Abstract Major behavioral and neurochemical features observed between inbred C57BL/6 and DBA/2 mouse strains can be reproduced within rodent strains following dietary-induced reductions in brain docosahexaenoic acid (DHA, 22:6n-3) composition. It was therefore hypothesized that C57BL/6 and DBA/2 mice exhibit constitutive differences in brain DHA composition that are independent of diet. To test this, adult C57BL/6J and DBA/2J prefrontal cortex, hippocampus, ventral striatum, and midbrain fatty acid composition was determined by gas chromatography. After correction for multiple comparisons, C57BL/6J mice exhibited significantly lower DHA composition in the hippocampus and ventral striatum, but not prefrontal cortex or midbrain, and significantly greater regional arachidonic acid (ARA, 20:4n-6):DHA ratios, relative to DBA/2J mice. C57BL/6J mice also exhibited significantly lower regional adrenic acid (ADA, 22:4n-6) composition, and a significantly smaller ADA:ARA ratio, relative to DBA/2J mice. C57BL/6J mice exhibited significantly smaller oleic acid:stearic acid ratio in the hippocampus and ventral striatum relative to DBA/2J mice. Among all mice, DHA composition was positively correlated with the ADA:ARA ratio and inversely correlated with the oleic acid:stearic acid ratio. These data demonstrate that inbred C57BL/6J and DBA/2J mouse strains exhibit constitutive

and region-specific differences in fatty acid composition independent of diet, and suggest that heritable genetic factors are an important determinant of central fatty acid composition.

Introduction

Mammalian brain lipids are composed of a ratio of saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids (PUFA). The principal PUFAs in the mammalian brain are the omega-6 fatty acid arachidonic acid (ARA, 20:4n-6) and the omega-3 fatty acid docosahexaenoic acid (DHA, 22:6n-3). Within brain tissues, DHA and ARA preferentially accumulate in synaptic membranes [1, 2] where they are predominantly esterified into the *sn*-2 position of phosphatidylethanolamine and phosphatidylserine phospholipids [3]. Following mobilization by different phospholipase A₂ (PLA₂) isoforms, ARA and DHA have opposing effects on second messenger [4] and inflammatory [5] signaling pathways. Dietary-induced elevations in the brain ARA:DHA ratio secondary to reduced DHA composition during perinatal development are associated with abnormalities in neurotransmitter systems including dopamine and serotonin [6] and behavior [7] in adult rodents. Moreover, significant deficits in DHA composition, and elevations in the ARA:DHA ratio, are observed in postmortem prefrontal cortex of patients with recurrent neuropsychiatric disorders, including schizophrenia [8], bipolar disorder [9], and major depression [10]. These data suggest that a

high ARA:DHA ratio may be detrimental to normal brain development and function.

Because mammals are incapable of synthesizing omega-3 and omega-6 fatty acids *de novo*, they are entirely dependent on dietary sources to procure and maintain adequate peripheral and central tissue content. The dietary omega-3 fatty acid precursor alpha-linolenic acid (ALA, 18:3n-3) and dietary omega-6 precursor linoleic acid (LA, 18:2n-6) are converted to DHA and ARA, respectively, following a series of common and competitive microsomal desaturation-elongation reactions mediated predominantly by the liver [11]. The final synthesis of DHA requires additional metabolism within peroxisomes [12]. Stearoyl-CoA desaturase (*SCD*, delta-9 desaturase) mediates the synthesis of oleic acid from stearic acid [13], and *SCD* expression and activity is down-regulated by PUFAs including DHA [14]. Major desaturase (*FADS1*, delta-5 desaturase, *FADS2*, delta-6 desaturase), elongase (*ELOVL2/5*), peroxisome biogenesis (*PEX*), and the *SCD* gene are expressed in both liver and brain [11, 15–17]. Additionally, multiple gene products regulate cellular fatty acid transport [18]. Inherited polymorphisms in PUFA biosynthetic genes are associated with deficits in human peripheral and/or central membrane PUFA composition [19–22]. Collectively, these data indicate that heritable genetic factors are an important determinant of tissue fatty acid composition independent of diet.

C57BL/6 (C57) and DBA/2 (DBA) mice have been inbred for over 200 generations and are among the most widely used mouse strains in genetic research. Comparative studies have revealed major phenotypic differences that are independent of diet, including hippocampus protein kinase C (PKC) expression/activity [23], hippocampus-dependent learning performance [24], regional dopamine D₂ receptor binding density [25], mesocorticolimbic dopamine activity [26], locomotor response to psychostimulant drugs [27], and immobility in the forced swim test [28]. Importantly, within rodent strains dietary-induced reductions in brain DHA composition, and associated elevation in the ARA:DHA ratio, are also associated with phenotypic differences, including hippocampus PKC expression [4], hippocampus-dependent learning performance [29], regional dopamine D₂ receptor binding density [30], mesocorticolimbic dopamine neurotransmission [31], locomotor response to psychostimulant drugs [32], and immobility in the forced swim test [33]. Furthermore, we have recently found that dietary-induced deficits in brain DHA composition significantly augment behavioral sensitization in response to repeated amphetamine treatment within both adult C57 [34] and DBA [35] strains. Based on these data, it was hypothesized that C57 and DBA mice maintained on the same diet would exhibit constitutive differences in regional brain DHA composition. To test

this, we determined the fatty acid composition of the prefrontal cortex, hippocampus, ventral striatum, and midbrain of adult male C57BL/6J and DBA/2J mice maintained on the same diet.

Experimental Procedures

Animals and Diet

Adult (8 week) male inbred DBA/2J and C57BL/6J mice were purchased from Jackson Laboratories (Bar Harbor, MA). Mice were housed in groups of 4 per cage and food and water were available *ad libitum*. Mice were maintained on the same commonly used Purina LabDiet (5010) from conception until the time of sacrifice. Diet nutrient composition can be obtained at <http://www.labdiet.com/5010-head.htm>, and diet fatty acid composition is presented in Table 1 (described below). Following 2 weeks of acclimation to the animal vivarium, mice were sacrificed by decapitation (at 10 weeks), brains extracted and placed into ice-cold 0.9% NaCl for 2 min. Brains were then dissected on ice to isolate bilateral prefrontal cortex, hippocampus, ventral striatum (inc. nucleus accumbens, islands of Calleja), and midbrain (inc. ventral tegmentum, substantia nigra). The olfactory tubercle and residual striatal tissue were dissected from the prefrontal cortex. Tissues were placed in cryotubes, flash frozen in liquid nitrogen, and stored at –80 °C. All experimental procedures were approved by the University of Cincinnati Institutional Animal Care and Use Committee, and adhere to the guidelines set by the National Institutes of Health.

Gas Chromatography

Total (triglyceride, phospholipid, and cholesteryl ester) fatty acid composition was determined using the saponification and methylation methods originally described by Mecalfe et al. [36]. We have previously demonstrated that this method yields the same fatty acid composition as Folch (chloroform:methanol) extraction [9]. Brain samples (30–80 mg wet weight) were placed in a 20 ml glass vial into which 4 ml of 0.5 N methanolic sodium hydroxide was added, and the sample heated at 80 °C for 5 min. Following a 10 min cooling period, 3 ml of boron trifluoride in methanol was added to methylate the sample. After an additional five minutes of heating in the water bath (80 °C), the sample vial was allowed to cool, and 2 ml of a saturated solution (6.2 M) of sodium chloride and 10 ml of hexane was added. The samples were then mixed by vortex for 1 min. The hexane fraction was then transferred into a 20 ml vial containing 10 mg of sodium sulfate to dry the sample. The hexane solution was then removed for GC analysis. Samples were analyzed with a Shimadzu GC-2014 equipped with an auto-injector (Shimadzu Scientific Instruments Inc., Columbia MD). The column was a DB-23 (123–2332): 30 m (length), I.D. 0.32 mm wide bore, film thickness of 0.25 μ M (J&W Scientific, Folsom CA). The GC conditions were: column temperature ramping by holding at 120 °C for one minute followed by an increase of 5 °C/min from 120–240 °C. The temperature of the injector and flame ionization detector was 250 °C. A split (8:1) injection mode was used. The carrier gas was helium with a column flow rate of 2.5 ml/min. Fatty acid identification was determined using retention times of authenticated fatty acid methyl ester standards (Matreya LLC Inc., Pleasant Gap PA). Analysis of fatty acid methyl esters is based on areas calculated with Shimadzu Class VP 4.3 software. The mole percent (mol%) of fatty acids was calculated from the molecular weight of fatty acids and relative area percent. All samples were processed by a technician that was blind to genotype.

Statistical Analysis

Strain differences in fatty acid composition (mol%) and fatty acid ratios were analyzed with unpaired *t*-tests (two-tailed). We used Bonferroni correction with a group-wise error rate of $\alpha = 0.05$ to define significant strain differences in fatty acid composition ($n = 8$) and fatty acid ratios ($n = 3$) ($\alpha = 0.05/11 = 0.0045$). In cases of statistical significance, effect size was calculated using Cohen's *d*, with small, medium, and large effect sizes being equivalent to *d*-values of 0.30, 0.50, and 0.80, respectively. Parametric linear regression analyses were used to determine relationships between brain fatty acid composition

and fatty acid ratios within brain regions. All statistical analyses were performed using GB-STAT software (Dynamic Microsystems, Inc., Silver Springs MD).

Results

Diet Fatty Acid Composition

In the present study, mice from both strains were maintained on the same commonly used Purina LabDiet (5010), which is autoclaved prior to use in murine SPF facilities. In the present study, autoclaved pellets were randomly selected from cage hoppers for analysis by gas chromatography, and diet fatty acid composition is presented in Table 1. In this diet, ALA (18:3n-3) was the only omega-3 fatty acid, representing 3.7% of total fatty acid composition, and linoleic acid (18:2n-6) was the only omega-6 fatty acid, representing 39% of total fatty acid composition. This diet did not contain preformed DHA or ARA, or intermediate omega-3 fatty acid or omega-6 fatty acid precursors.

Regional Fatty Acid Composition

Consistent with prior mouse [37] and rat [38] studies, differential DHA composition was observed across brain regions. Specifically, DHA composition was greatest in the prefrontal cortex ($20 \pm 0.07\%$) and hippocampus ($17 \pm 0.10\%$) and lower in the ventral striatum ($15 \pm 0.10\%$) and midbrain ($13 \pm 0.09\%$). Conversely, oleic acid, which is enriched in brain white matter [39], was greatest in the ventral striatum ($20 \pm 0.13\%$) and midbrain ($25 \pm 0.13\%$), and lower in the prefrontal cortex ($15 \pm 0.07\%$) and hippocampus ($16 \pm 0.15\%$).

Strain Differences in Fatty Acid Composition

After correction for multiple comparisons, palmitic acid (16:0) (4%, DBA < C57, $P \leq 0.0001$, $d = 4.5$) was the only fatty acid that differed significantly between strains in the prefrontal cortex (Fig. 1a). In the hippocampus, there were significant strain differences observed for oleic acid (18:1n-9) (6%, DBA < C57, $P \leq 0.0001$, $d = 3.5$), adrenic acid (22:4n-6) (7%, DBA > C57, $P \leq 0.0001$, $d = 3.2$), and DHA (22:6n-3) (4%, DBA > C57, $P = 0.0003$, $d = 2.6$) compositions (Fig. 1b). In the ventral striatum, there were significant strain differences observed for *cis*-vaccenic acid (18:1n-7) (5%, DBA < C57, $P = 0.0027$, $d = 1.9$), oleic acid (18:1n-9) (4%, DBA < C57, $P = 0.0002$, $d = 2.6$), adrenic acid (22:4n-6) (18%, DBA > C57, $P \leq 0.0001$, $d = 7.0$), docosapentaenoic acid (22:5n-6) (12%, DBA > C57, $P = 0.002$, $d = 1.9$), and DHA (22:6n-3) (4%, DBA > C57, $P = 0.0002$, $d = 2.7$)

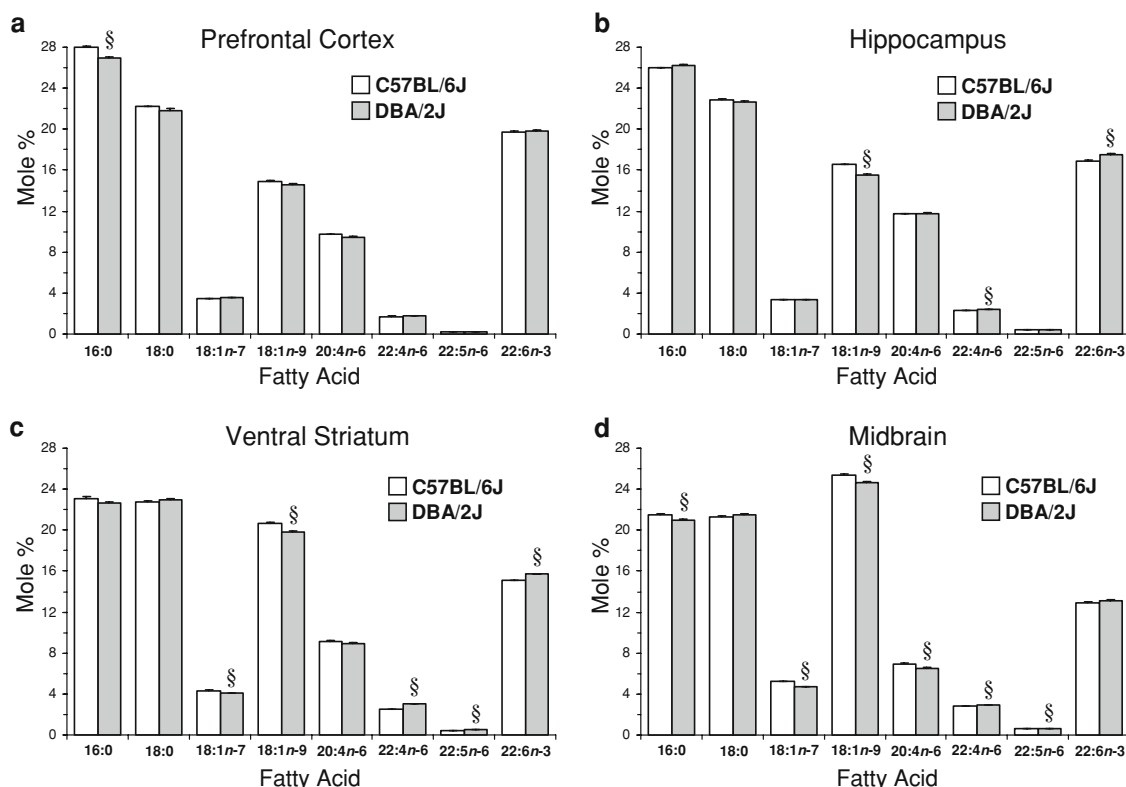

Fig. 1 Comparison of fatty acid composition (mol%) in the prefrontal cortex (a), hippocampus (b), ventral striatum (c), and midbrain (d) of adult male C57 ($n = 8$) and DBA ($n = 8$) mice. Note that significant strain differences in fatty acid composition are region-specific. 16:0, palmitic acid; 18:0, stearic acid; 18:1n-7, *cis*-vaccenic

acid; 18:1n-9, oleic acid; 20:4n-6, arachidonic acid; 22:4n-6, adrenic acid; 22:5n-6, docosapentaenoic acid; 22:6n-3, DHA. Values are means \pm SEM. § Significant at $P \leq 0.0045$ (P values and effect sizes are presented in the “Results” section)

compositions (Fig. 1c). In the midbrain, there were significant strain differences observed for palmitic acid (16:0) (3%, DBA > C57, $P \leq 0.0001$, $d = 3.5$), oleic acid (18:1n-9) (3%, DBA < C57, $P = 0.0002$, $d = 2.6$), *cis*-vaccenic acid (18:1n-7) (10%, DBA < C57, $P \leq 0.0001$, $d = 7.7$), ARA (20:4n-6) (4%, DBA < C57, $P = 0.0005$, $d = 2.4$), adrenic acid (22:4n-6) (24%, DBA > C57, $P \leq 0.0001$, $d = 13.1$), docosapentaenoic acid (22:5n-6) (12%, DBA > C57, $P = 0.0002$, $d = 2.7$), and DHA (22:6n-3) (4%, DBA > C57, $P = 0.005$, $d = 1.8$) compositions (Fig. 1d).

Strain Differences in Fatty Acid Ratios

C57 mice exhibited a greater ARA:DHA (20:4n-6/22:6n-3) ratio in the hippocampus (+5%, $P = 0.0009$, $d = 2.2$) ventral striatum (+7%, $P = 0.004$, $d = 1.8$) and midbrain (+7%, $P \leq 0.0001$, $d = 4.8$) relative to DBA mice, and there was a non-significant trend in the prefrontal cortex (+4%, $P = 0.01$, $d = 1.4$) (Fig. 2). C57 mice exhibited a smaller ADA:ARA (22:4n-6/20:4n-6) ratio, an index of elongase (*ELOVL2/5*) activity, in the hippocampus (−7%, $P \leq 0.0001$, $d = 3.0$), ventral striatum (−21%,

$P \leq 0.0001$, $d = 8.9$), and midbrain (−25%, $P \leq 0.0001$, $d = 10.7$) relative to DBA mice (Fig. 3a). C57 mice exhibited a greater oleic acid:stearic acid (18:1n-9/18:0) ratio, an index of SCD (delta-9 desaturase) activity, in the hippocampus (+6%, $P = 0.0002$, $d = 2.6$) and ventral striatum (+6%, $P = 0.0002$, $d = 2.7$) relative to DBA mice, and there was a non-significant trend in the midbrain (+4%, $P = 0.006$, $d = 1.7$) (Fig. 3b).

Correlations

Among all mice from both strains ($n = 16$), DHA composition was positively correlated with the ADA:ARA ratio in the hippocampus ($r = +0.56$, $P = 0.02$), ventral striatum ($r = +0.73$, $P = 0.001$), and midbrain ($r = +0.53$, $P = 0.03$), but not in the prefrontal cortex ($r = -0.25$, $P = 0.35$). Conversely, the ARA:DHA ratio was negatively correlated with the ADA:ARA ratio in the hippocampus ($r = -0.60$, $P = 0.01$), ventral striatum ($r = -0.72$, $P = 0.002$), and midbrain ($r = -0.87$, $P \leq 0.0001$), but not in the prefrontal cortex ($r = -0.03$, $P = 0.90$). DHA composition was negatively correlated with the oleic acid:stearic acid ratio in the prefrontal cortex

Fig. 2 Comparison of the ARA:DHA (20:4n-6/22:6n-3) ratio in the prefrontal cortex (PFC), hippocampus (HPC), ventral striatum (STR), and midbrain (MB) of adult male C57 ($n = 8$) and DBA ($n = 8$) mice. Note that DBA mice exhibit a significantly smaller ARA:DHA ratio in the hippocampus, ventral striatum, and midbrain relative to C57 mice. Values are means \pm SEM. § Significant at $P \leq 0.0045$ (P values and effect sizes are presented in the “Results” section)

($r = -0.76$, $P = 0.0007$), hippocampus ($r = -0.63$, $P = 0.008$), ventral striatum ($r = -0.63$, $P = 0.009$), and midbrain ($r = -0.80$, $P = 0.0002$).

Discussion

Based on prior findings that the prominent neurochemical and behavioral phenotypic differences observed between inbred C57 and DBA mouse strains could be reproduced within outbred rat and inbred mouse strains by dietary-induced deficits in DHA composition, we hypothesized that C57 and DBA mice maintained on the same diet would exhibit constitutive differences in regional brain DHA composition. In support of this hypothesis, C57 mice exhibited significantly lower DHA composition in the hippocampus and ventral striatum relative to DBA mice. Moreover, C57 mice exhibited a greater ARA:DHA ratio in the hippocampus, ventral striatum, and midbrain relative to DBA mice. C57 mice also exhibited significantly lower ADA composition, and a significantly smaller ADA:ARA ratio, in the hippocampus, ventral striatum, and midbrain, and lower docosapentaenoic acid (22:5n-6) composition in the ventral striatum and midbrain, relative to DBA mice. C57 mice exhibited significantly greater oleic acid (18:1n-9) composition in the hippocampus, ventral striatum, and midbrain relative to DBA mice, and a significantly smaller oleic acid:stearic acid ratio in the hippocampus and ventral striatum. Among all mice, DHA composition was positively correlated with the ADA:ARA ratio in the hippocampus, ventral striatum, and midbrain, and inversely correlated with the oleic acid:stearic acid ratio in all brain regions. Collectively, these data demonstrate that inbred C57 and DBA mice exhibit constitutive differences in

Fig. 3 Comparison of **a** the ADA:ARA (22:4n-6/20:4n-6) ratio, an index of elongase (*ELOVL2/5*) activity, and **b** the oleic acid:stearic acid (OLA:STA, 18:1n-9/18:0) ratio, an index of stearoyl-CoA desaturase (δ -9 desaturase) activity, in the prefrontal cortex (PFC), hippocampus (HPC), ventral striatum (STR), and midbrain (MB) of adult male C57 ($n = 8$) and DBA ($n = 8$) mice. Note the significant strain differences in ADA:ARA and OLA:STA ratios are region-specific. Values are means \pm SEM. § Significant at $P \leq 0.0045$ (P values and effect sizes are presented in the “Results” section)

regional brain fatty acid composition that are independent of diet.

A major finding of the present study is that C57 mice exhibited significantly lower DHA composition in the hippocampus and ventral striatum relative to DBA mice. The similarities between regional brain DHA compositions found in this study using total (triglyceride, phospholipid, and cholesteryl ester) fatty acid composition and a prior mouse study using isolated phospholipids [37] suggest that triglyceride and cholesteryl ester DHA composition comprise a relatively small percentage of total DHA composition. Although strain differences in regional brain DHA composition were small (4%), effects sizes were large (>0.8) and our prior study found that small ($\sim 10\%$) dietary-induced reductions in regional brain DHA composition were sufficient to significantly augment amphetamine-induced behavioral sensitization in adult C57 mice [34]. In the present study, prefrontal

cortex and midbrain DHA composition did not exhibit significant strain differences indicating regional-specificity. In prior studies, chronic dietary ALA depletion is associated with reductions in DHA composition in all brain regions including the prefrontal cortex and midbrain [34, 35, 37], suggesting that the present region-specific differences in DHA composition cannot be wholly attributable to strain differences in ALA-DHA biosynthesis. This is further supported by the finding that ARA composition, which is dependent upon the same biosynthetic pathway as DHA, did not exhibit significant strain differences, with the exception of the midbrain where DBA mice exhibited lower ARA composition. Moreover, dietary-induced brain DHA deficits are associated with reciprocal lower docosapentaenoic acid (22:5n-6) composition [34, 35, 37], whereas lower docosapentaenoic acid (22:5n-6) composition was observed in brain regions of C57 mice. Strain differences in regional brain DHA composition may therefore be due to region-specific differences in calcium-independent PLA₂-mediated turnover. Future investigations will be required to evaluate this and other mechanisms.

The significantly lower DHA composition, and similar or reduced ARA composition, observed in the hippocampus, ventral striatum, and midbrain of C57 mice relative to DBA mice was associated with a significantly greater ARA:DHA ratio in these regions. Because DHA inhibits, and ARA stimulates, PKC activity [4], the greater ARA:DHA ratio observed in the hippocampus of C57 mice may contribute in part to the greater PKC activity [23] and PKC-dependent synaptic plasticity [40] found in the hippocampus of C57 mice relative to DBA mice. Furthermore, elevated PKC-mediated substrate phosphorylation within the ventral striatum is associated with amphetamine-induced behavioral sensitization [41–43], and C57 mice develop significantly greater behavioral sensitization than DBA mice in response to repeated amphetamine treatment [27]. Moreover, dietary-induced reductions in regional brain DHA composition, and associated increases in the ARA:DHA ratio, significantly increase amphetamine-induced behavioral sensitization in adult DBA mice [35]. Together, these data suggest that constitutive strain differences in DHA composition and the ARA:DHA ratio may contribute to strain differences in PKC activity and associated synaptic and behavioral plasticity.

C57 mice exhibited lower ADA (22:4n-6) composition, and a significantly smaller ADA:ARA ratio, in the hippocampus, ventral striatum, and midbrain relative to DBA mice. This may reflect strain differences in elongase (*ELOVL2/5*) expression/activity, which directly mediates the synthesis of ADA from ARA [44]. The same elongases (*ELOVL2/5*) also mediate the conversion of eicosapentaenoic acid (20:5n-3) to docosapentaenoic acid (22:5n-3), a

prerequisite step in the biosynthesis of DHA from ALA. Therefore, it is possible that reduced elongase (*ELOVL2/5*) expression/activity in C57 mice may account for the lower regional brain ADA and DHA composition relative to DBA mice. Additionally or alternatively, strain differences in the ADA:ARA ratio may reflect greater shunting of ARA away from elongase-mediated fatty acid biosynthesis to cyclooxygenase-2 (COX-2)- and/or lipoxygenase-mediated prostaglandin or leukotrienes biosynthesis in C57 mice. This is supported in part by the findings that the downstream fatty acid metabolites of ARA, ADA and docosapentaenoic acid (22:5n-6), were lower in brain regions of C57 mice, and the ADA:ARA ratio was positively correlated with DHA composition. Furthermore, dietary-induced reductions in brain DHA composition are associated with elevated COX-2 expression and activity in rat brain [45]. Together, these data suggest that dietary-induced or constitutive reductions in DHA composition may promote shunting of ARA to prostaglandin biosynthesis.

DBA mice exhibited significantly lower oleic acid composition, and a smaller oleic acid:stearic acid ratio, in the hippocampus and ventral striatum relative to C57 mice, and a similar trend was observed in the midbrain. This finding is consistent with region-specific strain differences (C57 > DBA) in *SCD* (delta-9 desaturase) activity, which mediates the synthesis of oleic acid from stearic acid [13]. Consistent with the repression of *SCD* gene expression/activity by DHA [14], we also found that the oleic acid:stearic acid ratio was inversely correlated with DHA composition in all brain regions. These and our prior human postmortem findings [9, 46] suggest that DHA composition is an important determinant of brain *SCD* expression/activity. This finding may take on additional significance in view of evidence implicating *SCD* in central [47] and peripheral [48] myelin synthesis and age-related oligodendrocyte pathology [49, 50]. Moreover, we have recently found that *SCD* mRNA expression and the oleic acid:stearic acid ratio are significantly reduced, and DHA composition significantly increased, in postmortem brain tissue from patients with multiple sclerosis (McNamara et al., manuscript in preparation). Future studies will be required to determine whether strain differences in regional *SCD* expression/activity are associated with predicted differences in regional oligodendrocyte/myelin integrity.

In summary, we present evidence that inbred C57 and DBA mouse strains exhibit constitutive and region-specific differences in brain DHA composition, and associated differences in ARA:DHA, ADA:ARA, and oleic acid:stearic acid ratios, that are independent of diet. These data add to a growing body of preclinical evidence for strain differences in regional brain fatty acid composition [51, 52] and hepatic lipogenic activity [53], as well as an association between a greater brain ARA:DHA ratio and

augmented dopamine-mediated behavior [26, 27, 32, 34, 35, 52]. Furthermore, these data suggest that to-be-identified genetic factors are an important determinant of central fatty acid composition. This and prior clinical evidence for polymorphisms in lipogenic genes [19–22] suggest that genetic factors may contribute in part to the brain fatty acid composition abnormalities observed in patients with heritable psychiatric disorders including schizophrenia [8–10].

Abstract Patients with metabolic syndrome (MetS) usually have low high density lipoprotein cholesterol (HDL-C) levels. We determined the HDL distribution profile as well as the HDL-related lipoprotein associated phospholipase A₂ (HDL-LpPLA₂) and paraoxonase-1 (PON1) activities in subjects with MetS ($n = 189$) but otherwise healthy. Age and sex-matched individuals ($n = 166$) without MetS served as controls. The lower HDL-C concentration in MetS patients was due to a reduction in both large and small HDL subclasses ($P < 0.001$ and $P < 0.05$, respectively). As the number of MetS components increased, the HDL phenotype comprised of a greater percentage of small HDL-3 and less large HDL-2 subclasses, resulting in a decreased HDL-2/HDL-3 ratio ($P < 0.001$ for all trends). Multivariate analysis revealed that HDL-2 levels and the HDL-2/HDL-3 ratio significantly and independently correlated with HDL-C (positively) and TG (negatively) levels. HDL-3 concentration significantly and independently positively correlated with HDL-C and TG levels. HDL-LpPLA₂ activity was decreased in MetS patients ($P < 0.01$), a phenomenon that may contribute to the defective antiatherogenic activity of HDL in MetS. PON1 activity did not differ between groups. We conclude that

MetS, in addition to the decrease in HDL-C concentration, is associated with alterations in the HDL phenotype, which is comprised of a greater percentage of small HDL subclasses. Furthermore, HDL-LpPLA₂ activity is decreased in MetS patients.

Introduction

The term metabolic syndrome (MetS) is used to describe a constellation of cardiovascular risk factors that have become a problem of epidemic proportions [1]. The diagnostic components of this syndrome involve abdominal obesity, dyslipidaemia, impaired carbohydrate metabolism and hypertension [1, 2]. Dyslipidaemia associated with MetS may substantially contribute to the increased cardiovascular disease (CVD) risk [3]. The most common lipid abnormalities associated with the MetS are elevated triglyceride (TG) and low high density lipoprotein cholesterol (HDL-C) concentrations [1, 4]. There also seems to be a preponderance of small, dense low density lipoprotein (sdLDL) subclasses [1, 4].

Numerous clinical and epidemiological studies have demonstrated the inverse and independent association between plasma HDL-C levels and the risk of coronary heart disease (CHD) [5]. It is well known that HDL does not represent a sum of identical particles but is rather comprised of discrete subfractions that differ with respect to size, density, composition, charge and other physicochemical

properties [6]. Of interest, the HDL subfraction distribution may have a greater predictive value for CHD events than HDL-C concentration [7–9].

HDL exhibits various anti-atherogenic, anti-oxidant, anti-inflammatory, anti-coagulant and anti-thrombotic properties [6, 9, 10]. An essential role in these beneficial functions of HDL may be played by enzymes associated with this lipoprotein, such as the lipoprotein associated phospholipase A₂ (HDL-LpPLA₂) and paraoxonase-1 (PON1) [11, 12].

The purpose of this study was to determine the distribution of HDL subclasses and the HDL-LpPLA₂ and PON1 activities in patients with and without MetS. The effects of metabolic variables on the concentration and relative distribution of HDL subclasses in this population were also assessed.

Methods

Subjects

Greek individuals ($n = 189$) who fulfilled the National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III) criteria [13] for the diagnosis of MetS but otherwise healthy were included in the study. Age and sex-matched individuals ($n = 166$) with less than three criteria for the diagnosis of MetS served as controls. Of these, 175 (105 with MetS, 70 controls) subjects participated in a previous study that assessed the LDL subclass distribution [4]. All participants gave informed written consent prior to their enrollment in the study, which was approved by the Ethics Committee of the University Hospital of Ioannina, Ioannina, Greece.

Exclusion Criteria

Individuals were excluded if they had type 2 diabetes mellitus (T2DM; fasting glucose levels >126 mg/dL; 7.0 mmol/L) or a history of CVD. In addition, patients with thyroid function abnormalities, abnormal hepatic function (aminotransferase activity >3 times the upper limit of the reference range), impaired renal function (serum creatinine levels >1.5 mg/dL; 132 μ mol/L), as well as those receiving drugs that may interfere with glucose or lipid metabolism were also excluded.

Determination of Anthropometric and Metabolic Variables

Body Weight, Waist Circumference and Blood Pressure (BP)

Body weight was determined to the nearest 0.1 kg with a calibrated beam balance and standing height was measured

to the nearest 1 cm. The body mass index (BMI) was calculated as weight (kg) divided by height squared (m^2). Waist circumference was measured midway between the lower ribs and the iliac crest. BP measurements were obtained at the same time (morning) in the sitting position, in duplicate using the right arm, following a 10-min rest and using a validated mercury sphygmomanometer (model no. FC114, Focal Corporation, Toyofuta, Kashiwa City, Chiba Pref., Japan). The appropriate cuff size was used.

General Biochemical Variables

All laboratory determinations were carried out following overnight fasting (water only allowed). Serum concentrations of fasting glucose, total cholesterol (TC) and TG were determined enzymatically on an Olympus AU600 analyzer (Olympus Diagnostica, Hamburg, Germany). HDL-C was determined by a direct assay (Olympus Diagnostica, Hamburg, Germany). Low density lipoprotein cholesterol (LDL-C) was calculated using the Friedewald formula (provided that TG were <400 mg/dL; 4.5 mmol/L) [14]; nonHDL-C was calculated as TC – HDL-C. Serum apolipoprotein (apo) AI and B levels were measured with a Behring Holding GmbH (Liederbach, Germany). Fasting serum insulin levels were measured by an AxSYM microparticle enzyme immunoassay on an AzSYM analyzer (Abbott Diagnostics, Illinois, USA). The homeostasis model assessment (HOMA) index was calculated as follows: fasting insulin (mU/L) \times fasting glucose (mg/dL)/405. Serum concentrations of high sensitivity C-reactive protein (hsCRP) were measured by the N High Sensitivity CRP method (Dade Behring Marburg GmbH, Marburg/Germany) based on particle enhanced immunonephelometry.

HDL Subclass Analysis

Analysis of the apo AI-containing lipoprotein subclasses was performed using the Lipoprint HDL System (Quantimetrix, Redondo Beach, California, USA) [15, 16]. After electrophoresis, very low density lipoprotein (VLDL) and LDL remained at the origin (Retention factor, $R_f = 0.0$), whereas albumin migrated to the front ($R_f = 1.0$). In between, up to nine bands of HDL were detected whose R_f s are 0.05, 0.10, 0.15, 0.20, 0.25, 0.29, 0.38, 0.48 and 0.53. Bands 1–3 ($R_f = 0.05$ –0.15) correspond to large HDL-2 subclasses, whereas bands 4–9 ($R_f = 0.20$ –0.53) comprised the small HDL-3 subclasses [15]. The cholesterol concentration of each HDL subclass was determined by multiplying the relative area under the curve (AUC) of each subclass by the HDL-C concentration of the sample [15].

LDL Subclass Analysis

Electrophoresis was performed using high resolution 3% polyacrylamide gel tubes and the Lipoprint LDL System (Quantimetrix, Redondo Beach, CA) according to the manufacturer's instructions [17]. LDL subclasses were estimated by the Rf between the VLDL fraction (Rf = 0.0) and the HDL fraction (Rf = 1.0). LDL is distributed as seven bands, whose Rfs are 0.32, 0.38, 0.45, 0.51, 0.56, 0.60 and 0.64 (LDL1–LDL7, respectively). LDL1 and LDL2 are defined as large, buoyant LDL, while LDL3 up to LDL7 are defined as sdLDL. Cholesterol concentration of each LDL subclass was determined by multiplying the relative AUC of each subclass by the TC concentration of the sample. Mean particle size was provided by the Lipoprint System [17, 18].

LpPLA₂ Activity

LpPLA₂ activity in total plasma as well as in HDL-rich plasma (i.e. after the precipitation of all apo B-containing lipoproteins with dextran sulfate-magnesium chloride), was determined by the trichloroacetic acid precipitation procedure using [³H]-platelet activating factor (PAF; 100 μM final concentration) as a substrate [19]. The reaction was performed for 10 min at 37 °C and LpPLA₂ activity was expressed as nmol PAF degraded per min per mL of plasma.

PON1 Activity

PON1 activity in serum was measured using paraoxon or phenylacetate as substrates, in the presence of 2 mM Ca²⁺ in 100 mM Tris-HCl buffer (pH 8.0) for paraoxon and 20 mM Tris-HCl buffer (pH 8.0) for phenyl acetate [20].

Statistical Analysis

Continuous variables were tested for normality by the Kolmogorov–Smirnov test and logarithmic transformations were performed if necessary. Data are presented as mean ± standard deviation (SD) and the median (range) for parametric and non-parametric data, respectively. An unpaired *t*-test was used for comparisons between study groups, while differences in proportions were assessed with a chi square test. One-way ANOVA or the Kruskal–Wallis test was used for comparisons between subjects with different numbers of MetS components. Analysis of covariance (ANCOVA) was used to assess the possible effect of HDL-C in the percentage of HDL subclasses in subjects with or without MetS. The relationships between study variables were investigated using the Pearson correlation coefficient (*r*), whereas correlations including at

least one non-normal distributed variable were performed using Spearman's correlation coefficient (*r_s*). Differences were considered significant at *P* < 0.05. Analyses were performed using the SPSS 15.0 statistical package for Windows (SPSS Inc., Chicago, Illinois).

Results

We enrolled 355 patients (148 men and 207 women). Of these, 189 individuals had MetS, while 166 subjects did not fulfill the criteria for this syndrome (Table 1). There were no differences in the age and sex distribution between study groups (Table 1). There was also no difference between groups in terms of smoking or menopausal status.

Anthropometric Variables

Patients with MetS had significantly greater waist circumference as well as higher BP values compared with controls (Table 1).

General Biochemical Variables

MetS patients had higher fasting glucose and insulin concentrations, as well as elevated values of the HOMA index, compared with controls (Table 1). MetS patients were characterized by an adverse lipid profile which comprised of elevated concentrations of non-HDL-C, TG and apo B, and lower levels of HDL-C and apo AI. TC levels were marginally increased in MetS patients, but LDL-C concentrations did not differ significantly between the two groups (Table 1).

Levels of hsCRP were significantly higher in MetS patients compared with controls (Table 1). There was a significant trend for elevation in the hsCRP concentration with the increase of MetS components (Kruskal–Wallis, *P* < 0.001).

HDL Subclasses

MetS patients had significantly lower cholesterol concentration in both large HDL-2 and HDL-3 subclasses (Table 2). Therefore, the decrease in HDL-C concentration in MetS patients can be attributed to the reduction of both HDL subclasses (but mainly of large HDL-2). When the cholesterol concentration of HDL-2 subclass was expressed as a percentage of HDL-C, MetS patients had significantly lower values compared with controls (Table 2). In contrast, the percentage of HDL-3 in the total HDL-C was significantly higher in MetS patients compared with controls (Table 2).

Table 1 Clinical and biochemical characteristics of the study population

	Controls	Metabolic syndrome	<i>P</i>
<i>n</i>	166	189

Men	51 ± 10	42 ± 8	<0.001
Women	64 ± 11	52 ± 10	<0.001
NonHDL-C (mg/dL)	167 ± 39	188 ± 39	<0.001
LDL-C (mg/dL)	147 ± 34	149 ± 39	NS
Apo AI (mg/dL)			
Men	144 ± 18	127 ± 20	<0.001
Women	163 ± 26	139 ± 27	<0.001
Apo B (mg/dL)	102 ± 25	109 ± 25	<0.05
hsCRP (mg/dL)	1.6 (0.21–8.5)	2.2 (0.2–9.0)	<0.01

Values are mean ± SD or median (range) or as stated in parentheses. To convert values for glucose to mmol/L, multiply by 0.0555. To convert total cholesterol, LDL-C and HDL-C levels from mg/dL to mmol/L, multiply by 0.0259. To convert triglyceride levels from mg/dL to mmol/L multiply by 0.0113

n number of patients; *NS* not significant; *BMI* body mass index; *BP* blood pressure; *HOMA* homeostasis model assessment; *HDL-C* high density lipoprotein cholesterol; *LDL-C* low density lipoprotein cholesterol; *apo* apolipoprotein; *hsCRP* high sensitivity C-reactive protein

There was a significant decrease in the percentage of HDL-2 as the number of MetS components increased (Kruskal–Wallis, $P < 0.001$, data not shown). In contrast, there was a significant increase in the percentage of HDL-3 as the number of MetS components increased (Kruskal–Wallis, $P < 0.001$, data not shown). Furthermore, there was a decrease in the HDL-2/HDL-3 ratio in parallel with the number of MetS components (Kruskal–Wallis, Fig. 1). The assessment of the above percentage differences with ANCOVA using the serum concentrations of HDL-C as covariate revealed same results (data not shown).

We performed multivariate analysis for the prediction of HDL-2, HDL-3 levels, as well as of the HDL-2/HDL-3 ratio, as an index of the HDL phenotype. This analysis revealed that HDL-2 levels and the HDL-2/HDL-3 ratio significantly and independently correlated with HDL-C (positively) and TG (negatively) levels (Tables 3, 4). HDL-3 levels significantly and independently positively correlated with HDL-C and TG levels (Table 3).

LpPLA₂ and PON1 Activities

Total LpPLA₂ activity was significantly increased in MetS patients compared with controls (Table 2). In contrast, HDL-LpPLA₂ was significantly decreased in MetS subjects. There was a significant trend for decrease of HDL-LpPLA₂ as the number of MetS components increased (Kruskal–Wallis, $P < 0.001$, Fig. 2). HDL-LpPLA₂ significantly negatively correlated with waist circumference, TG, VLDL-C, sdLDL-C, glucose, insulin and HOMA index, as well as with the percentage of HDL-3 (all $P < 0.05$).

PON1 activities towards both paraoxon and phenylacetate did not significantly differ between MetS subjects and controls (Table 2).

LDL Subclasses

As previously reported [4] MetS patients had significantly higher cholesterol concentrations in the VLDL and sdLDL subclasses (Table 2). When cholesterol concentrations in the sdLDL subclass were expressed as a percentage of total LDL-C, patients with MetS had significantly higher values compared with controls (Table 2). There was a significant increase in cholesterol concentrations of sdLDL subclasses as the number of MetS components increased (Kruskal–Wallis, $P < 0.001$, data not shown). The same results were obtained when cholesterol concentrations in sdLDL subclass were expressed as a percentage of total LDL-C values (Kruskal–Wallis, $P < 0.001$).

MetS patients had decreased mean LDL particle diameter compared with controls. There was a significant decrease in mean particle diameter as the number of MetS components increased (Kruskal–Wallis, $P < 0.001$, data not shown).

Discussion

The present study shows that the decrease in HDL-C concentration in patients with MetS is due to a reduction in both large and small HDL subclasses. Patients with MetS have an altered HDL phenotype comprising of an increased percentage of small HDL-3 subclass compared with

Table 2 Metabolic variables of the study population

	Controls	Metabolic syndrome	<i>P</i>
sdLDL (mg/dL)	4 (0–50)	12 (0–79)	<0.001
sdLDL (%)	3 (0–28)	9 (0–56)	<0.001

percentage of small HDL-3 subclass. Furthermore, our analysis showed that the differences in the HDL phenotype are probably due to the presence of MetS and not only to lower HDL-C levels.

The HDL-C concentration independently correlated with both HDL-2 and HDL-3 levels. This suggests that the decrease in HDL-C levels affected both HDL subclasses. The HDL-2/HDL-3 ratio independently positively correlated with the HDL-C levels, suggesting that when the cholesterol content of HDL increases, this results in an increase in large HDL-2 subclass. Small HDL-3 subclass readily acquire cholesterol at cellular membranes via efflux mediated by the ATP-binding cassette transporter A1 [6, 21]. Subsequent esterification of cholesterol by the enzyme lecithin: cholesterol acyltransferase (LCAT) converts small HDL-3 to large HDL-2 [6, 21].

However, HDL-2 can be inversely converted to HDL3. This conversion occurs through several actions, including cholesteryl ester transfer protein (CETP)-mediated exchange of cholesterol esters and TGs between HDL and apoB-containing lipoproteins, selective uptake of cholesterol esters by hepatocytes mediated by scavenger receptor type BI, and phospholipid and TG hydrolysis by hepatic lipase [6, 21]. The results of multivariate analysis showing an independent positive association between TG levels and HDL-3 levels may be explained via the action of CETP. Indeed, an increase in the size of TG-rich lipoprotein pool accelerates the CETP-mediated exchange of TG and cholesterol esters between apo B-containing lipoproteins and HDL. Then, the TG in HDL are hydrolyzed by hepatic lipase, resulting in smaller HDL particles [6, 21, 22].

Our observations agree with previous studies using different HDL sub-fractionation methods. In 2,993 Framingham Heart Study participants (mean age 51 years; 53% women) without CVD, the lower HDL-C levels in MetS subjects were attributed to the decrease in all HDL particles [determined by nuclear magnetic resonance analysis (NMR)], but mainly of large HDL particles, in both men and women [23]. Other studies with small numbers of patients also showed using ultracentrifugation that HDL-C decrease in MetS is mainly due to the reduction of the light HDL-2 subfraction [24, 25]. There is no global agreement whether large or small HDL subpopulations are more anti-atherogenic. These discrepancies could be partially explained by the differences in the methodologies used for the subfractionation of HDL [6]. Epidemiological studies showed a predominance of small rather than large HDL particles among patients with CHD as compared with control subjects [7]. However, the presence of large HDL particles may have greater predictive value for imminent CHD-related events than HDL-C [7, 26, 27]. In the Veterans Affairs High Density Lipoprotein Intervention Trial (VA-HIT) the reduction of CHD events with gemfibrozil was attributed to the increase in HDL-C levels and especially the increase in NMR-deter-

mined small HDL particle numbers [28]. Nevertheless, there is evidence that low HDL-C states, as well as states with the presence of elevated inflammatory markers such as MetS and atherosclerosis, are associated with increased small HDL particles; these particles are dysfunctional, exhibiting lower anti-oxidant and anti-inflammatory activity [10, 29].

LpPLA₂ degrades PAF and oxidized phospholipids to generate lysophospholipids and oxidized fatty acids [19, 30]. Plasma LpPLA₂ activity is primarily associated with LDL, while a small proportion of the enzyme activity is associated with HDL. Although LDL-associated LpPLA₂ may exert pro-inflammatory effects, there is evidence that HDL-LpPLA₂ may have an atheroprotective role [11, 30]. The decreased HDL-LpPLA₂ activity in our MetS subjects is in agreement with previous observations that HDL in MetS has impaired antiatherogenic activity [24, 31, 32]. In fact, we observed a decrease in HDL-LpPLA₂ activity as the number of MetS components increased. In a previous study our group also found significantly decreased HDL-LpPLA₂ activity in MetS subjects [33].

PON1 is an esterase present in plasma in association with HDL [20, 34]. In vitro PON1 hydrolyzes paraoxon and phenyl acetate. In contrast, the in vivo substrates for this enzyme are considered to be phospholipid hydroperoxides and cholesteryl ester hydroperoxides, molecules that are formed during LDL oxidation [20, 35]. PON1 is able to retard LDL oxidation and to reduce the pro-inflammatory properties of oxidized LDL [20, 36, 37]. In our study, PON1 activity did not differ between MetS patients and controls. Other investigators have also shown similar PON1 activity in subjects with or without MetS [32]. However, others showed decreased PON1 activity in MetS and T2DM patients [38–44]. The impaired glucose tolerance and more marked glycaemia in T2DM, compared with MetS, may account for this difference [32, 45, 46].

MetS patients had increased concentrations of sdLDL cholesterol and hsCRP, as well as increased total plasma LpPLA₂ activity. We previously reported in a smaller study (which included some of the participants of the present study) that MetS patients have elevated sdLDL-C levels [4]. The elevation in total plasma LpPLA₂ activity in MetS has also been previously reported by another group as well as by us [17, 33, 47]. Indeed, it has been shown that higher plasma levels of total plasma LpPLA₂ activity increase the risk for incident CVD regardless of MetS [47]. This may be related to the fact that LpPLA₂ activity is a marker of the atherogenic sdLDL particles [17]. The parallel increase in hsCRP levels with the components of MetS has also been described [48]. The presence of increased sdLDL-C and hsCRP levels, as well as total

plasma LpPLA₂ activity, may aggravate the increased CVD risk of MetS patients [49–51].

Conclusions

Patients with MetS, in addition to lower HDL-C levels, have an altered HDL phenotype compared with individuals who do not have MetS. As the number of MetS components increases, the HDL phenotype comprises of a greater percentage of small HDL-3 and a lower percentage of large HDL-2 subclass. The HDL-LpPLA₂ activity is decreased in MetS patients, an effect that may contribute to the impaired anti-atherogenic activity of HDL. Furthermore, patients with MetS had increased levels of sLDL-C. Therefore, MetS, in addition to the alterations of lipoprotein quantity, is associated with changes in the quality of both LDL and HDL.

Conflict of interest statement The present study was carried out independently; no pharmaceutical company supported it financially. Some of the authors have given talks, attended conferences and participated in advisory boards and other trials sponsored by various pharmaceutical companies.

Abstract Chemical and enzymatic interesterification are used to create spreadable fats. However, a comparison between the two processes in terms of their acute metabolic effects has not yet been investigated. A randomised crossover study in obese (plasma TAG > 1.69 mmol/L, and BMI > 30 (BMI = kg/m²) or waist circumference > 102 cm, *n* = 11, age = 59.3 ± 1.8 years) and non-obese (plasma triacylglycerol (TAG) < 1.69 mmol/L, and BMI < 30 or waist circumference < 102 cm, *n* = 10, age = 55.8 ± 2.2 years) men was undertaken to compare the effects of chemical versus enzymatic interesterification on postprandial risk factors for type 2 diabetes (T2D) and cardiovascular disease (CVD). TAG, cholesterol, glucose, insulin and free fatty acid concentrations were measured for 6 h following consumption of 1 g fat/kg body mass of non-interesterified (NIE), chemically interesterified (CIE), enzymatically interesterified (EIE) stearic acid-rich fat spread or no fat, each with 50 g available carbohydrate from white bread. Interesterification did not affect postprandial glucose, insulin, free fatty acids or cholesterol (*P* > 0.05). Following ingestion of NIE, increases in serum oleic acid were observed, whereas both oleic and stearic acids were increased with CIE and EIE (*P* < 0.05). While postprandial TAG concentrations in non-obese subjects were not affected by fat treatment (*P* > 0.05), obese

subjects had an 85% increase in TAGs with CIE versus NIE (*P* < 0.05). The differences in TAG response between non-obese and obese subjects suggest that interesterification may affect healthy individuals differently compared to those already at risk for T2D and/or CVD.

Keywords Stearic acid · Spreadable fat · Chemical interesterification · Enzymatic interesterification · Randomisation · Postprandial · Triacylglycerol metabolism

Abbreviations

AUC	Area under the curve
BMI	Body mass index
CIE	Chemically interesterified test fat
CVD	Cardiovascular disease
DAG	Diacylglycerol
EIE	Enzymatically interesterified test fat
GC	Gas chromatography
HOMA-IR	Homeostasis model of insulin resistance
HPLC	High performance liquid chromatography
IE	Intesterification
NIE	Non-interesterified test fat
SEM	Standard error of the mean
SSS	Tristearin
T2D	Type 2 diabetes
TAG	Triacylglycerol

Introduction

Intesterification is a process used by the food industry to alter the physical properties of fats and oils and to create structured lipids for nutritional purposes. The process involves re-arrangement of the fatty acids within and between triacylglycerol (TAG) molecules. Interesterification

(IE) can be achieved by either chemical or enzymatic methods. Chemical interesterification (CIE) typically results in complete randomisation of the fatty acids present at each position on the glycerol backbone, while enzymatic interesterification (EIE) can be manipulated, primarily through enzyme selection, to achieve positional and/or fatty acid specificity for the production of desired TAGs. Because of the desire to reduce or eliminate *trans* fatty acids in processed foods, North American interest in IE has grown in recent years [1, 2], and IE fats are increasingly being used by the food industry. In particular, there is interest in interesterifying blends of hardstocks rich in saturated fatty acids with highly unsaturated oils to produce *trans* fatty acid-free fat spreads and shortenings as a strategy for chronic disease prevention [1, 3]. This trend has been fuelled by evidence that both oleic and stearic acids neither raise nor lower total cholesterol, high density lipoprotein (HDL), low density lipoprotein (LDL) or very-low density lipoprotein (VLDL)-cholesterol [4]. To date, no clinical studies have been published that directly compare the impact of chemical versus enzymatic IE methods on postprandial lipemia and glucose-related risk factors for type 2 diabetes (T2D) and cardiovascular disease (CVD). Particularly in light of the recent controversy regarding the effect of fat interesterification on CVD risk factors [5], well designed studies to address the effects of interesterification on acute and chronic risk factors are required.

TAG molecules consist of three fatty acids esterified to a glycerol backbone. The fatty acids at positions *sn*-1 and *sn*-3 are metabolized differently than the fatty acid at *sn*-2 due to the action of pancreatic lipase in the duodenum. Pancreatic lipase preferentially cleaves the fatty acids at *sn*-1 and *sn*-3, resulting in the formation of a 2-monoglyceride and two fatty acids, which are absorbed by the enterocyte [6]. Plasma cholesterol and TAG concentrations following ingestion of a fat appear to depend only on the saturation of fatty acids present at position *sn*-2, and not on the fatty acids located at *sn*-1 or *sn*-3 [7]. In this regard, the presence of saturated fatty acids, at the *sn*-2 position appears to increase absorption efficacy and result in elevated postprandial lipemia [8–11] than do corresponding monounsaturated fatty acids [12–14]. This is important since increased plasma TAG concentrations in the postprandial state may play a role in the progression of CVD just as postprandial concentrations of glucose and insulin are associated with T2D [15–17].

Since interesterification changes the positional distribution of saturated and monounsaturated fatty acids within and between TAG molecules, the process may affect postprandial metabolic risk factors implicated in T2D and CVD development and the effects may be different between chemical and enzymatic methods. However, to date, a comparison of IE methods on postprandial lipemia and glycemia following the ingestion of a highly saturated

fat with a monounsaturated-rich oil have not been evaluated. Thus, the objective of this study was to compare postprandial TAG and cholesterol concentrations, as well as glucose, insulin and free fatty acid responses in non-obese and obese men following ingestion of a NIE, CIE or EIE fat blend of a stearic acid-rich hardstock and an oleic acid-rich oil in the presence of a carbohydrate source. This study investigated both non-obese men with normal fasting TAG and obese men with elevated fasting TAG levels in order to assess the influence of existing T2D and CVD risk on the postprandial response. We hypothesized that IE of the blend would modify metabolic risk factors in the postprandial state, and that these would differ between IE methods.

Subjects and Methods

Subjects

Twenty-four male subjects between the ages of 40–70 years, who were non-smokers and not on medication to control glucose, cholesterol or TAG were recruited from the Guelph community. Subjects attended a screening visit and provided a fasting blood sample for lipid profile determination (Cholestech LDX v2.0, Hayward, CA). Non-obese subjects ($n = 12$) met the following criteria: fasting whole blood TAG < 1.69 mmol/L along with BMI < 30 and/or waist circumference < 102 cm [18]. In contrast, subjects were classified as obese ($n = 12$) if they displayed fasting whole blood TAG > 1.69 mmol/L along with BMI > 30 and/or waist circumference > 102 cm. Three subjects withdrew during the course of the study: two due to palatability of the test fats and one due to time constraints. Twenty-one subjects completed the study, of whom ten were classified as non-obese and 11 as obese. This study was approved by the University of Guelph Research Ethics Board, and informed consent was obtained from all participants.

Test Fats

A 70:30 wt% blend of high oleic sunflower oil (Vegetol 80RBD, Acatris, Minneapolis, MN, 76% oleic acid) with canola stearin (fully hydrogenated canola oil, CanAmera, Oakville, ON, 88% stearic acid) was prepared in the Guelph Food Technology Centre by heating the lipid mixture at 80 °C until all of the fat had melted and thoroughly mixing. This 70:30 (oil:stearin) physical blend constituted one of the treatments and is referred as the NIE test fat.

Samples of NIE were then interesterified by either chemical or enzymatic means, using conditions designed to

mimic industrial operations. The CIE test fat was prepared using the catalyst sodium methoxide (0.3% w/w, Sigma, St Louis, MO) and conducting the reaction at 85 °C under a nitrogen blanket for 60 min. Citric acid (2% v/w of a 20% solution, Sigma, St Louis, MO) was then added to stop the reaction and the samples were washed repeatedly with water to remove soaps and free fatty acids. Samples were then dried under vacuum using a rotary evaporator at 85 °C. Bleaching clay (1.5% w/w, courtesy of Bunge Canada, Toronto, ON) was added and the mixture was held at 85 °C for 20 min under nitrogen before being filtered, blanketed with nitrogen and stored at –20 °C until use. The EIE test fat was prepared using the non-specific *Candida antarctica* lipase immobilized on polyacrylic resin (Novozym 435, Sigma, St Louis, MO) at 5% w/w. The reaction vessel was maintained at 70 °C for 24 h in an elliptical shaking water bath. The oil was then filtered, blanketed with nitrogen, and stored at –20 °C prior to use.

To improve the sensory characteristics of the test fats, annatto (0.01% w/w, Sensient Food Colors, Kingston, ON) and butter flavour (0.4% w/w, Excellentia Flavours, Surrey, BC) were added to each spread. All fats were melted at 80 °C and portioned into individual servings corresponding to 1 g fat/kg body mass. The fats were then stored at 4 °C until the day before use when they were fully melted in a microwave to remove crystal memory and were immediately returned to 4 °C storage to solidify overnight. On the morning of each trial, the fats were spread on toasted and cooled bread, as described below.

Study Protocol

This study utilised a randomised, crossover design, with double-blinding on all fat-containing treatments but not bread alone. Postprandial responses to the test meals were measured over 6 h on four occasions, each visit separated by at least 1 week. Three-day food records were obtained from each subject before each trial and analysed using ESHA Food Processor V 9.9.0 (ESHA Research, Salem, OR) for total energy, % energy from fat, carbohydrate, dietary fibre, sugar, protein, total fat, saturated fat, *trans* fat, monounsaturated fat, polyunsaturated fat, alcohol and caffeine intake. Subjects were instructed to refrain from alcohol, strenuous exercise and caffeine for 48 h prior to each trial day and they consumed a standardised meal, containing 2,968 kJ (710 kcal), 58% energy from carbohydrate, 25% energy from fat and 17% energy from protein between 6 and 8 pm the night before followed by an overnight fast before each trial. At each visit, subjects were weighed upon arrival at the laboratory. In addition, bio-electrical impedance analysis (BodyStat 1500, Douglas, UK) was used to measure body composition at the third treatment visit.

On each of the four study days, a cannula was inserted into an antecubital vein to facilitate blood collection throughout the day. After fasting blood samples were collected, the test meal was administered. Each subject completed four treatments—a control meal of bread and water, and each fat load (either NIE, CIE, or EIE) with bread and water. Each meal consisted of three slices of toasted commercial white bread (WonderBread, Weston Bakeries, Toronto, ON, Ingredients: enriched wheat flour, water, sugar/glucose–fructose, yeast, vegetable oil (soybean and/or canola), salt, defatted soya flour, calcium propionate, stearyl-2-lactylate, monoglycerides) providing 50 g of available carbohydrate (along with 285 Calories, 3 g fat (0.6 g saturated), 1.5 g fibre, 10.5 g protein), 500 mL ambient temperature water and, if applicable, 1 g test fat/kg body mass. This approach to fat dosage is commonly used in postprandial lipid metabolism studies, especially when comparing two groups of subjects with variability in body weight and blood volume [19, 20]. Subjects consumed the test meal in less than 12 min, at which point time 0 min was set and blood samples were subsequently obtained at 15, 30, 45, 60, 90, 120, 180, 240, 300, and 360 min. Throughout each visit, subjects rested in the sitting position, were allowed to take short walks, and were permitted to consume water ad libitum throughout the day.

Serum and heparinised plasma were obtained at each time point and immediately placed on ice. Samples for glucose, insulin, TAG, total cholesterol and HDL were frozen at –20 °C prior to analysis. Serum samples for fatty acid composition analysis were stored at –80 °C until analysis.

Analytical Methods

The fatty acid and TAG composition of each test fat was determined by gas liquid chromatography (described below) and isocratic reverse phase HPLC, respectively. The Shimadzu HPLC was equipped with an Econsil C18 column and an evaporative light scattering detector (Sedex 75, Sedere, France) and used acetonitrile/chloroform (70:30 v/v) as the mobile phase. The solid fat content of NIE, CIE and EIE was measured in triplicate by pulsed nuclear magnetic resonance (American Oil Chemists' Society official method Cd 16-81) with a Bruker PC20 Series NMR analyzer (Bruker, Milton, ON).

Plasma glucose was analysed in duplicate by the glucose oxidase method (YSI 2300, YSI Incorporated, Yellow Springs, OH). Serum insulin was measured in duplicate by ¹²⁵I iodine radioimmunoassay (Diagnostic Products Corporation, Los Angeles, CA) and the homeostasis model of insulin resistance (HOMA-IR) at baseline was calculated for each subject (HOMA-IR = fasting plasma glucose × fasting

serum insulin/22.5) [21]. Serum free fatty acids were measured in duplicate using the colorimetric assay (Wako HR Series NEFA-HR [2], Wako Diagnostics, Richmond, VA).

Plasma TAG, total cholesterol and HDL-cholesterol were analysed at Guelph General Hospital (Guelph, ON) on a Uni-Cel Dx C 600i (Beckman-Coulter, Fullerton, CA) and LDL-cholesterol concentration calculated using the Friedwald method [22]. This method is not valid when TAG exceed 4.52 mmol/L, resulting in a lack of LDL data for three subjects over the course of the study. Postprandial TAG change from baseline was calculated at each time point for each subject for each treatment using the time 0 value for that day and calculating the group averages using these obtained values. This was completed to control for the observed wide inter-subject variation in fasting TAG.

Serum fatty acids were extracted by dissolving 200 μ L serum into 2 mL 2:1 chloroform/methanol and 200 μ L milli-Q water, followed by centrifugation at 780g for 10 min at 20 °C. The lipid-containing layer was dried under nitrogen, re-dissolved in 1 mL of iso-octane and fatty acids converted to fatty acid methyl esters (FAME) through the addition of 100 μ L of 2N potassium hydroxide in methanol and neutralisation with 2N hydrochloric acid. Heptadecanoic acid (17:0) was used as internal standard. The organic phase (0.8 μ L) was injected into a Shimadzu 8A-GC equipped with a flame ionisation detector and glass column (1.5 m \times 5 \times 3 mm) packed with 10% Silar 9CP on 80/100 Chromasorb WHP. Samples were injected at 230 °C and heated from 120 to 210 °C at 4 °C per min. Fatty acids present at greater than 5 wt% included palmitic, stearic, oleic and linoleic acids. The total area for these four fatty acids were summed and used to determine the relative concentration of each major fatty acid present. The change in relative serum concentration of each fatty acid was then calculated as the difference from 0 to 6 h.

Statistical Analysis

Incremental area under the curve (AUC) calculations were performed for each endpoint with GraphPad Prism (v 3.03, GraphPad Software, San Diego, CA), using the trapezoidal rule. All statistical methods used the SigmaStat statistical package (v 2.03, SigmaStat, San Jose, CA). Baseline fasting characteristics between the non-obese and obese groups were compared using a Student's *t* test while baseline fasting characteristics between the treatments and AUC responses were compared using a one-way analysis of variance. Postprandial endpoint comparisons were made using a two-way analysis of variance and Tukey's test for multiple comparisons was used for all post hoc analyses. *P*-values < 0.05 were considered significant. Data are presented as mean \pm SEM.

Results

The chemical composition and solid fat content of the test fats are shown in Table 1. Accordingly, NIE, CIE and EIE had similar fatty acid compositions, but differed extensively in both TAG composition and solid fat content. NIE contained 23% of the high melting TAG tristearin (SSS, melting temperature \sim 68 °C), compared with CIE and EIE which contained only 0.5 and 0.4% tristearin, respectively. Similarly, while NIE contained \sim 22% of OOL (melting temperature < 0 °C), CIE and EIE contained only 3.6 and 7.7% OOL, respectively. In contrast, CIE and EIE contained higher concentrations of SSO/SOS (melting temperature \sim 40 °C) and OOS/OSO (melting temperature \sim 23 °C) species. Such differences indicate that the solid

fat content of NIE around body temperature (i.e. 37 °C) was 18.6%, while only 5.4 and 5.6% solids remain in the CIE and EIE, respectively, at this temperature. There are also implications in terms of the physical functionality of the fats. For example, because of their greater variety of TAG species, compared with NIE, CIE and EIE have wider ranges of plasticity, an attribute which is required for spreadability and desired for various applications in the food industry.

By design, the non-obese and obese subject groups differed significantly in terms of BMI, waist circumference and fasting TAG. They also differed in terms of body weight, total cholesterol, insulin and HOMA-IR (Table 2). In comparing the 3-day energy and nutrient intakes leading up to each study visit, no significant differences were observed (data not shown).

Table 3 shows the change in relative serum concentrations of palmitic (16:0), stearic (18:0), oleic (18:1n-9) and linoleic (18:2n-6) acids from 0 to 6 h following ingestion of each test meal. Both the non-obese and obese subjects showed similar changes: palmitic and linoleic acid concentrations were lower following each of the NIE, CIE, and EIE meals due to the influx of exogenous stearic and oleic acids from the test fats. Stearic and oleic acid concentrations were increased after the CIE and EIE test meals, in a ratio that was similar to that in the test fats fed (approximately 2:1 oleic:stearic). In contrast, following the NIE treatment, both groups showed an increase in serum oleic, but not stearic acid concentration. As expected, ingestion of bread alone did not result in a difference in serum fatty acid content, with the exception of an increase in linoleic acid presumably from endogenous depots, as minimal fat was provided in this test meal.

Postprandial changes in plasma TAG from baseline with each treatment are shown in Fig. 1. No significant differences were observed between mean fasting TAG concentration across study days in the non-obese and obese groups ($P > 0.05$). As expected, in both subject groups, plasma TAG concentration significantly increased after consumption of each fat-containing meal as compared to

Table 3 Changes in postprandial total serum fatty acid composition (wt%) between 0 to 6 h for non-obese and obese groups following ingestion of test fats NIE, EIE, CIE with bread and bread control

	NIE	EIE	CIE	Bread

Treatments across a row without common letter differ ($P < 0.05$)

Baseline serum fatty acid composition for each group (non-obese/obese); 14:0 (0.8 ± 0.1|1.1 ± 0.3), 16:0 (28.1 ± 5.4|23.6 ± 0.5), 16:1n-7 (2.9 ± 0.5|2.7 ± 0.2), 18:0 (10.8 ± 1.7|7.6 ± 0.3), 18:1n-9 (28.3 ± 5.0|27.7 ± 1.0), 18:2n-6 (25.1 ± 3.4|20.3 ± 0.5), 18:3n-3 and 20:0 (0.8 ± 0.1|1.6 ± 0.3), 20:1 (0.8 ± 0.1|1.4 ± 0.3), 20:2 (0.9 ± 0.2|1.6 ± 0.3), 20:3 (3.4 ± 0.5|1.9 ± 0.2), 20:4n-6 and 22:0 (9.5 ± 1.6|5.5 ± 0.4), 20:5n-3 (1.8 ± 0.3|1.0 ± 0.2), 24:1 (1.7 ± 0.2|1.7 ± 0.2), 22:6n-6 (3.3 ± 0.4|3.1 ± 0.4)

Fig. 1 Mean (\pm SEM) postprandial plasma TAG (triacylglycerol) concentrations from baseline during 6 h after ingestion of NIE (broken line, bar with dots), EIE (dotted line, bar with open and closed squares), CIE (dot with broken line, bar with horizontal lines) or bread-alone (solid line, filled bar) meal for non-obese (a, $n = 10$) and obese (c, $n = 11$) groups. 0–6 h incremental AUC in non-obese (b) and obese (d) subjects is also presented. Independent effects of treatment and time were observed for triacylglycerol changes ($P < 0.05$). Differences between treatments in terms of incremental AUC are indicated by different letters ($P < 0.05$)

the bread alone treatment ($P < 0.05$). In addition, AUC analysis shows that obese subjects had a greater increase in plasma TAG concentrations in response to fat-containing treatments compared with non-obese subjects (Fig. 1a vs. b). In both groups, independent effects of time and treatment on TAG response to fat-containing treatments were observed ($P < 0.05$).

Differences amongst the fat treatments were less striking. No differences were observed between NIE, CIE and EIE in the non-obese group. In the obese group, the TAG response was 85% higher following CIE compared with NIE, although there was no difference between CIE and EIE or NIE and EIE. Also, as expected, treatment had no effect on postprandial total cholesterol, HDL-cholesterol, or LDL-cholesterol between 0 and 6 h in either subject group for this acute study (data not shown).

Postprandial glucose, insulin and free fatty acid concentrations are shown in Fig. 2 (non-obese) and Fig. 3 (obese). As expected, obese subjects had higher glucose and insulin responses compared with non-obese subjects. In both groups, time and treatment significantly influenced postprandial plasma glucose concentration ($P < 0.05$). Ingestion of bread alone resulted in a significantly higher plasma glucose peak compared with when the fats were present ($P < 0.05$). However, there were no differences between the fat treatments in terms of glucose response. With respect to insulin, an elevated postprandial peak was observed in both non-obese and obese subjects with ingestion of the bread alone compared with the three fat treatments. Compared with the bread alone treatment, insulin AUC in the non-obese group was 37 and 34% lower after NIE and CIE, respectively, although neither fat load differed from EIE. Serum free fatty acids decreased sharply

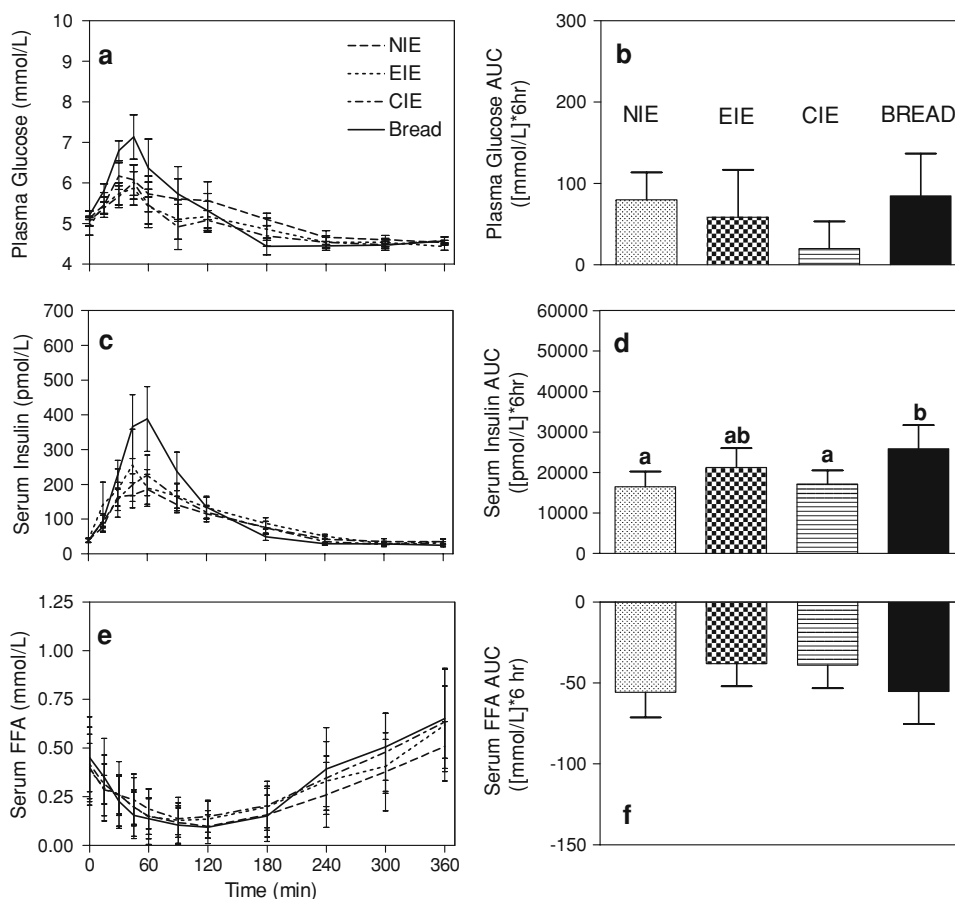

following ingestion of the test meals, and then progressively increased. There was, however, no effect of treatment or subject group with respect to serum free fatty acid response ($P > 0.05$).

Discussion

Interesterification of stearic-rich hardstocks with oleic-rich oils has been gaining popularity in the North American food industry, as this process produces a plastic fat without creating *trans* fatty acids [1, 2]. While IE can be accomplished by either chemical or enzymatic methods, a comparison of these methods on acute T2D and CVD risk factors has not yet been investigated. We sought to investigate this comparison in two subject groups which represented very different metabolic states. According to classic fasting clinical risk factors, the obese subject group was at elevated risk for T2D and CVD [23].

Analysis of serum fatty acid composition provided a means of assessing the uptake of fat with each treatment. Relative increases in stearic and oleic acids in the serum were observed with both CIE and EIE, in roughly the same proportions as in the test fats. In contrast, with NIE, no increases in serum stearic acid were observed, while oleic acid concentration increased significantly ($P < 0.05$). Although all three fat spreads had the same fatty acid composition (Table 1), the concentration of these fatty acids in the blood differed between the fats. This is likely related to the fact that the majority of stearic acid present in the NIE treatment existed as tristearin, while the stearic acid in CIE and EIE was distributed between a wider range

Fig. 2 Mean (\pm SEM) postprandial concentrations and 0–6 h incremental AUC in plasma glucose (**a**, **b**), serum insulin (**c**, **d**) and serum free fatty acids (**e**, **f**) over 6 h following ingestion of NIE (broken line, bar with dots), EIE (dotted line, bar with open and closed squares), CIE (dot with broken line, bar with horizontal lines) or bread-alone (solid line, filled bar) meal for non-obese subjects ($n = 10$). Independent effects of treatment and time were observed for glucose and insulin ($P < 0.05$). A significant effect of time was observed for serum free fatty acids ($P < 0.05$). In terms of incremental AUC, significant differences between the treatments were only observed for insulin (**d**), as indicated by different letters ($P < 0.05$)

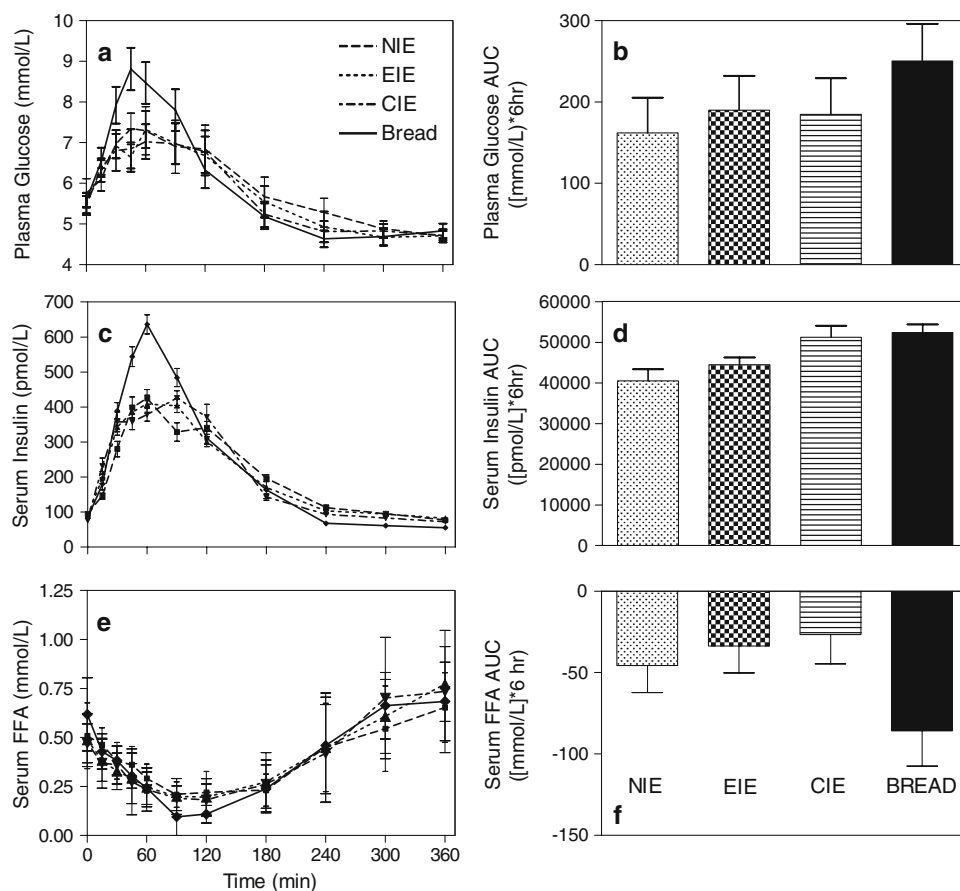

of TAG species (see Table 1). Owing to tristearin's high melting point ($\sim 68^\circ\text{C}$), this molecule is relatively unavailable for digestion by lipolysis and absorption by the enterocyte [24]. A comprehensive review of stearic acid absorption concluded that, while this fatty acid is relatively well absorbed from most TAG sources, this is not the case for tristearin for which only 15% of the stearic acid may be absorbed, due to reduced pancreatic lipase accessibility to the solid molecule [25]. Therefore, when the same amount of stearic acid is present, but is distributed amongst TAGs with lower melting temperatures (as in the CIE and EIE spreads), lipolysis and absorption are enhanced, leading to greater serum stearic acid concentrations.

As shown previously in the literature, the postprandial change in plasma TAG concentration differed between non-obese and obese subjects [19, 20]. The non-obese men showed no difference in response to any of the four treatments, suggesting they were able to effectively metabolise the fat load with minimal disturbance to blood lipid homeostasis and accumulation of plasma TAG [19]. In contrast, in the obese group, CIE resulted in a significantly increased TAG response over 6 h, compared to NIE, although neither NIE nor CIE differed significantly from EIE. Postprandial TAG metabolism can be affected by the positional distribution of the fatty acids in a test meal [7],

although the exact mechanism for this is not yet clear. Fats which differ in positional distribution have been shown to alter intestinal uptake of lipids [13] and the positional distribution of TAG in chylomicrons [26, 27], but not the clearance of TAGs by lipoprotein lipase at the adipocyte surface [27, 28]. Any of these outcomes could have affected the postprandial TAG response. In addition, the test fats had differing solid fat contents, which has been shown to affect fat absorption in the small intestine [24], and to have an effect upon postprandial lipemia [29, 30].

The reason for the apparent differences in TAG response between the NIE and CIE treatments, but not with the EIE (for the obese group only), cannot be explained by solid fat content or positional distribution arguments. Although the differences in solid fat content between the NIE and interesterification fats are consistent with the changes in serum fatty acid content, no differences were observed between the EIE and CIE samples in terms of solid fat content and therefore, the anticipated solubility during digestion would be similar. Furthermore, while the positional distribution of the test fats could not be determined, both IE reactions proceeded in a random fashion, leading to relatively similar fatty acid positional distributions in the CIE and EIE fats. Therefore, the biggest differences in positional distribution would have existed between NIE

Fig. 3 Mean (\pm SEM) postprandial concentrations and 0–6 h incremental AUC in plasma glucose (**a, b**), serum insulin (**c, d**) and serum free fatty acids (**e, f**) over 6 h following ingestion of NIE (broken line, bar with dots), EIE (dotted line, bar with open and closed squares), CIE (dot with broken line, bar with horizontal lines) or bread-alone (solid line, filled bar) meal for obese subjects ($n = 11$). Independent effects of treatment and time were observed for glucose ($P < 0.05$). There was also a significant effect of time ($P < 0.05$) and a trend to a treatment effect ($P = 0.057$) for insulin in the obese group and an effect of time for serum free fatty acids ($P < 0.05$)

and the interesterification fats, not between the interesterification fats themselves. The only difference observed between the CIE and EIE spreads, in terms of composition, is the amount of partial acylglycerols, specifically the diacylglycerols (DAG) present (see Table 1). The NIE, CIE and EIE contained 0.0, 1.2, 6.6% DAG, respectively. The consumption of DAG has been shown to affect postprandial lipemia in healthy persons, leading to an attenuated increase in serum TAGs compared to the ingestion of an equal amount of TAG of identical fatty acid composition [31]. Therefore, the greater amount of DAG in the EIE sample might explain the fact that the CIE response was greater than the NIE response, but no differences were observed between plasma EIE and NIE for the obese subjects.

The influence of fat-spread composition on the glycemic response can be assessed by considering the glucose, insulin and free fatty acid responses following each test meal. In both non-obese and obese subjects, interesterification did not result in any differences in circulating glucose, insulin or free fatty acid concentrations. This agrees with previous reports demonstrating that when carbohydrates are fed with meals that contain fats of identical mass and fatty acid composition, the fatty acid positional distribution does not influence the digestion,

absorption or clearance of glucose from the bloodstream, nor does it affect the secretion of insulin or its removal from the circulation [26, 32]. Interestingly, addition of any fat treatment (NIE, CIE or EIE) to the bread alone resulted in a significantly reduced and delayed peak and decline of glucose and insulin in both subject groups. This agrees with previous reports that even low levels of fat, when added to a carbohydrate challenge, can significantly reduce and delay the glycemic response [33]. The proposed mechanism for this effect is that the presence of fat in a meal results in a slower gastric emptying, leading to a delayed and diminished presentation of carbohydrate to the small intestine for absorption [34].

As mentioned above, differences were observed between non-obese men with relatively healthy metabolic profiles and obese men with pre-existing risk factors for T2D and CVD. Specifically, obese subjects had exaggerated plasma TAG, glucose and insulin responses to the test meals, compared with non-obese subjects. Therefore, the presence of classical fasting risk factors for T2D and CVD was associated with further dysfunctional postprandial metabolism in all test meals, agreeing with existing literature [19, 20]. Also, considering that postprandial TAG response is related to CVD risk [35] and that acute [36] and chronic [15–17] glucose and insulin control are related to

T2D and CVD progression, the postprandial impairments observed in obese subjects may be associated with further progression of chronic disease.

This study is the first to compare between the effect of CIE and EIE of a stearic-rich fat spread on acute postprandial metabolism. The data suggest that neither method of IE affects the acute glucose, insulin or free fatty acid response in the presence of carbohydrate. Interesterification had no effect on overall plasma TAG concentration in non-obese, healthy men. While both CIE and EIE of the fat spread led to alterations in the postprandial serum concentrations of stearic acid in the obese subjects, only CIE resulted in elevated postprandial TAG concentrations. This suggests that method of IE does not have an effect on relatively healthy individuals, but may affect the metabolism of people already at risk for CVD and/or T2D. Additional research to further elucidate the effect of IE on human metabolism in both the acute and chronic states is warranted.

Acknowledgments We thank the study participants for their time and commitment. We thank Mehrnoosh Kashani and Ricky Lam for their technical assistance and the Human Nutraceutical Research Unit at the University of Guelph and the Guelph Food Technology Centre for the use of their facilities. We also thank Bunge Canada for supplying the fully hydrogenated canola stearin and the Ontario Ministry of Agriculture, Food and Rural Affairs for funding.

Abstract Changes in bile synthesis by the liver or alterations in the enterohepatic circulation due to a variety of etiological conditions may represent a novel source of liver disease-specific biomarkers. Bile from patients with liver diseases exhibited significant changes in the levels of glycine- and taurine-conjugated bile acids, phospholipids, cholesterol and urea relative to non-liver disease controls. Cholangiocarcinoma and non-malignant liver diseases (NMLD) showed the most significant alterations. Further, hepatocellular carcinoma (HCC) could be differentiated from NMLD ($p = 0.02$), as well as non-liver disease controls ($p = 0.02$) based on the amounts of bile acids, phospholipids and/or cholesterol. HCC also differed with cholangiocarcinoma although not significantly. Urea increases somewhat in non-malignant liver disease relative to non-liver disease controls, while the bile acids, phospholipids and cholesterol all decrease significantly. The ratio between some major bile metabolites also distinguished NMLD ($p = 0.004$ – 0.01) from non-liver disease controls. This snapshot view of bile homeostasis, is obtainable from a simple nuclear magnetic resonance (NMR) approach and demonstrates the enormous opportunity to assess liver status, explore biomarkers for high risk diseases such as cancers and improve the understanding of normal and abnormal cellular functions.

Introduction

Liver diseases remain a daunting health problem, with primary liver cancer being the most lethal. Hepatocellular carcinoma (HCC) is the leading cause of gastro-intestinal cancer deaths [1]. Clinical silence during the early stages has made early diagnosis of HCC highly challenging. Unfortunately, late diagnosis parallels high mortality rates because therapeutic options are limited and less effective. Patients with Hepatitis B and/or Hepatitis C are at particularly high-risk for the development of cancer. Cancer risk increases with the development of cirrhosis, implying that there are measurable molecular changes within the microenvironment of the liver with the progression of underlying liver disease that account for this increased risk. Targeting such molecular changes has immense potential for early disease detection. The most information-rich techniques currently employed in small molecules analyses are nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS) [2–5]. Recently, application of NMR spectroscopy to the detection of pancreatic, lung, ovarian, prostate and liver cancers based on small molecules is demonstrated using urine, blood or tissue samples [6–10].

A few studies have indicated the potential of metabolite detection in bile for assessing hepatobiliary diseases including cancers of the liver, pancreas and the biliary tract [11–14]. For example, the potential for screening cancer based on the alteration in phospholipid

content in human bile between malignant and non-malignant patients has been recently reported [14]. Monitoring the concentration of bile acids in human bile is reported to serve as a reliable indicator for liver function after hepatobiliary resection for biliary cancer [13]. Altered bile cholesterol levels have been implicated in gallstone related problems, including gallbladder cancer. Increased levels of bile acids in serum have also been reported in liver disease, indicating the altered physiology of biliary metabolites in patients with liver related problems [15–20].

Utilizing the fact that a large amount of bile fluid exists in the gallbladder (40–50 mL in humans), attempts to determine bile metabolites non-invasively using in vivo localized magnetic resonance spectroscopy have yielded encouraging results [21, 22]. However, so far no systematic studies have assessed liver diseases based on the measurement of multiple bile metabolites. Advancements in in vitro studies of bile will also benefit translational research for exploring clinical applications of bile in vivo. Therefore, methods providing a reliable snapshot of the major bile metabolites that reflect the global functional status of the liver are highly desired. From a series of comprehensive NMR studies of bile and its metabolites, we recently developed simple NMR methodologies for detecting several bile metabolites, such as individual glycine- and taurine-conjugated bile acids, phospholipids, cholesterol and urea [23–27]. Among the various bile acids, individual conjugated bile acids such as glycocholic acid, glycodeoxycholic acid, glycochenodeoxycholic acid, taurocholic acid, taurodeoxycholic acid and taurochenodeoxycholic acid have been identified, simultaneously, from a single NMR measurement. With this database of information, we can now study these major metabolites of liver origin in gallbladder bile from patients with liver diseases, and, as a result, provide a global view of liver function. Changes

in metabolite profiles due to a variety of etiologies indicate the opportunities for using metabolomics to assess disease status and obtain better insights into the cellular biochemistry of malignant and non-malignant liver diseases (NMLD).

Materials and Methods

Chemicals and Bile from Patients

Deuterated dimethylsulfoxide (DMSO), deuterium oxide (D₂O), and sodium salt of trimethylsilylpropionic acid-d₄ (TSP) were purchased from Sigma-Aldrich (Milwaukee, WI, USA).

Bile Collection

Gallbladder bile was obtained from 44 patients at the time of operation. Of these, 17 were controls (non-liver disease) which were collected from patients undergoing gallbladder procedures unrelated to liver disease. Liver diseases include both malignant, HCC ($n = 11$) and cholangiocarcinoma ($n = 7$), and non-malignant ($n = 9$) diseases. Patient profile and the sample subsets are shown in Table 1. All bile samples were collected at the commencement of the case to minimize ischemic changes, if any. A purse string suture was placed in the fundus of the gallbladder and 10 mL of bile taken via an 18 gauge needle. The bile was transferred to a 10-mL tube containing sodium azide (with a final concentration of 0.1%). The specimen was then divided into 1-mL aliquots and stored at $-80\text{ }^{\circ}\text{C}$ until analysis. An Institutional Review Board protocol, approved at both Indiana University School of Medicine and Purdue University, was in place for the collection, storage, and analysis of human bile for research purposes.

Table 1 Patient profile

Patients		Number	Gender	Mean age (years)
Liver disease (malignant)	Hepatocellular carcinoma (HCC)	11	7 male, 4 female	56.8
	Cholangio-carcinoma (CC)	7	5 male, 2 female	52.7
Liver disease (non-malignant)	Alcoholic cirrhosis (AC)	3	3 male	50.3
	Hepatitis C (HEPC)	3	2 male, 1 female	52.3
	Non-alcoholic steatohepatitis cirrhosis (NASH)	1	1 female	60
	Choledochal cyst (CHLC)	1	1 male	31
	Primary sclerosing cholangitis (PSC)	1	1 female	24
Non-liver disease (controls)	With gallstone	8	1 male, 7 female	39.8
	Without gallstone	5	2 male, 3 female	41.2
	Biliary dyskinesia	2	2 female	56.5
	Colorectal cancer	2	1 male, 1 female	52.5

NMR Experiments

All ^1H -NMR experiments were performed on a Bruker Biospin Avance 500 MHz NMR spectrometer using a 5-mm CHN inverse probehead equipped with shielded z -gradients. The temperature was kept at 25 °C for all the samples.

Spectral Analysis in Aqueous Medium

Bile solutions were prepared by diluting 100 μL of bile to 600 μL using doubly distilled water. Amide signals of individual conjugated bile acids are more accurately represented when the pH of the bile solution is in the range 6 ± 0.5 [23, 26]. Hence, the pH of each bile solution was brought to this range by the addition of 1–2 μL of 1 N hydrochloric acid. A reusable co-axial capillary tube containing TSP in D_2O was inserted into the NMR tube before recording ^1H -NMR spectra. While D_2O served as a field-frequency locking solvent, TSP served as chemical shift as well as a quantitative reference. We have observed that individual glycine- and taurine-conjugated bile acids signals are better distinguished when the coupling of their characteristic amide protons with the attached methylene protons is removed by decoupling [23]. Hence, one-dimensional ^1H spectra were obtained using a one pulse sequence incorporating both water suppression by presaturation and homonuclear decoupling of the methylene protons. Simultaneous decoupling is achieved with the decoupling frequency set at 3.65 ppm, which is between the chemical shifts of the methylene protons of conjugated taurine (3.56 ppm) and conjugated glycine (3.75 ppm). Typical parameters used were: spectral width 6,400 Hz, time domain data points 32 K, flip angle 45°, acquisition time 2.5 s, relaxation delay 6 s, number of transients 32, spectrum size 32 K points.

Spectral Analysis in Non-aqueous Medium

Well-resolved NMR signals for the bile metabolites are shown to be obtainable when the bile is mixed with an organic solvent such as DMSO. Such spectra enable distinct observation of all major metabolites such as cholesterol, lipids, total bile acids, glycine-conjugated bile acids, taurine-conjugated bile acids and urea, in addition to other metabolites using a single experiment [24]. For profiling the metabolites under these conditions, one-dimensional ^1H -NMR experiments were performed: Each bile sample (20 μL) was dissolved in 500 μL DMSO and loaded into a 5-mm NMR tube. A reusable co-axial capillary containing the TSP reference was inserted into the NMR tube and ^1H spectra were obtained using a one pulse sequence. As optimized for bile metabolites detection using

T_1 relaxation studies, 45° radiofrequency excitation pulse and a recycle delay of 6 s were used to ensure complete recovery of magnetization of all the bile metabolites as well as the TSP signal [24].

Quantitative Analysis of Bile Metabolites

Integral areas of the characteristic peaks of glycine-conjugated bile acids, taurine-conjugated bile acids, total bile acids, cholesterol, phospholipids and urea were determined for all the bile samples with reference to the TSP peak area. The bile metabolite concentrations were calculated by taking into account (1) volume of gallbladder bile used in obtaining the NMR spectra, (2) concentration of TSP reference, and (3) NMR peak areas and number of protons that contributed to the measured NMR signals for both metabolites and the reference. Although a known concentration of TSP solution was used in the capillary tube, its concentration was further calibrated from a separate ^1H -NMR experiment using a secondary reference solution of glycine. The bile metabolite quantities and their ratios were statistically compared using the unpaired t test.

Results

Proton NMR spectra of gallbladder bile in liver diseases and controls look qualitatively similar. However, the intensities of the signals greatly varied with marked differences visible between different liver diseases and control bile.

Bile in Aqueous Medium

Due to the aggregation of the amphipathic bile metabolites in an aqueous medium, the NMR signals appear relatively broad (Fig. 1). In addition, cholesterol and bile acids have a very close structural resemblance, resulting in the overlap of most of the bile acids and cholesterol signals with one another and with the phospholipid signals. With the aim of identifying individual metabolites from such complex spectra, we previously developed a library of bile acid chemical shifts by extensively analyzing one- and two-dimensional proton and carbon NMR spectra of a large number of unconjugated and glycine- and taurine-conjugated bile acids [25]. Subsequently, the analysis was extended to gallbladder bile using 1D- and 2D-NMR experiments at different field strengths (400, 700 and 800 MHz) [23]. This resulted in the detection of six conjugated bile acids in human bile (glycocholic acid, glycochenodeoxycholic acid, glycodeoxycholic acid, taurocholic acid, taurochenodeoxycholic acid and taurodeoxycholic acid). In the present study, all six of these bile

Fig. 1 $^1\text{H-NMR}$ spectrum of a representative gallbladder bile from non-liver disease controls ($n = 17$) (100 μL bile diluted to 600 μL) obtained at 500 MHz

acids were invariably detected in the control bile, and the ratio of taurine- to glycine-conjugated bile acids was observed to be nearly 1:3 (Fig. 2). In both malignant (HCC, CC) and NMLD liver disease samples, bile acids were reduced, both in their quantity and in number. Portions of typical spectra of bile from a control, a malignant- and a non-malignant liver disease are shown in Fig. 2.

Bile in Organic Medium

The use of DMSO as a solvent provides a method for the dispersion of aggregated bile metabolites. NMR experiments performed for both liver disease and control bile using this method showed highly resolved signals, and the characteristic peaks for major bile metabolites such as total

bile acids, cholesterol, phospholipids, total glycine-conjugated bile acids, total taurine-conjugated bile acids and urea are distinctly isolated in the spectra (Fig. 3). Using the integrated areas of the characteristic marker peaks with reference to the TSP signal at 0.0 ppm, quantities of the major bile metabolites were determined (Table 2). Table 2 also provides data on the standard deviation as well as the results of unpaired t tests among the malignant and non-malignant liver disease and the controls for each of the measured bile metabolite. Portions of the bile NMR spectra that highlight altered major bile metabolite concentrations in different hepatobiliary diseases are shown in Fig. 4.

As shown in Table 2, and summarized in Fig. 5, liver diseases including hepatocellular cancer and cholangiocarcinoma exhibited significant changes in the levels of phospholipids, glycine- and taurine-conjugated bile acids, cholesterol and urea in the bile. Among the liver diseases, CC and NMLD showed most significant variation relative to the control samples. In addition, HCC patients could be differentiated from NMLD based on the amounts of phospholipids ($p = 0.02$), total bile acids ($p = 0.02$), glycine-conjugated bile acids ($p = 0.03$) and cholesterol ($p = 0.02$). Even CC could be differentiated somewhat from HCC based on bile acids ($p = 0.06$) and phospholipids ($p = 0.05$), although weakly. The differences in metabolite concentrations between CC and NMLD were not statistically significant. In benign liver disease samples (NMLD), the urea levels were increased somewhat relative to non-liver disease samples with the difference nearly significant ($p = 0.06$), while the levels of bile acids, phospholipids, and cholesterol were all significantly decreased ($p < 0.0001$) in all cases.

Fig. 2 Portions of the $^1\text{H-NMR}$ spectra for representative gallbladder bile from a control (non-liver disease, $n = 17$) and liver disease patients (malignant; $n = 18$) and non-malignant $n = 9$). One or more bile acids in the liver disease are significantly reduced or completely missing as shown in the figure

Fig. 3 $^1\text{H-NMR}$ spectrum of a representative gallbladder bile from non-liver disease controls ($n = 17$), dissolved in an organic solvent (20 μL bile dissolved in 500 μL DMSO) obtained at 500 MHz. Characteristic marker signals for all major bile components are distinctly isolated, thus enabling their quantitation in a single step

The extent of the reduction of individual bile metabolites in liver diseases varied greatly. For example, while glycine-conjugated bile acid levels were reduced to very low levels in the both malignant and NMLD, the reduction in taurine-conjugated bile acids was generally smaller (Table 2, Fig. 5). To further illustrate such compositional variations in both malignant and non-malignant diseases, ratios between some major bile metabolites were compared. As shown in Fig. 6, the ratio of glycine- to taurine-conjugated bile acids (Gly/Tau) and total bile acids to phospholipids (BA/PL) were lower ($p = 0.004$ and $p = 0.01$, respectively), and the ratio of phospholipids to cholesterol (PL/Chol) was higher ($p = 0.01$) in NMLD compared to controls.

Discussion

A key to interpreting alterations in bile metabolites for a given liver disease state is the understanding of the consequences associated with these alterations that would allow us to identify patients at high risk for disease progression. For example, underlying liver disease is the most potent correlate to the development of primary liver cancer. However, our ability to identify which patients with Hepatitis C, NASH or alcoholic cirrhosis are at most risk for the development of cancer is unknown. To determine the ability of NMR to distinguish between controls (NLD) and liver disease or liver disease and liver cancer, we evaluated bile from several unique clinical subsets: controls, patients with underlying liver disease, patients with identifiable risk factors for cancer, but no cancer at the time of bile collection and high risk patients who have gone on to develop cancer, with the bile taken after the diagnosis of cancer was made. All bile was collected at the time of surgery. Control bile was from patients undergoing surgery for non-liver related problems. Bile from patients

Table 2 Average values, along with the standard deviation, of the quantities of the bile metabolites (in mmol) determined in hepatocellular carcinoma (HCC), cholangiocarcinoma (CC), non-malignant liver diseases (NMLD) and non-liver disease controls (NLD). The errors are expressed as standard deviations; p values are from the unpaired t test between different groups; ns: non-significant

Patients	Total bile acids	Cholesterol	Phospholipids	Glycine-conjugated bile acids	Taurine-conjugated bile acids	Urea

with underlying liver disease includes patients with Hepatitis C, NASH cirrhosis, or alcoholic cirrhosis.

Bile acids, phospholipids and cholesterol are the major constituents of bile. Bile acids alone constitute a group of a large number of mainly glycine- and taurine-conjugated derivatives. Of these, conjugates of chenodeoxycholic acid and cholic acid are the primary bile acids. Primary bile acids are directly synthesized in the liver from cholesterol. Conjugates of deoxycholic acids, in contrast, are thought to be the products of bacterial deconjugation occurring during enterohepatic circulation. This pilot study using $^1\text{H-NMR}$ spectroscopy clearly shows altered bile homeostasis among different liver diseases and controls. Concentrations of major bile metabolites, including bile acids, are significantly reduced in liver disease. Importantly, apart from distinguishing from controls based on the homeostatic changes, the two malignant diseases, HCC and CC could be somewhat differentiated from each other, although weakly.

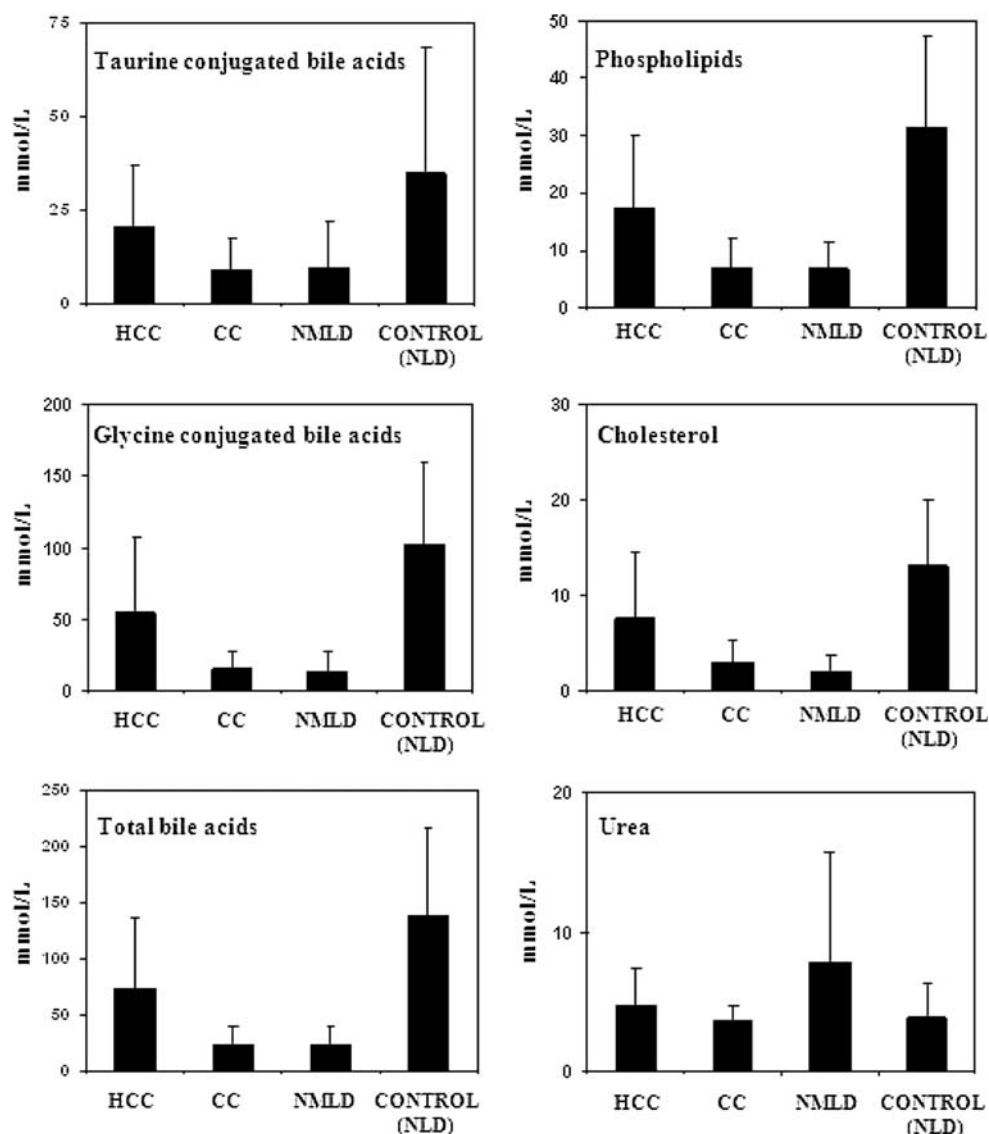

Several factors may contribute to the decreases in several major bile metabolites seen in liver diseases. These

factors may include the impairment of bile synthesis and aberrant enterohepatic circulation, arising from the obstruction of flow of biliary metabolites due to the damaged bile ducts. However, the contribution of each effect may also depend on the nature and/or the severity of the disease process. In the present study, CC and NMLD caused the highest disturbance, while HCC caused the least. Apart from the reduction in major bile metabolites in both malignant and NMLD, altered ratios of the metabolites, in some cases to a significant limit, highlight the specific etiological contributions to the bile metabolites synthesis/enterohepatic circulation (Fig. 6). Thus, metabolite ratios, together with the generally decreased absolute concentrations, may have diagnostic value in the management of different liver diseases. For bile acids, however, the possibility of changes in their concentrations due to aberrant enterohepatic circulation with no relation to liver function can not be ruled out.

In liver diseases, aberrations in enterohepatic circulation may also result in accumulation of bile metabolites in the diseased liver. A recent study on liver tissue using high resolution magic angle sample spinning NMR spectroscopy has indicated large amounts of bile acids in liver tumors compared to the non-tumor tissue [10]. Such accumulations of bile acids in the liver may also cause their elevation in circulating blood. Indeed, bile acids in blood have been shown to increase in liver disease and their measurement in serum has been reported to have diagnostic value for liver diseases including liver cancer [15–20]. A drastic reduction in several conjugated bile acids, some even to an undetectable level (Fig. 2), may indicate that depending on the nature of cellular damage, one particular conjugated bile acid synthetic pathway may be favored over the other. Such a difference in the profiles of the same bile acids between malignant and non-malignant liver disease may potentially serve as a diagnostic tool for the cancer detection. Moreover, identifying changes in specific metabolic pathways of bile acid synthesis may have implications for prognosis, similar to the finding that the patients with liver diseases with serum chenodeoxycholic acid levels exceeding $15 \mu\text{mol/L}$ are more likely to die of the disease or need liver transplantation [17].

One of the main functions of the liver is ammonia detoxification. Ammonia produced from the deamination of amino acids is converted to urea through the urea cycle and excreted through the kidney. While nearly 50% of urinary solids constitute urea, blood contains only 2.5–7.5 $\mu\text{mol/mL}$ dissolved urea. Using $^1\text{H-NMR}$ spectroscopy, we have previously shown that in a patient with non-functional liver, urea levels decrease drastically in urine [28]. In bile, we reported the observation of a urea signal using $^1\text{H-NMR}$ spectroscopy [24]. In the present investigation, we used this approach to show somewhat

Fig. 5 Comparison of differences in metabolite concentration in hepatocellular carcinoma (HCC, $n = 11$), cholangiocarcinoma (CC, $n = 7$), non-malignant liver diseases (NMLD, $n = 9$) and non-liver disease controls (NLD, $n = 17$)

increased urea levels in benign liver diseases relative to non-liver disease controls (Table 2, Fig. 5). This is in contrast to other major bile metabolites, which decrease significantly in disease relative to controls. With the exception of a very old study reporting that urea formation and bile secretion are related [29], no definite connection between the urea and the major bile metabolites identified in this study has been documented. It remains to be seen whether the increased trend of urea levels in NMLD has anything to do with the deconjugation and deamination of taurine and/or glycine associated with bile acids. Such deconjugation has long been attributed only to gut bacterial action.

Generally, studies aimed at detecting or understanding pathological conditions are often based on the measurement of a single metabolite. For example, a decrease in the concentration of phospholipids is shown to occur in bile

from patients with HCC [14], increased cholesterol levels is shown to cause gallstone diseases, increased urea is an indicator of malfunction of the liver, and altered individual bile acids levels have been implicated in several liver diseases. In reality, the biological picture is more complex: liver synthesizes bile that has cholesterol, phospholipids, urea and several conjugated bile acids as its major constituents. Observing the status of bile homeostasis through an approach that detects such multiple metabolites quantitatively and in parallel should provide more reliable information on liver status. Analytical methods that enable visualization of these metabolites in one step thus, have far reaching implications for better understanding the specific cellular functions associated with bile synthesis and/or enterohepatic circulation under normal and disease conditions. MS, a highly sensitive analytical method, has been extensively used by a number of research groups for bile

Fig. 6 Comparison of the ratios between some major bile metabolites in different patient groups (HCC, $n = 11$; CC, $n = 7$; NMLD, $n = 9$ and NLD, $n = 17$). *BA/Chol* total bile acids to cholesterol ratio, *BA/PL* total bile acids to phospholipids ratio, *PL/Chol* phospholipids to cholesterol ratio, *Gly/Tau* glycine- to taurine-conjugated bile acids ratio. acids analysis and investigating bile acid metabolism associated with liver disease [30, 31]. A more recent review describes a number of MS approaches for the quantitative analysis of lipids in intact biological samples [32]. Utilization of such advancements in MS potentially complements and supplements the analysis of multiple metabolites in human bile using NMR spectroscopy.

Conclusions

This investigation details how changes within the bile can be visualized by use of in vitro proton magnetic resonance spectroscopy of intact gallbladder bile, a simple approach that distinctly measures several major bile metabolites simultaneously. This is the first pilot study that explores variation of several major bile metabolites using a simple one step analysis NMR method in malignant and non-malignant and, non-liver disease controls. While serum-based bile acids are shown to increase in liver diseases, this investigation on bile finds that several major bile metabolites, including bile acids, significantly decrease in various liver disease states.

Although, the study was conducted on a relatively small number of patients, significant alterations in the amounts and ratios of several major metabolites potentially indicate the immense value in the diagnosis of liver diseases. To

assess changes in the bile metabolites more accurately, we performed studies in bile after diluting and adjusting the pH or by dissolving in an organic medium. However, several major bile metabolites such as phospholipids, glycine-conjugated bile acids and taurine-conjugated bile acids can be detected in intact bile with reasonably good accuracy. These metabolites can be subjected to automated analysis using a software package when high throughput analysis is required.

In this study, the concentrations of bile metabolites were determined with no consideration of the differences in gall bladder bile concentration, if any. Studies that take into account such differences may further improve the classification of patients. Use of normalization approaches for the gallbladder bile data, when proved meaningful, and/or measurement of biliary drainage from the liver, would strengthen the findings of this study, provide better insights into the bile metabolic profile, and possibly open avenues for clinical applications.

Further, high sensitivity of bile homeostasis to liver function/disease combined with the high concentrations of major bile metabolites in gallbladder makes it convenient to assess bile using in vitro $^1\text{H-NMR}$ spectroscopy and, this may possibly provide avenues for translational research in detecting and following their dynamic variations in clinical settings using non-invasive in vivo magnetic resonance spectroscopy.

Abstract Lipase-catalyzed interesterification was used to prepare different structured lipids (SL) from rice bran oil (RBO) by replacing some of the fatty acids with α -linolenic acid (ALA) from linseed oil (LSO) and n-3 long chain polyunsaturated fatty acids (PUFA) from cod liver oil (CLO). In one SL, the ALA content was 20% whereas in another the long chain n-3 PUFA content was 10%. Most of the n-3 PUFA were incorporated into the *sn*-1 and *sn*-3 positions of triacylglycerol. The influence of SL with RBO rich in ALA and EPA + DHA was studied on various lipid parameters in experimental animals. Rats fed RBO showed a decrease in total serum cholesterol by 10% when compared to groundnut oil (GNO). Similarly structured lipids with CLO and LSO significantly decreased total serum cholesterol by 19 and 22% respectively compared to rice bran oil. The serum TAGs level of rats fed SLs and blended oils were also significantly decreased by 14 and 17% respectively compared to RBO. Feeding of an n-3 PUFA rich diet resulted in the accumulation of long chain n-3 PUFA in various tissues and a reduction in the long chain n-6 PUFA. These studies indicate that the incorporation of ALA and EPA + DHA into RBO can offer health benefits.

Keywords Rice bran oil · n-3 PUFA · Linseed oil · Cod liver oil · Enzymatic acidolysis · Serum lipids · Liver lipids

Introduction

Over the past 20–30 years, intake of n-6 fatty acids (FA) has increased because of excess use of vegetable oils in our diets [1]. The fatty acid composition of our diet plays a key role in health and disease prevention [2]. Studies have shown that diet and dietary lipids have an important role to play in the prevention of risk of cardiovascular diseases [3, 4]. Clinical and epidemiological studies have shown the cardiovascular protective effects of n-3 polyunsaturated fatty acids (PUFA) [5, 6]. Based on surveys conducted on Indian dietary patterns, Ghafoorunissa [7, 8] has estimated that Indians derive 12.6 g of linoleic acid (LA) per day, equivalent to 4.8 energy % (en %) from visible and invisible fat. The requirement of LA as an essential FA is 3 en %, hence Indian diets provide adequate amounts of LA. However the intake of n-3 PUFA by Indians is in the range of 0.3 g in the rural population and 0.6 g in the urban population, equivalent to 0.2–0.3 en % [8, 9]. Dietary recommendations have been made for n-3 FA, including α -linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) to achieve nutrient adequacy in order to prevent and treat cardiovascular diseases. These recommendations are based on a large body of evidence from epidemiologic and controlled clinical studies. The n-3 FA recommendation to achieve nutritional adequacy is defined as the amount necessary to prevent deficiency symptoms and is 0.6–1.2% of energy for ALA and up to 10% of this can be provided by EPA or DHA [10]. The evidence base supports a dietary recommendation of

approximately 500 mg/day of EPA and DHA for cardiovascular disease risk reduction [11]. To achieve the recommended ALA intakes, food sources including flaxseed and flaxseed oil, walnuts and walnut oil, and canola oil are recommended. Linseed (*Linum usitatissimum*), which is rich in ALA, is an economically important oilseed crop used for edible purposes in the central and north-eastern regions of India. Green and Marshall [12] reported that linseed oil with its higher degree of unsaturation reacts immediately with oxygen to develop off flavour and rancidity and hence the shelf life of linseed oil is poor. Linseed oil is a rich source of α -linolenic acid, which is an essential fatty acid, can be utilized as a source of ALA for the synthesis of structured lipids. n-3 PUFA are considered to be anti-inflammatory, whereas the n-6 PUFA are considered to be pro-inflammatory [13]. Rice bran is a by-product of the rice milling industry. RBO obtained from rice bran is a rich source of tocopherols, tocotrienols and γ -oryzanol [14]. γ -Oryzanol has been reported to possess hypocholesterolemic and antioxidant activity [15–17]. RBO contains approximately 38% oleic acid (18:1n-6), 34% linoleic acid (18:2n-6) and 18.6% palmitic acid (16:0) [18]. However, RBO does not contain long chain n-3 PUFA, hence n-6 to n-3 ratio is high in RBO. The ratio of n-6 to n-3 fatty acid is often used to assess the balance between essential fatty acids in the diet. The WHO/FAO suggests a ratio of 5:1–10:1 [19], on the basis of proposed adequate intakes the NIH suggests a ratio of 2:3–3:1 [20]. The accretion of long chain n-3 fatty acids in tissue phospholipids may be dependent on the particular n-3 fatty acid that is provided in the diet [21]. Oily fish can provide sufficient n-3 PUFA such as EPA and DHA, however many Indians refrain from eating fish, as it is not a vegetarian food [22]. The beneficial properties of LSO and CLO have been enumerated [23–25]. LSO could be exploited as an alternate source of n-3 fatty acids. However LSO has very limited use in diet because it is oxidized rapidly due to its high level of unsaturated fatty acids. Among all unconventional edible oils, RBO seems to have great promise for use in SL and blends because of its beneficial nutritional properties due to its oryzanol, tocopherols and tocotrienol content which may confer oxidative stability to PUFA rich oil. The interest in the production of SL containing specific fatty acids have been increasing continuously because the nutritional value of triacylglycerol depends (TAG) both on fatty acid composition as well as the positional distribution of acyl groups within the TAG molecule. Therefore SL provides an opportunity for using specific end uses by improving physical and nutritional properties. Earlier investigations have revealed that SL which are enriched in n-3 PUFA may exhibit significant beneficial effects when compared to physical mixtures of oils having similar fatty acid composition. The SL may behave differently from

physical mixtures by exhibiting differences in their digestion, absorption and transport [26]. The TAG of blended oils retain their original absorption rates, whereas in SL in which the TAG are restructured have a different absorption rate [27]. Enhanced lymphatic absorption of medium chain fatty acids (MCFA) in rats was observed with a structured TAG containing MCFA (C10:0 and C8:0) in the *sn*-2 position and linoleic acid in the 1- and 3-positions compared with the physical mixture of these fats [28]. Though several groups have studied SL with respect to absorption and transport, very few studies have examined their lipidemic effects. Lee and Akoh reported that SL with n-3 PUFA like EPA and DHA when fed to mice lowered TAG and low density lipoprotein (LDL) cholesterol levels more efficiently when compared to soybean oil n-3 PUFA [29]. One of the major objectives of the present investigation was to enhance the consumption of RBO by making value added products from it. In this study the influence of SLs with RBO rich in n-3 PUFA was studied in experiment animals for their hypo-lipidemic properties.

Materials and Methods

Materials

Refined RBO, GNO and CLO were obtained from a supermarket of Mysore, Karnataka, India and LSO was purchased from Palampur, Himachal Pradesh, India. Lipozyme IM 60 was a gift from Novo Nordisk Bioindustrial Inc., (Danbury, CT, USA). Cholesterol, triolein, dipalmitoylphosphatidylcholine and thiobarbituric acid (TBA) were purchased from Sigma Chemical Co. (St Louis, MO, USA). Heparin and manganese chloride were obtained from the Sisco Research Laboratory (Mumbai, India). Digitonin was purchased from BDH Chemicals (Mumbai, India). All solvents were of analytical grade and distilled before use.

Synthesis of Structured Lipids and Preparation of Blended Oil

SLs enriched in ALA and EPA + DHA were synthesized from RBO by enzymatic acidolysis using 1,3 specific lipase, Lipozyme IM60 from *Rhizomucor miehei*. FFA obtained by alkaline hydrolysis of LSO and CLO were used as the source of ALA and EPA + DHA respectively (unpublished data). Large scale synthesis of structured lipids were prepared in stirred batch reactions. Reactions were carried out in 1-L stoppered conical flasks using optimum conditions derived for the incorporation of ALA into RBO by response surface methodology. Optimum conditions used for the preparation of SLs are as follows:

RBO and ALA were taken in 1:5.5 molar ratio, enzyme concentration (Lipozyme IM 60 from *Rhizomucor miehei*) was 1% of total substrates weight, incubated at 37.5 °C for 8 h with constant agitation. In the case of SL from RBO rich in EPA + DHA reactions were carried out using optimum conditions derived for incorporation of EPA + DHA by response surface methodology. Following optimum conditions were used: RBO and EPA + DHA were taken in 1:7.75 molar ratio, 7.75% enzyme concentration (Lipozyme IM 60 from *Rhizomucor miehei*) total substrates weight and incubated at 32.5 °C for 37 h with constant agitation. At the end of the incubations the newly synthesized SLs were purified using column chromatography and the solvent was removed by using a flash evaporator and SLs were stored under nitrogen at –20 °C.

Blended oils were prepared by physically mixing RBO and LSO in 3:2 (w/w) proportion by weight and stirring overnight under an inert atmosphere. Another blend was prepared with RBO and CLO in 1:1 (w/w) proportion under similar conditions. The ratios of blending oils were chosen in such a way that their ALA and EPA + DHA composition was similar to that of the SLs prepared.

Analysis of Fatty Acids in the *sn*-2 Position of TAG

The nature of FA in the *sn*-2 position of TAG purified through thin layer chromatography (TLC) after acidolysis was determined following the method of Luddy et al. [30]. Briefly, 1 mg of TAG was mixed with 1 mL of 1 M Tris–HCl buffer (pH 7.6), 0.25 mL of 0.05% sodium cholate, and 0.1 mL of 2.2% CaCl₂ and 1 mg of pancreatic lipase. The mixture was incubated in a water bath at 37 °C for 3 min, mixed vigorously for 1 min, centrifuged, extracted with 3 mL diethyl ether and dried over anhydrous sodium sulphate. Samples were spotted on TLC plates coated with silica gel G and developed in hexane: diethyl ether: acetic acid (50:50:1; v/v/v). The band corresponding to 2-monoacylglycerol reference standard was eluted with chloroform: methanol (2:1 v/v). The lipid was saponified with 0.5 N KOH in methanol and fatty acids were methylated with BF₃/methanol and analyzed by gas chromatography (GC) [31].

Experimental Animals

Male Wistar rats 36.0 ± 3.0 g were grouped by random selection into six dietary groups (*n* = 6 per group). They were placed in individual cages in the animal house facility of the institute and fed fresh diets daily. The animals had free access to food and water throughout the study. All the animal experiment protocols were approved by the Animal Ethical Committee of the Institute.

Diet Composition

The ingredients used in the basal diets were (g/100 g): casein 20, cellulose 5, sucrose 60, AIN-76 mineral mix 3.5, AIN 76 vitamin mix 1, methionine 0.3, choline chloride 0.2, and fat 10 [32]. Rats were fed with different diets based on groundnut oil, RBO, SL (RBO and CLO and RBO and LSO), blends of RBO + CLO and RBO + LSO.

Serum and Liver Lipid Analysis

At the end of the experimental feeding period of 60 days, rats were allowed to fast overnight and sacrificed under ether anesthesia. Blood was drawn by cardiac puncture and serum was separated by centrifugation. Liver and other tissues were removed and rinsed with ice-cold saline, blotted, weighed and stored at –80 °C until analyzed. Lipids were extracted from serum and tissues by the method of Folch et al. [33]. Serum lipid peroxides and TBA reactive substances (TBARS) in the liver were analyzed as described by Yagi [34] and Berg and Aust [35] respectively. Serum and liver cholesterol content was quantitated by the method of Searcy and Bergquist [36]. High density lipoprotein (HDL) cholesterol in serum was measured after precipitating apo B containing lipoproteins with heparin–MnCl₂ reagent [37]. LDL + VLDL cholesterol was obtained by subtracting HDL cholesterol from total cholesterol. Phospholipids were analyzed by the method of Stewart [38] using dipalmitoylphosphatidylcholine as the reference standard. TAG were estimated by the method described by Fletcher [39].

The fatty acid composition of dietary lipids, serum and tissue lipids were analyzed as methyl esters (ME) by gas chromatography (Shimadzu 14 B fitted with FID) using a fused silica capillary column 25 m × 0.25 mm (Konik Tech, Barcelona, Spain). The ME of fatty acids were prepared using BF₃/MeOH as described by Morrison and Smith [31]. The injector and detector temperatures were 230 and 240 °C, respectively. The column temperature was held isothermally at 220 °C and nitrogen was used as the carrier gas at a flow rate of 1 mL/min. Individual fatty acids were identified by comparing with retention times of standards.

Statistical Analysis

Data were expressed as mean ± SEM and analyzed by one-way analysis of variance (ANOVA) for any significance at *P* < 0.05. Mean separation was accomplished by Duncan's dunnet statistical analysis [40].

Results

Fatty Acid Composition of Dietary Lipids

Dietary lipids containing SL with LSO had 20% ALA and that with CLO had 3.7 and 5.4% EPA and DHA respectively. Blends of RBO with LSO and CLO had ALA, EPA and DHA at the same level as their SL (Table 1). Analysis of fatty acid composition at the *sn*-2 position of different dietary lipids is also given in Table 1. RBO and GNO contained only oleic acid and linoleic acid at the *sn*-2 position whereas SL with LSO contained 15% ALA and SL with CLO contained 8.1% EPA + DHA. On the other hand, a blend with LSO contained 18% ALA and a blend with CLO contained 21% of EPA + DHA.

Effect of Dietary Lipids on Growth Parameters

The influence of various dietary fats with different types of fatty acids on growth is given in Table 2. The fat content of various diets was kept constant at 10%. The amounts of diet consumed by animals in different groups were comparable except in SL with LSO and blend with CLO which showed a significant increase in food intake. There were no significant changes in body weight gain and the food efficiency

ratio except in blends with CLO where the food efficiency ratio was significantly higher compared to the other groups. Weights of heart, brain and spleen of rats fed different dietary fats were comparable. Similarly there were no changes in liver weight in any of the groups (Table 3).

Effect of Feeding Different n-3 PUFA on Serum Lipid Profile

The serum lipid profile of rats in response to different dietary lipids is given in Table 4. Rats fed RBO showed a decrease in total serum cholesterol by 10% when compared to GNO. Structured lipids with CLO and LSO significantly decreased total serum cholesterol by 19 and 22% respectively compared to rice bran oil. In the case of blends also the total cholesterol decreased significantly compared to RBO group. This reduction occurred both in the HDL and LDL fractions. There was no difference in total cholesterol content of serum in rats fed SLs and blends but HDL cholesterol was increased in blends compared to SL.

The serum TAGs level of rats fed SLs and blended oils also significantly decreased by 14 and 17% respectively compared to RBO. Serum phospholipids concentration was not altered in all n-3 PUFA fed animals except in rats fed blended oil with CLO where it was decreased. There was

no difference in TAGs and phospholipids in rats fed SLs and blends.

Serum Fatty Acid Profile Rats Fed with n-3 PUFA

Significant changes were observed in SL with CLO compared to blend with CLO. The n-3 fatty acids level in rats given SLs and blends with CLO and LSO (Table 5). The ALA content was 5.4 and 4.5% in SLs and a blend with LSO respectively. A significant increase in EPA + DHA levels and arachidonic acid content significantly decreased in blends as well as in SLs both. ALA, EPA and DHA were not detected in the serum of RBO and GNO fed groups. On the other hand feeding of SLs and blends with CLO resulted

in a significant increase in the levels of all n-3 PUFA. Feeding of SLs and blends rich in n-3 PUFA significantly decreased the oleic and linoleic acid content of serum lipids.

Liver Lipid Profile of Rats Fed with n-3 PUFA

The total cholesterol content in the liver was significantly decreased in rats fed SLs with CLO and LSO compared to RBO but blends did not alter. TAG content was decreased significantly in SL with CLO and a blend with LSO compared RBO (Table 6). There was no change in TAG levels between SL and blends. Reduction in TAG content in other groups was not statistically significant compared to RBO fed group.

Liver Fatty Acid Profile

The fatty acid composition of the liver lipids of rats fed SLs and blended oils with CLO and LSO is given in Table 7. Feeding of SLs and blended oils with CLO resulted in a significant reduction of arachidonic acid (45%) and an

accumulation of EPA and DHA. At the same time, oleic and linoleic acids were decreased by 50 and 37% respectively, compared to the RBO fed group. On the other hand, feeding LSO either in SL or blended oils resulted in an accumulation of ALA, EPA and DHA and a reduction in the level of arachidonic acid, oleic and linoleic acids compared to the RBO fed group.

Fatty Acid Composition of Heart, Brain, Eye and Adipose Tissues

The dietary n-3 PUFA level influenced the FA composition of heart (Table 8), brain (Table 9), eye (Table 10) and adipose tissues (Table 11). The fatty acid composition of the heart was significantly influenced in rats fed n-3 PUFA containing SLs and blended oils. LSO feeding either as SLs or blended oil resulted in the significant accumulation of ALA, DHA and EPA compared to the RBO fed group. The level of DHA was significantly increased in the heart tissues of rats given SL and blends with CLO compared to RBO fed group. There was a 5.3 fold increase in the DHA

level of rats fed SL with CLO compared to RBO, whereas in rats fed SL and a blend with LSO, the increase in DHA was only 2.9 fold compared to the RBO fed group. Rats fed

SL and blends with CLO significantly decreased the levels of oleic and linoleic acids. In the brain, small amounts (2.4 and 1.6%) of ALA was detected in rats fed structured lipids

and blends with LSO respectively, whereas this fatty acid was not detected in other dietary groups. The basal level of DHA in RBO and GNO was 4.4 and 4.7% respectively of the total FAs, whereas it was increased to 10.4 and 8.1% in SL with CLO and LSO respectively compared to RBO fed group. Similarly it was increased in the case of blends up to 9.4 and 7.4% of the total FAs in the blended oil groups as compared to RBO and GNO. In the eye, the DHA content was increased significantly in all groups of animals compared to RBO. Whereas only small amounts of EPA were detected in these animals. ALA was detected only in LSO fed animals. There was a significant reduction in arachidonic acid. In the adipose tissue of rats fed structured lipids and blends with LSO had 10.5 and 10.3% of ALA respectively of the total fatty acids, whereas it was not detected in rats of other dietary groups. EPA and DHA were found only in small amounts in rats fed SL and blends with CLO.

Discussion

The present investigation was aimed at enriching rice bran oil with ALA from linseed oil and EPA + DHA from cod liver oil and studying the effect of these modified lipids on changes in the serum and hepatic lipid profiles of rats when fed as the sole source of dietary fat. The effect of SLs synthesized was also compared with that of blends of RBO with CLO and LSO with similar levels of n-3 PUFA. Even though 1, 3 positional specific lipase from *Rhizomucor miehei* [41] was used as a catalyst, amounts of ALA (15%) and EPA + DHA (8.1%) were incorporated into the SLs synthesized with LSO and CLO respectively. This indicated that most of the ALA and EPA + DHA in the modified lipids was incorporated in the 1 and 3 positions of the triacylglycerol molecule of RBO. The small increase in the ALA and EPA + DHA at the *sn*-2 position of SLs could be attributed to acyl migration and such acyl migration was reported by Xu et al. [42, 43]. In the case of blended oils, fatty acid composition was similar to that of the SL and their fatty acid content at the *sn*-2 position was similar to that of SLs. Numerous studies have shown that SLs have unique metabolic pathways and exhibit many superior metabolic benefits in comparison to that of the blended oils. Studies have shown that rats receiving SLs containing both medium chain and long chain fatty acids showed the greatest gain in body weight, enhanced skeleton muscle and liver protein synthesis as well as a marked increase in nitrogen retention over comparable groups of rats given physical mixtures of long chain TAG and medium chain TAGs [44, 45]. Even though many studies have clearly shown that there are significant differences in the mode of absorption of fatty acids based on acylglycerol

structures, very few studies have addressed the lipidemic effects of modified lipids. The SLs containing n-3 PUFA showed a significantly higher hypolipidemic effect than that of the blended oils when fed as a sole source of fat in the diet. A similar hypolipidemic effect of SL was also observed in liver. Feeding SL and blends increased the ALA and EPA + DHA levels in the liver and other tissues lipids. This also resulted in an incremental increase in the accumulation of EPA + DHA in the serum, liver and other tissues. This indicated that conversion of ALA to long chain PUFA takes place in rats. The increase in EPA and DHA was higher in rats fed fats containing these fatty acids in a preformed state. Both blended oils and SL increased the 18:3 and EPA + DHA levels in the liver and other tissues. One reason for this may be the higher levels of EPA and DHA in the diets containing modified lipids. Another reason could be due to the slow conversion of ALA to long chain n-3 PUFA (EPA and DHA). Preformed EPA + DHA was taken up by serum and liver much more efficiently than that obtained from ALA. The level of arachidonic acid in heart tissue decreased when n-3 PUFA was included in the diet. Earlier studies have shown that feeding a diet containing ALA can increase the level of this FA as well as the level of long chain metabolites, to varying degrees [46–51]. Rats fed SLs and blends with n-3 PUFA increased the amount of n-3 PUFA in the liver and heart tissue which is in agreement with the findings of Medeiros et al. [52].

The brain is a unique organ characterized by the presence of a high concentration of DHA, which influences its structure and functional properties [53]. The high level of DHA in the brain of a number of mammalian species irrespective of their size led to early speculation that this fatty acid plays a crucial role in the nervous system. Many studies using ALA deficient diets have shown a reduction in the level of DHA in the brain and loss of many cognitive functions [54]. Studies have reported that supplementation of arachidonic acid and DHA can remedy the cognitive dysfunction due to organic brain damage or aging [55]. Feeding rats with SLs and blends containing 18:3 and EPA + DHA increased the DHA levels in the brain compared to RBO and GNO fed rats. We also observed that rats fed preformed DHA in the form of SL and blend with CLO showed a higher levels of DHA in the brain as compared to those fed SL and blends with LSO. This finding is in agreement with an earlier report showing that preformed DHA is incorporated efficiently into brain tissue [50, 56]. Earlier studies have shown a small but significant increase in the 18:3 and EPA levels in brain tissue when the diet was high in n-3 FAs [56]. Studies indicated that feeding a diet high in ALA to guinea pigs increased the EPA and DHA levels in liver, heart, and adipose tissues when compared with a diet low in ALA [57–59]. However, in our study,

EPA and DHA were not detected in the adipose tissue when rats fed with SL and blends containing ALA. Similarly, other study has reported that ALA enriched diets resulted in the accumulation of ALA, but not EPA and DHA [59]. These studies may indicate that with a high intake of n-3 PUFA, ALA can accumulate in adipose tissue but its elongation to EPA and DHA is restricted. However these fatty acids can accumulate in adipose tissue when given in a preformed state. The American Heart Association recommends for those individuals without heart disease that they eat a variety of fish at least twice a week and include oils and foods rich in ALA (flaxseed, canola, and soybean oils; flaxseeds and walnuts) [60].

In conclusion, the present studies indicated that ALA and EPA + DHA were efficiently absorbed from SLs as well as from blended oils. The food intake and growth of animals also showed that the SL was as efficient as a blended oil in supporting the growth of the animals without having any adverse effects. Rice bran oil enriched with n-3 PUFA significantly lowered the serum and liver lipids which are high risk factors for cardiovascular diseases. Therefore, RBO can be enriched with ALA and EPA + DHA by lipase catalyzed interesterification reactions and these modified lipids exhibited hypocholesterolemic and hypolipidemic effects in rats when compared to unmodified RBO. Use of an immobilized enzyme for the preparation of structured lipids offers the advantage of adding desirable fatty acids at a specific position of TAG.

Oolichan Grease: A Unique Marine Lipid and Dietary Staple of the North Pacific Coast

Abstract Oolichan grease, a dietary fat prepared from smelt-like fish, is highly prized by north Pacific coast aboriginal cultures. The composition of oolichan grease is unclear, with one report indicating a high 22:6n-3 content consistent with cold-water marine oils, but another reporting a much lower value. We noted that oolichan grease remains solid up to 15 °C, suggesting a low polyunsaturate content. After extracting total lipids from four fresh oolichan fish and four samples of grease, fatty acids were quantitated by high resolution gas chromatography (GC), as were additional samples of fish lipid and grease that were fractionated into triglyceride (TG), phospholipid (PL), and free fatty acids by thin-layer chromatography. In contradistinction to one prior report, we found EPA and DHA in fresh fish total lipids to be 0.9 and 2.2 wt%, respectively, while in the extracted grease, both were reduced to 0.5 wt%. Only the fresh fish PL fraction contained appreciable DHA. The bulk of the grease consisted of saturated fatty acids (30.3 wt%) and mono-unsaturates (55.0 wt%), explaining its high melting point. Excepting its very low omega-6 content (<2 wt%), oolichan grease is

quite similar in composition to human adipose TG. Its solid state at environmental temperatures and low peroxidizability index made it suitable for storage and transport, explaining its status as a preferred trade item among regional aboriginal groups.

Keywords Oolichan grease · Eulachon · Dietary fat · Low carbohydrate diet

Introduction

Dietary fat serves a host of functions, providing two classes of essential fatty acids, a vehicle for fat soluble vitamins, imparting flavor and texture, and functioning as an energy dense (and thus efficiently transportable) calorie source. Particularly among aboriginal hunting cultures, fat was highly valued, and the annual hunting/fishing cycle was often timed to yield selected animals at points of highest body fat content.

Much has been written about the “Paleolithic diet”, and it has been variously characterized as relatively high in protein with moderate fat [1] or low in protein and high in carbohydrate [2], but most researchers in the field of nutritional anthropology have avoided or ignored traditional diets providing less than 20% of energy as carbohydrate. It is also a common assumption that non-farming aboriginal cultures conformed to a primitive mixed dietary pattern until the adoption of agricultural foods. However even a cursory look at pre-Columbian North American dietary patterns reveals a great diversity food sources and nutrient mixes.

As one moves north in the area that is now the US and Canada, both the opportunity to farm and the availability of wild nuts, seeds, and fruit is decreased. At the geographic

apex of this climate-determined food pyramid, the Inuit culture evolved the tools and skills over 3,000 years necessary to live year round in the Arctic [3], where dietary carbohydrate was essentially unavailable. Based upon the observations of acculturated European explorers who lived among them, the Inuit diet consisted mostly of fat, was moderate in protein, and was virtually devoid of carbohydrate [4–6].

The experience of Stefansson [5] is particularly worthy of note, as he lived for a decade among the Inuit in the Arctic and ate their diet exclusively for periods of up to 2 years without re-supply. When challenged by the emerging nutrition establishment in the 1920s, Stefansson and another explorer consented to prove that a European could subsist on just meat and fat, doing so under observation for a year [6, 7]. Although they ate foods available in New York at the time, these explorers were effectively demonstrating a pattern of eating directly derived from the Inuit culture. And based upon proximate analysis of meals consumed, their diet consisted of 85% of energy from fat, 15% from protein, and inconsequential carbohydrate [7].

High fat, moderate protein, low carbohydrate eating patterns were not unique to Arctic cultures. Some Native American and First Nations cultures in the central continental region did not or chose not to farm, subsisting principally upon the buffalo, with a well-documented group being the Lakota/Dakota/Nakota Nation [8]. Further west, farming was not practiced on the Pacific coast north of what is now Mexico; and north of Puget Sound, the only dietary carbohydrate source was seasonal berries.

Of particular importance to the aboriginal cultures along the north Pacific coast was a small fish called the oolichan (ooligan, eulachan, candle fish—*Thaleichthys pacificus*). Along the coast from northern California to the Bering Strait, this smelt-like fish was harvested in great quantities when it spawned in the spring. It was eaten fresh, dried, and smoked; however the bulk of the harvest was fermented, mixed with water and boiled in wooden tubs, and the released fat (about 20% by weight in the fresh fish) was skimmed and saved for use throughout the year [9].

In addition to being used locally along the coast, this oolichan oil, commonly called “grease”, was a highly prized commodity of trade, being carried inland as far as 300 miles on established footpaths known as grease trails. This network of trails supported extensive trading amongst the aboriginal bands in the region; and while many other items such as copper, flint, furs, and dried meat were transported over them, they existed principally for the purpose of carrying oolichan grease inland.

In conversations with First Nations elders along the British Columbia coast, one is struck by the uniformly strong appreciation of oolichan grease as a cornerstone of their diet and culture. Now increasingly rare due to the

disappearance of the oolichan fishery, oolichan grease was a major part of the daily diet in this region up until the last generation. Discussions with elders in rural areas suggest that up to half of the daily dietary energy was supplied by oolichan grease prior to European contact.

Oolichan grease from the British Columbia coast has been previously studied for its fatty acid composition [9, 10]. The report by Kuhnlein et al. [10] indicates that it contained a relatively high DHA content (18–23%) typical of cold-water fish oils. In contrast, Iverson et al. [11] reported that fat extracted from fresh oolichan contained 1.5% EPA and 2.5% DHA. Given that oolichan grease is a semi-liquid at room temperature, the second report by Iverson is more consistent with its physical properties, as DHA has a very low melting point. To better understand its nutrient composition and the reason for the strong cultural preference for this unusual fat source, we obtained samples of oolichan fish and the extracted grease to evaluate their fatty acid compositions.

Methods

To determine the initial fatty acid composition of the oolichan fish and how the traditional extraction process (i.e., fermentation and boiling) might change the mix of fatty acids in the prepared grease, four individual fresh frozen fish from the 2006 Nass River harvest and four samples of grease (three from the 2005 harvest and one from 2006) were analyzed. All samples of fresh fish and grease were shipped frozen and stored at -80°C until analysis.

The total fatty acid composition of these eight samples (four fresh fish, four samples of grease) were determined by the methods described below. In addition, one sample each of the fish and grease was also subjected to thin-layer chromatographic separation into individual lipid fractions (triglycerides, phospholipids, and free fatty acids) and the composition of these individual fractions was also determined by high resolution gas chromatography.

Whole fish samples were weighed and homogenized in a laboratory blender in the presence of a determined amount of water. Lipids were then extracted from the homogenized fish (and also directly from the grease) according to the method of Bligh/Dyer whereby mixtures of plasma, methanol, chloroform and water were prepared such that lipids are recovered in the resulting nonpolar chloroform layer. Resulting lipid extracts were maintained under an atmosphere of nitrogen at all times following extraction and kept frozen prior to additional processing. Immediately prior to lipid class separation, lipid samples were dried under a gentle stream of nitrogen, rediluted in $50\ \mu\text{l}$ of chloroform and prepared for lipid class separation. Lipid

classes including total phospholipid (PL), free fatty acids (FFA) and triglyceride (TG) were separated on commercial available silica gel G plates (AnalTech, Newark, DE, USA). The chromatographic plates were developed in a solvent system consisting of distilled petroleum ether (b.p. 30–60°C):diethyl ether:acetic acid (80:20:1, by vol). Following development, the silica gel plates were sprayed with a methanolic solution containing 0.5% 2,7-dichlorofluorescein which was then used to visualize lipid classes under ultraviolet light. Desired corresponding lipid bands were then scraped into Teflon line screw cap tubes. The samples were then transesterified with 4% sulfuric acid in methanol in an 80 °C water bath for 90 min. Resulting fatty acid methyl esters were extracted with water and petroleum ether and stored frozen until gas chromatographic analysis was performed.

Lipid class fatty acid methyl ester compositions were determined by capillary gas chromatography. Methyl ester samples were blown to dryness under nitrogen and resuspended in hexane. Resulting fatty acid methyl esters were separated and quantified with a Shimadzu capillary gas chromatograph (GC17) utilizing a 30 m Restek free fatty acid phase (FFAP) coating. The instrument was temperature programmed from 190 to 240 °C at 7°C/min with a final hold of 10 min, separating and measuring fatty acid methyl esters ranging from 12:0 to 24:1.

Detected fatty acids were identified by comparison to authentic fatty acid standards (NuChek Prep, Elysian, MN, USA) and processed with EZChrom software (Scientific Products, CA, USA). Resulting data are expressed in percent composition by weight. Individual peaks, representing as little as 0.05% of the fatty acid methyl esters, were distinguished.

Results

Consistent with the observed high melting point, all four samples of the oolichan grease were found to have a significant component of saturated fatty acids and very low levels of the long-chain omega-3 fatty acids that are typically found in most cold-water fish oils. Specifically, both EPA and DHA were each present at approximately 0.5%, as opposed to the 10–20% contents of each in salmon, herring, and cod liver oils. The dominant fatty acid class in the oolichan grease was mono-unsaturated fat, which is typical of both olive oil and also human stored body fat [12]. Also of note was the very low level of omega-6 fatty acids, with linoleate (18:2n-6) at 0.8% and arachidonate (20:4n-6) at 0.2%.

The whole fish analysis yielded similar composition profiles to that of the grease samples, with the exception that there were two to fourfold greater proportions of EPA and DHA in the whole fish. This result is explained by the analysis of the individual lipid fractions from the fish, in which the phospholipid fraction had 10% EPA and 33% DHA. These results are shown in Table 1. The higher levels of long-chain omega-3 fatty acids in the PL fraction would be required for cell membranes to function in the frigid waters in which these fish live. However, these PL fatty acids are clearly not extracted into the oolichan grease during processing, thus making the final product less prone to peroxidation and rancidity than the whole fish from which it comes.

The oolichan grease samples were not specifically analyzed for cholesterol content but there was very little cholesteryl ester evident on the thin-layer chromatography plate, suggesting that the total cholesterol content is quite

low. There was, however, a large unidentified peak observed during the GC analysis, consistent with a high squalene content. Squalene is a lipid found in modest amounts in olive oil and has previously been reported to occur at high levels in the oolichan fish [13]. Squalene is found in human skin and is a valued ingredient in skin moisturizer preparations.

Discussion

The key observation of this report is the very low content of omega-3 HUFA (specifically EPA and DHA) in oolichan grease. This, along with its dominant proportions of mono-unsaturates and saturates, is consistent with its relatively high melting point. Together, these properties reduce its propensity for rancidity and improve its portability as a solid at environmental temperatures, thus explaining in part its popularity as a storable fat and desirable unit of trade.

Our results from the analysis of fresh oolichan fish are consistent with those of Iverson et al. [11], and both differ from the reported high DHA content by Kuhnlein et al. [10]. What is also apparent from our results is that the traditional process of aging and slow extraction of oolichan grease as practiced by coastal First Nations further reduced the HUFA content in the grease, thereby further raising its melting point and reducing its peroxidizability.

In addition to benefitting its portability and shelf life, this reduction in HUFA as a result of the traditional extraction procedure would not have significantly altered the nutritional benefits of the grease in the context of the local diet. For one thing, the local diet included a great deal of salmon plus the blubber and flesh of sea mammals such as seal, sea lion, and whale—all rich sources of omega-3 fatty acids. One also needs to keep in perspective the fact that the local diet was very low in carbohydrate. Because a low carbohydrate diet for humans is necessarily high in fat, the high omega-3 fatty acid content of most marine lipids (seen as a benefit when used as an occasional food or

dietary supplement) might become a liability when used as a dietary staple.

If oolichan grease were used to supply about half of an adult's daily energy intake (4–5 oz/day), the total EPA + DHA intake would be less than 2 g compared to 30 g or more if the same amount of energy was obtained from seal, whale or fish oil. While a sustained intake of EPA + DHA at 30 g per day may be tolerable for a number of months, it is probably not beneficial (as evidenced by Prof. Hugh Sinclair's [14] bleeding tendency after eating only seal meat and blubber for 100 days). Thus, given the dietary conditions of the region, oolichan grease has unique nutritional properties that would have made it the preferred fat source for the traditional diet.

It is interesting to note the similarity of the composition of oolichan grease to that of human adipose tissue (Table 2). Assuming that the composition of human adipose tissue reflects the preferred mix of fatty acids to be used when human metabolism is utilizing mostly fat for fuel (e.g., during a famine), then the composition of oolichan grease would appear to be well suited as a dietary mainstay during a low carbohydrate diet. The human fat data used in this table came from people eating an industrial diet in California [12], which explains their much higher (but not necessarily healthier) 18:2n-6 level and very low levels of EPA and DHA.

One question raised by our results is the disparity in the reported DHA contents from fresh oolichan and the extracted grease between our study and that of Kuhnlein et al. [10]. The prior study analyzed 19 samples from 5 geographic sites compared to our four samples from one site, and both studies also examined lipids extracted from fresh fish. However, in the current report we performed the additional step of thin-layer chromatographic separation of the fish and grease lipids to determine the individual compositions of the TP, PL, and TG. Of particular note on the GC runs of the crude lipid extracts of both the raw fish and the grease was a single broad peak that eluted late, shortly after the elution time for DHA. Given both its separation from the small DHA peak found in these lipid

samples and its breadth, this peak was clearly not DHA. However, it would have been tempting for a chromatographer to identify it as such, particularly given the expectation of finding appreciable DHA in a cold-water marine oil sample.

There are a number of interesting conclusions that can be drawn as a result of our study. By selecting this small fish as a starting material and through its processing by fermentation and hot water extraction, First Nations cultures along the north Pacific coast developed a unique dietary lipid that is highly suited for human consumption, particularly in the context of the high fat diet that was traditional to that region. Furthermore, the low PUFA and HUFA contents afforded it both a high melting point and reduced peroxidizability, improving its ability to be stored and transported compared to other concentrated fat sources in the region. And yet, when eaten in quantity as a dietary staple (e.g., 2–4 oz per day) the 100–200 mg/day each of arachidonate and EPA/DHA would easily satisfy daily needs for these two essential fatty acid classes [15].

In conclusion, seen from the perspective of its fatty acid composition and related physical properties, oolichan grease can be appreciated as a refined fat that was uniquely suited for the needs of the regional population and their pre-contact low carbohydrate, high fat diet. Given these properties, the strong appreciation for oolichan grease throughout the region and the development of this unique fat product as a major item of pre-Columbian trade can be better appreciated.

Acknowledgments Numerous members of First Nations Bands in British Columbia contributed both samples and invaluable insight critical to the genesis of this report. We would like to especially thank Eva Dick and Barb Cranmer of the Namgis First Nation and Chester and Mary Moore, Bill Moore, CJ Martin, and Willard Martin of the Nisga'a First Nation. The authors also note the mentorship and

guidance of Prof. Ralph Holman. This project was supported in part by a grant from Health Canada.

Abstract Linseed, a source of linolenic acid, is used in ruminant diets to increase polyunsaturated fatty acids (FA) in animal products. Seed processing is known to have an impact on FA rumen metabolism, but few data are available for linseed. We studied the effect of linseed lipid on ruminal metabolism and intestinal digestibility in cows. Three modes of linseed processing: rolled linseed (RL), extruded linseed (EL) and linseed oil plus linseed meal (LO), supplemented at 7.5% of DM intake, were compared to a control diet (C). Duodenal flows, intestinal digestibility and plasma composition were determined. The duodenal flow of linolenic acid was similar among diets. The sum of t10 and t11-18:1, which were coeluted, was increased with lipid-supplemented diets and represented more than 60% of *trans* 18:1 for EL and LO diets. The main 18:2 isomers were c9, c12 and t11, c15 among the non-conjugated isomers, and t11, t13 among CLA. Linseed supplementation increased the duodenal flow of unsaturated intermediates of biohydrogenation, and this effect was more pronounced for extruded seeds and oil than for rolled seeds. For most 18-carbon FA, intestinal digestibility was slightly higher for C and LO diets than for RL and EL. Plasma concentrations of non-conjugated 18:2 and linolenic acid were similar among the lipid-supplemented diets. Within diet, profiles of 18:1

isomers (except c9) remained very similar between duodenal and plasma FA.

RL	Rolled linseed

Introduction

Linolenic acid, along with other fatty acids (FA) of the n-3 series, is known to have positive effects on human health, particularly by decreasing the incidence of cardiovascular diseases [1]. It has been suggested that the nutritional value of milk and beef could be improved by increasing linolenic acid content in ruminant diets. The two main sources of linolenic acid are grass, both fresh and ensiled [2], and linseed. Linseed is easy to incorporate in production rations and, despite extensive biohydrogenation (BH) in the rumen; it has been demonstrated to increase linolenic acid content significantly in both milk [3, 4] and meat [5–8]. Furthermore, these authors showed that animal products following linseed intake are enriched in c9, t11-18:2, which is an isomer of conjugated linoleic acid (CLA) that may have a positive effect on human health by decreasing the

incidence of cancer [9, 10]. Linseed incorporation also increases proportions of other FA such as t11-18:1 or c11, t15-18:2. These modifications in product composition arise from modifications in ruminal FA metabolism [11]. At the same time, it has been shown that moderate amounts of linseed added to rations do not impair organic matter or fiber digestion [12], whereas important amounts of linseed oil strongly reduced organic matter and fiber digestion [13].

Oilseeds can be either given as whole seeds or processed by different techniques, the most common being extrusion. In the case of linseeds, since digestion may not be optimized following the intake of whole seeds that have not been mechanically treated, it is recommended to supply them as rolled or ground seeds [7]. Theoretically, since the extrusion process breaks down plant cells, it is expected that cytosolic triglycerides are more accessible to rumen bacteria than when whole seed is given, meaning they are more rapidly available for lipolysis and BH. In two experiments recently carried out with extruded linseed, Akraim et al. [14] did not find any effect of linseed extrusion on duodenal FA composition, whereas Gonthier et al. [15] found that extrusion increased the disappearance of linolenic acid but also increased the proportion of intermediate compounds such as *trans* 18:1 FA in duodenal flow. These inconsistent data need to be verified, especially because Akraim et al. [14] did not measure duodenal flows while Gonthier et al. [15] did not determine *cis* and *trans* 18:1 composition in detail. Moreover, oil within the seed needs to be compared with free oil, firstly to evaluate the effects of oil accessibility according to its form of presentation, and secondly because published experiments have focused exclusively on either linseed oil or linseed but never the two in the same experiment and in the same amount. The aim of this study was thus (1) to investigate the consequences of a linseed supply on the changes in organic matter and fiber digestion (evaluated in a complementary paper [16]) and in the composition of absorbable FA; (2) to compare three modes of processing, i.e. rolled seeds, extruded seeds, and oil of this FA composition.

Materials and Methods

Experimental Design, Animals and Diets

All details on experimental design, animals, diets and samplings were described by Doreau et al. [16]. Briefly, four dry cows fitted with ruminal and duodenal cannulas were used in a 4 × 4 Latin square design with 5-week periods, with sampling during the last week of each period. They received four treatments: (1) control diet (C); (2) diet C supplemented with 7.5% rolled linseeds on dry matter

(DM) basis (RL); (3) diet C supplemented with 7.5% extruded linseeds on DM basis (EL); (4) diet C supplemented with 4.9% linseed oil and 2.6% linseed meal on DM basis (LO). Diets were given in limited amounts (i.e. 90% of individual voluntary intake determined in a pre-experimental period) to avoid refusals and differences in intake among diets. All diets comprised 60% corn silage, 10% hay, 14% dairy concentrate, 15% experimental concentrates, 0.5% urea and 0.5% of a concentrate mineral–vitamin premix (DM basis). Extruded linseeds were supplied as Croquelin[®] (Valorex, Combourtillé, France) which is an extruded mixture of 50% linseeds, 30% wheat bran and 20% sunflower meal (DM basis). Extrusion was performed with a one-screw extruder at 120°C after a low-temperature (72°C) preconditioning with steam for 157 min. In the RL diet, the linseeds of the same batch as that used to make Croquelin[®] were rolled with a roll crusher. Particle size, determined by dry sieving, was 22.6% > 2.0 mm, 62.0% between 0.8 and 2.0 mm; 9.4% between 0.4 and 0.8 mm, and 6.0% > 0.4 mm; the proportion of intact seeds was very low. Linseed oil was obtained by cold pressing and provided by Vandeputte (Mouscron, Belgium). Corn silage was offered in two equal portions at 9.30 a.m. and 4.30 p.m. Hay and concentrates, including oil, were offered at 9.00 a.m.

Fatty Acid Analyzes, Duodenal Flow and Intestinal Digestibility Calculations

Fatty acids in feedstuffs, duodenal digesta and feces were directly transmethylated, essentially as described by Sukhija and Palmquist [17] with modifications according to Loor et al. [11] in order to decrease isomerization of *cis*–*trans* conjugated double bonds due to too high temperature and too acidic pH. Total plasma lipids were extracted according to the method described in Folch et al. [18] using a chloroform/methanol mixture (2:1, by vol) (3 mL plasma + 20 mL mixture) and then rinsed with 6 mL distilled water and recovered in 1 mL hexane. Extracted FA were methylated with 2 mL of 0.5 N NaOCH₃ at 50°C for 45 min followed by 2 mL 5% HCl in methanol at 50°C for 45 min. After neutralization with 6% K₂CO₃ and additional hexane, a hexanoic phase containing FA methyl esters was recovered. Methyl tricosanoate was used as internal standard. Samples were injected by auto-sampler into a Varian CP-3800 gas chromatograph equipped with a flame ionization detector. Methyl esters from all samples were separated on a 100 m × 0.25 mm i.d. CP-Sil 88 fused-silica capillary column. Hydrogen was the carrier gas. Injector pressure was held constant at 23 psi. Pure methyl ester standards purchased from Supelco (Bellefont, USA), Sigma (St Louis, USA), Nu-Chek Prep (Elysian, USA), and Biovalley (Conches, France) were used to identify peaks, except for

certain *trans* and *cis* 18:1 isomers that were identified in order of elution and according to Kramer et al. [19], and t11, c15-18:2 that was identified according to Ulberth and Henninger [20].

Satisfactory separations of most *cis* and *trans* 18:1 and CLA isomers were obtained with a single chromatographic run. There was a partial coelution of different monounsaturated *cis* and *trans* 18-carbon isomers as well as c9, c11-18:2, and 21:0, as previously reported with the CP-Sil 88 100 m capillary column. In particular, due to the imperfect separation between t10 and t11-18:1 in some samples, the results give the sum of these two isomers.

Duodenal flows and intestinal digestibility of fatty acids were determined from duodenal flow of DM and fecal DM as described by Doreau et al. [16], and from FA determination in duodenal contents and feces. Rumen BH was computed as $(\text{intake} - \text{duodenal flow})/\text{intake} \times 100$.

Statistical Analyses

Statistical analyzes of fatty acid duodenal flows and digestibilities were performed as a 4×4 Latin square using the PROC MIXED procedure of the SAS statistical analysis software suite [21]. The statistical model included the effect of cow as random effect and the effects of period and treatment as fixed effects. Differences among means were determined using the Student–Newman–Keuls test. Differences at $P < 0.10$ were considered to be significant.

Results

Fatty acid intake was increased by 235 g/day on average between the C diet and the lipid-supplemented diets, with similar dry matter intakes (Table 1). This increase was mainly due to linolenic acid (+140 g/day) and, to a

lesser extent, linoleic acid (+30 g/day) and oleic acid (+40 g/day).

Duodenal Flow of Fatty Acids

Duodenal flows of total FA were similar among the three lipid-supplemented diets and higher than for the control diet (Table 2). The ratio of duodenal flow to intake of total FA was 1.18, 0.87, 0.96 and 0.98 for diets C, RL, EL and LO, respectively (SEM = 0.03), and was significantly lower for lipid-supplemented diets than for the C diet ($P < 0.01$). The difference among diets in duodenal flow of total FA was due to differences in 18-carbon FA. Duodenal flows of 18:0 and total *cis* 18:1 FA was lower for diet C than for the other 3 diets. Duodenal flows of total *trans* 18:1 and total CLA were highest with the EL and LO diets, lowest with the C diet, and intermediate with the RL diet (not significantly different from the other three diets). Duodenal flow of total non-conjugated 18:2 was higher with diets EL and LO than with diets C and RL. Duodenal flow of linolenic acid was numerically maximal with the EL diet and minimal with the C diet, but the differences were not significant due to high inter-animal variability. No significant differences were found for the other FA. Except for t5 and c9-18:1, there were between-diet differences for all the 18:1 isomers (Table 3). For t6 + t7 + t8, t9, t12, t13 + t14 + c6, c10 + t15, c12, c13, c14 + t16 and c15-18:1, the duodenal flows were similar among linseed-supplemented diets and significantly higher than with control diet. For the coelution t10 + t11 and c11-18:1, the duodenal flows were higher with EL and LO diets compared with C and RL diets. For t4-18:1, the duodenal flow was higher with EL and LO diets than with the RL diet, all three surpassing the C diet.

Among non-conjugated 18:2, the flow of linoleic acid did not differ among diets; the flow of t11, c15-18:2 was higher with the EL and LO diets than with the C and RL diets, the flow of c9, t12-18:2 was higher with the RL, EL and LO diets than with the C diet, and the flows of t9, t12 and t9, c12-18:2 were higher with the LO diet than with the C diet and intermediate with RL and EL diets (Table 3). Among CLA, t10, c12-18:2 flow did not differ among diets, the duodenal flow of the coelution of c9, t11 and t8, c10-18:2 was higher with the EL and LO diets than with the C and RL diets, the flow of the coelution of t11, c13 and c9, c11-18:2 was higher with the LO diet than with the C and RL diets, EL diet being intermediate, and the flow of t11, t13 and of other t, t-CLA was higher with the RL, EL and LO diets than with the C diet.

The BH of oleic and linoleic acids was higher with the RL diet than with the C diet, and intermediate with EL and LO diets (Table 4). The biohydrogenation of linolenic acid did not significantly differ among diets (Table 4).

C control diet, RL control diet supplemented with 7.5% rolled linseed, EL control diet supplemented with 7.5% extruded linseed, LO control diet supplemented with 4.9% linseed oil and 2.6% linseed meal

Means with different letters within a row are significantly different ($P < 0.05$)

Fatty Acid Digestibility

Intestinal digestibility of total FA was higher with the C and LO diets than with the RL diet, the EL diet being intermediate and not significantly different from the three other diets (Table 5). Digestibility of 12- to 17-carbon FA, and digestibility of linolenic acid did not differ among diets. Digestibility of *cis* and *trans* 18:1 isomers and of 18:2 isomers was highest with the LO diet and lowest with the RL diet. Considering 18:1 isomers, digestibility was the lowest with the RL diet for all 18:1 isomers, the difference being significant for most of them (Table 6). Digestibility was the highest with the LO diet for most isomers, especially those for which duodenal flow was high, i.e. t10, t11, c9 and the coelution of c10 and t15-18:1. Digestibility of t11, c15-18:2 did not differ among diets, whereas digestibility of linoleic acid was lower with the RL diet than with the other three diets. Digestibility of individual CLA isomers and minor non-conjugated 18:2 isomers was not calculated because the very low duodenal flows resulted in inaccurate measurements.

Plasma Fatty Acids

Among the saturated FA, only 14- to 16-carbon FA and 17:0 differed among diets in their plasma content, with a higher proportion for C diet compared to the others (Table 7). Among monounsaturated FA, the proportion of oleic acid ranged between 9.8 and 11.5% according to diet and did not differ significantly among diets (Table 8). The

percentage of t11-18:1, which was the main *trans* 18:1 isomer, was higher with the EL and LO diets than with the C and RL diets. There were no between-diet differences in t4, t5, t9, t10, c9, c10 + t15, c11 and c13-18:1 (Table 8). There were higher proportions of the coelution of t13, t14 and c6-18:1 with the RL and LO diets than with the C diet, the EL diet being intermediate. There was a higher proportion of c12-18:1 with the RL diet than with the C and EL diets, the LO diet being intermediate.

Conjugated linoleic acids were present in very small amounts. There was a lower proportion of c9, t11-isomer (coeluted with t8, c10) in total FA with the RL diet (0.19%) than with the LO diet (0.36%), the C (0.27%) and EL (0.34%) diets being intermediate ($P < 0.05$). Other isomers were found in some animals, but only in trace amounts.

Discussion

Duodenal Flow and Biohydrogenation

The rumen balance of total FA is consistent with the equation published in Schmidely et al. [22], with a positive balance (a net synthesis of both C12–C17 and C18 FA) in the C diet, and a slightly negative balance for the lipid-supplemented diets.

The main monounsaturated C18 isomers at duodenum for lipid-supplemented diets were found in peaks corresponding to the coelution of t10 and t11-18:1, the coelution of t13, t14 and c6-18:1, c9-18:1 and the coelution of c10

and t15-18:1. These data are similar to those found with linseed oil-supplemented diets [11, 23] and in vitro data [24], and these isomers most probably arise from partial BH of linolenic acid and dietary c9-18:1. The high amount of t11, c15 among non-conjugated 18:2 isomers and t11, t13 among CLA confirms the importance of carbon 13 and

carbon 15 desaturated C18 as BH intermediates of linolenic acid [24]. In all diets, the duodenal flows of total CLA represented less than 10% of the non-conjugated 18:2.

Among the different lipid-supplemented diets, RL exhibited the highest BH for oleic and linoleic acid, whereas linolenic acid BH did not seem to be affected by the supplement. The duodenal flows are consistent, since the RL diet induced a higher flow of 18:0 and lower flows of BH intermediates (*trans* 18:1 and 18:2) compared to EL and LO diets.

The most surprising result of this experiment was the numerically higher amount of linolenic acid at the duodenum with the EL diet than with the RL diet. Other data showed either a lower amount of linolenic acid with extruded linseed [15] or no variation [14]. A part of these differences among trials may be explained by differences in technological processes. In our trial, the small particle size of rolled linseeds probably results in a rapid release of oil. The extrusion process apparently shows limited

differences in temperature with processes used in other publications, but preconditioning before extrusion modifies biohydrogenation [14], due to changes in oil availability (Enjalbert, Chesneau, Troegeler-Meynadier, Nicot, unpublished data). Our finding is confirmed by a series of 6

feeding trials on bulls and steers receiving linseeds either rolled or extruded with the same process [5]: muscles contained more linolenic acid with EL than with RL. Similarly, Petit et al. [25] observed that extrusion of soybean and canola led to higher linoleic acid deposits in lamb

muscle. These authors explained the protection of polyunsaturated FA in extruded oilseeds by the decrease in protein degradability following extrusion, which would protect lipid droplets against hydrogenation. However, in the present experiment, proteins were not protected by extrusion [16]. In the present experiment, measurements of the FA composition of rumen fluid [26] confirmed the fact

that lipids are rapidly released in rumen from extruded seeds, leading to a higher passage rate towards the duodenum. Under this hypothesis, a slower release of FA from rolled seeds may lead to a more complete BH, whereas a more rapid release of FA may result in a higher bypass if the rates of isomerization and hydrogenation is lower than the rate of lipolysis. This latter hypothesis is consistent

with in vitro and in vivo data [27, 28]. Isomerization and hydrogenation rates may be lowered by the toxic effect of the free polyunsaturated FA released in the rumen. The duodenal flows of most FA obtained with the EL and LO diets were very similar and not significantly different. The majority of comparisons between extruded and raw oilseeds have been made on dairy cows through comparison of milk FA profiles, giving highly inconsistent data, with some authors observing lower levels of unsaturated FA with extruded seeds compared to raw seeds (Chouinard et al. [29] on soybean) while other authors reported the opposite trend (McNamee et al. [30] on rapeseed, McGuffey and Schingoethe [31] on sunflower seed, Chouinard et al. [32] on soybeans). The effects of extrusion on 18:0 and 18:1 isomers are also very different among studies.

Intestinal Digestibility

Intestinal digestibility of total FA and differences between the main FA are consistent with the means of published data [22, 33, 34]. For 18:1 FA, *trans* isomers proved to be more digestible than *cis* isomers, which is consistent with recent data (e.g. Doreau et al. [35, 36], Loor et al. [11], review by Glasser et al. [34]). This is probably due to the stereochemical configuration of these FA. In the present experiment, oleic acid had a lower digestibility than other *cis* isomers. This has been observed only by Doreau et al. [35] with forage diets, but not by other authors with forage or mixed diets containing linseeds. A reason could be that duodenal oleic acid is still mainly dietary oleic acid and hence in the esterified form whereas the other *cis* isomers are mainly BH intermediates and hence in the unesterified form. This lower intestinal digestibility corresponds, both in Doreau et al. [35] and in the present experiment, to a high level of BH.

In the present experiment, digestibilities of oleic, linoleic and linolenic FA were always lower for the RL diet compared to the other diets. In contrast, Gonthier et al. [15] observed a lower digestibility of the control diet compared to linseed-supplemented diets, and no difference among linseed-supplemented diets. The digestibility of the control diet may differ according to the basal ration. The differences observed among the lipid-supplemented diets in the present study may be partly due to between-diet differences in the availability of intracellular oil. However, the low duodenal flow of linolenic acid ($\leq 5\%$ of intake) means that at least 95% of dietary lipids were hydrolyzed and hydrogenated, and virtually all the FA were released from their original matrix. The absence of variation of digestibility with diet for palmitic acid is explained by its origin: palmitic acid is derived mainly from dietary compounds other than linseeds, or from microbial synthesis. We observed

the same differences in digestibility between the 3 forms of linseeds (i.e. $RL \leq EL \leq LO$) for 18:1 and 18:2 isomers resulting from BH. These differences among diets can be explained by differences in FA metabolism in the large intestine and/or by differences in mechanisms of FA absorption in the small intestine. These hypotheses remain to be evaluated.

As numerical differences in digestibility were low compared to differences in duodenal flows between FA, the apparently absorbed amounts were highly correlated to duodenal flows. However, between-diet differences in duodenal flow and digestibility may be compensated for or increased when apparently absorbed amounts are considered. Absorbed amounts of linolenic acid were similar between RL, EL and LO diets (3.7, 5.6 and 4.9 g/day, respectively) whereas they were lower with RL than EL and LO for linoleic acid (4.8, 9.5 and 9.4 g/day) and oleic acid (6.8, 10.0 and 10.9 g/day), as well as for BH intermediates such as the coelution of t10 and t11-18:1 (19.1, 41.3 and 52.1 g/day) and t11, c15-18:2 (2.9, 9.8 and 13.0 g/day). These differences may result in differences in plasma and milk composition. In particular, the milk and meat contents of CLA derived from absorbed vaccenic acid may be higher when linseed is extruded or as oil than it is rolled.

Use of Plasma FA Composition as a Predictor of BH Pathways

Total plasma FA composition does not reflect FA absorption because it contains all lipoproteic fractions and is a criterion of global lipid metabolism, including lipid mobilization, organ uptake, hepatic lipid metabolism [37]. For example, plasma FA composition always shows high levels of linoleic acid whereas the absorbed amounts of this FA are very low. However, studies performed by Sinclair et al. [38] with sheep, Scislawski et al. [6] with steers and Loor et al. [23] with dairy cows have shown that diet supplementation with linseed oil results in an increased proportion of linolenic acid in plasma lipids. This was not observed in the present experiment, perhaps due to the very low increase in absorbed linolenic acid in lipid-supplemented diets compared to the control diet. We observed a global increase in total plasma FA content, mainly due to 18-carbon FA, whose proportions in total FA increased at the expense of 12- to 17-carbon FA. Non-conjugated 18:2 isomers (mainly linoleic acid) and linolenic acids were present in much higher proportions in plasma and were not linked to the absorbed amounts, reflecting an endogenous regulation of their plasma levels, independently of their dietary supply.

Similarly, there was a higher proportion of c9-18:1 in plasma FA than in duodenal flow, probably because of endogenous delta-9 desaturation of 18:0 in enterocytes and

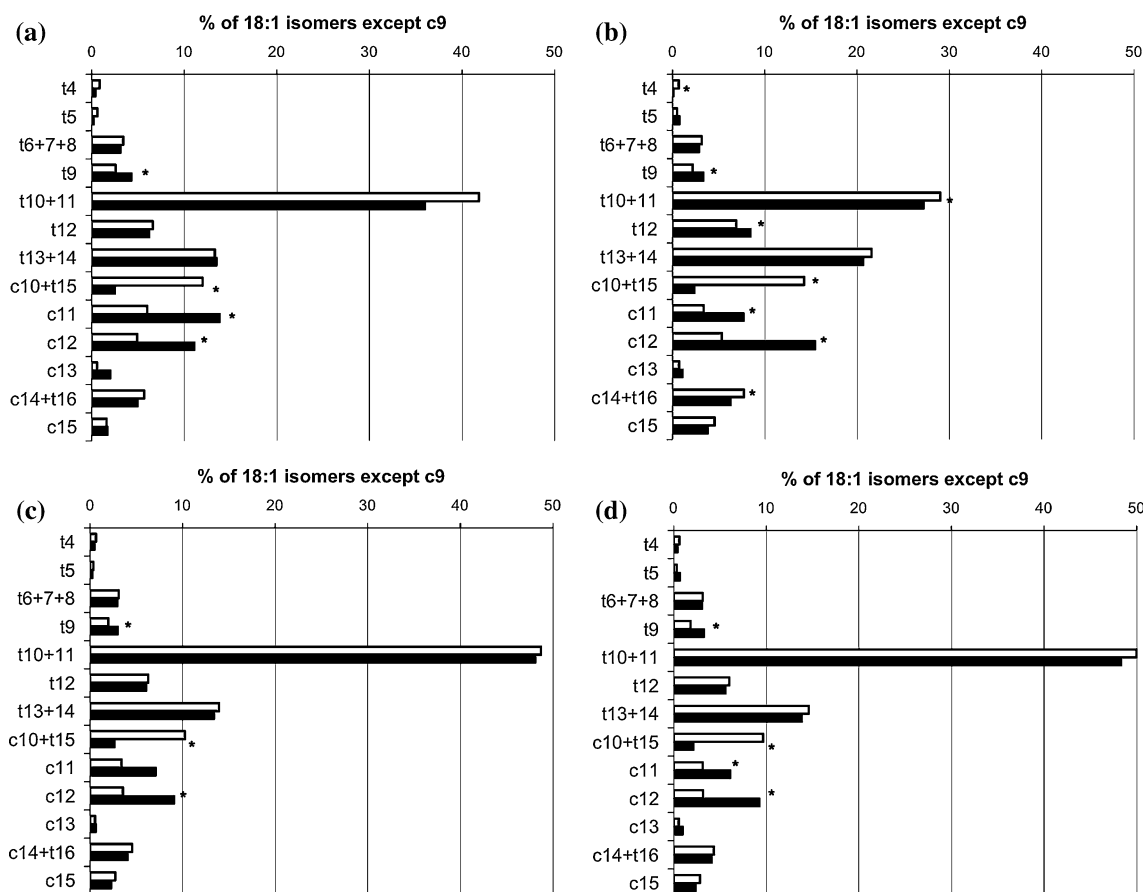

Fig. 1 Comparison of 18:1 isomers (expressed in % of total 18:1 isomers except c9-18:1) between duodenal fluid (white bars) and plasma (black bars) from cows fed a control diet (C, **a**), or a control diet supplemented with 7.5% rolled linseed (RL, **b**), 7.5% extruded

linseed (EL, **c**) or 4.9% of linseed oil and 2.6% linseed meal (LO, **d**). Asterisk a significant difference between duodenum and plasma (Paired *T* test, $P < 0.05$)

other tissues. When 18:1 isomer proportions were compared between duodenum fluid and plasma (not taking into account c9-18:1 for the above-cited reason), *trans* 18:1 profiles in plasma closely reflected the respective profiles at the duodenum, which was also observed for some but not all *cis* 18:1 isomers, as shown by Fig. 1. Unfortunately, we did not determine the t10:t11 ratio due to coelutions in duodenal samples. This profile similarity has recently been observed in experiments on dairy cows receiving either two different diets supplied with linseed oil [3, 11] or receiving three different oils [4, 23]. However, in the latter experiments, the t10:t11 ratio in duodenal contents was imperfectly predicted by plasma composition. Additional experiments are required in order to propose prediction equations. The similarity of *trans* 18:1 profiles between duodenal and plasma FA means that these isomers have similar metabolisms (no difference in organ uptake or oxidation according to the position of the double bond).

In conclusion, linseed supplementation increased the duodenal flow of unsaturated intermediates of biohydrogenation, and this effect was more pronounced for extruded

seeds and oil than for rolled seeds. Duodenal flow of linolenic acid was however similar among diets, due to its very high ruminal hydrogenation, which was not affected by linseed supplementation.

Acknowledgments This experiment was funded by the ACTA (Association pour la Coopération Technique Agricole, Paris, France). The authors thank the various INRA staff for their skills in animal care, feeding and sampling.

Abstract Two novel ceramides, Candidamide A (**1**) with a phytosphingolipid structure, and Candidamide B (**2**) with a tertiary amide structure, together with 12 known compounds (**3–14**) have been isolated from the bulbs of *Zephyranthes candida*. The structures of **1** and **2** have been elucidated to be 1,3,5,6-tetrahydroxy-2-(2'-hydroxytetra-cosanoyl amino)-8-(*E*)-octadecadiene (**1**) and (2*S*,3*S*,4*R*,8*E*,2'*R*)-2-[*N*-(2'-hydroxyoctadecanoyl)-*N*-(1'',2''-dihydroxy-ethyl)-amino]-8-hexacosene-1,3,4-triol (**2**) on the basis of spectroscopic evidence including IR, MS, NMR (¹H-NMR, ¹³C-NMR, DEPT, ¹H-¹H COSY, HSQC, HMBC). The known compounds were identified as (2*S*)-3',7-dihydroxy-4'-methoxyflavan (**3**), (2*S*)-4'-hydroxy-7-methoxyflavan (**4**), (2*S*)-4',7-dihydroxyflavan (**5**), 7-hydroxy-3', 4'-methylene-dioxyflavan (**6**), ambrettolide (**7**), β -sitosterol (**8**), β -dau-costerin (**9**), rutin (**10**), pancratistatin (**11**), lycorine (**12**), haemanthidine (**13**), and haemanthamine (**14**). In the anti-microbial assay, candidamide A (**1**) and candidamide B (**2**) displayed moderate activities against bacteria *Staphylo-coccus aureus* and *Escherichia coli*, and fungi *Aspergillus niger*, *Candida albicans* and *Trichophyton rubrum*.

Keywords *Zephyranthes candida* · Amaryllidaceae · Ceramides · Phytosphingolipid · Tertiary amide · Candidamide A · Candidamide B · Antimicrobial

Abbreviations

CC	Column chromatography
COSY	Correlation spectroscopy
DEPT	Distortionless enhancement by polarization transfer
HMBC	Heteronuclear multiple bond correlation
HSQC	Heteronuclear single quantum correlation
HR	High resolution
LCB	Long chain base
FA	Fatty acid
MICs	Minimum inhibitory concentrations

Introduction

There are about 60 species in the genus *Zephyranthes*, family Amaryllidaceae [1], mainly distributed in the warm-temperate regions of Western Hemisphere. Only two species, *Zephyranthes candida* and *Z. carinata* grow in China, and *Z. candida* is used as ornamental and medicinal plant in China. Plants of this genus are well known in many countries for their pharmacological activities and are widely used in folk medicine. *Z. candida* has been employed in Africa as a treatment for diabetes mellitus and *Z. parulla* appears in a history of Peru for treating tumors, *Z. rosea* and *Z. flava* are used for variety of therapeutic purposes in India [2–5]. Previous chemical investigation of this genus mainly led to the isolation of many alkaloids with cytotoxic activity and some flavans [6–10].

Except for the isolation of a flavonoid glycoside, kaempferol-3-*O*-rhamnoglucoside [11], five alkaloids, lycorine, zephyranthine, tazettine, nerinine and haemanthidine [12], and a cytostatic alkaloid, *trans*-dihydronarci lasine [13], a more detailed chemical study of *Z. candida* has not been reported previously. In our work for a search of potent bioactive alkaloids from the plants of family Amaryllidaceae, we investigated the chemical constituents from the bulbs of *Z. candida*. Two novel ceramides (namely, candidamide A (**1**) and candidamide B (**2**), Scheme 1) with a phytosphingolipid and a tertiary amide structure, respectively, were characterized. This paper describes the isolation, structural determination and antimicrobial activity of candidamide A (**1**) and candidamide B (**2**), together with 12 known compounds, (2*S*)-3',7-dihydroxy-4'-methoxyflavan (**3**), (2*S*)-4'-hydroxy-7-methoxyflavan (**4**), (2*S*)-4',7-dihydroxyflavan (**5**), 7-hydroxy-3', 4'-methylenedioxyflavan (**6**), ambrettolide (**7**), β -sitosterol (**8**), β -daucosterin (**9**), rutin (**10**), pancratistatin (**11**), lycorine (**12**), haemanthidine (**13**), and haemanthamine (**14**) from the bulbs of *Z. candida*.

Ceramides are a unique class of secondary metabolites, and various ceramides have been isolated from a number of marine organisms, fungi, and some plants, some of which exhibit cytotoxic [14, 15], antifungal [15, 16], antimicrobial [17, 18], antileishmanial and immunomodulatory [19], and cytostatic activities [20]. Due to their scarcity in natural sources and their promising biological and pharmacological activities, they have aroused increasing research interest.

Scheme 1 Chemical structures of **1** and **2**

Experimental Procedures

Chromatographic and Instrumental Methods

Melting points were measured using a SGW X-4 micro-melting point apparatus and uncorrected. Optical rotations were measured with a JASCO P-1020 optical rotation apparatus. IR spectra were recorded on an IMPACT 400 spectrometer in KBr discs. NMR spectra were obtained on a Bruker spectrometers operating at 500 MHz (500 MHz for ¹H NMR and 125 MHz for ¹³C NMR) using TMS as internal standard and chemical shifts were recorded as δ values. Mass spectra (EI-MS and ESI-MS) were measured on Agilent 1100 LC/MSD SL mass spectrometer. HR-ESI-MS spectra were obtained on Agilent 1100 LC/MSD TOF mass spectrometer.

Materials

Silica gel for column chromatography (CC) (100–200 and 200–300 mesh) and TLC plates (10–40 μ m) were the products of Qingdao Marine Chemical Co., Ltd (Qingdao, People's Republic of China). Sephadex LH-20 was purchased from the Pharmacia Corporation. RP-18 reverse-phase silica gel was purchased from the Merck Corporation. D101 was purchased from Tianjin Chemical Factory (Tianjin, People's Republic of China).

The bulbs of *Z. candida* were collected from Nanjing Agricultural University, Jiangsu Province, People's Republic of China, in August, 2006. A voucher specimen (no. 61018/JSH) documenting the collection was authenticated at the Herbarium by Prof. Yun-Fa Dong, Phytochemist, Institute of Botany (Nanjing Botanical Garden Mem. Sun Yat-Sen), Jiangsu Province and Chinese Academy of Sciences, where it was deposited.

Extraction and Isolation

The air-dried and powdered bulbs (cut the ground parts) of *Z. candida* (2.1 kg) were extracted with 95% EtOH (10 L \times 3) at room temperature for 3 days. The aqueous EtOH phase was evaporated under reduced pressure and the residue was dried in vacuo. The resulting residue was dissolved in H₂O, basified to pH 8–9 with 10% aqueous NH₃ solvent, and extracted with CHCl₃ (3 \times) and then CHCl₃/MeOH (3:2, vol/vol). The extracts were combined and evaporated. The crude residue (126.0 g) was purified by silica gel column chromatography eluting with petroleum ether/EtOAc from 95:5 to 5:95 (vol/vol, 800 ml each) gradients, finally, EtOAc/MeOH (50:50, vol/vol, 800 ml). All fractions were collected and combined on the basis of analytical TLC, and five main crude fractions (Fr. 1–5) were yielded. Fr. 1 (23.0 g) was subjected to CC by elution with CHCl₃/MeOH (20:1; 18:1;

15:1; 12:1; 9:1, vol/vol, 200 ml each) to yield compounds **3** (11 mg), **4** (8 mg), **5** (20 mg), and **6** (14 mg). Fr. 2 (21.5 g) was applied to CC by elution with $\text{CHCl}_3/\text{MeOH}$ (12:1; 10:1, vol/vol, 200 ml each) to afford compound **7** (21 mg), compound **8** (207 mg) and compound **13** (8 mg). The antimicrobial fraction (Fr. 3, 9.5 g) was separated by CC with $\text{CHCl}_3/\text{MeOH}$ (10:1; 8:1, vol/vol, 250 ml each) to give two subfractions (Fr. 3-1, 87 mg and Fr. 3-2, 38 mg) and further purified by Sephadex LH-20 eluted with $\text{CHCl}_3/\text{MeOH}$ (1:1, vol/vol, 200 ml each) to yield compounds **1** (33 mg) and **2** (28 mg), respectively. Compound **9** (52 mg) was crystallized from the petroleum ether/EtOAc (1:1, vol/vol) solution of fraction (Fr. 4, 18.0 g). Fr. 5 (25.0 g) was subjected to D101 column eluted with 25% EtOH, 40% EtOH, 55% EtOH, 70% EtOH, and 85% EtOH to give several subfractions. The 25% EtOH and 40% EtOH subfractions (210 mg) were purified by Sephadex LH-20 eluted with 60% MeOH to yield compound **10** (57 mg), and the 55% EtOH subfraction (760 mg) was successively purified by CC with $\text{CHCl}_3/\text{MeOH}$ (8:1, vol/vol, 600 ml) and RP-18 (MeOH) to afford compounds **11** (9 mg), **12** (79 mg) and **14** (22 mg).

Antimicrobial Assay

Evaluation of antimicrobial activities of fractions and pure compounds **1** and **2** was performed by using a reference agar dilution method [17].

Antibacterial activities were evaluated against a Gram positive bacterium *Staphylococcus aureus* and a Gram-negative bacterium *Escherichia coli*. Antifungal activities were evaluated against fungi *Aspergillus niger*, *Candida albicans* and *Trichophyton rubrum*. Reference drugs penicillin G and ketoconazole were used as positive controls to the growth of bacteria and fungi, respectively. The samples were dissolved in DMSO at a concentration of 0.1 mg/ml. Suitably quantified volumes of these test solutions were mixed with agar medium (20 ml) to prepare plates with a given concentration (≤ 0.1 mg/ml) of the tested material. Test bacteria were subsequently incubated in these 'drug-containing' plates. The lowest concentration in which no growth of test microbes could be discerned was accordingly defined as the minimal inhibitory concentration (MIC).

Results and Discussion

The antimicrobial fraction (Fr. 3) from the extract of the bulbs of *Z. candida* was separated by CC on silica gel to give two subfractions (Fr. 3-1 and Fr. 3-2) and further purified by Sephadex LH-20 to yield compounds **1** and **2**, respectively. Their structures were elucidated as follows.

Compound **1** was obtained as white amorphous powder, $[\alpha]_D^{25} = +16.67$ ($c = 0.06$, pyridine). The ion at m/z 698 ($[\text{M} + \text{H}]^+$) in the ESIMS was in agreement with the formula $\text{C}_{42}\text{H}_{83}\text{NO}_6$, which was confirmed by the positive HRESIMS ($[\text{M} + \text{Na}]^+$ ion at m/z 720.4150). The IR spectrum featured absorptions (3,345, 3,200, 1,615, and $1,540\text{ cm}^{-1}$) indicating the presence of hydroxyl, amide carbonyl and olefinic functions, respectively. The ^1H -NMR spectral data of **1** (Table 1) indicated the presence of two terminal methyl protons at δ_{H} 0.85 (6H, t, $J = 6.7$ Hz), methylenes protons at δ_{H} 1.25–1.45 ($br\ s$), an amide proton signal at δ_{H} 8.54 (1H, d, $J = 8.9$ Hz), signals of a *trans*-olefinic bond at δ_{H} 5.47 (1H, dt, $J = 13.7, 4.7$ Hz) and 5.52 (1H, dt, $J = 13.7, 4.7$ Hz) and six characteristic signals of geminal carbon protons to hydroxyl groups were also observed at δ_{H} 4.60 (1H, m), 4.50 (1H, dd, $J = 11.0, 4.5$ Hz), 4.40 (1H, dd, $J = 10.5, 5.0$ Hz), 4.33 (1H, m), 4.25 (1H, m), 4.27 (1H, m). Another signal at low field was observed at δ_{H} 5.08 (1H, m) for a methine proton vicinal to the nitrogen atom of an amide linkage, the data indicated a phytosphingolipid structure [21, 22].

To further confirm, ^{13}C -NMR spectral data of **1** (Table 1) showed one quaternary carbon at δ_{C} 175.3 (CONH), two olefinic methine carbon atoms at δ_{C} 130.7 and 130.8 (C=C), as well as five methines at δ_{C} 53.0 (CHNH), 76.8 (CHOH), 72.9 (CHOH), 73.0 (CHOH), 72.5 (CHOH) and one methylene at δ_{C} 62.1 (CH_2OH). The C-8,

C-9 alkenyl bond was found to be *trans*, as the evidence, the geometry (*E*) of the double bond in the unsaturated long chain base (LCB) was determined on the basis of the ^{13}C -NMR chemical shifts of C-7 and C-10 (δ_{C} 33.3, 33.0) of the methylene carbon next to the olefinic carbon, which usually appears at $\delta \approx 27$ in (*Z*) isomers and at $\delta \approx 33$ in (*E*) isomers [23], and the coupling constant of H-8 and H-9 was 13.7 Hz. The structure of **1** was deduced by combined analysis of DEPT, HSQC and HMBC spectra (Scheme 2). All these spectral data revealed that **1** possessed two aliphatic long chains containing one double bond and five hydroxyl groups, and suggested it to be a phytosphingosine type ceramide.

The fragmentation pattern of compound **1** in EI mode was consistent with the pattern obtained in ESI mode. The number of carbons in the LCB and the fatty acid (FA) were determined to be 18 and 24, respectively. The negatively and positively charged ESIMS of **1** showed significant

Scheme 2 Key HMBC and ^1H - ^1H COSY correlations of **1**

Scheme 3 EI-MS fragment analysis for compound **1** (*peak not observed)

fragment ions at m/z 570 $[M-C_9H_{19}]^-$ and 163 $[LCB + H-C_{11}H_{21}]^+$ suggesting the C=C bond to be located at C-8 and C-9. This was confirmed on the basis of the typical fragment ions at m/z 128 $[LCB-CH_2OH-CH_2-CHOH-C_8H_{16}]^-$ and 247 $[M + H-C_{22}H_{45}-CHOH-C_8H_{16}]^+$ in the negatively and positively charged ESIMS which were formed by elimination of octene through McLafferty rearrangement [24, 25]. On the other hand, the presence of 2-amino and 1, 2', 3, 5, 6 pentahydroxyl groups as well as C-8 and C-9 double bond in the main chain were also able to be established from the fragments observed after McLafferty rearrangement [26] (Scheme 3).

The 1H - 1H COSY spectra of **1** showed a pair of double doublets of oxygenated methylene at δ_H 4.50 (1H, dd, $J = 11.0, 4.5$ Hz) and 4.40 (1H, dd, $J = 10.5, 5.0$ Hz) coupled to the nitrogen bearing methylene signal at δ_H 5.08 (1H, m), which coupled further to the signal at δ_H 4.33 (1H, m). Olefinic protons at δ_H 5.47 (1H, dt, $J = 13.7, 4.7$ Hz) and 5.52 (1H, dt, $J = 13.7, 4.7$ Hz) showed coupling with methylene protons resonated at δ_H 1.93 (1H, m) and 1.93 (1H, m). In the HMBC spectrum of **1**, the signal at δ_H 4.60 correlated to the quaternary carbon and methylene carbon resonated at δ_C 175.3 and 35.7, respectively. The proton at δ_H 5.08 showed correlation with oxygenated methylene (δ_C 62.1) and oxygenated methines (δ_C 76.8) (Scheme 2). With these information and compared with the literature [27], the structure of compound **1** was assigned as 1,3,5,6-tetrahydroxy-2-(2'-hydroxytetracosanoyl amino)-8-(*E*)-octadecadiene, and designated to be candidamide A.

Compound **2** was also obtained as a white amorphous powder. The compound was optically active, with $[\alpha]_D^{25} = +45.82$ ($c = 0.055$, pyridine), and had the molecular

formula $C_{46}H_{91}NO_7$, as determined according to the ion peak at 792.3570 ($[M + Na]^+$; calc. 792.3575) in the positive HRESIMS. The IR spectrum showed the presence of OH groups ($3,335\text{ cm}^{-1}$), amide carbonyl ($1,610\text{ cm}^{-1}$), and aliphatic long chains (718 cm^{-1}). The 1H - and ^{13}C -NMR spectra of **2** (Table 2) indicated the presence of hydroxyl, amide groups and two aliphatic long chains. All these information suggested that compound **2** has a ceramide nature. The position and geometry of the double bond were confirmed by 1H , 1H -COSY analyses, EIMS and ESIMS fragments analyses and ^{13}C -NMR data of carbon next to the double bond.

There were six carbon atom signals bearing hydroxyl groups (δ_C 61.9, 76.8, 73.3, 76.3, 73.0 and 72.8) and one double bond (δ_C 130.8, 130.7) in the ^{13}C -NMR of compound **2**. The signal at δ_H 5.12 (H-2) showed a cross-peak with the signals at δ_H 4.41, 4.46 (H-1) and 4.33 (H-3) in 1H , 1H -COSY spectra of **2** and the latter correlated with the signal at δ_H 4.52 (H-4). The correlations were also observed in 1H - 1H COSY spectra between δ_H 4.26, 4.20 (H-2'') and 4.27 (H-1''), δ_H 2.28, 1.87 (H-3') and 4.73 (H-2'), δ_H 2.05, 1.97 (H-5) and 4.52 (H-4), δ_H 1.63 (H-6) and 2.05, 1.97 (H-5), δ_H 2.15 (H-7) and 1.63 (H-6). The structure of **2** was deduced by combined analysis of HSQC and HMBC spectra (Scheme 4). In the 1H -NMR of **2**, however, there were no signals between the δ_H 8–9, which indicated a tertiary amide may be present [28].

The length of the LCB and the fatty acid (FA), together with the presence of 2-amino and 1, 2', 3, 4 tetrahydroxyl groups as well as C-8, C-9 double bond were established due to EIMS and ESIMS fragment pattern analysis (Schemes 5, 6). The fragmentation pattern of compound **2** in EI mode was

Scheme 4 Key HMBC and ^1H - ^{13}C COSY correlations of **2**

Scheme 5 EI-MS fragment analysis for compound **2**

Scheme 6 ESI-MS fragment analysis of compound **2**

consistent with the pattern obtained in ESI mode. Fragments at m/z 514, 486, 468, 450, 432, and 358 were the six significant ions of compound **2**, predicting 26 and 18 carbons in the LCB and FA, respectively, and that the double bond must be located in the LCB (Scheme 6). In addition, the fragments at m/z 486 and 358 suggested compound **2** was a tertiary amide. Further investigation of the EIMS showed two important fragment ions at m/z 265 and 239 suggesting the C=C bond to be located at C-8 and C-9. This was confirmed in the EIMS of **2** which displayed the characteristic peaks at m/z 171 [LCB-H-C₁₇H₃₅]⁺ and 145 [LCB-H-C₁₉H₃₇]⁺. Moreover, the C-8, C-9 double bond of **2** was proven by EIMS spectra, giving typical fragment ion at m/z 186 [LCB-H-C₁₆H₃₂]⁺ formed by elimination of hexadecene through McLafferty rearrangement [17, 24]. The 8, 9 alkenyl bond should be *trans* according to the chemical shifts of C-7 and C-10 (δ_{C} 33.9 and 33.3) [29, 30] and the coupling constant of H-8 and H-9 (14.8 Hz).

Regarding the stereochemistry, the formulated relative configuration of compound **2** was based on the carbon chemical shifts at δ_{C} 61.9 (C-1), 53.1 (C-2), 76.8 (C-3), 73.3 (C-4), 174.0 (C-1'), 76.3 (C-2'), which happened to be fairly close to those previously reported for (2*S*, 3*S*, 4*R*, 2'*R*) sphingosine moieties [31–33]. Including biogenetic considerations, compound **2** was determined to be (2*S*, 3*S*, 4*R*, 8*E*, 2'*R*)-2-[*N*-(2'-hydroxyoctadecanoyl)-*N*-(1'', 2''-dihydroxyethyl)-amino]-8-hexacosene-1,3,4-triol. We have named compound **2** candidamide B.

Antimicrobial activities of the fractions and the individual isolated compounds **1** and **2** against Gram positive and Gram negative bacteria and against fungi were tested using the reference agar dilution method.

In the antibacterial assay, compound **1** exhibited no activity against Gram positive bacterium *S. aureus* and Gram negative bacterium *E. coli*, while compound **2** exhibited moderate activities against *S. aureus* and *E. coli*, with minimum inhibitory concentrations (MICs) of 30 and 50 µg/ml. The MICs of the positive control penicillin G against *S. aureus* and *E. coli* were 0.46 and 0.77 µg/ml.

In the antifungal assay, the results indicated that compound **1** inhibited growth of fungi *A. niger* and *C. albicans*, with MICs of 20 and 50 µg/ml. Compound **2** inhibited growth of fungi *C. albicans* and *T. rubrum* with MICs of 50 and 40 µg/ml. The MICs of the positive control ketoconazole against *A. niger*, *C. albicans* and *T. rubrum* were 0.87, 0.92 and 1.26 µg/ml, respectively.

The 12 known compounds, (2*S*)-3',7-dihydroxy-4'-methoxyflavan (**3**) [34], (2*S*)-4'-hydroxy-7-methoxyflavan (**4**) [35], (2*S*)-4',7-dihydroxyflavan (**5**) [35], 7-hydroxy-3',4'-methylenedioxyflavan (**6**) [4], ambrettolide (**7**) [36], pancratistatin (**11**) [8], lycorine (**12**) [37], haemanthidine (**13**) [38] and haemanthamine (**14**) [38] were identified by their spectral data and by comparing their spectral data with those reported, β-sitosterol (**8**), β-daucosterin (**9**), and rutin (**10**) were identified by their spectral data and by co-TLC with authentic samples.

A literature survey revealed that compound **1** belongs to a kind of rarely occurring class of ceramide with a phytosphingolipid structure [27], and compound **2** containing a tertiary amide structure has been very uncommonly reported both for natural occurring and synthetic ones [31]. To the best of our knowledge, there has been no report on ceramide constituents to date in the genus *Zephyranthes*, and even family Amaryllidaceae. The presence of ceramides in *Z. candida* suggests a so promising biochemical research as to further obtain valuable bioactive compounds except alkaloids from the plants of genus *Zephyranthes*.

Acknowledgments This work was financially supported in part by the Natural Science Foundation of Jiangsu Province (BK2004062). The authors wish to acknowledge Professor Y.-L. Wu at State Key Laboratory of Bio-organic and Natural Products Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, Shanghai China, for making suggestions on this paper.

Abstract Two new acetylenic alcohols (**1–2**) and a new dihydrothiopyranone (**3**) were isolated from the tropical sponge *Reniochalina* sp. Their structures were determined by spectroscopic and chemical methods to be (3*R*)-hydroxyoctatriacont-(4*E*)-en-1-yne (**1**), 5-hydroxyheptatriacont-(3*Z*)-en-1-yne (**2**) and 2-hexadecyl-2,3-dihydrothiopyran-4-one (**3**). The acetylenic alcohol (**1**) exhibited significant growth inhibitory effect against human tumor cell lines.

Introduction

Acetylenic alcohols, a group of sponge metabolites, exhibit great structural variations in chain length and functional groups [1–18]. Most of these compounds have shown various interesting bioactivities such as brine shrimp lethality [1], cytotoxicity [2–6, 9–14], α -glucosidase inhibition [15] and HIV-1 integrase inhibition [16].

During the course of our search for biologically active constituents from tropical marine invertebrates [19], we tested a crude extract of a sponge of the genus *Reniochalina* (class Demospongiae, order Halichondria, family Axnellidae) from the Federated States of Micronesia. This extract displayed moderate growth inhibition against several human tumor cell lines. Guided by the results of ¹H-NMR analysis, fractions of the crude extracts were obtained by solvent partitioning followed by the isolation and purification of compounds using different chromatographic methods including reversed-phase vacuum flash chromatography and C₁₈ HPLC. This resulted in the isolation of two pure acetylenic alcohols (**1**, **2**) and a dihydrothiopyranone (**3**) (Fig. 1). In this paper, we describe the structural elucidation and evaluation of the bioactivities of these secondary metabolites.

Materials and Methods

General Experimental Procedure

The IR spectra were recorded on a Varian 1000 FTIR spectrophotometer as thin films. Optical rotation of the samples was measured on a JASCO DIP-370 automatic polarimeter. The ^1H NMR spectra were recorded on a Varian Unity 500 spectrometer at 500 MHz and the ^{13}C NMR spectra on the same instrument at 125 MHz. Chemical shifts are expressed on a δ (ppm) scale and CDCl_3 (^1H , 7.26 ppm; ^{13}C , 77.0 ppm) and CD_3OD (^1H , 3.30 ppm; ^{13}C , 49.0 ppm) were used as internal standards. Mass spectra were obtained with a Micromass Auto Spec spectrometer.

Animal Material

The specimens of *Reniochalina* sp. (Sample No. 06CH-105) were collected by Dr. H. S. Park at a depth of 25–35 m from Chuuk Atoll, Federated States of Micronesia, in July 2006. The sponge specimen was identified by C. J. Sim on the basis of macro- and micromorphological feature analysis. A voucher specimen (Registry No. 06CH-105) is currently deposited at the Natural History Museum, Han-nam University, Korea under the curatorship of C. J. Sim.

Extraction and Isolation

The fresh sponge was frozen immediately after collection and stored at -25°C until analyzed. The specimens were lyophilized (dry wt 160.2 g) and then extracted twice with 300-mL portions of MeOH and once with 300 mL of CH_2Cl_2 . The resulting extracts were pooled, filtered and concentrated under reduced pressure to yield a residue of

30.1 g of crude extract. This residue was partitioned between H_2O and *n*-BuOH to yield 10.9 g of organic-soluble material. The *n*-BuOH phase was re-partitioned with 15% aqueous MeOH (1.93 g) and *n*-hexane (8.78 g). The residue of the aqueous MeOH layer was subjected to C_{18} reversed-phase flash chromatography using gradient mixture of MeOH and H_2O . The fraction eluted with 100% MeOH was dried (510 mg) and separated by reversed-phase HPLC (YMC ODS-A column, 1 cm \times 25 cm, 5% aqueous CH_3CN) to give 4.4 mg of compound **1** as a major products. The residue of the *n*-hexane layer was subjected to silica flash chromatography and eluted with a *n*-hexane: EtOAc gradient.

An aliquot (870 mg) of the fraction (3.88 g) eluted with *n*-hexane/EtOAc (80:20) was dried and separated by normal phase HPLC (YMC Sil column, 1 cm \times 25 cm) with a mobile phase of *n*-hexane/EtOAc (90:10). Two compounds were detected: in order of elution, compounds **3** and **2**. Further purification of these compounds was achieved by reversed-phase HPLC (YMC ODS-AQ column, 1 cm \times 25 cm, 15% aqueous CH_3CN) to give 1.5 and 11.6 mg of pure compounds **2** and **3**, respectively.

(3R)-Hydroxyoctatriacont-(4E)-en-1-yne (**1**)

IR (neat) 3,448, 1,637, 1,260, 749 cm^{-1} ; ^1H NMR (CD_3OD , 500 MHz) δ 5.84 (1H, dt, $J = 15.3, 7.2$, H-5), 5.54 (1H, dd, $J = 15.3, 6.1$, H-4), 4.73 (1H, dd, $J = 6.1, 2.0$, H-3), 2.85 (1H, d, $J = 2.0$, H-1), 2.07 (2H, m, H-6), 1.28 (62H, m, H-7 to H-37), 0.87 (3H, t, $J = 7.2$, H-38); ^{13}C NMR (CD_3OD , 125 MHz) δ 134.1 (C-5), 130.6 (C-4), 84.7 (C-2), 74.4 (C-1), 63.1 (C-3), 33.0 (C-6), 32.9 (C-7), 30.7 (29C), 23.7 (C-37), 14.1 (C-38); $[\alpha]_{\text{D}} -21.2$ ($c = 1.2$, MeOH); HRFABMS(+) m/z 567.5498 (M + Na), (calcd for $\text{C}_{38}\text{H}_{72}\text{ONa}$, m/z 567.5480)

5-Hydroxyheptatriacont-(3Z)-en-1-yne (**2**)

IR (neat) 3,446, 1,770, 1,632, 1,246, 1,055 cm^{-1} ; ^1H NMR (CDCl_3 , 500 MHz) δ 5.93 (1H, dd, $J = 10.7, 8.2$, H-4), 5.48 (1H, dd, $J = 10.7, 2.4$, H-3), 4.61 (1H, dt, $J = 8.2, 6.3$, H-5), 3.07 (1H, d, $J = 2.4$, H-1), 1.56 (2H, m, H-6), 1.22 (60H, m, H-7 to H-36), 0.82 (3H, t, $J = 6.8$, H-37); ^{13}C NMR (CDCl_3 , 125 MHz) δ 147.4 (C-4), 108.8 (C-3), 82.7 (C-1), 79.4 (C-2), 70.0 (C-5), 36.5 (C-6), 31.9 (C-7), 29.5(28C), 22.6 (C-36), 14.1 (C-37); $[\alpha]_{\text{D}} -18.3$ ($c = 0.8$, MeOH); HRFABMS(+) m/z 531.5490 (M + H), (calcd for $\text{C}_{37}\text{H}_{71}\text{O}$, m/z 531.5505).

2-Hexadecyl-2,3-dihydrothiopyran-4-one (**3**)

IR (neat) 1,770, 1,759, 1,375, 1,246, 1,054 cm^{-1} ; ^1H NMR (CDCl_3 , 500 MHz) δ 7.35 (1H, d, $J = 10.2$, H-2), 6.09 (1H,

d, $J = 10.2$, H-3), 3.42 (1H, m, H-6), 2.72 (1H, dd, $J = 16.3, 11.7$, H-5), 2.69 (1H, dd, $J = 16.3, 3.4$, H-5), 1.62 (2H, m, H-7), 1.20 (28H, m), 0.80 (3H, t, $J = 6.1$, H-22); ^{13}C NMR (CDCl_3 , 125 MHz) δ 194.7 (C-4), 145.8 (C-2), 123.3 (C-3), 44.5 (C-5), 43.0 (C-6), 33.9 (C-7), 29.5 (12C), 26.5 (C-8), 22.6 (C-21), 14.1 (C-22); $[\alpha]_{\text{D}} -14.6$ ($c = 0.9$, MeOH); HRFABMS(+) m/z 339.2713 (M + H), (calcd for $\text{C}_{21}\text{H}_{39}\text{OS}$, m/z 339.2722).

Preparation of MTPA Esters of Compound 1

(S)-MTPA Ester of 1 To a stirred solution of 3.2 mg of **1** in 0.5 mL of dry pyridine was added 30 μL of (–)-MTPA chloride. After stirring the mixture under N_2 for 3 h at room temperature, the solvent was removed by blowing with N_2 . The residue was purified with reversed-phase HPLC (YMC ODS column, 4.6 mm \times 25 cm, 5% aqueous MeOH) to yield 2.1 mg of **1S** as a colorless gum: ^1H NMR (CDCl_3 , 500 MHz) δ 7.53 (2H, m, Ar), 7.44–7.41 (3H, m, Ar), 6.07 (1H, dt, $J = 15.2, 6.6$ Hz, H-5), 6.01 (1H, br dd, $J = 6.6, 2.0$ Hz, H-3), 5.60 (1H, ddt, $J = 15.2, 6.6, 1.5$, H-4), 3.56 (3H, s, OMe), 2.59 (1H, d, $J = 2.0$ Hz, H-1), 2.08 (2H, m, H-6), 1.28 (62H, m, H-7 to H-37), 0.87 (3H, t, $J = 7.2$, H-38).

(R)-MTPA Ester of 1. Prepared as described for **1S**. From 3.1 mg of **1** and 30 μL of (+)-MTPA chloride was obtained 1.9 mg of **1R** as a colorless gum: ^1H NMR (CDCl_3 , 500 MHz) δ 7.54 (2H, m, Ar), 7.44–7.39 (3H, m, Ar), 6.04 (1H, br d, $J = 6.8$ Hz, H-3), 6.00 (1H, dt, $J = 15.1, 6.8$ Hz, H-5), 5.50 (1H, ddt, $J = 15.1, 6.8, 1.5$ Hz, H-4), 3.59 (3H, s, OMe), 2.63 (1H, d, $J = 2.0$ Hz, H-1), 2.04 (2H, m, H-6), 1.28 (62H, m, H-7 to H-37), 0.87 (3H, t, $J = 7.2$, H-38); $\Delta(\delta\mathbf{1S}-\delta\mathbf{1R})$ H-1 -20.5 Hz; H-3 -11.2 Hz; H-4 $+54.1$ Hz; H-5 $+37.5$ Hz; H-6 $+21.0$ Hz.

Oxidation of Compound 3

The sodium metaperiodate (2.4 mg, 11.2 μmol) was added to the thiopyran (**3**, 2.2 mg, 6.5 μmol) in the mixture (9:1, 3 mL) of methanol and dichloromethane solution. The resulting mixture was stirred at room temperature for 20 h and was filtered. The filtrate was concentrated under N_2 and subjected to silica HPLC (YMC silica column, 4.6 mm \times 25 cm) with *n*-hexane/EtOAc (90:10) to afford 0.3 mg of compound **4**.

2-Hexadecyl-2,3-dihydrothiopyran-1,4-dione (**4**)

^1H NMR (CD_3OD , 500 MHz) δ 7.11 (1H, d, $J = 10.9$, H-2), 6.31 (1H, d, $J = 10.9$, H-3), 3.54 (1H, dd, $J = 16.5, 3.41$, H-5), 3.30 (1H, dd, $J = 16.5, 11.7$, H-5), 2.97 (1H, m, H-6), 2.12 (2H, m, H-7), 1.50 (28H, m), 0.80 (3H, t, $J = 6.8$, H-22), ^{13}C NMR (CD_3OD , 125 MHz) δ 195.9

(C-4), 142.8 (C-2), 132.7 (C-3), 59.5 (C-6), 41.0 (C-5), 31.9 (C-7), 29.4 (12C), 26.3 (C-8), 22.6 (C-21), 14.1 (C-22); HRFABMS(+) m/z 355.2660 (M + H), (calcd for $\text{C}_{21}\text{H}_{39}\text{O}_2\text{S}$, m/z 355.2671).

Cell Culture and Growth Inhibition Assay

Human cancer cell lines of various origins, specifically, ACHN (renal), NCI-H23 (lung), MDA-MB-231 (breast), HCT-15 (colon), NUGC-3 (stomach) and PC-3 (prostate), were used for cell growth inhibition assays. The cells were cultured in RPMI 1640 medium supplemented with 5% fetal bovine serum at 37 °C in humidified air containing 5% CO_2 .

Inhibition of cell growth for an individual compound was determined with the total protein SRB assay described previously [20]. In brief, the cells were plated at a proper density in 96-well plates and incubated for 24 h. After further incubation for 48 h in the presence or absence of the compounds (at concentration of 0.1, 1, and 10 $\mu\text{g}/\text{mL}$) cells were fixed with 50% trichloroacetic acid and stained with sulforhodamine B. The absorbance was measured in quadruplicate at 540 nm using a microplate reader and the percentage of cell viability was calculated.

Results and Discussion

Frozen specimens of *Reniochalina* sp. were extracted with MeOH and CH_2Cl_2 . The combined extract was partitioned between *n*-BuOH and H_2O . The *n*-butanol layer was dissolved in 15% aqueous MeOH and extracted with hexane. Further separation of the methanolic phase by ODS flash chromatography, followed by reversed-phase HPLC, afforded an acetylenic alcohol (**1**). On the other hand, purification of the *n*-hexane layer on a silica gel column followed by reversed-phase HPLC led to the isolation of the acetylenic alcohol (**2**) and the dihydrothiopyranone (**3**).

Compound **1** was isolated as a colorless gum with the molecular formula $\text{C}_{38}\text{H}_{72}\text{O}$ determined by combined HRFABMS and ^{13}C NMR spectrometry. The characteristic features of the acetylenic alcohol appeared in the ^1H NMR spectra which exhibited signals corresponding to a terminal acetylene (δ 2.85), a oxymethine (δ 4.73) and a disubstituted double bond (δ 5.54, 5.84). The configuration of the double bond was assigned as *E* based on the vicinal coupling constant of the olefinic protons ($J = 15.3$ Hz). Corresponding carbon signals were observed at δ 74.4, 84.7 (acetylene), 63.1 (oxymethine), 130.6, 134.1 (double bond) in ^{13}C NMR spectra. In addition, DEPT data showed a quaternary carbon at δ 84.7 (C) and a methyl carbon at δ 14.1 (CH_3).

The structure of compound **1** was determined by 2D-NMR experiments. In a ^1H - ^1H -COSY experiment, the

olefinic proton signals showed correlations to an oxymethine at δ 4.73 and a methylene at δ 2.07. The signal at δ 4.73 was, in turn, correlated with a small coupling constant to the terminal acetylene proton at δ 2.85 ($J = 2.0$ Hz). A combination of the HSQC and HMBC data allowed assignment of the characteristic ^{13}C -NMR signals, and the HMBC correlations from H-3 to C-1, C-2, C-4 and C-5, from H-4 to C-2, C-3 and C-6, and from H-5 to C-3, C-6 and C-7 confirmed the location of acetylene, oxymethine, olefin, and two methylenes (Fig. 2). The number of methylenes which were overlapped at δ 30.7 in ^{13}C -NMR spectra were presumed with the integration of ^{13}C -NMR spectra and confirmed by MS data. A revision of existing literature revealed that structurally similar acetylenic alcohols had been isolated from the sponge *Cribrochalina vasculum* [1, 2]. However, compound **1** differs from other known metabolites in chain length. The absolute configuration of the asymmetric center at C-3 was determined by modified Mosher's method [21, 22]. Treatment of **1** with (–) and (+)-MTPA chloride in pyridine yielded the corresponding esters **1S** and **1R**, respectively. All of the key protons of both compounds were assigned by a combination of ^1H -NMR and ^1H -COSY data. The absolute configuration was defined as *R* by ^1H -NMR chemical shift difference values ($\delta\Delta = \delta\mathbf{1S} - \delta\mathbf{1R}$) for protons adjacent to the ester group (Fig. 3). Compound **1** is therefore (3*R*)-hydroxyoctatriacont-(4*E*)-en-1-yne.

The molecular formula of compound **2** was determined to be $\text{C}_{37}\text{H}_{70}\text{O}$ by HRFABMS. The ^1H - and ^{13}C -NMR spectra of this compound were similar to those of compound **1** except for the data from acetylenic and olefinic groups. The acetylenic proton signal in ^1H -NMR spectra was shifted to down fields (from δ 2.85 to δ 3.07) and

Fig. 2 Key HMBC correlations (H \rightarrow C) of compounds **1**–**3**

Fig. 3 Selected $\Delta(\delta\mathbf{1S} - \delta\mathbf{1R})$ of MTPA ester of compound **1**

olefinic signals in ^{13}C -NMR spectra showed large differences (from δ 130.6, 134.1 to δ 108.8, 147.4). The small coupling constant ($J = 2.4$ Hz) between the olefinic protons at δ 5.48 and the acetylenic proton δ 3.07 suggested that these were connected to each other via an acetylenic moiety. Additionally, the *Z* geometry of the double bond in compound **2** was assigned by the coupling constant of $J = 10.7$ Hz. The COSY, HSQC and HMBC experiments allowed the assignment of subunits. Important HMBC interactions of compound **2** are shown in Fig. 2. The number of methylenes in **2** had also been determined by ^{13}C -NMR spectra and MS data. Accordingly, the structure assigned to compound **2** was 5-hydroxyheptatriacont-(3*Z*)-en-1-yne which is also different to previously reported acetylenic alcohols in its chain length.

In addition to the acetylenic alcohols, a new dihydrothiopyranone (**3**) was isolated as a colorless gum. Using combined HRFABMS and ^{13}C -NMR analysis, the molecular formula for compound **3** was determined to be $\text{C}_{21}\text{H}_{38}\text{OS}$. The ^{13}C -NMR data of this compound contained signals of a quaternary carbon at δ 194.7, interpreted as a ketone, and two olefinic carbons at δ 145.8 (CH), 123.3 (CH). A further study of the molecular formula revealed that **3** had an additional degree of unsaturation, hence a cyclic framework. With this information, further 2D NMR experiments were carried out to determine the structure of **3**. According to results of the COSY and HSQC experiments, all of the proton-bearing carbons and their protons were matched except for the overlapped methylene signals at δ 1.20 (28H) in ^1H -NMR and δ 29.5 (12C) in ^{13}C -NMR spectra. The HMBC correlations between signals of the olefinic proton at δ 7.35 with carbonyl carbon δ 194.7 (C-4) and methyne carbon δ 43.0 (C-6) suggested the presence of a dihydrothiopyranone ring (Fig. 2).

For the confirmation of the presence of sulfur in the ring, mild oxidation with NaIO_4 was performed yielding the sulfoxide-form, compound **4** (Fig. 4).

With the aid of this experimental information, the structure of **3** was confirmed by comparison with literature spectral data of dihydrothiopyranone derivative [23]. The ^1H - and ^{13}C -NMR spectral data of the six-membered ring in 2-butyl-2,3-dihydrothiopyran-4-one, which was a synthetic intermediate, were similar to those of compound **3**.

The growth inhibitory activities of compounds **1**, **2**, and **3** against six human tumor cell lines including ACHN,

Fig. 4 Oxidation of compound **3**

Table 1 Growth inhibition (GI_{50} , $\mu\text{g/mL}$) of compounds **1–2** against human tumor cell lines

Compound	ACHN	NCI-H23	MDA-MB-231	HCT-15	NUGC-3	PC-3
1	0.156	0.117	0.386	0.345	1.493	0.732
2	>10	>10	>10	>10	>10	>10
Adriamycin	0.198	0.248	0.278	0.708	0.198	0.488

NCI-H23, MDA-MB-231, HCT 15, NUGC-3, and PC-3 were evaluated. In vitro growth inhibition activity was tested 48 h after treatment of the cells using the SRB (sulfurhodamine B) assay using adriamycin as a positive control. As can be appreciated by the results summarized in Table 1, compound **1** showed significant growth inhibition against ACHN, NCI-H23, and HCT 15 with GI_{50} values of 0.156, 0.117, and 0.345 $\mu\text{g/mL}$, respectively. In the case of compounds **2** and **3**, no cell growth inhibitory activity was observed against any of the tumor cell lines even at the highest concentration tested (10 $\mu\text{g/mL}$) thus no GI_{50} is reported.

Acknowledgments We are grateful to the Department of Marine Resources, State of Chuuk, Federated States of Micronesia, for supporting marine organism research. Abstract Membrane lipids of photosynthetic organisms consist of glycerophospholipids and glyceroglycolipids. We investigated a method for the simultaneous quantitative analysis of neutral and acidic lipids using HPLC–ELSD, and quantified monogalactosyldiacylglycerol (MGDG), digalactosyldiacylglycerol (DGDG) and sulfoquinovosyldiacylglycerol (SQDG). Ten complex lipid classes were separated with a binary gradient system consisting of chloroform and methanol–acetone–water–acetic acid (30:60:9:1, v/v/v/v) with 0.3% triethylamine (pH 4), and were eluted within 16 min. The contents of SQDG in ten edible plants ranged from 3 to 101 mg/100 g, and were positively correlated to the neutral glyceroglycolipids contents.

Keywords Glyceroglycolipid · Sulfoquinovosyldiacylglycerol · Monogalactosyldiacylglycerol · Digalactosyldiacylglycerol · Acidic lipid · Plant · Chloroplast · ELSD · Binary gradient · HPLC

Introduction

Glyceroglycolipids are major membrane lipids in photosynthetic organisms such as higher plants and algae. MGDG, DGDG and SQDG are all polar lipids particularly found in chloroplasts, and account for 90% of the total lipids in the chloroplast thylakoid membrane [1]. It has been established that SQDG, which is a negatively charged (acidic) sulfolipid present in the thylakoid membrane with phosphatidylglycerol, is important for preservation of structure and function of membranes, despite its slight amount [2, 3]. Moreover, these glycolipids have been evaluated for the functionality of their bioactive substances and are known to have various biological activities, including improving the intestinal environment [4], anti-tumor activity [5–7], anti-inflammatory activity [8, 9] and protection against cell death [7, 10]. Among them, SQDG has been identified as a new functional component because it has specific biological inhibitory activities against DNA polymerase [11–15], certain types of viruses [16–19], P-selectin receptor [20], telomerase [21], angiogenesis [22] and inflammation/proliferation [23].

People consume these glycolipids daily from plant foodstuffs. Sugawara et al. [24] analyzed the contents of neutral glycolipids in various plants using HPLC. In this way, the main neutral glycolipids in plants present no particular difficulties for analysis and are easily separated

from phospholipids by HPLC. However, since SQDG presents greater analytical problems because of its highly polar anionic (acidic) nature, the only methods that have been devised for their analysis is the TLC/densitometry method [25] and the complicated triadic gradient elution by HPLC [26]. Therefore, publications reporting SQDG contents in plants are rare. In the present study, we developed optimal HPLC conditions with a binary gradient system to separate and quantify neutral and acidic glyceroglycolipids in edible plants.

Materials and Methods

Materials

Chromatographically pure working standards of SQDG, MGDG and DGDG were prepared from spinach total lipids. Firstly, spinach TL (prepared as described below) was subjected to silicic acid column chromatography. After removing the non-polar lipids from the cartridge with chloroform, the glycolipid fraction was eluted with acetone [27]. The crude glycolipid fraction obtained was further fractionated with stepwise elution of chloroform–acetone [27]. The DGDG fraction, including SQDG, was applied to a DEAE column and separated to neutral DGDG and acidic SQDG lipid fractions as described below. Finally, each glycolipid was subjected to preparative TLC with a solvent system of chloroform–methanol–water (70:35:7, v/v/v) to give one spot. The glycolipids were dissolved in chloroform–methanol (2:1, v/v) and 0.001% butylhydroxytoluene (Wako, Japan) was added. Standard samples of cholesterol, phosphatidylethanolamine (PE), phosphatidylcholine (PC), phosphatidylglycerol (PG) from egg yolk, and phosphatidylinositol (PI) from soybeans were purchased from Sigma (St Louis, USA), and cerebroside (CE, lower spot) from bovine brain was purchased from Doosan Serdary Research Laboratories (Toronto, Canada). Commercial standards of MGDG, DGDG, acylsterylglucoside (ASG, from soybeans) and sterylglucoside (SG, from soybeans) were purchased from Funakoshi Co. (Tokyo, Japan). SQDG was purchased from Kanto Chemical Co. (Tokyo, Japan). They were used for comparing LC retention times.

Spinach (leaf, *Spinacia oleracea* L.), parsley (leaf, *Petroselinum crispum*), perilla (leaf, *Perilla frutescens*), Chinese chive (leaf, *Allium tuberosum*), green onion (leaf, *Allium cepa*), crown daisy (leaf and stem, *Chrysanthemum coronarium*), broccoli (flower and stem, *Brassica oleracea* var. *italica*), green pepper (fruit, *Capsicum annuum* cv. *grossum*), cucumber (fruit, *Cucumis sativus*) and pumpkin (fruit, *Cucurbita maxima*) were purchased at a local supermarket in Obihiro, Japan. The pumpkin fruit was cut into two pieces to remove the loose stringy pulp with seeds,

and the outer green epidermis was removed to obtain the isolated pumpkin flesh.

Extraction, Separation and Detection of Lipids

Fresh plant samples (5–50 g) were cut into pieces and heated in a microwave oven for 1 min to deactivate lipolytic enzymes and then extracted three times with chloroform–methanol (2:1, v/v) for 1 h, respectively, after homogenization (Polytron, Kinematica, Switzerland). After filtration using filter paper (Advantec No. 2, Toyo Roshi Kaisha, Japan), the extracts were combined and washed once with water in a mixture of chloroform–methanol–water (with a ratio of 8:4:3, v/v/v) [28]. After partition, the lower phase was concentrated to dryness using a rotary evaporator, and the lipids were weighed to yield the total lipids (TL).

Then, green pepper TL was separated into neutral and acidic lipid fractions by anion-exchange column chromatography. Briefly, 50 mg of TL was inserted into a diethylaminoethyl (DEAE) column (Toyopak DEAE M, Tosoh, Tokyo, Japan), and stepwise eluted with chloroform–methanol (neutral lipid fraction), followed by elution with chloroform–methanol–0.1 M ammonium acetate (20:80:0.2, v/v/v) [29]. The latter fraction was washed twice in a mixture of chloroform–methanol–water (with a ratio of 8:4:3, v/v/v), then the lower phase was concentrated to dryness to yield the acidic lipid fraction.

To detect glyceroglycolipids, TL was analyzed by silicic acid TLC (Silica gel 60, 0.25 mm, Merck, Germany) with a chloroform–acetone–methanol–acetic acid–water mixture (50:20:10:10:5, v/v/v/v/v). Glyceroglycolipid species were visualized after spraying with anthrone/sulfuric acid, followed by brief heating.

HPLC and GC Analyses

A portion of the total lipids was dissolved in chloroform–methanol (2:1, v/v) solution (1 mg/ml) and filtered (GL Chromatodisc, 0.45 μ m, GL science, Japan) for HPLC analysis. Plant TL was analyzed by a normal-phase HPLC equipped with an evaporative light scattering detector. Instrument: Shimadzu LC-10AD (Kyoto, Japan); mobile phase: solvent A, chloroform and solvent B, methanol–acetone–water–acetic acid (30:60:9:1, v/v/v/v) with 0.3% triethylamine (pH 4); gradient: Table 1; column: LiChrospher 100 Diol (column size 250 \times 4 mm i.d.; particle size 5 μ m, Merck, Germany) with an LiChroCART 4–4 guard column; flow rate: 0.9 ml/min; injection volume 10–20 μ l; column temperature 35 $^{\circ}$ C; detector ELSD (70 $^{\circ}$ C, 350 kpa, Sedex 75, Sedere, France). The amounts of SQDG, MGDG and DGDG in plant samples were calculated from the calibration curve of each standard

component described above, since ELSD provided a curvilinear response to mass of standard lipids. All data are averages \pm SD of independent experiments from three samples.

MGDG, DGDG and SQDG from spinach leaves were methanolized with 5% HCl/methanol at 95 °C for 2 h, and fatty acid methyl esters were analyzed by GC according to our previous report [30].

Results

HPLC Analysis of Standard Lipids and Component Fatty Acids of Glyceroglycolipids

Chromatographically pure working standards were analyzed by HPLC (Fig. 1). MGDG, DGDG and SQDG prepared from spinach leaves each exhibited a single peak (Fig. 1a) and were identified by co-chromatography with commercial standards, and were used as standard compounds for their calibration curves. The correlation coefficients were from 0.9980 to 0.9998. The detection limit of SQDG was 0.1 μ g. The predominant fatty acids were α -linolenic acid (68 mol%) and oleic acid (30 mol%) for MGDG, α -linolenic acid (86 mol%) for DGDG, and palmitic acid (46 mol%) and α -linolenic acid (46 mol%) for SQDG. The glycolipids (MGDG, SQDG, DGDG, ASG, SG and CMH) and phospholipids (PC, PE, PG and PI) were completely separated from each other (Fig. 1b–e).

TLC of Plant Total Lipids

Total lipids obtained from spinach leaf, broccoli flower and stem, green pepper fruit and pumpkin fruit were analyzed by TLC (Fig. 2). Spinach TL (lane A) contained not only a significant amount of neutral glyceroglycolipids such as MGDG and DGDG but also SQDG, which was located below the DGDG spot (identified by co-chromatography

with commercial MGDG, DGDG and SQDG standards). In this TLC system, SQDG could be clearly separated, but DGDG overlapped with PC. Broccoli TL (lane B) contained a significant amount of glycerophospholipids and a small amount of glyceroglycolipids. In green pepper TL (lane C), glycolipids such as sterylglucoside (SG) and ceramide monohexoside (CMH), were found in relatively significant amounts. In pumpkin TL (lane D), two large spots of Rf values 0.01 and 0.04 with positive coloring reaction to anthrone/sulfuric acid reagent were assumed to be triglycosyldiacylglycerol (TGDG) and tetraglycosyldiacylglycerol (TeGDG), respectively [31].

HPLC Profiles of Plant Total Lipids

Lipid extracts from four plant tissues shown in Fig. 2 were analyzed by HPLC (Fig. 3). Non-polar lipids and pigments including chlorophyll were eluted within 4 min after the start of analysis. Ten complex lipid species were detected from green pepper TL (injection amount 20 μ g), and all were eluted within 16 min. These peaks were identified by analyzing the neutral and acidic lipid fractions of green pepper, and comparing them with retention times of standard components (Fig. 1). It was confirmed that peaks 4, 6 and 11 shown in the acidic lipid fraction were PG, SQDG and PI, respectively. The peak at about 4 min in acidic lipid fraction was tentatively identified as free fatty acids. Although all glyceroglycolipids and glycerophospholipids were detected in spinach TL, SG and CMH, of which the contents are low, were not detected with an injection amount of 10 μ g (within the maximum detection limit of MGDG). When 20 μ g of broccoli TL was injected the SQDG peak was very small and the PC peak exceeded the detection limit of the ELSD. In pumpkin TL, peaks 12 and 13 around 18–19 min were assumed to be TGDG and TeGDG, respectively, because the preparative isolates obtained from HPLC analysis corresponded to Rf value and color reaction by anthrone/sulfuric acid of their spots on TLC shown in Fig. 2.

Determination of Glyceroglycolipids in Plant Foodstuff

Contents of MGDG, DGDG and SQDG in ten fresh edible plants were determined (Table 2). The glyceroglycolipid profile was significantly different among the plants. Contents of SQDG ranged from 3 mg/100 g for green onion to 101 mg/100 g for parsley. Total glycolipid contents were generally low in green onion, green pepper and cucumber with low TL contents (0.17/100 g). Although the TL content (1.1/100 g) of perilla was close to that of broccoli, the glycolipid content (397 mg/100 g) of perilla was three times higher than broccoli. Green leafy vegetables, such as spinach, parsley, perilla and chive, were rich in MGDG, whereas crown daisy, green pepper and pumpkin were

relatively high in DGDG. SQDG was highest in parsley (101 mg), followed by crown daisy (48 mg) and spinach (45 mg). Also, SQDG was comparatively rich even in pumpkin (26 mg), a fruit vegetable. Relative amounts of SQDG in glyceroglycolipids were high in cucumber, pumpkin and crown daisy.

Discussion

Glyceroglycolipids are the main lipid class present in photosynthetic plant tissues and are accompanied by glycerophospholipids. Acidic glycerophospholipids and glyceroglycolipids including PG, PI and SQDG, as well as neutral glycolipids including acylsterylglucoside, CMH, MGDG and DGDG, and neutral phospholipids including PC and PE, were detected in a single HPLC run without any pretreatment such as anion-exchange column chromatography. This may have resulted from not only addition of acid (acetic acid), but also a basic substance (triethylamine), which may have improved the dissolubility of acidic lipid groups.

Since green pepper TL contained almost all of the glycolipid and phospholipid classes detected by TLC analysis

(Fig. 2), it was possible to simultaneously detect both glycolipids and phospholipids from a single analytical HPLC. However, since broccoli TL was rich in glycerophospholipids, SQDG could not be detected within the detection limit of PC (Fig. 3). Moreover, since spinach TL was rich in glyceroglycolipids, SG and CMH could not be detected within the detection limit of MGDG. In these cases, in order to quantify all lipids including phospholipids, it may be necessary to analyze them repeatedly by

changing the injection volume, or to measure them separately by separating the neutral and acidic lipids using an anion-exchange column like DEAE (as shown in Fig. 3). Despite large quantitative differences in SQDG, this study revealed that plant glyceroglycolipids, including SQDG, could be simultaneously detected in all samples. Some research into the occurrence of TG DG has previously been reported in pumpkin [24, 31], but not research into TeGDG. Since TeGDG has also been identified in oat kernels

[32], further verification of these oligoglycosyl-DGs by determining the molar ratio of fatty acid/sugar or by using LC–MS will be needed.

The glycerolglycolipid levels in the various tissues (leaf, fruit, flower, and stem) of each common species were unique. The levels of MGDG were especially high in dark green leafy vegetables such as parsley, chive, and spinach. The levels of DGDG were especially high in crown daisy leaf and stem, pumpkin fruit, and were relatively high in green pepper. It was assumed that this is because the thylakoid membrane with high amount of MGDG in the chloroplasts develops in tissues with active photosynthesis, whereas non-photosynthetic tissues such as fruit, flower and stem were high in DGDG derived from the outer envelope of chloroplasts [1]. It was found that SQDG contents in vegetables were positively correlated ($R = 0.970$, $P < 0.01$) to neutral glycerolglycolipid contents (sum of MGDG and DGDG). Moreover, although sulfur compounds are present in allium including chive and green onion as allyl sulfide, and in broccoli as isothiocyanate, this was not related to the content of SQDG, which has the same sulfur component.

In the future, we plan to use this new HPLC method to compare the levels of SQDG in various agricultural by products and identify one or more of them as potential commercial sources of SQDG.

Abstract Lipoxygenases (LOX) catalyze the oxygenation of polyunsaturated fatty acids, the first step in the biosynthesis of a large group of biologically active fatty acid metabolites collectively named oxylipins. In the present study we report the characterization of the enzymatic activity of the six lipoxygenases found in the genome of the model plant *Arabidopsis thaliana*. Recombinant expressed AtLOX-1 and AtLOX-5 had comparable oxygenase activity with either linoleic acid or linolenic acid. AtLOX-2, AtLOX-3, AtLOX-4 and AtLOX-6 displayed a selective oxygenation of linolenic acid. Analyses by high-performance liquid chromatography and gas chromatography-mass spectrometry demonstrated that AtLOX-1 and AtLOX-5 are 9S-lipoxygenases, and AtLOX-2, AtLOX-3, AtLOX-4 and AtLOX-6 are 13S-lipoxygenases. None of the enzymes had dual positional specificity. The determined activities correlated with that predicted by their phylogenetic relationship to other biochemically-characterized plant lipoxygenases.

Introduction

Lipoxygenases (LOX) are non-heme iron-containing dioxygenases which catalyze the incorporation of molecular oxygen at a 1(Z),4(Z)-pentadienyl moiety of polyunsaturated fatty acids forming hydroperoxy fatty acids [1–3]. In plants, these primary products serve as precursors of a range of oxylipins which have important regulatory roles in development and in the defense towards microbial pathogens and herbivores [4–6]. Within a single plant species, distinct lipoxygenase genes are expressed in a temporal and spatial specific manner to initiate distinct biosynthetic pathways and generate specific functional derivatives. Thus, determination of the enzymatic activity catalyzed by individual isoforms is an essential requisite for assigning roles to distinct oxylipin biosynthetic pathways.

Lipoxygenases can be conveniently classified as 9- and 13-lipoxygenases, according to the position of oxygen incorporation in linoleic acid and linolenic acid, the most important substrates for LOX catalysis in plants [7, 8]. Moreover, lipoxygenases with dual 9- and 13-lipoxygenase activity have also been identified [9, 10]. Lipoxygenase reactions are further characterized by a high stereospecificity, with most lipoxygenases catalyzing the formation of (S)-configured fatty acid hydroperoxides. Specific oxylipins

that are implicated in different components of plant development include the 13-LOX-derived jasmonic acid in fertilization, and novel 9-lipoxygenase derivatives in lateral root development [11–13]. In addition, several lines of evidence indicate important roles of 9- and 13-lipoxygenases in plant defense reactions [14–17], e.g. the temporal correlation between lipoxygenase expression and different types of microbial infections of plants [18–21], the modification of the plant response to infection in mutants and transgenic lines altered in the synthesis of oxylipins [22, 23], the signaling activity of oxylipins as inducers of defense gene expression [24, 25], and the antimicrobial effect displayed by many oxylipins [26]. Among the various described lipoxygenase-derived plant lipid mediators, jasmonic acid has received most attention due to its important role in the protection of plants towards pathogens and insect pests via the activation of specific defense genes [13, 25, 27–29]. The first step in its biosynthesis is catalyzed by 13-lipoxygenase, yet it is still for the most part unknown which 13-lipoxygenase isoenzymes contribute to jasmonic acid biosynthesis under particular circumstances. Compared to 13-lipoxygenase, the function of 9-lipoxygenases and 9-lipoxygenase-derived oxylipins has not received as much attention, but its role has recently received increased appreciation [12, 30].

One of the model plant species employed extensively for the study of plant biology is *Arabidopsis thaliana*. Six predicted lipoxygenase genes are present in its genome, but the nature of their enzymatic activity has not been determined. *At-LOX* gene expression has been recently examined in *Arabidopsis* seedlings and a role for two putative 9-lipoxygenases, *AtLOX-1* and *AtLOX-5*, in lateral root development has been shown [12]. *AtLOX-1* is probably located in the cytosol and its gene expression is activated in roots, leaf senescence, pathogen infection and upon exposure to methyl jasmonate [31–33]. *AtLOX-2* is localized in the chloroplast thylakoid and envelope membrane [34], and is expressed in leaves and flowers [15]. *At-LOX-2* gene transcription is activated after exposure to methyl jasmonate [35] and green leafy volatiles [36], and is down-regulated during senescence [32]. *AtLOX-2* is essential for jasmonic acid formation upon wounding [15]. Substantially less is known about the localization, activity and function of other *Arabidopsis* lipoxygenases *At-LOX-3*, *At-LOX-4*, *At-LOX-5*, and *At-LOX-6*. The *At-LOX-3* gene is expressed in roots, and gene transcription of both *At-LOX-3* and *At-LOX-4* is known to be activated during leaf senescence [32], as well as by exogenous jasmonate [37].

Given the central regulatory roles of specific 9- and 13-lipoxygenase-derived oxylipins, a comprehensive understanding of the nature of enzymatic activity of lipoxygenases is fundamental. Biochemical characterization of a number of

lipoxygenases indicated that their catalytic activity can be predicted from their primary structure to a certain extent [7], but unequivocal assignment of regio- and stereo specificity of lipoxygenase-catalyzed fatty acid oxygenations requires direct experimental determination. In order to facilitate further studies on the role of lipoxygenases in plant development and defense, we set out to characterize biochemically the regio- and stereospecificity of the six lipoxygenases present in the *A. thaliana* genome. The presented results comprise the systematic characterization of the regio- and stereospecificity of the fatty acid oxygenations catalyzed by the complete family of lipoxygenases of *A. thaliana*.

Experimental Procedures

Cloning of *Arabidopsis* Ecotype Columbia Lipoxygenase cDNAs

LOX2, LOX4 and LOX5 cDNAs were obtained by using Protoscript^R First Strand cDNA Synthesis Kit (New England Biolabs, Ipswich, MA, USA) with RNA isolated from leaves 1 h post touching and amplified by PCR with the Expand High-Fidelity PCR System (Roche Diagnostics GmbH, Mannheim, Germany). LOX3 cDNA was obtained and amplified in only one step by RT-PCR using the Titan One Tube RT-PCR system (Roche Applied Science) with the above mentioned RNA, which was previously treated with DNase TURBO DNA-freeTM (Ambion) to remove contaminating DNA. LOX1 and LOX6 cDNAs were PCR-amplified from templates H3C1 and U15695 clones with GenBank accessions W43645 and BT010546, respectively, obtained from the *Arabidopsis* Biological Resource Center (Ohio State University, Columbus, OH, USA) by using *PfuUltra*TM High-Fidelity DNA Polymerase (Stratagene, La Jolla, CA, USA).

All amplification steps were performed with a GeneAmp PCR System 9700 thermal cycler (Applied Biosystems). Primers used and amplification products are described in Table 1. Products were initially cloned in plasmid pGEMTeasy (Promega, Madison, WI, USA), and later transferred to pFastBac1 expression vector (Life Technologies, Gaithersburg, MD, USA) by taking advantage of *SpeI* (LOX1, LOX2, LOX4, LOX5, and LOX6) or *NorI* (LOX3) restriction sites. Correctly encoded proteins were confirmed by DNA sequencing.

AtLOX-6 were generated using the Bac-to-Bac baculovirus expression system (InVitrogen, Paisley, UK). The recombinant pFastBac plasmids were transferred into DH10Bac *E. coli* cells containing the baculovirus shuttle vector bMON14272 and the helper plasmid pMON7124. Recombinant bacmid DNA was prepared from galactosidase-negative and kanamycin-, gentamycin- and tetracycline-resistant bacterial clones. High titer recombinant baculovirus was obtained by lipofectamine transfection of the bacmids into High Five insect cells after one round of viral amplification. AtLOX-1, AtLOX-2, AtLOX-3, AtLOX-4, AtLOX-5, and AtLOX-6 were expressed by infecting High Five insect cell cultures, grown at 28 °C in Tc-100 medium supplemented with 10% fetal calf serum, with the recombinant baculoviruses. At 48 h after infection, cells were collected by centrifugation (5 min, 3,000g), washed twice with Dulbecco's phosphate-buffered saline (pH 7.4), divided in aliquots and pelleted by centrifugation (5 min, 3,000g). Cell pellets were snap-frozen in liquid nitrogen and stored at -80 °C. Total protein lysates of lipoxygenase-expressing High Five insect cells were prepared in sample buffer (30 mM Tris, pH 6.8, 0.5% sodium dodecyl sulfate, 0.5% β -mercaptoethanol, 5% glycerol, 1 mM EDTA, 1 \times protease inhibitor cocktail (Sigma P-2714), 0.005% bromophenol blue), and separated by sodium dodecyl sulfate/polyacrylamide gel electrophoresis (9% cross-linked gels) at 100 V for 3 h in a Bio-Rad gel electrophoresis system [38]. Proteins were stained with Coomassie Brilliant Blue. The apparent molecular weight of the recombinant proteins was determined using molecular weight marker proteins (BenchMark, InVitrogen). Total protein content was determined by the Bradford method, using cell homogenates prepared in 0.1 M Tris buffer, pH 7.4 with 0.1% Triton X-100 [39].

Oxygenase Activity

Oxygenase activity was determined by measurement of oxygen consumption during lipoxygenase-catalyzed fatty acid oxygenation by means of a Clark-type oxygen electrode (Hansatech Instruments Ltd, Norfolk, UK). For oxygenation assays insect cell homogenates were prepared by brief sonication (4 °C, 3 \times 3 s at 35 W; Labsonic U sonicator, B. Braun) in 0.1 M Tris pH 7.4 containing 1 mM PMSF, 10 μ g/ml leupeptin, 10 μ g/ml chymostatin and 10 μ g/ml pepstatin, kept on ice, and analyzed immediately thereafter. Homogenates corresponding to approximately 20 μ g total protein were added to the measuring cell containing 1.5 ml 0.1 M Tris, pH 7.4 and 100 μ M linoleic acid, linolenic acid and arachidonic acid. Oxygen consumption was recorded at room temperature, and the rate of enzyme activity calculated as

nmol oxygen consumed during the first minute per mg protein.

Enzyme Incubations and Product Identification

For the determination of lipoxygenase product formation, homogenates of lipoxygenase-expressing High Five cells ($\sim 6 \times 10^6$ cells) were prepared by a brief sonication (3 times 3 s, 10 W at 0 °C) in 0.5 ml 0.1 M Tris buffer pH 7.4. Incubations (5 ml) were carried out with linoleic acid (100 μ M) in 0.1 M Tris buffer pH 7.4 at 23 °C for 30 min, under oxygen atmosphere. AtLOX2 and AtLOX-6-containing cell preparations were found to be very sensitive to enzymatic inactivation even when sonicated briefly, and were hence incubated by directly resuspending the frozen cell pellets in the incubation buffer. At the end of the incubations, hydroperoxides were reduced to hydroxides by the addition of 100 mg SnCl₂ in 20 ml of ethanol. Products were extracted with diethyl ether and derivatized to methyl esters with diazomethane. The regio- and stereochemistry of the HOD-methyl esters were determined essentially as previously described [40]. Thus, the composition of the 9- and 13-HOD (*E,Z*) and (*E,E*) isomers was determined by straight-phase HPLC using a Thermo SpectraSeries P100 HPLC pump and a column of Nucleosil 50-5 (250 \times 4.6 mm; Macherey-Nagel, Düren, Germany). The solvent system used was 0.6% 2-propanol/hexane (v/v) at a flow rate of 2 ml/min, and detection was at 234 nm using a Thermo SpectraSeries UV100 detector. The products were identified by co-elution with standards of the methyl esters of 9-hydroxy-10(*E*),12(*Z*)-octadecadienoic acid, 9-hydroxy-10(*E*),12(*E*)-octadecadienoic acid, 13-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid and 13-hydroxy-9(*E*),11(*E*)-octadecadienoic acid. For steric analysis, the HOD-methyl esters collected during straight-phase HPLC were further analyzed by chiral phase HPLC using a column of Chiralcel OB-H (250 \times 4.6 mm; Daicel Chemical Industries, Osaka, Japan) and standards of the methyl esters of 9*S*-, 9*R*-, 13*S*- and 13*R*-hydroxy-(*E,Z*)-octadecadienoic acids. Chromatographic conditions were: mobile phase, 2-propanol/hexane (1.5:98.5% v/v), flow rate 0.5 ml/min. Detection was at 234 nm. The most abundant oxygenation products were collected and converted to trimethylsilyl ether derivatives by treatment with trimethylchlorosilane/hexamethyldisilazane/pyridine (2:1:2, v/v/v) prior to analysis by GC/MS. A Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph equipped with a capillary column of 5% phenylmethyl siloxane (12 m, 0.33 μ m film thickness) were used for GC-MS analysis. Helium was used as the carrier gas, the inlet temperature was 200 °C, and the column temperature was raised from 120 to 300 °C at 10 °C/min.

Sequence Alignment and Phylogenetic Relationship Analysis of *Arabidopsis thaliana* Lipoxygenases with Other Enzymatically-Characterized Plant Lipoxygenases

Arabidopsis thaliana lipoxygenases were aligned with 28 enzymatically-characterized plant lipoxygenases using the Clustal W2 program [41] and subjected to phylogenetic analysis by the neighbor-joining and maximum parsimony methods using the PHYLIP package [42] through the facilities of the Mobylye platform from Institut Pasteur server (<http://mobylye.pasteur.fr/cgi-bin/MobylyePortal/portal.py>). To maximize the statistical significance of the phylogenetic trees generated by the distance and parsimony methods, 1,000 bootstrap replicates were obtained by both methods.

Results

Lipoxygenase Activity of *Arabidopsis thaliana* Lipoxygenases

Bioinformatic analysis of the *A. thaliana* genome indicates the existence of six lipoxygenase genes. No systematic study has been published which addresses the characterization of the complete *A. thaliana* lipoxygenase family. To determine if *A. thaliana* lipoxygenase-1, -2, -3, -4, -5, and -6 are authentic lipoxygenases, the corresponding full-length cDNAs were cloned and expressed in insect cells, and the regio- and stereospecificity of the oxygenase activity with fatty acids was determined. Infection of High Five insect cells with recombinant baculovirus containing the *At-LOX1-6/pFastBac* construct resulted in the expression of the six lipoxygenases at high level (Fig. 1). The molecular mass of the expressed proteins was in accordance with the calculated masses of the full-length proteins, namely 98–105 kD. Insect cells infected with baculovirus prepared from empty pFastBac vector did not express lipoxygenase (Fig. 1).

In oxygen consumption assays with linoleic acid, linolenic acid and arachidonic acid as substrate, homogenates of lipoxygenase-expressing insect cells displayed oxygenase activity (Fig. 1b). Maximal activities were measured at neutral pH for AtLOX-1, -3, -4, -5, and -6 (data not shown). AtLOX-2 displayed low oxygenase activities (≤ 10 nmol O₂ min⁻¹ mg⁻¹ protein), and no clear pH optimum could be defined. Maximal oxygenase activities were measured with AtLOX-1 using linolenic acid as substrate (554 ± 44 nmol O₂ min⁻¹ mg⁻¹ protein; mean \pm standard error, $n = 4$). A comparison of the oxygenation activities of each lipoxygenase revealed that AtLOX-1 and AtLOX-5 oxygenated both linoleic acid and

Fig. 1 Heterologous expression of *A. thaliana* lipoxygenases in insect cells. **a** SDS-polyacrylamide gel illustrating the expression of *A. thaliana* lipoxygenases in High Five insect cells infected with recombinant baculovirus. Lane 1, molecular mass markers (MW indicated in kDa); lane 2 cells infected with baculovirus without transposed gene (FB-); lanes 3–8 cells infected with recombinant pFastBac/AtLOX-1, AtLOX-2, AtLOX-3, AtLOX-4, AtLOX-5 and AtLOX-6 baculovirus, respectively, 48 h after infection. Each lane

corresponds to protein lysates derived from approximately 125,000 cells. **b** Oxygenase activity of the recombinant expressed *A. thaliana* lipoxygenases with linoleic acid (C18:2), linolenic acid (C18:3) and arachidonic acid (C20:4). Oxygenase activities are expressed as a percentage of the highest oxygenase activity measured (100% corresponds to $554 \text{ nmol O}_2 \text{ min}^{-1} \text{ mg}^{-1}$ protein for AtLOX-1 with $100 \mu\text{M}$ C18:3)

linolenic acid with similar activity (Fig. 1b). In contrast, AtLOX-2, AtLOX-3, AtLOX-4 and AtLOX-6 oxygenated linolenic acid more effectively than linoleic acid. Arachidonic acid was a relatively poor substrate for all six *A. thaliana* lipoxygenases. No oxygenase activity was detected in homogenates of insect cells infected with baculovirus devoid of lipoxygenase gene (FB-).

Straight-phase HPLC analysis of the reduced and methyl-esterified oxygenation products formed from linoleic acid established the positional specificity of the heterologously expressed lipoxygenases by co-chromatography with standards of the methyl esters of 13-HOD-*E,Z*, 13-HOD-*E,E*, 9-HOD-*E,Z* and 9-HOD-*E,E* (Fig. 2; Table 2). AtLOX-1 and AtLOX-5 were found to form exclusively 9-HOD-*E,Z*, whereas AtLOX-2, AtLOX-3, AtLOX-4 and AtLOX-6 formed 13-HOD-*E,Z*. Representative chromatograms for one 13-lipoxygenase (AtLOX-2) and one 9-lipoxygenase (AtLOX-5) are shown in Fig. 2. No enzymatic activity was detected in homogenates of insect cells infected with baculovirus devoid of lipoxygenase gene (Fig. 2, bottom panel).

The structure of the products was confirmed by gas chromatography-electron impact mass spectrometry after trimethylsilylation of methyl-esterified lipoxygenase products purified by straight-phase HPLC. Diagnostic ions for both 9-HOD-Me and 13-HOD-Me TMS derivatives were m/z 382 (M^+), m/z 311 ($(\text{CH}_3)_3\text{SiO}^+=\text{CH}-\text{CH}=\text{CH}-\text{CH}=\text{CH}-(\text{CH}_2)_7-\text{COOCH}_3$) and m/z 225 ($\text{M}^+-(\text{CH}_2)_7-\text{COOCH}_3$). The ratio of ion intensities of m/z 311/225 was

indicative of either 9-HOD-methyl ester (ratio 0.19) or 13-HOD-methyl ester (ratio 1.8), respectively (Fig. 3, lower panels). Only in the case of AtLOX-2 a low additional enzymatic activity could be confirmed mass-spectrometrically in addition to the formation of 13-HOD, namely 0.7% of the product was 9-HOD.

The stereochemistry of the lipoxygenase-catalyzed HOD acids from linoleic acid was determined by chiral phase HPLC. Steric analysis of the SP-HPLC-purified methyl esters of 9-HOD and 13-HOD demonstrated that all lipoxygenases catalyzed the incorporation of oxygen with the *S*-configuration (Fig. 3; Table 2). Representative recordings for one 13-lipoxygenase (AtLOX-2) and one 9-lipoxygenase (AtLOX-5) are shown in Fig. 3.

Sequence Alignment and Phylogenetic Relationship Analysis of *A. thaliana* Lipoxygenases with Other Enzymatically Characterized Plant Lipoxygenases

In order to determine whether the primary structure of the *A. thaliana* lipoxygenases accurately predicts the determined regiospecificity of oxygenation, a phylogenetic analysis was performed in which the extent of sequence diversification of the *A. thaliana* lipoxygenases was compared with that of 28 biochemically characterized plant lipoxygenases. The phylogenetic tree, shown in Fig. 4, displayed four main clusters, which were assigned the labels A–D. Calculation of evolutionary distances of the *A. thaliana* lipoxygenases to the other plant lipoxygenases

Fig. 2 Determination of positional specificity of *A. thaliana* lipoxygenases. Straight-phase HPLC analysis of 9- and 13-hydroxy-octadecadienoic acid formed by incubation of linoleic acid with homogenates of *A. thaliana* lipoxygenase-expressing insect cells. Products were identified as their methyl esters by co-elution with synthetic standards (*top panel*). Representative chromatograms are shown for the regiospecific oxygenation of linoleic acid by one *A. thaliana* 13-lipoxygenase (*AtLOX-2*), one 9-lipoxygenase (*AtLOX-5*), and homogenate of control infected insect cells (*FB-*)

indicated that AtLOX-1 and AtLOX-5, both characterized in the present study as 9*S*-lipoxygenases, grouped with several other plant 9*S*-lipoxygenases as well as with lipoxygenases with dual 9/13-specificity (Cluster C). Upon closer inspection the two *A. thaliana* 9-lipoxygenases grouped closely with 9-lipoxygenases from dicotyledonous plants (almond, tobacco, and three potato 9-lipoxygenases), whereas 9-lipoxygenases from monocotyledonous species formed a separate subgroup. All cluster D species are members of the legume family *Fabaceae*. Thus, lipoxygenase proteins in this group seem to have evolved independently of other dicotyledonous lipoxygenases. Most of the lipoxygenases in cluster D are 13-lipoxygenases although some harbor dual specificity. None of the *Arabidopsis* LOX proteins is included in this cluster. AtLOX-2, -3, -4 and -6 grouped together with plant lipoxygenases which are exclusively 13-lipoxygenases. Within this quite large group of 13-lipoxygenases from both mono- and dicotyledonous plant species, AtLOX-2 (Cluster A) appears to be distantly related to AtLOX-3, -4 and -6 (Cluster B). The latter three *Arabidopsis* lipoxygenases grouped closely together with one potato 13-lipoxygenase.

Based on their cellular localization, lipoxygenases have been classified as Type II, which contain a chloroplastic N-terminal localization peptide, and type I, including those proteins that do not show any apparent signal localization sequence [7]. Lipoxygenases grouped in Clusters A and B are Type II lipoxygenases with 13-LOX activity, whereas proteins in clusters C and D are Type I lipoxygenases of which some have known 9-LOX activity, some 13-LOX activity, and some are dual specificity lipoxygenases. In summary, the enzymatic activities of the six *A. thaliana* lipoxygenases characterized in this study correlate well with that predicted by their phylogenetic relationship to other biochemically characterized plant lipoxygenases.

Discussion

Plants have evolved elaborate signaling systems to regulate a variety of physiological responses to the environment, and to facilitate intercellular cross-talk in development and reproduction. Plant oxylipins comprise a large class of oxygenated fatty acid-derived lipid mediators that contribute to such signaling circuits [4, 43]. A variety of functions has been ascribed to different oxylipins, which encompass critical roles in plant defense against microbial pathogens and herbivorous insects, as well as in reproduction and organ development [5, 7, 12, 13, 29, 44]. The biosynthesis of plant oxylipins is initiated by primary fatty

Table 2 Measured retention times and diagnostic ions for AtLOX-1 to AtLOX-6-derived hydroxy-octadecadienoic acids, and hydroxy-octadecadienoic acid standards on straight-phase HPLC, chiral phase HPLC, and gas chromatography

Enzyme	Substrate	Straight-phase t_r (min)	Chiral phase t_r (min)	GC t_r (min)	Hydroxy acid ions	Hydroxy acid	Enzymatic activity

For GC/MS analysis the hydroxy acid products were derivatized with diazomethane and trimethylchlorosilane and analyzed by GC/MS as the methyl ester/trimethylsilyl derivative. Retention time differences of the methylated enzymatic products from the nearest eluting standard are indicated between parenthesis, and are labelled with (a) 9(*E/Z*)-HOD-me, (b) 13(*E/Z*)-HOD-me, (c) 9*S*-(*E/Z*)-HOD-me, and (d) 13*S*-(*E/Z*)-HOD-me

acid oxygenases, among which the 9- and 13-lipoxygenases have been studied most intensively [45].

Six lipoxygenase genes are known to be present in the *A. thaliana* genome, yet little information is currently available on the specific function of each isoform. Lipoxygenase activity in *A. thaliana* appears to be dominant in young leaves and gradually decreases as leaves grow older [8]. Detailed studies of the six lipoxygenase genes in *A. thaliana* seedlings revealed expression in leaves of *AtLOX-1*, *At-LOX-2*, *At-LOX3* and *AtLOX-4*. *AtLOX-1*, *At-LOX-3*, *At-LOX5* were actively expressed in root initials where a 9-lipoxygenase-derived oxylipin regulates lateral root formation [12], whereas no expression of *AtLOX-6* was observed in the examined seedlings. The specific activities of lipoxygenases in other *A. thaliana* tissues has been reported in little further detail and no published information is available for allowing the assessment of functional importance of the different lipoxygenases [46]. In view of the fundamental roles for plant physiology embodied by the lipoxygenases, it is of importance to determine the biochemical properties of individual members of this

family of fatty acid oxygenases before further insight into their physiological function can be obtained.

The present study provides a comprehensive biochemical analysis of the enzymatic activity of the six heterologously expressed lipoxygenases of *A. thaliana*. The determination of enzymatic activity revealed that all six *A. thaliana* lipoxygenases are *S*-lipoxygenases. Analysis of positional specificity indicated that *AtLOX-1* and *AtLOX-5* are 9-lipoxygenases, and *AtLOX-2*, -3, -4 and -6 are 13-lipoxygenases. No mixed activity lipoxygenases were identified. Homogenates of insect cells expressing *AtLOX-2* displayed very low activity in oxygenase assays and both *AtLOX-2* and *AtLOX-6* were found to only catalyze measurable amounts of HOD product when cell pellets were not sonicated. These observations possibly point to a more labile nature of these two enzymes.

Based on the protein primary structure, the positional specificity of lipoxygenases can be predicted with relatively high confidence. Alignment studies of known lipoxygenases have unveiled several determinants allowing to predict the positional oxygenation specificity on a molecular basis,

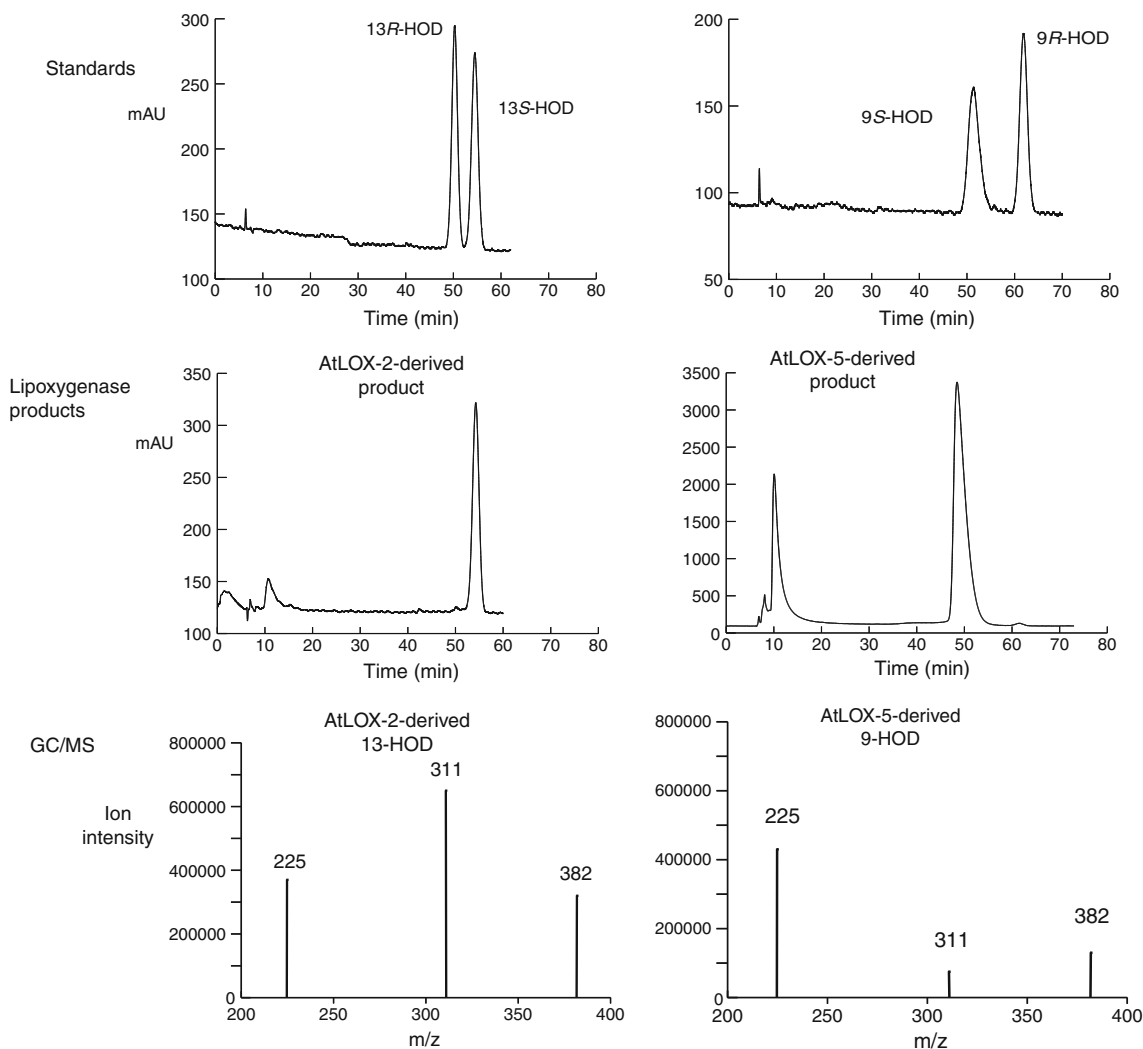

Fig. 3 Determination of stereospecificity of *A. thaliana* lipoxygenases. Steric analysis of 9- and 13-hydroxy-octadecadienoic acid formed by *A. thaliana* lipoxygenases, determined by chiral HPLC as their methyl esters, and GC/MS identification of the 9- and 13-hydroxy-octadecadienoic acid products analyzed as the methyl ester/trimethylsilyl derivative. Representative chromatograms are shown for the hydroxy-octadecadienoic acid products formed by one *A. thaliana* 13-lipoxygenase (AtLOX-2), and one 9-lipoxygenase

(AtLOX-5) (middle panels). Products were identified by co-elution with standards (top panels). Peaks collected from straight-phase HPLC were derivatized with trimethylchlorosilane and analyzed by GC-MS, as described under "Material and methods". Representative selected ion monitoring mass spectra are shown for AtLOX-2-derived 13-HOD (bottom left panel), and AtLOX-5-derived 9-HOD (bottom right panel)

including specific amino acids and surface loops which line the substrate cavity and determine substrate orientation and configuration [9, 47]. Based on their primary structure, AtLOX-1 and AtLOX-5 were predicted to be 9-lipoxygenases and AtLOX-2, AtLOX-3, AtLOX-4 and AtLOX-6 were predicted to be 13-lipoxygenases. In accordance with these predictions, our results on the biochemical characterization of the six *A. thaliana* lipoxygenases presented in this study fully confirm the activity of the distinct isoforms examined. However, prediction of enzyme activity cannot yet provide a complete understanding of catalytic behaviour for all

lipoxygenases. Thus, inspection of the phylogenetic tree indicates that protein similarity alone is not enough to fully predict lipoxygenase substrate specificity. Our phylogenetic analysis clearly shows that AtLOX-1 and AtLOX-5 group together with other biochemically-characterized 9-lipoxygenases as well as with dual specificity lipoxygenases (cluster C). Likewise, cluster D also groups both lipoxygenases with exclusively 13-LOX activity and dual specificity. Hence, results shown here illustrate that biochemical characterization remains essential to unequivocally assign enzymatic activity of plant lipoxygenases.

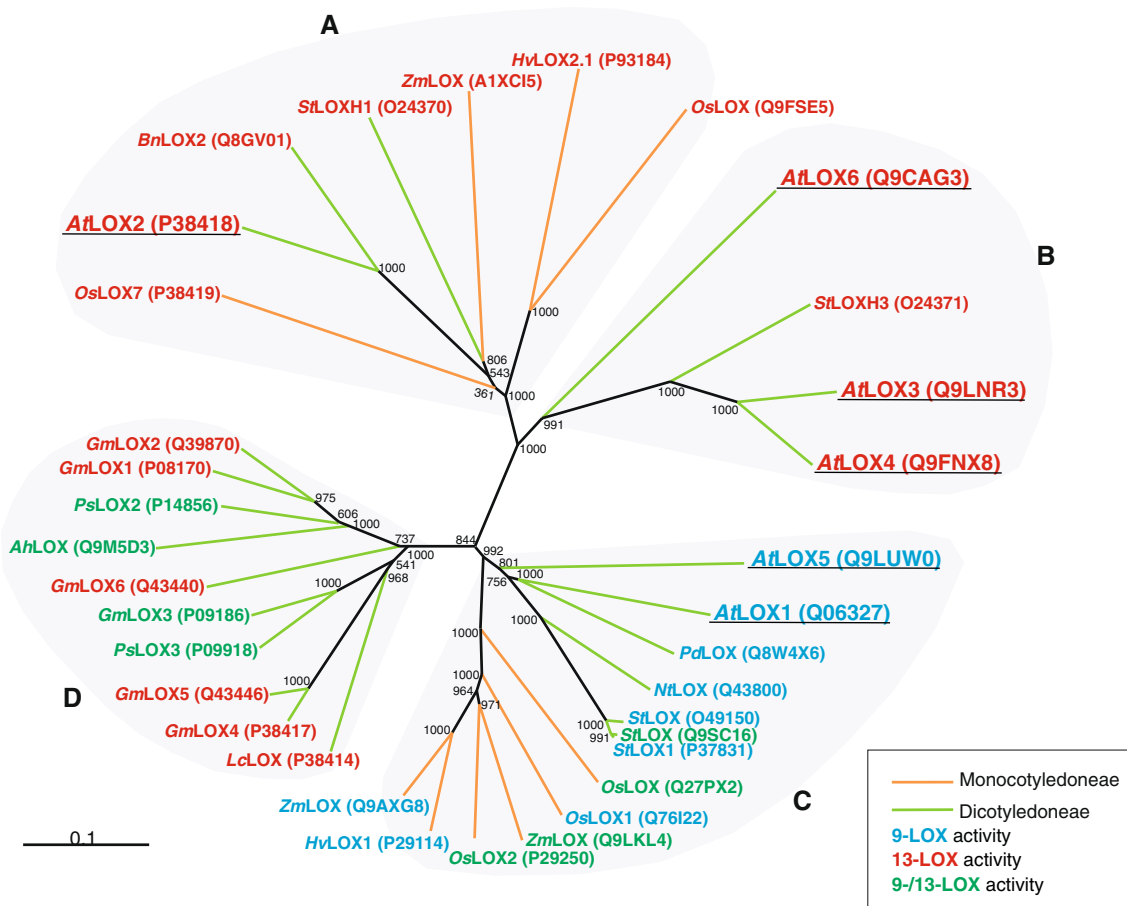

Fig. 4 Phylogenetic relationship between the characterized *A. thaliana* lipoxygenases and enzymatically characterized lipoxygenases from other plant species. Phylogenetic analysis of plant LOX proteins was carried out by using parsimony and distance methods. 1,000 bootstrap replicates were obtained by both methods, with nearly the same results, and only a single tree retrieved from the distance analysis is shown. The % reliability of each branch point of the unrooted tree, as assessed by the analysis of 1,000 trees is shown on each branch stem. Branches colored in *green* and *orange* represent lipoxygenases from monocotyledonous and dicotyledonous species, respectively. 9-Lipoxygenases are labeled in *blue*, 13-lipoxygenases in *red*, and lipoxygenases with dual specificity in *green*, and the six *A. thaliana* lipoxygenases are *underlined*. The identities of the individual lipoxygenase protein sequences are indicated by their Uniprot entry number (<http://www.pir.uniprot.org>). The scale bar corresponds to a distance of 10 changes per 100 amino acids positions. Four clusters in the phylogenetic tree have been arbitrarily assigned the names A, B, C, and D. Individual plant lipoxygenases: AtLOX1 (*Arabidopsis thaliana*; LOX1:At:1), AtLOX2 (*Arabidopsis thaliana*; LOX2:At:1), AtLOX3 (*Arabidopsis thaliana*; LOX2:At:2), AtLOX4 (*Arabidopsis*

thaliana; LOX2:At:3), AtLOX5 (*Arabidopsis thaliana*; LOX1:At:2), AtLOX6 (*Arabidopsis thaliana*; LOX2:At:4), AhLOX (*Arachis hypogaea*; LOX1:Ah:1), BnLOX2 (*Brassica napus*; LOX2:Bn:2), GmLOX1 (*Glycine max*; LOX1:Gm:1), GmLOX2 (*Glycine max*; LOX1:Gm:2), GmLOX3 (*Glycine max*; LOX1:Gm:3), GmLOX4 (*Glycine max*; LOX1:Gm:4), GmLOX5 (*Glycine max*; Q43446, LOX1:Gm:5), GmLOX6 (*Glycine max*; Q43440, LOX1:Gm:6), HvLOX1 (*Hordeum vulgare*; LOX1:Hv:1), HvLOX2.1 (*Hordeum vulgare*; LOX2:Hv:1), LcLOX (*Lens culinaris*; LOX1:Lc:1), NtLOX (*Nicotiana tabacum*; LOX1:Nt:1), OsLOX2 (*Oryza sativa*; LOX1:Os:1), OsLOX7 (*Oryza sativa*; LOX2:Os:1), OsLOX (*Oryza sativa*; Q9FSE5, LOX2:Os:2), OsLOX (*Oryza sativa*; Q27PX2, Os-lox-1), OsLOX1 (*Oryza sativa*; Q76I22, R9-lox-1), PsLOX2 (*Pisum sativum*; LOX1:Ps:2), PsLOX3 (*Pisum sativum*; LOX1:Ps:3), PnLOX (*Prunus dulcis*; LOX1:Pd:1), StLOX1 (*Solanum tuberosum*; LOX1:St:1), StLOX (*Solanum tuberosum*; LOX1:St:3), StLOXH1 (*Solanum tuberosum*; LOX2:St:1), StLOXH3 (*Solanum tuberosum*; LOX2:St:2), ZmLOX (*Zea mays*; A1XC15, LOX2:Zm:10), ZmLOX (*Zea mays*; Q9LKL4, Zm-lox.b), ZmLOX (*Zea mays*; Q9AXG8, Zm-lox-3)

The four characterized *A. thaliana* 13-lipoxygenases, AtLOX-2, AtLOX-3, AtLOX-4 and AtLOX-6 group together with so-called type II 13-lipoxygenases [7], which contain an N-terminal localization peptide which directs the lipoxygenase to the chloroplast. Both mono- and dicotyledonous 13-lipoxygenases are found in this group. The difference between the two clusters (A and B) that

make up this group could possibly reside in either differences in the sub-organellar localization of the chloroplast (thylakoid and stroma), or in their expression and functional characteristics. Two 13-LOX *S. tuberosum* proteins, LOXH1 and LOXH3, present in clusters A and B, respectively, are nearly equally present in both stroma (20%) and thylakoid (80%) but do display different

expression patterns. LOXH3 accumulates upon wounding in potato, and LOXH1 is present at constant levels in both non-wounded and wounded tissues [48]. This indicates that among the *Arabidopsis* 13-lipoxygenases, AtLOX-3, -4, and -6, present in Cluster B, could be more related to defense pathways than AtLOX-2 (Cluster A). By proteomic analysis both AtLOX-5 and AtLOX-6 have both been found to be present in chloroplasts [34]. AtLOX-5 is phylogenetically related to 9-lipoxygenases which do not contain an N-terminal localization peptide (group C), and its localization in chloroplasts is thus unexpected. This indicates that besides biochemical determination of positional specificity of oxygenase activity, biochemical characterization of subcellular localization of lipoxygenase also remains essential for confirmation of predictions based on primary sequence alone.

A comparison of the substrate specificity of the six lipoxygenases using linoleic acid, linolenic acid and arachidonic acid showed that AtLOX-1 and AtLOX-5 oxygenated both linolenic acid and linoleic acid with similar activity. In contrast, AtLOX-2, AtLOX-3, AtLOX-4 and AtLOX-6 oxygenated linolenic acid more effectively than linoleic acid. These results were obtained at high substrate concentrations (100 μ M), and future studies could aim to obtain a more detailed picture of catalytic activity. Nevertheless, the results demonstrate that linolenic acid is the preferred substrate for the *A. thaliana* 13-lipoxygenases. This observation suggests that, in plants, tissues with predominant expression of one of the 13-lipoxygenases may generate mostly 13*S*-hydroperoxyoctadecatrienoic acid, which can be used for jasmonic acid synthesis. In other tissues where 9-lipoxygenase expression is high, such as root initials [12], both 9*S*-hydroperoxyoctadecadienoic acid and 9*S*-hydroperoxyoctadecatrienoic acid are expected to be formed.

In summary, the present study concludes that AtLOX-1 and AtLOX-5 are 9*S*-lipoxygenases, and AtLOX-2, AtLOX-3, AtLOX-4 and AtLOX-6 are 13*S*-lipoxygenases. These results provide a firm basis facilitating future studies employing *A. thaliana* on the role of lipoxygenases in plant physiology and patho-physiology.

Abstract In cases of essential fatty acid deficiency, 5,8,11-eicosatrienoic acid (Mead acid, 20:3n-9) is synthesized from oleic acid as a 20-carbon analog of arachidonic acid. It was reported that 20:3n-9 levels were markedly higher in human fetal cartilage than in the muscle, liver and spleen. We, therefore, hypothesized that 20:3n-9 decreased osteoblastic activity. Goldfish scales were incubated either with 20:3n-9 or with oleic acid at 15 °C for 6 and 18 h. Both osteoblastic and osteoclastic activities in the scale were assessed by measuring alkaline phosphatase (ALP) and tartrate-resistant acid phosphatase, respectively. MC3T3-E1 cells (an osteoblast cell line derived from the mouse) were incubated with 20:3n-9 or oleic acid at 37 °C for 6 and 18 h. ALP activity in cell lysate was measured. In the case of experiments with scales, 20:3n-9 (1–100 μM) significantly suppressed osteoblastic activity after 6 and 18 h of incubation, whereas oleic acid did not change this

activity. Osteoclastic activity was not affected either by 20:3n-9 or by oleic acid. In the case with the cell line, osteoblastic activity was again significantly decreased with 20:3n-9 (10–30 μM) after 6-h incubation but not after 18 h incubation. The presence of 20:3n-9 in fetal cartilage may be important for the prevention of calcification in the cartilage. 20:3n-9 could be applied to some clinical situations where bone formation should be inhibited.

Introduction

In cases of essential fatty acid deficiency, 5,8,11-eicosatrienoic acid (20:3n-9), sometimes also called Mead acid, is synthesized from oleic acid as a 20-carbon analog of arachidonic acid (AA). Holman suggested that the ratio of trienoic to tetraenoic acids (20:3n-9/AA) could be used as a measure of essential fatty acid status, a value of 0.4 or greater defining essential fatty acid deficiency [1].

Adkisson et al. [2] measured the fatty acid composition of various tissues of young chickens, fetal calves and

newborn pigs, and found that the cartilage had unusually high levels of 20:3n-9 and low levels of n-6 polyunsaturated fatty acids. For example, the 20:3n-9 and AA concentrations in the chicken epiphyseal plate phosphatidylethanolamine fraction were 8.2 ± 1.3 and $2.8 \pm 0.6\%$ of total fatty acids, respectively. It was also reported that the 20:3n-9 levels were markedly higher in human fetal cartilage ($2.0 \pm 0.6\%$ of total fatty acids) than in fetal muscle ($0.2 \pm 0.2\%$), liver ($0.4 \pm 0.2\%$) and spleen ($0.1 \pm 0.2\%$) [3]. Because of the absence of blood vessels in cartilage, essential fatty acids do not easily reach the tissue, which is probably a major reason of increased synthesis of 20:3n-9 in the tissue. In fact, a considerable amount of 20:3n-9 (3.2% of total fatty acids in the polar lipid fraction) was also found in the calf lens [2]. Our question was whether there was any biological consequence for such high levels of 20:3n-9 in cartilage.

Except for bone tissues, calcification usually means a pathological condition. Of all the tissues that may be calcified in pathological conditions, cartilage is probably the most sensitive tissue. If cartilage is calcified, it might not be cartilage any more; it might be called bone. For instance, complete calcification of the epiphyseal plate, which of course has a high amount of 20:3n-9 [2], in growing long bones stops its function as longitudinal-bone-growth-promoting cartilage. From these considerations, we hypothesized that unusually high concentrations of 20:3n-9 found in the cartilage might have depressive effects against osteoblasts to keep it from ossification.

The teleost scale is a calcified tissue that contains osteoblasts, osteoclasts, and bone matrix like avian and mammalian bone [4, 5]. We had been using scales of goldfish as the source of osteoblasts and osteoclasts. Alkaline phosphatase (ALP) and tartrate-resistant acid phosphatase (TRAP) activities are measurable with scales from the same fish, and used as surrogate markers of osteoblastic and osteoclastic activities, respectively [5]. We tested our hypothesis using this scale system and a different system (an osteoblast cell line).

Materials and Methods

Goldfish (*Carassius auratus*)

Our previous study [6] found that mature female goldfish were more sensitive to calcemic hormones such as calcitonin than mature males. In the present study, therefore, mature female goldfish (30–50 g) were purchased from a commercial source (Higashikawa Fish Farm, Yamatokoriyama, Nara). All experimental procedures were conducted in accordance with the Guide for the Care and Use of Laboratory Animals of Kanazawa University.

Effects of 20:3n-9 and Oleic Acid on TRAP and ALP Activities in Cultured Scales

The methods for ALP and TRAP assays with cultured scales were performed as described previously [7]. Briefly, Eagle's minimum essential medium (MEM) containing antibiotics and HEPES buffer (20 mM, pH 7.0) was used as culture medium. Scales collected from goldfish under anesthesia were incubated for 6 or 18 h in the medium supplemented with either 20:3n-9 or oleic acid (Sigma-Aldrich Corporation, St. Louis, Missouri). Those free fatty acids were separately dissolved in ethanol and diluted in the medium at 0.01–100 μ M, and their effects were compared with those with oleic acid at the same concentrations. The final concentration of ethanol in the medium was less than 0.5% and this concentration did not affect TRAP and ALP at all. After incubation, scales were fixed in 10% formalin in a 0.05 M cacodylate buffer (pH 7.4) and kept in a 0.05 M cacodylate buffer at 4 °C until analysis. The assay methods of ALP and TRAP activities have been described previously [7]. Briefly, each scale was transferred to a 96-well-microplate and incubated with *p*-nitrophenyl-phosphate, the substrate. In the case of TRAP assay, 20 mM tartrate in a 0.1 M sodium acetate buffer (pH 5.3) was used. After incubation at 20 °C for 30 min, the reaction was stopped by adding 50 μ l of a 3 N NaOH–20 mM EDTA solution, and the absorbance was measured at 405 nm. ALP activity was measured under alkaline conditions (100 mM Tris–HCl, pH 9.5; 1 mM $MgCl_2$; 0.1 mM $ZnCl_2$). Other conditions were similar to those for the measurement of TRAP activity.

Cell Culture

Osteoblastic cell line MC3T3-E1 (5×10^4 cells) were plated in wells of a 24-well plate in 1 mL of α -MEM containing 10% FBS. After 3 days of incubation, the cells were washed with serum-free medium and were cultured for 6 or 18 h in α -MEM containing 1% FBS and free fatty acids (20:3n-9 or oleic acid). Ethanol was used for dilution of fatty acids as described above. The final concentration of ethanol was 0.1% and this concentration did not affect the ALP activity of cultured cells. ALP activity was assayed according to the method of [8] with slight modifications. Briefly, at the end of incubation, the medium was discarded, and the cells were washed. The cell lysate with sodium dodecyl sulfate was stocked in microtubes at -20 °C. Cell lysate was incubated with *p*-nitrophenyl phosphate at an alkaline condition (0.1 M sodium carbonate buffer, pH 10.0) for 30 min at 37 °C. The protein content in the cell lysate was estimated by the BCA method with bovine serum albumin as standard. One unit of ALP

was defined as the activity causing the release of 1 nmol of *p*-nitrophenol/min/mg protein.

Statistics

Results from eight scales are shown as means \pm SEM. In the case of the cell line, results from six wells are shown as means \pm SEM. The effects of fatty acids were compared with results with oleic acid by the *t* test after ANOVA. Differences were considered significant at $P < 0.05$.

Results

Experiments with Goldfish Scales

The effects of fatty acids on ALP activities assayed with scales are shown in Fig. 1. ALP activities of scales were significantly depressed after 6 (panel a) and 18 h (panel b) of incubation with 20:3n-9 at 1.0–100 μ M concentrations, whereas oleic acid did not affect ALP activities at any concentrations tested, irrespective of incubation times. TRAP activities after incubation with fatty acids are shown in Fig. 2. The two fatty acids did not exert any influence on TRAP activity at all.

Experiments with MC3T3-E1 Cells

The effects of 20:3n-9 on ALP were retested with a different assay system with an osteoblastic cell line, MC3T3-E1. 20:3n-9 depressed ALP activities after 6 h of incubation (Fig. 3, panel a), but not after 18 h of incubation (Fig. 3, panel b).

Discussion

We assayed the effects of bone-affecting hormones, endocrine disruptors, heavy metals with our scale co-culture system, and found that those agents influenced osteoblastic and osteoclastic activities exactly as in the case of mammalian bones [6, 9–11]. Incubation for 64 h with 0.1 μ M cadmium, the notorious heavy metal damaging the bone and kidney leading to itai-itai byo (ouch-ouch disease) [12], decreased ALP activity by about 27% in our scale system [10]. The decrease of ALP activity by 10 μ M 20:3n-9 for 6 h (about 25% as shown in Fig. 1) was comparable with ALP-depressing effects of cadmium. Moreover, effects of 20:3n-9 appeared much faster than cadmium; in fact, no effects on ALP activity were detected at 18 or 36 h of incubation with cadmium [10].

The bone complex includes osteoblasts, osteoclasts, and the bone matrix. An interaction between osteoclasts and osteoblasts has recently been noted in mammals (for a review, see [13]). In the same *in vitro* scale assay system used in the present study, we found that melatonin depressed both osteoclastic and osteoblastic activities [14]. Actually melatonin did stimulate proliferation and differentiation of isolated (not co-cultured) mammalian osteoblasts [15, 16]. The receptor activator of NF- κ B (RANK) and the RANK ligand (RANKL) have been identified in osteoclasts and osteoblasts, respectively [17]. Osteoclasts were activated by RANKL binding to RANK, and multi-nucleated osteoclasts (active type of osteoclasts) were then induced [17]. Application of parathyroid hormone activated osteoclasts through the RANK-RANKL system in our scale system (N. Suzuki, unpublished data). Consequently, co-culture systems with both

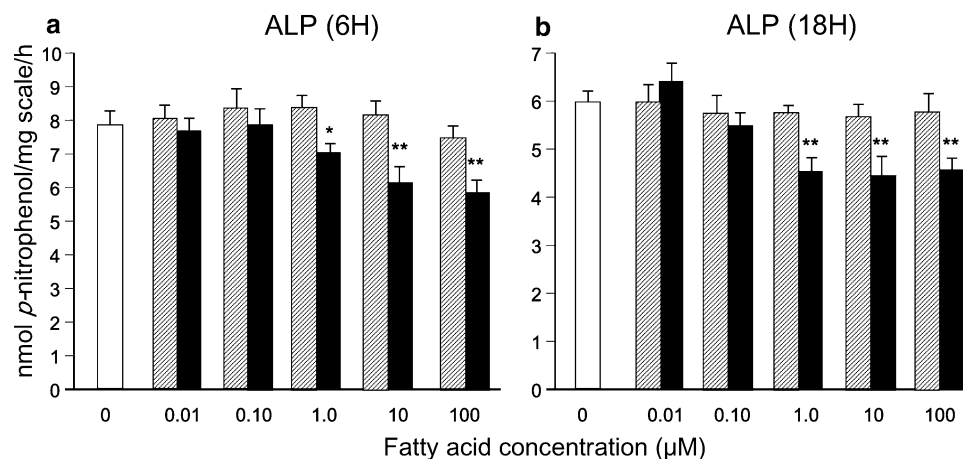

Fig. 1 The effects of 20:3n-9 and oleic acid on osteoblastic activity in goldfish scales. Goldfish scales were incubated with various amounts of 20:3n-9 and oleic acid for **a** 6 and **b** 18 h. Alkaline phosphatase (ALP) activity of scales was measured as osteoblastic

activity. ALP activities were compared with values obtained with oleic acid at the same concentrations. *Open column* activity without fatty acids, *hatched columns* those with oleic acid, *filled columns* those with 20:3n-9. $n = 8$. * $P < 0.05$, ** $P < 0.01$

Tartrate-resistant acid phosphatase (*TRAP*) activity of scales was measured as osteoclastic activity. *TRAP* activities were compared with values

obtained with oleic acid at the same concentrations. 20:3n-9 did not affect *TRAP* activities at all. *Open column* activity without fatty acids, *hatched columns* those with oleic acid, *filled columns* those with 20:3n-9. $n = 8$

Fig. 3 The effects of 20:3n-9 and oleic acid on osteoblastic activity in MC3T3-E1 cells (osteoblastic cell line). MC3T3-E1 cells were incubated with various amounts of 20:3n-9 and oleic acid for **a** 6 and **b** 18 h. ALP activity was measured as osteoblastic activity. ALP activities were compared with values obtained with oleic acid at the same concentrations. *Open column* activity without fatty acids, *hatched columns* those with oleic acid, *filled columns* those with 20:3n-9. $n = 3-4$. * $P < 0.05$

osteoclasts and osteoblasts are definitely required for accurate effect assessment of bioactive materials in the area of bone formation and resorption [18].

In this scale *in vitro* system, 20:3n-9 depressed only osteoblastic activity and not osteoclastic activity at all, which was different from the case of melatonin (see above). To the best of our knowledge, 20:3n-9 is the only biomaterial that depresses osteoblastic activity without affecting osteoclastic activity. In the present study we compared the effects of 20:3n-9 with those of oleic acid, the major n-9 unsaturated fatty acid. Actually the effects of a saturated fatty acid, stearic acid, were also investigated. There were no measurable effects of stearic acid at 0.01–100 μM at all (data not shown).

In order to rule out a slight possibility that the effects of 20:3n-9 on osteoblasts were observable only in fish scales, another system was employed; an osteoblastic cell line, MC3T3-E1. The results with the cell line were similar to

those obtained from scales, although the effects were detected at 6-h incubation and not at 18-h incubation. The reason why the effects disappeared after 18 h of incubation was not clear. It was possible that 20:3n-9 might be metabolized faster with MC3T3-E1 cells, which had probably more metabolically active surface areas than scales. Scales were mostly surrounded with scale pocket lining cells. The results with MC3T3-E1 cells also indicated that the depressive effects of 20:3n-9 were not mediated through osteoclastic cells.

The present study did not have any mechanistic research components, and it is difficult to speculate how 20:3n-9 exerted its effects. Owing to its analogy to AA, dietary supplementation with 20:3n-9 was shown to depress leukotriene B₄ (LTB₄) in rats [19, 20]. LTB₄ has been shown to stimulate bone resorption both *in vitro* and *in vivo* [21, 22]. Actually it was found that the bone-forming capacity of osteoblasts was impaired when cells were cultured in the

presence of 5-LO metabolites including LTB₄ [23]. Consequently, it is unlikely that the depressive effect of 20:3n-9 on LTB₄ synthesis might explain our findings. On the other hand, 20:3n-9 itself was reported to be converted to 11- and 13-hydroxyl metabolites by prostaglandin H synthase-1 and -2 [24], and also to 5-hydroxy and 5-oxo metabolites by 5-lipoxygenase [25]. However, it is not clear whether any of those metabolites might have any osteoblast-depressing effects. It might be a new interesting area of research. CB2 cannabinoid receptors are expressed by osteoblasts and osteoclasts. Their activation stimulates bone formation and suppressed bone resorption [26]. Chemically synthesized 20:3n-9 ethanolamide was found to be a potent agonist to the human CB2 receptor [27]. Consequently, it is unlikely that 20:3n-9 exerted its effects through its conversion to cannabinoid analogues.

Compared with normal controls, patients with cystic fibrosis (CF) were reported to have enhanced blood 20:3n-9 levels [28–30]. As life expectancy in CF patients increases, new clinical problems come to be noticed; osteoporosis is one of them [31]. A long list of the possible reasons was described for osteoporosis in CF [31]. Enhanced blood 20:3n-9 levels in CF patients may be filed in that list. As described in Introduction, except for the epiphyseal plate, calcification of tissues usually implies pathological conditions. For example, ossification of the posterior longitudinal ligament is a common pathological condition seen in Japan and other Asian countries [32]. The thickening of the ligament by ossification compresses the spinal cord and nerve roots. Is there any possibility that 20:3n-9 might stop or at least delay the progression of ossification? Other clinical applications might also be possible.

Our findings that 20:3n-9 depresses osteoblastic activity are very new; further research is warranted.

Acknowledgments The authors are grateful to Ms. Hiroko Hamatani for her technical assistance. This work was partly supported by Open Research Center, Kinjogakuin University, and Polyene Project, Ltd.

Abstract Studies show that n-3 polyunsaturated fatty acids (PUFA) inhibit proliferation and induce apoptosis in cancer cells. Recent reports indicate that this effect is due to activation of the unfolded protein response (UPR). However, what causes this activation has been unclear. We examined the effects of eicosapentaenoic acid (EPA) on the human leukemia cell line HL60 and the econazole (Ec) resistant HL60 clone E2R2. Ec depletes Ca^{2+} from the ER and blocks Ca^{2+} influx in mammalian cells, leading to activation of the UPR and apoptosis. EPA inhibited growth of HL60 cells strongly, while E2R2 cells were much less affected. Gene expression analysis of HL60 cells revealed extensive changes in transcripts related to the ER homeostasis, Ca^{2+} -homeostasis and cell cycle/apoptosis. Protein levels of phosphorylated eIF2 α , a selective translation

inhibitor and UPR hallmark, activating transcription factor 4 (ATF4) and sequestosome-1 were moderately increased, whereas the cell cycle/progression protein cyclin D1 was decreased in HL60. In contrast, EPA concentrations that strongly inhibited and caused activation of the UPR in HL60 cells had no effect on the expression level of these UPR markers in E2R2 cells. Given that the only known difference between these cells is Ec-resistance, our results strongly suggest that the inhibitory effect of EPA on HL60 cells is initially mediated through alterations of the Ca^{2+} -homeostasis followed by activation of the UPR.

Introduction

Epidemiological studies indicate an inverse relationship between dietary intake of n-3 polyunsaturated fatty acids (PUFA) and cancer, especially colon, prostate and breast cancer [1–5]. However, results of such studies are not entirely consistent [6]. Substantial experimental work from in vitro and animal models has shown that n-3 PUFA inhibit cancer cell proliferation, promote cell differentiation, limit angiogenesis and induce apoptosis [7–10].

Several mechanisms have been proposed to explain this including lipid peroxidation [11], activation of peroxisome proliferator-activated receptors (PPARs) [12], activation of retinoid X receptor alpha [13], altered activation of the Ras proteins [9], as well as modulation of eicosanoid production by inhibition of the cyclooxygenase-2 (COX-2) enzyme [5, 14]. However, the molecular mechanisms behind these effects are poorly understood. Our recent studies on colon cancer cells suggest that activation of the unfolded protein response (UPR) may play a major role in mediating the growth inhibitory effect of n-3 PUFA on these cells [15]. Similar pathways have been proposed by others [16]. However, what causes this activation has been unclear. In the present study we wanted to examine whether alterations in Ca^{2+} -homeostasis may precede activation of UPR in human leukemia HL60 cells after treatment with the n-3 PUFA eicosapentaenoic acid (EPA).

The endoplasmic reticulum (ER) is site of lipid synthesis and protein maturation [17]. It serves as an important intracellular Ca^{2+} buffer, and the concentration of Ca^{2+} is several times higher than in the cytosol. ER Ca^{2+} -levels control ER homeostasis by modulating numerous enzymatic cascades, the endomembrane Ca^{2+} -uptake and activation of Ca^{2+} release through channels in ER [18]. Eukaryotic cells can increase their cytosolic Ca^{2+} levels via two mechanisms: release of Ca^{2+} from intracellular stores or influx via plasma membrane channels. Channels in the plasma membrane, like the store-operated Ca^{2+} channels (SOC), regulate the influx of Ca^{2+} into the cell. Studies have shown that the antiproliferative effect of EPA and other PUFA may be mediated through the depletion of Ca^{2+} from intracellular stores [19, 20]. EPA induces Ca^{2+} release from intracellular Ca^{2+} stores by mobilizing the inositol 1,4,5-triphosphate (IP_3) sensitive Ca^{2+} pool through an IP_3 independent route, and inhibits Ca^{2+} influx through SOC in the plasma membrane [20, 21]. Over time this leads to depletion of intracellular Ca^{2+} due to leakage through the plasma membrane causing ER stress and activation of the UPR through the PERK/eIF2 α pathway that may lead to apoptosis [19, 22]. In contrast, studies show that the monounsaturated fatty acid oleic acid did not mobilize Ca^{2+} nor cause activation of the UPR in the same manner as EPA [15, 20, 21].

Conditions interfering with the function of ER are collectively called ER stress. The stress is induced by changes in Ca^{2+} concentration, nutrient deprivation, alterations in the oxidation-reduction balance, failure of post-translational modifications, or excessive protein synthesis, and can lead to the activation of a coordinated adaptive program called the UPR [23]. This co-ordinated response halts the build-up of proteins, allows time for the elimination of unfolded proteins, and re-establishes cellular homeostasis [24]. Figure 1 gives an overview of the UPR transducers and the response initiation following ER stress. Phosphorylation of eukaryote translation initiation factor 2 α (eIF2 α) by eIF2 α kinase 3 (EIF2AK3/PERK) leads to attenuation of global protein synthesis, but promotes translation of certain mRNAs, like ER resident protein chaperones, protein foldases and activating transcription factor 4 (ATF4) mRNA [24, 25]. If the stress cannot be resolved, the cell dies by apoptosis [26].

PUFA mobilize Ca^{2+} from the same intracellular pool as that mobilized by econazole (Ec) in leukaemia cells [27]. Ec is an antifungal imidazole that depletes Ca^{2+} from the ER and blocks Ca^{2+} influx in mammalian cells [28, 29]. This results in sustained depletion of Ca^{2+} from ER stores, activation of the UPR and eventually cell death [30]. However, Ec resistant cell lines have been isolated, like the E2R2 cell line, which is a clone of the human promyelocytic cell line HL60 [31]. E2R2 cells display increased SOC influx and resistance to depletion of Ca^{2+} stores in the

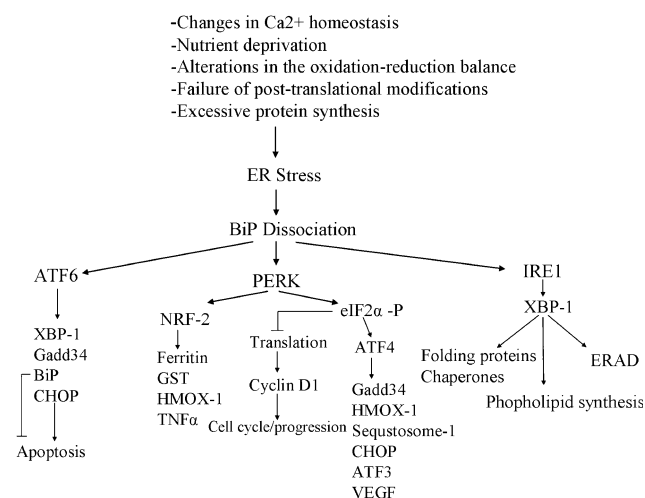

Fig. 1 Overview of the unfolded protein response. Three transmembrane proteins mediate the UPR-signal across the ER-membrane; inositol-requiring enzyme 1 (IRE1), eukaryote translation initiation factor 2 α (eIF2 α) kinase 3 (EIF2AK3/PERK) and activating transcription factor 6 (ATF6). Phosphorylation of eIF2 α by PERK leads to attenuation of global protein synthesis, but promotes translation of certain mRNAs, like activating transcription factor 4 (ATF4) mRNA. Loss of cyclin D1 during ER stress leads to G1-arrest and provides the cell with an opportunity to restore cell homeostasis. However, if the stress cannot be resolved, the cell dies by apoptosis

ER by Ec. E2R2 cells also maintain protein synthesis after treatment with Ec, as well as thapsigargin, most likely due to overexpression of ribosomal proteins. The increased SOC activity is likely to be responsible for the continuous replenishment of Ca^{2+} into the ER store, compensating for the ER Ca^{2+} store depletion caused by Ec. The HL60 cells on the other hand, do not display any of these properties and Ec treatment of these cells results in ER stress related cell death [31].

PUFA inhibit proliferation and induce apoptosis in a dose and time dependent manner in HL60 cells [32] and other leukemia cell lines [33]. In this study we wanted to investigate the role of Ca^{2+} -homeostasis in the antiproliferative effect of EPA. We therefore examined the effect of EPA on the Ec resistant HL60 clone E2R2 and HL60 cells. Cell proliferation was inhibited and several transcripts and proteins involved in the UPR were affected in HL60 cells by EPA treatment. In contrast, neither proliferation nor protein expression of key-mediators of the UPR were affected by treatment with 35 μM EPA in E2R2 cells. Altogether, these results indicate that alterations in Ca^{2+} homeostasis result in induction of ER stress and UPR response in HL60 cells after EPA treatment.

Experimental Procedures

Cell Culture and Fatty Acid Treatment

Human promyelocytic cells (HL60 cells) and E2R2 (generously provided by Zhang and Berger [31]) cells were cultured in RPMI 1640 medium supplemented with 2 mM L-glutamine (Invitrogen, Paisley, UK) and 10% (v/v) fetal bovine serum (FBS) (Euroclone, Pero, Italy) (complete growth medium) at 37 °C in an atmosphere of 5% CO_2 /air. The stock solution of EPA in ethanol (Cayman Chemical, Ann Arbor, USA) was stored at -20 °C and diluted in complete growth medium before experiments (35 μM) (final concentration of ethanol < 0.025% v/v). Cell density was determined using a Coulter Z1 counter, and 3×10^6 cells were seeded in 175-cm² cell culture flasks with 28 mL growth medium. No extra antioxidants were added to the medium as previous studies have shown that antioxidants do not influence the effect of EPA on cell proliferation and apoptosis [32, 34]. Cultures were supplemented with 20, 35 or 70 μM EPA or ethanol (control) and cell density was measured after 12, 24 and 48 h as described above.

RNA Isolation

HL60 cells were treated with EPA for 12, 24 or 48 h before centrifugation (500g, 7 min) and harvesting. Total RNA

was isolated using the High Pure RNA Isolation Kit from Roche Diagnostics (Mannheim, Germany) according to the instruction manual. RNA concentration and quality were determined using the NanoDrop1000 (NanoDrop Technologies, Wilmington, Delaware) and agarose gel electrophoresis.

Gene Expression Profiling

Synthesis of cDNA and biotinylated cRNA was performed according to the eukaryote expression manual provided by Affymetrix. In brief, 5 μg total RNA (HL60) was subjected to double-stranded cDNA synthesis using a T7-oligo(dT)₂₄-primer (Affymetrix, Santa Clara, CA) and the SuperScript™ Double-Stranded cDNA Labeling Kit (Invitrogen, Carlsbad, CA). After clean up (GeneChip Sample Clean Up Module, Affymetrix), all the prepared cDNA was used for in vitro transcription using the GeneChip® IVT Labelling Kit (Affymetrix). 20 μg fragmented cRNA were prepared for hybridization to the Human Genome U133 Plus 2.0 GeneChip (Affymetrix). Hybridization and washing/staining were performed using the Hybridization oven 640 and Fluidics Station 450 (EukGE-WS2v5 protocol). Staining was performed using Streptavidin, R-phycoerythrin conjugate (SAPE, Molecular Probes, Eugene, Oregon) and biotinylated anti-streptavidin antibody (Vector Laboratories, Burlingame, CA). The arrays were scanned using an Affymetrix GeneChip 3000 scanner controlled by GeneChip® Operating Software 1.4 (GCOS, Affymetrix). Expression profiling was performed in triplicate at all time points using total RNA isolated from independent biological replicates.

All experiments have been submitted to ArrayExpress with accession number E-MEXP-1389.

Statistical Analysis of Gene Expression Data

Statistical analysis was performed as described previously in Jakobsen et al. [15]. In short, gene expression summary measures were first computed from the raw data on the CEL-files, based on a linear statistical model for background-corrected, quantile normalized and log-transformed PM values, using the robust multiarray average (RMA) method [35]. Next, treatment effects were estimated by fitting a linear model to these RMA expression measures, and finally, tests for significant differential expression were performed using moderated *t* tests, in which variance estimates for each gene are found by borrowing strength from data on the remaining genes [36].

Differentially expressed genes were selected based on a threshold of 0.05 on adjusted *P* values, meaning that the expected proportion of genes falsely classified as differential expressed should be approximately 0.05. To account

for multiple testing, the *P* values were calculated controlling the False Discovery Rate (FDR) [37], where the estimated value of the proportion of non-differentially expressed genes was inserted [38]. Time effects in the control groups were considered negligible and omitted from the model. All statistical analyzes were performed in *R*, using the packages *limma* and *affy* from Bioconductor [39]. Annotation of differentially expressed genes was performed using the NetAffx Analysis Centre (<http://www.Affymetrix.com>) and NMC Annotation Tool/eGOn V2.0 (<http://www.GeneTools.no>).

Western Blotting

HL60 and E2R2 cells were treated with EPA for 3, 6 and 12 h before harvesting. The cells were washed in ice cold PBS-1 mM EDTA and pelleted by centrifugation (500g, 10 min at 4 °C). Nuclear extracts for detection of cyclin D1 and sequestosome-1 (SQSTM1) were prepared using a nuclear extract kit (Active Motif, Belgium) according to manufacturer's instructions. Total protein for detection of ATF4 was prepared as described by Akbari et al. [40].

To detect phosphorylated eIF2 α , pellets were lysed in 2 \times packed cell volumes of lysis buffer 20 mM HEPES, pH 7.5, 150 mM NaCl, 1% triton-X100, 10% glycerol, 1 mM EDTA, 100 mM NaF, 17.5 mM beta-glycerophosphate, protease inhibitor cocktail "Complete" (Roche), and phosphatase inhibitor cocktail 1 and 2 (Sigma-Aldrich, St. Louis, MO) on ice for 10 min. Equal amounts of protein were separated on 10% precast denaturing NuPAGE gels (Invitrogen, Carlsbad, CA) and transferred to PVDF membranes (Millipore, Billerica, MA). Membranes were blocked in PBS supplied with 5% non-fat dry milk and 0.1% Tween[®]-20 (BioRad, Herkules, CA) and further incubated overnight at 4 °C with the indicated primary antibodies; cyclin D1 (mouse monoclonal antibody, Cell Signaling Technology, Danvers, MA), SQSTM1 (rabbit polyclonal, Abcam), ATF4 (rabbit polyclonal, Santa Cruz Biotechnology, CA), phosphorylated eIF2 α (Serine 51, Cell Signaling Technology). The membranes were also probed for total eIF2 α (Cell Signaling Technology) as a control after stripping the membrane in Restore Western blot Stripping buffer (Pierce, Rockford, IL). All blots were reprobated with β -actin (mouse monoclonal, Abcam) as a loading control. For the eIF2 α antibody incubations and washing steps, TBST buffer (20 mM Tris-HCl, 137 mM NaCl, 0.1% (v/v) Tween-20) supplied with 5% non-fat dry milk was used. The blots were incubated with HRP-conjugated secondary antibodies (DAKO, Carpinteria, CA and Pierce, Rockford, IL) and detected by chemiluminescence using Super Signal West Femto Maximum Sensitivity Substrate (Pierce, Rockford, IL) and visualized by Kodak Image Station 4000R (Eastman Kodak Company, Rochester, NY).

Statistical Analysis

Statistical analysis of the effect of different concentrations of EPA on cell proliferation compared to control was carried out using a one-way ANOVA test followed by a Tukey HSD post-hoc test. The results from the western blot analysis were analyzed using a Student's *t* test. Differences were considered significant with a *P* < 0.05. The statistical analysis was performed using SPSS 15.0 for Windows.

Results

Effect of EPA on Cell Proliferation

Proliferation of HL60 cells was inhibited in a dose and time dependent manner by EPA in line with previous reports [32, 41]. EPA concentrations of 20 and 35 μ M reduced the cell number to approximately 50 and 60%, respectively, after 48 h, whereas treatment with 70 μ M abolished further proliferation (Fig. 2a). In contrast, E2R2 cells were much less affected after treatment with equal molar concentrations of EPA. EPA concentrations of 20 and 35 μ M did not affect cell proliferation, whereas treatment with 70 μ M reduced the cell number approximately 50% after 48 h (Fig. 2b).

Gene Expression Patterns and Signaling Pathways

Several complex gene networks and cell signalling pathways were affected after EPA treatment of HL60 cells. Even though the fold change value of most transcripts was modest, most of the changes in gene expression were seen already after 12 h, whereas the differences diminished with time, indicating that EPA causes early responses (Table 1). Transcripts were classified into several functional categories after annotation as shown in Table 2 and outlined below. Relevant proteins were detected by western blotting in both cell lines.

Ca²⁺ Homeostasis

PUFA have been shown to cause alterations in intracellular Ca²⁺ homeostasis [20, 21]. The mRNA level for a large number of genes involved in Ca²⁺ homeostasis was affected by EPA treatment of HL60 cells, most of them being upregulated (Table 2).

UPR

Alterations in ER Ca²⁺-homeostasis cause ER stress and activation of the UPR [23]. Several key transcripts involved in ER stress were upregulated in the HL60 cells

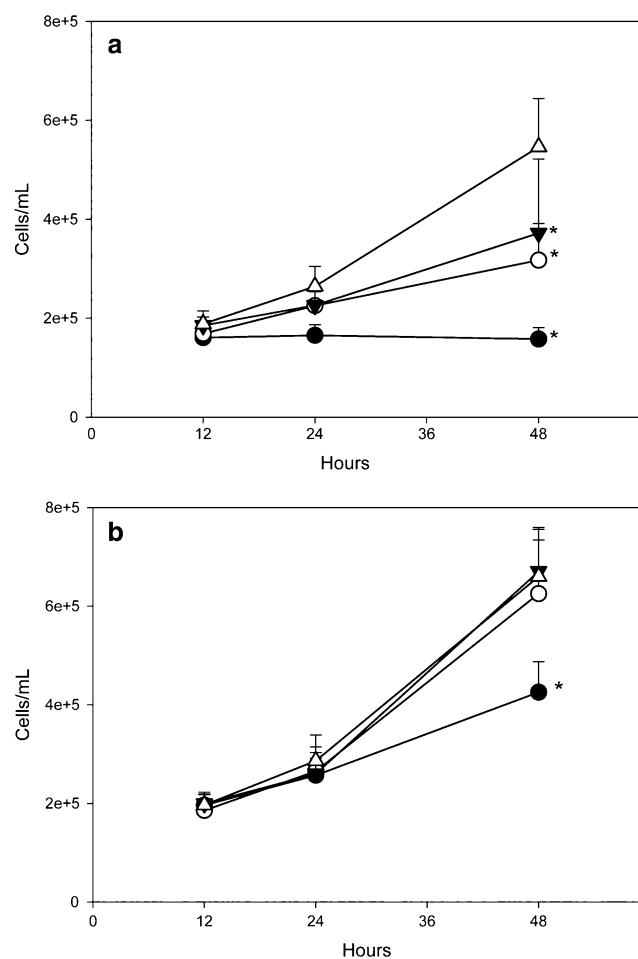

Fig. 2 Effect of EPA on cell proliferation. HL60 **a** and E2R2 **b** cells were cultured under standard conditions and treated with 20 (filled inverted triangles), 35 (open circles), 70 (closed circles) μM EPA or absolute ethanol (triangles) (control). Cell density was measured after 12, 24 and 48 h. The values represent the mean cell density + SD derived from three separate experiments. *Results analyzed by a one-way ANOVA test followed by a Tukey HSD post-hoc test and considered significant different from control ($P < 0.05$)

Table 1 Number of differently expressed genes at different time points in HL60 cells after treatment with EPA (35 μM)

Time point	Number of differently expressed genes HL60
12 (h)	2974 \uparrow 2247 \downarrow
24 (h)	908 \uparrow 138 \downarrow
48 (h)	90 \uparrow 11 \downarrow

after EPA treatment (Table 2). For example the upstream activator PERK (the eIF2 α kinase). Increased levels of phosphorylated eIF2 α were detected by western blotting as early as 3 h after EPA treatment (Fig. 3a). Phosphorylation of eIF2 α leads to attenuation of global protein synthesis, but promotes translation of certain mRNAs, like ATF4

mRNA [25, 42]. As expected from this, ATF4 was moderately upregulated at protein level after 12 h EPA treatment (Fig. 3a). Targets downstream from ATF4, like *HMOX-1*, *ATF3*, vascular endothelial growth factor (*VEGF*) and *SQSTM1* were also upregulated (Table 2). Moderately increased amount of SQSTM1 at protein level was also detected at 12 h (Fig. 3a).

Based on the results from the HL60 cells, protein expression of key-mediators of the UPR was investigated in the E2R2 cells after EPA treatment. Protein levels of phosphorylated eIF2 α , ATF4 and SQSTM1 were equally expressed in E2R2 cells treated with EPA and control cells (Fig. 3a).

Several members of the molecular chaperones, foldases and the ubiquitin/proteasome system were also upregulated at the mRNA level in HL60, indicating the presence of ER stress (Table 2).

Cell Cycle and Apoptosis

Activation of the UPR may halt cell cycle progression [24]. Gene expression studies of the HL60 cells showed 103 downregulated transcripts involved in cell cycle. Cyclin D1 is an important regulator of G1 to S phase progression and thereby cell cycle [43]. Cyclin D1 was downregulated at transcript as well as protein level in HL60 (Table 2; Fig. 3b). However, in E2R2 cells, cyclin D1 was not downregulated at protein level, but was equally expressed in treated and non-treated cells (Fig. 3b). Calcium/calmodulin-dependent protein kinase 1 (CAMK1) was downregulated in the HL60 cells. CAMK1 is important for cell cycle progression through activation of cyclin/cdk complexes [44]. This in addition to phosphorylation of eIF2 α may contribute to the inhibition of cell cycle/progression.

Activation of the UPR may trigger apoptosis mediated by several caspases. Caspase-4, -7 and -9 are among the most important mediators of ER stress-induced apoptosis [45, 46]. All of these as well as several other caspases and caspase related transcripts were upregulated at mRNA level in EPA treated HL60 cells (Table 2). The pro-apoptotic factor Tribbles homolog 3 (TRIB3), known to be induced by ER stress through the PERK-ATF4-CHOP pathway [47], was upregulated at several time points. In addition, pro-apoptotic transcripts related to Bcl-2 were upregulated (Table 2). All together 106 transcripts involved in cell death were upregulated.

Discussion

In this study we show that HL60 cells are strongly growth inhibited by EPA, while the Ec-resistant HL60 clone E2R2

is much less affected by the same treatment. The observed difference in EPA-sensitivity between the two cell lines is most likely mediated through alterations of Ca^{2+} -homeostasis and activation of ER stress and UPR.

Several transcripts involved in the Ca^{2+} -homeostasis were affected in the HL60 cells after EPA treatment (Table 2), indicating that EPA treatment causes alterations in intracellular Ca^{2+} levels. This is also in line with findings in our recent study on colon cancer cells showing that

DHA affects Ca^{2+} homeostasis [15], as well as several other studies on different cell lines [19–21].

Alterations in ER Ca^{2+} -homeostasis cause ER stress and activation of the UPR [23]. Several genes involved in the UPR response (Fig. 1) were affected at mRNA as well as protein level in the HL60 cells (Table 2; Fig. 3a). In particular, we found elevated levels of phosphorylated eIF2 α [48]. Altered mRNA expression of UPR transcripts and increased level of phosphorylated eIF2 α following n-3

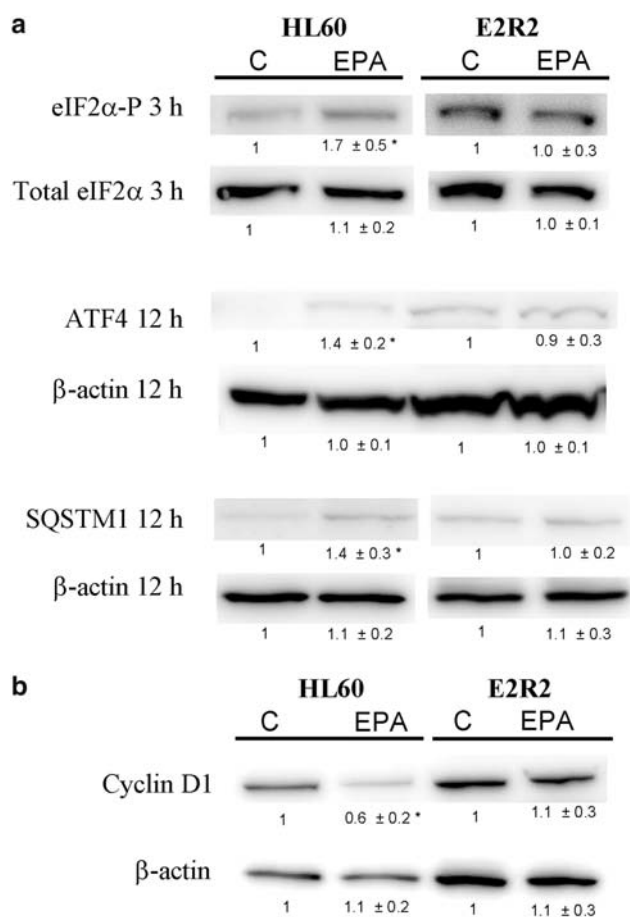

Fig. 3 ER stress signalling and UPR in response to EPA. Western blot analysis of proteins involved in the UPR pathway in HL60 and E2R2 cells cultured under standard conditions and treated with 35 μ M EPA or absolute ethanol (control C). Differences in protein levels are given as mean band signal strength ratio; EPA treated/control cells \pm SD for three or more independent experiments. One representative blot is shown. β -actin was used as a control for equal protein loading. *Results analyzed by Student's *t* test and considered significant different from control ($P \leq 0.05$). **a** eIF2 α -P and total eIF2 α : 3 h cytoplasmic extracts; ATF4: 12 h total protein extracts; SQSTM1: 12 h nuclear extracts. **b** Cyclin D1 12 h nuclear extracts

PUFA treatment are in line with previous reports on other cancer cell lines [15, 19]. Furthermore, upregulated mRNA levels of chaperones, foldases and transcripts involved in the ubiquitin/proteasome system indicate that EPA alters ER homeostasis (Table 2). Altogether, these data indicate that EPA treatment of HL60 cells causes ER stress. In contrast to the HL60 cells, EPA treatment of the E2R2 did not increase protein levels of key-mediators of the UPR like phosphorylated eIF2 α , ATF4 and SQSTM1 compared to control cells. This confirms that EPA treatment of the E2R2 cells does not result in activation of the UPR.

Loss of cyclin D1 caused by phosphorylated eIF2 α during ER stress leads to G1-arrest and provides the cell with an opportunity to restore cell homeostasis [49]. This is

in agreement with the finding that cyclin D1 was down-regulated at mRNA as well as protein level (Table 2; Fig. 3b), and in line with previous reports [15, 19]. Furthermore, this may explain why previous studies have shown that PUFA treatment of HL60 cells increase the portion of cells in the G1 phase of the cell cycle [8, 32]. In line with the same reports stating that EPA treatment inhibits cell cycle and causes apoptosis, we found several genes involved in cell cycle/progression to be downregulated, and genes involved in apoptosis to be upregulated.

Cyclin D1 has been shown to be important for the development and progression of several cancers including lymphoma, parathyroid adenoma and cancer of the breast, oesophagus, lung and bladder [50–55]. Cyclin D1 is a proto-oncogene and is an important regulator of G1 to S phase progression in many different cell types. It binds to cyclin dependent kinase 4 and 6 (CDK4 and CDK6) and forms active complexes that promote cell cycle progression by phosphorylating and inactivating the retinoblastoma protein (RB) [43]. It is also a transcriptional modulator regulating the activity of several transcription factors and histone deacetylase (HDAC3) [56]. Cyclin D1 is therefore used as a key marker of cell viability and established as an important prognostic marker in different types of cancer [57, 58]. In contrast to HL60 cells, protein level of cyclin D1 was not downregulated in response to EPA in the E2R2 cells, but equally expressed in control and EPA treated cells (Fig. 3b), indicating that cell cycle is not affected. This also confirmed the differences found in cell proliferation after EPA treatment (Fig. 2).

The only known difference between HL60 cells and E2R2 cells is that E2R2 is resistant to the imidazole Ec, which depletes Ca²⁺ from the ER and blocks Ca²⁺ influx in mammalian cells [28, 29]. Ec treatment of E2R2 cells does not cause ER stress by phosphorylation of eIF2 α or cell death [31]. The different response to EPA in these two cell lines, strongly suggests that the inhibitory effect of EPA on HL60 cells is mediated through alterations of the Ca²⁺ homeostasis, leading to activation of the ER stress response. This is to be expected, as studies have shown that PUFA mobilizes Ca²⁺ from the same intracellular pool as that mobilized by Ec [27]. E2R2 cells have been shown to display increased SOC influx compared to HL60 [31]. We therefore speculate that this is one of the main mechanisms that maintain cell viability in E2R2 cells compared to HL60 cells when exposed to EPA.

Several studies show an antiproliferative effect of EPA and other PUFA on cancer cells. However, no unified mechanism has been identified. Activation of the UPR has been suggested to mediate the inhibitory effect of PUFA on cancer, but what causes this activation has been unclear. In this study we show that EPA induces activation of the UPR in HL60 cells, but not in the Ec resistant HL60 clone E2R2.

This indicates that the antiproliferative effect of EPA is mediated through alterations in Ca^{2+} homeostasis, leading to activation of the UPR and thereby growth arrest/apoptosis.

Acknowledgments We thank Professor Stuart A. Berger, University Health Network, Toronto, Canada, for kindly providing the E2R2 cells. Thanks to Gro Leite Størvold, Hilde Bremseth, Anne Gøril Lundemo for technical assistance and Professor Kristian S. Bjerve for good support. The project was financed by The Faculty of Medicine, NTNU, The Cancer Research Fund, Trondheim University Hospital and The Research Council of Norway through grants from the Functional Genomics Program (FUGE). Microarray experiments were performed at the microarray core facility at the Norwegian Microarray Consortium (NMC), Trondheim, which is supported by FUGE, The Norwegian Research Council. Financial support was also given by the cross-disciplinary project “BIOEMIT-Prediction and modification in functional genomics: combining bioinformatical, bioethical, biomedical and biotechnological research”, NTNU.

Abstract Statins, inhibitors of HMG-CoA reductase, reduce plasma low-density lipoprotein (LDL) cholesterol levels decreasing the incidence of coronary events. However, the observed benefit of statins appears to extend beyond their lipid-lowering effects. Previous studies by our group have demonstrated that atorvastatin in oxidized LDL incubated macrophages modifies the gene expression profile of certain enzymes involved in fatty acid metabolism, mainly stearoyl-CoA desaturase (SCD). SCD is a rate-limiting enzyme in the biosynthesis of monounsaturated fatty acids and its expression is mediated by sterol regulatory element-binding protein-1 (SREBP-1). The aim of this study was to determine whether atorvastatin might affect the fatty acid composition in macrophages and if their SCD gene expression profile could explain this effect. Therefore, THP-1 macrophages were treated with atorvastatin and native or oxidized LDL, their fatty acid composition was determined by gas-chromatography, and the SCD and SREBP-1 gene expression profile was analysed using quantitative RT-PCR. We found that

atorvastatin reduces the percentage of palmitoleic and oleic acids in THP-1 cells incubated with oxLDL, which could be explained by the inhibition of SCD and SREBP-1 gene expression. The observed results were reversed when mevalonate was added to THP-1 macrophages. This would suggest that inhibition of SCD in THP-1 macrophages incubated with oxLDL and the change in fatty acid composition is an important effect of atorvastatin.

Introduction

Statins, inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, a rate-limiting enzyme for cholesterol synthesis, have revolutionized the treatment of hypercholesterolemia reducing the incidence of coronary events and the rate of mortality in coronary patients. They inhibit HMG-CoA reductase competitively, reduce low-density lipoprotein (LDL) cholesterol levels more than other cholesterol-lowering drugs, and lower triglycerides in hypertriglyceridemic patients [1]. Several landmark clinical trials have demonstrated the benefit of lipid lowering with statins for the primary and secondary prevention of coronary heart disease (WOSCOPS, AFCAPS/TextCAPS, HS, CARE, LIPID, HPS, TNT) [2, 3]. However, the observed benefit with statin therapy was much greater than might have been expected through the reduction of cholesterol levels alone. Results in these experimental studies suggested the possibility that some antiatherosclerotic effects of statins may not be a direct consequence of their influence on LDL cholesterol concentration [4, 5]. These

effects are known as pleiotropic effects of statins and they include improvement of endothelial dysfunction, increased nitric oxide bioavailability, antioxidant effects, anti-inflammatory properties and stabilization of atherosclerotic plaques [6, 7]. Some of the pleiotropic effects of statins may be explained by preventing the prenylation of small G proteins, including Ras and Rho proteins [8], since statins decrease availability of isoprenoids and they can not be attached to these signalling proteins [9, 10]. However, other effects may even be fully dissociated from inhibition of HMG-CoA reductase, and many take place at very low drug concentrations [6].

Previous studies in our group have demonstrated, using gene expression arrays, that atorvastatin in macrophages incubated with oxidized LDL (oxLDL) modifies the gene expression profile of certain enzymes involved in fatty acid metabolism, mainly Stearoyl-CoA desaturase (SCD), suggesting that statins could change fatty acid composition in macrophages ([11], M. Artieda, unpublished).

Stearoyl-CoA desaturase (SCD), also known as delta-9-desaturase, is an endoplasmic reticulum rate-limiting enzyme in the biosynthesis of monounsaturated fatty acids (MUFA) from saturated fatty acids and plays a central role in regulation of fatty acid metabolism [12]. SCD introduces the first *cis*-double bond in the delta-9 position (between carbons 9 and 10) in palmitic acid (16:0) and stearic acid (18:0), which are converted into palmitoleic acid (16:1) and oleic acid (18:1), respectively [13, 14]. These products are the most abundant monounsaturated fatty acids of phospholipids, triglycerides and cholesteryl esters [15]. Apart from being components of lipids, monounsaturated fatty acids also serve as mediators of signal transduction and cellular differentiation [16]. Overall, the expression of SCD can influence membrane fluidity, lipid metabolism and adiposity. Given the multiple roles of monounsaturated fatty acids, changes in SCD activity and alterations in the balance between saturated and monounsaturated fatty acids would be expected to have an effect in various diseases including cancer, diabetes, atherosclerosis and obesity [12].

The activity of SCD appears to be largely mediated by SREBP-1. It has been demonstrated that mice expressing an active form of SREBP-1 have increased expression of SCD and increased synthesis of MUFA, while knockout of SREBP-1 leads to a decrease in SCD expression [17, 18].

The aim of this study was to determine whether HMG-CoA reductase inhibitors might affect the fatty acid composition in macrophages, and if their SCD gene expression profile could be involved. In order to test our hypothesis, THP-1 macrophages were treated with atorvastatin and native or oxidized LDL, their fatty acid composition was determined by gas-chromatography, and the SCD and SREBP-1 gene expression profile was analysed using quantitative RT-PCR.

Materials and Methods

Cell Culture

THP-1 cells (European Collection of Cell Cultures, Salisbury, UK) were grown in suspension in T25 or T75 flasks (TPP) in RPMI 1640 containing 10% heat inactivated FBS (GIBCO®), 10 mM HEPES, 2 mM L-glutamine, 1 mM sodium pyruvate, 5×10^{-5} M 2- β -mercaptoethanol, non-essential amino acids, penicillin (100 U/ml), streptomycin (100 μ g/ml), and Fungizone (250 μ g/l) at 37 °C in 5% CO₂. To induce THP-1 differentiation into a macrophage phenotype, 1×10^6 cells per well were seeded in 6-well plates and stimulated with phorbol 12-myristate 13-acetate (PMA) (Sigma) at a final concentration of 10^{-7} mol/l for 48 h until they adhered to the well and exhibited macrophage-like morphology. For the experiments, the cells were allowed to reach 70–80% confluence.

Isolation and Oxidation of LDL

Low-density lipoprotein was isolated from one homozygous familial hypercholesterolemia patient who is regularly treated with dextran sulfate LDL-apheresis. The apolipoprotein B-containing lipoproteins retained by dextran sulfate were eluted from the column with 0.702 M NaCl, subjected to a single vertical spin density gradient ultracentrifugation in a VTI 50 rotor (Beckman Coulter Inc.), and dialyzed at 4 °C for 24 h against EDTA-free PBS. The protein content of LDL was determined by the Bradford method. LDL was diluted to 200 mg/l in PBS (without EDTA) to prevent its aggregation. Oxidation of LDL was performed by incubation at 37 °C with 8 μ mol/l CuCl₂ for 24 h. The reaction was stopped by adding 1 mmol/l EDTA and storing at 4 °C. Oxidation of LDL was confirmed by Sudan Black LDL staining and agarose gel electrophoresis, and conjugated diene formation assessment by spectrophotometry at 234 nm.

Experimental Design

To test the effect of atorvastatin on SCD gene expression and fatty acid composition, cells were incubated in the absence or presence of atorvastatin at a final concentration of 5 μ M. The same volume of DMSO was added to cells without atorvastatin and the total volume of DMSO added to the cell culture was under 0.1% of the total culture medium. To assess if the effects on SCD gene expression were due to atorvastatin, macrophages were incubated with 100 μ M of mevalonate (Sigma). The same volume of ethanol was added to cells without mevalonate and the total volume of ethanol added to the cell culture was under 0.1% of the total culture medium. Cells were incubated in the

absence/presence of atorvastatin and in the absence/presence of mevalonate for 1 h at 37 °C and 5% CO₂, before addition of 50 µg/ml native LDL (nLDL), oxidized LDL (oxLDL), or the same volume of PBS for control cells. Under these conditions, the cells were incubated for 18 hours at 37 °C and 5% CO₂. Atorvastatin calcium was kindly provided by Pfizer. All the experiments were run in triplicate.

Gene Expression Analysis

Total RNA was isolated from macrophage THP-1 cells using an RNeasy kit (Qiagen Inc., Valencia, CA, USA), following the manufacturer's instructions. Total RNA was quantified by spectrophotometry at 260 nm and its purity assessed by the ratio $A_{260\text{nm}}/A_{280\text{nm}}$. RNA integrity was verified by visualization of ethidium bromide-stained 1% agarose gels.

Two µg of each total RNA sample was treated with 1U DNase I (Ambion Corp., Austin, TX, USA), and it was reverse transcribed with 200 U SuperScript III RNase H⁻ Reverse Transcriptase (Invitrogen Corp.) using 150 ng of random hexamer primers (Invitrogen Corp.) to prime cDNA synthesis. Real-time RT-PCR was carried out using the ABI Prism 7000 HT Sequence Detection System, TaqMan Universal PCR Master Mix, unlabeled PCR primers and TaqMan MGB probes (FAM dye-labeled) from Assay-on-Demand (SCD, Hs00748952_s1; SREBF1, Hs01088691_m1; 18srRNA, Hs099999901_s1 and RPLP0, Hs99999902_m1) according to the manufacturer's recommendations (Applied Biosystems, Foster City, CA, USA). All samples were run in triplicate.

Sequence Detector Software (SDS) (Applied Biosystems) was used for data analysis. A threshold cycle (Ct) value was determined from each amplification plot. The relative expression ratios or fold changes of target genes were calculated using the comparative ΔCt method. Expression of target genes was normalized by the endogenous reference genes 18srRNA and RPLP0, using the geNorm method [19, 20].

Fatty Acid Analysis

Cells were washed twice with PBS, scraped from the culture wells with Versene (GIBCO®) and homogenized on ice by sonication for 10 s with a Soniprep 150 Sonicator set to maximum power. The extraction was performed with chloroform/methanol (2:1 v/v) according to the Folch method [21]. The aqueous phase was discarded and the organic phase was dried under nitrogen. The lipids extracted were subjected to methanolysis in 5% H₂SO₄ in methanol at 80 °C for 90 min [22]. The resultant fatty acid methyl esters were extracted with hexane.

Fatty acids were chromatographed as methyl esters on a 25-m fused silica column with an internal diameter of 0.20 µm. The column was wall-coated with 0.20 mm SP-2330. Analysis was performed on a Hewlett-Packard 6890 gas chromatograph equipped with a flame ionization detector of hydrogen/water. Nitrogen was used as the carrier gas. The split ratio was 17:1. The injection port temperature was 200 °C and the detector was at 250 °C. The column temperature was held at 80 °C for 5 min and this was raised in a step-wise fashion until a plateau at 220 °C. The gas chromatograph was calibrated using a standard mixture of fatty acids. ChemStation software (Hewlett-Packard) was used for the analysis of the chromatograms. Data were presented as a percentage of the fatty acid composition.

Statistical Analyses

Data are presented as means \pm standard deviation (SD). The distribution of quantitative variables was tested for normality. Differences between compared conditions were tested with the *t* test for continuous variables. Comparisons of quantitative variables without a normal distribution were made using the Mann–Whitney *U* non-parametric test. Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS Inc.) version 11.0, and a value of $P < 0.05$ was considered statistically significant for all analyses.

Results

Fatty Acid Composition

Fatty acid composition of THP-1 cells after treatment with atorvastatin in each studied condition: control, native LDL and oxidized LDL, is shown in Table 1. Saturated fatty acids, palmitic acid (16:0) and stearic acid (18:0), are the main substrates for Stearoyl CoA desaturase. Palmitoleic (16:1) and oleic (18:1) acids were the most affected by atorvastatin treatment reaching statistical differences only in the oxLDL situation.

Stearic acid (18:0) content increased significantly in the oxLDL situation after addition of atorvastatin ($19.0 \pm 2.4\%$ vs. $23.3 \pm 3.2\%$, $P = 0.026$). The percentage of stearic acid was also increased after addition of atorvastatin in the control situation and in the nLDL condition, although it was not statistically different. Its monounsaturated fatty acid, oleic acid (18:1), was significantly reduced after incubation with atorvastatin from $21.8 \pm 2.7\%$ to $17.5 \pm 3.2\%$, $P = 0.029$, in the oxLDL condition. Oleic acid content showed a tendency to diminish after addition of atorvastatin in the control

situation and in the ntLDL condition, although it was not statistically significant.

In the same way as stearic acid, palmitic acid (16:0) content increased under all the conditions after addition of atorvastatin at the same time that palmitoleic acid (16:1) diminished after addition of atorvastatin, although the differences did not reach statistical significance. Moreover, two saturated very long chain fatty acids (VLCFA), lignoceric acid (24:0) and hexacosanoic acid (26:0), were significantly decreased by atorvastatin addition from 3.2 ± 0.8% to 1.8 ± 1.1%, $P = 0.042$, and from 1.7 ± 0.5% to 0.9 ± 0.7%, $P = 0.035$, respectively, when the culture medium was supplemented with oxLDL.

The incubation of THP-1 cells with LDL also caused changes in the fatty acid composition (Table 1). OxLDL supplementation caused a decrease in the percentage of linoleic acid (18:2n-6) with respect to the control situation (3.2 ± 1.3% vs. 3.0 ± 0.4%). The opposite effect was observed in the percentage of alpha-linolenic acid (18:3n-3), which was increased in ntLDL (0.3 ± 0.1%) and oxLDL (0.3 ± <0.1%) stimulated culture cells with respect to the

control situation (0.2 ± <0.1%) ($P = 0.041$ for ntLDL vs. control). Incubation with LDL also produced an increase in the percentages of docosanoic (22:0) and lignoceric (24:0) acids: the ntLDL situation; from 2.0 ± 1.5% to 2.3 ± 1.2%, for docosanoic; and from 2.7 ± 0.7% to 2.9 ± 0.9%, for lignoceric, and in the oxLDL situation, from 2.0 ± 1.5% to 2.7 ± 1.3%, for docosanoic; and from 2.7 ± 0.7% to 3.2 ± 0.8%, for lignoceric.

In Table 2, the same results, but grouped in content of saturated (SAT), monounsaturated (MUFA), polyunsaturated (PUFA), n-3 and n-6 fatty acids, are shown. The addition of atorvastatin significantly decreased the proportion of monounsaturated (MUFA) fatty acids in the oxLDL condition from 27.9 ± 2.9% to 23.2 ± 3.5%, $P = 0.030$. Atorvastatin also diminished MUFA content from 28.8 ± 6.0% to 26.3 ± 3.6% in the control situation; from 26.5 ± 3.9% to 24.6 ± 3.9% in the ntLDL condition, although the differences did not reach statistical significance. Inversely, atorvastatin addition showed an increasing tendency of the proportion of SAT in all conditions, although these differences were not statistically significant (Table 2).

Effect of Atorvastatin on the Saturation Index (C18:0/C18:1)

The ratio of C18:0 and C18:1 fatty acid percentages in THP-1 cells under each condition studied is shown in Fig. 1. This saturation index was higher in THP-1 cells with atorvastatin as compared to those without atorvastatin. The C18:0/C18:1 ratio changed from 0.9 ± 0.3 to 1.1 ± 0.3 , in the control situation and from 1.0 ± 0.3 to 1.1 ± 0.3 , in cells supplemented with ntLDL, but these differences were not statistically significant. However, the saturation index significantly increased in cells supplemented with oxLDL from 0.9 ± 0.2 to 1.4 ± 0.4 , *P* = 0.015.

with atorvastatin and without or with mevalonate was analysed using real time RT-PCR to quantify SCD and SREBP-1 gene expression. The SCD gene expression results obtained are shown in Fig. 2. In Fig. 2a, results of SCD gene expression from THP-1 cells incubated with

ntLDL or oxLDL (without atorvastatin) are shown. When ntLDL or oxLDL were added in the culture medium, SCD mRNA was significantly decreased by 70 and 60%, respectively, compared with the control situation. Fig. 2b shows the SCD gene expression results obtained after treatment with atorvastatin and mevalonate in each studied condition: control, ntLDL and oxLDL. Atorvastatin did not produce any effect in the SCD gene expression when it was added to THP-1 cells in the basal situation, whereas SCD mRNA was reduced by 23% after administration of atorvastatin in macrophages incubated with ntLDL, and it was significantly decreased by 30% when incubated with oxLDL. In the presence of atorvastatin and mevalonate, SCD gene expression level was salvaged in each studied condition. The SREBP-1 gene expression results obtained are shown in Fig. 3. In Fig. 3a, results of SREBP-1 gene expression from THP-1 cells incubated with ntLDL or oxLDL (without atorvastatin) are shown. When ntLDL or oxLDL were added to the culture medium, SREBP-1 mRNA was significantly decreased by 44 and 18%, respectively, compared with the control situation. Figure 3b shows the SREBP-1 gene expression results obtained after treatment with atorvastatin and mevalonate under each studied condition: control, ntLDL and oxLDL. SREBP-1 gene expression decreased significantly when atorvastatin was added to THP-1 cells in the basal situation and when they were incubated with oxLDL by 54 and 67%, respectively, whereas SREBP-1 mRNA was reduced by 23% after administration of atorvastatin in macrophages incubated with ntLDL. In the presence of atorvastatin and mevalonate, SREBP-1 gene expression level was salvaged in each studied condition.

Discussion

The aim of this study was to determine whether the HMG-CoA reductase inhibitor atorvastatin might affect the fatty acid composition in macrophages THP-1 and if the SCD gene expression profile could be involved.

We demonstrated that administration of atorvastatin to THP-1 cells incubated with oxLDL causes an increase in the saturated fatty acid, stearic (18:0) acid, as well as a decrease in the percentage of its monounsaturated fatty acid, oleic (18:1) acid. Our results also show that saturated very long chain fatty acids, such as lignoceric acid (24:0) and hexacosanoic acid (26:0), in THP-1 cells, were significantly reduced by the treatment with atorvastatin. These changes produced an increase in the saturation index, a well-established surrogate of SCD activity [23], and we demonstrated that these effects were probably due to the ability of atorvastatin to inhibit SCD gene expression since mevalonate treatment was able to reverse this effect. The

Statistic was calculated by paired-samples *t* test

results of fatty acid composition obtained were very similar to those shown by other authors in THP-1 and human macrophages [24, 25].

Statins affect the production of long chain polyunsaturated fatty acids (PUFA) by increasing the conversion of linoleic acid to its derivatives through enhanced activities of the delta-5 and delta-6 desaturases [24, 26]. They also demonstrated that simvastatin decreases the production of oleic acid and delta-9 desaturase activity in THP-1 cells, whereas in HepG2 cells it is increased [24]. Our finding of lower formation of C18:1 in THP-1 cells incubated with oxLDL during treatment with atorvastatin is in agreement with this study. Moreover, we have demonstrated for the first time that atorvastatin inhibits stearyl-CoA desaturase gene expression when macrophages are exposed to oxidized LDL.

The expression of SCD is regulated by SREBP-1, which is induced by LXR/RXR ligands [27–31]. We have demonstrated that SREBP-1 and SCD gene expression was significantly decreased when native LDL and oxidized LDL were added to the incubation medium of THP-1. It is well known that PUFA and cholesterol are strong repressors of SREBP-1 activity and expression [32, 33] and that PUFA and cholesterol inhibit LXR transcriptional activity, and subsequently, SREBP-1 activity [32]. Therefore, the addition of LDL to the culture medium and its incorporation to the cells would increase the presence of PUFA and cholesterol in THP-1 cells.

Our data have also demonstrated that, when atorvastatin was added to THP-1 cells, SREBP-1 and SCD gene expression was inhibited and this effect was amplified when macrophages were incubated with oxLDL. The nuclear hormone receptor LXR/RXR serves as a sterol sensor to regulate the transcription of gene products that control intracellular cholesterol homeostasis, such as SREBP-1 [31]. SREBPs have been established as transcription factors of lipid synthetic genes, especially for cholesterol and fatty acid synthesis [34]. SREBP-1 seems to be involved in fatty acid and glucose/insulin metabolism, whereas SREBP-2 specifically regulates cholesterol synthesis [35, 36]. SREBP-1 and SREBP-2 are regulated in different ways, as demonstrated by Sheng et al. [37]. They showed that SREBP-2 protein was up regulated, while the nuclear form SREBP-1 decreased, after hamsters were treated with Colestipol and the HMG-CoA reductase inhibitor mevinolin [37]. This is consistent with another study that demonstrated that treatment with atorvastatin decreases the expression of SREBP-1, preventing fatty liver by inhibiting fatty acid synthesis, in a mouse model of type II diabetes [38]. Atorvastatin reduces the internalization of native and oxidized LDL in macrophages and endothelial cells [39, 40] diminishing the availability of oxysterols in the cells. This effect could explain the results observed in our experiments because atorvastatin could exert its action by reducing the natural ligands for LXR/RXR, subsequently reducing expression of SREBP-1, and as a consequence, inhibiting SCD gene expression. Moreover, mevalonate treatment was able to reverse SREBP-1 and SCD mRNA levels in the presence of atorvastatin, suggesting an HMG-CoA reductase dependent effect in the observed reduction of SREBP-1 and SCD gene expression.

Statins are highly effective cholesterol-lowering drugs, but such observations suggest that they may have biochemical effects beyond the simple inhibition of cholesterol synthesis. Previous works have analysed the effect of statins on fatty acid metabolism, and our findings are consistent with those showing that statins can influence desaturase enzyme activity and they can modify fatty acid composition in various cell types studied [26, 41, 42]. The

effects of statins in fatty acid composition in monocytes could explain some of the observed effects independent of changes in plasma LDL cholesterol. Inhibition of SCD gene expression in mice with targeted disruption of the SCD1 gene produces low levels of triglycerides and cholesteryl esters, and SCD activity correlates with plasma triglycerides in the mouse and humans [23]. This fact is in accordance with our results of SCD inhibition by atorvastatin, as it has been demonstrated that plasma triglycerides decrease after atorvastatin therapy in hypertriglyceridemic patients [1]. Moreover, findings that atorvastatin inhibits SCD activity and gene expression in monocytes treated with oxLDL would suggest that intracellular lipid levels might be an important factor in determining the effects of statins, as demonstrated by Zelvyte et al. [43] when analyzing the anti-inflammatory effects of statins. Further studies are required to evaluate the role of cholesterol loading on the effects of statins and to determine how relevant our observations are to arterial foam cells “in vivo”.

In conclusion, when studied “in vitro”, atorvastatin reduces the percentage of palmitoleic and oleic acids at the expense of their saturated fatty acids in THP-1 cells incubated with oxLDL, which could be explained by the induced inhibition of SCD and SREBP-1 gene expression. Moreover, these effects were reversed when mevalonate was added to THP-1 macrophages. All these data would suggest that inhibition of SCD in macrophages THP-1 would be an important effect of atorvastatin independent of plasma cholesterol lowering.

Abstract This study was to determine the effect of a seaweed *Ascophyllum nodosum* extract (SE) containing 220 mg g⁻¹ phlorotannins on differentiation and fatty acid accumulation in differentiating 3T3-L1 adipocytes. 3T3-L1 cells (2 × 10⁴ mL⁻¹) were seeded to 24-well plates and proliferated to reach confluence and then were treated with media containing 0, 12.5, 25, 50, 75 and 100 µg mL⁻¹ SE for 8 days. Dexamethasone, methyl-isobutylxanthine and insulin (DMI) were added to the media in the first 2 days to induce cell differentiation. On day 8 the adipocytes were harvested for measuring cellular fatty acid concentration and the activity of glycerol-3-phosphate dehydrogenase (GPDH). It was found that treatment with SE increased ($P < 0.01$, $n = 6$) cellular myristoleic acid (C14:1), palmitoleic acid (C16:1) and oleic acid (C18:1) and total monounsaturated fatty acids (MUFA) without significantly affecting the cell number and saturated fatty acid (SFA). Ratios of MUFA/SFA, C14:1/C14:0, C16:1/C16:0 and C18:1/C18:0 in cellular lipids increased ($P < 0.05$, $n = 6$) with the SE treatment in a dose dependent manner ($P < 0.001$). Treatment with 75 µg mL⁻¹ SE depressed ($P < 0.05$) cellular GPDH activity. The results indicate

that the biological factors in the SE may be involved in differentiation and MUFA accumulation in adipocytes.

Keywords 3T3-L1 cell line · Fatty acid accumulation · Glycerol-3-phosphate dehydrogenase · Adipocyte differentiation · Seaweed *Ascophyllum nodosum*

Abbreviations

DHAP	Dihydroxyacetone phosphate
DMEM	Dulbecco's modified Eagle's medium
DMI	Dexamethasone, methyl-isobutylxanthine and insulin
FA	Fatty acids
FBS	Fetal bovine serum
GPDH	Glycerol-3-phosphate dehydrogenase
MUFA	Monounsaturated fatty acids
NADH	β -Nicotinamide adenine dinucleotide, reduced form
PBS	Phosphate buffered saline
SFA	Saturated fatty acids

Introduction

Seaweeds have been used traditionally as food and feed in many countries. It was found in animal and human studies that some seaweed and their extracts had functional effects such as antitumor, antiproliferation [1, 2], antiobesity [3], immunomodulatory [4–6], antioxidation [7, 8] and antimicrobial [9].

Brown seaweed *Ascophyllum nodosum* meal or extracts have been used as natural feed additives for pigs [4], lambs [5] and beef cattle [10–12]. It was found that some extracts from the seaweed could improve animal production

performance, which may be attributed to their antioxidant and immunomodulatory characteristics. Recent studies found that supplementation with 2% *Ascophyllum nodosum* meal to cattle diet increased the amount of intramuscular fat, improved carcass quality and extended beef shelf life [13]. However, little information was available on the mechanism.

3T3-L1 cell lines have been used as a cell model for study on differentiation of preadipocytes to adipocytes [14] and fatty acid accumulation [15, 16]. After the 3T3-L1 cells grow to reach confluence they are able to start differentiating to adipocytes in a media with supplementation of additional dexamethasone, methyl-isobutylxanthine and insulin (DMI) [17]. The cellular glycerol-3-phosphate dehydrogenase [EC 1.1.1.8] (GPDH) is a main marker enzyme for the differentiation. The effect of biological factors on lipogenesis and adipogenesis can be estimated by determining GPDH activity and cellular fatty acid accumulation in the differentiating adipocytes [18, 19].

The object of this study was to determine effect of a seaweed extract (SE) from *Ascophyllum nodosum* on cellular fatty acid accumulation and differentiation of 3T3-L1 adipocytes. The SE with various dosages was supplemented to differentiation media during the overall differentiation period. The cell morphology, viability, cellular fatty acid accumulation and GPDH activity in the adipocytes treated with or without SE in various dosages were compared.

Materials and Methods

Preparation of Seaweed Extract

Brown seaweeds *Ascophyllum nodosum* were originally from the Atlantic coastline of Nova Scotia, Canada (Acadian Seaplants Limited, Dartmouth, NS, Canada). The seaweed extract was prepared using a procedure introduced by Wang et al. [20]. The ground seaweeds powder (diameter <500 µm) was mixed with aqueous methanol (80:100 v/v) in ratio of 1 g:25 mL. The mixture was stirred for 2 h at room temperature and then filtered through Whatman #1 filter paper. Methanol in the filtrate was then evaporated at 40 °C and the remaining aqueous fraction was freeze-dried as the seaweed extract for cell culture experiment. The SE contained 220 mg phlorotannins per g dry matter. This was determined by a method introduced by Stern et al. [21].

Cell Culture Experiment

The 3T3-L1 cell line was obtained from ATCC™ (VA, USA). The cells with a passage of five were used in the

present study. The cells were seeded to 24-well plates at a density of 2×10^4 cells per mL of Dulbecco's modified Eagle's medium (DMEM, Sigma, MO, USA) containing 10% fetal bovine serum (FBS, Sigma, MO, USA). The plates were placed in a humidified 5% CO₂ atmosphere at 37 °C for cell proliferation until they reached confluence. The cells were then treated with media containing 0, 12.5, 25, 50, 75 and 100 µg mL⁻¹ of the SE during the overall differentiation period for 8 days. An 80% ethanol water solution was used as carrier solvent for SE. It was added to the media in 1/1,000 (v/v). During the first two days all the groups were in a basal media containing 0.1 µmol L⁻¹ dexamethasone (Sigma, MO, USA), 1 mmol L⁻¹ methyl-isobutylxanthine (Sigma, MO, USA) and 0.1 µmol L⁻¹ insulin (Bovine insulin, Sigma, MO, USA) that acted as the main factors to induce initial differentiation. On day 8 at the end of culture experiment, subsets of cells were harvested for analysis of GPDH activity ($n = 6$ per treatment) and for fatty acids concentration ($n = 6$ per treatment). The remainder ($n = 4$ per treatment) of the plate was stained with Oil-Red O and then Mayer's hematoxylin (Sigma, MO, USA).

Harvesting and Counting Cells

To harvest the cells for cell counting and analysis of cellular fatty acids, cells were washed with a warm phosphate buffered saline (PBS, calcium and magnesium free, pH 7.08) and dissociated with PBS solution containing 0.25% trypsin and 100 mg L⁻¹ EDTA by incubation at 37 °C for 5 min. The cells were then counted on a haemocytometer. For preparing extract for analysis of GPDH activity, the cells were first washed with cold PBS, followed by addition of 0.5 mL Tris-EDTA (pH 7.5). The cells were collected mechanically and crushed under an ultrasonic cell disruptor (Microson™, NY, USA). After centrifugation at 12,800×g at 4 °C for 5 min the supernatant was taken for analysis of GPDH activity. All the harvested cells and extracts were stored at -80 °C for further analysis.

Staining and Photographing Cells

Briefly, 1 mL cold buffered formalin was added to the cell culture and left to stand at room temperature for 30 min. Then it was replaced with fresh 2 ml of cold buffered formalin for 1 h at room temperature to achieve fixation. Cells were then washed with deionised water and 1 ml 0.5% Oil-Red O (Sigma, MO, USA) in isopropanol:deionised water (3:2) was added to the fixed cells for 1 h to stain the oil bodies in the cells. Then the cells were washed with deionised water, and counterstained with Mayer's Hematoxylin (1 g L⁻¹, Sigma, MO, USA) for 3 min. The stained cells were washed with deionised water

again. The cell cultures were photographed using a microscope (Olympus CKX41, Olympus, Japan) with a digital camera (Moticam 2300, Motic China Group Co., Ltd. China).

GPDH [1.1.1.8] Activity and Protein Analysis

The GPDH activity was measured using the method of Wise and Green [18] with modifications. The measurement was done in 98-well micro plate. The following aliquots were added to the well in sequences: 50 μL solution (pH 7.5) that was formed by 0.5 mol L^{-1} triethanolamine, 10 mmol L^{-1} EDTA and 10 mmol L^{-1} 2-mercaptoethanol (TEA solution), 100 μL 5 mmol L^{-1} dihydroxyacetone phosphate (DHAP), 200 μL 0.5 mmol L^{-1} β -nicotinamide adenine dinucleotide with reduced form (NADH), and 50 μL of extract. The disappearance of NADH at 25 $^{\circ}\text{C}$ was measured by a spectrophotometric method at 340 nm with microplate spectrophotometer. The activity of GPDH was expressed as units per min = $[\text{NADH (100 nmol)} \times \text{change of OD}_{340}]/[1.25 \times \text{time (min)} \times \text{protein (mg)}]$. Protein content was measured with Total Protein Kit (Micro Lowry, Onishi & Barr Modification, Sigma-Aldrich Inc., MO, USA) based on the method of Lowry et al. [22].

Extraction of Cellular Lipids

The cellular lipids were extracted by using a procedure reported previously [16]. The harvested cells that had been stored in -80°C freezer were then transferred and washed into a test tube with 4 mL isopropanol. Then 4 mL hexane was added and the cells were crushed using an ultrasonic reactor for 10 min. After crushing the cells, 4 mL water was added to the mixture and the tubes were centrifuged at $2,000 \times g$ at 5 $^{\circ}\text{C}$ for 5 min. Then the upper layer was transferred to a new tube. After the hexane was evaporated under nitrogen in a 38 $^{\circ}\text{C}$ water bath, the residue was stored at -80°C for further analysis.

Methylation and Determination of Fatty Acids

A combined base/acid methylation method [23] with modifications was used. Nonadecanoic acid (C19:0) methyl ester (100 μL , 5.96 mg mL^{-1} hexane Nu-Chek Prep, Inc., MN, USA) was used as an internal standard added to the tubes containing lipids. Then 2 mL of sodium methoxide (0.5 mmol L^{-1} in methanol) was added to each tube. The tubes were flushed with nitrogen and mixed completely. They were placed in a 50 $^{\circ}\text{C}$ water bath for 10 min. After that 1 mL boron trifluoride (14% in methanol) was added and the tubes were reheated in a 50 $^{\circ}\text{C}$ water bath for another 10 min. After cooling down, 5 mL water and 2 mL hexane were added to the tube and the solution was mixed

completely. They were allowed to stand for 10 min and the upper layer (hexane) was taken into a GC vial flushed with nitrogen for fatty acid determination by gas chromatography. Fatty acid methyl esters were quantified by a gas chromatograph (Hewlett Packard GC System 5890; Mississauga, ON) equipped with a flame ionisation detector and SP-2560 fused silica capillary column (100 m with 0.2 mm film thickness; Supelco Inc., Oakville, ON). Samples were loaded on to the column via 5 μL splitless injections. The initial oven temperature (120 $^{\circ}\text{C}$) was held for 15 min and then increased at 5 $^{\circ}\text{C min}^{-1}$ to 160 $^{\circ}\text{C}$, and held for 15 min. Next the temperature was increased at 4 $^{\circ}\text{C min}^{-1}$ to 240 $^{\circ}\text{C}$ and held for 30 min. Inlet and detector temperatures were maintained at 220 and 275 $^{\circ}\text{C}$, respectively. The helium carrier gas flow rate through the column was 1.7 mL min^{-1} . Hydrogen flow to the detector was 34 mL min^{-1} , the air flow was 320 mL min^{-1} and the helium make-up gas flow rate was 29 mL min^{-1} . Peaks in the chromatograms were identified and quantified using pure methyl ester standards (Sigma-Aldrich, Oakville, ON) and reported as μg fatty acid per 10^5 cells. The recovery rates and correction factors were calculated based on the internal standard fatty acid.

Statistical Analysis

Analysis of variance (ANOVA) was conducted using SAS-PROC MIXED [24] to determine the effect of SE in various dosages on the cellular GPDH activity, fatty acids concentration and the ratio of saturated fatty acids to monounsaturated fatty acids. Tukey test was applied for multiple comparisons when a significant difference ($P \leq 0.05$) was found among the treatment groups. Pearson correlation (2-tailed) analysis was used for analysis of correlations between the ratio of MUFA/SFA and SE dosage [25].

Results

Adipocyte Morphology and Viability of the Cells

The images of the cells on day 8 and those Oil-Red O stained cells at the end of the experiment are shown in Figs. 1 and 2, respectively. The oil drops were observed in most of the cells in both the control and the treatment groups. Differences were shown in the appearance of the distribution of the cells between the control and the SE treatments. The adipocytes treated with SE especially those with 75 and 100 $\mu\text{g mL}^{-1}$ SE contained larger oil drops than those in the control (Figs. 1, 2). Also the cells in the wells treated with 12.5 and 25 $\mu\text{g mL}^{-1}$ SE were gathered to form radial scattered groups (Fig. 1). Treatment with SE

Fig. 1 Photos of 3T3-L1 adipocytes on day 8 of post-confluence treated with 0 (a), 12.5 (b), 25 (c), 50 (d), 75 (e) and 100 (f) $\mu\text{g mL}^{-1}$ seaweed extract during the experimental period. Bar = 50 μm

did not significantly affect the total number of the cells that were harvested at the end of experiment (Table 1).

GPDH Activity

The comparison on cellular GPDH activity in the adipocytes harvested at the end of experiment is shown in Fig. 3. Treatment with 75 $\mu\text{g mL}^{-1}$ SE decreased ($P < 0.05$) GPDH activity by approximately 20% (Fig. 3). Treatment with 25 $\mu\text{g mL}^{-1}$ did not significantly affect the GPDH activity although the value was relatively lower than that in the control.

Concentration of Cellular Fatty Acids

Supplementation with 12.5, 25, 50, 75 and 100 $\mu\text{g mL}^{-1}$ SE to the media significantly increased ($P < 0.05$) the amount of monounsaturated fatty acids (MUFA) in the adipocytes (Table 1). Concentration of cellular myristoleic acid (C14:1) and palmitoleic acid (C16:1) in the adipocytes treated with 12.5, 25, 50, 75 and 100 $\mu\text{g mL}^{-1}$ SE was higher ($P < 0.05$) compared to that of the control. Cellular concentration of cellular oleic acid (C18:1) in the adipocytes treated with 75 and 100 $\mu\text{g mL}^{-1}$ SE was also higher

($P < 0.05$) than that of the control. The amount of cellular total fatty acids and that of saturated fatty acids (SFA) in the adipocytes were not significantly affected by supplementation of SE to the media. Cellular concentration of palmitic acid (C16:0) and stearic acid (C18:0) were not affected by supplementation of the SE. However, cellular concentration of myristic acid (C14:0) in the adipocytes treated with the SE tended ($P = 0.07$) to be increased (Table 1).

Ratio of MUFA to SFA

The ratio of total MUFA to SFA as well as the individual ratios of C14:1/C14:0, C16:1/C16:0 and C18:1/C18:0 in adipocytes treated with 12.5, 25, 50, 75 and 100 $\mu\text{g mL}^{-1}$ SE were significantly higher ($P < 0.05$) compared to those in the control group (Table 1). The treatment with 100 $\mu\text{g mL}^{-1}$ SE had the highest ratio of total MUFA/SFA and that of C14:1/C14:0, C16:1/C16:0 and C18:1/C18:0 among the groups. There were significantly positive correlations ($P < 0.001$) between the SE dosage and the ratio of MUFA/SFA, C14:1/C14:0, C16:1/C16:0 and C18:1/C18:0 with coefficient of 0.8, 0.8, 0.6 and 0.5 respectively.

Fig. 2 Photos of fixed and Oil-Red O and Mayer's hematoxylin stained 3T3-L1 adipocytes at the end of experiment treated with 0 (a), 12.5 (b), 25 (c), 50 (d), 75 (e) and 100 (f) $\mu\text{g mL}^{-1}$ seaweed extract during the experimental period. Bar = 50 μm

Discussion

Extracts of seaweed have been tested as feed additives for improving animal health and production performance. The effects of seaweeds and their extracts may be diverse on their breed, preparation method and applied dosage. Brown seaweed *Ascophyllum nodosum* meal or extracts have been tested as feed additives for animal production [4, 5, 10, 11, 13]. Studies found that their supplementation to the diet could improve desirable intramuscular fat content in beef and extended shelf life of the meat products [13]. This may be attributed to the antioxidants and other biological components in SE which may affect the lipid accumulation and ratio of monounsaturated fatty acids in fat tissues. In the present study, it was found that supplementation of the SE increased MUFA concentration and composition in adipocytes without affecting the amount of cellular total fatty acid. The ratio of cellular MUFA/SFA increased in a dose-dependent manner only when the relative low doses (12.5, 25 and 50 $\mu\text{g mL}^{-1}$) were applied. With relative high doses (75, 100 $\mu\text{g mL}^{-1}$) the supplementation of SE did not show further improvement on the ratio of MUFA/SFA. One of the possible reasons is that not all the tannins added to the media were effective for the cells because they might form tannin-protein complexes with albumin in the media. More tannin molecules may be consumed when the relative high doses were applied.

The main biological components in the SE were phlorotannins [20], which were detected in amounts as high as 220 mg g^{-1} dry matter using a method by Stern et al. [21]. Phlorotannins from brown seaweed have been reported as possessing several biological activities such as being an antioxidant and preventing skin carcinogenesis [2, 26]. Liu et al. [27] have assessed the effect of tannic acids extracted from a banaba *Lagerstroemia speciosa* L. on

differentiation of 3T3-L1 adipocytes and found that the tannic acids inhibited the differentiation but stimulated glucose transport in 3T3-L1 cells. Similarly, in the present study, an inhibitory effect of SE on cellular GPDH activity (Fig. 3) was found and that may be attributed to the effect of phlorotannins. In animal studies Wriese and Lambert [28] observed that consumption of drinking water containing tannic acid resulted in a higher weight fat pad which may be caused by increased fatty acid accumulation through decreasing both basal and isoproterenol-stimulated lipolysis. However, Yoshikawa et al. [29] found that oral supplementation of the tannin fraction from *Salacia reticulata*, inhibited GPDH activity in epididymal fat tissue of Zucker fatty rats and therefore showed a mild antiobesity effect. The GPDH is the key enzyme catalysing conversion of dihydroxyacetone phosphate (DHAP) to glycerol-3-phosphate for further synthesis of fatty acids and triacylglycerol (TAG). Abnormal fat development was found in transgenic mice overexpressing GPDH [30]. Decline of GPDH activity indicated a slow down on de novo synthesis of fatty acids and TAG. It also reflected the inhibition on differentiation in the early differentiating preadipocytes and lipogenesis in the mature adipocytes.

Related to the results that SE improved the cellular MUFA in the adipocytes, a previous study by Cherian et al. [31] found that dietary supplementation of a sorghum Valpo Red, which contains high tannins, to broiler chicks significantly improved C16:1, C18:1 and total MUFA composition in breast muscle total lipids compared to the control and another sorghum Ruby Red which contains low tannins. All of these together with the findings in the present study suggest both terrestrial tannins and phlorotannins may be involved in the lipogenesis and adipogenesis of fat tissues.

Lipogenesis and lipolysis always concurrently exist in mature adipocytes. GPDH is the key enzyme for controlling the lipogenic synthesis rate in the cells, especially for those adipocytes in the differentiation period [19]. The inhibition on GPDH activity affects the lipogenesis and may result in a less de novo fatty acids synthesis. The previous study on effect of CLAs on the differentiation of 3T3 cells found there was a positive correlation between GPDH activity and cellular fatty acids, especially that of MUFA C16:1 and C18:1 [16]. However, in the present study, the concentration of MUFA in the cells as well as the composition in the total fatty acids were increased while the GPDH activity was decreased. It suggested that the increase of MUFA found in the present study was independent of the change in GPDH activity. The antioxidant effect of SE may contribute the most to accumulation and protection of MUFA against being oxidised and degraded.

The present study found that the cellular ratio of MUFA/SFA was increased in an SE dose dependent manner. The

ratio of MUFA/SFA such as C14:1/C14:0, C16:1/C16:0 and C18:1/C18:0 may be related to metabolic rate and physiological responses of the cells, and therefore may affect membrane fluidity of cells [32]. Changes in the ratio of MUFA to SFA may in turn affect lipogenesis and lipolysis in the adipocytes. Cellular lipid accumulation in mature adipocytes depends on both lipogenesis and lipolysis and may alter cell size and the cellular fatty acid composition. It was found [33] that in growing and fattening beef cattle the composition of cellular monounsaturated fatty acids such as C14:1, C16:1 and C18:1 had strong positive correlation with mean size of adipocytes, while that of saturated fatty acids C18:0 and C16:0 had a negative correlation with it. A similar correlation was found between the cellular fatty acids composition and adipocytes distributed in the same fat pad that excluded variations caused by animal, feed and environment [34]. In the present study the results on profiles of the adipocytes (Figs. 1, 2) show the SE groups, especially those treated with 75 and 100 $\mu\text{g mL}^{-1}$, had accumulated more large oil drops, which were also found to have a significantly higher ratio of MUFA/SFA (Table 1) compared to those in the control. These findings in the present study suggest that there is a similar correlation between the composition of fatty acids, especially the ratio of MUFA/SFA and the cell size, which is dependent on the cellular fatty acid accumulation.

Fatty acids and their composition in animal products may affect the quality, flavour and nutritional value. Diets high in saturated fatty acids may be correlated with an increased incidence of coronary heart disease [35]. Decreasing dietary SFA or increasing ratio of USFA/SFA could lower the plasma total and LDL-cholesterol [36] and this may lower the incidence of heart attack, cardiac death, heart failure or stroke [37]. The results suggest that a high-MUFA diet could also be an alternative to a low-fat diet for medical nutrition therapy in diabetes [38]. Therefore, the positive effect of the seaweed and the tannin fraction on the ratio of MUSF/SFA in the adipocytes that was found in the present study, and those in animal experiments [31] may contribute new knowledge to improve food quality and human health.

In conclusion, the present study found that supplementation of the SE from *Ascophyllum nodosum* to the medium significantly increased accumulation of cellular MUFA and the ratio of MUFA/SFA in a dose-dependent manner in differentiating 3T3-L1 adipocytes. Supplementation with a high dose of SE to the media inhibited the GPDH activity. The results suggest that SE may have diverse effects on differentiation and fatty acid accumulation in differentiating adipocytes. The biological factors in SE such as phlorotannins may be involved in lipogenesis and lipolysis, and may improve monounsaturated fatty acid accumulation in adipose tissue.

Abstract The biologic availability of two kinds of tococomonoenols, marine-derived tocopherol (MDT) and α -tococomonoenol, was investigated in ICR mice. Vitamin E-deficient ICR mice were fed MDT and α -tococomonoenol together with α -tocopherol, β -tocopherol, γ -tocopherol, and δ -tocopherol, and storage in liver, spleen, lung, and brain was quantified using reverse-phase high-performance liquid chromatography. The vitamin E relative biologic availability (VE-RBA) in liver was 100 for α -tocopherol, 26 ± 3 for β -tocopherol, 4 ± 2 for γ -tocopherol, not detected for δ -tocopherol, 49 ± 6 for MDT, and 30 ± 7 for α -tococomonoenol. The VE-RBA in brain was 100 for α -tocopherol, 5 ± 2 for β -tocopherol, not detected for γ -tocopherol and δ -tocopherol, 8 ± 1 for MDT, and 4 ± 1 for α -tococomonoenol. Tocopherols and tococomonoenols did not accumulate in the spleen or lung. MDT and α -tococomonoenol had high VE-RBA values. The VE-RBA value for MDT was much higher than that for β -tocopherol.

Keywords α -Tococomonoenol · Liver · Marine-derived tocopherol · Mouse · Vitamin E relative biologic availability

α -TTP	α -Tocopherol transfer protein
VEHTM	Vitamin E homologues and tococomonoenols mixture
VE-RBA	Vitamin E relative biologic availability

Introduction

Vitamin E is essential for maintaining cellular homeostasis in animals. The vitamin was originally discovered as an antisterility component in rodents [1], but this effect has not been observed in humans. It is currently recognized that the main role of vitamin E in the mammalian body is as an antioxidant [2–4]. Vitamin E is a generic term used to refer to eight homologues, α -tocopherol, β -tocopherol, γ -tocopherol, δ -tocopherol, α -tocotrienol, β -tocotrienol, γ -tocotrienol, and δ -tocotrienol. Approximately 10 years ago, however, two novel types of vitamin E were discovered in Japan [5, 6]. In 1995, α -tococomonoenol was found in rice bran and palm oil at levels of 7–14 mg/g [5]. The structure of α -tococomonoenol resembles that of α -tocopherol, except that one double bond locates between the 11' and 12' carbons of the phytyl side chain [5, 7]. Palm oil and rice bran characteristically contain α -tocotrienol. α -Tococomonoenol might be an intermediate substance formed by the metabolism of α -tocopherol to α -tocotrienol,

or by α -tocotrienol to α -tocopherol, in palm and rice. The other novel vitamin E was a different kind of tocomonoenol, named “marine-derived tocopherol” (MDT). The existence of MDT was first reported in 1999 [6]. MDT was originally found in salmon roe, but its presence in a wide range of marine organisms was later confirmed [6, 8, 9]. The structure of MDT is very similar to that of α -tocomonoenol, but the position of the double bond in the phytyl side chain is different. The double bond in MDT locates at the end of the side chain. MDT levels are conventionally expressed in %MDT, $100 \times \text{MDT}/(\text{MDT} + \alpha\text{-tocopherol})$, and the values range from 0 to 38 in marine organisms. Both tocomonoenols are present in human plasma [8], likely incorporated into the body via foods.

Relative vitamin E activity is a factor indicating the relative availability of vitamin E homologues in the mammalian body [3, 4]. A wide range of values in various animals have been determined by several methods, including liver-storage bioassay [10, 11], inhibition rate of fetal resorption [12, 13], inhibition rate of erythrocyte hemolysis [14], muscular dystrophy [15], in rat [12–14], chick [10, 11], and rabbit [15]. Representative values are 100 for α -tocopherol, 2–40 for β -tocopherol, 1–11 for γ -tocopherol, 1 for δ -tocopherol, 27–29 for α -tocotrienol, and 5 for β -tocotrienol [2]. These values have been used to determine the “Recommended Daily Amounts” for humans worldwide. Importantly, however, the values have not been examined in human clinical investigations. These values are thought to be strongly related to the affinity to α -tocopherol transfer protein (α -TTP) in the liver [16, 17].

As mentioned above, novel tocomonoenols were detected in human plasma, but their relative availabilities have not yet been investigated. There is a high consumption of marine fish worldwide and MDT is found in almost all marine organisms. Therefore, we investigated the vitamin E relative biologic availability (VE-RBA) of MDT in ICR mice and comparing it with that of β -tocopherol. The VE-RBA of α -tocomonoenol was also examined in this study.

Materials and Methods

Reagents and Ingredients

α -Tocopherol, β -tocopherol, γ -tocopherol, and δ -tocopherol were a kind gift from Eisai Co., Ltd. (Tokyo, Japan). Silica Gel 60 N (spherical, neutral) for column chromatography was purchased from Kanto Chemical Co., Inc. (Tokyo, Japan). Other chemicals used in the experiments were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan). Vitamin-free casein and AIN-93G mineral mixture were obtained from CLEA Japan, Inc. (Tokyo,

Japan). Vitamin E-free corn oil was obtained from Tama Biochemical Co., Ltd. (Tokyo, Japan). AIN-93 vitamin mixture and AIN-93 vitamin E-free vitamin mixture were purchased from Oriental Yeast Co., Ltd. (Tokyo, Japan).

Separation of Tocomonoenols from Tuna Oil Deodorization Scum

The deodorization scum formed from tuna oil was obtained from Nippon Suisan Kaisha, Ltd. (Tokyo, Japan). Deodorization scum (100 g) was mixed with 200 mL of 1 N KOH methanol solution, stirred with a magnetic stirrer for 10 min and placed in the dark for 30 min. The solution was separated into two layers and the upper layer was collected and neutralized with 12 N HCl. The neutralized solution was then separated into two layers and the upper layer was collected in a separating funnel and mixed gently with 200 mL of hexane and saturated NaCl solution. The separation funnel was placed in the dark and the upper layer was collected and evaporated with a rotary evaporator under vacuum at 40 °C. The evaporated upper layer was viscous and dark brown.

The Silica Gel 60 N was packed in a column using a mixture of hexane and ethyl acetate (95:5, v/v). The viscous dark brown substance was mixed with Silica Gel 60 N in hexane solution and dried completely with a rotary evaporator. The dried silica gel was charged onto the packed column and a mixture of hexane and ethyl acetate (95:5, v/v) was flowed onto the column continuously. Each liter of the eluted solution was collected and run on a high-performance liquid chromatography (HPLC) -fluorescence detector (FL) to evaluate the presence of vitamin Es after the solute was changed from the mixture of hexane and ethyl acetate to methanol. The HPLC system comprised a pump (L-6000, Hitachi High-Technologies Corporation, Tokyo, Japan), docosyl silyl (C22) column (DOCOSIL-B, 250 \times 4.6 mm, i.d. 5 mm, Senshu Scientific Co., Ltd, Tokyo, Japan), FL (RF-10AXL, Shimadzu Co., Kyoto, Japan), and Chromatopac integrator (C-R6A, Shimadzu Co., Kyoto, Japan). Methanol was used as an eluent; the flow rate was 1.0 mL/min and the column temperature was room temperature. The FL excitation and emission wavelengths were 298 and 325 nm, respectively. After the second fractionation, fractions containing tocopherols were collected and dried using a rotary evaporator.

The collected tocopherols were mixed with methanol and subjected to HPLC-FL for fractionation. The HPLC-FL system comprised a pump (L-6000), C22 column (DOCOSIL-B, 250 \times 10.0 mm, i.d. 5 mm), FL (FP-920, JASCO Corporation, Tokyo, Japan), and Chromatopac integrator (C-R6A). The flow rate was 3.0 mL/min. Other conditions were the same as described above. The peak

appearing before α -tocopherol was collected (Fig. 2). However, the peak really consisted of two peaks, at 32.66 and 33.70 min, and they were very difficult to fractionate separately because they were too close to each other.

Structure Analyses of Collected Tocomonoenols

The molecular weights were measured to identify the structures that gave the two peaks on the chromatogram (Fig. 2) using HPLC-Atmospheric Pressure Chemical Ionization Mass Spectrometry (Waters Alliance ZMD LC/MS system, Waters Corporation, Milford, MA) equipped with octadecyl silyl (ODS) column (Supelcosil LC-18, 150 \times 4.6 mm, i.d. 5 mm, Sigma-Aldrich Co., Bellefonte, PA). Methanol was used as an eluent; the flow rate was 1.0 mL/min and the column temperature was room temperature. Data acquisition, processing, and instrument control were performed using MassLynx software (Waters Corporation, Milford, MA). The APCI conditions of capillary voltage, positive mode cone voltage, negative mode cone voltage, heater temperature, gas flow and corona voltage were 4.0 kV, 80 V, 40 V, 400 °C, 500 L/h and 15 V, respectively. The analyses were performed in positive ion mode. Spectra were obtained over the range of m/z 250–450 with a scan time of 0.5 s.

Each of the two peaks was carefully collected and applied to HPLC-FL for fractionation. Each fraction was completely dried with a rotary evaporator at 40 °C and resolved in deuterium-labeled chloroform (CDCl_3). The CDCl_3 solution was placed into a micro-NMR sample tube (CMS-005J, Shigemi Co., Ltd., Tokyo Japan) and subjected to ^1H -NMR analyses (AVANCE 400 WB, Bruker, Karlsruhe, Germany) operated at 400 MHz. The ^1H -NMR spectra were acquired with the following conditions, temperature: 15 °C, pulse delay: 1.0 s, acquisition time: 2.0 s, data points: 32 K, pulse angle: 30°, number of scans: 512, spectra width, 20.55 ppm.

Preparation of “Vitamin E Homologues and Tocomonoenols Mixture”

The fractionated tocomonoenols were mixed with α -tocopherol, β -tocopherol, γ -tocopherol, and δ -tocopherol in ethanol, and the concentrations of MDT, α -tocopherol, β -tocopherol, γ -tocopherol, and δ -tocopherol were adjusted to be the same. Finally, the ethanol was removed from the solution and the residue was used as a “Vitamin E Homologues and Tocomonoenols Mixture (VEHTM)”. The actual ratios of the vitamin E homologues and tocomonoenols were reconfirmed using an HPLC-electrochemical detector (ECD). This HPLC system comprised a pump (PU-1580, JASCO Corporation, Tokyo, Japan), tandem-jointed octadecyl silyl columns (ODS, Supelcosil LC-18,

250 \times 4.6 mm, i.d. 5 mm), ECD (NANOSPACE SI-1, Shiseido Co., Ltd., Tokyo, Japan), and a Chromatopac integrator (C-R6A). The oxidation potential of the ECD was +600 mV (vs. Ag/AgCl) at the glassy carbon electrode. A mixture of methanol and distilled water (50/1, v/v) containing 50 mM sodium perchlorate was used for the elution and the flow rate was 1.0 mL/min. The analyses were performed under ambient conditions.

Animals and Diets

All the experiments were performed in accordance with the Kochi Women’s University Guidelines for Animal Use and Care. Four-week-old male ICR mice (Slc:ICR, Japan SLC, Inc., Shizuoka, Japan) were used in all the experiments. Twenty-four mice were fed an AIN-93G based diet without vitamin E for the first 28 days. After that, six mice were selected randomly and liver, spleen, lung, and brain were obtained from the mice. The organs were stored at -75 °C until use. The remaining mice were randomly divided into three groups of six mice. The first group was fed a normal AIN-93 based diet for next 14 days (Normal Feed Group). The second group was given an AIN-93 based diet including VEHTM for 14 days (Test Feed Group). The third group was continuously fed an AIN-93G based diet without vitamin E for 14 days (VE-free Feed Group) (Fig. 1). The composition of the respective diets is shown in Tables 1, 2, 3, 4, and 5. The mice in each group were housed in one cage under a controlled 12-h light and 12-h dark cycle at 22 ± 2 °C and $55 \pm 15\%$ relative humidity. The mice had free access to water and fed via a powder feeder apparatus daily (Rodent CAFE, Oriental Yeast Co., Ltd., Tokyo, Japan). On the last day in the morning, mice were weighed. The liver, spleen, lung, and brain were obtained from the mice and weighed. The organs were stored at -75 °C until use.

Extraction of Fat from Organs and Analyses of Vitamin E Homologues and Tocomonoenols

The removed organs were homogenized with two times their weight of normal saline. The homogenate was placed in a test tube with a screw cap and two times the volume of a chloroform and methanol mixture (2:1, v/v) was added to the homogenate. The solution was mixed vigorously with a vortex mixer and centrifuged at $700 \times g$ for 10 min. The bottom layer was carefully removed with a Pasteur pipette and placed in a new test tube to dry under a nitrogen stream. The dried sample was solved in ethanol for HPLC analysis. The ethanol solution was subjected to the HPLC-ECD system described above to analyze the ratio of the respective vitamin E homologues in each organ and tissue examined. The actual amounts of the respective vitamin E

homologues were determined using calibration curves. The calibration curves were prepared for α -tocopherol, β -tocopherol, γ -tocopherol, and δ -tocopherol using standard solutions dissolved in ethanol. The calibration curves for α -tocopherol were also adapted for the tocomonoenols because the structure of the chroman ring of α -tocopherol is the same as that of tocomonoenol.

The VE-RBA of vitamin E homologues and tocomonoenols was calculated using the following Equation

$$\text{VE-RBA} = ([A]/[B])/([C]/[D]) \times 100$$

where [A] is the concentration of vitamin E homolog or tocomonoenol in organ (mg/g), [B] is the concentration of vitamin E homolog or tocomonoenol in VEHTM (mg/g), [C] is the concentration of α -tocopherol in organ (mg/g), and [D] is the concentration of α -tocopherol in VEHTM (mg/g).

Results

Structure Analyses of Collected Tococomonoenols

Reverse phase HPLC-FL was used to fractionate MDT from tuna oil scum (Fig. 2). The elution order of tocopherols was δ -tocopherol, β - and γ -tocopherol, and α -tocopherol. Normally, MDT appears between the γ -tocopherol and δ -tocopherol peaks under reverse-phase HPLC conditions [8]; therefore, one of the two unidentified peaks was thought to be MDT. The two peaks were very close to each other at 32.66 and 33.70 min and it was difficult to separate each peak. Therefore, structure analyses of the compounds of each peak were conducted to identify the MDT peak and to elucidate the structure of the other compound. In the HPLC-APCI/MS, both unidentified

peaks were at m/z 428.3, corresponding to molecular ion peak $[M]^+$, and the value was within 2 of that of α -tocopherol (m/z 430.4) (Fig. 3). These results indicate that both unidentified compounds had the same molecular weight. ¹H-NMR analyses of both compounds were also performed and the results are shown in Fig. 4. One of the two peaks that appeared second in the HPLC-FL chromatogram showed characteristic triplet–quartet–quartet peaks at 5.09–5.12 ppm in ¹H-NMR spectrum (Fig. 4, right). In contrast, there was no peak around 5.10 ppm, and instead a characteristic broad singlet peak was observed at 4.69 and 4.67 ppm in the ¹H-NMR spectrum of the other compound, which appeared first in the HPLC-FL chromatogram (Fig. 4, left).

The Actual Ratio of Vitamin E Homologues in Prepared “Vitamin E Homologues and Tococomonoenols Mixture”

The prepared VEHTM was subjected to HPLC-ECD and the ratio of the respective vitamin homologues was calculated with respective calibration curves. The results are shown in Tables 1, 2, 3, 4, and 5 as “Composition of vitamin E in Test Feed”.

Biologic Availability of Tococomonoenols in Mouse

None of the mice died during the 42-day test period. The final body weight, liver weight per body weight, spleen weight per body weight, lung weight per body weight, and brain weight per body weight are shown in Table 6. Significant differences were observed in lung and brain among the groups. The contents of the vitamin E homologues and tococomonoenols in the various organs before and after

intake of the Test feed are summarized in Table 7. The VE-RBA of vitamin E homologues and tococomonoenols in liver and brain of the “Test Feed Group” were calculated and

are summarized in Table 8. The representative HPLC-ECD chromatograms of the liver extract are shown in Fig. 5.

Discussion

Commercially distributed natural vitamin E such as mixed tocopherol and δ -rich tocopherol are mainly prepared by molecular distillation from deodorization scum formed in the purification process of edible plant oils [18, 19]. Oil scum contains concentrated free fatty acids, sterols, and tocopherols, and therefore the deodorization scum formed from tuna oil was used as the source of MDT in the present study. MDT was present in high concentrations in the oil scum, along with the other vitamin E compounds. The molecular weights of both compounds were the same and within 2 of that of α -tocopherol (Fig. 3). This result indicates that both compounds are tococomonoenols. One of the

Fig. 5 Comparison of HPLC-ECD chromatogram between (A) vitamin E mixture in Test Feed and (B) extracted fat from the liver of the Test Feed Group

two compounds that eluted afterward in two peaks had characteristic triplet–quartet–quartet peaks at 5.09–5.12 ppm in the $^1\text{H-NMR}$ spectrum (Fig. 4, right). This peak corresponds to hydrogen binding at the 11' carbon (Fig. 6). Matsumoto et al. [6] reported that α -tococomonoenol had characteristic triplet–quartet–quartet peaks at 5.12 ppm. Therefore, the compound that eluted in the second of the two peaks was thought to be α -tococomonoenol. In contrast, because the two broad singlet peaks appeared at 4.69 and 4.67 ppm corresponded to hydrogens

located at the double bond at the 13' carbon at the terminal phytol side chain, the $^1\text{H-NMR}$ spectrum of the other compound was thought to represent MDT [5]. These speculations concerning both structures is reasonable because the reverse phase HPLC-ECD chromatogram of human plasma detected α -tococomonoenol and MDT, and MDT eluted ahead of α -tococomonoenol on the chromatogram. This is a strange result because there are no reports that marine organisms contain α -tococomonoenol. Thus, α -tococomonoenol might be formed by migration of the

Fig. 6 Structures of vitamin E homologues and novel tocomonoenols

double bond in MDT. The temperature used for the deodorization of the oil is about 250°C [18], which might be sufficient to induce migration of the double bond of MDT to form α -tocomonoenol. Furthermore, the location of the double bond in α -tocomonoenol is more stable than that in MDT from a thermodynamic point of view. Consequently, the α -tocomonoenol contained in fish oil scum is thought to be formed during the deodorizing process.

The separation of α -tocomonoenol and MDT was difficult; therefore, both were fractionated at the same time and mixed with α -tocopherol, β -tocopherol, γ -tocopherol, and δ -tocopherol for preparation of the VEHTM. The objective of this study was to evaluate the VE-RBA of MDT by comparing it with that of β -tocopherol because β -tocopherol is thought to possess the highest vitamin E relative activity among vitamin E homologues with the exception of α -tocopherol [3, 4]. Therefore, the contents of the tocopherol homologues were adjusted to that of MDT. As a result, the actual ratios of tocopherols and tocomonoenols in VEHTM were not adjusted completely and the VEHTM contained a 2.5-fold greater amount of α -tocomonoenol than of the tocopherols and MDT (Tables 1, 2, 3, 4, 5). Previous studies of relative vitamin E activity for respective tocopherols demonstrated that the feeding amount of tocopherol and conditions do not affect the results [12]. Therefore, this study uses a single feeding lot. Furthermore, all the VE-RBA values of α -tocopherol, β -tocopherol, γ -tocopherol, and δ -tocopherol obtained from the liver were consistent with the previously reported values (Tables 1, 2, 3, 4, 5); therefore, the Test feeding period was thought to be appropriate.

The classical methods used to determine relative vitamin E activities of vitamin E homologues include liver-storage bioassay, inhibition rate of fetal resorption, inhibition rate of erythrocyte hemolysis, muscular dystrophy, in rat, chick, and rabbit. The relative vitamin E activities currently in use are determined by those methods. In 1991, α -TTP, which binds tocopherols and enhances its transfer between membranes, was purified from rat liver [16]. The relative affinity of vitamin E homologues for α -TTP is now considered to be the “relative vitamin E activity” value [17]. Recently, α -TTP null mice were created and used for research on the role of α -tocopherol in animals [20–22]. These mice become vitamin E-deficient, which damages the body. In the present study, ICR mice were chosen as test animals not previously used to determine the biologic availability of vitamin E using the classical methods because it is apparent that α -TTP is present in the mouse liver.

In the present study, the wash-out period for endogenous tocopherols was 28 days because Mino et al. [23] reported that endogenous tocopherols in plasma and erythrocytes were almost absent in rat after 4 weeks of continuous ingestion of a vitamin E-deficient diet. The storage level of α -tocopherol and β -tocopherol in liver of the ICR mice decreased to less than 0.10 $\mu\text{g/g}$ organ weight after ingesting a vitamin E-deficient diet for 28 days (Table 7). The objective of this experiment was to evaluate the VE-RBA of MDT in comparison with that of β -tocopherol. Therefore, α -tocopherol and β -tocopherol depletion in liver after this wash-out period was thought to be sufficient for the experiment. Storage of the tocopherol homologues and

tocomonoenol was measured in four different organs and tissues, i.e., liver, spleen, lung, and brain, because liver is the organ classically used for the determination of “relative vitamin E activity”, spleen and lung are the organs that store large amounts of α -tocopherol in rat [24], and brain tissue contains high amounts of docosahexaenoic acid, and tocopherols are thought to accumulate to prevent the oxidation of docosahexaenoic acid. There were no significant differences in relative liver and spleen weights among the groups. In contrast, there were significant differences in lung and brain, but the differences were not greater in any one group, suggesting that the mice in all groups experienced equivalent growth. After the 28-day wash-out period, the endogenous tocopherols had disappeared in all organs examined except the brain, but a fairly large amount of α -tocopherol remained in the brain (Table 7). Ingold et al. [25] and Burton et al. [26] previously reported that the turnover of α -tocopherol in the brain, testes, and spinal cord is very slow. Our result is consistent with their finding, and suggests that α -tocopherol is important for maintaining homeostasis in the brain. The tocopherol content in mouse brain in the Normal Feed and Test Feed groups was one order of magnitude higher than that in VE-free Feed group, indicating that tocopherols are transported to the brain in greater amounts, because no tocopherols were observed in spleen and lung (Table 7).

The calculated results of VE-RBA of vitamin E homologues and tocomonoenols were shown in Table 8. These VE-RBA values obtained in the present study are consistent with previously reported values [2]. The VE-RBA values for MDT and α -tocomonoenol were high. Particularly, the VE-RBA for MDT was higher than that for β -tocopherol, indicating that the two novel tocomonoenols accumulate readily in liver. On the other hand, the VE-RBA values obtained from brain were smaller than the corresponding values in the liver, likely due to the endogenous α -tocopherol remaining in the brain after the 28-day wash-out period. Nevertheless, VE-RBA for MDT was higher than that for β -tocopherol in brain. Incidentally, tocopherol and tocomonoenol accumulation was not observed in spleen and lung, even though they are representative vitamin E storage organs in rat [24]. This might be due to species-specific differences.

There is only one double bond on the phytyl side chain in MDT and α -tocomonoenol, but it is located in a different position. MDT has a double bond between the 12' and 13' carbons. The location of the double bond in α -tocomonoenol is between the 11' and 12' carbons (Fig. 6). Despite the proximity of the double bonds on the phytyl side chain, the VE-RBA for MDT and α -tocomonoenol are much different. The relative vitamin E activity for α -tocotrienol, which has the same chroman ring structure as α -tocopherol and three double bonds located on the phytyl side chain, is

reported to be 27 to 29 or 17 to 25 [2]. The relative affinity of α -tocotrienol for α -TTP is also reported to be 12.4 [17]. Therefore, it is possible that α -TTP distinguishes the structure of not only the chroman ring, but also that of the phytyl side chain. Furthermore, as the VE-RBA for MDT is significantly higher than that for α -tocomonoenol, it is also possible that α -TTP recognizes the terminal structure of the phytyl side chain.

Marine-derived tocopherol and α -tocomonoenol are contained in marine fish and rice bran, respectively. These are commonly consumed foods in Japan and are central to a macrobiotic diet. Thus, it is important to clarify the function of these tocomonoenols.

NMR Spectra of α -Tocomonoenol

^1H NMR (400 MHz, CDCl_3) δ 1.62 (d, $J = 2$ Hz, 3H, 16'-H), 1.70 (d, $J = 2$ Hz, 3H, 13'-H), 1.97 (m, 2H, 10'-H), 5.09–5.12 (tq, $J = 7, 2, 2$ Hz, 1H, 11'-H).

NMR Spectra of MDT

^1H NMR (400 MHz, CDCl_3) δ 1.72 (s, 3H, 14'-H), 1.99 (br t, $J = 7$ Hz, 2H, 11'-H), 4.67 (br s, 1H, 13'-H), 4.69 (br s, 1H, 13'-H).

Acknowledgments We thank Dr. Yasukazu Yoshida for valuable comments. This work was supported by a grant from Nippon Suisan Kaisha, Ltd., Japan.

Abstract Lipase-catalyzed transesterification of triolein with cinnamic and ferulic acids using an immobilized lipase from *Candida antarctica* (E.C. 3.1.1.3) was conducted to evaluate the antioxidant activity of the lipophilized products as model systems for enhanced protection of unsaturated oil. The lipophilized products were identified using ESI-MS. Free radical scavenging activity was determined using the DPPH radical method. The polarity of the solvents proved important in determining the radical scavenging activity of the substrates. Ferulic acid showed much higher radical scavenging activity than cinnamic acid, which has limited activity. The esterification of cinnamic acid and ferulic acid with triolein resulted in significant increase and decrease in the radical scavenging activity, respectively. These opposite effects were due to the effect of addition of electron-donating alkyl groups on the predominant mechanism of reaction (hydrogen atom transfer or electron transfer) of a species with DPPH. The effect of esterification of cinnamic acid was confirmed using ethyl cinnamate which greatly enhances the radical scavenging activity. Although, compared to the lipophilized cinnamic acid product, the activity was lower. The radical scavenging activity of the main component isolated from lipophilized cinnamic acid product using solid phase extraction, monocinnamoyl dioleoyl glycerol, was as good as the unseparated mixture of lipophilized product. Based on the ratio of a substrate to

DPPH concentration, lipophilized ferulic acid was a much more efficient radical scavenger than lipophilized cinnamic acid.

Keywords Lipase-catalyzed transesterification · Cinnamic acid · Ferulic acid · Free radical scavenging activity · Antioxidant

Abbreviations

CA	Cinnamic acid
DPPH	2, 2-Diphenyl-1-picrylhydrazyl radical
EC	Ethyl cinnamate
ESI-MS	Electrospray ionization-mass spectroscopy
ESI-MS-MS	Electrospray ionization-mass spectroscopy-mass spectroscopy
ET	Electron transfer
FA	Ferulic acid
HAT	Hydrogen atom transfer
HBA	Hydrogen bond accepting
HPLC	High performance liquid chromatography
RSA	Radical scavenging activity
SPE	Solid phase extraction
TO	Triolein

Introduction

Phenolic acids are natural antioxidants that occur ubiquitously in fruits, vegetables, spices and aromatic herbs [1]. Phenolic acids are hydrophilic in character, which may reduce their antioxidant effectiveness in stabilizing fats and oils. According to Decker [2] and Massaeli et al. [3], the solubility of an antioxidant in relation to the site of oxidation is an important factor to be considered.

Lipophilization of phenolic acids, which involves esterification with a lipophilic moiety is a way to utilize their antioxidative properties [4–6]. The reducing properties of phenolics as hydrogen or electron donating agents predict their potential for action as free radical scavengers [7]. Many “antioxidant” studies used 1,1-diphenyl-2-picrylhydrazyl free radical (DPPH) to describe their free radical scavenging activity [8].

Cinnamic acid, 3-phenyl-2-propenoic acid, is an unsubstituted phenylpropanoid with limited antioxidant capacity. Previous studies reported the chemical and biocatalytic synthesis of cinnamoyl esters and glycerols [9, 10]. A recent work examined the kinetics of chemical esterification of glycerol with cinnamic acid and its derivatives [11]. As cinnamic acid has the backbone structure of the phenyl propanoids or cinnamic acid derivatives group of known antioxidants, Karboune et al. [12] investigated the lipase-catalyzed transesterification of cinnamic acid with triolein and found that the resulting mixture of cinnamoylated lipids had higher radical (DPPH) scavenging activity than that of cinnamic acid. Ferulic acid, present naturally in flaxseeds, is one of the ubiquitous compounds in nature. According to Kikuzaki et al. [13], ferulic acid and its esters have been recognized as antioxidants. The radical (DPPH) scavenging activity of ferulic acid was better than that of a series of alkyl ferulates [13] and ethyl ferulate [14]. However, in an ethanol-buffer solution of linoleic acid at 40 °C in the dark, the alkyl ferulates showed better antioxidant activity than that of ferulic acid [13]. A study by Safari et al. [15] involving the lipase-catalyzed transesterification of triolein with ferulic acid showed that the radical (DPPH) scavenging activity of feruloylated lipids was lower than ferulic acid.

The main objectives of this research were to characterize the lipophilized products from lipase-catalyzed transesterification of triolein (a model triacylglycerol having no antioxidant present) with cinnamic and ferulic acids and to evaluate their free radical scavenging activity as model systems for enhancement of antioxidant activity of unsaturated oils (usually with some levels of antioxidants present). Another objective of this research was to extend the work of Karboune et al. [12] by isolating and separating the cinnamoylated lipid classes produced by lipase-catalyzed transesterification of triolein with cinnamic acid to examine their structure-enhanced-activity relationship.

Experimental Procedure

Materials

Commercially available immobilized lipase B from *Candida antarctica* [E.C. 3.1.1.3; Novozym 435, with an

activity of 10,000 propyl laurate units per solid gram (PLU)], was a gift from Novozymes (Bagsværd, Denmark). Cinnamic acid (CA), ferulic acid (FA), triolein (TO), ethyl cinnamate (EC) and 2,2-diphenyl-1-picrylhydrazyl (DPPH) were purchased from Sigma Chemicals Co. (St Louis, MO, USA). Mega Bond Elut aminopropyl disposable columns (5 g) were purchased from Varian Sample Preparation Products (Harbor City, CA, USA). All the chemicals and solvents used were of analytical or HPLC grade.

Enzymatic Transesterification

The enzymatic transesterification of TO with CA or FA was carried out according to a modified method of Karboune et al. [12]. TO (1,000 mg) was dissolved in 10 mL of *n*-hexane in a 50 mL Erlenmeyer flask. CA (167 mg) or FA (55 mg) was added to the reaction mixture followed by Novozym 435 (236 mg for CA system; 211 mg for FA system). The mol ratio of TO:CA and TO:FA was 1:1 and 4:1, respectively. The flask was incubated under nitrogen at 50 °C, with continuous shaking, in an orbital shaker at 120 rpm (Model SS70, Chiltern Scientific, Auckland, New Zealand) for 2 weeks. The enzymatic reaction was stopped by termination of contact with immobilized lipase by filtration using Whatman glass microfiber filter paper C.

Removal of Unreacted CA/FA by Aqueous Solvent Washing of Reaction Components

The above product in *n*-hexane was washed with four volumes of acetone:methanol:water (7:7:6; 6 mL). This was followed by drying the recovered hexane fraction under nitrogen at room temperature.

Hydrolysis of Lipophilized Products for Quantification

Lipophilized products free from unreacted CA or FA (2.0–7.0 mg) were weighed into a glass tube (15.0 cm × 1.3 cm with Teflon-lined screw cap). One mL of 4 N methanolic NaOH was added and the hydrolysis was carried out under nitrogen at 50 °C for 3 h, followed by acidification with concentrated HCl. Acidity was checked using Litmus paper. This solution was then evaporated to dryness. The dried sample was dissolved in 2 mL isopropanol:hexane (4:1) prior to HPLC analysis.

The conversion of CA or FA was calculated as w/w ratio of CA or FA released from the hydrolysis of lipophilized products to its initial amount. Quantification was based on an external standard method where a calibration curve [25, 50, 75, 100, 125 and 150 µg CA or FA dissolved in 1 mL of isopropanol:hexane (4:1)] was prepared.

HPLC Analysis of Reaction Components

The enzymatic reaction components were monitored by HPLC analysis, according to the method of Sabally et al. [16]. The separation of reaction components was performed on a C-18 Phenosphere-Next column (250 × 4.6 mm, 5 μm; Phenomenex, Torrance, CA, USA.) using a Varian 9010 solvent delivery system (Varian Associates, Inc., Walnut Creek, CA, USA), a SPD-M10AV diode array detector (Shimadzu, Kyoto, Japan) and an analyzing software, Shimadzu Class-M10A. Detection of reaction components was achieved at 215 and 280 nm (CA system) and 215 and 290 nm (FA system). These wavelengths, 280 and 290 nm, were selected from the absorption spectrum of CA and FA, respectively. Elution of a 20 μL injected sample was carried out with a gradient system using an acetonitrile/methanol mixture (7:5, vol/vol) as solvent A and isopropanol as solvent B; the elution was initiated by a flow of 100% solvent A for 10 min, followed by a 20 min linear gradient to 100% solvent B, which was maintained for an additional 5 min. The flow rate was 1 mL/min. Typically, a 10 min equilibration period was used between samples, requiring about 45 min/sample.

Electrospray Ionization-Mass Spectroscopy (ESI-MS) and Electrospray Ionization-Mass Spectroscopy–Mass Spectroscopy (ESI-MS–MS) Analysis of Reaction Components

The reaction components were recovered by HPLC and analyzed using an ESI-MS system, Bruker microTOFQ (Bruker Daltronics, Bremen, Germany). Samples were introduced using direct infusion into the ESI source in a positive mode with a collision energy of 10 eV. Capillary voltage of –4.5 kV and a dry gas of 99% N₂ at 180 °C were employed. Sampling was averaged for 3 min over a *m/z* range of 100–1,000 amu. The mass was calibrated using an external calibrant of sodium formate clusters. Spectra were processed using Compass software version 1.3 (Bruker Daltronics, Bremen, Germany). Selected ions that were tentatively identified were chosen to undergo

further analysis by ESI-MS–MS with collision energy between 20–40 eV.

Separation of Lipophilized Products of Lipase-Catalyzed Transesterification of TO and CA Using Solid Phase Extraction (SPE)

A method of Vaghela and Kilara [17] using an aminopropyl bonded phase to separate lipid mixtures was modified in this study to separate the lipophilized products. Two aminopropyl Mega Bond Elut columns (5 g) were used in the separation and each column was preconditioned with 2 × 20 mL of hexane before applying the sample. Sample (40 mg) was dissolved in 2 mL of hexane and applied to the first column. Then the column was sequentially eluted with 60 mL of each solvent A, B and C, eluting the respective components as indicated in Table 1. After separation, solvents from each SPE eluent were evaporated using a rotary vacuum evaporator. The fractions from solvent A and B were combined and dissolved in 2 mL of hexane before loading on a second aminopropyl column. Then the column was sequentially eluted with 30 and 60 mL of solvents D and E, respectively, eluting the indicated components (Table 1). Again, eluting solvents were removed using a rotary vacuum evaporator. All fractions were stored at –20 °C until further analysis.

Determination of Radical Scavenging Activity (%RSA)

The %RSA of compounds was measured using a modified DPPH radical method of Sabally et al. [16]. The concentration of sample and DPPH solution was modified to suit the rate of reactivities of the samples analyzed here. For the evaluation of free radical scavenging activity of the FA system, four samples were tested [TO, FA, lipophilized product including unreacted TO from lipase-catalyzed transesterification of TO and FA following aqueous solvent washing to remove unreacted FA (abbreviated as TOFA) and mixture of TO and FA]. TO and TOFA concentrations were set at 25.0 mM. The amount of FA tested was equivalent to the amount of FA esterified to the oleoyl

Table 1 Solvents required for SPE with Mega Bond Elut aminopropyl column of reaction components of lipase-catalyzed reaction of TO and CA

Name	Solvents	Amount (mL)	Components eluted
A	1% (vol/vol) Diethyl ether, 10% (vol/vol) dichloromethane in hexane	60	TO, monocinnamoyl dioleoyl glycerol and dicinnamoyl oleoyl glycerol
B	10% (vol/vol) Diethyl ether, 10% (vol/vol) dichloromethane in hexane	60	Monocinnamoyl dioleoyl glycerol and dicinnamoyl oleoyl glycerol
C	2:1 (vol/vol) Chloroform/methanol	60	Monocinnamoyl oleoyl glycerol
D	5% (vol/vol) Diethyl ether in hexane	30	TO
E	15% (vol/vol) Diethyl ether in hexane	60	Monocinnamoyl dioleoyl glycerol

glycerols of TO in TOFA. The sample for analysis was mixed with 2×10^{-4} M DPPH solution in ethanol or ethyl acetate. The ratio of a substrate to DPPH concentration was $1:8 \times 10^{-3}$. The reduction of DPPH radical was monitored spectrophotometrically at 517 nm over a period of 30 min against a blank assay. The percentage of the remaining radical was calculated as the absorbance of the sample at 517 nm, divided by that of the DPPH control at the same time, multiplied by 100.

For the evaluation of %RSA of the CA system, seven samples were tested [TO, CA, lipophilized product including unreacted TO from lipase-catalyzed transesterification of TO and CA following aqueous solvent washing to remove unreacted CA (abbreviated as TOCA), mixture of TO and CA, ethyl cinnamate (EC), monocinnamoyl dioleoyl glycerol (OOCA) and monocinnamoyl oleoyl glycerol (OCAOH)]. Due to the limited fractions of cinnamoylated lipid obtained from SPE, the sample for analysis was mixed with 5×10^{-6} M DPPH solution in dichloromethane. The concentration of the six samples containing a CA moiety or addition of CA was set at 5.5 mM of CA equivalents to examine the structure–activity relationship. TO concentration was set at 5.5 mM. The ratio of a substrate to DPPH concentration was $1:9.1 \times 10^{-4}$. The reduction of DPPH was monitored spectrophotometrically at 517 nm over a period of 30 min, against a blank assay. The percentage of the remaining radical was calculated as the absorbance of the sample at 517 nm, divided by that of the DPPH control at the same time, multiplied by 100.

Results and Discussion

Figure 1 shows a chromatogram of reaction components of lipase-catalyzed transesterification of TO and CA after aqueous solvent washing. TO was detected at 215 nm. Lipophilized products and CA were detected at both 215 nm and 280 nm. Three lipophilized products were observed at the retention times of 9.734, 15.418 and 27.029 min at 280 nm. Using an external standard of TO, TO was detected at the retention time of 32.219 min at 215 nm. The extent of conversion of CA to lipophilized products was determined most accurately by measuring the amount of CA released from the hydrolysis of reaction components (after aqueous solvent washing) using HPLC. Quantification of CA was carried out using an external standard of CA. The average percentage conversion of CA in this lipase-catalyzed transesterification of TO and CA was 45.3%.

The identification of the 3 lipophilized product peaks of lipase-catalyzed transesterification of TO with CA was determined using ESI-MS (Table 2). The first peak at

Fig. 1 HPLC chromatogram at 215 and 280 nm of reaction components of lipase-catalyzed transesterification of TO and CA after removal of enzyme followed by aqueous solvent washing. Peaks were identified as follows: monocinnamoyl oleoyl glycerol (9.734); dicinnamoyl oleoyl glycerol (15.418); monocinnamoyl dioleoyl glycerol (27.029); triolein (32.219)

9.734 min at 280 nm in Fig. 1 was found to be monocinnamoyl oleoyl glycerol, with two positions on the glycerol having acyl groups (one CA and one oleic acid) and one position having a hydroxyl group (–OH) group. Peak 15.418 and 27.029 min at 280 nm in Fig. 1 were found to be dicinnamoyl oleoyl glycerol and monocinnamoyl dioleoyl glycerol, respectively. Karboune et al. [12] reported the formation of two molecular species (monocinnamoyl oleoyl glycerol and monocinnamoyl dioleoyl glycerol) but no dicinnamoyl product. This may be due to the use of different HPLC elution solvent, wavelength of UV detection (235 nm) and evaporative light scattering detection employed by Karboune et al. [12]. Karboune et al. [12] has indicated that a minor peak obtained using HPLC with both UV and evaporative light scattering detector has the presence of a phenolic ring in its structural formula but only suggested it to be a product of side-reaction with CA.

Figure 2 shows a chromatogram of reaction components of lipase-catalyzed transesterification of TO and FA after aqueous solvent washing. TO was detected at 215 nm. Lipophilized products and FA were detected at both 215 and 290 nm. Two lipophilized products were observed at the retention times of 6.009 and 22.451 min at 290 nm. Using an external standard of TO, TO was detected at the retention time of 32.241 min at 215 nm. The average percentage conversion of FA in this lipase-catalyzed transesterification of TO and FA was 24.8%. The percentage conversion of FA was lower than that of CA. These results were in agreement with that of Guyot et al. [18] for the esterification of cinnamic and ferulic acids with fatty alcohols. The difference in the reaction conversion was due to the electronic distribution of the phenolic acids which affected the reactivity of the carboxylic function [4, 18].

The identification of the two lipophilized product peaks of lipase-catalyzed transesterification of TO with FA was

Table 2 Summary of ESI-MS and ESI-MS–MS data of lipophilized products of lipase-catalyzed transesterification of TO and CA

Lipophilized products	HPLC (280 nm) retention time (min)	Molecular weight	ESI-MS (M + 23) ⁺	ESI-MS–MS fragmentation ^a

Fig. 2 HPLC chromatogram at 215 and 290 nm of reaction components of lipase-catalyzed transesterification of TO and FA after removal of enzyme followed by aqueous solvent washing. Peaks were identified as follows: monoferuloyl oleoyl glycerol (6.009); monoferuloyl dioleoyl glycerol (22.451), triolein (32.241)

determined using ESI-MS (Table 3). The first peak at 6.009 min at 290 nm in Fig. 2 was found to be monoferuloyl oleoyl glycerol, with two positions on the glycerol having acyl groups (one FA and one oleic acid) and one position having a hydroxyl (–OH) group. Peak 22.451 min at 290 nm in Fig. 2 was found to be monoferuloyl dioleoyl glycerol. Diferuloyl oleoyl glycerol was not detected in this study. These results were in agreement with the findings of Safari et al. [15].

Based on the study conducted here on the transesterification of TO with CA or FA by Novozym 435, an adaptation of the reaction scheme proposed by Safari et al. [15] is shown in Scheme 1. According to Laszlo and Compton [19], triacylglycerol could not serve as an acyl acceptor directly. Triacylglycerol must first undergo hydrolysis to generate a diacylglycerol containing a free hydroxyl group. The generated diacylglycerol then reacts with a phenolic acid to produce a phenolic lipid.

A substrate may react with DPPH via two different mechanisms: (1) a direct abstraction of a hydrogen atom by DPPH (hydrogen atom transfer, HAT reactions) and (2) an electron-transfer process to DPPH (electron transfer, ET reactions) [20]. The mechanisms for reaction of a substrate in the FA system with DPPH (adapted from Foti et al. [20] and Foti [21]) is shown in Scheme 2. The electron transfer

mechanism (k_1) would be favored in this system due to the substituted hydroxyl group on the benzene ring. Hydrogen bond accepting (HBA) solvents can favor the ET reaction (k_1) because of the stabilizing effect on the phenoxyl anion (ArO^-) and therefore accelerate the overall process but at the same time, HBA solvents can block the substrate into a hydrogen-bonded complex (k_3) making it unreactive toward the DPPH radical [21, 22]. It would be the fine balance of these opposing effects of solvation that determines the final effect of the solvent on the inhibition of free radical scavenging activity of a substrate [22]. Ethanol is the commonly used solvent in the DPPH test [23] and was the solvent used by Karboune et al. [12], Sabally et al. [16, 24, 25] and Safari et al. [15] in their investigation of free radical scavenging activity of phenolic lipids toward the stable free radical DPPH. Ethyl acetate was found by Espin et al. [26] in their characterization of the free radical capacity of vegetable oils and oil fractions using DPPH to give the best results. Other solvents investigated by Espin et al. [26] included hexane, chloroform, acetone and ether.

The %RSA of the FA system was tested in ethanol and ethyl acetate (Fig. 3). The HBA ability (the β^{H} parameter) of ethanol and ethyl acetate was 0.44 [27] and 0.45 [28], respectively. However, the slightly higher %RSA obtained for FA in ethanol (96.1%) than that in ethyl acetate (87.6%) indicates that the polarity of the solvent and solubility of FA may have affected its free radical scavenging activity. The relatively more polar ethanol may have increased the ET reaction rate of FA. When FA was added to TO and mixed, %RSA obtained for this mixture (TO + FA) was similar to that of FA, due to TO not having any free radical scavenging activity. TOFA underwent aqueous solvent washing to remove unreacted FA. The %RSA of washed TOFA tested in ethanol (65.9%) was lower than that in ethyl acetate (72.2%). The relatively more non-polar ethyl acetate may have increased the HAT reaction of TOFA. This reverse effect of solvent in free radical scavenging activity of TOFA as compared to that of FA again indicates that the polarity of the solvent and solubility of a substrate may have affected its free radical scavenging activity. The decrease in free radical scavenging activity after esterification of the carboxyl group of FA in this study was in

Table 3 Summary of ESI-MS data of lipophilized products of lipase-catalyzed transesterification of TO and FA

Monoferuloyl oleoyl glycerol	6.009	532	555	339 [-FA] 251 [-C18:1]
Monoferuloyl dioleoyl glycerol	22.451	796	819	603 [-FA] 515 [-C18:1]

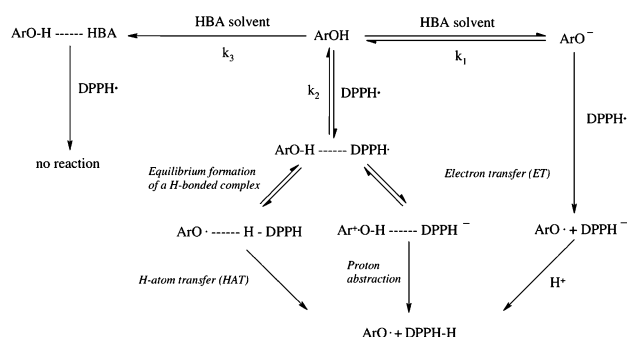

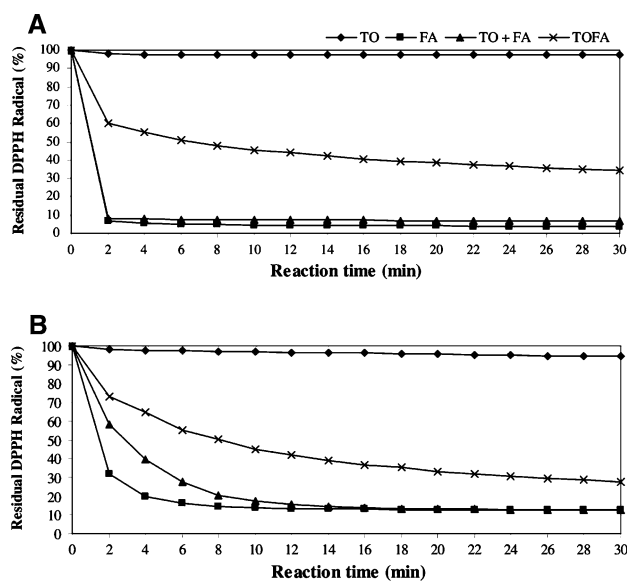

($M + 23$)⁺ represents the protonated molecular ion with a sodium (mass = 23)

^a The ESI-MS-MS fragment ions were protonated with hydrogen instead of sodium

**Scheme 1** Reaction scheme of lipase-catalyzed transesterification of TO with CA or FA. Adapted from Safari et al. [15]

agreement with the findings of Kikuzaki et al. [13] and Safari et al. [15]. These decreases are most likely due to the addition of an alkyl group to the carboxylic ethylene side chain of TOFA which may donate electrons inductively to the benzene ring and have less stabilizing effect on the ionization (k_1 in Scheme 2). The rate of ET reaction for TOFA would therefore be slower than that of FA and hence a lower free radical scavenging activity for TOFA.

The DPPH scavenging analysis carried out on TOCA using ethanol and ethyl acetate showed solvent interaction that precluded the measurement of its free radical scavenging activity. Upon mixing TOCA with DPPH, the absorbance increased and was higher than DPPH control. TOCA was then tested in ethanol and ethyl acetate without DPPH and again showed an increase in its absorbance. This interaction of TOCA with these two solvents may be due to a certain effect of solubility on the absorbance.

**Scheme 2** Mechanisms of reaction of a substrate in the FA system with DPPH. Adapted from Foti et al. [20] and Foti [21]. *ArOH* A hydroxyl-substituted phenylpropanoid substrate, *HBA* hydrogen bond accepting**Fig. 3** Time course for DPPH radical scavenging activity of FA system tested in ethanol (a) and ethyl acetate (b). Lipophilized product including unreacted TO from the lipase-catalyzed transesterification of TO and FA was abbreviated as TOFA. TOFA underwent aqueous solvent washing to remove unreacted FA. The mixture of TO and FA was abbreviated as TO + FA

The reaction pathway involving the ET mechanism was not favored in the CA system as there was no hydroxyl group substituent on the benzene ring of CA. A moderately polar aprotic solvent which cannot serve as a hydrogen-

bond donor, dichloromethane [29], was selected instead to evaluate the free radical scavenging activity of the CA system (Fig. 4). Dichloromethane was tested for any solvent interaction with TOCA and there was found to be none. In this solvent, the predominant mechanism for reaction of a substrate in the CA system with DPPH would be a HAT mechanism. No free radical scavenging activity was obtained for TO (Fig. 4). CA and the mixture (TO + CA) showed very little free radical scavenging activity. This is in accordance with the results obtained for CA in ethanol by Karboune et al. [12]. The %RSA of EC at 30 min of reaction was 45.2%. EC is more known as a compound with strong sensory properties at low threshold [30]. According to Bhatia et al. [31], EC was approved by the FDA as a flavoring agent. To the authors' best knowledge, there has not been study reporting the free radical scavenging activity of EC. The %RSA of TOCA at 30 min of reaction was 63.9%. These results indicate that esterification of the carboxyl group of CA resulted in an increase in the free radical scavenging activity and were in agreement with the findings of cinnamoylated lipids by Karboune et al. [12].

The increase in the free radical scavenging activity of TOCA and EC is most likely due to replacement of the carboxylic H at the $-\text{CH}=\text{C}-\text{COOH}$ part of the CA with an alkyl (C_2H_5) group (in the case of EC) and a larger alkyl group (in the case of TOCA). Alkyl substituents (such as CH_3) in substituted benzenes may donate electrons inductively to the benzene ring compared with a hydrogen. Electron-donating substituents thereby increase the reactivity of the benzene ring toward electrophilic substitution [32]. The addition of alkyl groups to the carboxylic

Fig. 4 Time course for DPPH radical scavenging activity of CA system tested in dichloromethane. Lipophilized product including unreacted TO from the lipase-catalyzed transesterification of TO and CA was abbreviated as TOCA. TOCA underwent aqueous solvent washing to remove unreacted CA. The mixture of TO and CA was abbreviated as TO + CA. EC Ethyl cinnamate, OOCA monocinnamoyl dioleoyl glycerol, OCAOH monocinnamoyl oleoyl glycerol

ethylene side chain of TOCA and EC may have increased the reactivity of the benzene ring towards a HAT reaction. According to Morrison and Boyd [33], the electron-donating strength of alkyl groups in carboxylic acids increases with alkyl chain length. The electron-donating strength of a longer alkyl group in TOCA may be greater than the alkyl (C_2H_5) group in EC and hence a higher rate of HAT reaction from TOCA to the DPPH than that in EC. Therefore, the rate of the HAT reaction of TOCA was faster than that of EC and very much faster than CA.

It was probable that dicinnamoyl oleoyl glycerol (OCAOCA) has free radical scavenging activity but it was not tested because it was not obtained individually by SPE. Overall, the components of TOCA, with a calculated ratio of OCAOH:OCAOCA:OOCA (1:2.1:7.7) based on CA equivalents and (1:2.6:12) on a molecular basis respectively, have each contributed to the free radical scavenging activity of TOCA. The %RSA at 30 min of reaction of OOCA was greater than that of OCAOH, which gave a similar activity to EC (Fig. 4). At 30 min of reaction, the free radical scavenging activity of TOCA was as good as OOCA. This was very likely as the main component in TOCA was OOCA on CA equivalents or molecular basis and a synergistic effect by OCAOCA and/or OCAOH on OOCA may have reinforced its individual action. This synergism was well documented for mixtures of hindered and non-hindered phenols [14].

Conclusions

The %RSA of FA was comparatively very high compared to CA, which showed limited activity. These results were in agreement with those of Velkov et al. [34]. Based on the ratio of a substrate to DPPH concentration tested, TOFA was comparatively a much better free radical scavenger than TOCA although the difference in solvents selected needs to be considered here. The choice of solvent for the DPPH assay is critical in evaluating the free radical scavenging activity of substrates of differing polarity, and support previous observations by other authors [2, 3] that the solubility of an antioxidant in relation to the site of oxidation is an important factor for consideration on the use of antioxidants. The synthesis and evaluation of the free radical scavenging activity of TOCA and TOFA in this study serves as model systems for the evaluation of free radical scavenging activity of the lipophilized products from lipase-catalyzed transesterification of unsaturated oil with cinnamic and ferulic acids under the same conditions.

Acknowledgments The funding provided by University of Otago Research and Enterprise Office to the author Wee Sim Choo for writing up this paper was greatly appreciated.

Abstract Dietary enrichment with phytosterols (plant sterols similar to cholesterol) is able to reduce plasma cholesterol levels due to reduced intestinal absorption. The aim of this study was to investigate the effect of phytosterol-enriched yogurt consumption on the major serum lipid parameters, low density lipoprotein (LDL) receptor activity, LDL-receptor affinity, and CD36 expression in hypercholesterolemic subjects. Fifteen patients affected by polygenic hypercholesterolemia were evaluated in a single-blind randomized crossover study after a 4 weeks treatment with a phytosterol-enriched yogurt containing 1.6 g esterified phytosterols (equivalent to 1.0 g free phytosterol). Lipid parameters were compared with a phytosterol-free placebo-controlled diet. The effect of the two treatments on each variable, measured as percentage change, was compared by paired samples *t* test and covariance analysis. The treatment induced a modest but significant decrease in LDL-cholesterol levels (4.3%, $P = 0.03$) and a significant increase in high density lipoprotein (HDL) 3-cholesterol (17.1%, $P = 0.01$). Phytosterol consumption had no effect on LDL-receptor activity whereas patient LDL-receptor affinity significantly increased (9.7%, $P = 0.01$) and CD36 expression showed a marked significant decrease (18.2%, $P = 0.01$) in the phytosterol-enriched yoghurt patients. Our data show that the oral administration of a phytosterol-

enriched yogurt has modest but significant effects on commonly measured lipid parameters. The improvement of LDL-receptor affinity and the reduction in CD36 expression may reflect an important antiatherogenic effect.

Keywords Phytosterols · Low-density lipoprotein receptor · Low-density lipoprotein affinity · CD36

Introduction

Changes in dietary habits represent an important action in the strategy to reduce cardiovascular risk not only in at-risk patients but also in the whole population [1].

Phytosterols, a commonly used term for plant sterols and stanols, are a complex class of compounds chemically resembling cholesterol present in vegetable and other food sources [1]. Previous studies have demonstrated that phytosterols dissolved in food fats, such as margarine or in a liquid formula, show recognized long-term cholesterol-lowering properties [2] due to their ability to reduce intestinal cholesterol absorption [3].

The lower cholesterol (Chol) flux to the liver results in a decreased Apolipoprotein (Apo) B-lipoproteins production and in a compensatory increase in low density lipoprotein (LDL) receptor activity resulting in a reduction of total and LDL-carried plasma cholesterol levels [4].

Although a lack of effect of phytosterols on lipid levels has recently been reported [5], long term studies have demonstrated the efficacy of phytosterols in reducing LDL-Chol levels with a decrease ranging from 3 to 25% [6, 7] and their use has also been recommended [8].

A beneficial effect of plant sterol ingestion on LDL particle characteristics has also been reported [9]. LDL

particles undergo physical–chemical alterations during their life-cycle in plasma and, instead of normal LDL-receptor uptake, these modified LDL are catabolized by CD36, a class B scavenger receptor involved in atherosclerosis [10].

The aim of this study was to examine the effect of the oral administration of single-dose phytosterol-enriched yoghurt on lipoprotein metabolism in 15 non-familial hyper-cholesterolemic patients. Lipoprotein levels, LDL-receptor activity, LDL-receptor affinity, and CD36 expression were evaluated before and after treatment.

Materials

Fetal calf serum and RPMI 1640 with L-glutamine were obtained from GibcoBRL (Life Technologies, Milan, Italy). Bovine serum albumin (BSA), 1,1'-Dioctadecyl-3,3,3',3'-tetramethyl-indocarbocyanine perchlorate (DiI), dimethyl-sulfoxide (DMSO), penicillin, streptomycin and lipoprotein deficient serum (LPDS) were obtained from Sigma (St Louis, USA). Lymphoprep was from Nycomed Pharma AS (Oslo, Norway). Millex-GV filters (pore diameter 0.22 μm) were obtained from Millipore S.A. (Molsheim, France). Conical tubes (50 mL and 15 mL), 50 and 100-mL flasks were obtained from Falcon, Becton Dickinson Labware (NY, USA). All commercially available materials were of the highest grade. OptiPrepTM was a kind gift from Axis-Shield (Sentinel, Milan, Italy). Fluorescent-labeled monoclonal antibodies PE-CD14 and FITC-CD36, nonspecific isotype matched control antibodies (PE-conjugated rat IgG2 α and FITC-conjugated rat IgG1) were from BD Pharmingen (Oxford, UK). QIAamp Blood Kit was from Qiagen-Geneco M-Medical s.r.l. (Florence, Italy). Taq DNA polymerase was obtained from Roche Diagnostic (Milan, Italy). HhaI restriction endonuclease was from New England Biolabs (Ipswich, USA). Silver staining was from Biorad (Milan, Italy).

Methods

Healthy Volunteers

Healthy unrelated volunteers were enrolled as lymphocyte and LDL donors from the staff and students of the Department of Internal Medicine, University of Turin, Italy.

Subjects and Study Design

Study subjects were 15 outpatients (10 males, 5 females), attending the Lipid Clinic of the Department of Internal Medicine at the University of Turin, affected by polygenic hypercholesterolemia. The diagnosis was made on the basis

of triglycerides levels <200 mg/dL, LDL-Cholesterol >160 mg/dL and absence of elevated blood cholesterol in first degree relatives. The patients were previously treated with statins but had discontinued the therapy due to appearance of clinical and hematological side effects.

The treatment protocol was designed to allocate patients to one of the two 4-week treatment sequences: diet + placebo or diet + phytosterols using a randomized, single-blind, crossover design. Each phase was followed by a three weeks-washout period during which the subjects consumed the diet, administered during the first phase.

A diet was designed based on the recommended nutrient intakes for Europeans to provide 2,250 kcal per 70 kg individual daily (males) and 1,800 kcal per 60 kg individual daily (females). The Harris–Benedict equation was used to estimate each patient's basal energy requirement [11], which was then multiplied for an activity factor of 1.4 to compensate for the additional energy needs of mildly to moderately active healthy adults. The nutrient content of the diet was calculated by using Winfood (Medimatica, Te, Italy). Dietary carbohydrate, fat and protein made up 55, 30 and 15% of ingested energy respectively; with a saturated fat less than 7% of total calories as suggested [8]. The diet was consumed by the patients at home without supervision. However, the patients were asked to keep an alimentary diary which was subsequently examined by the dietician during the patients visit.

Phytosterols were given as a commercially available yoghurt drink. This is semi-skimmed milk fermented with lactic acid bacteria, commonly used in the manufacture of yoghurt, with a caloric value of 69 kcal per 100 g of product and a Protein/Carbohydrate/Fat content of 3.2, 11.5 and 1.1 g, respectively. The fat content is 0.1 g of saturated fat, 0.68 g of monounsaturated fat and 0.32 g of polyunsaturated fat. The yoghurt is supplemented with 1.6 g esterified phytosterols (equivalent to 1.0 g free phytosterols) obtained from tall oil, a by-product of wood processing. The placebo drink was fermented pasteurized milk with a caloric value of 48 kcal per 100 g of product and a fat content of 1.5 g.

At recruitment, the patients had a session with a dietician who recorded their anthropometric characteristics, and gave them a controlled diet. A blood sample was drawn for plasma lipid measurement. The patients' anthropometric and biochemical characteristics are listed in Table 1. Patients were scheduled for a second visit 4–6 weeks later, when they were interviewed again by the dietician and a blood sample was drawn to measure their plasma lipid and lipoprotein values.

The patients were instructed to drink the placebo or the sterol-enriched yoghurt in the morning and all the patients completed the protocol. At the end of each treatment period, blood samples were collected from all patients.

Table 1 Anthropometric and plasma lipid baseline characteristics of the patients (Values are means \pm SD)

Age (years)	54.2 \pm 7.3
Sex (M/F)	10/5
BMI (kg/m ²)	24.3 \pm 1.7
Systolic blood pressure (mmHg)	131.5 \pm 10.3
Diastolic blood pressure (mmHg)	75.5 \pm 4.9
Smoke (Y/N)	2/13
Total cholesterol (mg/dL)	308.2 \pm 19.6
HDL cholesterol (mg/dL)	47.2 \pm 6.9
HDL2 cholesterol (mg/dL)	19.5 \pm 5.3
HDL3 cholesterol (mg/dL)	28.5 \pm 4.5
LDL cholesterol (mg/dL)	230.6 \pm 26.7
Triglycerides (mg/dL)	152.2 \pm 23.9
Blood glucose (mg/dL)	79.4 \pm 13.1
HbA1c (%)	5.3 \pm 0.6
Apolipoprotein B (mg/dL)	172.2 \pm 32.0
Apolipoprotein A1 (mg/dL)	134.7 \pm 9.3

Patients gave their informed consent and the protocol was approved by the local Ethical Commission.

To evaluate LDL metabolism, LDL-receptor activity was measured on patients' lymphocytes and LDL-receptor affinity was determined, by competitive assay, on LDL-receptors expressed by lymphocytes obtained from healthy control subjects. The receptor affinity of patients' LDL was measured after LDL isolation by self-generating gradient. LDL isolated from healthy volunteers and labeled with DiI were used to measure patients LDL-receptor activity and LDL-receptor affinity. The expression of CD36 was measured on patient CD14⁺ peripheral mononuclear cells isolated in the same analytical session.

Biochemical Measurements

Plasma total cholesterol, triglycerides (Tg), ApoAI and B were analyzed using a Hitachi 911 Automatic Autoanalyzer and commercial enzymatic kits (Sentinel, Milan, Italy). HDL-2 and HDL3-Chol were determined after precipitation of Apo B-rich lipoproteins. Plasma HDL2- and HDL3-Chol levels were determined according to Gidez et al. [12] HDL2 and HDL3 were separated after precipitation of ApoB-containing lipoproteins with heparin and manganese chloride, and HDL2 were further precipitated with dextran sulphate.

Apolipoprotein E Genotype

All the patients were typed for Apo E genotype, assessed by polymerase chain reaction (PCR) amplification of genomic DNA using specific oligonucleotide primers.

Genomic DNA was isolated from frozen EDTA whole blood using the QIAamp Blood Kit. Genomic DNA (0.5 μ g) was amplified in 25- μ l reaction mixture containing 10 mmol/L Tris-HCl (pH 8.3); 50 mmol/L KCl; 200 μ mol each of dATP, dCTP, dGTP and dTTP; 1.5 mmol/L MgCl₂; 200 pmol of each primer, and 1.8 U Taq DNA polymerase.

The amplification cycle was performed in a gene Gene Cycler (Biorad, Milan, Italy). Five minutes of denaturation at 94 °C was followed by 30 cycles of 1 min at 90 °C, 1 min at 60 °C and 2 min at 70 °C. PCR products were cleaved with 4 U of HhaI restriction endonuclease, as recommended by the manufacturer. Subsequently, the samples were electrophoresed through a 10% nondenaturing polyacrylamide gel and visualized by silver staining. The sizes of HhaI fragment were estimated by comparison with known size markers (MspI-digested pUC18 DNA).

Lymphocytes Isolation and Culture

Lymphocytes were prepared under sterile conditions, using a modified version of the method of Böyum [13] as previously described [14]. To obtain maximal receptor expression, lymphocytes were incubated for 72 h at 37 °C in a humidified carbon dioxide incubator (CO₂ 5.0%) in sterile RPMI with 10% human lipoprotein-depleted serum.

Briefly, diluted blood was layered upon lymphoprep (2:1 v/v) and centrifuged at 400 g for 30 min at 20 °C. The interface containing the lymphocytes was isolated, the cells were washed three times with sterile phosphate-buffered saline (PBS) and finally with RPMI enriched with L-glutamine (290 mg/L), penicillin (100,000 U/L), streptomycin (100 mg/L), and 10% fetal calf serum (FCS). After sedimentation the cell pellet was resuspended in the above solution in a 50-mL flask. Non-adherent cells were harvested and washed twice with cold RPMI/BSA (2 g/L). Cells were adjusted to obtain a final concentration of 0.8–1 \times 10⁶ cells/mL in each tube and used directly in the assay. Viability of the cells was >95% as assessed by the trypan blue exclusion test.

Isolation and Collection of Patients LDL with Self-Generating Gradient

Low density lipoprotein was isolated by a single-step centrifugation method using OptiPrepTM, an iodixanol self-generating gradient, as previously described [15] and outlined by the supplier (Axis Shield Reference Manual M10). In brief, a solution of plasma/OptiPrep (4:1 v/v), lower phase, was mixed in a plastic conical tube. The upper phase was made up of 0.75 parts of OptiPrep mixed with 4.25 parts of 0.14 M sodium chloride buffered to pH 7.4 with

HEPES (HBS). From the upper phase, 1.4 mL was transferred to Beckman Optiseal tubes for the TLN100 rotor; 1.4 mL of the lower phase was transferred to the bottom of the tube below the upper phase using a syringe with a long metal cannula. HBS (~0.1 mL) was carefully layered on top of the upper phase to fill the tube. The tubes were capped and centrifuged at 100,000 rpm (350,000g) for 2 h 30 min at 16 °C in the TL100 Beckman ultracentrifuge. LDL appeared as a distinct ring in the middle of the tube and was collected by piercing the tube using a syringe fitted with a large gauge needle. Purity was checked by agarose gel electrophoresis.

Isolation and Labeling of Normal LDL

Low density lipoprotein (density 1.019–1.063 g/mL) and lipoprotein deficient serum (density >1.210 g/mL) were isolated and purified by sequential preparative ultracentrifugation as described by Havel [16] and LDL was labeled with DiI (DiI-LDL) as described by Løhne et al. [17]. LDL specific activity was measured with a spectrofluorimeter. The difference in specific activity between different preparations of LDL was less than 14%.

LDL-Receptor Assay

LDL-receptor activity was determined on patient's lymphocytes incubated with normal DiI-labeled LDL as described by Løhne et al. [17] with at a final concentration of 10 µg/mL LDL protein for 2 h at 37 °C on a rotary shaker in a humidified carbon dioxide incubator (5.0% CO₂). Cells were then washed twice, resuspended in PBS and directly analyzed by flow cytometry. The final cell concentration was 0.4–0.6 × 10⁶ cells/mL. Each experiment was performed in duplicate.

LDL-Binding Assay

To assess binding, LDL from each subject was tested in a competition assay using DiI-labeled pooled human LDL as tracer. Whereas incubation at 37 °C allows binding and internalization of LDL through its own receptor, incubation at 4 °C reflects binding only [18]. Lymphocytes obtained from healthy subjects were incubated in the dark with increasing concentrations of the patient's LDL and a fixed dose of pooled DiI-LDL. The patient's LDL concentration which inhibited 50% of the binding of pooled LDL was determined by flow cytometry. The value obtained was defined as the binding or affinity of the patient's LDL, after normalization with a normal LDL competition curve and expressed as a percentage. Each experiment was performed in duplicate.

CD36 Expression

Mononuclear cells (0.5–0.6 × 10⁶ cells/mL) were isolated as above and incubated with 10 µL of fluorescent-labeled monoclonal antibodies PE-CD14 and FITC-CD36 for 20 min at room temperature in the dark. Staining with nonspecific isotype matched control antibodies (PE-conjugated rat IgG2α and FITC-conjugated rat IgG1) was performed in each experiment. Cells were washed twice with PBS and finally resuspended in 500 µL of PBS. Analysis of stained monocytes was performed on a FAC-Scan flow cytometer using the Cell Quest Software (Becton-Dickinson). For each sample 10,000 events were collected.

During analysis, monocytes were identified by their reactivity with CD14-FITC and their distinctive forward and orthogonal light scatter profile. Mean fluorescence intensity (MFI) values were used as indirect measures of antigen density after conversion from the logarithmic scale used for data acquisition to a linear scale for data analysis. MFI values derived for cells stained with isotype control antibodies were taken as indicators of autofluorescence, non-specific antibody binding or instrument noise and were subtracted from MFI values obtained by staining for CD14 or CD36.

Flow Cytometry Measurements

The uptake of DiI-LDL was measured on a FACScan flow cytometer (Becton-Dickinson, Mountainview, USA). A morphological scatter, forward-scatter FSC (cell size) and side-scatter SSC (cell granularity), for each lymphocyte or monocyte preparation was performed. DiI emission (FL2) was measured at 585 ± 21 nm using a bandpass filter from gated cell population. The fluorescence signals from 10,000 cells were routinely collected. The number of receptor-positive cells was determined setting the marker at the highest range of the unstained lymphocytes (autofluorescence) in the acquisition plot (SSC/FL2); in the following acquisition of stained lymphocytes, the fluorescence signals over the marker were expressed as percentage of positive cells out of total cells in gated region. The % value obtained (measured in duplicate) reflects the degree of DiI-LDL uptake (binding and internalization) by lymphocytes through the LDL-receptor. The mean intra-assay coefficient value was below 2.0%.

In the LDL binding assay, performed at 4 °C, the fluorescence signals over the marker reflect the concentration of the patient's LDL which inhibited the normal DiI-LDL binding to the cell surface. The concentration value which inhibited 50% binding of normal LDL was normalized to the normal LDL competition curve and expressed as a percentage.

Table 2 Effects of placebo and phytosterol-enriched yoghurt drink on plasma lipid, lipoprotein and apolipoprotein values

Variable	Placebo	$\Delta\%$	Yoghurt	$\Delta\%$	<i>P</i>
Triglycerides					
Before treatment	133.9 ± 26.8	1.5	133.3 ± 25.7	4.0	Ns

Values, mg/dL, are means ± SD. *P* indicate statistical difference evaluated by repeated measures covariance analysis, including treatment sequence in the model * *P* < 0.05, § *P* < 0.01 indicate difference before/after treatment evaluated by paired *t* test

Statistics

The effects of the two treatments on each variable were measured as percentage change (after treatment value/before treatment value × 100) and were compared by paired samples *t* test. Results were also compared by repeated measures covariance analysis (ANCOVA), including the treatment sequence in the model. All tests were two-sided and a *P* value below 0.05 was considered as statistically significant. All analyses were performed using the SAS statistical package v. 8.2 (SAS Institute, Cary, NC, USA). All data, if not specified otherwise, are means ± SD.

Results

All the patients enrolled completed the study and no adverse events were reported. The baseline anthropometric characteristics of the study subjects are presented in Table 1. During the control diet and the treatment period with phytosterols and the placebo, body mass index (BMI), blood pressure and fasting blood glucose levels showed no significant changes (data not shown).

The lipid parameters were analyzed over the 4-week phytosterol oral administration and over the placebo

period, measured as percentage change before/after treatment and compared by a paired sample *t* test. Analysis revealed the absence of significant changes after placebo treatment. By contrast, phytosterol consumption caused a reduction in LDL-Chol plasma levels (2.4%, *P* < 0.05 and 4.3%, *P* < 0.01, respectively) with a non-significant reduction in ApoB levels. In spite of a 4.3% increase of HDL-Chol (*P* < 0.05), a significant increase in HDL3-Chol (*P* < 0.01) with a non-significant reduction in HDL2-Chol levels was observed.

When the effect of the two treatments was compared by covariance analysis for repeated measures including the treatment sequence, total cholesterol became non-significant while the difference in LDL-Chol (*P* = 0.03), HDL-Chol (*P* = 0.01) and HDL3-Chol (*P* = 0.01) remained significant. Also ApoA1 levels showed a significant increase (*P* = 0.03) (Table 2).

Although the 4-week phytosterol consumption had no significant effect on LDL-receptor activity, LDL binding to LDL-receptors expressed by control lymphocytes in comparison to placebo was significantly increased (9.7%, *P* = 0.01) (Table 3).

CD36 expression measured as mean fluorescence intensity of CD14+ cells, showed a marked decrease after 4 weeks of phytosterol treatment in all patients (18%,

Table 3 LDL-receptor activity, LDL binding and CD36 expression

Variable	Placebo	$\Delta\%$	Yoghurt	$\Delta\%$	<i>P</i>
LDL uptake (%)					
Before treatment	68.6 \pm 7.3	1.7*	76.7 \pm 9.0	3.7*	Ns
After treatment	69.9 \pm 8.4		72.6 \pm 9.1		
LDL binding (%)					
Before treatment	71.6 \pm 6.7	1.6	72.1 \pm 11.6	9.7*	0.01
After treatment	72.6 \pm 6.6		78.8 \pm 13.7		
CD36 (MIF)					
Before treatment	1,904.1 \pm 411.6	2.6	2,286.5 \pm 476	18.2§	0.01
After treatment	1,849.5 \pm 410.1		1,806.3 \pm 246		

LDL uptake (%) by patients' lymphocytes is an expression of LDL-receptor activity. Throughout the paper, the terms are used as being synonymous. LDL binding (%) of the patients is the affinity of the particles to LDL-receptors expressed by normal lymphocytes. Throughout the paper the terms are used as being synonymous. Values are means \pm SD. *P* indicate statistical difference evaluated by repeated measures covariance analysis, including treatment sequence in the model

MIF mean intensity of fluorescence, expressed in arbitrary units

* *P* < 0.05, § *P* < 0.01 indicate difference before/after treatment evaluated by paired *t* test

P = 0.01). These differences retained their significance also when the treatment sequence was included in the analysis by ANCOVA.

All the patients were typed for Apo E genotype and were all homozygous for the most common ϵ 3 allele except one patient who was heterozygous for the ϵ 4 allele. Due to the low number of subjects in each Apo E genotype groups, no comparison was made between the different Apo ϵ alleles.

Discussion

The study was designed to evaluate the effect of a controlled diet supplemented with a fixed dose of phytosterols, provided as a yogurt drink, on lipoprotein metabolism in a group of patients with polygenic hypercholesterolemia. Polygenic hypercholesterolemia is the most common form of hypercholesterolemia caused by a susceptible genotype, still unknown, aggravated by excessive saturated fat, *trans* fatty acid and cholesterol intake. The patients did not exhibit any LDL-receptor defect and manifested a moderate hypercholesterolemia (240–350 mg/dL) with serum triglyceride concentrations within the reference range.

Phytosterol-consuming patients showed a statistically significant reduction in total cholesterol and LDL-Chol

levels, a significant increase in ApoA1, HDL-Chol and HDL3-Chol and a non-significant decrease in ApoB when measured as a percentage change before/after treatment and compared by paired sample *t* test. No statistically significant difference was observed after placebo treatment. When data were compared by covariance analysis the reduction of LDL-Chol remained significant (*P* = 0.03), as did the changes in HDL-Chol (*P* = 0.01), HDL3-Chol (*P* = 0.001) and ApoA1 levels (*P* = 0.03).

The decrease in LDL-Chol reported here (4.3%) agrees with the results presented in the literature. Some trials failed to lower plasma lipid levels [5, 19], but in a meta-analysis consisting of 41 stanol/sterol ester trials with the dose varying from 0.8 to 4.2 g of stanol/sterol per day, the majority of studies demonstrated an LDL-Chol decrease, although with a wide range (3–25%) [6]. As other authors [5, 19] observed, the reason for the slight changes of LDL-Chol levels in our patients may be due to the product formula and to the timing of consumption. Actually, the more significant reduction of lipid values was obtained using sterol-enriched solid food products, while recent studies on the effect of low-fat milk products on lipid profile showed a pooled 4.9% LDL-Chol difference after treatment, with a difference meal-time dependent [20]. The food product we used is a 1.6 g phytosterol-enriched yogurt and was consumed by our patients, in the morning outside mealtimes. As our patients were not ϵ 4 carriers, a determinant in cholesterol absorption [21], we speculate that the LDL-Chol decrease we obtained may be related to our study design with a reduced efficacy of phytosterol consumption as liquid products, outside of mealtimes. Thus, a reduction of LDL-Chol levels associated to an increase in HDL-Chol and HDL3-Chol represents a positive event due to phytosterol ingestion in regard to protection against atherosclerosis.

Moreover, the HDL3-Chol increase shows a generally positive effect of phytosterols on lipid metabolism: HDL3 particles exert an anti-atherogenic activity by way of antioxidative, anti-inflammatory, anti-thrombotic and anti-apoptotic actions [22].

The LDL-receptor pathway represents a key determinant in cholesterol homeostasis and normal LDL-receptor activity is a pre-requisite for normal cholesterol levels as LDL carry 60–80% of plasma cholesterol. Functional tests of LDL-receptor activity and LDL ligand function can theoretically identify defects in LDL catabolism, distinguish between receptor and ligand defects and provide useful information about pharmacological/dietetic intervention. These studies have been based classically on the use of ¹²⁵I-labeled LDL on cultured human fibroblasts [23]. Fluorescence flow cytometry represents a simple and fast technique allowing the quantification of LDL-receptor expression and LDL ligand function, also on patient's

peripheral blood mononuclear cells. Human lymphocytes, lacking scavenger receptors are a suitable and widely used model to investigate LDL metabolism both in normal and pathological states [24, 25].

The method used to measure LDL binding (which involved the use of patient's LDL in competition with normal DiI-labelled LDL for normally expressed LDL-receptor) gave information about the qualitative abnormalities in patient's LDL particle.

The reduction of LDL-Chol we observed was not associated with an increase in LDL-receptor activity, measured as LDL uptake by patient lymphocytes. Other authors reported plant stanol esters consumption led to a reduction in LDL-Chol linked to increased LDL-receptor activity [26]. Changes in LDL-receptor activity are dependent on cholesterol cell concentration, in turn to LDL-cholesterol plasma levels and cell synthesis.

Our inability to document an increase in LDL-receptor activity may be due to the small reduction in the LDL-Chol level. By contrast, LDL affinity increased significantly, with a near 10% increase after sterols consumption. The LDL particle's content and size is a major determinant in their recognition and catabolism through LDL-receptor and the role of small dense LDL in the development of atherosclerotic lesions is well known [27] and a decrease in smaller LDL particles by sterol-enriched diet was recently observed [9].

We can speculate that the increased affinity of LDL observed is related to a reduction of smaller LDL particles and, because of this, to a change in the LDL particle number, as stated by the LDL Chol and Apo B decreases. Consequently, the beneficial effect related to phytosterols results in a better catabolism of LDL.

The beneficial effect of a phytosterol supplemented diet is also the significant reduction (–18%) in CD36 expression after treatment. Class B scavenger receptor CD36 is a complex multifunctional protein that plays a critical role in the initiation of atherosclerotic lesions through its ability to bind and internalize modified LDL, facilitating the formation of lipid-engorged macrophage foam cells [10, 28, 29]. CD36 expression on the cell surface is up-regulated by oxidized LDL with a dose dependent increase [30, 31] and, as previously cited, a reduction in CD36 expression may indicate a decrease in oxidated LDL related to the phytosterol supplemented diet.

Our results confirm previous reports showing a significant decrease in plasma concentrations of oxidated LDL after a plant sterols enriched diet [32, 33].

In conclusion, our data indicate a positive effect of single-dose phytosterol-enriched yogurt on lipoprotein metabolism with a slight improvement in common lipid parameters in comparison to LDL behavior and cellular receptor expression.

Our data agree with the general consensus regarding the role of plant sterols in human cholesterol metabolism and may provide a further explanation of the mechanism of the action of phytosterols in hypercholesterolemic patients.

Acknowledgments We thank Franco De Michieli for helpful cooperation in the collection of data.

Abstract Diacylglycerol (DAG) supplementation has been shown to be associated with the reduction of postprandial triacylglycerol (TAG) concentration, although the extent of the association is uncertain. We quantitatively examined the effect of dietary DAG on postprandial serum TAG concentration by conducting a meta-analysis of randomized controlled trials. Potential papers were initially searched for in the electronic databases of Medline, Embase and Cochrane library. Inclusion criteria required the trial to be randomized with DAG as the treatment group, and TAG as the control group. Information was extracted independently by two investigators and the effect of DAG on postprandial TAG concentration was examined in Review Manager 4.2. Seven papers were included in the statistic pooling. DAG supplementation reduced the increment of postprandial TAG concentration significantly

at postprandial 2 h (Weighted mean difference (WMD) -0.07 mmol/L; 95% CI -0.13 to 0.00 mmol/L; $P = 0.05$), 4 h (WMD -0.15 mmol/L; 95% CI -0.24 to -0.06 mmol/L; $P = 0.002$) and 6 h (WMD -0.14 mmol/L; 95% CI -0.23 to -0.05 mmol/L; $P = 0.002$). Linear regression showed that the effect of DAG was positively correlated with the daily dosage at 2 h ($P = 0.095$) and 6 h ($P = 0.053$) after lipid loading. In conclusion, compared with TAG oil, DAG reduced the postprandial serum TAG concentration at 2 h, 4 h and 6 h postprandial and was positively correlated with daily dosage.

Abbreviations

DAG	Diacylglycerol
TAG	Triacylglycerol
MAG	Monoacylglycerol
TRL	Triacylglycerol-rich lipoprotein
WMD	Weighted mean difference
SMD	Standard mean difference
AS	Atherosclerosis
T2DM	Type 2 diabetes mellitus
NGT	Normal glucose tolerance
IGT	Impaired glucose tolerance

Introduction

Postprandial serum triacylglycerol (TAG), mainly in the form of triacylglycerol-rich lipoprotein (TRL), has revealed itself to be an independent risk for atherosclerosis

(AS) [1, 2]. Impaired postprandial serum TAG clearance has been shown to be associated with visceral obesity which is one of the strong predictors of type 2 diabetes mellitus (T2DM) [3, 4]. In fact, hypertriglyceridemia is commonly observed in patients with T2DM, and a strong correlation has also been confirmed between postprandial hypertriglyceridemia and insulin resistance [5]. Moderate hypertriglyceridemia persists even after the serum glucose was well controlled in patients with T2DM [6]. So the control of postprandial TAG concentration is important for patients with either AS or T2DM.

Some studies showed that the supplementation of dietary 1,3-diacylglycerol-rich oil (designated as DAG oil) reduced the postprandial serum TAG concentration compared with TAG oil in rats [7, 8] and humans [9, 10]. The effect of DAG was influenced by the duration of postprandial time because the increments of postprandial TAG concentration in the DAG group were not significantly smaller than those of the TAG group at all postprandial time points [9, 10]. Further, this effect might be influenced by daily dosage [9].

Meta-analysis is a statistical technique in which results of separate studies are combined to increase statistical power and clarity, and to estimate the size of treatment effects more accurately [11]. This method has some inherent weaknesses such as the sources of bias are not controlled and the heavy reliance on published studies. Despite these weaknesses, meta-analysis has still been employed in many clinical settings to evaluate efficacy and safety of a variety of therapeutic interventions due to its advantages. We therefore undertook a meta-analysis of randomized TAG-controlled trials to assess the association between DAG intake and postprandial serum TAG concentration.

Methods

Selection of Studies

Potential papers were initially searched in the electronic databases of Medline (1966–2007), Embase (1984–2007) and Cochrane library (2006–2007) using the terms in Table 1. The references of all located papers were searched for further studies.

Inclusion Criteria

The trials were included if the study was published in English as a full-length article; the study was a randomized controlled trial; the study was conducted on human subjects; DAG was the only intervention; and the study took postprandial serum TAG concentration as one of the endpoints.

Extraction of Information

The detailed information was extracted independently by two investigators (TX and XL) and differences were resolved by discussion with a third investigator (XM). Authors were contacted to provide additional information. Relevant data included the first author's name, year of publication, number of subjects, study design (Parallel or crossover; Open, single- or double-blinded), age and BMI of subjects, duration of washout, daily dosage of DAG or TAG, the mean change of serum TAG concentration from baseline at all postprandial time points along with corresponding standard deviation (SD) or standard error (SE).

Taguchi et al. [9] reported postprandial serum TAG concentrations in the form of a figure, and the author was asked for detailed data but we received no reply. So the specific data was obtained by measuring figure and sensitivity analysis was performed to determine whether the overall result was robust enough for inclusion of these studies. Data of 3 dosage groups (10, 20 and 44 g) were extracted as 3 independent studies [9, 12]. This extraction method was also used for the study conducted by He et al. [13]. Two separate cohorts from the study conducted by Joshipura et al. [14] were extracted and included as two independent trials.

Takase et al. [15] reported TAG concentration as mg/dL which was transformed to mmol/L before analysis. Ai et al. [16] examined the effect of DAG on postprandial serum TAG concentration in the normal glucose tolerance (NGT) and impaired glucose tolerance (IGT) groups independently, so the data of both groups was extracted as two independent studies. In this study, the SDs of mean increment in postprandial TAG concentration were not

reported. The author was contacted for detailed data but no reply was received. Therefore, the missing SDs were imputed using methods in the Cochrane Handbook [17].

Statistical Analysis

The validity of random design was tested by meta-analysis in advance. Then, the effect of DAG on postprandial serum TAG concentration was assessed using the software of Review Manager 4.2.2, developed by The Nordic Cochrane Center (Update Software Ltd, Oxford, England). The weighted mean difference (WMD) was taken as the effect size. The rationality of combining the results of different studies was examined with the Chi-square (χ^2) test. Values of P and I^2 were calculated in the Review Manager to assess whether there was more variation in the results of studies than would be expected by chance. It is generally regarded that if the P value is smaller than 0.1 or the I^2 value is larger than 25%, there is more variation than expected by chance, and it may not be advisable to combine these studies in meta-analysis. A fixed effect model was adopted when there was no heterogeneity among all studies and the random effect model was adopted when there was heterogeneity. Funnel plot asymmetry was used to detect any publication bias in the meta-analysis. Fail-safe number analysis was used to determine the number of studies with null effect that would have to exist to nullify the reported reduction efficacy. Sensitivity analysis was performed to test the influence of studies with imputed SDs on the overall result. The influence of daily dosage on the effect of DAG was assessed using linear regression in SPSS 12.0. Postprandial serum TAG concentration might be influenced by the altered glucose metabolism because hypertriglyceridemia is one of the complications of T2DM. Given that 3 from 7 papers involving subjects with altered glucose metabolism, the studies at each of the time points were divided into normal and abnormal glucose status groups to determine whether the DAG oil was effective in reducing the increment of postprandial serum TAG concentration in each group.

Results

Validity of Random Design

Seven papers with 151 subjects were included in the statistical pooling (Table 2). Initial fasting serum TAG concentrations were reported in five papers [10, 16, 18–20]. Meta-analysis showed that it was rational to combine them ($P = 0.91$, $I^2 = 0\%$) and there was no significant difference in fasting serum TAG concentration between DAG and TAG groups (WMD 0.00 mmol/L; 95% CI -0.15 to 0.15 mmol/L; $P = 1.00$).

Postprandial 0.5 h and 1 h

Only one study compared the postprandial 0.5-h and 1-h TAG concentrations between DAG and TAG groups [20]. There was no significant differences at 0.5 h (WMD -0.01 mmol/L; 95% CI -0.07 to 0.05 mmol/L; $P = 0.73$) and 1 h (WMD -0.03 mmol/L; 95% CI -0.13 to 0.07 mmol/L; $P = 0.56$).

Postprandial 2 h

The postprandial 2-h TAG concentrations were reported in 7 papers with 9 independent studies [9, 10, 15, 16, 18–20]. χ^2 test showed that there was no significant heterogeneity and it was rational to combine them ($P = 0.46$; $I^2 = 0\%$). Meta-analysis showed that there was significant difference between DAG and TAG groups (WMD -0.07 mmol/L; 95% CI -0.13 to 0.00 mmol/L; $P = 0.05$). The funnel plot was slightly asymmetrical for DAG suggesting a small publication bias (Fig. 1a).

Sensitivity analysis showed that the effect of DAG on postprandial serum TAG concentration was slightly reduced by removing those studies with imputed SDs (WMD -0.06 mmol/L; 95% CI -0.13 to 0.01 mmol/L; $P = 0.07$) [16]. In contrast, the removal of studies in which, the specific data was obtained by measuring the figure, increased the effect of DAG slightly (WMD -0.08 mmol/L; 95% CI -0.15 to 0.00 mmol/L; $P = 0.04$) [9]. It is noticeable that the removal of a study which distributed out of the 95% CI reduced the effect of DAG greatly (WMD -0.05 mmol/L; 95% CI -0.12 to 0.01 mmol/L; $P = 0.11$) [10].

The influence of dosage on the effect of DAG was investigated by plotting the change in TAG concentration against the dosage of DAG (g/d). The change in TAG concentration represented the difference between the increment of DAG and TAG groups from the baseline. In studies conducted by Tada et al. [10, 18], the daily dosage was reported as 30 g lipids/m² which was transformed to g/d using the Stevenson formulation of “body area = $0.0061 \times \text{height} + 0.0128 \times \text{weight} - 0.1529$ ”. Three studies were excluded from the dosage-effect analysis because they did not give detailed information about the calculation of the daily dosage in the unit g/d [15, 16]. Regression analysis showed that there was no significant correlation between dosage and the effect of DAG ($R^2 = 0.541$; $P = 0.095$) (Fig. 2a).

Sub-group analysis showed that DAG intake did not reduce the postprandial serum TAG concentration in normal subjects (WMD -0.05 mmol/L; 95% CI -0.13 to 0.03 mmol/L; $P = 0.19$) and subjects with abnormal glucose status (WMD -0.09 mmol/L; 95% CI -0.21 to 0.02 mmol/L; $P = 0.12$).

Table 2 Studies characteristics

Studies	Scores	M/F	Subjects	Age	BMI	Washout	Daily dosage
Ai et al. [16] (IGT)	5	14/0	IGT	44.00 ± 2.00	27.00 ± 1.00	1 week	17 g/m ² /d

3 and 2 independent studies were extracted from the paper conducted by Taguchi et al. and Ai et al. respectively

IGT Impaired glucose tolerance, NGT Normal glucose tolerance, H Healthy, NR Not reported, IS Insulin sensitive, IR Insulin resistance, 2-DM Type 2 diabetes mellitus

S and NS: There was or was not a significant difference between the DAG and TAG groups in the increment of TAG concentration. The presence of letter (S or NS) represented this time point were reported. S or NS represented the postprandial TAG concentration reaching the peak at this time point

Postprandial 3 h

Three papers reported postprandial 3 h TAG concentrations [10, 15, 19]. The χ^2 test showed that there was no significant heterogeneity ($P = 0.28$; $I^2 = 22.5\%$). Meta-analysis indicated that there was no significant difference in the increment of postprandial serum TAG concentration between DAG and TAG groups (WMD -0.12 mmol/L; 95% CI -0.26 to 0.01 mmol/L; $P = 0.06$).

Postprandial 4 h

Postprandial 4-h TAG concentrations were reported in 7 papers with 10 independent studies [9, 10, 15, 16, 18–20]. χ^2 test showed that there was no significant heterogeneity ($P = 0.81$; $I^2 = 0\%$). Meta-analysis showed that DAG decreased the increment of postprandial serum TAG

concentration significantly compared with TAG (WMD -0.15 mmol/L; 95% CI -0.24 to -0.06 mmol/L; $P = 0.002$). The funnel plot displayed good symmetry (Fig. 1b).

Sensitivity analysis showed that the removal of studies with imputed SDs did not influence the effect of DAG (WMD -0.16 mmol/L; 95% CI -0.26 to -0.06 mmol/L; $P = 0.002$) [16]. Although the removal of studies reporting TAG concentrations in the form of a figure reduced the effect of DAG greatly [9], there was still a significant difference between DAG and TAG groups (WMD -0.13 mmol/L; 95% CI -0.25 to -0.02 mmol/L; $P = 0.02$). Removal of all the above studies reduced the effect of DAG greatly too (WMD -0.15 mmol/L; 95% CI -0.29 to -0.02 mmol/L; $P = 0.02$).

Linear regression showed that there was no significant correlation between daily dosage and the effect of DAG ($R^2 = 0.101$; $P = 0.487$) (Fig. 2b).

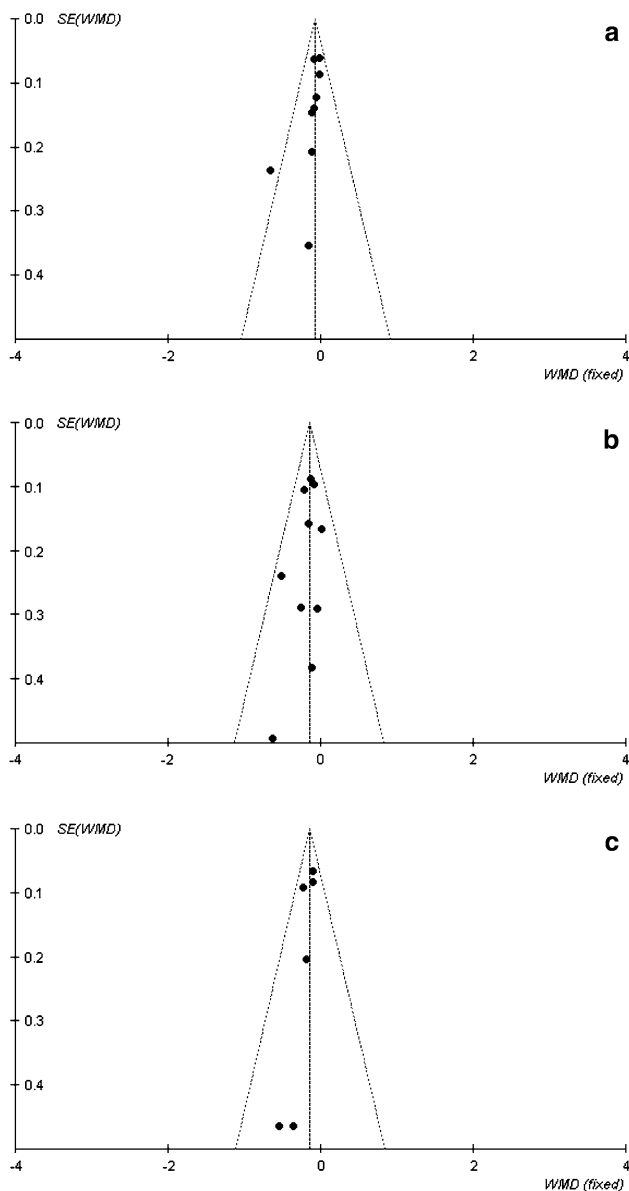

Fig. 1 Funnel plot of postprandial 2 h (a), 4 h (b) and 6 h (c)

Sub-group analysis showed that DAG intake reduced the postprandial serum TAG concentration in normal subjects (WMD -0.13 mmol/L; 95% CI -0.24 to -0.02 mmol/L; $P = 0.02$) and subjects with abnormal glucose status (WMD -0.18 mmol/L; 95% CI -0.34 to -0.01 mmol/L; $P = 0.03$).

Postprandial 6 h

Four papers with 6 independent studies reported the postprandial 6-h TAG concentrations [9, 11, 18, 19]. χ^2 test showed that it was rational to combine them ($P = 0.77$; $I^2 = 0\%$). Meta-analysis showed that DAG reduced the increment of postprandial TAG concentration significantly compared with TAG (WMD -0.14 mmol/L; 95% CI -0.23 to -0.05 mmol/L; $P = 0.002$). The funnel plot

Fig. 2 Correlation between daily dosage and the effect of DAG **a** $Y = -0.0095X + 0.143$ (2 h; $R^2 = 0.541$; $P = 0.095$) **b** $Y = -0.0040X - 0.135$ (4 h; $R^2 = 0.101$; $P = 0.487$) **c** $Y = -0.0068X - 0.060$ (6 h; $R^2 = 0.650$; $P = 0.053$)

indicated a low possibility of publication bias (Fig. 1c). Sensitivity analysis showed that the removal of studies reporting data in the form of a figure reduced the effect of DAG significantly (WMD -0.12 mmol/L; 95% CI -0.27 to 0.03 mmol/L; $P = 0.12$). Linear regression showed that there was no significant correlation between daily dosage and effect ($R^2 = 0.650$; $P = 0.053$) (Fig. 2c).

Sub-group analysis showed that DAG intake could reduce the postprandial TAG concentration in normal subjects (WMD -0.14 mmol/L; 95% CI -0.23 to -0.05 mmol/L; $P = 0.002$) but not in subjects with abnormal glucose status (WMD -0.18 mmol/L; 95% CI -0.58 to 0.22 mmol/L; $P = 0.38$).

Postprandial 8 h

The 8-h postprandial TAG concentrations were reported in 2 papers with 2 independent studies [9, 11]. χ^2 test showed

that there was no significant heterogeneity between two studies ($P = 0.74$; $I^2 = 0\%$). Meta-analysis showed that there was no significant difference in the increment of postprandial serum TAG concentration between DAG and TAG groups (WMD -0.24 mmol/L; 95% CI -0.56 to 0.07 mmol/L; $P = 0.13$).

Fail-Safe Number Analysis of All Time Points

Numbers of included studies and the corresponding fail-safe numbers were 1 and 1 at 0.5 h, 1 and 1 at 1 h, 9 and 11 at 2 h, 3 and 3 at 3 h, 10 and 28 at 4 h, 6 and 19 at 6 h, 2 and 0 at 8 h. The numbers of studies included with corresponding fail-safe numbers of each of the time points are shown in Fig. 3.

Discussion

In meta-analysis of continuous outcomes, WMD and standardized mean difference (SMD) are commonly used as the effect size in determining the effect of intervention. The influences of initial values are usually not taken into account because all the studies included were randomly designed. However, some evidence showed that the initial value of some variables incidentally differed between two groups although subjects were assigned randomly [21]. The effect of intervention might be related to the initial values, such as subjects with an abundance of visceral fat area tended to achieve larger loss of visceral fat after intervention [22]. Actually, a weak but significant correlation between the initial value and the loss of visceral fat has already been observed in study conducted by Nagao et al. [21]. Therefore, the difference in the initial values of tested variables needed to be examined, especially since no published meta-analysis was available. In this study, a meta-analysis was performed to test the validity of random

design. Results showed that no significant difference in the fasting TAG concentrations was found between DAG and TAG groups. This high comparability between 2 groups might be due to the crossover design. Therefore, where studies with parallel design are concerned, the validity of random design needs to be determined.

Only one study reported the postprandial 0.5 h and 1 h TAG concentrations. Although there was no significant differences in the increment of postprandial TAG concentration between DAG and TAG groups, the P values decreased from 0.73 (0.5 h) to 0.56 (1 h) which indicated that the beneficial effect of DAG might be increased by extending the postprandial time. Meta-analysis showed that DAG could reduce the increment of TAG concentration significantly compared with TAG ($P = 0.05$) at 2 h after intervention. However, the removal of the study which did not distribute in the 95% CI reduced the effect of DAG greatly ($P = 0.11$) [11]. The effect of DAG reached a peak at postprandial 4 h ($P = 0.002$) although this effect was reduced but still was significant by the removal of 3 studies in which all data were reported in the form of a figure [9]. This large effect persisted at 6 h ($P = 0.002$) but decreased at 8 h ($P = 0.13$) after lipid loading. P values at each of the time points are displayed in Fig. 4 which provides an intuitive expression. These results indicated that the beneficial effect of DAG on postprandial TAG concentration was significantly influenced by the duration of postprandial time.

Apart from being influenced by postprandial time, the effect of DAG might be influenced by daily dosage too. Linear regression showed that the effect of DAG was obviously correlated with daily dosage at postprandial 2 h, although this correlation was not significant ($P = 0.095$). This obvious correlation indicated that the study conducted by Tada et al., in which daily dosage of 30 g lipid/m² was the largest, favored the DAG group greatly and the removal of it reduced the effect of DAG greatly in sensitivity

Fig. 3 Relationship between number of included studies and fail-safe number

Fig. 4 Influence of postprandial time on the effect of DAG

analysis [10]. Linear regression also showed that there was a more obvious correlation between daily dosage and effect at postprandial 6 h ($P = 0.053$). This obvious correlation indicated that 2 studies with dosage of 20 g/d and 44 g/d were the most favored DAG interventions [9] and the sensitivity analysis of removing them reduced the beneficial effect greatly ($P = 0.12$). It was noticeable that the correlation at postprandial 4 h decreased greatly ($P = 0.487$). In all 10 independent studies, the number of studies in which TAG concentration reached the peak at postprandial 2 h, 3 h and 4 h was 1, 2 and 7 respectively. These results indicated that at least in 9 studies, TAG concentrations were increasing at 2 h, while in 10 studies TAG concentrations were decreasing at 6 h. This consistency in increasing or decreasing might result in these obviously positive correlations. However, TAG concentrations were rising in some studies and falling in others, and this inconsistency might result in the low correlation between daily dosage and the effect at postprandial 4 h.

Sub-group analysis (2, 4 and 6 h) showed that the WMDs of the group with abnormal glucose status were larger than those of the group with normal status which means that subjects with abnormal glucose status tended to achieve a higher reduction in the increment of postprandial TAG concentration after DAG oil supplementation. The smaller P values of abnormal glucose status groups at 2 h and 4 h also proved this trend. The larger P value of the abnormal group at 6 h compared to that of the normal group might be due to the greater 95% CI because its WMD was larger than that of the normal group. Data of the other time points was not analyzed by sub-group analysis because the number of included studies was small and it was inappropriate to split them.

There were several limitations to this study. Firstly, it was conceivable that some trials were not published although systematic efforts were made to locate and retrieve them. The distorting effects arising from publication bias and location bias have been reported repeatedly [23–25]. Secondly, necessary data for meta-analysis and linear regression were not reported in all studies. The overall results must have been affected by the use of imputed SDs although sensitivity analysis verified their rationality. Thirdly, there was some clinical heterogeneity among all studies although χ^2 tests indicated the non-existence of statistic heterogeneity. Different initial characteristics such as fasting TAG concentration ranging from 0.80 to 1.67 mmol/L [16], methodological diversity such as different washout periods ranging from 1 week [9, 15, 16] to 1 month [10], different test meal composition might influence the results of this study. Finally, although the greater fail-safe number indicated that the publication bias is not evident at the three important time points (2, 4 and 6 h), it was evident that publication bias might exist at 0.5,

1, 3 and 8 h respectively possibly due to the limited number of the studies included. The fail-safe number decreased with the decreasing number of the included studies indicating the possibility of an increased publication bias (Fig. 3).

In spite of these limitations, all papers were randomized, double-blind, TAG controlled, crossover designed which indicated high methodological quality. Funnel plots indicated the low possibility of publication bias. These results indicated the robustness of meta-analysis, demonstrating that DAG reduced the increment of postprandial TAG concentration significantly compared with TAG. This beneficial effect is most likely attributable to the different structure of DAG from TAG because its energy value and digestibility are similar to those of TAG [26]. The initial products of digested TAG are free fatty acids and 2-monooacylglycerol (MAG) and those for 1,3-DAG are free fatty acids and 1(3)-MAG [27]. The resynthesis of TAG in small intestinal epithelial cells from 2-MAG is faster than from 1(3)-MAG because the later involves the phosphatic acid pathway, a slower turnover pathway than the 2-MAG pathway. It suggests that the extent of postprandial TAG concentration increment after a single dose of DAG emulsion was less than that after a single dose of TAG emulsion.

In conclusion, compared to TAG oil, DAG reduced serum postprandial TAG concentrations significantly at postprandial 2 h, 4 h and 6 h which were positively correlated with daily dosage.

Determination of Triacylglycerols in Butterfat by Normal-Phase HPLC and Electrospray–Tandem Mass Spectrometry

P. Kalo · A. Kemppinen · V. Ollilainen

Received: 15 April 2008 / Accepted: 11 September 2008 / Published online: 24 October 2008

Abstract Here, we report the identification and quantification of the molecular species of long-, medium-, and short-chain triacylglycerols (TAG) in butterfat (BF), including TAG with an odd number of acyl carbons (ACN) and TAG with unidentified molecular species. In the present study, in addition to auto-MS², a large number of methods, each recording MS² for 1–4 ions, were used for identification of TAG species. For the quantification of long-chain, odd ACN TAG, and TAG with unidentified molecular species, molar correction factors (MCF) were calculated from the uncorrected mol% (area mol%) of each ACN:DB (number of double bonds) class in randomized butterfat (RBF), and the respective mol% in the calculated random composition of RBF. The butyrate, caproate, and medium-chain (C₈, C₁₀) TAG were quantified using regio- or acyl-chain-specific MCF calculated from their area mol% in RBF and mol% in the calculated random composition. These methods enabled us to identify ca. 450 TAG species in 184 quantified peaks of 88 ACN:DB classes. The proportions of saturated, monoene, diene, triene, tetraene, pentaene, and hexaene TAG were 40.0, 38.4, 16.2, 4.5, 0.6, 0.1, and 0.03 mol%, respectively. The proportions of TAG with not identified molecular species and odd ACN TAG were 11.8 and 5.7 mol%, respectively. The most abundant short-chain TAG species were

butyroyldipalmitoylglycerol + butyroylmyristoylstearyl-glycerol (5.25 mol%) and butyroylpalmitoyloleoylglycerol (4.08 mol%).

Introduction

Milk fat (MF) is one of the most complex natural fats for which the expression “the marvel of Nature” is very appropriate. More than 400 different, mainly esterified fatty acids (FA) have been identified, and a high number of triacylglycerol (TAG), phospholipid, glycolipid, diacylglycerol (DAG), and free fatty acid (FFA) molecular species as well [1]. The proportion of the major lipid class, TAG is 97–98% of total milk lipids. Owing to the high number of different FA, milk fat may theoretically contain a huge number of TAG, namely n^3 (n is the number of FA), and it is expected that FA are randomly distributed. However, the distribution of FA in native milk fat is specific, and the number of TAG species is markedly lower than n^3 . Regiospecific analysis of TAG showed that short-chain FA, C_4 and C_6 are preferentially, but not exclusively, esterified in the *sn*-3 position [2–4]. Separation and identification of milk TAG have been studied by high temperature gas–liquid chromatography (GC) [5–9], supercritical fluid chromatography (SFC) [10, 11], reversed-phase high performance liquid chromatography (RP-HPLC) [12–18], and normal-phase HPLC (NP-HPLC) [19]. Gresti et al. [14] determined more than 220 molecular species of even-numbered TAG by fractionation of MF using RP-HPLC and determination of TAG and FA compositions of these fractions by capillary GC. Kemppinen and Kalo [9] determined recently more than 130 molecular species of even-numbered TAG in butterfat (BF) and randomized BF (RBF) using silver ion chromatographic fractionation into saturated, monoene, and diene and triene fractions and GC-electron ionization mass spectrometry (EI-MS).

In NP-HPLC, TAG have been shown to elute in the order of the descending number of acyl group carbons (ACN), but in the order of the ascending number of double bonds [20, 21]. In recent years, NP-HPLC has been applied in lipid class separations in several studies as reviewed by Lin [22]. The small particle size, regular columns are able to separate regioisomers of acetate and propionate TAG [23] and microbore silica gel columns are able to separate regioisomers of acetate, butyrate and caproate TAG [19, 24]. Furthermore, microbore silica gel columns have been observed to separate molecular species in several lipid classes sufficiently to allow identification by electrospray tandem mass spectrometry (ESI-MS²)

[25]. The fragmentation mechanism in the ESI-MS² of $[M + NH_4]^+$ has been investigated in a number of studies [25–29].

In the direct inlet MS, the size of molecular ions and fragment ions [30–32] and the degree of unsaturation [30, 33, 34] have been found to affect the relative yields of ions and the correction factors. Furthermore, isobaric TAG with different acyl-chains and regioisomers have been shown to have different correction factors in direct inlet MS [33] and ESI-MS [19, 24]. In direct inlet HPLC-MS, the correction factors have been calculated from the ratio of the area percentage of total ion current and calculated TAG composition [33], in negative ion tandem MS (NI-MS²) from $[RCOO]^-$ ions in the daughter ion spectra of $[M - H]^-$ ions and respective ions in the spectra of standards [34]. In RP-LC-APCI-MS, Byrdwell et al. [35, 36] determined correction factors (1) by comparisons of FA values determined for TAG by GC and the sum of areas of all DAG peaks and protonated TAG peaks in MS, and (2) by dividing the expected TAG composition (calculated based on random distribution of FA) by the TAG composition determined by LC-MS. In NP-LC-ESI-MS, correction factors have been determined for short-chain TAG regioisomers by linear calibration using the plots $n(1)/n(ISTD)$, determined for TAG species in the randomized samples of three-acid standard mixtures by GC, versus area (1)/area (ISTD) in the ESI ion chromatograms of ammonium adducts [19, 24]. In GC-EI-MS, linear calibration has been used in the determination of correction factors for $[M - RCOO]^+$ ions as well [9].

Several acetate TAG have been identified in MF [5, 19, 37–39] and their relative ratios have been estimated [19], but their content in total milk fat have not been measured. TAG with odd ACN separate from the even ACN by GC on a polarizable capillary column [5] and by RP-HPLC [13]. In the latter research their total content was estimated at 11.6–15.1%.

In the present study, our aim was to identify and quantify the molecular species of long-, medium-, and short-chain TAG in BF, including TAG with odd ACN, by NP-HPLC-ESI-MS. Our aim was also to quantify long-chain even and odd ACN TAG, and TAG with not identified molecular species, using molar correction factors (MCF) calculated from the area data of each ACN:DB class and internal standard recorded for randomized butterfat (RBF) and the calculated random composition of TAG species. Further, our aim was to quantify butyrate, caproate, and medium-chain (C_8 , C_{10}) TAG using regio- or acyl-chain-specific MCF calculated from their areas in RBF and mol% in the calculated random composition.

Materials and Methods

Materials

Anhydrous BF was purchased from Valio Ltd (Helsinki, Finland). BF was dried under vacuum, below 3.3 kPa, for 100 min at 95 °C to the water content of 55–85 ppm and heated for 30 min at 95 °C with bleaching earth (2%). Randomized BF (RBF) was prepared by interesterification of a sample of dried and bleached BF with 1% of sodium methoxide as catalyst for 1 h at 85–90 °C [9, 24]. The standard mixture GLC74 of fatty acid methyl esters was purchased from Nu-Chek Prep (Elysian, MN, USA). All solvents were purchased from Rathburn (Walkerburn, United Kingdom) and were HPLC grade. Flash column chromatography grade silica gel 60 was purchased from Merck (Darmstadt, Germany) and had the characteristics described elsewhere [19].

Determination of Randomness of RBF by Lipase Hydrolysis

Isolation of TAG

Triacylglycerols were isolated from a ca. 12 mg aliquot of raw interesterification product of BF on a 0.5 g silica gel solid phase extraction (SPE) column STRATATM-SI-1 (Phenomenex). Prior to the introduction of the sample, the column was eluted with 5 mL hexane. The sample was introduced in 0.1 mL of 22/78 (v/v) dichloromethane:hexane and sterol esters and fatty acid methyl esters were eluted with 4 mL of the same solvent mixture. TAG were eluted with 4 mL of dichloromethane and partial acylglycerols with 4 mL of 40/60 (v/v) acetone/dichloromethane. The fractionation was monitored by thin layer chromatography on a 0.25-mm plain silica gel plate, which was eluted with hexane/diethyl ether/acetic acid 50:50:1 (v/v/v). After drying, the plate was sprayed with 2,7-dichlorofluorescein.

Transesterification of TAG

In order to transesterify the TAG to fatty acid methyl esters (FAME), 0.2 µL 2 M sodium methoxide in methanol and 20 µL hexane were added to a 0.3 mg aliquot of isolated TAG in a 0.25 mL insert of an autosampler vial, mixed for 1 min in a Vortex mixer and after centrifugation with 800–1,000 rpm for 10 min, 1 µL of supernatant was injected to a Micromat gas chromatograph equipped with a 30-m HP-Innowax capillary column with 0.25 mm i.d.

Determination of Fatty Acids in the *sn*-2 Position

A fat sample was hydrolyzed by porcine pancreatic lipase, type II (Sigma, St Louis, MO, USA) according to the principles presented by Hendrikse and Harwood [40] as follows: 5.3 mg TAG sample and 150 µL TRIS buffer, pH 8, 25 µL sodium cholate (1 g/L), and 10 µL calcium chloride (2.2%) were mixed in a 1.5-mL autosampler vial, heated for 1 min at 40 °C in a water bath, and mixed for 2 min in a Vortex mixer. After cooling with tap water, 50 µL 6 M hydrochloric acid and 0.2 mL diethyl ether were added and centrifuged 800–1,000 rpm for 1 min. The supernatant diethyl ether layer was drawn off with a Pasteur pipette. The extraction with 0.2 mL diethyl ether was repeated twice. The combined ether extracts were dried with anhydrous sodium sulphate and applied as a band on a 0.25-mm plain silica gel plate. The plate was developed as described above. The monoacylglycerol (MAG) band was scraped off and MAG were extracted from sorbent twice with 1 mL of diethyl ether. After evaporation of ether extract to ca. 0.1 mL, the extract was transferred to a 0.25-mL insert and evaporated to dryness and the *sn*-2 MAG were transesterified to FAME as described above for TAG.

Fractionation by Silica Gel Solid Phase Extraction

The SPE column (5.4 × 1.5 cm) was prepared in a 15-mL Isolute filtration column tube with microbore filters (International Sorbent Technology, Hengoed, United Kingdom) using a dry packing method. The BF sample (100 mg) was fractionated as follows: prior to elution of the TAG fractions, cholesterol esters were eluted with 40 mL 22/78 dichloromethane:hexane. TAG were eluted in four fractions I, II, III, and IV on the silica gel SPE. Fraction I was eluted with 60 mL of 60:40 dichloromethane/hexane, and fractions II, III, and IV with 40 mL of 65/35, 85/15, and 100/0 dichloromethane/hexane, respectively [19]. The amounts of trinonanoin (Sigma, St Louis, MO, USA) internal standard added were: 14.766 µmol to fraction I, 3.691 µmol to fraction II, 0.886 µmol to fraction III, and 0.148 µmol to fraction IV. The solvents were evaporated to dryness from fractions I–IV and following free fatty acid, diacylglycerol, sterol, and monoacylglycerol fractions. The weighing of evaporation residues revealed total recovery of 100%. The evaporation residues of fractions I–IV were dissolved in 5.0, 2.5, 1.0, and 0.3 mL of 2/1 chloroform:methanol. The same principles were used in the fractionation of RBF. To fraction I was added 7.773, to fraction II 3.887, to fraction III 1.555, and to fraction IV 0.777 µmol trinonanoin as the internal standard. After evaporation of the solvents, fractions I–IV were dissolved in 5.0, 2.5, 1.0, and 1.0 mL of 2/1 chloroform:methanol.

The BF and RBF fractions were stored in tightly closed vials at $-18\text{ }^{\circ}\text{C}$ under argon and kept in darkness.

Normal-Phase Liquid Chromatography–Electrospray Tandem Mass Spectrometry

The TAG fractions of BF and RBF were analyzed by normal-phase HPLC (NP-HPLC) using three Phenomenex Luna 3- μm silica columns, $100 \times 2.0\text{ mm}$, and a $4 \times 2.0\text{ mm}$ guard column, in series. The same multistage binary gradient of hexane (A) and hexane/methyl-*tert*-butyl ether/acetic acid (60:40:1), by vol. (B) as in the previous study [19] with the following parameters was used (time in min/%B by vol./flow in mL/min): 0/0/0.1, 2/5/0.1, 18/18/0.1, 30/18/0.1, 31/90/0.1, 49/90/0.1, 50/99/0.1, 64/99/0.5, 65/0/0.5, and 75/0/0.5. In order to compensate for a malfunction of the chromatograph, some samples were analyzed using B (50:50:1, by vol.). A 3D ion-trap Bruker Esquire LC–MS (Bruker Daltonic, Bremen, Germany) was operated in positive ESI mode. Capillary voltage was set to 3,000 V, capillary exit offset 60 V, skimmer potential 20 V, and trap drive value 55. The reagent solvent, chloroform/methanol/ammonia water (25%) 20:10:3 (by vol.), was pumped with a flow rate of 6.0 mL/min via a 1:100 split device to the effluent flow. Full scan ESI mass spectra were recorded in duplicate or triplicate using a scan range of 50–1,000 m/z and summation of 15 spectra. Nebulizer nitrogen pressure was 275 kPa, drying gas (nitrogen) flow 8 L/min, and drying temperature $300\text{ }^{\circ}\text{C}$. Auto-MS/MS spectra of two most intense ions eluting concurrently were recorded using helium (99.996%, 0.1 kPa) as the collision gas. In addition to auto-MS/MS, 78 methods with time-windows for isolation and fragmentation of 1–4 ions were used. Prior to the analyses of the BF and RBF fractions, the linearity of detector response was studied by injecting several volumes or dilutions of these SPE fractions. The injection volume/dilution selected was the one that showed the highest peak areas without affecting the area ratio of high abundance and low abundance peaks.

Determination of Molar Correction Factors for Correction of Ion Yield

The TAG in the fractions I–IV of RBF were analyzed by NP-HPLC with the three silica columns in series and the effluent flow was conveyed to the ion source of the mass spectrometer. Then 105 different ion chromatograms for TAG ammonium adducts were extracted from the MS data recorded in duplicate. These ion chromatograms of isobaric TAG were integrated. For identification of the molecular species of isobaric TAG in these ion chromatograms auto-MS/MS, and 78 methods with time windows for isolation and collision induced decay of 1–4 ions, were applied. The

presence of a known amount of internal standard (trinonanoic acid) in the four fractions permitted the calculation of uncorrected molar amount (area mol) of each integrated peak in each ion chromatogram. And the area mol% (uncorrected mol%) could be calculated from the mean of duplicate data for the respective uncorrected molar amount (area mol) and the sum of all area moles in the four fractions.

Results

Determination of the Randomness of RBF by Lipase Hydrolysis

A sample of RBF TAG was hydrolyzed by 1.3-specific pancreatic lipase according to the principles presented by Hendrikse and Harwood [40] and the *sn*-2-MAG of hydrolysate were isolated by TLC. Samples of TAG and *sn*-2-MAG were transesterified to FAME and their compositions were determined by GC. The percentage of C-6:0, C-8:0, C-10:0, C-12:0, C-14:0, C-14:1, C-15:0, C-16:0, C-16:1, C-17:0, C-17:1, C-18:0, C-18:1, C-18:2 in the *sn*-2 position was 29.5, 32.0, 37.5, 37.1, 36.5, 22.8, 38.0, 35.8, 28.2, 38.0, 35.1, 35.0, 29.1, 23.4%, respectively (on the average 32.7%, SD 5.3). Unfortunately, owing to the small sample of TAG subjected to lipase hydrolysis, the major part of C-4:0 MAG remained on the TLC plate. In order to avoid the impairment of other percentages, the percentages of C-4:0 had to be disregarded. The presented data indicate random distribution of FA among the three positions of TAG.

Identification of Molecular Species of TAG

The four SPE fractions of BF and RBF were analyzed by HPLC–ESI–MS using three micro-bore silica gel columns in series. Ion chromatograms (EIC) were extracted from ESI–MS data for 105 ACN:DB classes of TAG in BF and RBF and MS² were recorded for each peak with sufficient intensity using auto-MS² or/and a method with time windows for the ACN:DB class in question. The collision induced decay (CID) of ammonium adducts, $[\text{M} + \text{NH}_4]^+$, generated by ESI produced abundant $[\text{DAG}]^+$ ions, $[(\text{M} + \text{NH}_4) - \text{NH}_3 - \text{FA}]^+$, and low intensity $[(\text{M} + \text{NH}_4) - \text{NH}_3]^+$ ions. The acyl-chains of TAG were deduced from $[\text{DAG}]^+$ ions. The preferential loss of acyl-chains from the primary positions of long-chain [28] and short-chain TAG [19, 24] in the CID of ESI produced $[\text{M} + \text{NH}_4]^+$ ions that enabled the identification of chromatographically separated regioisomer of short-chain (C₂–C₆) TAG, and the predominant regioisomer of medium- and long-chain TAG (Table 3).

In a previous study [19], the resolution of regioisomers of butyrate and caproate TAG, in 20 randomized mixtures of three monoacid TAG, were studied under the same chromatographic conditions as in the present paper. The regioisomers of dibutyrate TAG were resolved with baseline resolution, R_S values between 1.5 and 2.0, and those of dicaproate TAG only partially with R_S in the range 0.5–1.1. In the present study, Fig. 1 demonstrates the resolution and identification of acyl-chain- and regioisomers of TAG 26:0 in BF. In the first peak (B) separated partially from peak C were eluted 12:0/10:0/4:0 + 14:0/8:0/4:0, in the peak C 14:0/8:0/4:0, in the partially separated peaks D and E regioisomers 16:0/6:0/4:0 and 6:0/16:0/4:0, and in the peak F 18:0/4:0/4:0. In contrast to the identification of regioisomers L/4:0/4:0 and 4:0/L/4:0 in the TAG 24:0 and 26:1, the regioisomer 4:0/18:0/4:0 was not identified.

In the randomized standard mixtures [19], the regioisomers of TAG with one butyryl chain were separated to the baseline with R_S between 1.6 and 2.9. Those of saturated TAG with one caproyl chain were separated close to the baseline with R_S in the range 1.0–1.5 and those of unsaturated TAG with one caproyl chain close to the baseline or partially with R_S in the range 0.5–1.3. In the present study, Fig. 2b shows the resolution of acyl-chain isomers of TAG 36:0 and identification of acyl-chain- and regioisomers. The MS² spectra B–F indicated that in the peak B eluted trilaurin and medium-chain TAG, in the peak C 16:0/14:0/6:0, in the peak D 16:0/16:0/4:0 + (18:0/14:0/4:0), in the peak E 18:0/2:0/16:0, and in the peak F 18:0/16:0/2:0 + 16:0/18:0/2:0.

Figure 3 demonstrates the separation and identification of acyl-chain isomers of odd-numbered long-chain TAG.

From the CID of peak B of TAG 51:0 were identified 19:0/16:0/16:0 and 19:0/14:0/18:0, from that of the peak C 20:0/15:0/16:0 and 20:0/14:0/17:0, and from that of peak D 18:0/17:0/16:0 and 18:0/15:0/18:0. Figure 4 shows EIC, MS, and MS² for TAG 50:1 as an example of the resolution and identification of acyl-chain isomers of long-chain even-numbered TAG. The CID of peak E of TAG 50:1 is consistent with 20:0/12:0/18:1, 20:0/16:0/14:1 + 20:0/14:1/16:0, 20:0/14:0/16:1 and that of peak F with 18:1/16:0/16:0, 18:1/14:0/18:0 (16:0/18:0/16:1). Figure 5 reveals the resolution and identification of TAG 56:1 regioisomers. The CID of peak B indicates regioisomers 20:0/18:0/18:1 + 20:0/18:1/18:0 and that of peak C regioisomer 18:1/20:0/18:0 together with 18:1/22:0/16:0.

Quantification of Molecular Species of TAG in an Interesterified Standard Mixture

In order to test the applicability of the proposed quantification method, the MS data of equimolar interesterified mixture of tributyrin, trimyristin and triolein recorded in the previous study [19] were reanalyzed. From duplicate area data for 15 TAG species in the solution A, were calculated the uncorrected molar amount, uncorrected mol%, and the mol% according to random distribution. The MCF obtained from the ratios of calculated mol% and uncorrected mol% are shown in Table 1. Molar amounts of the TAG species in the solution B of the same interesterified mixture were calculated from the MCF and area data. Molar amounts of TAG species in the solution B were similar or very similar to those determined by GC except

that for tributyrin. Regioisomeric ratios were on the average 0.501 (SD = 0.100, $n = 10$), as expected.

Determination of Molar Correction Factors for the Correction of the Ion Yield

For the determination of MCF, ion chromatograms for 105 ACN:DB classes were extracted from the ESI-MS data of four SPE fractions of RBF and the ion chromatograms were integrated. The TAG species in all peaks with sufficient intensity were identified from recorded HPLC-ESI-MS².

The uncorrected molar amount (area mol) was calculated from the area data and the amount of ISTD in each SPE fractions of RBF for the peaks in all EIC. The sum of all uncorrected molar amounts in the four SPE fractions for the respective peaks with similar relative retention time (RRT) and identity of TAG species was calculated. The uncorrected mol% of the TAG species in these peaks was obtained by dividing each sum of uncorrected molar amounts in the four SPE fractions with the sum of all uncorrected amounts. MCF for an ACN:DB-class was calculated by dividing the mol% of ACN:DB class calculated

according to random distribution by the sum of all experimentally determined uncorrected mol% for all peaks except acetates and the peaks with not identified molecular species eluting after acetate peaks (Table 2). The acyl-chain- and regiospecific MCF for butyrate and caproate TAG and acyl-chain-specific for medium-chain TAG were calculated by dividing the sum of mol% of the TAG species in the composition calculated according to random distribution, which were identified in the respective peak in RBF, by the experimentally determined respective uncorrected mol% (Table 2).

Molar correction factors varied widely, because the ion yield is affected by molecular size, unsaturation, and regioisomerism. Wide variation of MCF for BF TAG can be expected, because in BF TAG all these parameters vary extensively. The specific MCF showed a few trends: the ratios of MCF for $X/4:0/4:0$ and $4:0/X/4:0$ for 24:0 and 26:1 were 1.60 and 1.40, respectively. The ratio of MCF for even-numbered $X/X/4:0$ and $X/X/6:0$ in the ACN range 28–40 varied considerably and was on the average 2.86 (SD = 1.38, $n = 13$). The ratio of MCF for even-numbered $X/X/M$ and $X/X/6:0$ varied as well. In addition, a few trends were observed in the values of MCF for even-numbered saturated TAG. MCF increased from ACN:DB 18:0 to 24:0, 26:0 to 36:0, 40:0 to 48:0, and decreased to 54:0. Those for even-numbered monoene TAG varied considerably and increased from ACN:DB 22:1 to 26:1, decreased to 30:1, increased to 36:1, decreased to 38:1, increased from 40:1 to 50:1, and decreased to 54:1. Comparison of MCF for saturated and monoene TAG with the same ACN showed that those for saturated were higher for TAG 22 and 24, those for monoene higher for TAG 26–32,

those for saturated higher for TAG 34–48, and those for monoene higher for TAG 50–54.

¹³C may have a considerable effect in quantification of TAG that has to be corrected in direct ESI–MS as shown by Han and Gross [41]. However, in the present study using NP-HPLC–ESI–MS and MCF calculated from the ratio of calculated mol% and uncorrected mol% of randomized BF corrects isotope effects as well [19]. On the other hand, the partial resolution of isologous TAG with different unsaturation diminishes the isotope errors considerably.

Quantification of Butterfat TAG

For quantification of BF TAG, ion chromatograms for 105 ACN:DB classes were extracted from ESI–MS data of four SPE fractions (in duplicate (fractions I–III) and in triplicate (fraction IV), and the EIC were integrated. The peaks with sufficient intensity were identified from recorded HPLC–ESI–MS² data. The molar amounts of integrated peaks in duplicate or triplicate ESI–MS for four SPE fractions were calculated from the area data, the amount of ISTD, and the MCF determined (Table 2). A specific MCF was used when available. If not, the respective MCF for ACN:DB was used. For acetates the MCF of the butyrate with the same ACN was used. For TAG with ACN 55–57, the MCF of TAG 54 with the same unsaturation was used. In the next step, the sums of the means of molar amounts for respective peaks, with similar RRT and identity, in the four SPE fractions were calculated. Finally the mol% was obtained from the molar amount of TAG in each peak and the sum of all molar amounts of TAG (Table 3). Relative deviation for the identified peaks higher than 1 mol%, in

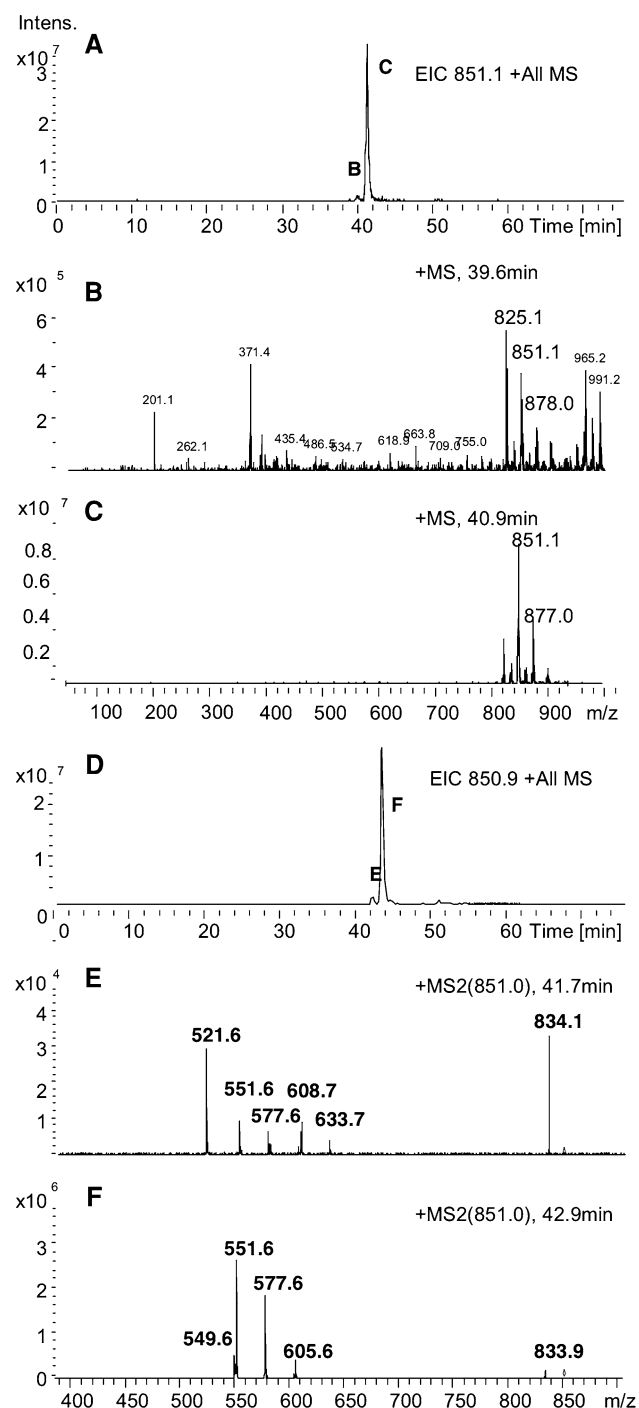

Fig. 4 Identification of the TAG 50:1 molecular species from the MS² data of fraction I. **a** EIC used for quantification of the ammonium adduct 50:1, $m/z = 851$. **b** MS at 39.6 min. **c** MS at 40.9 min. **d** EIC used for identification of TAG 50:1. **e** Tandem MS at 41.7 min: 20:0/12:0/18:1, 20:0/16:0/14:1 + 20:0/14:1/16:0, 20:0/14:0/16:1. **f** Tandem MS at 42.9 min: 18:1/16:0/16:0, 18:1/14:0/18:0, (16:0/18:0/16:1)

the range 0.1–1 mol%, and lower than 0.1 mol% was on the average 4.8, 9.1, and 10.6%, respectively. The proportions of saturated, monoene, diene, triene, tetraene, pentaene, and hexaene TAG were 40.0, 38.4, 16.2, 4.5, 0.6,

0.1, and 0.03 mol%, respectively. The proportion of TAG with not identified molecular species and odd ACN TAG were 11.8 and 5.7 mol%, respectively.

TAG Species in Butterfat

The TAG with two or three short acyl chains (C_2 , C_4 , C_6) in the ACN range 18–28 were detected predominantly in the fractions III and IV (Table 3). The total proportion of this category of TAG was 0.309 mol%. The caproates eluted before butyrates and butyrates before acetates. The regioisomers $X/S/S$ ($X/S/S'$) and $S/X/S$ ($S/X/S'$) (S denotes short acyl chain, and the structure in italics denotes chromatographically resolved regioisomer), separated from each other when present. The $L/S/S$ ($L/S/S'$) regioisomers (L denotes long-chain acyl C_{12} – C_{20}) were predominant, e.g., the molar ratios of $L/4:0/4:0$ and $4:0/L/4:0$ for ACN:DB 24:0 and 26:1 were 15.5 and 7.0, respectively. Butyrocaproates were identified in seven ACN:DB classes. In two ACN:DB classes both $L/6:0/4:0$ and $6:0/L/4:0$ regioisomers were found, in four ACN:DB classes $L/6:0/4:0$ and in one $6:0/L/4:0$ solely. Furthermore, one acetobutyrate and one acetocaproate were detected.

The even-numbered short-chain TAG (classified according to the shortest acyl-chain) with one short acyl chain in the ACN range 30–42 comprised 37.5 mol% and were found predominantly in the fraction II. All identified even-numbered butyrate and caproate TAG with one short acyl chain were $L/M/S$, $M/L/S$ or $L/L/S$ regioisomers. Acetate TAG species identified in the ACN range 22–38 comprised 0.232 mol%. The proportion of the most abundant acetate TAG, $18:0/16:0/2:0 + 16:0/18:0/2:0$ was 0.070 mol%. The $X/X/2:0$ regioisomers predominated. In four ACN:DB classes only $X/X/2:0$ regioisomers were detected, in one class only $X/2:0/X$ regioisomer, and in three classes both regioisomers with $X/X/2:0 : X/2:0/X$ ratios 2.6, 0.18, 0.56, respectively (Table 3). The most abundant peaks of short-chain TAG species were $16:0/16:0/4:0 + 18:0/14:0/4:0$ (5.25 mol%), $18:1/16:0/4:0$ (4.08 mol%), $16:0/14:0/4:0 + 18:0/12:0/4:0$ (3.34 mol%), $18:0/16:0/4:0$ (2.85 mol%), $18:1/18:0/4:0$ (1.99 mol%), and $18:1/14:0/4:0 + (16:0/16:1/4:0 + 16:1/16:0/4:0)$ (1.96 mol%).

The medium-chain TAG (C_7 , C_8 , C_{10}) eluted before caproates and comprised ca. 9.1 mol%. Those in the ACN range 30–34 were detected predominantly in SPE fraction II, and those in the range 36–46 in the fraction I. However, medium-chain TAG in the ACN range 40–46 coeluted with long-chain TAG (C_{12} or C_{14} as the shortest chain) (Table 3). Owing to the lack of chromatographic resolution of the medium-chain TAG regioisomers only the predominant regioisomer could be identified. The most abundant peak of medium-chain TAG (including one long-chain

^f The sum of regioisomers

TAG) in the ACN range 30–38 was 14:0/12:0/12:0, 16:0/12:0/10:0, 16:0/14:0/8:0, 18:0/10:0/10:0, 18:0/12:0/8:0, 14:0/14:0/10:0 (0.57 mol%) (the structure in normal font denotes the predominant regioisomer).

The odd ACN TAG species were quantified in the ACN ranges 23–25; 29–57 and the molecular species of the most abundant peaks were identified in the ACN range 33–57 (Table 3). The total content of odd ACN TAG was 5.7 mol%. The short-chain TAG with odd ACN in the ACN

range 33–43 eluted in separate peaks in the order caproate, valerate, butyrate, propionate, and were X/X/6:0, X/X/5:0 or X/X/4:0 regioisomers in the ACN range 39–43, X/X/6:0, X/X/4:0, and X/X/3:0 regioisomers in the ACN:DB class 37:0, X/6:0/X in 37:1, X/6:0/X, X/X/6:0, X/X/4:0, and X/X/3:0 in 35:0, and X/3:0/X, X/4:0/X in 35:1, X/X/4:0 and X/X/6:0 in 33:1. The long-chain TAG with odd ACN in the ACN range 45–57 eluted in two or three identified peaks (except TAG 45:1, 47:1). In the first of the two peaks

Italics in this table are relevant in assignments of regioisomers of short-chain (and a few other) TAG, which were chromatographically resolved and identified from MS². This enabled calculation of regio-specific MCF

- ^a The number of acyl group carbons:the number of double bonds
^b Uncorrected mol% (area mol%) of triacylglycerol species in randomized butterfat
^c Mol% of triacylglycerol species in randomized butterfat calculated according to random distribution
^d Molar correction factor MCF = calc.mol%/area mol%
^e Structure in italics indicates the regioisomer identified by MS²
^f Two or more triacylglycerol species identified
^g Included minor impurities of other identity
^h Included other regioisomer
ⁱ M denotes medium-chain acyl (C₈–C₁₀) and L long-chain acyl (C₁₂–C₂₄)
^j Structure in normal font indicates predominant regioisomer

eluted TAG with the longest odd ACN acyl (19:0) and in the second TAG with a shorter odd ACN acyl (15:0 or 17:0). When three peaks were identified, in the first eluted TAG with the longest odd ACN acyl (19:0), in the second TAG with the longest even ACN acyl (20:0), and in the third TAG with the shorter odd ACN acyl (15:0 or 17:0). In the first peak of TAG 55:1 eluted regioisomers *19:0/18:1/18:0* and *19:0/18:0/18:1*, and in the second peak regioisomer *18:1/19:0/18:0* together with 18:0/19:1/18:0. The most abundant peaks of TAG species with odd ACN were (18:1/15:0/16:0 + 18:1/16:0/15:0) + (18:1/17:0/14:0 + 18:1/14:0/17:0) + 16:0/17:1/16:0 + 16:0/16:1/17:0 (0.41 mol%), 15:0 14:0 10:0 + 12:0 17:0 10:0 + 12:0/13:0/14:0 + (15:0/16:0/8:0 + 15:0/8:0/16:0) + 16:0/16:0/7:0 + 14:0/18:0/7:0 (0.31 mol%), (18:1/16:0/17:0 + 18:1/17:0/16:0) + 18:0/17:1/16:0 + 18:1/15:0/18:0 (0.26 mol%).

^a Ammonium adduct^b Mass to charge ratio^c The number of acyl group carbons:the number of double bonds^d Relative retention time. Average of two or three chromatograms. In general, the SD was $\leq \pm 0.01$ ^e Standard deviations (SD_I , SD_{II} , SD_{III} , SD_{IV}) for molar amounts in each fraction (I, II, III, and IV) were calculated. The SD for the sum of the molar amounts was calculated using equation
$$SD = \sqrt{(SD_I^2 + SD_{II}^2 + SD_{III}^2 + SD_{IV}^2)}$$
 [43]. The SD for mol% was obtained by multiplying the mol% by the ratio of SD and the sum of molar amounts in the four fractions
^f Fractions from SPE fractionation^g Not identified molecular species^h Structure in italics indicates regioisomer identified by MS²ⁱ Structure in normal font indicates predominant regioisomer^j 18:1/6:0_/4:0 indicates 18:1/6:0/4:0 + 18:1/4:0/6:0

In the ACN range 36–40 eluted 12:0/12:0/12:0, 14:0/12:0/12:0, 14:0/12:0/14:0, 14:0/14:1/12 or 16:0/12:0/12:0 with some ACN:DB class of medium-chain TAG, and in the ACN range 42–46 medium-chain and long-chain TAG eluted in the same peaks with increasing proportions of long-chain TAG (Table 3). The total content of long-chain TAG (in the ACN range 43–57) was ca. 43.2 mol%. In the first peak of saturated TAG with 48–52 and 56 ACN, monoene TAG with 50–56 ACN, and diene TAG with 52 ACN eluted TAG with acyl 20:0, and in the second peak the longest acyl was C₁₈ or C₁₆ in TAG with 48–54 ACN, and 20:0, 22:0 or 24:0 in TAG with 56 ACN. The regioisomers *20:0/18:0/18:1* and *20:0/18:1/18:0* of TAG 56:1 eluted in the first peak and the regioisomer *18:1/20:0/18:0* together with 18:1/22:0/16:0 in the second peak. The regioisomer *20:0/18:0/18:0* of TAG 56:0 eluted in the first peak and the symmetric regioisomer *18:0/20:0/18:0* together with 16:0/22:0/18:0 and 16:0/24:0/16:0 in the second peak. The most abundant peaks of long-chain TAG species were 18:1/16:0/16:0 + (18:1/14:0/18:0 + 18:1/18:0/14:0) +

16:0/18:0/16:1 (4.77 mol%), 18:1/16:0/18:1 + 18:2/18:0/16:0 (3.71 mol%), (18:1/14:0/16:0 + 18:1/16:0/14:0) + 16:0/16:1/16:0 (3.08 mol%), (18:1/14:0/18:1 + 18:1/18:1/14:0) + 18:1/16:1/16:0 + 18:2/16:0/16:0 + 18:2/14:0/18:0 + 18:1/14:1/18:0 + 18:0/16:1/16:1 (2.80 mol%), (18:1/16:0/18:0 + 18:1/18:0/16:0) + 18:0/16:1/18:0 (2.75 mol%), 16:0/16:0/14:0 + 16:0/12:0/18:0 + 18:0/14:0/14:0 + 18:0/10:0/18:0 (2.56 mol%), 16:0/16:0/16:0 + 18:0/14:0/16:0 + (18:0/12:0/18:0) (2.39 mol%).

Discussion

Resolution and Identification of TAG

The studies of Plattner and Payne-Wahl [20] and Rhodes and Netting [21] showed that NP-HPLC has a relatively high potential for separation of TAG species with different chain-lengths and different unsaturation. The major application of NP-HPLC in lipid analysis has been lipid class

separations introduced by Christie [42]. In 1999, NP-HPLC was used for the separation of short- and long-chain TAG produced by interesterification of triacetin and soybean oil [22], and in 2003 and 2004 for analysis of short-chain TAG standards produced by chemical interesterifications [24] and short-chain TAG in BF [19]. Two 100×2 mm silica columns in series separated the *L/S/S* and *S/L/S* regioisomers, and *L/S/L* and *L/L/S* butyrate regioisomers ($S = 4:0$) to the baseline, and caproate regioisomers ($S = 6:0$) close to the baseline [24]. In the present work, similarly to the previous paper [19], the regioisomers of TAG with two short acyl chains eluted in different peaks: e.g. *14:0/6:0/4:0* and *6:0/14:0/4:0*, *16:0/4:0/4:0* and *4:0/16:0/4:0*, *18:1/4:0/4:0* and *4:0/18:1/4:0*. Furthermore, the regioisomers of TAG with one short acyl chain separated to the baseline as presented in the previous paper [19]. In addition, TAG with one or two medium chain acyls (C_8 or C_{10}) separated from caproates and *sn-2* and *sn-3* acetates from butyrates. In the ACN range 32–42, in the first peak of each even-numbered ACN:DB class eluted medium-chain TAG, in the second caproates, in the third butyrates, and if identified, in the fourth *sn-2* acetates, and in the fifth *sn-3* acetates. Thus the least polar eluted first and the most polar last. Unexpectedly, probably owing to the residual polarity of the column support, the same elution order has been observed in RP-HPLC [15, 16]. The expected reverse elution order was observed in the RP-HPLC analysis by Spanos et al. [17] and by the authors (P. Kalo, A. Kemppinen, V. Ollilainen, unpublished data). Medium-chain TAG in the ACN range 40–46 coeluted with long-chain TAG. Similar coelution was reported in the ACN range 42–46 in the RP-HPLC analysis [17].

As already noted, TAG 20:0/X/X eluted in the first peak of saturated TAG with 48–52 and 56 ACN, monoene TAG with 50–56 ACN, and diene TAG with 52 ACN. Some TAG of this category have been identified by RP-HPLC among other long-chain TAG species, but not in separate peaks [17, 18]. In general, the TAG species identified in the second peak with the longest acyl C_{18} or C_{16} in the 48–54 ACN range, are similar to those identified by RP-HPLC [17] although a higher number of TAG species have been identified in the present study. To our knowledge, the resolution of regioisomers of long-chain even-numbered TAG 56:1, *20:0/18:0/18:1* + *20:0/18:1/18:0* in the first peak and *18:1/20:0/18:0* in the second, and TAG 56:0, *20:0/18:0/18:0* in the first peak and *18:0/20:0/18:0* in the second peak have not been observed before.

The regioisomers of odd ACN TAG with one short acyl chain may be separated as the elution order of 35:0 TAG shows: *15:0/6:0/14:0*, *15:0/14:0/6:0*, *16:0/15:0/4:0* + *15:0/16:0/4:0*, *16:0/16:0/3:0* + *18:0/14:0/3:0*. There are also sufficient polarity differences between molecular species of odd long-chain TAG in ACN range 45–55 for

adequate separation. The least polar TAG 19:0/X/X eluted first, followed by second least polar TAG 20:0/X/X, and most polar 18:0/X/X. The resolution of TAG 55:1 regioisomers *19:0/18:1/18:0* + *19:0/18:0/18:1* in the first peak and *18:1/19:0/18:0* in the second peak has not been reported before.

Quantification of TAG

In our previous paper [19] we quantified short-chain TAG in BF by NP-HPLC on three microbore silica gel columns in series. EIC of $[M + NH_4]^+$ of TAG were integrated and MCF, determined for molecular species of TAG in a high number of interesterified mixtures of three monoacid TAG by linear calibration, were used to correct the ion yield. The composition of short-chain TAG was calculated by normalization from the molar amounts of TAG species and their total proportion determined by GC [8]. In order to be able to quantify, in addition to the short-chain TAG, also long-chain TAG, acetate TAG, odd ACN TAG, and non-identified TAG we decided to modify applicable in NP-HPLC–ESI the method used by Byrdwell et al. [35] in LC–APCI–MS for determination of response factors based on randomized fat and calculated random composition.

The TAG species with different levels of unsaturation have different molecular geometry. Similarly isobaric TAG species with different acyl chains have different molecular structure, as well as the regioisomers of short-chain TAG. This is valid for all short-chain TAG with ACN 22 and higher. These contain at least one long-chain FA. The difference in the molecular structure appears in different polarity and in separation by NP-chromatographic analysis and may appear in the different ion yield and MCF as well.

For comparison of the TAG composition determined in this study with that calculated according to random distribution, the experimental and random data for even ACN TAG are shown in Fig. 6a and those for odd ACN TAG in Fig. 6b. Figure 6a shows two maxima for experimental values, one at ACN 38 (11.2 mol%) and another at ACN 50 (11.9 mol%). All experimental sum values of TAG with different unsaturation differed from respective values calculated according to random distribution. This indicates the specific distribution of TAG in native BF. Furthermore, the non-randomness of TAG composition of BF can be easily deduced by comparison of ACN:DB classes in the experimental and random composition. Figure 6b shows two maxima for experimental values as well, one at ACN 37 and another at ACN 49. Likewise, for even ACN TAG, comparison of experimental and calculated values of ACN or ACN:DB classes indicate specific distribution of odd ACN TAG in BF.

In the present study, molar ratios of saturated acyls and double bonds calculated from the TAG data shown in

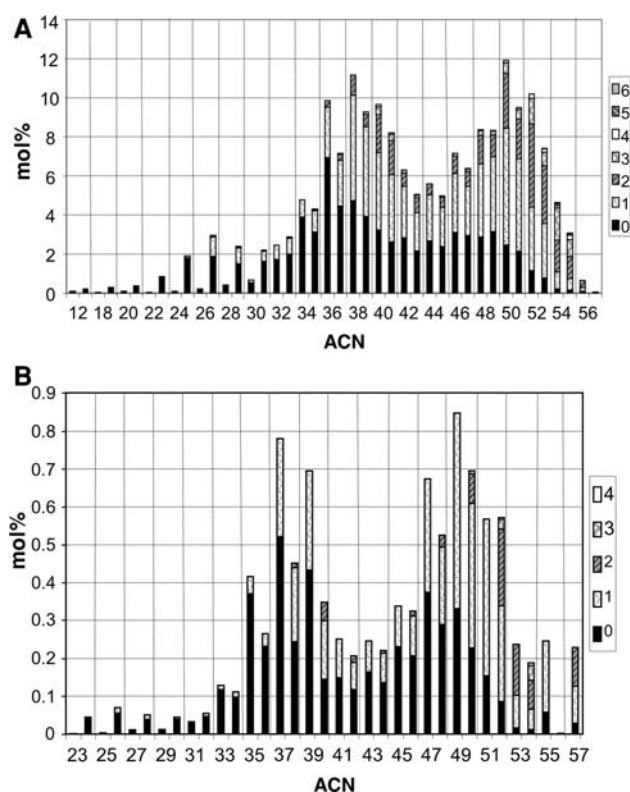

Fig. 6 Acyl carbon number:double bond (*ACN:DB*) class composition of butterfat triacylglycerols (*TAG*). In each acyl carbon number (*ACN*) class, the left column shows experimental data and the right column the *TAG* composition calculated according to the random distribution. **a** Even-numbered *TAG*. **b** Odd-numbered *TAG*. 0 Saturated, 1 monoene, 2 diene, 3 triene, 4 tetraene, 5 pentaene, 6 hexaene (at the top of *ACN* 54 a very small column) *TAG*

Table 3 and in Fig. 6a and b, and on the other hand from the FA composition, were 2.43 and 2.46, respectively. Ratios of butyrates and caproates calculated from *TAG* data and from FA composition were 2.58 and 2.51, respectively. Those of butyrates and medium-chain acyls ($C_8 + C_{10}$) 2.13 and 2.13, respectively, those of medium-chain acyls and caproates 1.22 and 1.18, respectively, and those of long-chain saturated and long-chain unsaturated 2.08 and 2.15, respectively.

Acetate *TAG*

Acetate *TAG* in milk lipids have been studied by thin layer chromatography (TLC) on plain silica gel and packed column GC [37] or capillary GC and GC–MS [5]. Investigation of the positional distribution of the acetyl group in milk fat *TAG* by chiral-phase HPLC of acetate *TAG* isolated by TLC, hydrogenated, and subjected to Grignard degradation [38] indicated that acetates are entirely in the *sn*-3 position. The regioisomeric structures of acetate *TAG* isolated by silica gel column chromatography from bovine udder were characterized by 1D- and 2D-NMR and

collision-induced dissociation tandem mass spectrometry coupled with fast atom bombardment [39], and indicated the presence of acetate in the *sn*-3 position in all molecular species of acetate *TAG*. On the contrary, determination of regioisomeric structures of acetate *TAG* in butterfat by normal-phase HPLC–ESI tandem MS [19] showed in the *ACN* range 22–30 the relative *X/X/2:0* and *X/2:0/X* regioisomer ratio 90.5:9.5. In the present study, the molar ratio of *X/X/2:0* and *X/2:0/X* regioisomers in the *ACN* range 22–38 was 1.82:1. In the present and previous study [19] the SPE fractionation ensured that *TAG* species of any size and polarity were eluted from the SPE column and were subjected to NP-HPLC–ESI–MS analysis. Thus the possible loss of *sn*-2 acetyl isomers during the fractionation step was minimized.

Odd *ACN* *TAG*

Myher et al. [5] studied the fourth most volatile 2.5% molecular distillate of milk fat by GC–MS, and found in the analysis on a polarizable capillary column that in the *ACN* range 33–41 several isobaric odd *ACN* *TAG* eluted in three peaks, which in full MS yielded the same “diacylglycerol” fragments. The three peaks were considered normal-, anteiso-, iso-odd acyl-chain *TAG*. The mol% of *TAG* species was estimated from the knowledge of the carbon number distribution and the flame ionization response in the GC. The same authors [15] identified by RP-HPLC in the most volatile 2.5% molecular distillate saturated branch- and normal-acyl-chain isomers of several odd *ACN* *TAG* species in *ACN* range 25–37. The compositions of saturated and monounsaturated *TAG* of molecular distillate were estimated by RP-HPLC from the area percentages that are derived from the sum of the diacylglycerol fragment intensities. Marai et al. [16] investigated randomized butteroil *TAG* by RP-HPLC with light-scattering and MS detection and identified saturated odd *ACN* *TAG* with 31–49 *ACN*. Only one molecular species was identified in each *ACN* class except in 37:0, where two isobaric butyrates were identified. The branched chain acyls were not shown among the identified odd *ACN* *TAG*. Uncorrected estimates of *TAG* species by HPLC–light-scattering detection and HPLC–MS were presented. Spanos et al. [17] studied milk fat *TAG* by RP-HPLC with light-scattering and desorption CI tandem MS and identified one caprylate and caproate, and two butyrate 37:0 *TAG*, and one 47:1 *TAG* species. Mottram and Evershed [18] identified in milk fat by RP-HPLC–APCI–MS one butyrate 33:0 and 35:0 *TAG*, two butyrate 37:0 *TAG* species, two long-chain (47:1 and 49:0) *TAG* species, and one 51:1 *TAG* species.

In the present study, acyl-chain- and regioisomers of short-chain odd *ACN* *TAG* were separated and the

regioisomers of the most abundant long-chain odd ACN TAG were deduced from MS² data. For quantification of abundant odd ACN TAG specific MCF were used.

Even-Numbered Butyrate and Caproate TAG

The molecular species of TAG with two or three short acyl chains in the ACN range 12–28 that were identified and quantified are more numerous here than in the GC–MS study of similar BF [9]. Even regioisomers of some butyrocaproates have been resolved in the present study. Furthermore tributyrin and tricaproin have been quantified. There is relatively good agreement with proportions of major short-chain TAG with one short acyl chain in these two studies although the ratio of saturated to monoene TAG showed different values, 40.1:38.4 in the present study and 44.9:34.1 in the GC–MS study [9]. If the same proportion of non-identified and odd ACN TAG is expected in the GC–MS as in the present study, 11.8 and 5.7 mol%, for a total of 17.5 mol%, the total mol% of identified TAG is 82.5. If the TAG determined by GC–MS are normalized to the sum of 82.5 mol%, the major TAG peaks in the present study and (in the GC–MS study [9]) are 16:0/16:0/4:0 + 18:0/14:0/4:0 : 5.25 (5.22) mol%, 18:1/16:0/4:0 : 4.08 (4.17) mol%, 16:0/14:0/4:0 + 18:0/12:0/4:0 : 3.34 (2.46) mol%, 18:0/16:0/4:0 : 2.85 (2.27) mol%, 18:1/18:0/4:0 : 1.99 (1.13) mol%, and 18:1/14:0/4:0 + (16:0/16:1/4:0 + 16:1/16:0/4:0) : 1.96 (2.51) mol%. Gresti et al. [14] studied much more unsaturated summer butterfat TAG than in the present study [13] by RP-HPLC fractionation and gas chromatographic determination of TAG and FA of fractions. Despite the difference in the degree of unsaturation of BF in the present study and in that of Gresti et al., there is relatively good accordance with the proportions of short-chain TAG containing one short-chain acyl. The major TAG species in this category in the present study and (in that by Gresti et al. [14]) were: 16:0/16:0/4:0 + 18:0/14:0/4:0 : 5.25 (4.55) mol%, 18:1/16:0/4:0 : 4.08 (4.17) mol%, 16:0/14:0/4:0 + 18:0/12:0/4:0 : 3.34 (3.41) mol%, 18:0/16:0/4:0 : 2.85 (2.47) mol%, 18:1/18:0/4:0 : 1.99 (1.58) mol%, 18:1/14:0/4:0 + (16:0/16:1/4:0 + 16:1/16:0/4:0) : 1.96 (2.21) mol%.

Medium-Chain TAG

There is also similarity in the proportions of medium-chain TAG in the present study, GC–MS [9], and in the study of Gresti et al. [14]. The proportions of the medium-chain TAG 38:0 (including one long-chain TAG) 14:0/12:0/12:0, 16:0/12:0/10:0, 16:0/14:0/8:0, 18:0/10:0/10:0, 18:0/12:0/8:0, 14:0/14:0/10:0 in the present study, in [9], and in [14] were 0.57, 0.86, and 0.91 mol%, respectively. The proportions of medium-chain TAG (including the coeluting long-chain TAG) in these three studies were: 40:0: 1.13,

2.36, 2.97; 40:1: 0.68, 0.25, 0.83; 42:0: 2.78, 3.09, 2.41; 42:1: 1.50, 1.08, 2.55; 44:0: 2.19, 2.45, 1.65; 44:1: 2.17, 1.73, 2.72; 46:0: 2.56, 2.63, 1.52; 46:1: 2.66, 2.85, 2.72 mol%, respectively.

Long-Chain TAG

There is relatively good accordance with the proportions of major unsaturated long-chain TAG in the present study and (in that reported by Gresti et al. [14]): 18:1/16:0/16:0 + (18:1/14:0/18:0 + 18:1/18:0/14:0) + 16:0/18:0/16:1: 4.77 (3.94) mol%, 18:1/16:0/18:1 + 18:2/18:0/16:0: 3.71 (2.39) mol%, (18:1/14:0/16:0 + 18:1/16:0/14:0) + 16:0/16:1/16:0: 3.08 (2.95) mol%, (18:1/14:0/18:1 + 18:1/18:1/14:0) + 18:1/16:1/16:0 + 18:2/16:0/16:0 + 18:2/14:0/18:0 + 18:1/14:1/18:0 + 18:0/16:1/16:1: 2.80 (2.18) mol%, (18:1/16:0/18:0 + 18:1/18:0/16:0) + (18:0/16:1/18:0) : 2.75 (2.39) mol%, but the higher degree of unsaturation in the BF analyzed by Gresti et al. [14], relative to our data, produced lower proportions of saturated long-chain TAG: 16:0/16:0/14:0 + 16:0/12:0/18:0 + 18:0/14:0/14:0 + 18:0/10:0/18:0: 2.56 (1.52) mol%, 16:0/16:0/16:0 + 18:0/14:0/16:0 + (18:0/12:0/18:0): 2.39 (1.09) mol%, 18:0/16:0/16:0 + 18:0/14:0/18:0: 2.04 (0.74) mol%, 18:0/16:0/18:0: 0.92 (0.43) mol%.

The methodology used in the analysis of BF TAG provides abundant information on the structures of a great number of molecular species of TAG. The ability of the NP-HPLC column used to resolve acyl-chain- and regioisomers of TAG with different polarities enabled the identification and quantification of a great number of TAG species by positive ESI–MS and –MS². Regioisomeric identification and quantification of TAG with two short acyl chains, even-numbered TAG with one short acyl chain, odd-numbered TAG with one short acyl chain, and identification and quantification of TAG species of medium-chain and long-chain even-numbered and odd-numbered TAG provide detailed structural and quantitative data of these major and minor sub classes of TAG in BF. This data may be exploited in the future in the studies of TAG absorption, metabolism, nutrition, crystallization, fractionation or modification.

Abstract Sandhoff disease (SD) is a glycosphingolipid (GSL) storage disease that arises from an autosomal recessive mutation in the gene for the β -subunit of β -Hexosaminidase A (*Hexb* gene), which catabolizes ganglioside GM2 within lysosomes. Accumulation of GM2 and asialo-GM2 (GA2) occurs primarily in the CNS, leading to neurodegeneration and brain dysfunction. We analyzed the total lipids in the brains of SD mice, cats, and humans. GM2 and GA2 were mostly undetectable in the normal mouse, cat, and human brain. The lipid abnormalities in the SD cat brain were generally intermediate to those observed in the SD mouse and the SD human brains. GM2 comprised 38, 67, and 87% of the total brain ganglioside distribution in the SD mice, cats, and humans, respectively. The ratio of GA2–GM2 was 0.93, 0.13, and 0.27 in the SD mice, cats, and humans, respectively, suggesting that the relative storage of GA2 is greater in the SD mouse than in the SD cat or human. Finally, the myelin-enriched lipids, cerebroside and sulfatides, were significantly lower in the SD brains than in the control brains. This study is the first comparative analysis of brain lipids in mice, cats, and humans with SD and will be important for designing therapies for Sandhoff disease patients.

Abbreviations

CHCl ₃	Chloroform
CNS	Central nervous system
GA2	Asialo-GM2
GSL	Glycosphingolipid
HexA	β -Hexosaminidase A
HPTLC	High-performance thin-layer chromatograph
MeOH	Methanol
SD	Sandhoff disease

Introduction

Sandhoff disease (SD) is an incurable lysosomal storage disorder that arises from an autosomal recessive mutation, which causes abnormal accumulation of ganglioside GM2 leading to progressive neurodegeneration [1, 2]. GM2 is catabolized by β -hexosaminidase A (HexA), which consists of an α and a β subunit encoded by the *Hexa* and *Hexb* genes, respectively, in complex with the GM2 activator protein. GM2 accumulation can result from inherited defects in either the hexosaminidase α or β subunit, or in the GM2 activator protein, leading to Tay-Sachs disease (B variant), Sandhoff disease (O variant), or GM2 activator deficiency (AB variant), respectively. SD patients have defects in the *Hexb* gene, and as a result, they lack activity of both β -hexosaminidase isozymes A ($\alpha\beta$) and B ($\beta\beta$). Consequently, patients accumulate GM2 and its asialo derivative, GA2, and also oligosaccharides and other hexosaminidase substrates within lysosomes [1, 2]. The onset of

disease ranges from infancy to adulthood, and excessive CNS GM2 accumulation leads to progressive neurodegeneration, brain dysfunction, and ultimately death.

Although the biochemical defect in SD has been known for many years, there are presently no therapies. The development of mouse models of lysosomal storage disorders has provided the necessary tools for advancement in possible therapies and treatments. However, with some success in bone marrow transplantation, gene therapy, stem cell therapy, caloric restriction, non-steroidal anti-inflammatory drug therapy, and substrate reduction therapy in SD mice, there are still no treatments available for patients [3–12].

A possible disconnect from mouse studies to clinical treatments is the difference in the applicable brain size between mouse and human. The brain weight of the mouse is around 0.4 g while an infantile human brain weighs around 400 g, representing a 1,000-fold difference in size [13–15]. A naturally occurring, authentic model of SD in cats (fG_{M2} Baker) has been previously characterized and could potentially serve as an intermediate model between mouse and man [16–19]. Although the feline brain is closer in size and complexity to the human brain, it is not clear how the mouse and the cat animal models of SD compare to the human patient.

While the CNS GM2 accumulation has been reported for the mouse and cat models of SD and in the patient [11, 19–22], the comparative total lipid analysis has never been done. In particular, our objective was to analyze similar brain regions, at a similar phenotypic time-point, using the same methodology to compare the total lipid distribution between mice, cats, and humans with SD. Knowledge gained from this study could help provide the foundation to bridge the gap between the successes in mouse studies to treatment in patients.

Experimental Procedures

Mice

The SV/129 *Hexb* $-/-$ (SD) mice were obtained from Dr. Richard Proia (NIH). These mice were derived by disruption of the murine *Hexb* gene and transferring this gene into the mouse genome through homologous recombination and embryonic stem cell technology as previously described [20]. *Hexb* $-/-$ mice were derived from crosses of *Hexb* $+/-$ females with *Hexb* $-/-$ males. Genotypes of mice were determined by measuring the specific activity of total hexosaminidase using a modification of the Galjaard procedure as previously described [23, 24]. *Hexb* $+/-$ and *Hexb* $-/-$ mice were propagated in the Boston College Animal Facility and were housed in plastic cages with filter tops containing

Sani-Chip bedding (P.J. Murphy Forest Products Corp., Montville, NJ, USA). Other conditions were as we recently described [12]. The cortical brain region from normal and SD mice was collected around 4 months of age (humane end-point) and stored at -80°C . All animal experiments were carried out with ethical committee approval in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals and were approved by the Institutional Animal Care Committee.

Cats

The SD cats were obtained from the fG_{M2} Baker colony and have been previously described [17, 19]. Sequence analysis determined that the causative mutation in this domestic shorthair SD cat resulted from a 25-base-pair inversion at the 3' end of the *Hexb* gene [16]. Affected cats have <3% normal hexosaminidase activity in cerebral cortex and, therefore, represent an authentic model to study Sandhoff disease. Animals were euthanized by pentobarbital overdose according to recommendations of the AVMA Panel on Euthanasia, then transcatheterially perfused with heparinized, cold saline (0.9% NaCl) until jugular perfusate was clear. Cerebral cortex samples were collected from normal and SD cats around 5 months of age (humane end-point) and were frozen immediately in liquid nitrogen and stored at -80°C until use. All animal procedures were approved by the Auburn University Institutional Animal Care and Use Committee.

Human Samples

Age-matched normal and SD human cortex samples were obtained from the NICHD Brain and Tissue Bank for Developmental Disorders at the University of Maryland, Baltimore.

Lipid Isolation, Purification, and Quantitation

Total Lipid Extraction

The lipids were isolated from frontal lobe regions of the SD patients and the cats, and from the entire cortex of the SD mice. Total lipids were extracted with chloroform (CHCl₃) and methanol (MeOH) 1:1 by volume and purified from the lyophilized brain tissue using modifications of previously described procedures [12, 25, 26].

Column Chromatography

Neutral and acidic lipids were separated using DEAE-Sephadex (A-25, Pharmacia Biotech, Upsala, Sweden)

column chromatography as previously described [27]. The total lipid extract, suspended in $\text{CHCl}_3:\text{CH}_3\text{OH}:\text{dH}_2\text{O}$, 30:60:8 by volume (solvent A), was applied to a DEAE-Sephadex column (1.2 mL bed volume) that had been equilibrated prior with solvent A. The column was washed twice with 20 mL solvent A and the entire neutral lipid fraction, consisting of the initial eluent plus washes, was collected. This fraction contained cholesterol, phosphatidylcholine, phosphatidylethanolamine and plasmalogens, sphingomyelin, and neutral GSLs to include cerebrosides and asialo-GM2 (GA2). Next, acidic lipids were eluted from the column with 35 mL $\text{CHCl}_3:\text{CH}_3\text{OH}:0.8\text{ M Na acetate}$, 30:60:8 by volume.

Ganglioside Purification

The acidic lipid fraction containing gangliosides was dried by rotary evaporation and then partitioned to separate the acidic lipids into the lower organic phase and the gangliosides into the upper aqueous phase as previously described [25, 28, 29]. The amount of sialic acid in the ganglioside fraction was determined by the resorcinol assay and then the ganglioside fraction was further purified with base treatment and desalting, as previously described [24, 26].

Acidic Phospholipid Purification

After the ganglioside fraction (Folch upper phase) was transferred, the acidic phospholipid fraction (Folch lower phase) was evaporated under a stream of nitrogen and re-suspended in 10 mL of $\text{CHCl}_3:\text{CH}_3\text{OH}$ (1:1 by volume). This fraction contained fatty acids, cardiolipin, phosphatidylserine, phosphatidylinositol, and sulfatides.

Neutral Lipid Purification

Neutral lipids were dried by rotary evaporation and re-suspended in 10 mL $\text{CHCl}_3:\text{CH}_3\text{OH}$ (2:1 by volume). To further purify GA2, a 4 mL aliquot of the neutral lipid fraction was evaporated under a stream of nitrogen, base treated with 1 N NaOH, and Folch partitioned as described previously [26]. The Folch lower phase containing GA2 was evaporated under a stream of nitrogen and re-suspended in 5 mL $\text{CHCl}_3:\text{CH}_3\text{OH}$ (2:1 by volume).

High-Performance Thin-Layer Chromatography

All lipids were analyzed qualitatively by high-performance thin-layer chromatography (HPTLC) according to previously described methods [25–27, 30]. To enhance precision, an internal standard (oleoyl alcohol) was added to the neutral and acidic lipid standards and samples as

previously described [27]. Purified lipid standards were either purchased from Matreya Inc. (Pleasant Gap, PA, USA), Sigma (St Louis, MO, USA), or were a gift from Dr. Robert Yu (Medical College of Georgia, Augusta, GA, USA).

For gangliosides and GA2, the HPTLC plates were developed and visualized as previously described [26]. For neutral and acidic phospholipids, the plates were developed to a height of either 4.5 or 6 cm, respectively, with chloroform:methanol:acetic acid:formic acid:water (35:15:6:2:1 by volume), and then both were developed to the top with hexanes:diisopropyl ether:acetic acid (65:35:2 by volume) as previously described [27, 31]. Neutral and acidic phospholipids were visualized by charring with 3% cupric acetate in 8% phosphoric acid solution, followed by heating in an oven at 165 °C for 7 min. The percentage distribution and density of individual bands was determined as previously described [26]. Briefly, the HPTLC plates were scanned on a personal Densitometer SI with ImageQuant software (Molecular Dynamics) or on a ScanMaker 4800 with ScanWizard5 V 7.00 software (Microtek). The total brain ganglioside distribution was normalized to 100% and the percentage distribution values were used to calculate sialic acid concentration of individual gangliosides as we previously described [32]. The density value for GA2 was fit to a standard curve of known lipid concentration and used to calculate concentration. For the neutral and the acidic phospholipids, each lipid was normalized to an internal standard (oleyl alcohol) and its concentration was quantified using a standard curve of each respective lipid.

Statistical Analysis

All data were analyzed by the two-tailed Student's *t* test to calculate statistical significance between the normal and the SD samples using Statview 5.0 software.

Results

Our objective was to compare the lipid distribution in the cerebral cortex of mice, cats, and humans with Sandhoff disease, using our established lipid isolation procedures. The comparative lipid analysis, to include gangliosides and neutral and acidic phospholipids, was done in age-matched normal and SD mice and cats at their respective humane end-points. Although the samples were not collected at “identical” time points in disease progression, they were collected at “similar” time points. Since the SD human samples were collected during autopsy from diseased patients, we elected to collect tissue from the SD mice and

cats at a humane end-point to correlate our analysis with the human samples. The humane end point used for the mice was about 120 days [11]. The SD cat samples were collected from mid to terminal disease stage under the guidance of Auburn University's Institutional Animal Care and Use Committee. Disease progression in SD cats is stereotypical and is charted primarily by neuromuscular function. Disease onset begins at about 8 weeks with a slight head tremor, and the animal progressively loses ability to ambulate. Mid-disease is reached at about 12 weeks, when the animal has an unstable gait and falls occasionally. The humane endpoint occurs at approximately 20 weeks, when the animal can no longer walk or sit upright. Our study is the first to compare the total lipid distribution at a similar point in disease progression in mice, cats, and humans with Sandhoff disease.

The *Hexb* mutations in the mice and cats studied in this report generate similar levels of residual total hexosaminidase activity in brain, about 3% of normal levels in both models [9, 10, 19, 20]. While the mouse mutation is a targeted disruption of the *Hexb* gene after the 12th of 14 exons, the cat mutation results in a premature termination codon in exon 14. While we are uncertain whether the artificial 4MUG substrate used for enzyme assays reflects the true enzymatic activity toward native gangliosides, we consider that the mouse and cat mutations are functionally equivalent. Consequently, differences in ganglioside storage profiles are more likely due to inter-species differences in ganglioside metabolism than to differences in residual enzyme activity.

Gangliosides

The total brain ganglioside concentration in mice, cats, and humans is shown in Table 1. In general, the total brain ganglioside concentrations in the normal animals are relatively similar among species. While all of the SD brains have significantly elevated total brain ganglioside concentrations compared to normal, the percent increase in total brain ganglioside concentration was greatest in the SD human (337%), followed by the SD cat (262%), and then the SD mouse (162%). The quantitative and qualitative distribution of individual gangliosides in the mice, cats, and human with SD is shown in Fig. 1 and in Table 2. The most significant finding was that GM2 comprised 38, 67, and 87% of the total brain ganglioside distribution in the SD mice, cats, and human, respectively. While the percent distribution for GM1, GD1a, GT1a/LD1, GD1b, GT1b, and GQ1b in the SD mouse and the SD cat were significantly different than that of normal, these differences were not associated with significant changes in the concentration for each ganglioside. Although ganglioside GT1a/LD1 was not detected in the normal cats, GT1a/LD1 was present in the

SD cat. In addition, GQ1b concentration was significantly reduced in the SD cat compared to the normal cat. The concentration of all major gangliosides (GM1, GD1a, GD1b, GT1b, and GQ1b) was reduced in the SD patient compared to the normal human, and these results are consistent with previous findings [21, 22]. In our analysis, we also observed an elevation in GD3 and GT1a/LD1 in the SD human.

While GA2 was undetectable in the normal brains, GA2 accumulated in the SD brains (Table 3). Since GA2 is derived from GM2 through the action of a sialidase, we

^b Concentration expressed as µg sialic acid/100 mg dry weight

looked at the ratio of GA2–GM2 (µmol/100 mg dry weight) (Fig. 2). The ratio of GA2–GM2 was 0.93, 0.13, and 0.27 in the SD mice, cats, and humans, respectively. Interestingly, the ratio of GA2–GM2 was greatest in the SD mouse while this ratio was significantly less in the SD cat and human.

Neutral Lipids

The qualitative and quantitative distribution of the neutral brain lipids in mice, cats, and humans with Sandhoff disease (SD) is shown in Fig. 3 and Table 4. The concentration of cerebroside, (the myelin-enriched glycolipid), was significantly lower in the SD brains compared to the age-matched control brains. These findings are consistent

with previous reports of lower cerebroside in SD mice and humans [11, 21]. Although statistically significant, the reduction in cerebroside in the SD mice was less pronounced than in the SD cats and humans. No statistical differences were found between the normal and SD brains for the concentration of cholesterol, ceramide, phosphatidylethanolamine, and phosphatidylcholine. Since sphingomyelin co-migrated with GA2 in our HPTLC solvent system, we did not quantify the concentration of sphingomyelin in the SD brains.

Acidic Lipids

The qualitative and quantitative distribution of the acidic lipids in mice, cats, and human with Sandhoff disease (SD)

is shown in Fig. 4 and Table 4. The most noticeable difference in the acidic lipid distribution was the reduction in sulfatides, another myelin-enriched glycolipid, in the SD compared to normal. As with cerebroside, the SD cat represented an intermediate between the SD mice and the SD humans in terms of the reduction of sulfatides. The presence of some GM2 on the HPTLC plate in the SD samples resulted from lower phase carryover during isolation. No significant differences were observed between the normal and the SD groups for the distribution or content of cardiolipin, phosphatidylserine, and phosphatidylinositol. We further analyzed cerebroside and sulfatides in SD as a percent of normal (Fig. 5). The myelin lipids were present at trace levels in the SD humans compared to the normal humans, and the concentration of cerebroside and sulfatides in the SD mouse was about

Fig. 3 HPTLC of cortical neutral lipids in normal and Sandhoff disease mice (M), cats (C), and humans (H). The amount of neutral lipids spotted per lane was equivalent to approximately 70 µg brain dry weight. The plate was developed to a height of 4.5 cm with chloroform:methanol:acetic acid:formic acid:water (35:15:6:2:1 by volume), then developed to the top with hexanes:diisopropyl ether:acetic acid (65:35:2 by volume). The bands were visualized by charring with 3% cupric acetate in 8% phosphoric acid solution. CE cholesterol esters, TG triglycerides, IS internal standard, Chol cholesterol, CM ceramide, CB cerebroside (doublet, indicated by arrow), PE phosphatidylethanolamine, PC phosphatidylcholine, SM sphingomyelin, GA2 asialo GM2, LPC lyso-phosphatidylcholine

58 and 76%, respectively, of that in the normal mouse. Interestingly, the concentration of cerebroside and sulfatides in the SD cat was about 11 and 14%, respectively, of that in the normal cat. Thus, the lipid profile in the SD cat brain is intermediate to the SD mice and the SD humans in terms of GM2 and GA2 storage, as well as the reduction in cerebroside and sulfatides.

Discussion

Our results show for the first time the comparative analysis of brain lipids in mice, cats, and humans with SD. In contrast to a previous study, which showed that GM2 was about 42% of the total brain ganglioside distribution in the SD cat, we show that GM2 accounts for 67% of the total ganglioside distribution in the SD cat [19]. The ganglioside distribution in the SD cat in the previous study was analyzed at an earlier age (11 weeks), which could account for

the lower GM2 distribution [19]. For our study, we analyzed the total brain ganglioside distribution at a similar time-point in disease progression in the SD mouse, cat, and human, and we showed that GM2 accumulation in the SD cat is intermediate between the SD mouse and the SD patient. In addition, we also observed an increase in GD3 in the SD human, suggesting an increase in reactive gliosis, perhaps as a result of disease progression [33]. The degree of GM2 accumulation in the SD patient compared to the SD mouse poses a major hurdle in developing therapy, and our results suggest that the SD cat is an appropriate intermediate model to study.

In addition to GM2, GA2 was also a major storage material in the SD brain of all the species [2, 11, 12, 20, 21]. The role of GA2 in disease progression is unclear. It is interesting to note, however, that GA2 is unlikely the primary cause of pathogenesis and neurodegeneration in GM2 gangliosidosis, since GA2 accumulation in Tay-Sachs disease is much less than in SD [2, 21]. Also, pathology in GM1 and GM2 retina was associated more with ganglioside accumulation than with accumulation of asialo-gangliosides [44]. The ratio of GA2–GM2 storage was greater in the SD mouse than in the SD cat or patient. Previous studies showed that sialidase activity is more active in SD mice than in humans and is able to convert significant amounts of GM2 to GA2 [20, 34–36]. Our results suggest that the activity of the feline sialidase is more similar to the human sialidase than to the mouse sialidase.

Fig. 5 Cortical concentration of cerebrosides and sulfatides as a percentage of normal in Sandhoff disease mice ($N = 3$), cats ($N = 4$), and humans ($N = 2$). Values shown are means \pm SEM, except for

the Human Sandhoff samples, where values are means \pm interquartile range. Trace amounts of cerebrosides and sulfatides were detected in the SD human samples

In addition to abnormal GSL storage, pathogenesis in lysosomal storage diseases is also associated with dysmyelination [21, 37–39]. Reductions in the myelin-enriched lipids, cerebrosides and sulfatides were shown in the SD mice and in patients with GM2 gangliosidosis [11, 21, 40]. Magnetic resonance imaging analysis also revealed significant white matter changes in the brains of patients and in animal models of GSL storage disorders [37–39, 41, 42]. Furthermore, low angle X-ray diffraction analysis showed hypomyelination in the optic nerves of SD mice [43]. These findings together suggest that the abnormal accumulation of GSLs may influence myelin and that dysmyelination may also contribute to disease progression. Our results showed that the myelin-enriched lipids, cerebrosides and sulfatides are significantly reduced in SD compared to normal. We also found that cerebrosides and sulfatides were significantly reduced in the SD cat compared to the normal cat. Like GM2 accumulation, the reductions in the myelin-enriched lipids in the SD cat were intermediate to that observed in the SD mouse and human.

It is interesting to note that disease onset and eventual death in the SD cats also occur intermediate to these milestones in the SD mice and patients. The SD mice begin to display phenotypic abnormalities at around 12 weeks of age and are humanely euthanized at 16 weeks of age [11, 20]. The onset of disease in the SD mice occurs after sexual maturation, and as a result, the SD mice are able to reproduce [11]. However, behavioral dysfunction is first detected in the SD cats at 6–8 weeks of age and in the SD patient at around 24 weeks of age [2, 19]. The SD cat and patient both succumb to the disease prior to reproduction. Our results show that GM2 storage is greater in SD humans and cats than in SD mice, but that GA2 storage is relatively greater in SD mice than in SD humans and cats. As much of the current progress has been limited to studies in mice, our results suggest that feline SD could be an important model to test and develop potential therapies for patients and could help translate the therapeutic success seen in mice to treatment in humans.

Acknowledgments We acknowledge the NICHD Brain and Tissue Bank for Developmental Disorders at the University of Maryland, Baltimore (NICHD contract # N01-HD-4-3368 and N01-HD-4-3383) for the human tissue samples. This work was supported in part from NIH grant (NS055195), the National Tay-Sachs and Allied Disease Association, and from the Lysosomal Storage Disease Research Consortium.

Abstract Lipoxygenases (LOX; linoleate:oxygen oxidoreductase EC 1.13.11.12) consist of a class of enzymes that catalyze the regio- and stereo specific dioxygenation of polyunsaturated fatty acids. Here we characterize two proteins that belong to the less studied class of 9-LOXs, *Solanum tuberosum* StLOX1 and *Arabidopsis thaliana* AtLOX1. The proteins were recombinantly expressed in *E. coli* and the product specificity of the enzymes was tested against different fatty acid substrates. Both enzymes showed high specificity against all tested C18 fatty acids and produced (9*S*)-hydroperoxides. However, incubation of the C20 fatty acid arachidonic acid with AtLOX1 gave a mixture of racemic hydroperoxides. On the other hand, with StLOX1 we observed the formation of a mixture of products among which the (5*S*)-hydroperoxy eicosatetraenoic acid (5*S*-H(P)ETE) was the most abundant. Esterified fatty acids were no substrates. We used site directed mutagenesis to modify a conserved valine residue in the active site of StLOX1 and examine the importance of space within the active site, which has been shown to play a role in determining the positional specificity. The Val576Phe mutant still catalyzed

the formation of (9*S*)-hydroperoxides with C18 fatty acids, while it exhibited altered specificity against arachidonic acid and produced mainly (11*S*)-H(P)ETE. These data confirm the model that in case of linoleate 9-LOX binding of the substrate takes place with the carboxyl-group first.

Introduction

Lipoxygenases (LOX) are a family of non-heme iron containing fatty acid dioxygenases that catalyze the insertion of molecular oxygen into polyunsaturated fatty acids containing a (1*Z*,4*Z*)-pentadiene system to produce

hydroperoxides in a regio- and stereo specific manner [1]. One mode of classification of plant LOX is based on the structural features of the proteins and specifically the presence or absence of an amino-terminal plastidic transit peptide, which directs the nascent protein to the plastid. Enzymes are separated into type 1-LOX, which consist of enzymes with high sequence similarity (~75%) and no plastidic transit peptide and type 2-LOX which carry a transit peptide sequence and show only moderate sequence similarity (~35%) [2]. A second, more common way classifies the enzymes according to the positional specificity of oxygen insertion into C18 fatty acids in 9- and 13-LOX [2], while mammalian LOX may be classified

according to the oxygenation of C20 fatty acids in arachidonate 5-, 8-, 9-, 11-, 12- or 15-LOX [1] (Fig. 1).

Two models have been used in order to describe the positional specificity of LOX. Based on data from mammalian LOX, the space-related hypothesis was established, according to which, the fatty acid penetrates the active site with its methyl end first and the depth of the substrate-binding pocket determines the site of hydrogen abstraction and position of oxygen insertion [3, 4]. In the case of plant LOX, the orientation-related hypothesis has been suggested, according to which, in 13-LOX, the substrate enters the active site with the methyl end first. In this class of enzymes, a phenylalanine or a histidine aligning with the so called

Fig. 1 Phylogenetic analysis of certain plant LOX. The circles indicate the grouping of the enzymes into subcategories. The analysis was performed with PHYLIP 3.5, and the proteins mentioned in the tree refer to the corresponding accession numbers in the gene bank. For clarification, within the tree only sequences from distinct plant species have been included and have been partially renamed according to the nomenclature of [43]: *Arabidopsis thaliana*: LOX1:At:1 (AtLOX1, Q06327), LOX2:At:1 (AtLOX2, P38418), LOX2:At:2 (AtLOX3, AAF79461), LOX2:At:3 (AtLOX4, AAF21176), LOX1:At:2 (AtLOX5, CAC19365), LOX2:At:4 (AtLOX6, AAG52309); *Glycine max*: LOX1:Gm:1 (Soybean LOX1, AAA33986), LOX1:Gm:2 (Soybean LOX2, AAA33987), LOX1:Gm:3 (Soybean LOX3, CAA31664), LOX1:Gm:4 (Soybean vlxa, BAA03101), LOX1:Gm:5 (Soybean vlxb, AAB67732),

LOX1:Gm:6 (Soybean vlxc, AAA96817), LOX1:Gm:7 (Soybean vlxd, S13381); *Lycopersicon esculentum*: LOX1:Le:1 (tom-LOXA, P38415), LOX1:Le:2 (tomLOXB, P38416), LOX1:Le:3 (tomLOX-tox, AAG21691), LOX2:Le:1 (tomLOXC, AAB65766), LOX2:Le:2 (tomLOXD, AAB65767); *Nicotiana tabacum*: LOX1:Nt:1 (NtLOX, S57964); *Solanum tuberosum*: LOX1:St:1 (SOLTULOX1, S44940), LOX1:St:2 (STLOX, AAD09202), LOX1:St:3 (StLOX1, P37831), LOX1:St:4 (CAA64766), LOX1:St:5 (CAA64765), LOX1:St:6 (POTLX-2, AAB67860) LOX1:St:7 (POTLX-3, AAB67865), LOX1:St:8 (POTLX-1, AAB67858), LOX1:St:9 (AAD04258), LOX1:St:10 (pLOX2, AAB81595), LOX1:St:11 (pLOX1, AAB81594), LOX1:St:12 (CAB65460), LOX2:St:1 (StLOXH1, CAA65268), LOX2:St:2 (St-LOXH3, CAA65269)

“Sloane determinants” controls the depth of the enzyme active site (Table 1). In 9-LOX the amino acid aligning with this position is usually a less space-filling valine residue. It is suggested that the presence of the smaller amino acid demasks a positively charged arginine residue, the so-called “Hornung determinant”, at the bottom of the substrate pocket, which can stabilize an insertion of the substrate with the carboxylic group first in the active site pocket leading to a preferable oxygen insertion in position 9 [5].

The molecular determinants of stereo specificity of the LOX reaction have been the focus of a number of recent studies [6]. These studies have highlighted the importance of a single amino acid residue, which is a conserved alanine in *S*-specific LOX and a glycine in the case of *R*-LOX. Conversion of the glycine of an *R*-LOX to an alanine and vice versa has been successful in partially switching the position of oxygenation and chirality of the product of the enzymatic reaction, for example converting a (13*S*)- into a (9*R*)-LOX enzyme [7]. Based on recent mutagenesis data obtained for a LOX from *Anabeana* sp. PCC 7120, the existing model for stereo control of the LOX reaction may be expanded for enzymes that seem to have in general a bulkier amino acid in *S*-LOX at this position that controls stereospecificity [8, 9].

Plant LOX are involved in a variety of processes of plant growth and development, e.g. through the mobilization of storage lipids during germination [10]. Furthermore, a class of these enzymes is thought to function as nitrogen storage proteins during vegetative growth [11]. Another important function of LOX secondary products, such as jasmonic acid, is their crucial role in defense responses against wounding and pathogen attack [12].

In most plant species, LOX are encoded by gene families, composed of a number of isozymes, differing in the position of substrate oxygenation, substrate specificity and kinetic parameters [13]. These enzymes are also often spatially and temporarily differentially expressed [14].

A relatively simple LOX family exists in *Arabidopsis thaliana*. It contains six putative lipoxygenase sequences

(AtLOX1-6) [2]. So far, physiological functions of four of these enzymes, AtLOX1 (*lox1:At:1*), AtLOX2 (*lox2:At:1*) AtLOX3 (*lox2:At:2*) and AtLOX4 (*lox2:At:3*) have been described, but biochemical characterization has still to take place. AtLOX1 has been previously described to be expressed in various organs of the plant and upregulated in response to pathogen attack [15], while AtLOX2 is expressed upon wounding [16]. AtLOX3 and AtLOX4 have been discussed to be involved in leaf senescence [17]. Based on sequence determinants and homology AtLOX1 (*lox1:At:1*) is postulated to harbor 9-LOX activity, whereas AtLOX2-4 may harbor 13-LOX activity (Table 1; Fig. 1).

In potato, a number of LOX cDNAs have been isolated from tubers, roots and leaves [18–24]. LOX belong to the group of genes that have been shown to be expressed early during potato tuber formation [22, 24], and LOX secondary products, such as jasmonic acid and its derivative tuberonic acid, have been shown to induce tuberization in vitro [25, 26]. Interestingly, the most abundant LOX activity detected was of 9-positional specificity and this activity increases upon wounding [27].

Our studies focus on two type 1-LOX, StLOX1 (*lox1:St:3*) and AtLOX1. StLOX1 is a LOX from potato tubers [19], which has a pH-optimum between pH 5.5 and 7.5, uses linoleic [18:2(n-6)] and α -linolenic acid [18:3(n-3)] preferentially, but can also use arachidonic acid [20:4(n-6)] as substrate. The later is converted primarily to 5-H(P)ETE. The specificity of this reaction is however lower than in the case of mammalian arachidonate 5-LOX [28]. AtLOX1 also belongs to the same class of enzymes, but its product specificity with C18 and C20 fatty acids has yet to be investigated. A comparison of the determinants of positional specificity of characterized LOX enzymes with *lox1:St:3* indicates that both enzymes carry the typical determinants of 9-LOX, namely a threonine and a valine (Table 1). In order to obtain a better insight into the factors determining the positional specificity of 9-LOX, we overexpressed the recombinant enzymes, investigated the enzymatic activity

Table 1 Alignment of amino acid residues possibly determining the positional specificity of plant and moss LOX

Enzyme	Acc. no.	Position of amino acid residues	Amino acid residues
9-LOX			
<i>Solanum tuberosum</i> StLOX1	P37831	575/576	Thr/Val
<i>Arabidopsis thaliana</i> AtLOX1	Q06327	576/577	Thr/Val

<i>Arabidopsis thaliana</i> AtLOX2	P38418	611/612	Cys/Phe
<i>Physcomitrella patens</i> PpLOX	CAE47464	654/655	His/Phe

with different substrates and generated and characterized a mutant of potato tuber LOX, where the typical Val determinant of 9-LOX has been exchanged for a Phe, which alters the specificity of the enzyme against arachidonic acid.

Experimental Procedures

The chemicals used were from the following sources: standards of chiral and racemic hydroxy fatty acids from Cayman Chem. (Ann Arbor, MI, USA), trilinolein and triarachidonin from Sigma (Deisenhofen, Germany), 1,2-diarachidonoyl-*sn*-glycero-3-phosphatidylcholine from Larodan (Malmo, Sweden); methanol, hexane, 2-propanol (all HPLC grade) from Baker (Griesheim, Germany). Restriction enzymes were purchased from MBI Fermentas (St Leon-Rot, Germany).

Site-Directed Mutagenesis

As a template for site directed mutagenesis plasmid pET-stLOX1 was used, consisting of the potato tuber LOX [19] in pET3b (Novagen, Germany). Mutagenesis was carried out by using the QuikChange site-directed mutagenesis kit (Stratagene, Heidelberg, Germany). The oligonucleotides used for mutagenesis contained apart from the appropriate base changes additional conservative base exchanges which either created new restriction sites or deleted existing ones for simplified identification of mutants. The following oligonucleotides were used: stLOX-V576Fa 5'-GGTGGGGTTCTTGAGAGTACATTCTTTCCTTCGA AATTTGCCATGGAAATGTCAG-3'; stLOX-V576Fb 5'-CGTACATTTCCATGGCAAATTTTCGAAGGAAAGA ATGTACTCTCAAGAACCCACC-3'. In addition all mutations were sequenced and at least three different bacterial colonies were expressed and used for analysis of enzymatic parameters.

Protein Expression and LOX Activity Assay

For expression analysis StLOX1 containing plasmids and pBS-SK-*AtLOX1* (ABRC clone H3C1T7) were transferred into *E. coli* strain BL21(De3) Star (Novagen, Germany). Thirty millilitre cultures were grown at 37 °C to an OD₆₀₀ of 0.6, induced with 1 mM IPTG and cultivated further at 16 °C for 48 h. Cells were harvested by centrifugation at 4 °C at 4,000×*g* resuspended in 5 ml lysis buffer [50 mM Tris-HCl, pH 7, 300 mM NaCl, 10% (v/v) glycerol, 0.1% (v/v) Tween 20] and lysed by sonification. Nine-hundred microliters of lysate was incubated with 250 µg of the respective fatty acids for 30 min at RT, the resulting hydroperoxides were reduced with 2.5 mg tin(II) chloride in methanol, acidified with glacial acetic acid to pH 3 and lipids were extracted by the

method of Bligh and Dyer [29]. Analysis of the fatty acids was performed on a HPLC (see below).

The activity of StLOX1 with trilinolein or triarachidonin was measured by incubating 900 µl lysate with 1 mg of the respective substrate under constant shaking for 30 min at room temperature. In order to test activity against 20:4-PC, 0.6 mg of substrate were incubated with the enzyme in 5 ml buffer (50 mM Tris pH 7, 4 mM sodium deoxycholate) under constant stirring in RT. In both cases reduction of the hydroperoxides was carried out as described above. The lipid bound fatty acids were then converted to the corresponding methyl esters by adding 500 µl of 1% sodium methoxide solution in methanol to the dried samples after chloroform evaporation and shaken for 20 min at room temperature. Five-hundred microliters of 6 M NaCl was added to the reaction and the methyl esters were then extracted twice with 750 µl hexane. The solvent was removed by evaporation under a stream of nitrogen and the sample was dissolved in 80 µl of methanol/water/acetic acid (85:15:0.1, v/v/v).

Analytics

High performance liquid chromatography (HPLC) analysis was carried out on an Agilent (Waldbronn, Germany) 1100 HPLC system coupled to a diode array detector. Reversed phase-HPLC (RP-HPLC) of the free fatty acid derivatives was carried out on a Nucleosil C-18 column (Macherey-Nagel, Düren, FRG; 250 × 2 mm, 5 µm particle size) with a solvent system of methanol/water/acetic acid (90/10/0.1, v/v/v) and a flow rate of 0.18 ml/min. The absorbance at 234 nm (conjugated diene system of the hydroxy fatty acids) and 210 nm (polyenoic fatty acids) were recorded simultaneously. Straight phase-HPLC (SP-HPLC) of hydroxy fatty acid isomers was carried out on a Phenomenex Luna Silica column (Aschaffenburg, Germany; 50 × 4.6 mm, 3 µm particle size) with a solvent system of *n*-hexane/2-propanol/trifluoroacetic acid (100/1/0.1, v/v/v) and a flow rate of 0.2 ml/min. The enantiomer composition of the hydroxy fatty acids (C18) was analyzed by chiral phase-HPLC (CP-HPLC) on a Chiralcel OD-H column (Diacel Chem. Industries, distributed by Merck, Darmstadt, Germany; 150 × 2.1 mm, 5 µm particle size) with a solvent system of hexane/2-propanol/trifluoroacetic acid (100/5/0.1, v/v/v) and a flow rate of 0.1 ml/min. For separation of chiral isomers of 12, 15, 11 and 8 hydroxy eicosatetraenoic acid (HETE) a solvent system of hexane/2-propanol/trifluoroacetic acid (100/2/0.1, v/v/v) was used. 5-HETE stereo isomers were analyzed using a solvent system of *n*-hexane/2-propanol/trifluoroacetic acid (100/1/0.1 v/v/v) at a flow rate of 0.2 ml/min. Methyl esters were separated by RP-HPLC with a solvent system of methanol/water/acetic acid (75:25:0.1, v/v/v) at a flow rate of 0.18 ml/min.

SP-HPLC analysis was carried out with a solvent system hexane: 2-propanol: trifluoro acetic acid (100:1:0.1, v/v/v) at a flow rate of 0.1 ml/min.

Phylogenetic Analysis

Phylogenetic tree analysis was performed on deduced amino acid sequences of selected LOX by using PHYLIP3.5 (Department of Genome Sciences, University of Washington) [30] using default parameters.

Results

Our studies aim was to analyze the substrate specificity of two putative 9-LOX, StLOX1, a LOX from potato tubers [19] and AtLOX1 (*lox1:At:1*), a LOX expressed in *Arabidopsis* leaves, roots inflorescences and young seedlings [31]. In order to characterize their regio- and stereospecificity, we overexpressed the enzymes in *E. coli* and investigated the enzymatic activity with different substrates. Moreover we generated and characterized a mutant that alters the specificity of StLOX1.

Product Analysis of StLOX1 and AtLOX1

For product analysis, crude cell extracts of *E. coli* expressing StLOX1 were incubated with 250 μ g of 18:2(n-6), 18:3(n-3), γ -linolenic acid [18:3(n-6)], and 20:4(n-6), respectively, and the reduced products were analyzed by HPLC. *E. coli* cell extracts expressing AtLOX1 were likewise incubated with 18:2(n-6), 18:3(n-3) and 20:4(n-6) and products were analyzed. When 18:2(n-6) was used as substrate StLOX1 produced 9-hydro(pero)xy octadecadienoic acid [9-H(P)ODE, 98%] with almost exclusively *S* stereo configuration (Fig. 2a). Racemic 13-H(P)ODE was only a minor byproduct. Correspondingly, 94% 9-H(P)ODE of primarily *S* configuration was the main product of 18:2(n-6) incubation with AtLOX1 (Fig. 3a; Table 2). 18:3(n-3) is converted in a comparable manner to 9-hydro(pero)xy octadecatrienoic acid [9-H(P)OTE; 94%], mainly of the *S* enantiomer by both enzymes (Figs. 2b, 3b; Table 2). Racemic 12-, 13- and 16-H(P)OTE were only minor byproducts. Similarly, upon incubation of StLOX1 with 18:3(n-6), the main product was (9*S*)- γ -H(P)OTE (72%), with racemic 6-, 10- and 13- γ -H(P)OTE as secondary products (Fig. 2c). The two enzymes, however,

chiral products by CP-HPLC is shown in the insets. Enzyme preparations of StLOX1 were incubated with their respective substrates at pH 7

Fig. 3 SP-HPLC analysis of products formed by wt AtLOX1 incubated with **a** 18:2(n-6), **b** 18:3(n-3) and **c** 20:4(n-6) (here in their reduced form). The separation of the enantiomers of chiral products by CP-HPLC is shown in the insets. Enzyme preparations of AtLOX1 were incubated with their respective substrates at pH 7

exhibited different product specificity when 20:4(n-6) was used as substrate. AtLOX1 exhibited notably decreased enzymatic activity against 20:4(n-6) in comparison to the tested C18 substrates as estimated by RP-HPLC analysis of products formed when a mixture of substrates was applied (data not shown). In addition the C20 fatty acid was

Table 2 Products formed from the reaction of wt AtLOX1 with various fatty acid substrates

Substrate	Products	Ratio (%)	S enantiomer (%)
18:2(n-6)	13/9-HOD	10:90	49:94
18:3(n-3)	13/16/12/9-HOT	1:1:4:94	49:51:47:98
20:4(n-6)	15/12/11/9/8/5-HETE	44:11:13:9:9:14	50:53:53:50:48:NA

NA not analyzed

converted into a mixture of racemic products of comparable amounts (Fig 3c; Table 2). On the other hand, StLOX1 converted 20:4(n-6) into a mixture of three major products, 5-H(P)ETE (43%), 11-H(P)ETE (26%) and 8-H(P)ETE (23%). Chiral analysis of the fatty acid hydroperoxides by CP-HPLC revealed that the main products, 5-, 11- and 8-H(P)ETE are primarily of the typical S configuration. Minor amounts of racemic 12-H(P)ETE, 15-H(P)ETE and 9-H(P)ETE could also be detected (Fig 2d).

Additionally, we tested the activity of StLOX1 against a number of esterified fatty acids as substrates. Trilinolein and triarachidonin were used as substrates under the conditions described for the cucumber lipid body LOX, CslbLOX [5], while 1,2-diarachidonoyl-*sn*-glycero-3-phosphatidylcholine, as has been described for other LOX enzymes [8, 9]. We could not observe activity against any of the substrates, which suggests that binding of the substrate takes place with the carboxyl-group first.

Mutagenesis of Positional Determinants Identified from Other LOX Isoforms

Mutagenesis studies on LOX identified that among plant enzymes, one conserved amino acid, bulky in the case of 13-LOX and smaller in the case of 9-LOX (Table 1), plays a crucial role in determining the positional specificity of the product. In the case of StLOX1, the amino acid aligning with this residue is the widely conserved among 9-LOX valine (V576). In order to investigate the influence of these residues on StLOX1, we introduced the more space filling phenylalanine at this position. This resulted in a pair of residues, similar to the ones found in the active site of sLOX-1, a 13-LOX from soybean (Table 1). Subsequently, we tested the specificity of the mutant obtained with the same substrates as the wt. 18:2(n-6), 18:3(n-3) and 18:3(n-6) were converted, in a comparable manner as the wt, primarily into their respective 9-hydroperoxides (data not shown). Interestingly, conversion of valine to a phenylalanine resulted in a shift of the major oxygenation product specificity from 5-H(P)ETE in the wt enzyme to 11-H(P)ETE (55%) in the mutant. Significant amounts of 8-H(P)ETE, comparable to the wt, were also formed (22%), while 12-H(P)ETE, 15-H(P)ETE, 5-H(P)ETE were only

V576F	4 (57)	9 (53)	55 (100)	22 (92)	10 (NA)

NA not analyzed

present in smaller amounts ($\leq 10\%$; Table 3). 9-H(P)ETE could only be detected in traces. Chiral analysis of the hydroperoxides revealed chirality of 11-H(P)ETE and 8-H(P)ETE in *S* configuration while 15-H(P)ETE and 12-H(P)ETE were racemic (Fig. 4). The amounts of 5-H(P)ETE and 9H(P)ETE were too low for CP analysis.

Discussion

In this study we aimed to characterize the product specificity of two predicted 9-LOX, a LOX from potato tubers

and a LOX from *Arabidopsis*. For this purpose, we analyzed the LOX reaction products after incubation of the recombinantly expressed proteins with different fatty acid substrates. We also performed mutagenesis studies on StLOX1 and altered one of the residues, which has been reported to play a role in determining the positional specificity of LOX.

StLOX1 could convert all tested C18 fatty acids, 18:2(n-6), 18:3(n-3) and 18:3(n-6), to the corresponding (9*S*)-hydroperoxides with high specificity. Similar results have been previously observed for other analyzed potato tuber LOX [24, 32]. AtLOX1 showed comparably high specificity against the C18 fatty acids 18:2(n-6) and 18:3(n-3). These 9-hydroperoxides can be further metabolized by enzymes, such as the hydroperoxide reductase, divinyl ether synthase and epoxy alcohol synthase to yield epoxy alcohols and divinyl ethers among other products [33]. The function of the 9-LOX-derived products is still unclear, but they have been implicated in responses against biotic and abiotic stress. One possibility is that they confer resistance against pathogen attack. For example, LOX pathway products accumulate in potato leaves when they are under *P. infestans* infection [34]. Additionally, upregulation of 9-LOX transcripts has been observed upon wounding [19]. Similarly, in *Arabidopsis*, AtLOX1 has been reported to be induced by the stress-related hormones abscisic acid and methyl jasmonate and pathogen attack [31]. Another postulated function of 9-hydroperoxide derivatives is in potato that they may play a role in tuber growth regulation [35].

Additionally, we analyzed the metabolism of 20:4(n-6) by AtLOX1 and StLOX1. AtLOX1 did not demonstrate any specificity against the C20 fatty acid, since a mixture of racemic products was obtained. LOX often show decreased specificity when the protein in the reaction is in limiting amounts. However, we incubated the protein with a mixture of substrates and C18 fatty acids were converted into chiral products while C20 fatty acids were not. Therefore, this explanation seems unlikely. There are no previous reports on the product specificity of *Arabidopsis* lipoxygenases with 20:4(n-6), so it appears that this fatty acid may not be a substrate for AtLOX1. On the other hand, potato tuber LOX have been studied for many years as a model for 5-LOX activity [36, 37]. In the case of StLOX1, 5-H(P)ETE was the main reaction product, while 11-H(P)ETE and 8-H(P)ETE were also produced in

Fig. 4 SP-HPLC analysis of products formed by **a** wt StLOX1 and **b** V576F “Sloane” mutant enzyme with 20:4(n-6) as substrate (here in their reduced form for SP-HPLC analysis). Enzyme preparations of wt and Val → Phe (V576F) were incubated with 20:4(n-6) at pH 7

significant amounts. For 5-H(P)ETE production a hydrogen atom is abstracted from the C7 carbon atom of 20:4(n-6). The resulting carbon-centered radical intermediate undergoes rearrangement in the (n-2) position and in a final step, oxygen is inserted at C5. Similarly, 11-H(P)ETE and 8-H(P)ETE are the result of hydrogen abstraction at C13 and C10, respectively and a subsequent introduction of oxygen in the (n-2) position. The relatively low specificity of the first step of the LOX reaction suggests that binding of the substrate in the active site is more flexible in comparison to C18 fatty acids, allowing in the case of 20:4(n-6) abstraction of hydrogen atoms from different carbon atoms in comparison to C18 substrates, where in all cases the hydrogen atom of C11 is preferentially abstracted. The percentages of product formation are similar to the ones reported for the tomato enzyme [38]. The relative amount of 5-H(P)ETE is smaller though than the ones reported from a previously characterized potato tuber LOX [39] and a barley isozyme [40]. Chiral phase analysis showed that the hydroperoxides were of *S*-configuration. Similar results have been reported from other analyses of 5-hydroperoxides from plant enzymes [38, 40].

Regarding the substrate binding in the active site of StLOX1, the fact that no reaction products could be observed with trilinolein and triarachidonin or 1,2-di-arachidonoyl-*sn*-glycero-3-phosphatidylcholine supports that the fatty acids can only bind with their carboxyl group first. This is a similar mode of binding as has been previously suggested for 9-LOX [41, 42].

In addition the product specificity of a StLOX1 mutant in which a valine residue aligning with one of the “Sloane” determinants was exchanged against a bulkier phenylalanine was examined. Remarkably, this exchange did not influence the product specificity of the enzyme, when C18 fatty acids were used as substrates. According to the existing models, the residue in question is in close proximity to an arginine residue positioned on the bottom of the active site pocket. In 13-LOX the phenylalanine is thought to shield the positive charge of this arginine and lead to a preferential entry of the fatty acid with the methyl group first, leading to oxygenation at position C13 [5]. However, our data on StLOX1 suggest that the valine to phenylalanine exchange may not be sufficient to change the product specificity of C18 fatty acid conversion for this enzyme and therefore does not alter the favored substrate orientation in the active site of the enzyme. When the mutant enzyme, however, was incubated with 20:4(n-6) we observed an altered specificity, namely 11-H(P)ETE was the main product. This change suggests that inserting a bulky amino acid at the bottom of the active site pocket influences at least the alignment of the bulkier fatty acid 20:4(n-6) in the active site, although the substrate orientation is not altered either. In summary our data support the

previously suggested active site model that in case of 9-LOX the substrate binds with its carboxyl-group first that seem to be the natural substrates of these enzymes.

Abstract Many reports have shown the beneficial effects of consumption of pine seeds and pine seed oil. However, few studies have examined the biological effect of pinolenic acid (PNA; $\Delta 5,9,12-18:3$), the main fatty acid in pine seed oil. In this study, using murine macrophage RAW264.7 cells as a model, we examined the effect of PNA on polyunsaturated fatty acid (PUFA) metabolism, prostaglandin (PG) biosynthesis and cyclooxygenase-2 (COX-2) expression. Results showed that PNA was readily taken up, incorporated and elongated to form eicosatrienoic acid (ETrA, $\Delta 7,11,14-20:3$) in macrophage cells. A small portion of this elongated metabolite was further elongated to form $\Delta 9,13,16-22:3$. The degree of incorporation of PNA and its metabolites into cellular phospholipids varied with the length of incubation time and the concentration of PNA in the medium. Incubation of PNA also modified the fatty acid profile of phospholipids: the levels of 18- and 20-carbon PUFA were significantly decreased, whereas those of 22-carbon fatty acids increased. This finding suggests that PNA enhances the elongation of 20-carbon fatty acids to 22-carbon fatty acids. The syntheses of PGE₁

from dihomo- γ -linolenic acid (DGLA, $\Delta 8,11,14-20:4$) and PGE₂ from arachidonic acid (ARA, $\Delta 5,8,11,14-20:4$) were also suppressed by the presence of PNA and its metabolite. As the expression of COX-2 was not suppressed, the inhibitory effect of PNA on PG activity was attributed in part to substrate competition between the PNA metabolite (i.e., $\Delta 7,11,14-20:3$) and DGLA (or ARA).

Introduction

Pine seed and pine seed oil (PSO) have been consumed for years by the general public in many parts of the world. Several animal studies have shown that PSO supplementation lowers blood lipids, reduces blood pressure and affects lipoprotein metabolism [1–4]. However, the mechanism as to how PSO exerts these beneficial effects is still not fully understood. Pinolenic acid (PNA, $\Delta 5,9,12-18:3$) is the main fatty acid present in PSO. It is a rare n-6 octadecatrienoic acid, belonging to a group of non-methylene-interrupted polyunsaturated fatty acids (NMIFAs). Its chemical structure is very similar to its positional isomer, gamma-linolenic acid (GLA; $\Delta 6,9,12-18:3$). Previously, GLA supplementation has been demonstrated to exert beneficial effects, such as lowering inflammation-related diseases [5, 6], hypertension and other chronic diseases [7, 8]. In mammals, dietary GLA is rapidly elongated to form dihomo- γ -linolenic acid (DGLA; $\Delta 8,11,14-20:3$) [9, 10], a precursor of anti-inflammatory eicosanoid, prostaglandin E_1 (PGE_1). DGLA competes with arachidonic acid (ARA; $\Delta 5,8,11,14-20:4$) as substrate for cyclooxygenase-2 (COX-2), and subsequently reduces the synthesis of pro-inflammatory prostaglandins [11]. Thus, the effect of GLA was exerted through modulation of n-6

PUFA metabolism and eicosanoid synthesis (Scheme 1, [12]). Similar to GLA, PNA can also be elongated by the fatty acid chain elongation system (FACES) in rat liver microsomes and human hepatoma HepG2 cells to form eicosatrienoic acid (ETrA, $\Delta 7,11,14-20:3$) [10, 13]. It has also been shown that ETrA, similar to its isomer DGLA ($\Delta 8,11,14-20:3$), could substitute ARA for incorporation into cellular phospholipid fractions [13]. Therefore, the present study, using murine macrophage-like RAW264.7 cells as a model, was carried out to examine whether PNA and/or its metabolites affect the polyunsaturated fatty acid (PUFA) metabolism and prostaglandin production.

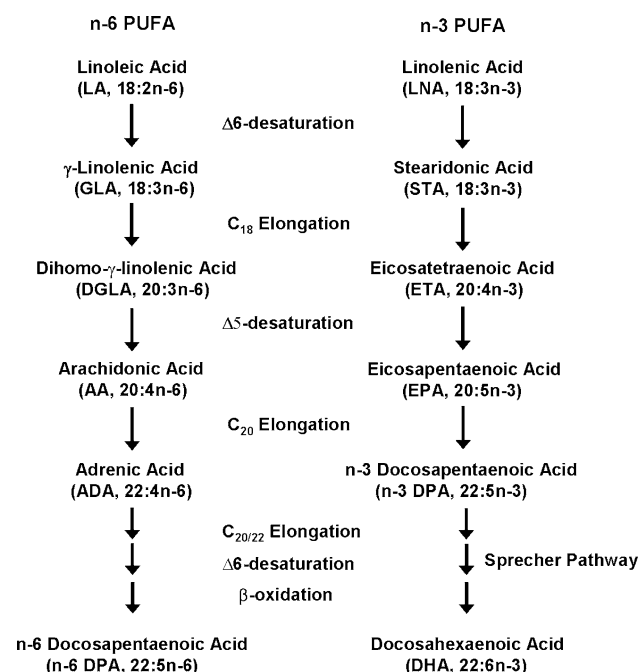

Experimental Procedures

Chemicals

Authentic fatty acids, i.e., PNA, ARA and n-3 eicosatetraenoic acid (n-3 ETA, $\Delta 8,11,14,17-20:4$) and PGE_2 assay kit were obtained from Cayman Chemicals (Ann Arbor, MI). GLC standard RL-461, triheptadecanoin, and DGLA were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). Lipopolysaccharide (LPS, from *Escherichia coli* 026:B6), dimethyl sulfoxide (DMSO), cell proliferation kit, Tween-20, protease inhibitors were supplied by Sigma Chemical (St. Louis, MO). Dulbecco's modified Eagles medium (DMEM), fetal bovine serum (FBS) and phosphate-buffered saline (PBS) were obtained from Gibco (Carlsbad, CA). PGE_1 assay kit was purchased from Assay Designs, Inc. (Ann Arbor, MI). All reagent-grade organic solvents were from Burdick & Jackson (Muskegon, MI).

Cell Culture and Culture Conditions

The murine macrophage RAW 264.7 cell line was obtained from the Bioresource Collection and Research Center (Hsinchu, Taiwan). Cells were maintained in DMEM medium supplemented with 10% heated-inactivated FBS, and incubated at 37 °C and 5% CO_2 in a humidity-controlled atmosphere. Macrophage cells (5×10^5) were seeded in a 100-mm tissue culture plate, and allowed to adhere for 4 h at 37 °C. After cell adhesion, the culture medium was replaced by DMEM medium with different levels of PNA. The first study was carried out to examine the uptake and metabolism of PNA, cells were incubated in the DMEM serum medium supplemented with 50 μM PNA for 24 h. The second study was performed to examine whether the uptake of PNA was time- or dose-dependent, the same number of macrophage cells (5×10^5) were cultured in the same DMEM medium supplemented with 50 μM of PNA for 12, 24, 48 or 72 h, or with different levels of PNA (0, 10, 25, 50 or 100 μM) for 24 h. The cell

Scheme 1 n-6 and n-3 polyunsaturated fatty acid metabolism in mammalian cells [19]

viability was monitored by the methods of trypan blue dye exclusion [14] and MTT assay [15].

Lipid Extraction and Fatty Acid Analysis

After incubation, cells in plates were collected and harvested by centrifugation. The pellet was washed twice with sterile PBS. Total cellular lipids were then extracted following with minor modification the Folch method [16]. Briefly, cell pellets were extracted with 15 ml chloroform–methanol (2:1, v/v) at 4 °C for overnight. After adding 3 ml of 0.9% (w/v) NaCl solution, the mixture was vortexed and centrifuged. The chloroform phase containing the total lipid extract was then removed from the aqueous phase, and evaporated at 40°C using a stream of nitrogen. To separate the total phospholipid fraction, the lipid extracts were fractionated by thin-layer chromatography using hexane/diethyl ether/acetic acid (70:30:1, v/v/v) as the developing system. Fatty acids of the phospholipid fraction were methylated, and fatty acid methyl esters analyzed by an Agilent 6890 gas chromatography (GC) equipped with a flame-ionization detector and a fused-silica capillary column (Omegawax; 30 m × 0.32 mm, i.d., film thickness 0.25 μm, Supelco, Bellefonte, PA, USA) [17]. To separate the isomer of eicosatrienoic acid (ETrA), an HP-88 capillary column (100 m × 0.25 mm, i.d., film thickness 0.2 μm, Hewlett-Packard, Sunnyvale, CA, USA) was utilized. For quantitation of fatty acids, a known amount of triheptadecanoin was added to each lipid sample as the internal standard. The identity of PNA elongated metabolite was determined by gas chromatograph mass spectrometry (GC-MS), using a Hewlett Packard mass selective detector operating at an ionization voltage of 70 eV with a scan range of 20–500 Da.

In-Vitro Study of PGE₁ and PGE₂ Production

RAW264.7 cells were seeded in 24-well plates at 5×10^5 cells/well with complete DMEM medium containing 10% FBS. The cells were allowed to adhere for 4 h at 37 °C. After 24 h of treatment of PNA and/or other fatty acids, cells were stimulated with 0.1 μg/ml LPS for 16 h. Cell-free supernatants were collected and concentrations of both prostaglandins (PGE₁ and PGE₂) were analyzed with respective enzyme immunoassay kits.

Detection of COX-2 Expression by Western Blotting

Confluent macrophage cells (2.5×10^7) were pre-incubated with 50 μM of PNA and/or other fatty acids for 24 h and then stimulated with LPS for 16 h. Total protein was extracted from cells, and its concentration determined using the BCA Protein Assay Reagent Kit (Pierce, Rockford, IL). Denatured proteins were separated by 10% sodium dodecyl

sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), and transferred on a polyvinylidene difluoride membrane. After nonspecific blocking, membranes were probed with a 1:500 dilution of anti-mouse COX-2 antibody (BD Biosciences, Franklin Lakes, NJ), washed with PBS-T (10% Tween 20), and then reacted with a 1:5,000 dilution of anti-mouse immunoglobulin-alkaline phosphatase (Sigma, St. Louis, MO, USA). Following further washing in PBS-T three times, the immuno-complexes were visualized by colorimetric blotting substrates BCIP/NBT (Sigma, St. Louis, MO, USA).

Statistical Analyses

Data were analyzed by analysis of variance (ANOVA) and Fisher's protected least significant difference (LSD) to determine differences between means of the uptake rates and between means of the conversion rates. Means differences were considered significant at $P \leq 0.05$.

Results

Uptake and Metabolism of PNA in Macrophages

To examine the uptake and metabolism of PNA by macrophage, RAW264.7 cells were incubated in the culture medium containing 50 μM of PNA for 24 h. Results from the gas chromatographic analysis (GC analysis) show that a significant level of PNA (14% by weight of cellular phospholipids) and eicosatrienoic acid (ETrA) (19% by weight of cellular phospholipids) were detected in cells incubated with PNA as compared to the control where neither PNA nor ETrA was detected (Fig. 1). Further GC analysis using the HP-88 capillary column (100 m × 0.25 mm) revealed that the ETrA peak contained two isomers (Fig. 1, inset A). Gas chromatography-mass spectrometric analysis shows that the major ETrA peak was the PNA elongation metabolite ($\Delta 7,11,14-20:3$), whereas the minor peak was DGLA (<3% of ETrA) (data not shown). A low level (2% of cellular phospholipids) of docosatrienoic acid (DTrA) was also observed. The DTrA peak has an identical retention time to n-6 docosatrienoic acid ($\Delta 10,13,16-22:3$), an elongation metabolite of DGLA (Fig. 1, inset B). As this peak could only be observed in cells incubated with PNA but not in the controls, it was tentatively identified as $\Delta 9,13,16-22:3$, a possible elongation product of $\Delta 7,11,14-20:3$.

Effect of Incubation Time and Dose Response on PNA Metabolism in Macrophages

To examine the effect of the length of the incubation time on PNA uptake and metabolism, cells were incubated with

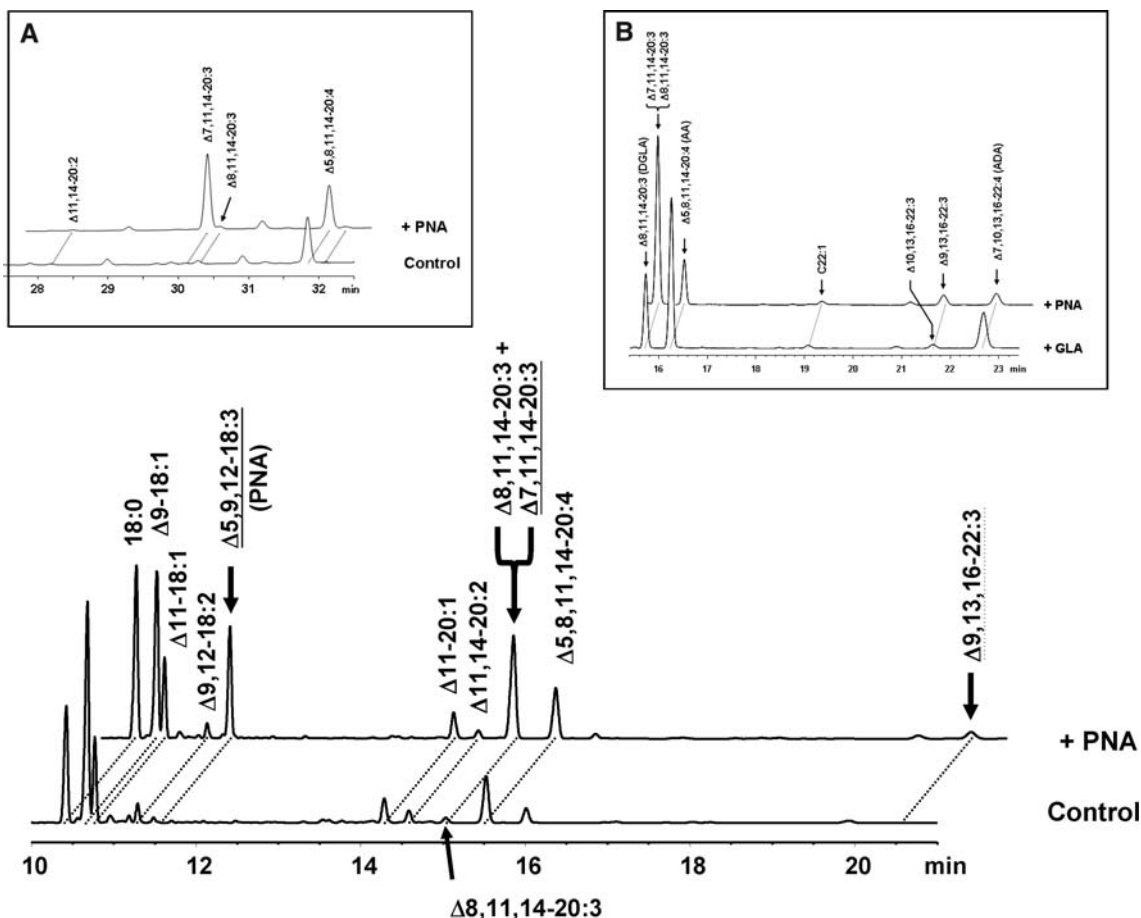

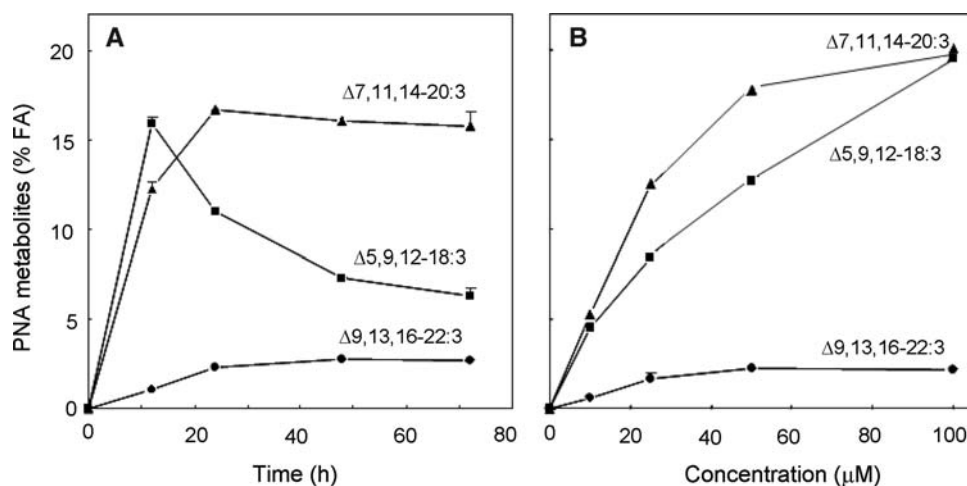

Fig. 1 Gas chromatogram of fatty acids of total lipids in the RAW264.7 cells cultured in the medium containing 50 μM of PNA. Solid arrows show the presence of pinolenic acid (PNA; $\Delta 5,9,12-18:3$), eicosatrienoic acid (ETrA; $\Delta 7,11,14-20:3$ and $\Delta 8,11,14-20:3$) and docosatrienoic acid (DTrA; $\Delta 9,13,16-22:3$), respectively. Inset A

shows the gas chromatogram of cellular phospholipids fatty acids in an HP-88 capillary column. Inset B compares gas chromatograms of fatty acids in cells incubated in medium containing either PNA or GLA

Fig. 2 Effects of different incubation times (a) and PNA concentration (b) on the levels of $\Delta 5,9,12-18:3$ (PNA) (■), $\Delta 7,11,14-20:3$ (▲) and $\Delta 9,13,16-22:3$ (●) in cellular phospholipids. RAW264.7 cells were incubated with medium containing 50 μM of PNA for 48 h, or different levels (0, 10, 25, 50, or 100 μM) of PNA for 24 h

50 μM PNA for 12, 24, 48 or 72 h. The phospholipids fatty acid composition in total cellular lipids was then analyzed. The results in Fig. 2a show that PNA was readily

incorporated into cellular phospholipids. The proportion of PNA elevated rapidly, reached the maximum at 12 h and fell thereafter. A significant portion of PNA was elongated

to $\Delta 7,11,14-20:3$. A small portion of $\Delta 7,11,14-20:3$ was further elongated to $\Delta 9,13,16-22:3$. The levels of these two PNA metabolites increased as the incubation time increased and reached a plateau after 24 h of incubation.

To examine the effect of varying PNA concentration in the medium on phospholipid fatty acid composition, the cells were incubated with 10, 25, 50 or 100 μM of PNA for 24 h. Results in Fig. 2b show that the level of PNA and its metabolites increased as the concentration of PNA in the medium increased.

Effect of PNA Incubation on Phospholipid Fatty Acid Composition

We also examined the composition of other fatty acids in cells incubated with different levels of PNA. The results in Fig. 3a show that when the levels of PNA and its metabolites in cellular phospholipids increased, those of total monounsaturated fatty acids and n-6 PUFA decreased. The effects were dose-dependent. With respect to levels of saturated fatty acids and n-3 PUFA, a significant lowering effect was observed only when the concentration of PNA in the medium exceeded 25 μM .

Among n-6 PUFA, incubation with PNA significantly lowered the levels of 18- and 20-carbon fatty acids, e.g.,

linoleic acid (LA; $\Delta 9,12-18:2$), GLA, eicosadienoic acid (EDA; $\Delta 11,14-20:2$), DGLA and ARA. In contrast, PNA incubation raised the levels of the 22-carbon fatty acids, i.e., adrenic acid (ADA; $\Delta 7,10,13,16-22:4$) and n-6 docosapentaenoic acid (n-6 DPA; $\Delta 4,7,10,13,16-22:5$). The increase reached a plateau when the concentration exceeded 50 μM .

To examine the effect of PNA incubation on n-3 fatty acid metabolism, macrophage cells were incubated with a medium containing 25 μM of n-3 eicosatetraenoic acid (n-3 ETA; $\Delta 8,11,14,17-20:4$) alone or in combination with 25 μM of PNA for 24 h. Results in Fig. 4a show that levels of the 20-carbon n-3 fatty acids (n-3 ETA and EPA) were decreased, whereas those of 22-carbon n-3 fatty acids, i.e., n-3 docosapentaenoic acid (n-3 DPA, $\Delta 7,10,13,16,19-22:5$) and docosahexaenoic acid (DHA; $\Delta 4,7,10,13,16,19-22:6$) were increased. However, the levels of total n-3 PUFA were decreased in cells incubated with PNA (Fig. 4b).

Effect of PNA on Synthesis of Prostaglandin E₁ and E₂

The results shown in Fig. 3b demonstrate that PNA incubation lowered the level of 20-carbon n-6 PUFA, i.e., DGLA and ARA in macrophage cellular phospholipids. It

Fig. 3 Effects of PNA on the level of total saturated fatty acids (SFA), total monounsaturated fatty acids (MUFA), total n-6 or n-3 polyunsaturated fatty acids (n-6 or n-3 PUFA) (a), and individual n-6 polyunsaturated fatty acids (b). RAW264.7 cells were incubated with the medium containing 0 μM (\square), 10 μM (\square), 25 μM (\square), 50 μM (\square) or 100 μM (\blacksquare) of PNA for 24 h. Each value represented the mean \pm SE of three independent experiments. In each fatty acid or group of fatty acids, values with different letters are significantly different from each other at $P < 0.05$

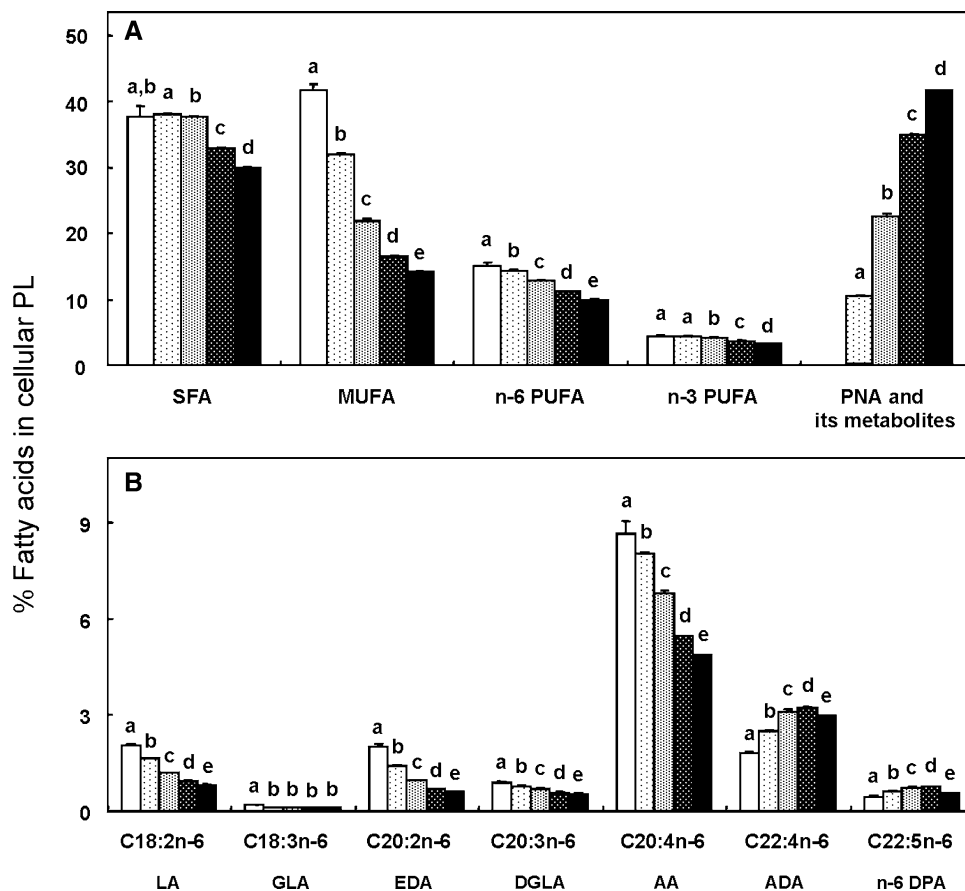

Fig. 4 Effects of PNA incubation on levels of total n-3 polyunsaturated fatty acids (n-3 PUFA) (a), and individual n-3 polyunsaturated fatty acids (b). Cells were incubated with 25 μ M of n-3 ETA alone (\square) or a combination of 25 μ M of n-3 ETA and 25 μ M of PNA (\blacksquare) for 24 h. Each value represents the mean \pm SE of three independent experiments. In each category, symbol (*) denotes the difference between 2 values is significant at $P < 0.05$

is possible that reduction of DGLA and ARA, could lead to a decrease in synthesis of PGE₁ and PGE₂, respectively. To examine this possibility, macrophage cells were incubated with varying levels of PNA (0, 12, 25, 50, and 100 μ M) for 24 h and then treated with LPS for 16 h to stimulate the prostaglandin synthesis. Results in Fig. 5 (upper panel) show that LPS stimulation increased significantly the synthesis of both PGE₁ and PGE₂. Addition of PNA in the medium decreased the levels of both PGE₁ and PGE₂. The effect was dose-dependent.

In a separated study, we examined the effect of PNA (50 μ M) on synthesis of PGE₁ or PGE₂ in macrophage cells pre-incubated with 50 μ M of DGLA or ARA. The results in Fig. 5 (lower panel) show that cells pre-treated with DGLA or ARA significantly increased the production of PGE₁ or PGE₂, respectively. However, addition of PNA into medium significantly suppressed the level of PGE₁ in cells pre-incubated with DGLA by 53%, and PGE₂ in cells pre-incubated with ARA by 22%.

Effect of PNA on Expression of COX-2 Protein

To understand the mechanism of the inhibitory effect of PNA on PGE₁ and PGE₂ activity, we examined the effect of PNA on the expression of COX-2 enzyme. Results in Fig. 6 show that expression of COX-2 in RAW264.7 cells was highly induced upon LPS simulation (Fig. 6, lane 2 vs. lane 1). When cells were treated with ARA or PNA alone, the levels of COX-2 protein in comparison with the control were increased by 18%, and 12%, respectively (lanes 3 and 5). When cells were treated with a combination of ARA and PNA, the levels of COX-2 protein were increased synergistically (26%, $P < 0.01$). In contrast, incubation with DGLA, the cellular level of COX-2 protein was decreased by 11% (lane 7). Addition of PNA in the medium eradicated the lowering effect of DGLA: the level of COX-2 protein was raised to between those in cells incubated with PNA and those with DGLA (lane 6).

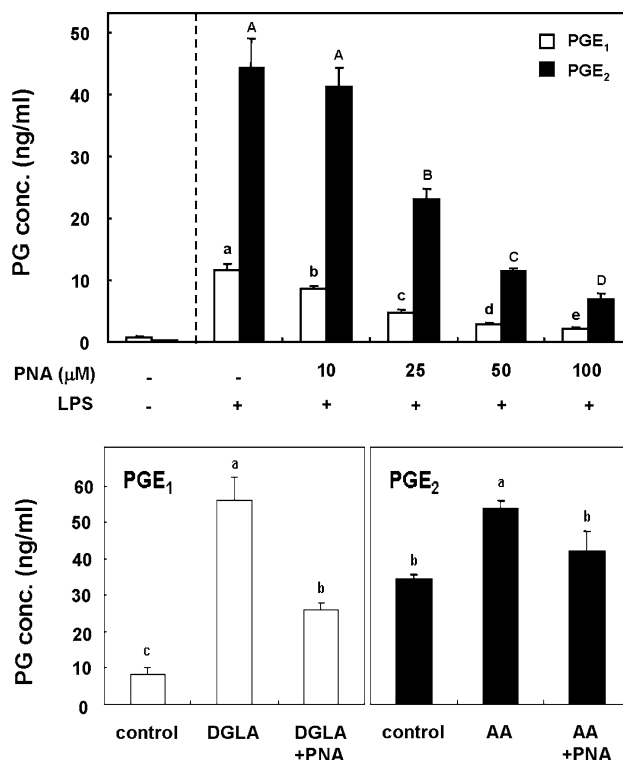

Fig. 5 Effect of PNA on formation of prostaglandin E₁ (\square) and prostaglandin E₂ (\blacksquare) in the LPS-treated RAW264.7 macrophage cells. Cells were incubated in the medium containing different levels (0, 10, 25, 50, or 100 μ M) of PNA (upper panel) for 24 h, or in the medium containing either 50 μ M of DGLA (or AA) alone or in a combination of 50 μ M of PNA and 50 μ M of DGLA (or AA) for 24 h (lower panel), followed by LPS treatment for 16 h. Each value represents the mean \pm SE of three independent experiments. In PGE₁ (\square) or PGE₂ (\blacksquare), values with different letters or numbers are significantly different from each other at $P < 0.05$

Discussion

In this study, we observed that PNA was readily taken up, incorporated and metabolized in murine RAW264.7 macrophage cells. In cells, PNA was rapidly elongated to form $\Delta 7,11,14-20:3$. A similar finding has previously been

Fig. 6 Effects of PNA on the expression of COX-2 in RAW264.7 macrophage cells. Cells were incubated with only medium, or medium containing 50 μM of AA, DGLA or PNA alone, or a mixture of 50 μM AA and 50 μM PNA or 50 μM DGLA and 50 μM PNA for 24 h, followed by LPS treatment for 16 h. Cyclooxygenase-2 expression was determined by Western blot analysis. α -tubulin was used as a loading control. Each value represents the mean \pm SE of three independent experiments. Values with different letters are significantly different from each other at $P < 0.05$

reported in human hepatoma HepG2 cells [13]. We have also observed the presence of $\Delta 9,13,16-22:3$ in cellular phospholipids (Fig. 1). The level of $\Delta 9,13,16-22:3$ increased as the length of incubation time and concentration of PNA in medium increased. These findings suggest that a portion of $\Delta 7,11,14-20:3$ underwent further elongation. This reaction was probably catalyzed by the fatty acid chain elongation system (FACES) which converts specifically 20-carbon fatty acids to 22-carbon fatty acids, such as ARA to ADA, EPA to n-3 DPA [19, 20]. Chapkin and his colleague has demonstrated in macrophages the elongation of DGLA ($\Delta 8,11,14-20:3$) to n-6 docosatrienoic acid (DTrA; $\Delta 10,13,16-22:3$) by this enzyme system [18].

Incubation of PNA also modified compositions of cell membrane fatty acids in RAW264.7 cells. In cells incubated with PNA, significant portions of total n-6 PUFA, 18-carbon and 20-carbon n-6 fatty acids in phospholipids were replaced by PNA and its metabolites (Fig. 3a). In spite of this, levels of 22-carbon ADA and n-6 DPA were increased significantly in cells incubated with PNA (Fig. 3b). Similarly, PNA decreased levels of total n-3 fatty acids, n-3 ETA and EPA when n-3 ETA was supplemented into the medium, but levels of 22-carbon n-3 fatty acids (i.e., DPA and DHA) were increased (Fig. 4b). These findings suggest that the metabolism of 20-carbon fatty acids to 22-carbon

fatty acids (conversion of ARA to n-6 DPA or EPA to DHA) was enhanced in cells incubated with PNA (Scheme 1).

In this study, we observed the inhibitory effect of PNA on eicosanoid production (Fig. 5). This effect could be exerted via the competitive incorporation of PNA and $\Delta 7,11,14-20:3$ into phospholipids which reduced the level of DGLA and ARA available for formation of eicosanoids (Fig. 3b and 5a). Previously, Li and his colleagues have shown that one of conjugated linoleic acid isomers (10*t*,12*c*-CLA) reduced LPS-stimulated PGE₂ production by decreasing the level of COX-2 protein expression in RAW264.7 cells [21]. Similarly, the inhibitory effect of PNA on PGE production could be due to its ability to modulate protein production. Results in the present study showed an increase in the level of COX-2 in macrophage cells treated with PNA (Fig. 6). This finding is comparable with the report that EPA treatment induced the expression of COX-2, but suppressed the formation of PGE₂ in cultured human lung cancer A549 cells [22]. Thus, the inhibitory effect of PNA on prostaglandin production was not exerted through suppression of COX-2 expression.

It is of interest to note that sciadonic acid ($\Delta 5,11,14-20:3$), another NMIFA found in *Podocarpus nagi* (Podocarpaceae) seed oil, behaves very similarly to PNA. This acid could be taken up, incorporated into phospholipids, and reduced both levels of ARA and PGE₂ in cultured skin keratinocytes [23]. In comparison with PNA, the inhibitory effect of sciadonic acid on the level of ARA in membrane phospholipids became evident only when the concentration of sciadonic acid in the culture medium exceeded 15 μM , and inhibition on PGE₂ production was observed only when the concentration of sciadonic acid reached 100 μM [22]; while the inhibitory effects of PNA on the level of DGLA (or ARA) and its respective prostaglandin could be observed when the concentration of PNA was only 10 μM (Fig. 2b and 5a). This finding suggests that PNA as compared to sciadonic acid is more potent on suppressing the PG production. The explanation may be attributed to the difference in chemical structures between these two acids: the PNA elongation product ($\Delta 7,11,14-20:3$) is more similar to DGLA ($\Delta 8,11,14-20:3$) and ARA ($\Delta 5,8,11,14-20:4$) than is sciadonic acid ($\Delta 5,11,14-20:3$) in competing for the catalytic sites of the COX-2 enzyme. This difference in chemical structure could also explain the greater inhibitory effect of PNA on conversion of DGLA to PGE₁ (53%) than that on conversion of ARA to PGE₂ (22%).

In this study, we have clearly shown that PNA was metabolized to form $\Delta 7,11,14-20:3$ and $\Delta 9,13,16-22:3$, and they significantly modulated n-6 PUFA metabolism and PGE synthesis. However, in rats, fed PSO failed to modulate prostacyclin [1, 24]. This could be due to low incorporation of PNA into phospholipid fractions (2–4% of

total fatty acids) [1, 25], and to a lower rate of elongation of PNA to $\Delta 7,11,14-20:3$ as compared to that of GLA to DGLA [1, 10, 24].

In conclusion, by using murine RAW264.7 macrophage cells, we demonstrated that exogenous PNA could be taken up, incorporated and metabolized to form elongation products. The incorporated PNA and its metabolite modulated fatty acid compositions of cellular phospholipids and PUFA metabolism. Since DGLA (or ARA) was substituted by PNA and its metabolites, the synthesis of PGE₁ (or PGE₂) were also influenced. The inhibitory effect was not due to suppression on COX-2 protein expression at the translation level, but due to substrate competition substitution of DGLA or ARA.

Abstract Oxidized low density lipoprotein (Ox-LDL) is a well-established risk factor in atherosclerosis and lysophosphatidylcholine (LysoPtdCho) is considered to be one of the major atherogenic component of Ox-LDL. The purpose of this work was to investigate the effects of two membrane n-3 long chain polyunsaturated fatty acids (n-3 PUFAs), EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid) compared to n-6 PUFA, ARA (arachidonic acid), on the activation of endothelial NO synthase (eNOS) by histamine in Ea hy 926 endothelial cells incubated during 24 h in the presence or the absence of LysoPtdCho. DHA (50 μ M) produced a ROS induction in cells and aggravated the LysoPtdCho-induced oxidative stress. It did not modify the basal eNOS activity but impaired the stimulation of eNOS induced by histamine and was unable to correct the deleterious effect of LysoPtdCho on histamine-stimulated eNOS activity or phosphorylation of Ser 1177. In contrast, EPA (90 μ M) did not modify the ROS level produced in the presence or absence of LysoPtdCho or basal eNOS activity and the stimulating effect of histamine on eNOS. However, it diminished the deleterious

effect of LysoPtdCho as well as on the histamine-stimulated eNOS activity on the phosphorylation on Ser 1177 of eNOS. The beneficial effect of EPA but not DHA on endothelial eNOS activity in Ea hy 926 could be also partially due to a slight decrease in membrane DHA content in EPA-treated cells. Consequently, the equilibrium between NO generated by eNOS and ROS due to oxidative stress could explain, in part, the beneficial effect of EPA on the development of cardiovascular diseases. By contrast ARA an n-6 PUFA was devoid of any effect on ROS generation or eNOS activity in the basal state or after histamine-induced stimulation. In vivo experiments should be undertaken to confirm these results.

Introduction

The oxidation of low-density lipoproteins (LDL) is a key event in atherogenesis. One of the major deleterious component of these oxidized LDL (Ox-LDL) is considered to be lysophosphatidylcholine (LysoPtdCho), which represents up to 50% of phosphatidylcholine [1, 2]. LysoPtdCho is also present in high concentration in the atherosclerotic plaques of the artery wall [3]. Thus, LysoPtdCho is believed to play an important role in atherosclerosis by altering various functions in different cell-types, including endothelial cells, smooth muscle cells, monocytes, macrophages, and T-cells [4]. In endothelial cells, the acute effects of LysoPtdCho have been extensively reported in the literature. It has been shown that the acute addition of LysoPtdCho to endothelial

cells in culture up-regulates the expression of cell adhesion molecules (ICAM 1 and VCAM 1) [5], induces the expression of chemotactic factors on the endothelial surface [6], prevents the activation of endothelial NO synthase (eNOS) [7] and increases the apoptosis of endothelial cells [8, 9]. By contrast, only few studies concern the chronic effects of LysoPtdCho in endothelial cells. During chronic administration of LysoPtdCho, a stimulation of the generation of reactive oxygen species (ROS) via NADPH oxidase activation in endothelial cells has been reported [10, 11]. One of the best documented toxic effects of oxygen radicals is peroxidation of polyunsaturated fatty acids (PUFAs) present in membrane phospholipids. However, PUFAs and particularly arachidonic acid are used in endothelial cells to generate prostaglandins, principally PgE2 and PgI2, which are implicated together with NO in the vasodilatation of arteries in response to aggressive agents. In this context, n-3 PUFAs, especially eicosapentaenoic acid (EPA, C20:5n-3) and docosahexaenoic acid (DHA, C22:6n-3) have been shown to exert beneficial effects in the prevention of cardiovascular disease [12]. At the level of vessels, EPA has been reported to be able to increase endothelium-dependent relaxation of coronary arteries [13] and was associated with a reduced morbidity and mortality in atherosclerosis [14]. When added to the culture medium of endothelial cells for 24 h, EPA, and DHA are well incorporated into the cell membrane phospholipids [15]. However, because of their high degree of unsaturation, the incorporation of n-3 PUFAs into membrane phospholipids may also promote peroxidation and the subsequent propagation of oxygen radicals decreasing the bioavailability of NO to produce vascular relaxation.

The present study was designed to reproduce the situation of atherosclerotic arteries in Ea hy 926 endothelial cells cultured for 24 h in the presence of LysoPtdCho in order to determine: (1) the basal eNOS activity and the effect of histamine on eNOS activity in these cells; (2) the modifications of basal and histamine-stimulated eNOS activity when Ea hy 926 cells were cultured in the presence of DHA or EPA compared with cells cultured in the presence of n-6 PUFA, i.e., ARA.

Materials and Methods

Materials

Fetal bovine serum (FBS) was purchased from Biowest (Nuaille, France). Penicillin (10,000 U/mL), streptomycin (10,000 µg/mL) and D-MEM (4,500 mg/L glucose, glutamax) were obtained from Invitrogen (Cergy Pontoise, France). HAT (Hypoxanthine, Aminopterin, Thymidine) medium supplement (50X), cis-5,8,11,14,17-eicosapentaenoic acid (EPA), cis-4,7,10,13,16,19-docosahexaenoic acid

(DHA), arachidonic acid (ARA), lysophosphatidylcholine, namely 1-palmitoyl-*sn*-glycero 3 phosphocholine (LysoPtd Cho) and L-nitroarginine methyl ester (L-NAME) were purchased from Sigma (Saint Quentin Fallavier, France). The anti eNOS and anti phospho-Ser-1177 eNOS antibodies were obtained from Cell Signaling (Ozyme, Saint Quentin en Yvelines France), the secondary antibody was obtained from Sigma. The fluoroprobe 5-(and 6)-chloromethyl-2'-7'-dichlorodihydro fluorescein diacetate acetyl ester (CM-H₂DCFDA) was from Molecular Probes (Cergy Pontoise, France).

Cell Culture

Ea hy 926 is a permanent endothelial cell line derived from human umbilical vein endothelial cells that express factor VIII antigen [16], oxidatively modified human LDL receptor [17] and show calcium-dependent stimulation of endothelial nitric oxide synthase (eNOS) [18]. Cells were kindly provided by Dr Cora-Jean Edgell [16]. They were cultured in a phenol-red-free DMEM culture medium supplemented with 10% FBS, 2% HAT medium supplement (the final concentration of hypoxanthine, aminopterin, thymidine was 100 µM, 0.4 Mm, and 16 µM, respectively) and 1% penicillin/streptomycin. ARA, EPA, and DHA were linked to albumin, for 3 h at 37 °C, by mixing 1 mg free fatty acid/16 mg albumin/40 mL culture medium, as previously described [19]. The final molar ratio ARA, EPA, or DHA/albumin was close to 3.

To investigate the effect of ARA, EPA, or DHA on eNOS expression and activity, the cells were seeded (200,000 cells/well) on six-well plates and were grown until confluence. Then they were preincubated with different PUFA concentrations (25–120 µM in the culture medium) and/or different LysoPtdCho concentrations (10–100 µM) during 24 h, before acute treatment with histamine (10 µM, 10 min).

Cell Viability Assay

We used the tetrazolium salt MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide) assay to investigate the viability of cells cultured in the presence of different treatments. Briefly, the cells were seeded onto 96-well flat-bottomed culture plates at 15×10^4 cells/mL and cultured until confluence. The cells were treated with ARA, EPA, or DHA in the presence or absence of 60 µM LysoPtdCho for 24 h. MTT (0.5 mg/mL) was added to each well during the 4 last hours. The medium was discarded and 150 µL DMSO was added to each well to solubilize the formazan crystals and the absorbance of each well was measured at 540 nm using a microplate reader (ELX 800G). Mitochondrial dehydrogenase of viable cells can

reduce MTT to insoluble formazan which can be dissolved by DMSO.

eNOS Activity (Citrulline Assay)

eNOS activity in intact cells was determined by following the conversion of incorporated (^3H) L-arginine to (^3H) L-citrulline [20–22]. The cells were incubated at 37 °C for 45 min in arginine deprivation buffer (109 mM NaCl, 5.4 mM KCl, 1.8 mM CaCl_2 , 1 mM MgSO_4 , 25 mM HEPES, 5 mM glucose, pH 7.4). The reaction was started by the addition of 10 μM arginine and L-(^3H) arginine (0.5 μCi , 200 Ci/mmol). eNOS activity was evaluated in the absence or in the presence of 10 μM histamine. After 10 min, the reaction was stopped with cold buffer 1 (PBS, 5 mM L-arginine, 5 mM EDTA) and the cells were lysed with cold buffer 2 (40 mM sodium acetate, 1 mM L-citrulline, 2 mM EDTA, 2 mM EGTA). After sonication, the lysate was applied to 3-mL DOWEX 50X8-400 columns (Aldrich), pre-equilibrated in buffer 2. Citrulline was eluted with 2 mL of buffer 2, and radioactivity corresponding to [^3H] L-citrulline was quantified by liquid scintillation counting. The eNOS activity was expressed as dpm citrulline/mg of total cell protein produced in 10 min.

Measurement of Intracellular Reactive Oxygen Species (ROS)

The determination of intracellular ROS generation was based on the oxidation of the fluoroprobe CM- H_2DCFDA which is hydrolyzed to DCFH in the cell. DCFH is oxidized to highly fluorescent DCF in the presence of ROS. Cells were seeded in 96 well plates at 15×10^4 cells/mL. After confluence, cells were incubated with ARA, EPA, or DHA and/or LysoPtdCho for 24 h in phenol-red-free medium and 10 μM CM- H_2DCFDA was applied on cells during the last 30 min. Thereafter, the cells were washed in PBS, 1 mM CaCl_2 , 5 mM MgCl_2 , and 5 mM glucose. DCF fluorescence was monitored on a microplate fluorimeter reader (Tecan, Polarion, Trappes, France) using 485 nm excitation and 535 nm emission wavelengths.

Western Blot

After the different treatments, cells were washed with cold PBS and homogenized in lysis buffer (150 mM NaCl, 50 mM Tris, 1 mM EDTA, 50 mM NaF, 1 mM Na_3VO_3 , 1 mM PMSF, 1% Sigma inhibitor cocktail and 1% Nonidet P-40). The lysate was clarified by centrifugation (15 min, $12,000 \times g$, 4 °C). The protein concentration of the supernatant was determined using the Biorad Protein Assay. Cell proteins of lysates (20 μg) were separated on NuPAGE 4–12% Bis-Tris gels (Invitrogen) and transferred onto a

nitrocellulose membrane. The membranes were blocked with 5% non-fat dry milk and incubated overnight at 4 °C with primary antibodies (diluted 1/1000). Secondary specific horseradish-peroxidase linked antibodies (diluted 1/5000) were added for 1 h at room temperature. Bound antibodies were detected using the enhanced chemiluminescence system (ECL, Amersham Bioscience) with Kodak Biomax light films. The bands of immunoblots were scanned and quantified by densitometric analysis using Scion Image software (Scion Corp., Frederick, MD).

Fatty Acid Analysis

Cells were harvested in 1 mL distilled water, and lipids were extracted in a 2:1 chloroform: methanol mixture [23]. Fatty acids were trans-methylated with BF_3 -methanol. The methyl esters were analyzed by gas chromatography on an econocap EC-WAX capillary column (0.32×30 m, Alltech Associates) using heptadecanoic acid (C17:0) as internal standard, as previously described [24].

Conjugated Dienes Analysis

Conjugated dienes were measured by UV absorbance at 235 nm according to Grau et al. [25] with slight modifications. Cells from 3 wells of six-well plates were washed with cold PBS and lysed in 1 mL of 0.02% EDTA and 1.6% NaCl. The suspension was mixed with 4 mL of chloroform: methanol (2:1), homogenized for 2 min in a glass-Teflon potter and centrifuged 10 min at $400 \times g$. The chloroform phase was filtered through anhydrous sodium sulfate (Whatman number 1) which was washed with 2 mL of chloroform. The organic solvent was removed under nitrogen stream and the extracted lipid fraction was dissolved in 2 mL cyclohexane. The absorbance was determined at 235 nm in 1 cm quartz cuvette against cyclohexane.

Statistical Analysis

The results are expressed as means \pm SEM. Statistical analyses were performed by one-way analysis of variance, followed by a Bonferroni *t* test. Values of $p < 0.05$ were considered as statistically significant.

Results

Effect of LysoPtdCho on eNOS Activity

In the absence of LysoPtdCho, 10 μM histamine induced a 3.5-fold increase of arginine conversion to citrulline (Fig. 1). The addition of 1 mM L-NAME, an eNOS inhibitor, 30 min before histamine stimulation, prevented

Fig. 1 Dose-effect of LysoPtdCho on histamine stimulation of eNOS activity in Ea hy 926 cells. Ea hy 926 cells were pre-incubated for 24 h with increasing concentrations of LysoPtdCho (0–150 µM). Then, the cells were incubated with 10 µM [3 H] L-arginine in the presence or absence of 10 µM histamine for 10 min. [3 H] L-citrulline production was considered as an indicator of eNOS enzyme activity. Each point represents mean \pm SEM of three or four independent experiments. All values were significantly different between groups ($p < 0.05$) except for 100 and 150 µM LysoPtdCho where they were no significantly different (NS)

citrulline formation completely. In these conditions, the stimulating effect of histamine was reduced by $99 \pm 5.2\%$. The presence of low concentration of LysoPtdCho in the incubation medium (15 or 30 µM) led to no significant modification of histamine-induced eNOS activity. By contrast, with concentrations higher than 30 µM, LysoPtdCho decreased dose-dependently the activation of eNOS induced by 10 µM histamine. The presence of LysoPtdCho was devoid of any cellular toxicity until a concentration of 80 µM in the incubation medium as evaluated by the number of living cells and MTT test (data not shown). However, when LysoPtdCho concentration was superior to 80 µM, the viability of cells was decreased. To evaluate the effects of ARA, EPA, and DHA on the impairment of eNOS activation induced by LysoPtdCho, all further experiments were performed with a concentration of 60 µM LysoPtdCho to obtain a maximal amplitude of eNOS response to PUFAs in the absence of toxicity for the cells. In our system containing 10% SVF, LysoPtdCho added in our culture media accounted for 15% of total phospholipids.

Effect of LysoPtdCho on Ser 1177 eNOS Phosphorylation

The expression of total eNOS and phospho-Ser-1177 eNOS in Ea hy 926 is presented in Fig. 2. Histamine stimulated phosphorylation of Ser 1177 eNOS in control cells in the absence of LysoPtdCho. However, a pretreatment of cells for 24 h with 60 µM LysoPtdCho abolished quite completely the phosphorylation of eNOS on Ser 1177 site. On

the other hand, increasing the doses of LysoPtdCho between 10 and 60 µM did not modify the expression of total eNOS protein. LysoPtdCho modified in a similar manner the phosphorylation of eNOS on Ser 1177 site and the protein activity as demonstrated by the similar patterns of the curves depicted in Figs. 1 and 2.

Effect of ARA, EPA, or DHA on eNOS Activity

The effects of ARA, EPA, or DHA on eNOS activity in the presence or in absence of LysoPtdCho are summarized in Table 1. The cellular eNOS activity was similarly increased by histamine in control, ARA and EPA-treated cells (90 or 120 µM). L-NAME (1 mM) blocked completely the histamine-induced eNOS stimulation as well in control cells as in all PUFAs-treated cells: the stimulating effect of histamine on eNOS was reduced by 98.2 ± 5.0 , 103.1 ± 7.8 , and $92.0 \pm 4.8\%$ when 120 µM ARA or EPA or 50 µM DHA were added to the culture medium, respectively. LysoPtdCho neither in control cells nor in ARA- and EPA- or DHA-treated cells significantly modified the basal activity of eNOS. On the other hand, when cells were incubated for 24 h with 90 or 120 µM EPA, the chronic inhibitory effect of LysoPtdCho on histamine-stimulated eNOS activity was significantly decreased. Thereby, EPA protected the cells against the deleterious effect of LysoPtdCho. The treatment of the cells with 50 µM EPA did not produce any effects on eNOS activity versus control cells whatever the experimental condition (data not shown). eNOS activity of cells incubated with 90 or 120 µM ARA was similar to that of control cells under all the incubation conditions. By contrast, the chronic incubation of cells in the presence of 25 or 50 µM DHA significantly decreased the stimulation of eNOS by histamine and failed to affect the deleterious effect of LysoPtdCho on histamine-induced eNOS activity. In these conditions, the global effect of DHA on eNOS can be considered as deleterious due to its capacity to decrease NO generation. All these effects were observed in the absence of cellular toxicity as estimated by the MTT test (Fig. 3). However, increasing DHA treatments to 90 and 120 µM, concentrations used in EPA and ARA groups, led to cell death (Fig. 3).

Effect of ARA, EPA, or DHA on Ser 1177 eNOS Phosphorylation

As shown in Fig. 4, the induction of eNOS phosphorylation on Ser 1177 by 10 µM histamine was decreased in the presence of 60 µM LysoPtdCho as expected. However, the presence of 90 µM EPA in the incubation medium of cells during 24 h abolished the LysoPtdCho-induced inhibition of phosphorylation of eNOS, outlining a protective effect

Fig. 2 Dose-effect of LysoPtdCho on Ser 1177 phosphorylation of eNOS induced by histamine in Ea hy 926 cells. Ea hy 926 cells were pre-incubated for 24 h with increasing concentrations of LysoPtdCho (0–100 μ M). Then, the cells were stimulated or not with 10 μ M histamine for 10 min. The cells were lysed and a western blot analysis was performed using anti-Ser1177 phospho-eNOS and eNOS antibodies. The presented blot is representative of four independent experiments. The graph represents the densitometric analysis (mean \pm SEM) of blots of four separate experiments. All values were significantly different between groups ($p < 0.05$) except for LysoPtdCho concentrations above or equal to 50 μ M

Table 1 Effect of ARA, EPA, or on eNOS activity

	Control	ARA		EPA		DHA	
		90 μ M	120 μ M	90 μ M	120 μ M	25 μ M	50 μ M
Basal activity	100	106 \pm 11	110 \pm 13	97 \pm 4	92 \pm 8	87 \pm 12	95 \pm 16
10 μ M Histamine	415 \pm 37	448 \pm 41	464 \pm 25	396 \pm 59	464 \pm 19	305 \pm 46*	197 \pm 13**

10 μ M Histamine	116 \pm 17	120 \pm 18	111 \pm 29	166 \pm 13*	192 \pm 8**	145 \pm 30	112 \pm 7
60 μ M lysoPtdCho							

Ea hy 926 cells were pre-incubated for 24 h in a control culture medium or in a medium containing ARA, EPA, or DHA at the indicated concentrations in the presence or not of 60 μ M LysoPtdCho. Then, the cells were incubated with 10 μ M [3H] L-arginine in the presence or absence of 10 μ M histamine for 10 min to test eNOS activity. Citrulline production was expressed as percentage of citrulline liberated in control cells. Each value represents mean \pm SEM of four independent experiments. Asterisks in the column indicate a significant difference between control cells and EPA or DHA treated cells (* $p < 0.05$; ** $p < 0.01$)

of EPA on eNOS activation. By contrast, the presence of 50 μ M DHA in the incubation medium of cells during 24 h did not restore the inhibitory effect of LysoPtdCho on phosphorylation of eNOS. Similarly, the presence of 90 μ M ARA in the incubation medium during 24 h did not protect the cells from the deleterious effect of LysoPtdCho on the phosphorylation of eNOS.

Effect of LysoPtdCho on Intracellular ROS Generation

The generation of ROS, as measured using CM-H₂DCFDA probe was investigated in cells exposed to LysoPtdCho in the

presence or absence of ARA, EPA, or DHA for 2, 4, and 24 h (Fig. 5). With LysoPtdCho alone, ROS generation was slightly, but significantly increased after 2 h, then returned to basal level at 4 h until 24 h. Treatment of cells with ARA or EPA even in the presence of LysoPtdCho did not change the level of ROS with respect to cells incubated in the control culture medium. In contrast, treatment of cells for 24 h with DHA alone led to a three-fold increase in ROS generation. When the cells were incubated in the presence of LysoPtdCho and DHA, we observed an important production of ROS after 2 and 4 h and a more higher production of ROS at 24 h (eight-fold increase versus control).

Fig. 3 Effect of LysoPtdCho and PUFAs on cell viability assessed by the MTT test in Ea hy 926 cells. Cells were incubated for 24 h in a culture medium containing the indicated concentrations of PUFAs in the presence or absence of 60 µM LysoPtdCho. The results correspond to the absorbance of formazan determined at 540 nm. Each symbol indicates mean ± SEM of three experiments (each experiment was carried out in triplicate). ***: significant difference ($p < 0.05$), ARA or EPA versus DHA group; NS: non-significant difference

Effect of ARA, EPA, or DHA on Conjugated Dienes Generation

Conjugated dienes were evaluated in Ea hy 926 cells incubated for 24 h with or without 60 µM LysoPtdCho in control or in ARA-, EPA-, or DHA-supplemented medium. As shown in Fig. 6, the conjugated dienes content of ARA-, EPA-, and DHA- enriched cells did not change as compared with control cells. The presence of 60 µM LysoPtdCho in the cells incubation medium induced no

further generation of conjugated dienes neither in control cells nor in cells grown in ARA- or EPA-supplemented medium, but significantly increased the conjugated dienes content of DHA treated cells.

Effect of ARA, EPA, or DHA Supplementation in the Incubation Medium on Fatty Acids Enrichment of Ea hy 926 Cells

Incubation of Ea hy 926 cells during 24 h with different concentrations of ARA (90 or 120 µM), EPA (50, 90, or 120 µM) or DHA (25 or 50 µM) significantly and dose-dependently increased the cell content of each added PUFA in cell phospholipids (Fig. 7d, a, c). The supplementation with EPA led also to an important dose-dependent enrichment of cells in docosapentaenoic acid (DPA, C22:5n-3) (Fig. 7b), indicating a significant elongation of EPA in DPA. By contrast, no further desaturation of DPA in DHA occurred and the DHA level in EPA-supplemented cells was even significantly decreased with 90 and 120 µM EPA (Fig. 7c). The concomitant addition of 60 µM LysoPtdCho to either ARA-, EPA-, or DHA- enriched medium did not modify the incorporation of either ARA, EPA, or DHA in cell structure in comparison with cells treated with ARA, EPA, or DHA alone (Fig. 7a, c, d). However, the presence of LysoPtdCho in EPA-treated cells significantly reduced the enrichment of the membranes in DPA in comparison with EPA-treated cells (Fig. 7b) suggesting that LysoPtdCho modifies the elongation of EPA or the structure or remodeling of phospholipids.

Fig. 4 Effect of ARA, EPA, or DHA on the impairment by 60 µM LysoPtdCho of histamine-induced phosphorylation of eNOS. Ea hy 926 cells were pre-incubated for 24 h with 60 µM LysoPtdCho added or not of 90 µM EPA or ARA or 50 µM DHA. Then, the cells were stimulated with 10 µM histamine for 10 min. Proteins of cell lysates were analysed by western blotting using anti-Ser1177 phospho-eNOS and eNOS antibodies. The blots presented are representative of four

independent experiments. The results of the densitometric analysis of blots (Ser 1177 P-eNOS/eNOS) are summarized at the bottom of the figure. Each column represents the mean ± SEM of 3–4 independent experiments. Different letters indicate a significant difference between groups ($p < 0.05$), the same letter indicates no significant difference between groups

Fig. 5 Intracellular ROS generation in Ea hy 926 cells exposed to LysoPtdCho during different time periods in the presence of ARA, EPA, or DHA. Ea hy 926 cells were pre-incubated with 60 μ M LysoPtdCho in the presence or absence of 90 μ M ARA or 90 μ M EPA or 50 μ M DHA from 2 to 24 h. Then, the cells were loaded with 10 μ M CM-H₂DCFDA during 30 min. After washing, DCF

fluorescence of cells was analyzed at 485/535 nm (excitation/emission). Each column indicates the mean \pm SEM of DCF fluorescence per μ g of proteins. Asterisks indicate a significant difference between control cells without LysoPtdCho treatment and DHA treated cells (*** p < 0.001; ** p < 0.01; * p < 0.05)

Fig. 6 Effect of ARA, EPA, or DHA on conjugated dienes content of cells. Ea hy 926 cells were incubated with 90 μ M ARA or 90 μ M EPA or 50 μ M DHA in the presence or absence of 60 μ M LysoPtdCho for 24 h. After washing, the cells were harvested in 1.6% NaCl, 0.02% EDTA. After lipid extraction in chloroform:methanol 2:1 (v:v), conjugated dienes were measured by UV absorbance at 235 nm. Each column indicates the mean \pm SEM of arbitrary units/g of proteins (n = 4 separate experiments). Asterisk indicates a significant difference with control cells (* p < 0.05)

Discussion

The present results demonstrate that the chronic incubation of Ea hy 926 endothelial cells with LysoPtdCho decreased the stimulating effect of histamine on eNOS activity. The incorporation of EPA in cell phospholipids prevented this deleterious effect of LysoPtdCho. Conversely, the presence of DHA in similar conditions displayed deleterious effects on endothelial function by decreasing histamine-induced eNOS activation and increasing the oxidative stress (ROS

generation and conjugated dienes). In contrast, ARA had no effect on either histamine-induced eNOS activation on ROS or conjugated dienes formation.

The present study was designed to simulate the pathophysiological status of endothelial cells of the arterial wall continuously exposed to oxidized LDL in vivo during the atherosclerotic process. Thus we exposed Ea hy 926 cells for 24 h to LysoPtdCho, which is a major component of oxidized LDL playing an important role in the alteration of endothelial function during atherosclerosis development. In these conditions, LysoPtdCho induced a decrease in the stimulating effect of histamine on eNOS activity and a concomitant decrease in Ser 1177 eNOS phosphorylation. This result is in agreement with the decreased endothelial release of NO by LysoPtdCho as reported in the literature [26, 27]. Several mechanisms have been proposed to explain the effect of LysoPtdCho including a decrease of arginine availability due to an inactivation of the arginine transporter [28], an increased production of asymmetric dimethyl arginine (ADMA), an endogenous eNOS inhibitor [29], or still a decrease in eNOS expression [30]. In the present work, we showed that the chronic exposition of cells to LysoPtdCho similarly impaired both the histamine-induced activity and the histamine-induced Ser 1177 phosphorylation of eNOS suggesting that a kinase signaling pathway could be involved in the impairment of eNOS activity by LysoPtdCho. In contrast, LysoPtdCho did not modify the total eNOS expression, contrary to the result

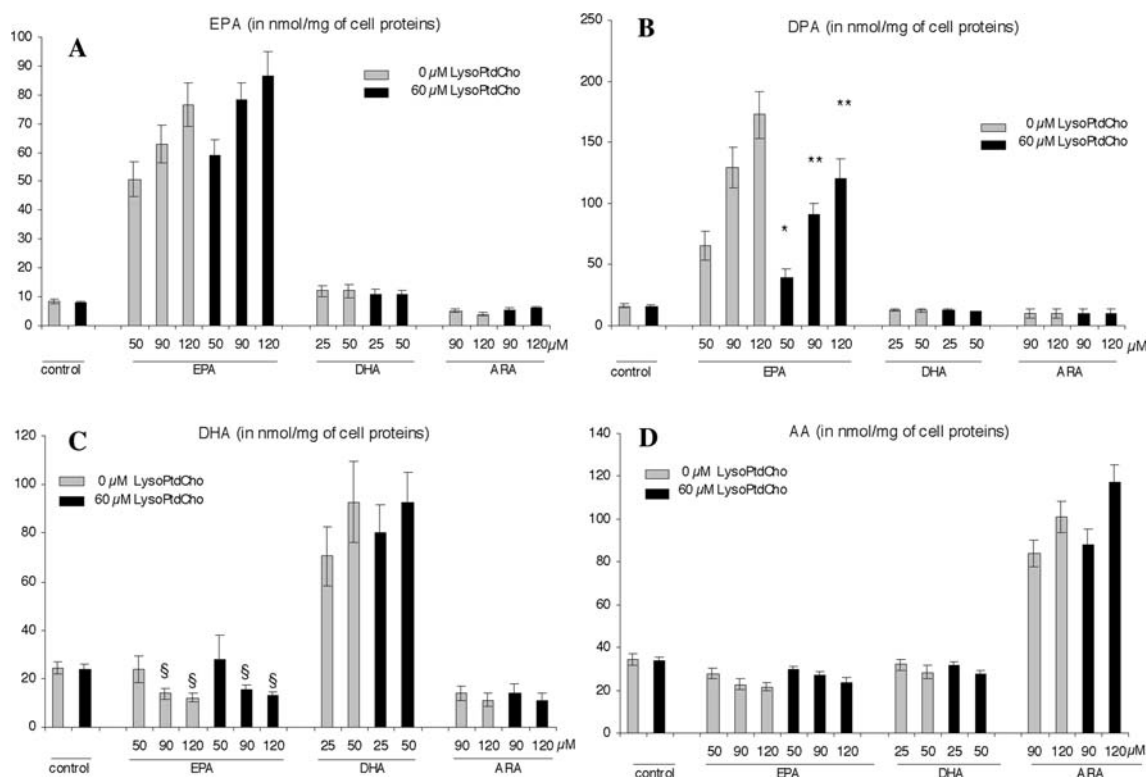

Fig. 7 Effect of the supplementation of the culture medium in ARA, EPA, or DHA in the presence or absence LysoPtdCho on the incorporation of ARA, EPA, and DHA in Ea hy 926 cells. Ea hy 926 cells were incubated with increasing concentrations of ARA, EPA, or DHA in the presence or absence of 60 μ M LysoPtdCho during 24 h. After washing, the cells were lysed in chloroform–methanol 2/1 (v/v) and fatty acids were extracted. Fatty acids were trans-methylated with BF₃-methanol and the methyl esters were analyzed by gas

chromatography. The content of cells in EPA (a), DPA (b), DHA (c), and ARA (d) was expressed in nmol/mg of cell proteins. Each column represents the mean \pm SEM of 4 separate experiments. Asterisks (*) indicate a significant difference between EPA and (EPA + LysoPtdCho)-treated cells for DPA content in the cells (* p < 0.05; ** p < 0.01). § indicate a significant difference between treated and control cells (in absence of LysoPtdCho) (§ p < 0.05)

reported in HUVEC with a very high concentration of 100 μ M LysoPtdCho often considered as a detergent [31]. Yet the 60 μ M LysoPtdCho concentration used in our culture medium is higher than the concentrations used in other studies [30, 32], but our medium contained antioxidants and albumin which is able to bind a part of LysoPtdCho as in physiological conditions.

Besides its effect on eNOS activity, LysoPtdCho can also impair NO availability by its capacity to generate superoxide anions which scavenge NO three times faster than their degradation by superoxide dismutase [33]. The stimulation by LysoPtdCho of the production of superoxide anions in endothelial cells has been attributed to a stimulation of NADPH oxidase [34, 35], or to a stimulation of the mitochondrial pathway [32]. The present study documented a significant increase of ROS generation after 2 h of exposition of Ea hy 926 cells to LysoPtdCho. However, the peak of ROS was obtained 2 h after incubation with LysoPtdCho and returned slowly to the basal level within 24 h, suggesting an adaptation of the cells to the oxidative stress by induction of antioxidant protective pathways as previously reported [36].

Concerning the chronic effects of PUFAs, we have demonstrated that the incorporation of ARA, DHA, and EPA in Ea hy 926 endothelial cells was proportional to the concentration of the three PUFAs in incubation medium, as previously reported [15]. EPA appeared more readily incorporated than DHA in Ea hy 926 phospholipids, since the cells accepted a concentration of 120 μ M EPA in the medium without apparent cellular toxicity, whereas cellular viability was impaired above 50 μ M DHA. Additionally, the conversion of DPA to DHA was not achieved in the EPA-treated cells and their DHA content was even largely decreased, probably in agreement with the human origin of the Ea hy 926 cell line characterized by their extremely low conversion of DPA to DHA as described in the literature [37].

The present study demonstrated different effects of EPA and DHA on the activation of eNOS by histamine. While EPA at a concentration of 90 or 120 μ M in the incubation medium did not modify the basal activity of eNOS nor the stimulating effect of histamine on eNOS, as reported by others [38], it decreased the deleterious effect of LysoPtdCho on the histamine-stimulated eNOS activity as well

as on the phosphorylation on Ser 1177 of eNOS. Such a protective effect was not observed in our previous study [15], when eNOS activity was measured in the presence of 25 mM glucose which is known to decrease NO production in endothelial cells [39] and when the cells were exposed to LysoPtdCho for a short time (15 min). The use of a physiological glucose concentration (5 mM) in the present study and the duration of exposure to LysoPtdCho may explain the differences between the non-similar effects of the PUFAs between the two studies. The mechanisms involved in the two conditions are probably also different. Our results were consistent with other studies which showed that EPA is able to induce eNOS translocation by dissociation from caveolin, eNOS phosphorylation, and NO synthesis in HUVECs [38]. By contrast, DHA was devoid of action on basal eNOS activity, but impaired histamine-induced eNOS activation and was unable to correct the deleterious effect of LysoPtdCho on histamine-stimulated eNOS activity or phosphorylation of Ser 1177. The difference between the two n-3 long chain PUFAs may be related to a higher membrane fluidity of endothelial cells grown in the presence of DHA than in the presence of EPA [40]. Such modifications in membrane properties may directly affect the functionality of membrane-bound proteins including eNOS or the accessibility of different membrane receptors including receptors for histamine or LysoPtdCho.

Our results also evidenced a difference between EPA and DHA in terms of ROS production and conjugated dienes formation, especially in the presence of LysoPtdCho. EPA and DPA are less unsaturated than DHA and may confer to the cells a lower sensitivity to radical attacks than DHA-enriched membranes [41]. Furthermore the incubation of cells with EPA induced a decrease of the membrane content in DHA. However, there are some discrepancies in the studies concerning the effect of DHA and EPA on lipid peroxide generation, either showing no modification [40] or showing a moderate increase of lipid peroxidation [42]. The amount of antioxidant compounds in the culture medium may partly explain these discrepancies. We also observed that the presence of LysoPtdCho in EPA-treated cells induced a decrease of DPA content in the cell membranes. Our study reported a large stimulation of ROS production at 24 h in cells cultured in the presence of DHA, especially in the presence of LysoPtdCho. This indicates probably that DHA must be incorporated in plasma membranes to become the target of free-radicals attack at their double bonds. This incorporation takes some time and explains the delayed effect of DHA on ROS production. The production of ROS was increased even more after concomitant exposure of cells to DHA and LysoPtdCho. The plasma membrane is probably modified by the presence of DHA and LysoPtdCho and the

antioxidant defense system located in plasma membranes becomes ineffective under such conditions. Similarly, oxidized LDL which contain large quantities of LysoPtdCho also induce ROS production in a time-dependent manner up to 4 days in monocytes/mononuclear cells [43].

In summary, the results of the present study show that the enrichment of Ea hy 926 cells with DHA favored ROS production in living cells, as already reported in an intestinal cell line [44] and aggravated the LysoPtdCho-induced oxidative stress. Furthermore, membrane DHA enrichment had no effect on basal eNOS activity, but impaired the stimulation of eNOS induced by histamine and was unable to correct the deleterious effect of LysoPtdCho on histamine-stimulated eNOS activity and Ser 1177 phosphorylation. By contrast, enrichment with EPA did not modify the ROS level produced in the presence or absence of LysoPtdCho, nor the basal eNOS activity and the stimulating effect of histamine on eNOS. However, it decreased the deleterious effect of LysoPtdCho on the histamine-stimulated eNOS activity as well as on the phosphorylation on Ser 1177 of eNOS. The dietary supplementation with n-3 PUFA is an increasing practice which could be justified by the beneficial role of EPA in vascular diseases. However, high intake of such fatty acids may have deleterious effects on endothelial cells, in particular those situations involving oxidative stress in which the balance between the synthesis of nitric oxide and its inactivation by oxidative stress may be unbalanced or improved by PUFAs. Oxidation susceptibility of n-3 PUFA requires to be counterbalanced by antioxidants. In-vivo human studies conducted in dyslipidemic subjects, have effectively demonstrated the positive potentials in combining n-3 PUFA dietary supplementation with vitamin E, niacin and γ -oryzanol to improve the lipid pattern, decrease serum ROS concentration and increase the total antioxidant capacity of serum together [45]. Convincing beneficial effects of a combination of vitamin E, vitamin C, and L-arginine, the natural precursor of NO, have been provided both on eNOS and oxidation-sensitive gene expression in human endothelial cells exposed to shear stress *in vitro* and *in vivo* [46]. Recently, nanomolar concentrations of DHA applied for 7 days on human coronary endothelial cells increased weak expression of eNOS in response to Akt kinase activation [47]. The effects of n-3 PUFAs remain conflicting between different experimental models and further studies will be required to confirm the real effects of DHA and EPA on atherogenesis. By contrast ARA a n-6 PUFA had no effect on ROS generation or eNOS activity in the basal state or after histamine-induced stimulation.

Acknowledgments The authors would like to thank Anne-Marie Gueugneau and Jean-Paul Macaire for their expert technical assistance and Kim NG Bonaventure for carefully reading the manuscript.

Abstract The study was undertaken to determine whether eicosapentaenoic acid (EPA, 20:5 n-3) and docosahexaenoic acid (DHA, 22:6 n-3), esterified in phospholipids (PL) as liposomes or in triglycerides (TG) as oil, exhibited comparable fates in liver lipids and whether these fates were associated with gene expressions related to fatty acid (FA) metabolism. PL and TG mixtures with close contents in EPA and DHA were administered to rats over 2 weeks. Most relevant events occurred after 3 days for both treatments. At that time, liposomes, compared with oil, increased the liver content in PL with a FA composition enriched in n-6 FA, comparable in DHA and much lower in EPA. Moreover, liposomes increased the activity and mRNA levels of carnitine palmitoyltransferase (CPT) I. In contrast, fish oil exerted opposite effects on CPT I and increased the genic expression of lipogenic enzymes. Liposomes, unlike fish oil, apparently increased the mRNA levels of acyl-CoA oxidase and the activity of the peroxisomal FA-oxidising system. Concomitantly, mRNA levels of hepatic lipoprotein receptors were increased with both diets, but intracellular proteins involved in free FA uptake and lipid synthesis were up-regulated only with liposome-treated rats. The quasi absence of EPA in hepatic PL of

liposome-treated rats on the short term could result from increased β -oxidation activities through metabolic regulations induced by more available free EPA and other PUFA.

Keywords Liposomes · Fish oil · EPA · Hepatic and plasma lipids · Mitochondrial and peroxisomal oxidation · Enzymes for lipogenesis · Proteins and enzymes for lipid transport

Abbreviations

AA	Arachidonic acid
ACC	Acetyl-CoA carboxylase
ACO	Acyl-CoA oxidase
CS	Citrate synthase
CPT	Carnitine palmitoyltransferase
CTPpct	Phosphocholine cytidylyltransferase
DAG	Diacylglycerol
DGAT	Acyl-CoA:diacylglycerol acyltransferase
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
FA	Fatty acid
FAS	Fatty acid synthase
FFA	Free fatty acids
FAT/CD36	Fatty acid translocase
GC	Gas chromatography
HAD	Hydroxyacyl-CoA dehydrogenase
LDL-R	LDL-receptor
LRP	Low density lipoprotein receptor-related protein
MAO	Monoamine oxidase
MUFA	Monounsaturated fatty acids
PFAOS	Peroxisomal FA-oxidising system
PPAR α	Peroxisome proliferator activated receptor α
PL	Phospholipids

PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
TLC	Thin layer chromatography
TG	Triglycerides

Introduction

Polyunsaturated fatty acids (PUFA) of the n-3 series, especially eicosapentaenoic acid (EPA, 20:5 n-3) and docosahexaenoic acid (DHA, 22:6 n-3), have received considerable interest since they were associated with beneficial health effects regarding atherosclerotic vascular disease [1–3] or inflammatory disease [4, 5]. In this context, there is a growing interest to increase the intake of n-3 PUFA. Different strategies have been developed consisting in using food enriched in n-3 PUFA [6, 7], diets supplemented with marine oils [8, 9], free fatty acids (FFA) [10] or ethyl-fatty acid (FA) esters [11–13]. Furthermore, some studies have focussed on the difference in the chemical form of the FA esters because it may affect the absorption, distribution and metabolic fate of long-chain PUFA, especially when these are given as triglycerides (TG) or phospholipids (PL) [14–19].

Liposomes are currently prepared from different PL sources such as egg or soybean [20]. Phospholipids extracted from marine organisms were also used as they presented nutritional interests due to their high PUFA contents [21]. In marine lipid-based liposomes, PUFA were shown to be not very sensitive to oxidation under conditions resembling those within the gastrointestinal tract [21, 22]. Besides, marine PL were actively hydrolysed by phospholipase A₂ within preformed interfaces [21, 22]. These properties made it possible to use liposomes for PUFA supplementation and, thus, to compare the intestinal fate of marine lipid-based liposomes (PL essentially) with that of fish oil (TG essentially). In rats fed any dietary lipid source presenting a close FA composition, lymphatic TG and PL amounts were similar [23] and a hypotriglyceridemic effect was observed in both cases over the 2 weeks of the trial [24]. Fish oil induced a decrease in plasma PL over the whole period but, with liposomes, plasma PL decreased only after 3 days of treatment with progressive reversion to the initial value [24]. At the end of the two dietary treatments, FA compositions of plasma lipids strongly differed presumably resulting from the alteration of the liver lipid FA compositions with possible consequences on lipid-related regulations occurring during the first 2 weeks of the trial. The aim of the present study was therefore to determine whether EPA and DHA, esterified in PL as liposomes or in TG as oil, exhibited comparable effects on liver lipid metabolism. This was performed, first, through the determination of the time course distribution of the main PUFA

in the liver and plasma lipids of rats orally injected with liposomes or fish oil over 2 weeks. Second, we investigated whether the changes in liver FA distribution resulted from altered activities involved in EPA and other PUFA β -oxidation, and whether these changes were associated with the modification of the expression of genes related to lipid transport and esterification.

Experimental Procedure

Animals and Diets

Official French regulations for the care and use of laboratory animals were followed. Five-week-old male Wistar rats weighing 250–300 g obtained from Elevage Janvier (Saint-Berthein, France) were housed in a controlled environment with constant temperature ($21 \pm 1^\circ\text{C}$) and humidity (50%). They were fed ad libitum a standard diet (AO4, UAR, Epinay, France) for 5 days, then a fat-free diet (UAR) for 2 days before and during the supplementation experiments. Every morning of the experimental period, they were injected, through a gastric cannula, with 3 g of lipids per kg of body weight as either fish oil (rich in TG) or liposome suspension (rich in PL [23, 24]). The lipid source referred to as fish oil was composed of a mixture of a n-3 PUFA rich oil derived from several fish oils (EPAX 2050 TG, Polaris, France), a commercial vegetable oil and cholesterol (Sigma, Saint Quentin Fallavier, France) to balance the lipid species and FA compositions of the liposome suspension based on a crude marine lipid extract. This allowed the accurate comparison of fates of EPA and DHA originating from fish oil and liposomes. For both diets, n-3 PUFA, n-6 PUFA and cholesterol contents were adjusted to get a final fat bulk providing $\sim 9.3\%$ of energy. In particular, EPA and DHA represented 19 and 39% of total FA in fish oil, and 15 and 37% of total FA in liposomes, respectively. Lipid classes and their FA compositions as well as liposome preparation have been previously detailed [21, 23–25]. At least four rats were killed each time: on day 0 as common controls, thereafter on days 3, 7 and 13, on both lipid treatments. The animals were killed after pentobarbital anesthesia, their livers were removed, washed with a saline solution (9% NaCl), blotted and weighed. One part of the livers was immediately used for the isolation of a mitochondrial fraction as already described [26], while the remaining part was stored at -20°C for further analysis.

Analytical Methods

Total lipids from liver samples with glyceryl triheptadecanoate and 1,2-dipentadecanoyl-*sn*-glycero-3-phosphocholine added as internal standards for further TG and PL

quantification, respectively, were extracted with 20 vol of chloroform/methanol (2:1, v/v) according to the method of Folch et al. [27]. TG and PL were separated by thin layer chromatography using hexane/ether/methanol/acetic acid (90:20:3:2 by vol) as a developing solvent. The Merck silica gel (60G) glass plates (20 × 20 cm, 0.5 mm thickness) were previously activated at 110 °C for 1 h. FA of TG and PL were transmethylated by boron trifluoride-methanol complex [28] and their methyl esters were analysed by gas chromatography (GC) separation on a Carbowax 20 M capillary column (30 m long, 0.32 mm i.d., helium as a carrier gas). The GC system was a gas chromatograph Packard (model 438) equipped with a flame ionisation detector Shimadzu CR3A. The injector and the detector were maintained at 230 °C. The column temperature was first fixed at 80 °C for 1 min, then increased from 80 to 170 °C over 3 min and from 170 to 210 °C over 10 min. The monitored FA-related peak surfaces were treated by a Shimadzu integration system. FA from Sigma France and natural extracts of known composition were used as standards for column calibration.

Hepatic Enzyme Activities

The content of liver in mitochondria was indirectly estimated through the determination of activities of monoamine oxidase (MAO) [29] and citrate synthase (CS) [30], as marker enzymes of mitochondrial outer membranes and matrix, respectively, and in peroxisomes through the determination of urate oxidase activity [31]. Carnitine palmitoyltransferase (CPT) I activity was measured on isolated mitochondrial fractions as previously detailed [26]. The measurement of CN⁻-insensitive palmitoyl-CoA-dependent NAD⁺ reduction [32], described as the peroxisomal FA-oxidising system (PFAOS), gave specific information about the peroxisomal very long chain FA β -oxidation capacity. Measurements of MAO, CS, urate oxidase and PFAOS activities were performed on crude liver homogenates and were expressed per g of liver.

Gene Expression

Total mRNA was extracted from the livers by the Tri-Reagent method adapted from the procedure of Chomczynski and Sacchi [33]. Tri-Reagent was provided by Euromedex (Souffelweyersheim, France). Total mRNA was reverse-transcribed using the Iscript cDNA kit (Bio-Rad). Real-time PCR was performed as described previously in a 96-well plate using an iCycler iQ (Bio-Rad) [34]. Primer pairs were designed using 'Primers!' software and were synthesised by MWG-Biotech AG (Ebersberg, Germany). The sequences of the forward and reverse primers used were: 5'-atcgagcaggatagag-3' and 5'-accacctgtcaagcatcttc-3'

for CPT I; 5'-aggagcgtcttgaaaacag-3' and 5'-actctcgcaaaagaatggc-3' for hydroxyacyl-CoA dehydrogenase (HAD); 5'-cgaactgtccgctacttc-3' and 5'-tgagttaccccaaatgc-3' for peroxisome proliferator activated receptor α (PPAR α); 5'-aggtggctgtaagaagagtgc-3' and 5'-ccgagatgccatattccctc-3' for acyl-CoA oxidase (ACO); 5'-gctgggggactcagaat-3' and 5'-aggaaaagcagtaccgaac-3' for acetyl-CoA carboxylase (ACC) 1; 5'-cctgatagtgcgggaaag-3' and 5'-tctgggtggtcgaataacttg-3' for fatty acid synthase (FAS); 5'-gcctacgctgtttctcacc-3' and 5'-ggcctcgccattagaatg-3' for low density lipoprotein receptor-related protein (LRP); 5'-tgggtcca taggtttctg-3' and 5'-ttgggatcaggctggtat-3' for LDL-receptor (LDL-R); 5'-tccagaaccagacaacca-3' and 5'-ccaatg ccagcacacata-3' for fatty acid translocase (FAT/CD36); 5'-tcctaccgggatgcaatct-3' and 5'-ctcgtagtgcaggtgtgcc-3' for diacylglycerol acyltransferase (DGAT1); 5'-gattgattcgtc gccat-3' and 5'-cctgctcttgatgtgctta-3' for phosphocholine cytidylyltransferase (CTPpct); 5'-tgagcttagcgttcttttg-3' and 5'-agctttcttggggtcagc-3' for HMG-CoA reductase; 5'-aga-gtaatacatgccgacg-3' and 5'-accgggtggtttgatct-3' for 18S. Data were analysed using the Bio-Rad software and Microsoft Excel. The relative gene expression quantitation was calculated from standard curves for each gene established using four dilutions (1/10–1/10,000) of cDNA positive controls and normalised with 18S.

Statistical Analysis

Differences between the two groups were tested for significance by using the ANOVA or Fisher's *t* tests and were considered significant at *P* < 0.05. Data were expressed as mean values \pm SEM.

Results

Fatty Acid Contents of Liver and Plasma Lipids

Between the common starting time (day 0) and day 13 on the diet supplemented with fish oil or liposomes, variations of very low amplitude were observed in liver TG, expressed as their contents in total FA (Fig. 1a, dotted lines). Over the 13 days, for both treatments, the amounts of total FA in TG remained under 5 mg/g of liver (Fig. 1a, dotted lines) and under 2 mg/g of liver for saturated fatty acids (SFA) (Fig. 1b, dotted lines) and monounsaturated fatty acids (MUFA) (Fig. 1c, dotted lines). Regardless of the treatment, the content of TG in the main FA of n-3 and n-6 families remained under 1 mg/g of liver (Figs. 2, 3, dotted lines). From 25 mg of total FA in PL per g of liver at the beginning of the trial period, an increase reaching 27 and 30 mg/g of liver was observed after 3 days of fish oil or liposome treatment, respectively. Over the whole period,

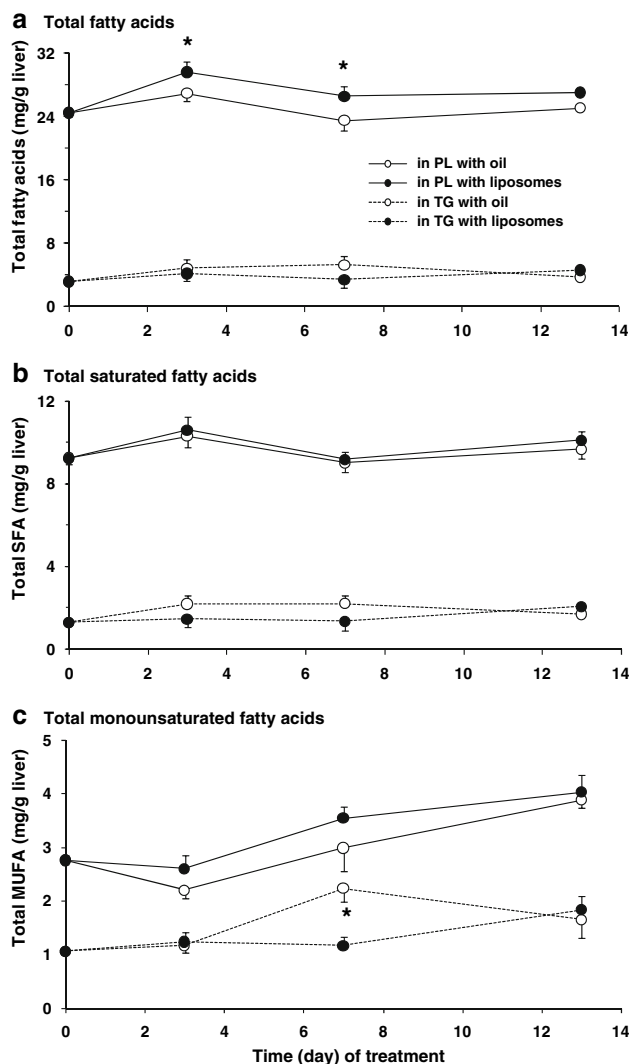

Fig. 1 Time course content in total (a), saturated (b) and monounsaturated (c) fatty acids of TG and PL in the liver of rats fed fish oil or liposomes over 13 days. Values of each point (with symbols defined in a) are means \pm SEM ($n \geq 4$ rats). Means at a time on either lipid source, given with an asterisk, differ at $P < 0.05$

the values expressed per g of liver with the liposome group were significantly greater (~ 3 mg) than with the fish oil group (Fig. 1a, continuous lines). As regards SFA and MUFA that originated from dietary source, lipogenesis, and possibly desaturation, there was no statistical difference between values obtained from fish oil and liposome groups at any time of the trial (Fig. 1b, c, continuous lines). In total FA of liver PL, 12% were n-3 PUFA, with more than 90% represented by EPA and DHA. Between days 0 and 3, DHA contents of liver PL increased nearly similarly with both diets (Fig. 2a, continuous lines), while the enrichment in EPA of PL was 4 times lower with liposomes than with fish oil (Fig. 2b, continuous lines). Concomitantly, there were significant greater contents in

Fig. 2 Time course content in docosahexaenoic (DHA) (a) and eicosapentaenoic (EPA) (b) of TG and PL in the liver of rats fed fish oil or liposomes over 13 days. Statistical data as indicated in the legend of Fig. 1

the main two representative n-6 FA, arachidonic (AA, 20:4 n-6) and linoleic (18:2 n-6) acids in rats fed liposomes than in those fed fish oil (Fig. 3a, b, continuous lines). On the whole, giving fish oil or liposomes containing close FA contents very differently affected both the distribution and content of EPA and representative n-6 PUFA in total liver PL.

The time course content in plasma TG and PL has been previously given by Cansell et al. in [24], while the present study detailed the distribution of the main n-3 and n-6 PUFA in total plasma lipids (Fig. 4a–d). The percentage in DHA was shown to increase from day 0–3, then plateaued until day 13 with both treatments. This was not the case with EPA, whose increase with liposomes was nearly 3- and 2-times less elevated than with fish oil on days 3 and 13, respectively (Fig. 4b). Inversely, AA and linoleic acid, that initially represented 18 and 15% of total FA in plasma lipids, respectively, dropped to nearly 11 and 5% after 13 days, with no significant difference from each FA between both treatments all over the whole trial period (Fig. 4c, d).

Mitochondrial and Peroxisomal Activities

The mitochondrial content of livers was estimated through two marker enzyme activities unrelated to FA

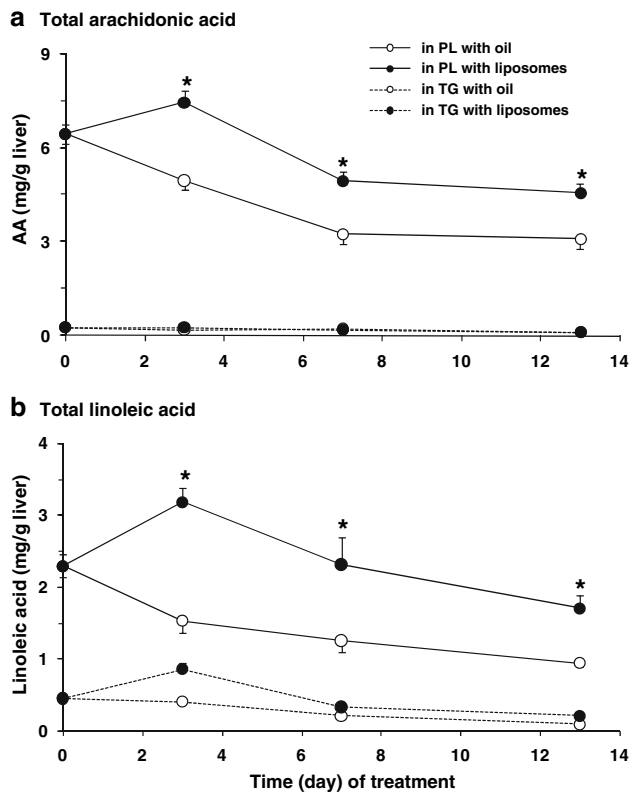

Fig. 3 Time course content in arachidonic acid (AA) (a) and linoleic acid (b) of TG and PL in the liver of rats fed fish oil or liposomes over 13 days. Statistical data as indicated in the legend of Fig. 1

oxidation, thereby unlikely to be altered by both lipid treatments, one being located in the mitochondrial outer membrane (with MAO), the other one representing a key step of the tricarboxylic acid cycle in the matrix (with CS). Figure 5a shows that there was no significant difference for enzyme activity between fish oil and liposomes, which suggested no change in the mitochondrial content of the livers of rats receiving both lipid sources. As regards the corresponding FA oxidation pathway, CPT I activity was significantly greater with the liposome treatment than with the fish oil one at all the times studied, as pointed out by an increasing activity with liposomes on day 3 and a decreasing activity with fish oil at all the times (Fig. 5b). The results with liposomes nearly paralleled the levels of mRNA found for CPT I and HAD (Fig. 5c, d), whose activities catalyse the entry of FA into mitochondria and the beginning of the β -oxidation cycle, respectively. With fish oil, the levels of mRNA for either enzyme were all decreased, except on day 3 for HAD (Fig. 5c, d).

The peroxisomal content of the livers was estimated through the activity of urate oxidase, a specific component of rat liver peroxisomes. All values were comparable with both treatments, except on day 3 (Fig. 6a), probably

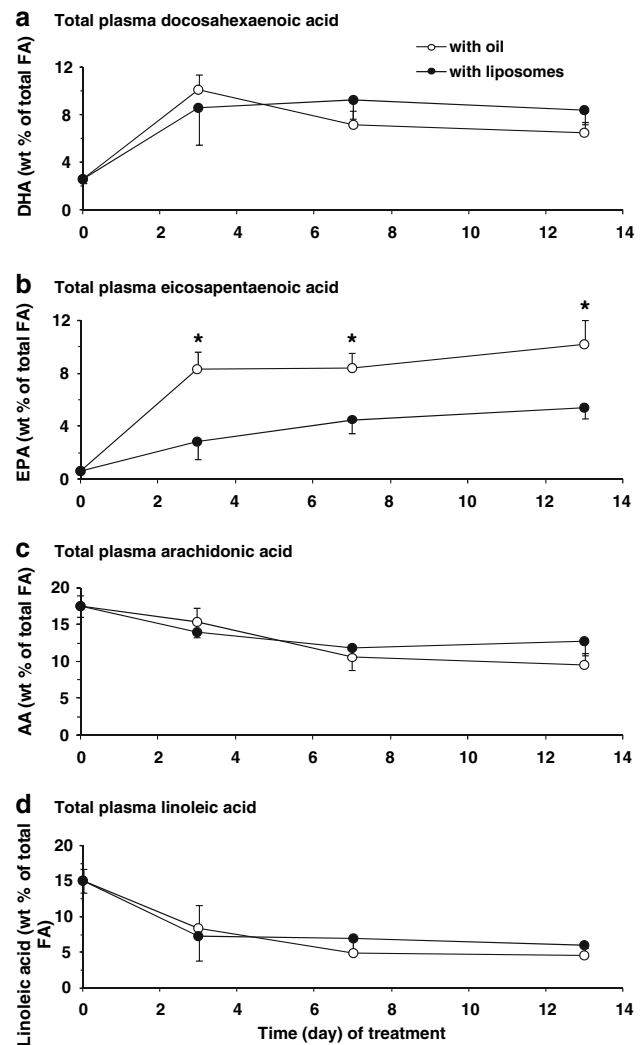

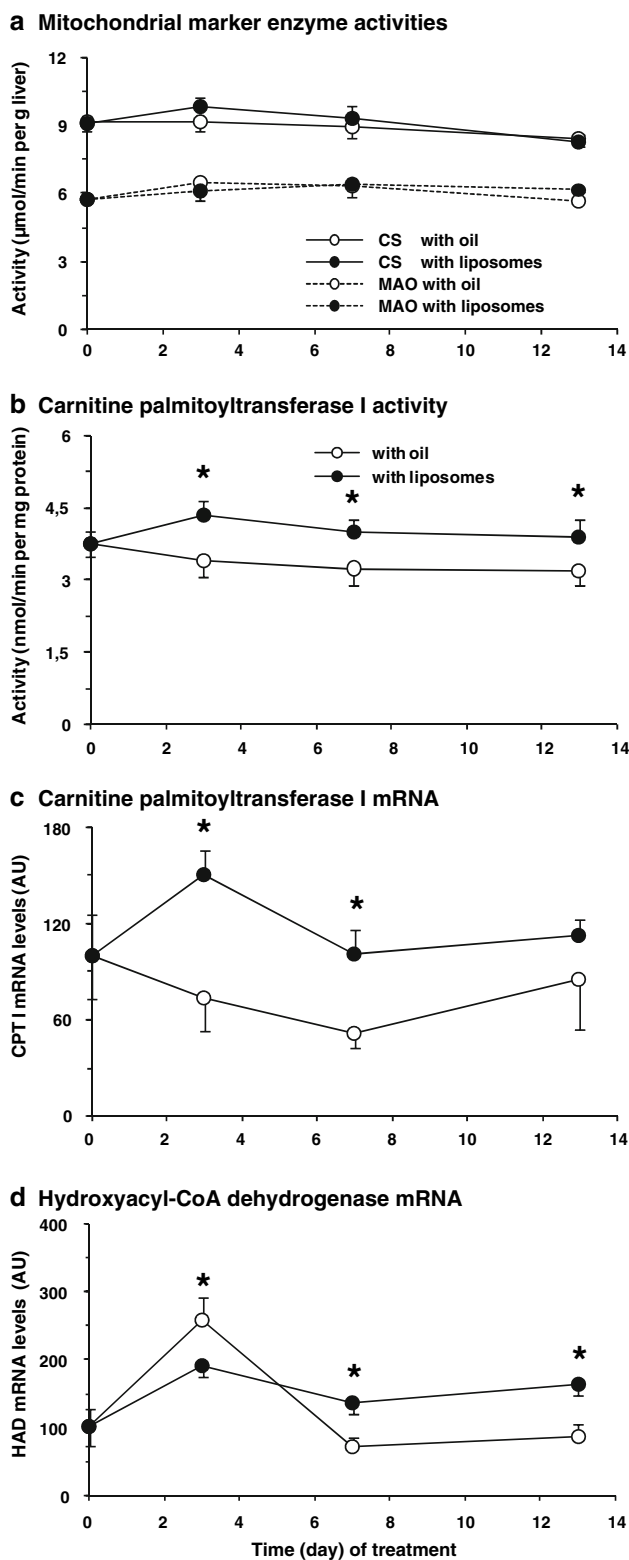

Fig. 4 Time course weight percentage of docosahexaenoic (DHA) (a), eicosapentaenoic (EPA) (b), arachidonic (AA) (c) and linoleic (d) acids in total plasma lipids of rats fed fish oil or liposomes over 13 days. Statistical data as indicated in the legend of Fig. 1

accounting for undetermined molecules interfering in the reaction. However, stable and comparable values on days 0, 7 and 13 suggested that the initial amounts of peroxisomes per g of liver were preserved in rats fed fish oil or liposomes. As regards PFAOS (a group of enzymes acting at the beginning of the peroxisomal β -oxidation cycle, particularly on long- and very-long chain FA), its activity moderately increased from day 0 to 13 with both diets (Fig. 6b), but earlier and to a greater extent in rats ingesting liposomes, especially on day 3. Over the whole trial, PPAR α mRNA levels were unaffected with any of the lipid sources, except a down-regulation on day 7 with fish oil (Fig. 6c). Expression levels of ACO, that is the first enzyme of the PFAOS sequence, are very sensitive to PPAR α activation and statistically increased at any time of

the liposome treatment (Fig. 6d). These data contrasted with the neutral or negative (on day 7) effect of fish oil on ACO mRNA levels (Fig. 6d).

Fig. 5 Time course activities of mitochondrial marker enzymes (a) and carnitine palmitoyltransferase I (CPT I) (b), and mRNA levels of CPT I (c) and hydroxyacyl-CoA dehydrogenase (HAD) (d) in the liver of rats fed fish oil or liposomes over 13 days. Activity rates of citrate synthase (CS) were given as $\mu\text{mol}/\text{min}$ per g of liver and those of monoamine oxidase (MAO) were increased 10 times to fit nearly in the middle of the graph. CPT I activity was given as nmol of palmitoyl-CoA whose palmitoyl moieties were transferred to carnitine per min and per mg of mitochondrial protein. Gene expressions are given as arbitrary units (AU) by reference to those obtained on day 0 (=100). For each gene, 18S was used for normalisation. Statistical data as indicated in the legend of Fig. 1

Gene Regulation of Enzymes and Proteins Providing Liver Cells with Lipids

From the lipogenic point of view, the levels of ACC1 mRNA increased and were almost comparable with both lipid sources over the whole trial period (Fig. 7a). The levels of FAS mRNA on day 3 were significantly more elevated with fish oil and practically unchanged with liposomes, but, on day 13, they increased only with liposomes (Fig. 7b). Concerning circulating fats, liver cell-surfaces are equipped with LRP, a property of which is to recognise chylomicron remnants via their ApoE moieties. Figure 8a shows that LRP mRNA levels dramatically and similarly increased with both fish oil and liposomes only on day 3. LDL-R of liver cell membranes have the capacity to take up LDL from blood and their expression levels reached a maximum on day 3 in rats fed fish oil, with a same though delayed increase on day 13 in rats fed liposomes (Fig. 8b). As regards FAT/CD36, a role of which is to take up/transport FFA from cell membranes to the cytoplasm through translocation mechanism, its expression levels were unchanged with fish oil over the whole trial period, but sharply increased (more than 10 times) only with liposomes on day 3 (Fig. 8c).

Expression Levels of Enzymes Involved in FA Esterification

Liver FA arising from lipogenesis and circulating lipids are β -oxidised or ascribed to TG and PL synthesis for fat deposit, membrane building and lipoprotein assembly. The expression levels of key enzymes of TG synthesis (DGAT) and of phosphatidylcholine synthesis (CTPpct) were unchanged with fish oil at any time of the trial, but with liposomes there was a significant increase in mRNA levels of DGAT and CTPpct only on day 3 (Fig. 9a, b). Cholesterol used with TG and PL for lipoprotein assembly mainly arises from internalised LDL and from the activity of HMG-CoA reductase, a key enzyme of the cholesterol synthesis whose level depends on available acetyl-CoA moieties. Figure 9c shows that there were increased levels of HMG-CoA reductase mRNA mainly on day 3 with both lipid sources, but to a nearly twice greater extent with liposomes than with fish oil.

Fig. 6 Time course activities of peroxisomal urate oxidase (a) and peroxisomal FA oxidising system (b), and mRNA levels of peroxisome proliferator-activated receptor alpha (PPAR α) (c) and acyl-CoA oxidase (ACO) (d) in the liver of rats fed fish oil or liposomes over 13 days. Statistical data and gene expressions as indicated in the legends of Figs. 1 and 5, respectively

Discussion

The study shows that the administration of two marine fats essentially consisting of TG (fish oil) or PL (liposomes) with nearly identical n-3 PUFA contents resulted in early

Fig. 7 Time course mRNA levels of acetyl-CoA carboxylase (ACC) (a) and fatty acid synthase (FAS) (b) in the liver of rats fed fish oil or liposomes over 13 days. Statistical data and gene expressions as indicated in the legends of Figs. 1 and 5, respectively

distinct time course fates of EPA and n-6 PUFA in liver PL. On day 3, the apparent increase of liver PL in arachidonic and linoleic acids with liposomes was particularly unexpected because these n-6 PUFA were absent from the lipid mixture ingested [24]. The amounts of PUFA of n-3 and n-6 series recovered in liver TG were too low after the administration of both lipid sources to provide any relevant information about the early events related to lipid metabolism. The changes in FA composition of liver PL were expected to depend on particular reciprocal exchanges between blood and liver lipids, and also on specifically regulated activities in hepatocytes.

Influence of Extrahepatic Fats on Liver Lipids

The rats were sacrificed 24 h after the last administration of both lipid mixtures. In the meantime, chylomicrons derived from ingested fats were partially used for the metabolic requirements of most organs and the replenishment of

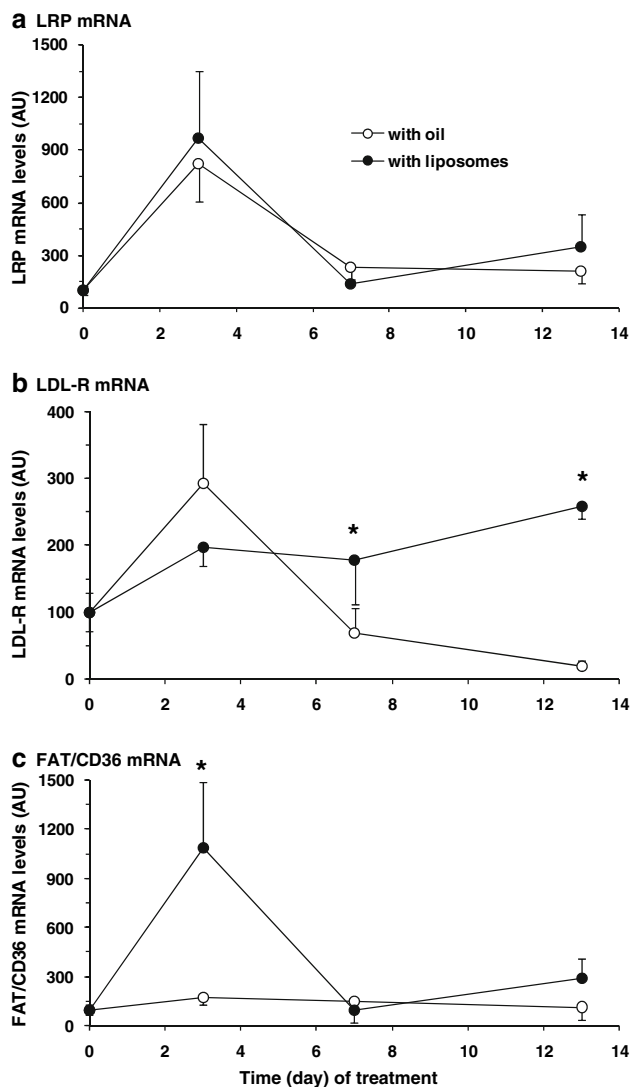

Fig. 8 Time course mRNA levels of LRP (a), LDL-R (b), and FAT/CD36 (c) in the liver of rats fed fish oil or liposomes over 13 days. Statistical data and gene expressions as indicated in the legends of Figs. 1 and 5, respectively

adipose tissues. Chylomicron remnants were then recognised, via their ApoE moieties, by LRP present on liver cell-surfaces [35] and internalised. The apparent comparable up-regulation of these receptors only on day 3 for both treatments showed that the underlying mechanisms were unrelated to the nature of the lipid source. During the time of dietary fat deprivation, VLDL secreted by the liver and used in most organs evolved as LDL that were removed from blood via LDL-R of liver membranes. These receptors were also up-regulated on day 3 with both lipid sources. However, their up- and down-regulation at the end of the trial period with liposomes and fish oil, respectively, suggested that the lipid assembly of VLDL within liver cells largely depended on the origin of ingested fats and/or on particular intrahepatic lipid-related activities. It is worth

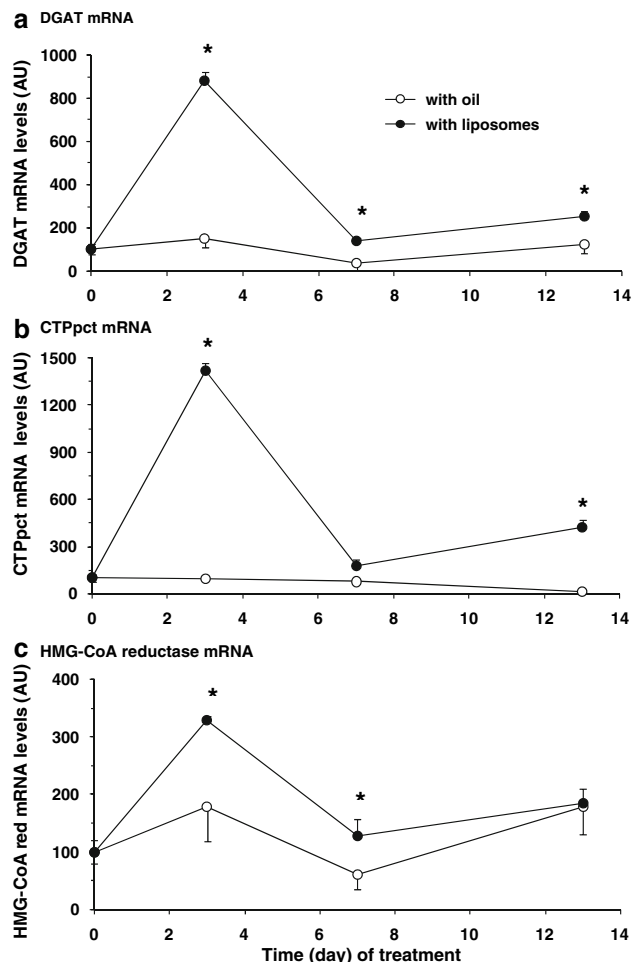

Fig. 9 Time course mRNA levels of DGAT (a), CTPpct (b) and HMG-CoA reductase (c) in the liver of rats fed fish oil or liposomes over 13 days. Statistical data and gene expressions as indicated in the legends of Figs. 1 and 5, respectively

noting that FAT/CD36 was strongly up-regulated only on day 3 with liposomes. This suggested a greater entry of FFA into liver cells, after increased extra hepatic lipolytic activities. This hypothesis could explain the punctual increase in arachidonic and linoleic acids of liver PL on day 3 with liposomes characterised by the lack of n-6 PUFA [24].

Esterification, Assembly and Secretion of Liver Lipids

The very low level of liver fats with each of our lipid sources suggested that the levels of VLDL secretion was maximum, but was not associated with excess blood fats, as this has been observed in other comparable situations [36, 37]. Yet, liposomes were shown to increase, only on day 3, the levels of expression of DGAT and CTPpct implied in TG and PL synthesis, respectively, but there was no marked difference in liver and blood lipid contents

between both treatments. VLDL assembly requires, in addition to TG and PL, cholesterol that was provided by dietary fats and endogenous synthesis. The induction of HMG-CoA reductase, only on day 3 with liposomes, could be considered as complementary of TG and PL synthesis for VLDL assembly. Yet, none of these up-regulations with liposomes appeared to be essential because fish oil exhibited comparable effects on liver and blood lipids [24]. Since EPA was reported to down-regulate lipogenic genes [38–42], the transitory up-regulation of DGAT and CTPpct on day 3 with liposomes could result from other FA released from extrahepatic tissues.

Metabolic Fates and Regulatory Effects of Liver PUFA

Dietary fats exert versatile effects in the liver through their constitutive FA, as membrane lipid building, cell energy requirement and gene regulation. The minimal amounts of EPA from liver PL and blood lipids in the very short term with liposomes, compared with fish oil, strongly suggested that EPA was largely oxidised during the first days of treatment. This n-3 PUFA was demonstrated to be oxidised both in mitochondria and peroxisomes, while DHA oxidation was shown to occur only in peroxisomes [43]. The data collected showed that the mitochondrial and peroxisomal contents of liver were unchanged no matter what the lipid source. Moreover, the increased activities and mRNA levels of key enzymes related to corresponding FA oxidation pathways after 3 days of liposome treatment could be responsible for the early oxidation of EPA. This effect should be mainly mediated through CPT I whose activity was always greater with liposomes than with fish oil. The difference in CPT I activity between both treatments might appear to be of too low amplitude considering the almost absence of EPA in PL on day 3 with liposomes, but could be much greater by taking into account the characteristic of CPT I to be more active at low malonyl-CoA concentrations. Indeed, as already mentioned, the animals were killed 24 h after the last intragastric injection of the lipid mixture, but were provided in the meantime with a fat-free diet. This diet containing carbohydrates should increase the lipogenic pathway via insulin secretion. This normal physiological answer was illustrated by the two times increase in ACC expression with both lipid sources, but was only consistent on day 3 of the fish oil treatment with FAS expression that increased 3 times. This means that, if the expression levels were equally effective on enzyme synthesis and activity, malonyl-CoA produced by the former reaction was not only used for FA synthesis, but also for CPT I inhibition [44] and thus EPA preservation. By contrast, with liposomes, malonyl-CoA formation should normally give rise to reduced CPT I activity, but that happened without any increased FAS expression. These

apparently inconsistent data might result from particular effects of PUFA on enzymes of the lipogenic pathway. Indeed, ACC was demonstrated to be activated by insulin and inactivated in the presence of PUFA through reversible enzyme conformation [45]. This means for instance that existing and newly synthesised ACC were deactivated in the presence of increased free PUFA concentration. Besides, free EPA was shown to inhibit not only ACC (as some other PUFA), but also the whole lipogenic pathway with FAS [42]. Under these latter conditions, FA synthesis might be reduced partly because of a decreased malonyl-CoA synthesis, which increased CPT I activity and consequently the mitochondrial oxidation of EPA and other PUFA. As EPA is oxidised in mitochondria to a greater extent than AA [46], it was coherent that, on day 3 with liposomes, EPA was reduced and AA increased in PL by comparison with fish oil (Figs. 2b vs. 3a). In addition, with greater ACO expression levels in liposome-fed than in fish oil-fed rats, peroxisomal oxidation was expected to target more efficiently EPA and AA. However, the increase in AA on day 3 with liposomes indicated that the peroxisomal activity was insufficient to prevent the temporary increase of PL in AA, yet absent from the lipid source. The increase in both the expression and activity of CPT I, with a nearly basal level of PPAR α expression with liposomes, might be due to a sufficient activation of existing receptors by cell PUFA as already observed [47] and to the fact that liver CPT I was also regulated by PUFA through a PPAR α -independent pathway [48].

Origin of Increased Free n-6 PUFA in the Liver of Liposome-Fed Rats

The above results implied that efficient free PUFA concentrations existed in liver cells during the first 3 days of the liposome treatment and originated from extrahepatic lipolytic activities. In vivo data show that PL or PL-derived compounds exert lipolytic effects on adipose tissues in mice [49], rabbits [50] and humans [51], but our previous studies did not reveal any significant difference in the lipid class composition of intestinal lymph between both lipid sources [23]. By contrast, direct EPA administration was shown to reduce the level of retroperitoneal adiposity through the inhibition of the adipogenic transcription factor PPAR γ gene expression [52]. Very recently, EPA was demonstrated to increase lipolysis in 3T3-L1 adipocytes through up-regulation of the lipolytic gene expression and down-regulation of the adipogenic gene expression [53]. Finally the release of EPA from blood lipids, to a greater extent with liposomes than with fish oil, appeared to be a prerequisite for the early dissimilar fates of EPA and n-6 PUFA in liver PL. The greater bioavailability of EPA in rats fed liposomes compared with fish oil might originate

from the initial distribution of PUFA in plasma lipids. Indeed, we previously showed that EPA was less abundant in the *sn*-2 position of chylomicron TG in rats fed liposomes than in those fed fish oil [23]. A similar unequal distribution was found in plasma and liver TG from rats fed diets enriched in seal oil, with more EPA in the *sn*-1 position [54]. Assuming that this latter position was more sensitive to hydrolysis than the *sn*-2 one [55], EPA might be more rapidly released and might immediately exhibit its lipolytic effect on adipose tissues. EPA and other PUFA taken up by liver cells might then act on gene regulation, resulting particularly in early mitochondrial EPA oxidation and a decrease in lipogenic activity.

This time course study underlined the importance of events occurring in rats fed marine fats for 3 days and demonstrated that EPA present in fish oil and marine liposomes did not exert comparable effects on liver lipid related-metabolic pathways with direct consequences on its own distribution in PL. Because of the beneficial effects of marine fats on health, the early specific hydrolysis of EPA as a free form from liposome-derived blood lipids deserves to be clarified further.

Abstract In this study, we assessed the ability of six strains of bifidobacteria (previously shown by us to possess the ability to convert linoleic acid to *c*9, *t*11-conjugated linoleic acid (CLA) to grow in the presence of α -linolenic acid and to generate conjugated isomers of the fatty acid substrate during fermentation for 42 h. The six strains of bifidobacteria were grown in modified MRS (mMRS) containing α -linolenic acid for 42 h at 37 °C, after which the fatty acid composition of the growth medium was assessed by gas liquid chromatography (GLC). Indeed, following fermentation of one of the strains, namely *Bifidobacterium breve* NCIMB 702258, in the presence of 0.41 mg/ml α -linolenic acid, 79.1% was converted to the conjugated isomer, C18:3 *c*9, *t*11, *c*15 conjugated α -linolenic acid (CALA). To examine the inhibitory effect of the fermented oils produced, SW480 colon cancer cells were cultured in the presence of the extracted fermented oil (10–50 μ g/ml) for 5 days. The data indicate an inhibitory effect on cell growth ($p \leq 0.001$) of CALA, with cell numbers

reduced by 85% at a concentration of 180 μ M, compared with a reduction of only 50% with α -linolenic acid ($p \leq 0.01$).

Keywords *Bifidobacterium* · α -Linolenic acid · Conjugated α -linolenic acid (CALA) · Cancer · Health promotion

Introduction

α -Linolenic acid is an essential dietary fatty acid, which has been reported to exhibit anti-carcinogenic effects in animals [1, 2]. Recently, minute concentrations of α -linolenic acid biohydrogenation intermediates, such as the *c*9, *t*11, *c*15 C18:3 isomer have been identified in milk [3]. It has been reported that a conjugated form of α -linolenic acid may be more potent in terms of health promoting benefits than the parent α -linolenic acid molecule. Indeed, the conjugated linoleic acid (CLA) isomers (in particular, *c*9, *t*11 CLA and *t*10, *c*12 CLA) have been the focus of considerable research efforts in recent years, and are now known to confer many health benefits including anti-cancer [4–7], anti-obesity [5, 8, 9] and anti-atherosclerotic [5, 10, 11] effects. Recent evidence has also highlighted health promoting properties with regard to other conjugated PUFAs [12, 13]. These include fatty acids such as *c*9, *t*11, *t*13 α -eleostearic acid (α -ESA) [14–16] demonstrating anti-cancer properties, and *c*9, *t*11, *c*13 conjugated linolenic acid which has demonstrated a hypolipidemic effect [17]. Indeed, α -ESA was shown to have a more potent anti-tumour effect than *c*9, *t*11 and *t*10, *c*12 CLA in nude mice with DLD-1 human colon cancer cells [15]. Furthermore, when conjugated α -linolenic acid (CALA) and CLA were examined separately during the initiation and promotion

stages of PhIP-induced mammary gland carcinogenesis in rats, both CALA and CLA retarded development of mammary tumours and decreased mammary carcinogenesis in the post-initiation period with inhibition of cell proliferation [18].

Previously, we have shown that bifidobacteria of human origin are capable of producing the biologically active *c9*, *t11* CLA and *t9*, *t11* CLA isomers from linoleic acid during fermentation [19–21]. The aim of this study was to assess the ability of a selection of CLA-producing bifidobacteria to grow in and isomerise α -linolenic acid during fermentation in MRS medium. Furthermore, the inhibitory effects of the fermented fatty acids obtained following fermentation of *B. breve* NCIMB 702258 in the presence of α -linolenic acid were assessed and compared with the unfermented α -linolenic acid control.

Materials and Methods

Bacterial Strains

The bacterial strains used in this study are detailed in Table 1, and were selected based on their ability to isomerise linoleic acid to *c9*, *t11* CLA [19]. The bifidobacteria were grown anaerobically (anaerobic jars with Anaerocult A gas packs; Merck, Darmstadt, Germany) in MRS medium (Difco Laboratories, Detroit, MI, USA) with 0.05% (w/v) L-cysteine hydrochloride (98% pure; Sigma Chemical Co., St Louis, MO, USA) (cys-MRS), at 37 °C for 24–48 h.

Bioconversion of α -Linolenic Acid by Bifidobacteria

A selection of bifidobacteria (see Table 1 for details) were grown (2% inoculum) in cys-MRS with added α -linolenic acid (C18:3 *c9*, *c12*, *c15* octadecatrienoic acid, Sigma

Chemical Co.) to assess bioconversion of this substrate by the bifidobacteria. The α -linolenic acid was added as a 30 mg/ml stock solution in distilled water containing 2% (v/v) Tween 80. The α -linolenic acid stock solution was previously filter-sterilised through a 0.45 μ m Minisart filter and stored in the dark at –20 °C. The strains were incubated anaerobically for 42 h at 37 °C. Following incubation, the fatty acid composition of the bacterial supernatant was assessed following fat extraction and gas liquid chromatography (GLC) analysis, as described in Coakley et al. [19]. The fatty acid content in samples following the bioconversion assays were corrected against the fatty acids in the cys-MRS medium.

Identification of the Fatty Acid Product from Bioconversion of α -Linolenic Acid by Bifidobacteria

The bioconversion product resulting from the growth of bifidobacteria in medium containing α -linolenic acid was identified using diode array (DAD) and mass spectrometry (MS) detectors in line, following separation by HPLC. Separation of the product was carried out with a Hewlett–Packard 1100 HPLC system (Hewlett–Packard, Palo Alto, CA, USA) equipped with a diode array detector. A C-18 Inertsil 5 ODS-2 Chrompack column (5- μ m particle size, 150 \times 4.6 mm) (Chrompack International BV, Middleburg, The Netherlands), was used with a mobile phase of CH₃CN/H₂O/CH₃COOH (70/30/0.12, v/v/v) at a flow rate of 1.5 ml/min [22]. Conjugated diene unsaturated fatty acids were detected at 234 nm. Analytes in the HPLC mobile phase displaying second derivative UV spectra characteristic of the conjugated diene chromophore were further characterised by using HPLC Agilent 1100 HPLC system (Agilent, Palo Alto, CA) equipped with a APCI-MS in ion positive mode using a mobile phase of CH₃CN/H₂O/CH₃COOH (30/70/0.12, v/v/v) at a flow rate of 1 ml/min. For the HPLC-MS analyses, the mobile phase was modified with 2 mM of NH₄O₂CCH₃, as described previously [23].

Generation of CALA Oil for Assessment of Inhibitory Activity in SW480 Colon Cancer Cells

The CALA oil for the cell culture study was generated by growing *B. breve* NCIMB 702258 in cys-MRS supplemented with α -linolenic acid (0.5 mg/ml). A control for the cell culture study was generated with cys-MRS medium supplemented with 0.5 mg/ml α -linolenic acid (no bacteria added, thus no conversion). The oil (either the α -linolenic acid (control) or CALA (experimental) was extracted from the medium, as described above and assessed by GLC prior to use in the cell culture study. The oils were stored in ethanol under nitrogen at –20 °C. Human colon cancer

cells were obtained from the European Collection of Cell Cultures (ECACC, Porton Down, Salisbury, UK). Human colon cancer cells (SW480) were cultured in the presence of different concentrations of the fermented CALA oil and the unfermented α -linolenic acid control oil. Culture media and supplements were purchased from Sigma Aldrich Ireland Ltd. (Dublin, Ireland). The SW480 cells were maintained in Dulbecco's Minimum Essential Medium (DMEM) supplemented with 5% (v/v) fetal bovine serum, 0.2 mmol/L L-glutamine, 1 mmol/L HEPES and 1 unit/ml penicillin and streptomycin. SW480 cells were grown in 96 well plates and maintained at 37 °C in a humidified atmosphere. The pH of the media was maintained at 7.2–7.4 by a required flow of 95% air and 5% CO₂. Initially, 1×10^4 cells were seeded in wells and cultured for 24 h at 37 °C, allowing the cells to attach to the substratum. The medium was then replaced with media containing either of the two oils to yield CALA or α -linolenic acid concentrations ranging from 10 to 50 μ g/ml. Control flasks were supplemented with equivalent volumes of ethanol (0.5% v/v). Following incubation for 5 days, cell viability was determined using the MTS method (Promega Corporation, Madison, WI, USA), a colorimetric method for determining the number of viable cells in proliferation or cytotoxicity assays subsequent to incubation with MTS tetrazolium compound. Following incubation with MTS for 2 h, the absorbance was recorded at 492 nm with a 96-well plate reader. Cell viability (%) after treatment was expressed relative to the ethanol control which represents 100%. Three independent experiments were performed in triplicate for each treatment and the Student's *t* test was used to determine significant differences between treatments (* $p \leq 0.05$; ** $p \leq 0.01$; *** $p \leq 0.001$).

Results

Bioconversion of α -Linolenic Acid by Bifidobacteria

To assess whether the bifidobacteria in this study (Table 1) could generate a bioconversion product from α -linolenic acid, the strains were grown in the presence of the fatty acid for 42 h. While five of the *Bifidobacterium* strains assessed demonstrated the ability to convert α -linolenic acid to a modified fatty acid (based on GLC) (Fig. 1), *B. lactis* Bb12 did not exhibit the ability to modify the α -linolenic acid substrate. Furthermore, the *B. breve* strains exhibited intra-species variation in efficiency of modification of α -linolenic acid, varying from 67.6 for *B. breve* DPC 6035 to 80.7% for *B. breve* NCIMB 8807 in 0.24 mg/ml α -linolenic acid and 49.4 (*B. breve* NCTC 11815) to 79.1% (*B. breve* NCIMB 702258) in 0.41 mg/ml α -linolenic acid. All of the active *B. breve* strains were derived

from human intestinal sources (infant intestine, nursing stools and neonatal faeces).

Identification of the Bioconversion Product

The presence of conjugated double bonds in the modified fatty acid derived from fermentation of *B. breve* strains with linolenic acid was initially verified by UV spectrophotometry [24], by measuring the absorbance of the fat soluble hexane layer at a wavelength of 233 nm. Fatty acids with conjugated double bonds are characterised by an absorption peak at 233 nm.

The product resulting from the bioconversion of α -linolenic acid by *B. breve* NCIMB 702258 was subsequently identified (using DAD and MS detectors in line, following separation by HPLC) as *c9, t11, c15* CALA (data not shown). A further characterization of *c9, t11, c15* CALA was obtained by the UV and MS spectra (Fig. 2). The bioconversion product showed a mass spectrum with three signals at *m/z* 279.4, 296.4 and 301.4, which were identified as the $[M^+H]^+$, $[M^+NH_4]^+$ and $[M^+Na]^+$ quasi-molecular ions consistent with the molecular weight 278.4 Da of CALA.

Another peak on the bioconversion profile, generated at a much lower concentration than the *c9, t11, c15* CALA isomer, was tentatively identified as *t9, t11, c15* CALA (Fig. 3) by its lower max absorption with respect to the major peak attributed to *c9, t11, c15*. A similar lower max absorption was detected with *t9, t11* with respect to *c9, t11* [25]. In addition, the production of *t9, t11, c15* CALA from α -linolenic acid in combination with *c9, t11, c15* CALA also reflects the generation of *t9, t11* CLA from linoleic acid by *B. breve* NCIMB 702258, which was produced directly from *c9, t11* CLA [20]. However, future studies

Fig. 1 Bioconversion of α -linolenic acid by a selection of bifidobacteria. The strains were grown in a medium containing 0.24 mg/ml (filled squares) and 0.41 mg/ml (open squares) α -linolenic acid. Conversion to conjugated α -linolenic acid (CALA) was assessed in the bacterial supernatant

Fig. 2 Identification of CALA by UV spectrum (a) and MS spectrum (b)

Fig. 3 HPLC separation of *c*9, *t*11, *c*15 conjugated α -linolenic acid from another CALA isomer, which has been identified as *t*9, *t*11, *c*15 CALA

will aim at a definitive identification of the geometrical isomerism by more MS sophisticated techniques.

Generation of CALA Oil and α -Linolenic Acid Oil for Inhibitory Effects on Colon Cancer Cell Growth

Small concentrations of C14:0, C16:0, C18:0, C18:1 *t*11 and linoleic acid were present in the CALA oil sample for the cell culture study. However, these fatty acids

were also present in similar quantities in the control sample (α -linolenic acid) (Table 2). The major difference between the control and CALA oils was the concentration of C18:1 oleic acid. There was 9.7% oleic acid in the control oil compared to 17.2% in the CALA oil due to the bioconversion by *B. breve* NCIMB 702258. However, at the concentrations examined, oleic acid did not have any impact on SW480 cell growth (data not shown).

Table 2 Percent fatty acids present in control oil and CALA oil samples for cell culture studies

Fatty acids	Total fatty acids (%)	
	Control oil	Experimental oil
C14:0 Myristic acid	3.7	4.8
C16:0 Palmitic acid	1.8	2.4
C18:0 Stearic acid	2.1	3.1
C18:1- <i>t</i> 11 Vaccenic acid	0.6	1.1
C18:1 <i>c</i> 9 Oleic acid	9.7	17.2
C18:2 Linoleic acid	2.6	1.2
C18:3 Linolenic acid	61.0	5.0
CALA	4.5	55.6
Total	100	100

Biological Activity of CALA in Cell Culture

SW480 cells were incubated for 5 days in the presence of varying concentrations (10–50 $\mu\text{g/ml}$) of either CALA or α -linolenic acid, enabling the effect of both CALA and its precursor on SW480 cell viability to be examined (Fig. 4). A dose-dependent decrease in cell numbers occurred with increasing CALA concentrations with CALA being more potent in reducing cell numbers than α -linolenic acid. Maximal difference in this inhibitory effect occurred at 180 μM (50 $\mu\text{g/ml}$), resulting in an 85% reduction in cell numbers in cultures exposed to CALA, compared with a 50% reduction in cells exposed to α -linolenic acid. However, CALA did not exhibit as potent an inhibitory effect on SW480 colon cancer cells as *c*9, *t*11 CLA or *t*9, *t*11 CLA, as we have shown previously, where incubation with 10 $\mu\text{g/ml}$ of *c*9, *t*11 CLA or *t*9, *t*11 CLA caused 32 and 43% reductions in SW480 cell numbers, respectively [20].

Fig. 4 Comparison of cell viability of SW480 colon cancer cells following 5 days exposure to the same concentrations of α -linolenic acid (shaded squares) and CALA (filled squares) (Statistical analysis: * $p \leq 0.05$; ** $p \leq 0.01$; *** $p \leq 0.001$)

Discussion

In total, there are 28 different isomers of CLA, however, health benefits have mainly been associated with two of these isomers, namely, *c*9, *t*11 and *t*10, *c*12 CLA [5, 26]. It has previously been demonstrated in our laboratory that bifidobacteria, some of human intestinal origin, have the enzymatic capability to synthesise the *c*9, *t*11 and *t*9, *t*11 CLA isomers from free linoleic acid [19, 20]. Bifidobacteria are natural inhabitants of the human gastrointestinal tract and confer probiotic properties, with some having exhibited potential anti-carcinogenic effects [27, 28]. Recently, several unique biological effects have been associated with conjugated linolenic acids, which are produced as a result of isomerisation of α -linolenic acid [13–16, 29, 30]. Until recently, conjugated linolenic acids have only been produced in the laboratory from linolenic acid by alkali-isomerisation, while Ogawa et al. [31] successfully produced CALA using a strain of *Lactobacillus plantarum*.

In this study, six bifidobacteria strains were assessed for their ability to produce conjugated linolenic acid from α -linolenic acid. Interestingly, the five strains of human origin were able to perform the bioconversion. This result is significant in itself, as the ability of bifidobacteria to produce bioactive fatty acid metabolites is possibly linked to their health promoting properties and adds further weight to the anti-proliferative activities associated with intestinal bifidobacteria. While the majority of the substrate required for this conversion is likely absorbed in the small intestine, unabsorbed dietary fatty acids have been found in the colon. Indeed, Vonk et al. [32] proposed that 6–8 g of lipids enter the colon per day, while Hill [33] estimated that 5 g of long chain fatty acids enter the colon on a daily basis. In addition, considering the low levels of *c*9, *t*11, *c*15-CALA in dietary sources [3, 34], the use of CALA-

producing bifidobacteria provides a suitable method for enhancing the physiological concentration of this fatty acid. The bioconversion product produced by one of the five strains, namely, *B. breve* NCIMB 702258, which originated from an infant intestine, was further analysed and identified as *c9, t11, c15*-CALA. Furthermore, *t9, t11, c15*-CALA was identified, but at much lower concentrations.

Evaluation of the inhibitory effects of *c9, t11, c15*-CALA on SW480 colon cancer cells indicated that the presence of this conjugated fatty acid in the growth medium led to a suppressive effect on tumour cell growth. Indeed, a concentration of 180 μ M resulted in 85% reduction in cell numbers, indicating that the conjugated fatty acid was more potent than α -linolenic acid, which resulted in only a 50% reduction in cell numbers. While there are no data available on the physiological concentration of CALA, it has been reported that ALA is found in plasma at a concentration of $0.26 \pm 0.06\%$ of total fatty acids [35]. Thus, the concentrations of ALA used in the present study [10–50 μ g/ml (0.001–0.005%)] are within physiological range.

Typical species associated with the infant gastrointestinal tract are *B. breve*, *B. infantis* and *B. longum*, while *B. catenulatum*, *B. adolescentis*, *B. bifidum* and *B. pseudocatenulatum* are more generally found in adult faeces. *B. adolescentis* has been reported as the most common species in adults [36], although others have found *B. catenulatum* to predominate in adults [37]. Thus, while *B. breve* is not considered a major inhabitant of the adult intestine, it has been identified in faecal samples from adults in the region of 10^8 cells/g [38, 39]. In addition, studies from population dynamics of bifidobacteria in human faeces during raffinose administration to adults indicated that minor species such as *B. breve* proliferated [40]. Development of this strain as a supplement in a probiotic product such as yoghurt would likely increase its presence in the adult/elderly intestine thus targeting the population most at risk from diseases of the colon.

The ability of isomers of conjugated linolenic acids to inhibit cancer cell growth may be linked to a number of cellular effects. For example, to date, the inhibitory properties of isomers of CLA have been attributed to a number of mechanisms including alteration of lipid peroxidation, tissue fatty acid composition, eicosanoid metabolism, gene expression, cell cycle regulation, cell proliferation and apoptosis [41]. In the case of conjugated linolenic acid isomers, earlier studies indicated that these exerted their effects through lipid peroxidation [15]. Indeed, several studies have indicated that lipid peroxidation alone can induce suppression of growth and apoptosis [42–45]. A more recent study comparing the effects of all-*trans*-conjugated linolenic acids on human colon cancer Caco-2 cells

indicated that β -eleostearic acid (*t9, t11, t13*) and β -calendic acid (*t8, t10, t12*) have signalling pathways different from those of α -ESA and α -calendic acid (*t8, t10, c12*), and exhibit high potency for reducing the cell viability of Caco-2 cells [13]. In another study, α -ESA was found to induce apoptosis through the up-regulation of GADD45, p53 and PPAR γ in human colon cancer Caco-2 cells [14]. Yasui et al. [16] also observed an increase in the levels of PPAR γ in HT-29 cells which were treated with α -ESA. Indeed, PPAR γ is one of the target molecules in cancer prevention [46, 47]. Furthermore, the *t9, t11, c13* isomer from catalpa seed oil was shown to suppress the development of colonic aberrant crypt foci induced by azoxymethane in rats through down-regulation of cyclooxygenase-2 (COX-2) [29]. Interestingly, studies using rat intestine demonstrated that while both α -ESA and *c9, t11, c13* conjugated linolenic acid were slowly absorbed, a portion of both fatty acids was quickly converted to the biologically active isomer *c9, t11*-CLA through a Δ 13-saturation reaction [48], suggesting that in the colon the therapeutic effects of conjugated linolenic acids may also be due to the increased production of biologically active CLA isomers. Thus, it is evident that different fatty acid structures exert the same effect through different pathways. Further studies will be required to determine the biological mechanisms of the *c9, t11, c15*-CALA isomer in this study resulting in the inhibition of growth of SW480 colon cancer cells.

Conclusion

This study showed that five strains of bifidobacteria, all of human intestinal origin converted α -linolenic acid to conjugated α -linolenic acid. This microbially produced conjugated α -linolenic acid exhibited inhibitory effects on the growth of SW480 colon cancer cells, in vitro. The ability of bifidobacteria of human intestinal origin to biosynthesise biologically active lipids such as *c9, t11* CLA and conjugated α -linolenic acid may be linked to their suggested therapeutic effects.

Abstract Human milk was obtained from 97 healthy lactating women from five different regions in China. Twenty-four hour dietary questionnaire identified the foods consumed that showed distinct differences in food types between cities. The southern and central regions had higher levels of total *trans* fatty acids (TFA) and conjugated linoleic acids (CLA) in human milk than the northern region. The major isomers in human milk from the northern region were vaccenic and rumenic acids, whereas the other regions had a random distribution of these isomers. This was consistent with the isomer distribution in the refined vegetable oils used and their increased formation during high temperature stir-frying. The human milk composition showed little evidence that partially hydrogenated fats were consumed, except eight mothers in Guangzhou who reported eating crackers, plus four other mothers. The TFA concentration in these human milk samples was higher (2.06–3.96%). The amount of n-6 (1.70–2.24%) and n-3 (0.60–1.47%) highly unsaturated fatty acids (HUFA) in human milk and the resultant ratio (1.43–2.95) showed all mothers in China had an adequate supply of HUFA in their

diet. Rapeseed oil was consumed evidenced by erucic acids in human milk. The levels of erucic acid were below internationally accepted limits for human consumption. The levels of undesirable TFA and CLA isomers in human milk are a concern. Efforts to decrease the practice of high temperature stir-frying using unsaturated oils, and a promotion to increase consumption of dairy and ruminant products should be considered in China.

Keywords Human milk · Survey · *trans* Fatty acid · Conjugated linoleic acid · Polyunsaturated fatty acid · Erucic acid

Abbreviations

ARA	Arachidonic acid
BCFA	Branch chain fatty acid
CLA	Conjugated linoleic acid
DHA	Docosahexaenoic acid
DUFA	Diunsaturated fatty acid
HUFA	Highly unsaturated fatty acid
FA	Fatty acid
FAME	Fatty acid methyl ester
MCFA	Medium-chain fatty acid
MUFA	Monounsaturated fatty acid
PHF	Partially hydrogenated fat
PUFA	Polyunsaturated fatty acid
SFA	Saturated fatty acid
TFA	<i>trans</i> Fatty acid
TUFA	Triunsaturated fatty acid

Introduction

The importance of breastfeeding is well recognized as providing infants with complete nutrition for development

and immunological protection in the first few months. The fat in human milk plays a key role in supplying energy and essential n-3 and n-6 polyunsaturated fatty acids (PUFA), and specifically the highly unsaturated fatty acids (HUFA) arachidonic (ARA 20:4n-6) and docosahexaenoic acids (DHA 22:6n-3), required for growth and optimal mental and vision development [1–4]. Infants lack the capacity to synthesize sufficient n-3 and n-6 HUFA from the linolenic (18:3n-3) and linoleic acid (18:2n-6) precursors [5, 6], and for this reason an adequate supply and balance of these HUFA are recommended in the mother's diet [3, 4, 7, 8]. The fatty acid (FA) composition of the maternal diet is known to influence the composition of human milk within 24 h of consumption [9]. Several surveys have been undertaken to assess the HUFA status of human milk in different populations [10, 11]. Studies have also been conducted to determine any detrimental effects associated with the higher consumption of n-3 HUFA by mothers, particularly fish products, a major source of DHA, which may possibly be contaminated [12].

In recent years the issue of *trans* fatty acids (TFA) in the human diet has become a major concern because of health implications [13]. Infants are equally exposed to TFA since they pass through the placenta and into the milk [14–16]. TFA generally occur in foods containing partially hydrogenated fats (PHF) and ruminant products, which differ in their *trans* isomer composition [17, 18]. Moreover, TFA can also be produced during domestic frying [19–21] and deodorization [22] with both generating a random distribution of TFA isomers. There has been a significant drop in the total TFA content in Western Europe in the 1990s as the result of voluntary discontinuation by industry of PHF production [23]. During the discussion period to introduce mandatory TFA labeling of food products in Canada [24], a decline in total TFA content in human milk has also become evident in Canada [16, 25].

Another group of FA of interest in infant development are the conjugated linoleic acids (CLA) known to provide protection against cancer [26] and other benefits [27] in experimental animals. Further research is needed to demonstrate that humans receive the same benefit [28, 29]. Possible benefit of ruminic acid for breast-fed infants needs to be examined since breast-fed infants have a higher content of *Bifidobacteria* in their gut than formula-fed infants, and these bacteria are known to synthesize vaccenic (11*t*-18:1) and ruminic acids (9*c*11*t*-18:2) from 18:2n-6 [30, 31].

A few surveys on the fat composition of human milk are currently available from China. These surveys basically focused on the DHA status and were restricted to the Beijing [32–34], the northeast coastal region [35] and one city in the west-central region of China [11, 36]. The occurrence of CLA was only reported in one of the surveys

[11]. In none of the studies was there an attempt to evaluate the TFA profile that would reflect the type of fats consumed, whether derived from ruminants, hydrogenated fat, oils after stir frying, or deodorized vegetable oils. In addition, all these studies reported the presence of erucic acid in human milk [11, 32–36]. Erucic acid was also found to be present in blood lipids of Chinese children [37].

The present study was designed to evaluate the TFA, CLA, HUFA and erucic acid content, composition and variation of human milk from five regions in China known for their distinct differences in diet and method of food preparation. We were particularly interested in determining the TFA and CLA profiles since they would provide a good indication of the dietary fat sources consumed (ruminants or partially hydrogenated products), the type of frying process used, and the occurrence of erucic acid in human milk from different regions.

Subjects and Methods

Subjects

Breast milk was collected from 97 healthy lactating women who had given birth in hospitals and were generally from the middle CLAs. Five cities in China were selected which were Guangzhou (GZ, $n = 25$) and Shanghai (SH, $n = 25$) coastal cities in the south and east, respectively, Nanchang (NC, $n = 25$) in central China, Harbin (HA, $n = 11$) in Manchuria a major cereal producing region, and Hohhot (HT, $n = 11$) in Inner Mongolia a region known for extensive dairy and beef production. Milk samples were collected between January and April (NC, SH) and August–November 2004 (GZ, HA, HT). Written informed consent was obtained from each volunteer. At the time of sample collection, all the mothers were asked to complete a 24-h dietary recall questionnaire prior to collection that identified the foods consumed at each meal and snacks. Mothers consumed self-selected diets without being given any dietary recommendations. A quantitative measurement of the amount consumed was not requested because of the difficulty of estimating each food type when meals are prepared at home that consisted of mixtures of meat, vegetables and rice. The study was approved by the Human Ethics Committee of the University of Nanchang and the Yili Company in Inner Mongolia.

Milk was obtained from each woman at 9 a.m. on each collection day; transitional milk at day 10 and 13 after delivery, and mature milk at day 21 and 25. Under the supervision of professional nurses, nursing mothers were instructed to manually express breast milk to fill a 15-mL sterile disposable polypropylene tube fitted with a cap (Zhejiang Gongdong Medical Plastic Company, Hangzhou,

China). The tubes had been previously washed with 10% HNO₃ and deionized water. All tubes were capped and frozen in domestic freezers and transported as soon as possible to medical facilities where they were frozen at -70°C . After completion of sample collections they were shipped under refrigeration to the University of Nanchang where they were stored at -70°C until analyzed.

Fatty Acid Analysis

Milk lipid samples were thawed to room temperature and thoroughly mixed to assure homogeneity. One mL of total milk was extracted by using chloroform/methanol (1:1) and the total lipids were methylated using sodium methoxide as described previously [38]. The fatty acid methyl esters (FAME) were analyzed by gas chromatography equipped with an autosampler, and a flame ionization detector (Model 6890 N, Agilent Technologies, Shanghai, China). A 100 m H 0.25 mm (ID) (0.2 μm film thickness) fused silica capillary column coated with 100% cyanopropyl polysiloxane was used (CP-Sil 88, Chrompack; Middelburg, The Netherlands). The initial temperature of the program was 45°C held for 4 min, and then increased at a rate of $13^{\circ}\text{C}/\text{min}$ to 175°C , and held for 27 min. The oven temperature was then further increased to 215°C at a rate of $4^{\circ}\text{C}/\text{min}$ and held for 35 min [38]. All peaks were identified by comparison of their retention times with a standard FAME mixture (#463) spiked with a mixture of four positional CLA isomers (#UC-59 M) and 21:0, 23:0 and 26:0. All of these FAME were obtained from Nu-Chek Prep Inc. (Elysian, MN).

Selected foods were analyzed to determine the source of certain FA in human milk. Retail bovine milk was purchased in the Nanchang area from different suppliers and production dates during the same time human milk was collected to evaluate the milk FA composition. In addition, most of the refined vegetable oils available in the market in China were analyzed for their FA composition [39]. Crackers similar to those consumed by mothers in Guangzhou were analyzed and compared to other PHF. Several vegetable oils (soybean, canola, peanut and corn oil) were locally purchased in Canada and subjected to typical wok cooking of Chinese cabbage. The oils before and after wok cooking were analyzed by GC according to published procedures [40; JKG, Kramer, unpublished data]. All the samples were analyzed using the same methods as described above.

Statistical Analysis

The FA composition data were analyzed using the GLM procedure of the statistical analysis system (SAS Release 9.1, SAS Institute Inc., Cary, NC, USA) based on a split

plot design in which cities are as main plots, time periods within cities as sub-plots, and mothers as replicates. The statistical model included city, time period, mother, and city by time period interaction. City effects were tested using the error term of mother nested within city. Least square means of FA composition were calculated using the option of LS-MEAN and statistical differences among cities and lactation periods were identified at $P < 0.05$ using the option of P-DIFF.

Results

Food Consumption Questionnaire

Based on the 24-h recall questionnaire completed each time milk was sampled (Table 1), all mothers consumed rice. Consumption of other carbohydrate sources (oats, steamed wheat buns, lotus roots, bread and cakes) was highest and most frequent in Shanghai and least in Guangzhou. All nursing mothers ate meat during lactation, but there were regional differences in the type of meat consumed. Pork consumption was much more prevalent in southern (96–100%) and central China (100%) than in the northern

Table 1 Dietary recall of food consumed by lactating women from five regions in China

Food groups	GZ	SH	NC	HA	HT
Carbohydrates (CHO)					
Only rice	80	20	72	60	55

Eggs	56	96	92	90	100
Vegetables and tofu	72	96	84	40	91
Fruit	60	48	32	10	18

The values are expressed as percentage of total number of mothers in each city

GZ Guangzhou, SH Shanghai, NC Nanchang, HA Harbin, HT Hohhot, *Only pork* mothers ate only pork and did not eat other meat products, *Always pork* mothers ate pork on all four collection days

regions (55–60%) where beef, sheep and poultry consumption was much higher. All mothers in Guangzhou and Shanghai consumed fish or shrimp caught in salt water, while the fish consumed in Nanchang (80%) and Harbin (70%) was mainly from fresh water. The lowest fish consumption was reported in Hohhot (18%), which agrees with rural women surveyed in Inner Mongolia [35]. Egg consumption was very prevalent during the lactation period in all regions of China (92–100%), with the exception of Guangzhou where only half of the mothers ate eggs (Table 1). Dairy consumption ranged from 20% in Harbin to 64% in Shanghai. It was surprising that dairy consumption of nursing mothers was only 55% in Hohhot, the major dairy region of China. Consumption of vegetables and tofu was a major component in most maternal diets in China (>72%), with the exception of Harbin in north east China (40%). Fruit consumption was generally found to be rather low in the northern cities of Harbin and Hohhot (10 and 18%; Table 1) despite the fact that the human milk was collected between August and November when a variety of fruits would have been available at a reasonable cost; similar results were reported in other surveys on human milk in China [33, 36]. On the other hand, fruit consumption was much higher in Guangzhou (60%) where most mothers reported eating papaya and chieh-qua that are available all year round.

Fatty Acid Composition of Human Milk

Human milk samples for each of the four collection periods were analyzed separately, but then combined into transitional (day 10 and 13) and mature milk (day 21 and 25) because of their similarity (Table 2). In general, there were significant regional differences for most of the FA in human milk, and only few differences between transitional and mature milk and between mothers within the same city; there were only few statistically significant interactions between lactation times and locations.

Saturated Fatty Acids

The total saturated fatty acids (SFA) of human milk ranged from 35 to 42% of total lipids, with palmitic acid (16:0) accounting for just over half of total SFA, followed by stearic acid (18:0) at about 6% of total FA, and the sum of the medium-chain fatty acids (MCFA; 8:0–14:0) at about 12% (Table 2). Significant differences were observed between the total SFA content of human milk from Nanchang and Harbin compared to the other three cities, due mainly to lower levels of 16:0, 14:0 and 12:0 (Table 2). Human milk also contains small amounts of branch-chain fatty acids (BCFA) that are generally derived from milk and meat of ruminants. Higher levels of BCFA were found in the

human milk fats from Hohhot, Shanghai and Guangzhou. Guangzhou also had higher levels of the long-chain SFA ($\geq 20:0$), which reflects the higher consumption of fruits and vegetables that contain these FA in the form of wax esters. Human milk from Shanghai contained the highest level of MCFA (13.62–14.57%). Consumption of high carbohydrate/low fat diets was reported to cause increased levels of MCFA in human milk [41, 42], but this was unlikely the case in Shanghai, since the level of total MCFA was about 14%, similar to that found in human milk from nursing mothers on a balanced diet in America (14%) [41]. In contrast, high MCFA were observed in human milk from Egypt (20%) [41], the Dominican Republic (45%) [42] and the Philippines (31%) [11].

cis Monounsaturated Fatty Acids

The *cis* monounsaturated fatty acids (MUFA) in human milk ranged from 31 to 38% of total lipids. The major isomer was oleic acid (9*c*-18:1) that accounted for about 85% of the total *cis*-MUFA; the highest levels were found in Nanchang and the lowest in Shanghai (Table 2). Other *cis*-MUFA included 11*c*-18:1 (2%) and 9*c*-16:1 (1.8%). Small amounts of erucic acid (13*c*-22:1) were found in all human milk samples indicating that rapeseed oil was available and consumed. There were regional differences in the amount of erucic acid found in human milk between Shanghai (0.08%) and Nanchang (0.22%), and the content of the individual human milk samples ranged from 0.00% (three in GZ and one in HA) to 0.90% (in NC).

trans Fatty Acids

Small amounts of *trans*-MUFA were present in all human milk samples ranging in content between 0.15 and 1.32% (Table 2), and the *trans*-18:1 isomers accounted for more than 96% of the total in the *trans*-MUFA in the southern and central regions, and somewhat less in the northern cities (85–96%). There were significant regional differences both in the total TFA content and the distribution of the *trans*-18:1 isomers. The two northern cities, Hohhot and Harbin, had significantly less total *trans*-18:1 than the other cities (Fig. 1, upper), but the human milk from several mothers had an isomer distribution that showed a greater similarity to ruminant fats with relatively more vaccenic acid (11*t*-18:1) (7 of 11 mothers from HT and 3 of 11 in HA). This compares with the other three cities where none of the human milk samples had this isomer distribution. Instead, all four *trans*-18:1 isomers from 6-9*t*- to 11*t*-18:1 were found to be similar in abundance. Typical representative GC separations of the 18:1 region are shown in Fig. 2 for two human milk samples with distinctly different *trans*-18:1 patterns. Human milk A was selected

Table 2 Fatty acids composition of transitional (T) and mature (M) human milk from five regions in China expressed as % of total fatty acids

GZ Guangzhou, SH Shanghai, NC Nanchang, HA Harbin, HT Hohhot, SEM standard error mean, BCFA branch chain fatty acid, CLA conjugated linoleic acid, DUFA diunsaturated fatty acid, HUFA highly unsaturated fatty acid, MCFA medium-chain fatty acid, MUFA monounsaturated fatty acid, PUFA polyunsaturated fatty acid, SFA saturated fatty acid, TFA trans fatty acid, TUFA triunsaturated fatty acid

Significant differences between cities, times, mothers and city by time interaction are: NS ($P > 0.05$); * ($P < 0.05$); ** ($P < 0.01$); *** ($P < 0.001$)

from one of eight mothers in Guangzhou who reported consuming crackers. Crackers were subsequently analyzed and found to contain 20.1% TFA which suggested that this product was a possible source of TFA; see the *trans*-18:1 profile of a cracker in Fig. 2. The human milk from one of these mothers showed a higher total TFA content (3.3%) and a random distribution of *trans*-18:1 isomers (human milk A, Fig. 2). The human milk of four more mothers, three from Nanchang and one from Shanghai, had an equally high TFA content, even though they did not report consuming products that could have contained PHF. Human milk B was selected from Hohhot in which 11t-18:1 was the most prominent *trans*-18:1 isomer (Fig. 2), and the total TFA content was about 0.6% of total milk fat. The FA composition of bovine milk collected in Nanchang

in 2004 (Table 3) shows that 11t-18:1 was the prominent *trans*-18:1 isomer (Fig. 2). The final GC graph shows the *trans*-18:1 profile of fully refined soybean oil after wok cooking (Fig. 2, wok fried oil; J Kramer, unpublished data).

Diunsaturated fatty acids (DUFA, mainly 9c12t- and 9t12c-18:2) and triunsaturated fatty acids (TUFA, mainly 9t12c15c-, 9c12c15t- and 9c12t15c-18:3) containing one *trans* double bond were also detected in the human milk samples from China (Table 2). In general, the content of these isomers was lower in the two northern cities than in southern and central China (Fig. 1, lower). In addition, there were differences in the distribution of the di- and triunsaturated isomers. In the southern and central regions, DUFA predominated arising mainly from linoleic acid,

Fig. 1 Total content of *trans*-18:1 and selected *trans*-18:1 isomers (percentage of total fatty acids) of transitional (*T*) and mature (*M*) human milk from five cities in China (*GZ* Guangzhou, *SH* Shanghai, *NC* Nanchang, *HA* Harbin, *HT* Hohhot). The lower graph shows the total content of mono *trans* containing diunsaturated fatty acids (DUFA) and triunsaturated fatty acids (TUFA) from the same human milk samples

while in the two northern cities the distribution of the DUFA and TUFA was generally similar.

Conjugated Linoleic Acids

The average total CLA content in human milk ranged from 0.11% in Harbin to 0.28% in Nanchang (Table 2). There were significantly higher levels of total CLA in the cities of southern and central China than in the two northern cities of Harbin and Hohhot. However, the CLA in these three cities

consisted mainly of CLA isomers other than rumenic acid (9*c*11*t*-18:2) (Fig. 3). Rumenic acid accounted for less than 44% of total CLA in human milk from Guangzhou, Shanghai and Nanchang, but more than 70% in Harbin and Hohhot. Examining the individual human milk samples (transitional and mature human milk per mother) showed a wide range of 0.05–0.56% for total CLA and 0.02–0.25% for rumenic acid. Interestingly, neither the highest levels of total CLA or rumenic acid were associated with human milk from the northern two cities (total CLA 0.05–0.24%; rumenic acid 0.03–0.18%). The total CLA content in bovine milk available in China (0.66% of total milk fat) consisted mainly of rumenic acid (89.09 ± 2.97%) (Table 3).

Fig. 2 Partial gas chromatographic separation of the 18:1 isomers of the fat in crackers from China, soybean oil after wok frying, bovine milk sampled in Nanchang China, and two human milk samples selected from Guangzhou (*A*) and Hohhot (*B*). The percentage of total *trans* fatty acid (*FA*) content of each of these samples is shown on the left hand side. The insert of 6*t*–8*t* to 11*t*-18:1 in human milk *B* was obtained using a GC temperature program described previously [40] to provide a better separation of these 18:1 isomers

Polyunsaturated Fatty Acids

The relative concentration of total n-6 PUFA in human milk ranged from about 17.42% of total FA in Guangzhou to about 25.81% in Harbin (Table 2). Linoleic acid (18:2*n*-6) consistently accounted for about 90% of total n-6 PUFA in all regions. On the other hand, the relative concentration of total n-3 PUFA in human milk ranged from about 1.69% in Guangzhou to about 3.67% in Harbin (Table 2). It is of interest to note that the relative proportion of linolenic acid (18:3*n*-3) to total n-3 PUFA increased with increased levels of total n-3 PUFA content in human milk from about 53% in Guangzhou to nearly 80% in Hohhot. A higher concentration of 18:2*n*-6 and 18:3*n*-3 is generally associated with the consumption of fruits, vegetables, and vegetable oils such as sunflower, soybean and rapeseed oils. The high consumption of chicken and fowl in the northern cities (Table 1) also contributed to the higher levels of 18:3*n*-3 in

Table 3 Fatty acid composition (%) of bovine milk from retail stores in Nanchang, China during time human milk was sampled

SFA Saturated fatty acids, *cis* MUFA *cis* monounsaturated fatty acids, *trans* MUFA *trans* monounsaturated fatty acids, *trans*-18:1 *trans*-18:1 isomers, CLA conjugated linoleic acids, *n*-6 PUFA *n*-6 polyunsaturated fatty acids, *n*-3 PUFA *n*-3 polyunsaturated fatty acids

this region. The *n*-6/*n*-3 ratio of total PUFA in human milk ranged from about ten in Guangzhou to about six in Hohhot (Table 2).

Several *n*-6 HUFA metabolites were present in all human milk accounting for nearly 2% of total FA, with only minor differences measured between cities (Table 2). The major *n*-6 HUFA were 20:2*n*-6, 20:3*n*-6 and ARA (20:4*n*-6). The content of ARA ranged from 0.54% in Guangzhou to 0.76% in Harbin, and showed a weak correlation ($R = 0.58$) to the content of 18:2*n*-6 in human milk. The content of ARA in all the human milk samples ranged from 0.24 to 1.19% of total milk fat.

Six *n*-3 HUFA metabolites were identified in human milk ranging in content from 0.60 to 1.47% of total FA, the highest levels were found in Harbin and the lowest in Hohhot (Table 2). DHA was the predominant *n*-3 HUFA present at 0.29 to 0.53% of total FA accounting for about half of the *n*-3

HUFA. As expected, there was no correlation of 18:3*n*-3 to DHA ($R = 0.0001$), since this conversion is known to be very low in humans [5–7]. The content of DHA in all the human milk samples (transitional and mature human milk per mother) ranged from 0.15 to 1.00% of total milk fat, but only three human milk samples had a level of less than 0.2% of total milk fat, and these were not from the same mother. Docosapentaenoic acid (22:5*n*-3), at 0.11–0.17% of total FA, was the second most abundant *n*-3 HUFA, and occurred at about 20% of total *n*-3 HUFA. On the other hand, eicosapentaenoic acid (20:5*n*-3) was only present in minor amounts (at 0.05, or 6% of total *n*-3 HUFA), and there were no significant differences between cities.

A comparison of the average *n*-6 and *n*-3 HUFA content and *n*-6/*n*-3 ratio shows that human milk from all regions investigated in this study contained at least 1.7% total *n*-6 HUFA and 0.6% *n*-3 HUFA, with a ratio of about 2.5

Fig. 3 Comparison of the average total CLA, rumenic acid (9*c*11*t*-18:2), and the combined *trans*, *trans*-CLA isomers (percentage of total fatty acids) from transitional and mature human milk of the five cities in China (GZ Guangzhou, SH Shanghai, NC Nanchang, HA Harbin, HT Hohhot) with the scale on the left side. The scale on the right side represents the percent of rumenic acid (9*c*11*t*-18:2) in total CLA (solid bars) for the five cities

Fig. 4 Comparison of the average total n-6 HUFA and n-3 HUFA content (percentage of total fatty acids) from transitional and mature human milk of the five cities in China (GZ Guangzhou, SH Shanghai, NC Nanchang, HA Harbin, HT Hohhot) with the scale on the left side. The scale on the right side represents the ratios of n-6 HUFA to n-3 HUFA (solid bars) for the five cities

(Fig. 4). Examining all the individual human milk samples (transitional and mature human milk per mother) showed a wide range of ARA to DHA from 0.73 to 3.41%, but only 20 samples had ARA levels less than DHA, i.e., below 1.00, and 13 samples were below 0.90; the lowest ratio was 0.72.

Discussion

Today, food consumption patterns are continually changing particularly with the introduction of FA and convenient foods and greater availability of variety and packaged foods. A better transportation network and an increase of disposable income are also making these foods more accessible to the general population. In this study we wanted to expand on previous surveys conducted in China that focused mainly on DHA [11, 32–36], by investigating the TFA and CLA contents in human milk not previously addressed. We also wanted to evaluate the levels of erucic acid in human milk in the various regions since rapeseed oil is used extensively for cooking in China. The rapeseed oil still contains appreciable amounts of erucic acid. An

analysis of human milk is a good indicator of the fat sources consumed by the mothers the previous day, since dietary FA [9], including TFA and CLA, have been shown to appear in human milk within 12–36 h later [43, 44]. The amount and isomer pattern observed in the human milk will reflect the type of TFA and CLA contained in the foods consumed [17, 18].

trans Fatty Acids

Generally, the major sources of TFA in human diet are derived from products containing PHF [23, 45] or ruminant fats [46, 47]. These two fats are distinguishable by their characteristic *trans*-18:1 isomer profile [18, 38]. In industrially produced hardened fats the distribution of the *trans*-18:1 isomers is random, i.e., the isomers from 6*t*-8*t* to 11*t*-18:1 are present in approximately equal amounts [19, 20, 23], whereas in ruminant fats vaccenic acid is the most abundant isomer in [40, 45]. Our results show that the average total TFA concentration of the human milk samples in China did not exceed 2% (Fig. 1). This is in marked contrast to many Western countries that reported averages of 3.8–7.2% total TFA in human milk [16, 18, 25, 48, 49]

and with some concentrations reaching as high as 15.4% [16]. The TFA in human milk are attributed to the consumption of food products containing PHF. There has been a noticeable decline in the TFA content in human milk in Western countries [25, 50] since the adoption of mandatory labeling of TFA in food products [24], and the current negative health image of TFA. In China, there was evidence that some mothers consumed food containing industrially produced hardened fats. Eight mothers in Guangzhou (Fig. 2, human milk A), three in Nanchang and one in Shanghai had increased levels of total TFA that ranged from 2.06 to 3.96% in their human milk. All eight mothers in Guangzhou reported eating crackers, a possible source of TFA; the other mothers with a similar high level of TFA did not provide any information on their questionnaire as to the source of their TFA. Subsequent analysis of common crackers available in Guangzhou showed that they contained 20.1% TFA (Fig. 2, cracker). Unfortunately, the dietary questionnaire did not provide information as to how many crackers were consumed, so a total TFA intake from these crackers could not be calculated. A direct correlation between the amount of TFA consumed and measured in human milk could not be established by Aitchison et al. [43], but the authors did conclude that dietary TFA are extensively transferred into human milk 12–36 h after consumption. It is evident from our results that only 12 nursing mothers out of 97 in our survey consumed any TFA containing foods, even though these products are available, such as crackers. It would appear that levels greater than 2% total TFA in human milk can be accounted for by the consumption of products containing PHF, but these products do not necessarily account for the remaining TFA in human milk.

If ruminant products (meat and milk) were the major source of TFA in the diet, one would expect a TFA profile with vaccenic acid as the major *trans*-18:1 isomer (Fig. 2, human milk B). Only in the northern cities of Hohhot and Harbin was there evidence that human milk samples had *trans*-18:1 patterns similar to those seen in the bovine milk sampled and analyzed in Nanchang (Table 3; representative GC graph of bovine milk in Fig. 2), but this *trans*-18:1 pattern was not observed in human milk samples from any of the other cities. The greater availability and consumption of ruminant products in Hohhot, a region known for extensive dairy and beef production, contributed to a higher level of total *trans*-18:1 and vaccenic acid in human milk in comparison to Harbin (Table 2; Fig. 1). In their study, Chulei et al. [35] surveyed human milk from the herdswomen in Inner Mongolia and reported high dairy consumption in this group of women. It would have been interesting to compare this human milk with samples of the urban women in Hohhot collected in this study. Unfortunately, the authors [35] did not provide the TFA

content and isomer composition of the human milk. It is unlikely that TFA from ruminant fats account for much of the TFA in human milk from the southern and central cities of China, because the pattern of *trans*-18:1 isomers in the southern and central cities was random, and unlike the typical pattern observed with ruminant fats. Furthermore, it is of interest to note that the total *trans*-18:1 content in Hohhot is about one-third that found in the southern and central cities (Fig. 1; 0.43 vs 1.10–1.28%). Therefore, sources other than ruminant and partially hydrogenated fats need to be considered to explain the higher levels TFA in human milk from the southern and central regions.

Fully refined vegetable oils have been identified as another source of TFA that are formed during the deodorization step [22]. The high temperature during deodorization results in the formation of geometric isomers of 18:3n-3 (*trans*-TUFA) and 18:2n-6 (*trans*-DUFA) [21, 51], and to a lesser extent of *trans*-MUFA. The vegetable oils currently available in the urban centers in China are fully refined and deodorized and were reported to contain 1–2% *trans*-MUFA and 0.1–0.2% *trans*-DUFA [39]. Consumption of these vegetable oils would contribute to the *trans*-DUFA and *trans*-TUFA in the southern and central regions (Fig. 1). However, it would not explain the much lower levels of all TFA observed in the two northern cities in China, particularly Harbin, where presumably refined vegetable oils were also used.

Less frequently investigated is the contribution of TFA arising from using PUFA-rich oils for frying at high temperatures [19–21]. Heating PUFA rich vegetable oils at temperatures in excess of 200 °C under nitrogen was reported to result in the geometric isomerization of 18:2n-6 and 18:3n-3 to form *trans*-DUFA and *trans*-TUFA, respectively, [19, 20, 52]. Wok cooking is popular in the southern and central regions of China, and during wok cooking oil temperatures of 240–280 °C have been reported [53]. This would explain the higher levels of *trans*-DUFA and *trans*-TUFA from human milk in the southern and central regions of China compared to the northern cities (Fig. 1), since soybean, rapeseed and peanut oils [54], all vegetable oils rich in PUFA are generally used for wok frying. However, it would not explain the higher levels of *trans*-MUFA with a random distribution of *trans*-18:1 isomers from 6*t*-8*t*- to 11*t*-18:1 (Fig. 2, human milk A) if we assume that heat treatment of vegetable oils is limited to geometric isomerization [19, 20, 52]. We suspected that frying at these high temperatures in open pans might not be limited to geometric isomerization of *cis*-unsaturated double bond, but may also cause positional isomerization. We therefore undertook a small study in which five common vegetable oils (soybean, canola, peanut, corn, and sunflower oils) were purchased and each in

turn was used in wok cooking of Chinese cabbage. Analysis indeed showed that the *trans*-MUFA, *trans*-DUFA and *trans*-DUFA content increased after wok cooking, and the *trans*-18:1 profile showed a random distribution of isomers (Fig. 2, wok fried oil; J. Kramer, unpublished data). This, in part, could explain the higher levels of TFA in the human milk from the southern and central regions of China compared to the northern cities (Fig. 1), where wok cooking is generally not practiced. Similar high levels of *trans*-DUFA were previously reported in human milk surveyed from Hong Kong [0.18%; 36] where wok cooking is common.

Recent studies have shown that *trans*-DUFA may be a greater risk factor for coronary heart disease than *trans*-MUFA [55]. These TFA have also been shown to be metabolized to *trans* containing PUFA that interfere with brain and retinal function [56, 57]. Based on the analysis of human milk in this study, levels of up to 4% total TFA in human milk may not appear to be a major concern compared to the much higher levels found in other countries [16, 25, 48]. However, frying in a wok at elevated temperatures resulted in increased proportions of *trans*-DUFA and *trans*-TUFA in human milk that may pose a greater risk. Therefore, a reduction in these undesirable TFA would be prudent by reducing the temperature during frying and consuming more ruminant products higher in vaccenic acid.

Conjugated Linoleic Acids

Bovine milk is generally a major source of CLA in the diet, and therefore, an analysis of bovine milk would be a good indicator of the quality of rumenic acid available to nursing mothers. Most of the bovine milk in China is produced in the northern region, as were the samples we collected in Nanchang. This bovine milk contained 0.66% total CLA and consisted mainly of rumenic acid (89.09%; Table 3). Only in the two northern cities of Hohhot and Harbin was there evidence from the human milk results that mothers consumed appreciable amounts of such ruminant products, since more than 70% of the total CLA in the human milk samples was rumenic acid (Fig. 3). CLA is known to be absorbed by nursing mothers [44] and CLA was shown to plateau between 8 and 28 h after consumption [58]. Both the total CLA and rumenic acid content in human milk from the northern region was in marked contrast to that found in the southern and central regions of China, where the total CLA content was found to be about twice as much, but the relative abundance of rumenic acid was less than 44% (Fig. 3). In addition, that human milk contained an equal amount of *trans,trans*-CLA (Fig. 3), as well as significant amounts of 9*t*11*c*-18:2 (Table 2).

The total rumenic acid content in the human milk surveyed in this study ranged from 0.07 to 0.11% of total milk fat, which is consistent with a previous report on human milk from China [11; 0.07%], and other countries in which consumption of dairy and meat from ruminant is generally low, such as in the Philippines (0.08%) and Japan (0.13%). On the other hand, in countries where dairy and meat consumption is high, average levels of 0.20–0.43% total rumenic acid are common [11, 18, 25, 44, 48], and values as high as 0.63 [18] and 0.66% [48] have been observed.

Conjugated linoleic acid has been shown to be produced during heating of PUFA rich oils at 220 °C [59] and during the deodorization step of refining vegetable oils [59]. The CLA isomer composition produced as the result of excessive heating was shown to be a random distribution of several CLA isomers with large amounts of *trans, trans*-CLA [60], similar to what was produced during partial hydrogenation [61]. This type of CLA isomer distribution was in fact observed in the human milk from the southern and central regions of China derived presumably from both refined vegetable oils and wok-type frying (Fig. 3).

When reporting the CLA it is important to include both the amount of rumenic acid as well as total CLA content. It is well known that the different CLA isomers have diverse biological effects. Some isomers have negative effects [28, 29, 62] that may even neutralize the beneficial effects of other CLA isomers, such as the interaction of 10*t*12*c*-18:2 and rumenic acid (9*c*11*t*-18:2) [62]. In general, rumenic acid appears to have a beneficial influence in animal models [63], cell cultures [26] and humans [62, 64, 65]. It would be of interest to know whether the biological effectiveness of rumenic acid is the same whether present at 70% of total CLA (as in the northern cities) or in mixtures with other CLA isomers (less than 44% of total CLA; as in the southern and central cities). When evaluating the health benefits of rumenic acid in infants, a comparison between breast-fed to formula-fed infants should be investigated, since the former have much higher levels of *Bifidobacteria* in their intestinal tract that are known to produce rumenic and vaccenic acids [30, 31].

Polyunsaturated Fatty Acids

The human milk sampled from all regions in China were found to contain appreciable amounts of both n-3 and n-6 HUFA that could have been derived from fish, eggs, or different meats (Table 1). Similar values of DHA were reported in three previous surveys from China [11, 35, 36]; except for mothers from Zhangzi Island and Inner Mongolia who had extreme values for DHA depending on whether they consumed a high amount of fish or very little, respectively, [35]. The results reported by Xiang et al. [32, 33] appear to be from a rather atypical population in the

Beijing area, since the HUFA content and profile observed in their human milk samples were similar to those generally found in North America [11].

The average content of ARA and DHA did not appear to show great differences between the different regions of China (Fig. 4). However, an assessment of the individual mothers was of interest since it showed a fivefold difference in the total ARA, and a sevenfold difference in total DHA content between human milk samples from all parts of China; in this study separate transitional and mature milk values were reported for each mother. Based on a recent report for health-care providers, a consensus recommendation was reached that a minimum of 0.2% and a maximum of 0.5% DHA in total milk fat is recommended for optimal visual and cognitive development for the fetus and neonate [66]. Furthermore, it was recommended that the levels of ARA and DHA should be similar [66], since the n-6 and n-3 PUFA compete for the same enzymes and produce eicosanoids generally involved in opposing physiological, immunological and inflammatory pathways [1, 4]. Using this criterion, only 3 of 168 human milk samples analyzed in this study had a level below the minimum recommended level of 0.2% DHA in total milk fat, while 49 samples exceed the level of 0.5% DHA. However, it should be noted that most of the high DHA values were generally accompanied with equally high ARA values. Only 13 human milk samples had an ARA to DHA ratio of less than 0.90. The average worldwide ratio of ARA to DHA in human milk was shown to be about 1.5, which is similar to that found in our study, but a variation from 0.36 in the Dominican Republic to 10 in Rural South Africa were reported [10]. Discussions will no doubt continue on to the optimal amount and ratio of ARA to DHA for human milk.

Contamination of fish and fish products has been well publicized, which is the reason many people in Western countries choose to reduce their intake of fish or seafood. However, seafood is an important source of DHA, beneficial for human health in general, and essential for the infant's retinal and brain development [3, 7, 8]. To improve the DHA status of mothers with a low fish intake, it has been suggested that the maternal diet should be supplemented with 200 mg/day DHA from mid-pregnancy through lactation [66, 67]. Based on the results of this study it would appear that there is sufficient DHA in the human milk, and the recommended daily supplementation of 200 mg DHA for nursing mothers [66] may not be necessary in China.

Erucic Acid

In the current survey, small amounts of erucic acid were found in most human milk samples (mean values ranged from 0.08 to 0.23%; Table 2), which is consistent with previous surveys reported in 1997 (0.16 and 0.58%) [36],

1999 (0.18 and 0.32%) [32], 2005 (0.32%) [33], and in 2006 (1.21%) [11]. Erucic acid is derived from rapeseed oil, the second most consumed vegetable oil after soybean oil in China [54]. This oil was shown to contain 4.3% erucic acid [39]. This level of erucic acid in the rapeseed oil is below the previous limit of 5% set by Canada [68] and the European Commission considered to be safe for adult consumption [69], but above the level of 2% set in the United States [70]. The limit of erucic acid is 2% in the latest CODEX standard for low erucic acid rapeseed oil [71]. For infant formulas, the limit of C₂₂ monoenoic FA in Canada is 1/100 kcal [72]. This compares to the United States where canola oil is excluded for use in infant formulas [70], and Europe where there is no specific regulations for the use of low erucic acid rapeseed oils in infant formulas. In the current study, the highest value of erucic acid in the human milk was 0.90%, which would be below the Canadian regulation for infant formulas [72].

Questions about the safety of erucic acid have occasionally been raised in the popular press. These concerns are based on publications in the early 1970s that erucic acid uncoupled oxidative phosphorylation [73] and caused lipid accumulation in rat heart tissue [74]. The reason for the reduced ATP production was subsequently found to be due to inappropriate isolation of rat heart mitochondria [75], while lipid accumulation was shown to be unique to rats that naturally have a low level of peroxisomal β -oxidative activity [76, 77], and tissue specific metabolism of erucic acid [78]. Continued feeding of erucic acid to rats was shown to induce peroxisomal β -oxidation resulting in a decrease of the accumulated lipid [76, 77]. Similar effects were not observed in pigs, monkeys and humans [77]. Furthermore, no differences were found in the oxidation rates between erucic and palmitic acids in isolated perfused pig hearts measured using ³¹P NMR, indicating that the decrease in oxidation rates and ATP production observed in isolated rat mitochondria [73] were not replicated in the intact pig heart [79]. Direct evidence that energy metabolism of erucic acid was normal and similar to palmitic acid was provided by an in situ ³¹P-NMR experiment, in which perfused hearts of newborn piglets were used as a model [80]. Therefore, safety concerns about erucic acid have no scientific merit. On the contrary, erucic acid (22:1n-9) is a normal component in mammals. It is an intermediate in the chain elongation of oleic acid (18:1n-9) to nervonic acid (24:1n-9) [81]. Moreover, nervonic acid is a major FA involved in maintaining the structural integrity of sphingomyelin, a ubiquitous constituent of all nervous tissues, the myelin sheath, adrenal cortex, and most mammalian cell membranes. Feeding erucic acid to rats was shown to increase the levels of nervonic acid at the expense of the very long-chain SFA in sphingomyelin [82]. This observation was used to further reduce the level of very long-chain SFA that could not be achieved by

dietary restriction of SFA in X-linked adrenoleukodystrophy (ALD) patients suffering from a peroxisomal disorder. In these patients, the very long-chain SFA (>23:0) accumulate in sphingomyelin because ALD patients lack the ability to metabolize very long-chain SFA [83]. The combination of restricting the consumption of dietary SFA and inclusion of erucic acid in the diet (Lorenzo oil) has led to a normalization of the very long-chain SFA in the plasma lipids of ALD patients. In a 6.9 ± 2.7 year follow-up study, 74% of the patients were found to have normal neurological brain MRI results [84]. Therefore, instead of a safety concern, erucic acid appears to provide a benefit for ALD patients. The levels of <5% in the rapeseed oil in China should therefore not be of any health concern.

Conclusion

In conclusion, the results of this human milk survey from five cities in China show characteristic FA patterns associated with the type of foods consumed and ways of preparation. Despite the lack of information from the questionnaire as to the composition and amount of foods consumed, it was possible to establish how few mothers availed themselves of food products containing PHF high in TFA. If there was a trend towards westernization in eating habits in any of the five cities reported, the nursing mothers surveyed certainly did not participate in it. The cities in the southern and central regions had significantly higher levels of total TFA and CLA in their human milk than the two northern cities, but the isomer distribution in the TFA and CLA were random. This originated mainly from the use of refined and unsaturated vegetable oils used in stir-fry (wok cooking). This is in marked contrast to human milk in the northern region where the major isomers were vaccenic and rumenic acids derived mainly from dairy and ruminant products. There appears to be an adequate amount of both n-6 and n-3 HUFA in all regions of China, with very few human milk samples having less than recommended 0.2% level of DHA and a 1:1 ratio of ARA to DHA. Rapeseed oil is readily available and used for frying purposes in China evident by small amounts of erucic acid detected in almost all human milk samples. A level of less than 5% erucic acid in the rapeseed oil and up to 0.90% in human milk would appear to be safe based on scientific evidence. The energy derived from fat appears to be lower in China compared to Western countries [33], but the TFA and CLA composition in human milk consists of isomers other than vaccenic and rumenic acids for all regions, except in the northern cities. Efforts should be encouraged to reduce these TFA isomers by decreasing the frying temperature, or increasing the consumption of dairy and ruminant meat products rich in vaccenic and rumenic acids.

Abstract We studied the interrelationship of diet and plant sterols (PS) on plasma lipids, lipoproteins and carotenoids. Mildly hypercholesterolemic men ($n = 13$) and postmenopausal women ($n = 9$) underwent four randomized, crossover, double-blind, controlled feeding periods of 23 days each. The design consisted of two levels of PS (0 and 3.3 g/day) and two background diets having fat content either typical of the American diet (total and saturated fat at 33.5 and 13.2% of energy, respectively), or a Step 1 type of diet (total and saturated fat at 26.4 and 7.7% of energy, respectively). Plasma total cholesterol (TC), high density lipoprotein (HDL) cholesterol, low density lipoprotein (LDL) cholesterol, Apo A1 and Apo B were 4.3, 5.3, 4.5, 2.8 and 2.5% lower, respectively ($P \leq 0.0001$; <0.0001 , 0.0016, 0.0006, and 0.0069), with the Step 1 diet than with the typical American diet. Diet had no effect on TC/HDL cholesterol ($P = 0.1062$). Plant sterol intake lowered TC, LDL cholesterol, and Apo B by 9.0, 12.4 and 6.1% and TC/HDL by 9.6% ($P \leq 0.0001$ for all), respectively,

without affecting HDL cholesterol and Apo A1 ($P = 0.2831$ and 0.732). The PS effect in lowering plasma TC and LDL cholesterol was independent of and additive to the effect due to dietary fat reduction. Responses of plasma carotenoids to PS intake were consistent with the literature.

Keywords Plant sterols · LDL cholesterol · Typical American diet · Step 1 diet

Introduction

The landmark study by Miettinen et al. [1] reported the year-long efficacy of a margarine enriched with plant stanol-esters in reducing the low density lipoprotein (LDL) cholesterol concentrations of mildly hypercholesterolemic adults. Since then, numerous human studies on the efficacy

and safety of plant sterols (PS) and plant stanols, either in free forms or as esters, and alone or in combination with each other, have been published. The LDL cholesterol-lowering effects of PS and plant stanols are equivalent and additive to those of diet or lipid-lowering medications and the optimal daily intake is 2–2.5 g/day [2–5].

Effects of PS incorporated into different food forms [6] have been studied but not the impact of the fat level and composition of the background diet. Earlier studies have suggested that increasing saturated fat and cholesterol intakes may enhance the PS induced LDL cholesterol-lowering effect [7, 8]. A review of the literature found that the background diets in previous studies were either uncontrolled, such as free-living subjects consuming their habitual diets [1, 9, 10]; semi-controlled, such as free-living subjects receiving dietary counseling [9, 11]; or controlled but unvaried [12–14]. The only study in which fat intakes were varied by design did not quantify the effect of dietary fat [15]. A direct comparison of diets with varying fat level and composition has not been reported to date.

In the United States, the recommendation for individuals with elevated serum LDL cholesterol concentrations is to replace their customary diets with a “therapeutic lifestyle change (TLC) diet” consisting of saturated fat intake at <7% of calories, and cholesterol intake at <200 mg/day and including the use of viscous fiber and plant stanols/sterols as an initial step towards achieving the LDL cholesterol goal [16]. We designed the present study to determine the effect of three daily servings of PS in the presence of two practical background diets differing in fat level and composition on responses in lipids, lipoproteins, retinol, tocopherols, and carotenoids. These diets represent a typical American diet (TAD, relatively high in fat and saturated fat) and a TLC like diet (Step 1 diet).

Experimental Procedure

Study Design

The four dietary treatments consisted of two background diets (TAD and Step 1) in combination with two levels of PS (0 and 3.3 g/day) in a double-blind, randomized cross-over design, with each participant consuming each of the diets for 28 days. The fundamental differences between the TAD and Step 1 diets were their fat levels (33.5 vs. 26.4% of the calories for TAD and Step 1 diet, respectively) and fat composition (saturated/*cis*-monounsaturated/*cis*-polyunsaturated/*trans* fat at 13.2/11.5/6.5/2.4 for the TAD and 7.7/8.9/7.1/2.6 for the Step 1 diet). Blood samples were collected during the fourth week, after 22 days of feeding. As it

has been established that new steady states for plasma total cholesterol (TC), high density lipoprotein (HDL) cholesterol, and TAG are reached in 3–4 weeks [17], study subjects were then switched to the next diet with no washout between periods. The study protocol was approved by the Johns Hopkins University, Bloomberg School of Public Health, Committee on Human Research (Baltimore, MD). A detailed description of the subject recruitment procedures and selection criteria has been presented elsewhere [13]. Subjects were blinded to the four experimental diets. The salad dressings and margarines, with and without added PS, were prepared specifically for this study and supplied color-coded and blinded to the investigators by Unilever Foods, NA (Englewood Cliffs, NJ). Biological samples were coded and blinded to the analysts.

Diets

The four experimental diets were planned using data from the United States Department of Agriculture (USDA) National Nutrient Database for Standard Reference, Release 19 [18]. Typical American diet and Step 1 diets were composed of foods commonly eaten in the United States. Ranch salad dressing (8 g fat/serving) and a 60% fat spread (8.4 g fat/serving) were fed as part of the TAD diets, and Italian salad dressing (3.8 g fat/serving) and a 32% fat spread (4.5 g fat/serving) were fed a part of the Step 1 diets. Salad dressings and spreads were either fortified with 1.1 g PS per serving (equivalent to 1.8 g/serving of PS as esters from vegetable oil sources) and used in +PS diets, or having no added PS and used in the –PS diets. One serving of margarine was included in the breakfast, and one serving each of margarine and salad dressing were served at dinner for a total of zero (–PS) or 3.3 g/day of add PS (+PS).

A 7-day menu rotation was used. From Monday through Friday all subjects consumed breakfast and dinner at the Human Study Facility of Beltsville Human Nutrition Research Center (BHNRC) under the supervision of a dietitian. At breakfast, each subject was provided with a carry-out lunch to be consumed off-site that day. Snacks were included in the daily menu, which the subjects were allowed to eat either at dinner or later in the evening. Meals for the weekend were packaged for home consumption and were provided to the subjects, with written instructions, after dinner on Friday. Unlimited amounts of coffee, tea, and diet sodas were allowed, but all additives (sugar and milk) for coffee and tea were provided with the meals. Only foods provided by the Human Study Facility were allowed during the study.

Each weekday morning the subjects were weighed before breakfast when they arrived at the Facility. Energy intake was adjusted in 200- or 400-kcal increments to

maintain initial body weight. The subjects were fed the same items and the same proportions of each item relative to total dietary energy intake. Therefore, the relative amounts of all nutrients, other than those provided by the margarine and salad dressing, were constant for all subjects. Each day, the subjects completed a questionnaire detailing beverage intake, factors related to dietary compliance, exercise, medications, and illnesses. The questionnaires were reviewed routinely by a study investigator and all problems identified were discussed with the subject during the next meal.

During each feeding period, two composites of the 7-day menu cycle were made at two energy levels for each of the four diets. The food items were collected and prepared as though they were to be consumed. They were then homogenized in a blender with ice added to prevent heat build-up. The blended samples were freeze-dried in pre-weighed containers and weighed again after drying. The samples were then pulverized, and a weekly composite for each energy level was prepared by mixing together 15% by weight of each day's freeze-dried sample. The eight diet composites were analyzed for dry matter, crude protein, crude fat, total dietary fiber, ash, and fatty acid composition (Covance Laboratories Inc., Madison, WI) and sterol content and composition [14]. The fatty acid composition of the food composites was analyzed by using method AOCS 996.06. Carotenoid concentrations were estimated by using the US Department of Agriculture–Nutrition Coordinating Center carotenoid database for US foods [19].

Blood Collection and Analysis

Baseline (i.e., pretreatment) blood samples were collected on two separate days during the week immediately before the start of the first controlled feeding period. Blood samples were also collected on days 22 and 24 of the fourth week of each controlled feeding period. Procedures for blood sampling and processing were those described in the protocol for the Lipid Research Clinics Program [20]. Plasma concentrations of TC, HDL cholesterol, and TAG were measured enzymatically with commercial kits (Sigma Chemical Company, St Louis, MO) at the Lipid Research Clinic Laboratory at the George Washington University Medical Center, which maintains standardization with the Centers for Disease Control and Prevention, US Department of Health and Human Services. Low density lipoprotein cholesterol was calculated using the Friedewald equation [21]. Plasma concentrations of apolipoproteins A1 (Apo A1) and B (Apo B) were measured by rate nephelometry (Beckman ICS Immunochemical Analyzer; Beckman Instruments, Fullerton, CA). For each analysis, samples from an individual subject were processed in the same analytical run. Plasma concentrations of lutein, α - and β -cryptoxanthin,

lycopene, α - and β -carotene, total carotenoids, retinol, and α -, γ -, and δ -tocopherol were measured by HPLC as previously described [22, 23]. The precision and accuracy of the HDL chromatograph (HPLC) system was verified by using standard reference material 968b (National Institute of Standards and Technology, Gaithersburg, MD).

Statistical Analyses

All analyses were performed using SAS (SAS, Cary, NC) for Windows (v.9.1 2002–2003). The analytic plan was designed a priori and described a mixed-effects model for analysis of the data for repeated measurements [24]. For each variable the mean of two sample measurements taken during week 4 of each feeding period was analyzed. Individual differences were accounted for using the baseline value as a covariate, and by including a random subject effect in the model. The remaining time series (residual) correlation was modeled as one parameter autoregressive. Contrasts between diets, PS, gender and diet and/or gender and/or PS were tested by a *F*-test for differences among groups. Significant differences between baseline adjusted means (LS mean) were determined by Tukey–Kramer *t*-tests [25]. Plasma carotenoids were analyzed statistically with and without lipid standardization. A SAS Proc TTest [25] was used to compare the mean baseline values of men and women, and lipoprotein cholesterol values under baseline and TAD–PS intakes.

Results

Subjects

The characteristics of the subjects prior to the start of the intervention are shown in Table 1. Fourteen men and nine postmenopausal women (who were not using hormone replacement therapy) completed the four dietary intervention periods. Data from one male subject were dropped from the analyses because of suspicion of noncompliance. The male participants were younger on average than the female participants. At baseline, mean plasma lipid and lipoprotein cholesterol concentrations for men and women were not different. Plasma concentrations of TC and LDL cholesterol were higher at baseline than during the TAD–PS controlled dietary periods ($P = 0.0189$ and 0.018 , respectively), whereas TAG and HDL cholesterol were comparable ($P > 0.05$ for both).

Diets

The compositions of the TAD and the Step 1 diet, which were formulated by adding control or test spreads and salad

^a Women were postmenopausal and were not receiving hormone replacement therapy

^b Average daily energy intake from all four diets

dressings to a common experimental background diet, are listed in Table 2. The TAD was designed to contain 34% of energy from fat with a ratio of saturated to total monounsaturated to total polyunsaturated fatty acids (S:M:P) of 1:1:0.5. The analytical results showed that the fat energy contribution was slightly lower than planned at 33.5%, but the S:M:P ratio was achieved. The ratio of saturated to *cis*-monounsaturated to *cis*-polyunsaturated fatty acids was 1.0:0.9:0.5. The Step 1 diet was planned to have less than 30% of energy from fat, to have less than 7% of energy from saturated fat, and to have an S:M:P ratio of 1:1.5:1. The analytical results showed that fat contributed 26.4% of energy and that saturated fatty acids contributed 7.7% of energy. The target S:M:P ratio was achieved, and the ratio of saturated to *cis*-monounsaturated to *cis*-polyunsaturated fatty acids was 1.0:1.2:0.9. The *trans* fat content of both diets was close to the mean US population intake of 2.6% of energy [26]. Both diets were designed to provide less than 250 mg cholesterol/day for the average subject, and

the Step 1 diet was designed to have approximately 30% less cholesterol than the TAD. The analysis of the dietary composites showed that the TAD had a total fat content of close to those reported in the 2005–2006 NHANES [27], and a slightly higher saturated fat content. The TAD and Step 1 diets had approximately equal dietary fiber content and provided about 26 g dietary fiber per day. This amount of fiber is considerably higher than the average intake reported for the US diet of 18.0 g/day and 14.3 g/day for men and women aged 19 years and over, respectively [27], but was constant across all treatments.

Excluding the PS-enriched foods, the TAD and the Step 1 diets contained comparable amounts of dietary noncholesterol sterols, with both diets providing less than 400 mg PS/day for intake of the average subject. Sitosterol and campesterol accounted for at least 70% of the PS. The profile of noncholesterol sterols in the two +PS controlled diets reflected that of the soybean PS ester extract incorporated in the spread and dressings. From the 3.3 g/day

Table 2 Diet composition of the typical American diet (TAD) and Step 1 type diet

	TAD	Step 1
Protein (% of energy)	16.2	17.4
Carbohydrate (% of energy)	50.3	56.2
Fat (% of energy)	33.5	26.4

Plant sterols ^a (mg/1,000 kcal)	145.7	143.0

^a The percentage distribution of PS in the +PS diets is brassicasterol 2.5, campesterol 24.6, campestanol 0.8, stigmasterol 18.2, β -sitosterol 47.7, β -sitostanol 1.3, D5-avenasterol 1.2; the percentage distribution of PS in the –PS diets is brassicasterol 2.2, campesterol 19.2, campestanol 1.5, stigmasterol 9.7, β -sitosterol 53.3, β -sitostanol 2.7, D5-avenasterol 3.8

intake of PS in the +PS diets, 1.56 g was sitosterol and 0.81 g was campesterol.

The carotenoid-containing foods in the four experimental diets were the same, were fed in equal amounts in proportion to energy intake, and provided α - and β -carotene intakes that exceeded those reported in the 2005–2006 NHANES [27]. The calculated carotenoid content of the common background diet contained 4.82 mg/1,000 kcal total carotenoids, 1.69 mg/1,000 kcal β -carotene, 0.39 mg/1,000 kcal α -carotene, 2.05 mg/1,000 kcal lycopene, and 0.64 mg/1,000 kcal lutein + zeaxanthin.

Responses of Plasma Lipids and Lipoproteins to PS Intake and Diet

Body mass index had no significant effect on any of the dependent variables studied. There was also no effect of sex on lipids or lipoproteins; therefore, data from both sexes were combined for analyses and reporting.

Main Effects

Independent of PS, plasma concentrations of TC, HDLC, LDLC, Apo A1 and Apo B were lower by 4.4, 5.3, 4.5, 2.8,

and 2.5%, respectively, with the Step 1 diet substituting for the TAD. Diet had no significant effect on plasma concentrations of TAG or the ratio of TC to HDLC (TC/HDLC). Independent of the type of diet, the consumption of 3.3 g PS/day reduced plasma concentrations of TC, LDLC, and TC/HDLC by 9.0, 12.4, and 9.6%, respectively. Plasma TAG, HDLC, and Apo A1 concentrations were not significantly affected by PS intake. In response to PS intake, plasma Apo B concentrations were reduced from 0.82 to 0.77 g/L, and the ratio of Apo B to Apo A1 was reduced from 0.60 to 0.55 (Table 3).

Interaction Effects

Diet \times PS interactions existed for the plasma concentration of Apo B ($P = 0.0035$) and the Apo B/Apo A1 ratio ($P = 0.0011$). When PS were not added to the diets, the plasma Apo B concentration after consumption of the TAD (0.85 g/L) was higher than that after consumption of the Step 1 diet (0.80 g/L). With PS intake, Apo B concentrations after consumption of both diets (to 0.77 g/L) were not significantly different. Without PS intake, there was no effect of diet on the ratio of Apo B–Apo A1. Subsequent to PS intake, however, the reduction in this ratio after consumption of the TAD was greater than after consumption of the Step 1 diet (Table 3).

Responses of Plasma Retinol, Tocopherols, and Carotenoids to PS Intake and Diet

The effects of diet and PS intake on the absolute and TC standardized plasma concentrations of retinol; α -, γ -, and δ -tocopherols; lutein; zeaxanthin; α - and β -cryptoxanthins; lycopene; and α - and β -carotene are presented in Table 4 with responses from each sex combined (the sex effect and the diet \times PS interaction were not significant, $P > 0.05$). Absolute plasma concentrations of all compounds except retinol and δ -tocopherol were reduced by the intake of 3.3 g PS/day. After standardization for TC, the effects of PS were limited to cryptoxanthins, lycopene, and carotenes; the reductions were 5.9% for α -cryptoxanthin, 7.8% for β -cryptoxanthin, 24.7% for lycopene, 14.3% for α -carotene, and 21.0% for β -carotene.

Diet had no effect on the absolute concentrations of retinol, α -tocopherol, β -cryptoxanthin, lycopene, and α -carotene. Concentrations of γ -tocopherol, lutein, zeaxanthin, and α -cryptoxanthin were higher, and the concentration of β -carotene was lower with a TAD background diet. Subsequent to standardization for TC, plasma concentrations of γ - and δ -tocopherols and zeaxanthin remained higher after the consumption of the TAD than after the Step 1 diet. There was no diet effect on concentrations of retinol, α -tocopherol, lutein, cryptoxanthins, and lycopene.

¹ Among four treatments, values in a row with different superscripts differ, $P < 0.05$ (Tukey–Kramer)

² LS mean

³ In the presence of PS, no diet effect was detected for plasma Apo B level ($P = 0.9982$). In the absence of PS Apo B after TAD feeding was higher than that after Step 1 feeding ($P = 0.0006$)

⁴ The PS induced lowering of Apo B/Apo A1 was greater after TAD feeding (a 11.5% reduction, $P < 0.0001$) than after Step 1 feeding (a 5.1% reduction, $P = 0.0277$)

Concentrations of α - and β -carotene were lower after consumption of the TAD background diet. The higher TC-corrected plasma retinol concentration after PS intake in the present study was mainly due to the significant reduction in TC related to PS, because there was no effect of PS on the uncorrected plasma retinol concentration.

Discussion

The main objective of the study was to investigate, whether the magnitude of reduction in blood concentration of LDL cholesterol in response to PS intake is different between a diet representing what average Americans eat and a diet representing what health professionals recommend for blood cholesterol management. Within the context of the present study design, a diet effect and a PS effect were observed. Because there was no diet × PS interaction, our data demonstrate experimentally, for the first time, that the effects of PS and diet on plasma lipoprotein cholesterol concentrations are additive, at least for diets ranging in composition from the Step 1 to the TAD.

The magnitude of PS induced reduction in plasma TC and LDL cholesterol concentrations found in this study is comparable with the changes reported in the literature in which 2–3 g PS/day was consumed in conjunction with various background diets. Under Step 1 feeding alone, three servings of PS produced a 12.7% reduction in LDL cholesterol which is consistent with our prior study in which two servings of PS were fed and a 9.7% reduction in LDL cholesterol was observed [13]. Most importantly, these data show that a 16.9% reduction in plasma LDL

cholesterol concentration and a 7.8% increase in the TC/HDL cholesterol ratio were accomplished by switching from a TAD to a Step 1 +PS diet. For the reduction in LDL cholesterol, 72.7% was attributed to the PS and 27.3% to the switch from the TAD to the Step 1 diet. For the reduction in the TC/HDL cholesterol ratio, 100% was attributed to PS.

Because of the power gained from using a crossover design of this study, we were able to report for the first time a diet × PS interaction for Apo B and Apo B/Apo A1. The diet effect on Apo B was detectable only in the absence of PS which may be explained by the greater effect of PS on Apo B masking the weaker diet effect. Apo B/Apo A1 ratio has been suggested to be a better index than TC/HDL cholesterol ratio, non-HDL cholesterol/HDL cholesterol ratio, or LDL cholesterol/HDL cholesterol ratio to predict coronary risk [28]. As such, our finding of a greater PS effect on Apo B/Apo A1 ratio with TAD feeding than Step 1 feeding is of practical significance as the majority of the Americans are consuming diets closer to the TAD than the Step 1 diet [27].

Consistent with the literature, the present study found no effect of PS on plasma TAG and Apo A1 concentrations, whereas LDL cholesterol and Apo B concentrations, and thus the Apo B/Apo A1 ratio, were lowered by PS intake. The diet effects on TC, HDL cholesterol, LDL cholesterol, Apo A1, and Apo B were as expected. A diet effect on TAG was not observed possibly because the number of subjects was insufficient for such a purpose [29]. The subject sample size in this study was determined based on the detection of a significant difference in LDL cholesterol and not TAG.

^a LS mean

Qualitatively, the responses of plasma retinol, tocopherols, and carotenoids to PS intake observed in the present study were as expected. Quantitatively, the responses are consistent with those reported by us previously but greater than those reported by others in studies in which comparable amounts of PS were consumed, particularly for α - and β -carotene and lycopene. Richelle et al. [30] recently identified reductions in absorption of β -carotene and α -tocopherol as a mechanism for the PS intake-associated reductions in the circulation. We found higher plasma TC standardized concentrations of γ -tocopherols and zeaxanthin after consumption of the TAD than the Step 1 diet.

This finding is consistent with the knowledge that an increase in fat intake promotes the absorption of tocopherols and carotenoids [31]. The observation that the TAD, as compared with the Step 1 diet, produced significant reductions in TC-corrected plasma α - and β -carotene concentrations was unexpected and unexplainable, but is probably not physiologically important because the differences are insignificant in the context of their typical ranges in plasma.

In conclusion, our study is the first example of a direct comparison of the influence of diets versus the influence of PS intake on blood lipoprotein concentrations. Our findings

confirm that the LDL cholesterol-reducing effects resulting from PS intake and from switching from the TAD to the Step 1 diet are independent of each other, and that both are important but the effect of PS intake is quantitatively far greater. Our findings should not be taken as a suggestion that diet is of no consequence, because in fact the diet effect and the PS effect are additive. A limitation of the present study, as in most other published studies of PS and plant stanols, is the possible lack of generalizability because study participation was restricted to mildly hypercholesterolemic adults and, in our case, middle-aged male and non-HRT using postmenopausal female subjects. It is important to extend this study to larger and more varied groups.

Acknowledgments This paper is dedicated to our late mentor, colleague, and friend, David Kritchevsky, Ph.D. We are grateful to Elke Trautwein, Ph.D., of the Unilever Food and Health Research Institute for helpful discussions; Richard A. Muesing, Ph.D., of George Washington University for determining plasma concentrations of lipids, apoproteins, and lipoprotein cholesterols. Supported in part through a Research Support Agreement between the Agricultural Research Service, US Department of Agriculture, and Unilever US, Englewood Cliffs, NJ.

Conflict of interest statement J.T. Judd, M. Kramer, B.A. Clevidence, and D.J. Baer, no conflicts of interest. S.C. Chen was an employee of Unilever Foods, NA at the time the dietary portion of the study was conducted. G.W. Meijer is an employee of Unilever.

Abstract We have studied some physical properties of mixed phosphatidylcholine (SOPC)–phosphatidylserine (SOPS) vesicles. In a previous work (Paredes et al. in *J Biol Phys* 32:177–181, 2006) it was shown that the shape of the vesicles depends on the SOPC:SOPS composition, and that coiled cylindrical vesicles exist in samples with low SOPS contents. In this work, we further studied the same system of mixed vesicles. Differential scanning calorimetry (DSC) experiments displayed peaks characteristic of lipid mixing in the liquid state, ruling out a possible phase transition as an explanation of vesicle coiling. In addition, small-angle X-ray scattering (SAXS) experiments allowed us to estimate the periodicity distance inside the vesicles. This distance is $d \approx 60 \text{ \AA}$, as revealed by the Bragg peaks observed in the experiments. Finally, the coiling transition of a cylindrical vesicle was observed under solvent flow. This observation indicates that the vesicle coiling reported previously for this system (Paredes et al. in *J Biol Phys* 32:177–181, 2006) does not depend on the SOPC:SOPS composition alone, but also on mechanical perturbations during the preparation steps.

Keywords Biological membranes · Vesicles · Phospholipids · SOPC · SOPS · Vesicle coiling

Introduction

Giant vesicles have been used as models for studying membrane properties that can be relevant in biological phenomena [1, 2]. For this reason, the development of new methods for the preparation of vesicles of controlled properties (size, shape, mono- or multilamellarity) is of current interest, as well as the understanding of the mechanisms underlying the established methods. From all these, the simplest one is the hydration method, where a dried phospholipid film is hydrated with an appropriate amount of a solvent, with the vesicles forming after shaking or stirring [3]. Regardless of its simplicity, the mechanisms that favor vesicle formation at each stage of the procedure (drying, hydration, shaking) are not fully understood so far [3].

In a previous work, we reported experimental results regarding the shapes of mixed phospholipid vesicles [4]. The aggregates were prepared by the hydration method from mixtures of phosphatidylcholine (SOPC) and phosphatidylserine (SOPS) in different proportions. Using optical microscopy, we showed that the shape of the vesicles depends on the SOPC:SOPS composition. The main results of reference [4] are summarized in Table 1. It is interesting to note that among the observed vesicle shapes, there are coiled cylindrical vesicles for SOPC:SOPS molar proportions between 90:10 and 70:30 [4]. The variety of structures was interpreted in terms of the packing parameter model [5], in which the geometry of the molecules determines the aggregate structure.

Table 1 Summary of the SOPC:SOPS vesicle shapes and sizes observed in [4]

SOPC:SOPS composition	Shapes of the observed vesicles	Characteristic dimensions of the observed vesicles (μm)
0:00–95:05	Spherical	$D_{\text{spheres}} = 17$
	Cylindrical	$D_{\text{cylinders}} = 5$
90:10–70:30	Spherical	$D_{\text{spheres}} = 16$
	Cylindrical	$D_{\text{cylinders}} = 5$
	Coils	See Table 2
60:40–0:100	Spherical	$D_{\text{spheres}} = 16$

In this paper we report experiments on the same system

In this work, we report further experiments in the SOPC:SOPS system. Our aim was a better characterization of the vesicles described in reference [4], as well as the coiling transition described therein. We performed differential scanning calorimetry (DSC) experiments in order to determine the phase transition temperatures of the phospholipid mixtures. Small-angle X-ray scattering (SAXS) experiments were performed in order to have an idea of the periodicity distance inside the multilayered vesicles. In addition, the same vesicles were hydrated with solutions of monovalent and divalent salts in order to screen electrostatic interactions in the membrane and to assess if electrostatic effects are relevant in the coiling of cylindrical vesicles. Finally, the coiling of a cylindrical vesicle under solvent flow was followed using optical microscopy.

Experimental Methods

Materials

Vesicles were made of 1-Stearoyl-2-Oleoyl-*sn*-Glycero-3-Phosphocholine (SOPC) and 1-Stearoyl-2-Oleoyl-*sn*-Glycero-3-Phospho-L-Serine (SOPS). The molecular weights of these lipids are 788.14 g/mol and 812.05 g/mol respectively. Both phospholipids were purchased from Polar Avanti Lipids, Inc. (Alabaster, AL) and received as 10 mg/mL chloroform solutions. Purity is greater than 99%. They were stored at $-20\text{ }^{\circ}\text{C}$. Sucrose was obtained from Sigma (St Louis, MO). Ultrapure water with a resistivity greater than $18\text{ M}\Omega\text{ cm}$ was used to prepare all solutions. For the samples hydrated with brine, we used two monovalent (NaCl, KCl) and two divalent (CaCl_2 , MgCl_2) salts, all obtained from Sigma (St Louis, MO).

Sample Preparation

The samples were prepared by vacuum drying appropriate amounts of SOPC:SOPS mixtures at room temperature (3 h); the total phospholipid mass in every sample was 200 μg . In all our experiments, the samples were hydrated with 1 ml of a 60 mM sucrose solution in glass vials. The solvent of the sucrose solution was pure water, but brine solutions were used when we studied the effect of mono and divalent salts. Hydration with higher volumes of solvent gave qualitatively the same kind of aggregates. Note that above the phospholipid concentration range 2–8 mM there is non-ideal mixing of SOPC and SOPS [6]. Thus, our samples were prepared below this range, i.e. the phospholipid concentration was 0.2 mM, in order to ensure ideal SOPC–SOPS mixing. The SOPC:SOPS proportions of our samples were the same as those of reference [4] (see also Table 1). We worked in slightly acidic conditions ($\text{pH} = 6$). This pH is above the pK of the serine group in SOPS, which is thus not protonated.

Vesicle Shape and Size

In order to observe and to take images of the vesicles, 20 μl of the vesicle suspension were transferred to an observation chamber made with microscope cover slides and sealed with vacuum grease. The aggregates were observed using a LEICA DMIL inverted optical microscope with objective lenses $20\times$ and $40\times$. From the microscopy pictures we characterized the vesicle populations and measured the aggregate dimensions by using a microscopic scale of 2 $\mu\text{l}/\text{division}$ (Edmund Industrial Optics, Barrington, NJ). The vesicle dynamics was followed using a video camera (30 frames/s). All the experiments were conducted at room temperature, well above the chain melting transition of both lipids.

DSC and SAXS Experiments

Calorimetry experiments were performed in order to know the temperature transitions of the mixtures. A volume of 700 μl of the samples was injected in a calorimeter (Provo, UT) which measured the heat flow in the interval between 5 and $30\text{ }^{\circ}\text{C}$, at a rate of $1\text{ }^{\circ}\text{C}/\text{min}$. Small-angle X-ray scattering (SAXS) experiments were also performed in order to have some information about the interbilayer distance in the samples. We use a Rigaku rotating anode source that produces the $\text{CuK}\alpha$ lines (1.54 \AA). The linear detector, with 512 channels, was placed 81 cm from the sample position. For the SAXS experiments, the samples were more concentrated in order to have a strong enough signal.

Experimental Results

In Fig. 1, we present DSC results for several SOPC:SOPS proportions. The DSC thermograms reveal a well-defined transition peak in the samples, indicating mixing of the phospholipids. The main transition for the mixtures lies between 8 and 18 °C, well below room temperature. All the transition temperatures lie between those of SOPC (≈ 6 °C) and SOPS (≈ 26 °C) [7]. This is an indication that effects related to the solid-liquid melting transition in the membranes can be ruled out. We can conclude that in our samples, the lipids are mixed in the liquid state.

Several vesicle shapes (spheres, cylinders, complex aggregates) appeared in the optical microscopy experiments, as reported in reference [4] and summarized in Table 1.

Since the vesicles were prepared by a hydration method, they should be multilayered aggregates. These vesicles can be pictured as onion-like structures, composed of layers of concentric spherical or cylindrical membranes. A representation of the vesicles is shown in Fig. 2. Due to the concentric layers, the aggregates have a local lamellar nature that should display a Bragg interference peak in scattering experiments. In order to have an idea of the

Fig. 3 SAXS spectra of a sample with 100:0 composition. The Bragg peak indicates a multilamellar structure. From the position of the peak, the periodicity distance is $d \approx 60$ Å

periodicity distance d of the lamellar structure inside the vesicles (Fig. 2), we have performed SAXS experiments. Since the scattering signal was too low with the concentrations used for the optical microscopy experiments, the samples for X-ray Scattering were more concentrated. The SAXS spectra displayed a well-defined Bragg peak (Fig. 3), indicating that the vesicles have a multilamellar structure. From the peak position we computed the periodicity distance d using the Bragg relationship, $d = 2\pi/q_{\max}$. In our vesicles, this interbilayer distance is $d \approx 60$ Å. Note that systematic SAXS experiments could be interesting in order to study properties such as the

Fig. 4 Two of the coiled vesicles observed in the 90:10–70:30 SOPC:SOPS proportion range. p is the pitch of the helical structure. The *bar* represents 10 μm

interbilayer distance and the membrane elastic constants [8] as a function of concentration, temperature and pH.

In reference [4] it was reported that a striking structure observed for some SOPC:SOPS proportions is that of coiled vesicles. In Fig. 4 we present two of such coiled aggregates. We have measured the characteristic dimensions of the coiled vesicles. These dimensions are: the length of the coiled vesicle (l), the radius of the coiled cylinder (r) and the pitch (p) of the helical structure. Note that since the coiled vesicles are double helices [4, 9], the pitch p is defined as the repetition distance (for a single cylinder) along the helical axis (Fig. 4). The measured dimensions are shown in Table 2. As the ratio between the pitch of the helix p , and the radius of the cylinder r , is an indication of the tightness (or looseness) of the coiled structure, in Fig. 5 we have plotted p as a function of r . We

Table 2 Measured length, cylinder diameter and pitch of typical coiled vesicles observed in the proportion range 90:10–70:30

Vesicle	Length l	Cylinder radius r	Pitch p
1	18.09	2.92	8.33
2	22.50	3.33	4.17
3	23.75	5.02	18.33
4	25.83	4.17	10.43

10	62.7	8.92	25
11	66.65	9.51	25.00

The values are given in microns

see in this picture that the pitch is linearly related to the cylinder radius. The ratio of the radius to the pitch is obtained from the slope of this curve; its value is $r/p = 0.22 \pm 0.09$. This value is very near to that of the tightly wound helices observed in the phosphatidylcholine/cardiophilin mixture in the presence of calcium ions ($r/p = 0.214$) [10]. Looser helix formation has been observed in egg-PC vesicles, where the radius/pitch ratio is $r/p = 0.175 \pm 0.015$ [11].

In order to assess if electrostatic effects, such as the charge relaxation mechanism [12], do play a role in the coiling of our vesicles, we performed experiments with different salt concentrations in the solvent. For this, we

Fig. 5 Dependence of the measured pitch on the cylinder radius for coiled vesicles. The ratio of the radius to the pitch is 0.22 ± 0.09 , as obtained from the slope of the linear fit

used monovalent (NaCl, KCl) and divalent (CaCl₂, MgCl₂) salts. The positive ions screen the repulsive electrostatic interactions between SOPS head groups. Our results indicate that the yield of vesicles depends on the type of ion. Monovalent salts inhibit the formation of vesicles. On the other hand, divalent ions promote the formation of mainly spherical vesicles. These results are somewhat similar to those obtained by Akashi and coworkers [13] with a slightly different hydration method. Interestingly, no coiling was observed in the few cylindrical vesicles obtained in our experiments. It is not clear if this effect is only due to the low yield of cylindrical vesicles or to electrostatic effects related with the screening of the Coulomb interactions between PS head groups.

Note that other possible source of electrostatic effects is the pH of the solutions. In our case, we work in a slightly acidic media (pH = 6), thus effects due to protonation of the phospholipids should be negligible. In fact, the phosphatidylcholine head group has a strong zwitterionic character [3], i.e., it bears a positive electrical charge (associated with the nitrogen atom) as well as a negative electrical charge (phosphorous atom). On the basis of titrimetric assays, PC is known to preserve its zwitterionic characteristics over the entire pH range, $1 < \text{pH} < 12$ [14]. Thus, it is expected that a modification of pH, at least in this range, does not change the SOPC properties. On the other hand, SOPS is an anionic phospholipid [3]. Its head group has three ionizable groups (the diester phosphoric acid, the α -amino group and the carboxyl group), and it bears a net negative charge above a pH = 4.5 [14]. Below this value of pH, the carboxyl group protonates and SOPS is in the zwitterionic form (two opposite-sign electrical charges) [14]. Thus, if pH decreases below 4.5, SOPS loses its net negative charge and its properties change.

This behavior of the PC and PS head groups has been confirmed by potentiometric titration and surface potential measurements in mixed PC:PS vesicles [15]. We expect that in the case of the shapes of our SOPC:SOPS vesicles, no modifications would be observed if the pH is varied in the range above 4.5. However, due to protonation of the PS head group, one would expect modifications in the shape and properties of the SOPC:SOPS vesicles below a pH = 4.5. It would be an interesting point to investigate if coiling is possible for these pH values. We leave this issue for a future work.

Coiling of the SOPC:SOPS vesicles diluted with pure water depends on the composition of the sample because it is only observed for compositions between 90:10 and 70:30 [4]. However, it seems that the appearance of helicoidal vesicles is not only due to specific compositions but also to hydrodynamical stresses. In Fig. 6 we show the coiling of a SOPC:SOPS vesicle under a hydrodynamic perturbation. The composition of this vesicle is 80:20. The sequence was

obtained following a long cylindrical vesicle after solvent dilution. Right after sample preparation, the cylindrical vesicle was observed for a period of time of 30 min and only thermal fluctuations were observed (Fig. 6a). Afterwards, the sample was diluted adding a small quantity (10 μl) of solvent with a pipette. The effect was to coil both ends of the vesicle (Fig. 6b). The vesicle remained stable in this state for several minutes. Only thermal fluctuations were observed. Again we added the same volume of solvent and both ends of the vesicle continued to coil (Fig. 6c). The resulting vesicle was again stable for 30 min. This procedure was repeated until a final highly packed coiled aggregate was obtained (Fig. 6i). Note that the scale in Fig. 6 was changed in the last two pictures because of the small size of the final vesicle. This kind of highly packed aggregate was also observed in other samples with these phospholipid compositions. It seems to be the final stage of a coiling dynamics triggered by a hydrodynamical perturbation. Thus, coiling does not only depend on the composition of the membrane, but also on mechanical perturbations. This is a possible explanation of why the shapes of the population of vesicles obtained by hydration methods depend on the mechanical treatment of the samples. Note that the added solvent volume in each step of Fig. 6 reduces the phospholipid concentration of the sample. By performing this series of dilutions, at the final stage (Fig. 6i) we changed the total phospholipid concentration to about 20% of its original value. This new concentration is well above the typical cmc of phospholipids [5]. It is possible that preparing the vesicles with this concentration could lead to modifications in the aggregate characteristics. However, in the experiments depicted in Fig. 6 we did not perform all the hydration steps (drying, hydration, shaking). Instead, we just added the solvent to the already hydrated vesicles, without shaking the sample. The effect was to modify the preformed vesicle in the form observed in Fig. 6. We did not measure the characteristics of the other remaining vesicles, but just followed this cylindrical aggregate.

Discussion

As reported in reference [4], coiled vesicles have been observed in other systems [9–13, 16–19]. In some cases, coiling is induced by adding an additional component to cylindrical phospholipid vesicles. This component is either an ion [10] or a polymer [9, 16].

From a theoretical point of view, several mechanisms have been proposed in order to understand the existence of helicoidal vesicles.

Some of these approaches explain the coiling of the vesicles as a result of the interplay between favorable and

Fig. 6 Coiling dynamics of a SOPC:SOPS vesicle under a hydrodynamic perturbation (see text). The phospholipid composition of this vesicle is 80:20. **a** Unperturbed cylindrical vesicle undergoing thermal fluctuations. **b–i** Coiling of the vesicle observed after

hydrodynamic perturbation (flow of solvent) in each step. **i** Final highly-packed coiled vesicle. The bar represents 10 μm (**a–g**) and 5 μm in (**h**) and (**i**)

unfavorable forces. For instance, Lin et al. [10] have explained the Ca^{2+} -mediated induction of helical liposomes in mixtures of DMPC and cardiolipin by membrane–membrane binding forces; they argue that weak membrane–membrane binding energies can overcome curvature elastic energies and stabilize coiled vesicles. On the other hand, Mishima et al. [11] have reported coiling of cylindrical vesicles of egg-yolk lecithin. In this work, the proposed mechanism of coiling is an interplay between intermembrane attraction and the forces opposing helix formation which arise from the bending energy of the membranes. In the case of the SOPC:SOPS vesicles studied in this paper, membrane adhesion should be weak because the SOPS proportions are relatively small and adhesion forces should be similar to the case of pure SOPC [9]. In addition, the electrostatic repulsion of SOPS is unfavorable to adhesion. We thus rule out a mechanism related to a balance between favorable and unfavorable forces.

Another possible mechanism is the coupling between membrane composition and local membrane curvature. This is the driving force in the case of coiling induced by anchoring a hydrophobically modified polymer into cylindrical phospholipid vesicles [9, 16]. It has been proposed

that the added polymer diffuses and creates inhomogeneities that reduce the free energy of the system; this process locally induces a spontaneous curvature which drives the coiling of the cylinders [9, 16]. In our case, local inhomogeneities could appear after demixing of the two phospholipids composing the vesicle membranes. However, the DSC experiments show that our experiments were performed at a temperature well above the chain melting transition, regardless of the SOPC:SOPS proportion. Thus, phase transitions in the membrane can be ruled out as a driving force for coiling.

In our system, the exact mechanism of coiling is so far unclear. It is possible that the vesicles undergo a coiling transition due to some spontaneous curvature appearing at specific SOPC:SOPS compositions. This is a mechanism reported in the framework of a theoretical model by Santangelo and Pincus [19].

However, as shown in Fig. 6, coiling can also be induced by an appropriate flow of solvent. It is possible that the hydrodynamic perturbation produced by this flow creates asymmetric stresses or forces around the cylindrical vesicle so as to drag the cylinder to coil around itself. These forces could be of hydrodynamic origin, like those

explained by the Bernoulli equation of fluid dynamics [20]. One of the main effects predicted by this equation is a variation in pressure correlated with variations in the local velocity in an incompressible fluid. If the velocity of the fluid is higher in one point than in another, in the first point the fluid pressure is lower than in the second. This could give rise to two forces: a drag force, parallel to the free-stream velocity, and a lift force, perpendicular to the free-stream. The effect of the drag force is to push an object along the fluid flow. However, the lift force can lead to a bending of a flexible object. In the case of the vesicle of Fig. 6, it is possible that the solvent flow around the cylinder had an asymmetric velocity distribution. The side of the vesicle exposed to a low solvent velocity is subjected to a higher fluid pressure (as compared with the side exposed to a high solvent velocity). Thus, a lift force acts on the cylinder, pushing it from low-velocity to high-velocity regions. This effect, combined with appropriate shape or curvature fluctuations, could lead to the process depicted in Fig. 6. However, this is a point that needs more clarification, both theoretically as well as experimentally. Meanwhile, it is clear that in our case coiling is a process that depends on the way the system is prepared. This result has implications regarding the preparation of vesicles by hydration methods. Steps like stirring or shaking can induce flows that change the vesicle morphology as in the case of Fig. 6. In fact, these effects could explain some of the differences observed in the population of vesicles obtained by different hydration procedures.

Conclusions

We studied some properties of phospholipid vesicles prepared by hydration of mixtures of phosphatidylcholine (SOPC) and phosphatidylserine (SOPS) in different proportions. We investigated this system because in a previous work it has been shown that the shape of the vesicles depends on the SOPC:SOPS composition [4]. Using SAXS experiments we have confirmed that the vesicles are multilayered and that the periodicity distance inside a vesicle is or the order of $d \approx 60 \text{ \AA}$. On the other hand, DSC experiments have shown that the membranes are formed by a homogeneous mixture of the two phospholipids, with melting transitions well below room temperature. This result rules out effects related to phase transitions as a driving force for the coiling of cylindrical vesicles observed in this system. Finally, coiling was induced in a cylindrical vesicle by a hydrodynamic perturbation. This result shows that this process not only depends on the SOPC:SOPS composition, but also on mechanical forces applied to the phospholipid vesicles. This observation has implications for understanding the mechanisms behind the

differences observed in the shapes and properties of vesicles prepared by hydration methods.

Abstract Ceramides are the major type of lipid found in stratum corneum from the skin, gingiva and hard palate. The present study examined the ceramides of the stratum corneum from the hard palate. Six fractions of ceramides were isolated by preparative thin-layer chromatography. The least polar fraction contained an unusual acyl ceramide (EOS) consisting of long ω -hydroxy acids amide-linked to sphingosine with mostly saturated fatty acids ester-linked to the ω -hydroxyl group. The second and third fractions contained normal fatty acids amide-linked to sphingosine (NS) and phytosphingosine (NP), respectively. In each of these ceramides, the fatty acids consisted of a mixture of saturated and monoenoic species. The three most polar fractions all contain amide-linked α -hydroxy acids. The fourth fraction contained long α -hydroxy acids amide-linked to sphingosine (ASI), while the fifth fraction contained short α -hydroxy acids amide-linked to sphingosine (ASs). The most polar ceramide contained α -hydroxy acids amide-linked to phytosphingosine (AP). EOS, NS and NP differed from their epidermal counterparts in terms of the compositions of the normal fatty acids. ASI, ASs and AP from palatal stratum corneum were essentially identical to their epidermal counterparts. The differences between palatal and epidermal EOS, NS and NP contribute to the differences in permeability of palate compared to skin.

Keywords Lipid · Ceramide · Stratum corneum · Skin · Oral mucosa · Keratinization

Introduction

The epidermis covering the skin and the epithelium covering the hard palate are both keratinizing epithelia, and as such, they undergo terminal differentiation to produce a stratum corneum [1]. This consists of an array of flat, keratin-filled cells embedded in a lipid matrix. In both epidermal and oral stratum corneum, ceramides, cholesterol, and fatty acids are major lipid types [2], and the ceramides in both epidermis and hard palatal epithelium consist of the same set of six structural types as judged by thin-layer chromatographic comparison [3]. These lipids determine the permeability of the tissue. In either case, the six chromatographically separable ceramides (EOS, NS, NP, ASI, ASs, AP; the ceramide nomenclature is according to Motta et al. [4] with the addition of the suffixes l or s to indicate long-chain fatty acids or short-chain fatty acids, respectively.) make up about half of the total lipids. The proportions of these major lipids are similar in oral and epidermal stratum corneum, except that there is notably lower ceramide EOS in the oral tissue [3].

Unlike epidermal stratum corneum, palatal and gingival stratum corneum contains small but significant levels of phospholipids and glycolipids [2]. In the epidermis, these polar membrane lipids are completely catabolized in the late stages of the differentiation process leading to formation of the stratum corneum [5]. The oral stratum corneum also contains somewhat variable amounts of triglycerides which are not thought to contribute to barrier function and which may be contaminants [6].

The phospholipids and glycolipids, with their relatively bulky polar head groups and unsaturated fatty acids, would be expected to cause disorder of chain-packing within membranes and thereby shift the balance from predominantly gel-phase membrane domains toward more permeable liquid crystalline domains [7, 8]. In accordance with this expectation, the permeability of oral stratum corneum is an order of magnitude greater than that of epidermal stratum corneum [2, 6].

The purpose of the present study was to determine the structures of the ceramides from porcine palatal stratum corneum and to compare them with the previously published structures of porcine epidermal ceramides [9]. The null hypothesis is that the oral ceramides will be identical in structure to the epidermal ceramides.

Materials and Methods

Stratum Corneum Lipids

Porcine hard palates were obtained at a local slaughter house. The epithelium was peeled off using forceps after 1 min of immersion in water heated to 65 °C [2]. The stratum corneum was isolated by digestion with 1% trypsin in phosphate buffered saline at 4 °C overnight, followed by extensive rinsing with distilled water [2]. The tissue was then frozen at –20 °C and lyophilized over night. During the freeze-drying process, the shelf temperature was kept at 0 °C, and the vacuum was below 13 Pa. In the morning the shelf temperature was raised to 23 °C for 30 min prior to releasing the vacuum.

Lipids were extracted from the dried stratum corneum using chloroform:methanol, 2:1, 1:1 and 1:2 for 2 h each at room temperature [10]. Solvent was removed by evaporation under a gentle stream of nitrogen in a 45 °C water bath.

Isolation of Individual Ceramides

Twenty × twenty centimeter glass plates coated with 0.25-mm-thick silica gel G (Adsorbosil-plus-1; Alltech Associates; Deerfield IL, USA) were washed with chloroform:methanol, 2:1, and activated in an oven at 110 °C. Stratum corneum lipids were dissolved in a small volume of chloroform:methanol, 2:1, and applied as a narrow streak 3 cm from the bottom edge of the plate. The chromatogram was then developed to the top with chloroform:methanol:acetic acid, 190:9:1, followed by hexane:ethyl ether:acetic acid, 70:30:1 [9]. After air drying, the plate was sprayed lightly with 0.01% 2',7'-dichlorofluorescein in ethanol. After drying again, the plate was viewed under ultraviolet light. Lipid bands

appeared as dark bands on a bright background. The lipid fractions of interest were marked using a pencil. The silica from each fraction of interest was scraped from the plate using a Teflon spatula and placed in a small glass column. Lipids were eluted from the silica gel with chloroform:methanol:water, 50:50:1. Solvent was evaporated under nitrogen at 45 °C.

Gas–Liquid Chromatography

Acyl ceramides (EOS) were isolated from both epidermal and palatal stratum corneum from the same pig. The EOS samples were treated with 10% boron trichloride in methanol at 50 °C for 60 min. The normal fatty acid methyl esters (FAME) were isolated by preparative thin-layer chromatography on silica gel with a mobile phase of toluene.

Each of the other ceramides from palatal stratum corneum was treated with 10% boron trichloride at 50 °C overnight to convert the amide-linked fatty acids into FAME, which were isolated by preparative thin-layer chromatography as described above.

The FAME were analyzed by gas–liquid chromatography using a Shimadzu GC-14A gas chromatograph equipped with a 30-m EC-Wax capillary column and a flame ionization detector. This was done isothermally with an oven temperature of 170 °C. The detector and injector temperatures were 250 °C. The standards used included one mixture containing methyl esters of linoleate (C18:2 ω 6), linolenate (C18:3 ω 3), arachidonate (C20:4 ω 6) and docosahexaenoate (C22:6 ω 3) and a second mixture containing straight-chained saturated FAME (C14:0, C16:0, C18:0, C20:0, C22:0 and C24:0). Fatty acids with chains longer than 24 carbons were identified using plots of \log_{10} (retention time) versus carbon number [11]. Such plots are linear for members of a homologous series.

Results

In epidermal stratum corneum the most abundant ester-linked fatty acids from ceramide EOS were linoleic acid (C18:2, 71.7%) and arachidic acid (C20:0, 14.3%). The remainder was mostly palmitic (C16:0) and stearic (C18:0) acids with only trace amounts of other components (Table 1). In contrast, the palatal ceramide EOS contained stearic acid (C18:0, 43.6%), palmitic acid (C16:0, 32.0%) as the most abundant species (Table 1). Linoleate was only 8.8% of the ester-linked fatty acid in palatal ceramide EOS. Longer saturated fatty acids (C20:0 and C22:0) were also present.

The compositions of the normal fatty acids from palatal ceramides EOS, NS and NP are given in Table 1. The

amide-linked fatty acids from epidermal ceramides NS and NP were completely straight-chained saturated species, mainly C24:0, C26:0 and C28:0. The present findings for the ceramides NS and NP also contain C24:0, C26:0 and C28:0 as the most abundant species, but the presence of abundant monounsaturated species is in striking contrast to the findings with the epidermal ceramides. The compositions of the α -hydroxyacids from ceramides ASI, ASs and AP are listed in Table 2. In contrast with the findings with ceramides NS and NP, the α -hydroxyacids found in palatal ceramides ASI, ASs and AP are essentially identical to those found in their epidermal counterparts. Representative structures of the ceramides from porcine hard palatal stratum corneum are presented in Fig. 1. The long-chain bases were assigned on the basis of chromatographic comparisons with the well characterized epidermal ceramides [2, 3, 9].

Discussion

Although the same structural types of ceramides are present in both oral and epidermal stratum corneum, the present results demonstrate numerous subtle differences in details of these structures. In epidermal ceramide EOS,

linoleate is the major ester-linked fatty acid [9]; however, in palatal stratum corneum straight-chained, saturated species prevail. Linoleate in ceramide EOS is essential for the barrier function of the skin [12]. Without a proper skin barrier, transepidermal water loss could lead to desiccation, thereby precluding life on dry land [13]. However, in the moist environment of the oral cavity there is no water gradient, and therefore, no need for a barrier to water loss.

As previously reported [9] for porcine epidermal ceramide NS, the major fatty acids in palatal ceramide NS are C24:0, C26:0 and C28:0; however, the presence of significant (23.9% of total) proportions of monounsaturated fatty acids is quite different. The amide-linked fatty acids from epidermal ceramide NS are entirely straight-chained saturated species. Also, palatal ceramide NP has C20:0, C22:0, C24:0, C26:0 and C28:0 as the most abundant amide-linked fatty acids as was the case with epidermal ceramide NP; however, there are again significant levels of monounsaturated fatty acids (7.4% of total) that are not found in epidermal ceramide NP.

Interestingly, the α -hydroxy-acid-containing ceramides (AS1, ASs and AP) are nearly identical to their epidermal counterparts. AS1 and ASs are presumed to be produced by hydroxylation of ceramide NS species with long or short fatty chains, respectively, and AP is presumed to be produced by vitamin C-dependent hydroxylation of NP [14]. Present results would be consistent with the suggestion that the α -hydroxylases that mediate these reactions act exclusively on substrates with saturated fatty acyl chains. The possibilities that fatty acids and/or dihydrosphingosine are hydroxylated prior to formation of the amide linkage cannot be ruled out.

As noted in the introduction, the presence of phosphoglycerides and glycosphingolipids in palatal stratum corneum would be expected to have a fluidizing effect on the intercellular membranes by virtue of having bulky polar head groups and some unsaturated acyl chains. The *cis* double bond in a monounsaturated fatty chain creates a kink in the chain thereby precluding a rod-like geometry and orderly chain-packing within membranes. The unsaturated fatty acids in palatal ceramides NS and NP would further contribute to membrane fluidization and, thereby, reduce barrier function.

One can only speculate about the effects of replacing most of the linoleate in ceramide EOS with saturated fatty acids. With epidermal stratum corneum lipids, it appears that ceramide EOS is required for the assembly of 13-nm trilamellar units [15, 16], and models have been proposed in which the linoleate chains from ceramide EOS are localized in the central lamella of these units [16, 17]. Perhaps the small proportion of linoleate in ceramide EOS is sufficient for formation of such functional units and

provision of a barrier function. The barrier requirements of oral mucosa are notably less than the requirements of skin. For one thing, the oral cavity is a wet environment, so there is no need for a water barrier. Perhaps, the EOS species with saturated fatty acids are capable of supporting an adequate barrier function for the oral cavity, and this allows for conservation of an essential nutrient—linoleic acid.

Aside from the roles of the ceramides in the permeability barrier of the stratum corneum, ceramides serve as substrates for ceramidases that liberate antimicrobial long-chain bases near the surface of the stratum corneum, thereby providing a microbial barrier [18].

Carbohydrate Restriction has a More Favorable Impact on the Metabolic Syndrome than a Low Fat Diet

Abstract We recently proposed that the biological markers improved by carbohydrate restriction were precisely those that define the metabolic syndrome (MetS), and that the common thread was regulation of insulin as a control element. We specifically tested the idea with a 12-week study comparing two hypocaloric diets (~1,500 kcal): a carbohydrate-restricted diet (CRD) (%carbohydrate: fat:protein = 12:59:28) and a low-fat diet (LFD) (56:24:20) in 40 subjects with atherogenic dyslipidemia. Both interventions led to improvements in several metabolic markers, but subjects following the CRD had consistently reduced glucose (–12%) and insulin (–50%)

concentrations, insulin sensitivity (–55%), weight loss (–10%), decreased adiposity (–14%), and more favorable triacylglycerol (TAG) (–51%), HDL-C (13%) and total cholesterol/HDL-C ratio (–14%) responses. In addition to these markers for MetS, the CRD subjects showed more favorable responses to alternative indicators of cardiovascular risk: postprandial lipemia (–47%), the Apo B/Apo A-1 ratio (–16%), and LDL particle distribution. Despite a threefold higher intake of dietary saturated fat during the CRD, saturated fatty acids in TAG and cholesteryl ester were significantly decreased, as was palmitoleic acid (16:1n-7), an endogenous marker of lipogenesis, compared to subjects consuming the LFD. Serum retinol binding protein 4 has been linked to insulin-resistant states, and only the CRD decreased this marker (–20%). The findings provide support for unifying the disparate markers of MetS and for the proposed intimate connection with dietary carbohydrate. The results support the use of dietary carbohydrate restriction as an effective approach to improve features of MetS and cardiovascular risk.

Introduction

The codification of a set of physiologic markers as a metabolic syndrome (MetS) [1] 20 years ago is now recognized as a turning point in our understanding of metabolism as it plays out in the clinical states of obesity, diabetes and cardiovascular disease. The clustering of seemingly disparate markers—overweight, hyperglycemia, hyperinsulinemia, atherogenic dyslipidemia [high triacylglycerol (TAG) and low HDL-C]—can now be rationalized as the expression of a single physiologic state [2]. The underlying factor is generally considered to be insulin resistance and an increasing number of markers beyond the original definitions appear to be associated with the syndrome [3]. Notable among these is the predominance of small dense LDL-C, also called pattern B [4, 5]. Despite its theoretical importance, there is disagreement over whether diagnosing a patient's collective markers as a syndrome would lead to a different therapeutic strategy than treating the individual signs [6–10].

Whereas traditional approaches to MetS generally involve combination therapy [11, 12], we have suggested that a carbohydrate-restricted diet (CRD) provides a therapeutic intervention that will simultaneously target all of the traditional and emerging markers of MetS [13, 14]. The underlying mechanism is assumed to be readjustment of glycemic and insulin control. Thus, while insulin-sensitizing drugs, such as the thiazolidinediones, are associated with significant weight gain and edema and may be associated with some cardiovascular risk [15–17], improvement in insulin sensitivity with CRD is generally accompanied by weight loss [18–20]. Similarly, while there are several drugs that will raise HDL-C, none will affect the other markers of MetS and no treatment, pharmacologic or otherwise, is as effective as low-carbohydrate diets at lowering TAG [14, 21–24]. Low-fat diets may be effective for weight loss but tend to lower HDL-C and, in addition, generally *require* weight loss for beneficial effects whereas CRD do not [25, 26].

That a collection of markers is improved by a single type of intervention argues for the idea of a syndrome and the existence of a common (carbohydrate-sensitive) mechanism. From a practical standpoint, a physician treating any one marker by reducing carbohydrate has the potential to prevent the onset of others which may not be present at the moment.

We tested this hypothesis in a prospective study in which 40 overweight subjects with atherogenic dyslipidemia were randomly assigned either to a hypocaloric CRD (~1,500 kcal; %CHO:fat:protein = 12:59:28), or, as a control, to a diet restricted in fat (low fat diet, LFD: %CHO:fat:protein = 56:24:20). We previously reported the greater benefit of the CRD on weight loss and the relation between circulating fatty acid species and inflammatory markers [27]. Here we describe the broad panel of CVD risk markers that were differentially improved by these diets. Whereas the controls showed improvement in some of the physiologic markers studied, the CRD was generally (and in some cases dramatically) more effective. We also show, for the first time, that the CRD showed greater improvement in retinol binding protein 4 (RBP4), a novel mediator of insulin resistance [28–30].

Methods

Study Design and Participants

This study was a randomized, controlled, dietary intervention trial that compared a CRD to a LFD over a 12-week period in overweight subjects with atherogenic dyslipidemia. Participants were men and women aged 18–55 years with a BMI > 25 kg/m². Exclusion criteria were any metabolic and endocrine disorders, use of glucose-lowering, lipid-lowering or vasoactive prescriptions or supplements, consumption of a CRD at baseline, or weight loss greater than 5.0 kg in the past three months. Eligible subjects had a 12-h fasting blood sample taken and subjects with both moderately elevated TAG (150–500 mg/dL) and low HDL-C [<40 (men) or <50 (women) mg/dL] were randomly assigned to the CRD or LFD group after being matched by age and BMI. Twenty men and 20 women completed the study. All procedures were approved by the Institutional Review Board, and all subjects provided written informed consent.

Study Protocol

Prior to starting the diet treatment, subjects attended two baseline morning visits after a 12-h overnight fast and 24-h abstinence from alcohol and strenuous exercise. On Visit 1, body mass and body composition were assessed using

dual-energy X-ray absorptiometry (DXA), and a blood sample was obtained from an arm vein after the subjects rested quietly for 10 min in the supine position. Visit 2 involved a 6-h oral fat tolerance test to assess postprandial lipemic responses. The same tests were repeated after the 12-week dietary intervention period. In females, all blood samples were obtained during the early follicular phase to control for possible effects of menstrual phase on dependent variables. Habitual physical activity was maintained throughout the study intervention and was documented daily by all subjects. Dietary intake was assessed with detailed and weighed seven-day food records collected at baseline to assess habitual intake.

Dietary Intervention

Subjects received individual and personalized dietary counseling from registered dietitians prior to the dietary intervention. Detailed dietary booklets, specific to each dietary treatment, were provided that outlined dietary goals, lists of appropriate foods, recipes, sample meal plans, and food record log sheets. All subjects were given a multivitamin/mineral complex that provided micronutrients at levels <100% of the RDA and instructed to consume one pill every other day. No explicit instructions were provided regarding caloric intake for either diet to allow expression of any noncognitive aspects on food intake. Subjects received weekly follow-up counseling during which body mass was measured, compliance was assessed, and further dietetic education was provided. Seven-day weighed food records were kept during weeks 1, 6, and 12 of the intervention and were analyzed for energy and macro/micronutrient content (NUTRITIONIST PRO™, Version 1.3, First Databank Inc, The Hearst Corporation, San Bruno, CA, USA). The nutrient analysis program had no missing values for the nutrients reported, and the database was extensively updated with new foods and individualized recipes.

The main goal of the CRD was to restrict carbohydrate to a level that induced a low level of ketosis. Subjects monitored ketosis daily using urine reagent strips that produce a relative color change in the presence of one of the primary ketones, acetoacetic acid. In this diet there were no restrictions on the type of fat from saturated and unsaturated sources or cholesterol levels. Examples of foods consumed by the subjects included unlimited amounts of beef, poultry, fish, eggs, oils and heavy cream; moderate amounts of hard cheeses, low-carbohydrate vegetables and salad dressings; and small amounts of nuts, nut butters and seeds. Subjects restricted fruit and fruit juices, dairy products (with the exception of heavy cream and hard cheese), breads, grains, pasta, cereal, high-carbohydrate vegetables, and desserts. Subjects were

instructed to avoid all low-carbohydrate breads and cereal products, and were limited to a maximum of one sugar alcohol-containing, low-carbohydrate snack per day. The LFD was designed to provide <10% of total calories from saturated fat and <300 mg cholesterol. Foods encouraged included whole grains (breads, cereals, and pastas), fruit/fruit juices, vegetables, vegetable oils, low-fat dairy and lean meat products. Standard diabetic exchange lists were used to ensure a macronutrient balance of protein (~20% energy), fat (~25% energy), and carbohydrate (~55% of energy).

Body Mass and Composition

Body mass was measured in the morning after an overnight fast to the nearest 100 g on a calibrated digital scale. Whole body and regional body composition was assessed by DXA (Prodigy™, Lunar Corporation, Madison, WI, USA). Analyses were performed by the same blinded technician. Regional analysis of the abdomen was assessed by placing a box between L1 and L4 using commercial software (enCORE version 6.00.270). This abdominal region of interest has been shown to be a highly reliable and accurate determinant of abdominal obesity compared to multislice computed tomography [31]. Coefficients of variation for lean body mass, fat mass, and bone mineral content on repeat scans with repositioning on a group of men/women were 0.4, 1.4, and 0.6%, respectively.

Oral Fat Tolerance Test

An oral fat tolerance test was performed before and after each dietary treatment using standard procedures in our laboratory. A flexible catheter was inserted into a forearm vein and blood samples were obtained from a three-way stopcock. The catheter was kept patent with a constant saline drip. Prior to consumption of the test meal, subjects rested in a seated position for 10 min and a baseline blood sample was obtained. A high-fat meal (225 mL whipping cream, sugar-free instant pudding, 28.5 g macadamia nuts) was then consumed within a 15-min time frame, providing 908 kcal, 13% carbohydrate, 3% protein, and 84% fat. Postprandial blood samples were obtained immediately (0 h) and hourly for hours 1–6 following the meal. Subjects rested quietly in a seated position and consumed only water during the postprandial period.

Blood Analyses

Whole blood was collected into tubes without preservative or an anticoagulant and centrifuged at $1,500 \times g$ for 15 min and 4 °C, and promptly aliquoted into storage tubes. A portion of serum (~3 mL) was sent to a certified

medical laboratory (Quest Diagnostics, Wallingford, CT, USA) for determination of total cholesterol, HDL-C, TAG, and calculated LDL-C [32] concentrations using automated enzymatic procedures (Olympus America Inc., Melville, NY, USA). The remaining serum and plasma was stored frozen at -80°C and thawed only once before analysis. Glucose and insulin concentrations were analyzed in duplicate from serum using a YSI glucose/lactate analyzer (YSI 2300 STAT, Yellow Springs, OH, USA) and I^{125} radioimmunoassay [Diagnostic Systems Laboratory (DSL)-1600, Webster, TX, USA], respectively, and used to calculate an index of insulin resistance [33]. LDL particle size of was determined in serum using nongradient polyacrylamide gel electrophoresis (PAGE; Lipoprint LDL System, Quantimetrix Co., Redondo Beach, CA, USA), as previously described [34]. Lipoprotein (HDL, LDL, and VLDL) particle size and number was determined using H-nuclear magnetic resonance (NMR) on a 400 MHz NMR analyzer (Bruker BioSpin Corp, Billerica, MA, USA), as previously described [14]. Lipoprotein subclasses were grouped based on particle diameters: large VLDL (>60 nm), medium VLDL (35–60 nm), small VLDL (27–35 nm), IDL (23–27 nm), large LDL (21.2–23 nm), medium LDL (19.8–21.2 nm), small LDL (18–19.8 nm), large HDL (8.8–13 nm), medium HDL (8.2–8.8 nm), and small HDL (7.3–8.2 nm). Total ketone bodies were determined in duplicate from serum by a kinetic enzymatic, colorimetric method that measures both acetoacetate and 3-hydroxybutyrate (CV 3.6%); nonesterified fatty acids were analyzed in duplicate from serum with an ACS-ACOD method (Wako Chemicals USA, Richmond, VA, USA). Apo A-1 and Apo B were quantified in duplicate from serum using a turbidimetric immunoassay method (Wako Chemicals USA) with intra-assay CVs of 8.0 and 6.6%, respectively. Leptin was determined in duplicate using an ELISA with a sensitivity of 0.05 ng/mL (DSL, Webster, TX, USA). Serum RBP4 was measured by quantitative Western blotting using full-length recombinant RBP4 protein standards on each gel, as previously described [30]. For fatty acid analyses, serum total TAG and cholesteryl ester (CE) were separated on commercial silica gel G plates for determination of fatty acid methyl ester composition by capillary gas chromatography. A detailed description of the methods for fatty acid determination, as well as the complete fatty acid data focusing on the polyunsaturated fatty acid responses in relation to inflammatory markers, is published elsewhere [27]. Here we report only the TAG and CE saturated fatty acid (SFA) and 16:1n-7 data.

Statistical Analyses

The mean of two fasting blood draws performed at the same time of day on separate days to account for diurnal and

day-to-day variation in lipids was obtained. An ANOVA with one between-effect (CRD vs. LFD) and one within-effect (week 0 vs. week 12) was used to compare responses over time in both groups. Significant main or interaction effects were further analyzed using a Fishers LSD post hoc test. For postprandial biochemical variables, the area under the curve was calculated using the trapezoidal method. Relationships among selected variables were examined using Pearson's product-moment correlation coefficient. The alpha level for significance was set at 0.05.

Results

Dietary Intake

Average nutrient intake is provided in Table 1. Although not specifically counseled to reduce calories, there was a reduction in total caloric intake in both groups. Spontaneous reduction in calories on CRDs was first shown by LaRosa in 1980 [35], and there are several studies showing that, in practice, people tend to remove carbohydrate without replacement of either fat or protein (e.g., [36]). Interventions where weight loss is at least an implied goal may generally have this effect. The Women's Health Initiative was a large low-fat trial where weight was lost on a LFD in the first two years [37] although the effect did not persist. The diets, thus, did not differ in energy consumption averaged over the 12 weeks of the intervention. The nutrient composition, however, varied significantly between the CRD (1,504 kcal: %CHO:fat:protein = 12:59:28) and LFD (1,478 kcal: %CHO:fat:protein = 56:24:20). Subjects consuming the LFD were successful at reducing saturated fat to 7% of total energy, compared to 22% in subjects following the CRD. Because of the reduction in caloric intake, however, the increase in the absolute amount of saturated fat for the CRD group was not great, an average of 34 g/day in subjects' habitual diet compared to 36 g/day during the experiment. In the LFD group, the absolute amount of saturated fat fell from an average of 26–11.7 g/day. Dietary cholesterol was significantly higher and fiber significantly lower on the CRD compared to the LFD. The presence of urinary acetoacetic acid is a qualitative but sensitive indicator of carbohydrate restriction. During weeks 2–12 of the CRD intervention, subjects reported the presence of urinary ketones above trace on 85% of the days, indicating a high degree of compliance.

Dietary Carbohydrate Restriction Enhances Weight Loss and Reduces Adiposity Out of Proportion to the Caloric Deficit

Despite similar reductions in calories, weight loss in the CRD group was, on average, twofold greater than in the

Table 1 Average nutrient intake of men and women who consumed a carbohydrate-restricted (CRD) and low-fat diet (LFD)

low-fat control (10.1 kg vs 5.2 kg). This apparent decrease in caloric efficiency with carbohydrate restriction has been observed many times (reviews: [38, 39]), although the current report is one of the more dramatic demonstrations. There was substantial individual variation, but 9 of 20 subjects in the CRD group lost 10% of their starting weight, more than all of the subjects in the LFD group. Indeed, none of the subjects following the LFD lost as much weight as the average weight loss for the experimental group. The number of subjects who lost >5% of body weight was 19 of 20 subjects for the CRD compared to 12 of 20 for the LFD. Despite greater absolute fat intake and similar total caloric intake, whole body fat mass decreased significantly more in subjects following the CRD (5.7 kg) than in subjects following the LFD (3.7 kg) (Table 2). Fat mass in the abdominal region, associated with many features of the insulin resistance syndrome, was similarly decreased significantly more in subjects consuming the CRD than subjects following the LFD (−828 g vs −506 g).

Dietary Carbohydrate Restriction Improves Glycemic and Insulin Control

The CRD resulted in a significant average reduction of 12% in fasting glucose (Table 3). Responses in the control LFD were variable with little average change. Fasting insulin responses were also decreased to a greater extent in

subjects following the CRD than in subjects following the LFD (−49% vs −17%), as were postprandial insulin responses to a meal high in fat (−49% vs −6%). Similarly, the homeostasis model assessment (HOMA), a measure of insulin resistance, was reduced to a greater extent in subjects following the CRD than controls (−55% vs −18%). All subjects in this study were overweight and had elevated values for leptin at baseline, an indication of leptin resistance. These values were markedly reduced in subjects following the CRD (−42%) compared to a smaller decrease of 18% in control subjects following the LFD. The significantly greater decrease in leptin in subjects following the CRD persisted after normalization of values to body mass and fat mass.

Dietary Carbohydrate Restriction Enhances Mobilization and Utilization of Lipid Substrates and Inhibits Lipogenesis

The hormonal milieu associated with dietary carbohydrate restriction is proposed to create a unique metabolic state characterized by enhanced reliance on lipid sources and more efficient processing of dietary fat. Compared to baseline, fasting serum total ketones were not different after the LFD (103 ± 73–94 ± 65 μmol/L), but were elevated threefold after the CRD (77 ± 36–212 ± 91 μmol/L), signifying enhanced mobilization of fatty acids from adipose tissue (Table 4). In accord with enhanced lipolysis,

fasting nonesterified fatty acids increased in subjects following the CRD and decreased in subjects following the LFD.

To better understand how carbohydrate restriction affects the processing of dietary fat, we measured clearance of an oral fat load providing 908 kcal and 85 g fat mainly from saturated fat. At baseline, we found that the fat

challenge induced a dramatic rise in TAG after 1 h that remained above fasting levels for the duration of the 6-h postprandial period. After 12 weeks on the CRD, the postprandial TAG pattern was dramatically decreased at all time points. The total postprandial TAG area under the curve (Fig. 1A) was significantly lower after the CRD than the LFD (−47 vs −15%). Although the CRD group

12 weeks. Mean total area under the curve (AUC) and integrated AUC were significantly different between the CRD and LFD ($P < 0.000$)

showed slightly lower fasting TAG levels, the area under the curve normalized to fasting TAG levels was significantly lower in subjects consuming the CRD (Fig. 1B).

Change in Fatty Acid Composition

To further explore the processing of dietary fat by carbohydrate restriction, we assessed fatty acid composition in serum lipid fractions (Table 5). The dietary intake of saturated fat was threefold higher on the CRD (36 g/day) compared to the LFD (12 g/day). Remarkably, the CRD showed consistently greater reductions in the relative proportions of most circulating SFAs in TAG and CE fractions (16), mainly attributed to greater reductions in myristic (14:0; 47% reduction) and palmitic (16:0; 10%) acids. With the exception of those with a low level at baseline, nearly all subjects consuming the CRD had a decrease in total saturates (17 of 20 subjects), whereas only half the subjects consuming the LFD had a decrease in saturates. Taking into account the change in absolute fasting TAG levels, the absolute concentration of total saturates in plasma TAG was reduced by 57% in response to the CRD, compared to 24% in response to the LFD. There was also a 31% decrease in palmitoleic acid (16:1n-7) in response to the CRD which, because of its low concentration in the diet, is a marker for de novo lipogenesis [40].

Dietary Carbohydrate Restriction Results in Consistently Greater Improvements in Atherogenic Dyslipidemia and Lipoprotein Markers

The CRD dramatically improved the features of atherogenic dyslipidemia compared to the LFD. Table 5 and Fig. 2 summarize the average and individual changes in

these parameters: the CRD shows more favorable responses in fasting TAG (−51 vs −19%), HDL-C (+13 vs −1%), and the TAG/HDL-C ratio (−54 vs −20%) ($P < 0.001$ in all cases). The dramatic decrease in TAG in response to carbohydrate reduction is one of the most reliable effects of any diet intervention [13, 41]. Whereas 12 of 20 subjects following the CRD showed a >10% increase in HDL-C, only 2 of 20 subjects following the LFD reached this point. Strikingly, the six subjects assigned to the CRD who already had the highest HDL at baseline further improved to a greater extent than any subject in LFD. An unexpected finding regarding HDL-C was a gender by diet effect, with women who started with higher baseline values exhibiting a more pronounced benefit on the CRD (17% women vs 8% men).

The CRD significantly improved other lipoprotein CVD risk factors. The total cholesterol/HDL-C ratio was reduced more in subjects during the CRD than during the LFD (−14 vs −4%). The Apo B/Apo A-1 ratio is considered the best indicator of risk for vascular disease [42] and was, similarly, improved in subjects following the CRD but was slightly worse on average for subjects of the LFD (−16 vs +8%). It should be pointed out, in addition, that the five subjects with the highest Apo B/Apo A-1 ratio in the CRD group improved (−29%), while the five subjects with the highest values in LFD got worse (4%).

Changes in LDL-C showed substantial variation in both the CRD and LFD groups. Although on average this marker was not reduced in subjects following the CRD, there were improvements in the vascular remodeling of particles, consistent with previous observations that the number of the small, dense, more atherogenic particles tend to increase as dietary carbohydrate is increased and dietary fat is reduced [4, 5, 26, 43]. We measured LDL subfractions

Table 5 Carbohydrate-restricted diet results in consistently greater improvements in atherogenic dyslipidemia and lipoprotein markers

PAGE, polyacrylamide gel electrophoresis; NMR, nuclear magnetic resonance

using two methods based on high-resolution PAGE or on NMR. The results from PAGE confirmed previous observations, showing a significant ($P < 0.001$) LDL particle redistribution in subjects following the CRD as reflected by a shift from smaller (LDL-3) to larger (LDL-1) particles, whereas there was little change in the concentration or size of LDL particles on the LFD. NMR results showed a similar significant reduction in the quantity of small and very small LDL particles and a concomitant increase in the quantity of large LDL particles. Mean LDL size increased significantly in subjects following the CRD using both PAGE and NMR. In addition to increased LDL particle

size, there was a significant increase in NMR-determined HDL size in subjects following the CRD.

Weight Loss and Dyslipidemia

To understand the extent to which the measured parameters are related, we compared change in BMI to change in the TAG/HDL-C ratio. Figure 3 shows that there is a very poor correlation between these variables for either the CRD ($R^2 = 0.0529$ from linear regression) or the LFD ($R^2 = 0.0012$). Surprisingly, for the LFD group, 7 of the 11 subjects who had the largest change in BMI showed the smallest change in TAG/

Fig. 2 Individual responses in lipid parameters after 12 weeks on indicated diets. Carbohydrate-restricted diet (CRD) is indicated by circles; low-fat diet (LFD) is indicated by triangles. Bars indicate mean values

Fig. 3 Correlation of changes in BMI and changes in TAG/HDL ratio. Carbohydrate-restricted diet (CRD) is indicated by black circles; low-fat diet (LFD) is indicated by dark gray squares. The light gray square highlights 7 of the 11 subjects in the LFD with the largest change in BMI. Linear regression for VLCKD: $\Delta(\text{TAG}/\text{HDL}) = -0.24117 + 0.259 \times (\Delta\text{BMI})$, $R^2 = 0.0529$, for LFD: $\Delta(\text{TAG}/\text{HDL}) = -0.923 + 0.05325 \times (\Delta\text{BMI})$, $R^2 = 0.0012$

HDL. Similar poor correlations were found for other markers of weight loss and lipids (data not shown).

Dietary Carbohydrate Restriction Reduces RBP4

We further explored the response in serum RBP4, and the associations with dietary input and other markers of insulin

resistance. Changes in serum RBP4 levels were variable but showed a significantly greater reduction in subjects consuming the CRD (34.6 ± 11.7 – 27.6 ± 8.0 $\mu\text{g}/\text{mL}$) compared to LFD (37.1 ± 14.3 – 39.0 ± 18.6 $\mu\text{g}/\text{mL}$); only two of the subjects in the CRD group, but 8 of 20 controls showed an increase. Changes were significantly correlated to responses in several metabolic outcomes (“[Electronic supplementary material](#)”). The only dietary nutrient that correlated with the change in RBP4 was carbohydrate (g/day) during the CRD. The absolute and percent changes in RBP4 were associated with changes in measures of adiposity only in the LFD controls, not the CRD. On the other hand, RBP4 was correlated to improvement in glucose, fatty acids, insulin, HOMA, and leptin during the CRD but not the LFD. Changes in RBP4 were correlated with changes in LDL particle size on both diets and to total and LDL-C on the LFD. Changes in several serum fatty acid species were correlated with RBP4, but they differed for the CRD and LFD. The highest correlation was between changes in RBP4 and phospholipid 18:0 ($r = 0.77$). There were no correlations between changes in RBP4 and markers of inflammation as assessed by 20 separate inflammatory markers. These findings link the role of RBP4 in insulin resistance, with studies showing a tight connection between carbohydrate restriction and features of MetS.

Discussion

Several recent diet comparisons have been published showing that CRDs are at least as effective as LFDs on weight loss, lipid profile, and other health markers [18, 27, 44–46] (reviews: [14, 23, 47, 48]), the most recent being a two-year study from Shai et al. [49]. The current study is distinguished from these in that we specifically tested the idea that carbohydrate restriction targets the markers of MetS, particularly the atherogenic dyslipidemia. Our results support the hypothesis, and further show that CRDs improve a wide spectrum of lipid markers of CVD risk, including effects on LDL particle size. Two other novel findings were that a CRD resulted in a decrease in plasma SFAs despite higher dietary saturated intake, and resulted in a significant decrease in RBP4, a molecule of current interest because of its association with MetS. Finally, we show that weight loss in hypocaloric diets correlates poorly with changes in lipid profile.

Markers of CVD Risk

The atherogenic potential of LDL-C appears to reside in the small dense particles, whose concentration is independent of total LDL-C concentration [4, 5, 43]. Shoji et al., for

example, measured carotid artery intima-media thickness (CA-IMT) and showed that when results on LDL-C were broken into small dense and large buoyant fractions, only the small dense LDL showed a significant positive association with CA-IMT [50]. Small dense LDL are now considered a feature of MetS, but the dichotomy between LDL, still the most common marker for CVD risk, and atherogenic dyslipidemia is unresolved. The results presented here show a significant decrease in small LDL particles in subjects consuming the CRD, consistent with the tight connection between dietary carbohydrate and LDL size established in the literature [4, 5, 43].

The reductions in TAG associated with the CRD are particularly striking—an effect probably due to decreased de novo lipogenesis and VLDL-TAG secretion as well as increased VLDL-TAG clearance. Regardless of the mechanisms, elevated circulating TAG is an independent risk factor for CVD [24, 51], and elevations in the post-absorptive and postprandial period directly contribute to the dyslipidemic state characterized by low HDL-C and increased prevalence of small LDL-C. Considering the established importance of increasing HDL-C as a therapeutic target for both men and women [52], the effect on HDL-C is perhaps the most important result from this and other studies of CRDs. HDL-C is one of the major targets of health agencies and one for which existing drugs are not entirely satisfactory. Consistent with previous work [53, 54], we showed that a LFD has minimal effect on HDL-C, and that women experience a larger increase in response to carbohydrate restriction than men. We also assessed alternative lipid markers. Evidence has been presented that the ratio Apo B/Apo A-1 is the best predictor of CVD [42], and that, in the current study, the CRD was distinguished by the very dramatic reduction in this parameter. In summary, our results are consistent with previous work showing the benefit of CRD compared to LFD [13, 34, 41].

Dietary and Plasma Levels of SFA

Carbohydrate-restricted diets, although relatively high in SFA, show effects on plasma fatty acid that are very different from those seen in studies conducted in the presence of moderate to high dietary carbohydrate. A high-carbohydrate diet prolongs circulatory exposure to dietary (or endogenous) SFA, and conversely, dietary restriction of carbohydrate (via reduced secretion of insulin) allows for greater rates of lipid oxidation and management of the incoming lipid mix. High dietary fat is thus expected to be deleterious only if there is sufficient carbohydrate to provide the hormonal state in which the fat will be stored rather than oxidized. An expression of this effect is that the CRD with a greater proportion of fat and saturated fat led to a *reduction* in plasma SFA, particularly palmitic acid

(16:0), whose presence has been linked to higher levels of adiposity [55, 56]. The likely cause is greater fat oxidation and attenuation of hepatic de novo lipogenesis, as indicated by a parallel reduction in palmitoleic acid, the product of the stearoyl CoA desaturase-1 (SCD-1), and a minor constituent in dietary fat. That the reduced proportion of 16:1n-7 in serum lipids with the CRD is not due to downregulation of SCD-1 is indicated by the fact that both 16:0 and 16:1n-7 were reduced in the subjects consuming the CRD, whereas the proportion of 16:0 would be expected to rise if less were subject to desaturation. The results indicate a greater effect of the CRD on reduction of glucose disposal via lipogenesis.

Correlation of Weight Loss and Lipid Markers

The rationale for using carbohydrate restriction to treat MetS is that a (carbohydrate-sensitive) physiologic state is expressed in the various markers of the syndrome. It is not excluded that, beyond carbohydrate, per se, decreasing adipose mass contributes to the change in lipid markers since they are also affected by adipokines. It is difficult in general to distinguish between mechanisms in a hypocaloric experiment; however, the experiments presented here do not support the decreased adipose mass as the primary stimulus for inducing improvement in MetS in subjects consuming a CRD. Although the CRD was significantly better at effecting weight loss, all but two subjects consuming the LFD lost at least some weight; yet the performance of the latter group on some of the lipid markers was not good, even in a qualitative sense. In addition, as shown in Fig. 3, there is only a very weak correlation between weight loss and dyslipidemia in both groups, suggesting that, even in the LFD, the reduction in body mass may be one of several *parallel* consequences of some central physiologic change.

Experiments in the literature further support this idea. Normal-weight people [34, 57] and subjects with diabetes [58, 59] on low-carbohydrate diets constrained to maintain body mass show improvements in atherogenic dyslipidemia. Also, in comparative studies in which weight loss is similar between different diets, the carbohydrate-restricted group shows better response on other markers [60, 61]. Finally, experiments in which isocaloric changes in macronutrient composition are separated in time from weight loss point to the beneficial effects of carbohydrate reduction before caloric restriction [25, 26].

Mechanism of Improvement of Dyslipidemia by CRD

We recently summarized the mechanisms by which CRD are understood to improve dyslipidemia [14, 23]. In brief, high insulin represses lipolysis and increases de novo lipogenesis,

leading to increases in TAG. This, in turn, enhances overproduction of larger TAG-enriched VLDL particles and the formation of small LDL particles and reductions in HDL-C. These effects are also associated with decreased catabolism of Apo B-containing particles and increased catabolism of Apo A-1-containing HDL-C. Carbohydrate restriction ameliorates these processes. Lower glucose and insulin concentrations also reduce ChREBP and SREBP1c expression, which activate key lipogenic enzymes, thereby reducing hepatic lipogenesis and VLDL production. At the same time, carbohydrate restriction leads to decreases in malonyl-CoA concentration and dis-inhibition of the carnitine acyltransferase, allowing for enhanced mitochondrial shuttle and β -oxidation of fatty acids. Lower glucose (and lower fructose, which may be associated with high-carbohydrate diets) also limits glycerol-3-phosphate production for the re-esterification of free fatty acids.

RBP4

A novel finding was that RBP4 was reduced by the CRD (–20%) but not the LFD (5%). Several lines of evidence point to increased circulating levels of RBP4 in insulin-resistant states [29, 30]. Transgenic overexpression or injection of purified RBP4 results in impairment of insulin-stimulated signaling in muscle, indicating that RBP4 may directly contribute to insulin resistance. In humans, RBP4 is elevated in subjects with obesity and type 2 diabetes and is correlated with components of the MetS [29]. Energy restriction with LFDs resulting in weight loss has been shown to result in decreased serum RBP4 [62, 63], whereas short-term overfeeding apparently has no effect [64].

The Reality of Metabolic Syndrome

Despite the conceptual importance of MetS, several workers have raised the question of whether it is truly clinically useful. Most recently, a study by Sattar et al. [10] and an associated commentary by Kahn [65] concluded that “metabolic syndrome and its components are associated with type 2 diabetes but have weak or no association with vascular risk.” This surely overstates the case in that the vascular complications associated with hyperglycemia are the most deleterious outcomes of diabetes. In this sense, diabetes is a vascular disease. In the end, it is a question of whether identification of MetS would lead to a different treatment than the sum of the treatments of the different markers. The work presented here supports the idea that there is an across-the-board benefit to carbohydrate restriction. That the collection of markers—here emphasizing atherogenic dyslipidemia, response to fat challenge, reduction in RBP4, and the previously reported improvement in inflammatory markers—is improved by a single

type of intervention argues for their being viewed as a syndrome. The close connection between dietary carbohydrate and insulin metabolism provides the underlying biological basis, consistent with the generally agreed-on principle that “insulin resistance plays an important part in risk-factor clustering for the MetS [65].”

From a practical perspective, MetS is a collection of risk factors, and it is to be expected that the expression of each pathology would appear at a different time or in response to different environmental stimuli. It seems reasonable that the best bet will be to treat one marker with the methodology that has the potential to treat all. There is no guarantee that the signs in MetS for an individual patient might not be indications of isolated risk for one disease state, but, until we know how to distinguish these cases, carbohydrate restriction may be the “default” approach.

Limitations

This 12-week diet intervention in a group of 40 subjects could be viewed as short in duration and small in sample size in comparison to larger clinical trials. In contrast to large-scale dietary trials where dietary compliance and attrition are high, this study had a high level of experimental control, which allows direct comparison of the biological effects induced by diets varying in macronutrient composition, as opposed to studying the effects of *prescribing* a diet (as is the case in many diet trials where compliance is poor). Although the sample size of 20 subjects per group might be considered modest, statistical significance was achieved on most variables, again attributable to the high level of standardization and subject compliance. There is also little to suggest that the effects will not persist as long as there is compliance. In addition, longer studies generally support the relative superiority of CRDs [49, 60, 66]. The study of Foster et al. [60] in particular showed that improvements in CVD risk markers are stable beyond the point at which the diets become similar and weight loss differences become small. Finally, we did not perform a direct measure of insulin resistance, nor did we perform a glucose tolerance test to assess their metabolic status in respect to glucose metabolism.

Summary

The results presented here show that a diet restricted in carbohydrate can provide a more comprehensive improvement in the clinical risk factors associated with MetS than a LFD at reduced caloric intake. There are many options for treating obesity or the individual components of MetS, but carbohydrate restriction has the ability to target the range of markers with a single intervention. That this collection of

metabolic markers responds in concert to carbohydrate restriction provides support for considering them as a single syndrome, and treating any of the individual MetS markers with carbohydrate restriction holds the promise of potential benefits to the others. Low-carbohydrate diets therefore represent an alternative strategy for general health beyond weight regulation.

Activation of T-Lymphocytes by LDL-Cholesterol

Borros Arneth

Received: 13 June 2008 / Accepted: 19 November 2008 / Published online: 17 December 2008
© AOCs 2008

Abstract Native LDL-cholesterol can be mechanically stressed by strong vortexing. According to one hypothesis, mechanical shear stress within the vessel can lead to an aggregation of LDL-cholesterol and subsequently to activation of CD4 and CD8 T-lymphocytes. The goal of this study was to determine the proportion of activated CD4 and CD8 T-lymphocytes that is induced by adding unstressed and mechanically stressed LDL-cholesterol to whole blood samples. Whole blood was taken from 12 healthy subjects. All probands fasted for at least 12 h before blood withdrawal. In each case, 1 ml of whole blood from each subject was incubated for 16 h at 32 °C (89.3 °F) with concanavalin A (A), without additive (B), with mechanically stressed LDL-cholesterol (C) or with native LDL-cholesterol (D). Subsequently, the samples were measured by four-color flow cytometry. CD3, CD4, CD8, and CD69 were measured as activity markers. CD69 was plotted against CD4 and CD8, and the proportions of activated CD4 and CD8 T-lymphocytes were determined. Native and vortexed LDL-cholesterol elicited significantly different types of T-cell activation. While native LDL activated CD4 T-cells to only a small extent, mechanically stressed (vortexed) LDL potently activated CD8 T-cells. Purely mechanically-induced changes in LDL-cholesterol may be one mechanism that contributes to the activation of CD8 cells and, as a consequence, the emergence of arteriosclerosis.

Keywords Arteriosclerosis · Activation · CD4 helper T cells · CD8 cytotoxic T cells · Cholesterol

Introduction

According to one theory [1], LDL-cholesterol under mechanical stress leads to a structural change in LDL-lipoprotein vesicles, and as a consequence, CD4 and CD8 T-lymphocytes become activated. The goal of this study was to determine the percentage of CD4 and CD8 T-lymphocytes that is activated after the addition of mechanically treated or untreated (unstressed) LDL-lipoprotein vesicles in human whole blood samples. Such methods may lead to a better understanding of pathophysiological processes in the human body since LDL-particles are also similarly mechanically stressed in systemic circulation. It is well known that patients who have high blood pressure and, in particular, patients who have a combination of high serum concentrations of LDL-cholesterol and high blood pressure, are at increased risk for arteriosclerosis [2, 3]. This association was first described in 1961 as a result of the Framingham study and has been confirmed in numerous subsequent studies [4, 5].

Experimental Procedure

Blood Withdrawal

From each of 12 healthy subjects, 9 ml whole blood was collected in the morning (Sarstedt S-monovettes[®], white 9 ml). Probands gave their informed consent and did not eat for at least 12 h before withdrawal. The study was approved by the relevant review board at the author's institution.

e-mail: arneth@zentrallabor.klinik.uni-mainz.de

Nadroparin (Fraxiparin[®], GSK, Glaxo Smith Kline, 16 IE/ml whole blood) was used as an anticoagulant and was added to the test tubes before blood withdrawal. Preliminary tests have shown that Nadroparin activates far fewer T-lymphocytes than Heparin. The whole blood was carefully mixed and aliquoted into nine tubes, each of which contained 1 ml.

Incubation

Isolated native LDL-cholesterol was mechanically stressed by vortexing for 15 min at maximal strength. Subsequently, the same quantities of mechanically stressed LDL and non-stressed (native) LDL were mixed with 1 ml-samples of fresh non-stressed human whole blood. The nine samples (tubes) per proband were then subjected to the following individual treatments: Tube No.1 (A), Concanavalin A as positive control (1 μ l, 1 μ g/ μ l, final concentration 1 μ g/ml); tube No.2 (B) remained untreated as negative control; tube No.3 (C) maximally vortexed LDL-cholesterol (10 μ l, 3 mg/ml), tube No.4 (D) native LDL-cholesterol (10 μ l, 3 mg/ml), tube No. 5 (E), a hemolyzing concentration of nadroparin (fraxiparin[®] 0.6 ml, 5700 IU anti-Xa), tube No. 6 (F), whole blood sample that was mechanically stressed (maximally vortexed for 15 min), tube No 7 (G), ascorbic acid in a lower concentration (20 μ l, 0.01 mg/ml), tube No 8 (H), ascorbic acid in a higher concentration (20 μ l, 0.05 mg/ml) and tube No 9 (I), a transfection reagent (Stratagene BioTrek protein delivery reagent, 1 cup per experiment).

Subsequently, the tubes were incubated for 16 h at 32 °C (89.6 °F). During this phase, the samples were carefully mixed every 2 h. Then, 50 μ l from each tube was stained with a dye that contained antibodies. Erythrocytes were lysed, and samples were evaluated by flow cytometry and the extent of CD4 and CD8 T-lymphocyte activation was examined.

The following conditions were fixed: Amount of LDL added, incubation time (16 h), incubation temperature (32 °C), and careful slight mixing of the samples every 2 h (Table 1).

LDL Preparation

The preparation of LDL was carried out according to Torzewski et al. [6]. Briefly, LDL particles were isolated from healthy subjects aged 18 to 65 years by preparative ultracentrifugation ($d = 1.019$ to 1.063 g/ml). Cholesterol concentrations refer to the total cholesterol concentration in the lipoprotein samples.

Plasma used for the isolation of LDL was obtained from healthy blood donors (blood bank). None of the donors had diabetes or hypertension, and none was taking any medication. No donors had any signs of ischemic heart disease.

Table 1 Human whole blood samples (1 ml each) from the same patient containing 16 I.U. Fraxiparin per ml whole blood were incubated for 16 h at 37 °C with these additives

Sample	Added
#1 A	Concanavalin A (positive control)
#2 B	Untreated control sample (negative control sample)
#3 C	15 min maximally vortexed LDL-cholesterol (10 μ l, 3 mg/ml)
#4 D	Native LDL-cholesterol (10 μ l, 3 mg/ml)
#5 E	A hemolyzing concentration of fraxiparin (0.6 ml, 5700 I.U. anti-Xa)
#6 F	A mechanically stressed whole-blood sample (maximally vortexed for 15 min)
#7 G	Ascorbic acid (20 μ l 0.01 mg/ml)
#8 H	Ascorbic acid (20 μ l 0.05 mg/ml)
#9 I	Transfection reagent (Biotrek, Stratagene)

Native LDL (nLDL, $d = 1.020$ to 1.062 g/ml) was isolated by a method based on preparative sequential ultracentrifugation using KBr gradients. The first gradient ultracentrifugation was accomplished using the density of the potassium bromide solution, $d = 1.019$ g/ml. Materials that have densities <1.019 g/ml migrate toward the surface, while those that have densities >1.019 g/ml are spun toward the bottom of the centrifuge container. One-third of the centrifuge container was filled at the bottom with a yellow sediment. The supernatant was discarded, and the sediment was further processed.

During the second centrifugation step using a potassium bromide solution of $d = 1.063$, a yellow supernatant was formed, filling approximately one-sixth (1/6) of the centrifuge container. This supernatant ($d < 1.063$ g/ml) represented the LDL fraction. Subsequently, LDL was purified by dialysis against Tris-NaCl buffer (5 mmol/l Tris and 150 mmol/l NaCl, pH 7.4). Cholesterol content, determined by an enzymatic test (Roche), was 300 mg/dl, triglyceride content was 73 mg/dl and protein content, analyzed by the Bradford method (Roth) was 2.1 mg/ml.

Therefore the cholesterol/triglyceride quotient was ~ 4.07 . The concentrations that are given refer to the total cholesterol concentration in the lipoprotein samples.

Mechanical Treatment of LDL

For each proband the LDL portion was first divided into two identical aliquots and placed in two reaction tubes. Then, one tube was vortexed, while the other tube remained untreated. Subsequently the contents of each reaction tube were transferred into the 1 ml whole blood samples, ensuring that the same amounts of cholesterol were added.

Under mechanical stress, the optical appearance of LDL-lipoprotein was changed. Native LDL-lipoprotein is a clear, slightly yellow solution, but its consistency changed when it was vortexed, turning cloudy. After strong vortexing (15 min at maximal strength), a white precipitate flocculated, resulting in a clear increase in turbidity caused by aggregated LDL particles.

Flow-Cytometric Investigation

To assess the phenotype of activated T-lymphocytes, four-color flow cytometry was used. In addition to CD4 and CD8, CD3 and CD69 also were measured.

In our assay, CD8 was labeled with fluorescein isothiocyanate (FITC), CD4 was labeled with allophycocyanin (APC), CD69 with phycoerythrin (PE), and CD3 with peridinin chlorophyll (PerCP). All reagents were purchased from Becton Dickinson Bioscience®. For flow cytometry, the FACS Calibur® Flow Cytometer was used (FACS Calibur, Becton Dickinson, New Jersey, US). First, in the CD3 versus side scatter plot, the T-lymphocytes were gated, and 30,000 lymphocytes were counted for each sample.

Next, the gated T-lymphocytes were measured on two different plots using Cell Quest Pro®-Software (Cell Quest Pro, Becton Dickinson, New Jersey, US): CD69 versus CD4, and CD69 versus CD8.

From these diagrams, the proportion of activated CD4 and CD8 T-cells was calculated using the following formula:

$$\begin{aligned} \% \text{ activated T-cells} &= q_4 \text{ or } q_8 \text{ respectively} \\ &= \text{UR}/(\text{UR} + \text{LR}) \times 100\%, \end{aligned} \quad (1)$$

where UR = number of events in the upper right quadrant and LR = number of events in the lower right quadrant.

To evaluate the effect of the additives, the differences in the proportion of activated CD4 and CD8 lymphocytes of treated samples and untreated samples (control samples) was calculated using the following formulas:

$$\Delta q_4 = (q_4 - q_{40}) \quad (2)$$

and

$$\Delta q_8 = (q_8 - q_{80}), \quad (3)$$

where q = proportion of activated T-cells, and q_{40} and q_{80} = proportion of activated T-cells in the untreated control sample of the same blood withdrawal from the same proband.

For each proband the same quantities of mechanically stressed LDL and unstressed (native) LDL were mixed with 1 ml fresh human whole blood. Afterwards, the amounts of activated CD4 and CD8 T-cells were examined by flow cytometry. Differences in activated T-cells were calculated for each proband.

Microscopy

All whole blood samples also were investigated by microscopy (Olympus CX21®, Olympus, Tokyo, Japan).

Statistical Analysis

For statistical analysis, paired Student t -tests were used (SPSS®, $P < 0.05$). The following experiments led to significant T-cell activations and/or inhibitions: addition of ascorbic acid in groups seven and eight led to significant CD8 activation compared to group two. Haemolysis in group five led to a significant CD8 activation and CD4 inhibition compared to group two. Comparison of groups three (addition of vortexed LDL) and four (addition of native LDL) revealed a significant difference in CD8 T-cell activation, which went from inhibition in the case of native LDL to activation in the case of vortexed LDL (Table 2).

Results

When native LDL was added to the whole blood sample, CD4 T-lymphocytes were clearly activated. In contrast, the addition of mechanically stressed LDL induced the activation of CD8 T-lymphocytes.

The same predominance of CD8 T-lymphocytes was seen after vortexing whole blood samples or after addition of a hemolytic quantity of nadroparin (fraxiparin®). Such a dominance of CD8 T-lymphocyte activation was seen under the following conditions:

Table 2 LDL, triglyceride, HDL and cholesterol values of the probands

- Addition of mechanically stressed LDL–lipoprotein particles, sample no #3
- Mechanically stressed human whole blood, sample no #6
- Hemolytic human whole blood, sample no #5
- Ascorbic acid-treated human whole blood, samples no #7, #8
- Incubation with transfection reagent, sample #9,

The results of the incubation of human whole blood with native LDL-cholesterol (#4) compared to incubation with mechanically stressed LDL-cholesterol (#3) are shown in Figure 1 with respect to the activation of T-lymphocyte subpopulations (CD4, white bars and CD8, black bars). A significant difference emerged between blood that was incubated with native LDL and mechanically stressed LDL. The native LDL sample exhibited a CD4 increase, while the stressed LDL sample exhibited a CD8 increase. This CD8 activation was accompanied by a simultaneous inhibition of CD4+ activation.

Figure 1 additionally shows the results of samples 5 (hemolyzed by fraxiparin), 6 (hemolyzed by mechanical stress, strong vortexing), 7 (lower dose of vitamin C), 8 (higher dose of vitamin C) and 9 (transfection reagent). In all of these cases, an increase in CD8 activation developed.

Fig. 1 Effect of native and mechanically stressed LDL-cholesterol on the activation of T-lymphocytes. On the ordinate, the portion of activated CD8 lymphocytes is given in comparison with the untreated control of the same proband (sample no 2). Increasing CD8 activity is given by the difference $q_8 - q_{80}$. This value (Δq_8) is shown by the black bars. Analogously, for CD4 activity, the $q_4 - q_{40}$ difference is relevant. This value (Δq_4) is represented by the white bars. Sample 1 was incubated with concanavalin A in each case and serves as a positive control. Sample 2 remained untreated in each case and serves as a negative control. Sample 3 was incubated in each case with mechanically stressed LDL-cholesterol, and Sample 4 was incubated with native LDL-cholesterol. Sample 5 was hemolyzed before incubation and Sample 6 was mechanically stressed (vortexed) before incubation. Samples 7 and 8 were treated with vitamin C. Sample 9 was treated with transfection reagent

Fig. 2 Change of the q_8/q_4 quotients. These quotients are given in comparison with the untreated sample. This was performed because the CD8/CD4 quotients are clinically relevant, and because these quotients are frequently measured in patients. An increase of the q_8/q_4 quotient is indicative of an increase of CD8 activation or a reduction of CD4 activation. Accordingly, a reduction of this quotient is an indication of either CD4 increase or decrease of CD8 activation. A decrease of this quotient only appears after the addition of native LDL (sample 4). The remaining experiments, however, are accompanied by an increase of this quotient. Statistical significant difference to #2 ($*p < 0.05$)

Table 3 CD4 and CD8 cell counts of the probands

Proband	CD4%	CD4 count	CD8%	CD8 count	CD4/CD8
#1	45	942	32	670	1.41
#2	42	586	29	404	1.45
#3	40	692	31	536	1.29
#4	37	958	28	725	1.32
#5	31	636	24	492	1.29
#6	34	651	26	498	1.31
#7	38	647	28	477	1.36
#8	43	1264	32	940	1.34
#9	51	697	37	505	1.38
#10	48	1225	35	893	1.37
#11	41	933	32	728	1.28
#12	45	414	33	303	1.37

Increased CD8 activation also resulted after incubation with mechanically stressed LDL, similarly to incubation with a transfection reagent. Figure 2 shows the changes of the q_8/q_4 quotients compared with the untreated sample (q_{80}/q_{40}). This was calculated because the CD8/CD4 quotient is known to be clinically relevant, and because these values are measured frequently in patients (Table 3).

Discussion

In this study, only the influences of mechanically stressed LDL (vortexed LDL) were investigated. Other forms of

modified LDL, such as oxidised or enzymatically modified LDL, were not included.

Our results describe the occurrence of two different reaction mechanisms according to whether native or mechanically treated LDL-cholesterol was added to human whole blood. That CD4 activation developed after the addition of native LDL suggests an MHC II-mediated process. To activate CD4+ cells, antigen-presenting cells (APC) first must take up antigen and express it in the context of MHC II [7]. In our study, macrophages were also activated by both native LDL and by mechanically stressed LDL as seen by microscopy.

In contrast, mechanically stressed LDL appears to activate CD8 T-cells by an MHC I-mediated pathway. These mechanisms are expected to be important for the pathogenesis of arteriosclerosis and related diseases.

Logically, native LDL-cholesterol is recognized as an extracellular antigen and is treated accordingly. Subsequently, a CD4-dominated immunological reaction takes place. In contrast, mechanically stressed LDL-cholesterol leads to a CD8-dominated immunological reaction. Here, the vesicular structure of LDL-cholesterol particles is degraded by mechanical stress. Larger lipid aggregates are then formed that flocculate and generate turbidity [8–10]. On one hand, LDL-aggregation is described to be prevented by both HDL [10] and albumin [8]. On the other hand, aggregated LDL is thought to be taken up by macrophages more easily [9]. Therefore LDL dissolubility seems to be a sensitive equilibrium disturbed by HDL deficiency and/or mechanical stress leading to LDL-aggregation and subsequently to an activation of immune cells (macrophages and T-cells).

CD8-dominated immunological reactions also are observed after 16 h of incubation following the addition of a protein transfection reagent, such as the Peqlab® Bio-Porter® reagent (Peqlab, Erlangen Germany) or the Stratagene® Biotreck® protein transfection reagent (Stratagene, USA), to human whole blood samples. According to the manufacturers' data, these transfection reagents are lipid mixtures that transport proteins into human cells. It also is possible that mechanically stressed LDL particles function as de facto transfection reagents and develop the ability to transport serum proteins into human cells.

Within nearly all human cells, intracellular proteins (or as here mostly albumin, after transfection through stressed LDL) are digested by the proteasome and presented via MHC I receptors [7]. The newly formed MHC I-antigen complex is targeted to the cell surface, where it leads to an MHC I:CD8 T-cell interaction and subsequent activation of CD8 T-lymphocytes. The proposed reaction pathways described here may provide an explanation for our results. These pathways may be important in establishing a better understanding of pathophysiologically relevant processes,

caused by LDL that is exposed to mechanical stress as a result of systemic circulation.

From clinical studies, it is well known that patients who have high blood pressure, high serum cholesterol concentrations, and especially those who suffer from both conditions, are at increased risk for arteriosclerosis. Here, we proposed and investigated a pathway whereby mechanically induced structural changes in LDL-cholesterol particles effects a subsequent immunological reaction and inflammation that is caused by the transfection of endothelial cells. This model appears to be a plausible and possible mechanism.

Likewise, a CD8-dominated immunologic reaction also results when a blood sample incurs strong mechanical damage, such as that observed when whole blood samples were subjected to hemolytic damage by strong vortexing. To this end, blood samples incurred robust cellular damage in our experiments as a result of hemolytic activity.

Cellular damage is primarily characterized by a defect in the cell membrane. Due to the defective cellular membrane, the export and release of intracellular substances and proteins into the extracellular space, as well as the crossing of extracellular substances (such as albumin) into the cell are affected. In the latter case, the extracellular components then are recognized as foreign and lead to a CD8-dominated reaction. This reaction overshadows the activation of CD4 T-cells by macrophages, which is driven by the release of intracellular components as a result of pronounced damage. This predominance also may be favored due to the fact that phagocytic cells actively clear cellular remnants, curtailing the expected CD4 reaction after pronounced damage.

When high doses of vitamin C (ascorbic acid) are administered, a patient activation of CD8 T-cells was observed. It is unknown whether this activation results from a direct influence on the T-cells or from an indirect phenomenon. Thus, ascorbic acid can enter into the cell (ascorbic acid is able to cross the membrane [11, 12]) and form antigenic epitopes inside the cells by redox reactions (ascorbic acid reacts with peptides/proteins [13, 14]).

Taken together, our results suggest a molecular explanation for the pathogenesis of arteriosclerosis in patients who have high serum cholesterol and high blood pressure. Lastly, the benefit of high doses of vitamin C remains questionable.

The result of addition of vitamin C to whole blood was unexpected. We predicted a predominance of CD4 activation, however strong CD8 activation occurred.

Generally, ascorbic acid is regarded as beneficial, and vitamin C often is regarded as being protective against arteriosclerosis. Frequently, very high doses of vitamin C are recommended for this purpose. Furthermore, vitamin C may provide some protection from oxidation of

LDL-cholesterol. Additional studies will be needed to investigate this possibility.

Here, a possible protective effect of vitamin C as a result of direct activation of T-lymphocytes was examined. Vitamin C was incubated with whole blood using physiological concentrations that develop after intake of recommended amounts of vitamin C. Activation of very few T-lymphocytes would be expected, but in fact, a pronounced activation of CD8 T-lymphocytes was detected. The question then arises as to which mechanism causes this activation of CD8 T-cells by vitamin C. Although stimulation of immune cells by vitamin C might be viewed as a beneficial effect, it is noteworthy that this also can be part of an uncontrolled excessive immune reaction. In our study, however, only the influences of pure mechanical stress on LDL-cholesterol and on whole blood samples were examined. The effect of oxidative stress was not examined in this model. Therefore, a protective effect of vitamin C regarding oxidation cannot be supported nor excluded.

Abstract Atherosclerosis is a disease whose pathogenesis involves inflammatory and immunological mechanisms, including an autoimmune reaction against heat shock proteins (Hsps). The purpose of this study was to analyze whether the antiatherogenic effect of statin therapy was not limited to its lipid lowering effect, but also included anti-inflammatory and immunomodulatory effects, paying special attention to the measurement of circulating concentrations of anti-Hsp70 and anti-Hsp60 antibodies previously related to vascular disease. Two-hundred and seventy-five subjects aged 40–60 years, randomly selected in an epidemiological study on the incidence of vascular risk factors, were studied. Laboratory tests included a complete lipid profile after a 12-h fast and measurements of glucose, C-reactive-protein, anti-Hsp70 and anti-Hsp60 antibodies. Subjects with hypercholesterolemia had significantly higher concentrations of anti-Hsp70 antibodies as compared to subjects with normal cholesterol concentrations. Statin therapy was associated with 11.63 and 15.3% reductions in total and LDL-cholesterol ($P = 0.005$ and

0.017, respectively) as compared to untreated subjects, and with lower concentrations of circulating anti-Hsp70 ($P = 0.016$) antibodies. No differences were found in C-reactive-protein values. Since statin therapy not only reduces lipid profile, but also anti-Hsp70 and anti-Hsp60 antibody concentrations, without changing C-reactive-protein values, it is suggested that such an effect could not be accounted for by the anti-inflammatory properties of statins, but by their direct immunomodulatory properties through their effects on lymphocyte function.

Introduction

Cardiovascular disease is the leading cause of death in most western countries [1]. Experimental and epidemiological studies and genetic forms of hypercholesterolemia have shown the association between serum cholesterol, and particularly LDL cholesterol, and atherosclerosis [2]. Hypercholesterolemia causes focal endothelial activation in large and middle-sized arteries. LDL infiltration and retention in the arterial intima starts an inflammatory response in the arterial wall [3]. LDL cholesterol reduction using lipid lowering drugs is associated to significant decreases in cardiovascular morbidity and mortality both in primary and secondary prevention [4], and therefore represents the first pharmacological target for the adult treatment panel III (ATP III) [2]. The advent of statins at the end of the 1980s and the beginning of the 1990s revolutionized treatment of hypercholesterolemia, since they were safe drugs that were administered once daily and

decreased LDL cholesterol levels by 25–35% [5]. Statins also decreased endothelial dysfunction, had direct anti-inflammatory effects, reducing content of inflammatory cells and their production of proinflammatory cytokines in the atherosclerotic plaque [6], and even exerted immunomodulatory effects, interfering with lymphocyte T function [7].

Both adaptive and innate immunity are also involved in the etiopathogenesis of atherogenesis [8]. Specific antigens starting immune response in atherosclerosis include oxidized LDL [9], heat shock proteins (Hsps) [10], and β 2-glycoprotein I [11].

Hsps have been involved in the pathogenesis of various diseases, and their role in atherosclerosis is among the most widely studied. Special attention has been paid to Hsp60 and Hsp70 [10]. Various studies have shown Hsp60 to be selectively located in atherosclerotic lesions rather than non-atherosclerotic areas of the arterial wall [12]. In advanced atherosclerotic lesions, Hsp70 are overexpressed in different cell types such as monocytes, macrophages, dendritic cells, and smooth muscle cells. Hsps have also been identified in soluble form in serum together with anti-Hsps antibodies, and various studies have shown a correlation between levels of these antibodies and severity of atherosclerosis. Anti-Hsp70 antibody concentrations are elevated in patients with established hypertension as compared to the normotensive control group [13] in patients with abdominal aortic aneurysm or peripheral vascular disease [14]. High titers of anti-Hsp60 antibodies have been found in patients with carotid atherosclerosis, coronary disease, or stroke [15].

The aim of this study was to explore whether statins not only achieved lower total and LDL cholesterol values in treated subjects as compared to an untreated population, but could also have anti-inflammatory and immunomodulatory effects in addition to their antiatherogenic effect, by measuring the circulating concentrations of anti-Hsp70 and anti-Hsp60 antibodies previously related to vascular disease.

Methods

Study Population and Design

This was an observational, cross-sectional, epidemiological study on the incidence of vascular risk factors. Inclusion criteria: randomly selected voluntary subjects of both sexes aged 40–60 years, employees (either active or not) of the Hospital General Universitario Gregorio Marañón in January 2004, who signed the informed consent. The study was approved by the Research Committee and the Clinical Research Ethics Committee of the center. All participants provided a clinical history and answered an epidemiological

survey including age, personal and family medical history, smoking (number of cigarettes per year and smoking duration; if former smokers, number of years elapsed since smoking cessation), alcohol intake (if yes, grams of alcohol daily), treatments, and occurrence or presence of disease of atherosclerotic etiology. Blood pressure (BP) was measured, and blood was taken for the appropriate laboratory measurements. Exclusion criteria included pregnancy or breast-feeding, any systemic infection in the past 3 months, current oncological disease or radiotherapy/chemotherapy, autoimmune disease (rheumatoid arthritis, systemic lupus erythematosus, sarcoidosis), endocrine disorders (except for diabetes), liver disease, renal failure, glomerulonephritis, congenital heart disorder, oncohematological disease, or allergic disorders.

Laboratory Tests

Venous blood was drawn after a 12-h fast and centrifuged, and serum samples were frozen at -70°C for subsequent testing. In order to assess causal and conditional vascular risk factors [4], total cholesterol, HDL cholesterol, LDL cholesterol, triglycerides, and glucose were quantified in a Hitachi Modular Analytic SVA autoanalyzer, Roche Diagnostics S.L., Barcelona, Spain. C-reactive protein (CRP) was quantified using a commercial ELISA (CRP-MTPL-EIA, DRG Instruments GMBH, Marburg, Germany) according to the manufacturer's instructions. Final absorbances were measured at 450 nm (Bio-Rad 3550 Microplate Reader, Bio-Rad Laboratories, Hercules, CA, USA). Values under $5\ \mu\text{g/mL}$ were considered normal. CRP concentrations in the samples were calculated by interpolation in the standard curve obtained (range $1.62\text{--}25\ \mu\text{g/mL}$). Homocysteine has been quantified by high performance liquid chromatography (HPLC); the established reference values (P_{95}) were $13\ \mu\text{mol/L}$ for men and $11\ \mu\text{mol/L}$ for women.

Definition of Vascular Risk Factors [2, 16]

Obesity

Obesity was defined as a body mass index (BMI kg/m^2) >30 , and overweight when the BMI was >25 .

Blood Pressure

The blood pressure (BP) of all participants was measured with an automated BP recording device after an individual had been sitting quietly for 5 min. Hypertension has been defined as a systolic blood pressure $\geq 140\ \text{mmHg}$ and/or a diastolic $\geq 90\ \text{mmHg}$ in at least two measurements taken separately.

Blood Lipids

Hypercholesterolemia was defined as a fasting total cholesterol level of ≥ 200 mg/dL, or LDL-cholesterol ≥ 130 mg/dL. By hypertriglyceridemia we understand a condition in which a fasting total triglyceride level is ≥ 150 mg/dL.

Blood Glucose

Diabetes has been defined as a fasting glycemia level ≥ 120 mg/dL, or post-prandial glucose of 130–160 mg/dL.

Measurement of Circulating Anti-Hsp70 and Anti-Hsp60 Antibodies

Titers of anti-Hsp70 and anti-Hsp60 antibodies in serum (diluted 1:1,000) were measured using two commercial

enzymimmunoassays [EKS-750, Anti-Human Hsp70 (IgG/IgM/IgA) ELISA Kit and EKS-650, Anti-Human Hsp60 (total) ELISA Kit, Stressgen Biotechnologies Corporation, Victoria, Canada] in a microplate coated with recombinant human Hsp70 or Hsp60, capturing anti-Hsp70 and anti-Hsp60 antibodies present in serum. The resulting absorbance was measured at 450 nm (Bio-Rad 3550 Microplate Reader, Bio-Rad Laboratories, Hercules, CA, USA). Anti-Hsp antibody concentrations in the samples, expressed as $\mu\text{g/mL}$, were obtained by interpolating in the standard curve the absorbances obtained in the samples.

Statistical Analysis

Results were analyzed using their means, medians, standard deviations, standard error of the mean (SEM), and ranges for quantitative variables, and using absolute frequencies and percentages for qualitative variables with a

95% confidence interval. Variable means were compared using non-parametric tests. A Mann–Whitney's *U* test for two independent samples, a one-way ANOVA test with Bonferroni correction for three independent samples, or a Kruskal–Wallis test was used for quantitative variables. Qualitative variables were analyzed using a Spearman's correlation test. The statistical significance level selected was $P < 0.05$. SPSS 12.0 software for Windows was used for statistical analysis.

Results

A total of 275 subjects were included in the study, 134 females (age 48.95 ± 0.57 years) and 141 males (48.35 ± 0.62). Of these, 159 participants (57.8%) [82 females (51.57%) and 77 males (48.42%)] had total cholesterol levels higher than 200 mg/dL or LDL cholesterol levels higher than 130 mg/dL.

Hypercholesterolemic individuals had significantly higher titers of circulating anti-Hsp70 antibodies (451.32 ± 21.5 $\mu\text{g/mL}$) as compared to subjects with

normal cholesterol levels (392.53 ± 23.13 $\mu\text{g/mL}$) ($P < 0.05$, Mann–Whitney's test), with no differences between both groups in the incidence of other population (age, sex, and social level) or vascular risk factors (glucose, hypertension, triglyceridemia, homocysteinemia and CRP, smoking, alcohol intake and its extent). Both effects, hypercholesterolemia and titers of anti-Hsp70i antibodies, therefore appear to be directly related and not influenced by other potential factors acting on such antibodies (Table 1).

Thirty-four subjects (11 females and 23 males) were being treated with simvastatin 10 mg/day at the time of the study. This treatment was associated to a significant 11.63% lower total cholesterol levels ($P = 0.013$, Mann–Whitney's test) and a 11.07% LDL cholesterol levels as compared to subjects with no statin therapy ($P = 0.011$, Mann–Whitney's test). Patients treated with simvastatin also showed higher glucose, triglyceride, BP, and CRP values (Table 2), probably due to the presence of additional vascular risk factors [4]. In this latter case, when population was segmented based on the degree of vascular risk according to the Task Force [16] or considering the cases of established atherosclerosis, statin therapy caused no

significant changes in CRP concentrations (Table 3). However a significant trend to a lowering in the concentration of anti-Hsp70i antibodies in individuals with VRF or established atherosclerosis has been proven ($P = 0.024$, Kruskal–Wallis test). Patients with atherosclerosis show the lowest levels of circulating anti-Hsp70i antibodies [($P = 0.008$, Mann–Whitney test). Hsp70i is the inducible form of the HSP70 family and is also known as Hsp72, based on its molecular weight [17]. Therapy with statins reduces anti-Hsp70i antibodies concentrations significantly in patients with VRF and atherosclerosis in comparison to an identical group of patients without such therapy ($P = 0.043$, one-way ANOVA) (Table 4).

Treatment with simvastatin was very significantly associated with lower concentrations of circulating anti-Hsp70 antibodies ($P = 0.016$, Mann–Whitney's test). In order to rule out the potential effect of other population and vascular risk factors on the decrease in concentrations of circulating anti-Hsp70 antibodies seen in the statin-treated group, the potential association between such factors and anti-Hsp antibodies was tested in the study population.

Table 4 Differences in Anti-Hsp70 antibodies concentration (µg/mL) between subjects with or without statin therapy according to the degree of vascular risk (Task Force [16])

VRF vascular risk factors

* P refers to anti-HSP70i Abs level and their relevance in vascular disease (Kruskal–Wallis test)

** P refers to the effects of the treatment on Anti-Hsp70i Abs concentration in the different groups analyzed by the Anova-one-way test

Circulating concentrations of anti-Hsp70i antibodies in the overall population were not associated with factors such as age, sex, blood glucose, triglycerides, BP, homocysteinemia, or CRP (Table 5).

Discussion

Monocytes–macrophages and T lymphocytes are involved in atherosclerosis, a chronic inflammatory disease. Hsps are immunomodulatory molecules that act as potent autoantigens. Hsps recognition by T lymphocytes would trigger an autoimmune response potentially involved in the inflammatory etiopathogenesis of atherosclerosis [18]. The finding of a significant increase in anti-Hsp70 antibody concentrations in hypercholesterolemic patients as compared to normocholesterolemic subjects in age- and sex-matched populations, in the absence of a hypothetical etiopathogenetic role of other associated vascular risk factors, agrees with reports by other authors [19]. This could be explained by an enhanced immunoactivation status associated to atherosclerosis in this group. High cholesterol levels not only activate or damage endothelium per se but may modulate the function of T and B cells. Cholesterol has been shown to increase the antigen presentation function of monocytes, and oxidized LDL may activate dendritic cells and promote in vitro the proliferation of T lymphocytes mediated by dendritic cells [20].

Both the recommendations by the National Cholesterol Education Program [2] and those derived from the Second Joint Task Force of European societies [16] emphasize the need for controlling individual risk of coronary disease. Dyslipidemia is clearly a major risk factor for coronary disease, though it is often modulated by the presence of other additional risk factors. Both recommendations state that reduction of LDL cholesterol levels represents a recognized target, essential for reducing coronary risk. Drugs affecting lipoprotein metabolism include HMG-CoA reductase inhibitors (statins), fibrates, bile acid sequestrants (resins), and nicotinic acid and its derivatives. They have all been shown to decrease coronary disease progression in

angiographic studies. However, both the most convincing angiographic evidence and the best evaluation criteria in clinical trials have been obtained using statins [21]. These drugs are also the safest to date and the easiest to use. Thus, statins currently are the first-choice lipid lowering drugs [22].

The antiatherogenic effect of statins is not limited to their effects on the reduction of circulating total and LDL cholesterol levels. This study has shown that patients treated with simvastatin not only had significantly lower total and LDL cholesterol levels, but also showed significant lower anti-Hsp70 antibody concentrations and

relevant but not statistically significant lower anti-Hsp60 concentrations which agrees with reports from similar studies [23]. Since anti-Hsp antibodies are positively related to the risk of vascular disease and involved in the etiopathogenesis of atherosclerosis, their reduction may decrease the chronic inflammation characteristic of atherosclerosis and contribute to stabilization of the atherosclerotic plaque. The mechanism by which statin therapy is associated to a decrease in circulating anti-Hsp antibodies could be the pleiotropic effects of these drugs, including immunomodulation, that are independent from the decrease in cholesterol levels, as also shown in this study. Statins have also been shown to be able to inhibit binding of the lymphocyte function-associated antigen-1 (LFA-1) to the intercellular adhesion molecule-1 (ICAM-1), thereby preventing leukocyte adhesion and extravasation at inflammation sites, as well as antigen presentation, and lymphocyte T costimulation [24]. This would explain the significant lower circulating anti-Hsp70 antibodies detected in the group of treated subjects.

The immunosuppressant effect of statins is not only independent of their lipid lowering effect, but also of their documented anti-inflammatory properties, resulting from a decreased activation of the nuclear factor kappa B (NF- κ B) that induces expression of multiple proinflammatory molecules [25]. Since statin therapy reduced not only the lipid profile, but also circulating concentrations of anti-Hsp70 and anti-Hsp60 antibodies without changing—even in patients with established atherosclerotic disease—CRP concentrations, a systemic inflammation marker attributed by some authors to an active role not only in the onset of atherosclerosis, but also as a biomarker of its course and prognosis [26], it is suggested that such an effect cannot be completely explained by its anti-inflammatory effects, but by its direct immunomodulatory properties.

Acknowledgments The authors thank Mrs. Maria Jesús Sánchez for her invaluable help in sample processing. The study was supported by the FIS grant 13/0318 and Fundación Mutua Madrileña.

Fatty Acid Biomarkers of Symbionts and Unusual Inhibition of Tetracosapolyenoic Acid Biosynthesis in Corals (Octocorallia)

Abstract Seven zooxanthellae-free species of octocorals (the genera *Acanthogorgia*, *Acabaria*, *Chironephthya*, *Echinogorgia*, *Menella*, *Ellisella*, and *Bebryce*) and two zooxanthellate octocorals (the genera *Paralemnalia* and *Rumphella*) were examined to elucidate their fatty acid (FA) composition. Arachidonic (about 40% of the total FA) and palmitic acids were predominant in all the species studied. Seven furan FA (F-acids) (up to 9.7%) were identified in the azooxanthellate octocorals. The main F-acids were 14,17-epoxy-15-methyldocosa-14,16-dienoic and 14,17-epoxy-15,16-dimethyldocosa-14,16-dienoic acids. In all specimens of *Bebryce studeri*, C_{25–28} demospongiac FA (about 20%) were identified. These FA reflect the presence of a symbiotic sponge in *B. studeri* and can be used as the specific markers for other corals. A significant difference ($P < 0.01$) between azooxanthellate and zooxanthellate corals was found for odd-chain and methyl-branched saturated FA, 18:1n-7, and 7-Me-16:1n-10; that indicated the presence of an advanced bacterial community in azooxanthellate corals. The zooxanthellate species were distinguished by significant amounts of 18:3n-6, 18:4n-3, and 16:2n-7 acids, which are proposed as the markers of zooxanthellae in soft corals. Contrary to the normal level of 24:5n-6 (9.4%) and 22:4n-6 (0.6%), unexpected low concentrations of 24:5n-6 (0.4%) accompanied by a high content of 22:4n-6 (up to 11.9%) were detected in some specimens. The presence of an

unknown factor in octocorals, specific for n-6 PUFA, which inhibited elongation of 22:4n-6 to 24:4n-6, is conjectured.

VLC	Very-long-chain

Introduction

Corals are polytrophic organisms, i.e. they simultaneously derive nutrients from various food sources, including the uptake of different classes of plankton and organic detritus [1–3]. In zooxanthellate coral species (zooxanthellae are endosymbiotic dinoflagellates of the *Symbiodinium* group), the phototrophic supply is delivered by symbiotic dinoflagellates living within gastrodermal host cells [4]. Filamentous algae colonize the skeletons in a variety of zooxanthellate and azooxanthellate scleractinian species [5]. A lot of bacteria associate with corals [6, 7]. All the food sources and the members of a whole coral colony mentioned above have different FA profiles and make their significant contributions to the total FA composition of corals. So, FA can serve as markers for a type of symbiotic

zooxanthellae [8]. The active transport of saturated and several unsaturated FA from zooxanthellae to the host is documented [9–13]. FA are most probably indicative of external food sources such as zoo- and phytoplankton [14]. The FA composition of corals is useful for the chemotaxonomic studies of reef-building and soft corals; and a clear division of coral specimens according to their family (sometimes, to their genus) has been consequently attained [15, 16].

A majority of investigations on the FA composition of corals have been performed on reef-building species. In general, octocorals exist in similar habitats as scleractinian corals but are able to tolerate a slightly wider range of conditions. For example, gorgonians survive in conditions where the temperature is between 19 °C and 36 °C (with a few exceptions). Studies of FA in soft corals have not so far been systematic, and data on the FA contents of total lipids of the corals, especially of gorgonian corals, are limited [17–24]. Only a few works describe the FA of symbiotic dinoflagellates of the reef-building corals [8, 11, 13, 25]. Data on the FA composition of zooxanthellae from soft corals have not been available until now. Nevertheless, it has been recently shown that the absence of an important lipid source, such as symbiotic dinoflagellates, leads to a significant difference in FA compositions between azooxanthellate and zooxanthellate soft corals [24].

Lipids of soft corals contain a large portion of unusual very-long-chain tetracosapolyenoic FA. Both 24:6n-3 and 24:5n-6 have been detected in the lipids of different octocorals [19, 20, 26]. It is noteworthy that the *Hexacorallia* species have no 24:6n-3 and 24:5n-6 acids; that is their main chemotaxonomic distinction from the *Octocorallia* species [19]. An investigation has recently been carried out on mammalian tissues and concluded that the tetracosahexaenoic FA are intermediates in the biosynthesis of C₂₂ Δ⁴ polyunsaturated fatty acids (PUFA) [27, 28]. Therefore, it is very likely that the *Octocorallia* species utilize a similar biosynthetic route, thus providing yet another interesting system for studying this type of biogenesis [29].

In our study, the FA composition of total lipids of nine octocoral species were examined to determine: (1) significant differences in the FA composition between zooxanthellate and azooxanthellate species; (2) the marker FA of organisms associated with corals; and (3) the distribution of tetracosapolyenoic FA and their biosynthetic intermediates.

Experimental Procedures

Nine soft coral species (Table 1) were collected by SCUBA in the South China Sea (Vietnam) in the Nha Trang Bay at depths of 2–4 m in November–December

2005, and one sample of *Bebryce studeri* was taken near Den Island (12°35'N, 109°18'E) at a 9-m depth in January 2005. The species identification was carried out under a light microscope (×200–400 magnification) using the arrangement of sclerites. The colonies were carefully cleaned of all noncoral debris. The samples collected were placed immediately into tanks under water at the collection site and transported to the laboratory within 0.5 h. Up to four different colonies of one species were used for a FA analysis.

The coral samples were crushed into 1–3 mm pieces, and total lipids were extracted by intensive homogenization in a chloroform/methanol (1:2, by vol.) mixture (30 ml for 10 g of coral weight). The homogenate obtained was filtered, and the residue was repeatedly extracted (6 h, 4 °C) in a chloroform/methanol (2:1, by vol.) mixture (2 × 30 ml). The extracts were then mixed and separated into layers by adding 35 ml of water and 30 ml of chloroform. The lower layer was evaporated, and the total lipids obtained were redissolved in chloroform and stored at –18 °C.

Fatty acid methyl esters (FAME) were obtained by a sequential treatment of the total lipids with 1% sodium methylate/methanol and 5% HCl/methanol according to Carreau and Dubacq [30] and purified by preparative silica gel thin-layer chromatography (TLC), using the precoated silica gel plates Sorbfil PTLC-AF-V (Sorbfil, Krasnodar, Russia) developed in benzene. *N*-acylpyrrolidide derivatives of FA were prepared according to Andersson [31] by direct treatment of the FAME with pyrrolidine/acetic acid (10:1, by vol.) in a capped vial (1 h, 100 °C) followed by ethereal extraction from the acidified solution and purification by preparative TLC developed in ethyl acetate.

A gas chromatography (GC) analysis of FAME was carried out on a Shimadzu GC-17A chromatograph (Shimadzu, Kyoto, Japan) with a flame ionization detector. A Supelco MDN-5S (Bellefonte, PA) capillary column (bonded and crosslinked (5% phenyl) methylpolysiloxane; 30 m × 0.25 mm i.d.) was used at 160 °C with a 2 °C/min ramp to 270 °C held for 30 min. The injector and detector temperatures were 270 °C. Helium was used as the carrier gas at a linear velocity of 30 cm/s (split ratio was 1:30). FAME were identified by a comparison with authentic standards (a mixture of PUFA methyl esters No. 3 from Menhaden oil was purchased from Supelco, Bellefonte, PA) and with the use of a table of equivalent chain-lengths (ECL) [32]. The structures of FA were confirmed by gas chromatography–mass spectrometry (GC–MS) of their methyl esters and *N*-acylpyrrolidide derivatives. GC–MS of FAME was performed with a Shimadzu GCMS-QP5050A instrument (Shimadzu, Kyoto, Japan). Ionization of samples was undertaken by electron impact at 70 eV. Helium was used as the carrier gas at a linear velocity of 30 cm/s (split ratio was 1:10). The Supelco MDN-5S was

* Indicate significant differences of FA contents between zooxanthellate and azooxanthellate species (*t* test $P < 0.05$)

^a Zooxanthellate species

used at 160 °C with a 2 °C/min ramp to 270 °C held for 20 min. The injector and detector temperatures being 270 °C and 240 °C, respectively. GC–MS of *N*-acylpyrrolidides was performed on the same instrument, the injector and detector temperatures being 300 °C and 270 °C, respectively, the column temperature was 210 °C with a 3 °C/min ramp to 300 °C that was held for 40 min.

To compare the differences between zooxanthellate and azooxanthellate species, Student's *t* test was performed using MS Excel 2002. Differences were considered statistically significant at $P < 0.05$.

Results

Tables 1 and 2 show the distribution of fatty acids (FA) in the total lipids of 22 soft coral specimens belonging to nine genera (*Acanthogorgia*, *Acabaria*, *Rumphella*, *Chironephthya*, *Echinogorgia*, *Menella*, *Paralemnalia*, *Ellisella*, and *Bebryce*). *Rumphella aggregata* and *Paralemnalia thyrsoides* contained zooxanthellae (endosymbiotic dinoflagellates), other genera were azooxanthellate [33]. Arachidonic (20:4n-6) and palmitic (16:0) acids were predominant in all species. Apart from *R. aggregata*, the content of 20:4n-6 amounted about 40% of total FA. Other principal FA were 14:0, 16:1n-7, 7-Me-16:1n-10, 18:0, 18:1, 20:5n-3, 22:5n-6, 22:6n-3, 24:5n-6, and 24:6n-3. For azooxanthellate species, the content of some ordinary even-chain acids, such as 18:2n-6, 18:4n-3, 20:1n-9, and 20:3n-6, did not exceed a value of 2%, but saturated odd-chain and methyl-branched FA were detected in a quite appreciable amount (up to 5.2% in the total). The average ratio between oleic and *cis*-vaccenic acids, 18:1n-9/18:1n-7 was 17.9 and

1.5 for zooxanthellate and azooxanthellate species, respectively. FA of (n-6) series were the predominant PUFA in the octocorals investigated, the (n-6)/(n-3) ratio ranged from 2.7 to 17.1 with the average value of 7.0. We did not detect a significant difference between zooxanthellate and azooxanthellate coral species in the (n-6)/(n-3) ratio.

Seven furan FA (F-acids) were detected in the most coral species investigated (Tables 1, 2, 3). Five of these F-acids were characterized by a furan ring, which carries in one α -position an unbranched FA chain with 9, 11 or 13 carbon atoms and in the other α -position a pentyl residue (Table 3). Either of the two β -positions of the furan ring were substituted by a methyl residue or, otherwise, only the β -position adjacent to the long aliphatic chain had a methyl group. The other two F-acids contained a furan ring with an unbranched FA chain with 11 or 13 carbon atoms in one α -position and a propyl group in the other α -position (Table 3). In this case, both β -positions of the furan ring were substituted by methyl group. Among all F-acids, the highest concentrations were registered for 14,17-epoxy-15-methyldocosa-14,16-dienoic acid (Me-F22) and 14,17-epoxy-15,16-dimethyldocosa-14,16-dienoic acid (diMe-F22) in *Menella praelonga* (2.0% of total FA) and *Chironephthya variabilis* (5.1%), respectively (Table 1).

The mass spectrum of Me-F22 acid methyl ester gave molecular ion peaks (M^+) at m/z 378 (Fig. 1). Allylic cleavage of alkyl carboxylic chain at the furan ring produced the base peak at m/z 165, whereas allylic cleavage of the alkyl chain yielded a fragment ion at m/z 321. The ring itself gave rise to a fragment ion at m/z 109 characteristic of trisubstituted furan acids [34–36]. The mass spectrum of diMe-F22 acid methyl ester is shown in Fig. 1.

Analogously to Me-F22 acid methyl ester, the base peak at m/z 179 was produced by cleavage of the alkyl carboxylic chain, and a fragment ion at m/z 335 was yielded by cleavage of the butyl group. The tetrasubstituted furan ring itself gave rise to a fragment ion at m/z 123. The same fragmentation scheme was observed in mass spectra of other F-acid methyl esters (Table 3).

A number of very-long-chain saturated, mono-, and dioenoic FA (24:0, 24:1, 26:1, and 26:2) and demospongiac acids, such as 25:2(5,9), 26:2(5,9), 26:3(5,9,19), and 28:3(5,9,19), were identified in all specimens of *B. studeri* (Table 2).

The mass spectra of methyl esters of 24:0, 24:1, 26:1, and 26:2 gave molecular ion peaks (M^+) at m/z 382, m/z 380, m/z 408, and m/z 406, respectively, confirming the presence of a C_{24} or C_{26} chain and the corresponding number of double bonds in the original FA. Additionally, strong peaks at m/z 348 and m/z 376 ($[M-MeOH]^+$, characteristic of monoenoic FAME) were observed in mass spectra of 24:1 and 26:1. The mass spectra of the *N*-acylpyrrolidide derivatives of 24:1(n-9) and 24:1(n-7) gave molecular ion peaks at m/z 419 (M^+) and diagnostic fragments with the gap of 12 amu at m/z 280, 292 and m/z 308, 320, respectively [31].

The mass spectra of methyl esters of 25:2(5,9), 26:2(5,9), 26:3(5,9,19), and 28:3(5,9,19) acids gave molecular ion peaks (M^+) at m/z 392, m/z 406, m/z 404, and m/z 432, respectively. A combination of abundant ions at m/z 81, 109, and 141, which was observed in the mass spectra of these demospongiac acid methyl esters, indicated the presence of a 5,9-dienoic fragment in the fatty chain. The mass spectra of the *N*-acylpyrrolidide derivative of 25:2(5,9), 26:2(5,9), 26:3(5,9,19), and 28:3(5,9,19) acids gave molecular ion peaks (M^+) at m/z 431, m/z 445, m/z 443, and m/z 471, respectively. In these mass spectra, the gap of 12 amu between m/z 140 and 152, as well between m/z 194 and 206 confirmed the presence of double bonds in positions 5 and 9. The gap of 12 amu between m/z 332 and 344 was found in the mass spectra of the *N*-acylpyrrolidide derivative of trienoic demospongiac acids, indicating that double bond was localized at the 19th carbon atom of the original FA. Also, the spectra from 5,9-unsaturated FA

N-acylpyrrolidide derivatives exhibited an intensive peak at m/z 180 which was higher than a peak at m/z 126 [37].

One rather unusual 7-methyl-6-hexadecenoic acid was identified in all coral specimens with a relative abundance ranging from 0.2 to 6.7%. This acid was characterized by GC–MS as previously described [38]; an abundant ion at m/z 138 in the mass spectra of methyl ester is very characteristic for these compounds.

For each of the 56 C₁₄–C₂₄ FA from Tables 1 and 2, the average contents in four zooxanthellate specimens were compared to those in 18 azooxanthellate coral specimens. The statistically significant difference ($P < 0.05$) between the azooxanthellate and the zooxanthellate corals was indicated only for 14 FA, namely ai-15:0, ai-16:0, 17:0, i-17:0, ai-17:0, br-18:0, 18:1n-7, 18:2n-9, 19:0, ai-19:0, 20:1n-7, Me-F20, diMe-F20, and Me-F22. A comparison of the average contents of each FA between zooxanthellate *P. thyrsoides* and all azooxanthellate species indicated a statistically significant difference ($P < 0.01$) for 7-Me-16:1n-10, 18:3n-6, and 18:4n-3 (Fig. 2). Compared to all azooxanthellate species, the level of 7-Me-16:1n-10 in the zooxanthellate species *R. aggregata* did not differ significantly but, similar to *P. thyrsoides*, the average contents of 16:0, 18:3n-6, and 18:4n-3 were significantly higher (Fig. 2). Two (n-7) series FA, 16:2n-7 and 18:2n-7, were found in *R. aggregata* only, and contributed on the average 2.2 and 2.3% of total acids, respectively (Table 1).

The most gorgonians studied showed the presence of a high level of tetracosapolyenoic acid 24:5n-6 ($9.4 \pm 3.5\%$, in average \pm SD). However, an unexpected low concentration of 24:5n-6 (0.2–0.6% of total FA) was detected in the single specimens of *Acanthogorgia isoxia*, *M. praelonga*, and *Ellisella plexauroides* (Table 1). In all the cases, an extremely low amount of 24:5n-6 was accompanied by a substantial rise in the content of 22:4n-6 up to $11.9 \pm 1.9\%$ (in average \pm SD) from the value of $0.6 \pm 0.4\%$ calculated for the specimens with normal high level of 24:5n-6. At the same time, abrupt variations in the

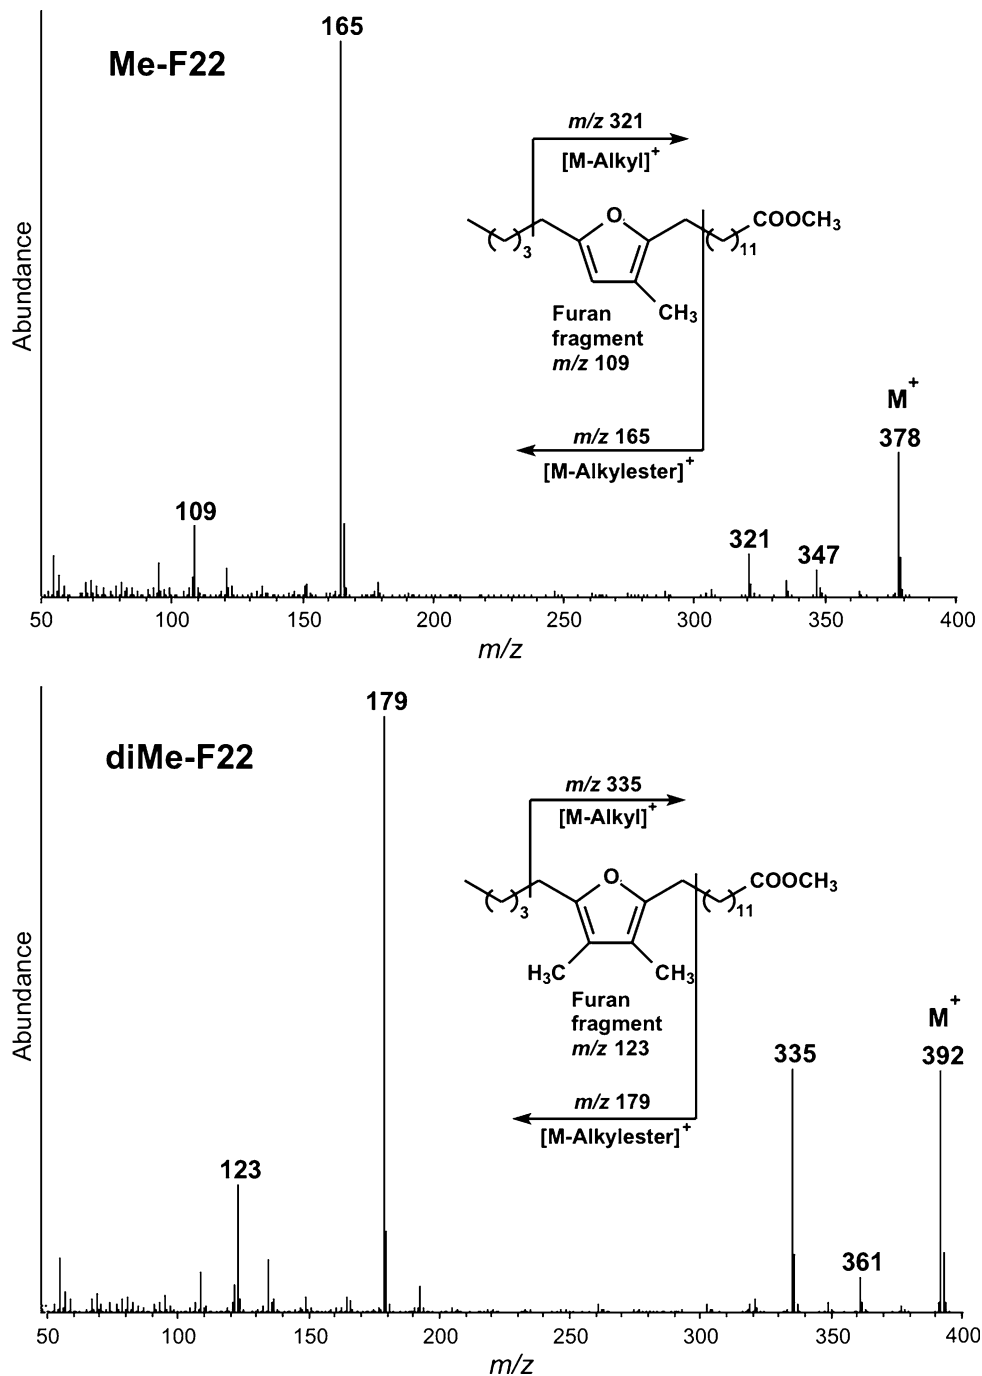

amounts of C_{22–24} (n-3) series FA, 22:5n-3, and 24:6n-3 were not found.

Discussion

The FA compositions of *Bebryce indica* and *R. aggregata* have been previously investigated by the use of a parked steel GC column [18, 39]. Incorrect determination of 18:4n-3 as 18:3n-3, 24:5n-6 as 24:5n-3, the loss of VLC FA, and other mistakes, made for *B. indica* and *R. aggregata*, were corrected in this study (Tables 1, 2). The FA compositions of octocorals of the genera *Acanthogorgia*, *Acabaria*, *Chironephthya*, *Echinogorgia*, *Menella*, *Paralemnalia*, and *Ellisella* were determined in the present study for the first time. In general, the qualitative FA profiles of total lipids of the nine coral genera investigated were similar enough and close to that of other gorgonians, such as *Mopsella aurantia* [18], *Paragorgia arborea* [19], *Euplexaura erecta*, *Subergorgia suberosa* [39], and *Leptogorgia piccola* [40] described earlier. The considerable proportion of arachidonic acid (about a half of the total FA), the high level of tetracosapolyenoic FA (24:5n-6 and 24:6n-3), and predomination of (n-6) polyunsaturated FA (n-6/n-3 > 1) should be considered as the distinguishing features of the gorgonian corals.

A lot of marine invertebrates, including corals, contain symbiotic bacteria and/or microalgae, and their FA make important contributions to the total FA composition of these organisms [41]. The FA composition and biosynthetic pathways of FA are essentially different in bacteria, photoautotrophic microalgae, and host animals [42]. The overwhelming majority of bacteria synthesize saturated and monounsaturated even- and odd-chain FA with 14–18 carbon atoms. Generally, only microalgae can synthesize C_{18–22} polyunsaturated fatty acids (PUFA) of the n-6 and n-3 series. The capability of marine invertebrates to produce C₁₈ PUFA is limited [43]. In a symbiont–host coral

Fig. 1 Electron impact mass spectra of methyl esters of 14,17-epoxy-15-methyldocos-14,16-dienoic acid (Me-F22) and 14,17-epoxy-15,16-dimethyldocos-14,16-dienoic acid (diMe-F22). Mass spectrometric conditions are described in the “Experimental Procedures”

community, different symbionts, such as endosymbiotic dinoflagellates (zooxanthellae), bacteria, filamentous algae or sponges which colonize the skeletons lay down their specific FA patterns that can be recognized in total coral lipids.

Numerous examinations of the interactions between corals and microbes have shown that there is a dynamic microbiota living on the surface and, possibly, within the tissue of corals [44, 45]. However, it is still unknown whether microbes play specific roles in coral biology or if

the observed associations are merely opportunistic interactions of the coral animal with water-column bacteria. The appreciable level of *cis*-vaccenic acid 18:1n-7 and the number of odd-chain and methyl-branched FA (Tables 1, 2) that are regarded as biomarkers of bacteria [46] were found in the FA of azooxanthellate coral species. The statistically significant difference ($P < 0.05$) between the azooxanthellate and the zooxanthellate corals was shown for the contents of these common bacterial FA. It indicated the presence of an advanced bacterial community in

Fig. 2 Average contents of principal fatty acids (% of total FA) in *Rumphella aggregata*, *Paralemnalia thyrsoides* (zooxanthellate species), and azooxanthellate coral species (*Acabaria erithraea*, *Acanthogorgia isoxia*, *Chironephthya variabilis*, *Echinogorgia* sp., *Ellisella plexauroides*, *Menella praelonga*, *Bebrycce studeri*). BactFA was the sum of ai-15:0, ai-16:0, i-17:0, ai-17:0, 17:0, br-18:0, ai-19:0, and 19:0

azooxanthellate gorgonian species. A similar increase of the part of bacterial acids in total FA of azooxanthellate alcyonarians (the genus *Dendronephthya*) compared to the alcyonarians with zooxanthellae has been described earlier [24]. Also, this azooxanthellate alcyonarians are distinguished by the high level (up to 7.3% of total FA) of 7-methyl-6-hexadecenoic acid (7-Me-16:1n-10) presumably attributed to a bacterial origin. At the same time, the average concentration of this interesting component is $1.1 \pm 0.7\%$ (mean \pm SD) of total FA in 13 species of zooxanthellate alcyonarians [24]. In the azooxanthellate gorgonian specimens studied, the proportions of 7-Me-16:1n-10 ($2.4 \pm 1.2\%$ is the average \pm SD) were significantly higher than those in the zooxanthellate alcyonarians mentioned above ($P < 0.01$). This particular FA has been encountered before in several marine invertebrates, such as sponges, anemones, and gorgonians, it contributes on the average 2.9% of total acids of polar lipid fractions in the genus *Gorgonia* [20]. Nevertheless, the perceptible variations of the content of 7-Me-16:1n-10 and the occurrence of 2.7% of this acid in zooxanthellate *R. aggregata* (Table 1) did not allow us to fix unambiguously a direct correlation between the increase in the 7-Me-16:1n-10 content and the absence of zooxanthellae. Probably, 7-methyl-6-hexadecenoic acid does not characterize the whole bacterial community but can serve as a biomarker of some specific bacterial group associated with soft corals or consumed by the coral with food.

Another group of unusual acids, namely F-acids, which can be regarded as a useful biomarker, was identified in the gorgonians studied. These F-acids seem to be widely distributed in all living matter and are found in marine sponges, algae, invertebrates, crayfishes, crabs, and fishes [47]. It is recognized that plants and algae synthesize the carbon skeleton of F-acids from linoleic acid (18:2n-6). Then, the F-acids are elongated by acetate units to higher homologs. The occurrence and biosynthesis of F-acids in phototrophic bacteria has been reported by a few authors [34, 36]. All of these bacteria are common for many kinds of marine animals. It has been concluded that F-acids detected in the animals are derived from marine bacteria and/or algae [34]. Among corals, the presence of 3,4-dimethyl-5-pentylfuryl-proioic acid is reported for the soft corals *Sarcophyton glaucum* and *S. gemmatum* [48]. In the present study, a number of F-acids with 18–22 carbon atoms in the basic chain were for the first time identified in the six azooxanthellate gorgonian species (except for *A. isoxia*). All these compounds have been detected earlier among the predominant F-acids in the biological objects mentioned above [34, 36, 47].

Nevertheless, the F-acids were detected in all the specimens of the zooxanthellate corals studied. In the azooxanthellate species, the content of total F-acids varied between specimens appreciably namely from 0 to 9.7% of the total acids. Analogously to other marine animals, possible sources of F-acids in the octocorals may be microalgae consumed as a food or microorganisms associated with corals such as bacteria or microalgae. All the corals studied were collected at the same place and had similar food sources that, in general, resulted in a decrease in the differences in FA compositions between species. Taking this into account, we prefer the hypothesis of a temporary nonspecific association of azooxanthellate octocorals with phototrophic bacteria or/and some microalgae, which play a role of endosymbiotic dinoflagellates of the *Symbiodinium* group lacking there. In this case, the proportion of these associated microorganisms in the whole coral colony can be estimated by the content of F-acid markers.

At the beginning of our study, the unexpected occurrence of C_{25–28} Δ 5,9 unsaturated VLC FA (demospongiac acids) in *Bebrice* coral—the acids are very characteristic for sponges [49]—was perceived as an artifact. Nevertheless, the same demospongiac FA were found in all the three different colonies of *B. studeri* collected in the Nha Trang Bay and in one sample of the same species from the Den Island (Table 2). Demospongiac FA were never detected in other species studied. All *Bebrice* coral colonies were visually free of biofouling, but the presence of an endosymbiotic sponge has been described for the genus *Bebrice* by Fabricius and Alderslade [33]. Thus, the occurrence of

demospongiac acids in total FA unambiguously reflects the presence of a symbiotic sponge in the gorgonian coral *B. studeri*, and the acids can serve as a useful specific marker of symbiotic sponges for other coral species. It is known that FA constitute about 25 and 6% of tissue dry weight of corals and sponges, respectively. We found that the demospongiac acids amounted to $20.3 \pm 4.5\%$ (mean \pm SD) of the total FA of *B. studeri*. Thus, at a crude guess, the symbiotic sponge may contribute up to 50% of the total dry tissue of *B. studeri*.

According to different estimations, zooxanthellae may contribute from 5 to 30% of the total coral biomass [13]. The presence of this amount of zooxanthellae in a coral colony should appreciably influence the total FA composition, because the FA profile of photoautotrophic organisms significantly differs from that of the heterotrophic host animal. Another way of the influence on the FA composition of a whole colony consists in the transfer (and possible accumulation) of FA synthesized by zooxanthellae to the coral host [10, 12]. For reef-building corals, the transfer of saturated FA have been shown; the transfer of some PUFA have been supposed [9, 11, 13, 25], but the mechanism of this process is under discussion [50]. We described earlier for alcyonarians the significant excess of saturated FA in zooxanthellate species compared to species without zooxanthellae [24]. In the present investigation, the content of palmitic acid (16:0) was significantly higher ($P < 0.01$) in zooxanthellate corals (Table 1). If we suppose that zooxanthellae of octocorals, similar to those of Scleractinia, are a source of saturated FA for the host, the absence of this source may be the cause for the increased content of 16:0 discovered in zooxanthellate soft coral species.

The main PUFA of pure zooxanthellae isolated from reef-building corals are 18:3n-6, 18:4n-3, 18:5n-3, 20:4n-6, 20:5n-3, 22:4n-6, and 22:6n-3 [8, 25]. Data on FA composition of pure zooxanthellae from soft corals is not available, but zooxanthellae from reef-building and soft corals are attributed to the same *Symbiodinium* group of dinoflagellates. We suppose that PUFA profiles of the zooxanthellae from soft and reef-building corals are quite similar and some of these acids can be applied as zooxanthellae markers for soft corals. The use of C_{20–22} PUFA, such as 20:4n-6, 20:5n-3, 22:4n-6, and 22:6n-3, are limited, because high intraspecific variations of the content of these acids exceed interspecific differences [23, 24]. In the total FA of corals, octadecapentaenoic acid (18:5n-3) is absent or found only in trace amounts [15, 24]. At the same time, the comparison the average contents of 18:3n-6 and 18:4n-3 between the zooxanthellate *R. aggregata* and *P. thyrsoides* and the azooxanthellate species indicated the significant difference ($P < 0.01$) (Fig. 2). Therefore, 18:3n-6 and 18:4n-3 seem to be the

most suitable as the markers of zooxanthellae in soft corals.

The absence of 18:3n-6 and the low level of 18:4n-3 in azooxanthellate alcyonarians have been previously described [24]. Negligible amounts (less than 1% of total FA) of 18:3n-6 and 18:4n-3 are found in azooxanthellate reef-building corals *Tubastrea coccinea* and *T. micrantha* [51]. On the contrary, the level of these acids in hermatypic corals range from 2 to 15% of total FA [15, 51]. A comparison of the content of 18:3n-6 and 18:4n-3 in total FA of healthy and completely bleached colonies of the hermatypic coral *Pavona frondifera* has shown that the loss of zooxanthellae leads to decrease in the content from 12.2 to 1.8% [52]. Evidently, it is related to that 18:3n-6 and 18:4n-3 are the main FA of glycolipids, which play the key role in thylakoid membranes of zooxanthellae of reef-building corals [25, 53]. Thus, the presence of more than 2% of 18:3n-6 and 18:4n-3 in total FA can be regarded as the criterion of the presence of zooxanthellae in soft corals.

Genetic analyses based on ribosomal DNA have shown that zooxanthellate populations of scleractinian and soft corals are not homogeneous and contain different proportions of several *Symbiodinium* phylotypes [54, 55]. Variability of the FA profile in different species belonging to the same genus of the free-living dinoflagellates has been demonstrated by Mansour [56]. Also, the FA composition of zooxanthellae isolated from different species of reef-building corals, clams, and Foraminifera is found to vary according to the host [8, 25]. In the gorgonian coral *R. aggregata*, the level of 18:3n-6 was significantly low ($P < 0.01$) as compared to that in *P. thyrsoides* (Table 1; Fig. 2). The presence of a certain *Symbiodinium* phylotype with the specific FA composition may be the possible reason for this distinction. Two PUFA of the n-7 series (16:2n-7 and 18:2n-7) were detected in *R. aggregata* only (Table 1). The same 16:2n-7 acid is found in zooxanthellate alcyonarians (up to 11.9% of the total FA for *Sarcophyton* aff. *crassum*) [24]. Hence, 16:2n-7 acid is believed to originate mainly from a specific phylotype of zooxanthellae with the following elongation to 18:2n-7. The different FA markers may indicate different compositions of zooxanthellate populations in *P. thyrsoides* and *R. aggregata*. With its high level of 18:3n-6, the zooxanthellate population of *P. thyrsoides* was close to that of some hermatypic corals; and, because of the presence of 16:2n-7, the gorgonian coral *R. aggregata* is similar to the alcyonarians.

The Octocorallia species, irrespective of the presence of zooxanthellae, have 24:6n-3 and 24:5n-6 acids; that is their main chemotaxonomic distinction from the Hexacorallia species (stony corals) [20, 26]. Recently, newly revised pathways for the biosynthesis of n-3 and n-6 PUFA in animal cells have been proposed [27]. This report

concludes that 24:5n-6 is formed by elongation of 20:4n-6 to 22:4n-6 and then to 24:4n-6 followed by further desaturation (20:4n-6 → 22:4n-6 → 24:4n-6 → 24:5n-6); a similar formation of 24:6n-3 from 20:5n-3 have been proposed. C₂-degradation via β-oxidation of 24:5n-6 and 24:6n-3 acids is postulated as a pathway to 22:5n-6 and 22:6n-3 acids, respectively. It is very likely that gorgonians and other soft corals utilize a similar biosynthetic route, thus providing another interesting system for studying this type of biogenesis. It is noteworthy that C₂₄ PUFA are synthesized in the host cells of soft corals without a participation of zooxanthellae enzymes [24].

In the present investigation, several gorgonian specimens of *A. isoxia*, *E. plexauroides*, and *M. praelonga* were distinguished by extremely low quantities of 24:5n-6 acid (Table 1). The revised metabolic pathway for C₂₄ n-6 PUFA shows that three acids are chain-elongated, and two of these chain elongation reactions take place in the sequence 20:4n-6 → 22:4n-6 → 24:4n-6 [27]. The average content of 22:4n-6 acid was 20 times higher in the specimens with the deficiency of 24:5n-6 acid (Table 1); this showed an unusual inhibition of the second step of the chain-elongation reactions. Significant changes in the amount of analogical PUFA of n-3 series were not detected (Table 1). These results of our studies were consistent with the presence of both chain-length-specific condensing enzymes and different enzyme complexes for n-3 and n-6 series PUFA in gorgonians. The average content of 22:5n-6 acid in the abnormal specimens was also four times higher (Table 1) as a possible result of Δ⁴-desaturation of the excess of 22:4n-6 acid. The nature of a specific inhibitor of elongation of 22:4n-6 and 22:5n-6 acids is not clear and needs further investigation.

The comparative study of FA composition of the octocorals has allowed us to determine several lipid markers of microorganisms associated with the host coral; these markers will be useful for further investigation of the symbiotic community of soft corals. The octocorals were shown to be an interesting model system for studying the biosynthesis of C₂₂ Δ⁴ and C₂₄ Δ⁶ PUFA as well as a possible source of specific inhibitors for the regulation of biogenesis of the essential FA, e.g. docosahexaenoic acid.

Abstract Mammals express four isoforms of glycerol-3-phosphate acyltransferase (GPAT). The mitochondrial isoform GPAT1 may have been the acyltransferase that appeared first in evolution. The hepatopancreas of the crustacean *Macrobrachium borellii* has a high capacity for triacylglycerol (TAG) biosynthesis and storage. In order to understand the mechanism of glycerolipid biosynthesis in *M. borellii*, we investigated its hepatopancreas GPAT activity. In hepatopancreas mitochondria, we identified a GPAT activity with characteristics similar to those of mammalian GPAT1. The activity was resistant to inactivation by SH-reactive *N*-ethylmaleimide, it was activated by polymyxin-B, and its preferred substrate was palmitoyl-CoA. The reaction products were similar to those of mammalian GPAT1. A 70-kDa protein band immunoreacted with an anti-rat liver GPAT1 antibody. Surprisingly, we did not detect high GPAT specific activity in hepatopancreas microsomes. GPAT activity in microsomes was consistent with mitochondrial contamination, and its properties were similar to those of the mitochondrial activity. In microsomes, TAG synthesis was not dependent on the presence of glycerol-3 phosphate as a substrate, and the addition of monoacylglycerol as a substrate increased TAG synthesis 2-fold. We conclude that in *M. borellii* the de novo triacylglycerol biosynthetic pathway can be

completed in the mitochondria. In contrast, TAG synthesis in the ER may function via the monoacylglycerol pathway.

Keywords Triacylglycerol · Crustacean · Glycerolipid synthesis

Abbreviations

BSA	Bovine serum albumin
DGAT	Diacylglycerol acyltransferase
DTT	Dithiothreitol
EDTA	Ethylenediaminetetracetic acid
ER	Endoplasmic reticulum
GPAT	Glycerol-3-phosphate acyltransferase
NEM	<i>N</i> -ethylmaleimide
TAG	Triacylglycerols

Introduction

The most important organ for crustacean metabolism is the hepatopancreas, which is analogous to the vertebrate liver and insect fat body because it synthesizes and secretes digestive enzymes, absorbs digestive dietary products, stores mineral reserves and organic substances, metabolizes lipids and carbohydrates, and aids in distributing stored reserves during the intermoult cycle and xenobiotic metabolism [1]. The hepatopancreas of *Macrobrachium borellii*, a Decapod Crustacean, is active in triacylglycerol (TAG) biosynthesis. During the winter season the TAG content of hepatopancreas comprises more than 80% of the total lipid mass of the organ [2], and in vivo incubation of *M. borellii* with [¹⁴C]palmitic acid revealed that the hepatopancreas is the principal organ for TAG synthesis [3]. The hepatopancreas mobilizes TAG

when the animal is deprived of food or subjected to thermal stress [4, 5]. These facts suggest that, in addition to the hepatopancreas' digestive and biosynthetic roles, it functions to synthesize and store TAG, analogous to adipose tissue in vertebrates.

The first steps in the de novo biosynthesis of glycerolipids include the activation of fatty acids by acyl-CoA synthetases and their subsequent esterification by *sn*-glycerol-3-phosphate acyltransferases (GPAT, EC 2.3.1.15). Historically two types of GPAT have been characterized in mammals [6]: (1) a microsomal form, which comprises 90% of total GPAT activity in most organs, is sensitive to sulfhydryl reagents like *N*-ethylmaleimide (NEM), and lacks long-chain acyl-CoA substrate preference, and (2) a mitochondrial isoform that is resistant to NEM inactivation and prefers to use saturated acyl-CoA. The mitochondrial NEM-resistant isoform (GPAT1) was cloned twenty years ago from mouse and rat liver [7, 8]. More recently, a second mitochondrial NEM-sensitive isoform (GPAT2) [9] and two endoplasmic reticulum (ER) isoforms (GPAT3 and GPAT4) were cloned [10–12]. Although the specific roles of each isoform are not yet well understood, several studies [13, 14] strongly suggest that the mitochondrial NEM-resistant isoform (GPAT1) initiates the synthesis of TAG in rat liver under conditions of high carbohydrate feeding and caloric excess.

We previously reported that microsomes from *M. borellii* hepatopancreas have a significant acyl-CoA synthetase activity [15] and that the entire synthesis of TAG may occur in the ER of crustacean hepatopancreas [3]. Moreover, a mitochondrial type of acyl-CoA synthetase activity was described in this organ [16]. However, little is known about the acyltransferases that are present in invertebrates. Taking into account the preponderant role of *M. borellii* hepatopancreas in TAG synthesis, we hypothesized that glycerolipid biosynthesis compartmentalization in this crustacean would be similar to that of mammalian liver, so at least two GPAT isoforms would be present in both mitochondria and ER. Our aim was to characterize GPAT activity in these two cellular compartments in order to understand the mechanism of TAG synthesis in an organ intimately connected with versatile aspects of lipid metabolism.

Experimental Procedures

Animals

Adult specimens of *M. borellii* were collected in a freshwater stream near Rio de la Plata, Argentina. They were kept in the laboratory in glass aquaria containing

dechlorinated tap water at room temperature until they were used for experiments. All animal protocols were approved by the Committee for Care and Use of Laboratory Animals, School of Medicine, University of La Plata.

Isolation of Subcellular Fractions from Hepatopancreas of *M. borellii*

Approximately 60 animals were used in each isolation experiment. Specimens were kept on ice for 20 min and the hepatopancreas were quickly dissected and submerged in pre-cooled buffer H (10 mM Hepes-KOH, pH 7.4, 0.25 M sucrose, 1 mM EDTA, and 1 mM dithiothreitol (DTT)) with 0.002% v/v protease inhibitor cocktail (general use, Sigma). The total homogenate was prepared with 10 up-and-down strokes in a motor-driven Teflon-glass homogenizing vessel. Large debris and nuclei were removed by centrifuging twice at $600\times g$ at 4°C for 5 min, and the supernatant (post-nuclear homogenate) was centrifuged for 15 min at $10,000\times g$ at 4°C in a Sorvall refrigerated centrifuge. The resulting pellet was resuspended and recentrifuged twice with ice-cold buffer H to obtain the mitochondrial fraction. Additional purification of the mitochondrial fraction was performed by density-gradient centrifugation as previously described [17]. The combined supernatants were centrifuged for 1 h at $100,000\times g$ (Beckman LE-80K ultracentrifuge, rotor 70.1 Ti) to obtain microsomes. All steps were performed at 4°C and the fractions were aliquoted and frozen at -70°C . The total protein content of each fraction was determined with bovine serum albumin (BSA) as the standard [18].

GPAT Activity

GPAT activity was assayed in each fraction (100 μg of total protein) [19]. The incubation buffer contained 0.8 mM glycerol-3-phosphate (0.5 μCi [^{14}C]glycerol-3-phosphate, Amersham Biosciences), 75 mM Tris-HCl pH 7.4, 4 mM MgCl_2 , 2 mg/ml BSA, 8 mM NaF, 1 mM DTT, and the indicated concentrations of palmitoyl-CoA or oleoyl-CoA. The reaction was incubated at 30°C for 10 min and total radioactivity from the organic phase was quantified by liquid scintillation counting. In order to determine the effect of *N*-ethylmaleimide (NEM) or polymyxin B on GPAT activity, samples were pre-incubated for 30 min on ice in the presence of varying concentrations of NEM or polymyxin B. Products of the GPAT reaction were analyzed by thin-layer chromatography on silica-gel G plates. The solvent systems used to separate the products were hexane/ethyl ether/acetic acid (80:20:1.5; v/v) and chloroform/methanol/acetic acid/water (65:25:1:4; v/v) for neutral and polar lipids, respectively.

Marker Enzyme Activities

Arylesterase activity (ER marker) was measured as described previously [20], NADPH cytochrome c reductase (ER marker), and cytochrome c oxidase (inner mitochondrial membrane marker) were determined using cytochrome c oxidase and cytochrome c reductase (NADPH) assay kits (Sigma).

Immunoblotting

Fifty or one hundred microgram of total protein for each subcellular fraction were separated on an 8% SDS-PAGE, transferred to a polyvinylidene difluoride membrane (Bio-Rad), and probed with a 1/10,000 dilution of anti-GPAT1 antibody in phosphate buffer saline +0.05% Tween-20. Anti-GPAT1 antibody was obtained from rabbits immunized with recombinant rat liver GPAT1 expressed in insect cells and purified from inclusion bodies [21]. The membranes were then washed extensively and probed with horseradish peroxidase-conjugated goat anti-rabbit IgG (Pierce). For chemiluminescent detection, the membranes were incubated with Super Signal detection kit (Pierce).

Lipid Biosynthesis, Extraction and Separation

[¹⁴C]palmitate (3.5 nmol; 0.2 μCi) dissolved in 10 μl of propylene glycol was incubated with 300 μg of total microsomal or mitochondrial protein at 30°C for 60 min. The incubation mixture contained 75 mM Tris-HCl pH 7.4, 2 mM MgCl₂, 2 mg/ml BSA, 5 mM DTT, 5 mM ATP, and 0.2 mM CoASH (lithium salt) in a final volume of 0.35 ml. The reactions were carried out in either the presence or the absence of 20 mM glycerol-3-phosphate in the incubation mixture. 1-Monostearoyl-*rac*-glycerol dissolved in ethanol was added to the reaction in the absence of glycerol-3-phosphate at a final concentration of 100 μM. Lipids were extracted by the Folch procedure [22] and the radioactive lipid products were separated by thin-layer chromatography on silica-gel G plates using the same solvent systems described above. The radioactivity associated with each spot was quantified using a STORM 840 scanner (Amersham, Biosciences). Appropriate standards, run simultaneously, were visualized by exposure to iodine vapor.

Results

Characterization of the Cell Fractions Obtained from *M. borellii* Hepatopancreas

In this study we used total cellular homogenate, mitochondrial and microsomal subcellular fractions from

M. borellii hepatopancreas. To confirm the purity of these fractions, we tested them for marker enzymes that are widely used in mammals. The purity of the fractions was good (Table 1). Cytochrome c oxidase activity indicated some mitochondrial contamination of the microsomal fraction (near 20% of the total protein). Two different ER marker enzymes were tested: NADPH cytochrome c reductase and arylesterase activities. Both activities were present in the microsomal fraction but not in mitochondria. The mitochondrial fraction (10,000 g pellet) was further purified in a Percoll gradient. This technique is widely used to separate mitochondrial membranes from ER contaminants in lipid-biosynthetic organs like rat liver, and yields highly purified mitochondria and a separate band of ER-derived membranes [23, 24]. When *M. borellii* hepatopancreas mitochondria were purified by this method, no band corresponding to ER-derived membranes could be visualized (results not shown). These results are consistent with the absence of ER-markers in the 10,000 g mitochondrial pellet.

GPAT Activity was Primarily Recovered in the Mitochondrial Fraction

GPAT activity was assayed in hepatopancreas total homogenate, and in mitochondrial and microsomal fractions (Table 1, Fig. 1a). Because *M. borellii* GPAT is unstable after long freezing periods, all experiments were performed within two weeks of fractionation. GPAT activity was measured either in fresh and frozen-thawed samples, and no differences were observed in the specific activity values (results not shown). GPAT activity was highly enriched in the mitochondrial fraction (21-fold higher than homogenate) and 47% of total GPAT activity was recovered. In microsomes only 9% of the total GPAT activity was recovered and the enrichment was only 1.4-fold, similar to that of cytochrome c oxidase activity. These results suggest that all the GPAT activity present in microsomes was due to mitochondrial contamination.

The Main Product of GPAT Activity in Mitochondria was Phosphatidic Acid

Radioactive lipids were extracted from mitochondrial GPAT enzymatic assays and analyzed by thin-layer chromatography (Fig. 1b). The distribution of radioactivity associated with the glycerolipids synthesized from [¹⁴C]glycerol-3-phosphate was consistent with the products of the mammalian GPAT1 reaction [20]. In the mitochondrial fraction, the major product was phosphatidic acid (56%). The presence of diacylglycerols (11%) and TAG (32%) suggests that the enzymatic activities acyl-glycerol-3-phosphate acyltransferase (AGPAT), phosphatidic acid

Table 1 GPAT activity was enriched in the mitochondrial fraction of *M. borellii* hepatopancreas

	Cytochrome c oxidase			GPAT			Arylesterase			Cyt c Red		
	Specific activity (mU/mg)	Total activity (U)	Fold enrichment	Recovery (%)	Specific activity (pmol/mg min)	Total activity (pmol/min)	Fold enrichment	Recovery (%)	Specific activity ($\mu\text{mol/mg min}$)	Fold enrichment	Specific activity (mU/mg)	Fold enrichment
Total Homogenate	8.5 \pm 1.9	2.07	–	–	23 \pm 7	5,377	–	–	148 \pm 16	–	3.6 \pm 0.6	–
Mitochondria	181 \pm 14	1.43	21.3	69	322 \pm 38	2,524	14	47	–	–	–	–
Microsomes	11.9 \pm 1.0	0.44	1.4	21.2	34 \pm 7	515	1.5	9.6	519 \pm 32	3.5	10.9 \pm 0.7	3.0

GPAT specific activity was measured in total homogenate and in mitochondrial and microsomal fractions from *M. borellii* hepatopancreas. The purity of the fractions was monitored assaying the marker enzymes cytochrome c oxidase (mitochondria), NADPH cytochrome c reductase (Cyt c Red) and arylesterase (endoplasmic reticulum). Results are expressed as the means \pm SD of three independent experiments. Fold enrichment was calculated with respect to total homogenate

phosphohydrolase (PAPase), and diacylglycerol acyltransferase (DGAT) are also present in mitochondria. The amount of radioactivity obtained from GPAT assays in microsomes was not sufficient to analyze the reaction products.

Mitochondrial GPAT Preferred Saturated Fatty Acyl-CoA

The substrate specificity of GPAT was determined using palmitoyl-CoA and oleoyl-CoA as acyl-CoA donors. In the mitochondrial fraction, palmitoyl-CoA was the preferred substrate (Fig. 2a). The V_{max} value calculated with oleoyl-CoA as a substrate was 4-fold lower than the value obtained when the substrate was palmitoyl-CoA. Since higher concentrations of palmitoyl-CoA inhibited the GPAT activity, it was not feasible to determine a K_m value for this substrate. In contrast, oleoyl-CoA did not inhibit GPAT activity at a concentration as high as 120 μM and the apparent K_m value for this substrate, calculated by Lineweaver-Burk transformation, was 31.2 μM . The same experiments were performed using microsomes and identical substrate specificities were obtained, although the specific activities were 80% lower (Fig. 2b).

Mitochondrial GPAT Activity was NEM Resistant and Activated by Polymyxin B

Mitochondrial GPAT activity was resistant to inhibition by NEM at concentrations as high as 10 mM (Fig. 3). In contrast, preincubation of the mitochondrial fraction with the antibiotic polymyxin B markedly stimulated GPAT activity; at 0.5 mg/ml polymyxin B GPAT activity increased 2.7-fold (Fig. 3). The microsomal GPAT activity was also resistant to NEM-inactivation (results not shown).

Mitochondria from *M. borellii* Hepatopancreas Contained an Anti-GPAT1 Immunoreactive Protein

The polyclonal anti-GPAT1 antibody raised against rat liver GPAT1 recognized an immunoreactive protein with a molecular mass of 70 kDa in the mitochondrial fraction from hepatopancreas (Fig. 4). No immunoreactive protein was detected when 50 μg of total protein from microsomes were loaded on the gel, but a weak band was detected with 100 μg . Consistent with the low GPAT specific activity found in microsomes, this band might be the result of mitochondrial contamination. The presence of this immunoreactive band suggests that hepatopancreas mitochondria contain a protein homologous to GPAT1, consistent with NEM-resistant GPAT activity. The molecular weight of this protein was lower than that of rat liver GPAT1 (90 kDa). However, ER-GPAT 3 and 4 both have

Fig. 1 **a** GPAT specific activity in mitochondrial (Mit) and microsomal (Mic) fractions from *M. borellii* hepatopancreas. Results are the means \pm S.E from three independent experiments. **b** Lipid classes distribution of [14 C]glycerol-3-phosphate esterified by mitochondria.

Results are representative of two independent experiments. The *inset* show the products of GPAT reaction resolved in TLC plates for polar (a) and neutral (b) lipids: PA phosphatidic acid; NL neutral lipids; DAG diacylglycerol; TAG triacylglycerol

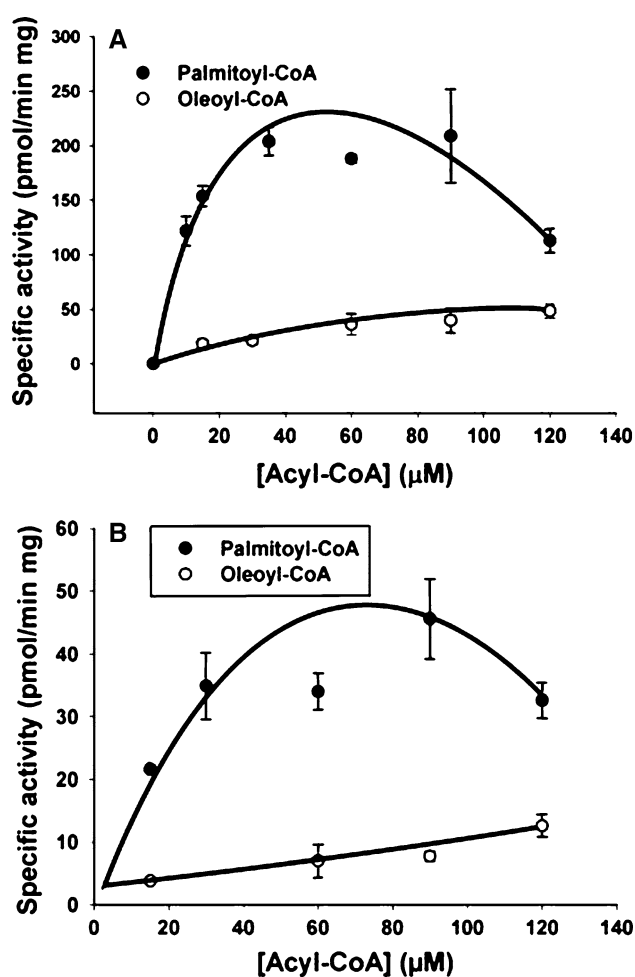

Fig. 2 Acyl-CoA substrate specificity of GPAT reaction in mitochondria (a) and microsomes (b). All assays contained 4 mM MgCl₂, 2 mg/ml BSA, 8 mM NaF, 1 mM DTT, 0.8 mM glycerol-3-phosphate (0.5 μ Ci [14 C]glycerol-3-phosphate per reaction) and the indicated concentrations of palmitoyl-CoA (filled circle) or oleoyl-CoA (open circle). Data points represent the means \pm SE of an experiment performed in duplicate and are representative of two independent experiments

Fig. 3 Effect of NEM and polymyxin B on GPAT activity. Mitochondrial samples were pre-incubated for 30 minutes on ice in the presence of the indicated concentration of NEM (filled triangle) or polymyxin B (filled circle) in the incubation mixture. The results represent the means \pm SD from three independent experiments. The baseline specific activity was 322 \pm 38 pmol/min mg protein

molecular weights of approximately 40 kDa [10, 12], indicating that smaller GPAT proteins are also active.

Microsomes from *M. borellii* Hepatopancreas Esterified [14 C]Palmitate in the Absence of Glycerol-3-Phosphate

We had previously reported that microsomes from *M. borellii* hepatopancreas actively synthesized TAG [3]. To investigate the TAG synthesis pathway, experiments were performed under previously optimized experimental conditions in either the presence or absence of glycerol-3-phosphate and monoacylglycerol. When glycerol-3-phosphate (20 mM) was added to the reaction mixture, 54% of

Fig. 4 Mitochondria from *M. borellii* contain an immunoreactive protein against GPAT1 antibody. **a** 50 µg or 100 µg of total protein from total homogenate (*H*), mitochondria (*Mit*), and microsomes (*Mic*) were loaded on SDS-PAGE 8%, transferred to PVDF membranes, probed with a polyclonal anti-rat liver GPAT1 antibody and visualized by ECL. The immunoreactive band molecular mass is 70 kDa. **b** 50 µg of rat-liver mitochondria were probed with the same antibody. The immunoreactive band molecular mass is 90 kDa

the [^{14}C]palmitate was esterified (104 pmol of esterified palmitate/min mg protein) (Table 2 and Fig. 5). Radioactivity was incorporated primarily into neutral glycerolipids (83.8%) and to a lesser extent into phospholipids (14%). The major neutral lipid product was TAG (about 65%). When glycerol-3-phosphate was omitted, 40% of the [^{14}C]palmitate was esterified, (78 pmol of esterified palmitate/min mg protein) and the distribution of the radioactivity among lipid classes was similar; under this condition adding 100 µM monostearoylglycerol increased TAG synthesis nearly 2-fold (Fig. 6).

In mitochondria, TAG synthesis required glycerol-3-phosphate as a substrate. [^{14}C]palmitate esterification into lipids was higher than in microsomes (74%, 144 pmol of esterified palmitate/min mg protein) (Table 2 and Fig. 5) and 70% of the radioactive palmitate was detected in the TAG fraction.

Discussion

In crustaceans, the hepatopancreas carries out essential functions of energy metabolism. We reported that the hepatopancreas of the fresh-water shrimp *M. borellii* is the major lipid-biosynthetic organ, and that the microsomal fraction synthesizes TAG [3]. Thus, we focused our studies on the enzyme that catalyzes the first and committed step in glycerolipid synthesis, GPAT, hypothesizing that, as in mammalian cells, more than one isoform might be present in different subcellular compartments to exert a specific metabolic function.

We measured GPAT activity following a method widely used in mammalian tissues [17]. Under these conditions,

Table 2 Microsomal and mitochondrial esterification of [^{14}C]palmitate

	Microsomes		Mitochondria
G3P addition	0	20 mM	20 mM
Specific activity (pmol/min mg) ^a	78 ± 4	104 ± 14	144.3 ± 10
Neutral lipids (%)	81.1 ± 7.3	83.8 ± 2.7	80.0 ± 8.2
Triacylglycerols (%)	56.6 ± 18.2	66.5 ± 11.3	70.7 ± 2
Phospholipids	18.4 ± 7.4	13.9 ± 4.2	17.8 ± 1.4

Esterification of [^{14}C]palmitate by microsomes and mitochondria from *M. borellii* hepatopancreas was measured either in the presence or absence of 20 mM glycerol-3-phosphate in the incubation mixture. Lipids were separated by TLC and the radioactivity quantified. Neutral glycerolipids include triacylglycerol, diacylglycerol, and monoacylglycerol. Triacylglycerol values are distinguished

^a Specific activity indicates the pmol of [^{14}C]palmitate esterified into lipids/min. mg protein

Fig. 5 Microsomal and mitochondrial glycerolipid biosynthesis from [^{14}C]palmitate. About 300 µg of hepatopancreas microsomal (lanes 1–4) or mitochondrial (lane 5) protein was incubated using [^{14}C]palmitate (0.2 µCi) as substrate either in the presence or in the absence of 20 mM glycerol-3-phosphate (G3P). Reaction products were analyzed by TLC and the radioactivity quantified by scanning proportional counting. TAG triacylglycerol, FFA free fatty acids, DAG diacylglycerol, MAG monoacylglycerol, PL phospholipids

GPAT activity can be detected in microsomes and mitochondria from rat liver. GPAT activities can be distinguished by their varying sensitivities to sulfhydryl reagents like

Fig. 6 Microsomal triacylglycerol biosynthesis is increased in the presence of monostearoylglycerol. About 300 μg of hepatopancreas microsomal protein was incubated using [14 C]palmitate (0.2 μCi) as substrate without any external source of glycerol (Control) and 100 μM monostearoylglycerol (MAG). Reaction products were analyzed by TLC and the radioactivity present in the TAG fraction quantified by scanning proportional counting. Specific activity values correspond to pmoles of synthesized triacylglycerol/min. mg of microsomal protein. Values represent the means \pm S.E of two independent experiments

NEM. In liver the NEM-sensitive activity comprises 50–60% of total GPAT activity whereas in most other organs it comprises about 90% of total GPAT activity [6]. In rat liver, the NEM-sensitive activity is attributed to microsomal GPAT3 and GPAT4 because expression of the mitochondrial NEM-sensitive isoform GPAT2 is very low [9].

Surprisingly, since microsomal fractions synthesize TAG [3], GPAT activity was recovered primarily in the mitochondrial fraction. Kinetic properties of the *M. borellii* mitochondrial activity were similar to those of rat and mouse GPAT1 [25]. The activity was NEM-resistant, it showed a preference for saturated-acyl-CoA substrates, and like mammalian GPAT1, it was activated by polymyxin B [26], an antibiotic that interferes with the glycerolipid packing in both bacteria and synthetic membranes. Activation of GPAT by polymyxin B was more striking in shrimp hepatopancreas than in rat liver mitochondria, suggesting that in the crustacean, membrane fluidity plays an important role in regulating GPAT activity. Finally, an anti-GPAT1 polyclonal antibody, raised against full-length recombinant rat GPAT1, recognized a single 70 kDa protein present in the mitochondrial fraction. These data suggest that GPAT1 from rat-liver mitochondria and the mitochondrial GPAT from *M. borellii* hepatopancreas may be homologous. Cloning and sequencing the *M. borellii* GPAT gene will be required to fully address this issue.

When hepatopancreas mitochondria were incubated with [14 C]glycerol-3-phosphate under the conditions optimized to measure GPAT activity, the major reaction product was phosphatidic acid, as observed in membranes

from rat liver that contain both GPAT and acyl-glycerol-3-phosphate acyltransferase. An additional 43% of the radiolabel was found in diacylglycerol and TAG. Under different conditions that were optimized for TAG synthesis, and which depended on the activities of several enzymes, the major reaction product was TAG (74%), indicating that mitochondria can perform the full pathway of de novo TAG synthesis.

Our results are consistent with the interpretation that the GPAT activity detected in microsomes is due to mitochondrial contamination. First, enrichment of GPAT activity in the microsomal fraction was equivalent to that of the mitochondrial marker enzyme cytochrome c oxidase. Second, the GPAT activity in microsomes had the same kinetic parameters and substrate preference as the mitochondrial activity. Finally, only a very faint band reactive to the anti-GPAT1 antibody was detected when 100 μg of microsomal protein was analyzed by western blot. Nevertheless, the possibility remains open that an independent microsomal GPAT isoform exists, that this activity has different kinetic parameters, and that the activity is not detectable under our experimental conditions.

The low GPAT activity in the microsomal fraction was unexpected because we had previously reported that the microsomal fraction incorporates [14 C]palmitate into TAG as the major product [3]. In that study, assays were performed in the presence of glycerol-3-phosphate, and we had assumed that TAG was synthesized de novo via the glycerol-3-phosphate pathway. In the present study, we showed that in the absence of glycerol-3-phosphate, microsomes retain 75% of their capacity to esterify [14 C]palmitate into glycerolipids. We attribute the difference in microsomal specific activity values for palmitate esterification in the presence and absence of high concentrations of glycerol-3-phosphate (104 and 78 pmol of esterified palmitic acid/min mg, respectively) to mitochondrial GPAT activity that is contaminating the microsomal fraction (about 20%).

Taking into account the absorptive function of the hepatopancreas and the TAG-lipase activity that has been reported in hepatopancreas cells from *M. borellii* [16] and other crustaceans [1], we considered the possibility that an alternative substrate, different from glycerol-3-phosphate, might account for the high rate of TAG synthesis observed in the microsomal fraction. Replacing glycerol-3-phosphate with 100 μM monoacylglycerol caused a 2-fold increase in TAG synthesis, suggesting that in microsomes, TAG synthesis occurs mainly via the monoacylglycerol pathway.

The initial step in glycerolipid synthesis in bacteria is catalyzed by a single gene product, *plsB* (GPAT) in Gram-negative bacteria and by *plsY* (acyl-ACP:phosphate transacylase) in Gram-positive bacteria. In contrast, both lower and higher eukaryotes express more than one GPAT

isoform and at least one of the isoforms is located in the ER. Information about TAG synthesis in invertebrates is scarce. Only a single report from more than three decades ago, described the incorporation of [^{14}C]glycerol-3-phosphate into the lipids of the insect *Ceratitis capitata* and demonstrated that TAG could be synthesized in mitochondria, although a higher rate of TAG synthesis was observed in microsomes [27].

We conclude here that de novo synthesis of TAG is initiated in mitochondria, whereas in microsomes TAG synthesis occurs by an alternate pathway, probably the monoacylglycerol pathway. Although the *M. borellii* GPAT gene has not yet been cloned, its properties suggest that it could be homologous to *PlsB* and to mitochondrial GPAT1, members of a highly conserved acyltransferase family.

Abstract The aim of this study was to examine the influence of dietary fat on lipid composition, as well as on the steroidogenic function of interstitial cells isolated from Wistar rats that had been fed semi-synthetic diets containing four different commercial oils (S soybean, O olive, C coconut, and G grape seed). Steroidogenic enzyme activities, lipid composition, and androgen production were measured in testicular interstitial cells. Lipid analysis included measurement of the contents of major lipid subclasses (neutral lipids, polar lipids, free and esterified cholesterol), as well as principal polar and neutral lipid fatty acyl compositions. Significant differences in lipid composition were observed among the groups, most of them reflecting the specific fatty acyl composition of the diet tested. Testosterone concentration was higher in O and C groups compared with S or G. In agreement with this observation, the activity of both key enzymes involved in testosterone biosynthesis (3β -HSD and 17β -HSD) was higher in O and C groups with significant differences between them ($O > C$). A significant negative correlation was found between cellular testosterone production and cellular cholesterol ester content. Additionally, testosterone concentration directly correlated with cholesterol levels. We conclude that dietary oils qualitatively and quantitatively modified the lipid composition of interstitial cells, producing either a direct or indirect regulatory effect on testicular steroidogenic function.

Introduction

It has long been known that changes in dietary fat [1–3] and/or cholesterol intake [4, 5] modify membrane

phospholipid composition in many tissues and cell types, thus influencing normal cell function. In the testis, it has been demonstrated that lipids strongly influence the histology and physiology of this tissue [6–8]. Different situations, such as essential fatty acid deficiency [9, 10] or alterations in fatty acid metabolism under diabetic conditions [10, 11], have been associated with testicular malfunction. Regarding androgen biosynthesis, it has been demonstrated that feeding rats with rapeseed oil rich in polyunsaturated fatty acids (PUFA) was associated with a high level of testosterone [12]. In contrast, decreased androgen concentration was measured in rats fed palm oil, which is rich in saturated fatty acids [12]. Total fat intake was also related to the level of sex steroid hormones. Some studies on men and rats have revealed that there was an increase in plasma androgen concentration after being fed a high-fat diet [13, 14]. In contrast, a reduction in total fat intake caused a decrease in plasma testosterone concentration [15]. Most studies on the relationship between dietary fat and testicular steroidogenesis have been carried out by analyzing the lipid composition of the whole testes. Additionally, we are unaware of any information concerning the possible relationship(s) between androgen production and a particular change in the lipid composition of interstitial cells. Therefore, the aim of this study was to evaluate the effect of diet supplementation, using four oils commercially available world wide, on lipid composition of interstitial cells and their impact on steroidogenic function.

Materials and Methods

Chemicals

Solvents (HPLC grade) were provided by Carlo Erba (Milano, Italy). Other chemicals were from Sigma Chem. Co. and Fluka Chemie AG (Buenos Aires, Argentina). Lipids used as standards were from the Serdary Research Lab (London, ON, Canada) or from Nu-Check-Prep (Elysian, MN). Collagenase was obtained from Worthington, Freehold, NJ. The commercially available oils that were added to the diets were from Molinos Río de La Plata SAIC and Platafarm SA (La Plata, Argentina).

Diets and Animal Treatment

Male Wistar rats weighing 180 ± 10 g with had been certified as specific-pathogen free (Laboratory Animal Care and Supply Facilities, Veterinary Medical School, UNLP) were used. Upon arrival, the rats were allowed to acclimatize for a week before starting the experiments. Rats were housed individually and maintained under controlled

conditions at a temperature of 25 ± 2 °C with a normal photoperiod of 12 h dark and 12 h light. They were fed with standard Purina chow (Cargill type “C”) from Ganave Co. (Santa Fe, Argentina) and water ad libitum throughout gestation and lactation. Clinical examinations together with body weight evaluation were performed every week during the experiment. Male pups (47 ± 4 g/animal) were divided into four groups of ten animals each, and fed specific diets ad libitum. Isocaloric diets (Table 1) were prepared in an identical manner, except for the lipid source, which was added as commercial oil (70 g/kg diet): soybean (S), olive (O), coconut (C), or grape seed (G). The fatty acyl composition of each diet is detailed in Table 2. Rats were fed according to the American Institute of Nutrition [16]. Animal maintenance and handling were conducted as recommended by NIH guidelines [17]. All procedures were approved by the local Laboratory Animal Committee, Facultad de Ciencias Médicas, UNLP, Argentina.

Experimental Design

Rats were sacrificed after being fed with the diets for 60 days. In order to avoid individual differences among animals, all rats were fasted for 24 h on day 59, giving access to the appropriate diet for 2 h, and killed by decapitation 12 h after the re-feeding period. Food intake,

water consumption, and body weight were individually registered during the feeding period. After sacrifice, testes were removed, weighed, and used for the isolation of interstitial cells.

Interstitial Cell Isolation

The technical procedure for interstitial cell isolation was described in detail in a previous report [18]. Briefly, cells were removed from the interstitial space of the testicular tissue by mechanical shaking with collagenase in a

metabolic incubator, at 34 °C, according to the method of Suescun et al. [19]. Cells were suspended in Krebs-Ringer bicarbonate glucose (KRBG 0.1%), albumin (0.1%), pH 7.4, examined for viability (85–90%) by exclusion of trypan blue [20], and counted in a hemocytometer to adjust cell concentration. Aliquots of cell suspensions were subjected to protein determination by the micromethod of Bradford [21]. Interstitial cell preparations consisted of Leydig cells (70%) and of spermatids, spermatocytes and small cytoplasmic fragments (21%). The homogeneity of cell preparations was assessed by means of observation of smears fixed in acetone and stained with hematoxylin-eosin.

Lipid Analysis of Diets and Interstitial Cells

The fatty acid compositions of the diets were routinely checked by gas-liquid chromatography after derivatization by methanolic boron trifluoride as described below for lipid cell isolation and analysis. Total cell lipids were extracted using the Folch procedure [22]. Neutral (NL) and phospholipids (PL) were isolated from the total lipid extract by silicic acid microchromatography [23]. Absolute content of the major lipid subclasses was obtained using commercial silicagel G-60 TLC plates (Merck, Darmstadt, Germany) as previously described [24]. The total amount of lipids in each fraction was determined by either inorganic phosphorous quantification [25] or gravimetrically [26]. Lipids separated by TLC were visualized and identified using the method of Nakamura and Handa [27]. R_f values were as reported previously [24]. Individual lipid components were quantified densitometrically [28]. Cholesterol content (FC) was enzymatically measured [29]. Triacylglyceride content (TAG) was assayed using a kit from the Wiener Lab (Rosario, Argentina). Total fatty acyl methyl esters (FAME) were prepared by transesterification with methanolic boron trifluoride [30] and analyzed by capillary gas-liquid chromatography (c-GLC) in a Hewlett Packard HP 6890, with a terminal computer integrator system. FAMES were identified by comparison of their relative retention times with authentic standards.

Steroidogenic Enzyme Activities

Sonicated interstitial cells were centrifuged (10,000g, 15 min, 1–2 °C). Aliquots of supernatants were employed to determine 3-β-hydroxysteroid-dehydrogenase (3-β-HSD) and 17-β-hydroxysteroid-dehydrogenase (17-β-HSD) enzyme activities using the method of Marugesan et al. [31].

Hormone Measurement

For the determination of testosterone levels in cells, interstitial cell suspensions were washed twice with cold

PBS and centrifuged (4,000g, 5 min). Pelleted cells were resuspended and homogenized by sonication (three 30-s bursts at 50% output in a Heat Systems Ultrasonic sonicator model W-220F from Plainview, NY) in 65 mM Tris–HCl buffer (pH 7.0) containing 10% sucrose and antiprotease inhibitor cocktail (from Sigma Chem. Co., Buenos Aires, Argentina) at the concentration recommended by the manufacturer. Cellular and plasma testosterone and plasma luteinizing hormone concentrations were determined by radioimmunoassay (RIA) using a commercial kit from Radim (Ponenzia, Italy).

Statistics

Statistical significance of data values was analyzed by one-way ANOVA followed by Tukey's test with the aid of Systat (Version 8.0 for Windows) from SPSS Science (Chicago, IL). Results were also plotted and analyzed using Sigma Scientific Graphing Software (Version 8.0) from Sigma Chem. Co. (St Louis, MO). Multivariable regression analysis was performed as described by Kleinbaum and Kupper [32].

Results

Fatty Acid Composition of Diets

Significant differences in fatty acyl composition were observed among diets (Table 2). Saturated fatty acids (SFA) represent approximately 95% of the total fatty acid (FA) content of Diet C and are mainly comprised of short or medium carbon chain fatty acids. Diet O was characterized by the highest content of monounsaturated fatty acids (MUFA), mainly oleic acid. Polyunsaturated fatty acid (PUFA) levels were high in both Diets S and G, with linoleic acid being the predominant FA. α -Linolenic acid was found in very low levels in all diets, except S (approximately 7%). As concerns the n-6/n-3 ratios, they were varied widely among diets. We observed that the relative proportion of n-6 versus n-3 fatty acyl chains decreased in the order C > G > O > S. In agreement with the fatty acyl composition of each diet, the corresponding double bond index (DBI) decreased in the order G = S > O > C.

Influence of Diets on Growth Parameters

The influence of diets on feeding parameters is listed in Table 3. Diets did not significantly influence water consumption (approximately 15 g/day). Initial body weights were similar in all groups. However, final body weights, rate of body weight gain, and food efficiency ratio were

significantly elevated in Group C when compared with the others. Both absolute and relative testicular weights were significantly higher in Group O when compared to the other groups.

Changes Induced by Diets on Major Lipid Subclasses

Table 4 shows the effects caused by the diets on the absolute amount of major lipid subclasses of interstitial cells. Rats fed on Diets C and O displayed major amounts of total lipids compared with Groups S and G. The highest concentrations of phospholipids (PL) were present in Group O and those of the neutral lipids (NL) in Group C. The NL/PL ratio was three times higher in Group C with respect to those ratios observed in the other experimental groups. Group C was enriched in triacylglycerides, as well as in free cholesterol (FC). Esterified cholesterol (CE) was present in relatively small amounts in all groups. When comparing the FC/CE ratios, we observed similar values in Groups C and O, which were approximately five times higher than those calculated for the other groups.

The influence of dietary lipids on the main phospholipid subclasses is shown in Table 5. Interstitial cells from rats fed on Diet O exhibited significantly higher concentrations of PC, PE, and PI than in the other groups. Other phospholipids such as phosphatidylserine, sphingomyelin, phosphatidic acid, and phosphatidylglycerol, were present in similar amounts in all groups.

Dietary Effect on Fatty Acyl Composition of Lipid Subclasses

The relative distribution of fatty acids in PC, PE, and TAG lipids of interstitial cells is shown in Tables 6, 7, 8, respectively. We observed significant differences among groups. One of the most important changes occurred in phosphatidylcholine (PC) (Table 6) from Group C, of which 73% was composed of SFA, mainly 16:0 and 18:0, with minor amounts of short and medium carbon chain fatty acids (14:0 and 15:0). This group also showed the lowest level of both MUFA and PUFA. Group O was characterized by the highest MUFA content, mainly oleic acid, as well as the lowest levels of SFA (16:0 and 18:0). PUFA levels were similar to those observed in Groups S and C. Cells isolated from grape seed-oil fed rats were characterized by the highest amount of PUFA (45%), mainly 18:2, 20:4, and 22:5 acids of the n-6 series, with relatively low levels of SFA and MUFA. Group S was characterized by its high content of SFA followed by PUFA, especially 20:4 and 22:5 acids from the n-6 series. DBI calculated from PC fatty acyl compositional data decreased in the order G > O > S > C. Despite the fact that PE fatty acyl composition (Table 7) differs from that

of PC, the distribution pattern among different diets was similar. In summary, according to analytical parameters, SFA were the predominant fatty acids in Group C, MUFA were the most abundant acyl chains in Group O, and PUFA enriched the glycerolipids isolated from Groups S or G derived cells. Table 8 shows the fatty acyl composition of triacylglycerides (TAG) of interstitial cells. Group C exhibited the highest levels of SFA, as well as the lowest amount of MUFA. Group O was characterized by the highest levels of MUFA and the lowest levels of SFA. In Groups S and G, SFA amounts were quite similar. Group G exhibited the highest level of PUFA, similar to that of

Group O, followed by Groups S and C. However, the DBI in TAG decreased in the order O > G = S > C.

Dietary oils also influenced the fatty acyl composition of cholesterol esters (CE) (Table 9). In this case, the composition of the diet exerted a complex influence on the analytical profile, which did not reflect the relative abundance of the acyl chains in the oil. For example, the proportion of SFA was similar among groups and even less abundant (considering stearic acid level) in Group C, which was fed the most saturated oil. MUFA content was elevated in the olive-supplemented group, however, the other groups had similar proportions of oleic and palmitoleic acids. The

content of arachidonate (20:4n-6) was increased in Diet C, which was depleted in linoleic acid, while it was decreased in the other diets, especially those rich in MUFA (O). The content of 22:6n-3 fatty acid was approximately constant among groups and independent of the diet composition,

while the amount of 22:5n-6 was significantly different and not associated with the acyl composition of the dietary oil. For example, Group C had a 22:5n-6 level similar to that of Group G. The changes observed in the relative amounts of PUFA agreed with the DBI values calculated for each diet.

Influence of Dietary Lipids on Steroidogenic Function and Testosterone Production of Interstitial Cells

The activities of the two key enzymes for testosterone biosynthesis, 3- β -hydroxysteroid-dehydrogenase (3- β -HSD) and 17- β -hydroxysteroid-dehydrogenase (17- β -HSD), were significantly affected by the diets tested. Both enzyme activities were significantly decreased in interstitial cell homogenates from rats fed Diets S and G compared with the levels observed in Group O or C preparations (Fig. 1).

Testosterone concentrations in interstitial cell homogenates are shown in Fig. 2a. The highest androgen concentrations were found in cells from Groups O and C. The decrease in cellular testosterone concentration was in the order, O = C > S = G. Figure 2b shows the plasmatic levels of free testosterone and luteinizing hormone. The highest levels of testosterone were observed when the rat diet was supplemented with Oils O or C. In Groups S or G, plasma testosterone concentration was significantly lower. Luteinizing hormone followed the opposite trend (Fig. 2b)

with Groups S and G containing the highest levels and Groups O and C the lowest.

In Fig. 3 we have represented the linear correlation coefficient (r^2) between testosterone production and free or esterified cholesterol. Therefore, testosterone concentration directly correlated with free cholesterol (Fig. 3a). Additionally, a significantly negative correlation was found between cellular testosterone production and CE content (Fig. 3b).

Discussion

The control of testicular function is a complex process that requires the functional integrity of the seminiferous tubules and Leydig cells with a suitable multihormonal stimulation. The steroidogenic capacity of Leydig cells is essential for spermatogenesis. However, not only hormonal aspects are important in testis physiology; lipid composition is also crucial. Several factors have demonstrated that nutrition is an environmental factor of major importance [33]. Other

authors have demonstrated that dietary fats can modulate steroidogenic function of mammalian testis [12, 34]. However, little is known about the changes induced by dietary oils on lipid composition of interstitial cells and their eventual correlation with testosterone biosynthesis.

In this study, we demonstrated that commercial oils added to diets were able to affect lipid composition of interstitial cells, mainly Leydig cells, and that they markedly influenced their androgen biosynthesis capacity. The oils tested were selected by taking into account their massive consumption over the world and also because they were obtained from vegetable sources where cholesterol was absent. Differences among oils reflected their characteristics as a source of precursor FA, which, in turn, were then metabolized to MUFA and PUFA of the different fatty acid series.

Despite the fact that Oils S and G had the highest content of linoleic and/or linolenic acids they differed in the relative proportion of n-6 and n-3 fatty acid components. It was demonstrated that the ratio n-3/n-6 was important not only for cardiovascular disease prevention but also for a normal spermatogenesis [6]. However, the relationship between this analytical parameter and the androgenic capacity of interstitial cells is a matter that is still unsolved. We clearly demonstrated that oil-supplemented diets

strongly modified interstitial cell lipid composition. Especially important were the differences produced in the absolute amount of NL and PL, and in the ratios of FC/CE. Moreover, FA patterns of these major lipids strongly differed in their fatty acyl chains being SFA, MUFA and PUFA, concentrated in Groups C, O and S/G, respectively. Changes observed in the major lipid subclasses induced by the commercial oils were in accordance with those found for tissues other than testis [35].

The importance of the FA modifications observed in the main lipid subclasses is their capacity to influence the androgen metabolism. Testicular lipids have an active metabolism, and they arise from both dietary sources and from the processes of synthesis, elongation, desaturation, interconversion, esterification, and oxidation by the testicular tissue itself. Moreover, it is known that dietary fats can affect the testicular fatty acid composition in a similar way to that seen in hepatic tissue [7]. Also, certain dietary fats can modulate not only fatty acyl composition of testicular lipids, but also testosterone metabolism. It was demonstrated that diets rich in PUFAs depress Leydig cell function in rats [12]. In agreement with this report, our data demonstrated that diets supplemented with Oils S and G caused reductions in 3β - and 17β -HSD enzyme activities compared with Oils O and C. Decreased enzyme activities

were in agreement with an inhibition in testosterone production by Leydig cells. This pattern of response was also reflected in peripheral plasma [34].

We also observed that Diets C and O had the best comparative performance in testosterone production despite their very different fatty acyl composition. The role of SFA and MUFA in steroidogenic function is a controversial issue. Oleic acid was provided predominantly by olive oil. This fatty acid has regulatory functions in many tissues [36–41] and it is accepted that its endogenous biosynthesis is insufficient for normal cell function. Thus, this acid must be obtained from dietary lipids [42]. However, previous reports have suggested that excessive oleic acid supplementation appears to inhibit testosterone synthesis by decreasing cholesteryl esterase activity [43]. This finding contradicts previous experimental evidence, indicating a stimulating effect of MUFA and an inhibitory effect exerted by n-3 PUFA [44]. Similar controversial

results were observed in the relative amount of saturated fatty acids [45]. Other researchers have also reported that FA could inhibit steroidogenesis at one of the steps preceding the conversion of cholesterol to pregnenolone [46]. Taking into account all these previous results, it is likely that both excessive PUFA and/or MUFA may be deleterious for testosterone production. However, our findings indicate that a diet enriched in MUFA (olive oil) may be important to keep androgenic synthesis within the normal values whereas PUFA diets appear to depress Leydig cell function. Such a conclusion denotes the importance of dietary lipids in Leydig cell function.

The availability of free cholesterol from cholesterol esters is influenced not only by the quantity and quality of FA but also by hormonal levels. In rat Leydig cells, the cholesterol side-chain cleaving enzyme is subjected to LH regulation in a complex way, which depends on both the time and the intensity of the gonadotrophic stimulus [47].

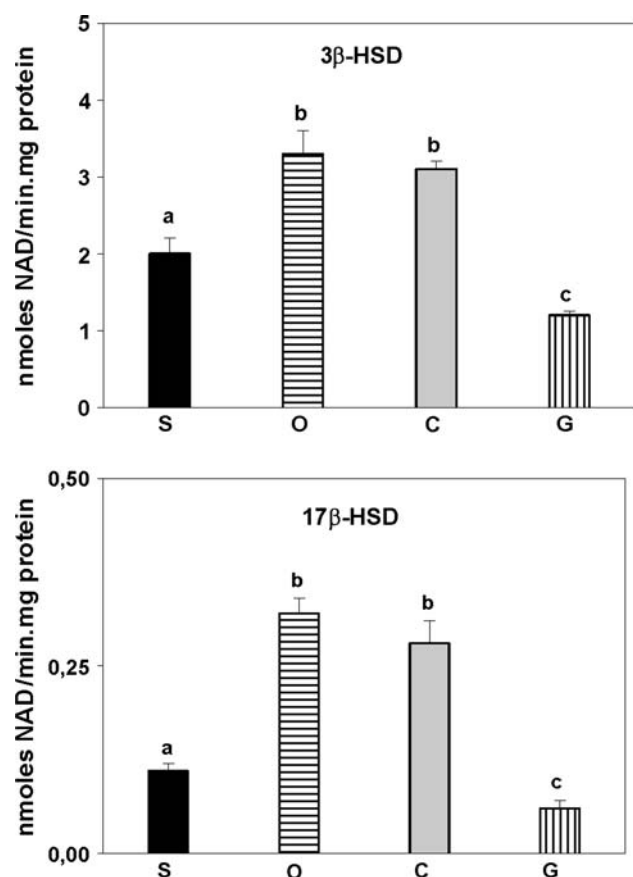

Fig. 1 Activities of the two key enzymes for testosterone biosynthesis: 3-beta-hydroxysteroid-dehydrogenase (3β -HSD) and 17-beta-hydroxysteroid dehydrogenase (17β -HSD) in interstitial cells from rats fed different diets (S soybean, O olive, C coconut, and G grape-seed oil-supplemented diet). Results presented as mean \pm 1 SD, $n = 10$. Different superscript letters indicate values significantly different ($P < 0.01$) as determined by one-way ANOVA and Tukey's post hoc test

As described in our paper, LH levels were elevated in Diets S and G compared to the other experimental groups. This stimulation may adversely affect the activity of the cholesteryl-side chain cleavage enzyme, and consequently, it may contribute to the inhibition of androgen production by decreasing the concentration of the precursor.

We also observed that the side chain of the esterified cholesterol is strongly influenced by the type of lipid present in the diet. This finding was in agreement with previous experimental evidence indicating that the composition of the cholesteryl esters in testis is more strongly affected than that of the other lipid subclasses [7].

The lipid changes we observed could also be involved in other mechanism(s) of action which depend on the physicochemical properties of interstitial cell membranes. It is well known that alterations in lipid proportions and/or fatty acyl chains acylated to complex lipids strongly influence several processes that occur in the cytoplasm and in the inner cell membranes, such as mitochondrial membranes

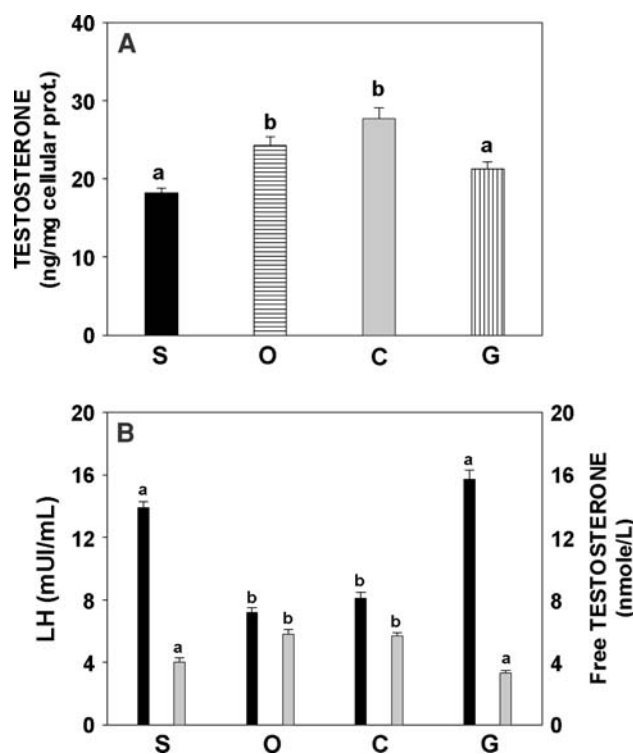

Fig. 2 Hormonal levels measured by RIA methodology for interstitial cells (a) or plasma (b) from rats fed different diets (S soybean, O olive, C coconut, and G grape-seed oil-supplemented diet). Values of free testosterone for interstitial cells were expressed as ng/mg cellular protein, and they were the mean \pm SD of ten independent determinations. Bars of b correspond to the concentration of LH (black mUI/mL) or free testosterone (gray nmole/L) in peripheral plasmas and they are the mean \pm SD of ten independent determinations. Statistical analyses were performed as indicated in "Materials and methods". In all cases different superscript letters indicate values significantly different ($P < 0.01$) as determined by one-way ANOVA and Tukey's post hoc test

[48–51]. Receptor-mediated signal transduction and even free cholesterol transport to the inner mitochondrial membrane are examples of processes that should be affected by lipid composition. It is well documented that the phospholipid content and the type of fatty acids acylated to phospholipids were both influenced by dietary manipulation and caused alterations on membrane-mediated gonadotropin action in testicular tissues [7].

Previous reports from other laboratories have described the stimulating effect of arachidonyl-CoA or free arachidonate on the activity of StAR protein and cholesterol transport into the mitochondria for androgen production [52]. Arachidonate involved in these regulatory processes would be obtained from the cholesteryl ester pool via the ACS4/Acot2 system [53] without the intervention of phospholipase A₂ [54]. The proportion of arachidonyl-side chains within the esterified cholesterol pool would probably regulate the proportion of free cholesterol available for testosterone biosynthesis. This speculation was not evident

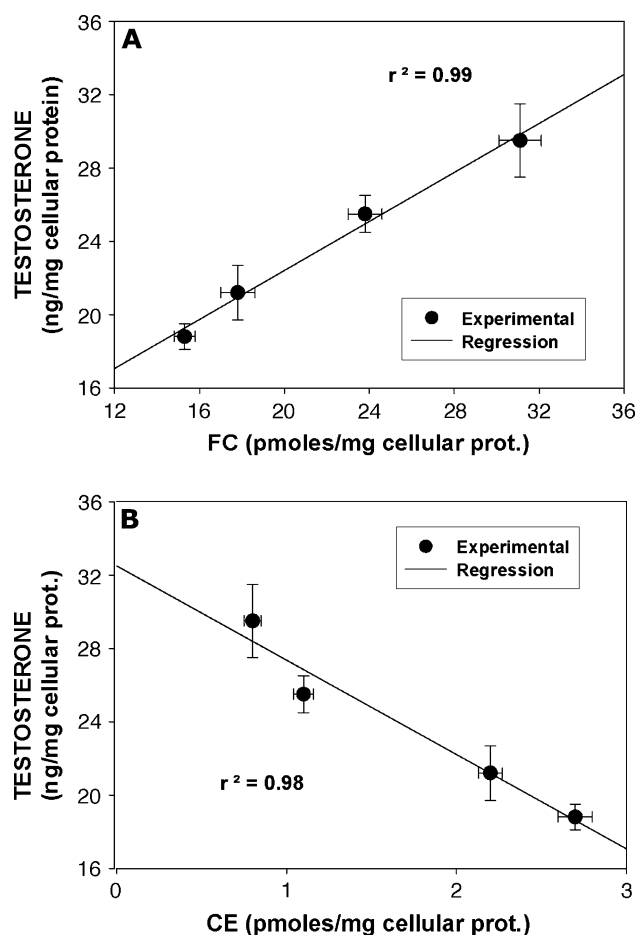

Fig. 3 Linear correlation coefficient (r^2) for regression plots between testosterone production by interstitial cells and (a) free cholesterol (FC) or (b) cholesterol ester (CE) levels. Data from Figure 1 and Table 4 were plotted and analyzed using the software described in “Materials and Methods”

from the compositional data. However, we demonstrated that the level of esterified cholesterol increased in the order $O > C > S > G$, while the level of the acylated cholesterol increased in the opposite way ($G > S > C > O$). Moreover, a positive linear correlation between androgen production and FC was evident, while this correlation became negative when CE was considered as the independent variable.

Data obtained from other laboratories also provide substantial support for the hypothesis that fat ingestion is sexually differentiated in humans. The regulatory stimuli controlling the consumption of fat arise from oral, gastric, intestinal, hepatic, and adipose sites [55]. However, environmental factors may modify this physiological behavior. In the past decades, a progressively significant worldwide decline in semen quality and androgenic performance was reported [56–59]. Within the environmental factors that determine this phenomenon, increasing pollutants for example [59–61], we think that lipid composition of the

diet should be considered as one of the most important. Future research in this area may contribute to the understanding of the mechanism(s) involved and also the prevention of the damage induced by an inadequate diet.

Acknowledgments The authors are grateful to Eva Illara de Bozzolo and Cristina Pallanza de Stringa for excellent technical assistance. This study was partially supported by grants from Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) and Universidad Nacional de La Plata (UNLP), Argentina.

Abstract Ricinoleate, a monohydroxy fatty acid, in castor oil has many industrial uses. Dihydroxy fatty acids can also be used in industry. The C_{18} HPLC fractions of castor oil were analyzed by electrospray ionization mass spectrometry of lithium adducts to identify the acylglycerols containing dihydroxy fatty acids and the dihydroxy fatty acids. Four diacylglycerols identified were diOH18:1-diOH18:1, diOH18:2-OH18:1, diOH18:1-OH18:1 and diOH18:0-OH18:1. Eight triacylglycerols identified were diOH18:1-diOH18:1-diOH18:1, diOH18:1-diOH18:1-diOH18:0, diOH18:2-diOH18:1-OH18:1, diOH18:1-diOH18:1-OH18:1, diOH18:1-diOH18:0-OH18:1, diOH18:2-OH18:1-OH18:1, diOH18:1-OH18:1-OH18:1 and diOH18:0-OH18:1-OH18:1. The locations of fatty acids on the glycerol backbone were not determined. The structures of these three newly identified dihydroxy fatty acids were proposed as 11,12-dihydroxy-9-octadecenoic acid, 11,12-dihydroxy-9,13-octadecadienoic acid and 11,12-dihydroxyoctadecanoic acid. These individual acylglycerols were at the levels of about 0.5% or less in castor oil and can be isolated from castor oil or overproduced in a transgenic oil seed plant for future industrial uses.

Introduction

Ricinoleate (OH18:1, Fig. 1a), a monohydroxy fatty acid, has many industrial uses such as the manufacture of aviation lubricant, plastic, paint and cosmetics. Ricinoleate occurs as acylglycerols (AG) in castor oil, and about 70% of castor oil is triricinolein (triricinoleoylglycerol) [1]. Castor oil is the only commercial source of ricinoleate. We have previously identified and quantified 14 molecular species of AG containing ricinoleate in castor oil using high-performance liquid chromatography (HPLC) and mass spectrometry (MS) methods [1–4]. We report here, the identification of 12 molecular species of AG containing dihydroxy fatty acids in castor oil. These dihydroxy fatty acids are proposed as 11,12-dihydroxy-9-octadecenoic acid (11,12-dihydroxyoleic acid, diOH18:1, Fig. 1b), 11,12-dihydroxy-9,13-octadecadienoic acid (diOH18:2, Fig. 1c), and 11,12-dihydroxyoctadecanoic acid (11,12-dihydroxystearic acid, diOH18:0, Fig. 1d). These fatty acids and the AG containing these fatty acids (Fig. 2) have not been previously reported. Dihydroxy fatty acids in higher plants also have not been previously reported. Oleic acid could convert to 7(*S*),10(*S*)-dihydroxy-8(*E*)-octadecenoic acid [5] and ricinoleic acid could convert to 10,12-dihydroxy-8(*E*)-octadecenoic acid [6] in a microbial culture. 8*R*-Hydroxyoctadecadienoic acid could convert to some dihydroxyoctadecadienoic acids in microbial cultures [7]. Dihydroxy fatty acids occur as eicosanoids in animals (acting as localized hormones) and cannot be used in industry as a source due to their low contents [8].

The presence of a hydroxyl group on fatty acid drastically changes the physical properties of the oil, e.g., viscosity, pour point, melting point, heat of fusion, solubility, crystal structure, and polymorphism [9]. Because of the physical and chemical changes from the normal fatty

acids, many industrial uses of ricinoleate have been found. The physical and chemical properties of dihydroxy fatty acids and AG containing dihydroxy fatty acids are different from those of monohydroxy fatty acids and normal fatty acids. The dihydroxy fatty acids and AG containing dihydroxy fatty acids can be used in industry different from or similar to those of ricinoleate. These dihydroxy fatty acids have not been used in industry to date as there has been no practical source but, in the future it may be isolated from castor oil or produced by a transgenic oil seed plant.

Experimental Procedures

Materials

Castor oil, ricinoleate, 9,10-dihydroxyoctadecanoic acid, 12-hydroxyoctadecanoic acid and lithium acetate were obtained from Sigma (St Louis, MO, USA). HPLC and GC grade methanol and 2-propanol (Burdick & Jackson) for LC-MS were purchased from VWR International (West Chester, PA, USA). High-purity nitrogen for LC-MS was acquired from Praxair (Oakland, CA, USA). Research grade (99.999%) helium (Praxair) was used as a collision gas.

HPLC Fractionation of the Molecular Species of AG in Castor Oil

The fractionation of the molecular species of AG in castor oil was as previously reported [1]. Chromatographic fractionation was performed using a Waters HPLC (Waters Associate, Milford, MA, USA) and a C₁₈ analytical column (Gemini, 250 × 4.6 mm, 5 μm, C18, Phenomenex, Torrance, CA, USA). One mg of castor oil was chromatographed at 22 °C (room temperature) with a linear gradient from 100% methanol to 100% 2-propanol in 40 min, at a 1 mL/min flow rate, and detected at 205 nm. One-half minute fractions were collected and corresponding fractions were pooled from 15 HPLC runs. Fractions eluted before triricinolein (fraction #20, retention time 9.5–10.0 min) were used for MS studies. The final sample solutions were prepared for direct infusion into the mass spectrometer by combining approximately one-fourth of each fraction with 50 μL of a methanol solution of 100 mM lithium acetate and diluting it to a total volume of 200 μL. The same diluted sample solution was also used for high-resolution MS.

Electrospray Ionization Mass Spectrometry (ESI-MS)

An LCQ Advantage quadrupole ion-trap mass spectrometer with Xcalibur 1.3 software (ThermoFinnigan, San Jose, CA, USA) was utilized for MS analysis of the various molecular species of AG. The infusion at a 2.5 μL/min flow rate from a syringe pump produced stable singly charged lithiated parent ions which were subsequently fragmented for MS², MS³ and MS⁴ analysis. ESI source conditions were as follows: 50 arbitrary units (au) nitrogen sheath gas flow rate, 4.5 kV spray voltage, 250 °C ion-transfer capillary temperature, 1.5 m/z isolation width, 100–1,000 m/z mass range, 5 min acquisition time, 38 V capillary voltage and normalized collision energy ranging 35–39% for MS², MS³ and MS⁴ fragmentations, varying between molecular species of AG and fatty acids.

High-Resolution (HR) ESI-MS and MS/MS

Samples were analyzed by HR-ESI-MS using a hybrid quadrupole/time-of-flight (TOF) mass spectrometer (Q-STAR Pulsar I, MDS Sciex/ABI, Toronto, ON, Canada). The TOF mass analyzer was calibrated with two fragment ions generated by the collision-activated dissociation of the +2 charge state of glufibrogen (m/z 785.8). TOF resolution was typically 8,000–9,000 full width half maximum (fwhm). Eight microliter of the diluted sample solution (as described earlier) was loaded into an ESI spray capillary (NanoES, Proxeon Biosystems) using a 10 μ L gel pipette tip. The spray capillary was centrifuged briefly to displace air in the end of the closed spray capillary. The spray capillary was mounted onto the source head, and a backing pressure of 1–8 atm was applied from a 10 mL glass Luer-lock glass syringe. MS instrument parameters were as follows: 1,800 V spray voltage; 15 au of current gas; m/z 100–2,000 mass range; 1 s accumulation time; 3 min acquisition time; 50 au of declustering potential; 220 V focusing potential; 15 au second declustering potential; 11 μ s ion release delay; and 10 μ s ion release width. For MS/MS experiments, the collision gas setting was 5 au and the collision energy setting was 70 au. High-purity nitrogen, used for the curtain and a collision gas, was supplied from liquid nitrogen boil off from a large Dewar flask.

Results and Discussion

Castor oil was fractionated by reversed-phase C_{18} HPLC and the fractions that eluted before triricinolein (fraction #20, 0.5 min/fraction) were used for MS studies. The HPLC chromatogram of castor oil using this HPLC system was previously reported [1]. Fractions #9, 10, and 11 contained diacylglycerols according to the MS studies. Figure 3 is the MS^2 spectrum of diacylglycerol, dihydroxyoleoyl-ricinoleoyl-glycerol (diOH18:1-OH18:1), in fraction #9. The spectrum shows the fragment ions from the losses of dihydroxyoleate and ricinoleate as $[M + Li - diOH18:1]^+$ at m/z 361.2 and $[M + Li - OH18:1]^+$ at m/z 377.2. The two free fatty acids are also shown as $[diOH18:1 + Li]^+$ at m/z 321.2 and $[OH18:1 + Li]^+$ at m/z 305.3. Two other significant ions are $[M + Li - C_6H_{13}CHO]^+$ at m/z 561.4 and $[M + Li - C_5H_{11}CH=C=O]^+$ at m/z 563.4. The fragment ions from the loss of $C_6H_{13}CHO$ and $C_5H_{11}CH=C=O$ are also shown in Fig. 5. Similar to Fig. 3, Fig. 4 is the high-resolution MS^2 spectrum of dihydroxyoleoyl-ricinoleoyl-glycerol (diOH18:1-OH18:1) from HPLC fraction #9. The measured high-resolution masses, $[diOH18:1 + Li]^+$ at m/z 321.2601 and $[diOH18:1-OH18:1 + Li]^+$ at m/z 675.5319

matched well with the calculated masses of m/z 321.2617 and m/z 675.5387 individually.

Figure 5 is the MS^3 spectrum of dihydroxyoleate $[diOH18:1 + Li]^+$ at m/z 321.2. Three significant fragment ions are $[diOH18:1 + Li - H_2O]^+$ at m/z 303.2, $[diOH18:1 + Li - C_5H_{11}CH=C=O]^+$ at m/z 209.2 and $[diOH18:1 + Li - C_6H_{13}CHO]^+$ at m/z 207.1. The loss of $C_6H_{13}CHO$ (or shown earlier as $C_7H_{14}O$) has been previously reported [3, 4, 10] from the cleavage between C-11 and C-12 of the ricinoleoyl chain for TAG containing ricinoleate. The proposed fragmentation pathway of this ion at m/z 207.1 is shown as Fig. 6a. The fragmentation showed the cleavage was between C-11 and C-12 of diOH18:1 and the two hydroxyl groups were at both side of the cleavage. The fragment ion at m/z 207.1 had gained an extra hydrogen atom from the hydroxyl group at the C-12 position as shown in Fig. 6a. The location of this 12-hydroxyl group of diOH18:1 is the same as that of the 12-hydroxyl group of ricinoleate (Fig. 1a). The loss of ketene, $C_5H_{11}CH=C=O$, also has been previously reported [4, 11]. The proposed fragmentation pathway of the ion at m/z 209.2 is shown as Fig. 6b. The fragment ion at m/z 209.2 had gained three extra hydrogen atoms from the other side of the carbon-carbon cleavage between C-11 and C-12 of diOH18:1 as shown in Fig. 6b. Comparing between the MS spectra of diOH18:1 (Fig. 5) and ricinoleate (Fig. 7), the spectrum of ricinoleate $[OH18:1 + Li]^+$ at m/z 305.3 showed only the significant fragment ions of $[OH18:1 + Li - C_6H_{13}CHO]^+$ at m/z 191.1 and $[OH18:1 + Li - H_2O]^+$ at m/z 287.2, and the ion from the loss of ketene $[OH18:1 + Li - C_5H_{11}CH=C=O]^+$ at m/z 193 was not detected. Apparently the hydroxyl group at the C-11 position facilitated the fragment ion at m/z 209.2 (Fig. 5). The location of this hydroxyl group other than C-11 could not cause the cleavage between C-11 and C-12 as well as the fragmentation from the loss of ketene. We propose the structure of diOH18:1 as being 11,12-dihydroxy-9-octadecenoic acid (Fig. 1b) and the two hydroxyl groups are attached to adjacent carbon atoms at the C-11 and C-12 positions.

Figure 8 is the MS^4 spectrum of dihydroxyoctadecadienoic acid $[diOH18:2 + Li]^+$ at m/z 319.3. This was originated from the MS^2 of dihydroxyoctadecadienoyl-diricinoleoyl-glycerol $[M + Li]^+$ at m/z 953.6 from the HPLC fraction #15 of castor oil and then MS^3 of $[M + Li - OH18:1]^+$ at m/z 655.5. In the MS^2 spectrum, the relative abundance of $[diOH18:2 + Li]^+$ at m/z 319.3 was very low (2%) and we need to use the ion at m/z 319.3 in MS^3 spectrum (26%) for the MS^4 spectrum of $[diOH18:2 + Li]^+$ at m/z 319.3. Figure 8 shows three significant fragment ions, $[diOH18:2 + Li - H_2O]^+$ at m/z 301.2, $[diOH18:2 + Li - C_4H_6CH=C=C=O]^+$ at m/z 209.1 and $[diOH18:2 + Li - C_5H_{11}CH=CHOH]^+$ at m/z 205.2. The proposed fragmentation pathway to m/z 205.2 is shown as Fig. 6c. The proposed fragmentation pathway to

Fig. 4 Centroided high-resolution ESI-MS² mass spectrum of dihydroxyoleyl-ricinoleoyl-glycerol $[M + Li]^+$ at m/z 675.53 in the HPLC fraction #9 of castor oil. diOH18:1 dihydroxyoleate, OH18:1 ricinoleate, C₅H₁₁CH=C=O ketene

Fig. 5 Ion trap mass spectrum of ESI-MS³ of dihydroxyoleate $[diOH18:1 + Li]^+$ at m/z 321.2 (collision energy 36%). This was from $[diOH18:1 + Li]^+$ at m/z 321.2 shown in Fig. 3. For abbreviations, see Fig. 3. For proposed fragmentation pathways, see Fig. 6a and b

ion at m/z 209.1 is the same as that of Fig. 6b. We propose the structure of diOH18:2 as 11,12-dihydroxy-9,13-octadecadienoic acid (Fig. 1c).

Figure 9 is the MS⁴ spectrum of dihydroxyoctadecanoic acid $[diOH18:0 + Li]^+$ at m/z 323.3. This was originated from MS² of dihydroxyloctadecanoyl-diricinoleoyl-glycerol

Fig. 6 Proposed fragmentation pathways of dihydroxy fatty acids. **a** [diOH18:1 + Li – C₆H₁₃CHO]⁺ at *m/z* 207.1 shown in Fig. 5. **b** [diOH18:1 + Li – C₅H₁₁CH=C=O]⁺ at *m/z* 209.2 shown in Fig. 5. The cleavage of the bond between C-11 and C-12, the electron pair transfer *a*, was after the formation of the double bond at the C-10 position (*a*). The electron pair transfer *b* to the hydrogen atom at C-12 is after the migration of the hydrogen atom at C-13 to C-11 (*b*). **c** [diOH18:2 + Li – C₅H₁₁CH=CHO]⁺ at *m/z* 205.2 shown in Fig. 8

Fig. 7 Ion trap mass spectrum of ESI-MS² of ricinoleate standard (collision energy 36%)

[M + Li]⁺ at *m/z* 957.7 from the HPLC fraction #15 of castor oil and then MS³ of [M + Li – OH18:1]⁺ at *m/z* 659.5. Again in the MS² spectrum, the relative abundance of [diOH18:0 + Li]⁺ at *m/z* 323.3 was very low (2.5%) and we need to use the ion at *m/z* 323.3 in the MS³ spectrum (48%) for the MS⁴ spectrum of [diOH18:0 + Li]⁺ at *m/z* 323.3. Figure 9 shows only one significant fragment ion. The ion at *m/z* 305.2 was the dehydration of the precursor ion [diOH18:0 + Li – H₂O]⁺. The locations of the two hydroxyl groups of diOH18:0 were likely to be the same as those of the diOH18:1 and diOH18:2 (Fig. 1b, c). The standard 11,12-dihydroxyoctadecanoic acid is not commercially available. Instead we used the standard, 9,10-dihydroxyoctadecanoic acid, for MS² (spectrum not given here) to compare with Fig. 9 of diOH18:0 from castor oil. These two MS spectra were similar when the same collision energy 37% was used including the relative abundances of the precursor ions (about 23%). The MS spectrum of

standard 12-hydroxyoctadecanoic acid (not given here) at the same collision energy 37% also showed the only one significant fragment ion [OH18:0 + Li – H₂O]⁺ at *m/z* 289.2. However, the relative abundance of the precursor ion was only 1.5%. This suggested that the diOH18:0 in castor oil contained two hydroxyl groups attached to adjacent carbon atoms. The dehydration [diOH18:0 + Li – H₂O]⁺ with two hydroxyl groups attached to adjacent carbon atoms on the fatty acid chain required more collision energy than that of [OH18:0 + Li – H₂O]⁺ with monohydroxyl group on the chain. We propose here the structure of diOH18:0 as 11,12-dihydroxyoctadecanoic acid (Fig. 1d).

The three new dihydroxy fatty acids were confirmed, within 5 ppm of the calculated exact mass, by duplicate high-resolution accurate mass MS² measurements of their lithium adducts (Table 1). An example of an accurate mass MS² spectrum is shown in Fig. 4. The measured masses of the lithium adducts of diOH18:2 and diOH18:0 were from

Fig. 8 Ion trap mass spectrum of ESI-MS⁴ of dihydroxyoctadecadienoic acid [diOH18:2 + Li]⁺ at *m/z* 319.3 (collision energy 39%). This was from the MS² (collision energy 35%) of [diOH18:2-OH18:1-OH18:1 + Li]⁺ at *m/z* 953.6 from the HPLC fraction #15 of castor oil and then the MS³ (collision energy 38%) of [diOH18:2-OH18:1-OH18:1 + Li - OH18:1]⁺. For proposed fragmentation pathways, see Fig. 6b and c

Fig. 9 Ion trap mass spectrum of ESI-MS⁴ of dihydroxyoctadecanoic acid [diOH18:0 + Li]⁺ at *m/z* 323.3 (collision energy 37%). This was originated from MS² (collision energy 36%) of [diOH18:0-OH18:1-OH18:1 + Li]⁺ at *m/z* 957.7 from the HPLC fraction #15 of castor oil and then MS³ (collision energy 39%) of [diOH18:0-OH18:1-OH18:1 + Li - OH18:1]⁺ at *m/z* 659.5

the high-resolution MS² spectra (not shown here) of [diOH18:2-OH18:1 + Li]⁺ at *m/z* 673.52 and [diOH18:0-OH18:1 + Li]⁺ at *m/z* 677.55 individually from the HPLC fraction #9. The errors were 5 ppm or less.

Figure 2 shows the four diacylglycerols and eight triacylglycerols containing dihydroxy fatty acids in castor oil identified by MS. The stereospecific locations of fatty acids on the glycerol backbones were not determined. The mass *m/z* of AG lithium adducts are also given in Fig. 2. Similar to Fig. 3, AG molecular species in Fig. 2 were identified by MS² of the individual AG lithium adducts. The MS² spectra (not shown here) showed the fragment ions from the loss of fatty acids, diOH18:2 *m/z* 312.2, diOH18:1 *m/z* 314.2, diOH18:0 *m/z* 316.2 and OH18:1 *m/z* 298.2. The MS³ (from diacylglycerols) and MS⁴ (from triacylglycerols) spectra (not shown here) of the dihydroxy fatty acids showed that these dihydroxy fatty acids were the same as those of the Figs. 5, 8 and 9.

Table 1 Calculated masses and duplicated measured masses by high-resolution MS² of lithium adducts of dihydroxy fatty acids [diOH-FA + Li]⁺ from the diacylglycerols in castor oil

diOH-FA	Calculated mass	Measured mass	Error in ppm
[diOH18:2 + Li] ⁺ ^a	319.2461	319.2446	5
[diOH18:2 + Li] ⁺ ^a	319.2461	319.2458	1
[diOH18:1 + Li] ⁺ ^b	321.2617	321.2601	5
[diOH18:1 + Li] ⁺ ^b	321.2617	321.2602	5
[diOH18:0 + Li] ⁺ ^c	323.2774	323.2760	4
[diOH18:0 + Li] ⁺ ^c	323.2774	323.2763	3

^a From the MS² of [diOH18:2-OH18:1 + Li]⁺ at *m/z* 673.52

^b From the MS² of [diOH18:1-OH18:1 + Li]⁺ at *m/z* 675.54

^c From the MS² of [diOH18:0-OH18:1 + Li]⁺ at *m/z* 677.55

In this HPLC fractionation, some AG detected by MS was eluted in many fractions (0.5 min/fraction). Individual AG in Fig. 2 were eluted in the fractions as: diOH18:1-

diOH18:1 (fractions #9–11), diOH18:2-OH18:1 (fractions #9, 10), diOH18:1-OH18:1 (fractions #8–12), diOH18:0-OH18:1 (fraction #9), diOH18:1-diOH18:1-diOH18:1 (fractions #11–14), diOH18:1-diOH18:1-diOH18:0 (fraction #13), diOH18:2-diOH18:1-OH18:1 (fraction #15), diOH18:1-diOH18:1-OH18:1 (fractions #12–18), diOH18:1-diOH18:0-OH18:1 (fractions #13–14), diOH18:2-OH18:1-OH18:1 (fraction #15), diOH18:1-OH18:1-OH18:1 (fractions #13–18), diOH18:0-OH18:1-OH18:1 (fractions #15–16). The HPLC resolutions of these AG containing dihydroxy fatty acids were not good and the accurate quantifications of these AG were difficult. However, according to the HPLC chromatogram of castor oil detected by evaporative light scattering detector using the same HPLC conditions published earlier [1]; the individual AG containing dihydroxy fatty acids were about 0.5% of castor oil or less. The total AG containing dihydroxy fatty acids was about 2.5% of castor oil. These AG were eluted before triricinolein. Among these 12 AG (Fig. 2), the contents of triacylglycerols diOH18:1-OH18:1-OH18:1, diOH18:0-OH18:1-OH18:1, diOH18:1-diOH18:1-OH18:1, diOH18:1-diOH18:0-OH18:1 and diacylglycerol diOH18:1-OH18:1 were higher than those of the other AG in castor oil.

We have reported the identification of 12 molecular species of acylglycerols containing dihydroxy fatty acids in castor oil. The structures of the three dihydroxy fatty acids were proposed as 11,12-dihydroxy-9-octadecenoic acid, 11,12-dihydroxy-9,13-octadecadienoic acid and 11,12-dihydroxyoctadecanoic acid.

Abstract Here we describe a study of the feasibility of lipid and phospholipid (PL) profiling using matrix assisted laser desorption/ionization (MALDI) Fourier transform mass spectrometry (FTMS) for two different applications. In this work PL profiles of different mammalian tissues as well as those of whole cell organisms were examined. In particular, comparative analysis of lipid and PL profiles of tissues from mice fed different diets was done and, in another application, MALDI FTMS was used to analyze PL profiles of genetically modified *Saccharomyces cerevisiae*. Computational sorting of the observed ions was done in order to group the lipid and PL ions from complex MALDI spectra. The PL profiles of liver tissues from mice fed different diets showed a cross correlation coefficient of 0.2580, indicating significant dissimilarity, and revealed more than 30 significantly different peaks at the 99.9% confidence level. Histogram plots derived from the spectra of wild type and genetically modified yeast resulted in a

cross correlation coefficient 0.8941 showing greater similarity, but still revealing a number of significantly different peaks. Based on these results, it appears possible to use MALDI FTMS to identify PLs as potential biomarkers for metabolic processes in whole cells and tissues.

Keywords Matrix assisted laser desorption/ionization mass spectrometry (MALDI) · Fourier transform mass spectrometry (FTMS) · *Saccharomyces cerevisiae* · Yeast transcription factor Met4 · High fat diet

Introduction

Analysis of phospholipids (PLs) by matrix assisted laser desorption/ionization (MALDI) was first described by Harvey [1] over a decade ago. Around the same time, Marshall et al. reported initial experiments for MALDI Fourier transform mass spectrometry (FTMS) of a number of biological PLs [2]. Since then, MALDI FTMS also has been successfully used for analysis of di-acyl PL profiles of whole cell organisms [3, 4] and mammalian tissues [5]. Lipid compositions as main components [6] of cell membranes are vital for the physiological functionality of biological cells. Cellular signaling, metabolic processes, structural functions and regulatory roles are some of the processes where PLs are important [7, 8]. As demonstrated in 2006, MALDI FTMS allows rapid and precise monitoring of PL profiles of different types of mouse tissues (brain, heart and liver) [5].

This study aimed to apply the proposed approaches [3–5] to real biological problems in an optimized manner. Two different biological problems were selected, (1) monitoring the impact of high fat diets on PL profiles of *Mus musculus*

(house mouse) and (2) evaluating the role of the yeast transcriptional regulator Met4 in PL homeostasis. Here the exceptional potential of MALDI high-resolution mass spectrometry ($>10^4$) for rapid, automated metabolite screens of complex biological samples is shown. This will allow researchers to achieve broader understanding of metabolic and signaling processes involving PLs.

Experimental Procedure

Reagents

The MALDI matrix used was 99% purity 2,5-dihydroxybenzoic acid (DHB) (Alfa Aesar, Shore Road, Heysham, Lancaster). Methanol was HPLC grade (EMC Chemical Inc., Gibbstown, NJ). Purified water was obtained from a Mill-Q gradient system (Millipore Corporation, Genay Cedex, France). The AIN-93G high fat diet was obtained from Dyets Inc., Bethlehem, PA. Trichloroacetic acid (TCA) was purchased from VWR, West Chester, PA.

Animal Care and Tissue Isolation

All animals were reared at Vanderbilt University. The protocols used in this study were performed and approved by the Institution for Animal Care and Use Committee of Vanderbilt University. Low density lipoprotein receptor LDLR $-/-$ mice on a C57BL/6J background were placed on high fat diets (39% calories from fat and 0.5% cholesterol) supplemented with 6% olive oil or 6% fish oil for 12 weeks. The fish oil in the mouse diet contained 140 mg eicosapentaenoic acid (EPA) and 95 mg docosahexaenoic acid (DHA) per gram of oil. The liver was removed, weighed and snap frozen before doing a MALDI FTMS analysis. Further experimental details are published elsewhere [9]. As matrix for homogenizing the frozen liver tissues, 1 M DHB in methanol/water (80:20, by volume) with 7.5% TCA was used.

Saccharomyces cerevisiae Growth Conditions

To analyze PL profiles of yeast, both wild type (wt) and mutant were grown in YEPD medium (1% yeast extract, 2% Bacto Peptone, 2% glucose, 0.04 g/L adenine sulfate, 0.04 g/L uracil) at 30 °C to mid-log phase ($OD_{600} = 1$). Yeast cells were harvested by filtration and washed in water. Washed cells were lysed in isopropanol with glass beads for 90 s at setting 4.5 in FastPrepTM FP120. Cell debris was separated by centrifugation (10 min 13,000 g). The supernatant was stored in dark tubes under nitrogen and analyzed within 2 days by MALDI FTMS. Yeast mutants lacking the *MET4* gene were generated by deleting

the entire open reading frame using a PCR-based strategy [10]. For MALDI FTMS a saturated solution of DHB in methanol/Mill-Q water (70:30 by volume) was used as matrix.

Instrumentation and Data Analysis

MALDI FTMS analysis was performed using the positive ion mode of a 9.4 Tesla FTMS (IonSpec/Varian, Lake Forest, CA) with an external ion source and a Nd-YAG laser operating at $\lambda = 355$ nm. PL assignments were accomplished via an optimized Windows version 3.8.28 of a lipid database and search program, utilizing a previously published assignment algorithm [4].

Results and Discussion

Following the methodology described above, reproducible MALDI FTMS spectra were observed. Figure 1 shows spectra of liver tissues from mice fed with different high fat diets. The spectra observed can be divided into three regions based on m/z values. PL fragment ions (PL-Hg) are found in the low mass region (550–700 m/z); PL ions such as those from phosphatidic acid (PA), phosphatidylethanolamine (PE), and phosphatidylcholine (PC) are found in the middle mass region (700–850 m/z); and the triacylglyceride ions (TAG) appear in the high mass region (850–1,000 m/z).

Triacylglycerides are of importance in this comparison because they are the major components of edible oils [11, 12]. In 2006 Lay et al. [11] observed that with the use of MALDI time-of-flight (TOF) mass spectrometry that edible oils can be identified through their TAG content. It is evident from the spectra shown in Fig. 1 that liver tissues from mice fed with the olive oil diet contain more TAG compared with liver tissues from mice fed with the fish oil diet. On the contrary, liver samples from fish oil fed mice have elevated PL contents compared with those from olive oil fed mice. The PLs and TAG content of the samples were binned together and a cross correlation calculation was done. The histogram correlation (Fig. 2) between the two samples is 0.2580 showing the expected low correlation. Based on these results, mice fed fish oil have lower TAG content than mice fed olive oil.

The results obtained in this study using MALDI FTMS are comparable to those obtained by Saraswathi et al. [9] using fatty acid methyl ester (FAME) analysis, wherein it was observed that the total TAG concentration in the liver for mice fed with the olive oil diet (74 mg/g tissue) is greater than that found in livers of fish oil fed mice (59 mg/g tissue). Although the biological importance of increased PLs in mice fed fish oil is not clear, our study demonstrates

Fig. 1 Representative spectra of liver tissues from mice fed high fat diets supplemented with 6% olive oil (*top*) and 6% fish oil (*bottom*). The spectra are divided into three regions **a** phospholipid fragments (PL-Hg) **b** PA phospholipids, PC, PE, etc., and **c** TAG triacylglycerides

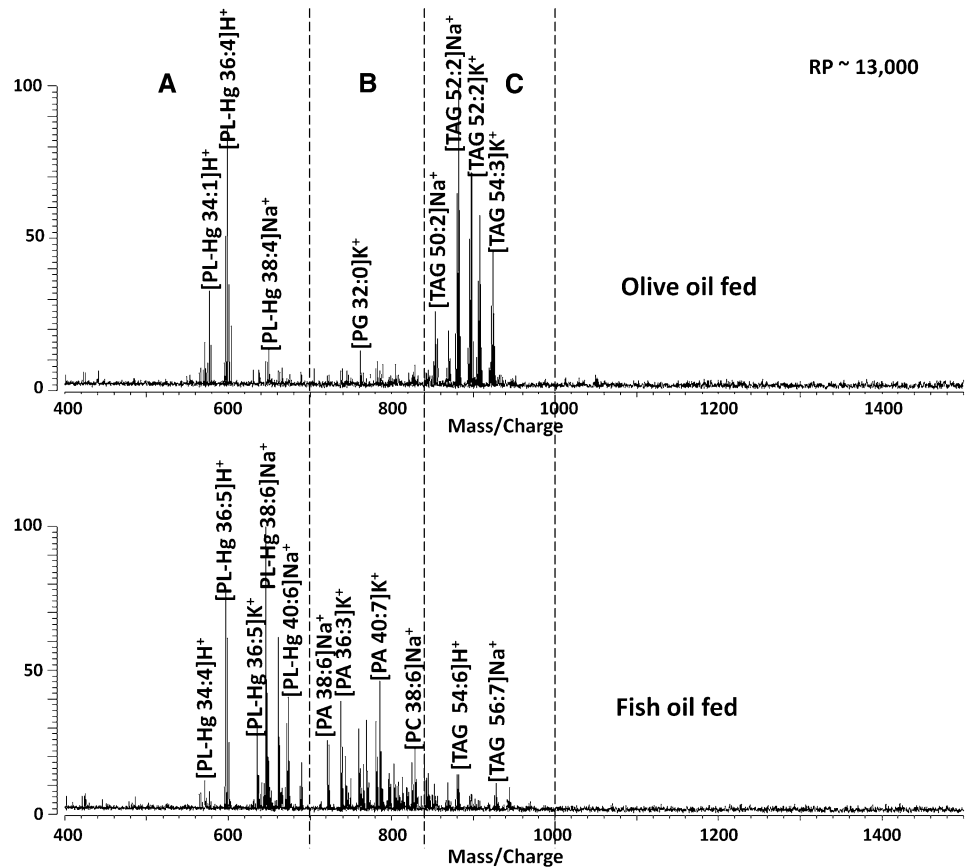

Fig. 2 Histogram plot of lipid and phospholipids found in liver tissues from mice fed a high fat diet supplemented with 6% olive oil (*top*) and fish oil (*bottom*)

that MALDI FTMS can be used to better characterize the PL species in biological samples. Several previous studies have analyzed the relationship between fish oil diets and

hypertriglyceridemia [13, 14] and all of their results reveal that dietary fish oil supplements reduce plasma TAG levels. The differences in their TAG content may be attributed to

Fig. 3 Representative MALDI FTMS spectra of wild type (wt) *S. cerevisiae* (top) and *met4Δ* mutant

the fish oil's ability to reduce hepatic triacylglyceride synthesis [9, 15]. Hypertriglyceridemia and hepatic steatosis have been linked to their contribution to cardiovascular diseases and diabetes [16, 17].

We also applied our PL profiling strategy to analyze the role of the Met4 transcription factor in PL homeostasis. The activity of Met4 is tightly regulated by the ubiquitin ligase SCF^{Met30} [18]. Met30 the substrate specificity factor within this ubiquitin ligase has previously been linked to PL homeostasis based on genetic studies [18]. We were therefore interested in testing whether Met4 is involved in lipid homeostasis, given that its regulator was connected to lipid metabolism. Met4 is best known as a master regulator that coordinates the expression of genes involved in the synthesis of sulfur containing amino acids which include methionine, cysteine, and *S*-adenosylmethionine. Met4 can also induce a cell cycle arrest and thus links metabolic pathways with cell proliferation to protect cellular integrity when key metabolites are suboptimal [19, 20]. To investigate a potential role of Met4 in lipid metabolism we lysed wild type cells (wt) and *met4Δ* mutants, which lack the entire *MET4* gene and analyzed the lysates by MALDI FTMS. Representative spectra of the two strains are shown in Fig. 3. Although the most abundant ions are PL fragments, this does not necessary mean that these are the most

important ions. Based on the spectra, it is not evident which PLs differ, however when histogram plots (Fig. 4) derived from the spectra were cross-correlated, the correlation coefficient was 0.8941. Yeast lysates that lack the Met4 transcription factor (*met4Δ*) contain lower PL compared with lysates from wt samples based on the relative abundances of the binned PL peaks. This shows that inactivation of Met4 in yeast cells reduces the presence of PA, PC and PE. These results clearly link the transcriptional activator Met4 to lipid homeostasis in yeast. Since Met4 coordinates metabolic pathways with cell proliferation it is tempting to speculate that the Met4 pathway coordinates lipid homeostasis and cell cycle progression. Further studies will be required to dissect these functions and the role of other components in the Met4 system, but this analysis demonstrates that application of the MALDI FTMS strategy to a genetic model system is effective in linking gene function to lipid homeostasis.

To summarize, the use of MALDI FTMS has been demonstrated as a tool for PL profiling both in microorganisms with different genetic components as well as in mammalian tissues from mice fed different high fat diets. Our data have implications in understanding the cellular pathways involved in the biosynthesis and/or transport of PLs.

Abstract In order to measure exactly the *trans*-fatty acids content in food materials, a preparative group separation of *cis*- and *trans*-isomers of unsaturated fatty acid methyl esters (FAMES) was achieved by an isocratic reversed-phase HPLC (RP-HPLC) method. The *trans*-isomers of 16:1, 18:1, 18:2, 18:3, 20:1 and 22:1 FAMES were readily separated from the corresponding *cis*-isomers by a COSMOSIL Cholester C18 column (4.6 mm I.D. × 250 mm, Nacalai Tesque) or a TSKgel ODS-100Z column (4.6 mm I.D. × 250 mm, TOSOH), using acetonitrile as the mobile phase. This method was applied for determining the *trans*-18:1 fatty acid content in partially hydrogenated rapeseed oil. The methyl esters of *cis*- and *trans*-18:1 isomers of the oil were collected as two separate fractions by the developed RP-HPLC method. Each fraction was analyzed by gas chromatography (GC) for both qualitative and quantitative information on its positional isomers. By a combination of RP-HPLC and GC methods, a nearly complete separation of *cis*- and *trans*-18:1 positional isomers was achieved and the *trans*-18:1 fatty acid content was able to be evaluated more precisely than is possible by the direct GC method. The reproducibility of *cis*- and *trans*-18:1 isomers fractionated by the RP-HPLC method was better than 98%. These results suggested that the preparative RP-HPLC method developed in this study could be a powerful tool for *trans*-fatty acid analysis in edible oils and food products as an alternative to silver-ion chromatography.

Introduction

The health risks of *trans*-fatty acids have been discussed for many years. It has been pointed out that excess consumption of *trans*-fatty acids increases the risk of coronary heart disease [1–3]. Therefore, some countries have issued regulations requiring manufacturers to label *trans*-fatty acid levels among the nutritional facts. These rules have prompted efforts to optimize the analysis of *trans*-fatty acid levels in food products. Such analysis is not so easy because of the wide range of positional monoene, diene and trine isomers. Generally, *trans*-fatty acid analysis is conducted by gas chromatography (GC) according to the official methods proposed by the academic societies [4, 5]. By the direct GC method, positional and geometrical isomers of monounsaturated fatty acid methyl esters (FAMES) can be resolved to some extent, but some of the *cis*-isomers overlap with the *trans*-isomers [6]. On the other hand, complete separation of *cis*- and *trans*-isomers of monounsaturated FAMES can be achieved by silver-ion chromatography (TLC or HPLC) and reversed-phase HPLC (RP-HPLC) prior to GC analysis. Among these methods, the silver-ion thin-layer chromatography (Ag-TLC) method is widely in use. But, Ag-TLC has some disadvantages; the most obvious being that it is a laborious process. The silver-ion HPLC method also has considerable potential for the separation of positional and configurational isomers of unsaturated fatty acids [7, 8]. Its difficulties include the low reproducibility and the contamination by a trace of silver salts into the fraction. Furthermore, small cartridge columns packed with a

bonded benzene sulfonate medium can be loaded with silver ions and used to achieve excellent separation of FAMES according not only to the geometrical configuration of the unsaturated bond but also to the degree of unsaturation [9].

As for the RP-HPLC method for preparative separation, Sevansson et al. first reported the geometric separation of long chain monounsaturated fatty acids by the RP-HPLC method [10]. Although RP-HPLC separation has been improved upon by various researchers [11–14], the method has not prevailed. In the previous RP-HPLC methods, plural HPLC columns and/or a gradient HPLC with polar organic solvents and water were needed for complete separation of *trans*- and *cis*-isomers of unsaturated FAMES. As a result, the volume of each fraction was considerably enlarged and its solvent contained water. These facts complicated the subsequent GC analysis.

The purpose of this study was to improve the RP-HPLC method for obtaining pure preparative fractions of *cis*- and *trans*-isomers of unsaturated FAMES. Recently, several RP-HPLC columns that can recognize the geometrical configuration of unsaturated double bonds in fatty acids have been developed. In this study, we selected two kinds of RP-HPLC columns in advance and examined the retention times of standard FAMES containing unsaturated *cis*- and *trans*-isomers using each column. After that, the method was applied to determine the exact *trans*-18:1 content of partially hydrogenated rapeseed oil.

Materials and Methods

Reagents

The chemical reagents were obtained from Wako Chem. Inc. (Osaka, Japan) and Sigma Chemicals Co. (St. Louis, MO, USA). Acetonitrile for the HPLC solvent was of analytical grade (Wako). Standard fatty acid methyl esters (FAMES) were purchased from SUPELCO (Bellefonte, PA, USA) and Funakoshi Co. Ltd. (Tokyo, Japan). Partially hydrogenated rapeseed oil was kindly donated by Tuki-shima Shokuhin Co. Ltd. (Tokyo, Japan). This oil was converted into corresponding FAMES using NaOH/methanol (0.5 mol/L) and BF₃/methanol (14%) according to the AOCS official method 2d-66.

HPLC Analysis

Separation of FAMES by the HPLC method was carried out on a solvent pump (JASCO 880-PU), a column oven (Shimadzu CTO-20AC), a UV spectrometer (Shimadzu SPD-20AV) and a chromatography manager (EZ Chrome, GL-Science, Tokyo, Japan). The injector was Rheodyne,

Model 7725-022. The columns selected for a preparative fractionation of FAMES were a COSMOSIL Cholesterol C18 column (4.6 mm I.D. × 250 mm, Nacalai Tesque, Kyoto, Japan) and a TSKgel ODS-100Z column (4.6 mm I.D. × 250 mm, TOSOH, Tokyo, Japan). The HPLC analysis was performed at 20 °C or 35 °C. Standard FAMES (about 5–10 µg, each) were chromatographed in 10 µL of acetonitrile to determine the retention time. The HPLC solvent system used for most FAMES was an isocratic one using 100% acetonitrile with a flow rate of 1 mL/min and initial pressure of 45 psi. For separation of *cis*- and *trans*-isomers of polyunsaturated FAMES, the isocratic solvent system was changed to 10% or 15% of water in acetonitrile, with a flow rate of 1 mL/min and initial pressure of 50–60 psi.

GC Analysis

The FAMES were analyzed by GC using a Shimadzu GC-2010 model, fitted with a split injector (250 °C) and a flame ionization detector (250 °C) coupled with a GC solution integrating system (Shimadzu). A CP-Sil 88 column (60 m × 0.25 mm I.D., 0.2 µm film thickness, SPELCO) was utilized and operated at 175 °C. For this column, nitrogen was used as a carrier at a velocity of 23.6 cm/s. Each FAME peak was identified and quantified with standard FAME mixtures of known composition. Most samples were run in triplicate.

Results and Discussions

The nature of the FAMES separation by RP-HPLC has been known for some time; i.e., that the retention time is prolonged depending on an increase in the total number of the carbon atoms of the fatty acids and is reduced by an increase in the total number of double bonds in this moiety [12–14]. Of the more than ten different kinds of RP-HPLC column examined in advance, the COSMOSIL Cholesterol C18 column (Cholesterol column) and TSK gel ODS-100Z column (100Z column) recognized best the configurational differences around unsaturated bonds of FAMES. The Cholesterol column possesses a cholesteryl group-bonded silica packing material. It offers strong stereo selectivity for hydrophobic compounds. On the other hand, the 100Z column contains a high-density monomeric C18 bonded phase for maximum retention and selectivity of small molecular weight compounds. Hence, the separation of various standard FAMES including the *cis*- and *trans*-isomers were investigated using the Cholesterol column and the 100Z columns. The retention times of FAMES eluted by the two kinds of column under various conditions are listed in Table 1. When 100% acetonitrile was used as the HPLC eluent and the column temperature was set at 20 °C,

elution patterns of saturated FAMES chromatographed by the Cholester column and by the 100Z column were similar to those obtained in previous RP-HPLC analysis [10, 11]. In the case of unsaturated FAMES, the retention times depended on the geometrical and positional configuration of the double bond, as shown in Table 1. In various 18:1

isomers of FAMES, *cis*-isomers were eluted slightly faster than the *trans*-isomers. For example, the retention times of *cis*-9 18:1 and *trans*-9 18:1 were 11.96 and 13.47 min, respectively, when the eluent was acetonitrile and the Cholester column was used at 20 °C (Fig. 1). Among the *cis*-18:1 isomers of FAMES, *cis*-11 18:1 was eluted the

Fig. 1 The reversed-phase HPLC separation of standard FAMES, *cis*-11 18:1, *cis*-9 18:1, *cis*-12 18:1, *cis*-7 18:1, *cis*-6 18:1, *trans*-11 18:1 and *trans*-9 18:1. Each standard (about 10 µg) in about 10 µL of 100% acetonitrile was chromatographed on one Cholesterol column at 20 °C. Eluent, 100% acetonitrile, flow rate = 1 mL/min

fastest, as shown in Fig. 1. The separation pattern of the geometrical isomers of 18:1 FAMES was in good accordance with that shown in previous reports using RP-HPLC methods [10, 11], although the chromatographic conditions of these previous works were more complicated than those of this study. Furthermore, not only 18:1 FAMES geometrical isomers but also of 16:1, 20:1, 22:1 and 24:1 FAMES were well separated using these RP-HPLC analysis conditions. It seemed to us that the RP-HPLC method just developed was very effective for a preparative isolation of *cis*- and *trans*-isomers of monounsaturated FAMES for further GC analysis.

In the case of 18:2 isomers, the *cis*-9/*cis*-12 18:2 FAME was separated from the other three isomers (*cis*-9/*trans*-12, *trans*-9/*cis*-12, *trans*-9/*trans*-12 18:2 FAMES), when they were chromatographed by Cholesterol column with an isocratic acetonitrile. By contrast, the 100Z column with acetonitrile resolved these four 18:2 geometrical isomers into three peaks. In addition to the *cis*-9/*cis*-12 18:2 FAME, the *trans*-9/*trans*-12 18:2 FAME was able to be isolated from the *cis*-9/*trans*-12 18:2 FAME and *trans*-9/*cis*-12 18:2 FAME, as shown in Table 1. When water was added to the HPLC eluent, the Cholesterol column could also resolve the geometrical differences of the four 18:2 isomers into three HPLC peaks (Table 1). Among the 18:3 isomers, *cis*-9/*cis*-12/*cis*-15 18:3 FAME was almost completely separated from the other seven *trans*-18:3 isomers by using acetonitrile/water (85/15, v/v) as an HPLC eluent. These results suggested that the RP-HPLC method examined in this study could also be applied to geometrical fractionation of polyunsaturated FAMES, especially for the effective separation of *trans*- from *cis*-isomers.

The RP-HPLC method was applied to the preparative separation of *trans*- and *cis*-18:1 isomers for estimating the exact content of *trans*-18:1 isomers in partially hydrogenated rapeseed oil. This oil was methylated and the FAMES were pre-fractionated by the RP-HPLC method. In the case of the Cholesterol column set at 20 °C using acetonitrile as

an eluent, the *trans*-18:1 isomer fraction of this oil was able to be successfully separated from the *cis*-18:1 isomer fraction, as shown in Fig. 2a. In the RP-HPLC analysis of the original oil, the head part of the first big peak around 11.7 min was composed of *cis*-11, 18:1 FAME (Fig. 2a upper), and that of the third peak around 13.5 min was of *trans*-11, 18:1 FAME, based on the elution time of each 18:1 isomer (Table 1 and Fig. 1). In the preparative separation by the RP-HPLC method, the peaks from 11.6 to 13.4 min were collected as a *cis*-fraction. For the *trans*-fraction, the peaks appeared from 13.4 to 15.4 min (Fig. 2a lower), in which the peak of 16:0 FAME was contained. In this *cis*-fraction, in addition to *cis*-11, 18:1 FAME, *cis*-6, *cis*-7, *cis*-8 and *cis*-12, 18:1 FAMES of the hydrogenated rapeseed oil should be present, at least from the results of each standard isomer analysis as shown in Fig. 1. Furthermore, no *trans*-18:1 isomers could be contained in this *cis*-fraction, because the *trans*-11, 18:1 FAME was eluted faster than any other *trans*-18:1 isomers under RP-HPLC conditions which were shown in Fig. 1 and in other previous studies [4, 12, 13]. The fractionated volume of the *cis*-fraction and that of the *trans* one were 1.8 mL and 2.0 mL, respectively, which were small enough to proceed with the subsequent GC analysis. The isomeric distribution of each fraction was examined by the GC method, after adding an internal standard (17:0 FAME). Gas chromatograms of the isomer distribution of 18:1 FAMES of the original partially hydrogenated rapeseed oil, of the *cis*-fraction and of the *trans*-fraction isolated by the RP-HPLC method are shown in Fig. 2b and c. Most peaks were assigned by the standard, commercially available FAMES, and by data from previous works [4, 12, 13]. The previous studies suggested that some *trans*-18:1 FAMES overlapped with the *cis* ones, as far example, *cis*-6,-7,-8 with *trans*-13,-14, 18:1 FAMES, *cis*-9 with *trans*-15, 18:1 FAME, and *cis*-14 with *trans*-16, 18:1 FAME [4, 12, 13]. In these experiments, the overlapping peaks were eluted in the retention time ranges from 16.3 to 16.6 min (*cis*-6,7,8 and

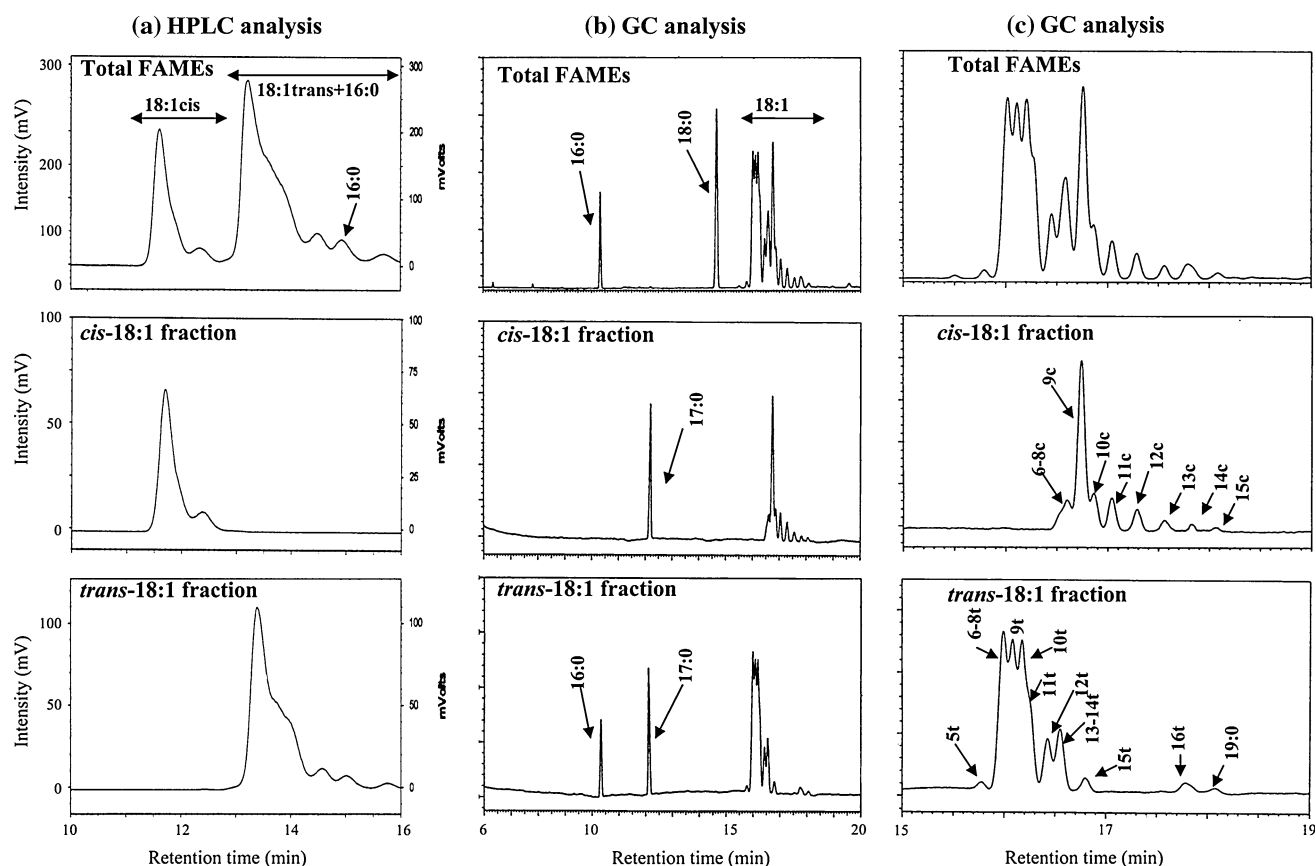

Fig. 2 **a** HPLC separation of total (original) 18:1 FAMES of hydrogenated rapeseed oil (upper). Methyl esterified hydrogenated rapeseed oil (about 0.1 mg) in about 10 μ L of 100% acetonitrile was chromatographed on one Cholesterol column at 20 $^{\circ}$ C. Eluent, 100% acetonitrile, flow rate = 1 mL/min. HPLC re-chromatogram of *cis*-18:1 fraction of **a** (middle). HPLC re-chromatogram of *trans*-18:1

fraction of **a** (lower). **b** GC separation of the total (original) 18:1 FAMES of hydrogenated rapeseed oil (upper), of the *cis*-18:1 fraction by the reversed HPLC method and 17:0 FAMES of internal standard (middle) and of *trans*-18:1 fraction by the reversed HPLC method and 17:0 of the internal standard (lower). **c** The same chromatograms as in **b**, with an expanded horizontal axis

trans-13,14), from 16.7 to 16.9 min (*cis*-9 and *trans*-15), and from 17.7 to 18.2 min (*cis*-14 and *trans*-16), respectively (Fig. 2c, upper and middle). In the case of unfractionated partially hydrogenated rapeseed oil, the peaks eluted in these regions were composed not only of *cis*-18:1 FAMES but also of *trans*-18:1 (Fig. 2b, c upper). The peaks of the *cis*-fraction eluted in these three regions must come from *cis*-18:1 isomers, but not *trans*-isomers, because the *cis*-fraction contained no *trans*-18:1 isomers as described for the RP-HPLC separation (Fig. 2c middle). For *trans*-fraction, the peaks eluted from 16.3 to 16.6 min and from 16.7 to 16.9 min were composed of *trans*-13,-14, 18:1 FAMES and *trans*-15, 18:1 FAMES, respectively, without contamination of *cis*-6,-7,-8, 18:1 FAMES and *cis*-9, 18:1 FAME. For the peaks from 17.7 to 18.2 min, the separation of *trans*-16, 18:1 FAME from *cis*-14, 18:1 FAME seemed to be incomplete. These results suggested that the developed RP-HPLC method was successful for a complete separation of *trans*-18:1 from *cis*-18:1 isomers.

When more than 3 mg of total FAMES from partially hydrogenated rapeseed oil was simultaneously injected into RP-HPLC for the pre-separation of *cis*- and *trans*-18:1 FAMES, the resultant contamination of *trans*-18:1 FAMES by *cis*-18:1 isomers was observed under our experimental conditions.

It is also worth noting that the preparative separation of *cis*- and *trans*-isomers by the RP-HPLC method developed in this study possessed high reproducibility. Indeed, two fractions, namely the *cis*-18:1 isomer fraction and the *trans*-18:1 isomer, which co-eluted with 16:0 FAME of partially hydrogenated rapeseed oils, were collected independently by the RP-HPLC method. The internal standard, 17:0 FAME, was added to these two fractions, before GC analysis. The absolute amount of total *cis*-18:1 isomers and total *trans*-18:1 isomers of the partially hydrogenated rapeseed oil was able to be determined easily by using both an internal standard (17:1 FAME) and 16:0 FAME co-eluted in the *trans*-18:1 fraction (Fig. 2b). The amounts of the two

Table 2 C18:1*cis*- and C18:1*trans*-fraction of hydrogenated rapeseed oil

	C18:1 <i>cis</i> -fraction (g/100 g)	C18:1 <i>trans</i> -fraction (g/100 g)	Total C18:1 (g/100 g)
Direct GC	20.2	13.1	33.3 (100.0)
HPLC/GC	22.1	10.6	32.7 (98.3)

Values in parentheses were the reproducibility (%)

The values were average of triplicated measurements

isomers were calculated from the results by the RP-HPLC method combined with GC analysis (HPLC/GC method) and which were compared with those obtained by the direct GC method. As shown in Table 2, the sum of *cis*-18:1 isomers and of *trans*-18:1 isomers by the HPLC/GC method was approximately the amount of the total 18:1 isomers estimated from the direct GC method. The yields of these two fractions were more than 98% of the original (Table 2), suggesting that a high reproducibility using the HPLC/GC method could be accomplished. In spite of the high reproducibility of the HPLC/GC method, the absolute amount of *trans*-18:1 isomers calculated by the HPLC/GC method (10.6 g/100 g) was about 20% less than that by the directed GC method (13.1 g/100 g), as shown in Table 2. Thus, the decrease must result from the complete elimination of *cis*-18:1 FAMES from the *trans*-fraction by the preparative RP-HPLC method. Thus, a more accurate measurement of *trans*-isomers of octadecenoic acid in partially hydrogenated rapeseed oil could be achieved by a prior preparative separation by the RP-HPLC method. It is suggested that the HPLC/GC method was essential for the accurate measurement of the total *trans*-18:1 content in food composed of partially hydrogenated edible oils.

In previous studies, *trans*-4, and *trans*-5, 18:1 isomers were not collected in the *trans*-18:1 fraction by the HPLC methods [12, 13]. On one hand, *trans*-5, 18:1 FAME was able to be fractionated by the RP-HPLC method developed in this study (Fig. 2c lower). On the other hand, the collection of *trans*-4 and *cis*-14, *cis*-15, 18:1 FAMES into the *trans*- and *cis*-fractions seemed to be incomplete even in this study. However, these isomers were a minor proportion in partially hydrogenated rapeseed oil (only a few percent of the total 18:1 isomers content).

Previously, the analysis of the isomeric distribution of *trans*-18:1 acid in milk fat was achieved by GC analysis with a pre-fractionation step by the RP-HPLC method [12, 13]. However, isomer distribution of *trans*-18:1 acid in partially hydrogenated edible oils has only been investigated by the silver-ion chromatographic method [15].

This study firstly demonstrated that the *trans*-18:1 isomer distribution (from *trans*-5 18:1 FAME to *trans*-16 18:1 FAME) contained in partially hydrogenated edible

oils could be analyzed by the RP-HPLC method. However, further investigation of preparative separation by RP-HPLC is needed to confirm the presence of minor *trans*-18:1 isomers, such as *trans*-4, and *trans*-16, 18:1 FAMES.

Because of the considerably higher reproducibility and simpler experimental procedure, the preparative separation of *trans*- and *cis*-isomers achieved by the RP-HPLC technique permits not only an accurate measurement of *trans*-18:1 acid content in food but also the analysis of the distribution of *trans*-18:1 isomers. Currently, silver-ion chromatography (Ag-TLC and Ag-HPLC methods) is widely used for complicated analysis of *trans*-fatty acids in foods. The RP-HPLC method developed in this study would be an attractive alternative to silver-ion chromatography for *trans*-isomer analysis.

In our laboratory, we are investigating the preparative separation of configurational isomers of other monounsaturated fatty acid (16:1, 20:1, 22:1 fatty acids) isomers contained in partially hydrogenated edible oils by the HPLC/GC method in order to identify their individual molecular conformations, which have not yet been identified. In future, the RP-HPLC method could be a powerful tool for the configurational separation of not only *trans*-isomers of monounsaturated FAMES but also those of polyunsaturated FAMES from corresponding *cis*-isomers.

Acknowledgments This work was supported (in part) by a grant-in-aid (Development of evaluation and management methods for supply of safe, reliable and functional food and farm produce) from the Ministry of Agriculture, Forestry and Fisheries of Japan.

Abstract High-performance TLC and ^{31}P -NMR were assessed as methods of observing the presence of numerous low polarity phospholipids: bis-phosphatidic acid (BPA), semi-lyso bis-phosphatidic acid (SLBPA), *N*-acyl phosphatidylethanolamine (NAPE), *N*-(1,1-dimethyl-3-oxo-butyl)-phosphatidylethanolamine (diacetone adduct of PE, DOBPE), *N*-acetyl PE, phosphatidylmethanol (PM), phosphatidylethanol (PEt), phosphatidyl-*n*-propanol (PP), phosphatidyl-*n*-butanol (PB). Both techniques are non-discriminative and do not require the prior isolation of individual lipids. It appears that 2D TLC is superior to ^{31}P NMR in the analysis of low polarity phospholipids. All phosphatidylalcohols were well separated by 2D TLC. However, some compounds which can present difficulty in separation by 2D-TLC (e.g., SLBPA and NAPE; or DOBPE and *N*-acetyl PE) were easily distinguished using ^{31}P NMR so the methods are complimentary. A disadvantage of 2D TLC is that *R_f* values can vary with different brands and batches of TLC plates. The chemical shifts of ^{31}P NMR were less variable, and so a library of standards may not be necessary for peak identification. Another advantage of ^{31}P NMR is the ease of quantification of phospholipids. The applicability of the methods was tested on natural extracts of fish brain and cabbage stem.

SM	Sphingomyelin
SPE	Solid-phase extraction

Introduction

Beyond a widely known group of major phospholipids (phosphatidylethanolamine, phosphatidylcholine, phosphatidylinositol, phosphatidylserine, phosphatidylglycerol, cardiolipin, phosphatidic acid and sphingomyelin), a number of other phospholipid groups exist, including low polarity phospholipids, phosphonolipids, etc. While these other groups are generally represented by minor components, their importance in lipid metabolism and signalling may be high [1].

In this work we present and compare selected analytical techniques that allow identification of low polarity phospholipids, a group of phospholipids noted for their high mobility on silica gel TLC in solvent systems generally used in analysis of major phospholipids. Low polarity phospholipids are naturally existing or artefact lipids produced mostly by modification of polar moieties of phosphatidylcholine (PC), phosphatidylethanolamine (PE), or phosphatidylglycerol (PG) (Figs. 1–3).

Low polarity phospholipids include phosphatidylalcohols, mostly artefact lipids produced predominantly from PC when samples containing active phospholipase D (e.g., plant samples) are extracted with appropriate alcohols [2]. This process is usually accompanied by formation of phosphatidic acid (PA) due to the presence of water in extraction media (Fig. 1). Of all phosphatidylalcohols the most important seems to be phosphatidylethanol, currently considered as a biochemical marker of alcoholism [3], which was reported to form from phospholipids in mammalian cell membranes affected by ethanol [4]. Other phosphatidylalcohols (e.g., PM [5], PB [6], PP [7]) were found to be useful markers in phospholipase D activity assays due to the ease of their chromatographic separation from the bulk of phospholipids.

Fig. 1 Phosphatidylcholine (PC) and the products of its transphosphatidylation by phospholipase D: phosphatidic acid (PA) and phosphatidylalcohols—phosphatidylmethanol (PM), phosphatidylethanol (PEt), phosphatidylpropanol (PP) and phosphatidylbutanol (PB)

PE is able to form adducts with aldehydes and ketones. Acetone (more correctly—diacetone) adduct (DOBPE, Fig. 2) can be formed even from an acetone solution of PE stored in a fridge [8]. A recent study suggested that this lipid may also be formed in diabetic blood [9]. Still, the most important of the PE-derived low polarity phospholipids seems to be NAPE, the immediate precursor of endogenous bioactive *N*-acylethanolamines [10].

One of *N*-acylphosphatidylethanolamines, namely *N*-acetyl PE was allegedly found in the mammalian brain and placenta [11], but reliably confirmed only in zygomycete *Absidia corymbifera* [12].

Fig. 2 Phosphatidylethanolamine (PE) and low polarity phospholipids, derived from PE: diacetone adduct, *N*-(1,1-dimethyl-3-oxobutyl)-derivative of phosphatidylethanolamine (DOBPE), *N*-acetyl PE, and *N*-palmitoyl PE (the major representative of *N*-acyl phosphatidylethanolamines, NAPE)

Fig. 3 Diastereomeric phosphatidylglycerols (PG), produced by transphosphatidylation of PC with glycerol, and low polarity phospholipids based on PG: semi-lyso bis-phosphatidic acid (SLBPA, also known as acyl phosphatidylglycerol), and bis-phosphatidic acid (BPA)

Two major low polarity phospholipids based on PG structure are BPA and SLBPA (Fig. 3). BPA was reported for marine bacteria [13], developing soybeans [14], fish brain [15], and degenerating cultured hamster fibroblasts [16]. BPA was also tentatively identified in some fish flesh [17]. SLBPA, also known as acyl phosphatidylglycerol, was found in a number of micro organisms, and also in plant and animal tissues [18].

The concern that some unnatural phospholipids, like PE adducts, may be produced during the course of industrial processing of food components, and as such may contribute to development of a pathology (e.g., diabetes) at epidemic or even pandemic scale was expressed recently [19]. However, it seems that low polarity phospholipids are not considered for quantitation by the majority of food quality control laboratories.

One of the reasons for that is the lack of analytical approaches to quantifying low polarity phospholipids. Attempts to identify low polarity lipids with chromatographic methods often resulted in misidentification. For example, low polarity phospholipids found in infarcted dog heart [20] and, later, in the brain of bony fish *Amia calva* [15] were identified as BPA. It took some time to find out that they were not BPA, but another low polarity phospholipid, NAPE [21], the structure already established for unusual dog heart phospholipid in another laboratory [22].

Similarly, controversial identifications were reported for other low polarity lipids. A phospholipid with high mobility on TLC found in developing soybean cotyledons was identified as NAPE [23], and as PM [24]. A phospholipid with chromatographic mobility higher than that of PE and containing nitrogen was found in beef brain lipids after prolonged contact with acetone. This lipid was identified as PE-acetone adduct [25] and as *N*-acetyl PE [11].

Application of MS and NMR-based techniques significantly improves reliability of low polarity phospholipids identification. For example, ^1H - ^{13}C 2D NMR experiments allowed distinguishing between SLBPA and NAPE in oats while HPLC-MS was useful in assessing their fatty acid composition [26]. A drawback of this approach is that a

combination of SPE and preparative TLC was required to isolate pure compounds for NMR.

It would be desirable to develop a non-discriminative technique that does not require isolation of individual lipids to distinguish between numerous low polarity phospholipids. In this publication we describe application of ^{31}P -NMR for analysis of low polarity phospholipids and compare the results with the data provided by high-performance TLC.

Materials and Methods

Egg yolk PE and PC were prepared according to Barsukov et al. [27].

Brain from three frozen and thawed red gurnards *Chelidonichthys kumu* was excised (total weight 839 mg) and extracted according to Bligh and Dyer [28]. The yield was 85 mg.

A methanolic solution of HCl (5%, 5 ml) was added to a portion of gurnard brain lipids for 5 min at 50 °C to remove vinyl ethers. Chloroform (0.5 ml) and water (0.5 ml) was added, and the mixture centrifuged. The lower layer was collected and solvent removed from the lipid under a stream of argon.

A cabbage (*Brassica oleracea* var. *capitata*) stem was extracted as follows:

1. 37.5 g of fresh stem was homogenised in the 100 ml Waring blender cup on high speed for two bursts of 30 s each, then extracted according to Bligh and Dyer method with 113 ml of chloroform-methanol (1:2, by v/v), followed by an extraction with 38 ml of chloroform, yielding 57.9 mg of lipids;
2. 37.6 g of fresh cabbage stem was boiled in water for 5 min, then extracted as above, yielding 89.4 mg lipids;
3. 34.7 g of fresh cabbage stem was homogenised in the 100 ml Waring blender cup on high speed for two bursts of 30 s each, then extracted as follows: 70 ml of

methanol was added, the mixture was homogenised again, and allowed to stay at room temperature for 20 min. After that, 35 ml of chloroform was added, the mixture was homogenised and filtered. The residue was extracted with 35 ml of chloroform. Combined extracts were rotary evaporated, yielding 72.8 mg lipids.

PG, PM, PEt, PP and PB were prepared by transphosphatidylation of corresponding alcohols (at 4% of media) and phosphatidylcholine by cabbage phospholipase D [2]. PG was produced by the same approach and purified by column chromatography on silica gel.

Bis-phosphatidic acid (BPA) and semi-lyso bis-phosphatidic acid (SLBPA) were prepared by acylation of PG by palmitoyl chloride using the method of Ellingson [29], modified by addition of few crystals of catalyst, 4-*N*, *N*-dimethylaminopyridine.

N-palmitoyl PE (NAPE) and *N*-acetyl PE were prepared by acylation of PE by palmitoyl chloride and acetyl chloride, correspondingly, using the method of Ellingson [29], modified as above.

N-(1,1-dimethyl-3-oxo-butyl)-derivative of phosphatidylethanolamine (acetone adduct of PE, DOBPE) was prepared by storing PE in acetone in a fridge for 2 weeks [8]. Other phospholipids were from Industrial Research Limited's collection of lipid standards.

Solvent systems for TLC were taken from Vaskovsky and Vysotskii [30]. To develop plates in the 1st direction the system used was chloroform–methanol–benzene–25% aqueous ammonia (60:15:10:1, by v/v/v/v). For 2nd direction the system acetone–benzene–glacial acetic acid–water (20:30:4:1, by v/v/v/v) was used. Development was performed in filter paper-lined tanks saturated with solvent systems for at least 1 h prior to development. Solvent systems in tanks were refreshed after each plate developed. TLC plates (10 × 10 cm glass-backed HPTLC-Plates Nano-Sil 20, Macherey-Nagel, Germany) were activated at 110 °C at least for 90 min and left to cool to room temperature in a vacuum desiccator prior to sample loading. Samples were loaded using 1- μ l capillary tubes (Billbatt Ltd, England). Between developments plates were ambient air-dried with a faint stream of argon applied.

Model mixtures of low polarity phospholipids were prepared as chloroform solutions with concentrations of individual components varying from 1 to 5 mg/ml.

Phospholipids were detected on TLC by phosphomolybdate spray prepared according to Vaskovsky et al. [31].

Complete removal of O-linked fatty acids from glycerolipids was achieved using monomethylamine [32]. Sample (10 mg) was weighed into a stoppered test tube and dispersed in ethanol (1.5 ml). Monomethylamine (40% solution in water, 4.5 ml) was added and the test tube

heated in a water bath at 55 °C for 1 h. Solvent was removed under a stream of argon on a heating block (60 °C). The residue was redispersed in ethanol (0.5 ml) and ethyl formate (100 μ l) added to neutralise any residual monomethylamine. The solvent was removed under argon and the sample dissolved in the NMR detergent as outlined below.

³¹P-NMR analysis was based on the method of Lehnhardt et al. [33]. A detergent solution was prepared containing: sodium cholate (10% w/w), EDTA (1% w/w) and phosphonomethylglycine (PMG) as an internal standard for quantification (0.3 g/L), pH was adjusted to 7.3 using sodium hydroxide. The detergent solution was an aqueous solution containing 20% D₂O for deuterium field-frequency lock capability. Sample (10 mg) was mixed with detergent solution (750 μ l) by vortexing, and then dispersed by ultrasonication at 60 °C for 10 min. The solution was then transferred to a 5-mm NMR tube for analysis.

Quantitative phosphorus NMR spectra using inverse gate proton decoupling for suppression of nuclear Overhauser effect were recorded on the two-channel Bruker Avance300 with the following instrument settings: spectrometer frequency for ³¹P 121.498 MHz, sweep width 6,067 Hz, 65,536 data points, 90 degree excitation pulse, 192 transients were normally taken, each with an 3.5 s delay time and free induction decay acquisition time of 5.4 s. Spectra were processed with a standard exponential weighting function with 0.2 Hz line broadening before Fourier transformation.

Chemical shifts were measured relative to the PMG internal standard, and also relative to SM [present naturally in samples which had been prepared from egg yolk lipids, or as an introduced standard (Avanti)].

Lecitase Ultra (5 μ l) was added to a NMR detergent containing fresh cabbage stem lipids followed by incubation at 40 °C for 20 min. The mixture was placed in boiling water for 10 min to deactivate the enzyme then reanalysed to confirm the peak positions of LPM regioisomers.

Results

Thin-Layer Chromatography

The use of the solvent systems developed for one-dimensional TLC separation of low polarity phospholipids [30] resulted in good separation for some lipids (Fig. 4).

Effect of chain length of polar heads of low polarity phospholipids on their TLC mobility was clearly observed: *N*-palmitoyl PE (NAPE) and *N*-acetyl PE were easily separated; PM, PEt and PP were also resolved from each other. Further increase in the substitute's chain length had

Fig. 4 TLC of low polarity phospholipids in solvent system chloroform-methanol-benzene-25% aqueous ammonia (60:15:10:1, by v/v/v), run twice. Detection—by phospholipid spray. Mixtures of phospholipids were applied as follows: *Lane 1* BPA + SLBPA; *Lane 2* NAPE + *N*-acetyl PE; *Lane 3* DOBPE + *N*-acetyl PE + PE; *Lane 4* PM + PP; *Lane 5* PEt + PB; *Lane 6* PB + SLBPA; *Lane 7* NAPE + SLBPA; *Lane 8* PP + SLBPA. Phosphatidylalcohols mixtures also small levels of PC and PA. DOPE exhibited a fainter spot than the other phospholipids which faded rapidly after visualisation

less pronounced effect: PB was clearly resolved from PP only at lower loadings.

SLBPA and PB were not resolved, while SLBPA and PP could be resolved only at low loadings. SLBPA and NAPE were poorly resolved even at low loadings under one-dimensional TLC.

Two-dimensional TLC produced significantly better separation of low polarity phospholipids (Fig. 5). All of the low polarity phospholipids were well resolved, including SLBPA and PB which could not be separated by one-dimensional TLC.

³¹P NMR

Results for the chemical shifts of the low polarity phospholipids relative to PMG and SM both as intact and deacylated lipids are presented in Table 1 with example spectra of mixtures of the nine less polar phospholipid classes in Figs. 6 and 7. Unlike with the TLC separation there is no clear trend in the chemical shifts based on the alcohol chain length of the phosphatidylalcohols. PM is well separated from the other phosphatidylalcohols, but PE, PP and PB are all within 0.03 ppm. The other low polarity phospholipids are well separated from each other.

Each of the low polarity phospholipids studied, except for BPA, produced a single signal. BPA produced two

Fig. 5 Two-dimensional TLC of low polarity phospholipids in solvent systems. 1st direction: chloroform-methanol-benzene-25% aqueous ammonia (60:15:10:1, by v/v/v/v), run twice; 2nd direction: acetone-benzene-glacial acetic acid-water (20:30:4:1, by v/v/v/v). Detection—by phospholipid spray. A faint spot of PC was seen on the plate at the sample loading zone

signals, split by 0.09 ppm, which possibly reflects the existence of two diastereomeric forms. This view is supported by the finding that PG we used as starting material for BPA synthesis was produced from PC via transphosphatidylolation by cabbage phospholipase D. It was demonstrated that such PG is, in fact, a racemic mixture of 1-phosphatidyl-D-glycerol and 1-phosphatidyl-L-glycerol [2], and, therefore, BPA used in our experiments was a diastereomeric mixture of *sn*-3/*sn*-3' and *sn*-3/*sn*-1' isomers (Fig. 3). Differences in chemical shifts have been observed previously between the ³¹P NMR of mixtures containing L-PS compared to D-PS [34]. However, these differences were noted in phospholipid aggregates, whereas the Na cholate of the NMR detergent used in the current study is present to disrupt such aggregates and achieve sharper signals for individual phospholipids. Preparation of pure diastereomers of BPA is required to confirm that the peak splitting is due to diastereomeric differences, and for correct assignment of each peak. However, if this is the cause of the peak splitting then the ability to differentiate between the diastereomers is an advantage of ³¹P NMR over that of 2D TLC.

Unlike TLC where separation is based on polarity and thus the low polarity phospholipids by definition are well separated from other phospholipids, there is some overlap of the ³¹P-NMR chemical shifts of the low polarity phospholipids and some other phospholipids. The examples of

Table 1 ^{31}P -NMR chemical shifts for the low polarity phospholipids both intact and deacylated

Phospholipid	Chemical shift (ppm)	
	Relative to SM	Relative to PMG

^b Identical to glycerophosphoethanolamine

^c Produced from deacylation of PG, BPA and SLBPA

**Fig. 6** ^{31}P -NMR spectrum of the intact mixture of nine less polar phospholipids in a sodium cholate/EDTA detergent system (pH 7.3). Test mixtures also contained PA and the internal standard PMG which were observed further downfield. Chemical shifts are shown relative to SM

this are: BPA(a) (-0.33 ppm relative to SM) and 1LPC (-0.34 ppm); BPA(b) (-0.24 ppm) and PS (-0.25 ppm); DOBPE (0.10 ppm) and dihydrosphingomyelin (0.09 ppm);

**Fig. 7** ^{31}P -NMR spectrum of the O-deacylated mixture of nine less polar phospholipids in a sodium cholate/EDTA detergent system (pH 7.6). Test mixtures also contained GPA and the internal standard PMG which were observed further downfield. Chemical shifts are shown relative to SM. The difference in chemical shift of Pi compared to the spectrum in Fig. 6 is due to a slightly higher pH

NAPE (0.37 ppm) and CL (0.36) and 2LPE (0.38 ppm) [35].

O-deacylation of the sample produced sharper peaks, which are better resolved both from other low polarity phospholipids and other phospholipids. GPB and GPP are not resolved, but all other O-deacylated low polarity phospholipids are separated from each other. However, deacylation converts BPA and SLBPA (as well as PG) to the single compound—glycerophosphoglycerol (GPG). Deacylation of DOBPE produced a single phosphorus-containing component, with chemical shift identical to that of glycerophosphoethanolamine, suggesting that acetone adduct is destroyed during deacylation.

To demonstrate the applicability of the described techniques to the real life samples analysis, a number of extracts were prepared. To illustrate a formation of an artefact phosphatidylmethanol during extraction of plant samples, a cabbage (*Brassica oleracea* var. *capitata*) stem was extracted as follows:

1. Fresh stem was extracted by a standard Bligh and Dyer method;
2. Boiled stem was extracted by a standard Bligh and Dyer method;
3. To demonstrate a danger of adding methanol first (as recommended sometimes, since methanol mixes better with tissues than chloroform), the methanol portion of Bligh and Dyer first extraction solvent was added first to the stem and allowed to stay for 20 min prior to addition of chloroform.

One-dimensional TLC demonstrated a formation of PM during extraction of fresh stem, especially when methanol was added prior to chloroform; no PM was formed during extraction of the boiled stem (Fig. 8).

Fig. 8 TLC of cabbage stem extracts: *A*—fresh stem extract, *B*—boiled stem extract, *C*—fresh stem extract with methanol added first. *PM*—phosphatidylmethanol standard. Solvent system: chloroform-methanol-benzene-25% aqueous ammonia (60:15:10:1, by v/v/v/v), run twice. Detection—by phospholipid spray

^{31}P NMR measured high levels of PM in both extracts from fresh cabbage stem (Table 2). There was measurable PM (0.4 mol %) even in the extract from boiled cabbage indicating some residual phospholipase D activity. Peaks due to 1LPM and 2LPM (−5.79 and −5.63 ppm relative to PMG respectively) were confirmed by a partial phospholipase A1 hydrolysis of a fresh cabbage stem extract.

The presence of low polarity phospholipid in red gurnard (*Chelidonichthys kumu*) brain was demonstrated by two-dimensional TLC (Fig. 9, left pane), and the fact that it differs from SLBPA was demonstrated by spiking the sample with SLBPA standard (Fig. 9, right pane).

A comparison with the reference standard, SLBPA, and a known low polarity lipid two-dimensional TLC pattern (Fig. 5) suggests that the low polarity phospholipid from red gurnard brain is NAPE.

As discussed above, the ^{31}P -NMR peak position of NAPE is very close to that of 2LPE and CL. NAPE was not observed in the spectrum of intact gurnard brain lipids (Fig. 10). Analysis of deacylated red gurnard brain lipids did not result in a significant NAGPE peak, but a peak did appear at 0.77 ppm relative to SM. Acid treatment to destroy vinyl ethers, followed by deacylation resulted in the disappearance of this peak, and presence of a NAGPE peak. This indicates that most of the NAPE present in red gurnard brain is in the plasmalogen form.

Discussion

In our search for NAPE in bony and cartilaginous fish we found that it is difficult to distinguish SLBPA and NAPE even by high-performance TLC, and chemical transformations are required to attribute an unknown lipid to one of these without employing physico-chemical methods of structure elucidation [30]. Later we demonstrated that reliable separation of SLBPA and NAPE requires the use of homemade HPTLC-plates coated with silica sol-bound microfractionated silica gel KSK, and low humidity [36].

One-dimensional TLC is helpful in screening of significant number of samples for low polarity phospholipids, but it has shortcomings, like poor resolution of NAPE, SLBPA, PB and PP.

In contrast, 2D TLC, while requiring significantly longer procession times, allows the separation of all the above mentioned low polarity phospholipids.

TLC separation of low polarity phospholipids requires a careful selection of solvent systems. An inappropriate solvent system seemed to be used in the analysis of NAPE from kenaf seeds with *N*-linked acids being predominantly linoleic, palmitic and oleic [37], since it was reported to have the same chromatographic mobility as *N*-acetyl PE, while these are clearly separable as it was demonstrated in the current work.

Apart from NAPE, an unknown lipid identified as BPA was reported for developing soybeans and soybean suspension cultures [14]. The authors mentioned that chromatographic mobility of the latter lipid is lower than that of NAPE, which allows separation of these two lipids by preparative TLC. Considering the previous findings that

Fig. 9 Two-dimensional TLC of red gurnard brain phospholipids. *Left pane*—brain extract, *right pane*—brain extract spiked with SLBPA. Solvent systems: 1st direction—chloroform-methanol-benzene-25% aqueous ammonia (60:15:10:1, by v/v/v/v), run twice; 2nd direction—acetone-benzene-glacial acetic acid-water (20:30:4:1, by

v/v/v/v). Detection—by phospholipid spray. Note that while all spots were clearly visible on the TLC plate as blue spots on white background, the scanned images required enhancement to make the spots visible, thus resulting in darker background

Fig. 10 ^{31}P -NMR spectra of red gurnard brain lipid extract. **a** HCl treated to remove plasmalogens then deacylated, **b** Deacylated, **c** Intact. Peaks: 1 deacylated CL, 2 N-acyl GPE, 3 lyso NAPE-plasmalogen, 4 GPE, 5 1-alkyl GPE, 6 LPE plasmalogen, 7 NAPE-plasmalogen, 8 2-LPE, 9 CL

SLBPA (e.g., partially deacylated BPA, thus more polar than BPA) has a mobility on TLC similar or equal to that of NAPE [29], it seems rather unlikely for BPA to have lower mobility than that of NAPE in normal phase chromatography.

In summary, it appears that 2D TLC is superior to ^{31}P NMR in the analysis of low polarity phospholipids. However, some compounds which can present difficulty in separation by 2D-TLC (e.g., SLBPA and NAPE; or DO-BPE and *N*-acetyl PE) are easily distinguished using ^{31}P NMR so the methods are complimentary. A disadvantage of 2D TLC is that *R_f* values can vary with different brands and batches of TLC plates. It is therefore important in the 2D TLC analysis to have standards for confirmation of the

identity of spots in analysis of real samples. The chemical shifts of ^{31}P NMR are less variable, and such a library of standards may not be necessary for peak identification. Another advantage of ^{31}P NMR is the ease of quantification of phospholipids. The peak splitting observed in the ^{31}P NMR of BPA has been attributed to the presence of diastereomers. Unlike ^{31}P NMR, the 2D TLC method used in this study cannot distinguish between these diastereomers.

Sugar Cane Policosanols do not Reduce LDL Oxidation in Hypercholesterolemic Individuals

Abstract Sugar cane policosanols (SCP) have been shown to exert antioxidant properties in various studies conducted in Cuba. Independent studies have since reported no significant effect of SCP consumption on oxidized LDL levels. The objective of the present study was to confirm the effects of Cuban SCP on LDL oxidation using a high-precision capture ELISA procedure in hypercholesterolemic individuals. Twenty-one otherwise healthy hypercholesterolemic men and post-menopausal women participated in a randomized double blind crossover study where they received 10 mg/day of policosanol or a placebo incorporated in margarine as an evening snack for a period of 28 days. Subjects maintained their usual dietary and exercise habits throughout the duration of the study. Blood was collected on the first as well as the last 2 days of the trial. LDL oxidation was measured from plasma using a solid phase two-site enzyme immunoassay. A lack of effect of SCP was observed on LDL cholesterol levels, as well as no difference in LDL oxidation between the SCP treatment and placebo at the end of the intervention period. Subject body weights remained stable throughout the study and showed no significant correlation with LDL oxidation levels. Absolute levels of plasma LDL cholesterol were significantly ($P < 0.05$) correlated with plasma concentrations of oxidized LDL. The findings of the present study suggest that SCP do not significantly affect LDL oxidation.

Our results align with results of recent policosanol research questioning the efficacy of these natural extracts as cardio-protective agents.

Keywords Sugar cane policosanol · Low-density lipoprotein · Oxidation · Hypercholesterolemia · ELISA

Abbreviations

ANCOVA	Analysis of covariance
EDTA	Ethylenediaminetetraacetic acid
ELISA	Enzyme-linked immunosorbent assay
HDL	High-density lipoprotein
HMG CoA	3-Hydroxy-3-methyl-glutaryl-CoA
LDL	Low-density lipoprotein
MDA	Malonaldehyde
SCAP	Sugar cane policosanols
TBARS	Thiobarbituric acid reactive substances

Introduction

Atherosclerosis remains the leading cause of death not only in developed [17] but in developing countries as well [26, 27], making cardiovascular disease a substantial global health burden. Several processes have been implicated in early atherogenesis, with competing theories on the key triggering events including lipoprotein aggregation, macrophage chemotaxis, foam cell formation and lipoprotein oxidation [33]. Atherogenesis has been suggested as being triggered by the stimulation of intramural synthesis of molecules promoting lipoprotein retention and subsequent oxidation proposed to be the second most central process in the development of atherosclerosis [3, 33]. policosanols (SCP), mixtures of long chain fatty alcohols, exert cardioprotective properties by reducing the susceptibility of LDL to oxidation as was shown in various studies by a research group based in Cuba [8, 19, 31]. Animal [20, 21, 24] and human [7, 23] studies have demonstrated reductions in lipid and LDL peroxidation as a result of SCP treatment, using markers of oxidative stress such as monitoring of conjugated dienes and measuring thiobarbituric acid reactive substances (TBARS). In animals [20, 21, 24] as well as humans [7, 23], SCP significantly prolonged the lag time, reduced the propagation of conjugated diene generation [7, 21, 23, 24] and decreased levels of TBARS [7, 20, 21, 23, 24]. TBARS and conjugated diene quantification are commonly used as an assessment method for lipid oxidation, however these methods have serious limitations such as lack of specificity and are often. Although independent research outside of Cuba examining the antioxidant power of SCP is limited, the outcomes of a recent study by Ng et al. failed to support previous positive findings, reporting no significant change of oxidation state in LDL from humans treated with a policosanol supplement [28]. While these negative findings have been supported by a growing body of evidence against the claimed cholesterol modulating properties of Cuban SCP [4, 9, 10, 14, 15, 25], no independent human trial had examined the antioxidant potential of this natural extract. Therefore, the objective of the present study was to evaluate the antioxidant effects of Cuban SCP in a compliance-controlled clinical feeding trial involving hypercholesterolemic individuals. It was hypothesized that there would be no significant difference in plasma oxidized LDL concentrations between subjects receiving SCP treatment versus placebo.

Materials and Methods

Subjects and Treatments

Potential participants were screened by phone interview, followed by blood biochemistry analyses to determine their lipid profile, as well as an examination conducted by the study physician. Subjects included in the clinical trial ($n = 21$) were healthy mildly hypercholesterolemic men and postmenopausal women living in the West Island of Montreal. Exclusion criteria included history of recent or chronic use of oral hypolipidemic therapy, chronic use of insulin, systemic antibodies, corticosteroids, androgens or phenytoin. Subjects were also excluded if they had experienced a myocardial infarction, coronary artery bypass or other major surgical procedures within the last 6 months, or reported recent onset of angina, congestive heart failure, inflammatory bowel disease, pancreatitis, or

hypothyroidism. Significant pre-existing diseases including cancer, chronic use of laxatives as well as smoking or consumption of more than two drinks per day were also considered to be part of the exclusion criteria. Before they were enrolled in the study, subjects were asked to sign a consent form outlining the details of the trial. The study protocol was approved by the Ethics committee of the medical faculty of McGill University. The SCP treatment administered to subjects during the trial was derived from Cuban SCP manufactured by Dalmer Laboratories (La Havana, Cuba) marketed under the brand Lipex, not to be confused with the simvastatin carrying the same name. SCP composition was 66.3% octacosanol, 13.0% triacontanol and 4.7% hexacosanol [18]. SCP pills were crushed into a powder and incorporated into margarine (Becel, Canada). Ten grams of the margarine containing 10 mg of SCP were spread on 60 g of bread and given daily to study participants as an evening snack. In the placebo margarine, the SCP powder was substituted by corn starch, the major excipient in the pill, which gave both margarines the same taste and texture. Subjects alternated between three types of bread snacks: zucchini bread, banana bread and tomato basil bread. The three snacks were adjusted to have similar macronutrient compositions. An average portion of 62 g contained on average 152 cal, 27.0 g of carbohydrates, 3.3 g of proteins, 3.7 g of fat and 1.0 g of fibre.

Protocol

The clinical trial was designed as a crossover whereby subjects consumed treatment and placebo margarines randomly over the course of two 28-day treatment phases. In order to eliminate the carryover effect of treatment, the two phases were separated by a 28-day washout period. During treatment and placebo phases, subjects were asked to maintain their habitual diets and exercise regimens and visit the research unit everyday to consume the evening snack under staff supervision at the Mary Emily Clinical Research Centre, in order to ensure absolute compliance. Alcohol was prohibited and caffeinated beverages were limited to one cup per day. We used 24 h recalls to ensure that subjects were following study guidelines. Body weights were recorded daily in order to monitor weight fluctuations throughout the study period. At the beginning and end of each feeding phase, blood draws were scheduled to check for health abnormalities at the onset of the trial and as a result of treatment. Subjects signed an informed consent form before entering the study.

LDL Oxidation Measurements

Subjects were scheduled for blood draws at the start and the end of each study phase. Blood was collected from

days 1 and 2 as baseline and 28 and 29 to determine endpoint oxidative states. Plasma was separated from red blood cells by centrifugation at 1,500 rpm for 20 min and was directly stored at -80°C until further analysis. Samples were maintained at -80°C prior to analysis and were analyzed within 2 years. Oxidized LDL was quantified using a solid phase two-site enzyme immunoassay (Oxidized LDL ELISA, Mercodia, Sweden) with murine monoclonal antibodies mAb-4E6. The plate wells used in this analysis were coated with the capture antibody. The test procedure was applied from the protocol accompanying the assay kit (Mercodia, Sweden). Briefly, plasma samples were thawed and diluted. Then, 25 μl of the sample was added to each coated well and incubated with assay buffer for 2 h at room temperature on a plate shaker. This first step insured that oxidized LDL in the sample bound to the solid phase antibodies. Wells were then thoroughly washed to eliminate other plasma components and peroxidase conjugated anti-human apolipoprotein B antibody was added to recognize the oxidized LDL attached to the solid phase. The labeled antibodies were detected upon the addition of 3,3', 5,5'-tetramethylbenzidine and absorbance at 450 nm was recorded. A standard curve was drawn for each run using four calibrators with different oxidized LDL concentrations as well as a low and a high concentration control. Plasma samples from the two phases belonging to each subject were run on one plate under the same laboratory conditions. Oxidized LDL concentrations of samples run on the same plate were calculated from the absorbance using the equation of a single standard curve.

Statistical Analysis

Effects of SCP on endpoint LDL oxidation were tested using a one way ANCOVA for crossover models including initial body weight and endpoint LDL cholesterol levels as covariates. Oxidized LDL values did not follow a normal distribution, therefore endpoint values were log transformed to achieve normality and differences in percent changes between groups were analyzed using the Wilcoxon Mann–Whitney non parametric test. Data were analyzed

using the SAS system for Windows version 8.0 (SAS Institute Inc.) and were reported as means \pm SEM. Statistical significance was set at $P < 0.05$.

Results

Twenty-two subjects were screened and accepted into the study. Twenty-one participants successfully completed the trial. Table 1 lists baseline characteristics of participants included in the trial. The policosanol treatment was odorless, colorless and tasteless; therefore subjects were not able to identify the SCP in their snacks. No adverse effects were noted during the study with the exception of four subjects reporting gastrointestinal discomfort and more frequent bowel movements. However, two of the subjects were allocated to the policosanol treatment, while the two others were allocated to the placebo intervention. Body weights remained stable throughout the study periods and blood biochemistry and hematology remained within normal ranges.

Plasma Lipid Levels

Plasma lipid levels were measured and results were published in a previous work [14]. Briefly, no significant differences were observed at endpoint between SCP treatment and placebo groups in plasma total, LDL, HDL and triglyceride levels. In addition, no significant effect of SCP was recorded on percent changes in lipid values.

Plasma Oxidized LDL Concentration

Concentrations of plasma oxidized LDL recorded at the end of the placebo and treatment phases are illustrated in Fig. 1. The effect of SCP on LDL oxidation was not significantly different from placebo ($P = 0.76$). When included in the model, initial body weight did not affect the concentration of oxidized LDL. A multiple regression of oxidized LDL on LDL, HDL cholesterol and triglyceride endpoint levels in the plasma demonstrated a significant effect of LDL cholesterol ($P = 0.03$) and approaching

Table 1 Baseline characteristics of subjects (means \pm SEM)

Variable	Males ($n = 12$)	Females ($n = 9$)	All ($n = 21$)
Age (years)	54.0 \pm 2.9 ^a	60.1 \pm 2.6 ^a	57.8 \pm 2.1
Weight (kg)	84.8 \pm 4.9 ^a	71.1 \pm 3.8 ^b	76.3 \pm 3.2
BMI (kg/m ²)	26.9 \pm 1.0 ^a	26.3 \pm 0.8 ^a	26.5 \pm 0.6
Total cholesterol	5.4 \pm 0.4 ^a	6.09 \pm 0.3 ^a	5.8 \pm 0.2

Fig. 1 Changes in oxidized LDL concentrations across treatment periods. Data reported as means \pm SEM. No significant difference recorded between control and SCP groups

Fig. 2 Regression of oxidized LDL concentration and LDL cholesterol levels in plasma. Regression equation: $y = 23.24x + 42.53$; $r^2 = 0.0961$; $P = 0.02$

significance for triglycerides ($P = 0.06$) on LDL oxidation. Figure 2 illustrates a simple regression of oxidized LDL levels on LDL cholesterol concentrations in the study population as a whole. Results show a significant relationship between endpoint values ($r^2 = 0.13$; $P = 0.023$) and approached significance for percent change values ($r^2 = 0.091$; $P = 0.061$). When oxidized LDL concentrations were expressed relative to LDL levels in the plasma, no effect of treatment was recorded.

The effect of the treatment phase was significant suggesting that plasma collected during the first phase of the study had higher concentrations of oxidized LDL than those samples collected during the second phase. When the model was adjusted for storage time, the effect of treatment phase disappeared and the treatment remained non significant. Percent changes in LDL oxidation after placebo and SCP treatments are reported in Fig. 3 and showed no difference between the two study margarines in terms of their effect on LDL oxidation ($P = 0.61$).

Fig. 3 Regression of change in oxidized LDL on change in LDL levels in plasma. Regression equation: $y = 0.34x + 0.012$; $r^2 = 0.09$; $P = 0.06$

Discussion

Results of the present randomized controlled study disagree with previous findings claiming efficacy of policosanols with respect to LDL oxidation reduction and agree with the independent in vitro study showing no antioxidant effect associated with SCP treatment [28]. Animal [1, 2, 20, 21, 24] and human [7, 23] trials previously demonstrated a clear-cut suppression of lipid peroxidation as a result of Cuban SCP treatment. In rabbits with exogenous hypercholesterolemia, SCP exerted a dose-dependant protective effect on atherosclerotic lesions, as 25 and 200 mg/kg of SCP resulted in less aortic fatty streaks with foam cells of macrophage origin [2]. Menendez et al. [21] conducted a dose response study in rats administering 0, 250 and 500 mg/kg/day to evaluate LDL oxidation induced by CuSO_4 . Continuous monitoring of conjugated dienes and TBARS showed a dose-dependent prolonged lag time, reduced propagation of conjugated diene generation and decreased levels of TBARS in LDL samples from rats on policosanol treatments. A similar experiment was conducted in healthy volunteers given 5 and 10 mg of SCP for a period of 8 weeks. SCP significantly decreased the rate of conjugated diene generation by 38% and lowered malondialdehyde (MDA) generation by 32% [23]. The antioxidant action of SCP was also compared to lovastatin, an HMG Co A reductase inhibitor, in a randomized double-blind study where both substances decreased conjugated diene and TBARS production, but only SCP increased the lag time of LDL peroxidation and total plasma antioxidant activity [7].

One limitation to the studies cited above was the methodology used to evaluate LDL-oxidation. Although TBARS is widely used for its simplicity, it is known to be affected by reaction conditions, namely the presence of EDTA [16]. In a comparative study conducted by Carru et al. [6], the authors reported that copper oxidation was not a suitable method for the clinical evaluation of LDL-oxidation because of the difficulty in standardizing the test and

the time needed to run it. More importantly, this procedure did not provide a reliable measurement of conjugated dienes. The method used in the present study was designed to quantify LDL oxidation using monoclonal antibodies directed at antigenic determinants of the oxidized apolipoprotein B molecule, making the test more specific than the assays used by the original research groups in terms of discriminating between the sources of oxidation. Since the conversion of native LDL to its oxidized form is a pivotal step in the process of atherogenesis, the choice of the test is crucial for the accurate determination of LDL oxidation. The LDL-ox ELISA method was also chosen in this study because its validity was shown not to be affected by storage time. Circulating oxidized LDL levels have been used as a coronary heart disease marker in previous studies in samples stored for up to 9 years [11, 12]. In addition, the LDL-ox ELISA was seen to be a reliable measure of LDL oxidation in a study examining different storage conditions, namely, freezing samples for up to 3 years [30]. Plasma samples from our subjects were stored at -80°C up to a maximum of 2 years; however, our results did show a significant effect of storage time on the concentration of oxidized LDL. Consequently, the data were adjusted for storage time as a covariate. Final results show that the difference between the treatment and placebo group remained non-significant.

The regression analysis and analysis of covariance performed on the present data revealed clear relationships between LDL levels as a predictor of oxidized LDL concentrations. Our results support previous research [11, 12] reporting this association. A multivariate analysis of the potential predictors of oxidized LDL concentrations showed that hypercholesterolemia is one of the strongest predictors of the LDL oxidation status [11]. These findings were later confirmed by a study investigating the relationship between oxidized LDL and other markers of atherosclerosis [12]. A significant powerful association was reported between circulating LDL levels and LDL oxidation [12]. Since LDL oxidation clearly varies with circulating LDL levels, the present data were also analyzed using standardized oxidized LDL concentrations relative to plasma LDL values for each subject. After normalization, the data continued to support the lack of antioxidant activity of SCP as shown by the absence of difference between the treatment and placebo groups.

The mechanisms of action by which SCP could potentially prevent *in vivo* LDL oxidation remain unclear, however, it was suggested that these alcohols possibly altered the lipid structure of LDL particles by affecting the ratio of unsaturated to saturated fatty acid content [23, 24]. Other fatty acids such as oleic acid have shown to reduce LDL oxidation by altering the fatty acid makeup of lipoproteins as well [5, 29]. Absorption rates of oleic acid

measured in the lymph reach 58% in rats [32]. In humans, fecal analysis of labeled oleic acid shows an absorption efficiency of 97.2% after a bolus administration [13]. If policosanol affects the lipid structure in a way similar to oleic acid as suggested by the original research group, it would be expected to have an absorption rate high enough to exert such an effect. Although the bioavailability of Cuban SCP has not been extensively researched, a study from Menendez et al. [22] demonstrated very low concentrations of octacosanol (30.1 ng/ml) and octacosanoic acid in plasma of hamsters after the administration of a 60 mg/kg SCP dose. These findings were later supported by Marinangeli et al. examining the content of the different alcohols in the plasma and tissues of hamsters on a SCP treatment [18]. The authors observed no trace of the alcohols in the plasma or tissues of the animals. Taken with the evidence originating from different independent laboratories showing no cholesterol-lowering effect on animals and humans [4, 9, 10, 15, 25], the authors' conclusion raises the possibility that SCP dose, absorption and uptake are not high enough to induce a systemic effect on lipoprotein metabolism and or oxidation status. Whether an action at the level of the intestinal wall is possible remains to be assessed.

In summary, the present investigation examined the claim that SCP play a preventive role in the development of atherosclerosis by reducing both circulating LDL concentrations and oxidation levels. The present data adds to the growing body of evidence raising doubts on the efficacy of SCP as a natural cholesterol-modulating antioxidant therapy.

Acknowledgments This study was supported by a research grant from the Advanced Foods and Materials Network—Networks of Centres of Excellence.

The Carotid Artery Plaque Size and Echogenicity are Related to Different Cardiovascular Risk Factors in the Elderly

The Prospective Investigation of the Vasculature in Uppsala Seniors (PIVUS) study

Abstract Carotid plaques can be characterised by ultrasound by size and echogenicity. Both size and echogenicity are predictors of cardiovascular events. The aim of this study was to examine whether traditional risk factors and markers of inflammation and oxidation were associated with plaque size and echogenicity. Computerised analysis of carotid plaque size and echogenicity (grey scale median, GSM) were performed by ultrasound in a population-based health survey in 1,016 subjects aged 70 years (PIVUS study). Information on cardiovascular risk factors was collected, together with markers of inflammation and oxidation. Increased Framingham risk score, systolic blood pressure, higher BMI and decreased HDL, lower glutathione levels were related to echolucent plaques. Previous or present smoking was common with significantly more pack-years related to the echorich plaques. Plaque size was associated with increased Framingham risk score, systolic

blood pressure, blood glucose levels, smoking, ApoB/A1 ratio, OxLDL, TNF alpha, HOMA insulin resistance, leucocyte count, decreased BCD-LDL and low levels of l-selectin. Low HDL, increased BMI and decreased glutathione levels were associated with the echolucency of carotid plaques, implying metabolic factors to play a role for plaque composition. Markers of inflammation were related to plaque size alone, implying inflammation to be predominantly associated with the amount of atherosclerosis. These results suggest that plaque size and echogenicity are influenced by different risk factors.

Keywords Atherosclerosis · Ultrasound · Plaque · Carotid artery · Risk factor · Lipids · Oxidation

Introduction

Plaque rupture is believed to be the precipitating event in the major clinical manifestations of atherosclerosis, e.g. myocardial and cerebral infarction. The vulnerable plaque is described as containing a large lipid-rich core, a thin fibrous cap and an increased number of inflammatory cells. The stable plaque, on the other hand, is characterised by a smaller amount of lipids, more collagen and calcium and less inflammatory cells. Apart from being able to quantify the size of the plaque, a useful imaging modality should also be able to analyse plaque composition.

The plaque can be characterised in two different dimensions, size and echogenicity by using externally applied ultrasound on the carotid arteries. Both size [1] and echogenicity [1–4] of carotid plaques have been shown to predict not only stroke, but also other clinical manifestations of atherosclerosis, such as acute coronary syndromes including myocardial infarction. Thus, both of these plaque

dimensions are of interest for risk stratification. Analyses of carotid plaque specimens after endarterectomy indicates that the echogenicity reflects the different histopathological components, with echolucent plaques being associated with a high lipid and haemorrhage content [5].

While several studies have found that traditional risk factors, such as age, male gender, cigarette smoking, systolic blood pressure, high serum cholesterol, diabetes mellitus and low levels of HDL [6–10] are associated with carotid plaque size, determinants of plaque echogenicity are less well established. The presence of echolucent carotid plaques has been associated with low HDL levels [11], and with elevated levels of fasting and postprandial triglyceride rich lipoprotein [3]. Echolucent plaques in the femoral artery have also been found to be related to high levels of oxidised LDL and CRP [12]. Thus, lipid oxidation and inflammation may be important risk factors for plaque echogenicity.

Our hypothesis was that plaque size and echogenicity are associated with different risk factors. Earlier studies indicate that plaque echolucency is associated with lipid status [11]. Since both inflammation and oxidative stress have been advocated to play an important role in the development of atherosclerosis [13], several markers of inflammation and oxidative stress were investigated along with traditional risk factors. Treatment with statins are believed to induce regression of established atherosclerotic lesions, lower CRP levels [14], and possibly affect plaque composition [15]. Therefore, adjustment for statin treatment was made in all analyses.

Our aim was to investigate the relationship between carotid artery plaque size and echogenicity and cardiovascular risk factors, including markers of inflammation and oxidation in the PIVUS study, a population based cohort. We used the Prospective Investigation of the Vasculature in Uppsala Seniors (PIVUS) study, initiated in more than 1,000 subjects aged 70 living in the community of Uppsala, Sweden [16], to study the relationships.

Materials and Methods

For a detailed description of the basic characteristics of the PIVUS cohort see the previous publication by Stenborg et al. [17].

Subjects

The Prospective Investigation of the Vasculature in Uppsala Seniors (PIVUS) study is a population based cohort. All 70 year olds living in the community of Uppsala, Sweden were eligible. They received an invitation letter within 2 months of their 70th birthday. Of the total of

2,025 invited, 1,016 subjects participated giving a participation rate of 50, 1%. The study was approved by the ethics committee of the University of Uppsala and the participants gave informed consent. The present study was based on the 942 individuals in whom ultrasound pictures of high quality were obtained.

Basic Investigation

The participants answered a questionnaire disclosing their medical history, smoking habits and medication. All subjects were investigated in the morning after an over-night fast. Neither medication nor smoking was allowed after midnight preceding the investigations. Recordings of height, weight, abdominal and hip circumference were performed. Blood pressure was measured using a calibrated mercury sphygmomanometer in the non-cannulated arm after at least 30 min of rest in the supine position. The average of three recordings was used. Lipid variables and fasting blood glucose were measured by standard laboratory techniques. The Framingham risk score was calculated from these data [18].

Ultrasound System

The imaging was performed using an external B-mode ultrasound system (Acuson XP128 with a 10-MHz linear transducer, Acuson Mountain View, California, USA). All subjects were examined by the same ultrasonographer.

Ultrasound Procedure

The images were stored using the cine function during the electrocardiographic R-wave in the cardiac cycle. Frozen images of the arterial wall were saved and measurements subsequently performed on the stored digital images. Analyses were made using the AMS program package [19]. The common carotid artery, carotid bifurcation and internal carotid artery were examined bilaterally for the presence of plaques.

A local thickening of the intima-media by more than 50% compared with the surrounding IMT (but plaque area <10 mm²) was defined as stage 1 plaques. Plaque volume exceeding 10 mm² was defined as stage 2, and presence of an increased velocity distal to the plaque measured with Doppler, indicating >50% stenosis, as stage 3.

A region of interest (ROI) was manually positioned around the largest plaque. The grey scale median (GSM) was calculated from pixel analysis within in the range 0–256. The blood was used as the reference for black and the adventitia as the reference for white. Plaques were defined as echolucent if GSM value was lower than 70, and as echorich if GSM was higher than 70.

Also, the area of the ROI was calculated. This analysis was carried out by the same ultrasonographer blinded to the clinical data.

Measurements of GSM and plaque size were repeated in 25 random subjects yielding coefficients of variation (CV) of 8.3 and 11.2%, respectively.

Insulin Resistance

Serum insulin was measured with an enzymatic-immunological assay (Boehringer Mannheim). HOMA insulin resistance index was defined as fasting blood glucose time's serum insulin/22.5.

Markers of Inflammation

High sensitive CRP was measured in human serum by an ultra sensitive particle enhanced immunoturbidimetric assay (Orion Diagnostica, Espoo, Finland) on a Konelab 20 autoanalyser (Thermo Clinical LabSystems, Espoo, Finland). The inter assay CV was 3.2%.

Cytokines, chemokines and adhesion molecules were analysed on the Evidence[®] array biochip analyser (Randox Laboratories, Ltd., Crumlin, UK).

The functional sensitivity for the different inflammatory markers was as follows: interleukin 6 (IL-6): 0.3, interferon-gamma (InfG): 1.8, tumour necrosis factor alpha (TNF-alpha): 1.8, monocyte chemotactic protein 1 (MCP-1): 19.4, intercellular adhesion molecule 1 (ICAM-1): 18.6, vascular cell adhesion molecule 1 (VCAM-1): 3.1, endothelial selectin (e-selectin): 3.1, platelet-selectin (p-selectin): 11.2, lymphocyte selectin (l-selectin): 32.8, C reactive protein (CRP): 0.1, leukocyte count: 0.2.

Markers of Oxidative Stress

Baseline conjugated dienes of LDL (BCD-LDL) were measured by using a previously validated method (see Ref. [20] for details). The within assay CV for BCD-LDL was 4.4% and the between assay precision was 4.5%. Enzyme-linked immunoabsorbent assay (ELISA) kits (Merckodia, AB) were used to determine serum oxidised LDL, within-assay variation coefficient was 6.3% and between-assay CV was 4.7%. All glutathione indices, conjugated dienes (CD) and total antioxidant capacity (TAOC) values were measured and calculated as previously described [20]. Homocysteine was measured by using Enzyme Immunoassay method (Axis-Shield Diagnostics Ltd) with an intra-assay CV of 6.8%.

Statistics

IL-6, TNF alfa, InfG, e-selectin and homeostasis model assessment (HOMA) index were log-transformed in order

to achieve a normal distribution. ANOVA was used to evaluate differences between groups after adjustment for gender, with the Bonferroni post-hoc test using a pre-specified number of tests (abnormal groups versus the normal group). All analyses were adjusted for the influence of gender and statin use. Two-tailed significance values were given and $P < 0.05$ was regarded as significant. StatView (SAS Inc., NC, USA) was used for the statistical calculations.

Results

Approximately 6% of the cohort reported a history of myocardial infarction, 2% reported stroke and 9% reported diabetes mellitus. Almost half of the cohort reported some cardiovascular medication (45%), with antihypertensive medication being the most prevalent (31%).

Fifteen percent reported use of statins, while insulin and oral antiglycemic drugs were reported in 2 and 6% respectively (Table 1).

Evaluation of Non-Participants

As the participation rate in this cohort was only 50%, we carried out an evaluation of cardiovascular disorders and medications in 100 consecutive non-participants. The prevalence of cardiovascular drug intake, history of myocardial infarction, coronary revascularisation, antihypertensive

Table 1 Basic characteristics of the study sample (%)

Gender	Total <i>n</i> = 942	Men <i>n</i> = 469	Women <i>n</i> = 473
Hypertension ^a	678 (72%)	328 (70%)	350 (74%)
Statin use	141 (15%)	75 (16%)	66 (14%)
Heart failure	38 (4%)	19 (4%)	14 (3%)
Diabetes mellitus ^b	85 (9%)	52 (11%)	33 (7%)
Previous myocardial Infarction ^c	57 (6%)	84 (8%)	14 (3%)

^a Defined as systolic blood pressure >140 or diastolic >90, or use of antihypertensive medication

^b Defined as history of diabetes mellitus or fasting sugar level >6.1

^c Previous myocardial infarction which required hospitalisation

^d Previous stroke which required hospitalisation

medication, statin use and insulin treatment were similar to those in the investigated sample, while the prevalence of diabetes, congestive heart failure and stroke tended to be higher among the non-participants.

Prevalence of Carotid Artery Plaque

The prevalence of unilateral plaque, defined as at least 50% increase of the intima-media thickness, in the carotid arteries was 34%, while the prevalence of bilateral plaques was 27%. Plaques were in general slightly more prevalent in men ($n = 322$) than in women ($n = 293$).

Individuals with carotid artery plaques had significantly higher Framingham risk score ($P < 0.0001$), higher levels of systolic blood pressure ($P < 0.0001$), higher levels of fasting blood glucose ($P = 0.02$), LDL/HDL-ratio ($P = 0.04$), ApoB/A1-ratio ($P = 0.013$), LDL ($P = 0.02$) and also a higher average of pack-years of cigarette smoking ($P = 0.008$) after adjustment for gender and statin use. No significant differences were seen for HDL-cholesterol, serum triglyceride level, DBP or body mass index (Table 2).

Relationships Between Plaque Size, Traditional Risk Factors, Markers of Oxidative Stress and Inflammation

A similar picture emerged, as described above, when traditional risk factors were related to plaque size and not to plaque prevalence. Framingham risk score, SBP, blood glucose, ApoB/A1-ratio, HOMA resistance index and smoking were significantly related to plaque size after adjustment gender and statin use. However, these relationships were not all significant in the post-hoc analysis in the group with flow-restricting plaque since there were only 27 subjects in this group. No significant relationships

were seen between plaque size and LDL-cholesterol, HDL-cholesterol, LDL/HDL-ratio ($P = 0.07$), serum triglycerides, DBP, or body mass index (Table 3).

BCD LDL levels were significantly higher, among subjects with plaques. Conversely, the total antioxidant capacity (TAOC) was lower among these subjects as could be expected. There was a trend of decreased BCD levels with increased plaque size, however non-significant in the post hoc analysis. OxLDL levels showed a stepwise increase with increasing plaque size. No other markers of oxidative stress were significantly related to plaque size.

TNF alpha, l-selectin (inversely) and leukocyte count and all markers of inflammation, were significantly related to plaque size after adjustment for gender and statin use (Table 3).

Relationships Between Plaque Echogenicity and Traditional Risk Factors and Markers of Oxidative Stress and Inflammation

Echolucent plaques were correlated with an increased Framingham risk score, elevated systolic blood pressure and higher BMI after adjustment for gender and statin use, while the levels of HDL were lower. Previous or present smoking was common in both groups of echolucent and echorich plaques with significantly more pack-years related to the echorich plaques. None of the other traditionally risk factors were significantly related to plaque echogenicity (Table 4).

Levels of total glutathione (TGSH), reduced glutathione (GSH) and oxidised glutathione (GSSG) were significantly lower among the subjects with echolucent plaques when compared to individuals with echorich plaques. None of the other markers of inflammation and oxidative stress were significantly related (Table 4).

Table 2 Traditional risk factors in subjects with and without carotid artery plaques

	No plaque	Plaque	<i>P</i> -value
No.	327	594

SBP systolic blood pressure, DBP diastolic blood pressure, LDL low density lipoprotein, ApoA1 apolipoprotein A1, ApoB apolipoprotein B

Discussion

The main result of this study was that different risk factors were related to the two different dimensions of carotid plaque, i.e. size and echogenicity. HDL-cholesterol, body mass index and glutathione were related to echogenicity; while markers of inflammation were related to plaque size and not to echogenicity.

Relationships Between Plaque Occurrence and Size and Cardiovascular Risk Factors

Plaque occurrence and size was associated with systolic blood pressure, fasting blood glucose, LDL, LDL/HDL-ratio, ApoB/A1-ratio and smoking in this population. These are established risk factors for carotid atherosclerosis.

Table 3 Relationships between plaque size and traditional risk factor and markers of inflammation and oxidation

SBP systolic blood pressure, HDL high density lipoprotein, BMI body mass index, TGSH total glutathione, GSH reduced glutathione, GSSG oxidised glutathione

These findings being consistent with several earlier studies of asymptomatic carotid arteriosclerosis [7, 8, 21, 22].

In the present study, plaque size was also related to increased levels of TNF *alfa*, a high leukocyte count and

low levels of I-selectin. The relationship between with carotid atherosclerosis and inflammatory processes has previously been investigated. In the Rotterdam Study, increased fibrinogen was an independent predictor of carotid artery stenosis [7]. An elevated leukocyte count was associated with carotid arteriosclerosis in a study by Elkind and co-workers [23]. While high leukocyte count has been shown to predict future cardiovascular events [24, 25], less is known of the effects of I-selectin on atherosclerosis. However, in a small study, I-selectin levels were shown to be reduced in patients with ischemic heart disease compared to controls, and it was hypothesised that the chronic inflammatory process of atherosclerosis leads to downregulation of leukocyte expression of I-selectin, thus rendering lower circulating I-selectin levels. This hypothesis is supported by in vitro studies demonstrating that stimulation of leukocytes leads to a rapid downregulation of surface I-selectin expression [26].

The oxidative stress markers TAOC was reduced and BCD-LDL was increased in subjects with small plaques but not in those with larger plaques. This may be a pattern associated with the early stages of plaque growth, but it remains to be confirmed.

OxLDL levels have previously been associated with carotid artery atherosclerotic plaques [27], and we could confirm that carotid plaque size was linked to OxLDL in a stepwise fashion in the present study.

It should be emphasised that the vast majority of plaques observed in the present study are quite small and do not cause any obstruction of flow. Therefore, the present study should be regarded as a study of asymptomatic atherosclerosis. Other results could have been obtained if subjects with clinically important or symptomatic carotid stenosis had been investigated.

Relationships Between Plaque Echogenicity and Cardiovascular Risk Factors

The ANOVA analysis demonstrated that some of the risk factors related to plaque size were also related to the plaque echogenicity, while other risk factors were related to echogenicity alone. Body mass index, HDL and glutathione metabolism were factors mainly related to plaque echogenicity. Low levels of HDL-cholesterol have previously been shown to be associated with echolucent plaques, as well as with plaque progression [11]. In the present study, HDL was associated with the echogenicity but not size. HDL is known to be as a reverse cholesterol transporter and by the removal of cholesterol from the plaque and also other actions of HDL, such as anti-inflammatory actions, may influence the echogenicity of plaques.

Glutathione, an intracellular antioxidant widely distributed in human tissues, acts as a cofactor for glutathione peroxidase. This enzyme reduces H_2O_2 , a reactive oxidant species produced during the course of metabolism, to oxidised glutathione (GSSG) and water [28]. The GSSG level could be a result of a low glutathione peroxidase activity, indicating a reduced antioxidant activity in turn resulting in more echolucent plaques.

Another interesting finding was that BMI was associated with plaque echogenicity but not to plaque size. It has been shown that plaques that increase in GSM over time have a slow progress with respect to growth [29]. This finding could indicate that a good oxidative defence and a lean stature are characteristics that make a small plaque to increase in collagen and/or calcium content and in turn slowing down in plaque growth.

It has previously been reported that diabetics [30] and subjects with elevated inflammatory markers [31] have an increased prevalence of echolucent plaques. We could however not confirm these findings. Conversely, blood glucose levels and insulin resistance was related to plaque size, and none of the large number of inflammatory markers measured in this study were related to GSM in the plaque.

Limitation of the Study

The present sample is limited to Caucasians aged 70. Caution should therefore be made to draw conclusions to other ethnic and age groups.

The present study had a moderate participation rate. Therefore, we carried out an evaluation of cardiovascular disorders and medications in 100 consecutive subjects who refused to participate [13]. The prevalence of cardiovascular drug intake, history of myocardial infarction, coronary revascularisation, antihypertensive medication, statin use and insulin treatment were similar to those in the investigated sample, while the prevalence of diabetes, congestive heart failure and stroke tended to be higher among the non-participants.

A large number of variables were evaluated in order to obtain a broad view on risk factors for plaque size and echogenicity. This approach does however increase the risk of false positive findings. Thus, the results need to be repeated in other cohorts.

In conclusion, of the two carotid plaque dimensions, size and echogenicity, Framingham risk score, systolic blood pressure, fasting blood glucose, HOMA insulin resistance, cigarette smoking, ApoB/A, OxLDL, TNF alpha, low levels of I-selectin, decreased TAOC, increased leucocyte count were related to size, while HDL-cholesterol, glutathione and body mass index mainly were related to echogenicity. These results suggest that plaque size and echogenicity partly are influenced by different risk factors.

Acknowledgments The outstanding work at the endothelium laboratory performed by Nilla Fors, Jan Hall, Kerstin Marttala and Anna Stenborg in the collection and processing of the data is gratefully acknowledged. We also gratefully thank the staff at Analytical Biochemistry at AstraZeneca for performing the analyses of cytokines, chemokines, and adhesion molecules. The financial support from Uppsala University, Thureus foundation and AstraZeneca R&D is highly valued.

Abstract The aim of this study was to determine the fatty acid composition and *trans* fatty acid and fatty acid contents of breast milk in Turkish women and to find the effect of breastfeeding mothers' diet on *trans* fatty acid and fatty acid composition. Mature milk samples obtained from 50 Turkish nursing women were analyzed. Total milk lipids extracts were transmethylated and analyzed by using gas liquid chromatography to determine fatty acids contents. A questionnaire was applied to observe eating habits and 3 days dietary records from mothers were obtained. Daily dietary intake of total energy and nutrients were estimated by using nutrient database. The mean total *trans* fatty acids contents was $2.13 \pm 1.03\%$. The major sources of *trans* fatty acids in mothers' diets were margarines-butter (37.0%), bakery products and confectionery (29.6%). Mothers who had high level of *trans* isomers in their milk consumed significantly higher amounts of these products. Saturated fatty acids, polyunsaturated fatty acids and monounsaturated fatty acids of human milk constituted $40.7 \pm 4.7\%$, $26.9 \pm 4.2\%$ and $30.8 \pm 0.6\%$ of the total fatty acids, respectively. The levels of fatty acids in human milk may reflect the current diet of the mother as well as

the diet consumed early in pregnancy. Margarines, bakery products and confectionery are a major source of *trans* fatty acids in maternal diet in Turkey.

Keywords Human milk · Diet · *Trans* fatty acids · Fatty acids

Introduction

Human milk has a 3–5% content of lipids which perform important functions in the breast-fed infants' nutrition. Lipids are the main source of calories in the human milk (approximately 50% of the total caloric value). Milk fatty acids (FAs) are either synthesized in the mammary gland or are derived from plasma FAs that originate from the diet, synthesis in nonmammary tissues, or lipid stores [1]. It is well established that the FA composition of the diet can alter milk FA composition [2]. *Trans* FAs are defined as those that contain at least one double bond in the *trans* configuration. They are formed during the chemical hydrogenation of vegetable oils to manufacture commercial fats or during the microbial biohydrogenation of FAs in the digestive tract of ruminant animals. Humans do not synthesize *trans* isomers of fatty acids therefore their presence in human milk is based on maternal diet. The consumption of *trans* FA-containing foods by lactating women results in the incorporation of *trans* FAs in their milk fat [3–5]. The content of *trans* fatty acids in human milk varies between countries, from 0.5% to 7.2% of total fatty acids [6, 7], because of variations in dietary exposure to *trans* isomers. In recent years, special attention has been given to the potential impairment of essential fatty acids metabolism to their long-chain metabolites by *trans* isomers in humans.

These long-chain polyunsaturates metabolites are physiologically important as essential membrane components and precursors for synthesis of prostaglandins and other eicosanoids during perinatal and postnatal development [8]. There have been several studies of the *trans* FA content of milk from women [9–21]. Many studies are available in the literature on the content of FAs in the milk of women from many countries, but little is known of the composition of FAs in the milk of Turkish women. Thus, this work was conducted to provide further information on the fatty acid composition of the milk of Turkish women living in Ankara, Turkey. The aim of this study was to determine the content of *trans* FAs and total FAs in mature human milk at 12–16th lactation weeks and to relate these results with the breastfeeding mothers' diet in Turkey.

Materials and Methods

This study involved 50 mothers who were exclusively breastfeeding their term (born at 37–41 weeks gestation) infants. Women having complication of pregnancy or other diseases and mothers of infants with any evidence of metabolic or physical abnormality were not included in the study. Infants who were given bottle feedings of formula or cow's milk were ineligible. Written informed consent was obtained from all participants. All mothers agreed to provide samples of breast milk at 12–16 weeks postpartum. No personal dietary instructions were given to any of the mothers and all women were consuming self-selected diets. Food and nutrient intake were estimated using 3 days dietary recall at 12–16 weeks of lactation. Each participant was informed and trained on how to carefully record all foods consumed, their quantity in grams or in household measures, and their brands. The 3 days food records were analyzed to determine the average daily intake of food products and total energy, protein, carbohydrates, fat and FAs for each individual by using a computer program including total nutrient contents of specific brand name food products and typical dishes in Turkey (BEBIS 11.3) [22]. Breastfeeding mothers' daily dietary intake of *trans* FAs was estimated on the basis of 3 days recall and *trans* fatty acid levels in food products were calculated by BEBIS and USDA nutrient database [22].

Samples (5–10 mL) of mature milk between 12–16th weeks of lactation were collected by manual expression from each mother into sterile polypropylene tubes, always after the first morning nourishing of the baby. Samples were immediately kept frozen in sterile plastic tubes and stored at -70°C until analysis. Analyses were performed within 3 months of collection.

Methods

Fatty Acid Analyses

Milk samples were defrosted at room temperature and tempered in a vortex mixer before analysis. Lipids were extracted using the method described by Bligh and Dyer [23] with some modifications. A 3-mL milk sample was mixed with 10 mL methanol, 5 mL chloroform and 1.30 mL of water (methanol:chloroform:water 2:1:0.8, v/v). The mixture was agitated for 30 min, followed by addition of 5 mL chloroform and 5 mL of 2% anhydrous sodium sulfate solution. The final mixture had a final proportion of 2:2:1.8 (methanol: chloroform:water). The mixture was agitated for 15 min and centrifuged at 2250g for 30 min. The lower phase was filtered through a filter paper containing about 2 g of anhydrous sodium sulfate. Chloroform (10 mL) was added to the remaining phase, and centrifuged under the same conditions. Extracts were pooled and solvent was evaporated under gentle nitrogen stream.

The preparation of the fatty acid methyl esters (FAMES) was conducted by the method described by Ledoux et al. [24]. One milliliter hexane solution (about 20 mg lipids) was transferred into a centrifuge tube and 0.5 mL internal standard (heptadecanoic acid methyl esters, 0.4 mg/mL (Sigma, ST Louis, MO) was added. The solvent was evaporated under nitrogen. Lipids were dissolved with 1 mL toluene, and esterified using 100 μL 2 N sodium methoxide (Merck, Darmstadt, Germany) for 20 min at room temperature. Then, 0.5 mL 14% boron trifluoride/methanol (Merck, Darmstadt, Germany) was added and allowed to react for 20 min at room temperature (ca. 20°C). FAMES were then extracted 2 times using 2 mL hexane in the presence of 5 mL sodium bicarbonate (Merck, Darmstadt, Germany). The FAMES were analyzed by gas liquid chromatography using a HP 5890 series II gas chromatograph (GC) (Hewlett Packard Company, Wilmington, DE) equipped with a flame ionization detector (FID) and an HP 7673A automatic injector (Agilent Technologies, Palo Alto, CA). Separations were performed on a DB 23 capillary column (60 m \times 0.25 mm i.d., 0.25 μm film thickness; J&W Scientific, Folsom, CA). The oven temperature was programmed from 140°C for 5 min, thereafter 3°C per minute up to 220°C , and maintained at this temperature for 20 min. Injector and detector temperatures were 250 and 260°C , respectively. Nitrogen was used as a carrier gas and the flow rate was 1 mL/min. The split ratio was 1/65. Peak identification was verified by comparison with reference standard mixes (37 component FAME mix, grain fatty acid methyl ester mix Supelco, Bellefonte, PA; linoleic acid methyl ester cis/trans isomers, linolenic acid methyl ester isomer mix standard, Sigma,

ST Louis, MO). Results were expressed as a percentage (% wt/wt) of all fatty acids detected with a chain length between 8 and 22 carbon atoms. Fatty acid analysis was performed in triplicate for single samples of each human milk samples and average values were reported.

Statistical Analysis

All data were analyzed by using Statistical Packages for Social Sciences (SPSS 13.0). Results were expressed as mean \pm SD. Correlations between the percentage by weight of each FA, total *trans* FAs, groups of similar FAs, and milk fat concentration were examined by using Pearson correlation coefficients. Analysis of variance was used to ascertain the relations between total *trans* and FA percentages. Relations were declared significant at $p < 0.05$.

Results

Physical Characteristics

The physical characteristics of lactating Turkish women are given in Table 1. The study was conducted in a moderate socio-economic status region in the city of Ankara in Turkey. Fifty lactating women meeting the criteria were selected, aged between 17–39 years old (mean \pm SD 26.16 ± 5.49 years). The mean body mass index (BMI) of the lactating women was 25.48 ± 4.61 kg/m². Age of marriage was 20.48 ± 3.89 years old. Age at first pregnancy was found to be low (21.44 ± 3.82 years). All of the subjects had only primary school education with an average attendance of 6.0 ± 1.9 years.

Fatty Acid Concentrations

The fatty acid distributions in Turkish mature breast milk are listed in the Table 2. The main fatty acids in the breast milk samples were oleic (18:1*c*; 27.3%), palmitic (16:0;

20.9%) and linoleic (18:2*n*-6; 24.3%) acids representing about 72.5% of the total FAs in the investigating stages (12–16th week) of lactation. The major FA groups and the total fat content (Table 3) were the saturated fatty acids (SFAs) (40.7%), of which 51.4% was palmitic acid, the monounsaturated fatty acids (MUFAs) (30.8%) of which 88.6% was oleic acid and the polyunsaturated fatty acids (PUFAs) (26.9%) of which 90.3% was linoleic acid. The mean total *trans* FA concentration was $2.13 \pm 1.03\%$ (min-max range 0.4–5.0%). As expected, *trans* isomeric octadecanoic acids (*trans*-18:1) made up the main *trans* isomer group in mature milk ($1.96 \pm 1.03\%$).

Trans fatty acids were found in all human milk samples but levels of *trans* isomers varied between mother. The mean value of *trans* isomers of octadecadienoic acid (18:2*t*) in mature milk was 0.15 ± 0.06 , whereas hexadecanoic acid (16:1*t*) *trans* isomers thereof were detected in very low concentrations and they were not present in all milk samples of mature milk at the investigated stage of lactation (Table 2).

On the basis of the wide variation in the total *trans* FA concentrations of these milk samples, the samples were grouped into 3 categories to evaluate the differences between the groups: high (samples containing $\geq 4\%$ total *trans* FAs; $n = 3$), medium (samples containing between 2–4% total *trans* FAs; $n = 20$), and low (samples containing $\leq 2\%$ total *trans* FAs; $n = 27$) *trans* FAs (Table 4). For simplicity, only data for major individual FAs and FA groups are shown. For stearic and linoleic acid concentrations, there were no significant differences between groups. Total SFA and PUFA concentrations were not significantly different between the groups; however MUFA concentrations were higher in the high *trans* FA group than in the low *trans* FA group ($p < 0.05$).

Maternal diet composition and major FAs profiles are listed in Table 5. Carbohydrates accounted for the 50.7%, protein for the 14.8% and lipids for the 34.5% of the total dietary energy intake. In the lipidic fraction, SFAs, MUFAs and PUFAs represent the 31.6%, 43.4% and 18.0% of the total dietary energy intake, respectively. The estimated daily intake of *trans* fatty acids was 2.16 ± 2.01 (min-max range 0.22–7.65) g/day in, representing 1.12 ± 1.09 (min-max range 0.06–4.75)% of the daily total energy intake and 3.16 ± 3.10 (min-max range 0.14–13.11)% of total fat (Table 5). The major sources of *trans* fatty acids in mothers' diets were margarines-butter (37.02%), bakery products such as cakes, cookies, pies, biscuits and muffins, confectionery, snack foods (29.62%) and breads (13.42%). Mothers who had high level of *trans* isomers in their milk consumed significantly higher amounts of these products (Table 6). However, the correlation between the human milk and maternal diet fatty acids was found statistically insignificant.

Table 1 Physical characteristics of the mothers ($n = 50$)

Physical characteristics	Mean \pm SD
Mother's age (y)	26.16 ± 5.49

Discussion

Fatty acids, an important component of milk, appear in milk as a result of dietary intake, mobilization from fat depots, and endogenous synthesis by the mammary gland [1]. FA composition of human milk responds rapidly and markedly to diet and is dependent on the amount and type of fat consumed, stage of lactation, and term or preterm milk and carbohydrate intakes, and also shows variance cross-culturally [2, 3]. The concentration of major FAs of Turkish lactating women milk (Table 2) with few exceptions were found differ from that of women consuming western diets in Europe and America. In this study, the SFA contents of mature milk (40.7% total FAs, Table 3) were very close to recent reviews on FA composition of human milk [7, 9, 18, 19]. Lactating women from Asian (Malay, India, Nepal) and Saudi Arabia showed higher SFA contents in milk lipid (51.7%, 50.5%, 65.8% and 56.2%, respectively) [9, 25, 26], whereas Chinese [9, 12], Canadian [7], Brazil [27], Western Iran [28] and European [29] lactating women showed similar values to those found in this study (38.5–44.9%). Percentages of medium-chain saturated FAs (C 8:0–C 14:0, MCSFAs) found in the milk of Turkish women (13.5%, Table 2) were within the range

of values found for other populations (range 12.7–42.5%) [25–31]. These FAs can either be synthesized *de novo* in mammary tissue or other maternal organs (primarily medium- and intermediate-chain fatty acids) or be derived from the mother's diet [18, 32–34]. The higher values of MCSFAs found in other studies were related to higher intakes of carbohydrates by the lactating women. Carbohydrate appears to favor the increased synthesis of MCSFAs by the mammary gland [33]. Van Beusekom et al. [34] found higher *de novo* FA synthesis in Dominican women, who had a diet richer in carbohydrates (70%) than in Belize women (55%). Similarly, Rocquelin et al. [31] and Kneebone et al. [9] observed human milk lipid in Congolese, Indian and Malay women populations, and they established the content of MCSFAs as to be 26.0% and 18.6% and 19.8% for those populations, respectively.

Bahrami et al. [28] reported that the milk of Iranian lactating women whose diet was mainly derived from low animal protein and high carbohydrates, showed MCSFAs contents of approximately 24%. The other study of Turkish lactating women who had a rich diet in carbohydrates (60–65%) [35] reported total SFA and MCSFA contents to be approximately 52.4%, and 28.4% respectively. In the present study, the content of MCSFAs was low (13.5%), probably depending on low carbohydrate intake (50.7%, Table 5).

Long-chain saturated fatty acids (LCSFAs, C15:0–24:0) contents were 27.3% (Table 2). These fatty acids are

Table 5 Daily energy and nutrient intakes of mothers (*n* = 50)

Percentage of energy (%)	50.70 ± 8.39

derived especially from diet and their sources may be oils or fat used in food preparation, animal fat and proteins. Some reports have shown that LCSFA values of approximately 28–30% in the milk of lactating women whose diet was mainly derived from animal fat and proteins [1, 9, 33–36]. In this study, it has been found that the main source of LCSFAs was oils or fat used in food preparation (margarine, butter etc.) and animal protein for the lactating women (49.6% of total protein, Table 5).

In this study, MUFAs represented 30.8% of the total FAs in the milk lipid of the lactating women. The major fraction was formed by *cis* monoenoic FAs, for the most part represented by C18:1. Oleic acid, which is considered an important source of energy for the breast-fed infant, was the highest in human milk. Although monoenoic FAs are nonessential and can be synthesized by human, their dietary intake may have physiologic effects by influencing membrane fluidity and cholesterol metabolism [1, 10, 18]. Our mean 18:1*c* value (27.3%) is in the range of 25–38% reported for 18:1 in some recent studies [18–21, 27, 28, 37]. In relation to the lactating women's eating habits, the main source of these FAs was probably vegetable oils

Table 6 Major sources of the *trans* fatty acids in the diet of breastfeeding women in Turkey

T*t*FA Total *trans* fatty acids

(soybean oil, olive oil) which contributed to their final content.

In the present study *trans* FAs accounted for 2.1% (min-max range 0.39–4.97). The major proportion of all of the *trans* isomers was contributed by 18:1*t* (1.96%), reflecting the composition of the maternal diet. The *trans* FA content in human milk depends mainly on the mother's recent dietary intake, most of which is derived from hydrogenated vegetable oils in margarines, shortenings, and processed foods [1, 3, 38].

The contribution of *trans* isomeric FAs to the FA composition of human milk in Turkey was found to be around 2% of the total FA content. This value is in good agreement with reports on mean percentage contributions of *trans* FAs to the FA composition of human milk in Europe [3, 10, 19, 20, 33, 39–41]. The mean values of *trans* FAs in mature milk reported for Poland (2.7%), Italy (Rome) (2.7%), Czech Republic (2.1%), France (2%) and Germany (2.4%) were all close to the value seen in our study. In contrast, considerably higher human milk *trans* FA values were reported for North America (Canada: 7.2%, USA: 7.0%) than for most European countries and the current study [42, 43]. The differences in total *trans* FAs in different countries may be partially attributed to differences in the diets consumed by the women in these various areas of the world. The consumption of foods that contain greater concentrations of *trans* FAs, such as processed foods made with partially hydrogenated vegetable oils and animal fat leads to greater intakes of total *trans* FAs, which are incorporated into milk fat [3, 38].

Our analysis of 3-day diet records estimated a mean *trans* FA intake of 2.16 g/day (min-max range 0.22–7.65 g/day), representing 1.12 (min-max range 0.06–4.75)% of energy intake and 3.16 (min-max range 0.14–13.11)% of total fat intake. The mean percentage of *trans* FAs in milk (2.13%) was similar to that calculated for the diet,

suggesting the estimated value of 2.16 g/day *trans* FAs is a reasonable estimation of the *trans* FA intake of the women in this study. The major sources of *trans* FAs in mothers' diets were margarines-butter (37.0%), bakery products (such as cakes, cookies, pies, and muffins), confectionery, snack foods, fried foods (29.62%) and breads (13.42%). Mothers who had a high level of *trans* isomers in their milk consumed significantly higher amounts of these products.

Numerous studies have shown that human milk FAs, particularly monounsaturated, n-6, n-3 and *trans* FAs, and their ratio change depending on maternal diet [19–21]. Concerns about dietary fat and health or lifestyle issues that alter maternal food choices may therefore influence the FA nutrition quality of breast-fed infants. It is particularly important to note that our results identified baked and prepared foods and breads as major sources of *trans* FAs providing <50% of the total *trans* FA intake. However, the relationship between intake dietary *trans* FAs and the *trans* FA level in mature breast milk was found to be statistically insignificant. Other factors may influence an increase in levels of *trans* FAs in milk. Besides dietary factors, maternal weight loss during lactation was also suggested as causing an increase of *trans* FAs in milk [3, 4, 13, 14, 38]. Numerous studies have shown that weight loss during lactation was an additional cause of the increase in *trans* FA concentrations in human milk [3, 4, 14]. In some studies, *trans* FAs have been shown to alter the incorporation of essential long-chain PUFAs into milk fat [7, 21, 38]. Larque et al. [38] showed that rats receiving dietary *trans* FAs had higher concentrations of linoleic acid in milk fat, but total long-chain PUFAs did not differ significantly. In contrast, other researchers [7, 21] found an inverse relation between essential all-*cis* n-6 and n-3 FAs and total *trans* FAs in human milk. However, in the current study, no correlation between total *trans* FAs or total 18:1*t* and linoleic, linolenic, total n-3, or total n-6 FAs in mature milk was detected (data not shown).

In this study, the total PUFA contents of mature milk were 26.9% (min-max range 16.1–38.9%) of total milk FAs (Table 2, 3). The levels of PUFA for the Turkish lactating women were higher than those found for the North American and European populations (10.0–16.6%) [18, 19, 28, 32, 44]. The essential fatty acid, linoleic (C18:2n-6), had a value of 24.3%. Linoleic acid contents in Turkish women milk lipid were higher (14.35–36.91%) than the range reported from different world locations (8.7–14.1%) [18, 19, 26–28, 32, 44, 45]. Dietary intake of 18:2 influences the content of this FA in milk [39]. Therefore, it seemed likely that the high percentage of 18:2 in the milk of Turkish women was a result of high dietary intakes of 18:2. Most of the women in our study group (95%) were consuming sunflower-based margarines and sunflower oil and also consumed olive oil.

The influence of maternal dietary fatty acids on the fatty acid composition of milk may be attributed to the great variation in the contents of linoleic (C18:2n-6), α -linolenic (C18:3n-3) acids. These changes are due to the consumption of polyunsaturated oils. For example, an increase in polyunsaturated oil consumption may lead to an increase in the content of PUFAs in the mother's milk [39]. Our results showed that there are relation between maternal PUFA intake and the content of PUFA in human milk. Mothers who had high level of n-6 PUFAs in their milk consumed significantly higher amounts of n-6 PUFA (Table 5). In this study, it was observed that the majority of the lactating women of Turkey used vegetable oils, especially sunflower oil as eating habit in their daily diets.

The essential FA, α -linolenic (C18:3n-3), presented a content of 0.59% (min-max range 0.26–1.29). It could be said that the α -linolenic acid level found in the milk of Turkish lactating women in this study was rather similar if range values reported for the world population (min-max range 0.10–1.4%) are considered [9, 19, 25, 26, 33]. The increased consumption of C18:2n-6 in Western societies would be capable of increasing the C18:2n-6/C18:3n-3 ratio in human milk. In USA the high level of C18:2n-6 in human milk also associated with an C18:3n-3 level often superior %1 of total FAs, so that the n-6/n-3 ratio generally never passes 16 [36]. In Turkey, it is quite different because C18:3n-3 only represents 0.59% of FAs in human milk. Thus, the C18:2n-6/C18:3n-3 ratio exceeds 20. A ratio superior to 20 in human milk has been recently observed by Scopesi et al. [44]. These observations suggest that different C18:3n-3 intakes are probably due to maternal dietary habits.

Total LCPUFAs showed a content of 1.49% in the milk lipids of Turkish lactating women (Table 2). In the present study, small proportions of n-6 LCPUFA (1.34%, min-max range 0.81–1.96%) were identified in the milk of the lactating women. The levels found for arachidonic acid (AA),

C20:4, (0.46%, min-max range 0.2–0.86%) were similar to those found in the milk lipids of women in France [36] (0.41–0.50%), Germany [18] (0.35%) and the USA [20] (0.47%). Koletzko [18] and Kneebone [9] demonstrated the lack of a correlation between linoleic (18:2n-6) and arachidonic acids (20:4n-6) in human milk and we did not find any correlation between both linoleic and α -linolenic acids and their respective LCPUFA metabolites either. Thus, the LCPUFA content of human milk appears not to be closely related to the maternal intake. This finding suggests inter-individual differences in the capacity of the desaturation/chain-elongation pathway and of the incorporation process of the LCPUFA metabolites into milk lipids. Among the n-3 LCPUFA, the main FA identified was docosahexaenoic acid (C22:6n-3) (0.15%, Table 2). The DHA (docosahexaenoic acid) was given with mean values of 0.45% for Western and 0.88% for Eastern women, and DHA value of 0.20–0.30% was accepted as a representative range [33, 39]. The amounts found in human milk corresponded to the amounts of DHA in foods, especially fish, in the diet of the lactating women [39]. In this study, DHA content was lower than the value recommended as representative. Because, Turkish lactating women do not habitually of consume fish frequently, the results found were probably due to the C18:3n-3 elongation–desaturation mechanisms.

In conclusion, this study showed that the milk of the women from Ankara, Turkey had a high content of linoleic acid and a low content of α -linolenic acid, confirming their frequent habit of consuming diets rich in polyunsaturated oils. Besides, low *trans* FAs contents were verified compared to populations from different localities. Thus, it is suggested that diet is an important factor that may influence and provide the differences observed in the compositions of FAs of populations from several regions worldwide. Although the negative effect of human milk *trans* FAs on breast-fed infants is not yet well documented, we suggest that infants ingest levels of *trans* FAs that reflect the current diets of breastfeeding mothers. In our study we identified margarines, butter, bakery products, and confectionery as the main sources of *trans* FAs in the maternal diet in Turkey and we conclude that breastfeeding mothers should avoid these products in their diet. However there is limited knowledge about *trans* FA levels in processed foods available in Turkey. Further studies are needed to improve the national nutrient database. In addition, more regional information is needed to fully describe the variation in the concentrations of *trans* FAs and FAs in human milk samples throughout the Turkey. The effect of *trans* FAs, PUFAs and LCPUFAs on human health is an important area of research. Identifying the concentrations of FAs in human milk fat will aid in identifying possible relations between *trans* FAs or FAs and infant growth or health.

Abstract The relationship between lecithin:cholesterol acyltransferase (LCAT) activity and weight loss in dogs was investigated. Four experimental weight-loss diets were fed to 12 obese female beagles for 56 days in a partial crossover design ($n = 6$). High- (HGI) or low- (LGI) glycemic index starch and diacylglycerol or triacylglycerol oils were combined to compose experimental diets with similar fatty acid profiles. Food intake and body weights were measured daily and weekly, respectively. Fasted blood samples were drawn at day 0, day 28, and day 56 to measure plasma LCAT activity and total (TC), unesterified (UC), and esterified (EC) cholesterol concentrations, and for fatty acid analysis of the phospholipid (PL) and EC fractions. The LGI groups lost more weight than the HGI groups due to starch digestibility differences. An HGI starch effect on TC and UC concentrations was observed but was unrelated to weight loss. LCAT activities increased over time but were not different after controlling for percentage weight loss. However, a positive linear correlation was found between LCAT and UC concentrations in all groups. Plasma PL fatty acid profiles reflected the diets fed, but increases in 16 and 18 carbon saturated and monounsaturated fatty acids in all groups appeared to be an effect of fatty acid mobilization from storage sites. Both plasma PL and EC fatty acid profiles were similar with both acylglycerol types and EC fatty acids reflected linoleic acid specificity with minimal diet or time effects.

Keywords Plasma esterified cholesterol composition · Plasma phospholipid composition · LCAT activity · Weight loss · Obese beagles

Abbreviations

DAG	Diacylglycerol
EC	Esterified cholesterol
FA	Fatty acid
FAMES	Fatty acid methyl esters
GC	Gas chromatography
HDL	High density lipoprotein
HGI	High-glycemic index
LCAT	Lecithin:cholesterol acyltransferase
LGI	Low-glycemic index
LPC	Lysophosphatidylcholine
MAG	Monoacylglycerol
MUFA	Monounsaturated fatty acid
PC	Phosphatidylcholine
PL	Phospholipid
PUFA	Polyunsaturated fatty acid
SFA	Saturated fatty acid
TAG	Triacylglycerol
TC	Total cholesterol
UC	Unesterified cholesterol

Introduction

Overweight and obesity are common problems among companion animals, affecting an estimated 25–40% of dogs and cats seen in private veterinary practice [1]. Significant health repercussions such as greater risk for earlier morbidity, shortened lifespan, insulin resistance, and osteoarthritis are associated with excess body weight in

dogs [2, 3]. Typically, this is addressed by decreasing calorie intake and increasing energy expenditure to promote weight loss [4]. Another approach proposed recently is the replacement of the typical form of fat found in the diet, triacylglycerol (TAG), with a form of fat normally found in very low quantities in the diet, diacylglycerol (DAG), especially 1,3-DAG [5].

Animal studies report suppression of diet-induced body weight and visceral fat gain in rats and obesity-prone mice fed diets containing 1,3-DAG versus TAG [5]. Human studies have demonstrated a decrease in visceral fat mass in normal weight, overweight, and obese subjects associated with 1,3-DAG versus TAG intake [5]. Because DAG and TAG oils have been observed to have similar digestibility, energy content per gram, and absorption, it has been hypothesized that the metabolic differences observed may be due to the structural differences between the two lipids [6, 7]. During digestion of TAG, the fatty acids at the sn-1 and sn-3 positions are hydrolyzed, resulting in 2-monoacylglycerols (2-MAG) and free fatty acids. After absorption into the intestinal mucosal cell, these components are re-esterified into TAG and packaged for circulation. In contrast, the digestion of 1,3-DAG produces free fatty acids (FA) and 1(3)-MAG, which exhibit less efficient re-esterification into TAG than 2-MAG in the intestinal mucosal cells [6, 8]. Alternatively, 1(3)-MAG may be entirely hydrolyzed to fatty acid and glycerol in the intestinal lumen prior to absorption but this process is not always complete [6]. The fate of the fatty acids that are not re-esterified in the intestinal mucosal cells after digestion of 1,3-DAG and absorption of its components is unclear. One possibility is that these fatty acids are oxidized within intestinal mucosal cells. Indeed, animal studies have demonstrated an increase in small intestinal β -oxidation in lean and obese mice fed diets high in DAG [9, 10].

One effect of obesity often observed in canines is increased plasma cholesterol [11]. This phenomenon has also been seen in cats, as well as a reduction in plasma cholesterol in conjunction with weight loss [12, 13]. This decrease in plasma cholesterol during weight loss could be explained by an increase in the activity of Lecithin:cholesterol acyltransferase (LCAT) in conjunction with efficient scavenging of the resultant esterified cholesterol (EC) as part of reverse cholesterol transport. LCAT facilitates reverse cholesterol transport by creating a concentration gradient of unesterified cholesterol (UC) between peripheral cells and high density lipoprotein (HDL) particles, onto which LCAT is reversibly anchored, resulting in cholesterol esterification [14–16]. Several studies have found strong positive correlations between plasma cholesterol concentrations and LCAT activities in both normal and obese subjects [17–19]. However, total

cholesterol concentrations do not appear to be determined by LCAT concentrations; instead the enzyme may be regulated as a response to changes in plasma cholesterol concentrations.

Current knowledge of canine LCAT activity is limited. No studies have reported the relationship between LCAT activity and weight loss in dogs, and few have reported the activity of canine LCAT in general. One study reported an increase in LCAT activity that was associated with an increase in plasma cholesterol concentrations in mixed-breed dogs fed a high-fat diet [16]. These data support the concept of a relationship between LCAT activity and cholesterol concentrations in dogs as has been found in other species. Through this dietary trial, relationships between LCAT activity and weight loss as well as plasma cholesterol concentrations were investigated. In addition, the effects of dietary DAG versus TAG on plasma PL and EC fatty acid compositions were studied. It was hypothesized that obese dogs undergoing weight loss would exhibit increased plasma LCAT activity and that the structural differences between DAG and TAG might influence plasma PL and EC fatty acid profiles.

Experimental Procedures

Animals and Diets

The protocol for this study was approved by the Texas A&M University Laboratory Animal Use Committee. Twelve adult intact female obese beagles, ages 2–6 years with body condition scores of 8–9 on a 9 point scale where five is ideal and nine is obese, were assigned equally to four diet groups. The dogs are part of an out-bred colony of beagles belonging to Texas A&M University. They were individually housed in approved sized kennels with 12 h light cycles and allowed free access to water and exercise during the study. All dogs were intentionally made obese by overfeeding a highly palatable mixed diet of commercial pet food, vegetable oil, and human grade cookies until stable obese body weights were attained. Complete details regarding the obesity induction and re-induction periods have been published [20]. Dogs were first fed an acclimation diet for 28 days and then one of the four experimental diets for 56 days, all at the estimated kcal required to maintain starting obese body weights. Initial levels of obesity were re-attained during a 17-week washout, weight re-gain period and a steady obese state was again achieved as evidenced by stable, yet high body weights. The acclimation and experimental diet periods were repeated in a partial crossover design. Food intake and body weights were measured daily and weekly, respectively.

Experimental diets incorporated gelatinized waxy corn starch (high glycemic index, HGI) or gelatinized high amylose corn starch (low glycemic index, LGI) paired with DAG or TAG oil having similar FA profiles (Table 1). The diets were designated HGI/DAG, HGI/TAG, LGI/DAG, and LGI/TAG. Starches and oils were provided by Kao Corporation (Tokyo, Japan). Chicken by-product meal (Tyson Foods, Inc., Oklahoma City, OK), starch, and a vitamin/mineral premix (Akey, Lewisburg, OH) constituted the dry diet mixture, which was combined with the specified oil and water to form gruel-based diets. Ingredients and FA profiles of the acclimation and experimental diets can be found in Tables 2 and 3, respectively. The acclimation diet consisted of a dry mixture of chicken by-product meal, HGI/LGI starch blend (50:50, by wt), and a vitamin/mineral premix combined with canola/vegetable oil blend (50:50, by vol) and water.

Blood Sample Collection and Analyses

Fasted blood samples (7 mL) were drawn into EDTA-tubes at day 0, day 28, and day 56 of experimental feeding. Plasma was harvested by low speed centrifugation and stored in aliquots at -20°C for subsequent analysis.

Plasma samples were analyzed in triplicate for TC, UC, and EC concentrations enzymatically according to the procedure described by Warnick [21]. Samples were also

assayed for LCAT activity in duplicate according to the procedure described by Gillett & Owens using radiolabeled tracer equilibrated with endogenous substrate [22]. Results were converted from percent UC esterified to nmol UC esterified/mL of plasma/h using individual plasma UC concentrations. LCAT activities were normalized between assays using control plasma samples from baseline which were determined with each assay.

Plasma lipids were extracted according to the method described by Folch et al. [23]. Lipid subfractions were separated by thin layer chromatography using hexane/ether/glacial acetic acid (80:20:1, by vol). The EC fraction was briefly visualized using I_2 vapor, outlined, and scraped into Teflon-lined screw capped tubes. Fatty acids in the PL and EC fraction were methylated by incubation with 4% H_2SO_4 in methanol for 1 h at 90°C . Fatty acid methyl esters (FAMES) were extracted into hexane and analyzed by gas chromatography (GC) using a Hewlett Packard 5890 Series II Gas Chromatograph (Hewlett Packard Co., Palo Alto, CA) with a flame ionization detector. The GC conditions were as follows: FAMEWAX fused silica capillary column (0.32 mm \times 30 m, 0.25 μm , Restek, Bellefonte, PA); initial velocity 28.3 cm/s and flow 1.25 mL/min of helium; initial oven temperature 160°C for 10 min, increased $1.0^{\circ}\text{C}/\text{min}$ until final temperature 220°C . Results were generated with Hewlett Packard ChemStation software package. Authentic FAMES standards (Nu-Check Prep, Inc., Elysian, MN) were used to identify individual FA peaks based on retention times.

Data Analysis

Statistical analyses were performed using SPSS 15.0/16.0 for Windows. The Shapiro–Wilks test was used to determine normal distribution of data. Nearly all of the data were normally distributed. However, in a few cases, non-normally distributed data were analyzed using Kruskal–Wallis one-way ANOVA. Repeated measures ANOVA, was used to test all data for main effects of time, starch, and oil and for interactions. Where there was a significant interaction between factors, data within days was analyzed by a 2×2 factorial and least square means were compared among and within diet groups to determine significant effects. In addition, two-way ANCOVA using % body weight loss as a covariate was used followed by L-matrix analysis to test the data for main effects of starch and oil as well as starch \times oil interactions at each time point to control for differences in weight loss between the groups. For all data, a p -value <0.05 was considered significant and multiple comparisons were performed where appropriate using least squares differences and linear regression analyses.

Table 2 Ingredients and metabolizable energy of diets fed

Results

Animals and Diets

The dogs consumed an average of only $68 \pm 4\%$ (mean \pm SEM) of the diets offered overall per day on a weight basis. Consequently, all dogs lost weight during the study with an average weight loss of $5.8 \pm 1.2\%$ (mean \pm SEM) by day 28 and $11.2 \pm 1.5\%$ (mean \pm SEM) by day 56 for all diet groups. However, dogs consuming the LGI-based diets lost significantly more weight as a percentage of starting weight than those eating the HGI-based diets (Table 4).

Plasma Cholesterol Concentrations

A time \times starch interaction was found for TC and UC concentrations using repeated measures ANOVA between day 0 and day 28 sample times. Further analysis revealed a starch effect for these cholesterol fractions at day 28 with HGI group values significantly higher than those of the LGI groups. Only a trend for this effect was observed at day 56 ($p < 0.066$) (Fig. 1). However, analysis of covariance using % body weight lost as a covariate eliminated any significant effects of starch during weight reduction of these dogs.

Plasma LCAT Activities

Repeated measures analysis revealed a main time effect but no diet effect or diet \times time interaction for LCAT activity (Fig 2). Plasma LCAT activity increased from day 0 to day 28 and remained elevated at day 56, though not as much as at day 28. Analysis of variance and covariance did not reveal any further significant differences among the diet groups or interactions. However, regression analysis revealed a significant positive linear correlation ($r = 0.638$, $p < 0.001$) between LCAT activities and UC concentrations but not with any other cholesterol fraction. These correlations were similarly positive whether the two starch diet groups were analyzed separately or together (HGI starch, $r = 0.622$,

Table 4 Body weights of dogs during the experimental period (kg)

Diet	Day 0	Day 28	Day 56
LGI/DAG	15.5 \pm 1.1	14.0 \pm 0.9 (9.7%) ^a	13.1 \pm 0.8 (15.5%) ^a
LGI/TAG	15.0 \pm 1.5	13.7 \pm 1.4 (8.7%) ^{a,b}	12.6 \pm 1.2 (16.0%) ^a
HGI/DAG	14.3 \pm 1.2	13.9 \pm 1.4 (2.8%) ^{b,c}	13.2 \pm 1.4 (7.7%) ^{a,b}
HGI/TAG	14.9 \pm 0.7	14.8 \pm 0.9 (0.7%) ^c	14.1 \pm 1.1 (5.4%) ^b

Values in parentheses indicate percentage of body weight lost compared to day 0

Letters not in common in a column are significantly different, $p < 0.05$

Fig. 1 Plasma total, unesterified, and esterified cholesterol concentrations of dogs fed diets differing in starch type (high-glycemic index [HGI] or low-glycemic index [LGI]) and oil type (diacylglycerol [DAG] or triacylglycerol [TAG]). Values are means \pm SEM; $n = 6$. Letters not in common indicate a significant difference between starch groups $p < 0.05$. When corrected for percent body weight loss, however, total cholesterol and unesterified cholesterol concentrations were not significantly different between starch groups

$p < 0.001$; LGI starch, $r = 0.658$, $p < 0.001$). Linear regression of LCAT activities with percent weight loss was only weakly positive with $r = 0.332$.

Plasma EC FA Composition

Few differences were observed between starch groups, oil groups, and diet (starch \times oil) groups in the plasma EC fatty acid profiles (Table 5).

Fig. 2 Plasma LCAT activity of dogs fed diets differing in starch type (high-glycemic index [HGI] or low-glycemic index [LGI]) and oil type (diacylglycerol [DAG] or triacylglycerol [TAG]). Values are mean \pm SEM; $n = 6$. Letters not in common indicate a significant difference between days by repeated measures ANOVA, $p < 0.05$

When LGI starch was fed, plasma 16:1n-7 concentrations of dogs were statistically significantly higher when DAG was included compared to TAG at day 56. Within the two TAG groups, higher 16:1n-7 values were found at day 56 with HGI versus LGI starch. A similar pattern of statistically significant differences were seen with 18:1n-7. It should be noted, however, that these differences were of small magnitude (<1 relative % each) in all groups. Several main time effects were noted by repeated measures ANOVA over the course of the 56 days of feeding and weight loss which included modest increases in polyunsaturated fatty acids, primarily 18:2n-6. In addition, main starch effects were seen for 18:1n-9 (LGI groups higher than HGI groups) and 20:4n-6 (LGI groups lower than HGI groups) and a main oil effect for 18:3n-3 which decreased in DAG versus TAG groups but only at day 28.

Plasma PL FA Composition

Statistically significant differences over time were seen in nearly all plasma PL fatty acids using repeated measures ANOVA (Table 6). Saturates and monounsaturates (i.e., 14:0, 16:0, 16:1n-7, 18:0, and 18:1n7) were higher overall at day 28 versus day 0 but these decreased to baseline values at day 56. By contrast, polyunsaturates and longer chain monounsaturates were lower at day 28. These changes, while numerically modest, were nonetheless statistically significant. Main starch effects included higher concentrations of 22:5n-3, 24:0, and total n-3 fatty acids, but lower 16:0, in the HGI group versus the LGI group. Main oil effects seen overall were higher 18:1n-7 and lower 18:3n-3 in the DAG groups compared to TAG groups. Controlling for differences in % body weight lost

using ANCOVA revealed an oil \times starch interaction only for 16:1n-7. In addition, main oil effects for 18:1n-7 at day 56 (DAG $>$ TAG) and for 18:3n-3 at day 0 (TAG $>$ DAG) were observed as well as a main starch effect for 18:1n-9 at day 56 (LGI $>$ HGI).

Discussion

In this study, the dogs were offered an estimated number of calories required to maintain their baseline obese body weights. However, the gruel form of the experimental diets resulted in voluntary restriction of actual intake to a similar extent in all groups. Consequently, consistent weight loss occurred in all groups over the course of the study. However, the percentage of initial body weight lost in the LGI groups was greater than that in the HGI groups. The principal reason for this effect was significantly decreased starch digestibilities of the LGI diets compared to the HGI based diets resulting in lower calorie availability (data not shown).

The starch effect observed on both TC and UC concentrations at day 28 revealed higher values in animals fed the HGI starch diets during weight loss. This effect appeared independently of any effects of dietary fat feeding. However, after controlling for % body weight lost as a covariate, the statistically significant differences in TC and UC concentrations were no longer observed. While the reason for this starch effect is unknown, the possibility exists that the less digestible starch diets (i.e., LGI diets containing high amylose corn starch) may have prevented cholesterol elevations during the feeding period compared to the HGI diets resulting in statistically significant relative elevations in dogs fed the HGI diets at day 28. This effect did not appear to be due to percent of body weight lost but more likely due to differences in starch digestibilities. Indeed, studies in rats and hamsters have observed hypocholesterolemic effects of dietary high amylose corn starch, a low glycemic index starch [24–27]. One study found that this effect was mediated by an enlarged bile acid pool and increased fecal bile acid excretion along with decreased starch digestibilities [27]. Thus, when LGI diets were fed to dogs in the present study, the possibility exists that increased bile acid-starch binding and less bile acid hepatic recycling may have occurred. This phenomenon could then account for the statistically significant increase in plasma TC and UC that occurred at day 28 when the HGI diets were fed and may have been a result of decreased bile acid excretion.

Of additional interest is that the elevation of LCAT activities with time was positively correlated with plasma UC concentrations and appeared to coincide with a modest increase of UC in the HGI group at day 28. Correlations

between LCAT and total cholesterol levels per se as well as over time have been previously reported in several studies [17–19]. Because UC serves as substrate for LCAT, enzyme induction may occur when its substrate concentrations are increased. After controlling for % body weight loss, no statistically significant effects were observed on LCAT activities. Thus, this enzyme activity did not change as a result of weight loss. Instead it was correlated with

plasma UC concentrations and may have been a response to relative elevations of this cholesterol fraction.

The acclimation and experimental diets used in this study were designed to have similar fatty acid profiles and any differences between them were likely due to normal variability in sampling and measurement. Consequently, fatty acid profiles of plasma EC and PL fractions demonstrated few statistically significant differences between

diets. As such, the isomeric differences between TAG and DAG oil did not translate into resultant differences in FA composition of the plasma PL or EC fractions. However, it is noteworthy that higher amounts of 16 and 18 carbon saturates and monounsaturates were seen in the PL and EC fractions over time during the feeding periods during weight loss, most notably at day 28. After controlling for percentage weight loss as a covariate at each time point in the analysis, only the amounts of 16:1n-7 remained statistically significant. Thus other factors besides weight loss

must have been responsible for this effect. One possibility is that it is due to differences in the fatty acid composition of diets fed. However, fatty acid compositions of the diets, including the acclimation diet, were similar to each other. Alternatively, these differences may be the result of calorie restriction and mobilization of these fatty acids types from storage depots. This possibility is consistent with the observation that adipose storage sites tend to be rich in 16 and 18 carbon saturates and monounsaturates in mammalian species [28]. Another possibility is that increased

de novo synthesis of these fatty acids may have occurred as a result of the dietary carbohydrate composition as has been reported by Forsythe et al. [29].

Finally, it should be noted that linoleic acid constituted the major fatty acid in plasma EC fractions in all diet groups, with concentrations much higher than those found in plasma PL. This finding is similar to an earlier report that canine LCAT exhibits substrate specificity for 18:2n6 [30]. Interestingly, this same phenomenon was also observed with 24:1. Concentrations of 24:1 detected in plasma EC were roughly five times those found in plasma PL on average, indicating that canine LCAT also shows specificity for this FA. A previous unpublished study in the authors' laboratory did not find substantial amounts of 24:1 in canine plasma EC; however, the experimental diets in that study did not contain detectable amounts of this fatty acid.

Summary

This investigation into diet and weight loss effects on LCAT activity and substrate specificity have contributed to the current knowledge of cholesterol metabolism in dogs. An increase in LCAT activity and positive correlation with plasma UC concentration was observed but did not appear to be associated with weight loss. Feeding diets containing HGI starch resulted in sustained plasma cholesterol concentrations during weight loss that became statistically significant when compared to LGI starch diets after 28 days of feeding. These effects also did not appear to be due to weight loss, per se, but possibly the result of decreased bile acid excretion with HGI starch and increased digestibility. Elevations of saturated and mono-unsaturated fatty acids occurred in all groups during weight loss most likely reflecting the composition of adipose storage sites in the animals. Finally, dietary oil type (TAG vs. DAG) did not affect the plasma EC or PL fatty acid compositions. This latter finding is likely due to the similar fatty acid composition of the experimental oils and indicates that positional isomers in oil do not affect resultant FA profiles.

Acknowledgments This research was supported by a grant from Kao Corporation, Tokyo, Japan, and by the Mark L. Morris Professorship in Clinical Nutrition, Texas A&M University. The authors wish to acknowledge the technical assistance of Daisuke Nagaoka and Dwayne Bandy during this study.

Lysophosphatidylcholine Exhibits Selective Cytotoxicity, Accompanied by ROS Formation, in RAW 264.7 Macrophages

Abstract Lysophosphatidylcholine (lysoPtdCho) is a component of oxidized low density lipoprotein, and is involved in the pathogenesis of atherosclerosis and inflammation. We studied the effects of lysoPtdCho on cytotoxicity, reactive oxygen species (ROS) production, activation of the extracellular signal-regulated kinase (ERK), mitogen-activated protein kinases and pro-inflammatory gene expression in RAW 264.7 murine macrophage cells. When cells were exposed to lysoPtdCho with various acyl chains in a culture medium containing 10% fetal bovine serum, only 1-linoleoyl (C18:2) lysoPtdCho showed a remarkable cytotoxicity, reaching the highest level at 24 h, and elicited ROS production, suggesting that oxidative stress might be implicated in the cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho. Presumably in support of this, antioxidants such as magnolol or trolox prevented 1-linoleoyl (C18:2) lysoPtdCho-induced cytotoxicity as well as ROS production, although only partially. Furthermore, the phosphorylation of ERK 1/2 and the expression of pro-inflammatory cytokines such as IL-1 β , CCL2 and CCL5 were augmented by 1-linoleoyl (C18:2) lysoPtdCho.

Meanwhile, there was no structural importance of the acyl chain for the cytotoxic action of lysoPtdCho during 10 min incubation in serum-free media. Taken together, it is suggested that in a serum-containing medium, 1-linoleoyl (C18:2) lysoPtdCho can cause a significant cytotoxicity through ROS production, probably accompanied by activation of ERK and induction of related inflammatory cytokines, in RAW 264.7 cells.

Introduction

Lysophosphatidylcholine (lysoPtdCho) is known to be generated from phosphatidylcholine by at least four enzymes, phospholipase A₂, lipoprotein-specific phospholipase A₂, lecithin/cholesterol acyltransferase or endothelial lipase [1, 2]. The cytoplasmic and secretory forms of PLA₂ are up-regulated in ischemia and inflammation, and a lipoprotein-associated PLA₂ is an independent risk factor for atherosclerotic complications [2]. Presumably in support of

this, lysoPtdCho accumulates in tissues during ischemia and in plasma of inflammatory arthritis [3]. In addition, a considerable increase in lysoPtdCho content during the routine storage of some blood cells has been reported [4]. However, a part of the lysoPtdCho in plasma may be bound by serum albumin or lipoproteins [5], albeit with a relatively lower affinity than alpha-1 acid glycoprotein, a major acute phase protein in plasma [6]. Alternatively, lysoPtdCho can be transferred directly to cell membranes from some specified lipids such as oxidized low density lipoprotein [7]. According to previous reports [8], lysoPtdCho elicits various pro-inflammatory and atherogenic phenomena. As a part of inflammatory actions of lysoPtdCho, previous studies reported that lysoPtdCho brought about the superoxide production in neutrophils [9]. In addition, lysoPtdCho caused superoxide generation by activating NADPH oxidase (NOX) in nonphagocytic cells, particularly in vascular endothelial cells [10]. Saturated lysoPtdCho such as 1-palmitoyl (C16:0) lysoPtdCho and 1-stearoyl (C18:0) lysoPtdCho were more potent in elevating the intracellular calcium ion level in neutrophils than 1-oleoyl (C18:1) lysoPtdCho [9]. In mechanistic analyses of lysoPtdCho effect, the increase of cytosolic Ca^{2+} and the reactive oxygen species (ROS) level was accompanied by stimulation of mitogen-activated protein kinase (MAPK) pathways [11]. A growing body of evidence suggests that ROS contribute to cell death, in part, through effects on various cellular signaling pathways including the MAPK pathways [12]. In addition, lysoPtdCho treatment elicits production of IL-1 β and MCP-1, proinflammatory cytokine, in human monocytes and rat aortic smooth muscle cells, respectively [13]. Further support for pro-inflammatory activity of lysoPtdCho is provided by the evidence of lysoPtdCho acting as a chemotactic factor for monocytes and T cells [14], and lysoPtdCho released by apoptotic cells has been proposed to constitute a phagocyte attraction signal [15]. However, most of the studies concerning the cellular effect of lysoPtdCho were performed in primary cell cultures using saturated lysoPtdCho or oleoylated lysoPtdCho [9, 16], and moreover, these studies were carried out in serum-free media, since serum components interfered with the action of lysoPtdCho. Therefore, it needs to be clarified further as to whether lysoPtdCho may exert any significant biological effect on cells in the medium containing serum. In the present study, we attempted to examine the effect of lysoPtdCho, saturated and unsaturated, on RAW 264.7 cells in either serum-free medium or serum-containing medium. Here, we report that 1-linoleoyl (C18:2) lysoPtdCho shows a selective cytotoxic effect on RAW 264.7 cells by causing ROS formation, accompanied by activation of extracellular signal-regulated kinase (ERK) and induction of inflammatory cytokines, in the medium containing serum.

Materials and Methods

Materials

1-Palmitoyl (C16:0) lysoPtdCho, 1-stearoyl (C18:0) lysoPtdCho, 1-myristoyl (C14:0) lysoPtdCho, 1-oleoyl (C18:1) lysoPtdCho, dilinoleoyl PtdCho and diarachidonoyl PtdCho were from Avanti Polar Lipids (Alabaster, AL, USA). Magnolol (purity >95%) was kindly provided by Dr K. Bae, College of Pharmacy, Chungnam National University. 2',7'-Dichlorofluorescein diacetate (DCFH₂-DA) was from Molecular Probe (Eugene, OR, USA), Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), penicillin, streptomycin and trypsin-EDTA were purchased from Gibco/BRL (Gaithersburg, MD, USA). Suramin, 3-(4,5-Dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT), phosphor-specific antibodies against ERK were obtained from BD Biosciences (San Jose, CA, USA), and all other reagents were from Sigma-Aldrich (St Louis, MO, USA) unless specifically described. 1-Linoleoyl (C18:2) lysoPtdCho and 1-arachidonoyl (C20:4) lysoPtdCho were synthesized by PLA₂-catalyzed hydrolysis of corresponding phosphatidylcholine species as described previously [17].

Cell Culture

RAW 264.7 cells were cultured in DMEM-supplemented with, penicillin (100 U/mL) and streptomycin (100 μ g/mL), 10% (v/v) heat-inactivated FBS at 37 °C in a humidified atmosphere of 5% CO₂ as previously described [18], and used between passages 6–13 at ~80% confluence unless otherwise stated. Cells were plated at a density of 5×10^4 /well in 96-well plate, and incubated overnight to allow for adherence.

Determination of Cytotoxicity

Cell respiration, an indicator of cell viability, was determined by measuring the mitochondrial-dependent reduction of MTT to formazan [18]. Briefly, the cells (5×10^4 /well), plated in the media, were incubated for indicated times at 37 °C in a 5% CO₂ incubator. MTT solution was added to cells to a final concentration of 500 μ g/mL, and the incubation was continued for 4 h at 37 °C. Then, the medium was aspirated, and the formazan products were solubilized with dimethyl sulfoxide. The cell viability was determined by measuring the difference of absorbance at wavelength 570 nm vs. 690 nm. To see the cytotoxicity during 10 min incubation, the cells were incubated with lysoPtdCho for 10 min in a serum-free medium. Separately, for delayed cytotoxicity of

lysoPtdCho, the cells were incubated with lysoPtdCho for 24 h in DMEM containing 10% FBS.

Measurement of Intracellular ROS

Oxidative stress of the cells was determined by using the fluorescent probe DCFH₂-DA [19]; DCFH₂-DA, cell-permeable, is converted into the fluorescent 2,7-dichloro-fluorescein by oxidative substances in cells. Briefly, cells (5×10^4 /well) were pretreated with antioxidants of various concentrations for 2 h at 37 °C. Subsequently, lysoPtdCho was added to the cells, and the incubation was further extended according to the specified time. At the end of the incubation, the cells were treated with fluorescent probe DCFH₂-DA (10 μM) for 30 min. The degree of fluorescence, corresponding to intracellular ROS, was determined using a spectrofluorometer (Wallac 1420, Perkin-Elmer, Turku, Finland) at 485 nm excitation and 530 nm emission wavelengths.

Prevention Against Cytotoxicity or ROS Formation

Cells (5×10^4 /well) were pretreated with antioxidant or other drugs, and then lysoPtdCho was added to the cells. The incubation was continued for 10 min in a serum-free medium or for 24 h in the medium containing 10% FBS. Determination of cytotoxicity or ROS formation was performed as described above.

Western Blot Analysis

RAW 264.7 cells were stimulated with or without 10 μM lysoPtdCho or 0.1 μg/mL lipopolysaccharide for 10 min. Cytosolic extracts were prepared in lysis buffer consisting of 0.2% NP-40, 10 mM HEPES, 15 mM KCl, 2 mM MgCl₂, 1 mM dithiothreitol, 0.1 mM EDTA and 0.1 mM PMSF. Equal amounts of protein (20 μg/well) were separated by 10% SDS-polyacrylamide gel electrophoresis, and transferred to a nitrocellulose membrane (GE Healthcare UK Ltd, Buckinghamshire, UK). Each membrane was blocked overnight at 4 °C with a blocking solution (10 mM Tris-HCl, pH 7.4; 125 mM NaCl; 0.1% Tween 20; 5% skim milk) and then incubated with antibodies to ERK and phospho-ERK (Cell Signaling, Danvers, MA, USA) at room temperature for 3 h. The blots were washed three times with washing buffer (20 mM Tris, 160 mM NaCl and 0.1% Tween 20), followed by a 1-h incubation with appropriate horseradish peroxidase-conjugated secondary antibody. The peroxidase activity was detected using the Immobilon Western HRP detection reagent (Millipore, Billerica, MA, USA). This immunoblots analysis was performed three times independently.

Quantitative RT-PCR Analysis

RAW 264.7 cells were treated with or without 10 μM lysoPtdCho for 12 h. The cells were harvested and total RNA was extracted using an Easy-Blue™ kit (INtRON Biotechnology, Korea) according to the manufacturer's instructions. A sample (1 μg) of total RNA was used for the synthesis of the first strand cDNA using the Omniscript (Qiagen, Valencia, CA, USA) according to the manufacturer's instructions. PCR amplifications were quantified using the SYBRGreen™ PCR Master Mix (Applied Biosystems, Foster City, CA, USA) against the expression of genes involved in proinflammatory mediators such as IL-1β, CCL2 and CCL5. The primers were provided in Table 1. After obtaining real-time fluorescence measurements, cycle threshold values were determined. Standard curves in the linear range (i.e., the exponential amplification phase) were used to calculate the quantity of each mRNA. The final data are expressed as the ratio of indicated mRNA to GAPDH mRNA.

Statistical Analysis

All values are expressed as means ± SD. The statistical analysis was done on an SPSS (Chicago, IL, USA) program. One-way analysis of variance and Duncan's multiple range tests were used to examine the difference groups. A value of $P < 0.05$ was accepted as statistically significant, unless otherwise stated.

Results

Lysophosphatidylcholine has been believed to play an important role in atherosclerosis and inflammatory diseases by altering various functions in a number of cell-types [20]. Previously, it was reported that lysoPtdCho expressed cytotoxicity primarily by causing an increase of intracellular calcium ions and the formation of ROS through activation

Table 1 Sequences of the primers used in qRT-PCR analysis

mRNA	Gene number	Primers sequence (5'-3')
IL-1β	NM 008361	F 5'-ATGAGGACATGAGCACCTTC-3'
		R 5'-CATTGAGGTGGAGAGCTTTC-3'
CCL2	NM 011333	F 5'-TCACCTGCTGCTACTCATTTC-3'
		R 5'-TACAGAAGTGCTTGAGGTGG-3'

		R 5'-GTTGTCATGGATGACCTTGG-3'

of NOX in primary suspension cells in serum-free media [21]. Separately, a remarkable formation of ROS by unsaturated lysoPtdCho was observed in human neutrophils in the serum-free media [16]; the most dramatic effect was expressed by 1-oleoyl (C18:1) lysoPtdCho, followed by 1-linoleoyl (C18:2) lysoPtdCho. However, little is known about the cytotoxic effects of polyunsaturated lysoPtdCho on adherent cells in the presence of serum. First, in this study, we examined the cytotoxic effect of lysoPtdCho on RAW 264.7 cells, representative adherent cells, since lysoPtdCho was believed to play an important role in atherosclerosis by altering various functions in monocytes and macrophages [22]. For this purpose, RAW 264.7 cells were exposed to lysoPtdCho with various acyl chains, saturated or unsaturated, in the serum-free medium, and the viability was determined using MTT assays [18].

Effects of lysoPtdCho on Macrophage Viability During 10 min Incubation in a Serum-Free Medium

First, when RAW 264.7 cells were incubated with 1-palmitoyl (C16:0) lysoPtdCho for 10 min in serum-free media, it was observed that 1-palmitoyl (C16:0) lysoPtdCho decreased the viability in a concentration-dependent fashion (Fig. 1); the remaining viability was reduced to 21% of the control level after 10 min incubation with 1-palmitoyl (C16:0) lysoPtdCho (20 μ M). A similar cytotoxic effect was also exhibited by the other lysoPtdCho species such as 1-stearoyl (C18:0) lysoPtdCho (remaining viability 24.9%), 1-myristoyl (C14:0) lysoPtdCho (42.9%),

Fig. 1 Cytotoxicity of lysoPtdCho in RAW 264.7 cells during 10 min incubation in serum-free media. RAW 264.7 cells were incubated with various concentrations (0–40 μ M) of lysoPtdCho for 10 min in serum-free media. Cell viability was determined by MTT assay, and the viability was expressed as a percentage of viable cells among total cells. Data are shown as mean \pm SD of three parallel experiments. *Filled squares* indicate 1-myristoyl lysoPtdCho, *open inverted triangles* indicate 1-palmitoyl lysoPtdCho, *open squares* indicate 1-stearoyl lysoPtdCho, *filled circles* indicate 1-oleoyl lysoPtdCho, *open circles* indicate 1-linoleoyl lysoPtdCho, *filled inverted triangles* indicate 1-arachidonoyl lysoPtdCho

1-oleoyl (C18:1) lysoPtdCho (33.5%), 1-linoleoyl (C18:2) lysoPtdCho (37.3%) or 1-arachidonoyl (C20:4) lysoPtdCho (39.9%) after a 10-min incubation. In comparison (Table 2), the greatest cytotoxicity was expressed by 1-palmitoyl lysoPtdCho (IC_{50} , 9.0 μ M), followed by 1-stearoyl (C18:0) lysoPtdCho (IC_{50} , 9.9 μ M), 1-oleoyl (C18:1) lysoPtdCho (IC_{50} , 13.0 μ M), 1-linoleoyl (C18:2) lysoPtdCho (IC_{50} , 11.6 μ M), 1-arachidonoyl (C20:4) lysoPtdCho (IC_{50} , 13.7 μ M) and 1-myristoyl (C14:0) lysoPtdCho (IC_{50} , 17.5 μ M), indicating that the cytotoxic effect of lysoPtdCho may differ according to the type of acyl chain of the lysoPtdCho. The greater cytotoxicity of saturated lysoPtdCho such as 1-palmitoyl (C16:0) or 1-stearoyl (C18:0) lysoPtdCho may imply that lysoPtdCho acts as a detergent on the plasma membrane and thereby disturbs membrane stability. However, such a possibility is not supported by the additional finding that unsaturated lysoPtdCho, possessing relatively higher critical micelle concentration (CMC) values [23], also expresses a similar degree of cytotoxicity at the same concentration range. However, in media containing 10% FBS, no remarkable cytotoxicity (<5%) was exhibited by any of lysoPtdCho, suggesting that a component(s) of FBS prevented the cytotoxic action of lysoPtdCho.

Effects of lysoPtdCho on ROS Production in RAW 264.7 Cells During 10-min Incubation in a Serum-Free Medium

Reactive oxygen species have been suggested to be involved in the cytotoxic effect of lysoPtdCho [24], which has been reported to induce NAD(P)H oxidase, and increase the formation of superoxide anion radicals in nonphagocytic cells [25], particularly in vascular endothelial cells [20]. To determine whether the death of RAW 264.7 cells by lysoPtdCho is related to ROS production, we measured the ROS generation in RAW 264.7 cells using a fluorescent probe (DCFH₂-DA). As shown in Fig. 2, when

Table 2 IC_{50} value of lysoPtdCho-induced cytotoxicity in RAW 264.7 cells

LysoPtdCho-types	IC_{50} (μ M)
1-Myristoyl lysoPtdCho	17.5 \pm 0.57 ^a
1-Palmitoyl lysoPtdCho	9.0 \pm 0.45 ^e
1-Stearoyl lysoPtdCho	9.9 \pm 0.11 ^d
1-Oleoyl lysoPtdCho	13.0 \pm 0.52 ^b
1-Linoleoyl lysoPtdCho	11.6 \pm 0.18 ^c
1-Arachidonoyl lysoPtdCho	13.7 \pm 0.33 ^b

Cells were incubated with each lysoPtdCho in serum-free media for 10 min, as described in Fig. 1. Cell viability was determined by MTT assay. The values represent the means \pm SD of three independent experiments

each lysoPtdCho was incubated with RAW 264.7 cells in the serum-free medium for 10 min, 1-linoleoyl (C18:2) lysoPtdCho induced a considerable ROS production in RAW 264.7 cells in a concentration-dependent manner up to 20 μM , confirming the previous finding [16] that 1-linoleoyl (C18:2) lysoPtdCho-induced ROS formation in human neutrophils in serum-free media. In addition, a similar result was also observed with 1-arachidonoyl (C20:4) lysoPtdCho, although it caused a lower extent of ROS formation, compared to 1-linoleoyl (C18:2) lysoPtdCho. Meanwhile, other lysoPtdCho species including 1-oleoyl (C18:1) lysoPtdCho were not effective in inducing ROS formation. Thus, a considerable ROS generation was expressed only by lysoPtdCho with a 1-linoleoyl (C18:2) or a 1-arachidonoyl (C20:4) group, suggesting that ROS production might be related to the cytotoxicity of polyunsaturated lysoPtdCho in RAW 264.7 cells in the presence of serum. To confirm the above notion, the protective effect of antioxidant agents against 1-linoleoyl (C18:2) lysoPtdCho-induced ROS generation was evaluated. Figure 3 indicates that ROS generation by 1-linoleoyl (C18:2) lysoPtdCho was reduced by magnolol partially at 30 μM and fully at 100 μM . Nonetheless, the viability was not restored to the control level in the presence of magnolol even up to 100 μM . These results suggest that the formation of ROS may not be responsible for the cytotoxicity of unsaturated lysoPtdCho during a short incubation in serum-free medium. Thus, ROS appear to play a negligible role in lysoPtdCho-induced cytotoxicity during short time

Fig. 2 Effect of lysoPtdCho on the formation of intracellular ROS. RAW 264.7 cells were incubated with various concentrations of lysoPtdCho (1, 3, 10 or 20 μM) for 10 min in serum-free media. Accumulation of intracellular ROS was monitored with DCFH₂-DA as described in the section “Materials and Methods”. Data are shown as means \pm SD of three parallel experiments. *Filled squares* indicate 1-myristoyl lysoPtdCho, *open inverted triangles* indicate 1-palmitoyl lysoPtdCho, *open squares* indicate 1-stearoyl lysoPtdCho, *filled circles* indicate 1-oleoyl lysoPtdCho, *open circles* indicate 1-linoleoyl lysoPtdCho, *filled inverted triangles* indicate 1-arachidonoyl lysoPtdCho

Fig. 3 Effect of antioxidants on lysoPtdCho-induced cytotoxicity and ROS production. RAW 264.7 cells were pretreated with magnolol (1–100 μM), and then incubated with 1-linoleoyl lysoPtdCho (20 μM) for 10 min in serum-free media. Data are shown as means \pm SD of three parallel experiments; * P < 0.05 vs. control, ** P < 0.01 vs. control. C without lysoPtdCho and magnolol

incubation in serum-free media. In the meantime, the inclusion of serum completely prevented the cytotoxicity of each lysoPtdCho as well as ROS formation by lysoPtdCho. These led us to examine whether the extended incubation of RAW 264.7 cells with lysoPtdCho may cause a remarkable cytotoxicity even in the presence of serum.

Effects of lysoPtdCho on Macrophage Viability During 24 h Incubation in a Medium Containing 10% FBS

In the subsequent experiment to see the delayed effect of lysoPtdCho, RAW 264.7 cells were incubated with each lysoPtdCho of various concentrations in media containing 10% FBS for 24 h, after which the viability of the remaining cells was analyzed by MTT assays [18]. First, when RAW 264.7 cells were incubated with lysoPtdCho of various concentrations for 24 h, a remarkable cytotoxic effect was demonstrated by 1-linoleoyl (C18:2) lysoPtdCho (Fig. 4); the viability decreased to 68.7% of control level after 24 h incubation with 1-linoleoyl (C18:2) lysoPtdCho (20 μM), and the increase of 1-linoleoyl (C18:2) lysoPtdCho concentration beyond 20 μM failed to further increase the cytotoxicity. Actually, the delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho started to appear after 9 h incubation. In addition, 1-arachidonoyl (C20:4) lysoPtdCho also seemed to show a similar cytotoxic effect, although the maximal decrease of viability was limited to 9.8%. Meanwhile, the other lysoPtdCho species such as 1-oleoyl (C18:1) lysoPtdCho, 1-myristoyl (C14:0) lysoPtdCho, 1-palmitoyl (C16:0) lysoPtdCho or 1-stearoyl (C18:0) lysoPtdCho exerted no significant cytotoxic effect (<5%). Thus, it seems that the delayed cytotoxicity seems to be expressed selectively by 1-linoleoyl (C18:2) lysoPtdCho.

Fig. 4 Cytotoxicity of lysoPtdCho in RAW 264.7 cells during 24 h incubation in serum-containing media. Cells were incubated with each lysoPtdCho (0–40 μ M) for 24 h in media containing 10% FBS. Cell viability was determined by MTT assay, and the viability was expressed as a percentage of viable cells among total cells. Data are shown as mean \pm SD of three parallel experiments. *Filled squares* indicate 1-myristoyl lysoPtdCho, *open inverted triangles* indicate 1-palmitoyl lysoPtdCho, *open squares* indicate 1-stearoyl lysoPtdCho, *filled circles* indicate 1-oleoyl lysoPtdCho, *open circles* indicate 1-linoleoyl lysoPtdCho, *dark filled inverted triangles* indicate 1-arachidonoyl lysoPtdCho

Effect of lysoPtdCho on ROS Production During 24 h Incubation in a Medium Containing 10% FBS

To determine whether the delayed cell death of RAW 264.7 cells by 1-linoleoyl (C18:2) lysoPtdCho was related to ROS production, we measured ROS generation in RAW 264.7 cells exposed to 1-linoleoyl (C18:2) lysoPtdCho in a medium containing 10% FBS for 24 h. As shown in Fig. 5, 1-linoleoyl (C18:2) lysoPtdCho induced evidently a considerable ROS production in RAW 264.7 cells in a concentration-dependent manner (1–100 μ M), reaching its peak at 40 μ M. The effective concentrations (10–40 μ M) of 1-linoleoyl (C18:2) lysoPtdCho for ROS formation was close to those for its cytotoxicity in RAW 264.7 cells. Meanwhile, the other types of lysoPtdCho including 1-arachidonoyl (C20:4) lysoPtdCho failed to express a significant formation of ROS. These data suggest that the structural requirement of the acyl group for the cytotoxicity of lysoPtdCho in a serum-free medium is apparently different from that in a medium containing FBS.

Protection by Antioxidants Against Cytotoxicity of 1-Linoleoyl (C18:2) lysoPtdCho and ROS Formation

To further examine the mechanism by which 1-linoleoyl (C18:2) lysoPtdCho decreased the viability of RAW 264.7 cells during a 24-h incubation in the presence of FBS, the protective effect of antioxidant agents on the delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho (20 μ M) was examined. As shown in Fig. 6a, magnolol (30 μ M)

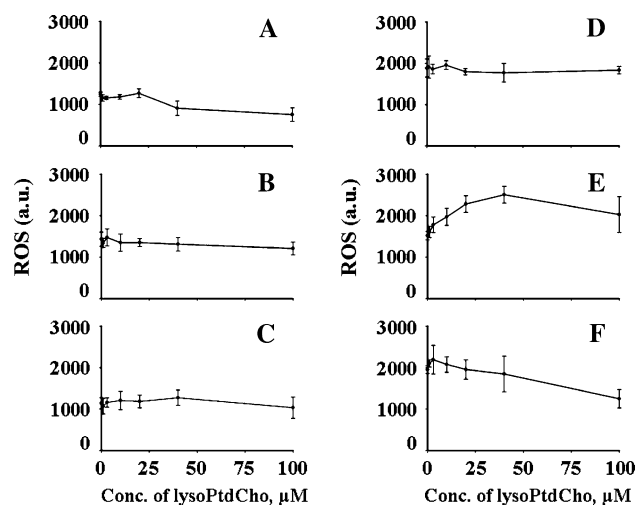

Fig. 5 Effect of lysoPtdCho on formation of intracellular ROS. RAW 264.7 cells were incubated with various concentrations of lysoPtdCho (1–100 μ M) for 24 h in media containing 10% FBS. Accumulation of intracellular ROS was monitored with DCFH₂-DA. Data are shown as means \pm SD of three parallel experiments. **a** 1-Myristoyl lysoPtdCho, **b** 1-palmitoyl lysoPtdCho, **c** 1-stearoyl lysoPtdCho, **d** 1-oleoyl lysoPtdCho, **e** 1-linoleoyl lysoPtdCho, **f** 1-arachidonoyl lysoPtdCho

Fig. 6 Effect of antioxidants on lysoPtdCho-induced cell death. RAW 264.7 cells were pretreated with increasing magnolol concentrations (a) or increasing trolox concentrations (b), and then incubated with 1-linoleoyl lysoPtdCho (20 μ M) for 24 h in media containing 10% FBS. Cell viability was determined by MTT assay, and the viability was expressed as a percentage of viable cells among total cells. Data are shown as means \pm SD of three parallel experiments; * P < 0.05 vs. control, ** P < 0.01 vs. control. C without lysoPtdCho and magnolol

prevented the delayed cytotoxic action of 1-linoleoyl (C18:2) lysoPtdCho in a concentration-dependent manner; the viability, which decreased to 68.7% in the presence of 1-linoleoyl (C18:2) lysoPtdCho, was restored to 93.5% in the presence of magnolol with an EC₅₀ of 9.05 ± 1.79 μ M. Additionally, trolox, another antioxidant, augmented the viability to 82.8% with an EC₅₀ of 143 ± 21.1 μ M (Fig. 6b). In a separate experiment, the effect of antioxidant agents on the ROS formation in RAW 264.7 cells, exposed to 1-linoleoyl (C18:2) lysoPtdCho (20 μ M) for 24 h in a medium containing FBS, was examined. As shown in Fig. 7a, the inclusion of magnolol reduced the 1-linoleoyl (C18:2) lysoPtdCho-induced ROS formation in RAW 264.7 cells in a dose-dependent manner with an EC₅₀

Fig. 7 Effect of antioxidants on lysoPtdCho-induced production of intracellular ROS. RAW 264.7 cells were pretreated with increasing concentrations of magnolol (a) or increasing concentrations of trolox (b), and then incubated with 20 μM 1-linoleoyl lysoPtdCho for 24 h in media containing 10% FBS. Data are shown as means \pm SD of three parallel experiments; * $P < 0.05$ vs. control, ** $P < 0.01$ vs. control

of $9.16 \pm 1.99 \mu\text{M}$. In addition (Fig. 7b), trolox also decreased the 1-linoleoyl (C18:2) lysoPtdCho-induced ROS formation in RAW 264.7 cells, although less effectively than magnolol. Thus, it is suggested that the delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho in RAW 264.7 cells may be likely related to the increased ROS generation. Separately, suramin, a lysophosphatidic acid receptor antagonist, was tested for the prevention of 1-linoleoyl (C18:2) lysoPtdCho-induced cytotoxicity or ROS formation, since lysoPtdCho could be converted to lysophosphatidic acid during 24 h incubation. However, the lysophosphatidic acid receptor antagonist did not diminish the cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho or ROS formation in RAW 264.7 cells (data not shown), excluding the possibility that the cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho may be related to the action of lysophosphatidic acid, a degradation product of lysoPtdCho. Taken together, all the results suggest that oxidative stress may be implicated in the cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho in RAW 264.7 cells challenged with 1-linoleoyl (C18:2) lysoPtdCho.

Induction of Phosphorylation of ERK by 1-Linoleoyl (C18:2) lysoPtdCho

Since previous studies showed that the lysoPtdCho-induced activation of MAPKs pathways, dependent on ROS production, was observed in monocytes and endothelial cells [26], it was supposed that the production of ROS by 1-linoleoyl (C18:2) lysoPtdCho might be related to activation of MAPKs in macrophages. In this respect, RAW 264.7 cells were exposed to each lysoPtdCho, and the phosphorylation of ERK1/2 was evaluated. As demonstrated in Fig. 8, Western blot analysis clearly showed that 1-linoleoyl (C18:2) lysoPtdCho caused a significant increase in phosphorylation of ERK1/2 in a dose-dependent manner. However, the other lysoPtdCho such as 1-myristoyl (C14:0) lysoPtdCho, 1-palmitoyl (C16:0) lysoPtdCho

Fig. 8 Effects of lysoPtdCho on phosphorylation of ERK 1/2 in RAW 264.7 cells. Cells were treated with various lysoPtdCho (10 μM) or LPS (100 ng/mL) for 10 min. Harvested cells were lysed, and the extracted proteins were separated on 10% SDS-polyacrylamide gels and transferred to nitrocellulose membrane. Phosphorylation of ERK 1/2 was detected by Western blotting as described in the section “Materials and Methods”. The membrane was stripped and reprobed with ERK 1/2 antibody as an internal control (a). Separately, cells were treated with dose-dependent 1-linoleoyl lysoPtdCho or 100 ng/mL LPS, and were analyzed as described above (b). *M* 1-myristoyl lysoPtdCho, *P* 1-palmitoyl lysoPtdCho, *O* 1-oleoyl lysoPtdCho, *L* 1-linoleoyl lysoPtdCho

and 1-oleoyl (C18:1) lysoPtdCho even at 10 μM were not effective. These findings indicate that ERK1/2 phosphorylation may be related to 1-linoleoyl lysoPtdCho-induced ROS formation in RAW 264.7 cells.

LysoPtdCho Induces Proinflammatory Cytokine and Chemokine Gene Expression in RAW 264.7 Cells

In the next study to assess the lysoPtdCho-induced signal transduction pathway of cytokines responsible for inflammatory reactions, we examined the expression of cytokines in response to 1-linoleoyl (C18:2) lysoPtdCho or 1-palmitoyl (C16:0) lysoPtdCho. For this purpose, lysoPtdCho was incubated with murine macrophages to produce cytokines, and 12 h later, RNA was extracted from RAW 264.7 cells, and analyzed by graphical representations of the fold changes in cytokines. Figure 9 indicated that the production of IL-1 β and CCL2 was increased by about 20 times in the presence of 1-linoleoyl (C18:2) lysoPtdCho at 10 μM , and the gene expression of CCL5 was up-regulated by ≥ 10 -folds ($P < 0.05$), compared to control. Thus, a more dramatic induction was observed for CCL2 acting mainly in inflammatory reactions. Meanwhile, there was no significant difference of cytokines gene expression after the exposure to 1-palmitoyl (C16:0) lysoPtdCho. These results

Fig. 9 Effect of lysoPtdCho on the expression of cytokines by RAW 264.7 cells. Cells were treated with 1-linoleoyl lysoPtdCho for 12 h. Expression levels of Interleukin-1 β (*IL-1 β*), CCL2 or CCL5, which were determined by a quantitative real time-polymerase chain reaction (qRT-PCR), were normalized to GAPDH, and plotted relative to those without 1-linoleoyl lysoPtdCho (control). All assays were performed in triplicate, and data are expressed as mean values \pm SD. * $P < 0.05$ vs. control, ** $P < 0.01$ vs. control. P 1-palmitoyl lysoPtdCho, L 1-linoleoyl lysoPtdCho

indicate that the cytotoxicity as well as ROS formation by 1-linoleoyl (C18:2) lysoPtdCho may implicate the upregulation of transcription of proinflammatory mediator genes in the RAW 264.7 cells.

Discussion

Lysophosphatidylcholine is believed to play an important role in patho-physiological conditions by altering various functions in a number of cell-types [27]. Earlier, the membrane effects of lysoPtdCho had been studied extensively in erythrocytes; lysoPtdCho, at concentrations above its CMC, disturbed membrane proteins, and disrupted plasma membrane integrity, leading to hemolysis [28]. Separately, lysoPtdCho, accumulating in the atherosclerotic arterial wall [29], has been suggested as playing a role in the progress of atherosclerosis, via receptor-mediated or independent actions, by causing vascular endothelial growth factor induction in macrophages, impairment of NO release, and upregulation of cell adhesion molecules, and acting as a monocyte chemoattractant [30]. In addition, the cytotoxicity of lysoPtdCho has been studied in vascular cells; for example, lysoPtdCho has been reported to induce apoptotic death in rat aorta smooth muscle cells at low concentrations (25–50 μ M), and induce necrosis at concentrations >100 μ M [31]. In human endothelial cells, lysoPtdCho at concentrations (25–300 μ M) has been shown to induce apoptosis, whereas primary necrosis has not been observed [22]. Our present data may provide an evidence for the cytotoxic effect of lysoPtdCho on RAW 264.7 cells. Thus, the effect of lysoPtdCho on cells may

depend on the lysoPtdCho concentration or the cell type as well as incubation conditions. Concerning the cytotoxicity of lysoPtdCho, lysoPtdCho as a detergent can be directly incorporated into the lipid matrix of cellular membranes and increase fluidity [28]. Further, lysoPtdCho at concentrations above its CMC values might induce micellar disruption, thus damaging membrane integrity. The present finding about the structure activity relationship for the cytotoxicity of saturated lysoPtdCho in RAW 264.7 cells in serum-free medium seemed to reflect the micellar property of lysoPtdCho [32] as had been observed with the cytotoxicity of lysoPtdCho in neutrophils [16]; the CMC value of saturated lysoPtdCho was inversely proportional to the size of acyl chain. However, this idea was not supported by another finding that 1-linoleoyl (C18:2) lysoPtdCho expressed a cytotoxicity below their CMC values (>20 μ M). Moreover, there was no significant difference of cytotoxicity between 1-oleoyl (C18:1) lysoPtdCho and 1-arachidonoyl (C20:4) lysoPtdCho, despite a great difference of their CMC values. Rather, it is supposed that the cytotoxic actions of lysoPtdCho may be explained by mechanisms different from detergent function [16]. One of them may involve the induction of oxidative stress, as had been previously observed in other types of cells [16, 31]. The formation of ROS through the activation of NOX had been observed with Jurkat T cells [33], fibroblast cell [32], human neutrophils [10] and endothelial cells [31] in the absence of serum, which prevented the cytotoxicity of lysoPtdCho [33]. However, in the present study, the cytotoxicity of lysoPtdCho during 10 min incubation in a serum-free medium was not addressed properly by ROS formation. Further, the cytotoxicity of lysoPtdCho was not prevented significantly by antioxidants. Meanwhile, the delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho in medium containing 10% FBS was supposed to be related to ROS formation, since the delayed cytotoxicity was accompanied by ROS formation. A further support is from the finding that antioxidants such as magnolol and trolox diminished cytotoxicity as well as ROS formation in RAW 264.7 cells. It is worth noting that the delayed cytotoxicity in the presence of serum was expressed remarkably by 1-linoleoyl (C18:2) lysoPtdCho and slightly by 1-arachidonoyl (C20:4) lysoPtdCho, but not by saturated lysoPtdCho. Moreover, 1-oleoyl (C18:1) lysoPtdCho also failed to show a significant formation of ROS in RAW 264.7 cells in the presence of serum, despite a remarkable ROS formation by 1-oleoyl (C18:1) lysoPtdCho in human neutrophils in a serum-free medium [16]. Thus, it seems that the delayed cytotoxicity of lysoPtdCho may be peculiar to 1-linoleoyl (C18:2) lysoPtdCho in RAW 264.7 cells. Additionally, the delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho might be cell-specific, since 1-linoleoyl (C18:2) lysoPtdCho did not show a delayed cytotoxic effect on RBL-2H3

cells. Taken together, the delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho seems to depend on the types of cells or lysoPtdCho as well as the incubation conditions.

Although a previous study indicated that albumin and lipoprotein fractions of plasma contained higher amounts of saturated lysoPtdCho than unsaturated ones [31], this could not provide a relevant explanation of the selective cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho. Separately, alpha-1-acid glycoprotein was observed to show a strong binding affinity toward unsaturated lysoPtdCho [6]. However, such an action of alpha-1-acid glycoprotein may lead to the reduction in the cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho, although the possible delivery of lipids by alpha-1-acid glycoprotein to cell membrane may not be neglected. Rather, the delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho is supposed to depend on free lysoPtdCho equilibrating with blood proteins- or lipoproteins-bound ones. Since the effective concentrations (10–20 μM) of 1-linoleoyl (C18:2) lysoPtdCho for delayed cytotoxicity was much below the reported CMC ($\sim 50 \mu\text{M}$) of lysoPtdCho in aqueous medium [34], it is more likely that the delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho may be due to the specific interaction, rather than non-specific lipid interaction, between 1-linoleoyl (C18:2) lysoPtdCho and RAW 264.7 cells. The plasma concentration of lysoPtdCho ranges from 100 to 190 μM [35]; the most abundant lysoPtdCho species in fresh plasma samples was 1-palmitoyl (C16:0) lysoPtdCho, comprising $\sim 40\%$ of total lysoPtdCho, followed by 1-linoleoyl (C18:2) lysoPtdCho, corresponding to $\sim 20\%$ of total lysoPtdCho. Based on this, the plasma concentration of lysoPtdCho was estimated to be $\sim 40 \mu\text{M}$ for 1-palmitoyl (C16:0) lysoPtdCho and 20 μM for 1-linoleoyl (C18:2) lysoPtdCho. Since the concentrations (10–20 μM) of lysoPtdCho for delayed cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho were close to the physiological level, it is supposed that 1-linoleoyl (C18:2) lysoPtdCho may be one of plasma lysoPtdCho species implicated in the patho-physiological states. It is possible that lysophosphatidic acid, generated from the incubation of lysoPtdCho with RAW 264.7 cells, may be possibly responsible for the cytotoxicity. However, this is not supported by the observation that 1-linoleoyl (C18:2) lysophosphatidic acid was less cytotoxic than 1-palmitoyl (C16:0) lysophosphatidic acid in RAW 264.7 cells during 24 h incubation in medium containing FBS (data not shown). Separately, it is conceivable that the 1-(13-hydroperoxy) octadecadienoyl (C18:2) lysoPtdCho, generated from 24 h exposure of 1-linoleoyl (C18:2) lysoPtdCho to RAW 264.7 cells, may express the cytotoxicity. However, 1-(13-hydroperoxy) octadecadienoyl (C18:2) lysoPtdCho up to 10 μM failed to show any cytotoxic effect on RAW 264.7 cells (data not shown). All these observations suggest that the cytotoxic effect of

lysoPtdCho on RAW 264.7 cells differed according to the incubation conditions as well as types of cells or lysoPtdCho. Overall, saturated lysoPtdCho species were more cytotoxic than unsaturated lysoPtdCho species in the serum-free medium, but the reverse seemed to be true for the 24-h incubation in the medium containing FBS. Especially, 1-linoleoyl (C18:2) lysoPtdCho at physiological concentrations demonstrated a remarkable delayed cytotoxicity. Another important finding addressed by the present study is the involvement of the MAPK pathways in the selective cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho in RAW 264.7 cells. This may be consistent with previous findings that lysoPtdCho causes the activation of MAPK during apoptotic cell death in certain types of cells [36], and induces the activation of MAPK such as ERK 1/2 and JNK in endothelial cells [37]. However, most of these studies were done with 1-palmitoyl (C16:0) lysoPtdCho or 1-oleoyl (C18:1) lysoPtdCho, which failed to activate MAPK significantly in our present study. Although this discrepancy was not further examined in the present study, one possibility is that the selective interaction between 1-linoleoyl (C18:2) lysoPtdCho and RAW 264.7 cells may be responsible for the cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho as well as activation of MAPK. In support of this, there is a good correlation between the level of 1-linoleoyl (C18:2) lysoPtdCho-induced ERK activation and the cytotoxicity of 1-linoleoyl (C18:2) lysoPtdCho, accompanied by ROS formation. This idea may be somewhat relevant to a recent report that ERK can contribute to exerting apoptotic cell death during the cellular response to oxidative stress [38], although the role of the MAPK pathway in apoptosis is still controversial. Alternatively, it is conceivable that 1-linoleoyl (C18:2) lysoPtdCho-induced MAPK activation may be responsible for NOX-mediated ROS production according to a NOX–ROS–ERK-dependent pathway [27], since NOX-generated ROS may aid the phosphorylation of ERK and thereby contribute to upregulation in a downstream gene that is mediated by the ERK-dependent pathway. Additionally, we demonstrated that 1-linoleoyl (C18:2) lysoPtdCho markedly induces the expression of cytokine IL-1 β , and chemokines CCL2 (MCP-1) and CCL5 (RANTES) in RAW 264.7 cells while 1-palmitoyl (C16:0) lysoPtdCho failed to induce the expression. The mechanism for the increase in the production of cytokine by lysoPtdCho may be related to the activation of MAPK, as previously observed with inflammatory cells [36, 39]. In this regard, it is conceivable that the induction of CCL2 by 1-linoleoyl (C18:2) lysoPtdCho may contribute to the pro-inflammatory response in atherosclerosis. Taken together, present observations suggest that 1-linoleoyl (C18:2) lysoPtdCho may exert proinflammatory actions by selectively inducing ROS formation, activation of MAPK and gene expression of cytokines in

some specific cells. Further study employing *in vivo* methods may divulge the role of 1-linoleoyl (C18:2) lysophosphatidylcholine in pro-inflammatory conditions.

Abstract Effects of feeding conjugated linoleic acid (CLA) to hens on progeny chick development and composition at hatch (NHC) and three weeks of age (TWC) were assessed. CLA (0 or 0.5%, composed of mixed isomers of *cis*-9,*trans*-11 or *trans*-10,*cis*-12-CLA) was fed to hens with either safflower (SO) or olive oil (OO) (3 or 3.5%) to assure successful hatch for 2 weeks prior to collection for incubation. Maternal CLA feeding had no effect on hatchability, but improved egg fertility ($p < 0.05$). Maternal feeding of CLA with SO increased 21 day-old progeny growth, while CLA with OO decreased growth (oil*CLA, $p < 0.05$). In 25 day-old chicks (TWC), but not NHC, maternal CLA decreased the proportion of total body water ($p < 0.05$) and increased body ash ($p < 0.05$). While monounsaturated fatty acids were decreased and saturated fatty acids increased in eggs and NHC from hens fed CLA, no differences in fatty acid composition were observed in chicks at 25 days of age from hens fed CLA. Maternal CLA feeding resulted in the presence of *c9,t11* and *t10,c12*-CLA in NHC, but only *c9,t11* in the TWC. In conclusion, hens fed CLA led to improved fertility and altered body composition at 3 weeks of age.

Introduction

A considerable amount of research has been published on the effects of conjugated linoleic acid (CLA) on the body composition and fatty acid composition of growing animals, including mice [1–4], rats [5, 6], pigs [7–9], and chicks [10–12]. Maternal feeding of CLA has been shown to also affect the growth [13–15], body composition [15, 16], and fatty acid profile of tissues [13–16] in the progeny.

The progeny of rats [13, 15] and pigs [14] exposed to maternal CLA during gestation and lactation had increased rates of gain and improved feed efficiency in comparison to pups from control-fed dams. The body composition of growing male rats from dams fed 0.5% CLA appeared to be altered, in that gastrocnemius muscle was heavier and an increase of tail length was observed, indicative of increased lean mass and increased skeletal growth, respectively, in comparison to male pups from control-fed dams [15]. Bee [14] showed that 0.2% CLA incorporated into the diet of gestating sows did not alter birth or weaning weight, however, piglets reared by CLA-supplemented sows exhibited increased feed intake, increased daily gain, and higher final body weights than piglets reared on sows supplemented with 18:2(n-6). Consistently, in these mammalian species, the fatty acid composition of tissues obtained from the offspring was altered [13–15]. Bee [14] showed significantly increased levels of the predominant isomers of CLA fed to the mother (e.g., *cis*-9,*trans*-11 (*c9,t11*) and *trans*-10,*cis*-12 (*t10,c12*)) in the back fat of the progeny in comparison to progeny from control sows fed high levels of 18:2(n-6). Bee [14], Chin [13], and Poulos et al. [15] showed an increase in saturated fatty acids (SFA, e.g., 18:0) and a decrease in monounsaturated fatty acids (MUFA, e.g., 18:1(n-9)) [13–15] in progeny tissues, including back fat of pigs, as well as liver and inguinal fat

pads of rats. Similar alteration in fatty acid data is also shown in tissues of newly hatched chicks from hens fed dietary CLA in comparison to tissues of offspring from control-fed hens [16].

The increased saturated fatty acids in eggs from laying hens fed 0.5% CLA in a basal diet with no added fat caused embryonic mortality [17–19]. Hatch of eggs obtained from CLA-fed hens could be “rescued” if the hen’s basal diet contained at least 3% oils exhibiting a fatty acid composition of either MUFA (e.g. olive oil or canola oil) or polyunsaturated fatty acids (PUFA, e.g. corn oil or soybean oil) [17, 19, 20]. Hence, the use of rescue oils allowed for the investigation of the effects of maternal CLA on avian progeny growth and composition. Using corn oil as a rescue oil, Cherian et al. [16] showed that newly hatched progeny from hens fed 0.5 or 1.0% CLA had decreased total carcass fat, while carcass weight, dry matter, and ash were not altered.

The purpose of this study was to extend the finding reported by Cherian et al. [16] in newly hatched chicks to the body composition and performance of chicks grown to three weeks of age that have hatched from hens fed mixed

isomers of CLA. To rescue hatchability in the presence of 0.5% maternal dietary CLA (containing equal parts *c9,t11* and *t10,c12*), oils rich in PUFA (safflower oil (SO), containing 80% 18:2(n-6)) or MUFA (olive oil (OO) containing 80% 18:1(n-9)) were used. The level of CLA selected was based on the lowest level reported by Cherian et al. [16] to reduce body fat in day old chicks without adversely affecting egg size, yolk weight, yolk lipid, or hatchability [18, 19, 21]. Hen egg production, egg fertility, fatty acid composition of yolk and subsequent offspring, as well as the body composition of newly hatched chicks (NHC) and three-week old chicks (TWC) was measured.

Experimental Procedure

Hens and Egg Management

Forty-eight individually housed single comb white leghorn (SCWL) hens were randomly assigned to 1 of 4 dietary treatments in a 2 × 2 factorial, where type of added fat and

Table 1 Composition of diets containing two types of added dietary fat with or without the presence of CLA

	SO	SO + CLA	OO	OO + CLA	Chick mash
Corn	60	60	60	60	63

Chick mash diet supplied per kg of diet: vitamin A, 5500 IU; vitamin D₃, 634 IU; B-12, 10 µg; riboflavin, 6.6 mg; calcium pantothenate, 14 mg; niacin, 28 mg; choline chloride, 1268 mg; zinc sulfate, 27 mg; manganese oxide, 42 mg

presence of CLA were factors. Dietary treatments consisted of 3.5% safflower oil (SO) (80% 18:2(n-6)), 3.5% olive oil (OO) (80% oleic acid, 18:1(n-9)), 3% safflower oil + 0.5% CLA (SO + CLA), and 3% olive oil + 0.5% CLA (OO + CLA), where CLA consisted of CLA-60 (BASF AG, Ludwigshafen, Germany; equal parts 9*c*,11*t*; 10*t*,12*c*, see footnote, Table 1, for exact composition). Dietary composition is shown in Table 1, while dietary fatty acid composition is shown in Table 2. Hens were fed dietary treatments for 2 weeks and then artificially inseminated with 0.05 mL pooled, fresh New Hampshire rooster semen once per week. Hens remained on experimental treatments throughout the remainder of the experimental trial. Hens were exposed to a 16:8-h light/dark daily lighting schedule. All procedures involving animals were approved by the University of Wisconsin Animal Care and Use Committee. Eggs were collected and stored at 15 °C for a minimum of 24 h and incubated weekly at 37 °C and 85% relative humidity in a forced-air incubator. Eggs were candled weekly to detect fertility and embryonic mortality. Eggs that candled clear were broken out to detect infertility or very early embryonic mortality.

Table 2 Fatty acid composition of hen dietary treatments

Growth and Feed Efficiency

To detect influences of maternal diet on growth and feed efficiency parameters, eggs from artificially inseminated hens fed the dietary treatments for 3 months were collected and incubated. Chicks that hatched were individually weighed and wing-banded. Chicks were then separated based on maternal dietary treatment and randomly assigned to 10 pens per maternal dietary treatment (5 chicks/pen). Individual chick weights and pen feed intake were measured weekly for 3 weeks and were used to determine growth rate and feed efficiency. Feed composition was the same across all chick treatment groups, as shown in Table 1.

Fatty Acid Composition

Relative fatty acid composition of diets, eggs, newly hatched chicks (NHC), and 25-day-old chicks (TWC) were determined. One 500 g sample of feed was taken from each hen dietary treatment and stored at −20 °C until analysis. Three eggs from each dietary treatment were randomly selected after hens were on diets for 14 days. Three NHC and 3 TWC from each maternal dietary treatment were euthanized via asphyxiation with CO₂ and frozen at −20 °C. Empty carcass weight (ECW) of TWC was determined post-euthanasia after flushing of the gastrointestinal tract with 0.8% NaCl solution. NHC and TWC were chopped and ground/pulverized with liquid nitrogen in a Waring blender. Freshly ground samples were thoroughly mixed and re-frozen at −20 °C. Three 1 g samples were taken from each feed sample, yolk, or chick slurry and fat was extracted using chloroform/methanol (2:1 v/v) according to the method of Folch et al. [22]. Briefly, fatty acid methyl esters (FAME) were prepared with 4 mL of HCl in 100 mL of methanol for 20 min at 60 °C. The composition of FAME in each sample was determined using gas chromatography (GC). GC was performed on an Agilent 6980N gas chromatograph (Agilent Technologies, Santa Clara, CA) fitted with a CP Sil 88 column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; manufactured by Chromapack, Middleburg, The Netherlands, and available from Varian Inc., Mississauga, Canada). GC temperature settings were previously described by Kramer et al. [23]. FAME were determined by comparison of retention times with known standards (standards #463 and #UC-59M, Nu-Chek-Prep, Elysian, MN) and expressed as percentage of total FAME.

Body Composition

Total body composition was determined for NHC and TWC. Five NHC and five TWC were euthanized via asphyxiation with CO₂ from each of the maternal dietary treatment groups.

Table 3 Effect of maternal dietary conjugated linoleic acid (CLA) with two types of oil, safflower oil (SO) or olive oil (OO) on newly hatched chick body composition

	ECW (g)	% Water	% Protein	% Fat	% Ash
SO	37.0 ± 0.7	78.3 ± 0.6	14.2 ± 0.8	5.5 ± 0.4	2.0 ± 0.1
SO + CLA	37.4 ± 0.5	77.0 ± 0.4	15.4 ± 0.4	5.6 ± 0.3	2.0 ± 0.0

Diets (g/100 g diet): SO, 3.5 g safflower oil/100 g; SO + CLA, 3 g safflower oil/100 g plus 0.5 g CLA/100 g; OO, 3.5 g olive oil/100 g; OO + CLA, 3 g olive oil/100 g plus 0.5 g CLA/100 g. Data are expressed as mean ± SE of 5 chicks per treatment group. No differences due to CLA, oil type, or oil type*CLA were found

ECW empty carcass weight (including the residual yolk)

Gut contents were removed via flushing with 0.8% NaCl solution from TWC post-euthanasia. Chick samples were then frozen at -20°C . NHC and TWC were chopped and ground/pulverized with liquid nitrogen in a Waring blender. Ground samples were then thoroughly mixed and weighed. Total ground NHC were placed in a freeze-drier for 60 h to determine total body water/dry matter content. Three 50 g samples of TWC were randomly selected from the ground slurry and placed in the freeze-drier for 60 h to determine total body water/dry matter content. Kjeldahl-N, lipid, and ash were determined in duplicate or triplicate on the freeze-dried ground samples (NHC) or sub-samples (TWC). Total body N was determined in samples digested with a sulfuric acid-hydrogen peroxide mixture [24] where ammonium levels were measured using a phenol-hypochlorite reaction [25]. Fat was extracted from freeze-dried sub-samples for both NHC and TWC using a soxhlet apparatus containing ethyl ether for 72 h and dried at 100°C for 24 h. Remaining fat-free dry material was then ashed at 750°C for 24 h and ash weight was determined.

Statistical Analysis

All data were analyzed by using two-way ANOVA as a 2×2 factorial with SAS (SAS Institute Inc., Cary, NC). Data were analyzed for main effects of added dietary oil, addition of CLA, as well as the oil*CLA interaction. Differences were considered significant at $p < 0.05$. Post-ANOVA analyses of mean treatment differences were determined using least squared differences.

Results and Discussion

Unlike previous reports involving mammalian species [1–9], where body composition was affected by maternal

CLA feeding, the body fat of the NHC and TWC progeny of CLA-fed SCWL hens was not reduced by maternally fed CLA (Tables 3 and 4, $p > 0.05$). In contrast to previous results, relative proportion of fat in TWC was increased (although not significantly, where the main effect of CLA was $p = 0.15$) and water was decreased (main effect of CLA was $p < 0.05$) as the result of maternally fed CLA regardless of additional fat source (no oil*CLA interaction, $p > 0.05$). The inability to show reduced total body fat in NHC from CLA-fed hens is in contrast to the finding of Cherian et al. [16]. In the work of Cherian et al. [16], newly hatched chicks from hens fed 0.5 or 1% CLA-75 (at the expense of 3% corn oil) had 16 and 26% less total carcass fat, respectively, than those obtained from control-fed hens. A significant reduction ($p < 0.05$) in hepatic total lipid and triacylglyceride content was also shown in their study, and it was suggested that the reduction was due to lack of mobilization of yolk lipid to the developing embryo. The inability to reproduce the significant body fat reductions ($p < 0.05$) in NHC due to maternal CLA feeding reported by Cherian et al. [16] in this study could be due to breed of hens. Cherian et al. [16] utilized heavier New Hampshire laying hens, whereas lighter SCWL hens were used in the present study. While similar levels of CLA were added to the maternal diets in both studies (0.5 g/100 g of feed), the New Hampshire females consume considerably more feed and were exposed to CLA-75, whereas SCWL hens [26] consume less and were exposed to CLA-60 hence, CLA exposure was likely higher in Cherian et al. [16].

The work reported here also extended the findings reported by Cherian et al. [16] in that the effects of maternal CLA on the composition of progeny grown to 25 days of age (TWC) was also investigated. A random sample of chicks ($n = 5$ or 6) from each treatment was selected from the larger population used to generate the gain data shown in Fig. 1, and body composition was

Table 4 Effect of maternal dietary conjugated linoleic acid (CLA) with two types of oil, safflower oil (SO) or olive oil (OO) on 25-day-old chick body composition

	ECW (g)	% Water	% Protein	% Fat	% Ash
<i>Treatment</i>					
SO	225.8 ± 10.1	71.1 ± 0.7 ^{ab}	20.4 ± 0.5	6.4 ± 0.5	2.2 ± 0.1 ^b

OO	225.8 ± 4.2	71.2 ± 1.1 ^a	21.3 ± 0.6	5.4 ± 0.6	2.2 ± 0.1 ^b
OO + CLA	210.8 ± 6.7	67.6 ± 1.1 ^b	22.1 ± 1.3	7.7 ± 0.7	2.7 ± 0.1 ^a
<i>p-Values</i>					
Oil type	0.77	0.87	0.16	0.40	0.10
CLA	0.17	0.03	0.69	0.15	0.009
Oil*CLA	0.82	0.12	0.69	0.17	0.42

Diets (g/100 g diet): SO, 3.5 g safflower oil/100 g; SO + CLA, 3 g safflower oil/100 g plus 0.5 g CLA/100 g; OO, 3.5 g olive oil/100 g; OO + CLA, 3 g olive oil/100 g plus 0.5 g CLA/100 g. Data are expressed as mean ± SE of 5 or 6 chicks per treatment group. Means with different letters within a column are significantly different ($p < 0.05$). Main effect of oil was not significant at $p < 0.05$ across all body composition measurements. Main effect of CLA on % water and % ash was significant at $p < 0.05$. Oil type*CLA interaction was not significant at $p < 0.05$ across all body composition measurements. Chicks were fed standard corn/soybean meal poultry chick mash ration from hatch until they were euthanized at 25 days of age. Chicks used in this analysis were a random sub-sample of chicks used to create data in Fig. 1. ECW (empty carcass weight) was greater than gain in Fig. 1 since the chicks were 4 days older and ECW also includes initial chick weight. ECW is not an accurate measurement of growth of the population due to random sub-sampling

ECW empty carcass weight

Fig. 1 Effect of maternal diets containing conjugated linoleic acid (CLA) with the presence of two types of oils, safflower oil (SO) or olive oil (OO) on 3-week progeny (chick) gain and feed efficiency. Diets: SO, 3.5 g safflower oil/100 g; SO + CLA, 3 g safflower oil/100 g plus 0.5 g CLA/100 g; OO, 3.5 g olive oil/100 g; OO + CLA, 3 g olive oil/100 g plus 0.5 g CLA/100 g. Feed efficiency = feed consumed per chick (g)/21 day gain per chick (g), where chicks consumed: SO = 375 g/chick; SO + CLA = 331 g/chick; OO = 338 g/chick; OO + CLA = 319 g/chick. Data are expressed as

means ± SE. Columns with different superscripts are significantly different, where $p < 0.05$, when analyzed as a 2×2 factorial, $n = 50$. Feed efficiency is shown at the bottom of each bar for each respective treatment. Main effect of oil type not significant, $p > 0.05$: growth, $p = 0.27$; feed efficiency, $p = 0.60$. Main effect of CLA not significant, $p > 0.05$: growth, $p = 0.80$; feed efficiency, $p = 0.29$. Oil type*CLA interaction significant, $p < 0.05$: growth, $p = 0.007$. Oil type*CLA interaction not significant, $p > 0.05$: feed efficiency, $p = 0.09$

analyzed as described in the experimental procedure. The mean treatment empty carcass weights (ECW, Table 4) of this small random sample were not significantly different between treatments and were not representative of the treatment differences shown in Fig. 1 in regards to gain. Even though ECW of randomly selected chicks did not

differ due to maternal treatment, an increase in % fat in TWC, due to maternal CLA feeding, was observed. This observation was unexpected based upon CLA's known effects on altering composition in mice, rats, and pigs [1–9]. However, the effect of CLA on body fat in the avian species has not been as consistent as in mammals. Javadi

et al. [10] reported a higher relative proportion of fat in broilers fed 1% CLA-80 for 21 days as compared to controls fed 1% Safflower oil. In contrast, Zhang et al. [11], using Beijingyou chickens showed that feeding 1–2% CLA-80 in place of maize oil for 126 days exhibited decreased intramuscular fat in breast and thigh as well as decreased abdominal fat. Similar results were shown by Szymczyk et al. [12] where abdominal fat was reduced in broiler chicks exposed to 0.5–1.5% dietary CLA-60 for 42 days in comparison to those fed corn oil. These conflicting results in regards to body fat could possibly be explained by the onset of CLA feeding during the growth phase of the chickens and/or length of CLA feeding. A significant CLA main effect on TWC body ash was unexpected (Table 4). Feeding CLA to growing mice has been shown to increase bone ash [2]. The mechanism by which dietary CLA increased bone mineral content was suggested to be related to CLA's inhibition of cyclooxygenase-2 and hence PGE₂ production in the bone tissue [27]. It is plausible that differences in carcass composition could have been partially affected by the random sampling method used in this experiment (e.g., treatment mean weight of sampled chicks were not reflective of the larger population used for determining gain).

Maternal feeding of CLA has been shown to improve the growth of the progeny in several mammalian model species [13–15]. In the study reported here, maternal feeding of CLA (main effect of CLA, $p > 0.05$) had no effect on progeny growth, feed intake, or feed efficiency to 3-weeks of age (3-week gain was 142 g vs. 141 g, consumption was 356 g/chick vs. 325 g/chick, and feed efficiency was 0.40 vs. 0.44 for maternal diets across oil type with 0 or 0.5% CLA, respectively, Fig. 1). Likewise, growth of progeny was not related to the maternal dietary oil used (3-week weight gain was 144 g vs. 140 g, consumption was 353 g/chick vs. 328 g/chick, and feed efficiency was 0.41 vs. 0.42 for maternal diets across CLA level with SO or OO, respectively). However, an oil type (SO or OO)*CLA interaction was observed ($p < 0.05$, Fig. 1) where feeding CLA increased growth when SO (7.2% increase) was fed, but decreased growth when OO (7.7% decrease) was fed in the maternal diet. Changes in gain were not likely due to differences in feed consumption since no difference in feed consumption and feed efficiency were observed ($p > 0.05$). One possible mechanism in which chick growth could have been reduced when the maternal diet contained OO + CLA was through a reduction of 18:2(n-6). Hargrave et al. [28] showed that the addition of CLA to diets marginal in 18:2(n-6) (coconut oil-based diet) resulted in a decrease in tissue 18:2(n-6), relative to those fed diets without CLA. However, the effect of these diets on growth rate was not reported. 18:2(n-6) has been shown to be an essential fatty acid

for avian growth and development [29]. Hopkins and Nesheim [30] showed that chicks from hens marginal in 18:2(n-6) (egg 18:2(n-6) content 3–4% total FAME) require increased 18:2(n-6) in the growing diets to achieve growth rates equal to chicks hatched from hens fed adequate levels of 18:2(n-6) (egg 18:2(n-6) content 12–16% total FAME). In the study reported here, the addition of CLA to the OO diet did not result in a further reduction of egg 18:2(n-6) (Table 5). Also, chick mash (Table 1) contained a calculated 18:2(n-6) content of 1.8% (Table 1). Hence the reduced growth due to the addition of CLA to the OO diet maternal diet did not appear to be 18:2(n-6)-dependent. It is possible that these differences are due to chance and additional studies may be necessary to validate the relevance of this significant interaction.

Maternal dietary treatments altered egg yolk and NHC tissue fatty acids in a similar manner (Tables 5 and 6), and in general were as expected based on the findings of others [16–21, 31]. Maternal diet effects on fatty acid profiles of egg yolk and NHC was unlikely due to changes in yolk weight and yolk lipid (not measured in this study) since 0.5% CLA has previously shown to have no effect on these parameters [18, 19, 21]. The maternal diets with SO (main effect of oil type) resulted in egg yolks and NHC with more 18:2(n-6) (and PUFA) and less 18:1(n-9) (and MUFA) as would be expected in comparison to egg yolks and NHC from mothers fed diets containing 3–3.5% OO, a fat source containing a high amount of 18:1(n-9) [20]. Feeding the hen SO resulted in a slightly higher 20:4(n-6) level in the egg yolk than eggs from hens fed OO ($p < 0.05$), but these differences were no longer evident in the NHC. The effects of oil type fed in maternal diets on fatty acid composition were no longer evident in TWC (Table 7).

In the egg yolk and NHC, maternal CLA feeding (main effect) decreased the MUFA and increased SFA. Effects of the *t10,c12* isomer on SCD-1 are well described [2, 32–34] and explain the reason for an increased relative abundance of SFA in the egg yolk and NHC. While egg yolk had reduced 20:4(n-6) due to CLA feeding, no differences in the NHC were evident. Maternal CLA feeding (main effect, $p < 0.05$) increased the relative abundance of egg yolk and NHC total CLA (*c9,t11* and *t10,c12*). The effects of maternal CLA feeding on fatty acid content of TWC was no longer evident, except that a small amount of *c9,t11* (0.1% total FAME) was still found in TWC. Disappearance of individual CLA isomers from tissues when dietary sources have been withdrawn has been previously reported in mice [35]. The *t10,c12* isomer appears to be metabolized more rapidly than the *c9,t11* isomer. The lack of fatty acid changes due to maternal feeding in the TWC seem to suggest that body compositional changes in the TWC (ash and water) due to maternal CLA feeding was likely the result of early (embryonic or at hatch) maternal effects on

progeny development. Alternatively, the presence of *c*9,*t*11 in the chick at 3-weeks of age could be responsible for the compositional changes seen in TWC.

The addition of CLA plus 3% rescue oil (SO or OO) to the laying hen diet did not effect egg production or hatchability (% hatch of fertile eggs, Fig. 2). Aydin et al. [20] showed that when CLA is added to a laying diet with no added fat, eggs completely fail to hatch within 6 days following the addition of dietary CLA. Aydin [17] also showed that the addition of 3% vegetable oil to the breeding hen diet in the presence of 0.5% CLA would prevent CLA-induced embryonic mortality. Hence the findings in this experiment are consistent with previous work. While egg production and hatchability were not altered as a result of feeding SCWL hens CLA, the addition of CLA to SO or OO in the laying hen diet led to an increase in fertility (main effect of CLA, *p* < 0.05) of approximately 5 and 10%, respectively, when compared to their respective control-fed hens. To the authors' knowledge, this is the first report of CLA's beneficial effects on fertility in the avian species. Bauman et al. [36] reported that incorporation of mixed isomers of *c*9,*t*11 and *t*10,*c*12 CLA into dairy cattle rations either prior to calving or at the onset of calving improves reproductive

performance in the cow. In a study where cows were fed less than 20 g/day of each CLA isomer, the interval between calving and first ovulation was shortened and maintenance of pregnancy was improved. These findings may be due to an improvement in energy balance post-calving, although the exact mechanism behind the improvement has not been elucidated. A possible reason that improved fertility was not observed by Aydin [17] may have been the use of both candling and egg breakout for the assessment of fertility in the current study. Aydin's [17] fertility assessment was by candling only at day 7 of incubation. Interestingly, previous reports have shown that a high amount of 18:2(n-6) in the laying hen's diet can negatively effect fertility and thereby cause a significant decrease in the reproductive success of the avian species [37–39]. In this study, there was not a decrease in fertility when the hens were fed 3% oil high in 18:2(n-6) compared to 3% oil high in 18:1(n-9) (main effect of oil type was not significant, *p* > 0.05). Since CLA tended to increase fertility regardless of the fat type used, the increase in fertility appeared to be independent of a direct effect of CLA on 18:2(n-6).

Noble and Cocchi [40] showed that the presence of 18:1(n-9) is necessary for the transport of yolk lipids to the

developing embryo. Nobel [41] suggested that the egg levels of 18:1(n-9) may be important for the reproductive success of avian species. Since both CLA (*t*10,*c*12 isomer) and 18:2(n-6) are inhibitors of SCD-1 [32–34, 42] the addition of both CLA and 18:2(n-6) as the predominate fatty acids in the diet of some of the hens used in this study (SO + CLA) should provide a means of testing the importance of 18:1(n-9) for embryonic chick development. Eggs from hens fed SO + CLA had approximately half the 18:1(n-9) content of eggs from hens fed OO. While the hatchability of the eggs from hens fed SO + CLA (72%) appeared reduced relative to those fed OO (82%), significant differences were not detected in this study. Using purified 18:2(n-6) or 18:1(n-9) fatty acids, Aydin [17] also showed that reducing the relative proportion of egg 18:1(n-9) from 38.3 to 16.6% by feeding 18:2(n-6) + CLA did not have an adverse effect on hatchability. Hence, the value of 18:1(n-9) in the egg for the developing embryo appeared adequate within the limits shown in this study (see Table 5).

The content of individual isomers of CLA in the diet of the hens showed a higher CLA concentration in the diet containing SO as compared to OO (Table 2). The differences observed cannot be explained within the context of artifacts described by Park et al. [43]. Methods used for

analyzing CLA in the diet attempted to minimize the formation of artifacts [43]. Yurawecz et al. [44] pointed out that the most appropriate method of hydrolysis and esterification can be largely matrix dependent. When the OO-based diet was analyzed using the HCl/MeOH acid-catalyzed methylation procedure [43], the content of the two CLA isomers were as predicted from calculation. The same procedure on the SO-based diets overestimated the isomer content. This overestimate of CLA when analyzing the SO-based diet is clearly an analytical artifact since the relative content of CLA and each of its isomers in the egg and day-old chick was similar between samples collected from hens fed the SO + CLA and the OO + CLA diets (Tables 5 and 6).

In conclusion, unlike results obtained in mammals, maternal feeding of CLA to SCWL did not result in improved progeny growth or feed conversion. Maternal feeding of CLA does alter progeny body composition (increased ash and decreased water) up to 25 days after hatch. Changes in body composition may be directly dependent on the fatty acid composition supplied maternally during embryogenesis or the early post hatch developmental stage; however, the effects were not evident until later in life. The increased fertility resulting from maternal CLA feeding, regardless of dietary rescue oil

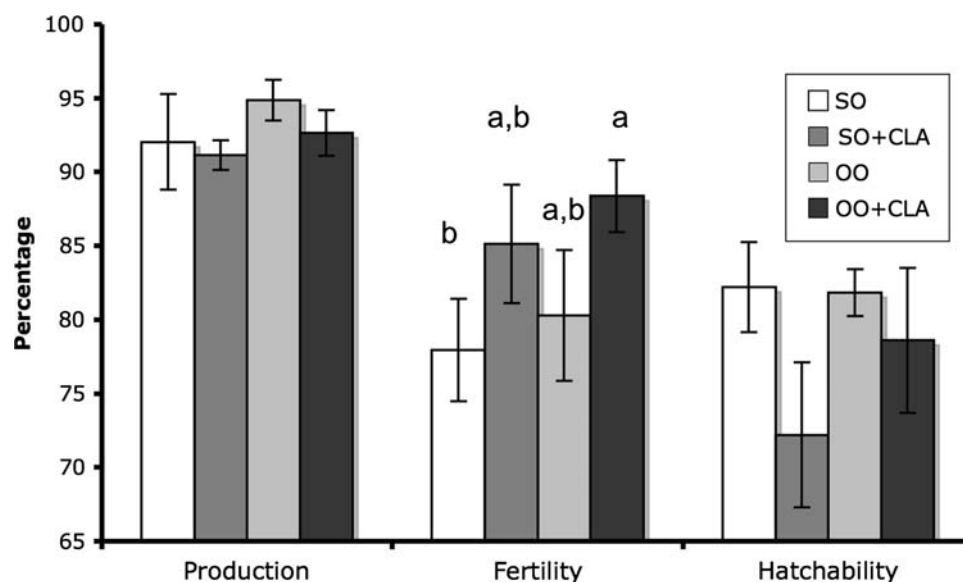

Fig. 2 Effect of diets containing conjugated linoleic acid (CLA) with the presence of two types of oils, safflower oil (SO) or olive oil (OO) on egg production, fertility, and hatchability. Diets (g/100 g diet): SO, 3.5 g safflower oil/100 g; SO + CLA, 3 g safflower oil/100 g plus 0.5 g CLA/100 g; OO, 3.5 g olive oil/100 g; OO + CLA, 3 g olive oil/100 g plus 0.5 g CLA/100 g. Parameters measured were hen egg day production, fertility (# fertile eggs/# of eggs produced), and hatchability (# eggs hatched/# of fertile eggs), where fertile eggs were determined via candling and egg breakout, $n = 12$ hens/trt. Data are

expressed as means ± SE. Columns with different superscripts are significantly different, where $p < 0.05$, when analyzed as a 2×2 factorial. Main effects of oil type: production, $p = 0.30$; fertility, $p = 0.42$; hatchability, $p = 0.46$. Main effects of CLA: production, $p = 0.45$; fertility, $p = 0.04$; hatchability, $p = 0.10$. Oil type*CLA interaction: production, $p = 0.74$; fertility, $p = 0.90$; hatchability, $p = 0.39$. Main effects of oil type and CLA, as well as oil type*CLA interaction were not significant for production or hatchability, however, fertility main effect of CLA was significant, $p < 0.05$

used, was unexpected and could prove of value for improving reproduction of avian species.

Acknowledgments The authors express their gratitude to S&R Farms (Whitewater, WI) for providing laying hens and to the staff at the University of Wisconsin-Madison Poultry Research Lab (Dawn Irish, George Bradley, and Angel Gutierrez) for support of research. The authors would like to thank Shane Huebner for his assistance in fatty acid analysis, Debra Schneider for her assistance in body composition analysis, and David Trott for assistance in certain aspects of this project. Research was supported through royalties received from the Wisconsin Alumni Research Foundation (WARF), as one of the authors (MEC) is an inventor on CLA patents assigned to WARF.

Conjugated Linoleic Acid Decreases MCF-7 Human Breast Cancer Cell Growth and Insulin-Like Growth Factor-1 Receptor Levels

Abstract In vitro work suggests that conjugated linoleic acid (CLA) isomers (c9,t11 and t10,c12) are cytotoxic to human breast cancer cells, however the mechanism remains unknown. Using human MCF-7 breast cancer cells, we examined the effects of c9,t11 and t10,c12 CLA compared to oleic acid (OA), linoleic acid (LA), or untreated cells on cell membrane phospholipid composition, cell survival, and the insulin-like growth factor-I (IGF-I) and the downstream insulin receptor substrate-1 (IRS-1). Both CLA isomers were incorporated into membrane phospholipids ($p < 0.05$). Compared to untreated cells, c9,t11 or t10,c12 CLA significantly reduced the metabolic activity of IGF-I stimulated MCF-7 cells, increased lactate dehydrogenase (LDH) release, and decreased cellular concentrations of the IGF-I receptor (IGF-IR) and insulin receptor substrate-1 ($p < 0.05$). Incubation with t10,c12 CLA also reduced the levels of phosphorylated IGF-1R. The effects on all of these measures were greater ($p < 0.05$) for t10,c12 CLA compared to c9,t11 CLA. There were few differences between LA-treated and c9,t11 CLA-treated cells, whereas cellular metabolic activity, LDH release, and IGF-IR concentrations differed between t10,c12 CLA-treated and LA-treated cells ($p < 0.05$). OA stimulated growth compared to the untreated condition ($p < 0.05$). In summary, this study demonstrated that the t10,c12 CLA isomer inhibits growth of MCF-7 cells and suggested that this may be mediated through incorporation into cellular phospholipids and

interference with the function of IGF-I and related signaling proteins.

Introduction

The role of dietary fat in the prevention or treatment of breast cancer remains controversial. The relationship between total fat intake and breast cancer risk or treatment outcome is not clear, potentially due to opposing effects of

the different dietary fats on tumour growth. Recently, there has been considerable interest in the potential anti-carcinogenic properties of conjugated linoleic acid (CLA). CLA consists of a group of positional and geometric (*cis-trans*) stereoisomers of linoleic acid (LA) that are commercially synthesised from plant oils [1] or formed during the biohydrogenation of LA by ruminant animals [2]. The *cis-9,trans-11* (c9,t11) CLA isomer is the most prevalent form found in ruminant-derived foods (e.g. milk and meat) [2]. The *trans-10,cis-12* (t10,c12) CLA isomer is present only in trace amounts in animal foods but is found in an approximate 50:50 ratio with c9,t11 CLA in many commercial CLA preparations [2]. The cytotoxicity (growth inhibition and induction of cell death) of CLA isomers in various animal and cell culture models of mammary cancer is well established [3]. The c9,t11 and t10,c12 CLA isomers have been shown in animal models to inhibit mammary tumour initiation, promotion and progression [4] and to reduce growth of human breast cancer cell lines in vitro [4–6]. Most of the animal research has used mixtures of CLA isomers, however in vitro work suggests that both major isomers (c9,t11 and t10,c12) have cytotoxic effects against cancer cells [7–10].

The mechanism by which the c9,t11 and/or t10,c12 CLA isomers inhibit mammary tumour growth is not clear. The plasma membrane is important in mediating cell growth and death [11], and alterations in membrane phospholipid composition by other dietary fats have been demonstrated to alter tumour cell function by changing membrane-mediated events and receptor functions [12]. The possible disruptive effect of the unique conjugated double bond structure of CLA on membrane function has not been studied in human breast cancer cells and may offer a possible mechanism for the anti-cancer effects of CLA. In vitro, CLA is incorporated into MDA-MB-231 breast cancer cell membrane phospholipids [8]. However, to our knowledge no studies have examined the effect of CLA incorporation into membrane phospholipids on the signal transduction of membrane bound proteins such as growth factor receptors.

Insulin-like growth factor I (IGF-I) is a mitogenic peptide that is believed to play a role in breast cancer development. In vitro, IGF-I stimulates growth and inhibits apoptosis of breast cells [13]. In humans, high circulating levels of IGF-I are associated with an increased risk of premenopausal breast cancer [14, 15]. During puberty, the formation of terminal end buds (the primary sites where breast cancer develops) is dependent on IGF-I signaling [16, 17]. CLA fed to rodents during puberty reduced the development of mammary tumours by altering mammary gland development, specifically by reducing the number of terminal end buds [18]. In vitro, Kim et al. [19] reported that CLA reduced HT-29 colon cancer cell responsiveness

to IGF-I signaling. These studies provide indirect evidence that CLA might influence IGF-I mediated effects.

The IGF-I receptor (IGF-IR) is located in the outer membrane of the cell. Upon binding of IGF-I, the IGF-IR is phosphorylated and initiates various signalling cascades, resulting in an increase in cellular proliferation and an inhibition of apoptosis [13]. The insulin receptor substrate-1 (IRS-1) is an essential component of IGF- type 1 receptor (IGF-IR) signaling, and links the receptor to key downstream signaling cascades [20]. Decreasing the amount of IRS-1 has been recently demonstrated to decrease the growth of MCF-7 cells [21]. The effect of CLA on IGF-I and related molecules has not been examined in breast cancer cell lines. The purpose of this study was to first establish whether the c9,t11 and t10,c12 CLA isomers inhibit IGF-I-induced proliferation of MCF-7 human breast cancer cells, which exhibit upregulated IGF-IR levels and IGF signaling [22]. Second, we sought to determine the effects of incubating c9,t11 and t10,c12 CLA on membrane phospholipid composition, the content of the total and phosphorylated IGF-1 receptor and the content of the insulin receptor substrate-1 (IRS-1), an important signaling protein in these breast cancer cells.

Experimental Procedure

Cell Culture

MCF-7 estrogen receptor-positive breast cancer cells were obtained from the American Type Culture Centre (Cedarlane Laboratories Ltd, Burlington, ON, Canada). The cells were cultured in 1:1 Dulbecco's Modified Eagle Medium: Nutrient Mix F-12 (DMEM:F12) with 15 mM HEPES and 365 mg/L of L-glutamine containing 5% v/v fetal bovine serum (FBS) and 1% v/v antibiotic/antimycotic (Invitrogen/Gibco Corporation, Burlington, ON, Canada). Cells were maintained at 37 °C in a humidified atmosphere in 5% v/v CO₂. The medium was changed every 2 days and cells were routinely passaged at 80–90% confluence.

Fatty Acids

Linoleic acid (LA; C18:2n-6), oleic acid (OA; C18:1n-9), and CLA isomers (C18:2-c9,t11 and C18:2-t10,c12) were purchased from Matreya (Pleasant Gap, PA). Stock solutions of fatty acids were prepared in ethanol or hexane at a concentration of 10 mg/mL and stored at –80 °C under N₂(g) until needed. Fatty acids were complexed to bovine serum albumin (BSA) depleted of essential fatty acids (Sigma-Aldrich Canada Ltd., Oakville, ON, Canada) at a 4:1 ratio as previously described [23]. Briefly, a 12-mg aliquot of the fatty acid stock was dried under nitrogen, and

then incubated with 1 mL KOH (0.1 M) for 10 min at 50 °C in a shaking water bath. Nine millilitres of sterile-filtered 7.5% v/v BSA in doubly distilled water was added. Solutions were vortexed, kept at room temperature for 3 h, incubated at 4 °C overnight, and then stored in sterile microcentrifuge tubes (Medicorp Inc., Montreal, PC, Canada) at –30 °C until used.

Determination of Growth Inhibition of IGF-I-Stimulated MCF-7 Cells

Growth experiments were performed in which the experimental fatty acids were added in isolation (at 128 or 256 μ M) or in combination with LA (128 μ M fatty acid + 128 μ M LA). An untreated condition was also included, in which no exogenous fatty acids were added to the medium. Cells were plated in 96-well flat-bottomed tissue culture plates (Thermo Fisher Scientific, Edmonton, AB, Canada) at a density of 3,000 cells/well in 200 μ L of 5% v/v FBS supplemented DMEM:F12 medium. After culture for 48 h, the medium was replaced with serum-free, phenol red-free DMEM:F12 (Invitrogen/Gibco) containing 0.5 mg/mL BSA (Sigma). After 24 h, cells were incubated for 24 or 48 h in serum-free medium containing 50 nM IGF-I (human recombinant expressed in *E. coli*; Sigma) plus one of the fatty acid treatments described above. Following incubation, viable cell counts were performed on a hemacytometer (Fisher Scientific, Edmonton, AB, Canada) by trypan blue and the WST-1 cell proliferation assay (Roche, Indianapolis, IN) was used to assess proliferation. Fresh serum-free medium was added (100 μ L/well) with 10 μ L/well of WST-1 cell proliferation reagent, and plates were incubated in a humidified atmosphere at 37 °C for 2 h. The assay principle is based upon the reduction of the tetrazolium salt WST-1 to formazan by cellular dehydrogenases. The plates were premixed for 60 s and the generation of the dark yellow coloured formazan is measured on a microplate spectrophotometer (Spectramax Plus, Molecular Devices, Sunnyvale, CA) was read at an absorbance of 440 nm. For all subsequent assays, the experimental fatty acids were provided in combination with LA (128 μ M).

Lactate Dehydrogenase Release during IGF-I Stimulation

MCF-7 cells were seeded and grown in 96-well flat-bottomed plates as above. After 24 h of fatty acid treatment, the medium was removed and centrifuged at 250 \times g. The supernatant was collected and analysed immediately or frozen at –30 °C until analysis. Lactate dehydrogenase (LDH) release was measured using the CytoTox 96 Nonradioactive Cytotoxicity Assay Kit (Thermo Fisher

Scientific, Edmonton, AB, Canada) according to the manufacturer's instructions. To determine maximum LDH release, some cells were lysed with 200 μ L of 1.5% v/v Triton X-100 (Thermo Fisher Scientific, Edmonton, AB, Canada) for 60 min at 37 °C, and the supernatant collected for analysis.

Membrane Phospholipid Fatty Acid Composition

Lipids were extracted from whole cell pellets after 24 h of treatment with IGF-I and fatty acids using a modified Folch procedure [24] as previously described [25]. Total phospholipids were isolated on silica gel thin layer chromatography plates (Thermo Fisher Scientific, Edmonton, AB, Canada) using an 80:20:1 v/v/v ratio of solvents (petroleum ether/diethyl ether/glacial acetic acid). The phospholipid band was identified using 8-anilino-1-naphthalene-sulfonic acid under long wave ultraviolet light. Fatty acid methyl esters were prepared by the addition of sodium methoxide and benzene [26] with heating at 50 °C for 10 min. Samples were then dissolved in hexane and the fatty acids were separated by automated gas liquid chromatography using hydrogen gas on a 100 m CP-Sil 88 fused capillary column (Varian Inc., Mississauga, ON, Canada) as previously described [27].

Western Blot Analysis for Total IGF-IR, IRS-1 and Phosphorylated IGF-IR

Whole cell protein lysates were prepared from IGF-I-stimulated and fatty acid-treated cells as previously described [28]. Protein content was determined by bicinchoninic acid protein assay (Sigma). Equal amounts of protein (40 μ g) from each treatment were separated by SDS-PAGE as previously described [28]. Precision Plus ProteinTM All Blue (BioRad Laboratories (Canada) Ltd., Mississauga, ON, Canada) molecular weight standards were used to monitor protein separation. Membranes were blocked for 1 h at room temperature in Tris-buffered saline plus Tween-20 (TBST: 0.01 M Tris-HCl pH 6.8, 0.15 M NaCl, 0.1% v/v Tween-20) and 5% w/v powdered milk. After rinsing with TBST, membranes were incubated overnight at 4 °C with either IGF-IR β C-20 primary antibody (Santa Cruz Biotechnology, Santa Cruz, CA) diluted 1:10,000 in TBST containing 1% w/v powdered milk, or IRS-1 (59G8) primary antibody (Cell Signaling Technology, Cedarlane Laboratories Ltd., Hornby, ON, Canada) diluted 1:1,000 in TBST containing 5% w/v BSA. For the phosphorylated-IGF-IR (2B9) (Santa Cruz Biotechnology, CA), the primary antibody was diluted 1:100 in TBST supplemented with 0.5% BSA and 0.5% milk. A 50 μ g aliquot of T-47D Cell Lysate (Santa Cruz Biotechnology, CA) was used as a positive control for the p-IGF-IR.

A 1:10,000 dilution of the secondary antibody, horseradish peroxidase-conjugated donkey anti-rabbit IgG (Jackson ImmunoResearch Labs, Cedarlane Laboratories), or goat anti-mouse IgG (Invitrogen, Burlington, ON, Canada) in TBST with 1% w/v powdered milk was incubated with the membranes for 1 h at room temperature. Membranes were developed using enhanced chemiluminescence (ECL Plus™) western blotting detection reagents (Amersham Biosciences, GE Healthcare, Baie d'Urfe, Quebec, Canada) and read on a Typhoon™ Trio+ variable mode imager (Amersham Biosciences). The intensity of target bands was quantified using ImageQuant™ TL software (Amersham Biosciences). Beta actin (Sigma, Oakville, ON, Canada) was used as an internal loading control as we found that it was not altered by treatments.

Statistical Analysis

Statistical analyses were conducted using SAS, version 9 (SAS Institute, Cary, NC) to compare the effects of fatty acid treatment on MCF-7 breast cancer growth and death. A one-way analysis of variance was used, blocking for passage number. When a significant effect of treatment ($p < 0.05$) was found, least squared means was used for post hoc analysis. Data are presented as means \pm SEM.

Results

CLA Isomers are Incorporated into MCF-7 Cell Membrane Phospholipids

The c9,t11 and t10,c12 CLA isomers were significantly incorporated into membrane phospholipids but t10,c12 CLA incorporation occurred to a greater extent than c9,t11 CLA incorporation (32% vs. 22% of total fatty acids, respectively; Table 1). The higher incorporation of t10,c12 CLA occurred at the expense of total saturated fatty acids (SFA), which made up a significantly lower proportion of total fatty acids than among c9,t11 CLA-treated cells. The relative content of total n-6 and n-3 fatty acids and the proportion of arachidonic acid (AA, C20:4n-6) did not differ between the two CLA treatment groups (Table 1).

Incubation with LA or OA significantly increased the incorporation of these fatty acids into membrane phospholipids (Table 1). Compared to the OA treatment group (which had the greatest cell growth), phospholipids from all other treatment groups had significantly less C18:1n-9. Compared to LA-treated cells, phospholipids from all other treatment groups had significantly less LA and C20:2n-6. There were significantly more SFA in the phospholipids of

LA-treated cells compared to those incubated with t10,c12 CLA (Table 1). Untreated cells had significantly less total n-6 PUFA, especially LA, compared to all fatty acid treatments; however the content of AA was higher than all other treatment groups. The untreated group had a greater proportion of SFA compared to OA- and t10,c12 CLA-treated cells, and a greater proportion of monounsaturated fatty acids (MUFA) compared to LA-, c9,t11 CLA- and t10,c12 CLA-treated cells (Table 1).

CLA Isomers Inhibit the Growth of MCF-7 Breast Cancer Cells Stimulated by IGF-I

MCF-7 cells were grown in IGF-I-containing serum-free medium for 48 h with or without 128 or 256 μ M of the experimental fatty acids. At both fatty acid concentrations, cells incubated with t10,c12 CLA had a significantly lower rate of proliferation ($p < 0.05$), as defined by their metabolic activity, compared to cells incubated with LA, c9,t11 CLA or no fatty acids (Fig. 1). When cells were incubated with the various experimental fatty acids in combination with 128 μ M LA, all fatty acid treatments stimulated metabolic activity ($p < 0.05$) after 24 h compared to untreated cells (Fig. 2). However, at 24 h there were significantly fewer viable cells in the wells from the t10,c12 CLA treated cells. After 48 h of treatment, both CLA isomers significantly inhibited growth compared to OA-treated, LA-treated or untreated cells ($p < 0.01$, Fig. 2); OA increased growth compared to all other fatty acid treatments ($p < 0.01$, Fig. 2). After 48 h, the t10,c12 CLA treatment reduced growth to a greater extent ($p < 0.01$) than the c9,t11 CLA treatment (Fig. 2).

t10,c12 CLA Increases Cell Death in IGF-1-Stimulated MCF-7 Cells

LDH release was measured to estimate cell death/necrosis. After 24 h, the t10,c12 CLA isomer in combination with LA resulted in a significantly higher LDH release ($p < 0.01$) compared to all other fatty acid treatments (Fig. 3). LDH release by the untreated or OA-treated cells was significantly less than the other fatty acid treatment groups ($p < 0.01$, Fig. 3).

t10,c12 CLA Reduces Total Cellular Total and Phosphorylated IGF-IR Levels in MCF-7 Cells

Treatment with the t10,c12 CLA isomer reduced total cellular IGF-IR protein levels in MCF-7 cells compared to all other treatment groups (Fig. 4). Both LA and c9,t11 CLA significantly reduced IGF-IR protein compared to OA-treated and untreated cells, but not compared to each

Table 1 Fatty acid composition of whole cell phospholipids

MCF-7 breast cancer cells were exposed to fatty acids for 24 h in serum-free conditions. Values are percentages of total fatty acids and are expressed as means ± SEM, determined from 3 to 4 experiments. Values within a row that do not share a common superscript letter are significantly different ($p < 0.05$). LA Linoleic acid; OA oleic acid; CLA conjugated linoleic acid; NS not significant; ND not detectable; SFA saturated fatty acids; MUFA monounsaturated fatty acids; PUFA polyunsaturated fatty acids. Fatty acids not shown: C17:0, C20:0, C22:0, C16:1(t9), C18:1(t11), C22:2(6), C22:4(6), C22:5(6), C20:5(3), C22:5(3)

¹ The fatty acid treatment used were, untreated (no additional fatty acids added), LA (256 μM LA), c9,t11 CLA (128 μM LA + 128 μM c9t11 CLA), t10,c12 CLA (128 μM LA + 128 μM t10,c12 CLA), OA (128 μM LA + 128 μM OA)

² Both CLA isomers contain two double bonds, therefore they are included in the total PUFA calculation

Fig. 1 Metabolic activity (mitochondrial enzyme activity) of IGF-I-stimulated MCF-7 breast cancer cells treated with 128 μM (mean absorbance was 1.66 ± 0.26) or 256 μM (mean absorbance was 1.50 ± 0.16) fatty acids for 48 h. Values are expressed as a ratio to the LA treatment, and represent the means ± SEM of three experiments. The untreated condition contained no additional fatty acids. Within each concentration, bars that do not share a common letter are significantly different ($p < 0.05$)

other (Fig. 4). The levels of phosphorylated IGF-1 were lower in MCF-7 cells incubated with t10,c12 CLA compared to LA. Band intensity ($n = 2$ /treatment), expressed, relative to LA, was for untreated cells ($1.56 ± 0.41$), c9,t11 CLA ($1.0 ± 0.01$), t10,c12 CLA ($0.52 ± 0.27$) and OA ($1.52 ± 0.68$).

CLA Reduces Total Cellular IRS-1 Levels Compared to Untreated and OA-Treated MCF-7 Cells

Treatment with c9,t11 CLA or t10,c12 CLA reduced total cellular IRS-1 protein levels in MCF-7 cells compared to untreated and OA-treated cells (Fig. 5). Although IRS-1 protein levels were affected by treatments in a pattern similar to that seen for IGF-IR, the CLA-induced reductions in IRS-1 protein levels were not statistically different from LA-treated cells (Fig. 5).

Fig. 2 Metabolic activity (mitochondrial enzyme activity) of IGF-1-stimulated MCF-7 breast cancer cells treated with various fatty acids in combination with LA for 24 or 48 h. Values are expressed as a ratio to the 256 μ M LA treatment (mean absorbance was 0.256 ± 0.037) and represent the means \pm SEM of 3–4 experiments. Each of the fatty acid treatments contained 128 μ M LA + 128 μ M of the experimental fatty acid. The untreated condition contained no additional fatty acids. Within each time point, bars that do not share a common letter are significantly different ($p < 0.05$). Cell counts ($\times 10^6$ /mL) were performed ($n = 5$ /group) at 24 h; untreated 19.2 ± 1.1^a , LA 17.5 ± 1.5^a , OA 17.4 ± 1.5^a , c9,t11 CLA 15.6 ± 1.7^a , t10,c12 CLA 9.6 ± 1.0^b

Fig. 3 LDH release from IGF-1-stimulated MCF-7 breast cancer cells treated with various fatty acids in combination with LA for 24 h. Values are expressed as a ratio to the 256 μ M LA treatment (mean % LDH released into media was 38 ± 6), and represent the means \pm SEM of 3–4 experiments. Each of the fatty acid treatments contained 128 μ M LA + 128 μ M of the experimental fatty acid. The untreated condition contained no additional fatty acids. Bars that do not share a common letter are significantly different ($p < 0.05$)

Discussion

The two most common dietary CLA isomers, c9,t11 and t10,c12, have been reported to reduce the incidence and size of mammary tumours in rodent models when fed together or individually [4, 29]. Consistent with the animal models, the anti-carcinogenic activity of these two isomers has been demonstrated in human breast cell lines [7–10]. While both isomers are reported to have anti-cancer activity, their respective level of growth inhibition and the mechanism by which they mediate their cytotoxic activity against tumour cells has not been established. In the current

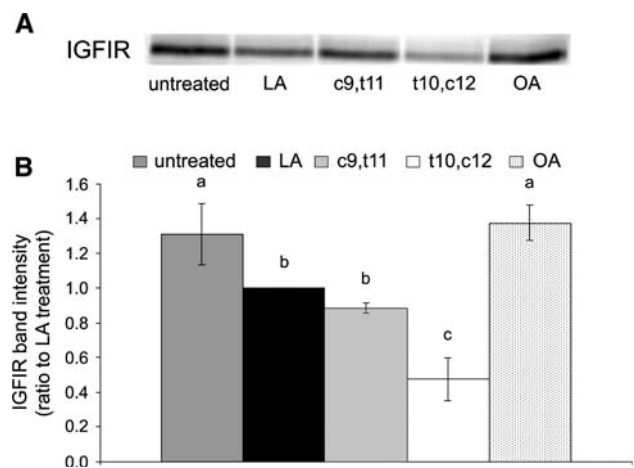

Fig. 4 Total IGF-IR protein levels in IGF-I-stimulated MCF-7 breast cancer cells after treatment with various fatty acids in combination with LA for 24 h. **a** Western blot analysis of total IGF-IR protein and β -actin levels among fatty-acid treated cells. The blot shown is representative of three independent experiments. **b** IGF-IR band intensity. Each of the fatty acid treatments contained 128 μ M LA + 128 μ M of the experimental fatty acid. The untreated condition contained no additional fatty acids. Bars that do not share a common letter are significantly different ($p < 0.05$)

The untreated condition contained no additional fatty acids. Bars that do not share a common letter are significantly different ($p < 0.05$)

study, the t10,c12 CLA isomer decreased metabolic activity after 48 h compared to all other treatment groups. These results are consistent with the literature [6, 9, 30] and demonstrate that on a gram per gram basis, t10,c12 CLA has a greater growth inhibitory effect (metabolic activity and cell number) on estrogen receptor positive MCF-7

cells. Previous work on CLA and cancer cells lines have performed experiments using the cell maintenance media that contains a very low concentration of fatty acids (only that from the serum), as the ‘control’ treatment [6, 7, 9, 10, 19, 31]. Serum provides only a very low (at 5% v/v would result in a concentration of 3 μ M LA; [8]) amount of essential fatty acids. CLA isomers have been reported to interfere with n-6 essential fatty acid metabolism when LA is in limited supply [32] but not when there is a sufficient level in the diet [33]. In most in vivo situations, LA is usually not in limited supply, thus we added LA to the media of all our experimental treatments to prevent concluding that the in vitro growth inhibition effects of CLA isomers on MCF-7 cells was due to effects on the availability of LA. Through a series of preliminary experiments we determined that the addition of 125 μ M LA to the media enabled us to maintain the concentration of LA in the membrane PL (higher than the untreated condition) and the concentration of C20:4(6) similar to the LA treatment (Table 1). Our work extends earlier growth studies by confirming that growth inhibition by the t10,c12 CLA isomer is maintained in the presence of LA and that the growth inhibitory effects of c9,t11 CLA appear when LA is present in the media.

The effect of CLA isomers on increasing LDH release (estimate of cell death) is consistent with the reduced metabolic activity measured in the WST-1 assay. Interestingly, incubation with t10,c12 CLA did not significantly decrease the metabolic activity of MCF-7 cells after 24 h, but it did increase our measure of cytotoxicity (LDH release) compared to the other treatments at 24 h. This might be a result of the ways that these two assays are measured. LDH release assesses the amount of LDH released into the media while the Wst-1 viability assay looks at the remaining live cells and assesses mitochondrial reductase activity. Our results suggest that at 24 h, a significant number of t10,c12 CLA-treated cells had died but the remaining cells had a similar mitochondrial activity to the other groups. We did not measure apoptosis in the current study; however, incubation of MCF-7 cells with mixtures of CLA isomers has been demonstrated to increase apoptosis by increasing pro-apoptotic and decreasing anti-apoptotic genes and proteins [34–36]. However, a recent study suggested that CLA isomers can inhibit the growth of MCF-7 cells without increasing apoptosis [37].

The orientation of fatty acid double bonds (e.g. *cis*, *trans*), or the length of a fatty acid chain, impacts the positioning and spacing of neighbouring fatty acids in the plasma membrane [38]. Changes to the fatty acid composition of the plasma membrane and subsequently the physical structure have been shown to alter lipid-protein interactions, and ultimately the function of the membrane

[38, 39]. Due to its conjugated *cis* and *trans* double bonds, the mechanism by which t10,c12 CLA inhibits MCF-7 breast cancer cell growth may be related to its incorporation into and subsequent disruption of cellular membrane functions. Both CLA isomers, c9,t11 and t10,c12, are structurally similar in that they contain two conjugated double bonds, one in the *cis* formation and the other in the *trans* position. Using synthetic model membranes, Yin et al. showed that incorporation of c9,t11 CLA perturbed membrane structure at the location of the conjugated double bonds and increased oxygen permeability, as compared to LA, MUFA and SFA [40]. Although this study used only the c9,t11 CLA isomer, the results are likely relevant to t10,c12 CLA. As t10,c12 CLA was incorporated into the cell membrane to a greater extent than c9,t11 CLA (33% vs. 22%, respectively) in the present study, this suggests that the membrane might be more disrupted by t10,c12 CLA treatment. In support of this, recently, it was demonstrated that the physical properties of these two isomers are quite different [41]. The greater incorporation of t10,c12 CLA was at the expense of SFA as compared to the LA- and c9,t11 CLA-treated groups. However it is unlikely that the change in SFA concentration in the membrane accounts entirely for the differences in growth as the concentration of SFA in the t10,c12 CLA treated group was not different from that of the OA treated group. Our results suggest that the high incorporation of the t10,c12 CLA isomer might be responsible for the difference in biological function, rather than the displacement of a specific saturated or unsaturated fatty acid. Future studies are planned to determine if the alteration in phospholipid composition, altered the positional distribution (sn-1 and sn-2) of fatty acids in membrane phospholipids.

Previously, OA has been shown to stimulate the proliferation of MCF-7 cells as compared to untreated cells [42]. Interestingly, the mixture of OA and LA in the presence of IGF-I led to a 1.5 fold increase in metabolic activity as compared to either LA-treated or untreated cells and resulted in the lowest level of LDH release at 24 h. To our knowledge there are no published studies that have examined the supplementation of LA and OA together on the viability of breast cancer cells. OA-treated and untreated cells had a higher relative content of MUFA than the other three treatments. The greater proportion of MUFA in the OA treated group was due to the high incorporation of OA, whereas for the untreated group 16:1n-9, 18:1n-9, and 18:1n-11 were all higher than the CLA- or LA-treated groups. The increased MUFA in the OA group occurred without a proportional replacement of any one specific fatty acid or fatty acid group. Our data suggests that a higher MUFA content (particularly 18:1) in phospholipids is associated with better survival/growth of MCF-7 cells. In support of this conclusion, incubation with

OA was reported to promote cell survival in MDA-MB-231, MDA-MB-468 and T47D breast cancer cells under serum-free conditions [42, 43] compared to LA, AA, docosahexaenoic acid (DHA) and palmitate [44].

Changes in the fatty acid composition of membrane phospholipids can alter the functional activity of cell membranes, including the activity of membrane associated receptors [45, 46]. Addition of long chain polyunsaturated fatty acids (DHA but not AA) was reported to increase the number of insulin receptors in retinoblastoma cells, although this same study did not find a change in the binding ability of IGF-I receptors, nor did they study the addition of LA or trans fatty acids [47]. The observed changes in total IGF-IR, phosphorylated IGF-IR and IRS-1 protein levels observed among the different treatments are consistent with the growth inhibition and LDH results. The untreated and OA-treated groups demonstrated the least amount of LDH release/cell death, higher metabolic activity, and had the greatest amount of total and phosphorylated IGF-IR and total IRS-1. In contrast, the t10,c12 CLA-treated group had the greatest cell death, lowest metabolic activity and the lowest amounts of total and phosphorylated IGF-IR and IRS-1. The amount of phosphorylated IRS-1 was not measured in the current study; however, it was recently demonstrated that the amount of IRS-1 in the cell was important for cell proliferation as reducing the translation of IRS-1 suppressed the growth of MCF-7 cells [21].

Consistent with our results, in HT-29 colon cancer cells, Kim et al. [19] demonstrated that a mixture of CLA decreased the amount of total IGF-1R and inhibited the IGF-1 induced phosphorylation of the IGF-1R in cells. Their work demonstrated that this decrease was associated with a reduced recruitment of the P85 PI3K to the receptor and the phosphorylation of Akt and extracellular signal-regulated kinase (ERK)-phosphorylation [19]. Our results confirm this observation in human breast cancer cells and unlike the previous work studied the effects of the two major CLA isomers. Additionally our findings demonstrated the effect of CLA isomers on the amount of IRS-1, which is upstream from Akt and Erk signalling.

As changes to the total protein levels of these signaling molecules are most likely due to changes at the genetic or transcription level, in the current study it is not possible to directly link the changes in total IGF-IR and IRS-1 protein levels to specific lipid changes in membrane phospholipids. However, the dramatic incorporation of t10,c12 CLA into cell phospholipids indicates a probable disruption of the function of these and/or other membrane associated proteins. Future studies are warranted to examine the activity levels of these molecules, and their downstream signaling mediators (e.g. phosphatidylinositol 3-kinase, extracellular

signal-related kinase). In addition, further studies are needed to examine the effects of CLA isomers on lipid “rafts” (microdomains of saturated lipids that cluster together in the plasma membrane) [48]. Our group has shown that incubation of estrogen-receptor negative MDA-MB-231 breast cancer cells with n-3 PUFA alters the fatty acid composition of lipid rafts, resulting in a reduction of raft-associated epidermal growth factor receptors (EGFR) and an increase in whole cell tyrosine phosphorylated EGFR, which was consistent with an increase in apoptosis [12]. As IGF-IR [49] and IRS-1 [50] have been reported to be located in lipid rafts, the disruption of the lipid composition of these microdomains due to CLA is a future area of investigation to pursue.

The CLA concentration (128 μ M) used in the current study is within the range used in previous studies to demonstrate an effect on cell growth on human breast cancer cell lines [6, 30, 34, 36, 51, 52]. Although the growth inhibition is similar to what is observed in animal feeding studies [5, 53–56], the physiological relevance of the amount of CLA incorporated into membranes remains to be determined. In summary, the results of this study demonstrate that the t10,c12 isomer of CLA inhibits the growth of MCF-7 cells and suggest that this may be mediated through incorporation into cellular phospholipids and interference with the function of IGF-I and related signaling proteins. Further investigation is required to definitively link this interference with modifications to the membrane of breast cancer cells.

Acknowledgments The authors would like to acknowledge the help of Patricia Biondo in putting together this manuscript and the technical assistance of Marnie Newell, Paige Sorochan and Susan Goruk. D. Amariù was the recipient of a post-graduate studentship from the Natural Sciences and Engineering Research Council of Canada. Abstract There are considerable differences in the plasma lipid profile between lean and obese individuals and between men and women. Little, however, is known regarding the effects of obesity and sex on the plasma concentration of enzymes involved in intravascular lipid remodeling. Therefore, we measured the immunoreactive protein mass of lipoprotein lipase (LPL), hepatic lipase (HL), cholesterol-ester transfer protein (CETP) and lecithin-cholesterol acyl transferase (LCAT) in fasting plasma samples from 40 lean and 40 obese non-diabetic men and premenopausal women. Women, compared with men, had ~5% lower plasma LCAT ($p < 0.041$), ~35% greater LPL ($p = 0.001$) and ~10% greater CETP ($p = 0.085$) concentrations. Obese, compared with lean individuals of both sexes, had ~30% greater plasma LCAT ($p < 0.001$), ~20% greater CETP ($p < 0.001$) and ~20% greater LPL ($p = 0.071$) concentrations. Plasma HL concentration was not different in lean men and women. Obesity was associated with increased (by ~50%) plasma HL concentration in men ($p = 0.018$) but not in women; consequently, plasma HL concentration was lower in obese women than

obese men ($p = 0.009$). In addition, there were direct correlations between plasma lipid transfer enzyme concentrations and lipoprotein particle concentrations and sizes. There are considerable differences in basal plasma lipid transfer enzyme concentrations between lean and obese subjects and between men and women, which may be partly responsible for respective differences in the plasma lipid profile.

Keywords Adiposity · Sex differences · Lipid transport · Lipid profile · Lipoprotein subclasses

Abbreviations

VLDL	Very low-density lipoprotein
LDL	Low-density lipoprotein
HDL	High-density lipoprotein
LPL	Lipoprotein lipase
HL	Hepatic lipase
CETP	Cholesterol-ester transfer protein
LCAT	Lecithin-cholesterol acyl transferase
CVD	Cardiovascular disease

Introduction

Obese subjects and men are at greater risk for cardiovascular disease (CVD) than lean subjects and women, probably because obese individuals and men have a more pro-atherogenic plasma lipid profile than lean subjects and women, respectively [1]. Several mechanisms, including hepatic and intestinal secretion of very low-density lipoproteins (VLDL), high-density lipoproteins (HDL), and possibly also low-density lipoproteins (LDL), intravascular delipidation and remodeling, and final catabolism and

removal from the circulation, act in concert to maintain a more or less pro-atherogenic lipid profile [2]. Intravascular remodeling of lipoproteins involves the exchange of core and surface lipids and apolipoproteins, mediated largely by the action of plasma lipid transfer enzymes, i.e., lipoprotein lipase (LPL), hepatic lipase (HL), cholesterol-ester transfer protein (CETP), and lecithin-cholesterol acyl transferase (LCAT) [3]. Although differences between lean and obese subjects and between men and women in the plasma lipid and lipoprotein profile are well established [1, 4], we know little regarding the effects of obesity and sex on the plasma concentration (i.e., the protein mass) of enzymes involved in intravascular lipid remodeling [5, 6]. A better understanding of the regulation of plasma lipid transfer enzyme concentrations may be clinically important because the immunoreactive protein mass of these enzymes has recently been shown to be related to CVD risk [7–12]. The relationship between plasma lipid transfer enzyme concentrations and CVD risk could simply be a reflection of their enzymatic actions and consequent changes in plasma lipid profile but likely goes beyond that because their function is not only limited to their catalytic activity, e.g., LPL [13] and HL [14] serve as bridges/ligands that facilitate lipoprotein uptake by various cell types. The purpose of our study therefore was to examine potential differences in basal plasma lipid transfer enzyme concentrations between lean and obese men and women. We studied non-diabetic, healthy, normoglycemic and normotriglyceridemic subjects with normal oral glucose tolerance to avoid potential confounding due to obesity-related metabolic complications [15, 16].

Experimental Procedure

Subjects

Eighty subjects between the ages of 18 and 50 years participated in the study: 40 (18 men; 22 premenopausal women) were lean with a body mass index (BMI) between 18.5 and 25 kg/m² and 40 (13 men; 27 premenopausal women) were obese with a BMI between 30 and 45 kg/m². Lean and obese subjects and men and women were matched on age. All subjects were considered to be in good health after completing a medical evaluation, which included a history and physical examination and standard blood tests. Subjects were included in the study if they were free of hypertension (blood pressure <140/90 mmHg) and were normoglycemic (plasma glucose concentration <5.5 mmol/L) and normotriglyceridemic (plasma triglyceride concentration <1.69 mmol/L); in addition, all obese subjects had normal oral glucose tolerance (plasma glucose concentration 2 h after a 75 g oral glucose challenge

<7.77 mmol/L). None of the subjects satisfied the criteria for metabolic syndrome, and none were smoking or taking medications known to affect glucose or lipid metabolism. Total body fat was determined by using dual-energy X-ray absorptiometry (Delphi-W densitometer, Hologic, Waltham, MA), and total abdominal, intra-abdominal, and subcutaneous abdominal fat areas were determined by magnetic resonance imaging on a 1.5T scanner (Siemens, Iselin, NJ), as previously described [17]. Written informed consent was obtained from all subjects before their participation in the study, which was approved by the Human Studies Committee and the General Clinical Research Center (GCRC) Advisory Committee at Washington University School of Medicine in St. Louis, MO.

Sample Collection and Analyses

Subjects were instructed to adhere to their regular diet and to refrain from physical activity for a minimum of 3 days before they were admitted to the GCRC where they consumed a standardized meal at ~1930 h, and then fasted (except for water) and rested in bed until fasting venous blood (total volume ~20 mL) was collected in chilled tubes containing sodium EDTA between 0700 and 0800 h the next day. Plasma was separated by centrifugation (3,000 rpm for 15 min at 4 °C) and stored at –80 °C until analyses were performed.

The concentrations of LPL, LCAT and CETP in plasma were determined with commercially available ELISA kits (Daiichi Pure Chemicals, Tokyo, Japan) [18] and plasma HL concentration was determined by using a sandwich ELISA method with monoclonal antibodies generated against human HL [19]; the assays used for LPL and HL do not cross-react with each other or with pancreatic lipase.

Plasma glucose concentration was determined by using an automated glucose analyzer (YSI 2300 STAT plus, Yellow Spring Instrument Co., Yellow Springs, OH). Total plasma triglyceride, VLDL-triglyceride and HDL-cholesterol concentrations, and plasma concentrations of VLDL, LDL, and HDL particles and average lipoprotein particle sizes (diameter in nm) were determined (LipoScience, Raleigh, NC) by using an AVANCE INCA NMR Chemical Analyzer equipped with a Bruker BioSpin UltraShield super-conducting magnet (Bruker BioSpin, Billerica, MA), as previously described [4].

Statistical Analysis

All data sets were normally distributed and are presented as means ± standard error (SEM). Two-way analysis of variance was used to evaluate the significance of differences between lean and obese subjects and men and women. In a secondary analysis, we compared the LPL, LCAT, and

CETP data obtained from a subgroup of 15 men and 15 women who were matched on percent body fat to evaluate the effect of sex independently of differences in body composition between men and women, by using the Student's *t*-test for independent samples. Plasma HL concentration measurements were excluded from this secondary analysis because we detected a significant interaction between sex and obesity on plasma HL concentration. Associations between variables of interest were assessed with Pearson's linear correlation analysis. A *p*-value < 0.05 was considered statistically significant.

Results

Plasma LCAT concentration was ~5% lower and plasma LPL concentration was ~35% higher in women than in men; women also tended to have higher plasma CETP concentration than men (Table 1). Obese subjects had 20–30% higher plasma LCAT and CETP concentrations than lean subjects, irrespective of sex; they also tended to have higher plasma LPL concentration than lean subjects (Table 1).

Plasma HL concentration was not different in lean men and women. Obesity was associated with ~50% higher plasma HL concentration in men but not in women; consequently, obese women had ~30% lower plasma HL concentration than obese men (Table 1).

There were no differences in plasma LPL and CETP concentrations between men and women who were matched on percent body fat (Table 2). However, women had ~20% lower plasma LCAT concentration than men, even when matched on percent body fat (Table 2).

Total body fat (% body weight) correlated positively with plasma LCAT ($r = 0.296$, $p = 0.008$), LPL ($r = 0.473$, $p < 0.001$), and CETP ($r = 0.351$, $p = 0.002$) concentrations, but not with HL concentration ($r = 0.104$, $p = 0.362$). Total abdominal fat (in cm²) was positively associated with plasma LCAT ($r = 0.451$, $p < 0.001$) and LPL ($r = 0.329$, $p = 0.013$) concentrations, but not with plasma CETP ($r = 0.181$, $p = 0.175$) and HL ($r = 0.201$, $p = 0.131$) concentrations. Intra-abdominal fat (% total abdominal fat) was not significantly associated with plasma lipid transfer enzyme concentrations (all *p*-values > 0.05).

Plasma LCAT concentration was inversely correlated with average HDL particle size. Plasma HL concentration correlated directly with average VLDL particle size and negatively with average LDL particle size (Table 3). There was no relationship between plasma LPL concentration and average VLDL, LDL, or HDL particle sizes. In addition, plasma LCAT concentration was directly correlated with VLDL (all), LDL (total and small), and HDL (total and small and medium) particle concentrations (Table 3). Plasma CETP concentration was directly correlated with the concentrations (total and small) of VLDL, LDL, and HDL in plasma (Table 3). Plasma HL concentration was

Table 1 Plasma lipid transfer enzyme concentrations in lean and obese men and women

directly correlated with the plasma concentration of small LDL and small HDL particles and inversely related to the concentration of large HDL particles. No robust relationships were found between plasma LPL concentration and lipoprotein concentrations (Table 3).

Discussion

We measured the immunoreactive protein mass of plasma lipid transfer enzymes in non-diabetic lean and obese men and women with normal oral glucose tolerance and plasma triglyceride concentrations, and found considerable

differences in plasma LPL, CETP, LCAT, and HL concentrations between sexes and between lean and obese subjects.

A few previous studies evaluated the effect of obesity on plasma CETP concentration without considering potential sex differences [5], and measured plasma LPL concentration in men and women without considering the potential role of obesity [6]. Furthermore, both of these studies included subjects with hypertriglyceridemia and of unknown glucose tolerance status, which might have confounded the results [15, 16]. We found that obese individuals have higher plasma LPL, CETP, and LCAT concentrations than lean individuals and obese men (but not obese women) also have higher plasma HL concentration than lean men. LPL is the central enzyme in plasma triglyceride hydrolysis, however, LPL also functions as a molecular bridge to enhance lipoprotein uptake into cells via pathways that are independent of its catalytic activity [13]. The absence of robust relationships between the immunoreactive protein mass of LPL and plasma lipoprotein concentrations suggests that the relationship between plasma LPL concentration and CVD risk [7, 12] may be related to recently discovered non-catalytic functions of the enzyme, such as tissue binding of VLDL [13] and native and oxidized LDL [20], and the facilitation of monocyte adhesion [21]. CETP primarily carries triglyceride from VLDL in exchange for cholesterol esters from other lipoproteins, especially HDL but also LDL [22, 23]. Depletion of core triglyceride makes the VLDL particle smaller and denser, whereas triglyceride enrichment of LDL [24] and HDL [25] eventually leads to the generation of small and dense LDL and small HDL particles. Consistent with

LCAT lecithin-cholesterol acyl transferase; LPL lipoprotein lipase; CETP cholesterol-ester transfer protein; HL hepatic lipase; VLDL very-low density lipoprotein; LDL low-density lipoprotein; HDL high-density lipoprotein

this metabolic cascade, we observed positive associations between plasma CETP mass and small VLDL, LDL, and HDL particles.

Differences between men and women in plasma LPL and CETP concentrations (women greater than men) seem to manifest secondary to typical male and female phenotypes (i.e., greater body fat in women than men). This is consistent with the observation that CETP and LPL mRNA is highly expressed in mammalian adipose tissue [26], as well as with the positive relationships found between percent body fat and CETP and LPL concentrations in plasma. On the other hand, sex differences in plasma LCAT and HL concentrations are independent of differences in total body fat accumulation between men and women, and might be considered true sexual dimorphism rather than a secondary phenomenon.

Plasma LCAT concentration was ~30% greater in obese than lean subjects and slightly (~5%) but significantly lower in women than men. Since women have more body fat than men, the difference in plasma LCAT concentration is unlikely to be due to differences in body composition between men and women. Indeed, in our subset of men and women who were matched on percent body fat, plasma LCAT concentration was ~20% lower in women than in men. LCAT is a lipoprotein-associated enzyme responsible for esterifying free cholesterol to cholesterol esters, primarily on the surface of HDL; hydrophobic cholesterol esters then move to the core of HDL thereby maintaining a free-cholesterol gradient from cells to HDL, which is essential for reverse cholesterol transport [9]. Thus, our results are in agreement with the lower HDL-cholesterol concentration and smaller HDL particle size in obese compared with lean subjects and in men compared with women [1, 4], because LCAT in plasma is mainly associated with HDL particles and large, cholesterol-rich HDL particles (in lean subjects and women) contain little or no LCAT [27]. Corroborating these observations, we found that plasma LCAT concentration correlated positively with small HDL particles and negatively with average HDL size.

In agreement with an earlier study that measured post-heparin plasma HL activity [5], we found that obesity was associated with increased plasma HL concentration in men but not in women. Although HL in non-heparinized plasma is catalytically mostly inactive [28], the difference in HL protein mass may be important for our understanding of the regulation of lipid metabolism because HL has multiple roles in lipoprotein metabolism and cellular lipid uptake. It hydrolyzes triglycerides and phospholipids present in circulating plasma lipoproteins, including intermediate-density lipoproteins and lipoprotein remnants, LDL, and HDL, resulting in the generation of smaller LDL and HDL particles [14, 29], consistent with the observed

relationships between plasma HL concentration and small LDL and HDL particles and average particle sizes. Besides its function as lipase, HL serves as a ligand that facilitates lipoprotein uptake by various cell types [14].

In summary, there are considerable differences in the plasma lipid transfer enzyme concentrations between lean and obese subjects and between men and women, which may be partly responsible for respective differences in the plasma lipid profile and CVD risk.

Abstract The purpose of this study was to determine whether dietary n-3 and n-6 PUFA may affect retinal PUFA composition and PGE₁ and PGE₂ production. Male Wistar rats were fed for 3 months with diets containing: (1) 10% eicosapentaenoic acid (EPA) and 7% docosahexaenoic acid (DHA), or (2) 10% γ -linolenic acid (GLA), or (3) 10% EPA, 7% DHA and 10% GLA, or (4) a balanced diet deprived of EPA, DHA, and GLA. The fatty acid composition of retinal phospholipids was determined by gas chromatography. Prostaglandin production was measured by enzyme immunoassay. When compared to rats fed the control diet, the retinal levels of DHA were increased in rats fed both diets enriched with n-3 PUFA (EPA + DHA and EPA + DHA + GLA diets) and decreased in those supplemented with n-6 PUFA only (GLA diet). The diet enriched with both n-6 and n-3 PUFA resulted in the greatest increase in retinal DHA. The levels of PGE₁ and PGE₂ were significantly increased in retinal homogenates of rats fed with the GLA-rich diet when compared with those of animals fed the control diet.

These higher PGE₁ and PGE₂ levels were not observed in animals fed with EPA + DHA + GLA. In summary, GLA added to EPA + DHA resulted in the highest retinal DHA content but without increasing retinal PGE₂ as seen in animals supplemented with GLA only.

Keywords Dietary polyunsaturated fatty acids · Retina · Prostaglandin · Rat

Abbreviations

ALA	α -Linolenic acid
ARA	Arachidonic acid
dGLA	Dihomo γ -linolenic acid
DHA	Docosahexaenoic acid
DPA	Docosapentaenoic acid
EPA	Eicosapentaenoic acid
GLA	γ -Linolenic acid
LA	Linoleic acid
LC-PUFA	Long chain polyunsaturated fatty acids
PG	Prostaglandins

Introduction

Long chain n-6 and n-3 polyunsaturated fatty acids (LC-PUFA) are essential components of cell structures and key factors influencing various cellular functions such as neurotransmission or inflammation [1]. Even if very few studies have documented the responses of tissue composition to increased dietary n-6 and n-3 PUFA, it has been shown that supplementing with n-3 PUFA in the absence of n-6 PUFA increases docosahexaenoic acid (DHA, 22:6n-3) but reduces tissue arachidonic acid (ARA, 20:4n-6) [2–4]. Thus it is generally agreed that LC-PUFA from both

families should be provided simultaneously. A recent work carried out on piglets confirmed these observations except for the brain and the retina where ARA accumulation was unresponsive to dietary ARA [5]. Previously, we reported that a dietary supplementation with eicosapentaenoic acid (EPA, 20:5n-3), DHA and γ -linolenic acid (GLA, 18:3n-6) is efficient in increasing the retinal levels of EPA, DHA and dihomo- γ -linolenic acid (dGLA, 20:3n-6) but not those of ARA after a 3-month supplementation in the rat [6].

Since some PUFA are metabolic precursors of eicosanoids, modifications in fatty acid composition of membrane phospholipids can have consequences on the production of these molecules [7]. Eicosanoids are composed of prostaglandins (PG), thromboxanes and leukotrienes that are involved in inflammatory processes. PG are the major eicosanoids that are synthesized from PUFA during inflammatory processes via the cyclooxygenase (COX) pathway. Series 2 PG (including PGE₂) are the most abundant eicosanoids derived from ARA [8, 9] and have pro-inflammatory properties [10]. Series 1 and 3 PG (including PGE₁ and PGE₃) are derived from dGLA [11] and EPA [12, 13], respectively. PGE₁ and PGE₃ are known to be less pro-inflammatory than PG from series 2 [14]. Because PUFA from n-6 and n-3 families compete for the same enzymes responsible for their conversion into either LC-PUFA (desaturases and elongases) or PG (COX), the dietary composition in n-6 and n-3 PUFA may affect the production and tissue accretion of PG. Considering the differences between PG in terms of induction of inflammation, a decrease in the ARA level counterbalanced by an increase in dGLA and EPA levels in cell membranes may reduce the cellular inflammatory potential by modifying the nature of the PG produced. Moreover, it is well known that EPA limits its own biosynthesis through the inhibition of $\Delta 5$ -desaturase, the enzyme that also converts dGLA into ARA [6, 15, 16]. As a consequence, EPA may limit the biosynthesis of ARA from dGLA and favor the production of PGE₁ at the expense of PGE₂. Therefore, EPA allows both the biosynthesis of PGE₃ and the limitation of PGE₂ production. Since GLA, a dietary metabolic precursor of dGLA, is able to increase PGE₁ [17], a diet combining EPA and GLA may decrease the inflammatory potential of the tissues in which they are incorporated.

Given that dietary PUFA such as EPA and GLA may affect the composition of retinal membranes in the rat [6], the aim of the present study was to investigate whether these modifications affect PGE₁ and PGE₂ levels in the retina.

Experimental Procedure

All experiments on the animals were conducted in accordance with the Association for Research in Vision and

Ophthalmology (ARVO) as well as the French regulations (personal agreement number 21CAE104 for C.S. and animal quarters agreement number A21 231010EA).

Animals and Diets

Animals were housed in animal quarters under controlled temperature (22 ± 1 °C) and light conditions (12-h light, 12-h dark cycle). Male Wistar rats (8 weeks of age, Centre d'élevage Janvier, Le Genest Saint Isle, France) were fed for 3 months with diets (Table 1) containing either: (1) 10% EPA and 7% DHA, (2) 10% GLA, (3) 10% EPA, 7% DHA and 10% GLA, or (4) no EPA, DHA and GLA, as previously described [6]. The fat components of the diets were prepared by using sunflower oil and canola oil in order to supply linoleic acid (LA, 18:2n-6) and α -linolenic acid (ALA, 18:3n-3), respectively. High oleic sunflower oil and palm oil were added to balance the levels of oleic acid and palmitic acid, respectively, whereas borage and tuna oils were specifically used to ensure GLA and EPA+DHA supplies, respectively. The detailed composition of dietary lipids is presented in Table 2. These dietary PUFA concentrations were chosen since they have been shown to significantly modify the retinal fatty acid composition in rats after 3 months of diet [6]. At the end of the feeding period, animals were euthanized and the retinas were carefully excised from the ocular globe, quickly frozen in liquid nitrogen and stored at -80 °C until further analyses.

Table 1 Composition of diets

Ingredient	Amount (g/kg diet)

Lipid Assay

Total lipids were extracted from retinas according to the Folch procedure [18] ($n = 6$ in each group). Total phospholipids were separated from neutral lipids using silica cartridges according to Juaneda and Rocquelin's method [19]. The phospholipid fraction was transesterified using boron trifluoride in methanol according to Morrison and Smith [20]. Fatty acid methyl esters (FAMES) were analyzed by gas chromatography on a Hewlett Packard Model 5890 gas chromatograph (Palo Alto, CA, USA) using a CPSIL-88 column (100 m \times 0.25 mm i.d. film thickness 0.20 μ m; Varian, Les Ulis, France) equipped with a flame ionization detector. Hydrogen was used as a carrier gas (inlet pressure, 210 kPa). The oven temperature was held at 60 °C for 5 min, increased to 165 °C at 15 °C/min and held for 1 min, and then to 225 °C at 2 °C/min and finally held at 225 °C for 17 min. The injector and the detector were maintained at 250 and 280 °C, respectively. FAMES were identified by comparison with commercial and synthetic standards. The data were processed using the EZChrom Elite software (Agilent Technologies, Massy, France).

Measurement of Prostaglandin Levels in the Retina

Retinas were immersed in 500 μ L of cell lysis reagent (CellLytic™ M, Sigma-Aldrich, Saint Quentin Fallavier, France) containing 10% of a protease inhibitor cocktail

(Sigma-Aldrich). After mechanical crushing and sonication for 30 min, samples were incubated overnight at 4 °C. Samples were then centrifuged for 10 min, at 1,000g, 4 °C. The supernatants were collected and stored at –80 °C until PG assay using an enzyme immunoassay kit (Assay Designs, Euromedex, Souffelweyersheim, France) according to the manufacturer's instructions. A cross-reactivity of 70% with PGE₁ was announced by the manufacturer for PGE₂ immunoassay. Since the neuronal tissue levels of PGE₂ are about 10-fold higher than those of PGE₁, we expected this cross-reactivity to have a minor influence on PGE₂ quantification [21–23]. Concerning PGE₁ immunoassay, the cross-reactivity with PGE₂ was of 6.5% only. PGE₁ and PGE₂ levels in the homogenates were expressed in picograms per milligram of total protein quantified using the Bradford method [24] ($n = 6$ in each group). We did not observe any difference in total protein content of retinal homogenates between the different diet groups.

Statistical Analyses

Data were expressed as means \pm standard deviation (SD). The Student–Newman–Keuls test was used to compare the data from the different groups using SAS software (SAS Institute, Cary, NC, USA). *p*-Values less than 0.05 were considered as significant.

Results and Discussion

Confirming our previous results [6], feeding the animals with GLA only significantly increased the retinal levels of ARA and docosapentaenoic acid n-6 (DPAn-6, 22:5n-6) compared to control animals (Table 3). The amount of total n-6 PUFA was increased from 12.1% in controls to 20.2% in the GLA group. Conversely, the amount of total n-3 PUFA was decreased from 31.7% in controls to 29.5% of total fatty acids in the GLA group, certainly as a result of the competition between n-6 and n-3 PUFA families for enzymes responsible for their conversion. The n-6/n-3 ratio was thus significantly enhanced in the GLA group (0.68) when compared to controls (0.38). These modifications in retinal lipid composition had repercussions on the PG levels, as shown by the significant increases in the retinal amounts of PGE₁ and PGE₂ when compared to retinas from controls (Fig. 1).

Animals fed with the EPA+DHA diet showed contrasting retinal fatty acid compositions when compared to those fed with GLA (Table 3). We observed a significant increase in the retinal levels of EPA and DHA compared to the control group, whereas the n-6 end-chain products were significantly decreased (ARA and DPAn-6). In the retina of animals from the EPA+DHA group, the level of PGE₁ was

Values are expressed as means ± SD in percentage of total fatty acids (*n* = 6–8). Values with different superscript letters (a, b, c, d) are significantly different (*p* < 0.05). nd: not detected (under the limit for the detection by gas chromatography, <0.05%)

similar to that of control animals despite a significant increase in the dGLA level, although moderate (from 0.12 to 0.18% of total fatty acids in control and EPA+DHA groups, respectively; *p* < 0.05) (Fig. 1). This slight but significant increase in dGLA can be explained by the retro-inhibition of $\Delta 5$ -desaturase by EPA [15], thus limiting the conversion of dGLA to ARA. However, the decrease observed in retinal n-6 end-chain products and particularly in ARA did not result in any significant change in the retinal PGE₂ level, suggesting that the level of PGE₂ is not limited to substrate availability (Fig. 1). Nevertheless, and considering the significant increase in the EPA level (from <0.1 to 0.52% of total fatty acids in control and EPA+DHA groups, respectively; *p* < 0.05), we would expect an increase in the level of PGE₃ [13]. Unfortunately, the methodology we used did not allow us to analyse that eicosanoid, which can only be quantified by high-performance liquid chromatography coupled with electrospray ionization tandem mass spectrometry (LC/MS/MS) [25].

Feeding the animals with EPA and DHA together with GLA resulted in retinal levels of ARA, and DPA n-6 that were higher than those of control animals and lower than

those of animals fed with GLA only (Table 3). These results are not in accordance with previous reports showing that the levels of cerebral and retinal ARA are unchanged after DHA and ARA supplementations on newborn piglets [5, 26, 27]. The specific incorporation rates of LC-PUFA during neonatal development and the fact that our supplements are not based on ARA itself but on GLA and EPA may have contributed to these differential responses of the retina to dietary LC-PUFA. Within fatty acids from the n-3 family, we observed a strong increase in retinal DHA, whose levels were above those measured in the EPA+DHA group (35.4 vs. 38.9% of total fatty acids in EPA+DHA and EPA+DHA+GLA groups, respectively; *p* < 0.05). This observation was confirmed by the amounts of total n-3 PUFA and total n-6+n-3 PUFA, whose values were higher than those observed in the EPA+DHA and GLA groups. Within retinal n-3 PUFA, the levels of EPA were reduced by more than 55% in animals fed both n-6 and n-3 PUFA when compared to those supplemented with n-3 PUFA only whereas the levels of C22:5n-3 were reduced by 10% only. Indeed, the strong increase in retinal DHA of animals supplemented with both n-6 and n-3

Fig. 1 PGE₁ and PGE₂ content of retinal homogenates of rats fed 3 months with diets enriched with n-3 and n-6 long-chain polyunsaturated fatty acids ($n = 6$ in each group). Results are expressed as means \pm SD in ng per mg of total protein in retinal lysate

PUFA may be at least partly due to the contribution of EPA to form DHA. However, the reasons why dietary GLA may potentially influence the conversion of n-3 PUFA remain unknown. The repercussions of these modifications on the retinal PGE₂ level matched expectations, since the measured values followed the ARA values by being comparable to those from control animals (Fig. 1). However, and unexpectedly, the level of PGE₁ in the EPA+DHA+GLA group was also unmodified when compared to control animals (Fig. 1), despite significantly higher amounts of dGLA (0.33 vs. 0.12% of total fatty acids in EPA+DHA+GLA and control groups, respectively; $p < 0.05$). This result suggests either that the increase of dGLA was not sufficient to significantly modify the retinal level of PGE₁ or that the level of PGE₁ is not limited to substrate availability. Nevertheless, this lack of repercussion on the PGE₁ level can be explained by the low concentrations of dGLA in the retinas, particularly when compared to the other PUFA such as ARA.

In conclusion, although the data we provide do not show a clear relationship between dietary PUFA and retinal

inflammatory potential through retinal PGE₁ and PGE₂ levels, we show that a concomitant supply of targeted PUFA from both n-6 and n-3 families, namely GLA, EPA and DHA (i) can enhance the retinal levels of DHA above those observed with n-3 PUFA supplementation only, (ii) without modifying the basal levels of retinal PGE₁ and PGE₂.

Abstract Since acne vulgaris is the combined result of a bacterial infection and the inflammatory response to that infection, we examined whether *Abies koreana* essential oil (AKE) possessed anti-inflammatory and antibacterial activities against skin pathogens. In this study, AKE showed excellent antibacterial activities against drug-susceptible and -resistant *Propionibacterium acnes* and *Staphylococcus epidermidis*, which are acne-causing bacteria. In addition, AKE reduced the LPS-induced secretion of tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), IL-6, NO and PGE₂ in RAW 264.7 cells, indicating that it has anti-inflammatory effects. Therefore, we suggest that AKE may be an attractive candidate for promoting skin health.

Keywords *Abies koreana* · Acne vulgaris · Essential oil · Inflammation · Skin pathogen

Introduction

Propionibacterium acnes is a skin-colonizing, gram-positive bacterium associated with sebum-excreting pilosebaceous follicles. *P. acnes* is involved in the development of inflamed lesions during the course of acne, in which an induced inflammatory response is presumably directed

against propionibacterial antigens [1]. In contrast, *Staphylococcus epidermidis*, an aerobic organism, is usually involved in superficial infections within the sebaceous unit [2].

Mild to moderate inflammatory acne sometimes responds well to topical treatment with anti-bacterial agents, usually erythromycin or clindamycin and less often tetracycline [3, 4]. Over the past 2½ decades, the incidence of resistance to erythromycin, clindamycin and/or tetracycline has increased among propionibacterial populations associated with inflammatory acne; this resistance presents a worldwide problem for the treatment of this condition [3, 5]. The development of antibiotic resistance is multifactorial, involving the specific nature of the relationship of bacteria to antibiotics, how the anti-bacterial is used, host characteristics and environmental factors. To overcome the problem of antibiotic resistance, essential oils have been extensively studied as alternative treatments for disease [2, 6]. Therapeutic agents for acne are also employed to inhibit inflammation. However, these remedies have been known to induce side effects. Benzoyl peroxide and retinoid cause xerosis cutis and skin irritation if they are used excessively [7], and several reports also suggest that prolonged use of antibiotics can lead to organ damage and immunohypersensitivity [8–10]. In addition, triclosan is converted into an environmental hormone when exposed to light, inducing severe environmental pollution [10]. Therefore, many researchers have sought to develop therapeutic agents for acne that have high antibacterial and anti-inflammatory activities with no side effects [11–16].

As part of our ongoing alternative medicine programs, we have directed our attention toward the identification of essential oils that combine a relatively narrow spectrum of activity against erythromycin- and clindamycin-resistant strains with good anti-inflammatory activity for potential

topical applications in patients with mild to moderate inflammatory acne. Here we report on the anti-bacterial and anti-inflammatory activities of *Abies koreana* essential oil (AKE) against drug-resistant *P. acnes* and *S. epidermidis*.

Experimental Procedures

An ethnobotanical survey was conducted on Jeju Island, South Korea, in October 2007. Voucher specimens were deposited at the herbarium of Jeju Biodiversity Research Institute (Jeju, Korea). The AKE was extracted by hydro-distillation as described by Baik et al. [17]. Briefly, approximately 1 kg of fresh *A. koreana* leaves was immersed in 3.5 l of distilled water in a 5-l three-neck flask. The sample was steam distilled for 12 h at atmospheric pressure. Gas chromatographic analyses were performed on a Hewlett-Packard 5890 gas chromatograph equipped with a polar Supelcowax column (30 m × 0.25 mm × 0.25 μm), an apolar DB-1HT column (30 m × 0.25 mm) and a split-splitless injection port (split mode). The temperature was set at 40°C for 5 min, ramped to 210°C at 10°C/min and held at 250°C for 28 min. Compounds were identified by their retention indices on both columns and by GC-MS using a Hewlett-Packard MSD 5972 mass spectrometer at 70 eV coupled to an HP 5890GC equipped with a DB-1HT column (30 m × 0.32 mm × 0.1 μm).

Nitric oxide production was assayed in the culture medium of cells stimulated with LPS (1 μg/ml) for 24 h in the presence of AKE. Cytotoxicity was determined using the LDH method. Supernatants were collected and PGE₂ concentration in the supernatants was determined by ELISA. iNOS and COX-2 mRNA expression and protein levels were determined by RT-PCR and immunoblotting, respectively. The primers used in this study were: β-actin (forward primer 5'-GTGGGCCCGCCCTAGGCACCAG-3' and reverse primer 5'-GGAGGAAGAGGATGCGGCA GT-3'), iNOS (forward primer 5'-CCCTCCGAAGTT TCTGGCAGCAGC-3' and reverse primer 5'-GGCTGTCA GAGCCTCGTGGCTTTGG-3'), COX-2 (forward primer 5'-CACTACATCCTGACCCACTT-3' and reverse primer 5'-ATGCTCCTGCTTGAGTATGT-3'). PCR products were electrophoresed in 1.5% agarose gels and stained with ethidium bromide. The β-actin, iNOS and COX-2 primers produced the expected amplified products of 603, 496 and 696 bp, respectively. The Student's *t*-test and one-way ANOVA were used to determine statistically significant differences between the values for the various experimental and control groups. Data are expressed as means ± standard errors (SEM) and the results are taken from at least three independent experiments performed in triplicate.

Values are the mean ± SEM of triplicate experiments. **P* < 0.05; ***P* < 0.01

Results and Discussion

Abies koreana is a shrub or broadly pyramidal evergreen tree endemic to the high mountains in southern Korea, including Mt. Halla. Recent reports demonstrated that *A. koreana* has several medicinal functions, including anti-tumor [18, 19] and memory-enhancing effects [20]. In addition, Jeong et al. [21] elucidated 68 chemical components and demonstrated the anti-microbial activity of AKE. However, anti-inflammatory effects or anti-bacterial activities against drug-resistant skin pathogens by AKE have not been described. In our study, *A. koreana* leaves were subjected to steam distillation. Nineteen compounds were identified in *A. koreana* leaves by GC/MS, representing more than 85.05% of the volatile compounds (Table 1). Bornyl acetate (30.35%) and limonene (18.95%) were the major components. Other chemical components included α-pinene (8.10%), camphene (7.39%), α-elemene (3.51%), alloaromadendrene (2.45%), γ-selinene (2.21%) and borneol (1.96%). In contrast, the main compounds identified by Jeong were borneol (27.9%), α-pinene

The GC/MS retention indices were calculated using a homologous series of *n*-alkanes C₆–C₃₁. Components were characterized based on library and literature searches and only those components showing matches exceeding 90% were selected. *RI* retention index, *RT* retention time

(23.2%), β -pinene (5.8%), terpinene-4-ol (3.8%), bornyl acetate (3.4%) and α -terpineol (3.1%). This difference in the main components may be due to the provenance of plant, harvest time or development stage, extraction technique, or the use of fresh or dried plant material. These are all factors that influence the chemical composition and biological activity.

The *in vitro* anti-bacterial activity of AKE against *P. acnes* and *S. epidermidis* was assessed by the presence or absence of inhibition zones and by MIC values. The MIC was recorded as the lowest concentration (highest dilution) of essential oils that inhibited visible growth (no turbidity). The MIC of AKE was determined using a two-fold serial dilution method. As shown in Table 2, AKE exhibited excellent anti-bacterial activity against drug-susceptible and -resistant *P. acnes* and *S. epidermidis*. We also determined the MIC of the major components of AKE (bornyl acetate, camphene, limonene, and α -pinene) and commercial essential oils (tea tree, lavender, and peppermint oils). In this experiment, the antibacterial activities of AKE were similar to those of the major components of AKE and the commercial essential oils. The MIC of AKE was far superior to those of the other compounds and oils against clindamycin-resistant *P. acne* SKA4.

In many studies, anti-inflammatory compounds have been investigated for their potential inhibitory effects *in vitro* using lipopolysaccharide (LPS)-stimulated RAW264.7 macrophages. Bacterial LPS is one of the best-characterized stimuli used to induce upregulation of pro-inflammatory proteins such as cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS). Inducible COX-2 is responsible for the high prostaglandin levels observed in many inflammatory pathologies. Similarly, iNOS produces large amounts of nitric oxide (NO) and is thought to play a central role in inflammatory disease. Numerous studies have

reported that NO and prostaglandin E₂ (PGE₂) participate in inflammatory and nociceptive events.

Since acne vulgaris is the combined result of a bacterial infection and the inflammatory response to that infection, we next examined whether AKE possessed anti-inflammatory activity. To investigate the effect of AKE on NO production, we measured the accumulation of nitrite, a stable oxidized product of NO, in culture media [22, 23] of RAW 264.7 cells stimulated with LPS for 24 h in the presence or absence of AKE. Nitrite levels in LPS-stimulated cells increased significantly compared to that in control cells. As shown in Fig. 1a, AKE (12.5, 25 and 50 μ g/ml) markedly and dose-dependently inhibited LPS-induced NO production by RAW 264.7 cells. COX-2 is induced by cytokines and other activators, such as LPS, in a variety of inflammatory cells, including macrophages, resulting in the release of large amounts of PGE₂ at inflammatory sites. Therefore, we examined the effects of AKE on PGE₂ production in LPS-stimulated RAW 264.7 macrophages. When macrophages were stimulated with LPS (1 μ g/ml) for 24 h, the levels of PGE₂ increased in the culture medium. As shown in Fig. 1b, AKE (12.5, 25 and 50 μ g/ml) suppressed LPS-induced PGE₂ production in a dose-dependent manner. As expected, the reference compounds, NS-398 (COX-2 inhibitor) and 2-amino-4-methyl pyridine (iNOS inhibitor) potently inhibited PGE₂ and NO production at 20 μ M, respectively.

Western blot and RT-PCR analyses were performed to determine if the inhibitory effects of AKE on pro-inflammatory mediators (NO and PGE₂) were related to the modulation of iNOS and COX-2 expressions. In unstimulated RAW 264.7 cells, iNOS and COX-2 protein and mRNA were not detected. But, LPS upregulated their protein levels, and pre-treatment with AKE inhibited this upregulation. To determine if the inhibition of

Skin pathogens were grown at 37°C for 24 h or 48 h (for *Propionibacterium* sp.) in each media. Culture suspensions were adjusted by comparing against 0.5 McFarland standard. For determination of MIC, the microdilution broth susceptibility assay was used

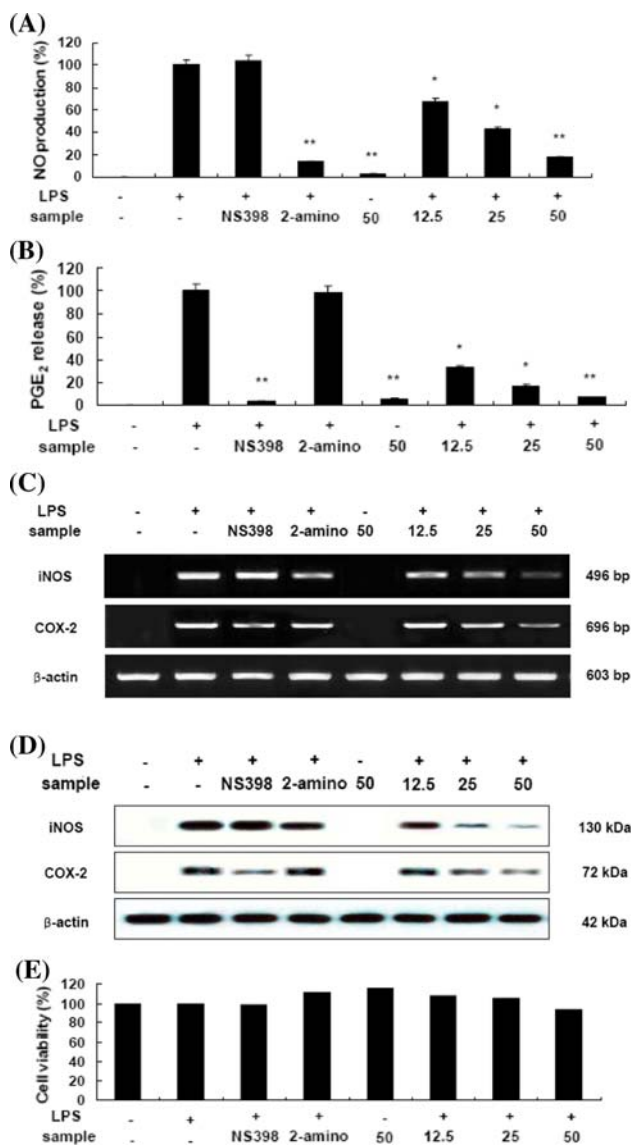

Fig. 1 Inhibitory effects of AKE on iNOS and COX-2 expressions in macrophage RAW264.7 cells. Nitric oxide production was assayed in the culture medium of cells stimulated with LPS (1 μ g/ml) for 24 h in the presence of AKE (a). Supernatants were collected and PGE₂ concentration in the supernatants was determined by ELISA (b). iNOS and COX-2 mRNA expression (c) and protein levels (d) were determined by RT-PCR and immunoblotting, respectively. Cytotoxicity was determined using the LDH method (e). As positive controls, we used 2-amino-4-methyl pyridine (20 μ M) and NS398 (20 μ M), which inhibit NO and PGE₂ production, respectively. Values are the mean \pm SEM of triplicate experiments. * P < 0.05; ** P < 0.01

LPS-stimulated NO and PGE₂ production by AKE was mediated by iNOS and COX-2 gene regulation, RT-PCR analyses were performed. As shown in Fig. 1c, AKE reduced the expressions of iNOS and COX-2 mRNA in a dose-dependent manner. By comparison, AKE did not affect β -actin expression, a housekeeping gene. As shown in Fig. 1d, AKE also dose-dependently reduced the expressions

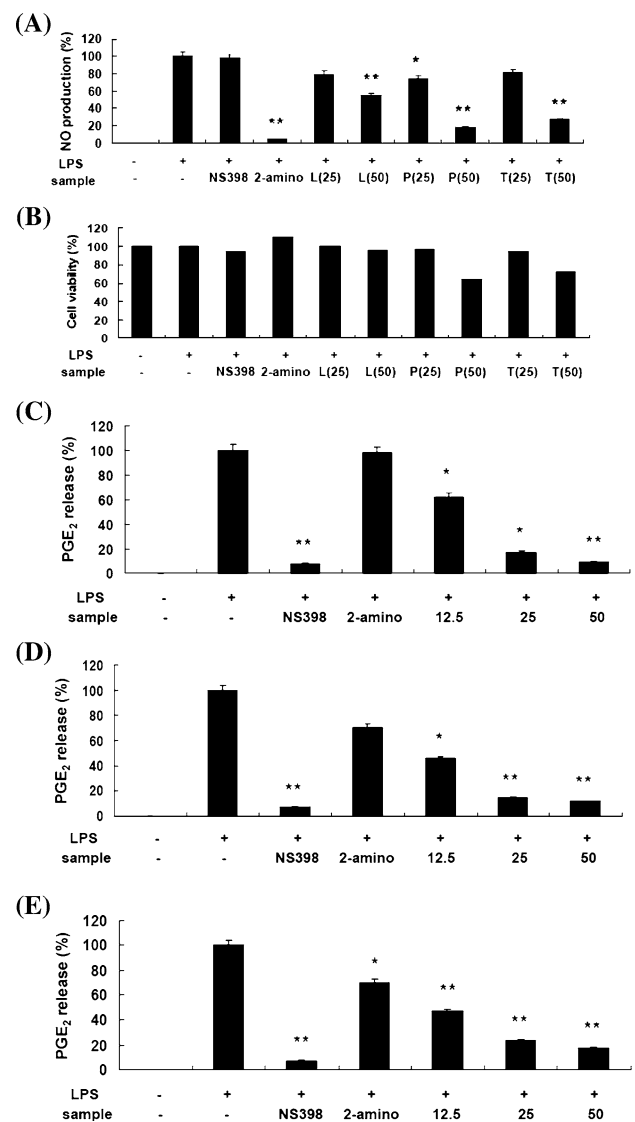

Fig. 2 Inhibitory effects of oil extract of lavender (L), peppermint (P), and tea tree (T) oils on nitric oxide and PGE₂ production in RAW 264.7 cells. Nitric oxide production was assayed in the culture medium of cells stimulated with LPS (1 μ g/ml) for 24 h in the presence of commercial oils (12.5, 25 and 50 μ g/ml), NS-398 (20 μ M) and 2-amino-4-methyl pyridine (20 μ M). Cytotoxicity was determined using the LDH method (b). (c), lavender oil; (d), peppermint oil; (e), tea tree oils. Values are the mean \pm SEM of triplicate experiments. * P < 0.05; ** P < 0.01

of iNOS and COX-2 protein. In general, these results indicate that the inhibitory effects of AKE on LPS-induced NO and PGE₂ production resulted from iNOS and COX-2 suppression. Furthermore, based on the RT-PCR analyses, the mRNA levels of iNOS and COX-2 correlated with their protein levels. The numbers of viable activated macrophages, as determined by LDH assays, were not altered by AKE, indicating that the inhibition of NO synthesis by AKE was not simply due to cytotoxic effects (Fig. 1e). Therefore, the inhibitory effect of AKE on iNOS and COX-2

gene expressions appears to be one of the mechanisms for the anti-inflammatory action of AKE.

We also investigated the *in vitro* anti-inflammatory effects of tea tree, lavender, and peppermint oils as commercially available essential oils in this study. As shown in Fig. 2, we found that low concentrations of commercial oils also inhibited the production of NO and PGE₂ within LPS-stimulated murine macrophages. The inhibitory effect of AKE on NO and PGE₂ production is greater than those of commercial oils in this study. Peppermint and tea tree oil exhibited cytotoxicities at 50 µg/ml. Also, many of the major components of AKE, including bornyl acetate, camphene, limonene, and α-pinene, had no inhibitory effect on NO and PGE₂ production and caused severe cytotoxicities above 25 µg/ml. Only limonene had an inhibitory effect on PGE₂ production (data not shown).

IL-1β, IL-6 and TNF-α are produced primarily by activated monocytes or macrophages. Because AKE potently inhibited pro-inflammatory mediators, we investigated its effects on LPS-induced IL-1β, IL-6 and TNF-α release by enzyme immunoassay (EIA). After 18-h pre-incubation, mRNA expression of pro-inflammatory cytokines was determined from a 24-h culture stimulated with LPS (1 µg/ml) in the presence of AKE. After 24-h incubation with both LPS and AKE, TNF-α, IL-1β and IL-6 production were remarkably inhibited in RAW264.7 cells.

Fig. 3 Inhibitory effects of AKE on TNF-α, IL-1β and IL-6 production by RAW 264.7 cells. Cells (1.5×10^5 cells/ml) were stimulated with LPS (1 µg/ml) for 24 h in the presence of AKE (12.5, 25, and 50 µg/ml). Supernatants were collected, and the pro-inflammatory cytokine concentrations in the supernatants were determined by ELISA. Values are the mean \pm SEM of triplicate experiments. * $P < 0.05$; ** $P < 0.01$

However, NS-398 and 2-amino-4-methyl pyridine had no effect on inflammatory cytokine production (Fig. 3).

In conclusion, we demonstrated that AKE has good anti-bacterial and anti-inflammatory effects. Therefore, we suggest that AKE should be explored further as a potential therapeutic agent to promote skin health.

Cholesterol Synthesis Inhibitor U18666A and the Role of Sterol Metabolism and Trafficking in Numerous Pathophysiological Processes

Richard J. Cenedella

Abstract The multiple actions of U18666A have enabled major discoveries in lipid research and contributed to understanding the pathophysiology of multiple diseases. This review describes these advances and the utility of U18666A as a tool in lipid research. Harry Rudney's recognition that U18666A inhibited oxidosqualene cyclase led him to discover a pathway for formation of polar sterols that he proved to be important regulators of 3-hydroxy-3-methyl-glutaryl coenzyme A reductase. Laura Liscum's recognition that U18666A inhibited the egress of cholesterol from late endosomes and lysosomes led to greatly improved perspective on the major pathways of intracellular cholesterol trafficking. The inhibition of cholesterol trafficking by U18666A mimicked the loss of functional Niemann–Pick type C protein responsible for NPC disease and thus provided a model for this disorder. U18666A subsequently became a tool for assessing the importance of molecular trafficking through the lysosomal pathway in other conditions such as atherosclerosis, Alzheimer's disease, and prion infections. U18666A also provided animal models for two important disorders: petite mal (absence) epilepsy and cataracts. This was the first chronic model of absence epilepsy. U18666A is also being used to address the role of oxidative stress in apoptosis. How can one molecule have so many effects? Perhaps because of its structure as an amphipathic cationic amine it can interact and inhibit diverse proteins. Restricting the availability of cholesterol for membrane formation through inhibition of cholesterol synthesis and intracellular trafficking could also be a mechanism for broadly affecting many processes.

Another possibility is that through intercalation into membrane U18666A can alter membrane order and therefore the function of resident proteins. The similarity of the effects of natural and enantiomeric U18666A on cells and the capacity of intercalated U18666A to increase membrane order are arguments in favor of this possibility.

U18666A	3- β -[2-(Diethylamino)ethoxy]androst-5-en-17-one

Introduction

The amphipathic steroid 3- β -[2-(diethylamino)ethoxy]androst-5-en-17-one, identified as U18666A by the Upjohn Company (Fig. 1), is a versatile chemical tool used in addressing questions on control of cholesterol biosynthesis, intracellular trafficking of cholesterol, trafficking of other molecules through endosomal and lysosomal compartments; and in understanding the pathophysiology of several diseases including epilepsy, cataracts, Niemann–Pick type C disease, atherosclerosis, Alzheimer’s disease, prion infections, and others.

After some historical perspective, the review will address the multiple actions of U18666A on sterol synthesis and its central role in discovery of the oxysterol synthesis pathway. The epilepsy and cataract disease models induced by the drug will be discussed, with less attention to cataracts because this model was previously reviewed [1]. The utility of U18666A in understanding intracellular trafficking of cholesterol and the mechanism of Nieman–Pick type C disease deserves special attention. Finally, the roles of oxidative stress and apoptosis in the actions of U18666A will be considered. I apologize in advance for failure to cite every article that used U18666A.

U18666A and Sterol Synthesis

Cavallini and Massarani [2] described the synthesis of 3- β -[2-(diethylamino)ethoxy]androst-5-en-17-one along with

Fig. 1 **a** Two-dimensional structures of the nonprotonated amine forms of U18666A. **b** Three-dimensional models of the two enantiomers. **c** An edge and top view of the superimposed enantiomers. (Reprinted with permission: Cenedella et al. [21])

the synthesis of other di-alkyl-amino-ethyl esters in 1951. The compounds were said to be strong coronary vasodilators, a claim not substantiated in the literature. The next mention of the compound, now named U18666A, was in 1963 when Upjohn Company made it available to Phillips and Avigan [3] to study its capacity to inhibit cholesterol biosynthesis. How Upjohn acquired rights to the compound is unclear. The late 1950s and early 1960s marked the start of a search for hypocholesterolemic drugs that culminated in the introduction of the statins in the mid-1980s. Several 3-dialkylaminoethoxy compounds were tested in the early 1960s for hypocholesterolemic activity. Most, including U18666A, caused the substitution of desmosterol for cholesterol [4–6]. One, {1-[*p*-(β -diethylaminoethoxy)-phenyl]-1-(*p*-tolyl)-2-(*p*-chlorophenyl)ethanol}, known as Mer 29 or triparanol, was introduced into humans and then promptly withdrawn from clinical use because of drug-related cataract formation [7, 8]. We reported in 1979 that U18666A was cataractogenic in rats and that it inhibited desmosterol reductase [9]. We found that it also inhibited sterol synthesis at a site prior to formation of squalene [10], but much higher drug levels were required to inhibit at the early site compared with reduction of desmosterol.

A controversy between Harry Rudney and Joseph Volpe over the consequences of U18666A inhibition of sterol synthesis on ubiquinone formation led Rudney to discover a pathway for formation of polar sterols and a regulatory role for polar sterols in cholesterol biosynthesis. Volpe and Obert [11] reported that ubiquinone synthesis was markedly increased in cultured C-6 glial cells exposed to 200 ng/mL of U18666A (about 0.5×10^{-6} M). A block at squalene synthase could divert isoprenes formed from mevalonate to ubiquinone. However, Rudney’s group [12], using cultured rat intestinal epithelial cells, clearly proved a year later that it was not ubiquinone that increased but rather squalene 2,3:22,23-dioxide (SDO). Squalene oxide (SO), the substrate for the inhibited 2,3-oxidosqualene cyclase (OSC), was diverted to SDO. Upon removal of U18666A from the media, SDO was converted to polar sterols. Both SO and SDO are substrates for the cyclase. In their following paper, Panini et al. [13] observed that 3-hydroxy-3-methyl-glutaryl coenzyme A (HMGCoA) reductase activity was decreased by addition of low concentrations of U18666A to the culture media, but activity increased when higher drug levels were added. They concluded that SDO formed at low drug levels underwent cyclization and conversion to polar sterols that inhibited HMGCoA reductase. As the concentration of U18666A was increased, cyclization of SDO was inhibited and formation of polar sterols ceased. These two seminal studies [12, 13], made possible because of the actions of U18666A, led the Rudney group to identify the oxysterols formed in the SDO pathway and their roles in regulating HMGCoA reductase [14, 15].

U18666A has continued to serve as a useful tool in studies of sterol synthesis in both plants and animals. In addition to inhibiting OSC and desmosterol reductase, it also has been shown to be an inhibitor of sterol- Δ^8 - Δ^7 isomerase, called sigma receptor or emopamil-binding protein [16, 17]. Thus, U18666A inhibits at least three membrane-bound enzymes in sterol synthesis. The inhibition of all three (OSC [18], sterol Δ^8 - Δ^7 isomerase [17], and Δ^{24} reductase or desmosterol reductase [19]) is reported as noncompetitive [18, 19]. The mechanism of inhibition, at least of OCS could involve mimicking a carbocationic intermediate due to the drug's cationic amine [18]; however, the kinetics of OCS inhibition by U18666A could be complex. Lenhart et al. [20] suggested that the OSC inhibitors could be “kinetically captured in the sequestering cavity, feigning a noncompetitive case.” We suggested that physical effects of U18666A on membrane order might also contribute to inhibiting multiple enzymes that catalyze different types of reactions. U18666A and its enantiomer equally inhibited sterol synthesis by cultured cells and induced apoptosis [21], and when added to model membranes, U18666A increased membrane structural order [22].

U18666A and Epilepsy

Our awareness of U18666A came from studies of changes in brain cholesterol and cholesterol ester levels associated with implantation of a small piece of cobalt wire in the cerebral cortex of rat [23]. The implanted rats developed epilepsy, and the affected cerebral cortex displayed a marked reduction in the concentration of unesterified cholesterol and a great increase in cholesterol ester [24]. George Bierkamper (then my student) posed the question in our journal club (1974), “Could drug-induced changes in brain sterols produce epilepsy?” Jim Culberson from the Anatomy Department of West Virginia University (Morgantown, West Virginia, USA) brought our attention to a then-recently published paper by Jurgelski et al. [25] that described induction of chronic epilepsy in opossums treated with U18666A (it was one of a number of cholesterol synthesis inhibitors tested). Based on their work, we succeeded in developing chronic epilepsy in rats with U18666A, but, unlike the opossum, the rat developed “absence” or petit mal epilepsy [26]. This epilepsy is defined by electroencephalogram seizure pattern without major motor involvement. As with the opossum, brain total sterols were essentially unchanged, but desmosterol replaced much of the cholesterol. However, Jurgelski et al. concluded that desmosterol is not the cause of the seizure state because another inhibitor of desmosterol reductase (Mer 29) increased brain desmosterol without causing

epilepsy. Even though the physical properties of cholesterol and desmosterol differed [27], we agreed with Jurgelski et al. that desmosterol was not the answer. Desmosterol can account for 80% of the total sterol in the ocular lens of U18666A-treated rats and yet the lens can remain clear [28], and replacement of cholesterol by desmosterol causes no structural or functional changes in the retina [29, 30]. Furthermore, desmosterol can support the normal growth of cultured cells [31, 32]. The epilepsy may be better related to desmosterol-independent changes in control of neural GABA_A receptor responses [33]. Perhaps of special significance to epilepsy, Sparrow et al. [34] reported that U18666A blocked voltage-regulated calcium channels in cultured neuroblastoma cells secondary to inhibiting potassium-evoked release of norepinephrine. The effect was attributed to U18666A's well-established inhibition of cholesterol synthesis and intracellular transport in cultured cells. As mentioned earlier, the effects of U18666A on membrane-related activities might also be due, at least partially, to drug-induced changes in membrane structure.

In 1990 Smith and Bierkamper [35] described how treatment of the neonatal rat with AY-9944 [*trans* 1,4-bis(2-chlorobenzylaminoethyl)cyclohexane] at 2 days of age followed by seven subsequent injections at 6-day intervals produced permanent petit mal (absence-like) epilepsy. AY-9944 was reported by Krami et al. in 1964 to be a potent inhibitor of 7-dehydrocholesterol reductase [36]. The mechanism of the AY-9944 seizure model appeared to involve GABA-ergic receptor stimulation, which was assumed to be secondary to replacement of 60–70% of the brain cholesterol with 7-dehydrocholesterol [35]. Perhaps because of the simplicity of treatment, the AY-9944 model has largely replaced U18666A in the study of epilepsy and has become a standard tool [37–50]. Studies continue to focus on the roles of GABA receptors in the mechanism of AY-9944-generated epilepsy and the importance of brain sterol changes. An unresolved question is why epileptiform activity persists after discontinuation of drug treatment and the subsequent normalization of brain sterols (disappearance of 7-dehydrocholesterol). Permanent damage to a localized region of the brain during the treatment phase might account for the continued seizures [39]. More recently, Serbanescu et al. [41] measured changes in brain sterols and development of absence seizures in rats treated with U18666A, AY-9944, or lovastatin. Both U18666A and AY-9944 increased 7-dehydrocholesterol (surprising for U18666A since others see elevation of desmosterol); and AY-9944, but not U18666A, decreased brain total sterol. Both AY-9944 and U18666A produced seizure activity as anticipated, but surprisingly lovastatin increased the abnormal brain electrical activity without any major effect on brain sterols. The authors

speculated that very localized changes in brain sterols might account for these findings or that the epilepsy is unrelated to sterols per se and might involve decreased synthesis of neurosteroids [41].

U18666A and Cataracts

Soon after beginning studies of epilepsy in U18666A-treated rats, we noticed development of cataracts in some animals. Increasing the dose caused cataracts in all animals. Several factors led us to begin studies into the mechanism of cataract induction by U18666A and other inhibitors of cholesterol biosynthesis. The National Eye Institute was interested in new animal models of cataracts, drug companies were becoming aware that appearance of cataracts in toxicology assessment could be a limiting factor in the development of hypocholesterolemic drugs, and recognition was developing that inherited diseases involving enzymes of the sterol synthesis pathway uniformly displayed increased risk of cataracts as a feature of the condition [reviewed in 51]. The working hypothesis was that altering the sterol content and composition of the lens fiber cell plasma membrane (PM) was the basis of lens opacification caused by treatment with hypocholesterolemic drugs or by genetic defect. Essentially all of the lens' total lipids are present in this unusual membrane, unusual because it contains the highest molar ratio of cholesterol to phospholipid in any known membrane, as high as 4 to 1 [1]. Treatment of rats with U18666A caused a decrease in this ratio, which led to altered membrane structure [1, 52], binding of crystalline proteins to the membrane, and presumed formation of light-scattering aggregates. New findings made since this mechanism was proposed [1] suggest that perturbation of lens membrane structure due to intercalation of U18666A could contribute to lens opacification. By using small-angle X-ray diffraction approaches, lens membrane structure was found to be more complex than anticipated, possessing "highly ordered, immiscible cholesterol domains" [53, 54]. The effects of U18666A on the order of membranes constructed from lens lipids were evaluated by both X-ray diffraction analysis and measurement of changes in the anisotropy of probes incorporated into these membranes [22]. Both approaches indicated that the presence of U18666A increased membrane order, which alone might contribute to increased light scatter. Analysis of the X-ray scatter data showed that U18666A intercalated into the hydrocarbon core of the membrane, resulting in a broad condensing effect. U18666A also induced apoptosis *in vitro* and *in vivo* in lens epithelial cells [22]. The possibility that physical properties of U18666A contribute to its assault on the lens is supported by finding that the natural and enantiomeric

forms of the drug equally inhibit sterol synthesis and induce apoptosis in lens epithelial cells [21]. The possible involvement of apoptosis in accounting for the multiple actions of U18666A is addressed later.

Role of U18666A in Understanding Trafficking of Cellular Cholesterol

U18666A's seminal role in understanding intracellular trafficking of cholesterol started with the key observation by Panini et al. that U18666A could completely block low density lipoprotein (LDL) suppression of HMGCoA reductase without affecting degradation of LDL [13]. The observation was unexplained since it is well established that LDL taken up by cells is degraded by lysosomes, that esterified cholesterol is converted to unesterified cholesterol, and that the free cholesterol is then released from lysosomes and acts to inhibit HMGCoA reductase activity in the endoplasmic reticulum [55]. Liscum and Faust [56] solved the paradox by demonstrating that U18666A inhibited the release of cholesterol from lysosomes. This discovery established the foundation for research into pathways of intracellular trafficking of cholesterol and led the Liscum laboratory and others to demonstrate that there is brisk transport of free cholesterol from lysosome to the PM and to the endoplasmic reticulum (ER) where it is re-esterified by acyl cholesterol acyl transferase (ACAT) and then stored as inert cholesterol ester. In the presence of U18666A, cultured cells accumulate free cholesterol in lysosomes, and LDL added to the media can neither support cell growth, suppress HMGCoA reductase, nor promote cholesterol re-esterification [56]. These observations were confirmed [57, 58] and extended to generate a broader view of the effects of U18666A on cellular cholesterol transport and, thereby, a clearer view of cholesterol transport pathways.

U18666A was shown to decrease movement of cholesterol from the lysosome to the ER, from the lysosome to the PM, and from the PM to the ER [59, 60]. It was without effect on the movement of LDL cholesterol to lysosomes. The transport of cholesterol from lysosomes to the ER was especially sensitive to inhibition by U18666 [61] and suggested that a distinct pathway utilizing vesicles was involved [60]. This selective sensitivity was more recently confirmed by Feng and Tabas [62]. They reported that concentrations of U18666A that blocked cholesterol trafficking to the ER by 90% decreased movement to the PM by only 10%.

Lange and coworkers proposed an alternative model for cholesterol exchange between cellular compartments based on their observations of U18666A effects on cholesterol trafficking [63–65]. They found little evidence for the

direct movement of cholesterol from lysosomes to ER, but rather movement from lysosomes to PM and from PM to ER [63]. U18666A was suggested to block cholesterol movement from PM to ER rather than from lysosomes to PM [63, 64]. The massive accumulation of cholesterol in lysosomes in U18666A-treated cells was attributed to accumulation of a special class of lysosomes, ones containing abundant lipid arranged as lamellar bodies from which egress of cholesterol is very slow [64].

The Liscum group affirmed their conclusion that U18666A and similar cationic-hydrophobic amines block efflux of cholesterol from the lysosome to the PM [60]. They suggested that Lange et al. [63] failed to see a U18666A-induced decrease in PM cholesterol because the cholesterol oxidase used reached an intracellular pool of cholesterol. Cholesterol oxidase is intended to attack cholesterol in only the outer leaflet of the PM. On the basis of the work of Liscum et al. described above and that of others [66–69], one can say that U18666A broadly inhibits intracellular trafficking of cholesterol and principally inhibits the movement of cholesterol out of lysosomes. What mechanism is responsible for this action?

Although the mechanism(s) by which U18666A inhibits cellular cholesterol trafficking (lysosome to ER and PM, and PM to ER) are unclear, several observations lead to a working hypothesis. U18666A inhibition of cholesterol trafficking appears independent of protein synthesis, integrity of the cytoskeleton, energy availability, pH of the lysosome, or *P*-glycoprotein function [57, 59]. Rather, U18666A's effects on cholesterol trafficking could involve direct interference with the Niemann–Pick type C protein (more on this below) or interference with this protein secondary to altering membrane lipid organization. Underwood et al. [61] reported that U18666A bound with high specificity to intact Chinese hamster ovary (CHO) cell membrane and suggested that this binding can alter the organization of membrane lipids. Other amphipathic cationic amines (imipramine, stearylamine, and sphinganine) could antagonize the binding and also interfere with cholesterol trafficking [61, 67], but they were orders of magnitude less potent than U18666A [61, 67]. Thus, physical properties of U18666A could contribute to its effects on intracellular cholesterol transport and perhaps to the many other actions of the drug. U18666A incorporation into model membranes increased structural order, which resulted in a broad condensing effect on membrane lipids. The equal capacity of natural and enantiomeric U18666A to inhibit cholesterol synthesis and induce apoptosis suggested that the drug might alter cell function because of physical characteristics of the molecule rather than through stereospecific interaction with proteins [21].

Role of U18666A in Understanding Niemann–Pick Type C Disease

U18666A has been used as a tool to probe the roles of cholesterol trafficking in numerous diseases and states. These include Niemann–Pick type C disease, atherosclerosis, Alzheimer's disease, prion infections, AIDS, Wilson's disease, and others.

Niemann–Pick type C disease is an autosomal recessive condition caused by a loss of function mutation in the protein product of the NPC1 gene. NPC is a hydrophobic–polytopic transmembrane protein that promotes lipid sorting and vesicular trafficking of both LDL-derived and endocytotic cholesterol [70–72]. The protein appears to reside in a novel set of vesicles or organelles that associate with lysosomes and functions to shuttle endocytotic cholesterol to the PM and ER [73–75]. Free or unesterified cholesterol accumulates in peripheral tissues, and glycosphingolipids accumulate in brain of patients lacking functional NPC protein [70, 76]. Although NPC protein may primarily affect intracellular trafficking of glycosphingolipids in brain, it may have a role in the transport of endogenously made cholesterol from neuronal cell body to distal axon where it is used for membrane synthesis. Axonal growth is impaired in primary cultures of neurons from mice with mutation in the NPC1 gene [77]. Autophagic cell death can result from blocking egress of cholesterol from endosomes/lysosomes due to NPC disease [78]. Autophagy is a process of cellular self-digestion that normally functions to aid survival during periods of starvation or deficiency in essential molecules [79]. The inaccessibility of the cell to the cholesterol trapped in lysosomes can be viewed as a nutritional deficiency.

U18666A has been a widely used chemical tool to model Niemann–Pick type C disease [70, 77, 78, 80–84]. The transport and subcellular distribution of NPC protein is altered when egress of cholesterol from lysosomes is blocked by U18666A [74, 80], and U18666A may produce its effects through direct interaction with the NPC protein [70]. A link between the NPC protein and U18666A is reinforced by seeing marked increases in NPC1 mRNA and protein levels when U18666A is added to normal steroidogenic cells [81]. Furthermore, Sugimoto et al. [83] demonstrated that U18666A's effect on lipid accumulation by NPC-deficient CHO cells is at least partially dependent on the presence of intact NPC protein. When transfected with mutated-nonfunctional NPC, cultured cells accumulate cholesterol and gangliosides, and treatment with U18666A causes no further increase. But “knock in” of the NPC protein restores U18666A's capacity to block lipid trafficking and raises cellular lipid content [83].

In summary, the presence of resident NPC protein in vesicles and organelles is necessary for the intracellular movement of lipids from lysosomes and late endosomes to various membrane compartments. The lysosomal lipids that accumulate in Niemann–Pick type C disease reflect defects in the intracellular trafficking of lipids (from both endocytotic and extracellular sources) due to a nonfunctional NPC protein. The capacity of U18666A to mimic Niemann–Pick disease appears at least partially due to blocking the NPC protein. The block may involve direct interaction of U18666A with the protein or changes in NPC protein function secondary to altering the membrane domain in which the protein resides. As described earlier, U18666A can alter the structure of model membranes [22], and it binds to intact cells with high affinity [61]. Since U18666A readily enters cells and associates with intracellular membrane [85], it may also alter intracellular membranes and the function of their resident proteins.

Role of U18666A in Understanding the Pathophysiology of Other Diseases

Atherosclerosis (Macrophage, High Density Lipoproteins)

Cholesterol ester-laden macrophages are foam cells, which accumulate in early atherosclerotic disease. Free cholesterol generated from esterified cholesterol through the action of cholesterol ester hydrolase is toxic to the foam cells and can lead to their death and necrosis [86–88]. U18666A has been used to explore the consequences of free cholesterol accumulation to the macrophage [86–88]. U18666A protects macrophages from free cholesterol, although U18666A-treated cells accumulate free cholesterol [88]. Location provides the answer to this paradox. The protection comes from trapping free cholesterol in the lysosome, which decreases the cholesterol concentration in the remainder of the cell. U18666A has also been used as a tool to reveal that the ABCA1 transporter protein can function intracellularly to withdraw endocytotic lipids from late endosomes and lysosomes and combine them with apoprotein A1 to form nascent high density lipoproteins that are then secreted from the cell [89].

Alzheimer's Disease

Interest in Alzheimer's disease and U18666A came from observations that endocytotic trafficking might play roles in the processing of β -amyloid precursor protein (APP) and secretion of the pathogenic amyloid β proteins. A 99 kDa fragment of the amyloid precursor protein carboxy terminal

was cleaved by secretases to generate peptides of 40 and 42 kDa, $A\beta_{40}$ and $A\beta_{42}$, respectively [90]. Blockage of lipid trafficking by treatment of cultured cells with U18666A induced increases of both free cholesterol and $A\beta_{42}$ amyloid in late endosomes [91]. The $A\beta_{42}$ amyloid was released from the endosome upon removal of the drug, but $A\beta$ amyloids were released as aggregates [91]. Furthermore, treatment of cultured neuronal cells with U18666A influenced the processing of amyloid proteins, reducing β -cleavage of full-length APP but increasing γ -secretase activity on the APP C-terminal resulting in increased production of both $A\beta$ fragments [92]. These changes were attributed to altered intracellular cholesterol trafficking. Kametaka et al. [93] also used U18666A to reveal that the APP-cleaving enzyme moves through a late endosomal compartment of HeLa cells. In the presence of U18666A, the protein appeared in multivesicular bodies (MVB) derived from late endosomes. These studies collectively demonstrated that many of the hallmark proteins associated with Alzheimer's disease require transit through late endosomal–lysosomal pathways for activation and function.

Can a common mechanism explain the cellular models of Niemann–Pick and Alzheimer's diseases induced by U18666A? U18666A has three known, broad actions that may account for its varied effect on cells: It inhibits cholesterol biosynthesis at multiple sites [10, 12, 13, 16–19], it interferes with intracellular trafficking of cholesterol [56–69], and it can intercalate into membranes and alter their order [22]. Addition of as little as 0.1 μ M U18666A to cultured cells can markedly inhibit sterol synthesis [21] and esterification of LDL-derived cholesterol [60, 61]. However, the inhibition of esterification appears independent of reducing cholesterol synthesis since U18666A continues to block esterification of cholesterol in cells treated with mevinolin, an inhibitor of HMGCoA reductase [56]. Blockage of cholesterol movement through the endosome may arise from direct interaction of U18666A with the NPC protein [70, 81, 83]. Although direct interference with the NPC protein may contribute to reduced transit of various molecules through the endosomal compartment, such as $A\beta_{42}$ -amyloid, a more generalized action of U18666A may also account for its diverse effects. When added to membrane preparations, it increases the anisotropic values of probes and has a broad condensing effect on membrane order as determined by Fourier transform analysis of X-ray scatter data; [22]. Thus, increased order of membrane domains may account for reduced transit of many molecules through endosomal compartments that are dependent on NPC or other regulatory proteins as a result of restricting the mobility of these proteins.

Prion Diseases

Once again, U18666A's capacity to alter cellular cholesterol trafficking led to its use to examine mechanisms and treatment of disease. The nonpathogenic (normal) prion protein PrP^c is anchored to neural membranes by attachment to glycosylphosphatidylinositol located in detergent-resistant membrane (DRM) domains. The pathogenic prion protein PrP^{Sc}, responsible for Creutzfeldt-Jakob disease in humans and bovine spongiform encephalopathy in cattle, replicates by inducing misfolding of the normal host protein. Because U18666A can cause redistribution of membrane cholesterol through interfering with cholesterol trafficking and biosynthesis, it was tested for antiprion activity [94]. U18666A added to infected neuroblastoma cells caused a major redistribution of cholesterol from the PM to intracellular sites and displayed very strong antiprion activity, that is, an EC₅₀ of 100 nM. U18666A caused total displacement of the infectious prion from DRM domains. The capacity of U18666A to halt progression of pathogenic prions in cultured neural cells was confirmed by Hagiwara et al. [95], EC₅₀ of 10 nM. But treatment of prion-infected mice with U18666A did not affect survival. The lack of effect was not surprising since there were no changes in the composition of brain sterols following treatment of 6-week-old mice. The absence of an effect was probably due to the age of mice at onset of treatment. We observed that almost all rats developed cataracts if treatment with U18666A started at one day of age, but few developed cataracts if treatment was delayed until 14 days of age [96].

Wilson Disease

Wilson disease is a genetic disorder characterized by the accumulation of copper in body tissues due to deficiency of ATP7B, which is a copper-transporting ATPase responsible for regulating copper secretion into plasma (with ceruloplasmin) and copper excretion into bile. ATP7B colocalized with NPC1 in late endosomes of Huh7 cells [97]. Addition of U18666A caused formation of late endosome-lysosome hybrid organelles.

HIV and Other Uses

GAG protein of HIV-1 is localized primarily to the host's PM in T-cells. In macrophages, however, GAG accumulates in MVB when treated with U18666A, indicating that trafficking of GAG through MVB is required for HIV particle production [98]. U18666A has also been used to probe the role of cycling through endosomal-lysosomal compartments in the activation and functions of annexins [99], small GTPase Rab7 [100], and the mannose 6-phosphate receptor [101, 102].

U18666A-Induced Apoptosis Could Contribute to Its Multiple Actions

Beginning in 2004, reports clearly established that U18666A can induce apoptosis in lens epithelial cells [22], melanoma cells [103], and cultured murine cortical neurons [104–109]. The apoptosis in all three models can be triggered by oxidative stress. Lipid peroxidation increases in lenses of U18666A-treated rats [110]. Apoptosis in the melanoma cells was attributed to U18666A inhibition of the product of the 7-dehydrocholesterol reductase 24 gene, also known as seladin-1 [103]. The gene product is desmosterol reductase. Seladin-1 stands for SElective Alzheimer Disease indicator 1 because it can protect neurons from the toxicity caused by β -amyloid peptide and is anti-apoptotic. The apoptosis induced by U18666A is dependent on oxidative stress and may occur through an action on the antioxidant pathway [103].

Cheung and coworkers investigated U18666A-induced apoptosis in cultured murine cortical neurons as it relates to Niemann–Pick type C disease and Alzheimer's disease [104–109]. Activation of caspases accompanied U18666A-induced apoptosis [104, 105]. Disruption of mitochondrial function and caspase activation was attributed to U18666A impairment of intracellular cholesterol transport [106]. Abundant cholesterol was seen to accumulate in the cultured neurons [104]. The group conducted an interesting experiment to examine the contribution of de novo cholesterol synthesis to the U18666A-induced cytotoxicity. Pravastatin, an HMGCoA reductase inhibitor, essentially blocked cell death from U18666A when added to the culture [104]. Since the concentration of U18666A was more than adequate to block cholesterol synthesis completely (0.5 μ g/mL) [10, 12], the protective effect of pravastatin was likely independent of decreasing cholesterol production. Since the flow of carbon through the sterol pathway would be blocked at squalene, the protective effect of pravastatin suggested that something in the sterol pathway between mevalonic acid and squalene was cytotoxic and could contribute to the apoptosis induced by U18666A.

As seen with U18666A in cultured melanoma cells [103], oxidative stress accompanied induction of apoptosis in the cortical neuronal cells. Here, U18666A increased reactive oxygen species and increased neuronal levels of A β 40 and A β 42 amyloid proteins [107]. The connection between damaging oxidation, accumulation of A β amyloid, and U18666A induction of apoptosis in the cultured neuronal was recently confirmed by Koh et al. [107]. The link between U18666A and apoptotic cell death was shown to be complex, involving decreased available energy, disruption of mitochondria, and increased production of reactive oxygen species with accompanying oxidation of cellular molecules such as lipids, proteins, and nucleic

acids. All of the following events could arise from the multiple actions of U18666A: inhibition of sterol synthesis, disruption of cellular cholesterol trafficking, and alteration of membrane order or fluidity. The combined actions of inhibited cholesterol synthesis and inhibited access to LDL cholesterol may induce autophagy, which could lead to apoptosis secondary to degradation of cytoplasmic organelles [111].

Summary/Conclusions

How can one drug have so many different effects and induce such widely different diseases in animals? U18666A inhibits three membrane-bound enzymes in sterol synthesis that catalyze very different reactions (a ring-forming cyclase, an isomerase, and a reductase); it blocks the egress of cholesterol and other molecules from lysosomes; it blocks the movement of cholesterol from the PM to the ER; it induces apoptosis *in vivo* and in cultured cells; when given to young rats it can cause permanent petite mal epilepsy and cataracts; and when added to cultured cells it can cause massive accumulation of unesterified cholesterol and thereby mimic the fatal human Niemann–Pick type C disease. Its structure as an amphipathic-cationic amine may be the basis of the diversity. Similar compounds can duplicate U18666A effects but generally at much higher concentrations. The finding that the natural and enantiomeric forms of U18666A equally inhibit sterol synthesis and induce apoptosis also argues for actions based on physical properties of the molecule. When incorporated into membranes, U18666A has an ordering or condensing effect. Whereas these observations do not exclude U18666A acting through binding to specific proteins, as for example the NPC1 protein, they do support the possibility that U1866A (and perhaps similar compounds) produces its actions by altering the physical properties of membranes and the function of the membrane's resident proteins.

Inhibition of Fatty Acid Synthase by Orlistat Accelerates Gastric Tumor Cell Apoptosis in Culture and Increases Survival Rates in Gastric Tumor Bearing Mice In Vivo

Abstract Orlistat, an anti-obesity drug, is a potent inhibitor of fatty acid synthase (FAS) and tumor cell viability. It can also induce apoptotic cancer cell death. We examined the effects of Orlistat on cultured NUGC-3 gastric cancer cells. We identified that inhibition of FAS via Orlistat exposure results in rapid cellular damage preceded by a direct but short-lived autophagic response. The Orlistat induced damage can be reversed through the addition of lipid containing media in a process that normally leads to cell death. By limiting exogenous lipid availability and inhibiting FAS using Orlistat, we demonstrated both a greater sensitivity and amplified cancer cell death by activation of apoptosis. We have identified “windows of opportunity” at which time apoptosis can be aborted and cells can be reversed from the death pathway. However, when challenged beyond the window of recovery, cell death becomes all but certain as the ability to be rescued decreases considerably. In vivo examination of Orlistat’s ability to inhibit gastrointestinal cancer was examined using heterozygous male C57BL/6J APC-Min mice, which spontaneously develop a fatal gastrointestinal cancer. Mice were fed either a high fat (11%) or low fat (1.2%) diet containing no Orlistat or 0.5 mg Orlistat/g of chow. Orlistat treated mice fed the high fat, but not low fat diet, survived 7–10% longer than the untreated controls.

Introduction

Fatty acid synthase (FAS) functions to form palmitic acid from acetyl and malonyl coenzymeA. It is highly expressed in many tumors that are dependent on de novo synthesis to supply the fatty acid needed for growth and proliferation [1–5]. The capacity of FAS inhibitors to kill cancer cells suggests a new approach to treatment of human cancers [6]. Orlistat is one of these FAS inhibitors.

Orlistat, an over-the-counter anti-obesity drug, decreases absorption of dietary fat by inhibiting gastric and pancreatic lipases through covalent modification of the enzymes [7]. It is also a potent inhibitor of FAS [8]. Using an activity-based proteomics screen for serine hydrolases, Kridel et al. [8] discovered that Orlistat irreversibly inhibits the thioesterase activity of FAS. The capacity of Orlistat to inhibit the proliferation of prostatic cancer cells cultured in serum free media appeared to be due to restricting the availability of fatty acids for growth, since the addition of palmitic acid to the media reversed the inhibition [8]. A decrease in DNA synthesis, arrest of cell progression through the G1/S boundary, and apoptotic cell death are all consequences of inhibiting FAS in cultured cancer cells with Orlistat [6, 9].

The effects of Orlistat on proliferation and viability of tumor cells have typically been examined after 24–72 h [8, 10] and even after 4–5 days [10] of continuous exposure to the drug. This approach assumes that the Orlistat has a linear-accumulative effect on tumor cells. Possible immediate or very rapid effects of Orlistat on tumor cells have not been reported. We searched for such effects and

e-mail: rcenedella@atsu.edu

observed that as little as one-half hour exposure of NUGC-3 cells to 100–500 μM Orlistat induced transient autophagy. In addition, we observed that 4 h exposure followed by removal of the drug reduced viability when examined at hour 48. The presence of Orlistat for the first 8 h of culture resulted in near total loss of viability when measured 40 h later. Acute-irreversible damage appeared to occur at the interface between 4 and 8 contact hours with Orlistat. We probed the mechanism of reduced viability by examining NUGC-3 cells for the emergence of autophagy and apoptosis following short-term exposure to the drug. Rapid onset of apoptosis was attributed to nutritional stress, in which altering the availability of nutrients places a stress on the cell to acquire alternative sources of nutrients to meet the cells biogenesis needs. In this case, nutritional stress was caused by the deprivation of fatty acids since the apoptosis could be arrested by addition of whole serum to the culture media.

Although Kridel et al. [8] demonstrated that intraperitoneally injected Orlistat suppressed the growth of implanted tumor cells, use of Orlistat to treat systemic tumors is limited by the fact that it is essentially unabsorbed following oral dosage [11]. However, since orally administered Orlistat would directly contact the gastrointestinal mucosa, the drug might be of value in treating gastrointestinal tumors exposed to the intestinal lumen. We tested this possibility by examining the effect of orally given Orlistat on the survival of C57BL/6J APC-Min mice (Min). The Min mice provide an excellent *in vivo* model for human gastrointestinal cancer, since the adenomas that develop in these animals result from inactivation of the same tumor suppressor gene associated with most human colon cancers [12]. The tumors develop due to a mutation in the murine AP gene, a homolog of the human APC gene (JAX MICE literature, The Jackson Laboratory). However, Min mice develop a heavy tumor load in the small rather than large intestines which results in death at several months of age [13–15].

Materials and Methods

Cell Culture and Reagents

All reagents were from Sigma Chemical Co. (St. Louis, MO) unless otherwise noted. NUGC-3 gastric cancer cells (human stomach) were obtained from the Health Science Research Resource Bank (Osaka, Japan). Bovine lens epithelial cells (local source) were used as a normal cell control. Cells were seeded at 30,000–40,000 per well in 96 well dishes and grown at 37°C and 5% carbon dioxide in RPMI-1640 media containing 10% fetal calf serum (FCS) plus 0.25% antibiotic/antimycotic containing mix. This is

called whole media (WM). Experiments were started 1–2 days later with cell layers 70–90% confluent. Orlistat from 5 to 120 mg Zenical™ capsules (obtained from a local pharmacy) was extracted by homogenization in 3–5 ml aliquots of 1:1 (v/v) chloroform:methanol and transferred to a weighed test tube. After evaporation of the solvent under nitrogen and further drying overnight under vacuum, the recovered Orlistat was dissolved in ethanol at 50 mg/ml. Aliquots were added to WM or serum deficient media (DM) containing 0.1% FCS to yield 500 μM . Serial dilutions provided media containing 200, 100, 50, and 25 μM Orlistat. The capacity of Orlistat to decrease cell viability was also examined in non-cancerous (normal) bovine lens epithelial cells. Culture conditions were as we described before [16].

Cell Viability

Cell layers in groups of 5 or 6 wells were incubated for 4–48 h at 37°C with 200 μl of WM or DM containing 0–500 μM Orlistat. Cell viability was assessed by the MTT (thiazolyl blue tetrazolium bromide) assay essentially as described by Carmichael et al. [17]. Test media was replaced with 200 μl of WM, 25 μl of MTT solution (5 mg/ml water) was added, and the samples incubated for 4 h at 37°C. The MTT solution was replaced with 100 μl of DMSO and the optical density at 570 nm measured 1 h later. Absorbance for each group was expressed as the mean \pm SEM. Statistical significance of differences ($P \leq 0.05$) was assessed by one-way ANOVA.

Measurement of Fatty Acid and Synthesis

Near confluent layers of NUGC-3 cells were washed twice in serum free media, after which 200 μl of plain RPMI-1640 media was added followed by 1 μl of ^{14}C -acetate (55 mCi/mmol, ARC Inc, St. Louis, MO). Serum free media was used to avoid dilution of the labeled acetate with competing sources of unlabeled acetate. Following 4-hour incubation in the absence or presence of varying concentrations of Orlistat, cell layers were washed twice with PBS. The cell layer in each well was dissolved in 200 μl of 1 N NaOH in 50% ethanol containing 100 μg of triolein and 100 μg of cholesterol added as carrier. Each well was washed with 4 additional 200 μl -aliquots of the 1 N NaOH and pooled into screw capped test tubes with the first 200 μl . Samples were saponified for 2 h at 100°C, diluted with 1 ml of water, acidified and the non-saponifiable plus saponifiable lipids extracted with 2–4 ml aliquots of hexane. The hexane extracts were washed with an equal volume of water to remove any water-soluble radiolabel. The hexane extracts were evaporated and the lipids separated by thin layer chromatography in silica gel

using a solvent of hexane:diethyl ether:glacial acetic acid (73:25:2; v/v/v). The sterol (cholesterol) band and the fatty acid band were recognized by exposure to iodine vapor and marked. After loss of the iodine by sublimation, the cholesterol and fatty acid bands were recovered and the radiolabel measured by scintillation counting.

We accounted for variation in incorporation from well to well in any given group by expressing the level of fatty acid synthesis as a ratio of incorporation of ^{14}C into fatty acid to cholesterol. Cholesterol controls were run to determine Orlistat's effect on total sterol synthesis. Significant differences were not seen in the disintegrations per minute (dpm) of ^{14}C -acetate incorporated into cholesterol between control and Orlistat treated cell layers. Decreases in the fatty acid:cholesterol ratio reflects inhibition of fatty acid synthesis, since Orlistat has no known effects on cholesterol biosynthesis.

Western Blotting: Changes in the Relative Mass of Fatty Acid Synthase (FAS)

NUGC-3 cells were grown in RPMI-1640 on 35 mm plastic dishes to assure adequate protein. Cell layers exposed or unexposed to Orlistat under varying condition were washed twice with PBS and dissolved in 0.50 ml of lysis buffer [18]. Samples were assayed for protein (aliquots containing 50 μg protein were separated on 8% PAGE gels 94% stacking gel), transferred to membranes which were then probed with 0.8 $\mu\text{g}/\text{ml}$ rabbit-polyclonal, antihuman FAS-antiserum (Santa Cruz Biotechnology) and HRP-conjugated goat-antirabbit IgG secondary antibody (1/60,000 dilution). Immunoreactive protein was detected by enhanced chemiluminescences and relative concentrations estimated by densitometric scanning of the exposed X-ray film as done before [18].

Detection of Autophagy and Apoptosis

Autophagic vacuoles were labeled with monodansylcadaverine (MDC) using a modified protocol as described by Biederbick et al. [19]. Briefly, cells were grown on coverslips, incubated at 37°C in WM, and DM \pm 500 μM Orlistat for varying time intervals. Media was removed; cells were washed once with PBS, and replaced with PBS supplemented with 0.1 mM MDC. Cells were allowed to incubate for 10 min at 37°C. Following incubation, cells were washed three times with PBS, fixed using 4% paraformaldehyde, and mounted using Fluoromount. Cells were examined using a NIKON Eclipse 80i upright fluorescent microscope equipped with a V2-A filter system (excitation 340 nm, barrier 514 nm). Images were captured using a NIKON DS-Qi1 digital camera and were processed using Image J.

Autophagic vacuole formation was measured using methods described by Munafo and Colombo [20]. Briefly, cells were grown in 60 mm dishes and treated using varying concentrations of WM and DM \pm Orlistat. To identify autophagy activity and duration, MDC incorporation was measured after 0.5, 1, 2, 4, 6, 8, and 10-hour Orlistat exposure. After varying times the media was removed and PBS was added with the addition of 0.1 mM of MDC and incubated at 37°C for 10 min. Following incubation the cells were washed three times with PBS and collected in 10 mM Tris-HCl, pH 8 with 0.1% Triton X-100. Intracellular MDC incorporation was measured using a BioTek FLx 800 Microplate Fluorescent Reader equipped with an excitation filter of 365/20 nm and an emissions filter of 528/20 nm. The number of cells per well were normalized by the addition of ethidium bromide to a final concentration of 0.1 μM to each well followed by the measuring of DNA fluorescence (excitation filter 528/20 nm and emission filter of 590/20 nm). The MDC measured was expressed as the percent of autophagic activity relative to whole media control.

The mechanism of cell death (apoptosis) was determined through the use of fluorochrome inhibitor of caspases (FLICA) (Immunochemistry Technologies, LCC). Activated caspase is an enzyme found active only in cells undergoing apoptosis. FLICA irreversibly binds to caspases (caspase-1, -3, -4, -5, -6, -7, -8, -9) allowing apoptosis to be measured [21, 22]. Caspase activity was visually examined using the suggested manufactures protocol for labeling caspases with FLICA. Briefly, cells were grown on coverslips and treated with various concentrations of Orlistat substituted in DM. Cells were then treated with FLICA solution in a 1:30 ratio (10 μl FLICA:290 μl media) and incubated for 1 h. Next, media was removed and replaced with fresh media (300 μl) containing 1.5 μl of 200 $\mu\text{g}/\text{ml}$ stock Hoechst stain solution (Immunochemistry). After 5 min cells were rinsed with wash buffer (Immunochemistry) and examined immediately using a NIKON Eclipse 80i upright fluorescent microscope equipped with a V2-A filter system (excitation 340 nm, barrier 514 nm). Images were captured using a NIKON DS-Qi1 digital camera and were processed using Image J.

Animals and Treatments

Heterozygous male C57BL/6J APC-Min (multiple intestinal neoplasia) mice were purchased from The Jackson Laboratory (Bar Harbor, ME). Heterozygous mice were used for these studies because homozygous mice die in utero. Mice in groups of 4–8 were fed either a high fat (11% fat) or low fat (1.2%) diet containing no Orlistat or Orlistat at 0.5 mg/g chow. Mice were started on the diets at either 50–60 days (Experiments 1 and 3) or 33–34 days

(Experiment 2) of age. Age at death varied from 104–229 days of age. Mice were housed in the Animal Care Facility at KCOM/ATSU and maintained according to the “Guide of the Care and Use of Laboratory Animals” from the National Research Council.

Recovery of Orlistat and Preparation of Test Diets

The contents of 4–6 Zenical capsules, each containing 120 mg of Orlistat, were pooled and extracted three times with 5 ml of 1:1 chloroform–methanol (v/v) using a Polytron-type homogenizer. The solvent from the pooled extracts recovered after centrifugation was evaporated under nitrogen. The residue was dried overnight to constant weight under high vacuum, and dissolved in ethanol to give a stock solution of 50 mg/ml. Mice in two studies were fed ground Purina Mouse Diet 5015 that contained 11% fat plus 0 (control) or 0.5 mg Orlistat/g chow. In a third study, mice were fed a customized powdered diet (AIN-93M, Purina Mills TESTDIET, Richmond, IN) containing 0.2% fat, from saturated and monounsaturated fatty acids, to which we added 1% linoleic acid to guard against essential fatty acid deficiency. Orlistat was added at 0 (control) or 0.5 mg/g (test) to this very low fat diet.

HPLC Analysis of Orlistat

The HPLC method of Souri et al. [11] was used to confirm the concentration of Orlistat in chow and to estimate the distribution of Orlistat in the mouse gut following oral dosage. Samples of mouse chow (11% fat) with Orlistat and sections of mouse gut removed at 4 h after oral dosage were extracted with 1:1 chloroform–methanol, and the recovered lipids were fractionated by thin layer chromatography on Silica Gel G plates using a solvent of hexane: diethyl ether:glacial acetic acid (73:25:2). Orlistat, visualized by exposure to iodine vapor, migrated with an R_f of between 0.1 and 0.2. After sublimation of the iodine, the TLC zone containing Orlistat was recovered and extracted twice with 3 ml aliquots of methanol. The residue remaining after evaporation of the methanol was dissolved in several hundred microliters of acetonitrile:0.1% orthophosphoric acid in water (90:10), centrifuged and aliquots injected onto a Waters C18 reverse phase column (10 μ m, 3.9 \times 300 mm, 125 A μ Bondapak) eluted at 1 ml/min with the 90:10 acetonitrile-acidic water and absorbance monitored at 205 nm. Ten micrograms of Orlistat standard (injected in 100 μ l) eluted at about 6 min.

Survival Statistical Analyses

To determine the effects of Orlistat on mouse survival, the end point analyzed was the difference in day of death

between untreated (control) and Orlistat treated animals (test). The Kaplan–Meier procedure [18] was used to estimate the probability of surviving a given time. Since all untreated animals die prematurely (4–7 months) compared to wild type mice (1.5–2 years), even slight prolongation of life due to treatment can be recognized. Using a statistical computer program (GraphPad Prism version 5.0 for Windows, GraphPad Software, San Diego, CA, USA) survival curves were generated by the Kaplan–Meier procedure [23] and analyzed by the Log-Rank (Mantel–Cox) and the Gehan–Wilcoxon Tests. The Log-Rank test is more powerful and gives equal weight to all time points.

Results

Potential use of Orlistat as an anticancer drug would likely be restricted to treatment of gastrointestinal tumors since it is essentially unabsorbed following oral dosage [2]. Therefore, we chose to examine the effects of Orlistat on a human derived gastric cancer cell line, NUGC-3 [24]. Viability of cells cultured for 48 h in serum deficient media, DM (0.10% serum), was decreased by more than 70% when continuously exposed to 25 μ M Orlistat (Fig. 1). Near complete inhibition was seen at 100 μ M. The dose response curve was markedly shifted to the right by including 10% serum in the media, called whole media (WM).

Although cell viability assays are typically performed following 48 h or more of continuous exposure to an inhibitor, we considered the possibility that the decreased viability observed at 48 h was due in part or total to cell injury induced soon after adding Orlistat rather than to a

Fig. 1 Effect of Orlistat on the viability of NUGC-3 gastric tumor cells. Cells were cultured for 48 h in RPMI-1640 media containing 10% fetal calf serum (whole media, WM) or 0.10% serum (deficient media, DM) and varying concentrations of Orlistat. Cell viability was assessed by the MTT assay. Each point is the mean \pm SEM of 6 cell wells

sustained accumulation of injury. Cells were incubated for 4, 8 or 12 h in DM containing 0 (control), 100 or 500 μM Orlistat, and then incubated to hour 48 in drug free media. Cell viability was significantly reduced from only 4-hour exposure to 500 μM Orlistat and an 8-hour exposure to 100 μM Orlistat (Fig. 2a). Four-hour exposure to 500 μM Orlistat decreased viability by about 65%, while 8-hour exposure to 100 μM decreased viability by about 40%. These brief exposure periods accounted for about two-thirds and one-half of the total decrease seen for cells cultured the entire 48 h in DM with 500 and 100 μM Orlistat, respectively. Addition of WM rather than DM to the NUGC-3 cell layers after 4 h exposure to 500 μM Orlistat and after 8 h exposure to 100 μM Orlistat totally rescued the cells; that is, there was no decrease in viability compared to cells cultured in the absence of Orlistat measured at 48 h (Fig. 2b). However, there were limits to the capacity of WM to rescue Orlistat exposed cell. For example, 12 h of exposure to 500 μM Orlistat in DM committed the cells to detachment and disintegration.

Orlistat toxicity likely begins with inhibition of fatty acid synthesis. Incubation of NUGC-3 cells with 200 μM Orlistat for 4 h decreased incorporation of ^{14}C -acetate into total fatty acids by about 75% (Fig. 3a). We expressed effects on fatty acid synthesis as a decrease in the ratio of incorporation of ^{14}C -acetate into fatty acid to total sterol. Since Orlistat had no effect on sterol synthesis, this

Fig. 2 Early effects of Orlistat on cell viability. **a** NUGC-3 cell layers were incubated in serum deficient media containing 0, 100 or 500 μM Orlistat. After 4, 8 or 12 h of incubation the media was replaced with Orlistat free DM and the incubation continued to hour 48 at which time cell viability was measured. Controls were cultured for 48 h in Orlistat free DM. The “48” hour groups were cells incubated with either 100 or 500 μM Orlistat-DM. **b** Controls are cells cultured for 48 h in Orlistat free WM. Cells were incubated for 4 h in DM containing 500 μM Orlistat or 8 h with 100 μM Orlistat and then switched to Orlistat free WM and the culture continued to hour 48 at which time viability was measured

expression should account for potential differences in cell numbers from well to well. Not only does Orlistat inhibit fatty acid synthesis, but also once exposed to this drug the inhibition seems permanent. Fatty acid synthesis continued to be inhibited after Orlistat was removed from the media. NUGC-3 cells were incubated for 4 h in media containing 200 μM Orlistat, the cell layers were washed and then incubated an additional 4 h in Orlistat free media containing ^{14}C -acetate. Synthesis was still inhibited by 80% (Fig. 3b). This finding supports the idea that Orlistat binds irreversibly to the thioesterase domain of FAS [8]. Up regulation of FAS expression might be a means to circumvent the near total inhibition of fatty acid synthesis; however, FAS protein levels (assessed by Western blotting) were not increased following exposure of Orlistat (data not shown). Thus, once exposed to Orlistat fatty acid synthesis appears permanently inhibited. This would make the cells dependent upon uptake of lipids from the media as the only source of fatty acids to sustain membrane turnover and cell proliferation.

As shown (Fig. 2), there was a narrow window of opportunity to rescue NUGC-3 cell from permanent injury and death when cultured in DM containing Orlistat. The response of the cells to this nutritional stress, no source of fatty acids, was extremely rapid induction of autophagy (Fig. 4). The autophagic response was Orlistat dose dependent, peaked at one-half hour of incubation and returned to baseline by 2 h. Thus, it seems unlikely that autophagy accounts for the irreversible injury and consequent cell

Fig. 3 Irreversible inhibition of fatty acid synthesis by Orlistat in NUGC-3 tumor cells. **a** Subconfluent cell layers in 96 well dishes were incubated for 4 h in serum free RPMI-1640 media containing 1 μCi of ^{14}C -acetate and 0 (Control C) or 200 μM Orlistat (Treated T). Total fatty acids and sterols recovered after saponification were separated by TLC, fractions isolated, the ^{14}C -content measured and results expressed as the ratio of incorporation into fatty acids to sterols. Each value is the mean \pm SEM of 5 cell layers. **b** Cell layers were incubated for 4 h with 0 or 200 μM Orlistat in the absence of ^{14}C -acetate; the media was then replaced with Orlistat free media containing the ^{14}C -acetate and incubated for a second 4-hour interval. Values are the mean \pm SEM of five cell layers

Fig. 4 Rapid induction and disappearance of the autophagic response to Orlistat. Fluorescence microscopy showing autophagic vesicles in NUGC-3 cells unexposed to Orlistat (a), exposed to 500 μ M Orlistat for 30 min (b) or 6 h (c). The graph shows the time course of autophagic response to varying concentrations of Orlistat. Values are the mean \pm SEM of 3 cell layers. Differences in cell numbers between wells normalized using ethidium bromide [21]

death seen with longer-term exposure. Rather, cell death could be due to induction of apoptosis. The onset and progression of apoptosis paralleled the loss of cell viability. Apoptosis was seen after 8 h exposure to 100 μ M Orlistat in DM (Fig. 5e), but not at 4 h (Fig. 5c). Loss of cell viability occurred after 8 but not 4 h exposure to 100 μ M (Fig. 2 a). At the higher drug concentration (500 μ M), apoptosis was evident after 4 h of incubation (Fig. 5d) and markedly increased by the 8 h of drug exposure (Fig. 5f). The progression of apoptosis over the 4–8 h interval was largely halted by exchanging the Orlistat-DM media for drug-free WM at hour four (Fig. 5g). This parallels the time-interval boundaries for rescue of NUGC-3 cell viability from exposure to 500 μ M Orlistat (Fig. 2).

Applying the information garnered from in vitro experiments, the potential of Orlistat to inhibit in vivo gastrointestinal cancer was evaluated by examining the effect of orally administered Orlistat on the survival of APC-Min mice that spontaneously develop a fatal gastrointestinal cancer. Mice were fed a high fat (11%) or low fat (1.2%) diet containing 0 or 500 mg Orlistat/kg chow. Each mouse weighed approximately 25 g and consumed an average of 3 g of chow per day, resulting in delivery of about 60 mg of Orlistat/kg body weight. The fecal fat content of Orlistat treated mice increased 4-to-6-fold

compared to untreated control mice when the animals were fed chow containing 11% fat (Table 1). In animals fed chow containing 1.2% fat, fecal fat increased about 2.5-fold in Orlistat treated mice versus untreated controls (Table 1). The increased fecal fat obviously reflects the inhibition of gastric lipases by the drug.

Orally administered Orlistat moves quickly through the GI tract. Four hours after giving a single oral 50 mg/kg dose of Orlistat (in aqueous emulsion) by gavage, the drug was detected almost exclusively in the large intestines (Fig. 6). Similar results were seen in a replicate experiment. This observation is consistent with GI transit times in the mouse being 4–6 h [25].

Considering the browsing feeding pattern of mice, the gut should receive multiple exposures to Orlistat during the day. The 500 mg of Orlistat/kg of chow corresponds to about 1 mM (MW = 497.5), a concentration in great excess of that needed to inhibit the viability of cultured, human-derived, NUGC-3 gastrointestinal cancer cells (Fig. 1). Fifty μ M Orlistat in serum deficient media (0.1% serum) and 200 μ M Orlistat in whole media (10% serum) both inhibited cell viability by about 80% (Fig. 1). Similar results were seen in replicate experiments.

Three experiments were conducted to evaluate the effect of orally administered Orlistat on survival times of the

Fig. 5 Antagonism of Orlistat induced apoptosis. Images show overlap fluorescence of apoptotic caspase stained (*green*) and nucleic acid stained (*blue*) cells. All cell layers, except **b** and **g**, were incubated in DM. **a** Control. **b** Staurosporine, 500 nM in WM for 3 h. **c** Orlistat, 100 μ M for 4 h. **d** Orlistat, 500 μ M for 4 h. **e** Orlistat, 100 μ M for 8 h. **f** Orlistat, 500 μ M for 8 h. **g** Cell layers were incubated for 4 h with 500 μ M Orlistat, the media was replaced with Orlistat free WM and the incubation continued an additional 4 h. These results are representative of triplicate experiments (color figure online)

APC-min mice (Fig. 7). Median survival times were increased 7–10% (25.5 and 9 days, experiments 1 and 2, respectively) in Orlistat fed mice (Fig. 7 top and middle panels). The difference was statistically significant by the log-rank test ($P = 0.047$) and the Wilcoxon test ($P = 0.0318$) in experiment 1 and was not significant in experiment 2 (Table 2). Experiment 3, using a low fat (1.2%) diet produced no significant results (Table 2), however, control mice fed the low fat diet produced a greater median survival time than their treated counterparts (Table 1).

Table 1 Effect of Orlistat on fecal fat content and median survival times

Experiment	Group	Fecal fat content ^a (mg fat/g dry feces)	Starting age (days)	Median survival (days)
1 High fat	Control	45.3	50–60	147
	Treated	197.8		172.5
2 High fat	Control	63.7	33–40	122
	Treated	388.8		131
3 Low fat	Control	22.4	58	194.5
	Treated	52		136

^a Controls were fed diets with either 11% high fat (Experiment 1 and 2) or 1.2% low fat (Experiment 3). Treated mice received the same diet but containing 0.5 mg Orlistat/g chow. Feces was collected from the cages of the various groups

Discussion

As stated above, cancer cells can place a great demand on FAS to supply the fatty acids required for membrane turnover and cell proliferation. NUGC-3 cells cultured in serum deficient media (0.1% serum) grew as well as when cultured in media containing 10% serum, indicating that lipogenesis can sustain growth. In contrast to cancer cells, viability of a normal cell line (bovine lens epithelial) decreased by about 50% when cultured in serum deficient media, indicating a major reliance on extracellular lipids (Fig. 8). Also, the normal bovine lens epithelial cells were virtually resistant to the growth inhibition mediated by high concentrations of Orlistat in WM, indicating little reliance on fatty acid synthesis (Fig. 8). The general toxicity of Orlistat is also addressed by this data. Since the viability of lens epithelial cells cultured in WM containing no Orlistat and high levels of Orlistat (200 and 500 μ M) were similar, Orlistat has no apparent toxicity to these cultured cells independent of its effect on FAS. This would appear to also include toxicity due to inhibition of triacylglycerol lipases, the basis of its use as an anti-obesity drug [7].

Perhaps the major findings of this work are the speed with which Orlistat can insult the cultured cancer cells and the capacity of whole media to rescue the cells from this insult, at least up to a point. The rapid untoward effects are attributed to near total restriction of fatty acids due to inhibition of synthesis coupled with the absence of media lipids. Because membrane phospholipids are highly dynamic and can turnover with half-lives in the minutes [26], a block in the availability of fatty acids could rapidly compromise membrane integrity. In view of this rapid turnover and because the restriction of fatty acids constitutes nutritional stress, it is not surprising that autophagy was activated within minutes of adding Orlistat. However, it was surprising that the autophagic response was over

Fig. 6 Distribution of Orlistat in the gastrointestinal tract estimated by HPLC analysis. Relative concentration of Orlistat in the GI tract at 4 h after a mouse was given (by gavage) 50 mg/kg of Orlistat in aqueous emulsion. Nearly all of the drug was found in the large

intestine and colon. Similar results were seen in a replicate experiment. The Orlistat standard (10 µg injected in 100 µl) eluted at about 6 min. Zones: 1 Stomach, 2 Upper small intestine, 3 Lower small intestines, 4 Large intestines and colon

within 2 h. This could reflect that there is a limited pool of cellular substrates for the autophagic response. The extent to which the autophagy damaged the cells is unclear, but it is clear that apoptosis was activated by 4–8 h of culture, depending on the concentration of Orlistat. Early signs of apoptosis, cellular blebbing, were observed in as little as 4 h following treatment with 500 µM Orlistat substituted DM and 12 h exposure to 100 µM Orlistat substituted DM. The apoptosis is linked to the nutritional deficiency since adding a source of fatty acids to the media suppressed its progression and reversed the signs of cellular blebbing. Apparently the cells can recover, re-attain normal viability, from initiated apoptosis. However, there is clearly a threshold of apoptosis inducing cell injury beyond which the cells cannot recover.

Knowles and coworkers [9] describe in a paper that the apoptosis induced in mammary and prostate cell tumor lines by Orlistat was dependent on inhibition of FAS but independent of fatty acid availability. This paradox is explained by a pleiotropic consequence of inhibiting FAS that involves up-regulation of a stress responsive gene, DDIT4, which inhibits the mTOR pathway. Our findings with the NUGC-3 gastric tumor cells are more consistent with apoptosis arising from nutritional stress due to decreased availability of fatty acids. Addition of lipid-containing media to NUGC-3 cells exposed to Orlistat for 4 h halted progression of apoptosis over the next 4 h. Even though Orlistat was removed from the media in the second incubation, FAS continued to be inhibited (Fig. 2b). Thus, in the face of continued inhibition of FAS, whole media alone (lipids) halted apoptosis. The differences between our findings and those of Knowles et al. [9] could be related to differences in the duration of incubation with Orlistat. Eight hours exposure of NUGC-3 cells to 100 µM Orlistat

clearly induced apoptosis (Fig. 5e). Perhaps a higher level of stress develops with 24 and 48 h of continuous exposure that activated the DDIT4 initiated apoptosis. Although we used higher concentrations of Orlistat, their observations at 50 µM and ours at 100 µM should be similar. Our use of a gastric cell line may also have contributed to differences between our findings. As stated above, if Orlistat is to have a role in treating cancer it would be most likely for gastrointestinal tumors that could come in direct contact with the orally administered drug.

The greater sensitivity to inhibition of NUGC-3 cells in serum deficient media was likely due to the low lipid content of this media, since viability was greater in WM. This observation is consistent with FAS being Orlistat's target in cancer cells and Orlistat being more toxic to the cancer cells when they are wholly dependent on FAS to supply the fatty acids needed for phospholipid synthesis and, therefore, membrane formation.

Because increased cell death was seen in cultured cancer cells treated with Orlistat in DM, we applied this information to one of our in vivo experiments. Orlistat was fed in a very low fat diet in experiment 3. Animals were 58 days of age at the start. Previous work in our laboratory had showed that when added to a lipid emulsion, Orlistat partitioned into the lipid phase (data not shown). Given this result, we reasoned that Orlistat might similarly partition into the increased intestinal fat content generated by inhibition of lipases, and therefore, be less available to the tumors. Therefore, Orlistat was administered in a very low fat diet in the third experiment with the goal of enhancing drug exposure to gastrointestinal tumors. No statistically significant differences were seen between control and Orlistat treated groups (Fig. 7 bottom panel, Table 2). Although no significant difference was observed, the

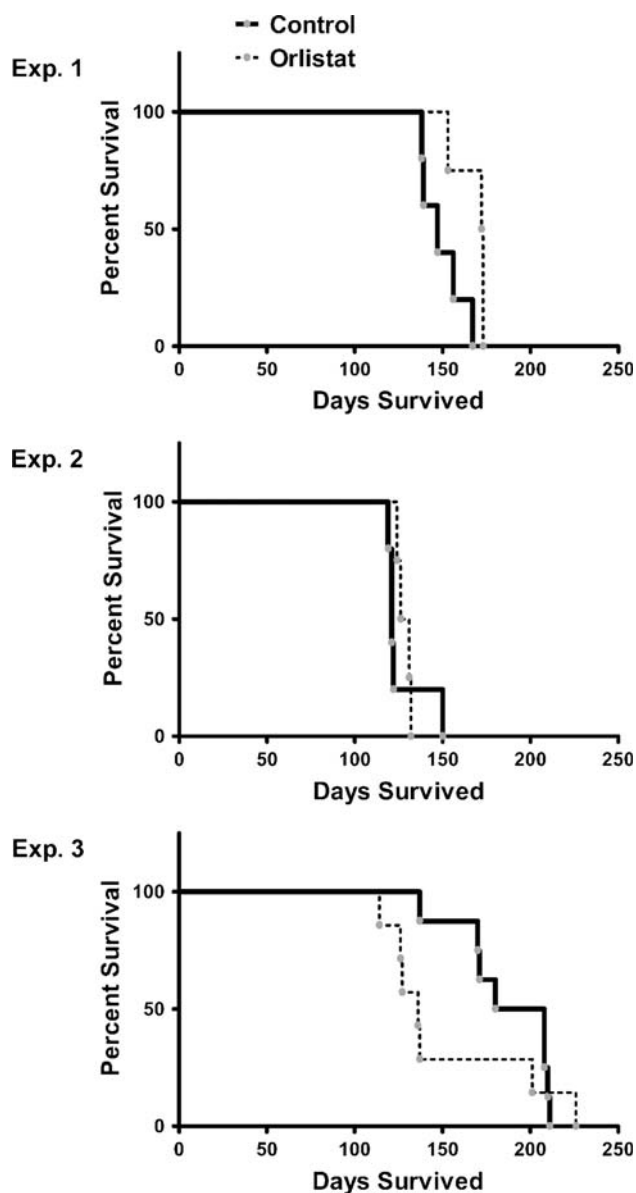

Fig. 7 Survival curves of control and Orlistat treated APC-min/+ mice. In experiments 1 and 2 mice were fed an 11% fat diet containing no Orlistat or 0.5 mg Orlistat/g chow. In experiment 3 mice were fed a 1.2% fat diet with and without 0.5 mg Orlistat/g chow

Fig. 8 Effect of Orlistat on the viability of bovine lens epithelial cells. Cells in 96 well plates were cultured for 48 h with varying concentrations of Orlistat added in either serum deficient DMEM (0.1% calf serum), DM, or DMEM containing 10% serum, WM. Cell viability was measured at hour 48 by the MTT assay. Values are mean \pm SEM of 4 wells

median survival time for untreated mice fed the low fat diet exceeded that of the Orlistat treated group. This data suggest that limiting exogenous sources of fatty acids via diet restrictions may offer potential in treating gastrointestinal cancers. However, a significant difference was seen when Orlistat was supplemented into the high fat diet. This data suggest that when supplemented into a high fat diet, Orlistat produced more beneficial results than supplemented into an already fat limited diet.

In conclusion, Orlistat appeared to slightly prolong the survival of mice with a fatal-genetic gastrointestinal cancer. There was no evidence that Orlistat accelerated death in these tumor-bearing animals. If the findings are applicable to humans, they support the idea that Orlistat inhibits this type of cancer. Long-term survival studies in rats and other mice strains are needed to further evaluate the potential of Orlistat to inhibit GI cancer.
