The majority of currently used clinical antifungal drugs (azoles)

are aimed at inhibiting the fungal sterol 14 $\alpha$ -demethylase (CYP51). Many of them have also been proven experimentally to be effective against human infections involving protozoa [8–11]. However, due to low amino acid identity of CYP51s across these two biological kingdoms (about 22–24% in average) without direct characterization of protozoan sterol 14 $\alpha$ -demethylases it has been difficult to predict the potential efficiency of the antifungal drugs against protozoan infections and impossible to conduct directed search for new more potent compounds.

Using heterologously expressed (*E. coli*) and highly purified CYP51 orthologs from *Trypanosoma cruzi* (TC) and *Trypanosoma brucei* (TB), we studied inhibition of their activity in vitro, in reconstituted enzyme reactions, followed by testing the effects of the most promising compounds on trypanosomal cells. Both of these protozoan parasites are human pathogens, the origin of endemic diseases that are deadly and so far very difficult to cure. TC is the causative agent of Chagas disease, or American trypanosomiasis; while TB species cause sleeping sickness, or African trypanosomiasis. The organisms belong to the same family of lower eukaryotes (*Trypanosomatidae*), both having complex life-cycles that include insect and mammalian stages which are significantly different between the trypanosomes. TB and TC differ in their insect vectors, preferred mammalian hosts (though both infect humans), localization in the host organism, and symptomatic manifestation. From our studies, the most interesting differences between the two trypanosomes lie in their sterol requirements. While TC produces endogenous sterols at all life stages, the TB in the mammalian (bloodstream) stage was shown to be able to use host cholesterol. Since sterols are known to play a dual role in eukaryotic organisms [12], we used TC as a model to study the effect of inhibition of the production of structural (most abundant) sterols, while TB was a model to test the possible importance of so called functional (sparking) sterols, which are synthesized at hormonal levels, and might be important for the parasite development and life cycle regulation. In both cases direct correlation between CYP51 inhibition and antiparasitic effect in trypanosomal cells has been observed.

**Fig. 1** Divergence in sterol biosynthesis: **a** in photosynthetic (cycloartenol) and non-photosynthetic (lanosterol) eukaryotes; **b** in *Trypanosomatidae*

either as a turnover number (initial rate,  $I/E_2$ , 5 min) or, for the most potent inhibitors, as percentage of substrate conversion per 1 h reaction ( $I/E_2$ , 60 min) [16]. Imidazole derivatives were from Novartis Research Institute (Vienna, Austria). Optical high throughput screening (HTS) of a 20,000 compound library of bioactive molecules (<http://www.fmp-berlin.de/kries/index1.html>) against TB and TC CYP51s took advantage of the P450 property to change the Soret band absorbance maximum upon ligand binding [16]. It was carried out at the Screening Unit, Leibniz Institute for Molecular Pharmacology (Berlin, Germany) and the details of screening will be described elsewhere. Web search for structural similarity to reactive molecules from the screening was done using ChemDiv data base (<http://chemdiv.emolecules.com>). Structure of substrate analogs, YNE and MCP, was confirmed by MS and NMR data. TB and TC cellular growth and inhibition experiments, extraction of TC cellular sterols and TLC analysis were carried out as described [16, 17]. Scanning electron microscopy of TC amastigotes grown in Brain Heart Infusion Medium +10% FBS exposed or not to CYP51 inhibitors was performed using a Hitachi 2700 scanning electron microscope [18].

## Results and Discussion

### TB and TC CYP51s Differ in their Substrate Preferences

*Trypanosomatidae*, like other non-photosynthetic eukaryotes (Fig. 1a), cyclize squalene 2,3-epoxide into lanosterol and not into cycloartenol [19, 20]. In TC, prior to the CYP51 reaction, lanosterol is converted to form 24-methylenedihydrolanosterol (Fig. 1b), suggesting that the postsqualene portion of sterol biosynthesis in this protozoa is similar to the pathway in filamentous fungi except that the major sterol products in TC are not limited to ergosterol [21]. TBCYP51, on the contrary, has strict preference toward the C4 monomethylated sterols as substrates [14]. In the reconstituted enzyme reaction in vitro the TBCYP51 turnover of obtusifoliol (the substrate of CYP51s from plants) and norlanosterol (C4-monomethylated analog of lanosterol) are more than 100-fold faster than the 14 $\alpha$ -demethylation of lanosterol, 24-dihydrolanosterol or 24-methylenedihydrolanosterol. We have shown earlier that the differences in the substrate preferences of TB and TC CYP51 are connected with a phyla-specific residue in the B'-helix (plant-specific F105 in TB and other CYP51s from *Trypanosomatidae* as opposed to animal/fungi-like I105 in TCCYP51) [15]. The same TB-like preference for C4-monomethylated sterol substrates have been observed for CYP51 from *Leishmania infantum* (NCBI accession

number EF192938) (unpublished). Based on the catalytic properties of TB sterol methyl transferase [22], detailed analysis of TB sterols [23] and information from the literature on sterol composition of *Leishmania* species [12], 31-norlanosterol rather than obtusifoliol appear to be the natural substrate of TBCYP51 and most likely of all other CYP51s from *Trypanosomatidae* except for TC (Fig. 1b). This finding strongly suggests that *Trypanosomatidae* developed a unique postsqualene portion of the sterol biosynthetic pathway.

### Functionally Irreversible Inhibitory Effect of $\beta$ -Phenyl Imidazoles is Specific for Trypanosomal CYP51s

Since TB and TC CYP51 share 83% amino acid sequence identity, it is not surprising that, regardless of the differences in their substrate preferences, they both were found to be strongly inhibited by the same groups of imidazole derivatives (example structures are shown in Table 1). The strongest inhibition was observed for the  $\beta$ -phenyl imidazoles. Several such compounds produced a functionally irreversible effect with complete inhibition of TB and TC CYP51 activity at equimolar ratio inhibitor/enzyme [16]. At the same binding parameters ( $K_d < 0.1 \mu\text{M}$ ) the inhibitory effect of the  $\alpha$ -phenyl azoles on the initial rate of TB and TC CYP51 reaction was similarly strong ( $I/E_2 < 1$ ), but reversible, the compounds being easily replaced by the excess of substrate upon long-term enzymatic reaction. Thus the difference in the  $I/E_2$  values per 5 min and per 1 h for the  $\alpha$ -phenyl azole shown in Table 1 is more than 10-fold for TCCYP51 and more than 35-fold in the case of TBCYP51. Finally, imidazoles without an aromatic group between the azole ring and the amide portion of the molecule were weakly binding ligands and weak inhibitors.

Proving the importance of detailed preliminary knowledge about target enzyme inhibition for further drug development, direct correlation between the  $\alpha$ - and  $\beta$ -phenyl azole potencies as CYP51 inhibitors and their antiparasitic effects in trypanosomal cells was observed [16]. The  $\beta$ -phenyl azole inhibitor shown in Table 1 produces  $EC_{50}$  values (effective concentration, inhibitor concentration in growth media which causes 50% cellular growth inhibition) of 7 and 1.3  $\mu\text{M}$ , respectively, in procyclic (insect stage) and bloodstream (mammalian stage) TB and  $EC_{50} < 1 \mu\text{M}$  in trypomastigotes (extracellular form) and amastigotes (intracellular form) of TC, while the  $EC_{50}$  values for the strongest  $\alpha$ -phenyl azole inhibitor, are 16 and 14  $\mu\text{M}$  in procyclic and bloodstream TB; 8 and 20  $\mu\text{M}$  in trypomastigotes and amastigotes of TC. Though the effect in TB is weaker than in TC, it strongly suggests that functional sterols must be important in the bloodstream form of the parasite and that inhibitors of sterol biosynthesis should be envisaged as potential anti-sleeping

<sup>a</sup> Molar ratio inhibitor/enzyme which causes a twofold decrease in the activity

sickness drugs. For the comparison, published  $EC_{50}$  values in TC cells for benznidazole, one of the two drugs currently used for clinical treatment of TC infections, were reported to be within 25–50  $\mu\text{M}$  [24–26]. Much lower values from our work suggest using the  $\beta$ -phenyl azoles as lead structures for anti-trypanosomal chemotherapy.

Scanning electron microscopy of the TC cells shows that treatment with 1  $\mu\text{M}$  CYP51 inhibitor affects the topology of the TC plasma membrane (Fig. 2a). Ultrastructural alterations include the formation of blebs at the plasma membrane, membrane disorganization and alterations in the parasite shape. Analysis of the sterol composition of TC amastigotes treated with this azole confirmed that the parasite membranes are lacking C14-demethylated sterols (Fig. 2b; TLC of TC epimastigotes and GC–MS analysis of their cellular sterols can be found in [16]).

Interestingly, extremely potent, functionally irreversible inhibition by the  $\beta$ -phenyl imidazoles demonstrated by TB and TC CYP51 appears to be specific for trypanosomal

sterol 14 $\alpha$ -demethylases (Table 1). The effect of SDZ 285604 on the fungal CYP51 ortholog (from *C. albicans*) is still strong but reversible ( $I/E_2$  per 60 min = 8), while the activity of human CYP51 is only slightly affected by the presence of up to 100-fold molar excess of both the  $\alpha$ - and  $\beta$ -phenyl azoles. The data indicate that development of species-specific drugs based on the comparative analysis of the drug target enzyme inhibition in vitro is possible.

#### Benznidazole as CYP51 Inhibitor

Despite >40 years of its clinical use as an anti-chagasic drug, the mechanism(s) of action of benznidazole have remained elusive. It has been proposed that in trypanosomes, the drug mediates parasite killing by inducing oxidative stress [27–29] or that it works as a prodrug activated by TC nitroheterocycle reductases which reduce the nitro-group leading to covalent binding or other types of interaction between nitroreduction intermediates and various cellular

**Fig. 2** Cellular effects of SDZ284692 (1  $\mu\text{M}$ ) on TC amastigotes. **a** Scanning electron microscopy. **b** TLC analysis of extracted sterols. **Fig. 3** Inhibitory effect of benznidazole on TCCYP51 activity.  $I/E_2$  inhibitor enzyme ratio

components, like DNA, lipids and proteins [30–32]. It has been shown experimentally that nitroaromatic compounds can be reduced by lipoamide dehydrogenase and trypanothione reductase from TC *in vitro*, as well as by other known electron transfer proteins including cytochrome P450 reductase [33].

Since benznidazole is an azole derivative, we tested it in our reconstituted TCCYP51 reaction to see whether the anti-chagasic activity of the drug might involve a sterol biosynthesis inhibitory component. The results show that benznidazole inhibits TCCYP51 with  $I/E_2 = 42$  (5 min) and, surprisingly,  $I/E_2 = 45$  (1 h) (Fig. 3). The rather high  $I/E_2$  value for inhibition of the initial rate of the reaction is most likely due to low affinity of the binding (benznidazole does not induce spectral changes in TCCYP51 so the binding parameters can not be estimated by spectral titration). The comparable  $I/E_2$  for the long-term inhibitory effect suggests that the drug might act as an irreversible CYP51 inhibitor, the nitro-group being reduced by cytochrome P450 reductase and then covalently bound to the P450 protein moiety. This hypothesis needs to be tested in more detail but it is not excluded that introduction of a nitro-group into the structures of some known CYP51 inhibitors might lead to the development of new, more potent drugs.

#### Search for CYP51 Inhibitors other than Azoles

It is known that azoles, at least those currently used as clinical and agricultural fungicides, upon long-term treatment often can cause resistance. The mechanism(s) for the resistance remain unclear, but the three most often suggested reasons are: increase in the sterol flow; mutations in the target enzyme, or accelerated azole efflux from the cells

[34]. In order to investigate alternative options for the development of new sets of CYP51 targeted anti-trypanosomal drugs, optical HTS of TB and TC CYP51 for binding ligands other than azoles has been undertaken and several compounds producing type 1 (substrate-like) or type 2 (azole-like) spectral responses in the cytochrome P450 Soret band were identified [best HTS hits are shown in Table 2(A)]. The most potent inhibitor, *N*-(4-pyridyl)-formamide, compound 3, has  $K_{dS}$  of 0.8 and 0.5  $\mu\text{M}$  and  $I/E_2$  (5 min) of 7 and 10 for TB and TC CYP51, respectively. It probably coordinates to the heme iron through the pyridyl nitrogen. This has been supported by results of a web-database search for structural similarity using compound 3 as template. The strongest ligands from the web search [Table 2(B)] have bulky structures attached to the *N*-(4-pyridyl)-amide moiety, suggesting influence of the configuration of the non-coordinated portion of the ligand molecule, which (similar to azole inhibitors) might enhance the inhibitory effect by forming interactions with amino acid residues in the CYP51 substrate binding cavity. Having strong but reversible inhibitory effect on TCCYP51, comparable with the effects of the  $\alpha$ -phenyl azoles, compound 5 has potential to serve as a lead for the design of novel non-azole CYP51 inhibitors. It has been tested in TC cells and produced the  $EC_{50}$  values of 5  $\mu\text{M}$  in amastigotes and 8  $\mu\text{M}$  in trypomastigotes.

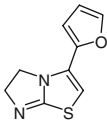

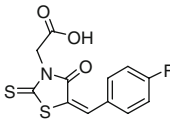

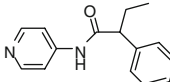

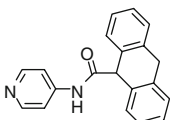

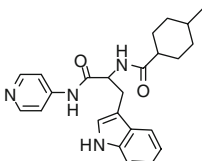

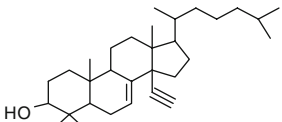

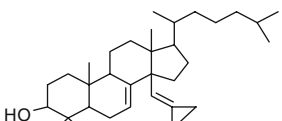

#### Substrate Analogs

The idea of using substrate analogs as inhibitors of sterol  $14\alpha$ -demethylase has been explored as an attempt to develop new hypocholesterolemic agents. It has been found that 7-oxo, 15-keto 15-keto, 15-oxime, 15-hydroxy, 26-oxo derivatives of lanosterol have potential to inhibit cholesterol biosynthesis in humans [35–37]. The advantages of use of substrate analogs as CYP51 inhibitors arise from their strict specificity for the target enzyme, better cellular permeability, longer lifetime in aqueous solutions in comparison to many azoles, and it is quite likely that being similar to endogenous sterols they would not cause resistance. The major problem, however, appears to be connected with very strict requirements that CYP51 enzymes have towards their substrates so that minor alterations in the structure of the sterol molecule can affect binding and inhibitory potency. Recently we have shown that two  $14\alpha$ -methylamino derivatives of lanosterol [4,4-dimethyl- $14\alpha$ -aminomethyl-cholest-7-en- $3\beta$ -ol (AL7) and 4,4-dimethyl- $14\alpha$ -aminomethyl-cholest-8-en- $3\beta$ -ol (AL8)] show inhibitory effect on CYP51 from TC and *C. albicans*, the  $I/E_2$  values for the initial rate of TCCYP51 catalysis being 11 and 14 for AL7 and AL8, respectively [15].

In this study two other  $14\alpha$ -derivatized sterols,  $\Delta^7$ - $14\alpha$ -methylene cyclopropyl didyrolanosterol (MCP) and  $\Delta^7$ ,

<sup>a</sup> Type 1 spectral response

14 $\alpha$ -yne-dihydrolanosterol (YNE), were studied as potential TC and TB CYP51 inhibitors (Table 2C). Contrary to the amino-derivatized AL7 and AL8 which induce type 2 spectral responses in TCCYP51, binding of MCP and YNE cause typical type 1 spectral response (Soret band maximum 393 nm) (Fig. 4a). Titration with YNE leads to 35–40% low to high spin transition in the heme iron of TB and TC CYP51 (not shown) while upon addition of MCP the high spin content in TBCYP51 reaches 85%, the highest currently observed for a CYP51 enzyme. Under the same conditions maximal high spin content in TCCYP51 is only 41%. Since TBCYP51 does not respond spectrally to the C4-double-methylated CYP51 sterol substrates, including dihydrolanosterol [14], the fact that structures longer than the methyl group at the 14 $\alpha$ -position (methyl-yne- and especially methyl-

cyclopropyl) having such a profound influence on the binding parameters was quite unexpected. To test whether these differences in the maximum spectral response are connected with the phyla-specific residue in the trypanosomal CYP51s described above, binding of MCP to the TBCYP51-like I105F mutant of TCCYP51 [15] was tested and 87% high spin form was reached.

Despite of the amplitude of the spectral responses and the calculated apparent binding parameters, both MCP and YNE were found to inhibit TCCYP51 activity much more strongly than they inhibit TBCYP51 (Table 2C). Based on the fact that in the case of MCP the  $I/E_2$  values for the initial rate of the reaction and long-term inhibitory effect are comparable (2 and 6, respectively), it is not excluded that MCP might act as a mechanism based inhibitor. Thus, the bulky phenyl residue in the B'-helix portion of the

**Fig. 4** MCP as a CYP51 inhibitor. **a** MCP induced type 1 spectral responses in TB and TC CYP51 and in the I105F mutant of TCCYP51. **b** Dose–response curves of trypanosomal cell growth inhibition. **c** Microscopic observation of the inhibition of TC multiplication by 30 μM MCP within cardiomyoblasts at 72 h. TC

pre-treated with control HPCD (used to dissolve MCP) showed high levels of parasite multiplication, whereas cells exposed to trypanosomes pre-incubated with MCP showed dramatic decrease in the number of intracellular parasites

CYP51 substrate binding cavity promotes displacement of the water molecule from the heme iron coordination sphere upon binding of MCP or YNE. However, it does not strengthen the enzyme–ligand interaction and both C4–double-methylated inhibitors, similar to the preferred substrates, remain selective for TCCYP51. This conclusion was confirmed by the results from MCP-treated trypanosomal cells: while  $EC_{50}$  for TB was higher than 50 μM, 50% cell growth inhibition of TC was reached at 3 μM (Fig. 4b), more than 90% of the parasite cells being cleared from TC infected cardiomyoblasts upon treatment with 30 μM MCP (Fig. 4c).

## Conclusions

- First, the fact that the β-phenyl imidazoles are strong, functionally irreversible inhibitors of trypanosomal but not fungal or human CYP51 opens an opportunity

for the development of species specific CYP51 inhibitors;

- Second, introduction of additional chemically reactive functional groups (e.g. nitro group) into the structure of known CYP51 inhibitors might strengthen their potency;
- Third, optical HTS followed by web-search for structurally similar compounds is a useful method to find new CYP51 inhibitors;
- Fourth, since so far TCCYP51 is the only trypanosomal sterol 14 $\alpha$ -demethylase with animal/fungal-like substrate preferences, C4-monomethylated substrate based inhibitors are likely to demonstrate selectivity towards CYP51 s from TB and all other *Trypanosomatidae* sequenced to date;
- We surmise that detailed knowledge of specific inhibition toward CYP51 might provide treatment for deadly human infections with protozoan parasites.

sterol 27-hydroxylase that catalyzes cholesterol 27-hydroxylation in many extrahepatic tissues. In addition, CYP27A1 also metabolizes bile acid intermediates in the liver and vitamin D<sub>3</sub> in the kidney [3]. Partial or complete lack of CYP27A1 activity results in a disease cerebrotendinous xanthomatosis manifested by a variety of phenotypes including tendon xanthomas, bilateral cataracts, premature atherosclerosis, osteoporosis, neurological and neuropsychiatric abnormalities [4]. Unlike CYP27A1, expression of CYP11A1 is limited to steroidogenic tissues and the brain, where it catalyzes the conversion of cholesterol to pregnenolone, the first step in overall steroid hormone biosynthesis [5]. Partial or complete lack of CYP11A1 activity results in a disorder of steroidogenesis in which cholesterol accumulates within the steroidogenic tissues, and the synthesis of all adrenal and gonadal steroids is impaired [2]. Several different approaches have been used previously to study membrane topology of mitochondrial P450s [6–10]. Ou et al. treated mitochondria from the bovine adrenal cortex with trypsin and digested CYP11A1 present in these mitochondria into two fragments. Mitochondria were then washed with sodium carbonate followed by evaluation of the association of the two fragments with the membrane [6]. Usanov et al. [7] studied the interaction of the mitochondrion-associated CYP11A1 with antibodies to the whole enzyme and its fragments. We investigated CYPs 27A1 and 11A1 by combining heterologous expression in *E. coli* and site-directed mutagenesis [8, 11]. Residues in the F-G loop, a putative site of the interaction with the membrane, were mutated, the mutant P450s expressed in *E. coli* and their subcellular distribution and catalytic activities compared with those of the wild type enzyme. Simultaneously with our studies, Headlam et al. [10] investigated the F-G loop as well as several other regions in CYP11A1 by utilizing cysteine mutagenesis followed by fluorescent labeling of the mutated residues and measurements of the changes in the fluorescence upon association of the mutant P450 with phospholipid vesicles. The N- and C-terminal truncated variants of CYP11A1 were also generated. Both groups suggested that the F-G loop is the site of interaction of mitochondrial P450s with the membrane. In the present investigation we continued elucidation of the membrane topology of mitochondrial P450s. We tested whether we can identify membrane-interacting areas in mitochondrial P450s other than the F-G loop by combining the methodologies of heterologous expression and proteolytic digestion with advances in mass spectrometry. CYPs 11A1 and 27A1 were expressed in *E. coli*, the *E. coli* membranes isolated and treated with trypsin. Peptides remaining after extensive washes of the trypsin-treated membranes with sodium carbonate were extracted and identified by MALDI MS. The data obtained suggest that

not only the F-G loop but also a part of the G helix is embedded in the membrane in mitochondrial P450s.

## Experimental Procedure

### Materials

Sequencing grade modified trypsin was from the Promega Corp. (Madison, WI, USA). All other chemicals were purchased from Sigma-Aldrich (St. Louis, MO, USA).

### Membrane Fractionation

Recombinant human CYP27A1 and bovine CYP11A1 were expressed in *E. coli* as described [12, 13]. Cells were harvested by centrifugation at 10,000 g for 10 min, resuspended in 10 mM HEPES (pH 7.8) containing 10% sucrose, and treated with 0.2 mg/ml lysozyme on ice for 30 min. Spheroplasts were pelleted at 10,000 g for 10 min, resuspended in 10 mM HEPES (pH 7.8) containing 10% sucrose and sonicated using six 10-s pulses at 40% duty cycle (Sonifier 450, Branson Ultrasonics Corp., Dandury, CT). The suspension was then layered over a cushion of 55% sucrose topped with 10% sucrose in 10 mM HEPES (pH 7.8) and subjected to centrifugation in a Ti70 rotor at 35,000 rpm for 60 min. The total membrane fraction was recovered from the 55% sucrose interface, washed twice with 25 mM NH<sub>4</sub>HCO<sub>3</sub> (pH 7.9), and placed in pre-weighed tubes.

### Trypsin Treatment

The wet membrane pellet (5 mg) was resuspended in 1 ml of 25 mM NH<sub>4</sub>HCO<sub>3</sub> (pH 7.9) followed by addition of 10 µg of sequencing grade modified trypsin. The suspension was sonicated as described above and left for proteolysis for 15 h at 37 °C. The sample was then subjected to 106,000 g centrifugation for 20 min in Optima TLX ultracentrifuge (Beckman Instruments, Inc., Fullerton, CA, USA). The pellet was collected and washed sequentially with 100 mM Na<sub>2</sub>CO<sub>3</sub> (pH 11.5) containing 0.3 M NaCl (5 times) and with water (1 time). Traces of water from the wet pellet were removed by adding 0.2 ml of methanol/chloroform mixture (4/1, v/v) and drying the sample in a Vacufuge (Eppendorf AG, Hamburg, Germany). The dried pellet was then vortexed with 0.2 ml of chloroform, the organic phase discarded, and the membranes dried again. Extraction of peptides from the dried membranes was carried out with 100 µl of 50% acetonitrile/0.1% trifluoroacetic acid (TFA). The extracted sample was further purified using ZipTip C<sub>18</sub> (Millipore Corporation, Bedford, MA, USA) according to the manufacture protocol.

## Mass Spectrometry Analysis

Peptide samples after ZipTip purification were dried, dissolved in 5 mg/ml  $\alpha$ -cyano-4-hydroxycinnamic acid in 50% acetonitrile containing 0.1% TFA, and manually spotted onto the ABI 01-192-6-AB target plate. Mass spectrometry (MS) analyses were performed using an AB4700 Proteomics Analyzer (Applied Biosystems, Framingham, MA, USA). MS-mode acquisitions consisted of 1,000 laser shots averaged from 20 sample positions. In the MS/MS-mode acquisitions, 6,000 laser shots were averaged from 60 sample positions for PSD fragments. Automated acquisition of MS and MS/MS data was controlled by 4000 Series Explorer software 3.0.

## Computational Analysis

Free energy of transfer from water to bilayer interface ( $\Delta G_{\text{WW}}$ ) was computed using Totalizer module of MPEx (<http://blanco.biomol.uci.edu/mpex>) based on the Wimley-White hydrophobicity scale. A function of “no end groups” as a subsequence of a longer sequence was used for this calculation. Hydrophobic moment ( $\mu_{\text{H}}$ ) was also computed using the Totalizer module of MPEx.

## Results

### Identification of the Membrane-Interacting Peptides in CYP27A1 and CYP11A1

A representative MS spectrum of the extract derived from trypsin-treated CYP27A1-containing *E. coli* membranes is shown in Fig. 1a. Manual analysis revealed 4 peptides with  $m/z$   $[M + H]^+$  values expected for the CYP27A1 hydrolysis with trypsin. Two of these peptides with  $m/z$   $[M + H]^+$  values 1329.72 and 1485.81 are labeled in Fig. 1a. Signals for two other peptides with  $m/z$   $[M + H]^+$  values 1645.78 and 1929.95 were very small and could be seen only after zooming (not shown). In the MALDI experiment, signal intensity does not linearly correlate with the concentration of analyte, therefore very small peaks were annotated as well. A summary of all the peptides identified in CYP27A1 is given in Table 1. The expected  $m/z$   $[M + H]^+$  values were calculated using MASCOT software and rounded to two decimal places. The accuracy of mass measurement in ppm was calculated as a difference between the expected and observed values divided by the observed value. Without the internal calibration, the observed  $m/z$   $[M + H]^+$  values for these peptides deviate from the expected  $m/z$   $[M + H]^+$  values in a range of 40 ppm. Figure 1b shows the MS/MS spectrum for the peptide ion with  $m/z$   $[M + H]^+$  value 1329.72. This

spectrum has an immonium ion for Trp and various  $y$ - and  $b$ -type fragment ions that collectively confirm the correct assignment of the amino acid sequence. The MS analysis of the CYP11A1 sample revealed two CYP11A1 peptides. One of them with  $m/z$   $[M + H]^+$  value 1675.80 is labeled in Fig. 1c. The zoomed spectrum for the second peptide with  $m/z$   $[M + H]^+$  value 1107.59 is shown in Fig. 1d. The intensity for this peptide was very low.

### Analysis of the Identified Peptides

Membrane-interacting protein sequences usually possess a unique combination of hydrophobicity and amphiphilicity. Therefore, the identified peptides were evaluated for two parameters that render peptides “membrane-seeking”: free energy of transfer from water to the bilayer interface and hydrophobic moment. Free energy of transfer ( $\Delta G_{\text{WW}}$ ) is a measure of solubility in the non-polar phase with the positive value of  $\Delta G_{\text{WW}}$  being unfavorable for partitioning the peptide sequence into the membrane interface. Hydrophobic moment ( $\mu_{\text{H}}$ ) detects periodicities in the hydrophobicity of amino acid sequences and is a measure of the amphiphilicity of a protein fragment [14, 15]. The  $\Delta G_{\text{WW}}$  and  $\mu_{\text{H}}$  values of the CYP27A1 and CYP11A1 peptides are shown in Table 1. All of the identified peptides except one,  $^{238}\text{AEKYTEIFYQDLR}^{250}$ , have negative values of  $\Delta G_{\text{WW}}$  and values of  $\mu_{\text{H}}$  from 1.98 to 6.12. This is consistent with the fact that they were extracted from the membrane. The  $^{238}\text{A-R}^{250}$  peptide has a positive  $\Delta G_{\text{WW}}$  value but a high  $\mu_{\text{H}}$  value which strongly increases the chances for this sequence to interact with the membrane. Trypsin cannot cleave amino acid residues embedded in the membrane. Therefore, the identified peptides contain both membrane-bound and soluble regions. If the soluble region is too long, this may affect the calculated  $\Delta G_{\text{WW}}$ , and could be the case with the  $^{238}\text{A-R}^{250}$  peptide.

In addition to the computational analysis, peptides were examined for the presence of the missed cleavage sites. One may assume that the missed cleavage sites are located either in the membrane or close to the membrane surface, and therefore resistant to proteolysis. Two peptides in CYP27A1,  $^{227}\text{W-R}^{237}$  and  $^{238}\text{Y-K}^{251}$ , and one peptide in CYP11A1,  $^{238}\text{A-R}^{250}$ , contain one missed cleavage site, and one peptide in CYP11A1,  $^{218}\text{L-R}^{225}$ , has two missed cleavage sites. Also, the CYP27A1 peptides with  $m/z$   $[M + H]^+$  values 1329.72 and 1485.81 represent the same sequence without and with the trypsin missed cleavage site, respectively.

The position of the membrane-interacting peptides in the primary and secondary sequences of CYPs 27A1 and 11A1 is shown in Fig. 2. Peptides in CYP27A1 represent a contiguous portion of the polypeptide chain comprising the

**Fig. 1** Membrane-interacting peptides in CYP27A1 and CYP11A1. **a** MS spectrum of the extract from the trypsin-treated CYP27A1-containing *E. coli* membranes. Peptides with  $m/z$   $[M + H]^+$  values 1329.72 and 1485.81 correspond to CYP27A1, all the other peptides are of the *E. coli* origin. **b** MS/MS spectrum of the peptide ion with  $m/z$   $[M + H]^+$  value 1329.72 that corresponds to the  $^{227}$ WTRPVLPFWK $^{236}$  peptide in CYP27A1. Multiple fragment ions

matching to this sequence are labeled as follows:  $b_2$ , WT;  $b_3$ , WTR;  $b_6$ , WTRPVL;  $b_9$ , WTRPVLPFW;  $y_2$ , WK;  $y_4$ , PFWK; and  $y_7$ , PVLOFWK. **c** and **d** Regular and zoomed MS spectrum of the extract from the trypsin-treated CYP11A1-containing *E. coli* membrane. Missed cleavage sites are underlined

<sup>a</sup> Free energy of transfer from water to the bilayer interface based on the Wimley-White hydrophobicity scale ( $\Delta G_{WW}$ ) and hydrophobic moment ( $\mu_H$ ) were computed using the Totalizer module of MPEX (<http://blanco.biomol.uci.edu/mpex>)

**Fig. 2** Location of the membrane-interacting peptides (underlined) in the primary and secondary structures of CYPs 27A1 and 11A1. Boxes indicate putative F and G helices. The secondary structure

consensus prediction program ([http://npsa-pbil.ibcp.fr/cgi-bin/npsa\\_automat.pl?page=/NPSA/npsa\\_seconcons.html](http://npsa-pbil.ibcp.fr/cgi-bin/npsa_automat.pl?page=/NPSA/npsa_seconcons.html)) was used to identify these structural elements

putative F-G loop and flanking portions of the F and G helices. In CYP11A1, the  $^{218}$ L-R $^{225}$  peptide is located in the F-G loop and the  $^{238}$ A-R $^{250}$  peptide in the C-terminal portion of the G helix.

## Discussion

In the current study, we used CYP27A1- and CYP11A1-containing *E. coli* membranes as a model system to study

membrane topology of these mitochondrial enzymes. Previously, we developed *E. coli* expression for both proteins, showed that they stay associated with the membrane fraction when expressed in *E. coli*, and are catalytically active in the *E. coli* membranes [8, 9, 12, 13]. The membrane topology of CYPs 27A1 and 11A1 was then studied by selecting a hydrophobic region in their primary sequence, the F-G loop, and evaluating how mutations within this region affect binding to the membrane and activity of the mutant P450s [8, 9]. Weakened binding of some the mutants indicated that the F-G loop indeed interacts with the membrane. Mitochondrial P450s are suggested as having a peripheral association with the membrane [16, 17]. However, it is not currently clear whether one or several segments of the primary sequence are associated with the membrane. Headlam and colleagues began to address this question by investigating three regions in CYP11A1, the F-G loop, A' helix, and the 14 amino acid residue-segment at the C-terminus [10]. These regions were selected based on hydrophobicity profiling and secondary and tertiary structure predictions. The data obtained indicate the involvement of the F-G loop and possibly A' helix, but not the C-terminus of CYP11A1, in the interactions with the membrane. Thus, although the computational analysis provided a reasonable prediction, not all of the putative membrane-interacting regions were then validated by other methods. In the present study a principally different approach was undertaken. It includes the protease degradation of the solution-exposed portion of the membrane-associated CYPs 27A1 and 11A1 and subsequent MS analysis of the recovered membrane-bound peptides. Consistent with previous studies, peptide(s) from the F-G loop were extracted from the membrane in CYPs 27A1 and 11A1. Identification of these peptides lends support to the validity of our approach and serves as additional evidence for the role of the F-G loop. We also identified one peptide in CYP27A1 ( $^{238}\text{Y-K}^{251}$ ) and one peptide in CYP11A1 ( $^{238}\text{A-R}^{250}$ ) that are located outside the F-G loop, in the N- and C-terminal parts of the G helix, respectively. The N-terminal part of the G helix represents a continuation of the F-G loop. Therefore identification of the  $^{238}\text{Y-K}^{251}$  peptide in CYP27A1 is not an unexpected finding. In fact, it provides an explanation of our previous observation that CYP27A1 is associated more tightly with the *E. coli* membrane than CYP11A1 [8]. A longer stretch of amino acid residues in the F-G loop region seem to interact with the membrane in CYP27A1 than in CYP11A1. Identification of the  $^{238}\text{A-R}^{250}$  peptide in CYP11A1 is a more interesting finding because the C-terminal part of the G helix has never been considered as a potential membrane-binding site in CYP11A1. Further studies are required to confirm this unexpected finding. As any method, the MS-based approach has a limitation. This

limitation is hidden in the procedure of analysis. Certain classes of long peptides with high hydrophobicity can escape MS analysis [18], therefore a set of identified peptides may never reach a full completeness. For example, when purified CYPs 27A1 and 11A1 are digested with trypsin in solution, we usually obtain peptides covering about 54% of the primary sequence. If each of the P450s is subjected to SDS PAGE and digested in gel, the coverage of the primary sequence by the identified peptides is  $\sim 46\%$ . When combined, tryptic peptides from solution and in-gel digestion cover  $\sim 65\%$  of the primary sequence. Thus, MS studies with purified CYPs 27A1 and 11A1 raise a possibility that not all of the membrane-interacting peptides in CYPs 27A1 and 11A1 were identified in the present study. Nevertheless, our approach provided a further insight into the membrane topology of CYPs 27A1 and 11A1 and is a valuable addition to the other methods in the field.

cytochromes P450 interact with electron transfer proteins. The cytochromes P450 are divided into ten classes depending on the nature of their redox partners [3]. In general, the soluble bacterial cytochromes P450 are more stable than the membrane bound P450s and therefore easier to express and to purify.

Besides playing an important role in physiological processes, e.g. steroid and vitamin D biosynthesis, drug biotransformation and degradation of xenobiotics, cytochromes P450 are important for biotechnology [1]. In particular, steroid-converting cytochromes P450 are useful in the steroid producing industry. The complex steroid molecule structure requires complicated, multi-step schemes for the chemical synthesis of respective steroid compounds. The preparation of intermediates with protection groups and their subsequent removal is often necessary, making the chemical synthesis expensive and time consuming. Furthermore, the basic ring structure of some steroid derivatives is sensitive to cleavage by a wide variety of chemicals. Chemical synthesis also requires the use of reagents that are hazardous to the health of production staff, and constitute a serious environmental disposal problem [4]. Currently, chemical and biochemical processes are often combined in the production of steroids. Biochemical reactions in the steroid industry are usually performed by whole-cell systems to avoid the costs of enzyme isolation, purification, stabilization, and to solve the problem of the NAD(P)H co-factor regeneration [4, 5]. The corresponding biochemical processes are used to produce various steroidogenic compounds, including 11 $\beta$ -, 11 $\alpha$ -, 15 $\alpha$ - and 16 $\alpha$ -hydroxylated products. These compounds are mainly used for the production of adrenal cortex hormones and their analogues [4, 6, 7]. They have a broad therapeutic application in contraceptives, anti-inflammatory, immunosuppressive, anabolic, and diuretic drugs.

Although biochemical processes are well established in the production process of steroids, there is still need for improvement of the product yield. Needed improvements include the hydroxylation specificity so as to have fewer by products, introduction of new hydroxylation sites into a known substrate or adaptation of the enzyme to a new substrate. The function of enzymes can be modified by replacing amino acids on positions responsible for the enzyme activity. Therefore, a basic knowledge of the structure–function relationship is required. For a predominant number of enzymes, little or nothing is known about the structure–function relationship. Directed evolution can be used to solve this problem. Herein, a number of random mutants in the whole gene or in parts of the gene are generated, and this library of mutants is screened using an appropriate test system to select a protein with the desired function. Thus, enzymes with an improved function (e.g. higher activity) or a completely new protein function can be generated.

The difficult part of the directed evolution process is creation of an efficient screening system. The screening system should allow selection of protein variants with a specific function. Development of a screening system for some selection processes is easy. Evolution of antibiotic resistance [8] or protein solubility [9] are examples of simple screening systems. In contrast, conventional detection methods for steroids, like HPLC and GC-MS, are time consuming and quite expensive. Appel et al. [10] presented a simple detection method for steroids. They used a fluorescence based test system to determine the conversion rate of 11-deoxycortisol to cortisol of a CYP11B1 expressing *Schizosaccharomyces pombe* culture. We established an adaptation of this method to micro titer plate format, and used it to measure the activity of the steroid hydroxylating CYP106A2 [11]. CYP106A2 was isolated from *Bacillus megaterium* ATCC 13368. This soluble cytochrome P450 is able to hydroxylate steroids such as progesterone, 11-deoxycortisol, and testosterone. It hydroxylates specifically 3-oxo- $\Delta^4$ -steroids, whereas 3 $\beta$ -hydroxy- $\Delta^5$ -steroids will not be converted. CYP106A2 hydroxylates mainly in the 15 $\beta$  position. Other hydroxylation positions described are 6 $\beta$ , 9 $\alpha$  and 11 $\alpha$ , when using progesterone as substrate [12, 13]. The expression yield in *Escherichia coli* is high (8.000 pmol P450/mg total protein, 13.700 nmol/l culture) [14]. Activity in vitro is achieved using the bovine adrenodoxin (Adx) and adrenodoxin reductase (AdR) as electron transfer partners [15, 16]. In a previous publication we described the co-expression of Adx and AdR together with CYP106A2 in *E. coli* to allow an in vivo activity of CYP106A2 [11]. In this paper, we demonstrate, (1) functionality of a fluorescence based test system for the directed evolution of a steroid hydroxylating enzyme, CYP106A2, (2) improvement of the activity of CYP106A2, and (3) application of the CYP106A2 model in order to understand the function of the identified randomly changed amino acid residues.

## Materials and Methods

### Reagents and Chemicals

11-deoxycortisol (RSS) and progesterone (P) were from Sigma Chemicals Co (St Louis, MO, USA). All other chemicals were from standard sources and of the highest purity available.

### Random Mutagenesis of CYP106A2

Random mutagenesis of CYP106A2 in pACYC\_FHH2\_8 was performed by error-prone-PCR using the GeneMorph random mutagenesis kit (Stratagene, La Jolla, CA, USA).

An average mutation frequency of 0–3 mutations per kb was achieved according to the manufacturer's protocol. After cutting the fragment ends with *NcoI/HindIII* and ligation with the vector pACYC, the resulting plasmids were introduced into electrocompetent *E. coli* Top10F', due to its better transforming efficiency. A 100-ml culture containing ampicillin (100 µg/ml) was inoculated, incubated 16 h at 37 °C and used for plasmid isolation.

The second mutant generation, with a mutation frequency of 0–4.5 mutations per kb, was obtained using GeneMorph II random mutagenesis kit (Stratagene). It was generated using mutant A106T/R409L as template.

#### Co-transformation, Co-expression and Screening for Improved activity

Co-expression of adrenodoxin, adrenodoxin reductase and CYP106A2 wild type enzyme or its mutants in *E. coli* is described in [11]. The screening procedure in micro titer plates is based on the method published previously [11].

#### Expression and Purification CYP106A2, CYP106A2 Mutants, and Adrenodoxin Reductase and Adrenodoxin

Expression of CYP106A2 wild type and mutants, located on pACYC\_FHH2\_8, was performed as described in Simgen et al. [16]. Purification was performed according to Lisurek et al. [13].

Recombinant bovine adrenodoxin reductase and a truncated form of bovine adrenodoxin (4–108) were expressed and purified according to Sagara et al. [17] and Uhlmann et al. [18].

#### In Vitro Catalytic Activity

Enzyme activity of CYP106A2 wild type, and mutants was measured in a reconstituted system with a final volume of 500 µl at 30 °C for 1 min in 50 mM HEPES buffer, pH 7.4 with 0.05% Tween 20. The reconstituted system contained 0.5 µM adrenodoxin reductase, 5 µM adrenodoxin (4–108), 0.25 µM CYP106A2, a NADPH-generating system (1 mM MgCl<sub>2</sub>, 5 mM glucose-6-phosphate, 1U glucose-6-phosphate-dehydrogenase, and 0.1 mM NADPH), and 25–750 µM of the substrate 11-deoxycortisol. Reactions with progesterone were performed using 140 µM substrate and stopped after 1 min incubation time by addition of chloroform. Steroids were extracted twice with 500 µl chloroform, organic phases were combined and evaporated. The remnant was dissolved in methanol and subjected to HPLC analysis.

A reversed phase Waters Nova Pak Nukleosil C18 (4 µm, 3.9 × 150 mm) (Waters, Milford, MA, USA),

using acetonitrile:water = 35:65 as mobile phase at a flow rate of 1 ml/min at 25 °C, was used for HPLC analysis.

The relative amounts of the products were determined using the relative peak area of the internal standard DOC, and the respective hydroxylation activity was calculated. Each reaction was performed a minimum of three times. Data were fitted by hyperbolic regression using Sigma Plot (Rockware, Golden, CO, USA).

#### Molecular Modeling of CYP106A2

The WebLab ViewerLite 4.2 program (Accelrys) was chosen to map substituted residues in the published model of CYP106A2 [19]. The Swiss Pdb-Viewer program [20] was used to simulate H bonds in CYP106A2 mutants.

## Results

### Development of a Screening System for CYP106A2 Activity

Fast and reliable assay systems are crucial for directed evolution, so we established a screening system for our purposes. We decided to use a fluorescence assay due to its high sensitivity and ease of handling. For this the previously described activity assay [10, 11] was adopted to micro titer plates and high-throughput conditions. Tests were performed to assess the general usability of the fluorescence assay for our purposes (Fig. 1). *E. coli* was co-transformed with plasmids pACYC\_FHH2\_8 and

**Fig. 1** To show the reliability of the fluorescence assay, some wells of a micro titer plate were inoculated with the *E. coli* culture and later the expression was induced by added IPTG. Steroid hydroxylation takes place only after expression of a functional hydroxylase system ("inoculated and induced"). The fluorescence intensity of the 11-deoxycortisol hydroxylating cultures is almost two times higher than of cultures without 11-deoxycortisol conversion (culture media in the wells are not inoculated or no expression of the hydroxylase system)

pBar\_Twin allowing the co-expression of CYP106A2, AdR, and Adx. To the *E. coli* cultures in the micro titer plate, 1 mM IPTG and/or 400  $\mu$ M RSS were added. The measured fluorescence of cultures containing IPTG and RSS was compared with *E. coli* cultures with induced protein expression (IPTG presence) but without RSS to estimate the background fluorescence caused by other compounds secreted by *E. coli*. Conversion of RSS in cultures with a functional hydroxylase system yielded a twofold higher fluorescence than of cultures without RSS conversion due to a non-expressed hydroxylase system (IPTG not present). Cultures with RSS conversion exhibit the highest fluorescence in this assay, whereas cultures without RSS show only minimum fluorescence (Fig. 1). The difference between unspecific and specific fluorescence is twofold, therefore the assay is sufficiently specific to be used as a reliable screening system.

For the screening, three positions on each 96-well plate were inoculated with clones expressing CYP106A2 wild type and AdR/Adx. The fluorescence intensity of these clones was used as a reference to select mutants with

higher activity towards RSS or P. As shown in Fig. 2, about 25% of mutants exhibit a higher fluorescence intensity than wild type CYP106A2 in the RSS hydroxylation assays. Only 30% of the mutants display a lower fluorescence intensity than wild type CYP106A2 indicating lower or no enzyme activity. The majority of the clones display a fluorescence intensity similar to the wild type controls. For further studies clones were selected which showed a clear increase in fluorescence intensity (at least 1.5- to 2-fold) compared to the wild type control (Fig. 2). Approximately 2.100 clones of the first mutant generation were screened using the substrate RSS and about 1.900 clones using P as substrate. Six CYP106A2 clones were selected using RSS as substrate and four clones were selected using P as substrate. Sequencing revealed that three of the clones from the screening with RSS contained the same A106T/R409L replacement, the other three mutants were A106T, D153V/I214F, or D217V replacements. Two of the four clones selected with P as substrate showed the A106T/R409L double mutation. A106T and F165I replacements were detected in the two other mutants.

**Fig. 2** Analysis of fluorescence formation of first generation CYP106A2 mutants After 48 h incubation cultures in the micro titer plates were harvested by centrifugation. The steroids were extracted with methyl isobutyl ketone (MIBK). The MIBK phase was transferred into another micro titer plate and treated with a sulfuric acid/acetic acid mixture. The developing fluorescence was measured in a micro titer plate reader ( $\lambda_{\text{ex}}$  485 nm,  $\lambda_{\text{em}}$  535 nm) (RFU relative fluorescence units). **a** Example of fluorescence values of one micro titer plate after RSS conversion. Positions 12F, 12G, and 12H (*black background*) were inoculated with wild type CYP106A2 giving an average fluorescence value for wild type CYP106A2.

(*gray background*) shows a mutant with more than twofold increase in fluorescence. **b** Distribution analysis of the measured fluorescence intensities of this micro titer plate. The measured fluorescence intensities were divided into groups (e.g. RFU of 13.487, 13.054, and 13.999 were combined in the 13.000 RFU group) and plotted versus the number of clones in this group. The distribution analysis shows that approximately one-third of the clones are less active or even inactive as indicated by a lower measured fluorescence intensity and one-fourth are more active than the CYP106A2 wild type. *Black bars* indicate groups that include the RFU values of the wild type

The A106T/R409L mutant with five detections was the most common mutation found in the screening, followed by A106T with two detections. Mutant A106T/R409L, which has the highest RSS hydroxylation rate of all first generation mutants, was chosen to generate the second mutant generation. In the screening assay of the second generation, where RSS was used as substrate, again about 2,100 clones were tested. The differences between the fluorescence intensities of the control (mutant A106T/R409L), and the highest measured fluorescence intensities were lower compared to the results of the first generation screening. Seven variants with an 1.2- to 1.5-fold increased fluorescence intensity were picked. One of these seven clones showed a A106T/Q189K/T399S/R409L mutation whereas the other six clones had an identical sequence as the template (mutant A106T/R409L). Furthermore, two additional silent mutations were found in A106T/R409L, as well as in the derived quadruple mutant A106T/Q189K/T399S/R409L.

After separation of the plasmid pACYC\_FHH2\_8 carrying the sequence of the cytochrome P450 from Adx and AdR containing plasmid pBar\_Twin, the P450 mutants were expressed in JM109 *E. coli* cells. The CYP106A2 wild type expressed with a yield of 453 nmol/l culture. The expression level of the mutants ranges from 17% (A106T) to 60% (D217V) of the wild type (Table 1). The double mutant A106T/R409L shows a slightly increased expression yield (+28 %), compared to the A106T single mutant. Purification of the proteins was done as described under “Materials and methods”. Spectra of the purified proteins ranged from 250 to 700 nm for the oxidized protein, and from 400 to 500 nm for the reduced versus reduced and CO-bound state. Spectra showed the characteristic absorption of oxidized cytochromes P450 with peaks at 280, 358, 417, 534 and 568 nm. The proteins were in low spin state. The CO difference spectra showed all P450 characteristics expected with maxima at around 450 nm. The correct size of the P450 mutants was checked by

**Table 1** Expression level of CYP106A2 and mutants in JM109 cells transformed with pACYC\_FHH2\_8 plasmid after 48 h incubation at 30 °C in TB media in the presence of 0.5 mM 5-amino levulinic acid and 1 mM IPTG

	CYP content (nmol/l culture)
CYP106A2-WT	453.0

SDS-PAGE. SDS-PAGE analysis show high purity of the proteins after purification (Fig. 3).

#### Kinetic Investigation of the Mutants

The activity of the purified CYP106A2 mutants was tested with the substrates RSS and P *in vitro*. The test system contained 0.25  $\mu$ M P450, 0.5  $\mu$ M AdR, and 5  $\mu$ M Adx. The apparent  $V_{max}$  and  $K_m$  values of the RSS conversion were determined. Activity of the mutants with P was calculated as the percentage of progesterone conversion after 1 min incubation time in the presence of 140  $\mu$ M substrate.

The apparent  $K_m$  value of the RSS conversion for all tested mutants was lower (36.9–67.5  $\mu$ M) than the  $K_m$  of the CYP106A2 wild type (93.4  $\mu$ M) reflecting an improved substrate binding of the mutants (Fig. 4, Table 2). Also, the

**Fig. 4** Kinetics of the selected CYP106 mutants. Apparent  $V_{max}$  (nmol 15 $\beta$ -OH-RSS/min\*nmol P450) (dotted, CYP106A2 WT; dash-dot-dot, D153V/I214F; short dash, D217V; solid, A106T/Q189K/T399S/R409L; dash-dot, A106T/R409L; long dash, A106T) is plotted versus 11-deoxycortisol concentration. The standard deviation was calculated from three independent experiments

**Table 2** Kinetic parameters of the 11-deoxycortisol conversion of CYP106A2 wild type and mutants. (\*) This CYP106A2 mutant was obtained from the second mutant generation when screened with RSS as substrate

	Apparent $K_m$ ( $\mu\text{M}$ )	Apparent $V_{\max}$ (nmol 15 $\beta$ - OH-RSS/nmol P450/min)	Apparent $k_{\text{cat}}/K_m$ ( $\text{M}^{-1} \text{s}^{-1}$ ) $\times 10^3$	Increase to WT
CYP106A2-WT	93.4 $\pm$ 8.8	172.1 $\pm$ 4.9	30.7 $\pm$ 3.0	1
D153V/I214F	37.3 $\pm$ 6.7	181.8 $\pm$ 7.6	81.2 $\pm$ 15.0	2.64
A106T/R409L	67.5 $\pm$ 5.4	374.1 $\pm$ 8.8	92.4 $\pm$ 7.7	3
D217V	65.9 $\pm$ 5.9	325.2 $\pm$ 8.5	82.3 $\pm$ 7.7	2.68
A106T	58.8 $\pm$ 3.6	343.4 $\pm$ 5.9	97.3 $\pm$ 6.3	3.17
A106T/Q189K/T399S/R409L*	36.9 $\pm$ 5.4	294.1 $\pm$ 9.9	132.6 $\pm$ 19.9	4.32

maximal RSS hydroxylation rate is improved as indicated by an increased apparent  $V_{\max}$  value. When calculating the catalytic efficiency  $k_{\text{cat}}/K_m$ , the differences between the CYP106A2 wild type and the mutants are more dramatic. For CYP106A2 wild type, an apparent  $k_{\text{cat}}/K_m$  of  $30.7 \times 10^3$  ( $\text{M}^{-1} \text{s}^{-1}$ ) of the 15 $\beta$ -OH-RSS production was calculated. Mutant A106T/R409L shows a number of  $92.4 \times 10^3$  ( $\text{M}^{-1} \text{s}^{-1}$ ), a threefold increase. The activity of these mutants towards P is similar to RSS hydroxylation activity. Mutants A106T and A106T/R409L show the highest progesterone conversion after 1 min incubation time (Table 3). The second generation mutant A106T/Q189K/T399S/R409L has an apparent  $V_{\max}$  of 294.1 nmol 15 $\beta$ -OH-RSS/nmol P450\*min, which is lower than the apparent  $V_{\max}$  of the double mutant A106T/R409L used as template (374.1 nmol 15 $\beta$ -OH-RSS/nmol P450\*min), but still significantly higher than the wild type with 172.1 nmol 15 $\beta$ -OH-RSS/nmol P450\*min. Despite the lowered  $V_{\max}$  this mutant shows an increased apparent  $k_{\text{cat}}/K_m$  due to an improved  $K_m$ . Therefore, the catalytic efficiency of CYP106A2 towards RSS could be improved in two mutant

**Table 3** Progesterone conversion of the CYP106A2 mutants compared to the wild type. The in vitro reactions were stopped after 1 min incubation time and the conversion of P was estimated by the percentage of total peak area (P and the hydroxylated progesterone products 11 $\alpha$ -, 9 $\alpha$ -, 6 $\beta$ -, and 15 $\beta$ -OH-progesterone) minus the peak area of the remaining P. The concentration of P was 140  $\mu\text{M}$ . (\*) This CYP106A2 mutant was obtained from the second mutant generation when screened with RSS as substrate. F165I was obtained exclusively in the screening with P as substrate

	Progesterone conversion after 1 min (%)	Increase to WT
CYP106A2 WT	34.8 $\pm$ 2.1	1
D153V/I214F	32.4 $\pm$ 1.5	0.93
A106T/R409L	49.9 $\pm$ 0.8	1.43
D217V	41.4 $\pm$ 1.6	1.18
A106T	50.0 $\pm$ 0.5	1.43
A106T/Q189K/T399S/R409L*	39.2 $\pm$ 0.1	1.13
F165I	43.5 $\pm$ 0.2	1.25

generations by more than a factor of four. In addition, also the conversion of P improved in these mutants.

## Discussion

CYP106A2 has application for biotechnological purposes. This enzyme is soluble, easy to express, and is one of the few known bacterial CYPs with steroid hydroxylation capability. Our intent was to improve the steroid hydroxylation activity of CYP106A2 using directed evolution. Previously, we described a method to obtain steroid conversion in CYP106A2 and redox partner protein expressing *E. coli* cells [11]. The in vivo activity of CYP106A2 in *E. coli* was obtained by co-transformation with plasmid pBar\_Twin carrying adrenodoxin and adrenodoxin reductase sequence, and with plasmid pACYC\_FHH2\_8 carrying the CYP106A2 sequences and subsequent expression of all three proteins. The use of two plasmids allows an easier mutagenesis of CYP106A2 as well as an easier expression of selected CYP106A2 mutants for further characterization. Both plasmids, pBar\_Twin and pACYC\_FHH2\_8, can be easily separated, and after transformation of pACYC\_FHH2\_8 into the *E. coli* expression host only the CYP106A2 mutants can be expressed.

This in-vivo steroid-converting recombinant *E. coli* system was used as a high-throughput screening system for our directed evolution studies. Directed evolution requires a fast screening system with high sensitivity and accuracy. Established steroid analysis methods are GC-MS, LC-MS, and immunosorbent assays [21–24]. The drawbacks of these methods are a lack of fast performance, high costs, and in the case of immunoassays, cross reactivities of the antibodies. For example, monoclonal cortisol antibodies show a cross reactivity of 19% with RSS [23]. We used a fluorescence assay based on a method described by Appel et al. [10]. Steroids exhibit fluorescence in acidic environment in which the intensity of the fluorescence depends on the numbers of hydroxyl groups [25]. This fact is also true for the steroid pair 11-deoxycortisol and cortisol [10, 11]. The results of our work show that the 11-deoxycortisol and progesterone

products of CYP106A2 hydroxylation give a higher fluorescence intensity than their precursors. CYP106A2 hydroxylates mainly in the  $15\beta$  position. Using progesterone as substrate, hydroxylations in  $6\beta$ ,  $9\alpha$  and  $11\alpha$  positions can be observed as side reactions [12, 13]. The mechanism of the fluorescence formation is not completely understood. However, steroids with keto groups, side chain on C17, and  $\alpha$  configuration of their hydroxyl groups exhibit a stronger fluorescence in an acidic milieu than other steroids [10].

Our work shows the functionality of the assay as a sensitive, accurate and reliable screening method. After screening of the first mutant generation, six mutants with higher 11-deoxycortisol hydroxylation rate, and four mutants with higher progesterone hydroxylation rate were selected. After further testing, A106T was identified as the best mutant. In comparison to A106T/R409L with an apparent  $k_{\text{cat}}/K_m$  of  $92.4 \times 10^3 (\text{M}^{-1} \text{s}^{-1})$ , A106T showed a slightly better apparent  $k_{\text{cat}}/K_m$  of the RSS hydroxylation of  $97.3 \times 10^3 (\text{M}^{-1} \text{s}^{-1})$  (Table 2). However, this single mutant seems to be less stable than the double mutant as indicated by a lower expression level, and by the number of selected clones carrying this single mutation. Only one clone with a A106T mutation could be selected out of six clones from the screening of the first mutant generation with 11-deoxycortisol and only one out of four in the screening with progesterone. Because of higher expression yield, mutant A106T/R409L was chosen as the template sequence to generate the second mutant generation. A106T/Q189K/T399S/R409L was selected in the screening of the second mutant generation with 11-deoxycortisol as substrate. It shows a lower apparent  $V_{\text{max}}$  value than A106T/R409L. However, due to a lower apparent  $K_m$ , this second generation mutant displays a much better apparent  $k_{\text{cat}}/K_m$  than the first generation mutant A106T/R409L (Table 2). Furthermore, A106T/Q189K/T399S/R409L can be expressed with an even higher yield of about 273 nmol/l.

In conclusion, evolution over two generations led to a 4.3-fold improved catalytic activity of CYP106A2 towards RSS. The estimated progesterone hydroxylation rate of the mutants is similar to that of the 11-deoxycortisol hydroxylation activity (Tables 2, 3). Here, mutants A106T and A106T/R409L hydroxylate the progesterone 1.4-fold faster than the wild type. A106T/R409L converts the progesterone and the 11-deoxycortisol 1.3-fold faster than A106T/Q189K/T399S/R409L. These results are expected since the structures of progesterone and 11-deoxycortisol differ only in additional hydroxyl groups on C17 and C21 of the 11-deoxycortisol.

We assume that the Q189 K and/or T399S mutations might have an influence on the flexibility of structure of the catalytically improved CYP106A2 mutants. The CYP106A2 model [19] predicts location of Q189 in the G

helix (Fig. 5a). The predicted location of T399 is in the  $\beta_4-1/\beta_4-2$  loop which is positioned above the heme (Fig. 5b).

The F and G helices form a flexible loop. The F/G loop is part of the substrate access channel. In several P450s, the substrate free protein shows an open conformation, and after substrate binding, the F/G loop moves towards the

**Fig. 5** Mapping of substitutions in the CYP106A2 model. The CYP106A2 model was obtained from Lisurek et al. [19]. Residues substituted in the catalytically improved CYP106A2 mutants are marked. **a** Residues D153, F165, Q189, I214, and D214 are associated to the F/G loop. D153 is located at the C terminus of the E helix, F165 in the F helix, Q189 in the G helix, I214 and D217 in the H helix. **b** Residue T399 is located in the  $\beta_4-1/\beta_4-2$  loop above the heme. **c** CYP106A2 structure as seen from the proximal site. Residue A106 presumably associated with adrenodoxin interaction is mapped. *Italic letters* indicate corresponding residues of CYP101 responsible for the putidaredoxin binding. Mutation of residue R409 might cause conformational changes of the N-terminus of CYP106A2

I helix in order to close the access channel. This movement was observed in CYP101 [26] and in CYP119 [27]. In CYP101 movement of the H and I helices upon substrate binding was shown, too. Activating effects of mutations in this regions of CYP106A2 suggest that the F/G loop in CYP106A2 undergoes significant conformational changes upon substrate binding. With I214F and D217V, two mutated residues located in the H helix of the CYP106A2 model could be identified (Fig. 5a). Furthermore, the loop between the E and F helix could act as a “hinge”. Residue D153, located in that region, might have influence on the flexibility of the F/G loop.

Comparison with the CYP101 structure suggests a function of A106 in CYP106A2 in the interaction with the redox partner adrenodoxin. Experimental evidence suggested that negatively charged amino acids on the electron donor [28–32] interact with positively charged residues at the proximal site of the cytochrome P450, which is usually centered over the cysteine-pocket of all bacterial cytochromes P450 that interact with ferredoxins [33, 34]. Three surface arginine residues on the proximal site of CYP101 are necessary for successful electron transfer from putidaredoxin [35]. These residues are R72 in the B-helix, R109 and R112 [36–38] in the C-helix. R112 could be involved in electron transfer [39]. There are corresponding positively charged residues in the CYP106A2 model, namely K53, R97 and R100. Additionally, R364 in the L-helix of CYP101 could contribute to putidaredoxin binding [40]. The corresponding position in CYP106A2 is an arginine (R362). A106 lies in close proximity to the residues R97 and R100 in or next to the C helix as shown by the CYP106A2 model (Fig. 5c). This fact and the nature of the substitution from a non polar alanine to a polar threonine imply a function of the mutant A106T in the binding of adrenodoxin. The effect of changed redox partner-cytochrome P450 binding on the activity of the P450 was previously also shown for the couple adrenodoxin/CYP11A1 [41].

Mutation R409L is most likely not involved in the interaction with adrenodoxin due to the distance from the charged residues in the proximal site (Fig 5c). R409 is connected via H bonds to H378, K377 in the 3-3 sheet, and to D131 in the  $\beta$ 3-1 sheet. Simulations of the CYP106A2 model show that L409 builds H bonds to H378 and to F376, both are located in the  $\beta$ 3-3 sheet (not shown). This might result in a minimal conformational change of the N-terminal part of CYP106A2.

In summary, increase of catalytic activity of CYP106A2 by more than a factor of four, proves the functionality of the screening system. It also demonstrates the usability of directed evolution as a tool to improve significantly the activity of this steroid hydroxylating P450. This assay system has great potential since it is easy to perform and

not limited to a specific hydroxylation position, making this test applicable for other steroid hydroxylating enzymes. The assay may be modified by reducing the incubation time and/or reducing the substrate concentration, which would elevate the selection pressure towards improved  $K_m$  values.

**Acknowledgments** The authors thank Wolfgang Reinle for excellent purification of adrenodoxin reductase and adrenodoxin. A grant of the Fonds der Chemischen Industrie to R.B. is acknowledged.

CYP enzymes are the main catalysts involved in the oxidation of drugs, steroids, and carcinogens and in many biosynthetic pathways producing sterols, steroids, prostaglandins, secondary metabolites. The reactions catalyzed usually require an external source of reducing equivalents, NADH or NADPH, and auxiliary proteins to transfer the electrons to the CYP to catalyze molecular splitting of atmospheric oxygen. CYP51 (EC1.14.13.70) is regarded as an ancestral CYP from which other CYPs evolved [9] and is an important enzyme (C14-demethylase) in the sterol biosynthesis pathway of most organisms. In yeasts CYP51 catalyzes the 14  $\alpha$ -demethylation of lanosterol, whilst in filamentous fungi CYP51 catalyzes the 14  $\alpha$ -demethylation of eburicol.

Recently CYP63s A1, A2 and A3 in *P. chrysosporium* have been characterized [10, 11] and CYP53 [12] following heterologous expression in *E. coli*. In the present study we describe the expression and characterization of CYP51 (GenBank FJ174578) as a prelude to further characterization of the CYPome of *P. chrysosporium*.

## Experimental Procedure

Cloning *CYP51* into pGEMT-Easy vector<sup>TM</sup>, pCWori<sup>+</sup> and pYES2.1 TOPO Vectors

A Lambda ZAP II cDNA library for *Phanerochaete chrysosporium* was constructed using Strategene reagents (La Jolla, CA, USA) from total RNA extracted from 3 day-old cultures of *P. chrysosporium* ATCC24725. Primer design was based on information provided by Dr. David Nelson (<http://drnelson.utm.edu/whiterot.html>). Primers against the *CYP51* gene were designed to incorporate an *Nde*I site in the forward primer (5'-CATCGCCATATGTC TCTCAGCCAGTACGGG-3') and a 4-His tag and *Hind*III site in the reverse primer (5'-ACTGCTAAGCTTCTAG TGATGGTGATGGTTCGAAGTTACGCCGCCT-3'). PCR was performed using an annealing temperature of 56 °C using Expand High Fidelity<sup>TM</sup> DNA polymerase (Roche, UK). The *CYP51* gene (FJ174578) was cloned into pGEMT-Easy vector<sup>TM</sup> (Promega, Southampton, UK). Positive recombinants were fully sequenced to establish integrity of each clone. The *CYP51* gene was excised and cloned into pCWori<sup>+</sup> vector by digestion with *Nde*I and *Hind*III followed by ligation with T4 DNA ligase (Roche, UK). Positive recombinants were sequenced to establish integrity prior to expression studies.

Forward (5'-ACCATGTCTCTCAGCCAGTA-3') and reverse (5'-GTCGAAGTTACGCCGCCT-3') primers were designed against the *CYP51* gene for use with the pYES2.1 TOPO (Invitrogen, Renfrew, UK) vector system. PCR was performed as described above and the PCR product used to

transform TOPO10 *E. coli* cells. The plasmids from positive clones were verified by sequencing and used to transform yeast AH22 $\Delta$ ura3 cells using the lithium acetate TRAF0 method [13].

## Heterologous Expression in *E. coli* and Isolation of Recombinant *CYP51*

The *CYP51*-pCWori<sup>+</sup> construct was transformed into *E. coli* strain DH5 $\alpha$  using ampicillin selection. Overnight cultures (10 ml) of *CYP51* transformants were used to inoculate one litre volumes of Terrific Broth supplemented with 20 g l<sup>-1</sup> peptone and 0.1 mg ml<sup>-1</sup> sodium ampicillin. Cultures were grown at 37 °C, 230 rpm for 6 h prior to induction with 1 mM IPTG and expression at 25 °C, 190 rpm for 18 h in the presence of 1 mM 5-aminolevulinic acid. CYP51 protein was isolated according to the method of Arase et al. [14] except that 2% (w/v) sodium cholate and no Tween20 were used in the sonication buffer. The solubilized CYP51 protein was purified by affinity chromatography using Ni<sup>2+</sup>-NTA agarose as previously described [15] with the modification that 0.1% (w/v) L-histidine in 50 mM sodium phosphate, pH 7.5, 25% (w/v) glycerol was used to elute non-specifically bound *E. coli* proteins after the NaCl washes and elution of CYP51 was achieved with 1% (w/v) L-histidine in 50 mM sodium phosphate, pH 7.5, 25% (w/v) glycerol. Protein purity was assessed by SDS polyacrylamide gel electrophoresis [16]. Isolated CYP51 protein fractions were stored at -80 °C.

## Heterologous Expression in *S. cerevisiae* and Isolation of Recombinant *CYP51*

Overnight cultures of *CYP51* transformants were prepared in 10 ml of 1.34% (w/v) yeast nitrogen base (YNB) containing 2% (w/v) glucose, 0.005% (w/v) histidine and grown at 30 °C, 200 rpm. These were used to inoculate one litre volumes of media containing 1.34% (w/v) YNB, 2% (w/v) glucose, 0.05% (w/v) leucine and 0.005% (w/v) histidine. The cells were grown for 20 h at 30 °C and 200 rpm prior to harvesting and washing under sterile conditions. The harvested cells were resuspended in fresh one litre volumes of media containing 1.34% (w/v) YNB, 3% (w/v) galactose, 0.05% (w/v) leucine and 0.005% (w/v) histidine. Galactose dependent expression of the CYP proteins was achieved by incubation at 25 °C, 120 rpm for 20 h.

All the following operations were performed at 4 °C. Following centrifugation at 1,500 $\times$ g, pelleted cells were resuspended in 0.1 M potassium phosphate buffer, pH 7.4 and homogenized using a C5 emulsiflex homogenizer (Glen Creston, Stanmore, Middlesex, UK) at 250,000 kPa pressure. The homogenates were centrifuged for 10 min at

3,000×g to remove cell debris and then twice at 20,000×g for 20 min to remove mitochondria. The microsomal fractions were recovered by ultracentrifugation at 100,000×g for 1 h. Microsomal pellets were resuspended in 0.1 M potassium phosphate buffer, pH 7.4, 20% (v/v) glycerol and frozen at −80 °C.

#### Spectral Determination of CYP51 Protein Concentrations

Cytochrome P450 concentration was determined by reduced carbon monoxide difference spectra according to Omura and Sato [17] with carbon monoxide being passed through the CYP51 solution prior to the addition of sodium dithionite. The extinction coefficient of 91 mM<sup>−1</sup> cm<sup>−1</sup> was used for the calculation of P450 concentration from the difference in absorbance units between 450 and 490 nm. Absolute spectra were determined as previously described [15] between 250 and 700 nm in 50 mM sodium phosphate, pH 7.5, 25% (w/v) glycerol for the oxidized protein, the sodium dithionite reduced protein and the reduced carbon monoxide-P450 complex. Total protein concentrations were determined by the bicinchoninic acid method using bovine serum albumin standards. Spectral determinations were made using a Hitachi U-3310 UV/VIS spectrophotometer (San Jose, CA, USA).

#### Azole-binding Spectral Determinations

Binding of azole antifungal agents to CYP51 was performed as previously described [18, 19]. Stock 0.1 mg ml<sup>−1</sup> solutions of clotrimazole, fluconazole, itraconazole, ketoconazole and voriconazole were prepared in dimethylsulfoxide (DMSO). Azole was progressively titrated against Ni<sup>2+</sup>-NTA agarose purified *P. chrysosporium* CYP51 (1.8 μM, 0.138 mg ml<sup>−1</sup> total protein) to a maximum DMSO concentration of 1.5% (v/v) with the spectral difference ΔA<sub>430–412</sub> determined after each incremental addition of azole. Each azole titration experiment was repeated in triplicate with the mean values and associated standard errors being used in subsequent data analyzes. Clotrimazole concentrations of 0.29, 0.58, 0.87, 1.16, 1.45, 1.74, 2.32, 2.90, 3.48, 4.35 and 5.80 μM were used. Fluconazole concentrations of 0.33, 0.65, 0.98, 1.31, 1.63, 1.96, 2.29, 2.61, 3.27, 3.92 and 4.90 μM were used. Itraconazole concentrations of 0.14, 0.28, 0.43, 0.57, 0.71, 0.85, 0.99, 1.13, 1.42, 1.70 and 2.13 μM were used. Ketoconazole concentrations of 0.19, 0.38, 0.56, 0.75, 0.94, 1.13, 1.32, 1.51, 1.88, 2.26 and 2.82 μM were used. Voriconazole concentrations of 0.29, 0.57, 0.86, 1.14, 1.43, 1.72, 2.00, 2.29, 2.86, 3.43, 4.29 and 5.72 μM were used. The *k<sub>d</sub>* values for each azole were determined by non-linear regression (Levenberg–Marquardt algorithm) of ΔA<sub>430–412</sub>

against azole concentration using the Hill equation [ $\Delta A = \Delta A_{\max}/(1 + k_d/[Azole]^n)$ ] [20]. The *k<sub>d</sub>* is defined here as the dissociation constant of the non-productive enzyme–azole complex. Curve-fitting was performed using the program ProfFit 5.0.1 (Quantumsoft, Zurich). The [Azole]<sub>0.5</sub> values were determined directly from the plot of ΔA<sub>430–412</sub> against azole concentration and are defined as the azole concentration required to obtain half the observed ΔA<sub>430–412</sub> maximum value.

#### Complementation of Yeast YUG37 Mutant by *P. chrysosporium* CYP51

The *CYP51*: pYES2.1 plasmid was re-engineered by PCR so that *CYP51* retained a stop codon but did not have the 6-His tag of the pYES2.1 plasmid. The forward and reverse primers used were 5'-ACCATGTCTCTCAGCCAGTA-3' and 5'-CTAGTCGAAGTTACGCCG-3', respectively. The *S. cerevisiae* strain YUG37 with the *CYP51* gene placed under the control of the doxycycline regulatable *tet-O7-CYC1* promoter was used in this study. The promoter down-regulates the endogenous *CYP51* gene in the presence of doxycycline and expresses transcripts to levels comparable to those observed with the strong *GAL1* promoter (pYES2.1) in the absence of doxycycline [21, 22]. This mutant allowed the study of *P. chrysosporium* CYP51: pYES2.1 complementation by induction in a doxycycline down-regulated growth condition. Growth rates of cultures were measured with a Bioscreen C<sup>TM</sup> instrument (Labsystems, Finland) by measuring the optical density at 600 nm in a working volume of 100 μl. An overnight culture was grown in 1.34% (w/v) YNB, 2% (w/v) raffinose, 3% (w/v) galactose and 0.01% (w/v) tryptophan from a single colony. The culture was diluted tenfold and 50 μl of diluted cells used to inoculate the Bioscreen<sup>TM</sup> plates with or without 100 μg ml<sup>−1</sup> doxycycline in the same media. The YUG37 strain requires an additional supplement of 0.01% (w/v) uracil.

#### Data Analysis

Construction and analysis of the *CYP51* gene and protein sequences were performed using the computer programs Chromas version 1.45 (<http://www.technelysium.com.au/chromas14x.html>), ClustalX version 1.8 (<ftp://ftp-igbmc.u-strasbg.fr/pub/>) and BioEdit version 5.0.6. (<http://www.mbio.ncsu.edu/BioEdit/bioedit.html>). The genomic DNA sequence for the *P. chrysosporium* CYP51 gene was extracted from scaffold 44 deposited in the JGI white-rot fungus database (<http://genome.jgi-psf.org/whiterot1/whiterot1.home.html>) using the initial predictions of Dr. David Nelson (<http://drnelson.utmem.edu/whiterot.fasta.html>). Phylogenetic trees were prepared using ClustalX

version 1.8 and Treeview version 1.6.1 (<http://taxonomy.zoology.gla.ac.uk/rod/treeview.html>). The online BLOCK MAKER program ([http://blocks.fhcr.org/blocks/make\\_blocks.html](http://blocks.fhcr.org/blocks/make_blocks.html)) was used to identify conserved ungapped 'MOTIF' segments between nine basidiomycete CYP51 sequences. The online SignalP 3.0 (<http://www.cbs.dtu.dk/services/SignalP/>) and TargetP 1.1 (<http://www.cbs.dtu.dk/services/TargetP/>) were used to predict of the N-terminal membrane anchor region of *P. chrysosporium* CYP51. Predotor 1.03 ([http://urgi.versailles.inra.fr/predotar/test\\_seq](http://urgi.versailles.inra.fr/predotar/test_seq)) and TargetP 1.1 were used to predict the subcellular location of *P. chrysosporium* CYP51. The analyzes of the Bioscreen C<sup>TM</sup> data were performed using ProFit 5.01 (QuantumSoft, Zurich, Switzerland).

## Chemicals

All chemicals, including fluconazole, itraconazole and ketoconazole, were obtained from Sigma Chemical Company (Poole, UK), unless otherwise stated. Voriconazole was supplied by Discovery Fine Chemicals (Bournemouth, UK). DIFCO growth media were obtained from Becton Dickinson UK Ltd (Cowley, UK).

## Results and Discussion

### Characterization of *P. chrysosporium* CYP51 Gene Organization

CYP51 was isolated by PCR from the cDNA library and cloned into the pGEMT-Easy vector<sup>TM</sup>. The full gene sequence of CYP51 was constructed using the Chromas 1.45, Clustal X 1.8 and BioEdit 5.0.6 computer programs with the genomic DNA as the template (Fig. 1). The 1,956 bp DNA sequence of the CYP51 cDNA clone, coding for a protein 550 amino acids long of 62,327 molecular weight and theoretical pI of 6.27, was compared against the predicted sequence (<http://drnelson.utmem.edu/whiterot.html>) and to a previously deposited predicted sequence Q68HC3 [23] for the *P. chrysosporium* CYP51 gene. The CYP51 cDNA clone was free of any nucleotide changes from the genome sequence and utilized the same strain. The CYP51 cDNA isolated was identical to the predicted sequence by Dr David Nelson (<http://drnelson.utmem.edu/whiterot.html>) except for one amino acid (T531A) found at the last intron-exon boundary. CYP51 was found to contain 7 exons and 6 introns compared to the 6 exons and 5 introns of the predicted Q68HC3 sequence. The extra intron was located close to the 3' end of the gene (1,839–1,893 bp). The stop codon of the CYP51 cDNA clone was a further 10 bases downstream of the predicted CYP51 sequence. The start codon of the Q68HC3 sequence is 67

bases downstream from the start codon in the CYP51 cDNA clone and Q68HC3 has a 9-base shorter exon 3 coding region than that observed for the experimental CYP51 cDNA clone. In addition, the CYP51 cDNA clone contained an extra 3 amino acid sequence (126-VYG-128).

These observed differences in the cDNA sequences translate into differences in the protein sequences in this, the first experimentally determined CYP51 sequence. The N-terminal anchor region, as predicted by SignalP and TargetP, extended to the same serine residue at position 40 of the CYP51 cDNA. TargetP predicted that *P. chrysosporium* CYP51 would be secretory and Predator 1.1 predicted CYP51 would be targeted to the endoplasmic reticulum. *P. chrysosporium* CYP51 expressed in *E. coli* during this study was localized in the membrane fraction, confirming the presence of a N-terminal membrane anchor. The extra intron found in the CYP51 cDNA clone between base pairs 1839 and 1893 was responsible for the last 20 amino acids of the CYP51 cDNA clone being different to those previously predicted, utilizing an alternate downstream TAG termination site. This 20 amino acid C-terminal region of *P. chrysosporium* CYP51 was found to have a high homology against the C-terminus of two basidiomycete CYP51 proteins with 55% identity against A8DBU6 (*A. cinnamomea*) and 60% identity against A8NUS3 (*C. cinerea*) and lesser homology (10 to 25%) to other basidiomycete CYP51s.

The presence of two possible ATG start codons suggests that alternate initiation sites for translation might exist. The existence of possible splice variants was investigated by PCR using the original forward primer (5'-CATCG CCATATGTCTCTCAGCCAGTACGGG-3') and a modified reverse primer (5'-ACT GCT AAG CTT CTA GTG ATG GTG ATG CGC CGC CTG TAG AGA ATG-3') designed to prime against the alternate stop codon (10 bases upstream) as previously predicted. The PCR products were cloned into pGEMT-Easy vector<sup>TM</sup>. Sequencing these revealed the presence of the same 7 exons and 6 introns as observed previously with no splice variants present.

### Phylogenetic Analysis of *P. chrysosporium* CYP51

Phylogenetic analysis of *P. chrysosporium* CYP51 was performed against other selected basidiomycete and ascomycete CYP51 proteins. Analysis of the primary amino acid sequences using Clustal X and Treeview programs (Fig. 2) established that *P. chrysosporium* CYP51 had greatest homology towards other basidiomycete CYP51 proteins with identities of 65, 65, 64, 57, 56, and 51% with *C. cinereus*, *C. cinerea*, *A. cinnamomea*, *M. globosa*, *C. neoformans* and *U. maydis* CYP51 proteins, respectively. However, *P. chrysosporium* CYP51 only had

**Fig. 1** *Phanerochaete chrysosporium* CYP51 gene structure. The DNA sequence of the CYP51 cDNA clone (GenBank FJ174578) was compared against the JGI genomic DNA sequence (<http://genome.jgi-psf.org/whiterot1/whiterot1.home.html>) using the programs Clustal X 1.8 and BioEdit 5.0.6. The genomic DNA sequence

contains both exons (*upper-case*) and introns (*lower-case*). The exon–intron boundaries were determined by sequencing the CYP51 cDNA clone. The possible alternate ‘start’ and ‘stop’ sites are underlined. The *P. chrysosporium* CYP51 gene is comprised of 7 exons and 6 introns

44–46% identity to the remaining fungal CYP51 proteins and identities of 39, 37 and 30% to rat (Q64654), human (Q16850) and sorghum (P93846) CYP51 proteins, respectively.

Expression of *P. chrysosporium* CYP51 in *E. coli*

Expression of CYP51 protein in *E. coli* resulted in the isolation of 62 nmol CYP51 per litre culture in the

**Fig. 2** Phylogenetic tree of basidiomycete and ascomycete CYP51 proteins. ClustalX 1.8 and Treeview 1.6.1 computer programs were used to construct the phylogenetic tree from selected basidiomycete and ascomycete CYP51 protein sequences. Basidiomycete sequences included were *Phanerochaete chrysosporium* (FJ174578), *Cryptococcus neoformans* (AAF35366), *Ustilago maydis* (P49602), *Antrodia cinnamomea* (A8DBU6), *Coprinus cinereus* (Q68HC4), *Coprinopsis cinerea* (A8NUS3), *Malassezia globosa* (A8Q3I7) and *Puccinia graminis* (PGTG07202; [http://www.broad.mit.edu/annotation/genome/puccinia\\_graminis](http://www.broad.mit.edu/annotation/genome/puccinia_graminis)). Ascomycete sequences included were *Candida albicans*

(P10613), *Candida tropicalis* (P14263), *Schizosaccharomyces pombe* (Q09736), *Saccharomyces cerevisiae* (P10614), *Penicillium digitatum* (Q9P340), *Ashbya gossypii* (Q759W0), *Mycosphaerella graminicola* (C\_100070; <http://genome.jgi.doe.gov/Mycgr1/Mycgr1.home.html>), *Aspergillus fumigatus* CYP51A (B0Y5N0), *Aspergillus fumigatus* CYP51B (B0YC83), *Aspergillus nidulans* CYP51A (AN1901—[http://www.broad.mit.edu/annotation/genome/aspergillus\\_group/MultiHome.html](http://www.broad.mit.edu/annotation/genome/aspergillus_group/MultiHome.html)) and *Aspergillus nidulans* CYP51B (AN8283; [http://www.broad.mit.edu/annotation/genome/aspergillus\\_group/MultiHome.html](http://www.broad.mit.edu/annotation/genome/aspergillus_group/MultiHome.html))

solubilized cellular protein fraction. Native CYP51 accounted for 1.1% of the total protein isolated in the solubilized fraction. Purification of CYP51 on Ni<sup>2+</sup>-NTA agarose increased the purity of the CYP51 preparation by 71-fold, with native CYP51 now accounting for 81.1% of the total protein and a 55% recovery of active CYP51 relative to the original solubilized fraction.

The purified CYP51 fraction gave characteristic absolute and reduced carbon monoxide difference spectra (Fig. 3a) of a P450 monooxygenase. The ferric-P450 form existed in the low-spin state, characterized by a heme Soret  $\gamma$  band at 417 nm in addition to  $\alpha$ ,  $\beta$  and  $\delta$  bands at 565, 535 and 355 nm, respectively. An additional spectral peak was observed in the near ultraviolet at 293 nm. One electron reduction of CYP51 with sodium dithionite resulted in small blue-shift of the Soret  $\gamma$  band from 417 to 415 nm. Reduction of CYP51 to the ferrous form also caused the  $\alpha$  and  $\beta$  bands to merge with an absorption maximum of 550 nm. Binding of carbon monoxide to the dithionite-reduced ferrous-P450 resulted in a typical red-shift of the Soret  $\gamma$  band from 415 to 445 nm in the formation of the

CO-ferrous P450 complex. A significant amount of P420 was also observed when carbon monoxide was bound to the dithionite-reduced form of the protein, suggesting instability in the presence of dithionite. This was supported by the observation that the carbon dioxide difference spectra obtained (Fig. 3b) contained no visible P420 as dithionite was added last just prior to the measurement of the absorbance spectrum.

SDS polyacrylamide gel electrophoresis indicated that the Ni<sup>2+</sup>-NTA agarose purified CYP51 protein was over 90% pure with an apparent molecular weight of 63 kDa.

#### Azole-binding to *P. chrysosporium* CYP51

Spectral titrations of Ni<sup>2+</sup>-NTA agarose purified CYP51 protein (1.8  $\mu$ M) against the five azole antifungal compounds clotrimazole, fluconazole, itraconazole, ketoconazole and voriconazole were performed in triplicate. Figure 4 shows the Type II spectral titration (Fig. 4a) obtained with fluconazole and the associated binding saturation curve (Fig. 4b). Similar Type II titrations and azole

**Fig. 3** Absolute and reduced carbon monoxide difference spectra of *P. chrysosporium* CYP51. The absolute spectrum of CYP51 was determined between 250 and 700 nm (a) in the absence (trace 1) and presence (trace 2) of 5  $\mu\text{M}$  sodium dithionite and in the presence of 5  $\mu\text{M}$  sodium dithionite saturated with carbon monoxide (trace 3). A reduced carbon monoxide difference spectrum (b) was obtained using

$\text{Ni}^{2+}$ -NTA agarose purified *P. chrysosporium* CYP51 expressed in *E. coli* (2.6  $\mu\text{M}$  and 0.2  $\text{mg ml}^{-1}$  total protein) as previously described by Omura and Sato [17] with the sample and reference cuvettes saturated with carbon monoxide prior to addition of dithionite to the sample cuvette only. The extinction coefficient was  $91 \text{ mM}^{-1} \text{ cm}^{-1}$

**Fig. 4** Spectral titration of fluconazole against *P. chrysosporium* CYP51. Fluconazole was progressively titrated against  $\text{Ni}^{2+}$ -NTA agarose purified *P. chrysosporium* CYP51 (1.8  $\mu\text{M}$ , 0.138  $\text{mg ml}^{-1}$  total protein) to a maximum DMSO concentration of 1.5% (v/v) with the spectral difference  $\Delta A_{430-412}$  determined after each incremental addition of azole (a). Fluconazole concentrations of 0.33, 0.65, 0.98,

1.31, 1.63, 1.96, 2.29, 2.61, 3.27, 3.92 and 4.90  $\mu\text{M}$  were investigated. The spectral titration was repeated in triplicate with the mean values and associated standard errors being used to construct the fluconazole saturation curve (b). Non-linear regression (Levenberg–Marquardt algorithm) of the Hill equation [ $\Delta A = \Delta A_{\text{max}}/(1 + k_d/[\text{Azole}]^n)$ ] was used to analyze the data

binding saturation curves were also obtained for clotrimazole, itraconazole, ketoconazole and voriconazole (not shown) indicative of the co-ordination of the triazole N-3 with the heme as a sixth ligand [24]. The binding of azoles to CYP51 was found to be sigmoidal obeying the Hill equation [ $\Delta A = \Delta A_{\text{max}}/(1 + k/[\text{Azole}]^n)$ ] [20]. The  $k_d$  values ( $\pm\text{SD}$ ) obtained for clotrimazole, fluconazole, itraconazole, ketoconazole and voriconazole were 0.25  $\mu\text{M}$  ( $\pm 0.05$ ), 0.35  $\mu\text{M}$  ( $\pm 0.04$ ), 0.45  $\mu\text{M}$  ( $\pm 0.06$ ), 0.40  $\mu\text{M}$  ( $\pm 0.02$ ) and 0.28  $\mu\text{M}$  ( $\pm 0.04$ ), respectively, indicating that *P. chrysosporium* CYP51 bound all five azoles with equal affinity. Apparent Hill numbers ( $\pm\text{SD}$ ) of 2.19 ( $\pm 0.22$ ), 1.85 ( $\pm 0.12$ ), 1.59 ( $\pm 0.09$ ), 1.62 ( $\pm 0.05$ ) and 2.27 ( $\pm 0.14$ ) were obtained for clotrimazole, fluconazole, itraconazole, ketoconazole and voriconazole, respectively. The  $[\text{Azole}]_{0.5}$  values obtained for clotrimazole, fluconazole, itraconazole,

ketoconazole and voriconazole were 0.54, 0.56, 0.51, 0.56 and 0.49  $\mu\text{M}$ , respectively, equating to 27–31% of the 1.8  $\mu\text{M}$  CYP51 protein present. The  $[\text{Azole}]_{0.5}$  values obtained were comparable to those previously obtained with *Candida albicans* [25, 26] at 0.13  $\mu\text{M}$  (33% of 0.4  $\mu\text{M}$  P450 present) for ketoconazole and 0.11  $\mu\text{M}$  (60% of the 0.2  $\mu\text{M}$  P450 present) for fluconazole.

Only one azole molecule can bind to the heme group at the P450 enzyme active site (one to one binding) as the sixth co-ordinated ligand to produce the characteristic type II binding spectra observed. Therefore there are two possible causes of the positive cooperativity observed for the binding of azoles to *P. chrysosporium* CYP51. Firstly, two or more specific azole binding sites exist on the cytochrome P450 molecule with positive cooperativity being exerted between the binding sites (multiple site

cooperativity) with only one azole molecule directly coordinated as the sixth ligand of the heme prosthetic group and the other azole molecule acting as a positive allosteric effector/regulator. Secondly, cytochrome P450 molecules aggregate in vitro to form oligomers which then display positive cooperativity between the monomers during azole binding (multimer cooperativity).

Ouellet et al. [20] have observed similar positive cooperative binding with clotrimazole and econazole to *Mycobacterium tuberculosis* CYP130. They established that for CYP130 the binding of econazole did not involve multiple binding sites within a single CYP130 molecule by determining a 1:1 stoichiometry for bound azole using econazole and miconazole, a structurally similar azole that exhibited no cooperativity. Ouellet et al. [20] managed to abolish the observed binding cooperativity towards econazole by the inclusion of 50 mM KCl, suggesting that the observed cooperativity may have arisen from protein–protein interactions between CYP130 molecules that were disrupted by the inclusion of the ionic KCl.

The azole binding buffer used for the *P. chrysosporium* CYP51 studies contained 92 mM sodium cations from the 50 mM sodium phosphate, pH 7.5 present and strong positive cooperative allosterism was observed for all five azoles, especially clotrimazole and voriconazole. The addition of an additional 0.5 M NaCl to the binding buffer did not dissipate the positive allosterism towards clotrimazole and voriconazole binding (data not shown). Both the  $k_d$  and apparent Hill number values did not significantly alter in the presence of 0.5 M NaCl, although the observed  $A_{max}$  values decreased by 10–12%. Therefore, the observed azole binding allosterism with *P. chrysosporium* CYP51 was not disrupted by the inclusion of 0.5 M NaCl, suggesting that the allosterism was not due to electrostatic protein–protein interactions between CYP51 molecules. However, the azole binding buffers used did not contain any detergent. Therefore the possibility that the allosteric azole-binding observed was caused by hydrophobic protein–protein interactions could not be excluded. Further investigations are required to confirm the origins of the observed allosterism for azole binding to *P. chrysosporium* CYP51 which exhibited a high affinity for all five azole antifungals examined in this study.

#### Expression and Functional Analysis

##### of *P. chrysosporium* CYP51 in *S. cerevisiae*

CYP51 protein was successfully expressed using the pYES2.1 vector in *Saccharomyces cerevisiae*, although overall protein yields were low at 1.5 nmol CYP51 per litre of culture in an AH22 host strain. In *S. cerevisiae* (yeast), the deletion of the *CYP51* (*ERG11*) gene has been shown to be lethal to the cell [27, 28]. Complementation studies were

performed using a yeast CYP51 mutant *YUG37:erg11*, which carries a doxycycline repressible *tet-O<sub>7</sub>-CYC1* promoter upstream of the native *CYP51* (*ERG11*) gene, in the absence and presence of 100  $\mu\text{g ml}^{-1}$  doxycycline. Control experiments in the presence and absence of pYES2 and addition of doxycycline caused a distinctive decrease in the growth levels (Fig. 5c, d) while complementation by the pYES2.1 *P. chrysosporium* CYP51 construct (Fig. 5b) was observed under the same conditions. The wild type parent *YUG37* yeast strain (Fig. 5a), was insensitive to doxycycline. These results confirm the ability of the *P. chrysosporium* CYP51 protein to couple with the native yeast cytochrome P450 reductase (CPR) in vivo to catalyze the 14 $\alpha$ -demethylation of lanosterol to 4, 4-dimethyl-ergosta-8, 14, 24-trienol when transcription of native CYP51 is down-regulated.

#### Other Properties of *P. chrysosporium* CYP51

A comparison of the nine basidiomycete CYP51 proteins using the BLOCKMAKER program identified nine conserved ‘MOTIF’ regions (Table 1). Only three of these nine basidiomycete CYP51s have been demonstrated to be functionally active (*P. chrysosporium* [this study]; *C. neoformans* [23]; *U. maydis* [29]). Blocks A, C, E and H are highly conserved with 46, 41, 44 and 43%, respectively, of the amino acid residues conserved among all nine fungal species. Blocks D, F and G are moderately conserved with 33, 33, and 29%, respectively, of the residues being absolutely conserved amongst all nine species. Block B was highly conserved (42%) for eight of the nine basidiomycete CYP51 sequences, with the exception of *P. graminis* CYP51 (PGTG07202.2) where block B appeared to be largely missing. Block B contains the B’helix–B’C loop region of the CYP51 molecule. The reason for the absence of this region in *P. graminis* CYP51 appears to be an incorrect assignment of the intron/exon boundaries in the genomic database, as within the designated ‘intron 2’ the amino acid sequence ‘LATPVFGTKMVDVPNAILMRPK’ can be deduced, which has a high homology (70% to A8Q3I7) to the first 23 residues of block B (Table 1). The DNA sequence deposited for ‘intron 2’ also contains a long run of unknown nucleotides (N) suggesting that this region was the end of a sequencing run leading to the remainder of block B being missing from the current deposited sequence.

Comparing the fungal CYP51 proteins with the published crystal structure for *M. tuberculosis* CYP51 [30], the heme and fluconazole binding domains could be identified. Block H contained the main C-terminal heme-binding domain PFGXGRHRCXGEXFAY. The other heme-binding domains PXHSXXR, AGQHTS, and AEEXYXXLTPVFGKXVVYDCPNXXLMEQKKFVKXGL are present in

**Fig. 5** Growth curves for the *YUG37:erg11* yeast strain measured using a Bioscreen C<sup>TM</sup> instrument in the absence (solid line) and in the presence of 100  $\mu\text{g ml}^{-1}$  doxycycline (dashed line). The sample frequency was 20 min. The response to doxycycline treatment of the wild-type *YUG37* strain (a), *YUG37:erg11* carrying the pYES2.1 plasmid with *P. chrysosporium* CYP51 (b), *YUG37:erg11* (c) and *YUG37:erg11* carrying the control pYES2.1 plasmid (d) was investigated

The on-line program BLOCKMAKER ([http://blocks.fhrc.org/blocks/make\\_blocks.html](http://blocks.fhrc.org/blocks/make_blocks.html)) was used to identify conserved ungapped 'MOTIF' regions of amino acid residues between *P. chrysosporium* CYP51 cDNA (FJ174578) and eight other basidiomycete CYP51 proteins from *Puccinia graminis* (PTGT07202 [http://www.broad.mit.edu/annotation/genome/puccinia\\_graminis](http://www.broad.mit.edu/annotation/genome/puccinia_graminis)), *Coprinopsis cinerea* okayama7#130 (A8NUS3), *Antrodia cinnamomea* (A8DBU6), *Coprinus cinereus* (Q68HC4), *Cryptococcus neoformans* var. grubbi (Q870D1), *Cryptococcus neoformans* var. neoformans (Q9P8P1), *Malassezia globosa* CBS7966 (A8Q3I7) and *Ustilago maydis* (P49602). Amino acid residues conserved between eight of the nine sequences are listed and non-conserved amino acid residues are represented by a star symbol. The conserved sequence of block B does not include data from *P. graminis* CYP51, as this region (B' helix–B'C loop) appeared to be absent from the assembled sequence PTGT07202. The amino acid sequence of block B therefore represents the conserved residues of seven out of the eight remaining sequences. The residue numbers of each block relates to the start position in the *P. chrysosporium* CYP51 protein

blocks F, E and B, respectively. Blocks B, E and F contain the binding sites for fluconazole and other azole drugs. The residues through which the azoles interact appear less

conserved than those of the heme-binding sites, allowing differences in azole specificity amongst CYP51 proteins from different species.

An alignment of deposited full length CYP51 sequences in the EXPASY (<http://expasy.org/>) and NCBI (<http://www.ncbi.nlm.nih.gov/Genbank/>) databases (93 sequences including 10 mammalian, 14 other animal, 42 yeast and fungal, 17 bacterial, 10 plant) and recently elucidated CYP51 sequences for *Mycobacterium avium*, Wheat, Poplar, Tomato, *Arabidopsis thaliana*, Dog, *Monosiga ovata*, *Aspergillus nidulans*, *Trypanosoma brucei* and *Aspergillus niger* was created using the computer program ClustalX. This alignment identified ten conserved amino acid residues amongst all the CYP51 proteins. For *P. chrysosporium* CYP51, the ten conserved residues corresponded to 219G, 380E, 383R, 393R, 446R, 488G, 490G, 492H, 494C and 496G. The amino acid residue 219G was located in block C and residues 380E, 383R and 393R were located in block F, which participates in binding azole antifungal agents. Residue 446R was located in block G and residues 488G, 490G, 492H, 494C and 496G were located in block H, the main C-terminal heme-binding region of *P. chrysosporium* CYP51. The eight conserved amino acids within blocks F and H confirms the importance of these two regions in correct CYP51 function. Many recently deposited CYP51 sequences have been identified from automated DNA sequencing results generated during genome mapping projects. In most cases functionality of 'putative' CYP51s have not been demonstrated by cloning and expression studies. Once more CYP51 sequences have been verified by cloning and expression, the number of conserved CYP51 residues may rise above 10 when only reliable CYP51 sequences are aligned.

Further studies on CYP51 and other CYPs present in *P. chrysosporium* are required to unravel the biological functions of this complex CYPome. Our study indicates the importance of analyzing actual transcript and protein when studying and comparing the annotated or unannotated cytochromes P450 sequences of genome projects such as for *P. chrysosporium* as well as in comparisons between the sequences of CYP51s across the Kingdoms of Life.

absorption and circulatory concentrations of non-cholesterol sterols. Berge et al. observed that lower baseline PS concentrations were associated with two common sequence variations, 145 G > C (D19H) and 1289 C > A (T400 K) of the *ABCG8* half-transporter gene [11]. Other researchers found that variations in T400 K may explain cross-sectional differences in plasma PS concentrations and determine the responsiveness for changes in plasma PS concentrations [12]. Further, variations in D19H may be associated with responsiveness to atorvastatin therapy [6]. In addition, these SNPs may also explain the inter-individual responsiveness to dietary PS [12] or cholesterol [3, 13] interventions in humans. Such findings implicate SNP variations in *ABCG5/G8* as playing key roles in regulating circulatory sterol concentrations. It remains nevertheless unclear whether *ABCG5/G8* polymorphisms could also affect sterol absorption and synthesis kinetics in response to PS intervention.

The *NPC1L1* protein is a key modulator of cholesterol influx from micelles into intestinal mucosal cells [1, 4, 14]. Variations in the *NPC1L1* gene have been shown to be associated with an improved LDL-C lowering effect [4], and may explain inter-individual variations in LDL-C level response to ezetimibe treatment [1, 15, 16]. Several rare genotype variations in *NPC1L1* are associated with reductions in sterol absorption and circulatory LDL-C concentrations [1]. Some common SNPs in *NPC1L1* such as 872 C > G (L272L) have shown to be associated with inter-individual variation in ezetimibe response [1, 16]. In terms of PS supplementation, however, human trials have yet to be performed to address whether *NPC1L1* polymorphisms play a role in the cholesterol lowering responsiveness.

Moreover, no data are currently available to identify the combined effects of the *ABCG5/G8* and *NPC1L1* genotype SNP variations on changes in sterol absorption, cholesterol synthesis and plasma sterol concentrations in context of PS intervention. Subsequently, the aim of the present study was to investigate in 82 hypercholesterolemic men whether the SNP variations in *ABCG5/G8* and *NPC1L1* are individually or mutually associated with (1) basal absorption and circulatory concentrations of cholesterol and PS, (2) with changes in absorption and circulatory concentrations of cholesterol and PS after supplementation with 2 g/day of PS, and (3) with inter-individual variation in cholesterol lowering response to PS intervention.

## Experimental Procedure

### PS Enriched Diet Intervention and Blood Lipid Analyses

A randomized, crossover design was employed with two 4-week intervention phases, separated by a 4-week washout

period in 82 hypercholesterolemic men characterized by high vs. low basal plasma PS concentrations. The experimental protocol was approved by the Ethics Committee of the Faculty of Medicine at McGill University. Details of volunteer recruitment, study diet, blood collection and analysis for testing serum concentrations of total cholesterol (TC), high density lipoprotein (HDL), LDL, triacylglycerol (TG) as well as plasma PS concentrations have been previously described by Houweling et al. [17].

### Analyses of Sterol Absorption and Synthesis

On day 25, subjects were randomly designated to receive a single bolus of either 100 mg of D<sub>7</sub>-campesterol ( $n = 43$ ) or D<sub>7</sub>-sitosterol ( $n = 39$ ) within a 10 g aliquot of margarine in order to measure campesterol or sitosterol absorption. Simultaneously, 75 mg of <sup>13</sup>C<sub>2</sub>-cholesterol was orally given to all subjects for measurement of cholesterol absorption. On day 28, subjects also received a 25 g oral dose of D<sub>2</sub>O (isotope purity > 99%), to measure cholesterol synthesis rate during the following 24-h period. All isotope chemicals were purchased from CDN Isotope, Pointe-Claire, Quebec, Canada.

The absorption indices of campesterol, sitosterol and cholesterol in the red blood cell (RBC) free sterol pool were assessed using a single stable isotope tracer method, which has been validated previously [18]. Total sterols were extracted and separated with the method as reported previously [19]. Free cholesterol <sup>13</sup>C enrichments were measured by differential isotope ratio mass spectrometry (IRMS), using an automated dual-inlet system (SIRA 12; Isomass, Cheshire, UK). Free PS deuterium (D) enrichments were measured by differential IRMS, using a dual-inlet system (VG Isomass 903 D; Cheshire, England). The absorption indices of campesterol and sitosterol were expressed as the averaged D enrichments between 24–72 h over baseline (0 h), relative to standard mean ocean water, in the RBC free sterol pool. The absorption index of cholesterol was expressed as the averaged <sup>13</sup>C enrichments between 24 and 96 h above the baseline level (0 h) in the RBC free sterol pool. Cholesterol fractional synthesis rate (FSR) was defined as the rate of incorporation of D from body water into RBC free cholesterol during the last 24 h of each treatment phase, and expressed as FSR in pools per day (pool per day) as previously described [19, 20].

### Analyses of *ABCG5/G8* and *NPC1L1* Genotype SNPs

The *ABCG5/G8* polymorphisms, 1950 G > C (Q604E), 145 G > C (D19H), 1289 C > A (T400 K) and 1572 (A632 V), as well as the *NPC1L1* polymorphisms, 872 C > G (L272L) and 3929 G > A (Y1291Y), were screened from the published SNP data demonstrating an established

functional significance for cholesterol modulation. DNA was extracted from 0.5 to 1.0 mL of plasma by QIAamp DNA Blood Mini Kit (Qiagen Inc, Canada). SNPs in *ABCG5/G8* and *NPC1L1* were determined using PCR-based TaqMan allele discrimination assays (Applied Biosystems, Foster City, CA, USA). The primers used for PCR have been described previously [6, 21–23]. A 7500 Real Time PCR thermal-cycler (Applied Biosystems, Foster City, CA, USA) was used for PCR analysis. Reactions were initially subjected to 92 °C for 10 min, and then 40 cycles, each of which was started at 95 °C for 15 s and 60 °C for 1 min for absolute quantification and then 60 °C for 1 min for allelic discrimination.

### Statistical Analyses

Subjects were classified according to the criteria of (1) the screening sum of basal circulatory plasma PS concentrations (campesterol + sitosterol) into a high PS group (>50th percentile,  $n = 41$ ) and a low PS group (<50th percentile,  $n = 41$ ), or (2) responsiveness in serum lipid profiles to PS intervention into PS responders and non-responders. Subjects demonstrating a placebo adjusted reduction in both TC and LDL in response to PS intake were classified as responders; they were otherwise classified as non-responders. The SNP variations whose allele frequencies were abiding by the Hardy–Weinberg distribution equation were included in the statistical analysis. Prior to the analysis of diet–SNP interaction, the minor homozygous variants (mutant homozygote,  $n \leq 4$ ) were collapsed to the heterozygote group. Similarly, in analyzing the combined effect of two transporter genes, due to the limited number of participating subjects and the similarity in phenotypes in terms of cholesterol metabolism, *NPC1L1* haplotypes with either or both heterozygous L272L and Y1921Y were combined into one heterozygous category. For serum TC, LDL-C, HDL-C and TG concentrations, data at baseline (day 1) and endpoint (day 29) of each phase were compared by performing analysis of covariance (ANCOVA) of proc mixed linear mode (SAS 9.1, Cary, NC, USA) to identify treatment effects and their interactions with high vs. low basal plasma PS concentrations and genotype variations. When treatment effect was identified as significant, Duncan's post hoc tests were utilized at particular time points. The normality distribution was evaluated with Shapiro–Wilk test ( $p > 0.05$ ). Unpaired one-tailed *t*-test or one-way ANOVA was employed between individuals with high and low basal plasma PS concentrations or among the different common polymorphisms within the same phase where appropriate. A two-way ANOVA was employed to examine the interaction of metabolic parameters with different common polymorphisms. The distribution patterns of two factors were

analyzed by chi-square test followed by one-sided Fisher's exact test. All data are expressed as mean  $\pm$  standard error of the mean. The level of significance was established at  $\alpha = 0.05$ , unless otherwise noted.

## Results

### Responders and Non-Responders to PS Intake

Eighty-two hypercholesterolemic men completed the crossover study with consumption of a placebo spread or a spread delivering 2 g/day of PS. Responders were those who showed a reduction (placebo adjusted) in both TC and LDL-C; otherwise they were classified as non-responders in that at least one of TC and LDL-C was not reduced. Responders ( $n = 51$ , 62%) and non-responders ( $n = 31$ , 38%) clearly manifested differing serum cholesterol responses to PS intervention for both TC ( $-12.7 \pm 1.2\%$  vs.  $4.42 \pm 1.2\%$ , respectively,  $p < 0.0001$ ) and LDL-C ( $-18.3 \pm 2.0\%$  vs.  $9.41 \pm 2.5\%$ , respectively,  $p < 0.0001$ ) (Table 1).

Absorption indices of campesterol, sitosterol and cholesterol did not differ among responders and non-responders (Table 2). In terms of cholesterol synthesis rate expressed as FSR, responders demonstrated a 20.7% lower FSR ( $4.68 \pm 0.27\%$  vs.  $5.65 \pm 0.43\%$ ,  $p < 0.05$ ) in comparison to non-responders during the control phase. In the phase of PS intake, however, the difference in FSR values between responders and non-responders became very narrow ( $6.30 \pm 0.37\%$  vs.  $6.64 \pm 0.48\%$ ), because the responders achieved a greater percentage increase in FSR ( $38.5 \pm 4.8\%$  vs.  $24.3 \pm 5.9\%$ ,  $p < 0.05$ ) than did non-responders.

Table 2 also indicates that subjects with low basal PS plasma concentrations were characterized as possessing low sterol absorption and high cholesterol FSR, a pattern that was reversed in subjects with high basal plasma PS concentrations. We also noticed a trend ( $p = 0.086$ , chi-square test, followed by Fisher's exact test) of responders converging in the high basal PS group vs. non-responders in the low basal PS group. Among responders there were less individuals categorized with low basal PS (43% of total 51 responders) than identified with high basal PS concentrations. Inversely, in the group of non-responders, there were more individuals possessing low basal PS levels (61% of total 31 non-responders).

### Relation of *ABCG5/G8* Gene Polymorphism Variations with Responsiveness to PS Intake

The genotype frequencies of *ABCG5/G8* common polymorphisms, T400 K, D19H and A632 V, were identified to abide with Hardy–Weinberg equilibrium [24]. As listed in

**Table 1** Baseline and endpoint plasma concentrations of plant sterols and lipid profiles between responders vs. non-responders

Values are means ± SEM

<sup>a</sup> Responders are those subjects who showed a reduction (placebo adjusted) in both TC and LDL-C; otherwise they were classified as non-responders (at least one of TC and LDL-C was not reduced)

<sup>b</sup> %Change is percentage change of endpoint value (day 29) over that of baseline (day 1). Differences between two values were analyzed by paired *t*-test, the significance was expressed as \* *p* < 0.05, \*\* *p* < 0.01, \*\*\* *p* < 0.001

<sup>c</sup> Inter-phase differences were the values of %change of PS intake phase subtracted by %change of control phase

Table 3, individuals with high and low basal plasma PS concentrations were almost equally distributed across the majority of the wild type homozygote SNP cohorts examined. However, in the heterozygote SNP cohorts, individuals with low basal PS out-numbered those with high basal PS concentrations. In terms of responsiveness to PS intervention, non-responders of heterozygous individuals were predominantly clustered within the low basal PS, but not within the high basal PS group. Most typically, for the *ABCG8* T400 K polymorphisms, TT and TK/KK, individuals with high and low basal PS concentrations were differently distributed (*p* < 0.05). Among homozygote (TT) carriers, 61 and 39% were categorized as high and low basal PS individuals, respectively. Among heterozygote (TK/KK) carriers, this distribution was reversed to be 33 and 67% in individuals with high and low basal PS concentrations, respectively.

In view of the distribution of responders and non-responders among different *ABCG8* T400 K polymorphisms, the numbers of responders and non-responders were not different (*p* = 0.38) among the high vs. low basal PS groups possessing TT polymorphism. However, for the

TK/KK polymorphism, 10 of 11 non-responders were concentrated in the low basal PS group and only one non-responder was characterized as having a high basal PS concentration (*p* < 0.05; Fig. 1). This pattern was consistently reflected in cholesterol response to PS intake. Individuals carrying the TT genotype manifested a similar cholesterol response among the high vs. low basal PS groups (Fig. 2). In the individuals carrying TK/KK genotypes, those in the high basal PS group presented a 2.5-fold greater response in TC (-10.4 ± 2.3% vs. -3.0 ± 3.4%, *p* < 0.05) and a 3.9-fold greater response in LDL-C (-16.6 ± 6.3% vs. -3.4 ± 5.7%, *p* < 0.05) as compared with those in the low basal PS group.

*ABCG8* T400 K polymorphisms were also identified to be associated with variations in basal plasma PS concentration. With the T400 K polymorphism, TT carriers presented higher plasma concentrations of campesterol (12.2 ± 0.8 μmol/L vs. 9.7 ± 0.9 μmol/L, *p* < 0.05), sitosterol (6.5 ± 0.4 μmol/L vs. 5.1 ± 0.5 μmol/L, *p* < 0.05) and sum of campesterol and sitosterol (18.7 ± 1.2 μmol/L vs. 14.8 ± 1.4 μmol/L, *p* < 0.05), respectively, as compared with TK/KK carriers (Fig. 3).

**Table 2** Sterol kinetic profiles in response to PS intake in hypercholesterolemic men with high and low basal PS concentrations

Distributions of responders and non-responders among subjects with high and low basal PS levels at different SNPs were analyzed by chi-square test, followed by one-side Fisher's exact test, significant was considered at \*  $p < 0.05$

<sup>a, b</sup> For description of responders vs. non-responders and H\_PS ( $n = 41$ ) and L\_PS ( $n = 38$ ), see Table 1

<sup>c</sup> Percentage in parenthesis represents the % of the stated subject numbers over the total subject numbers

**Fig. 1** Number of responders and non-responders with high and low basal plasma PS concentrations among different *ABCG8* T400 K polymorphisms *R* responder, *Non-R* non-responder. For description of *H\_PS* and *L\_PS* groups, see Table 2. Subject distributions between basal PS levels (*H\_PS* vs. *L\_PS*) and responsiveness (*R* vs. *Non-R*) in different SNP variations (TT vs. TK/KK) were analyzed by Chi-square test, followed by one-side Fisher's exact test (SAS 9.1). Significance of difference was set at \*  $p < 0.05$

**Fig. 2** Changes in plasma TC and LDL in response to PS intervention among subjects with different *ABCG8* T400 K polymorphisms. Analysis of covariance with mix linear mode (SAS 9.1) was used to analyze the interaction of PS levels and SNP variation in response to PS intervention. Main treatment  $p < 0.0001$ , interaction of SNP and PS levels (*H\_PS* vs. *L\_PS*),  $p = 0.079$  for TC and  $p = 0.016$  for LDL. Significance of difference in %TC and %LDL (both placebo adjusted) was set at \*  $p < 0.05$

#### Relation of *NPC1L1* Gene Polymorphism Variations with Cholesterol Responsiveness to PS Intake

Two sets of *NPC1L1* common polymorphisms, L272L and Y1291Y, were identified to abide with Hardy–Weinberg equilibrium and thus further analyzed. Results show that these SNPs were not related to basal cholesterol concentrations, nor with PS or cholesterol absorption indices (data not shown). Moreover, the numbers of responders and non-responders possessing different SNP variations were not

**Fig. 3** Basal plasma PS concentrations among subjects with different *ABCG8* T400 K polymorphisms. Unpaired *t*-test for differences among polymorphisms, significance of the difference was set at \*  $p < 0.05$

statistically different (Table 4). However, heterozygous carriers demonstrated a trend of an enhanced cholesterol lowering effect in response to PS intervention, as compared to homozygous counterparts. With L272L polymorphisms, the mutant G allele carriers ( $n = 37$ ) showed a trend of a greater reduction in TC ( $-9.8 \pm 2.0\%$  vs.  $-4.1 \pm 1.6\%$ ,  $p = 0.057$ ) and LDL-C ( $-14.5 \pm 3.3\%$  vs.  $-4.4 \pm 2.5\%$ ,  $p = 0.082$ ) in comparison with their wild type counterparts (C/C,  $n = 42$ ). Similarly, for the Y1291Y polymorphism, carriers of the mutant A allele ( $n = 24$ ) showed a trend toward a greater TC lowering effect ( $-9.4 \pm 2.1\%$  vs.  $-5.6 \pm 1.6\%$ ,  $p = 0.073$ ) compared with their wild type counterparts ( $n = 55$ ).

In terms of haplotypes of L272L and Y1291Y, individuals with either heterozygous L272L or heterozygous Y1291Y manifested a similar trend ( $0.05 < p < 0.1$ , two-way ANOVA) of greater reductions in TC and LDL-C as compared to their homozygous counterparts (Table 4). Subsequently, all haplotypes with any heterozygous SNPs were merged into one heterozygote category. TC concentrations in these individuals were lowered 1.3-fold more ( $-9.3 \pm 1.8\%$  vs.  $-4.1 \pm 1.7\%$ ,  $p < 0.05$ ) than those of homozygous subjects. Similarly, LDL-C was reduced 2.4-fold more ( $-13.4 \pm 3.0$  vs.  $-3.9 \pm 2.9$ ,  $p < 0.05$ ).

#### Interactions of *ABCG8* and *NPC1L1* Polymorphism Variations with Cholesterol Responsiveness to PS Intake

Since the functions of *ABCG5/G8* and *NPC1L1* transporters are counter-opposing, when the two genotype variations coexist in one subject, the contribution of an individual SNP variation to phenotype cannot be correctly appreciated unless background effects are adjusted. Subjects were hence categorized into four subgroups according to the

**Table 4** Single nuclear polymorphisms and haplotypes of *NPC1L1* on lipid in response to PS intake

heterozygosity of polymorphisms and phenotype characteristics: (1) Ho\_Ho (*ABCG8* T400T + *NPC1L1* homozygote); (2) He\_Ho (*ABCG8* T400 K + *NPC1L1* homozygote); (3) Ho\_He (*ABCG8* T400T + *NPC1L1* heterozygote); (4) He\_He (*ABCG8* T400 K + *NPC1L1* heterozygote) (Table 5).

These four subgroups showed an overall difference in PS induced alterations in plasma LDL-C concentration ( $p < 0.05$ , two-way ANOVA). It was further revealed that individuals with *ABCG8* T400 K heterozygous genotypes against homozygous *NPC1L1* background (He\_Ho) were the most refractory cohort to PS intervention, exhibiting a

minimal change in LDL-C. Indeed, LDL-C levels in these individuals were slightly increased ( $+1.6 \pm 7.2\%$ ) as a result of PS intake. In contrast, individuals with *NPC1L1* heterozygous genotypes against homozygous *ABCG8* background (Ho\_He) displayed the most pronounced LDL-C lowering effect ( $-13.6 \pm 4.0\%$ ). The LDL-C response in these two subgroups presented a striking contrast ( $p < 0.05$ ). A similar difference ( $p < 0.05$ ) was also seen for TC. As He\_Ho classified individuals demonstrated a limited reduction in TC ( $-1.9 \pm 4.4\%$ ), whereas Ho\_He individuals showed a more enhanced reduction in TC concentrations ( $-9.3 \pm 2.5\%$ ).

## Discussion

The present work represents the first investigation of the relationship between genotype polymorphism variations in two important sterol transporter genes, *ABCG5/G8* and *NPC1L1*, and their response in cholesterol absorption and synthesis kinetics, as well as serum cholesterol concentrations, to dietary PS intervention. Results indicate that variations in both *ABCG5/G8* and *NPC1L1* polymorphisms have a profound effect on inter-individual responsiveness of cholesterol concentrations.

Inter-individual variation in PS-induced cholesterol response exists as a re-occurring problem encountered in clinical trials [1–4]. In this trial approximately one third of subjects (38%) were non-responders. It has been postulated that genetic predispositions could be attributable for response variations. *ABCG5/G8* transporters have been suggested to limit sterol absorption by both pumping the sterol back to the intestinal lumen and promoting biliary secretion from the liver [9, 10]. The results of the current study with hypercholesterolemic men indicate that different SNP profiles of *ABCG5/G8* are related to varying serum cholesterol response. Our results exemplify that homozygous carriers of *ABCG8* T400 K polymorphisms are more likely to be responders, whereas carriers of heterozygous polymorphisms showed a trend to be classified as non-responders. *ABCG8* T400 K was previously suggested by Plat et al. [12] to explain the inter-individual variation in PS metabolism in healthy volunteers after consumption of PS esters. These investigators observed that TT carriers possessed higher plasma campesterol and sitosterol concentrations in comparison to TK/KK carriers, a finding consistent with the results observed in the present study. In view of polymorphism distribution, it was further noticed that individuals with high basal plasma PS concentrations were more likely to possess the TT polymorphism, whereas individuals with low basal PS were predominantly carrying the TK/KK polymorphism. In terms of cholesterol response to PS intervention, our study further revealed that the varying cholesterol response among carriers with T400 K polymorphisms were likely associated with basal plasma PS concentrations. A poor responsiveness to PS intervention is associated with heterozygous polymorphism (TK/KK) of *ABCG8* T400 K in addition to a low basal plasma PS concentration.

*NPC1L1* is another important sterol transporter protein that plays a critical role in intestinal uptake of both PS and cholesterol [14, 24]. *NPC1L1* protein is also the postulated target for ezetimibe intervention, by which cholesterol absorption is suppressed [2]. Previously, Hegele et al. observed that *NPC1L1* haplotype variations were associated with inter-individual differences in plasma LDL-C response to ezetimibe [1]. However, whether *NPC1L1*

polymorphism variations also explain the suppression in cholesterol absorption and plasma concentration as a result of PS intake remains unclear. The present study reveals the trends indicating that polymorphisms in *NPC1L1* L272L and Y1291Y augment the extent of PS-induced cholesterol lowering in comparison to wild type counterparts. There is an understanding that under certain circumstances, haplotypes may be a useful way to reduce the complexity of the candidate-gene association analyses [25], which is consistent with our findings that haplotypes of two SNP L272L and Y1291Y mutant alleles elicited a similar response to PS intervention. Obviously, our results are consistent with *NPC1L1* being closely involved in inter-individual variation in response to PS intervention, as it has been observed with ezetimibe therapy [1].

Another novel finding of the present study is the description of the combined effect of *ABCG8* and *NPC1L1* transporter genotype variations on the response to PS intervention. Kajinami et al. suggested that combined analysis of different polymorphisms is more informative than single locus analysis for defining the responsiveness of a patient to statin therapy [6]. These authors found that polymorphisms in *ABCG8* and *CYP7A1*, both of which are functionally significant in the secretion of cholesterol from the liver into bile, interact in an allele-cumulative manner in atorvastatin-treated subjects. However, in the present study, the combined actions of *ABCG8* T400 K and *NPC1L1* haplotypes of L272L/Y1291Y seem more complex than simply being cumulative; the phenotype expression of each individual polymorphism may interfere with the concurrence of two counteracting transporter gene polymorphisms. To more specifically expose the characteristics of target SNP variations, we singled out target SNP variants and pooled in common wild type background polymorphisms to more specifically portray the characteristics of target SNP variations.

Very recently, a case-control study by Rudkowska et al. [26] also tested the same sets of SNPs in *ABCG5/G8* and *NPC1L1* among 26 hyperlipidemic subjects after PS intervention, but small sample size in their study design made the results ineligible for statistical analysis. In extending of Rudkowska et al.'s [26] work, our trial recruited more subjects, and plasma lipid response was analyzed in context of background adjusted SNPs of *ABCG8* and *NPC1L1*. Subsequently, the results of the present trial managed to unravel that heterozygous *ABCG8* T400 K genotypes attenuate the cholesterol lowering response, while heterozygous haplotypes of *NPC1L1* L272L/Y1291Y enhance cholesterol lowering response to PS, in comparison with their respective wild type homozygous counterparts.

Limitations of this study include the fact that SNPs represent the most frequent form of polymorphism in the

human genome [24]. According to the National Center for Biotechnology Information database, so far, 280 of *ABCG5/G8* and 70 of *NPC1L1* common polymorphism variations have been identified in the human genome. This study involves less than ten common polymorphism candidates that have known or predicted functional consequences with sterol metabolism based on previous studies [1, 4, 12, 13, 15]. Whether these individual or combined common polymorphisms are adequate to fully explain inter-individual variations of sterol metabolism cannot be fully identified from previous [1, 4, 12, 13, 15] and the present studies.

In conclusion, this study examined the role of *ABCG5/G8* and *NPC1L1* transporter gene common polymorphisms in explaining inter-individual responsiveness to PS intervention in the context of their impact on cholesterol absorption and synthesis. In the *ABCG8* T400 K polymorphism, heterozygous carriers with low basal plasma PS concentrations showed a minimal cholesterol reduction as compared to homozygote carriers. In contrast, among *NPC1L1* L272L/Y1291Y haplotypes, heterozygous carriers manifested a maximal cholesterol reduction as compared to homozygote carriers. Such a pattern was more obviously demonstrated after background SNP adjustment. Results suggest that common polymorphisms of sterol transporter genes, together with basal circulating plasma PS concentrations, are indicative of the expected cholesterol lowering effect induced by dietary PS intake.

## Introduction

Cholesterol is required for the proper structure and function of multiple transport and signaling pathways in mammalian membranes, especially plasma membranes [1–9]. Furthermore, cholesterol is also a required substrate for peroxisomal enzymes involved in the synthesis of bile acids (for intestinal lipid absorption) and for the synthesis of steroids—potent hormones that regulate glucose metabolism, lipid metabolism, reproduction, etc. Conversely, accumulation of excess cholesterol results in formation of cholesterol crystals in membranes [10–12] and lysosomes [13–15]. Accumulation of excess cholesterol in the plasma membranes inhibits numerous intracellular functions (mitochondrial ATP–ADP exchange, microsomal UDP-glucuronyltransferase,  $\text{Na}^+$ – $\text{Ca}^{2+}$  exchange in heart sarcolemmic reticulum) but also plasma membrane functions such as ion transport ( $\text{Na}^+$ ,  $\text{K}^+$ -ATPase, anion transport), receptor function (acetylcholine receptor, insulin receptor), nutrient transport (glucose), proteins involved in transmembrane signaling (adenylate cyclase), and others [13, 16, 17]. Formation of intracellular cholesterol crystals is cytotoxic [13, 18] and can result in formation of atherosclerotic plaques [19–26]. It is thought that excess cholesterol-induced death of macrophages is the main cell type that undergoes necrosis near the lipid cores of atherosclerotic lesions [13]. Thus, excess cholesterol is associated with significant pathologies including atherosclerosis, cardiovascular disease, Niemann-Pick C disease, Alzheimer's disease, as well as others.

While enhanced free cholesterol efflux, increased esterification, and decreased cholesteryl ester droplet hydrolysis have been considered as serving protective roles against cholesterol-induced macrophage cytotoxicity [13]), some early studies suggest a potential role for intracellular sterol binding/carrier proteins such as sterol carrier protein-2 (SCP-2). SCP-2 has been detected in macrophages and arteries [27, 28]. Furthermore, incubation of rat peritoneal macrophages with acetylated LDL (AcLDL) resulted in a dose- and time-dependent increase not only in cellular cholesterol, but also in both SCP-2 protein and mRNA which were upregulated as much as 2.6-fold [15, 29]. In contrast, hepatic SCP-2 and SCP-x (product of alternate transcription site of the SCP-2 gene) were both deficient in adult Niemann-Pick C mice, a murine model sharing similar pathologies and lysosomal cholesterol accumulation as observed in human NPC disease [30, 31]. Finally, hepatic SCP-2 protein levels were reduced 60% in mildly and 90% in severely hypercholesterolemic diabetic rats [32]. Taken together, these data suggest a potential protective role for SCP-2 in accumulation of crystalline cholesterol and cytotoxicity.

However, the mechanism(s) whereby SCP-2 may be protective is as yet unclear. However, both in vitro and intact cell studies indicate that SCP-2 dramatically enhances cholesterol transport from a variety of model and biological membranes, including lysosomal membranes [1–3, 33, 34]. While these studies suggest that SCP-2 similarly facilitate removal of cholesterol from cholesterol crystals, this possibility remains to be examined.

Because cholesterol is not readily visualized in real-time, either in vitro or in living cells, the availability of a fluorescent sterol with properties closely mimicking those of cholesterol represents a major technological advance for elucidating the mechanism(s) of protein-mediated sterol crystal dissolution, sterol organization in membranes, sterol dynamics, and sterol-protein interactions. Since the discovery of dehydroergosterol (DHE) in membranes of eukaryotes such as yeast *Candida tropicalis* [35] and Red Sea sponge *Biemna fortis* [36], DHE has been studied in model membranes [37–40], biological membranes of various intracellular organelles including plasma membrane sub-fractions [1–3, 9, 34, 41–43]), lipoproteins [44–47], cholesterol binding protein-sterol complexes [48–50], and annular cholesterol surrounding hormone receptors [51, 52]. These studies have shown DHE to be an excellent probe molecule with structural and functional properties that closely mimic those of cholesterol. More recent studies involve fluorescence resonance energy transfer (FRET) from DHE [3, 41, 53] to other sterols or to protein aromatic amino acid residues to determine intermolecular interaction distances [48, 54–56]. DHE has provided direct visualization of sterol in living cells by early confocal [41], multiphoton [41], and video [57] studies. Three-photon excitation laser scanning microscopy has enhanced real-time visualization of DHE in sterol-rich and -poor domains in the plasma membrane of living cells [38, 58, 59] while improved video imaging allowed resolution of DHE in larger structures such as microvilli/filopodia in living cells [60, 61].

Because of these properties of DHE and the propensity of DHE to form microcrystals in aqueous buffers [39, 48, 54] at very similar concentrations as cholesterol [19, 20, 62, 63], DHE was used in the present investigation to: (1) elucidate the crystal structure of DHE monohydrate, (2) examine spontaneous transfer from DHE microcrystals, (3) determine if SCP-2 enhances DHE transfer from DHE microcrystals to acceptor cholesterol crystals, model membranes, plasma membranes, and sub-fractionated vesicles, (4) examine the real-time intracellular effects of SCP-2 on microcrystalline DHE within living cells by multi-photon laser scanning imaging microscopy (MPLSM).

## Materials and Methods

### Materials

Ergosterol (Fig. 1a) was used to synthesize dehydroergosterol (Fig. 1b) as described previously [38, 64]. The ergosterol (98% pure) was purchased from Steraloids (Wilmington, NH). Materials used in the synthesis included Burdick-Jackson (Muskegon, MI) “Purified Plus” solvents (methanol, chloroform, ethyl ether) and JT Baker (Mallinckrodt Baker, Phillipsburg, NJ) “Baker Analyzed” glacial acetic acid (99 + % pure), acetic anhydride (99+ % pure) from VWR (Atlanta, GA), and anhydrous mercuric acetate from Fisher Scientific (Pittsburgh, PA) in order to obtain the highest purity of DHE (>99%) determined as described [65, 66]. Human recombinant 13.2 kDa SCP-2 was isolated and purified as described earlier [67]. Lipids including 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 1,2-dioleoyl-*sn*-glycero-3-[phospho-L-serine] (DOPS), and cholesterol were purchased from Avanti Polar Lipids (Alabaster, AL).

### Crystal Growth

Colorless needle shaped crystals of DHE were grown by slow evaporation of a saturated 95% ethanol solution. A Bausch and Lomb 10 × microscope was used to identify a suitable colorless needle 0.2 mm × 0.2 mm × 0.05 mm from a representative sample of crystals of the same habit. The crystal was coated in a cryogenic protectant (mineral oil), and was then fixed to a glass fiber which in turn was

fashioned to a copper mounting pin. The mounted crystal was then placed in a cold nitrogen stream (Oxford) maintained at 110 K.

### Crystallography

A BRUKER SMART 1000 X-ray three-circle diffractometer was employed for crystal screening, unit cell determination, and data collection (Bruker-AXS, Madison, WI). The goniometer was controlled using the SMART Software Suite, version 5.056 (Microsoft NT operating system). The sample was optically centered with the aid of a video camera so that no translations were observed as the crystal was rotated through all positions. The detector was set at 5.0 cm from the crystal sample (CCD-PXL-KAF2, SMART 1000, 512 × 512 pixel). The X-ray radiation employed was generated from a Mo-sealed X-ray tube ( $K_{\alpha} = 0.70173 \text{ \AA}$  with a potential of 50 kV and a current of 40 mA) and filtered with a graphite monochromator in the parallel mode (175 mm collimator with 0.5 mm pinholes).

Dark currents were obtained for the appropriate exposure time 30 s and a rotation exposure was taken to determine crystal quality and the X-ray beam intersection with the detector. The beam intersection coordinates were compared to the configured coordinates and changes were made accordingly. The rotation exposure indicated acceptable crystal quality and the unit cell determination was undertaken. Sixty data frames were taken at widths of  $0.3^{\circ}$  with an exposure time of 30 s. Over 200 reflections were centered and their positions were determined. These reflections were used in the auto-indexing procedure to determine the unit cell. A suitable cell was found and refined by nonlinear least squares and Bravais lattice procedures (Table 1). The unit cell was verified by examination of the *hkl* overlays on several frames of data, including zone photographs. No super-cell or erroneous reflections were observed. After careful examination of the unit cell, a standard data collection procedure was initiated. This procedure consists of collection of one hemisphere of data collected using omega scans, involving the collection 1201  $0.3^{\circ}$  frames at fixed angles for  $\phi$ ,  $2\theta$ , and  $\chi$  ( $2\theta = -28^{\circ}$ ,  $\chi = 54.73^{\circ}$ ), while varying omega. Each frame was exposed for 30 s and contrasted against a 30 s dark current exposure. The total data collection was performed for duration of approximately 13 h at 110 K. No significant intensity fluctuations of equivalent reflections were observed.

**Fig. 1** The structural differences between ergosterol and fluorescent reduced ergosterol (DHE). **a** Ergosterol (ergosta-5,7,22-trien-3 $\beta$ -ol) contains three double bonds. **b** Reduced ergosterol (ergosta-5,7,9(11),22-tetraen-3 $\beta$ -ol) contains an additional double bond located between carbon 9 and carbon 11 of the third ring, forming a conjugated triene system

### Analysis of Crystal Structure

The structure of dehydroergosterol was solved by standard direct methods and further refined employing

**Table 1** Comparison of low temperature structure (173 K) of ergosterol and the low temperature structure (110 K) of dehydroergosterol (reduced ergosterol)

Lobkovsky (2000) private communication (ergosterol). This work (reduced ergosterol)

SHELXS and SHELX97 [68]. CCDC 639255 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via [http://www.ccdc.cam.ac.uk/data\\_request/cif](http://www.ccdc.cam.ac.uk/data_request/cif). Since chirality is known, reflections were merged since the configuration would be determined. In this file, the hydrogen atoms of the water molecules were disordered and therefore omitted. A large ratio of  $U_{eqmax}/U_{eqmin}$  was due to terminal CH<sub>3</sub> groups that may be dynamically disordered and as such was not modeled.

#### Dehydroergosterol Donors: Microcrystals in Aqueous Buffer

DHE microcrystal dispersions were formed by adding small amounts of DHE from ethanolic stock solutions to a buffered solution of PIPES, pH 7.4 as described earlier [38, 66]. No filtering was performed and the microcrystals were observed previously to exist in irregular shapes with sizes ranging up to several microns when created by this technique [38, 54].

#### Cholesterol Acceptors: Microcrystals in Aqueous Buffer

Cholesterol acceptor microcrystal dispersions were formed by adding small amounts of cholesterol from ethanolic stock solutions to a buffered solution of PIPES, pH 7.4 similarly as described for DHE earlier [38, 66]. The resultant solution of microcrystals was not filtered.

#### Membrane Acceptors: Large Unilamellar Vesicles

Large unilamellar vesicles composed of POPC: DOPS: cholesterol (55:10:30 molar ratio) were formed exactly as described earlier [38, 69, 70].

#### Membrane Acceptors: Plasma Membrane, Caveolin-1 and Cholesterol-Rich Sub-Fraction (CAVCR), and Non-caveolin-1 and Cholesterol-Poor Sub-Fraction(non-CAVCP)

Madin-Darby canine kidney (MDCK, American Type Culture Collection) cells were grown as described previously [71] for 72 h at 37 °C and 5% CO<sub>2</sub> in the presence of Dulbecco's Modification of Eagle's medium (D-MEM) (Cellgrow/Mediatech, Herndon, VA). The high glucose medium was supplemented with 2 mM L-glutamine, 1 mM sodium pyruvate, 0.25  $\mu$ g/L Fungizone, 100 units/L penicillin, 100  $\mu$ g/L streptomycin, and 5% serum supreme from (Bio-Whittaker/Canbex, East Rutherford, NJ) as well as 0.1 mM nonessential amino acids (Cellgrow/Mediatech, Herndon, VA), and 43.9 mM sodium bicarbonate (Invitrogen, Carlsbad, CA). Following washing with phosphate buffered saline (PBS), the cells were covered with serum-free medium and incubated with DHE (20  $\mu$ g/ml) added directly to the media from a stock solution derived from absolute ethanol and containing <1 mol% butylated hydroxytoluene (BHT) that was originally stored at -80 °C. The amount of ethanol added was kept below 0.3% to prevent any deleterious effects on the cells. CAVCR (binding fraction) and non-CAVCP (non-binding fraction) were resolved by concanavalin-A affinity chromatography from purified plasma membranes [42, 43, 71–73]. Purity of the plasma membrane, binding, and non-binding fractions was determined as described in the cited papers using western blotting of a panel of protein markers for plasma membranes (Na<sup>+</sup>K<sup>+</sup>-ATPase, SRB1), caveolae (caveolin-1 and GM1), and non-caveolae (Na<sup>+</sup>K<sup>+</sup>-ATPase).

#### Excitation and Emission Anisotropy of DHE

Measurements of the wavelength dependence of anisotropy for both the excitation and emission of DHE were performed using a Cary Eclipse spectrofluorometer (Varian, Palo Alto, CA) with a Peltier temperature controlled holder kept at 24 °C. The slits of both the excitation and emission monochromators were set to 5 nm bandwidths with scan speed set at 120 nm/min. The emission scan of anisotropy was performed with an excitation wavelength of 324 nm. Two excitation scans of anisotropy were made with the fluorescence emission collected at 375 nm and 425 nm.

## Measurement of DHE Fluorescence Anisotropy During Exchange Assays

All measurements of fluorescence anisotropy over time ( $\sim 4$  h) were made using a T-format of an ISS PC1 spectrofluorometer (ISS Instruments, Champaign, IL) with rotating cuvette turrets as well as with UV-grade Glan-Thompson excitation and emission polarizers. The excitation wavelength was set at 324 nm and the emission was collected using a Schott KV389 cutoff filter (Schott Optics, Duryea, PA). Baseline DHE fluorescence anisotropy of the donor microcrystals (2.5  $\mu$ M 10 mM PIPES buffer, pH = 7.4) was measured for 20 min to ensure a stable baseline and obtain initial DHE anisotropy. After addition of 10-fold excess of acceptor (contains no DHE), DHE anisotropy was recorded at 20 s intervals for 4 h to monitor sterol transfer between DHE microcrystal donors and acceptor cholesterol microcrystals or membranes. Residual light scatter contributions were corrected using controls and subtracting the residual fluorescence anisotropy from all experimental data. To prevent inner filter artifacts, absorbance of sample solutions at the excitation wavelengths were  $<0.15$ . The equations  $r = \frac{I_{pl} - I_{pd}}{I_{pl} + 2I_{pd}}$  where  $r$  is the anisotropy,  $I_{pl}$  and  $I_{pd}$  is the emission intensity measure with polarizers parallel and perpendicular, respectively, to the excitation polarizer set vertically, and  $I_T$  is total emission intensity [74].

### Determination of Sterol Exchange: Polarization Assay

Sterol exchange between DHE microcrystal donors and acceptor cholesterol microcrystals, large unilamellar vesicles, plasma membranes, binding fraction, or non-binding fractions was determined by using a fluorescent sterol (DHE) exchange assay as previously established [42, 43, 71, 75]. Time dependent anisotropy changes was modeled with the equation

$$r(t) = f_d(t)r_d(t) + f_a(t)r_a(t) \quad (1)$$

where  $r(t)$  was the measured anisotropy over time,  $f_d(t)$  was the fractional intensity resulting from the donor,  $f_a(t)$  was the fractional intensity resulting from DHE transfer into the acceptor,  $r_d(t)$  was the donor anisotropy, and  $r_a(t)$  was the acceptor anisotropy for the membrane. Crystalline donor anisotropy ( $r_d = 0.09$ ) was constant for microcrystalline DHE and approximately independent of the concentration of crystals. DHE crystalline anisotropy was highly depolarized as compared to the anisotropy of DHE within membrane vesicles, which varied depending upon concentration as a result of self-quenching effects as seen in other studies [76–79]. The acceptor anisotropy was

typically derived from the a standard curve that must be measured from varying dehydroergosterol mole fractions ( $X_a = C_a/C_T$ ) of the particular acceptor and fit to the equation

$$r_a(X_a) = r_0 + b_1^*X_a + b_2^*(X_a)^2 \quad (2)$$

where  $r_0$  is the anisotropy at infinite dilution [71]. However, since for 10-fold dilution  $0 < X_a < 0.1$  and  $\frac{dr}{dX_a} \sim 0$ , the effect of self-quenching would be minimal so that  $r_a(t)$  was fixed to  $r_0$  of each acceptor membrane type.

The fractional intensity contribution to the anisotropy of the DHE in the acceptor was described by the following equation:

$$f_a(t) = f_1(1 - e^{-at}) + f_2(1 - e^{-bt}) \quad (3)$$

where  $f_1$  and  $f_2$  are related to the fractional pool sizes of easily exchangeable cholesterol within the acceptor membrane vesicle with half-times

$$t_{1/2}^1 = \frac{\ln(2)}{a} \quad \text{and} \quad t_{1/2}^2 = \frac{\ln(2)}{b} \quad (4)$$

The donor fractional intensity is related to the acceptor contribution by the following equation:

$$f_d(t) = 1 - f_a(t) \quad (5)$$

Combining these concepts formulated the equation,  $r(t) = (1 - f_a(t))r_d + f_a(t)r_a$  which is further simplified:

$$r(t) = r_d + [f_1(1 - e^{-at}) + f_2(1 - e^{-bt})](r_a - r_d) \quad (6)$$

The anisotropy curves were plotted and fitted by non-linear regression to Eq. 5 using Sigma Plot 8.0 (Systat Software, San Jose, CA) and the half-times were calculated using Eq. 3. The initial rates of the exchange of sterol from the microcrystalline form of DHE to membrane vesicles was calculated from the derivative of  $r(t)$  evaluated at  $t = 0$ .

$$\left. \frac{dr(t)}{dt} \right|_{t=0} = [f_1a + f_2b](r_a - r_s) \quad (7)$$

### DHE Spectra at the Beginning and at the End of Exchange Assays

Steady state fluorescence emission spectra of DHE excited at 324 nm were obtained with a PC1 Photon Counting Fluorometer (ISS Instr., Champaign, IL). Light scatter was minimized by use of narrow excitation slits, low concentration, and cutoff filters. Residual Raman scattering was subtracted. Absorbance at the excitation wavelength was maintained below 0.15 to avoid potential inner filter effects. Spectra were analyzed with Grams32 (Thermo Galactic, Salem, NH).

## Cell Culture of Control and SCP-2 Overexpressing L-cells

Murine L cells and L-cells transfected with cDNA corresponding to the 15-kDa pro-SCP-2 protein were cultured on Lab-Tek Chambered coverglass (Nunc, Naperville, IL) at 37 °C and 5% CO<sub>2</sub> overnight in Higuchi medium [80], supplemented with 10% fetal bovine serum (Hyclone, Logan, UT), as described earlier [42]. The cells with transfected cDNA overexpressed SCP-2 protein so that it comprised 0.036% of the total cytosolic proteins while the level in the control mock transfected L-cells was negligible. Subsequently, the cells were washed with PBS followed by the addition of serum-free medium containing DHE (20 µg/ml) added directly from the ethanolic stock solution previously described (<0.3% ethanol added). The cells on the cover glass was incubated for 24 h and washed with PBS followed by the addition of serum containing media. Cells were removed for imaging at approximately 12 h time points.

## Multi-Photon Laser Scanning Microscopy (MPSLM) of Dehydroergosterol

A Bio-Rad MRC-1024 MP (Zeiss, Thornwood, NY) laser scanning confocal/multi-photon microscopic imaging system was used to obtain images of the fluorescence emission of the structural distribution of DHE within living cells over the 60-h time period. The MRC-1024 MP was coupled to a Zeiss Axiovert 135 inverted microscope (Zeiss, Thornwood, NY) with heated incubator and stage. A Zeiss 40 × Plan-Apochromat (1.4 N.A.) was used for real-time imaging from  $t = 0$  to  $t = 60$  h. The cells on chambered cover glass were maintained in a 37 °C CO<sub>2</sub> incubator between imaging time points. Imaging software, MetaMorph 4.5 (Molecular Devices, Downingtown, PA), was used to determine the mean integrated intensities from labeled cells (both control and SCP-2 overexpressing L-cells) at each time point from collective measurements of ~50 cells while mean integrated intensities of autofluorescence were obtained similarly using unlabeled cells (both control and SCP-2 overexpressing L-cells). Multi-photon excitation of the DHE was provided by a pulsed mode-locked Coherent Mira 900F (Coherent, Palo Alto, CA) tuned to 900 nm. Two photomultipliers of an external detector system (Dr. Zipfel, Cornell University, Ithaca, NY) was used in combination with two emission filters (Chroma Technology, Rockingham, VT), 375/50 nm and 455/30 nm, to simultaneously collect the emission in two distinct spectral regions. The ratio of the integrated measurements collected from the two channels was used to determine the intracellular monomeric versus crystalline distributions of DHE.

## Data and Statistical Analyses

Curve-fitting and non-linear regression analyses were performed within the scientific data and analysis and graphing software, SigmaPlot v.8 (Systat Software, Inc., San Jose, CA).

## Results

### Dehydroergosterol Monohydrate Crystal Structure Solution and Refinement

DHE monohydrate crystal screening, unit cell determination, and data collection on a suitable cell were performed as described in “Materials and Methods”. The data was reduced (SAINT, Bruker-AXS, Madison, WI) and merged. The structure of DHE was solved by standard direct methods and further refined using software developed by G.M. Sheldrick as described in “Materials and Methods”. The crystal refinement results were provided in Table 2.

A dehydroergosterol monohydrate crystal was grown from saturated 95% ethanol solution to the dimensions  $0.20 \times 0.20 \times 0.10$  mm<sup>3</sup> along the  $a$ ,  $b$ ,  $c$  axes. The dehydroergosterol monohydrate symmetry of diffraction was found to be monoclinic (Note: the cholesterol monohydrate has an apparent monoclinic symmetry, but close inspection of the twinned crystals revealed triclinic symmetry; [81, 82]). The space group was thus P2<sub>1</sub>, with reduced cell parameters  $a = 9.9747(11)$  Å,  $b = 7.4731(9)$  Å,  $c = 34.054(4)$  Å,  $\alpha = 90^\circ$ ,  $\beta = 92.970^\circ(2)$ ,  $\gamma = 90^\circ$ . The DHE unit cell is smaller than that reported by Bernal [83] who reported an A2 structure of eight molecules in the unit cell with  $a = 9.5$  Å,  $b = 7.5$  Å,  $c = 75.2$  Å,  $\beta = 96^\circ$  from data recorded with photographic film from an impure crystal. In this case the cell reported by Bernal in 1940 was a superstructure of the cell reported in this manuscript. The volume of the dehydroergosterol monohydrate crystal unit cell was  $2535.1(5)$  Å<sup>3</sup>, with a density of  $1.081$  mg/m<sup>3</sup>, in agreement with that calculated from the assuming the unit cell contained  $4(\text{C}_{28}\text{H}_{44}\text{O}_2) \cdot 4\text{H}_2\text{O}$ . A dimer unit of two  $(\text{C}_{28}\text{H}_{44}\text{O}_2) \cdot \text{H}_2\text{O}$  forms the asymmetric volume of the unit cell with four molecules of  $(\text{C}_{28}\text{H}_{44}\text{O}_2) \cdot \text{H}_2\text{O}$  in the unit cell (Fig. 2a, b) similar to ergosterol monohydrate, while cholesterol monohydrate has eight molecules in its unit cell. From the 32,269 reflections collected, only 8,865 with intensity  $I > 2\sigma(I)$  were obtained and used for resolving the structure. Large amplitudes of atomic thermal vibrations primarily accounted for the high proportion of weak reflections. All 64 (only asymmetric volume atoms are detected, the remainder are generated by symmetry) n-hydrogen atoms were detected in electron density maps. A full-matrix least-squares on  $F^2$  revealed goodness of fit of 1.041, final  $R$  indices [ $I > 2\sigma(I)$ ] of  $R1 = 0.0688$  and

$R$ indices (all data)	$R1 = 0.1180$ , $wR2 = 0.2142$
Absolute structure parameter	0 (3)
Largest diff. peak and hole	0.505 and $-0.331 \text{ e \AA}^{-3}$

$wR2 = 0.1766$ , and  $R$  indices (all data)  $R1 = 0.0688$  and  $wR2 = 0.1766$ .

The molecules are packed in staggered layers (Fig. 2a, b) with the intermolecular separation of 5.50(1) Å between the centroids of the molecules. The hydrophilic ends of the DHE molecules are located inward toward the water molecules while the hydrophobic ends of the molecules are directed outward toward the hydrophobic ends of the adjacent DHE molecules. The hydrogen atoms apart of the water molecules were disordered and have not been included (Fig. 2a, b). The ring system of the DHE molecule (Fig. 1b) is approximately planar where the ring A had a chair conformation, ring B was significantly planar, ring C was formed a partial chair structure with that was planar except for the last carbon joining ring D, and ring D was a distorted. The DHE molecules stack in a parallel mode normal to the diagonal of the  $a$  and  $c$  axes.

**Fig. 2** Crystal structure of dehydroergosterol monohydrate. ### The Effect of Excitation and Emission Wavelength on Anisotropy of Aqueous Dispersions of Microcrystalline Dehydroergosterol

Anisotropy excitation spectra were acquired as described in the “Materials and Methods” and graphed as shown in Fig. 3a. The open circles represent the excitation anisotropy spectrum acquired with the emission monochromator fixed to 375 nm with a 5 nm bandwidth. This spectrum revealed that the anisotropy was relatively constant across much of the excitation wavelengths with only a slight increase in anisotropy at the longer wavelengths. Typically this observation has been made when transition moments are near collinear which occurs when the emission originates from the same state as the absorption band. The closed circles (Fig. 3a) represent the excitation anisotropy spectrum acquired with the emission monochromator fixed to 425 nm with a 5 nm bandwidth wherein the greatest enhancement in emission arises under crystal formation. In this spectrum, the anisotropy was relatively constant across the shortest wavelengths but decreased gradually at the longer wavelengths indicative of a larger displacement of

**Fig. 3** Excitation and emission anisotropy of DHE. **a** Plots of the anisotropy versus excitation wavelength over the region 280–350 nm for emission collected at 375 nm (*open circles*) and 425 nm (*closed*

*circles*). **b** Plot of emission anisotropy over the region 370–550 nm, resulting from excitation at 324 nm. Bandwidths were 5 nm for both excitation and emission monochromators

transition moments. Due to the restrictive environment within the crystal and the observed higher quantum yield, this was suggestive of an involvement in a different state possibly the result of formation of an excited state dimer rather than simple homotransfer or self-quenching that has been observed in vesicles [38, 54]. Despite the different states involved in the fluorescence emission, the emission anisotropy spectrum (Fig. 3b), acquired with excitation wavelength fixed to 324 nm and a 5 nm bandwidth, showed very little dependence upon wavelength. This was in agreement with the excitation anisotropy measured at 324 nm (Fig. 3a) where only a slight difference existed using the acquisition emission wavelengths of 375 nm and 425 nm.

#### Sterol Exchange Between Donors and Acceptors

DHE has proven to be a useful probe for cholesterol transfer because it is a naturally-occurring fluorescent sterol [35, 36] exhibiting structural and functional properties closely resembling those of cholesterol as detailed in the Introduction [1, 2, 38, 39, 45, 51, 75, 84–87]. The theoretical basis for the DHE exchange assay has been previously established with respect for exchange of sterol from donor membranes to acceptor membranes [42, 43, 71, 76, 77, 88, 89]. Briefly, at high concentrations of DHE in membranes, significant depolarization or decrease in anisotropy occurs as a result of resonance energy transfer (RET) between DHE molecules. Upon addition of 10-fold excess (by sterol) acceptor cholesterol microcrystals or acceptor membranes, the donor DHE microcrystal exchanges DHE one-for-one with cholesterol in the acceptor, resulting in release of DHE from self-quenching, thereby increasing polarization or anisotropy. Typically, a

standard curve is determined by measuring the polarization or anisotropy as a function of the mole fraction of the fluorescent sterol within donor and acceptor (if different membrane type). Thus, a determination is made from the standard curve of the mol percent of DHE that has been exchanged. However, in this study, the donor consists of microcrystalline DHE with low anisotropy ( $r \sim 0.09$ ) that remains constant until the amount of aqueous DHE falls below the critical micelle concentration (CMC) which is quite low ( $\sim 30$  nM). By implication, sterol exchange observed by increasing anisotropy would be the result of increasing localization of sterol within the acceptor. Because of the 10-fold excess of acceptors, the acceptor anisotropy occurs between  $r(X_a = 0) = r_0$  (anisotropy at infinite dilution) to  $r(X_a = 0.1) \approx r_0$ . This approximation implies that only the fractional contributions of the anisotropy depend upon the sterol mole fractions (see “Materials and Methods”).

#### Effect of Cholesterol Transfer Proteins on the Sterol Exchange Between Crystalline Dehydroergosterol and Crystalline Cholesterol

Sterol exchange between dehydroergosterol microcrystals and cholesterol microcrystals was determined with a fluorescence polarization assay as described in “Materials and Methods”. Baseline anisotropy of DHE microcrystals in buffer alone was essentially unchanged over a 4 h time period (Fig. 4a). At the end of this incubation period, the emission spectrum of DHE microcrystals (excited at 324 nm) was obtained. As shown in Fig. 4b, the raw emission spectra exhibited four major peaks near 355, 373, 397, and 426 nm. After correction for background, the ratios of emission peaks as 426 nm/355 nm and 426 nm/

**Fig. 4** Anisotropy and spectral measurements of microcrystal disruption involving DHE and cholesterol. Exchange of sterol was monitored using polarized light as described in the “Materials and Methods” with excitation at 324 nm. **a** 2.5  $\mu\text{M}$  DHE was added to buffered 10 mM PIPES (pH 7.2) to form microcrystals. The polarization was monitored for 225 min and converted to anisotropy. This curve represents the donor only curve and remains flat over the time period. **b** Emission spectrum of the DHE microcrystals after baseline anisotropy measurement of (a), approximately 4 h. **c** Time-dependent changes in anisotropy involving donor 2.5  $\mu\text{M}$  DHE as a result of the addition of 25  $\mu\text{M}$  cholesterol to the solution as a 10-fold

excess of acceptor. **d** Emission spectrum after measurement of the spontaneous sterol exchange in (c), at approximately 4 h. **e** Sterol exchange between a donor 2.5  $\mu\text{M}$  DHE microcrystal dispersion in the presence of 25  $\mu\text{M}$  cholesterol microcrystal dispersion with the addition of 2.5  $\mu\text{M}$  BSA. **f** Emission spectrum acquired after the sterol exchange in (e) at approximately 4 h. **g** Sterol exchange between a 2.5  $\mu\text{M}$  DHE microcrystal dispersion (donors) in the presence of 25  $\mu\text{M}$  cholesterol microcrystal dispersion (acceptors) with the addition of 2.5  $\mu\text{M}$  SCP-2. **h** Emission spectrum of the combination in (g) acquired at 4 h

373 nm were 3.7 and 2.5, respectively—consistent with DHE being localized primarily in crystalline structures as described earlier [38, 48, 54]. The ratio of 455 nm/375 nm was 1.5 at the endpoint.

To examine spontaneous sterol exchange between donor and acceptor microcrystals, 10-fold excess acceptor cholesterol microcrystals were added to donor DHE microcrystals in aqueous buffer. The DHE anisotropy increased slowly (Fig. 4c), consistent with one-for-one exchange of DHE in the donor DHE microcrystals and cholesterol in the cholesterol microcrystal acceptors. Analysis as described in “Materials and Methods” revealed that the anisotropy change best fit a single component with a long half-time  $t_1^{1/2} = 130$  min and a very low exchangeable fraction of 0.057 of the total donor sterol (Table 3). After correction for background, the ratio of 455 nm/375 nm was 1.4—again consistent with DHE being localized primarily in crystalline environment. These findings suggested that very little DHE had transferred to the cholesterol microcrystal and the environment basically exhibited similar properties as that in DHE microcrystals determined by spectral analysis.

To determine if proteins known to enhance lipid transfer between membranes might also facilitate DHE exchange between microcrystals, the effects of two classic cholesterol transfer proteins were tested: (1) An extracellular cholesterol transfer protein (bovine serum albumin, BSA); (2) An intracellular cholesterol transfer protein (SCP-2). Addition of albumin or SCP-2 to DHE microcrystal donors alone did not significantly alter the anisotropy or spectral properties (not shown). Addition of bovine serum albumin to DHE microcrystal donors in the presence of 10-fold excess cholesterol microcrystal acceptors (Fig. 4e)

significantly decreased the half-time of transfer (Table 3). The initial rate did not change significantly and the overall exchangeable fraction, though slightly lower, was similar to the spontaneous (Table 3) as corroborated by the spectral properties (Fig. 4f) where the ratio of 455 nm/375 nm was 1.3. In contrast, SCP-2 rapidly increased the DHE anisotropy with increasing time of DHE exchange between DHE microcrystal donors and cholesterol microcrystal acceptors (Fig. 4g). Analysis of the exchange curves as described in “Materials and Methods” indicated that they optimally fit two components: (1) the contribution  $t_1^{1/2} = 74 \pm 4$  min with a total exchangeable fraction of  $0.0867 \pm 0.0003$  and (2) the contribution  $t_2^{1/2} = 6.1 \pm 0.3$  min with a total exchangeable fraction of  $0.0732 \pm 0.0006$ . The first fraction was increased only about 1.5-fold more than the spontaneous (Table 3), but the 2.5  $\mu$ M SCP-2 significantly reduced the half-time  $t_1^{1/2}$  of DHE exchange by 2.2-fold which was similar to the 2.5  $\mu$ M BSA (Table 3). Furthermore, SCP-2 induced the formation of a second component, nearly as large as the first. The half-time  $t_2^{1/2}$  of the new component induced by SCP-2 was very short, near 6 min or a nearly 22-fold faster exchange (Table 3) which contributed to an initial rate increase of 29-fold over the spontaneous. Finally, SCP-2 significantly altered the emission spectra of DHE at the end of the exchange process (Fig. 4h). After correction for background, the ratio of 455 nm/375 nm was 0.6—consistent with a significant amount of transferred DHE being localized in a less crystalline/more disordered region of the acceptor cholesterol microcrystals.

In summary, spontaneous DHE exchange between DHE microcrystals and cholesterol microcrystals was best fit by a single, very slow component. While BSA only decreased

Fluorescence polarization exchange curves for DHE sterol transfer from DHE donor to cholesterol crystals and membrane vesicles. The exchanges involving LUV, PM, CAVCR, and non-CAVCP were measured in the absence or presence of SCP-2 (1.5  $\mu$ M) followed by determination of initial rates and kinetic analysis as described in “Materials and Methods”. Half times  $t_1^{1/2}$  and  $t_2^{1/2}$  were in minutes with the corresponding fractions,  $f_1$  and  $f_2$ , representing the fractions due to the exchangeable components. Values represent the mean  $\pm$  SE ( $n = 3$ –4)

<sup>a</sup> Value was fixed during fit

the half-time of the slow component of DHE exchange without inducing a rapid exchangeable component, the intracellular cholesterol transport protein SCP-2 dramatically facilitated DHE exchange by decreasing the half-time over twofold and inducing the formation of a second DHE pool with very short, nearly 22-fold shorter, half-time, thereby nearly tripling the total fraction of sterol available for exchange under the experimental conditions.

#### Effect of SCP-2 on Sterol Exchange Between Crystalline Dehydroergosterol and Model Membranes of Large Unilamellar Vesicles

Large unilamellar vesicles consisting of 55 mol% POPC: 35 mol% Chol: 10 mol% PS were made by extrusion as described in the “Materials and Methods”. The exchange assay previously described was used to examine the ability of SCP-2 to enhance sterol exchange from out of a crystalline domain with that of model membrane associated cholesterol. DHE was added to 10 mM PIPES buffer at pH 7.2 to form a 1.5  $\mu$ M solution of DHE. The aqueous dispersion of microcrystalline DHE (not shown) gave a baseline anisotropy of  $r = 0.09$  and remain unchanged over a 4 h period similar to Fig. 4a. This experiment was repeated in the presence of 1.5  $\mu$ M SCP-2 (not shown), which also was unchanged over a 4 h time period. However, when the 55:35:10 (POPC:CHOL:PS) LUVs were added in 10-fold excess to the 1.5  $\mu$ M DHE microcrystalline dispersion, the anisotropy began to slowly rise with time indicative of sterol exchange as observed in Fig. 5a (closed circles). After 4 h, a spectrum of the solution was acquired which revealed a significant drop in the amount of crystalline DHE (Fig. 5b) as revealed by the ratio of 455 nm/375 nm = 0.82. As shown in Table 3 a single half-time component of  $813 \pm 1$  min was calculated with the fraction fixed to 1 at infinitely long time. This was justified by the near linear slope of the curve over the 4 h time period. The initial rate calculated was very close to that of the BSA mediated and spontaneous DHE to cholesterol crystal exchange. Another solution of 1.5  $\mu$ M DHE microcrystalline dispersion was made in PIPES buffer, after 10 min the acceptors ( $10 \times$  LUVs) was added along with SCP-2 for a final protein concentration of 1.5  $\mu$ M. This created a significant increase in anisotropy over the period of the 4 h as seen in Fig. 5a (open circles) with a corresponding increase in monomeric DHE content as seen in the emission spectrum (Fig. 5c) acquired immediately after the exchange time period. This spectrum showed very little excimeric emission as demonstrated by the low ratio of 455 nm/375 nm = 0.18. As shown in Table 3, a long half-time component of  $133 \pm 1$  and an extremely short half-time of  $0.31 \pm 0.07$  were calculated. The respective fractions of  $0.8684 \pm 0.0007$  and  $0.0314 \pm 0.0002$

**Fig. 5** Sterol exchange between donor DHE microcrystals and large unilamellar vesicles (LUVs). Large unilamellar vesicles (55 mol % POPC: 35 mol % cholesterol: 10 mol % PS) were prepared as described in the “Materials and Methods”. **a** Spontaneous and SCP-2 mediated exchange of sterol between a 1.5  $\mu$ M solution of DHE microcrystals (donor) and a 10-fold excess of LUVs (acceptors) in PIPES buffer were monitored by anisotropy measurements with excitation at 324 nm. **b** Spectrum acquired after 4 h of the spontaneous exchange (DHE + 10-fold excess LUV). **c** Spectrum acquired after 4 h of the SCP-2 mediated exchange (DHE + 10-fold excess LUV + 1.5  $\mu$ M SCP-2)

revealed that the majority of the exchangeable sterol was in the slower fraction but 3% was located in a rapid exchangeable fraction which contributed to an initial rate of  $40 \pm 10$  pmol/min. The addition of SCP-2 to the sterol

exchange involving DHE microcrystals and LUVs boosted the initial rate 92-fold. The overall exchangeable sterol was 90% of the total sterol, which was clearly evident of the spectrum acquired after 4 h (Fig. 5c).

#### Effect of SCP-2 on Nonfluorescent Mechanisms in Mixtures of Crystalline Cholesterol and Model Membranes of Large Unilamellar Vesicles

In order to determine if the time-dependent enhancement of anisotropy was independent of the fluorescent sterol DHE and potentially a result of changes in residual scatter, several control experiments were performed using the same experimental and instrumental parameters but with cholesterol crystal donors. First, the anisotropy of cholesterol crystals in PIPES buffer was monitored for 4 h. Second, the anisotropy of the mixture of cholesterol crystal donors in the presence of 10-fold excess of LUV cholesterol acceptors was monitored for 4 h. Last, the anisotropy of the mixture of cholesterol crystal donors in the presence of 10-fold excess of LUV acceptors and SCP-2 was monitored for 4 h as shown in Fig. 6. In all three cases, the anisotropy of the weak residual light scatter leaking through the KV389 filter remained constant over time implying that the changes in anisotropy in the case of DHE were not a scatter artifact involving crystals, LUVs, and the protein.

#### Effect of SCP-2 on Sterol Exchange Between Crystalline Dehydroergosterol and Biological Membranes of Three Types: Plasma Membranes as well as the Sub-Fractions: CAVCR and Non-CAVCP

Biological membranes in the form of vesicles were isolated by previously established methods and used to determine the significance of crystalline sterol domain exchange in complex systems. The plasma membranes of MDCK cells were isolated using differential (Percoll) centrifugation with subsequent sub-fractionation into two portions, CAVCR and non-CAVCP, through the use of concanavalin A affinity purification technique as described in “Materials and Methods” and characterized in studies involving diverse cell types [42, 71–73, 90]. The cholesterol-rich sub-fraction (CAVCR) also contained proteins such as caveolin-1 and GM1 gangliosides as opposed to the cholesterol-poor sub-fraction (non-CAVCP). They were also highly purified and relatively free of contamination from endoplasmic reticulum.

Baseline anisotropy of DHE microcrystals in buffer alone was again essentially unchanged over a 4-h time period. The anisotropy of the 1.5  $\mu$ M DHE microcrystals in the presence of 10-fold excess of MDCK PM acceptor membrane vesicles showed no change over 4 h (Fig. 7a) and the spectrum acquired after the 4 h showed almost no

**Fig. 6** Time dependent anisotropy measurements of cholesterol microcrystals with large unilamellar vesicles (LUVs). Large unilamellar vesicles (55 mol % POPC: 35 mol % cholesterol: 10 mol % PS) were prepared as described in the “Materials and Methods”. **a** Using the same instrumental setup for measuring the anisotropy of DHE (Fig. 4), residual scatter was monitored for approximately 4 h using a 1.5  $\mu$ M solution of cholesterol microcrystals (donor) and a 10-fold excess of LUVs (acceptors) in PIPES buffer

change in the spectrum (not shown). However, with the same conditions and including 1.5  $\mu$ M SCP-2 at the time of addition of acceptors changed the dynamics completely (Fig. 7a). The anisotropy increased rapidly in nearly 4 h, corresponding to a single large exchangeable fraction of  $0.9431 \pm 0.0006$  with a half-time of  $72.9 \pm 0.6$  min (Table 3). The emission spectrum at 4 h (Fig. 7d) revealed mostly monomeric type emission as evidenced by the emission ratio of  $455 \text{ nm}/375 \text{ nm} = 0.2$ . The CAVCR sub-fraction of the MDCK PM also exhibited enhanced exchange in the presence of 1.5  $\mu$ M SCP-2 as shown in Fig. 7b (closed circles) albeit with the introduction of two components, one slow and one fast. The slow component resulted in a half-time of  $270 \pm 20$  min with an exchangeable fraction of  $0.299 \pm 0.003$  and the fast component in a half-time of  $3.7 \pm 0.3$  min albeit a small fraction of  $0.0453 \pm 0.0002$ . No changes were evident in the spontaneous exchange of the CAVCR sub-fraction without SCP-2 as shown in Fig. 7b (open circles). As previously observed in the PM, the spectrum after the exchange in the presence of SCP-2 was that of mostly monomeric DHE with an emission ratio of  $455 \text{ nm}/375 \text{ nm} = 0.3$  (Fig. 7e). Sterol exchange, whether spontaneous or with SCP-2, was nonexistent in the non-CAVCP sub-fraction of the PM (Fig. 7c) with the spectrum (Fig. 7f) revealing a crystalline type emission with an emission ratio of  $455 \text{ nm}/375 \text{ nm} = 1.5$ . Herein SCP-2 provided greater enhancement of sterol transfer within the first hour as compared to an earlier study using CAVCR membrane vesicles containing DHE as donors to similarly obtained cholesterol containing acceptors [71]. Also, SCP-2 did not

**Fig. 7** Sterol exchange between donor DHE microcrystals and acceptors of biological plasma membrane fractions and sub-fractions. Plasma membranes were isolated from Madin-Darby canine kidney (MDCK) cells followed by sub-fractionation of the plasma membrane isolation, to yield CAVCR and non-CAVCP vesicles as described in the “Materials and Methods”. Sterol exchanges were performed in a quartz cuvette with a 1.5 μM solution of DHE microcrystals as donors and a 10-fold excess of acceptor membrane vesicles in 10 mM PIPES buffer at pH 7.2. The anisotropy was measured with an ISS PC1 spectrofluorometer using excitation at 324 nm and the kinetic curves

significantly enhance sterol exchange between DHE containing donor non-CAVCP acceptor vesicles [71].

#### Multi-Photon Laser Scanning Microscopy of Dehydroergosterol Monohydrate

DHE in a solution of 90% ethanol and 10% water was evaporated at room temperature on chambered cover glass and imaged by multi-photon laser scanning microscopy using the instrumental setup described in the “Materials and Methods”. Many microcrystals of DHE monohydrate were formed as seen by the small fluorescent plate structures (Fig. 8). Changes in shape and sizes occurred

plotted for the spontaneous and SCP-2 mediated exchange of sterol from the donor DHE microcrystals to the following acceptors: **a** plasma membrane; **b** CAVCR; and **c** non-CAVCP. After a 4 h sterol exchange assay, spectra were acquired at 324 nm excitation to determine the structural form of the DHE. Spectra were plotted for the SCP-2 mediated exchanges (DHE donor microcrystals + 10-fold excess acceptors + 1.5 μM SCP-2) for the following acceptors: **d** plasma membrane after 4 h showing mostly monomeric DHE; **e** CAVCR after 4 h showing mostly monomeric DHE; **f** non-CAVCP after 4 h showing microcrystalline DHE

depending upon conditions such as concentration, temperature, and water content and subsequently rate of evaporation. DHE in anhydrous ethanol evaporated under nitrogen, typically formed longer structures as observed in cholesterol [20].

#### Multi-Photon Imaging of Crystalline Dehydroergosterol Disappearance in SCP-2 Overexpressing Cells as Compared to Control L-cells

L-cells and L-cells overexpressing SCP-2 were cultured as described in the “Materials and Methods”. After supplementing the cells with crystalline DHE for 24 h, cells were

**Fig. 8** Multi-photon laser scanning microscopy of DHE monohydrate microcrystals. The microcrystals were formed by evaporation from a solution of DHE in 90% ethanol and 10% water onto a chambered cover glass. The microcrystals were then imaged through a Zeiss 63X plan-Apochromat 1.4 NA oil immersion objective using a Bio-Rad MRC-1024 MP laser scanning microscopy imaging system with a Coherent titanium:sapphire femto-second mode-locked laser tuned to an excitation wavelength of 900 nm. This grayscale image of the plate-like structures represents the DHE crystalline enhanced fluorescence filtered through a Chroma Technology 455/30 nm dichroic filter. White scale bar in the lower right-hand corner of the image represents 4  $\mu\text{m}$

washed and serum containing media was added. Both control and SCP-2 overexpressing cells with phagocytosed crystals of DHE were immediately imaged by multi-photon microscopy using dual channel detection as described in the “Materials and Methods” at time  $t = 0$ . Power, gain, and black level were adjusted initially to minimize photobleaching, saturation, and dynamic range and maintained throughout the time based experiment. After the instrumental acquisition parameters were set appropriately, images of the autofluorescence of L-cells were acquired. Due to the brightness of the emission of microcrystalline DHE, no autofluorescence was observable in either the blue channel (Fig. 9a) or UV channel (Fig. 9b). Similar images (not shown) of the SCP-2 overexpressing cells were acquired. Images of the DHE emission from microcrystals of DHE in control cells and cells overexpressing SCP-2 were obtained by collecting the fluorescence in the blue and UV channels at  $t = 0$ . Figure 9c, d were multiphoton images acquired of the microcrystalline DHE in L-cells overexpressing SCP-2 at the initial time point. Subsequently, cells on several chambered cover glass were imaged at 12 h increments using multi-photon laser

scanning microscopy using both channels. Representative images acquired from the blue (Fig. 9e) and UV channels (Fig. 9f) reveal the character of the remaining DHE in L-cells overexpressing SCP-2 after 60 h. Integrated intensity measurements were made of the dual channel acquisition images of cells across multiple regions of each slide and the mean integrated intensity was plotted as a function of time for both SCP-2 overexpressing and control cells (Fig. 10a). The rate of disappearance of DHE crystalline fluorescence (Fig. 10a) appeared linear over the period of 60 h for both cell types and did not appear significantly different between cell types due to large variability especially in the control L-cells. The SCP-2 overexpressing cells took up more microcrystals and trended toward faster disappearance as compared to the control cells. The emission at in the UV channel (375 nm) also decreased more rapidly even than that of the blue channel (455 nm) as seen in the graph of the ratio of the blue channel to UV channel (455 nm emission/375 nm emission) over time (Fig. 10b); which implied that at longer time points, monomeric DHE was distributed faster throughout the cellular membranes with a substantial portion effluxed out of the cell [89].

## Discussion

Excess cholesterol is cytotoxic and can result in deleterious accumulation of crystalline cholesterol within the cell [10–12]. While increased excretion, intracellular esterification of cholesterol, and reduced hydrolysis of cholesteryl esters can in part prevent toxicity due to excess cholesterol [13], other factors may exist to enhance dissolution of crystalline cholesterol and transport from the cell. Early studies with macrophages, NPC fibroblasts, and hypercholesterolemic rats suggested a potential role for intracellular sterol binding/carrier proteins such as SCP-2 [15, 30–32]. In fact SCP-2 has been shown to enhance transfer of DHE out of microcrystals and exchange with cholesterol within intact lysosomal membranes [38]. This was somewhat surprising since even though DHE microcrystals appeared in large quantities of lysosomes as determined by fluorescence imaging/colocalization and isolation of intact lysosomes, SCP-2 has been observed in only very small amounts within lysosomes. Since cells can accumulate excess cholesterol in microcrystalline patches within the plasma membrane [10], a part of the current study was undertaken with dehydroergosterol, a naturally-occurring fluorescent sterol analog, and purified SCP-2 to determine if this protein enhanced the transfer/exchange of sterol between crystals and between crystals and membrane acceptors, especially plasma membranes and associated membrane domains. Together the data presented herein provide new

**Fig. 9** The effect of SCP-2 overexpression on DHE microcrystals in living cells. Living cells on chambered cover glass were incubated with DHE microcrystals for 24 h. Cells were washed with PBS three times and the replaced with serum containing media. The cells were immediately imaged at  $t = 0$  using multi-photon laser scanning microscopy imaging. Multi-photon excitation of the DHE was accomplished at 900 nm with simultaneously mostly crystalline DHE fluorescence emission was collected using a D455/30 nm filter (blue channel) and mostly monomeric DHE fluorescence emission was collected using a D375/50 nm filter (UV channel). The cells on chambered cover glass were returned to the incubator and subsequently imaged every 12 h up to 60 h. Image of L-cells without DHE labeling (autofluorescence) collected using the blue channel **a** and the UV channel **b**. The gain and black levels were adjusted to reduce the autofluorescence to near zero as seen in the images (**a**, **b**). Fluorescence emission of DHE microcrystals in living cells overexpressing SCP-2 as imaged in the blue channel **c** and UV channel **d** at time  $t = 0$ . Fluorescence emission of DHE microcrystals in living cells overexpressing SCP-2 as imaged in the blue channel **e** and UV channel **f** at time  $t = 60$  h. Scale bar in lower right corner represents 10  $\mu\text{m}$

insights on the potential role of SCP-2 in dissolution of crystalline sterol and transfer of crystal derived sterol to cellular derived membrane fractions of enriched cholesterol and caveolin-1.

At the outset, the crystal structure of dehydroergosterol monohydrate was determined for the first time from DHE synthesized with a purity >99%. Comparison with the crystal structure of cholesterol monohydrate reveals overall

similarities such as its organization into a bilayer system albeit with subtle differences, suggesting that it would be a suitable donor for SCP-2-mediated sterol transfer. Similar to ergosterol monohydrate, dehydroergosterol monohydrate crystallizes in the space group  $P2_1$  with two molecules in the asymmetric unit while cholesterol monohydrate crystallizes in the space group  $P1$  with four molecules in the asymmetric unit. If the unit cell of dehydroergosterol

**Fig. 10** Disappearance of microcrystalline DHE from L-cells and L-cells overexpressing SCP-2. **a** The background corrected integrated intensities obtained from images of DHE emission collected through the D455/30 nm filter (blue channel) were plotted for both control L-cells and cells overexpressing SCP-2. **b** The ratio of the background corrected integrated intensities of monomer to crystalline that were acquired using the D455/30 nm filter (blue channel) and the D375/50 nm filter (UV channel) were plotted for both control L-cells and L-cells overexpressing SCP-2. Each point was derived from mean integrated intensities obtained from collective measurements of ~50 cells and corrected for residual background autofluorescence; the error bars represent the standard error

monohydrate was doubled and the space group reduced to P1 then the transformed unit cell of dehydroergosterol monohydrate would be comparable to cholesterol monohydrate. Although, cholesterol monohydrate has triclinic symmetry, it does have some pseudo-symmetry such that the cholesterol monohydrate can easily be mistaken for monoclinic [81, 82]. The low temperature monohydrate crystalline structure of ergosterol was quite similar to the reduced form (Table 1) where the main effect of the addition of the two double bonds (Fig. 1) forming the conjugated system brought about the shortening of the longest axis  $c$  and with the decrease in the angle  $\beta$  bringing it closer to approximating an orthorhombic system. The space group reduced cell parameters of dehydroergosterol monohydrate measured to be slightly smaller ( $a = 9.9747(11) \text{ \AA}$ ,  $b = 7.4731(9) \text{ \AA}$ ,  $c = 34.054(4) \text{ \AA}$ ,  $\alpha = 90^\circ$ ,  $\beta = 92.970^\circ$  [2],  $\gamma = 90^\circ$ ) than those of cholesterol

monohydrate ( $a = 12.39 \text{ \AA}$ ,  $b = 12.41 \text{ \AA}$ ,  $c = 34.36 \text{ \AA}$ ,  $\alpha = 91.9^\circ$ ,  $\beta = 98.1^\circ$ ,  $\gamma = 100.8^\circ$ ) as reported previously [81]. In comparing dehydroergosterol monohydrate to the cholesterol monohydrate reported by Craven [81, 82] the intermolecular distance between the centroids of the staggered ring system for dehydroergosterol monohydrate [5.50(1)Å] was significantly shorter than cholesterol monohydrate [6.33(1) Å]. Consistent with previous measurements of force-area isotherms of monolayers formed using mixtures of either high mol% dehydroergosterol or cholesterol with POPC, the density of dehydroergosterol monohydrate ( $\rho_{\text{DHE}} = 1.081 \text{ mg/m}^3$ ) was slightly larger, with a ratio of  $\rho_{\text{DHE}}/\rho_{\text{Chol}} = 1.034$ , than that of cholesterol monohydrate ( $\rho_{\text{Chol}} = 1.045 \text{ mg/m}^3$ ) [38, 81]. Taken together, these data would suggest that dehydroergosterol was arranged in a slightly closer packed configuration than cholesterol.

DHE in its crystalline form yields enhanced red shifted emission reminiscent of the excimeric emission of pyrene although with much less increase in fluorescence and some spectral structure. Pyrene forms crystals that are monoclinic with four molecules in a unit cell and belong to the space group  $P2_1/a$  such that the pyrene molecules are arranged as sandwich dimers, forming the basis of the excimer. Such a parallel arrangement observed of the stacking of parallel dehydroergosterol molecules could also form the basis of excimeric sandwich dimers although at interplanar distances ~1.5-fold greater than in pyrene crystals. The larger distance in the DHE crystal could explain the lower amount of enhanced emission from monomer to excimer as compared to the pyrene crystal. Also, the vibrational level structure observed in the difference spectra (crystalline-monomer) could indicate a somewhat longer-lived ground state dissociative dimer. At the present time, the enhanced red-shifted emission seems to be relegated to the crystalline form as this spectral characteristic has not been observed in highly concentrated solutions (not saturated and with no observable crystals) of DHE in ethanol. As such the existence of such enhancement in emission has proven to be a very useful tool to detect the existence of crystalline form in biological systems [91, 92].

Kinetic experiments, utilizing anisotropy measurements of aqueous dispersions of DHE microcrystals in the vicinity of 10-fold excess of acceptors, suggested that the addition of SCP-2, but not albumin, significantly enhanced disruption of the DHE microcrystalline structure when in the presence of excess cholesterol. Of greater significance, in experiments with model membranes containing POPC, cholesterol, and DOPS, SCP-2 enhanced exchange of sterol between microcrystals and LUVs nearly 92-fold more in the initial rate than the spontaneous exchange, even affecting two dynamic pools of cholesterol within the

model membrane acceptors. The question remains, however, whether model membrane system studies would reflect the DHE transfer between microcrystals and biological membranes such as the plasma membrane.

The plasma membranes of many types of cells contain specialized cholesterol-rich microdomains [13, 18]. The localization of the protein caveolin to these regions can result in membrane invaginations (50–100 nm) which are morphological features visualized by electron microscopy and defined as caveolae. By selectively partitioning specific lipids and proteins, these membrane regions represent a nexus organizing multiple cell membrane functions such as reverse cholesterol transport, cell recognition, signaling, immune function, and potocytosis [4, 9, 93–97]. Although plasma membrane cholesterol-rich microdomains such as caveolae are important not only in normal cell physiology, aberrant microdomains are associated with metabolic diseases (cardiovascular, diabetes, obesity, Niemann-Pick C disease, Alzheimer's disease, as well as others) [19–26], pathogen entry, and the action of many bacterial and viral toxins [98–104]. In order to better understand the potential role of such microdomains in the removal of crystalline sterol, kinetic experiments were repeated with vesicles derived from the plasma membrane of MDCK cells: (1). plasma membrane acceptors and (2). affinity-purified acceptors consisting of CAVCR and non-CAVCP membrane vesicles sub-fractionated from plasma membrane isolation. Although the CAVCR sub-fraction was previously shown to contain proteins such as caveolin-1 and GM1 that are typically considered caveolae proteins and the non-CAVCP were shown to be void of these proteins, the argument remains at the edge of the definitive due to the invasive nature of the isolation [71, 73, 105]. Whether or not the cholesterol-rich vesicles can truly be considered to behave similarly to intact caveolar membranes, the two sub-fractions, respectively represent biological derived membrane substrates with and without a complement of active proteins thought to be involved in sterol uptake/efflux [9, 106]. As such, these fractions were used to characterize the interaction of crystalline sterol and active proteins in a biologically relevant lipid microsystem. In the plasma membrane fraction, a rather large amount (94%) of the sterol was exchangeable with a half-time on the order of 73 min, a value somewhat faster than that of MDCK membrane fractions but typical of other organellar types [71, 107]. Due to the large size of this rapid exchangeable pool and variability in isolations, it is possible that a much smaller fast component was obscured. Noticeably, in the binding sub-fraction (CAVCR) of the MDCK plasma membrane, a significantly faster component emerged that represented about 5% of the total sterol and 13% of the total exchangeable pool. However, only about 35% of the total sterol was exchangeable compared to approximately

58% when using plasma membrane binding fraction donors as well [71]. Similar to the plasma membrane vesicles, in LUVs almost all of the sterol was available for exchange in both the spontaneous and the SCP-2 enhanced. Two dynamic pools were observed wherein the majority (87%) pool had exchange rates on the order of a typical cholesterol-rich microdomain sub-fraction and a small pool (3%) had a very fast exchange rate (half-time on the order of s). Significant enhancement, as a result of the addition of SCP-2, occurred for the transfer of DHE out of microcrystals into membranes vesicles, both model and cellular except for the non-CAVCP, as might be expected at the outset. Although the largest bulk transfer occurred from plasma membrane vesicles, the CAVCR showed significant decrease in half-time but with less exchangeable sterol availability, possibly due to an intrinsic protein-cholesterol binding interaction (e.g., caveolin).

Multi-photon laser scanning microscopy with its optical sectioning capability has proven indispensable in observing naturally occurring fluorophores like DHE that absorb in ultraviolet wavelengths. With this technique, microcrystals of DHE have been observed to incorporate into L-cells [38]. This was not surprising since L-cells have been shown to take up latex beads nearly 2  $\mu\text{m}$  in diameter [108]. Noninvasive spectroscopic imaging measurements revealed that living cells work to reduce the amount of intracellular crystalline sterol and showed that lysosomes play a major role in this process but little was known about whether SCP-2 might aid in the intracellular dissolution process [38]. L-cells overexpressing SCP-2 were used to determine the rate of disappearance of microcrystalline DHE monohydrate in real-time as compared to control cells. Cellular monomeric DHE that remained within the cell localized in lipid storage droplets and intracellular membranes with substantial accumulation in the plasma membrane as formerly observed in L-cells [38, 58].

Previous studies have demonstrated the ability of protein interaction in facilitating uptake of aqueous dispersions of cholesterol aggregates. In cells overexpressing the scavenger receptor class B type I (SR-BI) it was shown that SR-BI effected uptake of free radiolabeled cholesterol ( $^3\text{H}$  cholesterol) to stimulate cholesterol esterification after a 5 h incubation period with similar effectiveness as lipoproteins [109]. Moreover, SR-BI was shown to facilitate uptake of cholesterol from mixed bile salt micelles [110].

In conclusion, not only the low solubility of cholesterol in aqueous media but also the build up of crystalline patches in cellular membranes presents many challenges to biological systems. However, small lipid binding proteins such as SCP-2 in combination with specialized regions of lipid-protein systems can facilitate and mediate the exchange of sterol though sequestered in microcrystalline form in order to adequately transport and access the sterol

for further utilization. Therefore the observed enhanced transfer effects with SCP-2 reveal the possibility of lipid-protein processes to remediate cholesterol aggregation within the cell. This was demonstrated herein through the use of the naturally occurring fluorescent cholesterol analog, DHE, in monohydrate crystalline structures somewhat resembling that of cholesterol monohydrate but with unique fluorescent spectral properties.

## Historical Perspective

In order to resolve the dynamics and factors governing cholesterol trafficking within cells, it is important to recognize that the cholesterol molecule has very few polar constituents (Fig. 1a). Consequently, cholesterol is poorly soluble in aqueous environments such as cytosol as evidenced by critical micellar concentrations of cholesterol and other sterols being very low, near 20–30 nM [1–5]. The physiological impact of cholesterol's low aqueous solubility is that spontaneous cholesterol desorption from the cytofacial leaflet of the plasma membrane or lysosomal membrane into the cytosol for transfer to intracellular sites for esterification, oxidation, or secretion is extremely slow ( $t_{1/2}$  3 h-days) [6–9]. Therefore, it is important to resolve factors that influence the solubility of cholesterol in the cytoplasm as well as to understand how the architecture and properties of cholesterol in the plasma membrane govern cholesterol movement from serum lipoproteins/albumin into the membrane exofacial leaflet, across the bilayer, and from the membrane cytofacial leaflet into the cytoplasm either as vesicles or to cholesterol binding proteins.

Multiple physical approaches in model or fixed cell systems have been used to resolve the properties of cholesterol in membranes and the influence of cholesterol on membrane structure. Membrane cholesterol organization has been examined using electron microscopy to visualize the membrane at magnifications up to 100,000 $\times$  [10]. X-ray diffraction has been applied to membranes to determine cholesterol orientation and depth as well as determine lipidic crystal structures [11, 12]. By using deuterated molecules and cooled neutron beams, neutron

scattering profiles of phospholipid/cholesterol bilayers have been measured and neutron scatter off of the deuterium atom has been used to accurately determine cholesterol's location within the membrane [11, 12]. Electron scattering has had limited use due to high vacuum requirements but has yielded some packing orientation of cholesterol-rich domains [11–13]. Calorimetry or thermal analysis resolves the effects of cholesterol level on lipid phase transitions in model membranes of various lipid compositions [14]. Unfortunately the complexity of lipid compositions in biological membranes broadens/abolishes lipid phase transitions—thereby limiting the usefulness of calorimetry. By placing the membranes in a strong magnetic field with exposure to electromagnetic radiation, nuclear magnetic resonance (NMR) measurements involving the interaction with the nonzero spin of certain nuclei such as  $^1\text{H}$  and  $^{13}\text{C}$  have provided not only detailed structural information (e.g. order parameter) on cholesterol but also its interaction strengths with phospholipid constituents of the membrane [12, 15, 16]. While  $^1\text{H}$  and  $^{13}\text{C}$  labeled cholesterols provide probes with structure most closely resembling that of cholesterol, it is difficult to incorporate large amounts of these labeled sterols into biological membranes and the time-scale of NMR measurements precludes resolution of cholesterol dynamics on the biological time scale [17]. Another technique, electron spin resonance (EPR) involves the exploitation of the paramagnetism of certain molecules with unpaired spins, usually  $^{14}\text{N}$  [15]. Due to the nature of the low natural paramagnetism of lipids, EPR probes are synthesized with spin labels such as nitroxide free radicals (e.g. dimethyl nitroxide referred to as doxyl). The properties of doxyl labeled sterol analogs such as

**Fig. 1** Structures of cholesterol and fluorescent cholesterol analogs. **a** Naturally occurring sterols: cholesterol and fluorescent sterol dehydroergosterol (DHE). **b** Photo-activatable cholesterol analog (FCBP). **c** Cholesterol-rich microdomain preferring cholesterol analogs: Dansyl-cholesterol (DChol); BODIPY-cholesterol analog (LZ260). **d** Cholesterol-poor microdomain preferring cholesterol analogs: BODIPY-coprostanol analog 3; BODIPY-cholesterol analog LZ110a; 22-NBD-cholesterol

SL-cholestane, SL-cholesterol, and SL-androstane have recently been examined in POPC large unilamellar vesicles (LUVs). Using EPR, it was found that the SL-cholestane was moved deeper within the membrane as a result of the bulky doxyl replacing the OH group but with correct membrane orientation similar to the SL-cholesterol which had the doxyl replacing two methyl groups in the cholesterol tail [16]. However, EPR showed that the SL-androstane molecule was upside down in membrane orientation. This was due to the hydroxyl at the terminal end of the lipid chain and the replacement of the OH by the doxyl group [16]. Other techniques to examine cholesterol architecture in membranes have included radiolabeled methods, Raman scattering, and absorption techniques including infrared and optical rotation dispersion/circular dichroism. While these approaches have been very useful for studies of model membrane systems, purified biological membrane fractions in vitro, or membranes of fixed cells, they have not provided much insight into cholesterol dynamics in living cells.

Obviously, a great deal of effort has been made to design both suitable cholesterol analogs and the respective experimental methods to gain insights into the lipid domain structure and dynamics of biological membranes. Nevertheless, there is concern whether the behavior of the cholesterol analogues truly reflects that of cholesterol. Most of the probes have been chosen for the respective studies based on their close structural and organizational resemblance to the cholesterol molecule in both natural and artificial membranes. Until recently it was almost universally accepted that cholesterol represents the unique and essential building block of the cell membrane which defines, to a great extent, the normal function of biological organisms including man and most animals. Under this paradigm even small alterations in the chemical structure of cholesterol would be predicted to be incompatible with animal life (rev. in [18]). But is cholesterol really essential for normal cell organization and function? How stringent are the stereo- and physico-chemical criteria for the membrane sterol molecule that creates a platform (environment) for membrane proteins? Several studies suggest that many aspects of the original paradigm—i.e. compatibility with life—may be met by sterols other than cholesterol. (i) Simple animal cells such as yeast (*Candida tropicalis*, *Saccharomyces cerevisiae*) and Red Sea sponge (*Biemna fortis*) synthesize dehydroergosterol (DHE, Fig. 1a) as a major membrane sterol component [19–21]. DHE differs from cholesterol by having an ergosterol side-chain (i.e. branched methyl and double bond), an ergosterol B ring (two double bonds), and a C ring with an additional double bond that maintains the extended cyclopentanophenanthrene ring structure (Fig. 1a). (ii) DHE completely replaces the requirement for cholesterol as the only sterol

source in the diet of the worm *C. elegans* [19]. (iii) Mouse L-cell fibroblasts lack the enzyme  $3\beta$ -hydroxysteroid- $\Delta^{24}$ -reductase (desmosterol reductase, Dhcr24) [22]. Desmosterol differs from cholesterol in having an extra double bond in the side chain. When cultured in chemically defined medium the L-cells synthesize desmosterol, replace membrane cholesterol with desmosterol, and grow normally despite the absence of cholesterol [22, 23]. (iv) Mouse L-cells cultured in chemically defined medium containing DHE accumulate DHE which replaces as much as 90% of endogenous membrane sterol without adverse effects on membrane phospholipid or fatty acid composition, sterol/phospholipid ratio, activity of cholesterol sensitive enzymes in the plasma membrane, or cell growth [24]. Similar observations have been made with cultured human fibroblasts and MDCK cells [25–27]. (v) Most of the cholesterol in the developing and early neonatal rat retina can be replaced by desmosterol without alteration in function [28]. (vi) Ablation of the enzyme  $3\beta$ -hydroxysteroid- $\Delta^{24}$ -reductase (desmosterol reductase, Dhcr24) in mice is not lethal and such mice exhibit only a mildly altered phenotype evidenced by disturbances occurring in steroid homeostasis [18, 29]. The development of these viable “cholesterol-free mice”, where almost all of the cholesterol is replaced by desmosterol, shows that there is not an absolute requirement for cholesterol to maintain life [18, 29]. It should be noted, however, that the same mutation in humans causes severe abnormalities, likely due to the inability of human embryos to access maternal cholesterol which is in contrast to mouse embryogenesis where maternal cholesterol is available [18]. Taken together, these data suggest that the membranes of mammalian and other animal cells can tolerate small changes in the structure of the cholesterol side (desmosterol, DHE) and ring structure (DHE) and remain viable. However, not all small changes in the cholesterol structure are equally well tolerated. For example, loss of the Dhcr7 gene in mice (Smith–Lemli–Opitz syndrome in humans) results in accumulation of 7-dehydrocholesterol and very short-lived mice (rev. in [29]). Much further work needs to be done to establish the exact substitutions/changes in cholesterol structure that can be accommodated to maintain viability.

### Advent of Fluorescent Sterols

More recently fluorescence detection has been widely used to study cholesterol not only in vitro, but also in real-time imaging of fluorescent sterols (Fig. 1b–f) in living cultured cells or in vivo. Fluorescent sterols, like other fluorescent probes, provide ease of handling with very high level sensitivity of detection, relatively short detection times, and multiplexing of several probes [17]. These characteristics of

fluorescence detection have made it very beneficial in utilizing small quantities of fluorescent sterols not only for use with traditional spectrofluorometers but also in newly developed systems. In particular, fluorescent sterols and other probes have brought about the widespread use of laser scanning confocal microscopy (LSCM) and multiphoton laser scanning microscopy (MPLSM) to simultaneously study the interaction of lipids like cholesterol and proteins/receptors in real-time within living cells.

With rare exception, the fluorophores present in most commercially available fluorescent sterols (Avanti Polar Lipids, Alabaster, AL; Invitrogen, Carlsbad, CA; Sigma, St. Louis, MO, USA) as well as those synthesized in individual laboratories are synthetic chemical tags that have been used to localize cholesterol in membranes. This includes the weakly fluorescent photoactivatable free cholesterol benzophenone FCBP that photocross-links to proteins or lipids (Fig. 1b), the cholesterol-rich microdomain preferring cholesterol analogs such as dansyl-cholesterol (6-dansyl-cholestanol) and BODIPY-cholesterol analog LZ260 (Fig. 1c), and the cholesterol-poor microdomain preferring BODIPY-coprostanol, BODIPY-cholesterol analog LZ110a, 22-NBD-cholesterol (Fig. 1d), 25-NBD-cholesterol (not shown), etc. [16, 30–38]. Although there is considerable discussion regarding the solubility and orientation of these synthetic fluorescent sterol probes in membrane bilayers, especially 22-NBD-cholesterol and 25-NBD-cholesterol, at low concentrations some are thought to mimic the distribution and orientation of cholesterol [16, 35–37]. However, relatively few have been examined with regards to their ability to be bound by intracellular cholesterol-binding proteins (e.g. SCP-2, ADRP) or their real-time uptake, distribution, and efflux dynamics in living cells. One exception is 22-NBD-cholesterol which has been shown to be not only bound with high affinity (nM  $K_d$ 's) by SCP-2 and ADRP, but with orientation within the binding site similar to cholesterol—suggesting that this probe may be suitable for study of intracellular cholesterol trafficking [4, 39–44]. Indeed, 22-NBD-cholesterol has proven useful for real-time imaging of HDL-mediated cholesterol uptake, efflux, and intracellular trafficking in living cells such as L-cell fibroblasts as well as rat macrophages and lymphocytes [43, 45, 46]. Sterol carrier protein-2 (SCP-2) overexpression facilitated (i.e. decreased  $t_{1/2}$  of efflux) of protein mediated NBD-cholesterol cytosolic efflux [43]. Concomitantly SCP-2 overexpression decreased the slower, vesicular cholesterol transfer—likely by binding and sequestering ligands (i.e. phosphatidylinositides, fatty acyl CoAs) that regulate vesicular trafficking [43, 47–53].

However, there is a small group of naturally fluorescent lipids that includes sterols such as DHE (Fig. 1a) as well as some fatty acids (parinaric acids), retinoids (retinol,

retinoic acid), carotenes, and steroids (estriol). Because of the tremendous interest of biologists and membraneologists in cholesterol-rich microdomains (also called lipid rafts or caveolae) over the past 15 years (review in [54–63], DHE has emerged as a popular, potentially less perturbing fluorescent sterol probe since it does not contain additional bulky fluorescent groups added to the sterol structure. Although this ultraviolet (UV) light absorbing and fluorescent sterol (i.e. DHE) was first chemically synthesized over 50 years ago [64], it was its detection at high level in membranes of eukaryotes such as yeast *C. tropicalis* [19] and Red Sea sponge *B. fortis* [21] that suggested its potential usefulness as a probe for cholesterol. Consequently, the focus of the remainder of the current review is on the use of naturally fluorescent DHE as a probe of cholesterol behavior in sterol-protein interactions, lipoproteins, model membranes, biological membranes, and lipid rafts/caveolae. Since cholesterol itself has very few structural/chemical features suitable for UV/VIS or optical imaging, the advent of DHE with many properties mimicking or very similar to those of cholesterol, has proven to be a major asset for probing/elucidating real-time sterol dynamics by video and MPLSM imaging in living cells. For additional insights, the reader is referred to earlier reviews on DHE, synthetic fluorescent sterols, spin labeled sterols, photoreactive sterols, and chemical tags of cholesterol [65–68].

### Effect of Sterol Structure and Purity on Sterol Architecture and Dynamics in Membranes

Despite the fact that DHE is a naturally occurring fluorescent sterol appearing in sponge and yeast, it is not generally obtained from these sources. Instead, DHE from commercial (Sigma, St. Louis, MO, USA) as well as laboratory sources is chemically synthesized by an adaptation of a 50-year-old method [64, 69–71]. However, synthetic DHE prepared by this established method, especially that obtained from commercial sources, may contain a significant sterol impurity, varying from batch to batch, and as high as 20–40% [43, 70, 71]. It is important to note that not only the quantity, but also the chemical structure of the sterol and the presence of cholesterol oxidation products are known to significantly affect the structure and/or function of model membranes (rev. in [54, 55, 70, 72, 73], biological membranes [13, 74–80], lipid raft/caveolae [58, 81–88], and cholesterol-requiring plasma membrane receptors [66, 89–91]. Because of this sensitivity it is essential that fluorescent sterols such as DHE not contain other sterols (e.g. ergosterol starting material or side products produced during DHE synthesis) or oxidation products. Such sterols/oxidation products may be

non-fluorescent, potentially toxic (e.g. oxidized sterols), alter membrane structure, and/or not faithfully reflect the properties of cholesterol as accurately as pure DHE. This is even more important for real-time imaging of fluorescent DHE in living cells where such impurities may compete with DHE for uptake and/or may be toxic. Therefore, the following text deals with procedures for removing unreacted substrate (ergosterol), identifying side reaction or oxidation products, removing impurities, and modifying the synthesis procedure to prevent these artifacts. The DHE synthesis procedures described below tested ergosterol substrate obtained from several manufacturers (Steraloids, Wilmington, NH, USA; Aldrich Chemical Co., Milwaukee, WI, USA; Fluka Chemie, Steinheim, Switzerland; Sigma Chemical, St Louis, MO, USA), but all other reagents were in common from the same manufacturer: “Purified Plus” methanol, chloroform, and ethyl ether were from Burdick–Jackson (Muskegon, MI, USA); “Baker Analyzed” 99+ % pure glacial acetic acid was from Mallinckrodt Baker (Phillipsburg, NJ, USA), 99+ % pure acetic anhydride was from VWR (Atlanta, GA, USA), and anhydrous mercuric acetate was from Fisher Scientific (Pittsburgh, PA, USA).

#### Identification of Potential Impurities Obtained Through the Classical DHE Synthesis Procedure

DHE was synthesized from ergosterol by a classical procedure established over 50 years ago [64, 69]. Purity of DHE was determined by high performance liquid chromatography as described [69]. The HPLC elution profile was monitored as follows: absorbance at 205 nm (all constituents), absorbance at 325 nm (DHE), and fluorescence emission at 375 nm (DHE). When the elution profile of commercially available DHE was monitored at 205 nm absorbance, at least two major peaks were obtained with retention times of 11.75 and 15.3 min, respectively (Fig. 2a). The latter peak comprised at least 20% of total sterol. To determine which of these peaks represented DHE, the elution profile was monitored by absorbance at 325 nm (Fig. 2b) and fluorescence emission at 375 nm (Fig. 2c). Only the larger peak near 11.75 min absorbed at 325 nm (Fig. 2b) and fluoresced (Fig. 2c). The smaller peak at 15.3 min comprising about 20% of total sterol was not DHE since it did not absorb or fluoresce at wavelengths typical of DHE. HPLC chromatograms (not shown) of DHE prepared by our laboratory from only one lot of ergosterol (Steraloids), but not from subsequent lots from the same or other sources, yielded pure DHE (>99%). All other preparations yielded DHE which was highly (20–40%) impure. To further resolve the impurity, complete absorbance spectra were obtained. The absorption spectrum of >99% pure DHE showed maxima at 310, 325, and 342 nm (Fig. 3a). In contrast, absorbance spectra of impure

**Fig. 2** HPLC analysis of DHE. **a–c** DHE synthesized by established method as described in Methods. **d–f** DHE synthesized by an improved method as described in Methods. Reversed phase HPLC was performed and elution of organic compounds was detected by absorbance at 205 nm (**a, d**). Elution of DHE was specifically detected by absorbance at 325 nm (**b, e**) and by fluorescence emission at 375 nm upon excitation at 325 nm (**c, f**). The peak with retention time at 11.75 min was due to DHE while that at 15.3 min was due to a non-fluorescent sterol

synthetic DHE exhibited several additional peaks at 235, 242, and 251 nm (Fig. 3b), more clearly revealed by a difference spectrum (Fig. 3c). The latter absorbance maxima were not consistent with the starting material, ergosterol, which exhibited absorption maxima at much longer wavelengths 271, 281, and 293 nm (not shown). It is important to note that HPLC elution profiles, whether monitored at 205 or 242 nm (wavelength at which the impurity absorption was highest), were unable to clearly distinguish whether the impurity was unreacted ergosterol or an as yet unidentified compound with similar retention time (not shown). While mass spectra of the impure DHE detected DHE at  $(M + 1)^+$  of 395.3 and  $(M-OH)^+$  of 377.5 as expected (Fig. 4a), an additional component appeared with  $(M + 1)^+$  of 397.3 and  $(M-OH)^+$  of 379.3 (Fig. 4a).

**Fig. 3** Absorption spectra of DHE. **a** Pure (~99%) DHE synthesized by an improved method as described in Methods. **b** Commercially available DHE (Sigma). **c** Difference spectrum was calculated by subtraction of **a** from **b**. This spectrum shows the triene impurity alone. Note: it was necessary to use absorbance spectra to characterize the impurity, since the emission and excitation spectra determined the impurity was non-fluorescent (not shown). **d** UV absorbance spectrum of ergosterol acetate. **e** UV absorbance spectrum taken after 16 h dehydration of ergosterol acetate. **f** UV absorbance spectrum of the resultant DHE acetate with impurity from the dehydration step

Surprisingly the APCI mass spectrum of this additional component was identical to that of ergosterol (Fig. 4b)—suggesting that the impurity was possibly an isomer of ergosterol. Indeed it was reported nearly 60 years ago that small amounts of nitric acid or mercuric nitrate catalyze not only the formation of the tetraene DHE but also a side product, i.e., mercurated triene, of ergosterol due to double bond rearrangement [92, 93]. The spectral characteristics (i.e., maxima at 235, 242, and 251 nm) of the DHE impurity were the same as those of an isomer of ergosterol (5,7,22-cholestatrien-24 $\beta$ -methyl-3 $\beta$ -ol) known as ergosterol  $\text{D}$  [64, 94]. Ergosterol  $\text{D}$  is a triene [i.e. (7,9(11),22-cholestatrien-24 $\beta$ -methyl-3 $\beta$ -ol)] which differs from ergosterol (i.e. 5,7,22-cholestatrien-24 $\beta$ -methyl-3 $\beta$ -ol) in that the double bonds in the B ring are each displaced one carbon atom position.

Based on the above data, a general scheme of DHE synthesis and formation of the ergosterol  $\text{D}$  isomer was established (Fig. 5). This scheme suggests that the synthesis of pure DHE involved steps I, II (but *not* IIA), and III (Fig. 5). The presence of some as yet unknown factor (“impurity”) in starting material ergosterol, however, resulted in rearrangement in the double bonds in the B

ring of ergosterol (essentially a competing side reaction) as shown in step IIA (Fig. 5). This side reaction product was an isomer of ergosterol, ergosterol  $\text{D}$  [i.e. (7,9,22-cholestatrien-24 $\beta$ -methyl-3 $\beta$ -ol)] distinct from the original ergosterol (5,7,22-cholestatrien-24 $\beta$ -methyl-3 $\beta$ -ol) and DHE. In further support of this scheme, the absorbance spectrum of each product during DHE was monitored (Fig. 5). The UV absorbance spectrum of ergosterol acetate (step I, Fig. 5) exhibited three absorption maxima (Fig. 3d) essentially identical to pure ergosterol (not shown). Hence, ergosterol acetate formation did not alter UV absorbance spectrum of ergosterol. In Fig. 3e is shown the UV absorbance spectrum of the intermediate product taken 16 h into the 18 h dehydration step (step II, Fig. 5). This spectrum was broad with vibrational bands that were no longer distinct (cf. Fig. 3d). Figure 3f clearly showed that during formation of DHE acetate (step II in Fig. 5), the side reaction product ergosterol  $\text{D}$  acetate (step IIA in Fig. 5) was concomitantly formed. Finally, saponification (step III, Fig. 5) of the DHE acetate and the ergosterol  $\text{D}$  acetate and recrystallization resulted in a UV absorbance spectrum (Fig. 3f) consistent with presence of both DHE (longer wavelength peaks) and

**Fig. 4** Atmospheric pressure chemical ionization (APCI) mass spectra of the DHE and ergosterol. Mass spectral analysis was performed with a Thermo Finnigan LCQ Deca ion trap liquid chromatograph mass spectrometer (Thermo Finnigan, San Jose, CA, USA) in atmospheric pressure chemical ionization (APCI) ion mode with sample flow rates of 200  $\mu\text{l}/\text{min}$  near the quadrupole ion trap mass analyzer involving ultra-high purity helium gas. Samples were brought up in 1  $\mu\text{M}$  solutions of equal volumes of MeOH and  $\text{H}_2\text{O}$  where both the methanol and  $\text{H}_2\text{O}$  were HPLC grade Burdick and Jackson (Muskegon, MI, USA) purchased from VWR (Atlanta, GA,

USA). **a** Mass spectrogram of impure DHE (Fig. 2a–c). The daughter ion resulting from the parent ion minus a hydroxyl group was indicated by  $(\text{M}-\text{OH})^+$  while plus a proton was indicated by  $(\text{M}+1)^+$ . The impurity was observed as a daughter ion resulting from the parent ion losing a hydroxyl group  $(\text{M}-\text{OH})^+$  and gaining a proton  $(\text{M}+1)^+$ . **b** Mass spectrogram of commercially available ergosterol (99% pure), with the observed  $(\text{M}+1)^+$  and  $(\text{M}-\text{OH})^+$  daughter ions. Note that the ergosterol had the same mass as the triene impurity

ergosterol **D** (peaks between 230 and 260 nm) as indicated.

#### Removal of Impurities from DHE: Modified DHE Synthesis Procedure

The fact that HPLC, absorbance spectra, and mass spectral analysis did not detect any other organic contaminant in ergosterol starting material suggested that a water soluble inorganic contaminant might be a contributing factor to the formation of the non-fluorescent ergosterol **D** side reaction product. Therefore, in an effort to remove potential water-soluble contaminants, the ergosterol was dissolved in chloroform, washed at least three times with an equal amount of deionized water, dried under  $\text{N}_2$ , dissolved in hot methanol and recrystallized three times, and then dried under  $\text{N}_2$ . HPLC analysis to detect all constituents (absorbance at 205) revealed only a single peak was detectable, retention time 11.7 min (Fig. 2d). Likewise, when DHE was specifically monitored by absorbance at

325 nm (Fig. 2e) and fluorescence emission at 375 nm (Fig. 2f) in each case only a single peak was detectable, again with retention time of 11.7 min. HPLC chromatograms and absorbance spectra indicated that DHE synthesized by the modified method was  $\geq 99\%$  pure. Furthermore, APCI mass spectroscopy detected only a single peak with  $>99\%$  (not shown).

#### Monomeric Versus Crystalline DHE

Many of the spectroscopic properties of DHE as a fluorescent sterol probe have been elucidated in organic solvents [64, 65, 95] and in aqueous buffers [69, 70, 96]. In organic solvents such as ethanol, DHE exhibits three UV excitation maxima (311, 324, and 340 nm) and three red-shifted emission maxima (354, 371, and 390 nm) characteristic of the DHE monomer. Interestingly, however, in aqueous buffers DHE exhibits a prominent spectral enhancement of the emission maxima near 404 and 426 nm

**Fig. 5** General scheme of synthesis of DHE. Step I is the conversion of ergosterol to ergosterol acetate. Step II is the dehydration of the ergosterol acetate to form a new double bond in the C ring. Step IIA is the competing side reaction which causes formation of the triene impurity in DHE. Note that this triene impurity had the same molecular mass as ergosterol because it was an isomer of ergosterol, i.e. ergosterol d. Step III is the saponification of the DHE acetate to yield DHE product

as a possible result of excimeric emission—reflecting DHE in microcrystalline structures, but with only a slight (about 5 nm) red shift in both absorbance maxima and emission maxima [70]. For instance, the respective excitation and emission maxima at 324 and 370 nm in ethanol shifted to 329 and 375 nm in aqueous such that the difference in the similar vibronic levels was maintained at 46 nm. This was consistent with solvent polarity (i.e. dielectric constant) or pH having only a very minor effect on DHE and that charge separation does not occur. Many different organic solvents were used in a previous study to show that the Stokes shift varied between 3,867 and 4,000  $\text{cm}^{-1}$  [95]. The DHE excitation and emission of the aqueous dispersion was similar to spectra of DHE polycrystalline powder; and both forms also exhibited similar lifetimes and corresponding fractions in a dual lifetime analysis [96].

Advantage has been taken of the distinction in the spectral characteristics to differentiate monomeric and microcrystalline (mostly in lysosomes) forms of DHE in living cells visualized by multiphoton imaging [70]. In

order to determine quantitatively the amount of the crystalline component and monomeric, the DHE was examined by fluorescence spectroscopy wherein the ratio of fluorescence intensity measurements at the wavelengths 426 and 373 nm was computed. Under monomeric conditions, such as the case in an organic solvent (e.g. ethanol) or low concentrations of DHE in model membranes (e.g. large unilamellar vesicles or LUVs), the ratio was measured as  $I_{426}/I_{373} \sim 0.3$  and would increase to approximately  $I_{426}/I_{373} \sim 3.4$  for an aqueous dispersion of DHE in a buffered solution with pH. 7.4 [70]. Thus, the spectral properties of DHE give important insights on the cholesterol organization in membranes or organelles (e.g. lysosomes).

#### DHE Properties in Lipoproteins, Cholesterol-Binding Proteins, and Peptides

Dehydroergosterol has been directly incorporated into lipoproteins in vitro [97–99] or in vivo by feeding animals (rats,

rabbits) dietary DHE followed by isolation of serum lipoproteins [100, 101]. These studies showed that DHE was localized in the surface monolayer surrounding the neutral lipid cores of triglyceride/cholesteryl ester rich lipoproteins similarly as cholesterol. In addition, DHE and a similar synthetic fluorescent cholesterol analog (cholestatrienol, CTE) have been used to examine the structure of the sterol binding site of cholesterol-binding proteins such as sterol carrier protein-2 (SCP-2) [2, 39, 102–105] and liver fatty acid binding protein (L-FABP) [2, 106, 107]. SCP-2 and L-FABP generally bound one mole of fluorescent sterol/mole protein. The fluorescent DHE or CTE were highly ordered in the binding pockets as indicated by markedly increased polarization as compared to aqueous buffer. The intermolecular distance between the DHE or CTE fluorophore and Trp or Tyr residues of these proteins measured by a fluorescence resonance energy transfer (FRET) in these studies was in the range of 16–19 Å, indicating close molecular interaction [108]. Finally, FRET between Trp of mellitin (peptide from bee venom) and DHE incorporated in model membranes indicated that mellitin bound to the membrane, bound mellitin Trp was in close proximity to DHE (i.e. a few angstroms), and DHE was non-randomly distributed within the model membrane [109]. Taken together these findings were consistent with DHE as a useful probe for examining the interactions and location of cholesterol in cholesterol-binding proteins and lipoproteins.

## DHE Properties in Membranes

### Model Membranes

The usefulness of DHE and cholestatrienol (CTE) as fluorescent cholesterol analogs in model membranes in a series of investigations spanning several decades demonstrated the usefulness of these probes to monitor cholesterol structural (polarization, limiting anisotropy, order) and dynamic (lifetime, rotational rate) properties in membranes [12, 65, 70, 95, 96, 108, 110–120]. The lifetime studies resolved for the first time at least two DHE domains in model membranes, one less sensitive to the aqueous than the other, and that these domains were dependent on the lipid composition, temperature, and other properties of the membrane [54, 119]. This possibility was further supported by model membrane studies of DHE exchange which provided kinetic evidence for the existence of multiple sterol containing domains in membranes [118, 121–124]. DHE was especially useful for these studies because the spontaneous exchange of DHE between model membranes was very similar to that of radiolabeled cholesterol [117]. Further, these dynamic and kinetic pools of DHE represent lateral sterol-rich and—poor domains rather than pools in the outer vs. inner leaflet

because: (i) the transbilayer distribution of sterol across model membrane bilayers is uniform, unless membranes are very highly curved (rev. in [12]), (ii) the transbilayer migration rate of DHE is very rapid (much faster than kinetic exchange rates between membranes) and is very similar to that of cholesterol [108], (iii) Dynamic (lifetime) and DHE kinetic exchange studies determined that the presence of a large and a small DHE pool, (iv) DHE kinetic exchange studies determined that the large sterol pool corresponded to very-slowly (days) exchangeable sterol, while the small pool (generally <10%) was rapidly exchangeable. The pool size and half-times of exchange were dramatically affected by the presence of acidic phospholipids and, even more so by the presence of sphingolipids in the model membranes. The sterol carrier protein SCP-2 rapidly facilitated DHE transfer between model membranes by decreasing the half-time of exchange and increasing the size of the rapidly exchangeable domain. This action of SCP-2 was mechanistically due not only to the presence of a sterol binding site in this protein, but also the membrane interaction domain comprised on a positively charged face of an N-terminal amphipathic  $\alpha$ -helix [125–127]. These studies demonstrated that the properties of DHE and/or CTE closely reflected those of cholesterol in model membranes.

### Suitability of DHE as a Probe for Cholesterol in Biological Membranes

Dehydroergosterol is non-toxic to animal cells as shown by its presence in membranes of yeast (*C. tropicalis*, *S. cerevisiae*) and Red Sea sponge (*B. fortis*) as well as its ability to completely replace cholesterol as the only sterol source in the diet of animals such as *C. elegans* or cultured L-cells [19–21, 24, 128]. Unlike most synthetic fluorescent tagged sterols which can only be incorporated at very low amounts into cell membranes, DHE taken up by cultured cells can replace nearly 90% of total cholesterol without adverse effect on cell viability, plasma membrane structure, plasma membrane phospholipid composition or sterol/phospholipid ratio, or plasma membrane sterol sensitive enzymes [24]. Plasma membrane receptors such as the oxytocin receptor are exquisitely sensitive to the structure of the sterol with which it interacts. In cholesterol-depleted membranes, only cholesterol and DHE are effective in reconstituting activity of this highly sterol-sensitive plasma membrane protein [89–91]. In cultured cells DHE codistributes with cholesterol in plasma membranes, microsomes, mitochondria, and lysosomes [24, 129, 130].

### Delivery of DHE into Cultured Cell Membranes

Dehydroergosterol may be delivered to living cells for uptake and incorporation into plasma membranes by

several methods: (i) While relatively slow, the simplest is *delivery as micro-crystalline DHE* from a stock solution in ethanol over a 2-day period as described previously [24, 70]. DHE can enter the cells by exchange between the micro-crystals and the cell surface plasma membrane, a process that may be facilitated by albumin in the medium [131–134]. Concomitantly, the cultured cells also phagocytose DHE micro-crystals from the medium as shown by MPLSM colocalization with lysosomal markers [70]. Over time the endocytosed DHE micro-crystals may be digested/disrupted in the lysosome or outside the lysosome by intracellular cholesterol-binding proteins such as SCP-2. Consequently, most DHE delivered in this fashion is codistributed similarly as cholesterol in all subcellular membranes including plasma membranes, plasma membrane cholesterol-rich lipid rafts, plasma membrane cholesterol-poor non-rafts, lysosomes, endoplasmic reticulum, and mitochondria [6, 7, 24, 26, 27, 129, 135–137]. The presence of DHE micro-crystals in MPLSM images of cells cultured with DHE micro-crystals can be reduced by pulse labeling the cells with DHE micro-crystals for several hours followed by washing and incubation in DHE free medium for several days. (ii) An even slower, but more physiological method is to *deliver DHE complexed to serum lipoproteins* [100, 101]. In this method, the DHE is dissolved in organic solvent which is used to coat the inside of a tube or (to increase surface area) a tube containing celite (diatomaceous earth), the solvent is evaporated, serum lipoproteins are added in buffer with antimicrobial agent, incubated overnight with shaking at 37 °C, followed by sedimentation to remove particulates and filtration to assure sterility. (iii) A faster, but less efficient method to *deliver DHE as a component of large unilamellar vesicles (LUVs)* over a 1-day period as described previously [70]. The DHE present in the LUVs enters the cell either by exchange with the cell plasma membrane (potentially facilitated by albumin in the medium) or, depending on the charge of the LUV, by facilitated fusion with the cell plasma membrane. While the LUV method completely avoids the presence of micro-crystalline DHE, less total DHE is incorporated into the cells since incubation with larger amounts of LUVs concomitantly results in incorporation large amounts of carrier phospholipid which itself may alter cell membrane properties depending on the specific phospholipid polar head group (e.g. choline, ethanolamine, etc.) and esterified fatty acids (saturated, monounsaturated, polyunsaturated). (iv) The most rapid method for delivery of large amounts of DHE into cells is to *deliver DHE as dehydroergosterol-methyl- $\beta$ -cyclodextrin (DHE-M $\beta$ CD) complexes* prepared by adding DHE to an aqueous solution of M $\beta$ CD (3 mM DHE and 30 mM M $\beta$ CD). This mixture was overlaid with N<sub>2</sub>, continuously vortexed under light protection for 24 h at room

temperature, and filtered through a 0.2- $\mu$ m filter to remove insoluble material and DHE crystals. Then, 20  $\mu$ g of DHE was added to the cells in the form of DHE-M $\beta$ CD complexes and allowed to incubate for 45 min at room temperature in PBS. Prior to imaging, cells were washed three times with PBS. With this technique DHE enters the cell by exchange between the DHE-M $\beta$ CD complexes and the cell plasma membrane. The cyclodextrin-based method for DHE delivery to the cell may proceed, in addition to the clathrin mediated pathway, through the caveolae-dependent endocytosis due to non-selective cholesterol loading onto the plasma membrane by cyclodextrin. The major drawback of this method is that large excess of M $\beta$ CD by itself can deplete cells of cholesterol while very high quantities of DHE-M $\beta$ CD at high molar ratios can increase total sterol content. Therefore, care must be taken to optimize the DHE-M $\beta$ CD molar ratio and concentration in the medium to maintain unaltered total sterol content in the cell and cell membranes.

In summary, the above methods of DHE delivery differ in rapidity, the amount of DHE that can be delivered, and potentially DHE distribution in the cell may differ from one loading method or another. The latter may be an advantage of a particular method if it is desirable to preferentially label a specific cellular compartment. Alternately, if uniform distribution of DHE is desired, this potential problem may be minimized if the cells are incubated over sufficient time for the DHE to equilibrate between all cellular compartments.

#### DHE Architecture in Purified Biological Membranes

Dehydroergosterol has been used to probe the structural (polarization, limiting anisotropy, order), dynamic (lifetime, rotational rate), and kinetic (exchange) environment of cholesterol in plasma membranes [6, 7, 54, 55, 135, 138–141], microsomes [6, 7], mitochondria [6, 7, 142, 143], and lysosomes [8, 129]. DHE has revealed several important structural and dynamic aspects of the cholesterol microenvironment in biological membranes.

First, in contrast to model membranes, DHE was found to be asymmetrically distributed across the plasma membrane bilayer (rev. in [12, 144, 145]). DHE revealed that the cytofacial leaflet of plasma membranes from L-cell fibroblasts [12, 24, 146, 147], erythrocytes [144], and brain synaptosomes [145, 148–151]. While other methods (filipin staining, exchange, cholesterol oxidase accessibility, neutron diffraction, etc.) have also been used to measure transbilayer cholesterol distribution, many have significant limitations including accessibility of membrane cholesterol (filipin, cholesterol oxidase), production of a potential perturbant (cholesterol oxidase produces cholesterone), and poor dynamic resolution (neutron diffraction) (rev. in [12]).

While measurements of transbilayer sterol distribution by different methods may therefore not necessarily agree, multiple methods (DHE, NBD-cholesterol quenching, and exchange assays) indicate that the cytofacial leaflet of erythrocytes has more cholesterol than the exofacial leaflet [144, 152]. Likewise, several methods (DHE, cholesterol oxidase) indicate that the synaptosomal plasma membrane has more cholesterol in the cytofacial leaflet than the exofacial leaflet [12, 145, 148–150]. The transbilayer distribution of sterol is a major determinant of the transbilayer fluidity gradient present in these membranes, the cytofacial cholesterol-rich leaflet is more rigid (less fluid) than the relatively cholesterol-poor exofacial leaflet (rev. in [146, 147, 149, 153–159]). The transbilayer migration rate of DHE in model membranes and plasma membranes is relatively fast,  $t_{1/2}$  of sec–min depending on the membrane examined (rev. in [12, 108, 144, 145]). Rapid transbilayer migration of DHE is also supported by the finding that uptake of DHE into and non-vesicular transport across cultured hepatocyte-derived cells (i.e. from basolateral to canalicular plasma membrane) is also very rapid, i.e.  $t_{1/2}$  of 1–3 min [160]. The finding of rapid transbilayer sterol movement suggested that the asymmetric transbilayer distribution in the plasma membrane was not due to restricted movement of cholesterol from one leaflet to the other, but was instead a property of the lipid bilayer itself. DHE transbilayer distribution has broad applicability in studies of the action of anesthetics, cholesterol lowering drugs (statins), alcohol (chronic and acute), lupus erythematosus, aging, apoE, and sterol carrier proteins all of which can alter plasma membrane or synaptosomal plasma membrane transbilayer sterol distribution and/or transbilayer fluidity [26, 135, 136, 145, 149, 150, 154, 161–172].

Second, the DHE lateral distribution in both model and biological membranes was not uniform, but instead reflected sterol-rich and poor domains (rev. in [54, 55]). The exchange kinetics of DHE and radiolabeled cholesterol between model membranes was indistinguishable [117]. For a kinetic sterol exchange assay between biological membranes, cellular organellar membranes can be isolated from cells supplemented with DHE to act as donors and without supplementation of DHE to act as acceptors. Not only exchange kinetics but also lifetime analysis resolved multiple sterol domains; and cholesterol binding/transfer proteins such as SCP-2 (and less so L-FABP) rapidly facilitated DHE transfer from these purified membrane fractions to other intracellular membranes in vitro [54, 55]. With regards to cholesterol movement between purified intracellular organelle membrane fractions, the most rapid spontaneous DHE transfer occurred from mitochondrial membranes to microsomal membranes, mitochondrial to lysosomal and to plasma membranes, and plasma membranes to microsomal membranes [173]. Least rapid

spontaneous DHE transfer occurred from lysosomal to plasma membranes. However, in the presence of the SCP-2, the DHE transfer was markedly enhanced in the approximate order of plasma membrane to microsomal membranes and plasma membranes to lysosomal membranes [173]. This order was followed by enhanced transfer from mitochondrial membranes to microsomal membrane, mitochondrial membranes to plasma membranes, and a nearly equal transfer between mitochondrial and plasma membranes. Other than the transfer between mitochondrial and plasma membranes, the reverse transfer was markedly slower in both spontaneous and SCP-2 mediated [173]. Thus, in vitro exchange dynamics of DHE revealed that: (i) spontaneous sterol transfer was very slow, but vectorial; (ii) spontaneous sterol transfer from lysosomes and lysosomal membranes was extremely slow, despite the fact that this is the route of LDL-receptor mediated cholesterol uptake; (iii) cholesterol-binding proteins such as SCP-2 rapidly enhanced the extent and directional transfer of sterol transfer from lysosomes and lysosomal membranes to the plasma membrane.

#### Physiological Significance of in Vitro Studies with DHE and Other Fluorescent Sterols: Cultured Cells and Animals

The significance of the above findings in living cells was confirmed with DHE and other fluorescent sterols in a variety of cultured cells including L-cells, CHO cells, macrophages, and hepatocyte derived cell lines [39, 43, 45, 160, 174–176]. Studies with transfected L-cells showed that uptake and efflux of fluorescent sterols was highly dependent on the expression of cholesterol binding proteins (e.g. such as SCP-2) in the cytosol. Furthermore, transhepatocyte transfer of DHE was very rapid and not vesicular. Since hepatocytes have very high levels of intracellular cholesterol binding proteins (e.g. SCP-2, L-FABP) taken together such data suggested that rapid transhepatocyte cholesterol trafficking from the basolateral to canalicular membrane for efflux was facilitated by these proteins in the cytosol. The physiological impact of cholesterol binding proteins such as SCP-2 and L-FABP on cholesterol uptake, esterification, and excretion into bile was confirmed by studies with SCP-2 transgenic (i.e. overexpressing or antisense cDNA treated) mice and rats [177–179] and gene-targeted mice wherein SCP-2/SCP-x [180–182], SCP-x [183], or L-FABP [184–189] were ablated.

Studies with radiolabeled cholesterol were consistent with many of the findings shown with the fluorescent DHE and other sterols in cultured cells [43, 45, 172, 190–197]. In one study, it was shown that overexpression of L-FABP in L-cell fibroblasts enhanced the transfer of radiolabeled cholesterol from the plasma membrane to the endoplasmic

reticulum for esterification [194]. Transfer was inhibited by drugs that bound/competed with cholesterol for the L-FABP binding site. In another study, L-cells were transfected with the cDNA that encodes for the 13.2 and 15 kDa SCP-2 proteins respectively. In nearly all tissues and cells examined the 15 kDa SCP-2 undergoes complete N-terminal post-translational cleavage to yield the mature 13.2 kDa SCP-2 (rev. in [173]). Despite the fact that only the 13.2 kDa protein was found in both cases, different effects on the intracellular trafficking of cholesterol were observed [191]. In early experiments using radiolabeled cholesterol, 15 kDa SCP-2 transfected L-cells showed an enhanced uptake of [<sup>3</sup>H]cholesterol after 4 hours including a resultant increase in esterification of the exogenous radiolabeled cholesterol as shown by the 30% increase in [<sup>3</sup>H]cholesteryl ester levels with no enhancement in the 13.2 kDa SCP-2 transfected L-cells as compared to the control cells. Both the 15-kDa- and the 13.2-kDa SCP-2 transfected L-cells showed a significant increase (15- and 11-fold, respectively) in the initial [<sup>3</sup>H]cholesteryl ester synthesis rate compared to control cells after treatment with sphingomyelinase. This experiment was important in order to examine the effect of SCP-2 expression on the intracellular movement of cholesterol from the plasma membrane to the endoplasmic reticulum for esterification [192]. The resulting data corresponded with the aforementioned fluorescent *in vitro* assays where greater enhancement occurred in the direction of exchange of DHE from plasma membrane to microsomal vesicle [6, 173]. The increased rate in ester synthesis resulted in a 1.5 increase in the [<sup>3</sup>H]cholesteryl ester levels, while at saturation (1 hr treatment), the radiolabeled cholesteryl ester levels were increased 1.6- and 1.3-fold for 15- and 13.2-kDa SCP-2 overexpression [192]. Inhibition of microsomal cholesteryl ester synthesis by drug treatment in the sphingomyelinase treated cells showed no differences. The overexpression of 13.2-kDa SCP-2 did not elevate cholesterol homeostasis of free cholesterol while elevating esterified cholesterol levels [192]. Treatment with [<sup>3</sup>H]oleic acid revealed that the 15-kDa SCP-2 overexpression resulted in a specific increase of cholesterol esterification as opposed to the 13.2-kDa SCP-2 overexpression which resulted in esterification into triacylglycerols [192]. Using [<sup>3</sup>H]cholesterol and the fluorescent 22-NBD-cholesterol in conjunction with high density lipoproteins (HDL), L-cells overexpressing SCP-2 were shown to inhibit the HDL mediated efflux of cholesterol of 61 and 157%, respectively [43]. However, most of the inhibition occurred in the slower component while the faster component of the efflux pool (protein-mediated) was somewhat less affected. Clearly, both the radiolabeled cholesterol uptake and HDL-mediated 22-NBD-cholesterol efflux studies in living cells reveal that the effects of SCP-2

expression on cellular cholesterol transport become increasingly significant over longer time periods.

Overexpression of SCP-2 also had an inhibitory effect on the *in vitro* enhancement of SCP-2 on the exchange of DHE and cholesterol between purified lysosomal membranes as seen by the initial rates [8]. Lipid analysis of lysosomal membranes revealed a significant decrease in the cholesterol to phospholipid ratio as a result of a small decrease in the cholesterol mass with a corresponding increase in phosphatidylserine; however, lyso-bis-phosphatidic acid (LBPA), which is involved in lysosomal cholesterol trafficking, was dramatically decreased by nearly threefold. Furthermore, sterol exchanges involving lysosomal membranes isolated from normal CWN human fibroblasts and NPC1 human fibroblasts revealed an apparent similar effect [25]. The exchange of sterol from the fast kinetic pool was increased dramatically (twofold increase in initial rate) upon addition of SCP-2 *in vitro* for the NPC1 lysosomal membranes when compared to the control CWN lysosomal membranes as determined by DHE polarization exchange assays. The decreased expression of SCP-2 in NPC1 fibroblasts, as seen in murine models of Niemann-Pick type C disease [198], allowed for a higher exchange rate of the fast kinetic pool as compared to CWN fibroblasts with larger normal expression of SCP-2. In fact, the lysosomal membranes from CWN human fibroblasts showed much slower spontaneous initial rate of sterol exchange as well. However, the trend was reversed in the slower but larger kinetic pool, where higher levels of SCP-2 caused a higher rate of sterol transfer *in vitro*. Both cell types exhibited similar sterol kinetic pool fractions for the isolated lysosomal membranes [25] despite differences in sterol transfer rates. With the exception of the pool fraction sizes, sterol transfer characteristics examined as a function of expression of SCP-2 in lysosomal membranes isolated from control and transfected murine fibroblasts appeared consistent with those seen in CWN and NPC1 human fibroblasts [8] possibly through membrane lipid domain alteration and/or involvement with LBPA [199]. Exchanges between lysosomal donors to mitochondrial acceptors revealed similar results whereas SCP-2 overexpression removed the fast kinetic pool but enhanced the slower kinetic pool both in rate and in pool size [173]. In the reverse exchange (mitochondrial donor to lysosomal acceptors), no fast kinetic pool was detected in the control. However, SCP-2 overexpression still reduced the early exchange of sterol as seen by the 6-fold reduction in initial rate by shifting most of the sterol into the non-exchangeable pool [173]. In part, this might explain the large pool of non-exchangeable sterol observed in exchange assays using mitochondrial membrane vesicles isolated from steroidogenic MA-10 Leydig cells [143].

Thus, modulation of directional cholesterol transport and cholesterol esterification as well as membrane lipid composition has been demonstrated to occur as a function of expression levels of L-FABP or SCP-2, possibly through the interaction of proteins/receptors involved with cholesterol trafficking and lipid sensing/signaling. The resulting evidence has been obtained with assays using different labeled sterols including the fluorescent cholesterol analog DHE.

### Plasma Membrane Sterol-Rich Microdomains: In Vitro Studies

Based on findings with delivery of dansyl-cholesterol, the method and duration of fluorescent sterol delivery (e.g. micro-crystals, lipoproteins, LUV, or cyclodextrin complexes) may affect the distribution of fluorescent sterol to lipid rafts/caveolae or non-rafts (see Sect. 6.3 and [32]). When transformed cells (L-cells, MDCK cells) or primary mouse hepatocytes were cultured with DHE (micro-crystals or LUV) under conditions to maximize DHE incorporation and equilibration, biochemical fractionation by affinity chromatography of purified plasma membrane vesicles yielded sterol-rich lipid rafts/caveolae, caveolae, and lipid rafts, respectively [26, 27, 70, 136]. DHE was codistributed similarly as cholesterol into sterol-rich and—poor domains [26, 27, 70, 82, 102, 135, 136, 172, 182, 196]. Lipid raft/caveolae associated receptors such as the oxytocin receptor are sensitive to the structure of the sterol with which it interacts and both cholesterol and DHE, but not other sterols, are effective in reconstituting activity of this highly sterol-sensitive plasma membrane protein in cholesterol-depleted lipid rafts/caveolae [89–91]. DHE mobility (fluorescence polarization) differed significantly in lipid rafts/caveolae from non-rafts. While spontaneous DHE transfer from lipid rafts/caveolae was relatively slow, that from non-rafts was essentially non-detectable. SCP-2 dramatically enhanced DHE transfer from lipid rafts/caveolae, but not from non-raft domains. Further examination of the plasma membrane cholesterol partitioning revealed that sterol transfer, as resolved using DHE in fluorescence polarization kinetic assays, from caveolae/raft domains with introduction of SCP-2 was enhanced as compared to plasma membrane vesicles [136]. Principally, the initial rate of the caveolae/raft fractions was increased by a factor of 5 with a larger portion of the sterol arranged in an exchangeable kinetic pool as compared to the overall plasma membrane fraction [136]. A possible mechanism for this enhancement may involve: (i) SCP-2 directly binding cholesterol as shown by fluorescent sterol binding assays and cross-linking by photoactivatable cholesterol (Fig. 1b) [39–41,

44]; (ii) SCP-2 directly interacting with caveolin-1 within the plasma membrane as observed from in vitro (coIP, CD) and in vivo (two hybrid, double immunofluorescence FRET, double immunogold EM) assays that revealed an average molecular interaction distance of  $\sim 48\text{\AA}$  was measured [200]. Specifically, SCP-2 has been shown to directly interact with the N-terminal sequence of amino acids of caveolin-1 [201]. Finally, DHE transfer from lipid rafts/caveolae to serum lipoproteins was remarkably specific for the type of lipoprotein/apoprotein, while that to non-rafts was very slow and not specific [27]. The importance of resolving cholesterol structure and dynamics in these cholesterol-rich plasma membrane microdomains is underscored by the fact that lipid rafts/caveolae function not only in reverse cholesterol transport, but also in cell recognition, signaling, immune function, and potocytosis (rev. in [58, 60, 82, 84, 85, 87]). Furthermore, lipid rafts/caveolae were shown to mediate the action of potential bioterror toxins and serve as entry portals for a host of bioterror pathogens (rev. in [82, 202]).

### Plasma Membrane Sterol-rich Microdomains: Real-time Imaging of DHE in Plasma Membranes of Living Cells

Recent improvements in imaging microscopy allowed the direct, real-time visualization of DHE in living cells by conventional (DHE delivered as micro-crystals) or video (DHE delivered as cyclodextrin complexes) UV fluorescence microscopy [39, 160, 174–176] and by MPLSM (DHE delivered as LUV or micro-crystals) multiphoton laser scanning microscopy [71, 82, 203, 204]. Analysis of intracellular localization and distribution of DHE at the plasma membrane can be accomplished after segmentation of specific regions of interest such as cellular organelles and performed on a cell by cell basis [70, 203]. Previously, two techniques involving image segmentation of the plasma membrane of cells labeled with DHE and multiple fluorescent probes (i.e. Nile Red, ECFP-Mem, and DiO) were validated and compared [203]: (i) subtraction and sliding window and (ii) rank statistic-based methodology. The subtraction technique was performed with the DHE and Nile Red colocalization experimental results by subtracting the DHE channel from the Nile Red channel. This procedure worked very well with Nile Red as it only very weakly stained the PM as compared to the significantly brighter labeling by the DHE. Noise was reduced by using a sliding window analysis technique where window size, intensity thresholding, and the signal to noise ratio was optimized. In the rank statistic-based technique, two small windows are created in the image

and the pixel intensities in each window ranked from the lowest to highest; then a comparison is made by using Miller's rank statistic. The solution is optimized based upon intensity thresholding. The segmented plasma membrane regions were smoothed using geometric moments functions based on the intensity distribution within the segmented PM. Subsequently, geometric reference and spatial intensity measurements were calculated. Spatial statistical analysis was performed using pixels with DHE intensities higher than the median intensity to test for complete spatial randomness (CSR). Monte Carlo simulations were run using the narrowed

data set (peak intensities—relative higher concentrations) as well as the complete data set [203].

#### Multiphoton Imaging of DHE Incorporated into L-Cells from Ethanolic Stock Diluted in Aqueous Medium

L-Cell fibroblasts grown on chambered coverglass were incubated with the fluorescent sterol analog, DHE, from ethanolic stock solution as described above and imaged by multi-photon microscopy. Despite multiple washings of the cells, images from a single channel covering the range 350–450 nm revealed very bright patches of fluorescence

**Fig. 6** Real-time multiphoton imaging of DHE in living L-cell fibroblasts. L-cells were plated onto chambered coverglass incubated with DHE by three different techniques and imaged by multi-photon laser scanning microscopy using a MRC-1024MP system with external non-descanned detection. Excitation occurred at a wavelength of 900 nm using a femto-second modelocked titanium:sapphire laser and the emission was detected through a D400/100 and UV 440LP dichroic filter. **a** Image of L-cells that were incubated for two days with 20 µg DHE from ethanolic stock solution added to 1 ml media (ethanol < 0.5%) wherein large accumulation of crystalline

DHE occurred. The high intensities (crystalline DHE) was kept under saturation levels and within the instrumental dynamic range; thus lowering the sensitivity of detection of monomeric DHE within the plasma membrane. **b** Image of L-cells that were incubated for one day with 20 µg DHE in the form of large unilamellar vesicles (65:35 mol % POPC:DHE). **c** Image of L-cells that were incubated for 45 min with 20 µg dehydroergosterol methyl-β-cyclodextrin complexes. *Insets* Regions that included a section of the plasma membrane and outlined in a white rectangle were magnified  $\times 2.5$ . *Bars* 20 µm

emission (Fig. 6a). By monitoring the ratio of the 455 to 375 nm region, the areas that were either mostly micro-crystalline or mostly monomeric were distinguished [70]. The micro-crystalline DHE phagocytosed by the cells was largely found to be in lysosomes [70] but breakdown of the microcrystals occurred over time ( $\sim 2$ –3 days) such that monomeric DHE was distributed throughout the cell into the plasma membrane, lipid storage droplets, endoplasmic reticulum, and other organellar membranes. This was also observed in organelles isolated from cells incubated for several days on DHE from ethanolic stock solution [6, 8, 70, 102, 129]. As a result of the increased localized concentration of micro-crystalline DHE and its enhanced excimeric fluorescence, difficulties arise in detecting low to moderate amounts of monomeric DHE (Fig. 6a, inset). This is due to the intense emission arising from crystalline DHE which can cause saturation of the PMTs [70, 204]. Plasma membrane sterol can be detected by imaging cells that do not have residual large amounts of crystalline DHE.

#### Multiphoton Imaging of DHE Incorporated into L-Cells from LUV Diluted in Medium

Dehydroergosterol in the form of LUVs was taken up by living cells (Fig. 6b) in largely monomeric form as indicated by the emission peak ratios [70]. There was almost no appearance of DHE micro-crystals [70]. As a result, sensitivity of detection can be increased by using an emission dichroic/filter combination with broader bandwidth and higher photomultiplier gain. Thus, DHE with its low quantum yield can easily be detected at the plasma membrane (Fig. 6b, inset) and in intracellular compartments as had been observed from previous spectroscopic studies [8, 70, 102, 135, 172]. Signal saturation may occur as a result of accumulation of unesterified or esterified monomeric DHE in lipid storage vesicles (Fig. 6b), distinct and much less intense than micro-crystalline DHE observed in lysosomes upon culturing cells with DHE micro-crystals. MPLSM images of cells supplement with DHE as LUV revealed that DHE was non-randomly distributed into sterol-rich and poor-domains within the plasma membrane of living L-cells [70, 203, 204].

#### Multiphoton Imaging of DHE Incorporated into L-Cells from DHE-M $\beta$ CD Complexes Diluted in Aqueous Medium

L-Cell incubation with DHE-M $\beta$ CD complexes also yielded the monomeric DHE form as visualized by real-time multi-photon imaging in a confocal slice through the cell (Fig. 6). Within 45 min, heterogeneous regions of the plasma membrane were strongly labeled with DHE (Fig. 6c, inset), evidenced by the strong patchy outline at

the cellular periphery. Other intracellular membranes were weakly labeled throughout the cell (Fig. 6c). In many of the cells, morphological structures such as microvilli and filopodia were also visible as a result of the strong signal from the fluorescent DHE. The non-random distribution of DHE in to sterol-rich and poor-domains at the plasma membrane was consistent with other studies wherein DHE was supplemented as LUV to the cells [70, 203, 204]. This would suggest that supplementation of cells with DHE-M $\beta$ CD complexes also non-selectively loaded the different domains in the plasma membrane.

#### Image Analysis of DHE Distribution After Multiphoton Imaging

While MPLSM and visual inspection of DHE at the plasma membrane of cells supplemented with DHE as micro-crystals, LUV, or DHE-M $\beta$ CD complexes revealed that DHE was non-randomly distributed into sterol-rich and poor domains, a mathematical framework substantiating this observation requires additional analysis [70, 203, 204].

Image analysis originally consisted of intensity measurements using region of interests and the use of colocalization, ratiometric, and fluorogram techniques. Further structured segmentation of the plasma membrane has permitted examination of the distribution of DHE through the use of inferential statistics, utilizing hypothesis testing and correlation determination, and has opened up an opportunity to do distributional modeling [71, 203]. Segmentation analysis of the MPLSM images of cells supplement with DHE as LUV confirmed that DHE was indeed non-randomly distributed into sterol-rich and poor-domains within the plasma membrane of living L-cells [203, 204].

#### Summary and Discussion

The naturally occurring fluorescent sterol DHE [19, 21] has proven a powerful probe for use in investigating membrane structure and cholesterol domain dynamics in vitro [8, 54, 55, 65, 70, 102, 172], for examining cholesterol-protein interactions in vitro [2, 39, 96, 101, 102, 108, 205], and for first time visualization in real-time of the distribution of cholesterol in the plasma membranes in living cells [70, 203, 204]. Successful application of the fluorescent DHE to investigation of the function and organization of sterols in membranes, especially lipid raft/caveolae microdomains of living cells, requires the use of highly purified DHE. This is due to the fact that lipid rafts/caveolae are highly sensitive not only to cholesterol content [58, 60, 82, 84, 85, 87, 88], but also to sterol structure [89], and sterol oxidation. The

present review yielded new insights into this problem and potential applications of DHE imaging in living cells.

The presence of a non-fluorescent sterol impurity was observed not only in commercially available DHE, but also in DHE synthesized in the present laboratory from ergosterol obtained from multiple commercial sources. The appearance of the non-fluorescent sterol impurity was somewhat variable (20–40%) depending on the commercial source and batch of the ergosterol substrate but without dependence on any other reagent used for the synthesis. While both HPLC and APCI mass spectroscopy suggested that the impurity was either ergosterol or an ergosterol isomer, the unique UV spectral absorption characteristics of this impurity provided evidence that the non-fluorescent sterol impurity was an isomer of the initial ergosterol (5,7,22-cholestatrien-24 $\beta$ -methyl-3 $\beta$ -ol). This isomer, known as ergosterol D [i.e. 7,9(11),22-cholestatrien-24 $\beta$ -methyl-3 $\beta$ -ol], was not present in the ergosterol starting material but potentially arose from the rearrangement of double bonds in the B ring of the ergosterol during the dehydration step (Step IIA, Fig. 5). Purifying the ergosterol created a non-detectable yield of the ergosterol D impurity during DHE synthesis. While the nature of the water soluble component facilitating formation of the side reaction ergosterol D isomer was not identified, it has been reported that small amounts of nitric acid or mercuric nitrate catalyze the formation of the tetraene DHE as well as a side product, i.e., mercurated triene, and so such impurities may be possible contaminants in the original ergosterol [64].

Recently, real-time multiphoton imaging of the naturally occurring fluorescent sterol DHE in the plasma membrane of living cells [70, 82, 203, 204] was used to examine sterol distribution directly with high optical sectioning capability [206–209]. While subcellular distribution (plasma membrane, lysosome, lipid droplet, etc.) of DHE was highly dependent on the method of delivery (microcrystals, LUV, M $\beta$ CD), DHE at the plasma membrane was found to be distributed non-randomly into sterol-rich and sterol-poor regions in plasma membranes of living cells with the size range of sterol-rich clustering domains estimated to be from 200 (limit of optical microscopy) to 565 nm [70, 71, 82, 203]. Due to the diffraction limit of resolution, there is uncertainty about whether these regions, as visible under laser scanning microscopy, are contiguous lateral domains [70, 71, 203] or represent artificial enhancement of the intensity as a result of microvillar/filopodial extensions and/or folding [210, 211] of the plasma membrane.

Video imaging studies involving HepG2 cells had resolved regions in the size range of 2,000–3,000 nm and had shown evidence of sterol-rich and sterol-poor distribution in the plasma membrane as well as canalicular microvilli of the polarized cells [210]. It was concluded, however, that these were not regions of enrichment but

represented microvilli [210]. This same conclusion was reached following subsequent video imaging studies involving methyl- $\beta$ -cyclodextrin complexes using a pulse chase method and the cell lines Hep G2, J774, and TRVb1 [211] where artifactual enhancement of the fluorescent emission was the result of rough surface topology and cell protrusions [211]. However, other studies using filipin, which labels all cholesterol in the plasma membrane without differentiating between sterol-rich or sterol-poor, did not reveal any enhancement in intensity as a result of plasma membrane ruffling or tubule sizing issues [212, 213].

Differences in results obtained by video imaging may be due to several factors: strong photobleaching of the fluorescent sterol as a result of video imaging techniques, saturation of all the plasma membrane with fluorescent sterol for video imaging, and video imaging's weak resolution in the Z-axis facilitating the need for deconvolution. In contrast, the MPLSM imaging studies used a loading methodology wherein only small amounts (non-saturable) of DHE were introduced into the plasma membrane over longer period of time to minimize the initial perturbations within the membrane [70, 71, 203]. With multi-photon excitation used in MPLSM, less extraneous photobleaching of the fluorescent sterol occurred with fluorescence emission from only the excitation volume at a radial resolution on the order of 300 nm while shorter dwell times minimized photodamage. The combination of probing sterol organization and distribution with low amounts of fluorescent sterol together with the resolution enhancement resulting from low yield in the 3-photon excitation volume element, cross-interference from the rough surface topology was reduced.

Available data from many experimental studies of the plasma membrane in general suggest cholesterol is the driving force for microdomain formation and cholesterol is not uniformly or homogeneously distributed but that the plasma membrane of living cells consists of areas of cholesterol segregation (regions that are cholesterol-rich and cholesterol-poor) [56, 214]. Biochemical studies also support this concept and demonstrate that purified cholesterol-rich microdomains isolated from cultured cell (L-cell, MDCK, primary hepatocytes) represent nearly one-third of the plasma membrane, are rich in cholesterol as well as saturated/monounsaturated fatty acylated phospholipids, and are comprised of physically distinct, liquid-ordered membrane phases intermediate between fluid liquid-crystalline and rigid gel phases [26, 82, 102, 136, 172, 182, 215–217]. Studies with purified microdomains from L-cell and MDCK plasma membranes showed that both exogenous (e.g. HDL) and endogenous (e.g. SCP-2) cholesterol binding proteins preferentially donate or extract cholesterol from cholesterol-rich, but not cholesterol-poor,

microdomains [26, 27, 136, 137, 172]. The microdomain/lipid raft concept, despite controversy in details, provides a framework for biologists studying localization and function of membrane protein receptors, transporters, and downstream signaling molecules that regulate uptake of cholesterol [86, 87, 218–239], fatty acids [240–242], glucose [243–254], and other activities [216, 255–260].
