Abstract We studied modifications induced at the membrane lipid level by over-expression of the anti-apoptotic protein Bcl-2. When total cell phospholipids were analyzed, the transformation led to a moderate decrease in poly-unsaturated fatty acids, compensated by an increase in mono-unsaturated species. At the mitochondrial membrane level, the changes were more important and occurred in saturated and dimethyl acetal fatty acids, which became more abundant, while unsaturated fatty acid content diminished. This indicates a decline in oxidation-sensitive fatty acids (unsaturated species) together with a gain in oxidation-insensitive saturated fatty acids and in plasmalogen (as detected by dimethyl acetal fatty acids) considered as oxygen species scavengers. These changes, combined with the protective role of Bcl-2 against oxidation due to its effect on the redox potential, should protect cells from apoptosis starting in mitochondria.

Keywords Bcl-2 · Fatty acid species · Phospholipids · Mitochondrion · Plasmalogens · Cardiolipin

Abbreviations

ADP	Adenosine 5'-diphosphate
ANT-1	Adenine nucleotide translocase-1
ATP	Adenosine 5'-triphosphate
BSA	Bovine serum albumin
C:16	16 Carbon-long fatty acids
C:18	18 Carbon-long fatty acids
DMA	Dimethylacetal
EDTA	Ethylenediaminetetraacetate
FA	Fatty acid
GLC	Gas liquid chromatography
HRP	Horse radish peroxidase
MUFA	Mono-unsaturated fatty acid
NADPH	β -Nicotinamide adenine dinucleotide phosphate, reduced
PBS	Phosphate buffered saline
PtdCho	Phosphatidylcholine
PtdEtn	Phosphatidylethanolamine
PtdIns	Phosphatidylinositol
PtdSer	Phosphatidylserine
PKC	Protein kinase C
PUFA	Poly-unsaturated fatty acid

Introduction

The lipid composition of membranes directly affects their physical properties that are, among other roles, important

for the cell structure. It is well established that the fatty acid composition of phospholipids plays a role in membrane packing and lipid-protein interaction in the bilayer [1–5]. Thus, membrane curvature, cell deformation, vesicle formation and membrane fusion are dependent on the lipid composition of each membrane compartment [6–8]. Moreover, several lipids and lipid metabolites are involved in signaling pathways in response to various stimuli [9]. Modification in fatty acid and phospholipid composition can affect membrane association of extrinsic proteins, including some involved in signal transduction [10, 11]. Thus, both structural and signaling properties of lipids are involved in control of cell functions, such as proliferation, endocytosis, exocytosis, polarity, migration, or cell death by apoptosis [12–15].

The oncogene bcl-2 was first identified on the basis of its involvement in B cell malignancies where chromosomal translocation t(14;18) activates bcl-2 in many human B-cell lymphomas [16]. This protein is present in several membrane compartments, in particular in the outer membrane of mitochondria [17–20] and possesses an ion channel activity [21]. Its role as a blocker of apoptotic cell death is to maintain the integrity of the mitochondrial barrier by preventing its nonspecific permeabilization [22, 23]. However, Bcl-2 would maintain the exchange of small molecules including ATP, ADP, NADPH, and thus, normal mitochondrial functions (see reviews [24, 25]). Most of Bcl-2 effects were confirmed by gene transfer experiments in various cell types. Bcl-2 over-expression blocks cell death generated in a wide variety of cells by various agents, including growth factor withdrawal, cytotoxic lymphokines, virus infection, DNA damage, anticancer drug and radiation. However, it has no protective effect on programmed cell death induced by other stimuli [26].

So far, only a few studies have dealt with the effect of Bcl-2 expression on lipids (e.g. [27]) although the role of lipids in maintaining membrane integrity is essential. However, it is well established that apoptosis is accompanied by exposure of phosphatidylserine at the cell surface as assessed by annexin V binding to plasma membrane, a modification used for apoptosis measurement [28].

In the present study, we investigated whether a change in Bcl-2 expression could have an effect on membrane phospholipid distribution or on fatty acid species associated with phospholipids in HL-60 cells.

Materials and Methods

Materials

RPMI-1640, antibiotics and glutamine were purchased from Gibco BRL. Fetal bovine serum was from Dutcher.

All inorganic solvents were obtained from VWR and were of analytical grade.

Silica gel 60A plates (20 × 20 cm) for thin layer chromatography (TLC) were obtained from Merck and the fused-silica capillary column (50 m × 0.32 mm) used for GLC came from SGE.

Mouse monoclonal antibodies recognizing a human 65-kDa mitochondrial protein (mAB 1273), Bcl-2 (clone 7) and porin (clone 31HL) were purchased from Chemicon, BD Transduction laboratories and Calbiochem, respectively; rabbit polyclonal antibodies against adenine nucleotide translocase-1 (ANT-1) were from Oncogene Research products. HRP conjugated secondary antibodies to mouse and rabbit IgG were purchased from Cellular Signaling and anti-mouse IgG conjugated with fluorescein was from Cappel. Antibodies were used at the dilution indicated by the manufacturer. Tetramethylrhodamine methyl ester (TMRM) was obtained from Molecular Probes Europe BV.

Methods

Cell Culture and Cell Treatments with Agents

A stable clone of HL-60 cells transfected with the empty vector (neo) and a HL-60 clone over-expressing Bcl-2 were obtained from Dr. M. Allouche (Toulouse, France) and cultured in the presence of G418 (0.5 mg/ml) as reported [29]. Both clones were cultured in suspension in RPMI-1640 medium containing 10% fetal bovine serum, 2% L-glutamine, 1% penicillin-streptomycin and 1% G418 to maintain the gene selection at 37 °C in a humidified incubator containing 5% CO₂.

Purification of Mitochondria

Mitochondria from the two clones of HL-60 cells (see above) were purified according to Susin et al. [30]. Briefly, two to three liters of cells at confluency ($2\text{--}3 \times 10^9$ cells) were centrifuged, washed three times with ice-cold PBS and resuspended in cold homogenization buffer made of 300 mM saccharose, 5 mM Tris(hydroxymethyl)methyl-2-aminomethanesulfonic acid (TES), 0.2 mM EDTA, pH7.2, and containing a cocktail of protease inhibitors (complete mini tablets (Roche)). All the subsequent steps were performed at 4 °C. Cells were homogenized in a Potter homogenizer and the homogenate was centrifuged for 10 min at 800 g to remove nuclei. The supernatant was centrifuged for 10 min at 9,000g. After centrifugation, the pellet was recovered and resuspended in 1 ml of the homogenization buffer, put on the top of a discontinuous Percoll-saccharose gradient made of equal volumes of 60%, 30%, and 15% Percoll solutions, and centrifuged for

10 min at 9,000g. Mitochondria at the lower interface (between 60 and 30% Percoll) were recovered with a syringe, diluted 10 times in a buffer made of 10 mM MOPS-KOH, 10 mM KCl, 1 mM EDTA, pH 7.3, and centrifuged. The pellet of purified mitochondria was resuspended in 0.7 ml and lipids were then extracted as described below after removal of an aliquot kept for protein analysis.

Protein Analysis by SDS-PAGE and Immunoblotting

The amount of three mitochondrial proteins, namely Bcl-2, ANT-1 and porin, was measured in purified mitochondria from neo and Bcl-2 over-expressing HL-60 cells. Equal amounts of mitochondrial proteins purified from the two clones were loaded on a polyacrylamide gel (PAGE) and analyzed by SDS-PAGE. Samples separated by SDS-PAGE were transferred to nitrocellulose membrane (Hybond™ C-extra, Amersham) and blocked in phosphate-buffered saline containing 0.1% Tween 20 (PBST) and 5% BSA and incubated with primary antibodies diluted in PBST for 1 h at room temperature then washed 5 times for 10 min and incubated for 1 h at room temperature with species-matched HRP-conjugated secondary antibody diluted in PBST. After membrane washing in PBST, the specific signal was detected by enhanced chemiluminescence (ECL kit; Pierce). Quantitation of immunoblots was performed using a densitometer (Fuji-system) and expressed as mean \pm SD of three experiments.

Flow Cytometry Analysis

Flow cytometry was used to analyze cell size and to measure mitochondrial membrane potential in living cells using tetramethylrhodamine methyl ester (TMRM), as described in [31].

Analysis of Mitochondrial Density and Morphology by Immunofluorescence

Cells were fixed at room temperature with 3% paraformaldehyde (PFA) for 20 min and incubated in a solution of NH_4Cl (50 mM) containing 10 mM CaCl_2 and 10 mM MgCl_2 for 10 min. After several washes with PBS, cells were permeabilized with Triton X-100 (0.5% final) for 5 min. The primary antibody, diluted in PBS containing 0.5% BSA, was then incubated for 1 h with cells and after several washes, the fluorescent-labeled secondary antibody was incubated for 30 min with cells at the required dilution. After cell washing, samples were mounted in Mowiol and observed with a confocal laser scanning microscope (BioRad MRC-100) attached to a diaphot 300 microscope (Nikon). Using the Metamorph analysis program, the number of mitochondrial structures, their size and intensity

of fluorescence were measured on 7 cell pictures acquired using the same parameters.

Lipid Extraction, Preparation of Total Phospholipid Extract, Separation of Phospholipid Classes and Fatty Acid Analysis by Gas Chromatography

Cells (1.20×10^8) were initially washed three times in PBS containing 0.1 mM EDTA, and resuspended in the same medium at a density of 40×10^6 cells/ml. Lipids were then extracted according to Folch et al. [32] and separated on silica gels plates by 2-D thin layer chromatography (TLC) developed by chloroform/methanol/ammonia 28% (65/25/5 v/v/v) (first dimension), and chloroform/methanol/acetone/acetic acid/water, (50/10/20/10/4, v/v/v/v/v) (second dimension) [33]. The spots of lipid were visualized by iodine vapor (supplemental Fig. 1) and phospholipid spots were scraped off. As the PtdSer and PtdIns spots were very frequently overlapping, these two phospholipids were treated as a whole. Phospholipids were then transmethylated by methanol/sulfuric acid (97.5/2.5) at 70 °C for 60 min [34]. FA methyl esters were then analyzed by fused-silica capillary column (50 m \times 0.32 mm) coated with carbowax 20 M on GLC (Model 3300; Varian). Quantitative analysis of fatty acid methyl esters was carried out using methylheptadecanoate (C17) as an internal standard introduced before transmethylation reaction. Capillary GLC allows a good separation of DMAs and FA isomers, particularly of long chain polyunsaturated FAs. A similar protocol was used to analyze lipids from purified mitochondria.

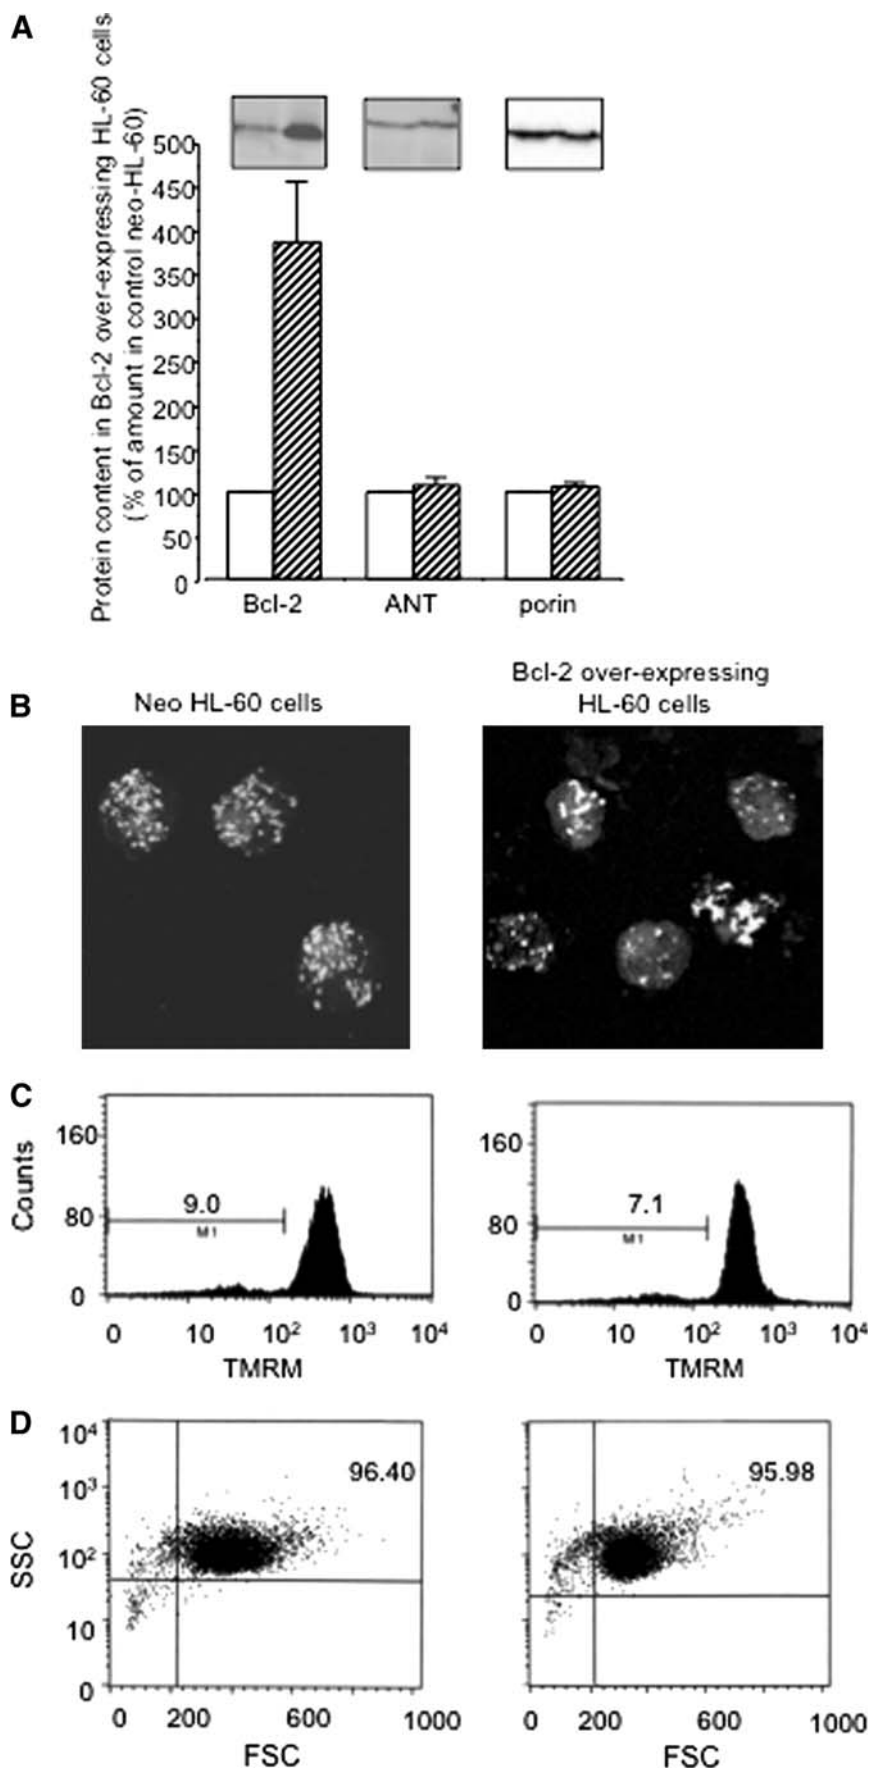

Statistical Analysis

The values are expressed as weight per cent of the total FAs \pm SD. Statistical differences between Neo HL-60 cells and Bcl-2 over-expressing HL-60 cells were calculated by the Student *t* test applied to unpaired samples, **P* < 0.05.

Results

The effect of Bcl-2 over-expression in an established HL-60 clone was initially checked by studying a few characteristics of mitochondria. Firstly, the amount of this anti-apoptotic mitochondrial protein as well as that of two other mitochondrial proteins, ANT-1 (located in the internal membrane) and porin (also called voltage-dependent anion channel and located in the external membrane), were measured in Bcl-2 over-expressing HL-60 cells and compared to those present in neo HL-60 cells. As reported in Fig. 1a, the Bcl-2 over-expressing HL-60 cells contained

Fig. 1 Modifications at mitochondrion level and of cell size induced by Bcl-2 over-expression. Mitochondria from HL-60 cells over-expressing or not Bcl-2 were analyzed for different parameters. **a** Bcl-2, ANT-1 and porin levels were measured in purified mitochondria from neo (*empty bars*) and from Bcl-2 over-expressing HL-60 cells (*stripped bars*). **b** Neo and Bcl-2 over-expressing HL-60 cells were examined by confocal immunofluorescence microscopy after fixation with PFA followed by staining with a mouse monoclonal antibody to mitochondria (mAB 1273) and revealed with a secondary antibody labeled with FITC. **c** Mitochondrial membrane potential ($\Delta\Psi_m$) was measured with tetramethylrhodamine methyl ester (TMRM) as described in [31]. **d** Cell size was measured by forward scatter (FSC)

4 times more Bcl-2 than neo-HL-60 cells. In contrast, no modification in the amount of ANT or porin was observed between both clones indicating that over-expression of Bcl-2 did not induce major changes in the amounts of other well known proteins of the mitochondrion. Cell content in mitochondria and morphology of these organelles were then studied in both clones, using an antibody (mAB1273) against a 65-kDa mitochondrial protein. As observed in Fig. 1b, the number of mitochondria in Bcl-2 over-expressing cells was lower than in neo cells, 45 ± 24 and 69 ± 28 , respectively. Mitochondria were bigger in Bcl-2 over-expressing cells than in neo-HL-60 cells (36.2 ± 18.9 and 15.8 ± 6.2 surface units, respectively). Moreover, intensity of fluorescence of these organelles was increased in Bcl-2 over-expressing cells (9462 ± 5825 arbitrary units) compared to that in Neo cells (2315 ± 442). All data on mitochondria analysis in neo and Bcl-2 over-expressing cells are expressed as means \pm SD (number of cells studied = 7). All these observations on mitochondria suggest that a high level of Bcl-2 might modify mitochondrial membranes. Whether Bcl-2 over-expression could have an impact on mitochondrial membrane potential was then explored. As shown in Fig. 1c, over-expression of the anti-apoptotic Bcl-2 protein does not modify the cell mitochondrial membrane potential ($\Delta\Psi_m$) as only 9% and 7% of control and Bcl-2 over-expressing cells, respectively, exhibited a low $\Delta\Psi_m$. As observed by flow cytometry analysis, cells over-expressing Bcl-2 were slightly smaller than neo HL-60 cells (Fig. 1d). In the HL-60 cell-line used to establish both Bcl-2 and neo clones, cells of different sizes were present, thus, the difference in cell size observed between the two clones could be due to their clonal origin. Bcl-2 is well established to play a role in cell survival (for a review, see [35]) and its over-expression together with that of c-myc has been shown to initiate proliferation [36]. Therefore, cell growth was measured in the two clones. As shown in Fig. 2, no obvious difference was observed in the growth curves between neo-HL-60 cells and Bcl-2 over-expressing cells cultured in the same conditions. Through these characteristics, concerning cell growth, mitochondrion protein expression (except, as expected, that of Bcl-2) and mitochondrial morphology and function, no gross differences could be detected between the two clones.

Lipids are known to play an important role in membrane stability and in various signaling pathways. Membrane content in proteins often modifies lipid composition. Thus, we analyzed the fatty acid composition of total phospholipid content in neo and Bcl-2 over-expressing HL-60 cells. Phospholipids present in membranes were separated by two-dimensional thin layer chromatography and the respective percentage of each phospholipid was estimated. Then, fatty acid composition of each major phospholipid

Fig. 2 Cell growth curves of neo and Bcl-2 over-expressing HL-60 cells. On day 0, cells were diluted in RPMI 1640 medium supplemented with 10% FCS and the number of cells/ml was counted in 3 different samples. Cells were then counted every day before being diluted on day 4. Data represent the means \pm SD of three different experiments

class was analyzed. To determine whether specific changes would occur at the level of mitochondrial membranes, we purified these organelles from the two clones and subsequently the same FA composition analysis of total lipids and specific phospholipid classes were performed.

As reported in Table 1, no drastic change in the whole cell content of fatty acids was observed between HL-60 cells transfected with the empty vector or with the vector containing the bcl-2 gene. However, mono-unsaturated fatty acid (MUFA) content appeared to be slightly higher in cells over-expressing Bcl-2 than in neo cells, at the expense of polyunsaturated fatty acids (PUFAs). Amongst the polyunsaturated fatty acids detected, arachidonate, which is the most abundant, appeared to be the most affected representing 8% of total fatty acids in neo HL-60 cells and only about 3% in cells over-expressing Bcl-2. The change in the MUFA vs. PUFA ratio that occurred in the Bcl2 overexpressor is consistent with what was reported in a human keratinocyte cell line [27]. However, in this latter case, the amount of saturated fatty acids (SFAs) also decreased, so that the unsaturation index of the surexpressor cell was slightly increased (from 129.6 to 138.5). In our cell system, the amount of SFAs did not change in the total cell extract, and the decrease in PUFAs led to a decrease of the unsaturation index (from 118.3 to 93.8).

In purified mitochondria, the most significant changes in total lipid composition due to Bcl-2 over-expression were an increase in the percentage of saturated fatty acids, in particular that of 16:0, and a decrease mostly in PUFAs. In

After separation of phospholipids by TLC followed by their transmethylation as described in the Methods section, Fatty acid composition of phosphatidylcholine was analyzed by capillary GLC. The values are expressed as weight per cent of the total FAs ± SD

* Significantly different from control cells with $P < 0.05$

addition, DMA fatty acids, derived from plasmalogens by methanolysis, were increased by a factor 3 in Bcl-2 over-expressing mitochondria, whereas they were not modified in total lipid cell extracts.

As shown in Table 2, in lipid cellular extracts, Bcl-2 over-expression induced an increase in the percentage of PtdCho to the detriment of the other classes. Moreover, it is normal that the percentage of cardiolipin, a specific lipid of mitochondria, was limited in these extracts. In contrast, it represents about a quarter of the total lipid content in purified mitochondria from neo and Bcl-2 over-expressing cells (Table 2).

To investigate whether changes observed in the fatty acid composition of Bcl-2 over-expressing cells concern all phospholipids, fatty acid compositions of the three major phospholipid spots separated by TLC from total cell extracts were analyzed. These major spots contained

phosphatidylcholine (PtdCho), phosphatidylethanolamine (PtdEtn), and phosphatidylserine (PtdSer) plus phosphatidylinositol (PtdIns).

The tendency to an increase in the percentage of MUFAs at the expense of PUFAs found in total phospholipids of cells over-expressing Bcl-2 compared to those of neo HL-60 cells was also observed in each individual glycerophospholipid (see Tables 3, 4, 5). It was more marked in PtdEtn than in the other phospholipids. In addition, in PtdEtn, over-expression of Bcl-2 induced a substantial decrease in total SFAs, which concerned only stearic acid (18:0) (Table 4). In PtdCho, PtdSer and PtdIns, DMA FAs, reflecting plasmalogen content, represented less than 1%. In PtdEtn this content reached 10% in control cells, and subsequently increased to more than 15% upon Bcl-2 over-expression.

Analysis of the impact of Bcl-2 over-expression on FA composition of PtdCho, PtdEtn, PtdIns and cardiolipin

* Significantly different from control cells with $P < 0.05$

from purified mitochondria showed that in the three first phospholipids, over-expression of Bcl-2 induced a marked decrease in PUFA percentage by a factor 3, 2 and 1.5 in PtdCho, PtdEtn and PtdIns, respectively. Moreover, DMA fatty acids representing in neo cell mitochondrial phospholipids around 1, 2 and 4%, respectively, of total FAs, were increased to about 3, 5 and 12% in those from Bcl-2 over-expressing HL-60 cells (see Tables 3, 4, 5). As to cardiolipin, specifically located in mitochondria, more drastic changes were observed upon Bcl-2 over-expression. SFAs were doubled in Bcl-2 over-expressing cells whereas PUFAs were halved. Moreover, DMA fatty acids were also doubled compared to those present in neo cells (Table 6). These major changes in cardiolipin FA composition are likely to be related to the increased expression of Bcl-2 in these organelles and to be involved in the protection against apoptosis from mitochondrial origin.

Discussion

In the present work we have shown that in the human promyelocytic cell line, HL-60, over-expression of the major anti-apoptotic protein Bcl-2 leads to changes in membrane lipids that could take a part in their observed resistance to apoptosis. Although PUFAs represented only a small percentage of all FAs, their content decreased upon Bcl-2 over-expression in total cell lipids and in individual phospholipid classes. Taken together with the increase in MUFAs observed in cellular lipid extracts and in individual phospholipid classes, PUFA decrease might suggest a lower sensitivity of Bcl-2 over-expressing cells to oxidation, a phenomenon that contributes to cell apoptosis.

Looking at changes in mitochondrion composition induced by over-expression of Bcl-2 protein, they all indicate that this organelle would be less prone to injuries

leading to apoptosis. As expected, the Bcl-2 content is greatly increased, and this protein is known to have anti-apoptotic properties when apoptosis is induced by agents that activate caspase via the intrinsic pathway initiated by mitochondrial outer membrane and release of cytochrome *c* [37]. In addition, over-expression of Bcl-2 regulates amplification of caspase activation by cytochrome *c*. In addition, over-expression of Bcl-2 has been shown to shift the cellular redox potential to a more reduced state (see reviews [38, 39]) not favoring oxidation of cell components. Using the same two clones, we have previously reported that apoptosis by disruption of mitochondrial homeostasis induced by the lethal toxin from *Clostridium sordellii* did not occur in Bcl-2 over-expressing cells [40].

The changes in mitochondrial lipid composition noted in Bcl-2 over-expressing cells are indicating that the

membranes are significantly less unsaturated. There was a net decrease in PUFA content (ca. 2 times) together with a smaller reduction in MUFA content. These decreases were compensated by an increase (ca. 10%) in SFAs and in DMA-FAs. All together, these changes led to a drop of ca. 20% in the unsaturation index of the mitochondrial membrane (from 105.2 to 82.7). However, this rearrangement in fatty acid composition has to be further analyzed to show the tendency of the membrane to be more resistant to (per)oxidation. Indeed, susceptibility to peroxidation of fatty acids is complex, with number of unsaturations, chain length and n-3 and n-6 series being important [41]. Combining all these parameters, it is possible to calculate a peroxidation index, which is a measure of the membrane susceptibility to peroxidation [41]. This index was lower by ca. 30% (66.4 vs. 47.8) in mitochondrial membranes

After separation of phospholipids by TLC followed by their trans-methylation as described in the Methods section, Fatty acid composition of cardiolipin from mitochondria preparations was analyzed by capillary GLC. The values are expressed as weight per cent of the total FAs ± SD

* Significantly different from control cells with $P < 0.05$

purified from Bcl-2 over-expressors, confirming that the bilayer should be less prone to oxidative damages.

DMA-FAs originate from plasmalogens, a class of lipids which are known to act as scavengers, protecting other lipids from oxidative reactions [42, 43]. The increase (2.5–3 times) in plasmalogen species was found in all the lipid classes of mitochondrial membranes.

Changes in unsaturation of fatty acyl chains concerned all the mitochondrial phospholipids, especially cardiolipin. Indeed, its content in SFAs doubled while the amount of PUFAs was diminished by 50%. Thus, cardiolipin should become more resistant to (per)oxidation (peroxidation index decreasing by 33%), disfavoring cytochrome *c* release leading to apoptosis [44].

Although the amount of cardiolipin was not affected by Bcl-2 over-expression, the fatty acid composition changes could modify interactions with apoptotic or anti-apoptotic proteins, either in the inner membrane or at the contact sites where this lipid is enriched [45].

In conclusion, the present work shows that over-expression of Bcl-2 protects from apoptosis starting in mitochondria not only through the specific properties of the protein, but also by changes in membrane fatty acids.

Abstract Cholesterol metabolism as initiated by mitochondrial sterol 27-hydroxylase (CYP27A1) is a ubiquitous pathway capable of synthesizing multiple key regulatory oxysterols involved in lipid homeostasis. Previously we have shown that the regulation of its activities within hepatocytes is highly controlled by the rate of mitochondrial cholesterol delivery. In the present study, we hypothesized that increasing expression of the mitochondrial cholesterol delivery protein, steroidogenic acute regulatory protein (StAR), is able to lower lipid accumulation in liver, aortic wall, as well as in serum in a well-documented animal model, apolipoprotein E-deficient (apoE^{-/-}) mice. ApoE^{-/-} mice, characterized by increased serum, liver, and endothelial cholesterol and triglyceride levels by 3 months of age, were infected with recombinant cytomegalovirus (CMV)-StAR adenovirus to increase StAR protein expression. Six days following infection, serum total cholesterol and triglycerides had decreased 19 and 30% ($P < 0.01$), respectively, with a compensatory 40% ($P < 0.01$) increase in serum HDL-cholesterol in increased StAR expressing mice as compared to controls (no or control virus). Histologic and biochemical analysis of the liver demonstrated not only a dramatic decrease in cholesterol ($\downarrow 25\%$; $P < 0.01$), but an even more marked decrease in triglyceride ($\downarrow 56\%$; $P < 0.01$)

content. En bloc Sudan IV staining of the aorta revealed a $>80\%$ ($P < 0.01$) decrease in neutral lipid staining. This study demonstrates for the first time a possible therapeutic role of the CYP27A1-initiated pathway in the treatment of dyslipidemias.

Keywords Lipids · Cholesterol · Lipoproteins · Steroidogenic acute regulatory protein

Abbreviations

ALP	Alkaline phosphatase
ALT	Alanine aminotransferase
apoE ^{-/-}	Apolipoprotein E-deficient
AST	Aspartate aminotransferase
BAS	Bile acid synthesis
CMV	Cytomegalovirus
CTX	Cerebrotendinous xanthomatosis
CYP7A1	Cholesterol 7 alpha-hydroxylase
CYP27A1	Sterol 27-hydroxylase
EGFP	Enhanced Green fluorescent protein
HDL	High density lipoprotein
HDL-CHO	HDL cholesterol
IDL	Intermediate-density lipoproteins
LDL	Low density lipoprotein
NS	Normal saline
O.C.T	Optimum cutting temperature compound
PC-TP	Phosphatidylcholine transfer protein
PPAR γ	Proliferation peroxysome activator receptor gamma
StAR	Steroidogenic acute regulatory protein
START	StAR-related lipid transfer domain
T-CHO	Total cholesterol
TG	Triglyceride
VLDL	Very low-density lipoproteins

Introduction

Dyslipidemias, as characterized by abnormal serum lipoprotein profiles, are a risk factor for atherosclerosis [1]. Although current strategies have led to significant advances in their treatment, there is great interest in exploring new therapeutic strategies to treat and prevent what remains a leading cause of morbidity and mortality throughout the world.

Steroidogenic acute regulatory protein (StAR/StarD1), an intracellular cholesterol transport protein, was first identified in steroidogenic tissues. This protein is a member of a family that contains a StAR homologue domain that has been found capable of binding and transporting sterols within cells. This family includes the phosphatidylcholine transfer protein (PC-TP/StarD2) [2], MLN64 (StarD3) [3, 4], and the newly discovered StarD4, StarD5, and StarD6 [5–8]. All of these proteins have a similar structural lipid-binding domain referred to as the StAR-related lipid transfer (START) domain. StAR, first detected in the adrenal, was shown to facilitate cholesterol delivery to the inner mitochondrial cholesterol side-chain cleavage system in the initiation of steroidogenesis [9, 10]. StAR was initially considered to be confined to steroidogenic tissues such as adrenal gland, ovary, and testicle [7, 11]. However, StAR has since been found in other tissues/cells inclusive of the liver, brain, endothelium, and macrophages [12–15].

In the liver, StAR has been shown to facilitate cholesterol delivery to the inner membrane of the mitochondria where cholesterol can be oxidized by sterol 27-hydroxylase (CYP27A1) to an important regulatory oxysterol, 27-hydroxycholesterol, before ultimately being metabolized to bile acids [16]. Most recently, we have shown that in addition to its metabolism of cholesterol to 27-hydroxycholesterol and subsequently to bile acids, CYP27A1 is also capable of metabolizing cholesterol to 25-hydroxycholesterol with subsequent conversion to its sulfated form [17]. Like 27-hydroxycholesterol, both 25-hydroxycholesterol and sulfated 25-hydroxycholesterol are regulators of intracellular lipid metabolism [17–19]. Both 27- and 25-hydroxycholesterol are known to down-regulate cholesterol synthesis while stimulating cell cholesterol secretion [18, 19]. Sulfated 25-hydroxycholesterol has recently been shown to decrease fatty acid synthase as well as activate a nuclear receptor responsible for fatty acid mobilization/secretion [20].

It is possible that increased metabolism of cholesterol as initiated through the CYP27A1 could result in a coordinated lipids lowering response. Increasing StAR expression would be expected to not only increase cholesterol catabolism to bile acids as we have previously shown, but produce key regulatory oxysterols of intracellular lipid homeostasis [12, 16, 21]. In support of this supposition, our recent *in vitro* findings in THP-1 macrophages showed that up-regulation

of StAR induced a coordinated mobilization and reduction of cell cholesterol [14]. Therefore, it seems reasonable to hypothesize that the StAR/CYP27A1-initiated metabolism of cholesterol is not only a pathway of cholesterol catabolism, but an important intracellular pathway capable of directing intracellular lipid homeostasis.

Apolipoprotein-E mediates the clearance of serum lipids such as cholesterol and triglyceride [22]. Apolipoprotein E-deficient (apoE^{-/-}) mice develop hypercholesterolemia as a result of an accumulation of chylomicron remnants, very low-density lipoproteins (VLDL), and intermediate-density lipoproteins (IDL) [23]. Mice homozygous for the inactivated apoE gene spontaneously develop hypercholesterolemia and aortic lipid accumulation [24, 25]. The lipid lesions which develop in the aortas of mice fed a standard rodent chow diet are similar to the early lipid accumulations found in humans [23, 26, 27]. In addition, apoE^{-/-} mice are also known to develop significant hepatic lipid (i.e. cholesterol/triglyceride) accumulation. Therefore, apoE^{-/-} mice provide not only a practical model for the study of early developmental atherosclerosis [28], but an excellent model for the outlined study.

The described trial was simply designed as “an *in-vivo* proof of concept” that increasing CYP27A1-initiated cholesterol metabolism as facilitated by the mitochondria-directed cholesterol transport protein, StAR, could represent a novel approach to reduce serum and tissue cholesterol and triglyceride levels. As shown, increased StAR expression led to a coordinated response in serum triglycerides and HDL cholesterol. Furthermore, hepatic cholesterol was significantly reduced. Of equal importance, neutral lipid levels in the serum, liver, and aorta were also dramatically reduced in this classic animal model of dyslipidemia.

Experimental Procedure

Materials

TRIzol reagent and SuperScript TMIII First-Strand Synthesis System for RT-PCR were purchased from Invitrogen (Carlsbad, CA). Taq DNA Polymerase, dNTP mix and PageRuler Prestained Protein Ladder were purchased from Fermentas MBI (San Diego, CA). Primary antibody against StAR and GAPDH were purchased from Abcam Ltd (Cambridge Science Park, Cambridge, UK) and Kangcheng Bio-Tech (Shanghai, China), respectively. Second antibody against rabbit and mouse IgG were obtained from Kirkegaard & Perry Laboratories (Guildford, UK). SuperSignal West Pico Chemiluminescent Substrate was obtained from Pierce Biotechnology, Inc (Rockford, IL). All other reagents were from Sigma-Aldrich Chemical Co. (St. Louis, MO) unless otherwise indicated.

Experimental Animals

C57BL/6 J mice and homozygous apoE^{-/-} mice (same inherited background as the C57BL/6 J mice) were purchased from the Department of Laboratory Animal Science, Peking University Health Science Center (Beijing, China). The animals were allowed to acclimatize for 1 week while being maintained at a room temperature of 22 ± 2°C on a 12 h light/dark cycle with free access to standard rodent chow food and water (Standard sustain feed, from Institute of Laboratory Animal Science, Shanghai, China). Housing facilities and all experimental protocols were approved by the Animals Care and Use Committee of Fudan University Shanghai Medical College which adopts the guidelines for the care and use of laboratory animals published by the US National Institutes of Health (NIH Publication No. 85–23, revised 1996).

Ninety-six C57BL/6 J and apoE^{-/-} mice of both sexes at 1, 3 and 5 months old were used to determine serum level of lipids. An additional 27 6-month-old male apoE^{-/-} mice were used to investigate the effect of StAR overexpression on serum, liver, and aortic lipid levels. Prior to and post infusion, the animals dietary intake was not significantly different from either control group. Before sacrificing, the mice were fasted for 12 h. The mice were then anesthetized (60 mg pentobarbital/kg body weight, intravenously) and euthanized. Blood was collected from the retro-orbital plexus and aliquots of plasma were stored at –70°C until determination of serum parameters as described below. The liver was excised, weighed, snap frozen in liquid nitrogen, and stored at –70°C until further analysis. The aorta and liver were harvested for gross and histological examination.

Preparation of Recombinant Adenoviruses

The recombinant adenoviruses encoding StAR were prepared as previously described [29]. The virus was then amplified by infecting confluent monolayers of human embryonic kidney 293 cells as previously described [30]. Aliquots of the amplified virus were stored at –70°C until used. The control adenoviruses expressing the enhanced green fluorescence protein were purchased from the Vector Gene Technology Company Ltd (Beijing, China). The infection and particle titers of the viruses were determined using plaque and optical density assays, respectively.

Intravenous Infusion of Adenovirus

For the adenovirus infections, the 27 6-month-old apoE^{-/-} mice fed a standard rodent chow diet were equally and randomly divided into three groups. Eighteen of mice were tail vein injected with 1 × 10¹¹ virus particles of

Ad~CMV~StAR or Ad~CMV~EGFP. In nine non-transduced (control) mice the virus was replaced with the same volume of normal saline (NS). Six days after infection, the animals were briefly anesthetized and euthanized after fasting for 12 h. Blood was collected for determination of serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP) and lipid levels. Organs were harvested for histology and biochemical analysis. The histological specimens were fixed in 10% formalin. Additional tissue (liver) was quickly frozen in liquid nitrogen and stored at –70°C for further analysis.

Determination of Blood Parameters

The levels of triglyceride (TG), total cholesterol (T-CHO), and HDL cholesterol (HDL-CHO) in serum were measured by enzymatic methods [31] according to the manufacturer's instructions using the detection kit purchased from Rongsheng Biotechnology Company Ltd (Shanghai, China). Serum ALT, AST, and ALP activities were determined by the clinical laboratory at the Longhua Hospital (Shanghai, China).

Histology

After adenoviruses infection, the StAR protein expression in heart, coronary artery and liver were detected by immunohistochemistry by ABC methods as previously described by the authors [13]. A portion of liver was harvested and embedded in optimum cutting temperature compound (O.C.T compound, Sakura Finetek, Inc., Torrance, CA), mixed with sucrose (20%), and stored at –80°C. Ten-micrometer cryosections were made lengthwise through the liver lobe. All cryosections were fixed for 1 min in formaldehyde solution, stained for 10 min with Oil Red O (stains lipids red), and counterstained for 1 min with hematoxylin. En face lipid accumulation was determined by removing the aortas from the aortic arch to the ileal bifurcation. The aortas were fixed in 10% neutral buffered formalin. To increase the reliability of lipid quantification, only the aortic segment from left subclavian artery to ileal bifurcation was used for the measurement. The aortas were cut longitudinally, splayed, and pinned in a dish filled with Sudan IV stain for 10 min, destained in 80% ethanol for 5 min, and then photographed. Quantitation of neutral lipid staining was performed by measuring stained area using ImageM software (Department of Physiology and Pathophysiology, Shanghai Medical College, Fudan University, China). The accumulated stained area in a given aorta was calculated as a percentage of the total surface area of the aorta.

Liver Lipid Measurement

Lipids were extracted from liver according to a published method [32]. Triglyceride and cholesterol were measured using the same method described previously for blood lipid analysis [31].

Determination StAR Protein Levels in Tissues

Total proteins of heart, lung, liver, spleen, and adrenal gland from the infected mice were isolated using $1 \times$ SDS-PAGE sample buffer (50 mM Tris-Cl buffer, pH 6.8, 2% (w/v) SDS, 2% mercaptoethanol, 10% (v/v) glycerol, and 0.1% (w/v) bromophenol blue). Protein was quantitated using the bicinchoninic acid assay purchased from Pierce (Rockford, IL). Fifty micrograms of total protein were separately on 10% SDS-PAGE gels. Western blot analysis of StAR was performed as previously described by the authors [13].

Statistics

Data were reported as mean \pm standard deviation (SD) and subjected to ANOVA analysis. *F* test and the *Student-Neuman-Keuls post* test analyses were performed on these data to analyze the variances and significances between groups. Statistical significance was defined as $P < 0.05$.

Results

Plasma Lipid Levels Increased in ApoE^{-/-} Mice

The absence of apoE^{-/-} in humans and animal models is associated with increases in serum, liver, and aortic lipid

levels. To simply confirm the apoE^{-/-} mouse model available as representative and as a viable model for examining the effects of increased StAR expression on serum, aortic, and liver lipids, serum lipids were determined at 1, 3, and 5 months of age and compared to C57BL/J6 mice. On a standard rodent chow diet (4.4% fat; 0.06% cholesterol), apoE^{-/-} mice had a significantly higher T-CHO and a significantly lower HDL-CHO at all time periods versus age-matched C57BL/6 J mice (Table 1). Serum triglycerides were not significantly different. Of note is that a significant steady decrease in HDL-CHO was observed from month 1 to 5 in apoE^{-/-} mice. The results indicated that the apoE^{-/-} mice available for study to be a representative and would serve as a viable apoE^{-/-} model. Certain assumptions were made, i.e. that there would be significant liver and aortic lipid accumulation.

Recombinant StAR Gene was Successfully Expressed in ApoE^{-/-} Mice

To determine if StAR protein was being overexpressed following mouse infection with Ad~CMV~StAR, 6 days following infection selected organs were screened for StAR protein expression by immunohistochemistry and Western blotting. After infection, StAR expression was higher in the mice infused with adenovirus encoding CMV-StAR than the other two groups in heart, coronary artery and liver tissue. The increases of StAR in the heart and coronary arteries were marginal (Fig. 1a). StAR protein was detected in the adrenal gland, spleen, liver, and lung of controls (NS: normal saline, Ad~CMV~EGFP), with large amounts of StAR found in the spleen and adrenal gland. Following Ad~CMV~StAR infection, StAR protein was found in all

Table 1 Increased plasma lipid levels in apoE^{-/-} mice

Mice	Total cholesterol		Triglyceride		HDL-cholesterol

major organs after StAR overexpression as shown in **b**. NS apoE^{-/-} mice injected with normal saline, EGFP apoE^{-/-} mice injected with control adenovirus encoding CMV-EGFP, StAR apoE^{-/-} mice injected with adenovirus encoding CMV-StAR. Bar 10 μ m

tested tissues with the largest increases found in the liver, a known reservoir for infecting adenovirus (Fig. 1b).

Liver Transaminases

Serum ALT, AST, and ALP activity levels in mice were measured to determine if there was liver injury following adenovirus infection. No significant differences were observed among the three groups of NS, Ad ~ CMV ~ StAR and Ad ~ CMV ~ EGFP (data not shown).

Transduction of Ad ~ CMV ~ StAR Decreases Lipid Accumulation in the Serum and Liver of ApoE^{-/-} Mice

Sera six days following infection with Ad ~ CMV ~ StAR, the serum T-CHO and TG were 19 and 30% ($P < 0.01$) lower in apoE^{-/-} mice receiving Ad ~ CMV ~ StAR than in those receiving NS or Ad ~ CMV ~ EGFP, respectively. In contrast, there was a dramatic reversal in the HDL-CHO levels with HDL-CHO in their plasma about 40% higher ($P < 0.01$) than controls (Table 2).

Liver tissues Liver sections stained with Oil Red O to evaluate the hepatic accumulation of lipids showed that the lipid levels were significantly less in the livers of Ad ~ CMV ~ StAR mice as compared to NS and Ad ~ CMV ~ EGFP mice (Fig. 2a). To confirm these results, lipids were extracted from the liver tissues and measured using commercial colorimetric kits for both cholesterol and triglycerides (Rongsheng Biotechnology Company Ltd, Shanghai, China). The hepatic cholesterol and triglyceride concentrations in the Ad ~ CMV ~ StAR mice decreased 25 and 56% ($P < 0.01$) as compared to NS and

Ad ~ CMV ~ EGFP mice, respectively (Fig. 2b, c). There were no significant differences in hepatic cholesterol and triglyceride levels between the NS and Ad ~ CMV ~ EGFP groups (Fig. 2b, c).

Transduction of StAR Reduces Aortic Neutral Lipid Accumulation in ApoE^{-/-} Mice

A previous study has shown that apoE^{-/-} mice will develop visible aortic lipid accumulation at 20 weeks on a normal mouse diet [23]. We found the microscopic presence of aortic lipid accumulation by the 3rd month with accumulation grossly visible by the 5th month in apoE^{-/-} mice fed a similar diet. Six days following Ad ~ CMV ~ StAR transduction, examination en face of aortas from

Fig. 2 Transduction of Ad~CMV~StAR decreases lipid accumulation in the liver of apoE^{-/-} mice fed with normal diet. **a** Oil Red O-stained liver sections (*bar* 10 μ m) of apoE^{-/-} mice. **b** Total hepatic cholesterol. **c** Hepatic triglyceride. Data are mean \pm SD. ***P* < 0.01 versus NS mice. ##*P* < 0.01 versus Ad~CMV~EGFP mice. NS apoE^{-/-} mice injected with normal saline (*n* = 11). EGFP apoE^{-/-} mice injected with control adenovirus encoding CMV-EGFP (*n* = 9). StAR apoE^{-/-} mice injected with adenovirus encoding CMV-StAR (*n* = 9)

Ad~CMV~StAR injected mice using ImageM software revealed significantly less neutral lipid than in NS or Ad~CMV~EGFP mice (Fig. 3a). The amount of lipid accumulation in aortas between NS and Ad~CMV~EGFP mice was found to not be different (Fig. 3a). The accumulated area of lipid stained lesions had decreased from $21.03 \pm 2.66\%$ and $19.42 \pm 2.39\%$ in NS and Ad~CMV~EGFP mice, respectively, to $3.74 \pm 1.57\%$ (Fig. 3b).

Discussion

Hyperlipidemia is an important risk factor for atherosclerosis. The treatment response to current medications is frequently inadequate. Therefore, there remains great interest in developing new therapeutic strategies. Based upon recent observations, it was hypothesized that facilitating mitochondria-directed cholesterol transport could elicit in an in vivo model a sequence of metabolic events resulting in both serum and tissue cholesterol lowering. The current study was designed to explore this hypothesis by increasing expression of StAR, a mitochondrial directed cholesterol transport protein, in a well-described animal model of dyslipidemia.

Fig. 3 Effect of transduction of StAR on aortic lipid accumulation in apoE^{-/-} mice. **a** En face staining of Sudan IV-stained aortas of mice fed with normal diet. Arrows indicate neutral lipid stained plaques. **b** Quantification of neutral lipid staining presented as percentage of total en face aorta surface area of mice fed with normal diet (see “Experimental Procedure”). ***P* < 0.01 versus NS. ##*P* < 0.01 versus Ad~CMV~EGFP. NS, EGFP and StAR represent apoE^{-/-} mice injected with normal saline, control adenovirus encoding CMV-EGFP, and adenovirus encoding CMV-StAR, respectively

Cholesterol metabolism as initiated via mitochondrial CYP27A1 is subsequently metabolized to key regulatory oxysterols of cholesterol homeostasis; and within the liver, continued catabolism to bile acids. For proper function, inner mitochondrial cholesterol levels must be tightly controlled, and it has been suggested that the key function of CYP27A1 is to initiate the metabolism of cholesterol to a metabolite that can be more easily mobilized out of the mitochondria. As CYP27A1 has been detected in all examined peripheral tissues as well as the liver, others have suggested that the conversion of cholesterol to 27-hydroxycholesterol as important under conditions of cholesterol excess. Under these conditions it has been proposed that the 27-hydroxylation can facilitate a process of reverse cholesterol transport of cholesterol from peripheral tissues to the liver with 27-hydroxycholesterol's subsequent elimination as bile acids [16, 33–36]. In support of this hypothesis, CTX (Cerebrotendinous xanthomatosis), characterized by the inability of cells to 27-hydroxylate sterols, is associated in humans with early dementia, premature atherosclerosis, and cataracts due to abnormal tissue sterol accumulation [37, 38]. As a function of these observations, CYP27A1 was overexpressed in transgenic mice, but interpreted as having little appreciable effect on lipid metabolism [39]. We also found that following overexpression of CYP27A1 in hepatocyte cultures only a modest increase in the rates of bile acid synthesis was observed as compared to the 8 to 10-fold increase consistently seen following CYP7A1 overexpression [40]. This suggested that inner mitochondrial substrate availability could be the rate-determining step in the CYP27A1-initiated pathway.

As described, StAR has been shown to not only facilitate cholesterol delivery to the inner mitochondrial cholesterol side-chain cleavage system in the initiation of steroidogenesis, but that increasing its expression would markedly increase steroidogenesis [9, 10]. Applying this concept to hepatocytes, we demonstrated that increased StAR expression markedly increased the rates of bile acid synthesis (BAS) in both in vitro and in vivo models [16, 21]. Our inability to up-regulate bile acid synthesis in CYP27A1^{-/-} mouse hepatocytes demonstrated that StAR's effects were mediated through the CYP27A1-initiated pathway [17].

Recently, Ren et al. demonstrated for the first time that CYP27A1 also metabolizes cholesterol to 25-hydroxycholesterol. 25-hydroxycholesterol, in a manner like 27-hydroxycholesterol, can down-regulate cholesterol synthesis, stimulate cholesterol secretion and stimulate fatty acid synthesis [17, 18]. Sulfated 25-hydroxycholesterol, a newly uncovered and subsequent metabolite of 25-hydroxycholesterol, like its precursor, also down-regulates cholesterol synthesis [17–19]. However, in direct contrast to 25-hydroxycholesterol and 27-hydroxycholesterol,

sulfated 25-hydroxycholesterol down-regulates fatty acid synthetase [19]. Furthermore, it is capable of activating PPAR γ , a nuclear receptor known to play a role in the redistribution of body fat as well as increase tissue insulin responsiveness [41, 42]. All three oxysterols are increased following increased StAR expression as evidenced by their increased cytosolic and nuclear levels [16, 18, 21, 30]. Furthermore, in addition to their intestinal lipid solubilization properties, bile acids, an end product of cholesterol/27-hydroxycholesterol metabolism, are also known regulators of key steps of lipid homeostasis [43–45].

Based on these observations, we hypothesized that increased cholesterol metabolism as initiated by the CYP27A1 pathway and stimulated by increased StAR expression would result, not only in increased cholesterol elimination as bile acids, but elicit a homeostatic response as a function of increased levels of at least three known regulatory oxysterols. More specifically, these oxysterols, working in a coordinate fashion, should lead to decreased cholesterol synthesis and increased cholesterol export; responses that would be expected to decrease serum and tissue cholesterol levels. Although not originally considered, a metabolic response in fatty acid metabolism should have been entertained given how tightly cholesterol and fatty acid metabolism are interwoven.

The apoE^{-/-} mouse was chosen as the animal model to explore this hypothesis as it is a well studied model of atherogenesis that on a rodent chow diet will develop serum and tissue dyslipidemia as it ages. The model was first confirmed with serum lipid analysis. As predicted, based upon prior in-vivo studies in rats and mice, 6 month old mice tolerated the level of increased StAR expression for 6 days without any detectable adverse effects or dietary differences from controls. Increased StAR expression led to a dramatic normalization of both serum and tissue cholesterol levels in apoE^{-/-} mice. Serum and tissue triglyceride levels demonstrated an even greater response. These responses demonstrate for the first time a possible therapeutic role for the CYP27A1-initiated pathway in the treatment of dyslipidemias.

Abstract Most epidemiological surveys have confirmed the association of low HDL-cholesterol and high triglyceride levels with cholesterol gallstones. Our objective was to analyze the relationship between plasma lipid levels and common polymorphisms of *ABCB11* (encoding the bile salt export pump, BSEP) and *ABCB4* (encoding the phospholipid transporter into bile, MDR3) genes. Plasma lipids were measured in 108 index patients of sib pairs with gallstones and in 260 controls. Using PCR-based assays with 5'-nuclease and fluorescence detection (TaqMan), the *ABCB11* coding SNP p.A444V and four haplotype-tagging SNPs covering the *ABCB4* gene (c.504C > T, c.711T > A, p.R652G, *rs31653* in intron 26) were genotyped. Plasma lipids were compared in carriers of the common versus rare allele of these polymorphisms using Student's *t* test and Pearson's correlation. BMI and triglyceride levels were higher and HDL-cholesterol levels were lower in affected siblings than in controls. Among cases, triglyceride and cholesterol levels were higher in carriers of the common versus rare (hetero/homozygous carriers) allele of the SNPs p.A444V of *ABCB11* and C.504C > T of *ABCB4*. HDL-

cholesterol was lower in carriers of the common allele of *rs31653*. In controls, significant differences of cholesterol and HDL-cholesterol levels were found in carriers of *ABCB4* polymorphisms. Our results do not support the hypothesis of a link between *ABCB4* and *ABCB11* polymorphisms, lithogenic dyslipidemia, and gallstone risk.

Keywords Serum triglycerides · HDL cholesterol · Gallstones · Candidate genes · Polymorphisms · *ABCB4* · *ABCB11*

Introduction

The prevalence of cholesterol gallstone disease is rising in industrialized countries in Europe and North America [1–6]. Given the higher incidence at advanced ages, the longer life expectancy of the population, and the high costs of cholecystectomy, gallstones are a significant burden for these societies. Sustained efforts are presently directed to elucidate the genetic susceptibility factors of this common disease, with the objective of identifying high-risk groups and preventing gallstone formation.

Although supersaturation of bile with cholesterol is a prerequisite of lithogenesis, and cholesterol and bile acids in bile are the only ways of eliminating cholesterol from the body, even the largest series did not find an association between serum cholesterol level and gallstones. However, most case-control studies have confirmed the association of low serum HDL-cholesterol levels and hypertriglyceridemia with cholesterol gallstones [7, 8].

In a previous study we found that some common polymorphisms in the *ABCG5/ABCG8* genes, which encode the hepatic cholesterol transporter into bile, were significantly associated with high triglyceride and low HDL-cholesterol

levels in siblings with gallstones, in contrast to gallstone carriers without positive family history [9].

Cholesterol gallstone formation is not only because of elevated biliary cholesterol concentrations, but also related to the bile acid and phospholipid contents of bile.

Serum lipid profiles in patients with rare mutations causing familial intrahepatic cholestasis are scarce, but point to increased triglyceride levels and the appearance of triglyceride-rich LDL particles in the setting of normal total cholesterol and low HDL levels [10–12], which are reminiscent of alterations reported for gallstone patients. Therefore, we have now evaluated levels of plasma lipids in siblings with gallstones in relation to common polymorphisms in the *ABCB4* and *ABCB11* genes encoding the hepatobiliary phospholipid and bile acid transporters, respectively. *ABCB11* (the gene encoding BSEP, the bile salt export pump) and *ABCB4* (the gene encoding MDR3, the phospholipid transporter across the canalicular membrane of the hepatocyte) have been designated as candidate genes for gallstone formation in mice, but studies in humans regarding the association of common variants of these genes with gallstone disease are sparse.

Materials and Methods

Subjects

All subjects were recruited prospectively at the Department of Gastroenterology, University of Cluj-Napoca, between November 2002 and April 2007.

The inclusion criteria for patients were: previous cholecystectomy for gallbladder stones or actual gallbladder stones (abdominal ultrasound) plus a family history of gallstone disease (at least one sibling with gallstones). Age, sex, and body mass index (BMI) were recorded on inclusion in the study. From 229 siblings with gallstones, belonging to 108 sib pairs, the index patients (i.e. the first ones recruited from each pair) were analyzed—94 females and 14 males with a mean age of 54.6 ± 11.2 years.

The inclusion criteria for the controls were: absence of gallstones or cholecystectomy, no relation to cases, and negative personal or family history of gallstone disease. Controls were comparable with cases with respect to ethnicity, geographical residence, hospitalization, and time of recruitment. Two hundred and sixty controls matched for gender and age were recruited (228 females and 32 males, mean age 52.9 ± 10.9 years).

Informed consent was obtained from each subject included in the study. The study protocol was approved by the Ethical Committee of the University of Medicine and Pharmacy at Cluj-Napoca.

Clinical Chemistry

Plasma levels of cholesterol, HDL-cholesterol, and triglycerides were assessed, after an overnight 12-h fast, by use of standard enzymatic colorimetric methods (Konelab 30 equipment, Finland).

Genotype Analysis

Genomic DNA was isolated using the QIAamo DNA extraction procedure (Qiagen). Employing PCR-based assays with 5'-nuclease and fluorescence detection (Taq-Man), the following SNPs were genotyped: the *ABCB11* coding SNP p.A444V (*rs2287622*), which is known to affect transporter expression (*rsXX*), and four haplotype-tagging SNPs covering the *ABCB4* gene (c.504C > T – *rs1202283*; c.711T > A – *rs2109505*; p.R652G – *rs8187799*; *rs31653* in intron 26), which were identified in our previous study [13].

Statistical Analysis

Results are expressed as mean \pm standard deviation (SD). Siblings with gallstone disease were divided into:

1. homozygotes for the common allele, and
2. heterozygotes or homozygotes for the minor allele.

Allele and genotype frequencies between cases and controls were compared by use of the χ^2 test and Armitage's trend test, respectively. Plasma lipid values were analyzed in cases and controls, and in carriers of the common allele versus carriers of the rare allele of the studied polymorphisms by using Student's *t* test for independent variables. Statistical significance was defined as a probability of $P < 0.05$. The correlation between lipid levels and BMI was calculated using Pearson's correlation coefficient.

Power Calculation

Power calculations were performed using the P&S power and sample size program that is available online (<http://biostat.mc.vanderbilt.edu>). The study population was designed to detect a 2.5-fold increase of relative risk with a power of 85% based on a frequency of the risk allele of ≥ 0.1 (significance level 0.05).

Results

We analyzed 108 index patients with gallstones belonging to 108 distinct families. Most (96; 88.8%) pedigrees

consisted of two affected siblings; eleven pedigrees contained three affected siblings, and one pedigree was composed of four affected siblings.

BMI and plasma lipid levels were significantly different in the index patients of the sib pairs than in controls. Triglyceride levels were higher, whereas total and HDL-cholesterol levels were lower in siblings with gallstones (Table 1).

Allele and genotype frequencies for index patients and controls are given in Table 2. Of note, all minor allele frequencies are >5%, indicating that the polymorphisms are common in our population. Allele and genotype frequencies did not differ between cases and controls (all $P > 0.05$).

Significant differences were found for the following plasma lipid levels in the index patients of the sib pairs with gallstones (Table 3): higher triglyceride levels in carriers of the common versus rare alleles of the *ABCB11* SNP *rs2287622*, higher triglyceride and cholesterol levels in carriers of the common allele of the *ABCB4* polymorphism *rs1202283*; and lower HDL-cholesterol in carriers of the common allele of the *ABCB4* SNP *rs31653*.

Among the index patients, we found a correlation between plasma triglyceride levels and BMI for carriers of the rare allele of SNP *rs1202283* ($r = 0.266$, $P < 0.05$), and for carriers of the common alleles of *rs2109505* ($r = 0.219$, $P < 0.05$) and *rs8187799* ($r = 0.227$, $P = 0.02$), all of which are located in the *ABCB4* gene. No correlations of triglyceride levels with age or with other polymorphisms of the two genes studied were detected in these patients.

In controls, the following plasma lipid changes were significant (Table 4): higher cholesterol levels in carriers of the common versus rare alleles of SNPs *rs2109505* and *rs8187799*, and lower HDL-cholesterol for carriers of the rare versus common allele of *rs31653*. No changes of the triglyceride levels were found between carriers of the common and rare alleles of these polymorphisms.

When we compared the index patients with the controls, we found significant differences for triglyceride levels,

which were higher in siblings than in controls for carriers of the common alleles of almost all the polymorphisms studied. Cholesterol levels were higher in controls for carriers of the common alleles of the polymorphisms *rs2109505* and *rs8187799*, and HDL-cholesterol levels were lower in siblings versus controls for carriers of the rare alleles of SNPs *rs2287622* and *rs1202283* and of the common allele of SNP *rs31653*. These differences were in accordance with those between the mean values of triglyceride and HDL-cholesterol levels in affected siblings and controls (Table 1).

Discussion

Cholesterol gallstone disease is a complex disease, characterized by a genetic (polygenic) predisposition to develop gallstones associated with an important environmental effect. Many of the environmental (modifiable) risk

factors—obesity, rapid weight loss, hypertriglyceridemia, high calorie diet, highly absorbable sugars, low fibre diet—have been identified in epidemiological studies and measures targeting them have been included in the preventive strategy for gallstone formation. The current challenge is to identify the genetic factors determining susceptibility to lithogenesis, and research is very intense both in experimental models and in humans. More than 20 cholesterol

gallstone susceptibility genes (*Lith*) have been identified in mice by quantitative trait locus (QTL) mapping.

In humans, in most cases, no Mendelian inherited trait could be demonstrated for gallstone disease. With the exception of cholesterol gallstone disease associated with low biliary phospholipid levels because of rare mutations in the *ABCB4* gene [14–16] and of gallstone disease induced by single mutations in the cholesterol 7-alpha

hydroxylase gene (*CYP7A1*) [17] or the gene encoding the CCK receptor A [18], no variants have been linked to cholesterol gallstones. Additional analyses regarding common variants of *ABCB4* [19], *ABCB11* [19, 20], and *CCKAR* [21] did not confirm their association with cholesterol gallstone disease in the populations studied.

A translational study that confirmed an association of a mouse *Lith* locus (*Lith9* on chromosome 17) as a susceptibility factor for cholelithiasis in humans, or a human *LITH* gene, was recently reported [22]. The polymorphism *rs11887534* (p.D19H) of the *ABCG8* gene, which encodes the hepatobiliary cholesterol hemitransporter, is the first identified susceptibility factor for gallstones in humans [22, 23]. Our previous study of plasma lipid levels in siblings with gallstones, carriers of common polymorphisms of *ABCG5/ABCG8*, identified significant associations of SNP *rs11887534* with plasma cholesterol and triglyceride levels [9].

There have been no previous studies evaluating the plasma lipid profile in carriers of the common polymorphisms of the genes encoding the membrane transporters of the other two major lipids into bile, phospholipids and bile acids. We evaluated plasma lipid levels in patients with gallstones and a positive family history (at least one sibling with gallstones) and in controls with a negative family history in order to find evidence of a possible relationship with common polymorphisms of the *ABCB4* (*MDR3*) and *ABCB11* (*BSEP*) genes.

The *ABCB4* gene encodes the hepatic canalicular transporter for the major phospholipid phosphatidylcholine, which acts as a phospholipid floppase [24]. *ABCB4* mutations result in a wide spectrum of phenotypes, ranging from progressive familial intrahepatic cholestasis (PFIC type 3) to intrahepatic cholestasis of pregnancy or intrahepatic and gallbladder microlithiasis (low phospholipid associated cholelithiasis, LPAC syndrome) [14, 15, 25]. The *Mdr2*^{-/-} mouse model supports the concept that this gene is a monogenic risk factor for cholesterol gallstones [26]. Some variants of *ABCB4* have been identified and studied in women with intrahepatic cholestasis of pregnancy [13, 27]. Although rare *ABCB4* variants contribute to gallstone formation in LPAC, studies investigating the relationship between gallstone susceptibility and common *ABCB4* polymorphisms in German patients failed to find an association [19].

The bile salt export pump (BSEP) encoded by the *ABCB11* gene is also a member of the ABC transporter family. BSEP is the major hepatocanalicular efflux system for the excretion of conjugated bile salts. Inhibition of BSEP by some drugs might lead to drug-induced cholestasis. Defects in the gene coding for BSEP can cause hereditary disorders such as progressive familial intrahepatic cholestasis (PFIC type 2), whereas some missense

mutations have been found to cause benign recurrent intrahepatic cholestasis (BRIC type 2) [28]. *Abcb11* (*Bsep*) co-localizes with the *Lith1* locus in mice, and congenic mouse strains carrying susceptible *Lith1* alleles develop cholesterol gallstones when fed a lithogenic diet [29]. Nevertheless, further studies failed to find different levels of the BSEP protein in gallstone-susceptible versus resistant strains of mice [30]. In humans, a study performed in the POPGEN cohort in Northern Germany [20] showed that the common gallstone trait is not allelic to PFIC type 2 at the *ABCB11* locus. Recent studies have confirmed that the common *ABCB11* coding SNP *rs2287622* (p.A444V), which is known to affect transporter expression [31, 32], is not associated with an increased risk of gallstones [19].

In this study we evaluated sibling pairs in whom the *ABCG8* variant *rs11887534* has been found to confer genetic susceptibility to gallstone disease [22]. The relationship of plasma lipid values to common variants of the genes controlling two other hepatobiliary lipid transporters (*ABCB4* and *ABCB11*) were compared between siblings with gallstones and controls without gallstones. Although plasma lipid levels were significantly different among these groups for carriers of common alleles of some polymorphisms (Table 3), these differences were similar to those found between the mean values of plasma lipids in patients and controls (Table 1). We did not find any association between plasma lipid levels and the common variants of *ABCB11* and *ABCB4* in gallstone-affected siblings as compared with stone-free controls.

Our results do not support the hypothesis of a link between *ABCB4* and *ABCB11* common variants and gallstone risk and confirm previous studies suggesting that common polymorphisms of these genes are not related to gallstone susceptibility.

Abstract Bile acids constitute a group of structurally closely related molecules and represent the most abundant constituents of human bile. Investigations of bile acids have garnered increased interest owing to their recently discovered additional biological functions including their role as signaling molecules that govern glucose, fat and energy metabolism. Recent NMR methodological developments have enabled single-step analysis of several highly abundant and common glycine- and taurine- conjugated bile acids, such as glycocholic acid, glycodeoxycholic acid, glycochenodeoxycholic acid, taurocholic acid, taurodeoxycholic acid, and taurochenodeoxycholic acid. Investigation of these conjugated bile acids in human bile employing high field (800 MHz) ^1H -NMR spectroscopy reveals that the ratios between two glycine-conjugated bile acids and their taurine counterparts correlate positively ($R^2 = 0.83\text{--}0.97$; $p = 0.001 \times 10^{-2}\text{--}0.006 \times 10^{-7}$) as do the ratios between a glycine-conjugated bile acid and its taurine counterpart ($R^2 = 0.92\text{--}0.95$; $p = 0.004 \times 10^{-3}\text{--}0.002 \times 10^{-10}$). Using such correlations, concentration of individual bile acids in each sample could be predicted in good agreement with the experimentally determined values. These insights into the pattern of bile acid conjugation in human bile between

glycine and taurine promise useful clues to the mechanism of bile acids' biosynthesis, conjugation and enterohepatic circulation, and may improve our understanding of the role of individual conjugated bile acids in health and disease.

GDCA	Glycodeoxycholic acid
GCDCA	Glycochenodeoxycholic acid
TCA	Taurocholic acid
TDCA	Taurodeoxycholic acid
TCDCa	Taurochenodeoxycholic acid
NMR	Nuclear magnetic resonance

Introduction

Bile acids constitute a group of structurally closely related molecules. Their steroid-like moieties consist of mono-, di-, or tri-hydroxy groups. Tri- and di-hydroxy bile acids, such as cholic acid and chenodeoxycholic acid, respectively, are known as primary bile acids because they are biosynthesized from cholesterol in hepatocytes. The others are known as secondary bile acids. Secondary bile acids are thought to be the products of gut bacterial deconjugation during enterohepatic circulation. In human bile, both primary and secondary bile acids are normally conjugated to glycine or taurine. Conjugated bile acids are the major components of human bile, with their total concentration exceeding that of any other metabolite in bile.

Bile acids have long been known to play an important, but less appreciated, biological role in lipid absorption and cholesterol catabolism. Recently, they have also been recognized as signaling molecules with systemic endocrine functions [1]. In addition, it is shown that increased bile acid levels facilitate liver regeneration and decreased levels inhibit re-growth [2]. The role of bile acids in maintaining energy homeostasis has been recently highlighted [3]. Strong evidence for a previously unknown mechanism by which conjugated bile acids facilitate their antimicrobial effects in the small intestine was recently presented [4]. Bile acids are also shown to have close links with human diseases including hepatocellular carcinoma and cholangiocarcinoma [5–8]. Key differences in bile acid metabolism observed in diabetes based on investigations of human subjects, suggest yet another important role of bile acid metabolism [9, 10].

The link between bile acids and a multitude of deleterious effects in humans has increased the interest in better understanding of the bile acid physiology [11, 12]. Although, mass spectrometry based methods are highly useful for analyzing bile acids, establishing the relationship between glycine- and taurine-conjugation has not been possible so far [13–16]. This may be due to the tedious and often not so reproducible separation procedures associated with such analysis methods. In contrast, NMR spectroscopy is highly reproducible and quantitative. Hence, it is an attractive technique for analyzing a large number of bile acids in a single-step, particularly when the concentration is not a limiting factor. Recently, from a series of comprehensive NMR studies of human bile and authentic bile acids, we reported simple NMR methodologies for detecting and quantifying major bile metabolites including a number of conjugated bile acids in human bile [17–20]. Subsequently, using these methods we have shown significant differences in the concentrations of bile metabolites between liver disease patients and controls [21]. Such developments would be useful for discovering biomarkers in light of the emerging area of ‘metabolomics’, which is based on single-step analysis of multiple metabolites in biological systems [22–27]. In the present study, we hypothesized that understanding of the conjugation pattern of bile acids is important to explore its pathophysiological significance in human health and disease. Accordingly, continuing our studies of human bile, we have investigated bile acids conjugation pattern using NMR spectroscopy at high magnetic fields (800 MHz). The investigations reveal that glycine- and taurine-conjugation of bile acids in human bile is not random, but follows a highly correlative pattern. Such findings open new avenues for exploring physiology of bile acids in health and understanding the possible links between conjugation pattern and liver diseases.

Materials and Methods

Chemicals

Deuterium oxide (D_2O), and sodium salt of trimethylsilylpropionic acid- d_4 (TSP) were purchased from Sigma-Aldrich (Milwaukee, WI, USA).

Human Gallbladder Bile

Gallbladder bile was obtained from 44 patients (22 male; 22 female; mean age 50.7 years). These included both liver disease ($n = 27$) and non-liver disease patients ($n = 17$). Liver disease included both malignant, hepatocellular carcinoma ($n = 10$) and cholangiocarcinoma ($n = 7$), and non-malignant ($n = 9$) disease patients. Non-malignant liver disease included patients with alcoholic cirrhosis ($n = 3$); cirrhosis due to hepatitis C infection ($n = 3$); non-alcoholic steatohepatitis cirrhosis ($n = 1$); choledochal cyst ($n = 1$) and primary sclerosing cholangitis ($n = 1$).

Bile Collection and Storage

Gallbladder bile was taken at the beginning of the case, prior to any devascularization of the gallbladder. A purse string suture was placed in the fundus of the gallbladder. Through an 18-gauge needle, 10 mL of bile was removed and placed immediately into a red top tube treated with 0.1% sodium azide. The suture was tied down to eliminate any bile leakage and the gallbladder taken off the liver. Bile specimen was then divided into 1-mL aliquots and stored at $-80^\circ C$ until analysis. An Institutional Review Board protocol, approved at both Indiana University School of Medicine and Purdue University, was in place for the collection, storage, and analysis of human bile for research purposes.

NMR Experiments

All 1H -NMR experiments were performed on a Bruker Biospin Avance 800 MHz NMR spectrometer using a 5-mm CHN inverse probehead equipped with automatic tune and match, and shielded triple axis (x, y, z) gradients.

Bile solutions were prepared for NMR analysis by diluting 100 μL of bile to 600 μL using doubly distilled water. A reusable co-axial capillary tube containing TSP in D_2O was inserted into the NMR tube before recording 1H -NMR spectra. While D_2O served as a field-frequency locking solvent, TSP served as chemical shift as well as a quantitative reference. Recently, from the comprehensive analysis of bile 1H -NMR spectra, we have shown that the characteristic amide signals constituting three

glycine-conjugated bile acids, glycocholic acid (GCA), glycodeoxycholic acid (GDCA), glycochenodeoxycholic acid (GCDCA), and their taurine counterparts, taurocholic acid (TCA), taurodeoxycholic acid (TDCA) and taurochenodeoxycholic acid (TCDCA), invariably appear in the region 7.8–8.1 ppm [20]. We have also shown that these bile acids signals are better distinguished when the coupling between amide protons and the attached methylene protons is removed by decoupling. Hence, one dimensional $^1\text{H-NMR}$ spectra were obtained using a one pulse sequence with (and without) homonuclear decoupling of the methylene protons. Simultaneous decoupling of the amide protons of all the conjugated bile acids was achieved by setting the decoupling frequency at 3.65 ppm, in between the chemical shifts of methylene protons of conjugated taurine (3.56 ppm) and conjugated glycine (3.75 ppm).

It is shown from the experiments performed at different pH that the amide signals of individual conjugated bile acids represent more quantitatively over the pH range 6 ± 0.5 [18, 20]. Hence, the pH of each bile solution was adjusted to this range by the addition of 1–2 μL of 1 N hydrochloric acid. Typical parameters used were: spectral width: 12,000 Hz; time domain data points: 32 K; flip angle: 45° ; acquisition time: 1.4 s; relaxation delay: 3 s; number of transients: 64; spectrum size: 32 K points. This resulted in an acquisition time of 4.6 min for each NMR experiment. Water signal suppression was achieved by presaturation during the relaxation delay while

homonuclear decoupling was performed during the data acquisition. The recycle delay was chosen based on the optimization studies performed earlier using delays varying from 1 to 10 s [20]. Thus, we rule out any change in intensity of the amide signals either due to relaxation or NOE buildup during decoupling of the adjacent methylene protons.

Quantitative Estimation of Individual Conjugated Bile Acids

Peak areas for the characteristic bile acids' amide signals (between 7.8 and 8.1 ppm; see Figs. 1, 2) and the TSP reference were obtained by integration. The total bile acid concentration in each bile sample was first determined using these integrals and the concentration of the reference compound after taking into account the number of protons contributed from the bile acids as well as the reference compound. Subsequently, the relative area under each conjugated bile acid signal was determined by signal deconvolution using Bruker xwinnmr software. For the deconvolution of the spectra, Lorentzian line shape was used. The concentration of individual bile acids was then determined using the relative integrals of individual bile acids and the amount of total bile acids as determined above. Decoupled spectra were used for the analysis of bile acids.

Assessment of Bile Acids Conjugation

Glycine- and taurine-conjugation in human bile samples was assessed by comparing the bile acids individually and in the following combinations. (1) The ratio between glycine- and the corresponding taurine-conjugated bile acid in different bile samples was assessed by comparison. (2) The ratio between two glycine-conjugated bile acids was compared with the ratio between the corresponding taurine-conjugated counterparts. (3) The ratio between a glycine-conjugated bile acid and its taurine-conjugated counterpart was compared with the ratio between another glycine-conjugated bile acid and its taurine-conjugated counterpart. Linear regression analysis was performed for the ratios obtained in the latter two steps (steps 2 and 3) to estimate the inter-relationship between the ratios of the bile acids.

Finally, concentration of each conjugated bile acid was predicted using experimentally determined values of the other three bile acids. This prediction was based on the results of the regression analysis as described below which indicate that the ratio between two glycine-conjugated bile acids linearly correlates with the ratio between the

corresponding taurine-conjugated bile acids or, alternatively, the ratio between a glycine-conjugated bile acid and its taurine-conjugated counterpart linearly correlates with the ratio between another glycine-conjugated bile acid and its taurine-conjugated counterpart. The predicted bile acids concentrations were then compared with the experimentally determined values from the NMR spectra for the six conjugated bile acids, individually.

Statistical Analysis

All linear regression analyses were made using Microsoft Excel and R statistical package (version 2.8.1). The Excel software was first used to calculate the ratios of various combinations of the glycine- and taurine-conjugated bile acids (*TCA/TCDC*A, *GCA/GCDCA*, *TCA/TDC*A, *GCA/GDCA*, *TDCA/TCDC*A, *GDCA/GCDCA*, *GCA/TCA*, *GCDCA/TCDC*A, *GCA/TCA*, *GDCA/TDC*A, *GCDCA/TCDC*A versus *GDCA/TDC*A) for each patient using the concentration of individual bile acids obtained from ^1H -NMR spectra. The plots of the ratio of *TCA/TCDC*A versus *GCA/GCDCA*, *TCA/TDC*A versus *GCA/GDCA*, *TDCA/TCDC*A versus *GDCA/GCDCA*, *GCA/TCA* versus *GCDCA/TCDC*A, *GCA/TCA* versus *GDCA/TDC*A and *GCDCA/TCDC*A versus *GDCA/TDC*A were then made to assess the correlation of the ratios. Subsequently, using the Excel software, the linear regression analysis was made and, the equations for the line-fitting and the correlation coefficient (R^2) were determined. Further, the statistical significance of the correlations was determined using the R program using Pearson product moment correlation analysis.

Results

This investigation aims at understanding the conjugation pattern of glycine- and taurine-conjugated bile acids in humans. Considering the fact that the glycine and taurine conjugation depends on a number of factors and the amount of bile acids varies widely between the two types even across the non-liver disease patients (as shown later), it will not be possible to trace possible relationship between the two types of bile acids in humans from a glycine- and a taurine-conjugated bile acids. It thus necessitated comparison of the ratios of a pair of glycine- conjugated bile acids with the corresponding pair of taurine-conjugated bile acids. Hence, all the bile samples that showed less than a pair of glycine and the corresponding taurine-conjugated bile acids were omitted from the analysis (see for example, supplementary Fig. S1). In addition, four bile samples in which individual bile acids could not be quantified

Table 1 Patient profile and the number of bile acids observed by NMR

Disease type	Number of patients	Number of patients in which all six conjugated bile acids were detected ^a	Number of patients in which only four conjugated bile acids were detected ^b
Hepatocellular carcinoma	6	2	4
Cholangio-carcinoma	3	1	2
Hepatitis C	2	0	2
Alcoholic cirrhosis	1	0	1
Non-alcoholic steatohepatitis cirrhosis	1	0	1
Non-liver disease	11	7	4

^a Six bile acids detected were GCA, GCDCA, GDCA, TCA, TCDCA, and TDCA

^b Secondary bile acids, GDCA, and TDCA, were not detected in these patients

accurately due to excessive line broadening were also omitted to avoid possible error in the measurement of the signal integrals adversely influencing the outcome of the study (see for example, supplementary Fig. S2). Of the 44 bile samples, 24 met the minimum requirement which were used for evaluating the bile acids conjugation pattern. Table 1 shows the patient profile and the number of conjugated bile acids detected in each category of patients considered in this study.

Figure 1 shows a typical one-dimensional ¹H-NMR spectrum of intact human gallbladder bile obtained at 800 MHz. Owing to the amphipathic nature of major bile metabolites such as phospholipids, cholesterol and bile acids which exist in aggregated form, the spectral lines appear somewhat broad as seen in the figure. All major metabolites which contribute to the bulk of the complex NMR spectra of bile have recently been individually identified by exhaustive NMR studies at different magnetic fields [20]. Six of the metabolites were bile acids conjugated to glycine or taurine (GCA, GCDCA, GDCA, TCA, TCDCA, and TDCA). In the present study, all the six conjugated bile acids were observed in 14 of 24 bile samples, while only four (GCA, GCDCA, TCA, and TCDCA) were observed in the remaining 10 (Table 1). It may be noted that, in the entire set of 24 bile samples, all the glycine- conjugated bile acids were the counterparts of the taurine-conjugated bile acids or vice versa.

Not surprisingly, the concentration of the individual bile acids varied significantly across the sample set as shown in Figs. 2 and 3. Even the ratios between the total glycine- and taurine-conjugated bile acids (Fig. 4a) or between a glycine-conjugated bile acid and its taurine counterpart varied significantly (Fig. 4b–d). Interestingly, however, the ratios between two glycine-conjugated bile acids and between their taurine counterparts linearly correlated (Fig. 5) and the significance of the correlations was very high for all the ratios. The correlation coefficients and p values were, $R^2 = 0.83$ and $p = 0.006 \times 10^{-7}$ for the correlation of ratio of GCA and GCDCA with the ratio of TCA and TCDCA (Fig. 5a); 0.97 and 0.004×10^{-4} for the correlation of the ratio of GCA and GDCA with the ratio of

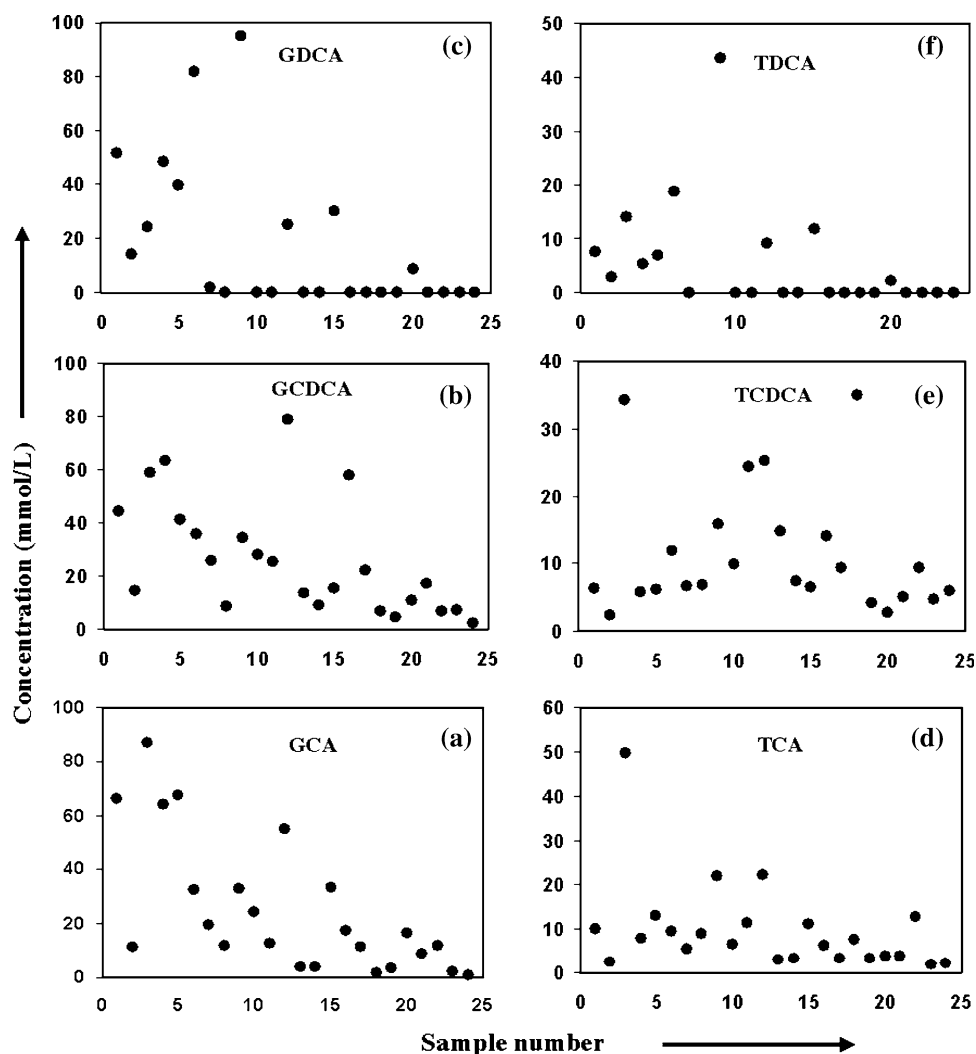

TCA and TDCA (Fig. 5b) and 0.92 and 0.001×10^{-2} for the correlation of the ratio of GDCA and GCDCA with the ratio of TDCA and TCDCA (Fig. 5c). Similarly the ratios between glycine-conjugated bile acid and its taurine counterpart, and those between another glycine-conjugated bile acid and its taurine counterpart were also highly linearly correlated: $R^2 = 0.92$ and $p = 0.002 \times 10^{-10}$ for the correlation of the ratio of GCA and TCA with that of GCDCA and TCDCA (Fig. 5d); 0.95 and 0.003×10^{-3} for the correlation of the ratio of GCA and TCA with that of GDCA and TDCA (Fig. 5e) and 0.94 and 0.004×10^{-3} for the correlation of the ratio of GCDCA and TCDCA with that of GDCA and TDCA (Fig. 5f). The regression equations of the correlations show a slope of close to one for the ratios of bile acids as shown in Fig. 5.

The concentration of individual bile acids in each bile sample was predicted using such correlations and experimentally determined values of the other three bile acids as follows. The concentration of GCA was predicted using the experimental values of TCA, GCDCA, and TCDCA; the concentration of GDCA using GCA, TCA, and TDCA; the concentration of GCDCA using GCA, TCA, and TCDCA; the concentration of TCA using GCA, GCDCA, and TCDCA; the concentration of TDCA using GCA, TCA, and GDCA and the concentration of TCDCA using GCA, TCA, and GCDCA. The correlations between the experimental and predicted values for the six conjugated bile acid are shown in the supplementary Fig. S3; as excepted from the results shown in Fig. 5, the experimental and predicted values for all the bile acids were highly correlated (supplementary Fig. S3).

Discussion

This study takes advantage of recent methodological advancements in NMR which enabled identification of major bile metabolites in intact human bile [19, 20]. Employing these methodologies and using ¹H-NMR spectroscopy at 800 MHz, we have studied human bile to investigate glycine and taurine conjugation patterns of bile acids.

Fig. 3 Concentration of individual bile acids (in mmol/L) for different bile samples. Abbreviations are as described before in Fig. 2 caption

Generally, in human bile, six conjugated bile acids can be detected using a simple one-dimensional NMR experiment (Fig. 1). These constitute two primary bile acids, cholic acid and chenodeoxycholic acid, and a secondary bile acid, deoxycholic acid, each of which is conjugated to glycine, resulting in GCA, GCDCA, and GDCA, or taurine, resulting in TCA, TCDCA, and TDCA. Depending upon the status of the liver, concentration of these bile acids vary in individual patients so much that, in the present study, bile acids in 16 patients were either undetectable or fewer than four. Since our aim was to investigate the conjugation pattern by comparing and correlating the ratios between two glycine-conjugated bile acids and their taurine counterparts or the ratios between glycine-conjugated bile acid and its taurine counterpart, we considered only those bile samples which showed at least a pair of glycine-conjugated bile acids and their taurine counterparts.

Significant variation in each of these bile acids concentration across the sample set (Figs. 2, 3) may be attributed to a number of factors such as altered

biosynthesis, cholestatic liver disease, bile acid malabsorption or disturbed enterohepatic circulation arising from the heterogeneity of the patients used in this study. Interestingly, from the systematic comparison of the variation in glycine- and taurine-conjugated bile acids concentrations within a bile sample as well as across a set of bile samples, a fundamental relationship between glycine- and taurine-conjugated bile acids levels in human bile could be established (Figs. 2, 5). Despite many factors that can affect individual bile acid concentration and the heterogeneity of the human subjects involved, who varied from non-liver disease patients to patients with liver diseases including hepatocellular carcinoma and cholangiocarcinoma, the ratios between glycine-conjugated bile acids and between taurine-conjugated bile acids did not vary randomly. This is particularly true for the six conjugated bile acids, GCA, GCDCA, GDCA, TCA, TCDCA, and TDCA commonly detected by NMR in a single step. The slope of nearly one for the line-fitting obtained from linear regression analysis and a very low *p* value clearly shows the

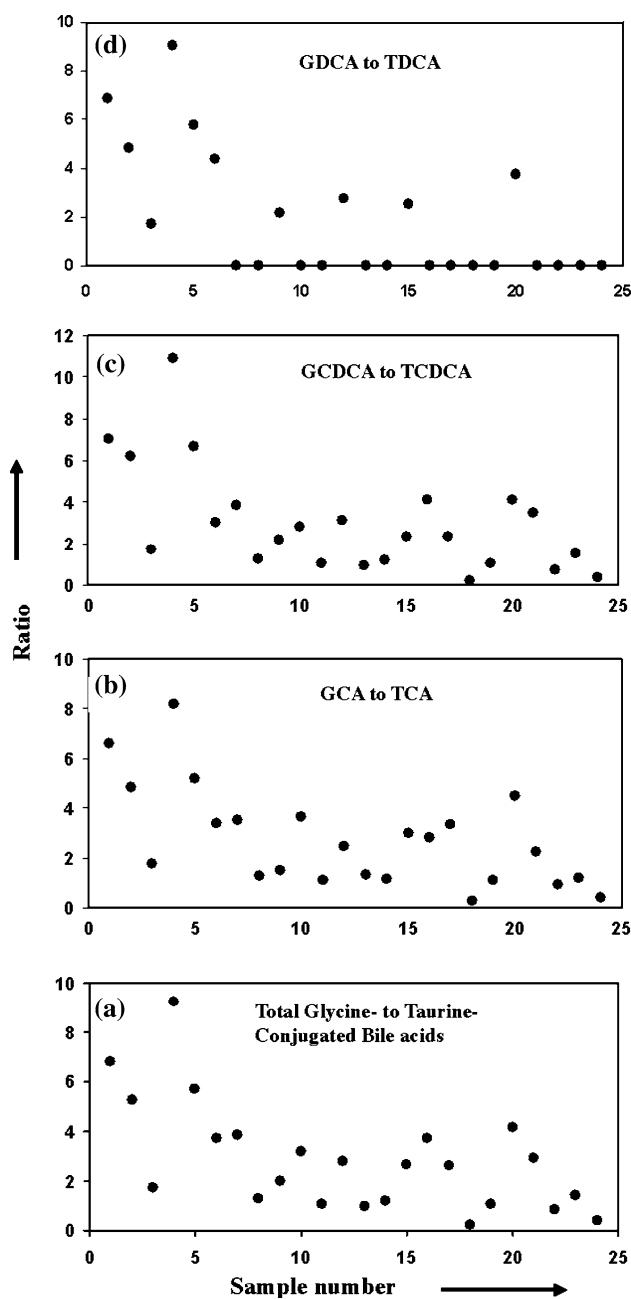

Fig. 4 Ratios of a glycine- to taurine-conjugated bile acids and b–d glycine to the corresponding taurine-conjugated bile acid. Abbreviations are as described before in Fig. 2 caption

linearity of correlation of bile acids ratios. An earlier investigation of bile using high pressure liquid chromatography reported somewhat constant proportion of the three glycine-conjugated bile acids in healthy humans (GCA, GCDCA, and GDCA) [28]. These results are in accordance with the relationship between glycine- and taurine-conjugated bile acids observed in the present study. Further, these results indicate that it is even possible to predict the concentration of a bile acid utilizing the

relationship of co-variation of the bile acids ratios (supplementary Fig. S3). Considering the fact that numerous factors affect individual bile acid's concentration and that it is not yet known whether damage to bile acids during enterohepatic circulation is corrected in the hepatocytes, either partially or completely [29], the findings of the present study that the individual bile acids do not vary randomly may provide clues to the mechanism of the regulatory make up of bile acids in the hepatocytes.

Interest in better understanding bile acids metabolism and their role in a variety of diseases has increased since the recent discovery of a nuclear receptor for bile acids, which regulates bile acids synthesis and controls glucose, fat and energy metabolism. A very recent study on bile acids kinetics showed significantly higher cholic acid synthesis in type 2 diabetes patients [9]. Although bile acids have common structural features, the number and the position of the hydroxyl groups, and the nature of conjugation is anticipated to make each of the bile acids exhibit widely differing biological functions. For example, taurodeoxycholic acid, but not glycodeoxycholic acid, has inhibitory potential against apoptosis [30], and chenodeoxycholic acid levels in blood exceeding 15 $\mu\text{mol/L}$ are indicative of end stage liver disease [31]. Hence, understanding the metabolism and physiology of individual bile acid conjugation becomes an important aspect of the study of bile acids. Most of the literature about bile acids to date deals with bile acids as a whole, such as the primary bile acids, cholic acid and chenodeoxycholic acid, and the secondary acids, deoxycholic acid and lithocholic acid. Specific roles for the individual taurine- or glycine-conjugated bile acids have not been extensively explored.

Present investigation was based on the six conjugated bile acids, GCA, GCDCA, GDCA, TCA, TCDCA, and TDCA that are commonly found in human bile at high concentrations. Conjugates of ursodeoxycholic acid and lithocholic acid that are also thought to be present commonly in bile were not detected by NMR in this study, probably, owing to their low concentrations. It is also quite likely that such undetected low concentration conjugated bile acids overlap with the signals of the abundant bile acids. In our earlier investigation, we have shown that all the bile acids' signals are resolved even at low magnetic fields (400 MHz) except the two, TCDCA and TDCA, and at 800 MHz, all the signals get resolved [20]. Now that the relationship between glycine- and taurine-conjugated bile acids is established, it would be possible to predict the concentrations of TCDCA and TDCA, even if they overlap, provided the integrals of the other four are known as described in the supplementary Fig. S3. Thus, the analysis of individual bile acids can be performed even using instruments with lower magnetic fields (for example 400 MHz) as long as the correlation of the ratios is valid.

Fig. 5 Plots showing the linear correlation of the ratios **a–c** between a pair of glycine-conjugated bile acids and between the corresponding taurine-conjugated bile acids; and **d–f** between a glycine-conjugated bile acid and its taurine counterpart and between another glycine-conjugated bile acid and its taurine counterpart. Abbreviations are as described before in Fig. 2 caption

Conclusions

Bile acids have been intensively studied over the last several decades; however, investigations with an emphasis on bile acids conjugation are sparse. With a multitude of new roles for bile acids in several diseases coming to light, the need to investigate and understand the specific role of each member of the bile acid family has gained significance. Utilizing the latest methodological developments in bile acids analysis, we have made a detailed correlative analysis of individual glycine- and taurine-conjugated bile acids, which normally occur abundantly in human bile. We show here that glycine- and taurine-conjugated bile acids do not vary randomly but follow a definite correlative relationship, despite significantly altered levels of individual bile acids across the sample set. Although, this

investigation involves a small sample set and only six conjugated bile acids, the correlations between the two classes of conjugated bile acids are highly consistent and striking. Further studies using a greater number of bile samples targeting additional number of bile acids that are undetected in the present study are needed to substantiate the findings and to further our understanding of the physiology of bile acids' conjugation. Further, it will be interesting and useful to understand the pathophysiological circumstances which contribute to the deviation of such a correlation, although present study on a small sample set has not detected any difference between liver diseases and non-liver disease controls.

Abstract Experimental studies have suggested an important role of the spleen in lipid metabolism, although with controversial results. Our purpose was to analyze the effect of a nutritionally balanced (NB) diet and a diet containing pork fat (PF) as source of lipids on the lipid profile of rats submitted to splenic surgery. Sixty adult male Wistar rats were divided into six groups of 10 animals each: 1 sham-operated, NB diet; 2 sham-operated, PF diet; 3 total splenectomy (TS), NB diet; 4 TS, PF diet; 5 TS followed by splenic autotransplantation (SA), NB diet; and 6 SA, PF diet. Blood samples were collected at the beginning (D0) and after 12 weeks of the experiment (D + 12) for plasma lipid determination. Morphologic regeneration of splenic tissues was observed, with no differences between groups 5 and 6. When D + 12 plasma lipid levels were compared to D0 levels there were no differences in groups 1, 3, and 5, while in groups 2, 4, and 6 total cholesterol (TC), low density lipoprotein (LDL), very low density lipoprotein (VLDL), and triacylglycerols (TAG) increased, and high density lipoprotein (HDL) decreased. At D + 12, groups 2, 4, and 6 had lower HDL than group 3. In conclusion, regardless of the surgical procedure applied to the spleen, an NB diet maintained

plasma lipid levels while a diet with PF as source of lipids changed the animals' lipid profile.

Introduction

It is well known that the spleen plays an important role in immunological processes and hemorheological homeostasis [1]. Since an increased risk of severe infection has been recognized to occur after splenectomy, even after many years, spleen-saving techniques, including autotransplantation of spleen fragments, have been performed when possible [2]. It has been demonstrated that splenic autotransplantation at an appropriate site successfully preserves splenic tissue after total splenectomy. Splenic autotransplants acquire the macro- and microscopic architecture of a

normal spleen and are capable of restoring immune function [3–5].

A possible role of the spleen in plasma lipid level regulation was first suggested by Robinette and Fraumeni Jr (1977) who showed a high incidence of ischemic heart disease in splenectomized World War II veterans [6]. Both clinical and experimental studies have documented the spleen's influence on lipid metabolism in two different situations, i.e., hyperesplenism and asplenia [7–10].

Previous studies on patients with myeloproliferative disorders associated with splenomegaly have shown decreased plasma cholesterol levels, which normalize after total splenectomy [11–13]. Conversely, an increase in plasma cholesterol and triglyceride levels has been demonstrated in animals after total splenectomy [12, 14, 15]. Other studies have also suggested that the presence of splenic tissue, even in small amounts, can prevent such metabolic disorders [10, 16, 17].

Hypercholesterolemia is a cause of concern in our society since it constitutes one of the major risk factors for the development of cardiovascular diseases such as atherosclerosis and its complications, remaining the leading cause of death and disability in the world [18, 19]. Diet is the first line of therapy for the management of plasma lipid levels in the prevention and treatment of cardiovascular disease, with particular emphasis on fatty acid quality, much more than total fat content proper [20, 21]. Controlled feeding studies have consistently found that a reduction in the consumption of dietary saturated fatty acids decreases plasma total cholesterol and LDL levels, reducing the morbidity and mortality due to cardiovascular disease [22, 23].

Based on the possible correlation between the spleen and lipid metabolism and on the lack of studies considering the effect of different sources of fat on lipid profile after surgical procedures affecting the spleen, the purpose of the present study was to assess the impact of a nutritionally balanced diet and a diet containing pork fat as the source of lipids on plasma lipid levels of rats submitted to total splenectomy alone or in combination with splenic autotransplantation.

Experimental Procedure

Animals

Sixty adult male Wistar rats weighing 240–270 g were housed in individual cages under conditions of controlled temperature and humidity and on a 12-h light/12-h dark photoperiod. The animals were randomly divided into six groups of 10 animals each: group 1 – Control – sham-operated, fed a nutritionally balanced (NB) diet; group

2 – Control – sham-operated, fed a diet containing pork fat (PF) as a source of lipid; group 3 – total splenectomy (TS), fed the NB diet; group 4 – TS, fed the PF diet; group 5 – splenic autotransplantation (SA), fed the NB diet; and group 6 – SA, fed the PF diet.

After animals were submitted to different surgical procedures at the beginning of the experiment, they were fed two types of diet, according to the groups, and were monitored daily over a period of 12 weeks. Then, animals were killed with an anesthetic overdose at the end of the experiment. The study was approved by the Ethics Committee on Animal Research of the Biology Institute Roberto Alcantara Gomes, Rio de Janeiro State University Brazil. All procedures rigorously followed current regulations on animal experimentation [24, 25].

Surgical Procedures

After a 12-h fast, the surgical procedures were carried out under conditions of asepsis and antisepsis and under general anesthesia with a combination of ketamine hydrochloride (50 mg/kg) (Ketamina Agener®, Agener União, Saúde Animal) and xylazine (5 mg/kg) (Calmiun®, Agener União, Saúde Animal) administered intraperitoneally. The day of the operation was considered to be the first day of the experiment (D0).

A supraumbilical midline laparotomy was performed. In the sham-operated groups (1 and 2), the animals were submitted to mobilization of the spleen to the wound surface followed by replacement to its original position in the abdomen. In groups 3 and 4, total splenectomy was performed, and in groups 5 and 6, the removed spleen was weighed and cut transversely into five slices, each about 2 mm thick. The splenic sections were implanted into the greater omentum using continuous 4-0 polyglycolic acid (Dexon II®, Brasmédica S/A, São Paulo, SP, Brazil) sutures. Slices were introduced alternately between the omentum and splenic tissue to allow interposition of omental tissue between them. Laparorrhaphy was carried out on two planes (peritoneal-aponeurotic plane and skin) using continuous 3-0 polyglycolic acid (Dexon II®, Brasmédica S/A, São Paulo, SP, Brazil) sutures.

Blood Analysis

Blood samples were first collected from the animals immediately before the surgical procedure by cardiac puncture under anesthesia and then 12 weeks later at the end of the experiment. The following biochemical parameters were analyzed: total cholesterol (TC), low-density lipoprotein (LDL), very low-density lipoprotein (VLDL), high-density lipoprotein (HDL), and triacylglycerols (TAG). Plasma concentrations of TC, HDL, and TAG were

measured by the enzymatic colorimetric method after centrifugation using an automatic analyzer A15 (BioSystems®). LDL and VLDL levels were determined by the Friedewald formula, as follows:

$$\text{VLDL(mg/dL)} = \text{TAG}/5$$

$$\text{LDL(mg/dL)} = \text{TC} - \text{VLDL} - \text{HDL}$$

Animal Feeding

The animals received commercial rat chow (Focus 1722 Roedores, Agrocere®) and had unrestricted access to water until reaching the ideal weight for the experiment. Starting during the immediate postoperative period, all animals received a manipulated rat chow based on the recommendations of the American Institute of Nutrition Rodents Diets (AIN-1993) [26]. Groups 1, 3, and 5 were fed a nutritionally balanced diet with soybean oil as the source of fat, as recommended by AIN-93M. Groups 2, 4, and 6 were fed a diet containing the same amount of fat, but with pork fat as the main source, which contains a high percentage of saturated fatty acids compared to soybean oil. The composition of the two diets is presented in Table 1. In these groups, 18% of the total fat was soybean oil in order to guarantee essential fatty acid content [27]. Animal's intake of chow as well as body weight were controlled weekly, always at the same time of day.

Statistical Analysis

Descriptive analysis was applied to calculate the mean and standard deviation for the following variables: chow intake, weight gain, percentage of splenic mass regeneration, and TAG, TC, HDL, LDL, and VLDL levels. The Wilcoxon test was applied to compare preoperative and postoperative plasma lipid levels. The Kruskal–Wallis test and Dunn's post-test were used to compare plasma lipid levels between groups at the beginning and at the end of the experiment, as well as data regarding body weight variation and chow

Table 1 Composition of the nutritionally balanced (NB) and pork fat (PF) diets used during the experiment (g/100 g)

Composition	NB diet (g)	PF diet
Carbohydrates	62.10	62.10 g
Protein	14	14 g
Fat	4	4 g
Saturated fat	0.67	1.56 g
Monounsaturated fat	0.97	1.65 g
Polyunsaturated fat	2.37	0.79 g
Trans fat	0	0 g
Cholesterol	0	2.36 mg
Fiber	5	5 g

intake. The Student *t*-test for independent samples was applied to compare splenic mass between groups 5 and 6. The level of significance was set at $P \leq 0.05$ in all analyses. Statistical analysis was performed with the Graph Pad Prism 4® software for Windows version 4.0 (2003) and the SAS Statistical Software Package® for Windows 2007.

Morphologic Study

Removed splenic implants were placed in a solution containing 10% buffered formalin. The tissue was processed with increasing concentrations of alcohol and xylol, cut into 4-mm-thick slices and embedded in paraffin. Slides prepared from these slices were stained with hematoxylin and eosin and analyzed by light microscopy.

Results

During the immediate postoperative period the animals recovered rapidly from the surgical procedure. No complications resulting from anesthesia or surgery were observed. Only one animal (group 4) died during the 6th week of the experiment. Examination of the abdominal and thoracic cavity of the dead rat did not reveal the possible cause of death.

Regeneration of the splenic implants was observed in all animals of groups 5 and 6, with no difference in percent regeneration between them ($P = 0.7716$). Microscopic examination revealed a normal morphological appearance in all animals submitted to total splenectomy combined with splenic autotransplantation, with the presence of red and white pulps, besides lymphoid follicles (Fig. 1).

Fig. 1 Microscopic morphology of a regenerated splenic autotransplant showing the presence of white pulp containing lymphoid follicles and of red pulp with pigments of hemosiderin phagocytized by macrophages ($\times 40$)

Table 2 Comparison of TC, HDL, LDL, VLDL, and TAG levels at weeks 0 and 12 of the experiment in each group of animals—*P* values

Variable	Group 1	Group 2	Group 3	Group 4	Group 5	Group 6

* Statistically significant

No difference was observed in body weight gain ($P = 0.8542$) or in chow intake ($P = 0.1846$) between the various animal groups during the 12 weeks of the experiment. All groups had similar plasma lipid levels at the beginning of the experiment. When plasma lipids were compared at weeks 0 and 12, no significant difference in levels of TC, LDL, HDL, VLDL, and TAG was observed in groups 1, 3, and 5, while in groups 2, 4, and 6 there was an increase in TC, LDL, VLDL, and TAG levels, and a decrease in HDL levels (Table 2; Fig. 2).

When all animal groups were compared at the end of the experiment, only the HDL levels of groups 2, 4, and 6 were lower than those of group 3 (Fig. 2). Additionally, when groups 1 versus 3 versus 5 and 2 versus 4 versus 6 were compared in order to identify the separate effect of the surgical procedures on the spleen, no difference was observed.

Discussion

For many years, total splenectomy has been usually performed due to trauma, some diseases, and for diagnostic purposes, since there was insufficient knowledge about its consequences [2, 15]. Once the importance of the spleen in host defense was recognized, the immunological consequences of total splenectomy were given more attention and the development of new conservative spleen procedures was recommended, in an attempt to avoid the complications of asplenism [28, 29]. Subtotal and partial splenectomies have been recommended in many situations. Nevertheless, when total splenectomy is unavoidable, splenic autotransplantation seems to be the only alternative [30, 31].

A variety of studies have confirmed morphological regeneration of autotransplanted splenic tissue [32–35]. However, splenic regeneration does not necessarily mean recovery of organ function. Several authors have shown that splenic autotransplantation is a simple, effective procedure [30, 36] and that, when performed at appropriate sites, it successfully maintains some spleen functions after total splenectomy, as demonstrated by indirect laboratory methods and scintigraphic techniques [4, 37]. Due to their blood supply and venous drainage into the portal vein, as is the case for the spleen in situ, splenic implants in the greater omentum seem to develop and function better than at other sites [38, 39]. Although the regeneration sequence begins hours after autotransplantation, the time needed for the occurrence of morphological and functional

Fig. 2 Comparison over time of the experiment (*Wilcoxon test*) and between groups of animals at the end of the experiment (*Kruskal–Wallis test*) of TC, HDL, LDL, VLDL, and TAG levels at weeks 0

(left column in each group) and 12 (right column in each group) in all groups of animals

regeneration has been reported to range from 8 to 12 weeks [40, 41].

In the present study, rats were submitted to total splenectomy for the induction of an asplenic condition in order to identify a possible role of the spleen in plasma lipid levels 12 weeks after the beginning of the experiment. Splenic autotransplantation following total splenectomy was performed to determine if such a simple procedure would protect the animals from these changes. Additionally, rats were fed two diets with different sources of lipids in order to identify the effect of such diets on the lipid profile of the animals after these surgical procedures.

The participation of the spleen in lipid metabolism has been investigated in clinical and experimental studies [42–44]. Studies performed in rats have demonstrated increased levels of cholesterol after TS, although with controversial results. Animals fed standard chow have been reported to show an increase in TAG and a decrease in HDL levels after TS compared with sham-operated animals [14], in contrast to the results from other studies showing an increase in TC and LDL and a decrease in HDL levels after the same procedure, with no alterations in TAG or VLDL levels [10], or elevation of all of these parameters [17].

Some theories have been proposed to explain the possible role of the spleen in plasma lipid levels. Increased macrophage activity in myeloproliferative disorders would lead to hypocholesterolemia through an increase in LDL catabolism [45–48]. Schmidt et al. [49] compared the spleen to a lipid reservoir that accumulates a great part of the fat in states of hypersplenism. Another explanation for the participation of the spleen in lipid metabolism would be the production of anti-oxidized LDL antibody, with spleen-associated immune activity protecting against the development of atherosclerosis [50].

Most of the studies that showed a correlation between the spleen and plasma lipid level regulation did not consider chow intake or weight gain during the experiment. In the present study, all animal groups showed similar weight gain and chow intake. There is evidence that excess body adiposity can lead to a worsening of cardiovascular risk factors, including dyslipidemia [51, 52], making the control of such variables extremely relevant in order to guarantee a correct interpretation of the results, avoiding, for example, an erroneous attribution of lipid profile alteration to a surgical procedure on the spleen.

Some authors have increased fat content in rat chow during the post-splenectomy period in order to induce hyperlipidemia and emphasize possible alterations in the lipid profile by adding cholesterol to the commercial chow [9, 17, 43]. Others have shown that increasing dietary

cholesterol results in higher plasma cholesterol concentrations [53, 54], with the addition of cholesterol itself being expected to alter plasma lipid levels. However, most studies have also demonstrated that dietary cholesterol is a less potent regulator of plasma cholesterol concentrations than dietary fatty acids [18, 55].

Recent evidence suggests that a consistent reduction in the risk of cardiovascular disease due to changes in the plasma lipoprotein profile can be achieved through changes in fat source consumption, such as replacing *trans* and saturated fat with mono- and polyunsaturated fatty acids [56–58]. In the present study, we changed the fat source instead of increasing fat content in an attempt to identify the impact of fat quality on lipid profile, using pork fat due to its high saturated fatty acid content.

In contrast to other experimental studies [12, 14–16], we did not observe any changes in plasma lipid levels after any surgical procedure on the spleen when rats were fed a nutritionally balanced diet. Thus, surgical trauma and total splenectomy alone or in combination with splenic autotransplantation did not influence the lipid profile of the animals. Rezende et al. [44] also showed similar plasma levels of cholesterol and its fractions in groups of mice fed a similar diet and submitted to the same surgical procedures. Comparable results were obtained by Caligiuri et al. [59], who did not detect changes in cholesterol levels in splenectomized mice, although atherosclerosis had drastically worsened after the surgical procedure.

When animals were fed a chow containing pork fat as a source of lipids, a worsening of all parameters was observed. Again, these changes occurred in all animals regardless of the surgical procedure on the spleen. Our findings confirm the results obtained in other studies that showed an increase in TC and LDL levels with the use of a high saturated fat diet [60–62]. Alterations in HDL, VLDL, and TAG levels may be due to changes in the fat content or fatty acid profile with the chow used during the postoperative period compared to the commercial chow used during the preoperative period.

Despite the possible role of the spleen in myeloproliferative diseases and in protective immunity against atherosclerosis, we did not find any effect of the spleen on plasma lipid levels. It was the quality of the fat, rich in saturated fatty acids, that significantly worsened the lipid profile of rats in contrast to a nutritionally balanced diet. This result suggests that the spleen, in the absence of diseases, does not seem to have an important role in the regulation of plasma lipid levels. Further studies dealing with other animal models and different contents and sources of fat in the diet are necessary to better elucidate the correlation between the spleen and the lipid profile.

Acknowledgments The authors wish to thank Albanita Viana de Oliveira (Discipline of Pathologic Anatomy of Sciences Medical School, Rio de Janeiro State University) for her support with morphological tissue analysis. Abstract The very-long-chain polyunsaturated fatty acid (VLC-PUFA), arachidonic acid (ARA, 20:4 ω -6) is a component of neuron tissues such as brain and retina cells and a primary substrate for the biosynthesis of biologically active eicosanoids. The green freshwater microalga *Parietochloris incisa* (Trebouxiophyceae) has been shown to accumulate an extraordinary high content of ARA-rich triacylglycerols. It was thus interesting to characterize the genes involved in lipid biosynthesis in this alga. We report here the identification of a cDNA encoding for a *P. incisa* PUFA elongase (*PiELO1*) and demonstrate that the expression of *PiELO1* in yeast *Saccharomyces cerevisiae* confers its elongase activity on C18 $\Delta 6$ PUFA. Phylogenetic analysis indicated that *PiELO1* is highly similar to functionally characterized $\Delta 6$ PUFA elongase genes from other green algae and lower plants. Quantitative real-time PCR expression studies showed that *PiELO1* is upregulated under nitrogen starvation, the condition triggering and enhancing storage oil and ARA accumulation in *P. incisa*.

Keywords Arachidonic acid · Fatty acid elongation · Nitrogen starvation · *Parietochloris incisa* · Subtractive hybridization · VLC-PUFA

Abbreviations

ARA	Arachidonic acid
DGLA	Dihomo- γ -linolenic acid
DHA	Docosahexaenoic acid
GLA	γ -Linolenic acid
EPA	Eicosapentaenoic acid
STA	Stearidonic acid
VLC-PUFA	Very-long-chain polyunsaturated fatty acid

Introduction

The very-long-chain polyunsaturated fatty acid (VLC-PUFA), arachidonic acid (ARA, 20:4 ω -6), is a component of neuron tissues such as brain and retina cells and an important component of the human diet. ARA is a primary substrate for the biosynthesis of eicosanoids, including the 2-group prostaglandins, 4-group leukotrienes, thromboxanes, and lipoxins that serve as biological effectors involved in inflammatory and immune responses and cell signaling [1, 2]. Being an important and dominant VLC-PUFA in human breast milk, ARA needs to be externally supplied for normal development of preterm babies if they are not breast-fed [1, 3]. Because of its beneficial properties there is a growing interest in the production of ARA for baby formulae. At present, the major commercial source of ARA is the filamentous fungus *Mortierella alpina* [4].

Microalgae are one of the richest sources of VLC-PUFAs [5–8]. Furthermore, algae can be used as sources of genes for implementation of VLC-PUFA biosynthesis in genetically engineered oil crops [9, 10]. Genetic information on enzymes involved in the biosynthesis of VLC-PUFA in some algae led to in-vivo applications of VLC-PUFA production in seed oil [11]. The gene pool

of the green freshwater microalga *Parietochloris incisa* (Trebouxiophyceae) is of special interest because it is the only microalga known to be able to accumulate extraordinary high amounts of ARA-rich triacylglycerols (TAG) [7, 8]. When *P. incisa* is cultivated under nitrogen starvation, the condition triggering storage oil accumulation, ARA constitutes about 60% of total fatty acids (TFA) and over 95% of cellular ARA is deposited in TAG in cytoplasmic lipid bodies [12].

The biosynthesis of VLC-PUFAs in algae follows various pathways, initiating from oleic acid exported from the chloroplast and employing polar extraplasmic lipids. In the $\omega 6$ and $\omega 3$ pathways, linoleic acid (LA; 18:2 ω -6) and α -linolenic acid (ALA; 18:3 ω -3) are successively converted by $\Delta 6$ desaturase, $\Delta 6$ elongase, and $\Delta 5$ desaturase to ARA and eicosapentaenoic acid (EPA, 20:5 ω -3), respectively [6]. For example, in *P. incisa* and in the red microalga *Porphyridium cruentum*, ARA biosynthesis proceeds via the $\omega 6$ pathway [13, 14]. Unusual elongations and desaturations leading to the biosynthesis of VLC-PUFA have been reported in the marine haptophyte *Isochrysis galbana* [15] and the fresh-water euglenophyte *Euglena gracilis* [16, 17]. In the alternative route, elongation of 18:2 ω -6 and 18:3 ω -3 by a C18- $\Delta 9$ -specific fatty acid elongase to the respective C20 intermediates precedes sequential $\Delta 8$ and $\Delta 5$ desaturations to ARA and EPA, respectively. It is assumed that in *E. gracilis* EPA produced by the $\omega 3$ - $\Delta 8$ pathway is further $\Delta 4$ desaturated and finally elongated to docosahexaenoic acid (DHA, 22:6 ω -3) [17].

Fatty acid elongation is a multi-step process involving four sequential enzymatic reactions: rate limiting condensation (of malonyl-CoA and acyl-CoA), reduction, dehydration and enoyl reduction [18]. Only the expression of the condensing enzyme component is required to reconstitute elongase activity in the heterologous host; there is no requirement for the co-expression of any other component of the elongase complex. Multiple microsomal elongation systems with different specificities to the acyl chain length exist in various organisms. Recent studies have identified and characterized PUFA-specific elongases, responsible for the elongation of PUFA in the nematode *Caenorhabditis elegans*, mammals, fish, algae, lower plants, and fungi [19–25]. The elongation of 18:3 ω -6 to 20:3 ω -6, the immediate precursor of ARA, was shown to be the rate-limiting step in ARA biosynthesis in *M. alpina* [26, 27]. Functional expression of the PUFA elongase condensation component in yeast revealed enzymes of various specificities for C18 and C20 acyl substrates. Thus, two types of PUFA elongases engaged in DHA biosynthesis have been cloned from the green microalga *Ostreococcus tauri* and the diatom *Thalassiosira pseudonana*: OtELO1 and TpELO1 are $\Delta 6$ C18-PUFA-specific and involved in the elongation of 18:3 ω -6 and 18:4 ω -3,

whereas OtELO2 and TpELO2 are $\Delta 5$ C20-PUFA elongases involved in the elongation of 20:5 ω -3 [28]. Bifunctional PUFA elongases able to elongate both $\Delta 6$ and $\Delta 5$ PUFA, and elongases of wide substrate specificity utilizing both C20 and C22 PUFA substrates, have been isolated from aquatic animals [28, 29].

In this paper we report the identification of a cDNA encoding for a *P. incisa* elongase (PiELO1) and that the expression of PiELO1 in yeast cells conferred its $\Delta 6$ PUFA elongase activity. Quantitative real-time PCR expression studies showed that *PiELO1* is up-regulated during nitrogen starvation and that the level of expression is correlated with the production of ARA precursors.

Experimental Procedures

Growth Conditions

Axenic cultures of *P. incisa* were cultivated on BG-11 nutrient medium [30] in 250-ml Erlenmeyer glass flasks in an incubator shaker under an air/CO₂ atmosphere (99:1, v/v) and controlled temperature (25°C) and illumination (115 $\mu\text{mol quanta m}^{-2} \text{s}^{-1}$) at a speed of 170 rpm [13]. For nitrogen starvation experiments, cells of daily-diluted cultures were collected by centrifugation, washed thrice in sterile double-distilled water, and resuspended in nitrogen-free BG-11 medium. Cultures were further grown under the same conditions for 14 days. To prepare nitrogen-free medium, NaNO₃ was omitted from the BG-11 medium and ferric ammonium citrate was substituted with ferric citrate.

RNA Isolation

Cells for RNA isolation were harvested from 40 ml log-phase culture (Time 0) grown in complete BG11 and cultured on nitrogen-free medium for 3, 7, and 14 days. The cultures were filtered through a glass-fiber paper filter (GF-52, Schleicher & Schuell, Germany), and cells were collected by scraping and immediately flash-frozen in liquid nitrogen and stored at -80°C for further use. Total RNA was isolated either using the RNeasy Plant Mini kit (Qiagen, Hilden, Germany) or by the procedure described by Bekesiova et al. [31], with minor modifications. Three independent RNA isolations were conducted for each growth period. For real-time PCR studies, the total RNA samples were further treated with RNAase-free DNAase (Epicentre, Madison, WI, USA).

Construction of Subtracted cDNA Library

The subtracted complementary DNA (cDNA) library was prepared from cDNAs enriched for differentially expressed

sequences obtained from *P. incisa* cultures in the log phase (driver) and after three days of nitrogen starvation (tester) [32], using a PCR-Select cDNA Subtraction Kit (Clontech, Mountain View, CA, USA). First, a double-stranded cDNA was synthesized from total RNA isolated from cells during log phase and N-starvation and digested with *RsaI*. Subtraction was then done in both directions. To enrich for “log phase” cDNAs, the cDNA sequences of N-starved cells were subtracted from those of log phase cells; conversely, to enrich for cDNAs of N-starved cells, log phase cDNA sequences were subtracted from those of N-starved cells. Two portions of the tester cDNA were ligated to adaptor primers. After two cycles of hybridization with excess of driver over tester, the ends of the enriched tester cDNA population were filled in by DNA polymerase and selectively amplified by PCR. Following a subsequent PCR with nested primers, the two differentially expressed cDNA populations were cloned into a pGEM-T vector (Promega, Madison, WI, USA) to produce clones of the subtracted libraries. Plasmids were sequenced by an ABI automated sequencer. Among the 56 differentially expressed sequence tags (ESTs) clones, one was found to be highly similar to PUFA elongases.

Generation of 5' and 3' End Fragments of the Putative *P. incisa* PUFA Elongase

To generate the full-length cDNA of the putative PUFA elongase, 3' and 5' rapid amplification of the cDNA ends (RACE) was performed using a BD smart RACE cDNA Amplification Kit (BD Biosciences Clontech, Foster City, CA, USA) according to the manufacturer's manual. To amplify the 5' end, the reverse gene-specific primers (GSP) 5'-CCCGGCTGCTGCCATGCTTCTGTG (EL5R1) and the nested 5'-TGGGGTAGGGAGAGTAGGCCCAAGT (EL5RN) were designed using Primer3 online software (<http://frodo.wi.mit.edu>). Based on the nucleotide sequence of the 5'-end fragment obtained, two forward GSPs, 5'-GCCTACATGTCCTCTGCCGCTGCTA (EL3R1) and the nested 5'-GCGGGACATGGGAGGGCTCATCTATA CC (EL3R2) were constructed to amplify the 3' end of the target gene. RACE PCR reactions were conducted using 5' and 3'-RACE-Ready cDNAs made from 1 µg total RNA of N-starved cells with 50× BD Advantage 2 polymerase mix (Clontech Laboratories, Mountain View, CA, USA). The PCR products of the expected size were excised, purified from the gel (NucleoSpin Extract II purification kit; Macherey-Nagel, Duren, Germany) and ligated into a pGEM T-Easy vector (Promega). The full-length cDNA corresponding to the *P. incisa* putative PUFA elongase (designated *PiELO1*) was assembled from the 5' and 3' RACE fragments and its ORF was further subcloned into a pYES2 vector (Invitrogen, Carlsbad, CA, USA).

Expression and Functional Characterization of *PiELO1* cDNA in the Yeast *Saccharomyces cerevisiae*

The ORF encoding for *PiELO1* was amplified using *PfuUltra* II fusion HS DNA polymerase (Stratagene, La Jolla, CA, USA) with the forward primer 5'-AGGAATT CAAAATGGCATTGACGGCGGCCT (PUFAEL5RES1) containing a restriction site (underlined) and a yeast translation consensus followed by ATG (bold) and the reverse primer 5'-CATTCTAGATTACTGCAGCTTTTGCTTGG CTGC (PUFAEL3RES2) containing a restriction site (underlined) and a stop codon (bold). The amplified sequence was then restricted with *EcoRI* and *XbaI* (NEB, Ipswich, MA, USA). The expected bands were gel-purified with NucleoSpin Extract II purification kit (Macherey-Nagel) and ligated into a *EcoRI-XbaI* cut pYES2 vector, yielding pY*PiELO1*. *Saccharomyces cerevisiae* strain W303 was transformed with pY*PiELO1* by the PEG/lithium acetate method [33]. The yeast cells harboring the empty pYES2 vector were used as control. Transformants were selected by uracil prototrophy on yeast synthetic medium (YSM) lacking uracil (Invitrogen). For functional expression, a minimal selection medium containing 2% (w/v) raffinose was inoculated with the pY*PiELO1* transformants and grown at 27°C for 24 h in a water bath shaker. Five milliliters of sterile YSM, containing 1% (w/v) Tergitol-40 and 250 µM of the appropriate fatty acid, was inoculated with raffinose-grown cultures to obtain an OD of 0.2 at 600 nm. Expression was induced by adding galactose to a final concentration of 2% (w/v) and cultures were further grown at 27°C for 48 h. Cells were harvested by centrifugation, washed twice with 0.1% NaHCO₃, freeze-dried, and used for fatty acid analysis.

Fatty Acid Analysis

Fatty acid methyl esters (FAMES) were obtained by transmethylation of the freeze-dried yeast or *P. incisa* cells with dry methanol containing 2% (v/v) H₂SO₄ and heating at 80°C for 1.5 h while stirring under an argon atmosphere. Gas chromatographic analysis of FAMES was performed on a Thermo Ultra gas chromatograph (Thermo Scientific, Italy) equipped with PTV injector, FID, and a fused silica capillary column (30 m × 0.32 mm; ZB WAXplus, Phenomenex). FAMES were identified by co-chromatography with authentic standards (Sigma Chemical, St Louis, MO, USA) and FAME of fish oil (Larodan Fine Chemicals, Sweden). Each sample was analyzed in duplicate.

Real-Time Quantitative RT-PCR

Template cDNA for real-time quantitative PCR (RTQPCR) was synthesized using 1 µg total RNA in a total volume

using the PrimerQuest tool (<http://test.idtdna.com/Scitools/Applications/Primerquest/>). Conditions were set for a primer length of 19–26 bp, primer melting temperature of $60.0 \pm 1.0^\circ\text{C}$, and an amplicon length of 90–150. Primer pairs were validated using seven serial 50-fold dilutions of cDNA samples, and standard curves were plotted to test for linearity of the response. The primer pairs and primer concentrations with reaction efficiencies of $100 \pm 10\%$ were chosen for quantitative RT-PCR analysis of relative gene expression. The nucleotide sequences and characteristics of primers used for quantitative RT-PCR analysis are presented in Table 1.

Gene Expression Profiling

Gene expression profiling was done by real-time quantitative PCR using duplicate reactions for each sample of three independent RNA isolations with a gene-specific primer pair using Absolute Blue QPCR SYBR Green ROX Mix (ABgene) in a real-time PCR 7500 system (Applied Biosystems). The amplification procedure was 50°C for 2 min, 95°C for 15 min, 40 cycles of 95°C for 15 s, and 60°C for 1 min. A dissociation curve was obtained for each pair of primers to confirm that a single, specific product was produced in each reaction.

Calculation of Gene Transcript Levels

The mean changes in gene expression, as multiples of the original values, were calculated according to the $2^{-\Delta\Delta\text{Ct}}$ method [34] using the average of threshold cycle (Ct) values from triplicate cDNA-primer samples. The ΔCt followed by the $\Delta\Delta\text{Ct}$ was calculated from the average Ct values of the target and the endogenous genes. The transcript abundance of the *PiELO1* gene was normalized to the endogenous control 18S SSU rRNA gene. The change in gene expression was calculated using $2^{-\Delta\Delta\text{Ct}}$ to find the expression level of the target gene which was normalized to the endogenous gene, relative to the expression of the target gene at time 0.

Results

Identification and Characterization of PiELO1

The BLASTX analysis (<http://www.ncbi.nlm.nih.gov/blast>) of clones obtained through subtractive hybridization revealed a clone of 141 bp whose putative amino acid sequence was highly homologous to the C-terminal region of PUFA elongases. Using GSP primers, the 870-bp 5'-end fragment was amplified and the sequence information was used to obtain the 3' end fragment from the 3' RACE

Ready cDNA. Alignment of the 800 bp 3'-end sequence with that of the 5'-end fragment provided an overlapping nucleotide sequence and included the partial 141 bp sequence, thus confirming the amplification of both ends of the expected gene. The assembled complete 867 bp cDNA sequence, designated *PiELO1*, was preceded and followed by 22 and 150 bp nucleotides at 5' and 3' UTR, respectively. *PiELO1* contained an ORF for 289 predicted amino acid residues consistent with functionally characterized PUFA elongase ORFs from fungi, lower plants, and algae (Fig. 1). The deduced amino acid sequence of the *PiELO1* was 50% identical to functionally characterized $\Delta 6$ PUFA elongases from *O. tauri* and *M. polymorpha*, while sharing 48 and 44% identity with *P. patens* $\Delta 6$ elongase and *M. polymorpha* $\Delta 5$ elongase, respectively. PiELO1 was also similar, yet with a lower score, to $\Delta 6$ elongases of fungal origin. It shared 40 and 36% identity with the $\Delta 6$ PUFA elongases of *Thraustochytrium* sp. and *M. alpina* (not included in the alignment), respectively. PiELO1 was 98% similar to a putative protein of the green microalga *Myrmecea incisa* (accession number ACF60496) which was not functionally characterized.

The predicted amino acid sequence of the PiELO1 contained four conserved motifs that are characteristic of PUFA elongases (Fig. 1, highlighted). The hydropathy plot of the PiELO1-deduced amino acid sequences was obtained using the algorithm available in the DAS transmembrane prediction server (<http://www.sbc.su.se/~miklos/DAS>) [35].

Fig. 2 Hydropathy plot of the amino acid sequence of PiELO1. The lower dashed line and the upper line represent the loose transmembrane region cutoff and the strict transmembrane region cutoff, respectively

The two strictly hydrophobic transmembrane domains were found about 50 amino acids downstream and upstream from the N and C termini, respectively, while the two less hydrophobic domains were located about 100 amino acids downstream and upstream from the N and C termini, respectively (Fig. 2).

Phylogenetic Analysis

An unrooted phylogenetic tree of PiELO1 and several functionally characterized PUFA elongases was constructed to identify their functional and phylogenetic relationships by the neighbor-joining program in MEGA4 [36]. From Fig. 3 one can see that PiELO1 falls into a group of PUFA elongases of lower eukaryotes. Although the group contains mostly PUFA elongases with $\Delta 6$ activity, some $\Delta 5$ elongases, e.g., those of *M. polymorpha* and *Thraustochytrium* sp., are more related to $\Delta 6$ elongases of lower eukaryotes than to $\Delta 5$ elongases of higher eukaryotes. PiELO1 makes a closely related subgroup with OtELO1, MpELO1, MpELO2, and PpELO1, the OtELO1 being the closest one.

Functional Expression of PiELO1 in *S. cerevisiae*

To characterize the enzymatic activity of PiELO1, the pYES2 plasmid containing the *PiELO1* ORF downstream of the *GAL1* promoter was transformed into *S. cerevisiae*. PiELO1 was expressed in the presence of the $\Delta 6$ PUFA elongase substrates, 18:3 ω -6 (γ -linolenic acid, GLA) and 18:4 ω -3 (stearidonic acid, STA). GC analysis of the FAMES of transformed yeast cells showed that PiELO1 elongated both GLA and STA, converting them into di-homo- γ -linoleic acid (DGLA, 20:3 ω -6) and eicosatetraenoic acid (20:4 ω -3), respectively (Fig. 4; Table 2). The yeast cells harboring the empty vector alone did not demonstrate any elongation activity on the added substrates, confirming that the *PiELO1* encoded enzyme has a $\Delta 6$ PUFA elongase activity. Feeding the *PiELO1* transformants with the $\omega 6$ fatty acids LA and ARA did not result in their elongation (not shown).

Real-time quantitative PCR was performed to quantitate the alterations in expression levels of the $\Delta 6$ *PiELO1* in *P. incisa* cells under nitrogen starvation. The change in the

expression level of the target gene in *P. incisa* cells grown for 3, 7, and 14 days on N-free medium was calculated relative to the expression level of the target gene in the log

Fig. 5 Quantitative real-time PCR analysis of the *PiELO1* gene expression in the log phase (time 0) and nitrogen starved (3, 7 and 14 days) cells of *P. incisa*. The transcript abundance of the gene was normalized to that of 18S SSU rRNA gene

phase (time 0). The results showed that during nitrogen starvation the mRNA of the *PiELO1* gene was induced to its highest level at day 3 (14-fold increase over time 0), decreasing thereafter to a level still higher than that of day 0 (Fig. 5). After 7 and 14 days, the expression level of the *PiELO1* gene was still 7.5 and 4.3-fold higher, respectively. The level of expression of the *PiELO1* gene correlated with the increase in the share of ARA and the C20/ (C16 + C18) elongation ratio (Table 3). The share of the elongation product, DGLA, increased sharply at day 3 (50% increase over time 0) and decreased thereafter.

Discussion

Recent successes in the production of VLC-PUFA by genetically modified oil plants has elicited further investigations concerning the characterization, role, and regulation of the genes and enzymes involved in VLC-PUFA biosynthesis. We isolated from *P. incisa* a cDNA (*PiELO1*) of an elongase encoding for a deduced protein, structurally similar to Δ 6 PUFA elongase gene products from microalgae, lower plants, and fungi (Fig. 1). The deduced amino acid sequence of the *PiELO1* ORF was about 50% identical with that of Δ 6 elongases from the liverwort *M. polymorpha* (AAT85662), the green marine microalga *O. tauri* (AAV67797), and the moss *P. patens* (AAL84174). In similarity to recently cloned PUFA elongases, the predicted protein is highly hydrophobic and has two strongly hydrophobic transmembrane regions, the first located about 50 amino acids downstream of the N-terminus and the second in the vicinity of the C-terminus. We identified in the *PiELO1* sequence a

C-terminal lysine-rich motif, important for the endoplasmic reticulum targeting [37], and four conserved motifs FYxSKxxEFxDT, QxxxLHVYHHxxI, NSxxHVxMYxYY, and TxxQxxQF, including a conserved histidine-rich box, suggested to be functionally important for PUFA elongation [28] (Fig. 1). These conserved motifs were not found in other classes of plant microsomal elongases, β ketoacyl CoA synthases, and fatty acid elongases (FAE) involved in extraplasmidial elongation of saturated and monounsaturated fatty acids. A variant histidine box, containing three amino acid replacements, in C18- Δ 9-PUFA-specific elongase from *I. galbana* (IgASE1), was shown to be essential for optimal enzymatic activity rather than for substrate specificity [38].

Similarly to GLELO of *M. alpina*, PiELO1 prefers the Δ 6 C18 PUFA substrates, GLA and STA [25]. Only these Δ 6 fatty acids were, when exogenously added, elongated to the respective products by *S. cerevisiae* cells transformed with *PiELO1* (Fig. 4). Transformation of a higher plant so as to render it to produce Δ 6 PUFA requires that the elongase used will have a high selectivity for Δ 6 PUFA, thereby reducing the appearance of side products in the transformed plant [11, 39, 40]. Bifunctional invertebrate PUFA elongases with both Δ 6 and Δ 5 activities (OmELO, XiELO, and CiELO) are less desirable in plant transformations [20, 28].

Phylogenetic analysis showed (Fig. 3) that the PUFA elongases are not strictly divided according to their substrate specificity. The Δ 6 elongases of algal (OtELO1, TpELO1, PiELO1) and moss (PpELO1) origin are functionally restricted to the elongation of Δ 6-C18-PUFAs, however, these elongases are placed in separate groups on the phylogenetic tree (Fig. 3) [28]. PiELO1 is closely related to OtELO1 isolated from a chloropyte and a lower plant rather than to a ELO1 gene isolated from a diatom, although both are specific for the elongation of Δ 6-C18-PUFAs (Fig. 3). PiELO1 is highly similar to, and is placed in the same group with, both Δ 6 and Δ 5 elongases of the liverwort *M. polymorpha*. Kajikawa et al. [41] suggested that MpELO2, a Δ 5 elongase, is likely to have originated through gene duplication of the *MpELO1* gene. In contrast, Δ 5 and Δ 6 PUFA elongases of *Thraustochytrium* sp. are located in distinct branches. The Δ 5 PUFA elongases of a marine chloropyte, a diatom and a haptophyte, OtELO2,

TpELO2 and the *P. salina* ELO1 [42], respectively, are more likely to share a common branch with the mammalian and animal Δ 5 PUFA elongases, OmELO [28] and HELO1 [20], while they are also similar to bifunctional PUFA elongases such as CiELO1/2 [28].

Quantitative real time PCR studies revealed that the expression level of the *PiELO1* gene was up-regulated during the time course of N-starvation (Fig. 5). Nitrogen starvation led to a continuous increase in the share of ARA and the C20/(C16 + C18) elongation ratio (Table 3). However, a major transcriptional activation of *PiELO1* which occurred on day 3 (14-fold increase in transcript level) coincided with the steep rise in ARA accumulation and elongation ratio (Table 3). The increase in *PiELO1* transcription level followed by enhanced biosynthesis of ARA may be interpreted as an increase in the PiELO1 enzyme level and/or enzymatic activity. The importance of the transcriptional activation of PiELO1 is supported by the fact that PUFA elongase gene was the only ARA biosynthesis-related gene that was obtained from the subtractive library. Possibly, the elongation of GLA by PiELO1 could be rate-limiting in ARA biosynthesis as it is in *M. alpina*. However, the significance of the coordinated transcription and action of desaturases, elongases, and enzymes of TAG assembly in biosynthesis of ARA-rich TAG in *P. incisa* is yet to be elucidated. Abbadì et al. [11] suggested that in transgenic plants modified with VLC-PUFA biosynthesis genes, substrate availability rather than enzymatic activity is rate-limiting in the Δ 6 elongation of PUFA. Moreover, the selective acyl channeling to TAG in engineered plant seeds is of major importance in regulating the final TAG acyl quality [11, 39].

In conclusion, PiELO1 is a Δ 6 PUFA elongase, specifically elongating GLA and STA to 20:3 ω -6 and 20:4 ω -3, respectively. The *PiELO1* gene is up-regulated under oleogenic conditions. This gene is a likely candidate for genetic transformations of oil seed plants that will enable the production of VLC-PUFAs in the transgenic plants. The up-regulation of the *PiELO1* gene under nitrogen starvation conditions must have significant physiological importance for adaptation of *P. incisa* cells to nitrogen deficiency.

Accession Numbers GenBank accession numbers for PiELO1 and 18S SSU rRNA of *P. incisa* are ACK99719 and FJ548971, respectively.

Acknowledgments This work was supported by a grant from the Israeli ministry of science, culture and sport.

Abstract Boraginaceae species, such as those from the genus *Echium*, contain high levels of the Δ^6 -desaturated γ -linolenic (18:3n-6) and octadecatetraenoic (18:4n-3) acids. These are unusual fatty acids among the plant kingdom that are gaining interest due to their benefits to human health. The potential utility of acyltransferases aimed at an increase in oil yield and fatty acid profiling has been reported. In this work, a gene encoding an acyl-CoA:diacylglycerol acyltransferase (DGAT, EC 2.3.1.20) was cloned from *Echium pitardii*. Genomic and cDNA sequences obtained revealed a gene structure composed of 16 exons, yielding a protein (EpDGAT) of 473 amino acids with high similarity to DGAT1 enzymes of plants. Protein features such as a predicted structure with a highly hydrophilic N-terminus followed by 10 transmembrane domains, as well as the presence of diverse specific signatures, also indicate that EpDGAT belongs to the DGAT1 family. indeed. DGAT activity of the protein encoded by *EpDGAT* was confirmed by heterologous expression of the full-length cDNA in a yeast mutant (H1246) defective in the synthesis of triacylglycerols. Fatty acid composition of the triacylglycerols synthesized by EpDGAT in H1246

yeast cultures supplemented with polyunsaturated fatty acids suggest a substrate preference for the trienoic fatty acids α -linolenic acid (18:3n-3) and γ -linolenic acid over the dienoic linoleic acid (18:2n-6). Site-directed mutagenesis has revealed the presence of a critical residue (P¹⁷⁸ in EpDGAT) within a reported thiolase signature for binding of acyl-enzyme intermediates that might be involved in the active site of the enzyme. Transcript analysis for *EpDGAT* shows an ubiquitous expression of the gene which is increased in leaves during senescence.

Introduction

Plant oils have become important renewable resources as biofuel and for human consumption [1–3]. Nowadays there is a growing demand, mainly due to an increase in the biodiesel market specially in Europe [1]. Consequently, any improvement in seed oil production is of interest, and great efforts are being made with this aim within the biotechnology field.

Plant oil is mostly composed of triacylglycerol (TAG), the main storage lipid. TAG is usually synthesized by sequential incorporation of acyl groups through the glycerol-3-phosphate (G3P) pathway, also known as the Kennedy pathway [4–6]. Briefly, G3P is first acylated by the action of the acyl-CoA:glycerol-3-phosphate acyltransferase (GPAT; EC 2.3.1.15), followed by a second acylation step catalyzed by the acyl-CoA:lysophosphatidate acyltransferase (LPAT; also called acyl-CoA:acyl-glycerol-3-phosphate acyltransferase, AGPAT; EC 2.3.1.51). The phosphatidic acid obtained is then dephosphorylated by a phosphatidate phosphatase (PAP; EC 3.1.3.4) to generate diacylglycerol (DAG) which is finally used as substrate for the acyl-CoA:diacylglycerol acyltransferase (DGAT; EC 3.2.1.20) to produce TAG [5, 6]. GPAT and LPAT are acyltransferases common to TAG and membrane-lipid biosynthesis while DGAT catalyze the only step which is committed to TAG biosynthesis [4, 5, 7].

Two alternative pathways for the synthesis of TAG have also been described involving the phospholipid:diacylglycerol acyltransferase (PDAT) and DAG:DAG transacylase (DGTA) enzymes, respectively [5, 8]. It has been suggested that PDAT has a role in directing unusual fatty acids (such as ricinoleic acid) to TAG, thus avoiding their incorporation into polar lipids and possible disturbances of membrane functions [9, 10]. The presence of PDAT in plants lacking such unusual fatty acids indicates that it may play a different role in lipid biosynthesis, though this function remains still unknown [11, 12]. Nevertheless, current evidence strongly suggests that PDAT is not a major determinant of TAG production in seed plants [9, 12–14]. With regard to DGTA, involvement in remodeling of TAG was proposed [15] although it does not seem to affect the net biosynthesis [8, 13].

There is growing evidence supporting a major contribution of DGAT to TAG synthesis in seed plants [14, 16]. The *AS11 Arabidopsis* mutant, bearing reduced DGAT

activity, showed a 75% reduction in seed lipids [17]. Conversely, DGAT over-expression determines a net increase in seed oil content in *Arabidopsis* [18]. Additional evidence is also available from studies of soybean [19], oil-seed rape [20], olive [21] and maize [3]. In agreement with this, it is considered that DGAT catalyzes a rate limiting step within the TAG biosynthesis pathway [5, 18, 20, 22, 23]. Consequently, DGAT is also regarded as being a key enzyme, from a biotechnological point of view, in order to increase oil content in oleaginous species [7, 23–27].

Another area of active research is the biosynthesis of oils containing particular fatty acid profiles. In this regard, the importance of acyltransferases for the production of ‘designer oils’ in genetically engineered plants has been emphasized [14, 24]. Though initial studies on DGAT activity had suggested a wide substrate utilization by this enzyme [24], later works indicated that the DGAT specificity is species-dependent. While DGAT from plant species like saffron or peanut showed wide acyl utilization [28], in others such as spinach, maize [28], castor bean [29], *Arabidopsis* [17], *Garcinia indica* [30], *Vernonia galamensis* and *Stokesia laevis* [31], this enzyme exhibited some acyl preference. This behavior opens the possibility of using appropriate *DGAT* genes to engineer TAG fatty acid profiles.

The first eukaryotic *DGAT* gene was cloned from the mouse, based on similarity to the acyl-CoA:cholesterol acyltransferase (ACAT) enzyme [32]. A similar gene was later cloned from *Arabidopsis* [33–35] and other plants species [36–41], all of them encoding proteins related to ACAT. A different family of enzymes with DGAT activity was uncovered after cloning of the *DGAT* gene from *Mortierella rammaniana* [42], and finding of similar genes in different plant species [13, 41]. Members of this group share homology with a broader family of genes that transfer acyl groups from coenzyme A to neutral lipids including monoacylglycerol, diacylglycerol, and fatty alcohol species [43]. Thus, two evolutionary unrelated DGAT families are present in plants, encoding membrane bound proteins, that have been named as DGAT1 (ACAT-related) and DGAT2 [23]. Recently, a new *DGAT* gene was reported encoding a soluble cytosolic enzyme [44]. This protein is closely related to bacterial bifunctional DGAT/wax ester synthetase, thus representing a third unrelated group named as DGAT3 [14].

Experimental evidence indicates that DGAT1 and DGAT2 are the major isoenzymes acting in the biosynthesis of TAG [14], while the contribution of DGAT3 seems to be just marginal [44]. The importance of DGAT1 for the synthesis of TAG in the seed has been well documented in *Arabidopsis thaliana* [12, 17, 18, 34, 35, 45, 46] and more recently in maize [3]. On the other hand, DGAT2 has proven to be essential in determining both TAG profile

and TAG content in *Vernicia fordii* [41]. Paradoxically, in that work, DGAT2 was shown to be less active in vitro than DGAT1, and yeast transformed with *DGAT1* were more efficient in producing TAG than that transformed with *DGAT2* [41]. Similar studies performed in castor bean (*Ricinus communis*) suggested that DGAT2 was the main enzyme for TAG synthesis in seeds [13] and metabolic engineering of *Arabidopsis* with both castor bean fatty acid hydroxylase 12 and DGAT2 resulted in a significant increase in ricinoleic acid in the seed oil [47]. However, another study on *R. communis* has shown a DGAT1 activity pattern matching in time to that of TAG accumulation [48]. Moreover, an extensive search for DGAT2 was unsuccessful in *Tropaeolum majus* suggesting that DGAT1 may be the sole DGAT in this plant species [7], and *Arabidopsis* DGAT2 showed no detectable activity in yeast complementation assays [41]. Therefore, the question about the relative contribution to TAG synthesis by DGAT1 versus DGAT2 is far from being answered [14, 23]. In this regard, it has been suggested that both DGAT isoenzymes may play distinct roles in different tissues and plant species [41, 48].

In this work, we report on the cloning of the *DGAT1* gene from *Echium pitardii* A. Chev. ex D. Bramwell (Boraginaceae). Boraginaceae species such as those from genus *Echium* are characterized by the accumulation of high levels of the Δ^6 -desaturated fatty acids, γ -linolenic (18:3n-6, GLA) and octadecatetraenoic (18:4n-3) acids, that are unusual among the plant kingdom. More specifically, Macaronesian species of *Echium* such as *E. pitardii* are considered among the richest sources of GLA found in nature, reaching 28% of total fatty acids in the seeds of *E. gentianoides* [49]. *E. pitardii* was chosen for our work since its herbaceous habit makes it appropriate for the study in the laboratory [50]. The highest content of GLA (19% for *E. pitardii*) is found in the seed, but it is also accumulated, although at a lower level, in other organs of the plant such as the leaves, roots and stem [50].

Molecular characterization of the *Echium DGAT* was performed in our study that included confirmation of the DGAT activity by heterologous expression in a yeast system.

Experimental Procedure

Biological Material

Seeds of *E. pitardii* A. Chev. ex D. Bramwell (= *E. lancerolettense* Lems et Holz) were collected from plants located in their natural habitat at Lanzarote (Canary Islands). Seedlings (6–8 leaves stage) were grown at 25°C, under the controlled conditions of growth cabinets with a 16 h

light/8 h dark photoperiod and 70% relative humidity. Leaf material from seedlings was used as a DNA source, while the different tissues of *E. pitardii* utilized for RNA extraction and Northern blot analysis were sampled from mature plants cultivated in a greenhouse.

The wild type yeast strain INVSc1 (purchased from Invitrogen), and the H1246 mutant strain (*Mat α yor245c::KanMX4 lro1::TRP1 are1::HIS3 are2::LEU2 ADE2 ura3*) [51], kindly provided by Dr. Stymne (Swedish University of Agricultural Sciences, Uppsala) were used to assay DGAT activities by heterologous expression.

Cloning of the DGAT1 Gene of *E. pitardii*

Cloning of the *EpDGAT* gene was achieved by RT-PCR amplification of a partial cDNA sequence, followed by bi-directional walking through inverse PCR (IPCR) on genomic DNA. Briefly, a cDNA was synthesized from 5 μ g of total RNA obtained from developing flowers of *E. pitardii* (RNeasy Plant Mini Kit, QIAGEN) by employing the kit “SuperScript First-Strand Synthesis System for RT-PCR” (Invitrogen), and following the manufacturer’s instructions. RT-PCR amplification on the cDNA was done using the degenerated oligonucleotide primers DAG1-Up (5'-ATTATCGARAAYYTIATGAAR TAYGG-3') and DAG2-Down (5'-GCRTTCCACCART CYTTRTARAAAYTC-3') designed against the DGAT conserved motifs IENLMKYG and EFYKDWNA, respectively. The reaction was performed using a proof-reading polymerase (AccuTaq, Sigma) and a program consisting of a denaturation step of 2 min at 94°C, followed by 40 cycles of 15 s at 94°C, 30 s at 45°C and 75 s at 72°C, ending with a 5 min step at 72°C. The resulting fragment (about 800 bp, spanning the central coding region) was cloned in the vector pGEM-T-Easy[®] (Promega), and several clones were sequenced that resulted in their being all identical. Starting with this partial sequence, a total of five successive IPCR rounds were carried out following the method reported in [52] with minor modifications [53]. DNA clones were sequenced on both strands using a Perkin-Elmer ABI-310 DNA automated sequencer, and the BigDye[®] Terminator v3.1 chemistry. About 7.5 Kb of genomic sequence were assembled which included the whole coding sequence and about 700 bp of the 5'-region upstream the ATG. A whole cDNA was obtained by RT-PCR as described before on mRNA from developing fruits, using the flanking primers DAG2-Up (5'-CATAGGTTACCATGGCAATATGGGAGTCGCCGG A-3') and DAG2-Down (5'-CATACTCGAGTCAGTTTGCATTAACCTTTTCTATTCAAGAC-3') which contained suitable restriction sites for cloning in the pYES2 vector and a single nucleotide change involving the second codon, ACA (Thr) \rightarrow GCA (Ala), to conform the Kozak

consensus and maximize expression in yeast. The cDNA and genomic sequences were deposited in the GenBank under the accession numbers FJ226588 and FJ226589, respectively.

Cladistic Analysis

Alignment of DGAT protein sequences was achieved using the program Clustal X v.1.7 [54] using the default settings, and further refined by visual inspection. The alignment output was used to generate a cladogram based on the minimum evolution method [55], as implemented in the MEGA package v3.1 [56]. The Poisson model was used together with the pairwise deletion of gaps option, and confidence of the tree branches was checked by bootstrap generated from 1,000 replicates. Rooting of the tree was accomplished by using the plant cytosolic DGAT3 sequences as outgroup. For sequences selected in Fig. 1, the alignment was visualized using the Boxshade v. 3.21 software.

Southern and Northern Blot Analysis

Genomic DNA was isolated from *Echium* seedlings by a CTAB-based extraction procedure [57]. DNA (about 5 µg) was restricted with the appropriate restriction enzymes, separated on a 0.8% agarose gel, and transferred by capillarity onto Hybond[®] N⁺ nylon membranes (Amersham). Filters were UV-crosslinked, pre-hybridized at 42°C for 5 h in the 50% formamide/high SDS buffer recommended by the DIG manufacturer (Boehringer-Mannheim), and hybridized at the same temperature and same buffer solution (stringent conditions), containing the digoxigenin-labeled *DGAT* specific probe. High stringency washes were performed twice at 65°C during 15 min in buffer containing 0.1× SSC, 0.1% SDS, and the luminogenic substrate CSPD[®] was used for the detection, following the instructions provided with the DIG detection kit. Images were obtained by exposure of Biomax[®] ML films (Kodak) for 10–25 min and final developing by standard procedures. The *DGAT* probe was obtained by random primed labeling from a cDNA fragment spanning 512 bp of the 5'-coding sequence.

Total RNA was extracted from different tissues of *Echium* plants, using the Concert[™] Plant RNA Reagent (Invitrogen) following the protocol provided by the manufacturer. About 10 µg per lane of total RNA was loaded onto an agarose/formaldehyde gel, electrophoretically separated, and transferred to Hybond[®]-N⁺ membranes. Filters were hybridized at 50°C (stringent conditions) as described for Southern analysis, and using the same *DGAT* specific probe. Stringent washes, accomplished at 68°C, and detection of the DIG-labelled probe were as indicated before.

Heterologous Expression of *EpDGAT* in Yeast

The whole *EpDGAT* coding sequence was transcriptionally fused to the *GALI* inducible promoter of the pYES2[®] expression vector (Stratagene), and the resulting plasmid used to transform *Saccharomyces cerevisiae* (INVSc1 or H1246 strains) according to the LiAcO method [58]. Cultures were grown at 28°C in standard minimal medium supplemented with the auxotrophic requirement of the strain plus 1% (w/v) raffinose, and expression was further induced on a 0.4 OD₆₀₀ culture by the addition of galactose 2% (w/v). Incubation under inductive conditions was prolonged for 48 h at the same temperature. Supplementation of cultures with LNA, ALA and GLA in some experiments was carried out with 0.5 mM of each, in the presence of 0.1% Tween-40 in the induction medium. Yeast cells were collected by centrifugation, further washed with 1.3% NaCl, and the resulting biomass subjected to lyophilization and pulverization in a mortar. The material was stored at –25°C until processed for lipid analysis.

Lipid Analysis

Fatty acid composition of the different materials (lipid extract, lipid fractions, etc.) was analyzed by GC of methyl esters, as previously described [59] and using heptadecanoic acid as the internal standard.

Total lipids were extracted from 200 mg of yeast lyophilized biomass as described elsewhere [60]. Particular care was taken with the procedure to minimize the action of endogenous lipases and subsequent liberation of free fatty acids. The lipid extract was dried in a rotary evaporator under an argon stream and then resolubilized in 2 ml of CHCl₃. The lipid extract was fractionated by column chromatography (CC) on a silica gel cartridge (Sep-Pack Classic, Waters) accordingly to [60] with some modifications. Briefly, after cartridge equilibration with CHCl₃, the lipid extract was adsorbed into the silica gel cartridge and lipid fractions were sequentially eluted with 30 ml of CHCl₃ (neutral lipids, NL) and then 30 ml of MeOH (polar lipids, PL). Lipid fractions were dried in a rotary evaporator as described above and resuspended in 2 ml CHCl₃.

Neutral lipid classes were separated by one-dimensional TLC using silica gel plates (Macherey Nagel). Plates were activated in an oven at 120°C for 2 h before use. Solvents employed were: petrol–Et₂O–HOAc (80:20:1) [61]. NL classes were visualized by iodine vapor, marked with a pencil and immediately scrapped-off and analyzed individually by GC as previously described. NL classes were identified by co-chromatography with authentic standards. The areas corresponding to NL classes were always scrapped-off and processed even when they were not

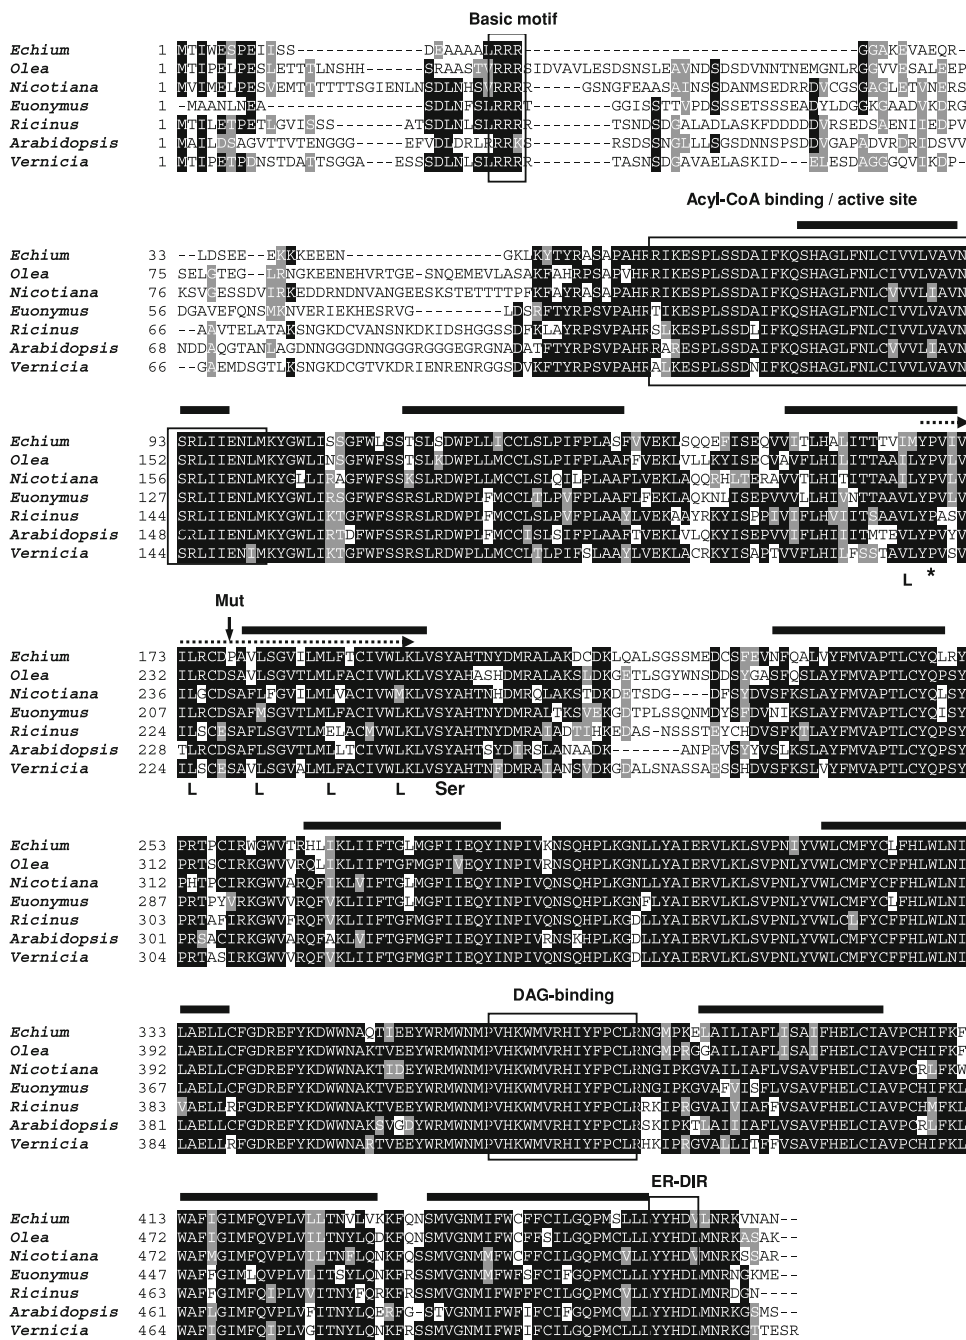

Fig. 1 Sequence comparison of EpDGAT with related DGAT1 enzymes from higher plants. The amino acid sequence of EpDGAT (GenBank accession no. FJ226588) was aligned, using the software ClustalX v1.7 together with those of characterized DGAT1 type I DGAT from *Olea europaea* (acc. no. AAS01606), *Nicotiana tabacum* (acc. no. AAF19345), *Euonymus alatus* (acc. no. AAV31083), *Ricinus communis* (acc. no. AAR11479), *Arabidopsis thaliana* (acc. no. AAF19262), and *Vernicia fordii* (acc. no. ABC94471). The Boxshade program is used to highlight the homology between protein sequences. Shading is applied when there is agreement for a fraction of sequences above 0.5. Amino acids identical to EpDGAT are enclosed in *black boxes* while similar residues are in *grey*. Gaps

introduced for maximum alignment are represented by *dashes*. Transmembrane domains inferred from the TMpred software [62] are marked by *horizontal solid bars*. Conserved motifs or putative signatures (see text for details) are boxed, such as the N-terminal basic motif, the Acyl-CoA binding signature, and DAG-binding and putative ER retrieval motifs (ER-DIR). The region containing a conserved leucine repeat (L) coinciding with a thiolase acyl-enzyme intermediate binding signature is also marked (*pointed arrow*) besides previously described critical Pro and Ser residues which are marked by *asterisks*. Position of the Pro residue in EpDGAT which was analyzed in this work by site-directed mutagenesis is indicated by an *arrow*

endoplasmic reticulum (ER) membrane. Little conservation is found for the amino terminal domain, which is unusually short in the *Echium* protein, except for the characteristic basic repeat [36] consisting of three arginine residues in EpDGAT. Also relevant is the presence of the reported acyl-CoA binding signature R⁶¹–G⁷⁹ [18, 37] close to residues (R⁹⁴–N⁹⁹) that have been involved in the active site, as well as a DAG/phorbol ester binding motif [18, 35]. A previously reported leucine zipper motif [23, 36] is also found overlapping with a putative thiolase acyl-enzyme intermediate binding motif reported for the *Arabidopsis* and *Tropaeolum* DGAT1 [7, 35]. This sequence contains an invariant proline residue (P¹⁶⁹ in EpDGAT, Fig. 1) that has been shown critical for DGAT1 activity [7]. Within the same domain it is also remarkable the presence of a proline residue at position 178 of EpDGAT instead of the extremely conserved serine present in other DGAT1 (Figs. 1, 7a). The relevance of the Pro replacement in EpDGAT was assessed in this work by site directed mutagenesis (see results below). A C-terminal YYHDV motif conforming the putative ER retrieval motif is also present in the *Echium* DGAT similarly to other DGAT1 proteins of plants [13].

Gene Structure and Genomic Organization of EpDGAT

A comparison between the genomic and cDNA sequences allows the identification of 15 introns interrupting the coding region (Fig. 3a, GenBank accession no. FJ226589). The same structure is also shared by *DGAT1* genes of dicot plant species such as *Arabidopsis* [35], *N. tabacum* [36], and *V. fordii* [41]. An exception to this rule are the DGAT genes of the legumes *Lotus* and *Glycine*, with only 14 introns, a difference that is likely due to combination of the last two exons [40]. When sequences around the inferred splicing sites are analyzed (Table 1 in Supplementary data) the usual GT pair in all donor splice sites is found, although a non-consensus acceptor splice sequence is observed in the third intron of the *EpDGAT* gene whose sequence (GG) differ from the common AG. This particular deviation has also been observed in other organisms and has been illustrated in the case of *A. thaliana* (http://www.tigr.org/tdb/e2k1/ath1/Arabidopsis_nonconsensus_splice_sites.shtml).

Genomic organization of the *EpDGAT* gene was investigated by Southern-blot on genomic DNA restricted with different enzymes under highly stringency conditions (Fig. 3b). The pattern obtained is in agreement to that

Fig. 3 **a** Genomic structure of *EpDGAT* together with a restriction map showing relevant endonuclease sites (Hae, *Hae*III; E1, *Eco*RI; EV, *Eco*RV; HIII, *Hind*III; V, *Vsp*I) for Southern analysis. Position of the cDNA probe used for hybridization experiments is represented correlating with exons covered in the genomic DNA. **b** Analysis of the genomic organization of *EpDGAT* by Southern blot. Genomic DNA of *E. pitardii* was restricted with the different enzymes indicated above each lane and analyzed as indicated in “[Experimental Procedure](#)”, using a digoxigenine labeled cDNA as a probe (see *upper panel*). Marker sizes (Kbp) are indicated. **c** Expression analysis of

EpDGAT by Northern blot in different tissues of *E. pitardii*. Equivalent amounts of total RNA (10 μ g) from roots (*R*) developing (*Ld*) or mature (*Lm*) leaves, floral stem (*S*) developing flowers (*Fl*) and developing fruits (*Fr*), collected from adult plants, were subjected to electrophoresis in an agarose/formaldehyde gel, run for 1 h at 110 V, blotted and hybridized with the *EpDGAT*-specific probe (see above) under highly stringency conditions, as indicated in “[Experimental Procedure](#)”. The ethidium bromide staining of the gel is also shown as a loading control

expected from the known genomic sequence and the cDNA probe used in the analysis (Fig. 3a, b). This also indicates that the *DGAT1* gene is represented by a single copy in the *Echium* genome. This is also suggested by the finding of identical sequences for the different cDNA clones obtained in the initial RT amplification using primers against highly conserved motifs (see “[Experimental Procedure](#)”).

Expression Analysis of *EpDGAT*

The transcript level of *EpDGAT* was determined by Northern blot on total RNA. An ubiquitous expression is observed among the different organs of the plant (Fig. 3c). This generalized expression pattern is also found for *DGAT1* genes of other plants such as *Arabidopsis*, *Brassica* and soybean [33, 35, 40, 45, 63], where expression is not restricted to typical oil-accumulating organs like seeds. As in the case of *Echium*, relatively high transcript levels are also present in flowers, stem, roots, and leaves, which may indicate a more generalized function in the plant. Low expression levels, though comparable to those of developing seeds, are found in the leaves of *Ricinus* [13] and tung tree [41], where a second DGAT enzyme (DGAT2) is also present with a location predominantly in the seed. However, a seed-specific pattern of *DGAT1* has been reported in the case of *Tropaeolum* [7]. It seems likely that differences may exist in the contribution of the DGAT isozymes and metabolic pathways to the synthesis of TAG in the diverse organs, among the plant species considered.

Interestingly, the mRNA level was remarkably higher in the old leaves of *Echium* than in young developing leaves. Up-regulation of the *DGAT1* gene during senescence has been also reported in *Arabidopsis* and soybean [40, 63], and a role in sequestering fatty acids mobilized from plastid galactolipids into TAG has been proposed [63]. Related to this, is the presence of two ethylene responsive motifs (ERE) in the 5'-regulatory region of *EpDGAT* located at -350 and -380 as a part of a wider direct repeat CACCTATATTTCAA (see GenBank accession no. FJ226589). Two direct ERE motifs are also found in the promoter of the *Arabidopsis DGAT1* gene that have been related with seed maturation [45]. However, a possible involvement of the ERE motifs in the regulation of *DGAT1* during the leaf senescence remains unknown, but it is also likely given the involvement of ethylene in the senescence of vegetative tissues [64, 65].

The Protein Encoded by *EpDGAT* Shows TAG Biosynthetic Activity

To assess DGAT activity of the *EpDGAT* product, a complementation assay was carried out using the H1246 strain of *S. cerevisiae* [51]. This is a *dgal1 lro1 are1 are2*

quadruple mutant that is defective in the *DAG1* and *LRO1* genes which are responsible for the TAG synthesis in the yeast, besides two other genes, *ARE1* and *ARE2*, with overlapping acyl-CoA:sterol acyltransferase (ASAT) activities, thus rendering the yeast unable to synthesize both triacylglycerol (TAG) and steryl ester (SE) [51]. Yeast transformation was performed with a pYES2 expression plasmid containing the *EpDGAT* gene, or the empty vector as a control. The lipid content (as total fatty acids, TFA) from galactose induced cultures was determined from the lipid extract and the lipid extract was fractionated into polar lipids (PL) and neutral lipids (NL) as indicated in “[Experimental Procedure](#)”. As shown in Fig. 4a, nearly a fourfold increase (from 11 to 40 mg/g) in the NL fraction is obtained relative to the control, when the yeast mutant is transformed with *EpDGAT*, while a reduction in the PL was found. Expressed as percentages, this results in an increment of the NL from 22 to 66% and a parallel decrease of the PL from 78 to 34%. Similarly, expression of *EpDGAT* in a wild type yeast strain (INVSc1) also results in a clear increase of the NL fraction (Fig. 4a). The higher PL content in the H1246 mutant as compared to the same cells transformed with *EpDGAT* or with the wild type strain may be attributed to the higher availability of the DAG, an intermediary that is also employed for the synthesis of major phospholipids in yeast [66].

The NL fraction was further analyzed by resolving the lipid classes by TLC, and each saponifiable NL class was quantitated by GC (see “[Experimental Procedure](#)”). As expected for the mutant strain H1246 [51] neither SE nor TAG was detected in the NL fraction of the pYES2 control, where the predominant NL classes were free fatty acids (FFA) (73%) and DAG (27%) (Fig. 4b). Conversely, TLC plates of NL reveal the appearance of a prominent band corresponding to TAG in the yeast transformed with *EpDGAT* that is lacking in the pYES2 control (Fig. 4b). Most of NL of yeast expressing *EpDGAT* correspond to TAG (91%), with FFA in much lower amount (9%), and undetectable levels of DAG and SE. These results indicate that *EpDGAT* encodes a protein with TAG biosynthetic activity, what together with sequence identity suggests that it is a DGAT1 enzyme.

Analysis of the Acyl-CoA Preference of *EpDGAT*

Echium pitardii accumulates substantial amounts of GLA, an ‘unusual’ PUFA in higher plants. Since it has been reported that DGAT enzymes from plant species with ‘unusual’ fatty acids (e.g. ricinoleic, vernolic, eleostearic acids) exhibit preference for substrates containing its ‘unusual’ fatty acid, it may be hypothesized that *EpDGAT* could exhibit preference for some PUFAs. In this regard, we devised an “in vivo” experiment in yeast to get some hint

Fig. 4 Synthesis of TAG directed by heterologous expression of *EpDGAT* in yeast cells. **a** Fatty acids content of the NL (black bars) and PL (grey bars) fractions from the defective H1246 or wild type INVSc1 yeast strains transformed with the empty expression vector (pYES2) or the same plasmid containing the *Echium* DGAT gene (*EpDGAT*). Lipids were extracted from the induced yeast cells and processed as indicated in the “Experimental Procedure” to obtain the NL and PL fractions. Fatty acids of acyl-lipids in these fractions were quantitated by GC analysis of methyl esters, as described in the “Experimental Procedure”, and expressed relative to the dry wt

biomass. Mean values ($n = 3$) are represented together with their SE. **b** Lipid analysis by TLC of the NL fraction obtained from H1246 cells transformed with the empty vector (pYES2) or with the plasmid containing *EpDGAT*. Lipids were visualized by iodine staining. Predominant acyl-lipid classes in the NL fractions are indicated: triacylglycerol (TAG), steryl esters (SE), free fatty acids (FFA) and diacylglycerols (DAG). In our chromatography system DAG overlap with sterols (ST), and estimation of the DAG amount is therefore not possible from direct visualization of the band intensity

on the possible acyl-CoA preference of *EpDGAT*. We compared the fatty acid profiles of the H1246 yeast mutant transformed with the *EpDGAT* gene with that containing the empty vector. Since the yeast does not synthesize PUFAs we supplemented the culture with equimolar amounts of LNA, GLA, and ALA together. As will be shown, these exogenous fatty acids are efficiently incorporated to the different cellular lipids. Similarly to the previous experiment, the lipid extract from the induced cultures was fractionated into PL and NL. As represented in Fig. 5a, the amount of PL fraction did not change significantly while a considerable increase was observed for the NL which increased from 14 mg/g in the pYES2 control to 129 mg/g in the yeast expressing *EpDGAT*. Overall these results are similar to those obtained in the experiment without added PUFAs, though a greater increase of the NL suggests a limitation of the FA supply for the synthesis of TAG in the non supplemented yeast, at least under our experimental conditions. Lipid class composition in the NL fraction reveals that, as expected, TAG are the main component (76%) when the yeast are transformed with *EpDGAT* (Fig. 5b). When fatty acid composition of the NL was determined (Fig. 5c) differences were observed among them, with a lower proportion of C16 fatty acids (16:0 and 16:1n-7) in *EpDGAT* expressing cells, relative to the control, while 18:0 is increased and 18:1n-9 remains

unchanged. With regard to the three PUFAs, exogenously provided, the trienoic acids, GLA and ALA, increased while LNA decreased in *EpDGAT* transformed yeast relative to the control (Fig. 5c). These differences were statistically significant as shown by ANOVA and non-parametric tests.

When PUFA contributions to the different lipids are compared (Fig. 6) several observations are remarkable. The three PUFAs are efficiently incorporated into the different lipids if we compare them to the endogenous fatty acids of the yeast. Nevertheless, GLA is incorporated in all lipids to a lower extent than LNA and ALA (Fig. 6), even though they are supplied to cultures in equimolar amounts. This indicates that, in the yeast, GLA is discriminated against by some of the yeast enzymes (acyl-CoA synthetases and/or acyltransferases) involved up to the synthesis of DAG. Thus, a LNA:GLA:ALA ratio of 1:0.25:0.93 in the total lipid extract (TL), and 1:0.36:1 in the NL fraction are obtained for the pYES2 control (Fig. 6a). However, when cells are transformed with *EpDGAT*, a remarkable change in the ratio of PUFAs is observed both in TL (1:0.57:1.56) and NL (1:0.69:1.86), so that LNA contribution is reduced relative to GLA and ALA, thus indicating that these two PUFAs are being favored in their incorporation to the TAG by the *Echium* DGAT (Fig. 6a) as compared to the rest of acyl-lipids. This suggestion is also supported by comparison of the PUFA composition of lipid

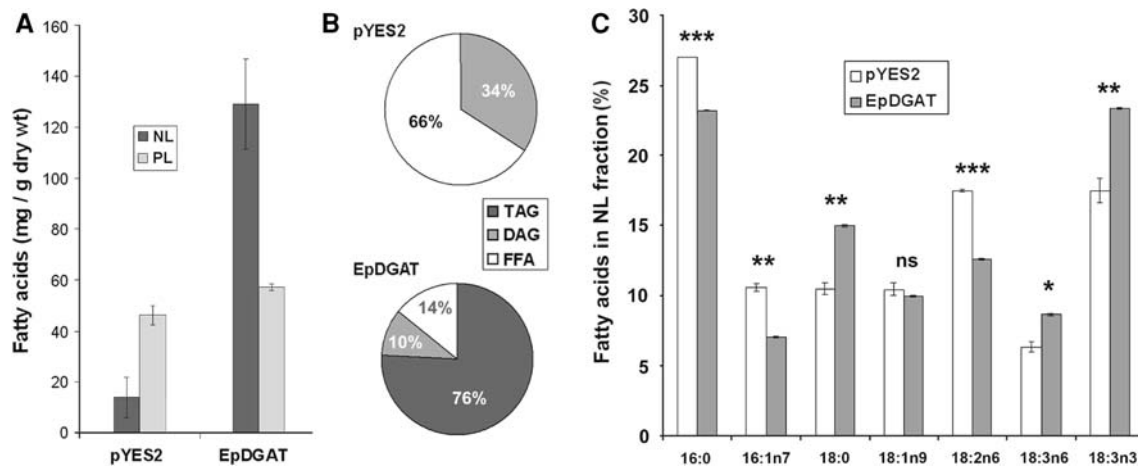

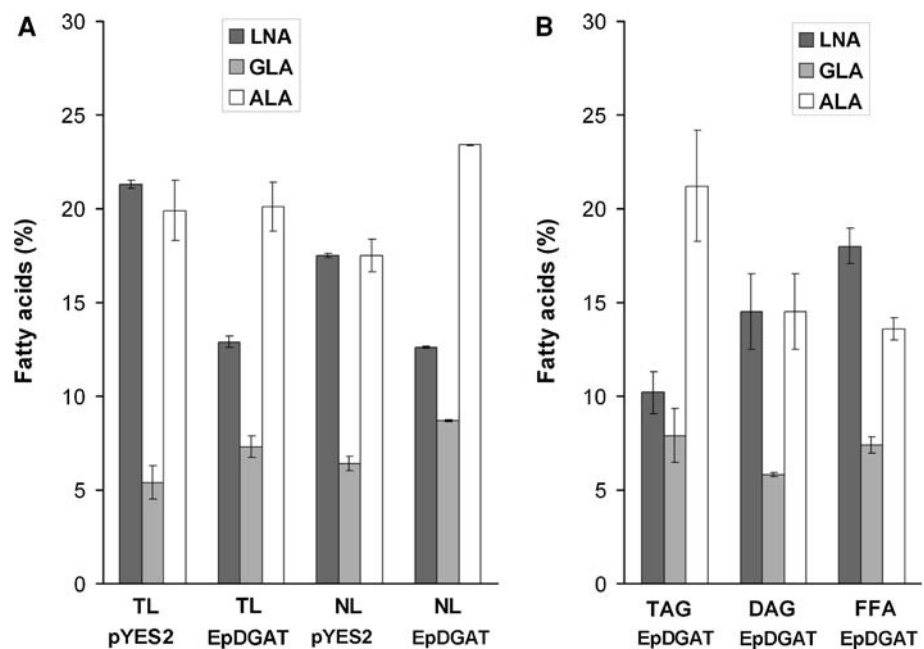

Fig. 5 Lipid synthesis directed by *EpDGAT* in H1246 yeast supplemented with PUFAs. **a** Fatty acids content of the NL (black bars) and PL (grey bars) fractions from the defective H1246 yeast strain transformed with the empty expression vector (pYES2) or the same plasmid containing the *Echium* DGAT gene (*EpDGAT*), and cultivated in the presence of equimolar amounts of LNA, ALA and GLA. Lipids were analyzed as in Fig. 4a. **b** Contributions of individual fatty acids in the NL fractions of H1246 yeast cells

transformed with pYES2 alone or the plasmid containing *EpDGAT* from cultures supplemented with PUFAs (see above). Values are expressed as percentage over total fatty acids in the NL fraction. Mean values ($n = 3$) are represented together with their SE. Significance of the differences was checked by ANOVA and non-parametric tests (*ns* non significant; $*P < 0.05$; $**P < 0.01$; $***P < 0.001$)

Fig. 6 PUFAs composition in different lipid fractions of H1246 yeast cells transformed with the empty vector (pYES2) or the vector containing *EpDGAT* (see experiment in Fig. 5). LNA, GLA and ALA contributions are represented for the total lipids in the biomass (TL in panel a), the NL (in panel a), and individual NL classes (TAG, DAG and FFA in panel b). Values correspond to percentages on the total FAs in each fraction. Acyl-lipid composition of the NL fraction is represented as a percentage for each lipid class (panel c). Mean values ($n = 3$) are represented besides their SE

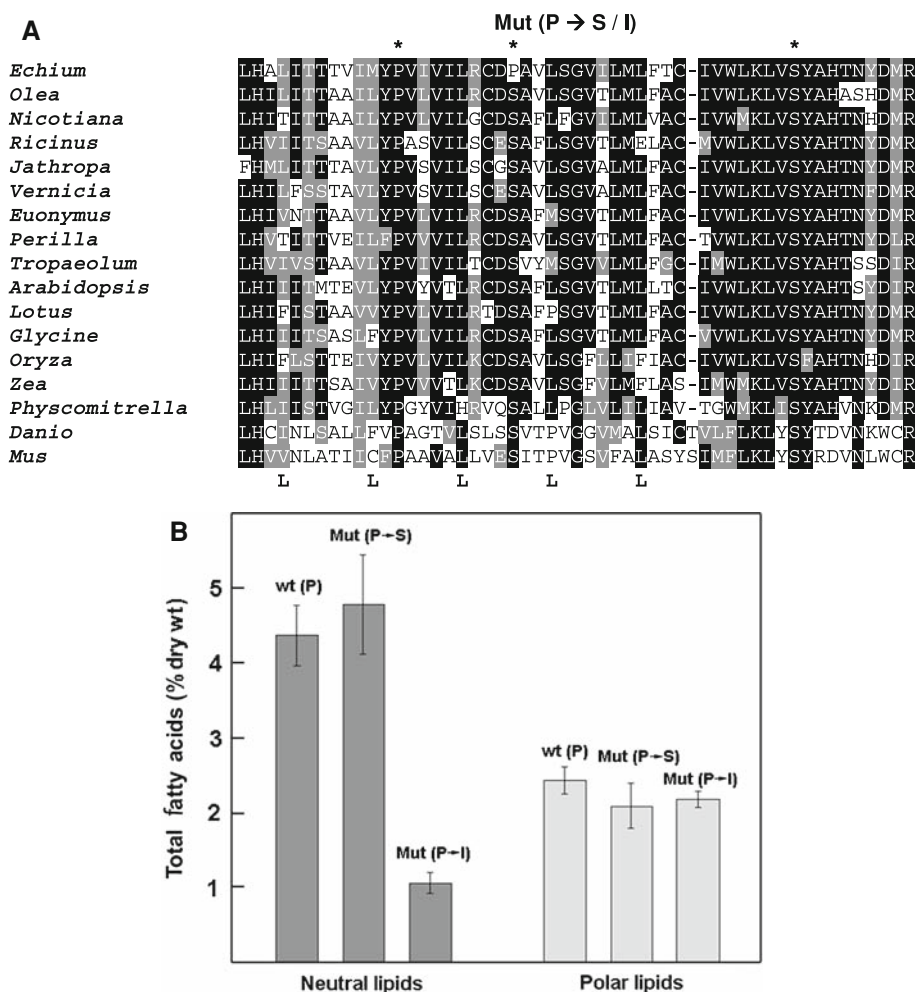

classes in the NL fraction of *EpDGAT* transformed yeast (Fig. 6b). A PUFA ratio of 1:0.77:2.08 was obtained for TAG while, in DAG and FFA, the ratios were 1:0.40:1 and 1:0.41:0.76, respectively, fairly similar to that of the NL fraction in control cells. In other words, GLA and ALA increased from DAG to TAG while LNA decreased (Fig. 6b). These differences in PUFA percentages between DAG and TAG were statistically significant ($P < 0.05$) by ANOVA and non-parametric tests. Since in the H1246 cells the synthesis of TAG comes exclusively from the

acylation of DAG via *EpDGAT* it seems likely that ALA and GLA are being preferentially selected against LNA in their incorporation to DAG by *EpDGAT*, thus increasing the proportion of the trienoic acids in TAG relative to that in the DAG substrate.

A number of reports on DGAT activity using microsomes from different species have indicated a preference for substrates containing particular acyl groups [23]. This is exemplified in plants like *Cuphea* and *Ricinus*, producing unusual and potentially toxic fatty acids such as lauric and

Fig. 7 Site-directed mutagenesis of EpDAGAT. **a** Protein alignment of the leucine repeat region showing the P¹⁶⁹ residue in EpDAGAT which was replaced either by Ser (P→S) or Ile (P→I). Positions of other critical amino acids in the same region, revealed in previous studies, are marked by asterisks. **b** Fatty acids content of the NL (grey bars) and PL (white bars) fractions from the defective H1246 yeast strain transformed with the wild type *EpDGAT* gene (wt) and the two replacement mutants (P→S and P→L). Lipids were extracted from the induced yeast cells and processed as indicated in the “Experimental Procedure” to obtain the NL and PL fractions. Fatty acids of acyl-lipids in these fractions were quantitated by GC analysis of methyl esters and expressed as a percentage over the dry wt biomass. The experiment was performed three times using independent cultures, and the mean value is shown besides their SE

ricinoleic acids, respectively [29]. In these cases it was proposed that fast conversion of DAG to TAG would act as a way to prevent incorporation of harmful fatty acids to membrane phospholipids [29]. Channeling of particular fatty acids into TAG has also been described in cocoa, for stearic acid [67], and rape, for erucic acid [68].

However, studies on substrate preference dealing with particular DGAT isoenzymes (DGAT1, DGAT2) are still scarce, and even a clear picture of their particular roles and distribution within the plant is lacking at the moment. It has been shown that DGAT1 of some plants like *Ricinus* [38] and *Tropaeolum* [7] favor the incorporation of their respective unusual ricinoleic and erucic fatty acids into TAG. However, in other species like *Vernonia* [69] and *Vernicia* [41], the DGAT1 enzyme does not show preference for vernolic and eleostearic acids, respectively, contrary to the results obtained with seed microsomes. In these cases the DGAT2 isoenzyme was proposed to be responsible for channeling of the unusual fatty acids. It seems therefore that substrate preference and isoenzyme contribution to the synthesis of TAG may be different in each plant.

There is little information available for Boraginaceae species. The analysis carried out with *Borago* seed microsomes indicated a strong selectivity of the DGAT activity by GLA-CoA [70]. Even though interpretation of our results must be cautious, data obtained for *Echium* DGAT do not show a strong preferential utilization of GLA-CoA. It is possible, as described above for other species, that additional activities (e.g. DGAT2) are involved in determining the fatty acid profile of TAG in Boraginaceae species. It should be also noticed that, contrary to *Borago*, the seeds of *Echium* accumulate high amounts of ALA [49], which is consistent with the observed preference of the *Echium* DGAT1 enzyme for this fatty acid.

Site Directed Mutagenesis of the Pro178 Residue of EpDAGAT

As previously stated, a proline residue is present at position 178 of EpDAGAT, a place where a serine is invariably found for DGAT1 proteins of plants and animals (Fig. 7a). We have performed SDM on this residue in

order to assess its importance for DGAT activity. In particular, the P¹⁷⁸ was replaced either by serine (P → S), the common residue, or by isoleucine (P → I), and DGAT activity was recorded by yeast complementation of the defective H1246 strain, as described before. As shown in Fig. 7b, the P → S replacement does not have an appreciable effect on the synthesis of TAG, estimated by the NL content, which is predominantly composed by TAG, as it was shown previously. On the contrary, changing of the P¹⁷⁸ to Ile produces a drastic reduction of the NL content thus showing the critical role of this residue for DGAT1 activity. As expected, none of the replacements had an appreciable effect on the PL content (Fig. 7).

Different studies have underlined the importance of this region for DGAT1 activity. Thus, two critical positions have been identified (Fig. 7a), a serine residue (Ser¹⁹⁹ in EpDGAT) which is essential for ACAT activity [71], and an extremely conserved proline (Pro¹⁶⁹ in EpDGAT) present in diverse acyltransferases [72]. This Pro was demonstrated to act as a catalytic site in GPAT enzymes [72], and a recent work also proved its importance for DGAT1 activity [7]. As stated before the P¹⁷⁸ is located between these two amino acids as a part of a sequence that contains a thiolase signature (PCDO0092) for binding of acyl-enzyme intermediates [7, 35]. The loss of activity produced by the P→I replacement suggests the possible involvement of this residue as a part of the DGAT1 active site. On the other hand, it was noticed that DGAT1 proteins of plants contain a regularly spaced leucine repeat overlapping the thiolase signature (Fig. 7a) which has been proposed to act as a leucine zipper in protein to protein interactions [37]. However, specialized leucine zipper prediction tools such as TRESPASSER [73] or 2ZIP [74] fail to recognize this structure, and it should also be noticed that the Leu repeat is absent from animal enzymes. The notion that this motif may not represent a leucine zipper is in agreement with our results since the presence in the EpDGAT of the Pro residue, a typical helix breaker, does not seem to affect enzyme activity which is similar to that of the Ser containing mutant.

The cloning and molecular characterization of the gene encoding the DGAT1 enzyme of *Echium* was achieved. Functional assay by heterologous expression in yeast show that the encoded protein promotes the synthesis of TAG, and increases the oil amount. We also report evidence that *Echium* DGAT1 catalyzes a preferential incorporation of ALA over LNA, and that it does not discriminate the GLA negatively. This is interesting regarding the possible utility of this gene to modify the fatty acid profile of transgenic plants in order to increase the contribution of trienoic fatty acids in oils, including the ‘unusual’ GLA.

Acknowledgments This work was supported by grants from the Ministerio de Ciencia y Tecnología (MCYT, AGL2005-01498/AGR) and Junta de Andalucía (P05-189-AGR). J.A. Garrido-Cárdenas and A. Mañas-Fernández were recipients of postgraduate fellowships from the MCYT and Junta de Andalucía, respectively. We are also grateful to J. Pérez-Parra and J.C. Gázquez for providing greenhouse facilities and technical assistance in plant culture at the “Estación Experimental Las Palmerillas (CAJAMAR)”. Dr. Stymne (Swedish University of Agricultural Sciences, Uppsala) kindly provided the mutant strain of *S. cerevisiae* H1246, and is gratefully acknowledged.

Abstract Mislabeling of farmed and wild salmon sold in markets has been reported. Since the fatty acid content of fish may influence human health and thus consumer behavior, a simplified method to identify wild and farmed salmon is necessary. Several studies have demonstrated differences in lipid profiles between farmed and wild salmon but no data exists validating these differences with government-approved methods to accurately identify the origin of these fish. Current methods are both expensive and complicated, using highly specialized equipment not commonly available. Therefore, we developed a testing protocol using gas chromatography (GC), to determine the origin of salmon using fatty acid profiles. We also compared the GC method with the currently approved FDA (United States Food and Drug Administration) technique that uses analysis of carotenoid optical isomers and found 100% agreement. Statistical validation ($n = 30$) was obtained showing elevated 18:2n-6 ($z = 4.56$; $P = 0.0001$) and decreased 20:1n-9 ($z = 1.79$; $P = 0.07$) in farmed samples. The method is suitable for wide adaptation because fatty acid methyl ester analysis is a well-established procedure in labs that conduct analysis of lipid composition and food constituents. GC analysis for determining the origin of North American salmon compared favorably with the astaxanthin isomer technique used by the FDA and showed that the fatty acid 18:2n-6 was the key indicator associated with the origin of these salmon.

Introduction

Farmed Atlantic salmon (*Salmo salar*) production currently provides approximately 50% of world-wide salmon consumption [1]. This popularity is due, in part, to the year-round availability of fresh farmed salmon and the low-cost which can be half that of wild salmon [2]. A direct result of these lower prices is greater availability of a high omega three fish product to the public. Additionally, as the catch of wild salmon becomes more variable, farmed salmon may provide a more stable supply. However, some concern exists over ecological damage from salmon cultivation. Extensive salmon farming may result in negative effects including dwindling fisheries of the small pelagic fish used as feed, interruption of salmon breeding patterns, dilution of the wild salmon gene pool by escaped farmed salmon, and transmission of infections from farmed to wild populations [3–7]. Farmed salmon have been reported to contain on average much higher levels of polychlorinated biphenyls (PCBs) and other nonpolar contaminants than their wild counterparts even after correction for the higher fat content of the farmed salmon [8, 9]. It may be possible to solve these problems;

some farmed salmon, such as those from Chile, have very favorable contamination profiles which may rival wild salmon such as Chinook [10–12]. Mozaffarian and Rimm make the valid point that some common foods also may have similar concentrations of PCBs to farmed salmon and although eating such fish may have certain risks, they believe the health benefits exceed the dangers [2].

Contaminated fishmeal and depletion of pelagic fish used in fishmeal may be motivating commercial fish farmers to develop alternate feeding strategies. The nutritional requirements of farmed salmon can be met in part by the substitution of plant derived oils and protein such as rapeseed, corn, palm, or soybean [13–16]. Some studies indicate that resultant feeds containing up to 100% terrestrial plant oils are well tolerated, support normal growth rates, and provide filets with acceptable flavor [14, 15, 17].

Deep cold water fish such as salmon have low delta-6 desaturase enzyme activity and therefore have a limited ability to convert linoleic acid (18:2n-6, LNA) to arachidonic acid (20:4n-6, ARA), and linolenic acid (18:3n-3, ALA) to eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA) [15, 17, 18]. Consequently, farmed deep cold water fish must be fed a “finishing diet” containing increased amounts of fish oils for the last few weeks before slaughter. This diet maintains the most beneficial fatty acid balance, including the higher levels of EPA and DHA that are fundamental to the health benefits of fatty fish consumption [13, 14, 19].

To maintain the characteristic reddish-orange color of their flesh, salmon must consume the carotenoids astaxanthin and canthaxanthin. Farmed salmon are fed fishmeal supplemented with various isomers of these carotenoids; wild salmon assimilate carotenoids by consuming krill. It is interesting to note that the color differences between wild and farmed salmon are often indistinguishable by visual inspection and thus advanced analytical techniques are required for authentication [14, 19–23].

Interest in farmed and wild salmon by both consumers and scientists has led to increased pressure to determine accurately the origin of different fish provided to the marketplace. In 1998, the United States Food and Drug Administration (FDA) developed an accurate method to authenticate the origin of salmon by measuring unique isomer ratios of astaxanthin [20]. The origin of the salmon in our study was verified by the FDA method that uses high performance liquid chromatography (HPLC) analysis of astaxanthin isomers. The HPLC method requires specialized equipment such as specific chiral columns or derivatization with chiral reagents. Our objective was to establish a facile gas chromatography (GC) fatty acid analysis technique for distinguishing wild and farmed salmon that

could be readily implemented with the resources of a typical biochemistry laboratory.

Materials and Methods

Thirty salmon filet samples were provided to our laboratory by Craft Technologies in Wilson, NC, USA. These samples had been collected during the interval between 2004 and 2006 at various fish markets in the Northeastern and central United States. All samples were stored frozen at -80°C and transported on dry ice.

Craft Technologies tested all samples for carotenoid profiles using the FDA method which includes a combination of normal-phase and chiral HPLC as described in references [20, 24]. Astaxanthin was extracted from the fish samples by homogenization with acetone. After centrifugation to remove protein debris, the extract was injected on a Chromegabond diol column (ES Industries), 15×0.46 cm, $5 \mu\text{m}$ particle size, with 96% hexane/4% isopropanol mobile phase, at 1.5 mL/min flow rate. Detection was at 450 nm. The astaxanthin fraction was collected, the solvent was evaporated, and the sample re-dissolved in 85% hexane/15% acetone for the next HPLC step. The isolated astaxanthin fraction was re-analyzed for enantiomer composition with two chiral columns in series: Chiralcel C18 250×4.6 mm (Diacel Chemical Industries, Ltd), $5 \mu\text{m}$ particle size. The mobile phase was 85% hexane/15% acetone, at 0.8 mL/min flow rate, and detection was at 450 nm [20].

Preparation of Fatty Acid Methyl Esters

One gram of each salmon filet was minced with single-edged razor blades and homogenized in 10 mL of 0.15 M NaCl, using a handheld glass Potter–Elvehem homogenizer. For extraction of lipids, 1 mL of the tissue homogenate was vortexed with 2 mL of chloroform/methanol (2:1) and 0.1% BHT as antioxidant. After centrifugation, the lower organic layer was collected and evaporated in an 8-mL vial under nitrogen.

The methylation reagent was generated by mixing 1 mL of acetyl chloride with 30 mL of MeOH, and was used within 5 days of preparation. One milliliter of this reagent was added to the residue from extraction, along with 200 μL of hexane in a tightly sealed 10-mL Teflon-capped glass vial, and the sample was heated at 100°C for 1 h to convert fatty acids to methyl esters. After addition of 1 mL of 0.15 M sodium bicarbonate and 2 mL of hexane, the sample was vortexed, centrifuged, and the upper hexane layer was transferred to a second 10-mL glass vial, evaporated under a nitrogen stream, and dissolved in 200 μL chloroform for GC analysis.

GC Analysis and Peak Identification

Samples were analyzed on an HP 5890 GC (Avondale, PA, USA), equipped with a flame-ionization detector. The column was a DB-23, 30M × 0.25 mm i.d. with film thickness of 0.25 μM (J & W Scientific, Folsom, CA, USA). The stationary phase was a (50% phenyl)-methylpolysiloxane. Helium was used as the carrier gas at 30 psi column pressure. One microlitre of sample was injected using an HP-6331 auto-injector, with a 1:15 split ratio. Initial column temperature was 160 °C, with a 1 °C/min gradient to 200 °C, and an additional 5 min at 200 °C. The injector and detector were set at 240 °C.

Calibration was done with fatty acid methyl ester standards from Nu-Chek Prep (Elysian, MN, USA). Chromatograms were collected and integrated with Lab-Calc software (Galactic Industries, Salem, NH, USA), on an IBM-PC. The total peak areas of the following fatty acids were determined: 14:0 myristic acid, 16:0 palmitic acid, 18:0 stearic acid, 18:1n-9 oleic acid, 18:1n-7 vaccenic acid, 18:2n-6 linoleic acid, 20:1n-9 eicosenoic acid, 20:4n-6 arachidonic acid, 20:5n-3 eicosapentaenoic acid, and 22:6n-3 docosahexaenoic acid. Each peak of interest was reported as weight percent of the sum of these major fatty acid components.

Research Design and Selection of Criterion Value

Our research design required two sample groups. The initial batch had five wild and five farmed salmon samples with known identities as determined by carotenoid chiral isomer ratios. This first batch was used to establish a criterion value for categorizing salmon as either wild or farmed. The second batch contained 20 samples whose categorization (wild or farmed) was not disclosed to the team analyzing the fatty acid composition.

After reviewing several fatty acids that might be used for discrimination within the sample of ten salmon with known classifications, we determined that LNA was the best indicator, as there was no overlap of LNA concentrations within the distribution of the pre-identified wild and farmed salmon. We then calculated the criterion value by choosing the lowest LNA (9.96%) value for the known farmed samples and the highest value (2.19%) from the known wild samples, and then taking the midpoint between those two values (6.1%).

We then tested the criterion value of 6.1% LNA on the remaining 20 unknown samples. The “unknown” samples were sent by Craft Technologies without any indication as to their carotenoid ratios or their classification as wild or farmed. Craft Technologies had previously categorized these 20 samples using the FDA-approved carotenoid chiral isomer ratios test.

Using the proposed 6.1% LNA criterion value, the 20 unknown samples were classified as farmed (LNA over 6.1%) or wild (LNA below 6.1%). The classifications for each of these 20 samples were then unblinded by Craft Technologies. The match between the criterion value classification and the carotenoid chiral isomer ratios classification was 100%.

Fatty Acid Statistics

Significant differences between farmed and wild salmon sample fatty acid ratios were noted by comparison of chromatographic peak areas. These results were recorded as percent of total weight of fatty acids. Difference of proportions tests were calculated on each fatty acid to determine statistical significance between farmed and wild salmon samples. This test produces *z* scores which are subsequently converted to *P* values, see Table 1 [25, 26].

Table 1 Fatty acid retention times, mean percent weight, standard deviation (SD) and *P* values

Fatty acid	Retention Time (min)	Mean peak area (%) Wild salmon	SD	Mean peak area (%) Farmed salmon	SD	<i>P</i> value
14:0	4	4.40	1.58	4.68	1.02	0.85
16:0	6.7	21.59	4.36	18.36	1.75	0.64
18:00	11.1	6.04	1.70	5.17	0.50	0.64
18:1n-9	11.7	25.68	8.31	29.10	8.47	0.73
18:1n-7	11.9	7.23	6.03	4.16	0.25	0.11
18:2n-6	13	2.10	0.61	12.73	2.59	0.0001
20:1n-9	18.5	4.75	3.21	2.65	0.94	0.07
20:4n-6	22.1	0.80	0.24	0.98	0.18	0.12
20:5n-3	24.8	11.84	4.01	9.97	3.41	0.62
22:6n-3	35.6	15.57	5.67	12.20	4.08	0.49
Total sat (%)	–	32.0	4.1	28.2	2.8	–
Mono (%)	–	37.7	8.6	35.9	8.4	–
n-6 (%)	–	2.9	0.5	13.7	2.5	–
n-3 (%)	–	27.4	7.7	22.2	7.2	–

All *P* values were determined by differences of fatty acids between all farmed and wild salmon tested *n* = 30 (note 18:2n-6 has a very high *P* value)

These calculations were carried out using Microsoft Excel version 2000.

Results

The fatty acid results for the initial sample of ten salmon that were analyzed are shown in Table 2. These salmon had all been pre-identified by chiral carotenoid analysis.

The highest LNA for wild salmon in this sample was 2.19%, and the lowest LNA for farmed salmon was 9.96%.

Representative carotenoid analyses are shown in Fig. 1. Wild salmon ingest predominantly a mixture of an astaxanthin from copepods and krill, which contain mostly the 3*R*,3'*R* and 3*S*,3'*S* astaxanthin isomers, and very little of the 3*R*,3'*S* isomer. Salmon fed yeast astaxanthin in their diet show primarily the 3*S*,3'*S* isomer, and salmon fed synthetic astaxanthin show an abundance of the central “meso” peak on the HPLC analysis, the 3*R*,3'*S* isomer.

Table 1 summarizes the fatty acid retention times and percent of total for each of the fatty acids reported in this analysis. This table was assembled after all the salmon samples had been classified as wild or farmed, using the criterion value of 6.1% LNA obtained from the initial set of identified salmon. There was complete agreement between assignment using LNA content and assignment using carotenoid analysis. These results are provided graphically in the histogram in Fig. 2, which emphasizes that LNA was the major peak that differs between wild and farmed.

Representative fatty acid profiles by GC of wild and farmed salmon are shown in Fig. 3. The elevated 18:2*n*-6 peak is highly distinctive and easily identifiable on the trace of the cultivated sample. Farmed samples may have

lower 20:1*n*-9, but this fatty acid was not statistically significant ($P = 0.07$). The other fatty acid components are generally comparable between wild and cultivated salmon and are not statistically different. Also, there was a non-significant trend toward decreasing percent of several major fatty acids in cultivated salmon reflecting the presence of increased 18:2*n*-6 (see Table 1; Fig. 2). The 22:1*n*-11 peak (sometimes called cetoleic acid), which elutes at 26.8 min in Fig. 3, is more abundant in many of the wild samples than in the farmed samples, but exhibits a high variance between samples. The peak is present at low abundance in all the farmed samples (1–2%) and in some

Fig. 4 The criterion value of 6.1 separates farmed from wild salmon samples by the percentage of 18:2n-6. Note that one sample of the wild salmon appears very close to the criterion value. See text for explanation

wild samples. This may reflect the fact that some of the wild-caught fish consumed copepods or other foods rich in 22:1n-11. Although of potential interest, this fatty acid cannot be reliably used for classifying the origin of the fish. Thomas et al. [27] also observed a much greater variance for 22:1n-11 in wild salmon than the other fatty acids reported in their study.

The percentage of LNA was plotted separately for all samples in Fig. 4; one sample, classified as wild by the LNA criterion, had a somewhat higher LNA content (4.3%) than the other 14 wild samples. This sample had an unusual carotenoid profile as well, intermediate between what is typically seen for wild and farmed salmon. Based on both the LNA content and carotenoid profile, we hypothesize that this sample is a farmed salmon that escaped and consumed a natural diet in the wild for an extended period.

Discussion

Wild and farmed salmon are similar in appearance and therefore it may be difficult for consumers to distinguish

between them by visual inspection. For this reason, the FDA developed the accurate, but complicated, HPLC method using chiral isomers of astaxanthin to identify farmed salmon. In our study, we analyzed fatty acid profiles in salmon samples that had been pre-identified using the FDA HPLC method.

Trends in the feeding practices for cultivated salmon could decrease the reliability of carotenoid analysis for determination of fish origins since wild krill and *Haematococcus* microalgae are being employed as part of the fish rations, and the astaxanthin isomer ratio in these fish could resemble that of wild salmon (see Fig. 1 for typical astaxanthin profiles) [23, 28]. By contrast, fatty acid analysis should continue to be a reliable method for classification. For example, Bell et al. [16] reported that when salmon flesh fatty acid content is plotted against their dietary intake of fatty acid for 20:5n-3 and 22:1, $r = 1.0$, while other fatty acids such as 18:2n-6 and 18:1n-9 result in the slightly lower flesh values of $r = 0.97$ and 0.98 , respectively. Current trends in fish feed development may lead to increased levels of 18:2n-6 in farmed fish, emphasizing the utility of fatty acid analysis in identifying farmed and wild salmon [15, 16, 19, 22, 29, 30].

Due primarily to price pressures, mislabeling of the origins of commercially sold salmon has been previously reported [27, 31]. Without quick, accurate, inexpensive, and commonly available testing procedures to authenticate wild and farmed salmon, mislabeling could become increasingly problematic. It therefore may be useful that readily available procedures such as fatty acid analysis by GC be applied to this question, and it should be possible to accomplish this analysis using the facilities in many nutrition and food science laboratories.

Our identification of farmed and wild salmon samples using fatty acid analysis demonstrated 100% agreement with the carotenoid isomer identification technique established by the FDA. The higher percent of 18:2n-6 in the farmed salmon flesh is an excellent marker for distinguishing

farmed and wild salmon, based on current feeding practices. Statistically, the percent of 18:2n-6 had a value of $P = 0.0001$ when the differences between all farmed and all wild ($n = 30$) samples were compared, indicating a high level of certainty that the amount of this fatty acid is dissimilar between the two groups of salmon. The only other fatty acid that approached statistical significance was the 20:1n-9, but it failed to reach 95% significance ($P = 0.07$). We chose not to employ it as a marker for identification.

As noted earlier, the fatty acids that salmon consume are assimilated into their flesh in proportion to dietary content (less any amount used for energy derived through beta-oxidation) [19]. Cultivated fish are currently being fed meal formulations with increasing ratios of plant-based oils [15, 16, 19, 22]. This change may reduce persistent organic contaminants, decrease the cost of fish feed, and ultimately increase the sustainability of aquaculture as a whole by preserving threatened pelagic fisheries [14, 16]. The practice of switching from fish oils to terrestrial plant oils leads directly to the increased 18:2n-6 content reported here, since 18:2n-6 is a major constituent of corn, rapeseed, and soybean oils that are typically used as components of the diet of farmed salmon. North American suppliers of salmon feed may use largely soybean oil and corn oil, consistent with the elevated n-6 fatty acid content of salmon feed in North America [32]. Salmon feed employed in Europe may have a different fatty acid profile, and the 18:2n-6 fatty acid content of farmed salmon from Scotland can be lower for some fish than farmed salmon from North America [8, 32].

Several studies that address the content of highly unsaturated fatty acids such as EPA and DHA have found that the relative percentages of these fatty acids were similar between farmed and wild salmon, but the total content of these fatty acids was higher in farmed fish because of the higher total lipid content [8, 22, 30, 33–35]. The percentage of EPA and DHA was not statistically different between wild and farmed salmon in the samples reported here, but we did demonstrate a consistently higher percentage of 18:2n-6 as seen in Table 1 and Fig. 2. In several previous studies, 18:2n-6 was also found to be significantly higher in farmed than in wild fish [27, 29, 30, 34]. However, our group was the first to apply a prospective blinded study design to test the hypothesis that 18:2n-6 could be an accurate marker for determining wild or farmed origin as compared with the current FDA-approved method. In one recent study, Thomas et al. [27] found 18:2n-6 to be the most reliable fatty acid for classification, but their validation procedure also used complex and expensive isotope ratio mass spectrometers. We feel that the mass spec method, which uses several different isotopic mass spectrometers equipped with either chemical analyzers or pyrolysis ovens [27], may be prohibitively

complex and expensive. Our data suggests that with this limited sample of fish obtained from North America, 18:2n-6 may be as accurate as using carotenoid chiral isomers, and therefore could be used as the sole identifier of farmed and wild salmon instead of the FDA-approved method. Additionally, the instrumentation for the HPLC analysis would require a capital investment of \$30,000, compared to \$10,000 for a standard GC. The labor required is also very different. A technician can complete 40 samples per week using fatty acid analysis, as opposed to ten samples per week for the FDA-approved astaxanthin chiral isomer identification test.

With any testing method for salmon, there may be samples that seem ambiguous. In our study, there was one wild sample with 18:2n-6 content of 4.3%, which approached the criterion value of 6.1% (see Fig. 4). The carotenoid profile of this fish was somewhat ambiguous as well. Farmed salmon sometimes escape from their pens and become feral salmon that are caught as wild. One study estimated that the number of escaped farmed salmon could be up to 40% of the total salmon caught as wild in the North Atlantic near the Faroe Islands, a center of fish farming [36]. The number was far lower for catches in the Pacific which averaged below 1%, although in some years higher numbers of escaped farmed salmon caught as wild in the Pacific have been reported [37]. It therefore is reasonable to expect that we could find at least one sample of wild caught salmon that could be a feral Atlantic salmon that escaped, was subsequently caught, and was identified with an intermediate fatty acid profile. Since it takes months for fatty acid and carotenoid profiles to change significantly, escapees may have a fatty acid profile with a ratio between that of typical wild and farmed salmon (see Fig. 4). For example, fish caught near the Faroe Islands might be more difficult to identify by either carotenoid or fatty acid profiles since this area is a center for salmon farming with a high escape rate. Therefore, to ensure consistency and accuracy with our method, continuous monitoring of the fatty acid composition of both cultivated and wild salmon should be considered. If a major change in LNA composition was detected for a given salmon population, the criterion value could be adjusted accordingly. This would eliminate error due to changes in either fishmeal fatty acid content or seasonal variation in wild salmon's diet. If greater assurances were needed, more sophisticated and time-consuming techniques, such as fish scale identification or multiprobe and multielement isotopic analyses [27, 38], could be employed.

One possible limitation of this study is that we reported each fatty acid as a percentage by weight, instead of the quantitative method using an internal standard to determine the absolute amount of each fatty acid per gram tissue. This study was focused on establishing a rapid, simple and

convenient procedure to distinguish farmed from wild salmon, thus the use of the percentage by weight of each fatty acid satisfies these requirements. Some investigators may want to quantify the amount of EPA and DHA in a sample to help identify fish that provide more of these fatty acids in the diet.

To our knowledge, this is the first published study to compare the FDA developed chiral isomer astaxanthin analysis method to the fatty acid analysis by the GC method of identifying farmed and wild salmon. The procedures reported herein are accurate, facile, and may be readily adapted in facilities with capillary GC. For this reason, fatty acid profiles could be of general value for discriminating wild and farmed salmon, with the potential to be applied to other seafood.

Low and High Fat Diets Inconsistently Induce Obesity in C57BL/6J Mice and Obesity Compromises n-3 Fatty Acid Status

Sir,

C57BL/6J mice are the background strain for multiple models of obesity and diabetes that have genes homologous to those identified in human obesity [1, 2]. C57BL/6J mice are also models of gene-environment induced obesity because they are more susceptible to an environment permissive to obesity and several publications show that high fat (HF) feeding (~40–70% of kcal) induces obesity, insulin resistance, hyperglycemia and leptin resistance [3–9]. We have used this model of high fat feeding to examine interactions of obesity and zinc status but showed neither level of dietary fat nor zinc had an effect on body weight, body mass index, glycemia, insulinemia or leptinemia in C57BL/6J mice [10]. This led to an opportunity to examine whether the inconsistency in development of diet induced obesity (DIO) is related to dietary fat level, or the metabolic derangements associated with greater weight gain. Thus, mice from the original data set [10] were stratified into low body weight (LBW) and high body weight (HBW) groups to determine relationships with metabolic parameters associated with obesity including variations in adipose tissue fatty acid composition and zinc status.

The LBW and HBW groups comprised mice fed both low fat (LF) and HF diets, and similar numbers of zinc deficient, control and supplemented mice (Fig. 1). The HBW group displayed greater fasting serum glucose and leptin concentrations (9.8 ± 0.5 vs. 8.2 ± 0.6 mmol/L and 42.6 ± 5.9 vs. 20.3 ± 4.4 ng/ml, respectively; $P < 0.05$) compared to the LBW mice. Fasting serum insulin,

homeostasis model assessment (HOMA) and zinc were not different between LBW and HBW mice (data not shown). Notably, mice fed a LF diet based on the AIN-93G diet (7 g soybean oil/100 g diet; 16% of calories as fat), were susceptible to obesity, contrary to what others have reported [11–13]. Furthermore, approximately half the mice fed the HF diet were resistant to obesity. The HF diet in our experiment contained a combination of lard and soybean oil (20.9 and 8.8 g/100 g diet, respectively; 55% of calories as fat) to ensure adequate intake of essential fatty acids and this resulted in a HF diet with slightly lower saturated fatty acid content and higher polyunsaturated fatty acid content from linoleic acid compared to protocols in which the high fat diet contains less soybean oil [6, 11]. There are other reports that show HF feeding does not consistently produce obesity in C57BL/6J mice [4, 8].

Fig. 1 Distribution of low and high body weight C57BL/6J mice by dietary treatment. *LF* low fat, *HF* high fat, *ZD* zinc deficient, *ZC* zinc control, *ZS* zinc supplemented; *LBW* low body weight, *HBW* high body weight. The distribution of LBW and HBW mice by level of dietary fat or zinc were not different by Chi-square analysis

Burcelin et al. [8], fed C57BL/6J mice a HF diet [72% kcal from corn oil and lard (proportions not specified)] for 9 months and found that only about 50% of the mice became obese with diabetes. Koza et al. [4] reported a fourfold difference in fat mass among C57BL/6J mice fed a HF diet (33.4 g hydrogenated coconut oil and 2.5 g soybean oil/100 g diet; 58% kcal from fat) and found important gene variations in mice that were high gainers compared to those that were low gainers, thus showing the importance of gene–diet interactions. Given that the level of fat used in the current study was comparable to what others have reported induces DIO [3–9, 11–13] and the findings of Koza et al. [4], these observations support a strong genetic predisposition to obesity in the affected mice. There are now over 30 candidate genes on 6 chromosomes linked to adiposity in mice. Some of the target pathways include CCAAT/enhancer binding protein

(C/EBP)- α , sterol regulatory element binding protein (SREBP)-1, peroxisome proliferator activated protein (PPAR)- γ and secreted frizzled-related sequence protein (SFRP)-5/Wnt signalling [2, 4, 14–16], to which the fatty acid environment of adipose tissue may be important [17].

Our results also demonstrate that adipose PL fatty acid composition was affected by diet and obesity (Table 1), whereas adipose TAG fatty acid composition generally resembled the dietary fatty acid content. The HBW mice had more C16:0 (15.3 ± 0.4 vs. $14.3 \pm 0.4\%$), C18:3n-3 (0.35 ± 0.07 vs. $0.24 \pm 0.04\%$) and C22:5n-3 (0.52 ± 0.02 vs. $0.46 \pm 0.02\%$), less C22:6n-3 (3.94 ± 0.22 vs. $4.49 \pm 0.25\%$), and a greater n-6:n-3 ratio (5.88 ± 0.24 vs. 5.15 ± 0.23) in adipose PL compared to LBW mice. There was an interaction of diet fat and body weight such that the HBW-LF mice had more C18:3n-3 and less C20:5n-3 in adipose PL than the LBW-LF mice, suggesting reduced

conversion of ALA to EPA in the HBW-LF mice (Table 1). These findings may be due to differences in delta 6 and delta 5 desaturation, β -oxidation or incorporation into membrane PL [18, 19], but this study is limited by the fact that these factors were not examined. Interestingly, both desaturase enzymes are regulated by SREBP-1 and PPAR α in mice [20], targeted genes in the pathology of obesity. Furthermore, people with diabetes have defects of delta 6 and delta 5 desaturases [21].

Insulin stimulates delta 6 desaturase and zinc is one cofactor, thus, it is also of interest that we have shown a reduced zinc concentration in adipose, pancreatic and liver tissue (Fig. 2a) in conjunction with a lower n-3 fatty acid status in adipose tissue PL in the HBW mice, independent of dietary fat (Table 1). However, when total zinc content was calculated in the same tissues, the effect was lost (Fig. 2b), implying that it was due to a dilution effect of excess fat and/or larger fat cells. Other studies investigating zinc status in obese or diabetic states have reported reduced tissue zinc concentrations but have not considered the effect on total tissue zinc content. For example, lower zinc concentrations were found in carcasses of obese mice,

pancreatic tissue of diabetic and obese mice, and hair or serum of obese people [22–26]. Recently it has been reported that zinc finger proteins (e.g. zinc finger protein 36) from omental fat are inversely related to insulin and insulin resistance in women [27] and zinc finger transcription factors (e.g. SLUG) are important for adipocyte differentiation in humans [28]. Thus, further investigation into mechanisms between zinc, obesity and lipid metabolism appear warranted.

In summary, these results suggest that body fat accumulation in C57BL/6J is not dependent entirely on a HF diet, and can in fact occur on a LF diet. Additionally, obesity in this model resulted in an unfavourable adipose PL n-3 fatty acid status which may be a result of, or further complicate obesity and diabetes.

Acknowledgments We would like to acknowledge Marily Latta and Thi Ly, Department of Human Nutritional Sciences for technical assistance, and the staff of the animal holding facility at the University of Manitoba.

Abstract Palm oil is one of the most important edible oils in the world. Its composition (rich in palmitate and oleate) make it suitable for general food uses but its utility could be increased if its fatty acid quality could be varied. In this study, we have modified a palm olein fraction by transesterification with the n-3 polyunsaturated fatty acids, α -linolenate or eicosapentaenoic acid (EPA). Evaluation of the potential nutritional efficacy of the oils was made using chondrocyte culture systems which can be used to mimic many of the degenerative and inflammatory pathways involved in arthritis. On stimulation of such cultures with interleukin-1 α , they showed increased expression of cyclooxygenase-2, the inflammatory cytokines tumour necrosis factor- α (TNF- α), IL-1 α and IL-1 β and the proteinase ADAMTS-4. This increased expression was not affected by challenge of the cultures with palm olein alone but showed concentration-dependent reduction by the modified oil in a manner similar to EPA. These results show clearly that it is possible to modify palm oil conveniently to produce a nutraceutical with effective anti-inflammatory properties.

GAPDH	Glyceraldehyde 3-phosphate dehydrogenase
TAG	Triacylglycerol
TNF- α	Tumour necrosis factor- α
VLCPUFA	Very long chain (>18C) polyunsaturated fatty acid

Introduction

The oil palm is one of the major commodity species grown in the world [1] and is, currently, the main crop grown for oil [2]. The oil palm produces two products. Palm kernel oil (which is enriched in laurate) is used by the soap, detergent and cosmetic industries as well as having specialised edible uses [1]. Palm oil, on the other hand, contains mainly palmitate (43–46%) and oleate (36–41%), and is used generally in the food industry.

Palm oil is a major source of sustainable and renewable raw material for the world's food, oleochemical and biofuel industries [3]. In that connection, there has been increasing interest in diversifying the use of palm oil. This could be done if its composition could be varied. However, genetic manipulation is more problematic for palm trees than for annual, dicotyledonous crops (such as soybean or canola) and limited progress has been made [4]. Alternative

strategies include the identification of suitable individual varieties (e.g. *Elaeis oleifera*) or by modification or fractionation of the crude palm oil.

There has been much recent interest in the beneficial properties of dietary omega n-3 PUFA [5]. There is strong evidence that such compounds can be of benefit for good health, particularly with regard to cardiovascular disease, brain development and function, arthritis and various other chronic inflammatory diseases [6]. Recently, there has been progress in elucidating the mechanisms by which n-3 PUFA exert this effect at the molecular level [7–9] where they reduce the metabolism of n-6 fatty acids to pro-inflammatory mediators, produce competing non- or anti-inflammatory metabolites as well as reduce the expression of pro-inflammatory cytokines and enzymes [6].

The first evidence for an important role of dietary n-3 fatty acids on inflammation was derived from epidemiological observations of the low incidence of autoimmune and inflammatory disorders in Inuits [see 10]. In addition, the first study showing positive effects with n-3 PUFA dietary supplementation was published in 1985 [11] although it has to be noted that a report in the London Medical Journal in 1783 extols the virtues of cod liver oil for the treatment of ‘rheumatism’ amongst other disorders [12]. Discussions of the potential anti-inflammatory properties of n-3 fatty acids relevant to arteriosclerosis, asthma and arthritis will be found in [13–22].

n-3 PUFA are produced by algae and plants and accumulate, via the food chain, in fish oils. The latter have traditionally been the main dietary source of very long chains (VLCs), such as eicosapentaenoic (EPA, all *cis*-5, 8, 11, 14, 17-eicosapentaenoic) or docosahexaenoic (DHA; all *cis*-4, 7, 10, 13, 16, 19-docosahexaenoic) acids [5]. With the decline in fish stocks in many parts of the world, there have been attempts to genetically manipulate plants to produce VLCs [23, 24] and also to use some of the waste products of the fishing industry better [25].

In this paper, we describe the lipase-mediated modification of palm oil using n-3 fatty acids and the utilisation of an in vitro model system which can be used to mimic some of the pathological pathways occurring in arthritis [26, 27]. Challenge of the chondrocyte cultures with mixtures of fatty acids allowed us to demonstrate that the n-3 PUFA EPA was able to reduce expression of inflammatory mediators and enzymes including proteinases important in the aetiology of arthritis. Although palm oil itself had no effect, the modified material (containing EPA) reduced the inflammatory factors that lead to cartilage matrix degradation in arthritis. These data show that it is possible to produce a value-added product from palm oil which would be beneficial to the health status of consumers.

Experimental Procedures

Materials

Collagenase TypeII, prepared from *Clostridium histolyticum* was obtained from Worthington Biochem. Corp. (NJ 08701, USA), pronase (*Streptomyces griseus*) from Boehringer (Bracknell, Berks RG12 8YS, UK) and DMEM and fetal calf serum from Gibco-BRL (now Invitrogen) (Paisley PA4 9RF, UK). Refined palm olein was obtained from the Malaysian Palm Oil Board (43000 Kajang, Selangor, Malaysia). Fatty acid standards were from Nu-Chek Prep. (Elysian, MN 56028, USA) and recombinant human interleukin-1 α was from Totam Biological (Peterborough PE1 5TX, UK). Other chemicals were of the best available grades and were from Sigma–Aldrich Co. (Gillingham, Dorset SP8 4XT, UK) or from Boehringer–Mannheim (now Roche Diagnostics Ltd., Burgess Hill, RH15 9RY, UK).

Isolation and Culture of Bovine Chondrocytes

Bovine metacarpo- and metatarsophalangeal joints (7-day-old calves) were obtained from the local abattoir. Cartilage was removed from the joint surfaces under sterile conditions and digested in 0.1% (w/v) pronase in DMEM containing 5% (w/v) fetal calf serum (FCS) for 3 h at 37 °C with roller agitation. It was further digested with 0.04% (w/v) collagenase in DMEM with 5% FCS for 24 h at 37 °C with roller agitation. After 24 h, cells were separated from debris by filtration through a 40 μ m Nitex filter (BD Bioscience, Bedford MA, 01730, USA) before cell numbers were estimated by microscopy. Cells were resuspended at 6×10^6 cells/ml in DMEM. Monolayer cultures were established in 60-mm dishes by plating 1 ml of the above medium/dish (to give a final density of approximately 20×10^5 cells/cm²). Experimental medium (4 ml/dish, DMEM containing 50 μ g/ml gentamicin) was then added to the cultures which were maintained at 37 °C under 5% (v/v) CO₂ for 6 h by which time monolayers had established.

Fatty acids to be added were made up in a complex with defatted bovine serum albumin. For the palm olein and modified palm olein preparations, these were hydrolysed first and then unesterified fatty acids purified by TLC. 300 μ g fatty acid/ml medium (20 mM HEPES, 140 mM NaCl, 4.5 mM KCl, 1 mM MgCl₂, 2.5 mM CaCl₂, 11 mM glucose, 3.5 mg BSA, pH 7.4) was incubated overnight (16 h) at 37 °C under nitrogen. After incubation, the mixture was filtered through a Sartorius (0.2 μ m pore size) Minisart filter unit (Sartorius Ltd., Epsom KT19 9QQ, UK) to sterilise the solution and ensure that any unbound, excess, fatty acids were removed. GC analysis was

performed to quantify the fatty acid–BSA complex and was found necessary, as samples could vary significantly in concentration after sterile filtration. Samples were diluted appropriately to give the final concentrations of fatty acids needed for experiments. Controls had medium alone added to the cultures. All cultures were maintained for 8 h in the absence or presence of fatty acids to allow for uptake into cells and incorporation into membrane lipids. Control experiments showed that uptake of fatty acids over 8 h was proportional to the amount added [28].

After 8 h incubation, the cultures were carefully washed three times with DMEM without FCS and incubated further for 4 days in DMEM with or without 10 ng/ml IL-1 α .

Determination of Lactate and Glycosaminoglycan in the Culture Medium

Lactate production was used as a measure of the metabolic activity of viable chondrocytes under the different experimental conditions. The concentration of lactate in the culture medium was measured with a lactate assay kit (Sigma–Aldrich) used according to the manufacturer’s instructions. Proteoglycan content in the culture medium was measured as sulphated glycosaminoglycan using a 1,9-dimethylmethylene blue (DMMB) assay [29] with chondroitin sulphate C as standard.

Transesterification

Lipozyme 1M60 in an immobilised form was purchased from Novo Nordisk A/S (Bagsvaerd 2880, Denmark). Other dried-powder lipases (*Pseudomonas* sp. Lip LS, *Rhizopus delemar* Lip D, *Rhizopus oryzae* Lip F, *Candida lipolytica* LipAk, *Rhizopus niveus* Lip N, *Penicillium roqueforti* Lip R) were a kind gift from Amano Enzyme Inc. (Nagoya 460-8630, Japan). The lipases were used at 10% (g/g) with the substrate mixture (except when the effect of enzyme amount was tested) at 55 °C. 10 ml hexane/g substrate was used and transesterification carried out in capped glass vials for up to 24 h with reciprocal shaking in a water bath at 100 r.p.m. All experiments were carried out in triplicate. For the experiment where the re-use of the enzyme preparation was tested, the Lipozyme 1M60 was filtered from the reaction mixture with glass wool, washed twice with hexane and dried under vacuum before re-use.

Analysis of Lipids

Samples were taken from the esterification mixture and extracted by the method of Garbus et al. [30]. The extracted lipids were separated by TLC on pre-coated silica gel 60 plates (Merck, 64293 Darmstadt, Germany) using

petroleum ether/diethylether/acetic acid (80:20:1, by vol.) as solvent. Lipid bands were detected by spraying plates with 0.2% 8-anilino-4-naphthalene sulphonic acid and exposing to UV light. Lipid standards (Sigma–Aldrich) were used to identify the TAG, monoacylglycerol, diacylglycerol, non-esterified fatty acid and fatty acid methyl ester bands. Bands were scraped off and lipids methylated with 2.5% H₂SO₄ in dry methanol/toluene (2:1, v/v) for 2 h at 70 °C.

Fatty acid methyl esters were separated on a glass column (1.5 m \times 4 mm) packed with 10% SP-2330 on 100/120 Supelcoport (Supelco, Sigma–Aldrich) using a Perkin–Elmer Autosystem X2 gas chromatogram. FAMES were identified using standard mixtures (Nu-Chek) and quantification performed using Perkin–Elmer internal software and a pentadecanoate internal standard.

RT-PCR Reactions and Semi-Quantification of Message Levels

RNA was extracted from chondrocyte cultures using Tri-reagent and isolated using RNeasy minicolumns and reagents (Qiagen Ltd., Crawley RH10 9NQ, UK). Reverse transcription-polymerase chain reactions (RT-PCR) were performed using a RNA PCR core kit (Applied Biosystems, Warrington WA3 7QH, UK). Primers and the annealing temperatures used are listed in Table 1. Hot-start was used for the IL-1 α and TNF- α and cold-start for the others. Thirty-four cycles were used. The fidelity of the primers was confirmed by isolation of the reaction product on agarose gels (below) and sequencing.

Following PCR, the reaction products were size fractionated on 2% (w/v) agarose gels containing ethidium bromide. Bands were visualised under UV light, photographed and stored as image files for further analysis. Individual gels ($n = 3$) were scanned using Kodak Digital IB Image Analysis apparatus to provide densitometric values for each of the PCR products of interest. Densitometric values of PCR products to the genes of interest were normalised to the densitometric values obtained for GAPDH (used as a constitutive gene) from the same cDNA samples.

Results

Interesterification Conditions for Palm Olein and Methyl Linolenate

In order to find efficient conditions for the incorporation of n-3 fatty acids into palm olein, we began investigative studies by screening a number of lipases (see “[Experimental Procedures](#)”). Two lipases (from *Penicillium*

Table 1 Primers used for RT-PCR

Target template	PCR primer sequences (5'-3')	Product size for bovine product (bp)	Annealing temperature (°C)

All products were verified by isolation on agarose gels and sequencing

roqueforti and *Rhizopus niveus*) showed low activity while three enzyme preparations (*Rhizopus miehei* Lipozyme 1M60, *Pseudomonas* sp. LipPS, *Rhizopus delemar* LipD) showed good activity (data not shown). Under standard conditions, all of the above three enzymes showed essentially complete equilibrium of palm olein with added methyl α -linolenate by the end of the reaction time with Lipozyme 1M60 giving a slightly higher percentage α -linolenate (48%) in the final triacylglycerol fraction. Because Lipozyme 1M60 was also an immobilized enzyme preparation, this was chosen for further use.

Varying the amount of Lipozyme 1M60 (with substrate) showed that a rapid equilibrium in lipid class composition (Fig. 1a) and also incorporation of α -linolenate into triacylglycerol (TAG) were reached with about 10 g enzyme prep./100 g substrates (Fig. 1b). Higher concentrations of enzyme did not increase the yield of TAG (Fig. 1a) nor its content of linolenate significantly (Fig. 1b) but led to elevated levels of free (un-esterified) fatty acids in the products (Fig. 1a), perhaps because of a residual amount of water in the immobilized enzyme preparation.

Examination of the reaction course showed that incorporation of α -linolenate into TAG was nearly complete after 30 min with only a small increase over the next 150 min (Fig. 1d). There was little change in the lipid class distribution over the first 2 h of incubation, apart from an initial release of unesterified fatty acids (Fig. 1c). The effect of temperature on the reaction in the range 40–80 °C was also examined. There was rather little change in the product composition over the range but the percentage of linolenate in the TAG fraction increased in the range 40–55 °C after which it plateaued (data not shown). The temperature of 55 °C was chosen for further incubations.

In order to modify a crude oil with a chosen fatty acid by interesterification, there is a trade-off between the cost

of the fatty acid and efficiency of its transfer into the TAG fraction. Examination of the effect of substrate ratio on lipid class distribution showed that, as expected, the final products reflected well the starting substrate ratio (Fig. 2a). Moreover, although there was a small increase in the percentage linolenate in the final TAG fraction on increasing the ratio of methyl linolenate: palm olein above 1:1 (Fig. 2b), the latter substrate ratio was efficient and a compromise with the potential cost of n-3 PUFA.

Although the initial experiments had been carried out using hexane as solvent, other solvents were checked for their efficiency. Twelve different solvents were tested (“[Experimental Procedures](#)”) and the more efficient ones in terms of TAG yield are shown in Table 2. Three other solvents gave yields of TAG which were comparable with that using hexane. These were acetone, petroleum ether and pentane. However, when the fatty acid composition of the final TAG product was analysed, then it was clear that little interesterification had taken place with acetone (Table 2). Since neither of the other two hydrocarbons showed any advantage to using hexane, the latter was used as the standard solvent throughout the research.

One possible advantage to using an immobilized enzyme preparation (certainly in commercial applications) would be that it has potential re-usability. Therefore, the enzyme activity of Lipozyme 1M60 was examined over a series of consecutive incubations (Table 3). Although the quality of the TAG product did not change noticeably, there was a steady decline in the amount of TAG yielded. This was mirrored by the increase of partial glycerides and unesterified fatty acids as the immobilised enzyme was re-used. However, although the yield of TAG declined, it was still present at high levels after three re-uses of the lipase preparation (Table 3).

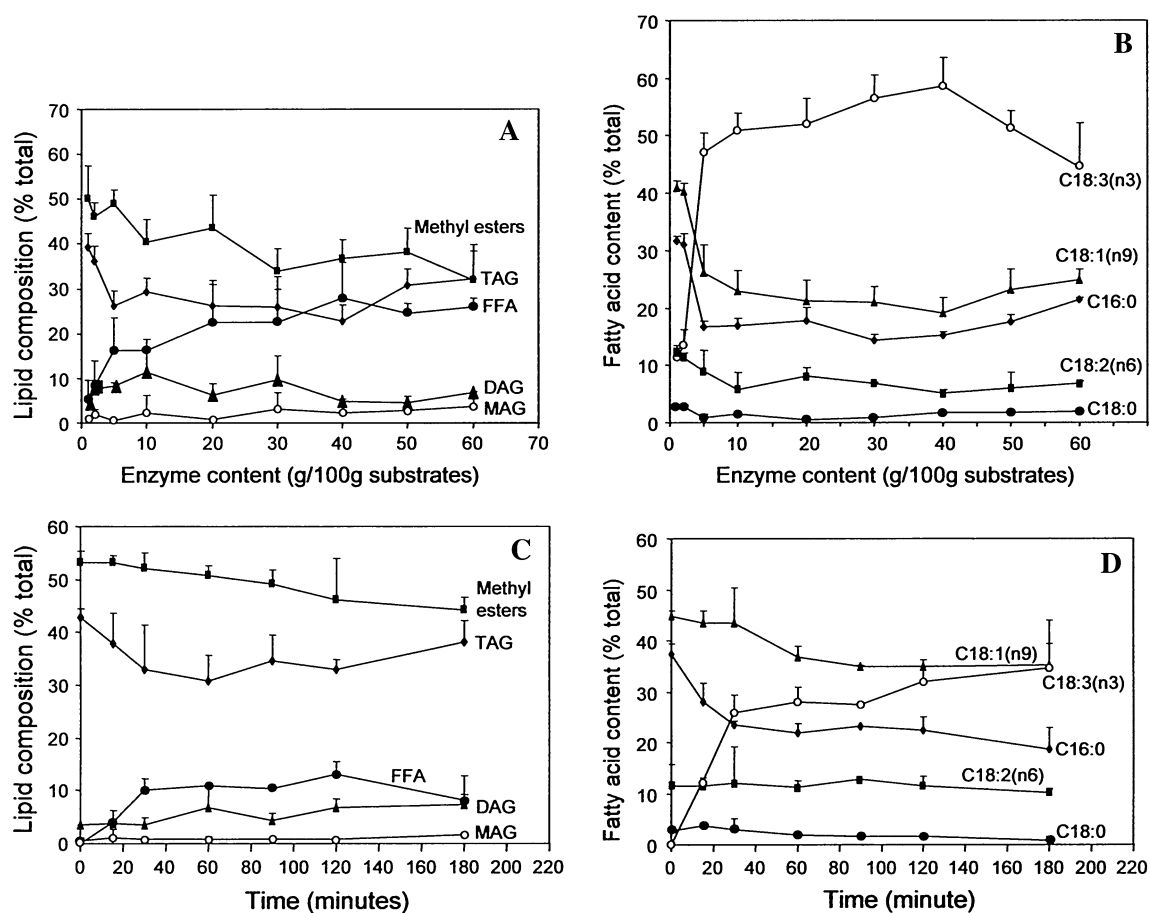

Fig. 1 Effect of enzyme concentration and incubation time on the reaction products following interesterification of palm olein with methyl linolenate. The figures show means \pm SD ($n = 3$) for lipid class distribution (a) and fatty acid composition of the TAG fraction (b) versus enzyme concentration, lipid class distribution (c) and fatty acid composition of the TAG fraction (d) versus incubation time.

Incubations were with Lipozyme 1M60 under conditions described in “Experimental Procedures” (except for changes in enzyme concentration or incubation time). TAG triacylglycerol, DAG diacylglycerol, MAG monoacylglycerol, FFA free (non-esterified) fatty acid, 16:0 palmitate, 18:0 stearate, 18:1 oleate, 18:2 linoleate, 18:3 α -linoleate

Interesterification with Eicosapentaenoate

Although α -linolenate is generally the major n-3 PUFA in human diets, it is not converted efficiently to the 20C precursor, EPA, for eicosanoid production [20]. Accordingly, most dietary advice suggests using eicosapentaenoate such as is found in oily fish or certain algae [1]. Since one of the major purposes of this work was to test the anti-inflammatory activity of modified palm oil, the interesterification reaction with EPA was also examined.

Lipozyme 1M60 proved to also interesterify efficiently with methyl EPA as the co-substrate. Incorporation of EPA into the TAG fraction of palm olein (Fig. 3b) was slower than that of linolenate (Fig. 1) but had still achieved values of 35% (total acids) by 3 h. The distribution of lipid classes in the products (Fig. 3a) was also similar to that found for transesterification with linolenate (Fig. 1). Other parameters for optimal enzyme activity were similar for the two

fatty acid substrates [28] and these standard incubation conditions were also used with EPA.

A large-scale preparation of palm olein TAG, containing EPA was made. The purified TAG fraction had a content of about 25% EPA (Table 4) and this preparation was used for the anti-inflammatory experiments.

In Vitro Model for Cytokine-Induced Cartilage Matrix Degradation in Arthritis

Monolayer cultures of bovine chondrocytes in the presence and absence of inflammatory cytokines are a useful test system with which to study inflammation in relation to osteoarthritis [26]. The chondrocytes can be easily stimulated by the inflammatory cytokine interleukin-1 α which increases transcription and activity of inflammatory mediators, prostaglandins, cytokines and cartilage matrix-degrading proteinases.

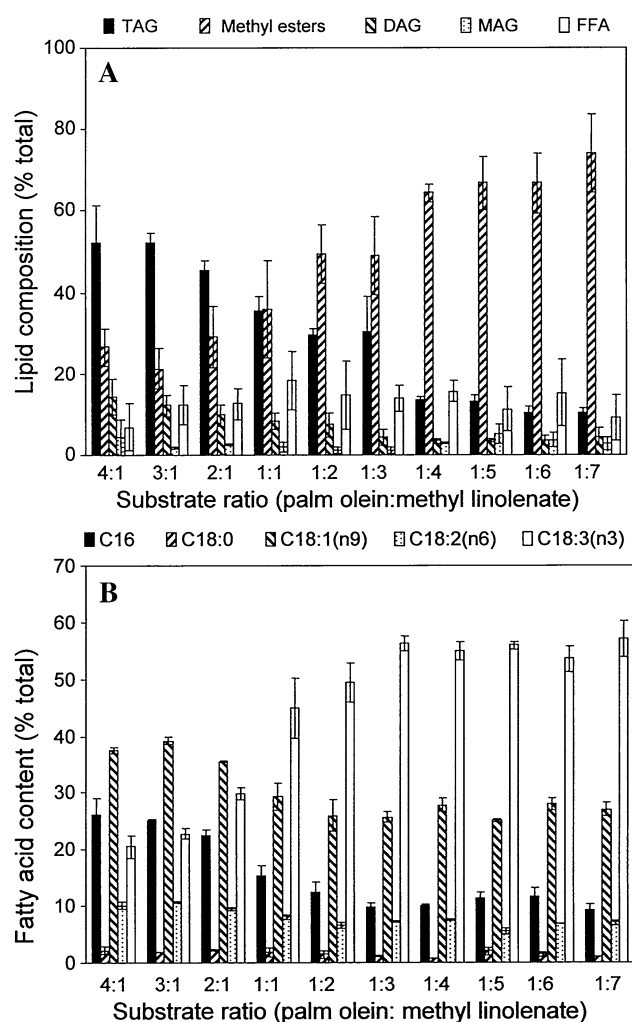

Fig. 2 Effect of substrate ratio on the reaction products and incorporation of linolenate into triacylglycerol. Lipid classes (a) were separated by TLC following incubation under standard conditions apart from changes in the ratio of substrates (palm olein, methyl α -linolenate). The fatty acid composition of the isolated TAG fraction is shown in (b). Means \pm SD ($n = 3$) shown. TAG triacylglycerol, DAG diacylglycerol, MAG monoacylglycerol, FFA free (non-esterified) fatty acid, 16:0 palmitate, 18:0 stearate, 18:1 oleate, 18:2 linoleate, 18:3 α -linoleate

In order to monitor cell viability and metabolism the cultures were examined by light microscopy and lactate production measured. The latter test can be used routinely to examine the metabolic state of the cells in such culture systems. Typical results are displayed in Fig. 4a. Lactate production was increased in all cultures by the addition of interleukin-1 α and this rise was not altered by previous incubation of the cultures with any of the fatty acid preparations up to 30 μ g/ml. The three fatty acid preparations (from palm olein, modified palm olein or EPA itself) did not have any effect on lactate production when they alone were added to control cultures. This showed that overall cell viability and metabolism was not affected by addition of the fatty acid preparation.

Table 2 Effect of solvent on the products of interesterification

	H	A	PE	B	T	P

Modified Palm Olein Reduces mRNA Levels for 'Inflammatory' Proteins

RT-PCR was used to examine whether the modified palm olein was able to show any anti-inflammatory properties when tested for its ability to reduce the expression of enzymes or proteins known to be involved in cartilage

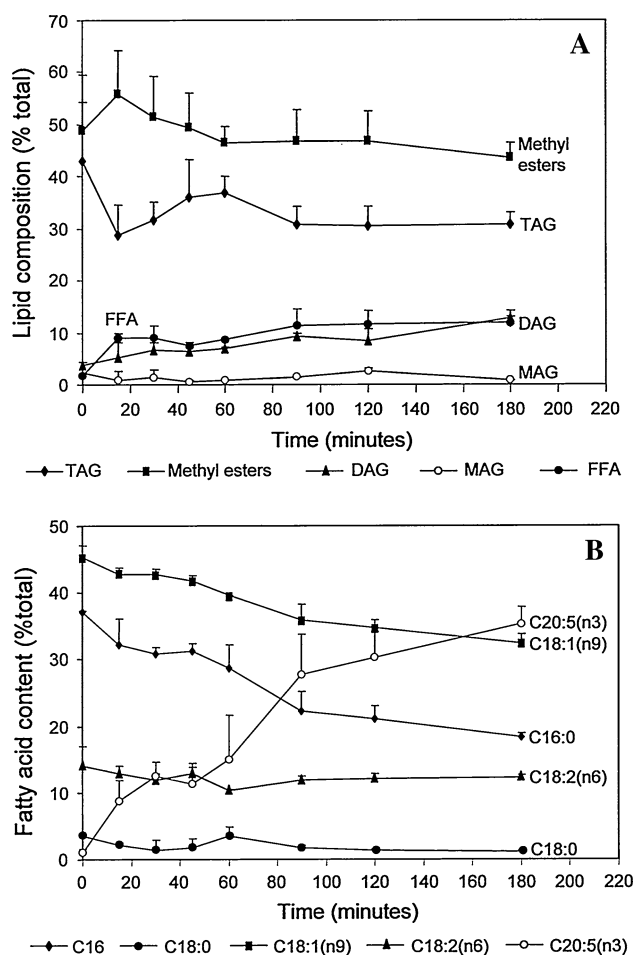

Fig. 3 Time-course for the incorporation of eicosapentaenoic acid into palm olein triacylglycerol by the action of Lipozyme IM60. EPA n-3 eicosapentaenoic acid. **a** Shows the reaction product distribution with incubation time and **b** Shows the change in TAG composition with time. Standard incubation conditions were used (“[Experimental Procedures](#)”) and means + SD ($n = 3$) are shown

matrix degradation during the pathogenesis of degenerative joint diseases; e.g. osteoarthritis.

We tested the action of the three fatty acid mixtures on the mRNA levels for cyclooxygenase-2 (COX-2, the inducible cyclooxygenase activity present in inflamed joints) and ADAMTS-4 (a disintegrin and metalloproteinase with

thrombospondin motifs, aggrecanase-1), which is one of the primary candidate enzymes believed to be responsible for aggrecan degradation in cartilage pathology (Fig. 5).

COX-2 mRNA levels were barely detectable in control cells, as expected for samples obtained from young, (healthy) joint tissue (Fig. 5a). However, COX-2 expression was clearly stimulated by the pro-inflammatory cytokine interleukin-1 α (IL-1 α). Pre-incubation of cultures with palm olein had no effect on the IL-1 α induced levels. In contrast, the modified palm olein was able to reduce COX-2 mRNA levels progressively with increasing concentrations of fatty acids. By 20 or 30 μ g/ml of the modified palm olein, the mRNA band for COX-2 was barely detectable. As expected, EPA was somewhat more effective with very low levels of the mRNA at 10 μ g/ml.

ADAMTS-4 expression was increased markedly by IL-1 α treatment and there was no obvious reduction in this by palm olein. However, again, both modified palm olein and EPA itself were able to reduce mRNA expression levels for ADAMTS-4 so that there was none detectable with modified palm olein at 30 μ g/ml and none at 20 μ g EPA/ml (Fig. 5b).

The expression of mRNA for a number of inflammatory cytokines was also monitored. Results for three of these (IL-1 α , IL-1 β and TNF- α) are shown in Fig. 6. Endogenous expression of IL-1 α by the cells was undetectable until they were stimulated by exogenous cytokine (Fig. 6a). The induced level of mRNA was unaffected by palm olein but reduced to undetectable levels by 20–30 μ g modified palm olein/ml or by 10–30 μ g EPA/ml. Similarly, IL-1 β mRNA was also induced by exogenous IL-1 α and this induction was reversed to very low levels by 30 μ g modified palm olein/ml or 20–30 μ g EPA/ml (Fig. 6b).

When tumour necrosis factor- α (TNF- α) was examined, exogenous IL-1 α induced detectable mRNA levels which were again unaffected by pre-incubation with palm olein. However, the modified palm olein was clearly able to reduce mRNA levels so that they were barely detectable at 30 μ g/ml. EPA reduced the TNF- α mRNA to very low levels at 10 μ g/ml (Fig. 6c).

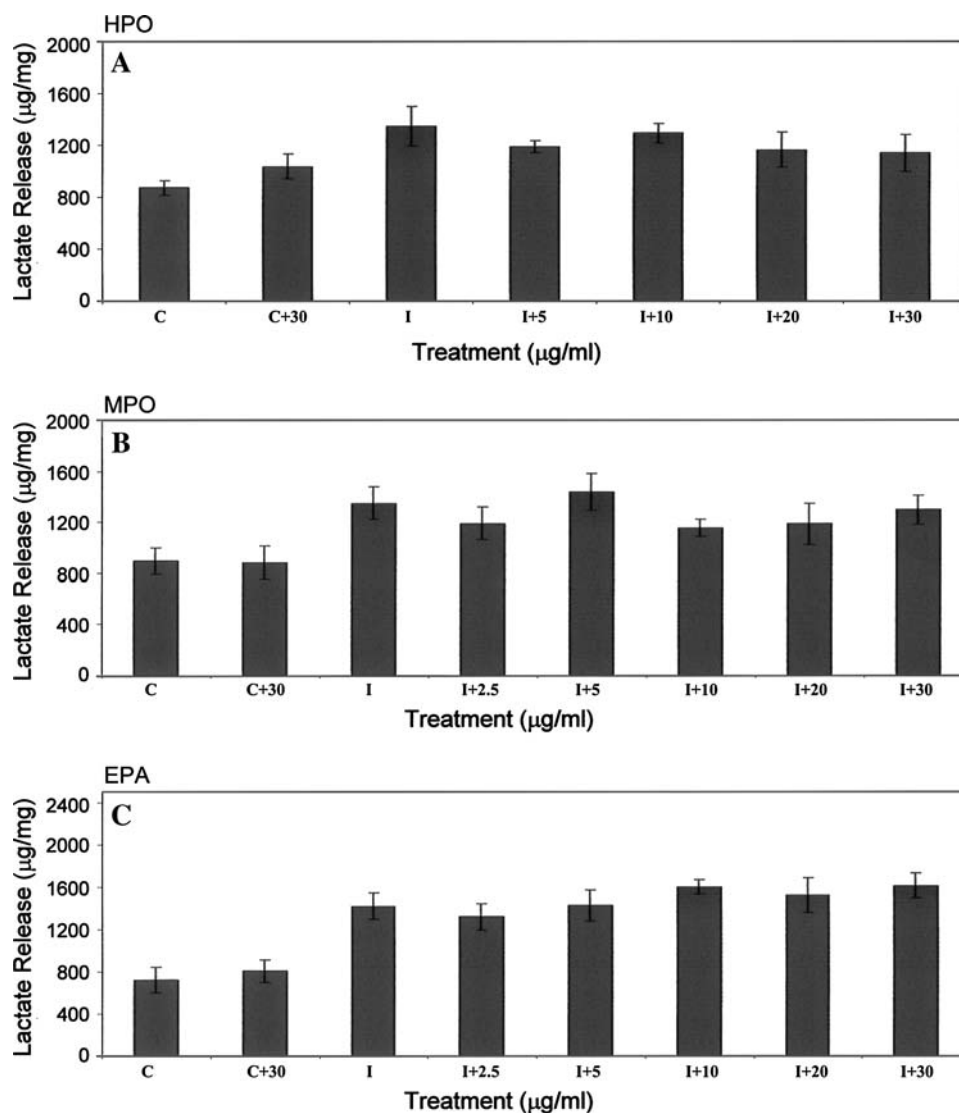

Table 4 Fatty acid composition of the palm olein triacylglycerols used for anti-inflammatory testing in chondrocyte culture systems

	Fatty acid composition (% total)						
	14:0	16:0	18:0	18:1	18:2	18:3	20:5
Palm olein	1.1 \pm 0.4	36.8 \pm 1.2	3.2 \pm 0.2	44.6 \pm 0.2	13.7 \pm 0.9	0.6 \pm 0.3	n.d.
Modified palm olein	0.3 \pm 0.1	27.9 \pm 1.6	2.9 \pm 0.8	35.0 \pm 2.6	8.6 \pm 4.4	0.2 \pm 0.1	25.2 \pm 7.4

Data as means \pm SD ($n = 3$). TAG fractions were purified by T.L.C and analysed further by G.L.C. (see “[Experimental Procedures](#)”)

n.d. not detected, 14:0 myristate, 16:0 palmitate, 18:0 stearate, 18:1 oleate, 18:2 linoleate, 18:3 α -linoleate, trace less than 0.5%, 20:5 n-3 eicosapentaenoate

Fig. 4 Test for monolayer chondrocyte viability and metabolism. Lactate release into the culture medium during the incubation is shown. Means \pm SD ($n = 3$) are displayed. The culture medium was supplemented with fatty acids ($\mu\text{g/ml}$) for 8 h before washing and continuing the incubation for 4 days in the presence (I) or absence (C) of interleukin-1 α . Discussion

Palm oil is the world's most abundant edible oil and huge quantities are exported from Indonesia and Malaysia [1]. However, there is a perceived need to diversify the fatty acyl quality of the oil [4]. One area would be to modify palm oil for added nutritional value and, with the increasing interest in n-3 s, this is one aspect where an obvious market exists. By incorporating n-3 fatty acids into palm oil by interesterification, one can produce a product which also has the good anti-oxidant properties of palm oil (e.g. with high β -carotene and vitamin E contents [31–33]).

We have shown that it is possible to modify palm olein by the incorporation of up to 50% of its fatty acids with either of the n-3 fatty acids, α -linolenate or EPA. A lipase from *Rhizomucor miehei* (Lipozyme 1M60) was the most effective of the seven lipases tested which also agreed with

recent reported data [34]. Lipozyme 1M60 is *sn*-1,3-specific so that, in theory, the *sn*-2 position of palm olein should not be involved in acyl exchange. However, it is well known that some acyl groups at the *sn*-2 position are always exchanged [1] and, indeed, the fatty acid compositions of modified palm olein (Table 4) would bear out this conclusion since the *sn*-2 position of palm oil is enriched in unsaturated acids (especially linoleate) [1]. Nevertheless, enrichment of the modified oil with n-3 fatty acids at the *sn*-1 and *sn*-3 positions might have a nutritional advantage since pancreatic lipase also shows specificity for the primary acyl esters [35].

Among many regioselective lipases tested for their ability to incorporate fatty acids into triacylglycerols, the best consistent results have been obtained with lipases from *Rhizomucor miehei* (such as Lipozyme 1M60), *Rhizopus delamar* and *Candida antarctica* [36, 37]. Lipozyme 1M60

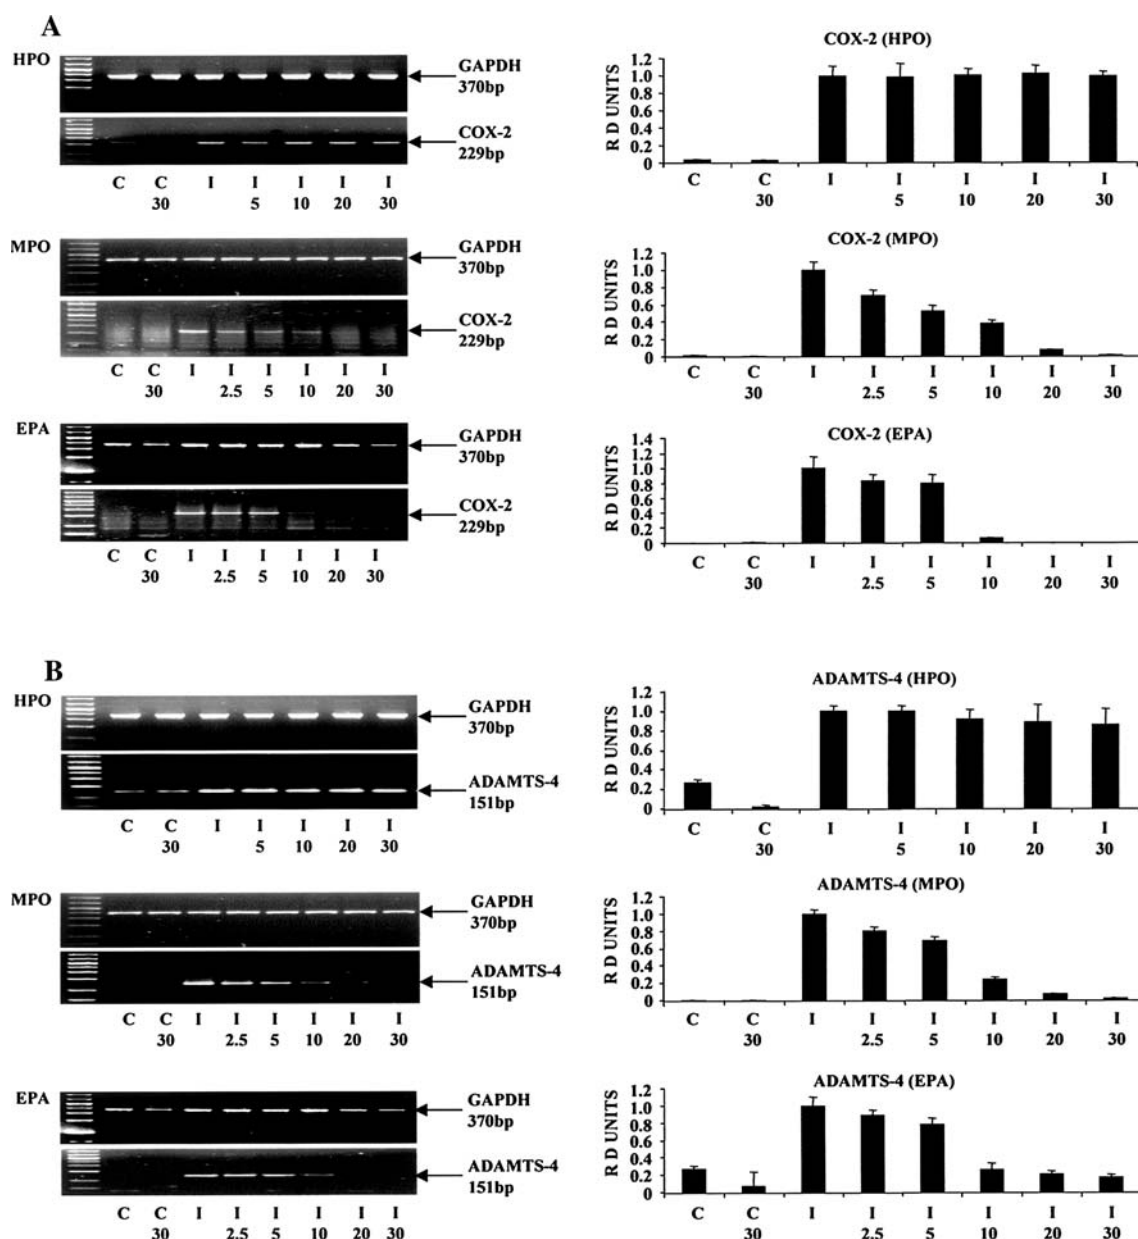

Fig. 5 Changes in mRNA levels for cyclooxygenase-2 (a) and ADAMTS-4 (b) in bovine monolayer cultures following exposure to interleukin-1 α and lipid preparations. The activity of EPA (eicosapentaenoic acid) and modified palm olein (MPO) are compared with those of hydrolysed palm olein (HPO). The culture medium was supplemented with fatty acids ($\mu\text{g}/\text{ml}$) for 8 h before washing and continuing the incubation for 4 days in the presence (I) or absence (C) of interleukin-1 α . For incubation details see “[Experimental](#)

[Procedures](#)”. Representative gel scans are shown and the histograms show semi-quantitative, relative, mRNA levels (means \pm SD) for three separate experiments [RD (arbitrary relative density) Units] corrected for gel loading by GAPDH mRNA levels. Control incubations (no cytokine) are indicated with C. Incubations in the presence of 10 ng/ml IL-1 α are labelled I. The amount of fatty acid added is shown in $\mu\text{g}/\text{ml}$

has been used extensively for the incorporation of n-3 fatty acids into edible oils [38–40] due to its high activity and temperature stability [41].

The reaction characteristics for interesterification were typical of other lipase-catalysed procedures [42–44]. The lipase used was stable to high temperatures, worked well with equal proportions of the substrates and preferred non-

polar solvents. Akoh and Huang [45] also showed that Lipozyme 1M60 gave good yields with hexane as solvent but poor incorporation with acetone (see Table 1). Other immobilised lipases have also been reported to prefer non-polar solvents [46]. While small amounts of water are needed for interesterification, it is known that it is necessary to carefully control quantities for efficient reactions

Fig. 6 Changes in mRNA levels for interleukin-1 α (a), interleukin-1 β (b) or TNF- α (c) in bovine monolayer cultures following exposure to interleukin-1 α and lipid preparations. The culture medium was supplemented with fatty acids ($\mu\text{g/ml}$) for 8 h before washing and continuing the incubation for 4 days in the presence (I) or absence (C) of interleukin-1 α . Incubation details are given in “Experimental Procedures”. Histograms show semi-quantitative, relative, mRNA levels (means \pm SD) for three separate experiments corrected for gel loading by GAPDH mRNA levels. EPA eicosapentaenoate, MPO modified palm olein, HPO hydrolysed palm olein

[47]. Indeed, the appreciable amounts of non-esterified fatty acids and partial glycerides which were found in some of our reactions can be attributed to the presence of water in the incubations. This water content would be increased successively during re-use of the immobilised enzyme [48] and the results of this were clearly seen in Table 3 where the yield of TAG decreased and that of the hydrolysis products increased with re-use.

Under the reaction conditions utilised, we were able to incorporate up to 52% α -linolenate and 45% EPA into the TAG fraction. In similar experiments for the modification of palm oil, Fajardo et al. [40] also used Lipozyme 1M60 but, despite using a higher ratio of n-3 PUFA to TAG, only obtained average incorporations of 21% EPA (and 16% docosahexaenoate) in their studies. Others have used different immobilised lipase preparations to incorporate n-3 PUFA into vegetable oils. Huang and Akoh [36] found a *Mucor miehei* (1,3-specific) lipase to be more efficient than that from *Candida antarctica* (non-specific) for the incorporation of EPA or DHA into soybean oil. However, when ethyl esters of EPA or DHA were used then the lipase from *C. antarctica* was more efficient.

The chondrocyte cell culture system used to test for anti-inflammatory properties of exogenous lipids has been well utilised as a model system to follow aspects of cartilage matrix degradation in degenerative joint disease; e.g. osteoarthritis. In these cultures, challenge with interleukin-1 α has been shown to up-regulate inflammatory mediators and cartilage-degrading proteinases [26]. While palm olein had virtually no effect on the IL-1 induced increases in mRNA levels for COX-2, ADAMTS-4, IL-1 α or IL-1 β or TNF- α , EPA was able to reduce these significantly when cultures were subsequently challenged with IL-1 α to induce an inflammatory response. This may be due to a direct effect of the n-3 PUFA on gene expression [49, 50] or indirectly through a change in the balance of eicosanoids [51] or other lipid mediators, such as E-series resolvins [52]. The anti-inflammatory properties of n-3 PUFA have been well-studied through feeding experiments and include their effects on cytokine release [e.g. 16].

The modified palm olein (containing about 25% EPA) was also able to reduce inflammatory responses in the chondrocyte culture system, as measured by lower levels of mRNA for ‘inflammatory’ proteins. These data indicate

that the nutritional properties of palm oil should be significantly enhanced by the incorporation of EPA into the TAG fraction. It would seem better to use EPA rather than

α -linolenate for this purpose because EPA has been shown to be more biologically potent than linolenate [19]. This would also agree with deductions from feeding studies [20] and with the fact that EPA can be converted directly to eicosanoids [21]. The effects of EPA on COX-2 (but not COX-1) [28] mRNA are also timely in that specific COX-2 inhibitors, which showed much promise for the treatment of chronic inflammatory diseases, have had to be withdrawn recently from pharmaceutical use [53].

Our results therefore reinforce information from epidemiological and clinical surveys that have shown significant benefits for the use of dietary n-3 fatty acids for the treatment of inflammation and pain in human arthritic disease [54, 55]. They also show that palm oil may be modified conveniently to produce a nutraceutical with effective anti-inflammatory properties.

Acknowledgments The authors acknowledge grant support from the Biotechnology and Biological Sciences Research Council (D16961) and a studentship provided by the Malaysian Palm Oil Board, for which we are grateful.

Abstract The effects of dietary supplementation with coconut oil on the biochemical and anthropometric profiles of women presenting waist circumferences (WC) >88 cm (abdominal obesity) were investigated. The randomised, double-blind, clinical trial involved 40 women aged 20–40 years. Groups received daily dietary supplements comprising 30 mL of either soy bean oil (group S; $n = 20$) or coconut oil (group C; $n = 20$) over a 12-week period, during which all subjects were instructed to follow a balanced hypocaloric diet and to walk for 50 min per day. Data were collected 1 week before (T1) and 1 week after (T2) dietary intervention. Energy intake and amount of carbohydrate ingested by both groups diminished over the trial, whereas the consumption of protein and fibre increased and lipid ingestion remained unchanged. At T1 there were no differences in biochemical or anthropometric characteristics between the groups, whereas at T2 group C presented a higher level of HDL (48.7 ± 2.4 vs. 45.00 ± 5.6 ; $P = 0.01$) and a lower LDL:HDL ratio (2.41 ± 0.8 vs. 3.1 ± 0.8 ; $P = 0.04$). Reductions in BMI

were observed in both groups at T2 ($P < 0.05$), but only group C exhibited a reduction in WC ($P = 0.005$). Group S presented an increase ($P < 0.05$) in total cholesterol, LDL and LDL:HDL ratio, whilst HDL diminished ($P = 0.03$). Such alterations were not observed in group C. It appears that dietetic supplementation with coconut oil does not cause dyslipidemia and seems to promote a reduction in abdominal obesity.

Keywords Medium chain fatty acids · Lauric acid · Dyslipidemia

Abbreviations

BMI	Body mass index
BMR	Basal metabolic rate
CVD	Cardiovascular disease
LCFA	Long chain fatty acids
MCFA	Medium chain fatty acid
SFA	Saturated fatty acid
TC	Total cholesterol
TEV	Total energy value
UFA	Unsaturated fatty acid
US-CRP	Ultra-sensitive C reactive protein
WC	Waist circumference

This article based in part on the Master's Dissertation of M.L. Assunção, presented to the Faculdade de Nutrição, Universidade Federal de Alagoas, Maceió, AL, Brazil, in 2007. A summary of the paper was presented at the IX Congresso Nacional da Sociedade Brasileira de Alimentação e Nutrição, São Paulo, SP, Brazil, 2007.

Introduction

In many countries obesity has reached epidemic levels, representing a serious public health problem and a matter of considerable concern for government and health services. In Brazil, the prevalence of obesity has risen from 5.7 to 10.8% of the adult population within the last 30 years, and currently 40.5% of adults are considered to

be overweight. Although dramatic increases in average body weight have affected the entire socioeconomic strata, they have been proportionally greater amongst poor women [1, 2].

Obesity results from a positive energy balance that leads to the accumulation of body fat at various anatomical sites. If fat accumulation occurs predominantly in the abdominal region the condition is known as visceral obesity, a factor that is strongly associated with increased risk of cardiovascular diseases (CVDs) [3]. The type of fat provided by the diet influences the incidence of obesity and also plays a significant role in the aetiology of various metabolic disorders including dyslipidemia [4]. Although many theories concerning the types of fatty acids that are beneficial or deleterious to health are contentious, it is generally considered that saturated fatty acids (SFAs) are hypercholesterolemic whereas unsaturated fatty acids (UFAs) are hypocholesterolemic [5].

Oil from coconuts (*Cocos nucifera* L.) contains a high proportion of medium chain fatty acids (MCFAs), principally the SFA lauric acid (12:0), in proportions that range from 45 to 50% [6]. A possible association between dietary intake of coconut oil and the incidence of CVDs was suggested four decades ago following studies carried out by the food industry involving hydrogenation of the oil and modification of some of the UFAs present, particularly oleic and linoleic acids. On the basis that the harmful effects of coconut oil observed in experimental animals resulted from the hydrogenation of UFAs, health professionals began to recommend the replacement of coconut oil by UFA-rich soy bean (*Glycine max* L.) oil [7]. However, studies involving African and South Pacific populations, whose diets contain large proportions of coconut oil (80% of daily lipid intake), have revealed that there is no association between the ingestion of coconut oil and the occurrence of obesity and/or dyslipidemia [8–10]. Additionally, coconut oil is frequently used in the treatment of obesity by virtue of its high content of MCFAs [11], since such lipids are easily oxidised and are not normally stored in the adipose tissue, thus diminishing the basal metabolic rate (BMR). However, the use of coconut oil in the diet remains controversial owing to the possible detrimental effects of SFAs and their association with dyslipidemia and CVDs [4, 12, 13].

Obesity is a particularly serious problem in the State of Alagoas, which is located in the north-east of Brazil and is a major producer of coconut oil. Considering the lack of evidence concerning the physiological effects of intake of coconut oil, the aim of the present study was to investigate the effects of dietary supplementation with coconut oil on the biochemical and anthropometric profiles of a population of women of low socioeconomic status living in Alagoas and suffering from abdominal obesity.

Materials and Methods

Study Design and Subjects

The project of work was submitted to and approved by the Ethical Committee in Research of the Faculdade de Ciências Biológicas e da Saúde, Fundação Educacional Jayme de Altavila, Maceió, AL, Brazil. Written informed consent was obtained from all participants prior to the commencement of the study.

The study took the form of a randomised, double-blind, clinical trial involving 40 women selected from those attending an outpatients unit located in Marechal Deodoro, AL, Brazil. The selection criteria were: (1) age between 20 and 40-years-old, (2) low socioeconomic status (per capita family income <USD\$1/day), and (3) presenting abdominal obesity as defined by waist circumference (WC) >88 cm [14]. Pregnant women were excluded from the selection, as were subjects presenting arterial hypertension, chronic degenerative diseases, endocrinopathies or body mass index (BMI) >35 kg/m². The exclusion of women >40-years-old and with a BMI >35 kg/m² was intended to reduce the probability of including individuals with unknown or undiagnosed morbidities in the sample population, as well as women with menopausal hormone alterations and those presenting a degree of obesity unresponsive to dietetic treatment.

The study population was randomly divided in two groups of 20, paired according to BMI, one of which (group S) received soy bean oil as dietary supplement, while the second (group C) received coconut oil. Individual dietary counselling for all participants was provided by a nutritionist throughout the entire experimental period of 12 weeks. Subjects were instructed to follow a diet that was balanced in respect of macronutrients with increased consumption of fruits and vegetables and reduced consumption of simple carbohydrates and animal fat. Participants were also advised to drink adequate amounts of water and to reduce or eliminate alcohol consumption and smoking. Under the supervision of a fitness trainer, all of the participants took part on 4 days every week in a physical activity program comprising elongation followed by 50 min walking. Both, the physical trainer and the nutritionist were not aware of the distribution of the individuals between the study groups.

The dietary intervention consisted in the daily ingestion of either 30 mL of soy bean oil (group S) or 30 mL of coconut oil (group C) distributed through the three main meals. Participants were instructed that the daily oil supplement should be used in the preparation of food as normal, but that the nutritional recommendations provided must be followed. Each subject received a supply of oil (sufficient for the experimental period) contained in a

numbered flask, together with a standardised measuring spoon. In order to ensure that neither the participant nor the researchers had knowledge of the dietary supplement applied, the oil flasks were filled and numbered according to a supplement key prepared by an investigator, who was not involved in the collection of data, and the flasks were distributed to the participants by another researcher who had no knowledge of the contents of the supplement key. Data relating to the variables of interest were collected 1 week before the start of dietary intervention (T1) and again 1 week after the 12th week of intervention (T2). The supplement key was not revealed to the participants or to the research team until all data had been collected and analysed.

Origin and Composition of Oil Supplements

Filtered coconut oil, obtained by pressing coconut pulp that had been dehydrated at 60 °C, was provided by a local manufacturer (Sococo Indústria Alimentícia, Maceió, AL, Brazil). Soy bean oil (Bunge Alimentos, Pernambuco, Brazil) was purchased from a local supermarket. The compositions of the oil supplements (Table 1) were determined by an accredited laboratory (SFDK Laboratório de Análise de Produtos Ltda, São Paulo, SP, Brazil). The two types of oil were of a similar colour but differed slightly with respect to odour and flavour. In order to conceal the differences, the oils were bottled in 600 mL amber flasks and could not be readily distinguished except by direct comparison.

Socioeconomic Evaluation

Socioeconomic information was obtained from each participant by application of a specific questionnaire relating to the type of accommodation occupied, number of rooms,

sanitary facilities, schooling, occupation and family income, number of family members, alcohol intake and smoking habits, and physical activities.

Anthropometric Evaluation

The body mass of each subject wearing light clothes was determined using Filizola SA (São Paulo, SP, Brazil) Personal PL 180 portable digital scales with a maximum capacity of 180 kg and a precision of 100 g. Heights of subjects (with bare feet) were measured using a WCS (Curitiba, PR, Brazil) stadiometer connected to a non-extendable 220-cm measuring tape (1 mm precision). WC was measured (with subjects standing upright and immediately after exhalation) at the mid point between the last rib and the anterior superior iliac spine using a non-extendable measuring tape of 200 cm. BMI was calculated by dividing body mass (kg) by the square of the height (m). Values were categorised in accordance with the cut-off points recommended by the World Health Organisation guidelines [14] for BMI [<18.5 , 18.5–24.9 (or <25.0), 25.0–29.9 (or <30.0) and >30.0 ; kg/m²] and WC ($</>88$ cm) or were considered as continuous variables.

Dietary Evaluation

In order to evaluate compliance with expected dietary intake, the effects of lipid supplementation, and possible confusing effects between the different groups, a 24 h dietary recall was applied to subjects for a 3 day period (1 day of which was during a weekend) immediately before and 12 weeks after dietary intervention. Images depicting different quantities of food were used to assist participants in assessing the amounts of food consumed [15]. Data were collected by the researcher in charge of nutritional supervision and were processed using Nutwin software (Departamento de Informática em Saúde, Universidade Federal de São Paulo, SP, Brazil). BMR values were calculated according to the procedure of the Food and Agriculture Organisation [16] taking into consideration differences between the age groups as follows: BMR (18–30 years) = $(14.7 \times \text{weight}) + 496$ BMR (30–60 years) = $(8.7 \times \text{weight}) + 829$.

Biochemical Evaluation

Blood samples were collected 1 week before the start of dietary intervention (T1) and 1 week after the 12th week of intervention (T2). In each case blood was taken in the morning following a 12 h overnight fast. Glucose, triglycerides, total cholesterol (TC) and LDL/HDL fractions were determined in triplicate for each sample using standard laboratory kits (Boehringer Mannheim, Germany).

Table 1 Main fatty acids present in soy bean and coconut oils

Fatty acid	Composition (%)	
	Soy bean ^a oil	Coconut ^b oil
Lauric acid (12:0)	0	49.0
Myristic acid (14:0)	0.1	17.5
Palmitic acid (16:0)	10.3	9.0
Stearic acid (18:0)	3.8	3.0
Oleic acid (18:1 ω -9)	22.8	5.0
Linoleic acid (18:2 ω -6)	51.0	1.8
Total	100.0	100.0

^a *Glycine max* L.

^b *Cocos nucifera* L.

The quotients TC/HDL and LDL/HDL were calculated on the basis of the plasma lipoprotein values. The levels of fibrinogen, ultra-sensitive C reactive protein (US-CRP) and insulin were determined by thermo-precipitation, nephelometry and chemiluminescence, respectively. The secretory function of pancreatic beta cells and insulin resistance were calculated using the homeostatic model assessments (HOMA- $\beta\%$ and HOMA-S, respectively) according to the equations proposed by Mathews et al. [17].

$$\text{HOMA-}\beta\% = \frac{20 \times \text{insulin}(\mu\text{U/mL})}{\text{glucose}(\text{mmol/L}) - 3.5}$$

$$\text{HOMA-S} = \frac{\text{insulin}(\mu\text{U/mL}) \times \text{glucose}}{22.5}$$

Statistical Analysis

The experiment was carried out according to a totally randomised design and took the form of a 2×2 factorial scheme (factor A—type of oil tested on the two groups; factor B—two assay periods during the 12 weeks of dietary intervention). There were four treatments: (1) soy bean oil at zero time, (2) soy bean oil after 12 weeks, (3) coconut oil at zero time; and (4) coconut oil after 12 weeks. The interaction between factors A and B was analysed statistically.

In order to reduce the magnitude of the error variance, analysis of covariance (ANCOVA), was performed considering or not the significant differences between the two groups in relation to the supposed covariate age. In this context, H_0 implies that all β_I are equal to β , whilst H_1 requires at least one β_I is not equal to β for the same factor means. The equation applied was $y_{ij} = \mu + \tau_i + \beta_I x_{ij} + e_{ij}$. The χ^2 test was used to determine if there were significant differences between the two groups of women with respect to frequency of alcohol consumption or smoking habit. The normality of the distribution and the homoskedasticity of the residual variances were analysed using Shapiro–Wilk and Levene tests, respectively, for all studied variables. These tests were also used to determine if body mass, BMI, US-CRP, triglycerides, insulin, HOMA- $\beta\%$ and HOMA-S obeyed the parametric assumptions. The values relating to these variables were then subjected to logarithmic transformation, i.e. $y_i = \log(X_i)$. The percentage values of protein components were arcsine transformed, i.e. $y_i = \arcsin X_i$. After the application of the Snedecor test (F test), multiple comparisons between treatments were carried out using the post hoc Bonferroni test ($P < 0.05$) with correction factor. Both tests were applied to all dependent variables.

The level of significance was established at 5% for all statistical tests. However, when the probability of the experimental error was >5 and $<10\%$ (i.e. $0.05 > P < 0.1$), the difference was taken to indicate the probability of a biological significance.

Results

Most participants (60%) lived in brick houses comprising three rooms on average but lacking sewage facilities. Most women were illiterate (68.2%) and their sole occupation was to act as housewife (90%). Each family unit consisted on average of 5 members with a per capita income of R\$ 1.86/day (equivalent to US\$ 0.82/day in January 2006). Approximately a quarter of the women (22.5%; 4 in group S and 5 in group C) smoked regularly, and more than half of the participants (52.5%; 11 in group S and 10 in group C) ingested alcohol occasionally. There were no significant differences ($P \geq 0.05$) between the two groups with respect to the variables alcohol and smoking habits (χ^2 alcoholism = 0.10 and χ^2 smoking = 0.143; $df = 1$ for both variables; P values = 0.759 and 0.705, respectively), indicating that these covariables exerted no significant antagonism or synergism on the outcomes.

The median height of the studied population was found to be 1.55 m, corresponding to an estimated ideal weight of 51.63 kg and an ideal daily energy intake of 1,975.6 kcal. The daily energy consumption of the population was determined to be 1,893 kcal on average at the start of the trial, and this corresponded to 95.8% of the ideal requirement estimated on the basis of assessed height.

The results at T1 showed that the diet of the participants was poor in lipids [19% of total energy value (TEV)] and proteins (0.77 g/kg of body mass per day), and this was associated with an elevated ingestion of carbohydrates (69% of TEV). Tubers, flour and bread derived from traditional carbohydrate-rich plants were consumed with abundance. The frequency of ingestion of foods with cardio-protective properties, such as fruit and vegetables, was practically zero, while the intake of fibre was around 10 g a day.

The relative contribution of macronutrients to the daily energy intake varied little between T1 and T2 for the S and C groups. The TEV supplied by carbohydrates was reduced from 69 to 61.8% during this period, whilst the TEV supplied by lipids remained almost unaltered (changing from 19 to 20.8%) despite supplementation of the diet with 30 mL/day of oil (equivalent to 270 kcal). Regarding proteins, at T1 the participants ingested a hypoproteic diet whereas at T2 the diet was considered normoproteic (0.99 g/kg of weight a day). The mean TEV was reduced from 1,893 (T1) to 1,732 kcal/day (T2) as a result of the hypocaloric diet presented to the subjects and supervised by researchers during the 12 week dietary intervention.

The results of the 24 h dietary recall performed at T1 and T2 are presented in Table 2. The energy intake and the amounts of carbohydrates, lipids, proteins and fibre were similar in both S and C groups. Within the groups, however, some differences of similar magnitude could be

observed. For example, there was a reduction of 10% in total energy intake and 16% in the ingestion of carbohydrates. In contrast, there was an increase (of approximately 50%) in the ingestion of proteins and fibres. The ingestion of lipids, however, remained unaltered.

The biochemical and anthropometrical data collected at T1 and T2 are presented in Table 3. ANCOVA analysis showed that there were no significant differences ($P \geq 0.05$) between groups S and C concerning the covariate age as determined by the H_o value. The Snedecor test (F test) showed a significant difference ($P < 0.05$) between the two groups concerning the type of oil (factor A) and assessment time (factor B). However, there was no significant interaction between factors A and B ($P \geq 0.05$) for any of the variables in this study (Table 3).

At the end of the trial period, reductions in body mass and BMI were observed in both groups ($P < 0.05$), but only group C presented a significant reduction ($P = 0.005$) in WC. The levels of total cholesterol, LDL and LDL:HDL ratio were significantly ($P < 0.05$) increased in group S, whilst the level of HDL was significantly ($P = 0.03$) diminished. Such alterations in the lipid profile did not occur in group C. In contrast, this group presented a tendency towards increased HDL although the alteration was not statistically significant ($P = 0.09$). At T1 the HDL level of group S tended ($P = 0.08$) to be higher than that of

group C, whilst at T2 the situation was reversed and the HDL level of group C was significantly higher, as shown by a P value of 0.03 consequently, at T2 the LDL:HDL ratio of group C was significantly ($P = 0.04$) lower than that of group S. According to the LDL:HDL ratios determined in the present study, the S and C groups cannot be considered to be at risk with respect to CVDs since the values were below 3.5.

The glucose levels of the S and C groups at T1 and T2 were similar. There was no change in the release of insulin in group S, whereas in group C the increase in hormone release observed, although not statistically significant ($P = 0.09$), was sufficient to increase the HOMA-S value of group C to a level significantly higher ($P = 0.03$) than that of group S. There were no significant differences between the S and C groups with respect to the remaining parameters (i.e. height, age, levels of triglycerides, US-CRP, fibrinogen, glucose and HOMA-β%) at both evaluations.

Discussion

The two groups of women presenting abdominal obesity endured similar socioeconomic conditions and lifestyles. The reductions in body mass and BMI of both S and C

groups observed at T2 may be attributed to the negative energy balance resulting from healthier habits (i.e. a more balanced diet and additional physical activity) arising from the counselling administered during dietary intervention. The reduction in abdominal fat in individuals of group C can be explained by their consumption of MCFA-rich coconut oil, since these components are not readily incorporated into the triglycerides of adipose tissue [20]. Moreover, unlike triglycerides containing long chain fatty acids (LCFAs), those comprising MCFAs are more susceptible to oxidation even under resting conditions. This difference may be explained by the fact that LCFAs are dependent on carnitine for mitochondrial transport, whilst MCFAs are transported through the inner mitochondrial membrane independent of the carnitine acyl transferase system [21].

Studies on the effects of a diet rich in MCFAs (equivalent to 45% of TEV) compared with a diet rich in LCFAs administered over a 21-day period showed that plasma TC, LDL and triglyceride levels increased by 11, 12 and 22%, respectively, as a result of the ingestion of MCFAs, while HDL levels remained unchanged [22]. However, a diet

providing an intake of MCFAs in excess of 30 g/day would be nutritionally unbalanced and likely to produce undesirable collateral effects, which might explain the results observed [23]. In the present study, the hypocaloric diet adopted by the individuals of group C was supplemented with MCFA-rich coconut oil (as the main source of lipids), but no undesirable alterations were observed in the lipid profile of the participants after 12 weeks. In contrast, some researchers [24] have observed that subjects supplied with an amount of lauric acid significantly greater than that used in the present study, exhibited hypercholesterolemia. These results may be explained, however, by the unbalanced relation between saturated, monounsaturated and polyunsaturated fatty acids in the diet applied.

The majority of studies that have focussed on the hypercholesterolemic effect of MCFAs have employed hyperlipidic diets from which essential mono and polyunsaturated fatty acids, such as linoleic (18:1) and arachidonic (20:4) acids, were absent. Arachidonic acid is an important modulator of anti-inflammatory responses and is a precursor of the eicosanoids (leukotrienes, prostaglandins, thromboxanes and lipoxins), which present diverse biochemical

and physiological roles [25]. Such diets would, therefore, have been unbalanced and could have given rise to numerous metabolic disorders.

The reduction in HDL levels within group S observed in the present study may be explained by the high content of linoleic acid (51%) present in the soy bean oil, which may have undergone conformational changes during cooking. The process of heating transforms *cis*-linoleic and *cis*-linolenic acids into their respective *trans* isomers leading to alterations in lipid metabolism and to the under-expression of LDL receptors and, consequently, to an increase in blood LDL [26]. Whilst no evidence was obtained in the present study to confirm the formation of *trans* UFAs, the ingestion of soy bean oil by subjects of group S definitely induced an increase in the concentration of serum LDL after 12 weeks. There is a consensus amongst researchers concerning the deleterious effects on the levels of LDL of *trans* UFAs in comparison with SFAs. For example, Roos and co-workers [27] carried out a comparative study of a diet rich in lauric acid and a diet rich in *trans* UFAs derived from soy bean oil and observed that individuals supplied with the former presented a healthier lipid profile. In the present study, it is clear from the 24 h dietary recall that the participants used the oil provided for frying foods and as a supplement to the diet. However, the time spent in cooking, the temperature used in the processes, and the possible formation of *trans* isomers were not directly investigated. Undoubtedly, the influence of such variables warrants consideration and such a study would contribute to the knowledge already gathered. Nevertheless, it is important to emphasise that prior to nutritional intervention, several participants reported that they used the same cooking oil twice or three times as an economy measure. Although such practice was strongly discouraged during the study and the amount of oil supplied was ample for the needs of the participants and their families, full compliance was out of the control of the research team.

Much research has focussed on attempts at elucidating the real effects of SFAs on the lipid profile and the possible association with CVDs [28–30] but the results achieved are controversial since the amounts of oil employed, together with their fatty acid compositions, varied in the different studies. Further factors that could also explain the diverse results deriving from the various investigations include the duration of the dietary intervention, the ingestion of dietary cholesterol, and the level of antioxidants ingested. In the present study, the daily ingestion of 30 g of coconut oil during a 12-week period did not alter the lipid metabolism of the women of group C, including those who had exhibited some degree of hypertriglyceridaemia at T1. This result may be explained by the rapid oxidation of MCFAs, particularly lauric acid, as well as by their low incorporation into VLDLs. MCFAs are poor substrates for Δ^6 and Δ^9

fatty acid desaturases and, unlike palmitic acid (16:0), cannot undergo elongation. The hypercholesterolemic activity of palmitic acid is a consequence of such elongation reactions and the subsequent formation of LCFAs [31]. The presence of antioxidant polyphenols in the coconut oil could also have contributed to the results obtained in the present study. It is of interest to note that reduced levels of LDL, VLDL and total cholesterol, together with increased levels of HDL, have been reported in experimental animals that had been fed with coconut oil [32].

Regarding the carbohydrate profile, it has been postulated that the secretion of insulin varies according to the type of fatty acids supplied in the diet [33]. UFAs, such as linoleic and linolenic acids, potentiate insulin secretion in response to the basal concentration of glucose, whereas SFAs diminish the response of the islets of Langerhans to glucose concentration [34]. In the present study, individuals of group C exhibited a tendency towards increased insulin secretion following 12 weeks on a diet rich in lauric acid, a finding that is in agreement with a previous report that supplementation of lauric acid in experimental animals stimulated the secretion of insulin [35].

It is important to emphasise that the HOMA-S values representing insulin resistance were higher than normal in both groups and at both evaluations, a condition probably associated with abdominal obesity that was common to all participants of the study. The levels of USCRP, an inflammatory marker and an independent predictor of CVD risk [35], were also above the normal limit (<1 mg/L) in both groups and at both evaluations. The levels of fibrinogen were, however, normal at both T1 and T2. This protein is an important component of platelet aggregation and is an indicator of acute conditions. When the levels are normal, fibrinogen performs a cardio-protective function even in the presence of high levels of cholesterol [36].

It is important to stress that the background diet of participants in the present study was richer in carbohydrates (about 70%) than that of most Western populations (around 50–55%). Stable isotope experiments have shown that individuals submitted to carbohydrate-rich diets exhibit higher rates of de novo lipogenesis [37, 38] and decreased VLDL clearance and fat oxidation [39] compared with those ingesting diets poor in carbohydrates and rich in fat. Considering that the subjects of this study did not increase fat intake significantly, and that the carbohydrate intake diminished by more than 15%, it is possible that metabolic adaptations were induced by their normal diet pattern that could have influenced the results obtained. For this reason, the effects of coconut oil reported here cannot be extrapolated to other populations. Additionally, the 24-h dietary recall presented various limitations that must be considered in the evaluation of food consumption. Among such limitations are recall bias and the fact that a

single dietary recall does not characterise the habitual feeding habits of an individual owing to high intra-personal variability [40]. In order to minimise reporting bias a photo album containing images of different portions of food was employed, and to reduce intra-personal variability three different 24 h dietary recalls were conducted including one at the weekend when variations in the usual consumption pattern are most likely to occur.

In conclusion, the ingestion of coconut oil did not produce undesirable alterations in the lipid profile of women presenting abdominal obesity, although dietary supplementation with this oil did give rise to a reduction in WC, which is considered to confer some protection against CVDs. On the other hand, the ingestion of coconut oil appeared to have induced an increase in peripheral insulin resistance. The results presented here indicate that SFAs cannot be characterised as the sole aetiological cause of obesity, dyslipidemia and risk factor for CVDs, but that the overall composition of the diet, particularly the fatty acid, cholesterol and antioxidant fractions, as well as the lifestyle of the individuals, must be taken into consideration. Within this context, it would be important to evaluate the effects of coconut oil over a prolonged period, and to investigate the composition and effects of the polyphenolic fraction of the oil.

Abstract The outcome of a total dietary approach using a wide range of n-3 polyunsaturated fatty acids (PUFA) enriched food items on cardiovascular diseases called for further investigation. The study objective was to assess the effect of an ALA-enriched food supply on cardiovascular risk factors in healthy males. A dietary intervention (single-blind field trial with pre- and post-measurements) was performed with 59 healthy males in a Belgian prison. Over a period of 12 weeks they were supplied with an n-3 enriched diet (containing 6.5 g n-3 PUFA/day compared to 4 g n-3 PUFA/day in the standard diet) that was substituted for their regular diet, increasing mainly the α -linolenic acid intake

(from 2.8 to around 5 g/day). The results indicated no impact on subjects waist circumference, weight and BMI or systolic blood pressure. In contrast, the diastolic blood pressure significantly decreased during the intervention period (from 74.6 ± 8.2 to 71.7 ± 10.1 mmHg; $P < 0.02$). Moreover, the HDL-cholesterol level increased in non-smoking participants (from 0.97 ± 0.25 to 1.06 ± 0.23 mmol/l; $P < 0.03$). In summary, the study demonstrated that enrichment of commonly eaten food items with n-3 fatty acids provides the opportunity to increase the n-3 fatty acid intake and to decrease the n-6/n-3 ratio which results in a decreasing diastolic blood pressure and an increase of HDL-cholesterol (in non-smokers).

Introduction

Cardiovascular diseases (CVD) are among the leading causes of disability and premature death in Western populations [1]. High LDL-cholesterol (LDL-C), low HDL-cholesterol (HDL-C) plasma levels and hypertension are among the major cardiovascular risk factors [2]. Nutrition can influence the development of CVD by modifying one or more of these risk factors. Within the diet, fat, particularly the type of fat rather than the amount consumed, seems to be the most important macronutrient in relation to CVDs. There is a growing body of evidence demonstrating that the regular consumption of n-3 PUFA is associated with significant health benefits in the prevention of CVD [3]. In the meantime, there are considerable indications that the current intake of n-3 PUFA via the Western diet is too low [4–8]. A possible solution to increase the n-3 PUFA intake is to increase the fatty fish consumption, the most important natural source of long-chain (LC) n-3 PUFA. However, Western societies consume little fish and many barriers exist to increase this current pattern [9]. Moreover, limited availability of fish stocks is an issue that has to be considered in the future [10]. An alternative strategy for enhancing n-3 PUFA intake may be to provide a wide range of commercial food products and ingredients fortified with n-3 PUFA, which can be incorporated in an existing diet. Many of these food items are currently available. Most of them have an increased content of α -linolenic acid (ALA; C18:3n-3), precursor of LC n-3 PUFA [11]. The Lyon as well as the Indo-Mediterranean Diet Heart Studies showed that a Mediterranean diet rich in ALA prevented the recurrence of cardiovascular events [12, 13]. Nevertheless, there is considerable evidence that LC n-3 PUFA have much greater efficacy in the prevention of CVD [14, 15]. Still, the efficacy of such n-3 PUFA enriched food items for the prevention and control of CVD remains a matter of debate.

The main objective of this study was to investigate the effect of an ALA enrichment in the diet of healthy male human volunteers on different cardiovascular risk factors. A group of volunteer prisoners were supplied with an n-3 enriched diet for 12 weeks. By using ALA-enriched food items, this total dietary approach—simulating a real-life situation—differed from previous supplementation studies

which used ALA-enriched capsules or single fortified products [16–19]. The study questioned whether this approach can be a useful nutritional strategy to prevent CVD.

Materials and Methods

The design of this dietary intervention study was a single-blind field trial with pre- and post-measurements in a group of healthy men. Each individual served as his own control.

Study Population

The study took place in a highly protected penitentiary institution (Andenne, Belgium) for male persons sentenced to long imprisonment (>5 years), with a capacity of 400 prisoners. Volunteers were recruited among 396 men present in the prison at the start of the study. The exclusion criteria were: specific diseases or organ dysfunction, special diet (vegetarian, diabetic, ...), alcohol abuse or use of drugs for CVD treatment or specific types of medication (e.g. medication decreasing the blood pressure). On the basis of these exclusion criteria, 102 men were eligible for participation. All eligible participants received a letter explaining the study's goal, timing and practical aspects. A short movie presentation was also made available in which the details of the dietary intervention study were explained by the organizing and scientific committee. Finally, an informative meeting was organised to answer prisoners' questions. After receiving complete information, 70 volunteers (68.8% of the eligible prisoners) registered to participate in the study and signed a written informed consent. During the study, 11 dropped out, resulting in a final group of 59 participants. Apart from one death (because of brain haemorrhage caused by aneurysm rupture), reasons for the volunteers' drop out were essentially being set at liberty or transfer to another prison. The organizing committee covered television subscription costs during the 5 months of the study as compensation for participation from the beginning until the end of the study.

The study protocol and the process for obtaining informed consent were approved by the Ethical Committee of the Erasmus hospital, Brussels.

Dietary Intervention

The standard catering system in the prison of Andenne follows repeating menu cycles consisting of 6 weeks. This study lasted three cycles in the year 2007 (from January to June) of which the first cycle did not include an n-3 intervention (Fig. 1). During the first cycle (standard menu), nothing was changed in the supplied food of the

Fig. 1 Graphical presentation of the time line of the dietary intervention study and the moments of blood sampling (*B*) and completion of the dietary questionnaires (*Q*)

participants except for the bread and the fact that all pre-packed foods were now packed in a neutral package. The refined bread provided by standard catering was changed in the first study cycle to wholemeal bread since the n-3 fortified bread used during dietary intervention (second and third cycle) was not available in a refined version. During the n-3 intervention cycles several standard supplied food items were replaced by n-3 fortified versions in the participants' menus, i.e. bread, margarine, meat and meat products (beef, pork, chicken), dairy products, cheese and eggs. The replacement was done for food items of breakfast, lunch and dinner. The quantity of n-3 fortified foods per day was determined by dietitians in order to reach an optimal ratio of linoleic acid (LA; C18:2n-6) and ALA, i.e. a ratio of less than 4 to 1 [20]. The n-3 fortified foods were provided by Belgian industrial companies of the ESV/GIE EQUILIBRIUM Industrial Partnership. The fatty acid composition of some food items used in the intervention is given in Table 1. For most of the food items of animal origin, the increased n-3 PUFA content resulted from feeding the animals with ALA-enriched feed. Apart from the higher n-3 content, all these foods were equal to the standard supplied versions for all other nutritional parameters, organoleptic characteristics, taste, etc. Moreover, during the whole study period (the cycle before the intervention and the two intervention cycles), the food items were prepacked in neutral package and identification could only be done by specific serial numbers, so that the participants could not notice the changes in their diet at T0. To determine the actual changes in the fatty acid content of the food provided during the three different menu cycles, chemical analyses of the supplied food were performed during the 18 study weeks. For this, two duplicate samples were collected each day from standard meal portions of all meals throughout the day. Samples were immediately frozen by the prison personnel and stored at -25°C for chemical analyses. The samples were thawed at 55°C and the edible part of the meal was isolated and weighed. All the food samples of a same day were mixed together in a R8 mixer (Robocoupe, Monceau-en-Bourgogne, France). For each sample, the total fat content was gravimetrically determined according to the general Weibuhl method, as described in the reference method ISO 1443. Furthermore, fat components were extracted according to the method of Folch et al. [21] adapted by Christie [22] to determine the fatty acid pattern by gas chromatography [23].

Dietary Questionnaire

On three different occasions during the study (Fig. 1), the participants had to complete questionnaires to evaluate their dietary habits. The questionnaires were specifically developed for the study purpose. A first questionnaire was used to evaluate the participants' dietary habits before the intervention, whereas the second and the third questionnaires were used to evaluate their behaviour during the two intervention cycles. Examples of questions used are given in Table 2. Two individual scores were calculated expressing the participants' compliance based on their answers. A first score (diet_score) was calculated as an indicator of the overall compliance to the provided menu. A second score called (fish_score) was determined to provide an indication on whether the participant consumed the fish present in the menu. A mean score for the three different study cycles was calculated per participant. Based on their individual score participants were divided in tertiles. These scores were not an endpoint as such but were used further as confounders in the statistical analyses.

Clinical Measurements

All participants underwent three medical visits which took place during the initial week of the first (T0) and second (T6) intervention cycle and during the first week after the intervention (T12). During these visits the medical staff of the prison measured waist circumference, weight and height. Further, two consecutive measurements of systolic and diastolic blood pressure were performed from the same arm, with subjects in a sitting position, after 15 min rest from the time the cuff had been placed on the arm. An extra blood pressure measurement was done 2.5 months after the end of the intervention in those participants who were still present in the institution, i.e. 48 out of the 59 participants who completed the whole study. At each medical visit, fasting blood samples were collected and immediately handled to analyse fatty acid profile in platelet phospholipids, plasma lipids, plasma apolipoproteins B (apo B) and A1 (apo A1), glucose, C-reactive protein (CRP; indicator of inflammation) and hepatic function tests. Platelet-rich plasma was separated from blood samples by low speed centrifugation at 228g for 10 min in a J2.21 centrifuge (Beckman Instruments, Fullerton, CA, USA). Platelets were then isolated from plasma by centrifugation at 1430g

Table 1 The fatty acid composition of some n-3 PUFA enriched food items used in both intervention cycles (NA: not available, no value given by the industry providing these foods)

Food item	Total fat g/100 g	SFA g/100 g	MUFA g/100 g	PUFA g/100 g	C18:2 n-6 mg/100 g	C20:4 n-6 mg/100 g	C18:3 n-3 mg/100 g	C20:5 n-3 mg/100 g	C22:5 n-3 mg/100 g	C22:6 n-3 mg/100 g

^a This food item is naturally rich in n-3 PUFA and is regularly put on the menu in the prison (not only during the intervention)

for 20 min. Fatty acid pattern was determined in platelet phospholipids by gas chromatography after separation of lipid components by thin layer chromatography [24]. Plasma total cholesterol (TC) and triglycerides (TG) were measured using enzymatic kits (Roche Diagnostics GmbH, Mannheim, Germany). HDL-cholesterol (HDL-C) was determined as the cholesterol remaining in plasma supernatant after precipitation of apolipoprotein B-containing lipoproteins with phosphotungstic acid manganese chloride [25, 26]. LDL-cholesterol (LDL-C) was calculated by the Friedewald formula [27]. Apo B and A1 were measured in plasma by ELISA using rabbit polyclonal antibodies for apo B and A1, respectively [28]. Plasma CRP level was determined by using high sensitive CRP immuno-turbidimetric method [29]. Finally, plasma glucose levels as well as common hepatic function tests consisting in the determination of glutamic oxaloacetic transaminase (GOT), glutamic pyruvate transaminase (GPT) and gamma glutamic transpeptidase (γ GT) were determined by standard clinical testing methods.

Statistics

The results of the measurements at the different time points (T0, T6 and T12) were compared on an individual level using a general linear model (GLM) for repeated measurements. The following parameters were taken into account as potential confounders: smoking behaviour, age, diet_score, and fish_score. When an interaction was found with one of these confounders, the GLM for repeated measurements was stratified by this confounder. For all

Table 2 Examples of questions used in the dietary questionnaires (the moments on which the questionnaires were completed are indicated in Fig. 1)

Examples of questions used in the dietary questionnaires
1. During the last 6 weeks, how frequently did you consume breakfast/lunch/diner?
2. During the last 6 weeks, did you use the margarine/bread/... [asked separately]
that was distributed?
2.1. If yes, what was your average bread consumption:
(a) I ate all the bread
(b) I left some bread (if yes, how many slices)
(c) I ate all the bread and I even ate extra self-bought bread
3. How frequently did you eat fish (or eggs or meat [asked separately]):
(a) Every time when it was on the menu
(b) From time to time
(c) Never

analyses, a significant effect of the intervention was assumed for a P value ≤ 0.05 . The statistical analyses were performed using SPSS software version 12.0.

Results

Dietary Intervention

As shown in Table 3, the mean contents of total fat, saturated fatty acids (SFA) and monounsaturated fatty acids (MUFA) in the supplied food were lower during the

Table 3 The mean content of fat and different fatty acids (g/day) of the supplied foods for the three menu cycles (mean value for a period of 6 weeks) calculated on the basis of two duplicates of all meals (breakfast, lunch and dinner) provided to the prisoners per day

		Standard menu	Intervention cycle 1	Intervention cycle 2
g/day	Total fat	109.92	107.26	104.30
	Saturated fatty acids (SFA)	45.01	42.34	38.84
	Mono-unsaturated fatty acids (MUFA)	39.78	36.90	37.79
	Poly-unsaturated fatty acids (PUFA)	23.28	25.62	25.95
	n-6 PUFA	19.33	19.18	19.69
	C18:2n-6 (LA)	18.07	17.86	17.82

	n-3 PUFA	4.03	6.48	6.50
	C18:3n-3 (ALA)	2.83	4.85	5.01
	C20:5n-3 (EPA)	0.30	0.40	0.38
	C22:5n-3 (DPA)	0.09	0.14	0.13
	C22:6n-3 (DHA)	0.50	0.66	0.61
	LA/ALA	6.24	3.59	3.82
	n-6/n-3	5.75	3.39	3.26

n-3 dietary intervention compared to the standard menu. In contrast, the mean content of PUFA in the supplied food increased. The mean n-3 PUFA content increased from 4.0 to 6.5 g/day; this was mostly accounted for by an increased supply of ALA (~5.0 vs. 2.8 g/day in the standard menu). Still, the LC n-3 PUFA content was also slightly increased (see Table 3). In contrast, the n-6 PUFA content (with LA and arachidonic acid (AA; C20:4n-6) as most important fatty acids) did not differ between the standard diet and the intervention diet (19.3 vs. 19.7 g/day). As a result, the LA/ALA and n-6/n-3 ratios decreased, respectively from 6.2 to 3.8 and from 5.8 to 3.3 during the intervention.

Subjects Baseline Characteristics

The 59 male volunteers who completed the study were aged from 22 to 65 years (a mean age of 41.5 ± 9.8 years). Of the 59 participants, 41 were smokers and 18 non-smokers. Anthropometrical and clinical characteristics of the participants at baseline can be found in Table 4.

Compliance to the Diet

On the basis of the dietary questionnaires and the calculated diet_scores, the participants were divided into tertiles: 19 were defined as having a poor compliance to the provided menu, 20 of them a moderate compliance and the other 20 participants a good compliance (on a relative scale). With respect to the calculated fish_score and the division in tertiles, 14 of the 59 participants did not consume regularly the provided fish, 24 consumed it from time to time, and 21 consumed most of the provided fish.

Effect of Dietary Intervention on Anthropometrical and Clinical Measurements

n-3 Dietary intervention had no significant effect on subjects anthropometrical characteristics (Table 4). Also no significant effect of the intervention was found on the systolic blood pressure. In contrast, n-3 dietary intervention was associated with a significant decrease of diastolic blood pressure from 74.6 ± 8.2 (T0) and 74.4 ± 9.3 mmHg (T6) to 71.7 ± 8.8 mmHg (T12) ($P < 0.02$). The diastolic blood pressure measured at 2.5 months after the end of the dietary intervention showed a return to initial values (74.7 ± 10.1 mmHg).

No significant effect of the intervention was found on TG, TC, LDL-C, Apo B, Apo A1, glucose, CRP and hepatic function tests (GOT, GPT, γ -GT) (Table 4). In contrast, the dietary intervention led to a significant increase of HDL-C, from 0.97 ± 0.25 on T0 to 1.06 ± 0.23 mmol/l on T12 in the group of non-smoking participants ($P < 0.03$).

Fatty Acid Composition in Platelet Phospholipids

The dietary intervention decreased the relative content of saturated, palmitic acid (C16:0) and arachidic acid (C20:0) in platelet phospholipids (Table 4). This was accompanied by an increase in the relative content of LA. For several other fatty acids, statistical analyses indicated a significant effect from one of the confounders. In particular, an effect of fish_score was found for C18:0, C20:4n-6 (AA), C20:5n-3 (EPA), and C22:6n-3 (DHA) (Table 5). Volunteers who consumed the fish provided by the diet most of the time showed a decrease in the relative content of AA, together with an increase of EPA and DHA; this led to decreased AA/EPA or AA/LC n-3 ratios.

Table 4 Anthropometrical and clinical characteristics and fatty acid composition of platelet phospholipids (molar % of total fatty acids) and at T0, T6 and T12 (mean \pm standard deviation) for the 59 participants

The detection limit for fatty acid analysis was 3.59 μ mol/l which corresponded to 0.1–0.6 mol% depending on the amount of fatty acid present in platelet phospholipid samples

GOT glutamic oxaloacetic transaminase, *GPT* glutamic pyruvate transaminase, γ *GT* gamma glutamic transpeptidase

Values within a row with different superscript letters indicate significant differences at $P = 0.05$ (general linear model for repeated measures)

^A For these fatty acids, fish_score was a confounder with a significant effect. Detailed results can be found in Table 5

Discussion

This study evaluated the effect of replacing various commonly eaten food items by dietary products naturally fortified with ALA for a period of 12 weeks on several cardiovascular risk markers in a group of middle-aged men. By using a wide range of ALA-enriched food items this

total dietary approach differed from previous supplementation studies which used ALA-enriched capsules or single fortified dietary products [16]. A systematic review of these previous supplementation studies found, however, that ALA supplementation did not appear to affect most cardiovascular risk markers, which is in contrast with the results of the study presented in this paper. Possibly, the

Values within a row with different superscript letters indicate significant differences at $P = 0.05$ (general linear model for repeated measures)

overall dietary approach used in this study and resulting not only in an increase of ALA and LC n-3 PUFA but also in a reduction of total fat, SFA and MUFA, can explain this difference.

The dietary intervention provided the participants with a more balanced diet regarding the fatty acid composition by substantially increasing ($\sim +50\%$) the supply of n-3 fatty acids, essentially ALA, and slightly decreasing the supply of saturated fatty acids. Nevertheless, it must be mentioned that the LC n-3 PUFA content of the standard menu was already high. The explanation is that fatty fish (a.o. mackerel, fatty acid composition of mackerel shown in Table 1) was regularly put on the menu in the prison. The increase in n-3 PUFA supply during the intervention led to a LA/ALA ratio of 4/1 and an n-6/n-3 ratio of 3/1; this allowed the diet to meet current dietary guidelines [20]. LA/ALA and n-6/n-3 ratios averaged 6/1 in the standard menu which was relatively low compared to data from national PUFA dietary consumption reports. Indeed, a study based on food consumption data of Belgian women collected in 2002 found a mean LA/ALA and n-6/n-3 ratio

averaging both 8-7/1 [5]. However, regarding this n-6/n-3 ratio, it recently came up that this is not the ideal dietary measure to use in the context of cardiovascular health, but that the absolute amounts of LA and ALA are of relevance to the efficiency of conversion of ALA to EPA and DHA [30]. Therefore, the fact that the absolute amount of LA in the supplied menu decreased while the absolute amount of ALA increased (Table 4) possibly had a beneficial effect on the ALA conversion to EPA and DHA.

Changes in the fatty acid composition of platelets appeared to be largely influenced by the fish consumption habits of the volunteers. Indeed, the relative content of LC n-3 PUFA increased in platelet phospholipids from participants regularly consuming the fish that was provided. This is in accordance with a previous study reporting increases in LC n-3 PUFA in platelet phospholipids [31].

Volunteers included in the study were slightly overweight but presented normal systolic and diastolic blood pressure. Dietary manipulation did not modify weight and BMI nor did it affect systolic blood pressure. Still, a significant decrease of 3 mmHg in diastolic blood pressure

was found after 12 weeks of n-3 enriched diet on a population level. The diastolic blood pressure returned to basal values when volunteers received their standard diet again. These results are in line with a recent international cross-sectional epidemiologic study (INTERMAP study) which concluded that dietary n-3 PUFA intake (ALA and LC) is inversely related to blood pressure in hyper- and normotensive persons [32]. However, in the INTERMAP study, a reduction of the systolic and diastolic blood pressure was found, whereas in our study no significant effect on the systolic blood pressure was found. No clear explanation for this difference could be found. Further, Paschos et al. [33] recently showed that supplementation with flaxseed oil, rich in ALA, lowers blood pressure in middle-aged men [33]. Since the blood pressure level is directly related to coronary heart disease (CHD) mortality [34], the decrease in diastolic blood pressure observed in the present study may be associated with a significant reduction in CHD risk and have important public health implications. Indeed, a decrease of 5 mmHg of diastolic blood pressure appears to be associated with a 20% lower risk of CHD and a 30% decrease of stroke [35].

Volunteers of the study manifested a dyslipidaemic profile with high LDL-C and low HDL-C plasma levels while the mean values for fasting plasma TC and TG levels were within normal ranges. Dietary manipulation had no effect on TC, LDL-C and TG levels; this is in accordance with previous short and long-term ALA supplementation studies [36–38]. In contrast, HDL-C levels which were low at the start of the study increased by more than 2 mg/dl during the intervention period in non-smoker participants. Such an increase in HDL-C may represent another important health benefit in relation to CHD. Indeed, every 1 mg/dl increase in HDL-C appears to decrease cardiovascular risk by 2–3% [39]. An increase in HDL-C was not found for the smoking participants, which can be explained by the fact that smoking decreases HDL-C [40].

For both effects, a reduced diastolic blood pressure and an increased HDL-C in non-smokers, the statistical analyses indicated no significant confounding effect of fish_score, indicating that the consumption of fish is not the crucial explanation behind both effects. Moreover, the diastolic blood pressure lowering effect and the HDL-C raising effect was only seen after the second intervention cycle, and not after the first intervention cycle. This can be explained by the fact that clinical benefits of dietary supplementation with n-3 PUFA are not immediate. The time course to alter clinical events may occur within weeks or months to years depending on the clinical effect studied as well as the type of n-3 PUFA used for supplementation. As reviewed by Mozaffarian et al. [41], the beneficial effect of fish or fish oil intake on blood pressure lowering occurs only within months of intake.

A limitation of this study is the control of the food consumption. The compliance to the provided diet was evaluated on the basis of questionnaires which do not reflect the precise amount of food ingested. Furthermore, volunteers also had access to food that they bought themselves in the canteen of the prison. On the basis of the data on purchasing behaviour which were listed up by the administration of the prison at any time, it could however be concluded that there was no difference in purchasing behaviour of food items during the intervention period compared to the standard period (details not shown).

In summary, providing ALA through a variety of fortified foods enables to considerably increase the n-6/n-3 ratio in the diet without changing the subject's dietary habits. Such an increased n-3 supply in a group of middle-aged men has beneficial effects on at least two CHD risk factors by lowering their diastolic blood pressure and increasing HDL-C in non-smokers.

Acknowledgments First of all, we wish to thank all the participants of the study as well as the director and all the staff members of the penitentiary institute, in particular the medical staff and the kitchen staff for their enthusiastic and fruitful collaboration. The dietician Thierry Denies is acknowledged for the excellent help in the organisation of the fieldwork and Professor Jean-Marie Pycke is acknowledged for the analyses of the food samples. We would like to express our appreciation to Patricia D'Hont, Valérie Delforge, Arleta Chwalik and Annie Dufour for their excellent technical assistance. All companies of the ESV/GIE EQUILIBRIUM Industrial Partnership are thanked for sponsoring this study by providing the n-3 fortified foods. Els Clays is thanked for statistical advice. The work was partly financed by the Walloon region of Belgium through the competitiveness cluster 'WALGRALIM'.

Abstract Evidence suggests that minor isomers of conjugated linoleic acid (CLA), such as *trans*8, *cis*10 CLA, can elicit unique biological effects of their own. In order to determine the effect of a mixture of *t*8, *c*10+*c*9, *t*11 CLA isomers on selected aspects of lipid metabolism, 3T3-L1 preadipocytes were differentiated for 8 days in the presence of 100 μ M linoleic acid (LA); *t*8, *c*10+*c*9, *t*11 CLA; *t*10, *c*12+*c*9, *t*11 CLA or purified *c*9, *t*11 CLA. Whereas supplementation with *c*9, *t*11 and *t*10, *c*12+*c*9, *t*11 CLA resulted in cellular triglyceride (TG) concentrations of 3.4 ± 0.26 and 1.3 ± 0.11 μ g TG/ μ g protein, respectively ($P < 0.05$), TG accumulation following treatment with CLA mixture *t*8, *c*10+*c*9, *t*11 was significantly intermediate (2.5 ± 0.22 μ g TG/ μ g protein, $P < 0.05$) between the two other CLA treatments. However, these effects were not attributable to an alteration of the Δ^9 desaturation index. Adiponectin content of adipocytes treated with *t*8, *c*10+*c*9, *t*11 mixture was similar to the individual isomer *c*9, *t*11 CLA, and both the *t*8, *c*10+*c*9, *t*11 and *c*9, *t*11 CLA groups were greater ($P < 0.05$) than in the *t*10, *c*12+*c*9, *t*11 CLA group. Overall, these results suggest that *t*8, *c*10+*c*9, *t*11 CLA mixture affects TG accumulation in 3T3-L1 cells differently from the *c*9, *t*11 and *t*10, *c*12 isomers.

Furthermore, the reductions in TG accumulation occur without adversely affecting the adiponectin content of these cells.

Introduction

Conjugated linoleic acid (CLA), a group of positional and geometric isomers of linoleic acid with conjugated double bonds, has been demonstrated to impact aspects of health and disease as varied as cancer, cardiovascular disease, diabetes, immune function and bone health [1]. The specific ability of CLA to affect body fat metabolism and consequently reduce fat mass accumulation in animals, including mice [2] and pigs [3], has led to a flurry of research activity into its potential use as an anti-obesity agent. The *cis*9, *trans*11 CLA (*c*9, *t*11 CLA), also known as

'ruminic acid' is the predominant isomer occurring in nature and the most widely studied. It has recently become clear that many of the biological effects are attributable to the *trans*10, *cis*12 CLA (*t*10, *c*12 CLA), which is a minor isomer and occurs naturally only in small amounts. However, it can be obtained in the same proportion as the *c*9, *t*11 isomer from dietary CLA supplements [4]. It is thought to act through inhibition of TG accumulation via decreased activity of lipoprotein lipase and stearoyl CoA desaturase, decreasing preadipocyte differentiation, and by increasing fat oxidation and perhaps lipolysis [5]. Of importance, however, is the fact that results are varied and somewhat equivocal according to the model used, the dosage and the duration of supplementation. In addition, the presence of small amounts of various lesser-known isomers in the mixture may also play a role.

It is well known that the synthesis of monounsaturated fatty acids (MUFA), the preferred fatty acid (FA) for incorporation into triglyceride (TG), membrane phospholipids and cholesteryl esters, is catalysed by the central lipogenic enzyme, stearoyl CoA desaturase (SCD1). Palmitoleate (16:1) and oleate (18:1) are the major MUFA synthesised by this enzyme from palmitate (16:0) and stearate (18:0), respectively. Perturbations in the ratio of MUFA to saturated FA have been shown to influence several disease states such as obesity, dyslipidemia and insulin resistance [6]. There is evidence to indicate that inhibition of SCD1 activity can improve glucose signalling and prevent obesity in SCD null mice [7], although the mechanism for this effect is unknown. In a recent study [8], targeted SCD1 inhibition in mice fed a high-fat diet improved hepatic insulin signalling, suggesting that SCD1 activity is implicated in the development of insulin resistance. It is already known that SCD1 activity can be modulated by CLA in animals [9, 10] and cell lines, and that the *t*10, *c*12 CLA isomer decreases the activity of this enzyme in 3T3-L1 preadipocytes [11] and HepG2 cells [12] with a decrease in the synthesis of MUFA.

Adiponectin is an adipocyte specific cytokine that is involved in carbohydrate and lipid metabolism. Circulating levels of this hormone are found to be depressed in obesity. Moreover, low plasma levels of the hormone have been associated with low HDL, high TG levels and small, dense LDL particles, which are risk factors for the development of heart disease. Furthermore, adiponectin is required for normal insulin action. It is thought that lowered adiponectin could contribute towards development of insulin resistance and Type 2 diabetes [13].

Results from very early studies report essentially the combined effects of crude CLA mixtures containing different amounts of various isomers. It is now becoming increasingly clear that the range of individual isomers that comprise CLA are likely to exert unique biological effects

of their own. It is important to have knowledge of such isomers that exert either beneficial effects or might be detrimental to health so that they might be excluded from, or included in the manufacture of dietary supplements. One isomer that has received very little attention to date is the *trans*8, *cis*10 CLA (*t*8, *c*10 CLA), which is present as a minor component of dietary CLA supplements [14]. This isomer, which can be formed as a by-product during the commercial production of CLA, used to be present as an 'impurity' in the CLA mixtures that were used in studies conducted in the 1990s [15]. Methodologies have since been developed to avoid the generation of the *t*8, *c*10 isomer in order to produce CLA supplements of a higher quality. Therefore, knowledge of the specific biological effects of this isomer might be useful in better interpreting the results of those earlier studies on CLA. More recently, however, this isomer has been produced in substantial amounts as part of an equimolar mixture of *t*8, *c*10 and *c*9, *t*11 CLA when high CLA containing butterfat was heated under specific conditions [16]. The results of this study suggest that this isomer can be produced during cooking of milk and other dairy products containing the *c*9, *t*11 isomer and can thus be potentially obtained from the diet. In addition, CLA supplements for animals such as cows and pigs sometimes contain the *t*8, *c*10 isomer [14, 17], which might be incorporated into the food derived from these animals, providing yet another potential dietary source of this isomer. In light of these findings, a study was recently conducted in which hamsters fed a purified diet supplemented with an equal mixture of *t*8, *c*10 and *c*9, *t*11 at 2% (w/w) showed increased plasma VLDL TG and cholesterol concomitantly with an increase in plasma glucose, compared with an equal mixture of *t*10, *c*12+*c*9, *t*11 CLA [18].

The objectives of this study were, therefore, to further investigate the physiological effects of *t*8, *c*10+*c*9, *t*11 CLA mixture in relation to TG metabolism in the adipocyte. For this purpose, we compared a mixture of *t*8, *c*10+*c*9, *t*11 CLA, which was the only source of *t*8, *c*10 CLA available on the market, with a pure *c*9, *t*11 CLA isomer, a mixture of *t*10, *c*12+*c*9, *t*11 CLA, and linoleic acid (LA). The well-characterised mouse preadipocyte cell line, 3T3-L1, was selected as a suitable model for conducting this research.

Based on previous data [18, 19], we hypothesised that the *t*8, *c*10+*c*9, *t*11 mixture of CLA would increase TG accumulation through effects on stearoyl CoA desaturase, as estimated by the desaturation index, compared with the pure *c*9, *t*11 CLA and *t*10, *c*12+*c*9, *t*11 CLA mixture. We also expected to see a decrease in adiponectin content following the *t*8, *c*10+*c*9, *t*11 treatment compared with the pure *c*9, *t*11 CLA and *t*10, *c*12+*c*9, *t*11 CLA mixture. LA has been used as a reference.

Materials and Methods

Chemicals

A mixture of *t*8, *c*10+*c*9, *t*11 CLA, in free fatty acid (FFA) form, was obtained from Natural Lipids (Hovdebygda, Norway) and contained approximately 40% each of the two isomers. Pure *c*9, *t*11 and *t*10, *c*12 CLA were purchased from Matreya LLC (PA, USA). The fatty acids used in all studies were complexed to 10% BSA. The *t*10, *c*12+*c*9, *t*11 CLA used in the experiments was a 50:50 mixture of the two purified isomers. Bovine serum albumin (BSA) and LA treated cells were used as controls. The fatty acid composition of the experimental fatty acids is presented in Table 1. LA as sodium linoleate, BSA, dexamethasone (DEX), isobutyl methylxanthine (IBMX), trimethylsilyl (TMS) and sodium methoxide were obtained from Sigma-Aldrich, Inc. (Oakville, ON, Canada). BSA standard for the protein assay was purchased from Pierce Biotechnology Inc. (Rockford, IL, USA). Dulbecco's Modified Eagle's Medium (DMEM), trypsin-EDTA and fetal bovine serum (FBS) were obtained from Invitrogen (Burlington, ON, Canada). Di-ethyl ether for thin layer chromatography (TLC) was obtained from EMD Chemicals Inc. (Hawthorne, NY, USA).

Cell Culture

3T3-L1 mouse preadipocytes (#CL-173) were purchased from the American Type Culture Collection (VA, USA) and were routinely maintained in a growth medium of Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum at 37 °C in a humidified atmosphere of 5% CO₂. Medium was changed

LA linoleic acid, CLA conjugated linoleic acid

every 2 days and cell monolayers were passaged at regular intervals until use in experiments.

For studies on TG accumulation and adiponectin expression, cells that were 50–60% confluent were seeded into 12-well cell culture cluster plates (Corning, NY, USA). For the fatty acid profile studies, cells were seeded into 60-mm cell culture plates (BD Falcon, Mississauga, ON, Canada). Cell layers in all culture dishes were allowed to grow to confluence.

Adipocyte Differentiation and Fatty Acid Treatments

Two days after 3T3-L1 cells had reached confluence, the differentiation process was induced by replacing growth medium with induction medium comprising DMEM, 10% FBS, 250 nM DEX, 0.5 μM IBMX and 5 μg/mL insulin (this was day 'zero' of the experiment). After 48 h, the induction medium bathing the differentiating cells was replaced by DMEM containing 10% FBS, 5 μg/mL insulin and either 100 μM BSA, LA, *c*9, *t*11 CLA, *c*9, *t*11+*t*10, *c*12 CLA mixture, or *t*8, *c*10+*c*9, *t*11 CLA. Media were changed on alternate days with addition of fresh BSA or fatty acids to each medium change. On day 10 of the experiment, cells were washed and harvested in 1 mL isotonic sucrose buffer containing 29 mM sucrose, 73 μM tris-HCl (pH 8) and 24 μM EDTA, and stored at –20 °C until the lipid extraction process. A further step was included for cells that were harvested for TG, protein and adiponectin measurements: cell layers were centrifuged to remove sucrose buffer, resuspended in 100 μL phosphate buffered saline, sonicated for 10 s at 20% output and stored at –20 °C.

Estimation of TG Content

TG content of 3T3-L1 cells was measured with a commercially available colorimetric kit from Diagnostic Chemicals Limited (Charlottetown, PEI, Canada) using glycerol as standard. Briefly, triglycerides are hydrolysed to glycerol and fatty acids. The glycerol moiety is phosphorylated and oxidised leading to the formation of hydrogen peroxide ultimately resulting in reactions leading to the formation of quinoneimine dye, which can be measured spectrophotometrically at 490 nm on a Microplate Reader (model 3550; Bio-Rad, Ramsey, MN, USA). The amount of dye formed is directly proportional to the amount of triglyceride. TG contents of samples were normalised to total cell protein and expressed as μg TG/μg protein.

Estimation of Protein Content

The DC Bio-Rad Protein micro-assay kit (Bio-Rad Laboratories, CA, USA) was used to estimate the protein

content of 3T3-L1 cells with BSA as the standard. This procedure is based on the principle of the Lowry assay [20] involving detergent solubilisation of the samples and colorimetric analysis on a Microplate Reader at 655 nm (model 3550; Bio-Rad, Ramsey, MN, USA).

Estimation of Adiponectin Content

The adiponectin content of 3T3-L1 cells was determined by western blotting analysis using mouse anti-mouse adiponectin antibody (Chemicon International Inc., Temecula, CA, USA) and goat anti-mouse secondary antibody (Bio-Rad Laboratories, CA, USA). Protein in 2 μ l whole cell homogenate was resolved, under reducing conditions, on a 10% SDS–polyacrylamide gel. The separated bands were transferred onto a nitrocellulose membrane (Bio-Rad Laboratories, CA, USA), blocked, and probed with the primary antibody followed by incubation with the horseradish peroxidase conjugated secondary antibody. The membrane was then revealed with BM Chemiluminescence Blotting Substrate solution (POD) (Roche Diagnostics, Laval, QC, Canada) and the signals recorded by autoradiography. Data were analysed using Scion Imaging Software (Scion Corporation, Frederick, MD, USA).

Extraction of Total Lipids from 3T3-L1 Cells

Total lipids were extracted from 3T3-L1 cells according to a modification of the method of Hara and Radin [21] using 40:1 ratio of isopropanol:hexane (v/v). Cell lipids thus obtained were separated into FFA and neutral lipid (NL) fractions. Thin layer chromatography (TLC) was used to further separate the NL fraction into its constituent lipid classes, including triglycerides.

Thin Layer Chromatography for Separation of Neutral Lipids

The NL fraction retained in hexane from the initial lipid extraction process was dried down under nitrogen, dissolved in 50 μ l of chloroform, and spotted on a silica TLC plate (250 μ m coating thickness, Sigma–Aldrich) that had been baked at 50°C for at least an hour and scored to accommodate multiple samples. A 0.02 g/mL standard of phosphatidylcholine/triolein/cholesterol oleate was also spotted on the plate. A double development method was used to separate the neutral lipids. The phospholipids were first separated by placing the plates in a glass chamber equilibrated with chloroform:methanol:acetic acid:water (70:30:12:1), and this was followed by separation of the triglyceride and cholesteryl ester fractions with hexane:diethyl ether:acetic acid (70:30:1). The plates were

dried in air, developed with iodine vapor and bands identified by comparison with the standard.

Preparation of Fatty Acid Methyl Esters (FAME)

FAME of FFA lipid fraction were prepared by incubation with 10% trimethylsilyl–diazomethane in hexane for 30 min at room temperature by the method of Hashimoto et al. [22]. Cellular triglycerides were trans-esterified to their methyl esters by heating for 20 min at 50°C in the presence of methanolic sodium methoxide [23].

Determination of Fatty Acid Composition by GC-FID Analysis

Analysis of all FAME, except those derived from cells treated with *t8*, *c10+c9*, *t11* CLA mixture, were performed on an Hewlett-Packard 6890 Capillary FID gas chromatograph equipped with a 60 m column (0.25 mm inside diameter) coated with 50% cyanopropyl polysiloxane (0.25 μ m film thickness; J&W DB-23; Folsom, CA, USA), and temperature programmed as isothermal at 153°C for 2 min, ramp at 1.7°C/min and hold at 174°C for 0.2 min, ramp at 2.5°C/min and hold at 220°C for 3 min. Methyl heptadecanoic acid (C17:0) was used as the internal standard. Data were analysed using HP ChemStation software (Hewlett-Packard, Agilent Technologies, Mississauga, ON, Canada).

The *t8*, *c10+c9*, *t11* CLA FAME were analysed separately on a 6890 Series II gas chromatograph (Hewlett-Packard) using the temperature and pressure program described previously by Destailats et al. [16]. This step was requisite as the two isomers co-elute when subjected to GC analysis under the conditions described above. Peaks were identified by comparing with commercially available mixture of FAME (GLC 15A), as well as pure *c9*, *t11* and *t10*, *c12* CLA methyl esters obtained from Nu-Check Prep (Elysian, MN, USA). The response factor for C17:0 was used to quantify the identified fatty acids.

Statistical analysis

Data were analysed using SPSS[®] (Statistical Package for Social Sciences; SPSS Inc., IL, USA), SAS[®] (Statistical Analysis Software; SAS Institute Inc., NC, USA) and GraphPad Prism software (GraphPad software Inc., San Diego, CA, USA). Means of the treatment groups were compared using one-way ANOVA with Tukey's post hoc test to detect significant differences between means at $P < 0.05$. Pearson's correlation coefficient was used to calculate relationship between cellular TG concentration and adiponectin content.

Results

Effect of Fatty Acid Treatments on TG Accumulation

The effect of fatty acid supplementation on TG accumulation in differentiating 3T3-L1 cells is presented in Fig. 1. The TG content in cells treated with *c9*, *t11* CLA was significantly higher ($3.4 \pm 0.26 \mu\text{g TG}/\mu\text{g protein}$, $P < 0.05$) than the two other CLA treatments, LA and BSA (no fatty acid). In direct contrast, *t10*, *c12+c9*, *t11* CLA mixture significantly inhibited TG accumulation in 3T3-L1 cells compared with all other treatment groups ($1.3 \pm 0.11 \mu\text{g TG}/\mu\text{g protein}$, $P < 0.05$). Cells that had been supplemented with *t8*, *c10+c9*, *t11* CLA mixture accumulated TG ($2.5 \pm 0.22 \mu\text{g TG}/\mu\text{g protein}$) to an extent that was intermediate between the pure *c9*, *t11* and the *t10*, *c12+c9*, *t11* CLA mixture ($P < 0.05$). This effect, however, was similar to that of both LA and BSA control.

Effect of Fatty Acid Treatments on Δ^9 desaturation index

Data on the Δ^9 desaturation index of the cellular TG fraction are presented in Table 2. This index is the ratio of monounsaturated to saturated fatty acid of palmitic acid (palmitoleic acid/palmitic acid; 16:1/16:0) and stearic acid (oleic acid/stearic acid; 18:1/18:0), and is used as an indicator of the activity of the lipogenic enzyme, stearoyl CoA desaturase. Supplementation of differentiating 3T3-L1 cells with *t10*, *c12+c9*, *t11* CLA mixture resulted in a significant decrease ($P < 0.05$) in the Δ^9 desaturation index, suggesting a decrease in the enzyme's activity when compared with BSA, LA, *c9*, *t11* CLA, or the *t8*, *c10+c9*, *t11* CLA mixture. No statistically significant differences were observed between the LA, *c9*, *t11* CLA, or the *t8*, *c10+c9*, *t11* CLA mixture groups.

Fig. 1 Effect of 100 μM BSA, LA, *c9*, *t11* CLA, *t8*, *c10+c9*, *t11* CLA or *t10*, *c12+c9*, *t11* CLA on TG accumulation in 3T3-L1 mouse (pre)adipocytes. Data are means \pm SD ($n = 3$). Means for a variable without a common letter differ at $P < 0.05$

Table 2 Effect of fatty acid treatment on Δ^9 desaturation index

Treatment	16:1/16:0	18:1/18:0
BSA	0.79 ± 0.16	5.00 ± 0.76
LA	0.52 ± 0.15	$2.89 \pm 0.52^\dagger$
<i>cis9</i> , <i>trans11</i> CLA	0.60 ± 0.20	3.92 ± 0.21
<i>trans8</i> , <i>cis10+cis9</i> , <i>trans11</i> CLA	0.53 ± 0.14	3.47 ± 0.98
<i>trans10</i> , <i>cis12+cis9</i> , <i>trans11</i> CLA	$0.07 \pm 0.06^*$	$0.25 \pm 0.05^*$

BSA bovine serum albumin, LA linoleic acid, CLA conjugated linoleic acid, 16:1 palmitoleic acid, 16:0 palmitic acid, 18:1 oleic acid, 18:0 stearic acid

* Significantly different from all other treatment groups at $P < 0.05$

† Significantly different from BSA at $P < 0.05$

Effect of Fatty Acid Treatments on Adiponectin Content

The results on the adiponectin content of 3T3-L1 cells in response to fatty acid supplementation are presented in Fig. 2. Among the five treatments, *t10*, *c12+c9*, *t11* CLA mixture had the most profound effect on adiponectin content of the differentiating cells by more than 30% compared to the other fatty acids ($P < 0.05$). Cells treated with this CLA mixture had the same level of adiponectin as cells treated without fatty acid. No significant differences in adiponectin were observed between cells treated with LA, pure *c9*, *t11* CLA or the *t8*, *c10+c9*, *t11* CLA mixture.

Fig. 2 Adiponectin content of 3T3-L1 mouse (pre)adipocytes treated with 100 μM BSA or fatty acids. Data are means \pm SD ($n = 3$). Means for a variable without a common letter differ at $P < 0.05$

Correlation Between TG Accumulation and Adiponectin Content

Correlation analysis revealed that there was a positive association between cellular TG concentration and adiponectin content in 3T3-L1 cells treated with BSA or different fatty acids ($n = 15$, $r = 0.72$, $P = 0.002$).

Discussion

The present study provided evidence that the *t8*, *c10+c9*, *t11* CLA mixture behaves in a manner that is unique compared to the other CLA isomers used in this study with regards to selected aspects of lipid metabolism in 3T3-L1 cells. The differences included TG accumulation, desaturation index, and cellular content of the cytokine adiponectin. 3T3-L1 preadipocytes are considered the gold standard for studying adipogenesis at the cellular level, and have been used in a number of studies to determine the effects of CLA on various aspects of lipid metabolism. 3T3-L1 is a non-transformed cell line derived from disaggregated mouse embryo cells that were selected for their ability to accumulate triglyceride droplets. These cells have undergone commitment, and when appropriately stimulated develop into fully functional adipocytes exhibiting the same metabolic features as adipocytes derived from adipose tissue [24]. In culture, these cells are responsive to the same differentiation-inducing agents as adipose tissue in vivo, and thereby represent appropriate models of preadipocyte differentiation [25]. A novel aspect of our research was the observation that *t8*, *c10+c9*, *t11* CLA mixture did not promote lipid filling of 3T3-L1 preadipocytes. In fact, this study shows that *t8*, *c10+c9*, *t11* CLA mixture partially counteracted the lipid filling of *c9*, *t11* CLA isomer, but did not reproduce the anti-adipogenic action of *t10*, *c12+c9*, *t11* CLA mixture.

The results on TG accumulation from the present study are in agreement with previously published data using similar experimental conditions from our lab [26], and others [27] comparing 41 μM *c9*, *t11* pure isomer with 100 μM *t10*, *c12+c9*, *t11* CLA mixture. It has been reported that the *c9*, *t11* CLA by itself elevates TG accumulation by increasing PPAR- γ dependent gene expression [28, 29]. In our previous study [26], TG levels in cells treated with *t10*, *c12* CLA alone, or with the *t10*, *c12+c9*, *t11* CLA mixture, were reduced similarly compared with the *c9*, *t11* pure isomer, suggesting that *t10*, *c12* was the CLA isomer exerting a dominant effect in the mixed isomer preparation. In support of this, in the present study, *c9*, *t11* isomer alone increased TG levels by 41% compared with LA, whereas the presence of *t10*, *c12* CLA in the *t10*, *c12+c9*, *t11* CLA mixture not only abolished the *c9*, *t11*

effect but additionally decreased TG levels by 46% compared with LA. On the other hand, the *t10*, *c12* isomer can suppress TG accumulation in 3T3-L1 cells at concentrations even as low as 25 μM [30], but usually within the range of 50–100 μM . The lower limit concentration of 50 μM (50% of the total concentration of the *t10*, *c12+c9*, *t11* CLA mixture) was used in the present study. Interestingly, a lower concentration range (3–30 μM) of this isomer was sufficient to produce similar results in human preadipocytes [31].

The exact mechanism by which *t10*, *c12* isomer reduces TG content is still unclear. The *t10*, *c12* CLA might act in adipocytes through such mechanisms as decreased de novo FA synthesis [29] and increased FA oxidation. In addition, the *t10*, *c12* CLA may also inhibit differentiation of preadipocytes by down regulating PPAR- γ expression and its downstream targets involved in fatty acid metabolism. This results in the formation of a fibroblast-like cell that demonstrates certain characteristics of a mature adipocyte such as leptin expression, but has a diminished ability to store TG [32]. It has been suggested by Choi et al. [11] that the *t10*, *c12* isomer of CLA may influence adiposity by inhibiting SCD activity, thereby reducing the monounsaturated to saturated fatty acid ratio, termed the ‘desaturation index’, as observed in the present study. According to Ntambi and Miyazaki [33] a decrease in the activity of SCD1 leads to decreased FA esterification, and thereby to reduced synthesis and accumulation of TG.

Reduced TG content of 3T3-L1 cells treated with the *t8*, *c10+c9*, *t11* CLA mixture compared with the *c9*, *t11* CLA isomer was, however, not due to a reduction in the desaturation index, such as was observed with the *t10*, *c12+c9*, *t11* CLA mixture. Indeed, in the present study, the palmitoleic/palmitic and oleic/stearic acid ratios elicited by the *t8*, *c10+c9*, *t11* CLA mixture were similar to those observed with LA and the *c9*, *t11* CLA, but greater than that observed with the *t10*, *c12+c9*, *t11* CLA mixture. In this respect, Choi et al. [11] suggest that a decrease in SCD1 activity might only be partly responsible for reduction in TG content. Therefore, the moderate but significant decrease in TG accumulation that was seen with the *t8*, *c10+c9*, *t11* mixture compared with the *c9*, *t11* CLA isomer alone suggests a mechanism other than direct inhibition of SCD1. It is possible that the presence of 40% *t8*, *c10* isomer in the *t8*, *c10+c9*, *t11* CLA mixture could have partially inhibited the PPAR- γ dependent gene expression stimulated by *c9*, *t11* CLA with a consequent reduction in TG accumulation.

Decreases in cellular and circulating adiponectin concentrations are usually seen as being unfavourable, and are associated with the development of obesity, insulin resistance, Type 2 diabetes and heart disease [34]. A decrease in adiponectin production is seen in obesity, where larger adipocytes with larger amounts of TG do not produce as much

hormone as their smaller counterparts [13]. On the other hand, low adiponectin concentrations could also indicate inadequate function of adipocytes. Therefore, the cellular level of adiponectin, which is a hormone secreted exclusively by adipocytes, may be considered a useful marker of differentiation and proper functioning of these cells. In the present study, there was a positive association between cellular TG concentration and adiponectin content in 3T3-L1 cells treated with BSA or different fatty acids ($n = 15$, $r = 0.72$, $P = 0.002$), suggesting that in the present context, adiponectin levels and TG accumulation together in the adipocyte may be seen as indicators of adequate functioning of 3T3-L1 cells. With supplementation of the *t8, c10+c9, t11* CLA mixture, there was no significant decrease in the cellular adiponectin content of 3T3-L1 cells and was similar to values for the pure *c9, t11* CLA and LA treatment groups, indicating adequate preadipocyte differentiation.

In marked contrast, this hormone was significantly lower in cells treated with the *t10, c12+c9, t11* CLA mixture than in those treated with LA or the other CLA isomers. There was a concomitant decrease in TG content of cells treated with the *t10, c12+c9, t11* CLA mixture, suggesting that the *t10, c12+c9, t11* CLA treatment could not sustain proper cell differentiation. Although this is in direct contrast to epidemiological data which indicates that reduced adiposity is associated with higher circulating adiponectin levels [35], it is in keeping with recent studies in mice where supplementation with the *t10, c12* isomer resulted in decreased concentrations of circulating adiponectin [36, 37] concomitant with a reduction in adipose tissue [36].

To the best of our knowledge, this is the first study to investigate the effects of a CLA mixture containing the *t8, c10* CLA isomer on lipid metabolism in the murine 3T3-L1 cell line. We have previously studied the effects of *c9, t11+t8, c10* CLA mixture compared to those of *c9, t11+t10, c12* CLA mixture and LA on lipoprotein profile, hepatic lipids, body composition and digestibility of dietary fat in hamsters [18]. We showed that whereas the *c9, t11+t8, c10* CLA mixture deteriorated VLDL TG and cholesterol, as well as glycemia compared with LA treatment [18], the *c9, t11* and *t10, c12* CLA isomers given separately had no effect on VLDL TG and cholesterol [19], thus indicating that the *c9, t11+t8, c10* effect on VLDL TG and glycemia could not be attributed to the *c9, t11* CLA isomer alone. This suggests a high possibility that the *t8, c10* CLA, although found at 35% concentration in this mixture, might be the physiologically active CLA isomer, being aware that other isomers could have also played a role [18].

In the present study, the *t8, c10+c9, t11* CLA induced similar TG accumulation as LA, and decreased TG accumulation in 3T3-L1 cells when compared with the *c9, t11* pure CLA isomer. Since the *t8, c10* CLA was supplemented as part of a mixture, it is difficult to attribute the

observed effects to this isomer alone. We cannot rule out the presence of other minor isomers (~15%) that could have affected the TG response in the preadipocytes, neither exclude the possibility that the TG response could also be a result of the lower concentration (40%) of *c9, t11* CLA in the mixture compared to the 98% purity of this isomer in the individual *c9, t11* CLA treatment. On the other hand, Brown et al. [27] have demonstrated that 3T3-L1 cells treated with half the concentration (41 μ M) of *c9, t11* CLA isomer had significantly higher TG content than 3T3-L1 cells treated with LA (100 and 44 μ M), *c9, t11+t10, c12* CLA mixture (100 μ M) and *t10, c12* CLA (44 μ M). Taken together, these data and the results of the present study suggest that the *c9, t11* CLA supplemented at either 100 μ M or half the concentration (~50 μ M) could both promote higher lipid accumulation than LA, the *t8, c10+c9, t11* and the *c9, t11+t10, c12* CLA mixtures in 3T3-L1 preadipocytes. Nevertheless, a limitation of the present study was the use of *t8, c10* CLA as a mixture with *c9, t11* CLA, rather than as the *t8, c10* single isomer. This prevents us from making clear distinctions between the effects of the two isomers. Therefore, all the results observed for this treatment group should be considered a combined effect of the isomers present in the *t8, c10+c9, t11* CLA mixture. However, because the *t8, c10* isomer was present at a proportion of ~40% in the mixture used, there is also a possibility that the suppressive effect on TG accumulation might be more pronounced with the *t8, c10* isomer administered in its pure form. Specific biological effects of the *t8, c10* isomer will be thus determined when the pure form of this isomer becomes available.

In conclusion, our CLA isomer mixture of interest, *t8, c10+c9, t11* CLA, can beneficially decrease TG accumulation as compared to the individual *c9, t11* CLA, without adversely affecting adiponectin content in 3T3-L1 cells, and in turn adipocyte differentiation, as did the *t10, c12+c9, t11* CLA mixture. Further studies on the *t8, c10* pure CLA isomer are needed to investigate metabolic effects in animals, and ultimately humans, in order to evaluate its potential usefulness in safe weight loss formulations of CLA.

Acknowledgment This study was conducted with the support of the Advanced Foods and Materials Network, as part of the Networks of Centres of Excellence, Canada.

Abstract *Schizochytrium* produces long chain polyunsaturated fatty acids (PUFAs) via a PUFA synthase. Targeted mutagenesis of one gene of this synthase was conducted to confirm PUFA synthase function and determine its metabolic necessity. The resulting mutants were auxotrophic and required supplementation with PUFAs. In vivo labeling experiments with radioactive fatty acids demonstrated the presence of several elongase and desaturase activities associated with the standard pathway of PUFA synthesis. However, this system was missing a critical $\Delta 12$ desaturase activity and was therefore not capable of synthesizing PUFAs from the 16- or 18-carbon saturated fatty acid products of the fatty acid synthase. Because *Schizochytrium* uses a PUFA synthase system for the production of PUFAs, the existence of a partial desaturase-elongase system (if not a simple vestige) is suggested to be either a scavenging mechanism for intermediate fatty acids prematurely released by the PUFA synthase or for PUFAs found in the organism's native environment.

Introduction

Schizochytrium sp. is one of several heterotrophic eukaryotic organisms used to make commercial amounts of long chain polyunsaturated fatty acids (PUFAs) by fermentation. *Schizochytrium* is a member of the Stramenopiles, a kingdom consisting of photosynthetic diatoms, brown algae and other algae commonly referred to as chromophytes [1]. Within this kingdom, the phylum Labyrinthulomycota contains two orders, the Labyrinthulales and the Thraustochytriales; the genus *Schizochytrium* is a member of the latter. *Schizochytrium* makes two PUFAs: docosahexaenoic acid (DHA) and docosapentaenoic acid (DPA) n-6. These fatty acids occur in a 3:1 ratio among total cellular lipids of this microalgae and are found in most known Thraustochytrids (although in different ratios) [2]. DHA and DPA n-6 can comprise >60% of the total lipid-associated fatty acids of cultured *Schizochytrium*, which in turn can be as much as 43% of the dry cell weight [2, 3].

Three genes, designated *PFA1*, 2 and 3 (and formerly *ORF A*, *B* and *C*) have been implicated in *Schizochytrium* PUFA biosynthesis [4, 5] based on sequence similarity to the products of the PUFA synthase gene clusters from the marine bacteria *Shewanella* [6] and *Moritella* [7] and on their functional expression in bacteria [8]. The mechanism behind double-bond insertion in PUFA synthase systems, proposed by Metz et al. [4, 5] is thought to be similar to the FAS-mediated biosynthesis of monounsaturated fatty acids in *E. coli*, which employs dual dehydratase and 2,3-isomerase activities of the FabA enzyme. The mechanics of

double-bond formation by the *Schizochytrium* PUFA synthase are thought to differ from the synthesis of *E. coli* monounsaturates in the need for an additional novel 2,2-isomerase activity [4].

Desaturase genes involved in the standard pathway of PUFA biosynthesis have also been identified in *Schizochytrium* [4], putting the relative contribution of the PUFA synthase for PUFA accumulation in this organism into question. Additionally, genes encoding enzymes for the standard pathway have been found in other thraustochytrids. *Thraustochytrium aureum*, a close relative of *Schizochytrium*, harbors several enzymes of the standard pathway of PUFA biosynthesis, including the first-discovered $\Delta 4$ desaturase [9]. To reconcile the apparent presence of two biosynthetic pathways for PUFA production in *Schizochytrium* [10], two different approaches were utilized. A transformation system for *Schizochytrium* was previously developed and data indicated that it was capable of vector-mediated homologous recombination [11]. This vector-directed homologous recombination method was used to disrupt the *PFAI* PUFA synthase gene in *Schizochytrium*. Second, the standard pathway elongase and desaturase activities were characterized by supplementation with radiolabeled precursors. This study presents direct functional evidence that the PUFA synthase is the sole system responsible for de novo biosynthesis of PUFAs in *Schizochytrium* and that those PUFAs are essential nutrients for this organism. The data also illustrate that while several fatty acid desaturase and elongase activities are present in *Schizochytrium*, that pathway for PUFA synthesis is incomplete.

Materials and Methods

Host Strains, Transformations, and Culture Conditions

All vectors and constructs were propagated in *E. coli* UltraMax DH5- α FT chemically competent cells (Invitrogen, Carlsbad, CA) for plasmid purification using Qiagen kits appropriate for a given scale of culture (Qiagen, Valencia, CA).

Schizochytrium sp. was isolated from a single colony of an ATCC stock culture (ATCC# 20888). *Schizochytrium* cultures were typically grown in 50 mL of “PB26-M2B” media consisting of 10 g L⁻¹ glucose, 0.8 g L⁻¹ (NH₄)₂SO₄, 5 g L⁻¹ Na₂SO₄, 2 g L⁻¹ MgSO₄·7H₂O, 0.5 g L⁻¹ KH₂PO₄, 0.5 g L⁻¹ KCl, 0.1 g L⁻¹ CaCl₂·2H₂O, 0.1 M MES (pH 6.0) 0.1% PB26 metals and 0.1% PB26 Vitamins (v/v). PB26 vitamins consisted of 50 mg mL⁻¹ vitamin B12, 100 μ g mL⁻¹ thiamine, and 100 μ g mL⁻¹ Ca-Pantothenate. PB26 metals were adjusted to pH 4.5 and consisted of 3 g L⁻¹ FeSO₄·7H₂O, 1 g L⁻¹ MnCl₂·4H₂O,

800 mg mL⁻¹ ZnSO₄·7H₂O, 20 mg mL⁻¹ CoCl₂·6H₂O, 10 mg mL⁻¹ Na₂MoO₄·2H₂O, 600 mg mL⁻¹ CuSO₄·5H₂O, and 800 mg mL⁻¹ NiSO₄·6H₂O. PB26 stock solutions were filter sterilized separately and added to the broth after autoclaving. Glucose, KH₂PO₄, and CaCl₂·2H₂O were each autoclaved separately from the remainder of the broth ingredients before mixing to prevent salt precipitation and carbohydrate caramelizing. All media ingredients were purchased from Sigma, St. Louis, MO. Cultures of *Schizochytrium* sp. were grown to log-scale and transformed with a biolistic particle bombardier (BioRad, Hercules, CA) with the gene disruption construct described below. The biolistic transformation procedure was essentially the same as described previously [12]. Primary transformants were selected on solid PB26-M2B media containing 20 g L⁻¹ agar (VWR, West Chester, PA), 50 μ g mL⁻¹ zeocin, and 0.5 mM DHA, DPA n-6 or myristic acid (NuChekPrep, Elysian, MN) complexed with 10–30 g L⁻¹ randomly methylated β -cyclodextrins (Cyclodextrin Technologies Development, Inc., High Springs, FL). All primary transformants were manually transferred to grid-plates containing or lacking polyunsaturated free fatty acid supplements. Putative auxotrophs were confirmed by a second round of inoculation on these plates. Transformants were further characterized after growth in liquid PB26-M2B with 15 g L⁻¹ β -cyclodextrins and 0.5 mM PUFA as indicated in the text. Equilibrium-radiolabeled cultures were typically grown in 10 mL of liquid “790” media; 1 g yeast extract, 1 g peptone, 5 g glucose (VWR), all per liter of Instant Ocean™ artificial seawater (Aquarium Systems, Mentor, OH) and 0.1 μ Ci mL⁻¹ of a 1-[¹⁴C]-labeled fatty acid (American Radiolabeled Chemicals, St. Louis, MO) as indicated in the text. Equilibrium-labeled cultures were grown under agitation (120 rpm) for at least 2 days at 27 °C.

Vector Construction

Materials used for cloning procedures including restriction enzymes, alkaline phosphatase, and T7 DNA polymerase were purchased from New England Biolabs (Beverly, MA) and used according to the manufacturer’s instructions. Restriction fragment and amplicon purification was done with either PCR clean-up kits or Qiaex gel extraction kits from Qiagen. Agarose gels were made with 1% SeaKem Agarose or 1% low-melt Agarose (Cambrex BioScience Rockland, Inc., Rockland, ME). DNA ligations were performed with the Rapid DNA Ligation Kit (Roche Diagnostics Corporation, Indianapolis, IN) and 2 μ L of each ligation were used to transform DH5- α competent cells (Invitrogen). Transformed bacterial colonies were grown in 5 mL mini-cultures of Luria broth (LB), 100 μ g mL⁻¹ ampicillin [13]. Plasmids were extracted from mini-cultures

with miniprep kits (Qiagen). All constructs were verified by DNA sequencing (Lark Technologies, Houston, TX). All reagents and kits described were used according to the manufacturer's instructions unless otherwise noted.

Construction of a vector harboring *Schizochytrium* PFAI (pBSK:A) and a vector capable of conferring resistance to zeocin when used to transform *Schizochytrium* (pTUB-ZEO11-2) have been described elsewhere [11]. Briefly, the vector contains the *ble* gene of *Streptoalloteichus hindustanus* [14] to confer resistance to zeocin. The endogenous *Schizochytrium* promoter for α -tubulin was used to drive expression of this selectable marker. A terminator from the SV40 virus coat protein locus (genbank accession M24873) follows the *ble* coding region. These three elements: promoter, *ble* coding region, and terminator, are collectively referred to hereafter as a "zeocin resistance cassette". Vector pBSK:A, which harbored only the coding region of PFAI in the vector background pBLUESCRIPT SK, was digested and linearized with *Sma*I. The zeocin resistance cassette was liberated from pTUBZEO11-2 by digestion with *Pst*I. The fragment was treated with T7 DNA polymerase to create blunt ends before ligation to the linear pBSK:A. *E. coli* cells were transformed directly with this ligation mix. Resulting transformants were mini-cultured from colonies and plasmids were purified and digested to screen for insertion of the zeocin cassette. One clone was selected for having a zeocin cassette encoded on the plus strand, relative to PFAI transcription. This plasmid, pBSK- Δ ORFA-zeoR#2, was prepared in large scale for use in *Schizochytrium* transformation.

Gas and High Pressure Liquid Chromatography

Fatty acid methyl esters (FAMES) were extracted and derived from freeze-dried biomass according to the method described elsewhere [15]. Injections of FAMES in 1 μ L volumes were separated on a GC fitted with a flame-ionizing detector and a FAMEWAX 30-meter column (0.25 mm i.d., 0.25 μ m) [16]. Eluted FAMES were identified and quantified by comparison to authentic standards.

HPLC separations of FAMES were performed using an adaptation of a common reverse phase protocol [17]. FAMES were resuspended in 50–200 μ L of acetonitrile after evaporating \sim 2 mL of hexane from the FAME reaction. FAME injections of 5–20 μ L were separated by HPLC with a Metachem 3 Taxsil, 250 \times 4.6 mm column (Varian, Palo Alto, CA) into which a gradient of acetonitrile was applied in water; 60% from 0 to 35 min, 60–70% from 35 to 40 min, 70% from 40 to 60 min, 70–60% from 60 to 61 min, and lastly held at 70% for an additional 9 min. Eluted radioactive FAMES were mixed in-line with Scintiverse LC (Fisher, Hampton, NH) liquid scintillant (1:2, v:v) for detection of beta-particle emissions. Fatty

acids were qualified and quantified by comparison to authentic reference standards.

Nucleic Acid Isolation

Wet pellets from 1 L of overnight *Schizochytrium* wild-type and mutant cultures were washed with sterile water, weighed, and lysed with Extraction Buffer (20 mM Tris-HCl pH 8.0, 50 mM NaCl, 10 mM EDTA, 0.5% SDS) (1 mL Extraction Buffer per 100 mg wet cell pellet) and 100 μ g mL⁻¹ proteinase K for \sim 45 min at 50 °C. After this, 100 μ g mL⁻¹ of DNase-free RNase A was added and the lysate incubated at 37 °C for an additional 15 min. DNA was then extracted from the lysate twice with an equal volume of phenol:chloroform:isoamyl alcohol (24:24:1) by gentle shaking for 30 min at room temperature. The aqueous phase of the extract was further extracted twice with an equal volume of chloroform:isoamyl alcohol (24:1). Genomic DNA (gDNA) was precipitated from the remaining aqueous fraction by addition of 0.1 v of 3 M sodium acetate and 2 v of 100% ethanol. DNA was gently wound out of the solution with a glass rod, washed with 70% ethanol, dried and resuspended in Tris-buffered water (pH 8.0).

For RNA preparation, flash-frozen pellets from 1 L of log-phase wild-type and auxotrophic mutant cultures of *Schizochytrium* were pulverized in liquid nitrogen-cooled mortars that had been oven-baked overnight at 350 °F. Total RNA was extracted from the resulting frozen powder in 30 mL of buffer containing 0.1 M Tris-HCl (pH 7.5), 1.5 M NaCl, 50 mM EDTA (pH 8.0), 20 g L⁻¹ cetyl trimethyl ammonium bromide (CTAB), and fresh dithiothreitol (DTT, 8 mg mL⁻¹). The slurry was centrifuged at 5,000 \times g for 20 min before mixing the supernatant with an equal volume of phenol:chloroform:isoamyl alcohol (25:24:1) (Biotechnology Grade, Midwest Scientific, St. Louis, MO). Phases were separated by centrifugation at 10,000 \times g for 30 min and the aqueous phase was re-extracted with phenol:chloroform:isoamyl alcohol. The aqueous phase was then mixed with an equal volume of isopropanol and allowed to chill at 4 °C overnight. The resulting precipitate was pelleted at 5,000 \times g for 20 min, washed with 80% ethanol, dried briefly, and resuspended in RNase-free water before treatment with RNase-free DNase (New England Biolabs, Beverly, MA) at 37 °C for 2 h. RNA was again extracted and precipitated as above.

Southern and Northern Blotting

100 μ g of gDNA was digested overnight at 37 °C with *Nco*I. Digested DNA was fractionated on 1% agarose gels (10 μ g per lane) and transferred to Nytran-Supercharge membranes (Whatman, Middlesex, UK) while RNA was

fractionated (10 µg per lane) using 2.2 M formaldehyde agarose gels [13] and transferred to Nytran-N membranes (Whatman) using the manufacturer's protocol for neutral transfers or RNA transfers as appropriate.

All probes were synthesized using dCT[³²P] (ICN, Costa Mesa, CA) and the Prime-a-Gene labeling system (Promega, Madison, WI) according to the manufacturer's instructions. A *PFA1*-specific probe template was created by digestion of *PFA1* (in pBSK:A) with *Nco*I and *Bsr*GI and gel purification of the resulting 1,146 bp band. RNA millenium markers (Ambion, Austin, TX) were electrophoresed and blotted with total RNA samples, while the Quanti-Ladder markers (Origene, Rockville, MD) were electrophoresed and blotted with DNA samples. Both marker-ladders were detected with probes made from *Hind*III digested, lambda phage DNA (Origene).

Southern and northern blots were probed in UltraHyb hybridization buffer according to the manufacturer's protocol (Ambion). After drying, blots were wrapped in cellophane and imaged on a BioRad Personal Molecular Imager FX (BioRad).

Results

Disruption Vector Construction

A vector construct for the disruption of *PFA1* of the *Schizochytrium* PUFA synthase was made to test the feasibility of PUFA synthase inactivation. The construct contained the coding region of *PFA1* (but not its corresponding promoter or terminator) and an additional insert of ~1,100 bp which conferred resistance to the antibiotic zeocin (Fig. 1). In some systems, long homologous flanking sequences have been reported to correlate with higher recombination efficiencies [18, 19]. Therefore, to improve the potential for recombination in this system, the construct was designed such that 1,500–7,500 bp of target gene sequence flanked either side of the zeocin cassette.

Generation of *Schizochytrium* Disruption Mutants

Cells bombarded with vector-coated tungsten particles were allowed to recover overnight before being transferred to solid media containing zeocin and myristic, docosapentaenoic (n-6), and docosahexaenoic acids complexed with cyclodextrins for further growth. One bombardment with supercoiled vector typically yielded 10–100 primary transformants. Each primary transformant was then re-plated to screen for auxotrophy by observing its ability to grow on solid media containing zeocin and cyclodextrins, but no free fatty acids. Between 10 and 40% of the

Fig. 1 Cartoon depicting the position of the zeocin disruption cassette in the *PFA1* coding region in a vector construct intended to mediate disruption of *PFA1* of the *Schizochytrium* PUFA synthase. The *PFA1* sequence is translated in the direction shown by an open arrow. The encoded resistance marker, “ZEO” protein (*sh ble*) is translated in the same direction as *PFA1*. The tubulin promoter, the SV40 terminator and the coding region of the zeocin resistance gene are indicated. Numbers given in parentheses or along the vector ruler are in base pairs, numbered from the first base pair of the bacterial backbone vector, pBLUESCRIPT SK

primary transformants failed to grow indicating that these clones were fatty acid auxotrophs.

Phenotyping of the Disruption Mutants of *Schizochytrium*

Verified auxotrophic mutants were further characterized by observing growth on solid media supplemented with a number of fatty acids (Table 1). The phenotypes of all verified auxotrophic mutants were similar. None were able to grow without supplemented PUFAs less complex than linolenic acid. Polyunsaturated fatty acids of 20 and 22 carbons in length were found to permit better growth of the mutant than linolenic acid. One *PFA1*-disrupted (*ZEO::PFA1*) mutant clone (A14) was grown in liquid cultures supplemented with several free fatty acids. The cultures were harvested for FAME derivation and analysis by GC (Table 2). These data show that the PUFAs which permitted growth of the mutants were converted to several more complex PUFAs; however, complete conversion to DHA and DPA n-6 did not appear necessary for survival.

Genotyping of the Gene Disruption of *Schizochytrium* Auxotrophs

To verify that the observed auxotrophies were caused by a targeted gene disruption event, nucleic acids of a

Schizochytrium mutant were compared to those of wild-type by Southern and northern blotting. Total gDNA was purified from a wild-type culture and from a putative *PFA1* disruption mutant clone (A20), which was identical in phenotype to all other PUFA auxotrophs. These gDNA preparations were digested with *NcoI* and separated on agarose gels for blotting. Blots were probed with fragments which specifically hybridized to coding regions of *PFA1*. Maps of wild-type *PFA1* and the integrated *PFA1* disruption cassette are shown in panels (a) and (b), respectively of Fig. 2. Probe annealing locations and predicted sizes of detectable *NcoI* fragments are also featured in these panels. The observed migrations of labeled fragments in the *PFA1*-probed Southern agreed relatively well with a predicted

single crossover event resulting in the genomic structure proposed in Fig. 2b.

Total RNA was also purified from a wild-type culture and from disruption mutant clone A20. These RNA samples were separated on agarose gels for northern blotting. Blots were probed with the same fragments used for Southern blotting. As shown in Fig. 3, transcripts of the *PFA1* disruption mutant A20 are clearly fragmented into weak bands of ~2,700 bases and ~1,800 bases, while the size of the band observed in the wild-type sample lane agrees with the expected size of a wild-type *PFA1* transcript (8,730 bases for the open reading frame, plus 5' and 3' UTR sequence lengths).

Characterization of the Standard Pathway in Wild-type *Schizochytrium*

To determine which standard pathway enzymes are active in *Schizochytrium*, liquid cultures of wild-type cells were equilibrium-labeled with [1-¹⁴C]-free fatty acids and patterns of conversion were observed (Table 3). Radiolabeled compounds were added during culture inoculation. After ~2 days growth, the culture was harvested and lipids were extracted and derivitized for radio-HPLC analysis as detailed in the previous section.

For improved sensitivity, an HPLC apparatus fitted with an in-line liquid scintillant β-RAM detector was used for separating and identifying radiolabeled FAMES. As is common with HPLC separations, some FAMES co-migrated precluding distinct quantification [17]. Specifically, 18:3 n-3, 20:4 n-3 and 22:5 n-3 all co-migrated. Separately, 18:3 n-6 and 22:6 n-3 co-migrated as a single peak as did 16:0 and 18:1 n-9 in yet another single peak. Despite the co-migrations, the data shown in Table 3 indicate that wild-type *Schizochytrium* possesses many but not all of the activities associated with a standard PUFA biosynthesis pathway. Total percent FAMES are listed in the column corresponding to the structurally simplest member of a

*wild-type culture, all other cultures were Δ*PFA1* mutant clone A14. All values are expressed as a FAME area percent of total FAME peaks

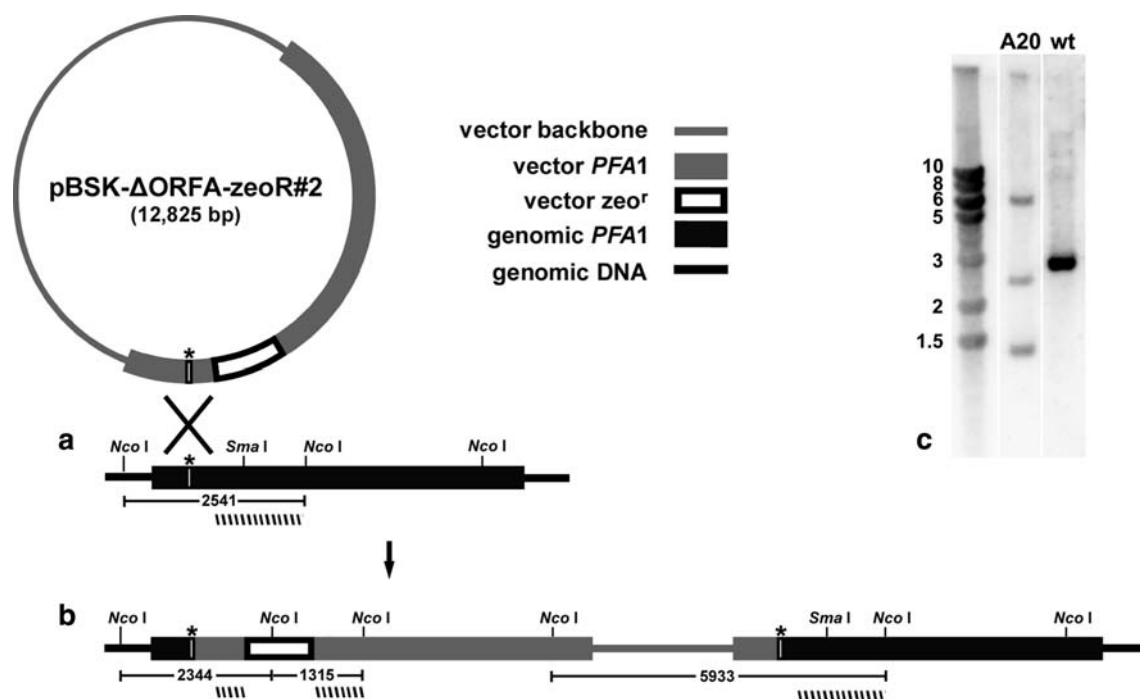

Fig. 2 *Schizochytrium* PUFA synthase *PFA1* disruption. **a** and **b** show maps of expected arrangement of *PFA1* gDNA resulting from a single crossover event in auxotrophic mutants transformed with pBSK- Δ ORFA-zeoR#2. The maps illustrate the locations of *PFA1*-specific probe annealing regions (*hatched bars*) and detectable *Nco*I restriction fragments, labeled according to their predicted size in base pairs, 2,541, 2,344, 1,315, and 5,933 (*stroked goalposts*). The proposed recombination site between the vector, within the *PFA1* coding region and upstream of the ZEO expression cassette is also shown (*asterisk*). Vector-backbone sequences are indicated by *grey lines* and genomic DNA sequences (other than *PFA1*) are indicated by *black lines*. The vector-encoded Zeocin resistance cassette, vector-encoded *PFA1*, and genome-encoded *PFA1* are shown as *open black*

boxes, *grey bars*, and *black bars*, respectively. All genes are transcribed left to right in linear sequence representations and counter-clockwise in circular representations. The *Sma* I site was used for cloning the zeocin resistance cassette and thus only appears in the wild-type *PFA1* reading frame. The Southern blot of *Nco*I-digested gDNA samples from wild-type “wt” and disruption mutant clone A20 (**c**) was labeled with an *PFA1*-specific probe created from a restriction fragment of wild-type *PFA1* (see Sect. “Materials and Methods”). The lane at left in **c**, containing molecular weight markers, was probed separately with a lambda virus-specific probe preparation and the bands are labeled according to their size in kilobase pairs

co-migrating group. Retro-conversion and β -oxidation of fatty acids was not observed, however, some fatty acids were converted to minor extractable products which did not co-migrate with any of the used standards.

Discussion

This study provides evidence for the essential role of the PUFA synthase in DHA and DPA biosynthesis in *Schizochytrium*. In addition to the *PFA1* disruption mutants described, disruption mutants of *PFA2* and *3* were also created and analyzed with similar results (data not shown). These mutants resulted from recombination events where components of the PUFA synthase were disrupted with a dominant selectable marker for zeocin resistance. All auxotrophic mutants generated had identical phenotypes and required supplementation with PUFAs for growth, indicating that each PUFA synthase component is

necessary for PUFA synthesis. This work confirms that of Metz et al. [4] and Hauvermale et al. [8] supporting the role of the PUFA synthase genes, *PFA1*, *2*, and *3* of *Schizochytrium* in PUFA biosynthesis and additionally demonstrates that this PUFA synthase is a critical enzyme component required for primary metabolism in *Schizochytrium*. This work also reveals a secondary and partially functional fatty acid desaturase and elongase-mediated PUFA pathway.

Wild-type *Schizochytrium* does not accumulate any significant amounts of PUFA other than DHA and DPA. However, knock-out mutants of the PUFA synthase components were able to grow when supplemented with PUFAs, some of which were only minimally converted to DHA or DPA, demonstrating a nutritional flexibility for complementation by fatty acids less complex than DHA and DPA. However, auxotrophs fed 20- and 22-carbon PUFAs grew significantly better than those fed 18-carbon PUFAs, indicating that PUFA auxotrophs preferred

Fig. 3 Northern blot of total RNA samples extracted from wild-type “wt” *Schizochytrium* and disruption mutant clone A20. Blots were labeled with the same *PFAI*-specific probe illustrated in Fig. 2. The lane at left was labeled separately with a lambda virus-specific probe preparation and the bands are annotated according to their size in kilobases

supplementation with longer chain PUFAs (Table 1). Additional studies will be needed to specifically address whether the requirement for PUFAs is limited to 22-carbon PUFAs or if unconverted 18- or 20-carbon PUFAs are adequate for minimal complementation of PUFA synthase mutants.

A requirement for monounsaturated fatty acids has been well documented among diverse organisms [20–22]. The absolute requirement for certain PUFAs (as observed here for *Schizochytrium*) might be considered unusual though, because other PUFA-producing organisms, such as the fungus *Mortierella alpina* and the cyanobacterium *Synechocystis* PCC6803, remain viable after suffering mutations that interrupt certain parts of PUFA biosynthesis (depending upon growth conditions) [22, 23]. Unlike the *Schizochytrium* system, however, both *M. alpina* and *Synechocystis* employ a standard pathway for PUFA synthesis, therefore any given mutation in a desaturase resulted in the accumulation of other structurally analogous PUFAs

which might have complemented the loss of the most complex PUFA made by the wild-type strain.

The nature of the genetic defect in these auxotrophic mutants of *Schizochytrium* was analyzed by Southern and northern blotting (Figs. 2, 3, respectively). The described disruption construct was designed to integrate at the loci encoding the PUFA synthase component, *PFAI*. The data are consistent with a single crossover event in the *PFAI* disruption mutant A20. Homologous recombination via a single crossover event should yield two copies of the targeted gene separated by the backbone of the vector encoding an ampicillin resistance gene and bacterial origin of replication (Fig. 2). Since the *PFAI* disruption construct only contained the coding regions of *PFAI* (and no *PFAI* promoter), the second, introduced copy of *PFAI* should not have appeared as an expressible gene, as long as the crossover occurred upstream of the zeocin selection cassette. The resulting *PFAI* locus would have a 5′ copy of *PFAI* containing the zeocin cassette and a second, uninterrupted 3′ copy of *PFAI*. The largest band of the Southern blot of A20 agrees well with the predicted size of the vector-backbone containing fragment found between the 3′-most *NcoI* site in the upstream, interrupted copy of *PFAI* and the first *NcoI* site found in the coding region of the downstream, uninterrupted, promoter-less copy of *PFAI*. The remaining bands also agree well with their predicted sizes. Northern blots (Fig. 3) demonstrate that the *PFAI* transcript was affected in the auxotrophic mutant. As shown, the *PFAI* transcript in the mutant appears as two fragments detectable by the probe used. These fragments, ~2,700 bases and ~1,800 bases in size, obviously do not sum to the wild-type transcript size (>9,000 bases). The size of the larger band agrees with the size expected for a transcript initiated by the *PFAI* promoter and stopped at the zeo cassette terminator. The smaller band may also have been formed by initiation from the *PFAI* promoter, but with premature termination or transcript fragmentation occurring at some point within the sequence of the zeocin cassette promoter.

Although our method of generating “knockout” mutants worked well for the current study, one might expect double cross-over recombination events to occur more frequently if linear vector had been used, as is the case in many other systems. Transformation efficiencies with linear vectors are being improved and should yield more facile recombinations in future studies.

A secondary desaturase/elongase PUFA pathway (a “standard” pathway) was detected in *Schizochytrium*, however, the enzymes of this pathway were unable to rescue cultures from the lethality of PUFA synthase disruption. The apparent absence of a $\Delta 12$ desaturation activity for 18:1 n-9 seems the most likely cause of this inability to self-complement disruptions of the PUFA

Table 3 Radiolabeled FAMES derived from total lipids of wild-type *Schizochytrium* cultures grown at 27 °C in 10 mL 790 liquid media supplemented with 1 μCi of the indicated 1-[¹⁴C] labeled free fatty acids

All values are expressed as percent of total recovered activity per FAME. Three distinct groups of FAME standards appeared as a single co-migrating peak during HPLC separation, precluding quantification of these FAMES individually:

* FAMES of 18:3 n-3, 20:4 n-3 and 22:5 n-3 co-migrated

FAMES of 18:3 n-6 and 22:6 n-3 co-migrated

φ FAMES of 16:0 and 18:1 co-migrated

? Includes percent activities of minor peaks which did not elute with any of the authentic standards used

synthase. This lesion in the standard pathway may not be limited entirely to the absence of the Δ12 desaturase activity. Even though the conversion of radiolabeled 18:2 to 18:3 was observed, 18:2 (and 20:2 n-6, data not shown) were unable to support growth of the PUFA synthase mutants, suggesting that the kinetics of these conversions are severely limited. Downstream of 18:2, most biosynthetic steps expected for the standard pathway could be identified or inferred (Fig. 4). Specifically, an omega-3 desaturase activity for the conversion of ARA to EPA was seen, as were several elongase activities. Additionally, Δ6 and Δ9 elongase activities for the conversion of both isomers of 18:3 to their 20 carbon products, and a Δ5 elongase activity for the conversion of EPA to 22:5 n-3, were observed.

It may be worth noting that conversion of 18:0 to 18:1 n-9 was not detected in the radiolabeling experiment (Table 3) despite the fact that the wild-type strain clearly accumulates an isomer of 18:1 (Table 2). The reason for this is unclear although it may be that the cultures responded differently to the different culture volumes and media compositions used in each set of experiments. The most

significant difference in media compositions being the masses of substrates used in the two experiments (0.5 mM unlabeled FFA vs. ~2 μM labeled FFA). This may also explain the fact that very little conversion of ARA or DPA n-6 was seen in cultures fed unlabeled substrate (Table 2), whereas these fats were converted more when fed as radiolabeled substrates (Table 3). Some of these differences might also be explained by potential alterations in the regulation of standard pathway enzymes in response to PUFA synthase disruption, when compared to wild-type cultures. It should additionally be noted that *Schizochytrium* has previously been shown to produce 18:1 n-7 and 16:1 n-7 along with 18:1 n-9 [24]. The n-7 isomer of 18:1 was not used as a substrate in this study because radiolabeled standard was not available and because no precedence exists for the conversion of n-7 fatty acids to n-3 or n-6 products. Double-bond positions of FAME products corresponding to 18:1 were not specified in Tables 2 or 3 because neither of the FAME separation techniques used in this study would have easily resolved the different mono-unsaturated fatty acid isomers. The primary products of the *Schizochytrium* FAS [8] are 14:0 and 16:0. Stearic acid is

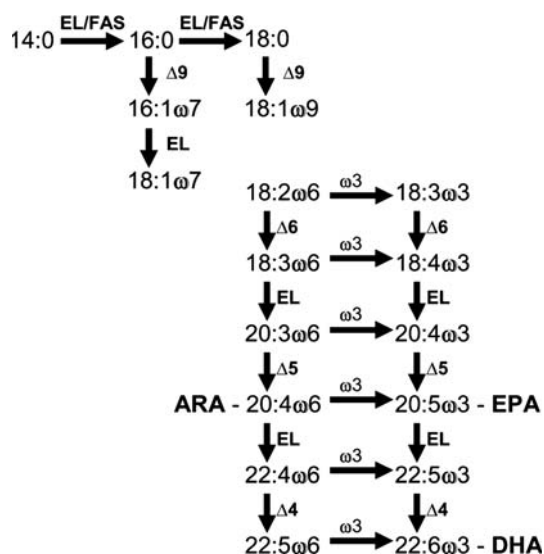

Fig. 4 A summary of elongation and desaturation activities corresponding to wild-type and auxotrophic mutant cultures of *Schizochytrium*. The most apparent “missing” activity corresponds to a Δ 12 desaturase although other activities immediately adjacent to the Δ 12 desaturase in the above pathway may be so inefficient as to be essentially non-functional. EL elongase, EL/FAS elongase or fatty acid synthase, ω 3 omega-3 desaturase activity, Δ 9 delta-9 desaturase activity, Δ 6 delta-6 desaturase activity, Δ 5 delta-5 desaturase activity, Δ 4 delta-4 desaturase activity. The saturated and monounsaturated fatty acid conversions shown are hypothetical and were not demonstrated by radiolabeling in this investigation. Their inclusion in the pathway above is based on the observed accumulation of each unlabeled saturated and monounsaturated fatty acid in *Schizochytrium* cultures described here and in other studies referenced in the text. Accumulation of stearic acid and monounsaturates in *Schizochytrium* appears to be dependent on culture conditions different from those used for radiolabeling experiments here

either a minor product of the FAS or a minor elongation product of 16:0 in wild-type cells. Disruption of the PUFA synthase appears to promote greater accumulation of 18:1 (Table 2), presumably formed either via elongation of 16:1 n-7 to 18:1 n-7 or desaturation of 18:0 to the n-7 or n-9 isomer of 18:1. If the predominant isomer produced by *Schizochytrium* PUFA synthase knockouts is 18:1 n-7, then the absence of a mechanism to form substantial quantities of 18:1 n-9 may represent yet another lesion in the standard pathway of this organism.

Lastly, *Schizochytrium* appears to harbor a Δ 4 desaturase activity as evidenced by the accumulation of DHA in cultures fed 22:5 n-3. This desaturase is likely to be very similar to its counterpart in *Thraustochytrium* [9]. In contrast to our results, Meyer et al. [25] reported that *Schizochytrium* was not able to convert significant amounts of DPA n-3 to DHA during 24 h incubation with label. All of the *Schizochytrium* fatty acid labeling data presented in this work was obtained using 2 day incubations, simply because preliminary experiments had established that

equilibrium was not yet attained after just 24 h. The *Schizochytrium* Δ 4 desaturase activity and others were only revealed when these longer incubation times were used.

As noted earlier, Thraustochytrid PUFA synthases [5, 26], like that of *Schizochytrium*, are most similar to PUFA synthases of proteobacterial systems. However, the Δ 4 desaturase isolated from *Thraustochytrium* (Genbank accession AAM09688) is, by BLASTP analysis, most similar to other “front-end” desaturases of other eukaryotes such as the Δ 4 desaturase of *Euglena* (of the alveolates), the Δ 5 desaturases of the liverwort, *Marchantia* (of the viridiplantae), and the fungi, *Mortierella* (Genbank accessions AAQ19605, AAT85663, and AAR28035, respectively). Isolation of additional standard PUFA synthesis pathway genes from other members of the order Labyrinthulida coupled with detailed phylogenetic studies may reveal that the desaturases and elongases were likely the only components of a PUFA pathway present in ancestors of *Thraustochytrium* and *Schizochytrium*, and that the PUFA synthase was a later, horizontally transferred acquisition from a bacterium to the *Schizochytrium* progenitor (and perhaps other ancestral eukaryotes). Precedence for such bacteria-to-eukaryote horizontal gene transfers exists beyond the common examples associated with the acquisition of plastids and mitochondria (especially among protists) [27]. Hypothetically, once the PUFA synthase stabilized in this ancestor, selective pressure to retain the standard pathway components could have been diminished to a secondary role in scavenging for environmental PUFAs or prematurely released PUFA synthase intermediates (possibly 18:5 n-3 for example, which could be converted to 20:5 n-3 (EPA) via a single β -ketoacyl synthase-mediated condensation, according to the scheme of Metz et al. [4]). Under such conditions, one would predict that the standard pathway enzymes involved in conversion of PUFAs with the least structural analogy to the native PUFAs, DHA and DPA would be under the least selective pressure and would thus decay faster. An environment rich in sources of 18-carbon PUFAs (perhaps from decaying vegetation) may relax the selective pressure on the early parts of the standard pathway in these organisms even further. Analysis of other members of Labyrinthulida (or even other eukaryotes) may reveal standard pathways in greater or lesser stages of decay depending upon specific environmental needs and the strength of an endogenous PUFA synthase system.

Acknowledgments We would like to acknowledge Jerry Kuner, Brad Rosenzweig, Craig Weaver, and Dan Doherty for helpful discussions and for supplying vectors without which this work would not have been possible. We would also like to acknowledge Paul Roessler’s development of the *Schizochytrium* transformation system and his observations of homologous recombination with it. Colin Ratledge is thanked for review of portions of the manuscript.

Abstract We report here our preliminary investigations on the mechanism of α -TTP-mediated ligand transfer as assessed using fluorescence resonance energy transfer (FRET) assays. These assays monitor the movement of the model α -tocopherol fluorescent derivative ((*R*)-2,5,7,8-tetramethyl-chroman-2-[9-(7-nitro-benzo[1,2,5]oxadiazol-4-yl amino)-nonyl]-chroman-6-ol; NBD-Toc) from protein to acceptor vesicles containing the fluorescence quencher TRITC-PE. We have found that α -TTP utilizes a collisional mechanism of ligand transfer requiring direct protein–membrane contact, that rates of ligand transfer are greater to more highly curved lipid vesicles, and that such rates are insensitive to the presence of anionic phospholipids in the acceptor membrane. These results point to hydrophobic features of α -TTP dominating the binding energy between protein and membrane.

Introduction

The human α -tocopherol transfer protein (α -TTP) is a soluble 32 kDa-protein chiefly expressed in the liver that is understood to be responsible for the selective retention of α -tocopherol from dietary sources over other forms of

vitamin E [1]. This role is exemplified by mutant forms of the protein that are known to cause neurological deficits in persons having “ataxia with vitamin E deficiency” (AVED) [2–6]. It is further underscored by mice in which the *tppA* gene has been deleted, that exhibit very low levels of plasma and tissue α -tocopherol [7–10] and present AVED-like neuropathological symptoms [11]. Despite these demonstrations of α -TTP centrality to tocopherol bioavailability and distribution, little is known about the molecular mechanism of α -tocopherol transport in hepatocytes, nor the means by which α -TTP assists in the re-secretion of α -tocopherol into the plasma where it is carried to extrahepatic tissues by plasma lipoproteins. For instance, while it is well documented that the majority of plasma tocopherol is carried by LDL and HDL, treatment of cultured hepatocytes with brefeldin A, which inhibits lipoprotein construction and secretion outside the cell, did not inhibit tocopherol secretion [12]. Similarly, mice in which the expression of liver microsomal triglyceride transfer protein (MTTP) is disrupted and thus do not secrete VLDL remain tissue-sufficient in tocopherol [13].

Lipid transfer proteins enable cells to transport hydrophobic compounds (e.g., fatty acids, phospholipids, sterols, retinoids, and α -tocopherol) across aqueous media inside cells. The means by which this is accomplished has been most thoroughly described for the fatty acid binding proteins (FABPs) that, in all cases except for the liver FABP [14, 15], bind directly to membrane surfaces where they extract or deliver their preferred ligand(s). In order to accomplish this task, FABPs take advantage of electrostatic forces between a collection of basic residues on an α -helical portal region and negatively charged membrane phospholipids [16].

In previous work using cultured hepatocyte cells it was shown [17, 18] that expressed α -TTP co-locates with a fluorescent form of α -tocopherol ((*R*)-2,5,7,8-tetramethylchroman-2-[9-(7-nitro-benzo[1, 2, 5]oxadiazol-4-yl amino)-nonyl]-chroman-6-ol; NBD-Toc) [19] in the late endosomal compartment. The localization of α -TTP to endosomes raises the possibility that the protein may prefer to associate with membranes of specific phospholipid composition, or defined curvature. We report here our investigations on the mechanism of α -TTP-mediated ligand transfer assessed using fluorescence resonance energy transfer (FRET) assays that monitor the movement of NBD-Toc from protein to acceptor vesicles. We have found that α -TTP utilizes a collisional mechanism of ligand transfer requiring direct protein–membrane contact, that rates of ligand transfer are greater for more highly curved lipid vesicles, and that such rates are insensitive to the presence of anionic phospholipids in the acceptor membrane.

Materials and Methods

Materials

Glutathione agarose and DNase I were purchased from Invitrogen (Burlington, ON, Canada). N-(6-tetramethylrhodaminethio-carbamoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanol-amine, triethylammonium salt (TRITC-DHPE) was from Molecular Probes (Invitrogen, Oregon, USA). Thrombin was obtained from GE Healthcare (Piscataway, NJ, USA). RNase A and Triton X-100 were from Sigma (St. Louis, MI, USA). Polycarbonate membranes for lipid extrusion were purchased from Avestin, Inc (Ottawa, ON, Canada). The following phospholipids were obtained from Avanti Polar Lipids (Alabaster, AL, USA): Liver bovine L- α -phosphatidylcholine (liver PC), soy L- α -phosphatidylcholine (soy PC), porcine brain L- α -phosphatidylserine (PS), bovine liver phosphatidylinositol (PI), 1,2-dioleoyl-*sn*-glycerol-3-phosphocholine (DOPC), oleoyl lysobisphosphatidic acid (LBPA), and 1,2-dioleoyl-*sn*-glycerol-3-phosphate (DOPA). NBD-Toc was previously synthesized in our lab [19]. All other reagents were from BioShop Canada Inc. (Burlington, ON, Canada).

Protein Expression and Purification

Human α -TTP flanked by NotI and SalI restriction sites was subcloned into pGEX-4T-3 vector. This construct was transformed into *E. coli* BL21 (DE3) for protein expression [20]. *E. coli* cultures were grown in baffled flasks at 37 °C until OD 600 nm was between 0.4 and 0.6. The bacterial culture was cooled to room temperature before being induced with 400 μ M IPTG. To improve the production of soluble α -TTP, the culture was grown at room temperature for 18 h. The cells were harvested and stored at –80 °C until use.

After being frozen and thawed three times, the *E. coli* pellet was re-suspended in buffer A (150 mM Tris pH 8.0, 150 mM NaCl, 1 mM EDTA, 10% glycerol, 0.1 mM DTT and 0.1 mM PMSF). Lysozyme (4 mg/ml) was added to the cell suspension and followed by 30 min incubation on ice. Nucleic acids were digested with the addition of 10 mM MgCl₂, DNase I (1,000 units/ml lysate) and RNase (50 μ g/ml), followed by an additional 30 min incubation on ice. The cells were then homogenized and centrifuged at 40,000g for 30 min at 4 °C. The supernatant was applied to a glutathione affinity column, and nonspecific binding proteins were removed by 15 column volumes wash each of buffer B (Buffer A plus 0.5% Triton X and 10 mM MgCl₂) and buffer C (50 mM Tris, pH 8, 150 mM NaCl, 10 mM MgCl₂ and 0.1 mM DTT), respectively. On-column thrombin cleavage of GST-TTP was completed after 2 h of incubation at RT with 50 units of thrombin in PBS

per 1 ml of resin. The α -TTP was eluted in buffer C and a final concentration of 0.5 mM PMSF was added to prevent further thrombin-induced degradation. GST bound on the column was eluted with PBS containing 20 mM glutathione, and the column was regenerated with 3 M NaCl in PBS. Each purified sample was subjected to SDS-PAGE analysis. The Bradford assay was used to determine protein concentration. Purified protein was stored at 4 °C and used within a few days after the purification. In general, α -TTP ligand transfer activity remained intact within 5 days of purification.

Lipid Vesicle Preparation

Acceptor lipid vesicles for ligand transfer assays contained 97 mol% PC and 3 mol% quencher TRITC-PE, unless otherwise specified. For anionic lipid vesicles, 15 mol% of indicated anionic phospholipid was incorporated in vesicle preparations. Chloroform was evaporated from lipid mixtures under a stream of N₂ and residual solvent removed by continued evaporation under 0.5 mmHg. Lipid mixtures were rehydrated in SET buffer (250 mM Sucrose, 100 mM KCl, 50 mM Tris, 1 mM EDTA, pH 7.4). The lipid suspensions were vortexed and incubated for 30 min at room temperature before liposome preparation. Large unilamellar vesicles (LUV) were prepared with a Liposfast mini-extruder (Avestin, Inc.). Briefly, lipid suspensions were extruded through a polycarbonate membrane (100-nm membrane for standard LUV preparation) for 15 passages to produce uniform size LUV. Small unilamellar vesicles (SUV) were prepared, following the procedure described by Schroeder and Thompson [21] with minor modifications. Briefly, lipid suspensions were sonicated using a titanium microprobe and a W-375 cell disruptor (Heat Systems-Ultrasonic, Inc.). Lipid samples were sonicated on ice for 45 min with output setting level of 2.5 and 35% duty cycle. The resulting liposomes were centrifuged at 110,000g for 2 h at 4 °C to remove large vesicles and titanium particles. To compare the difference between probe and bath sonicated SUV, SUV were also prepared by sonication for 45 min with a Branson bath sonicator Model 2510 (Branson, USA). SUV produced from both methods appeared to behave similarly toward α -TTP mediated tocopherol transfer. Ideally, a phosphorous assay should be performed to determine the phospholipid concentration after each vesicle preparation. However, due to the presence of a high sucrose content in the SET buffer, lipid samples turned black during acidic digestion at 190 °C, and thus such assays could not be used regularly to assess phospholipid concentration. To confirm that there is no loss of phospholipids due to extrusion and sonication procedures, the phosphorous assay was performed initially with SET buffer without sucrose, and the result suggested that

the lipid concentration remains the same before and after the preparation. For the experiments that compared the vesicles of different size, the same rehydrated lipid mixture (multilamellar vesicles) was used to generate SUVs or LUVs of the same stock concentration. An estimation of vesicle concentration can be determined based on the emission spectrum of quencher TRITC-PE at approximately 575 nm. Lipid samples were prepared freshly for each experiment.

We measured the size of all lipid vesicles using a single angle (90°) quasi-elastic light scattering (QELS) instrument (Bookhaven Instruments Corporation) with a Melles Griot HeNe Laser (35 mW, 632.8 nm) and BI-APD 8590 digital auto-correlator. A cumulative statistical method was used to calculate particle size distributions. We found that all vesicles have nominal diameters larger than expected from the pore size of the filters when the extrusion method is used. We also note that the sucrose-containing buffer elicited a significant background signal that led to an overestimation of the size of small vesicles. Increased vesicle size has been seen previously with vesicles made in sucrose-containing buffers [22]. In general, the size variation is larger than expected for smaller vesicles than for bigger ones.

The average diameters of vesicles (nm) and their polydispersity index (in parentheses) were, by probe sonication; 106 nm (0.283), bath sonication; 134 nm (0.262); and by extrusion through polycarbonate filters of nominal pore size 30 nm (91 nm, 0.122), 50 nm (107 nm, 0.119), 100 nm (158 nm, 0.116), and 200 nm (219, 0.103). When vesicles of expected size 100 nm were prepared in Tris buffer rather than SET, the average size was 114 nm (0.085) emphasizing the overestimation of vesicle size that occurs in SET buffer.

We also separately determined the size of the smallest vesicles we prepared by sonication and extrusion on a DyanPro™ NanoStar (Wyatt Technology). In this case probe sonication gave vesicles of an average size of 67 nm (polydispersity 0.326) and extruded vesicles using 30 nm filters, 55 nm (0.034).

Partition Coefficient of NBD-Toc Between α -TTP and PC Lipid Vesicles

Kinetic analyses of FRET-based ligand transfer assays are only useful if the transfer is essentially unidirectional. In this work we have monitored the decrease in fluorescence intensity as NBD-Toc bound to α -TTP (where the signal is high) is transferred to PC vesicles containing the quencher TRITC-PE (where the signal is low). In order to be assured of unidirectional transfer, the partition coefficient (K_p) of NBD-Toc between α -TTP and vesicles must be known. Once K_p is known, appropriate concentrations of donor

protein-ligand complex and acceptor vesicles can be chosen. The K_p of NBD-Toc was measured following literature procedures for fluorescent fatty acid transfer from albumins and FABPs to lipid vesicles [15, 23]. Briefly, several solutions were prepared containing a 9:1 ratio of α -TTP:NBD-Toc (final protein and ligand concentrations were 1 μ M α -TTP:0.1 μ M NBD-Toc in SET, pH 7.4) that assured the absence of appreciable amounts of free NBD-Toc. (The K_d of NBD-Toc for α -TTP was determined to be between 8.5 [24] and 56 nM [19] depending on the assay conditions and whether the α -TTP used was a GST or His-tagged fusion. Natural α -tocopherol has a K_d of 25 nM using a tritiated-tocopherol binding assay [25]). These high affinities of the protein for the ligand suggest that the α -TTP concentrations for both kinetic and partitioning experiments are sufficient to bind all available NBD-Toc. The samples were incubated for 15 min with gentle rotation. To each of these solutions were added amounts of LUVs or SUVs containing TRITC-PE (measured as μ M total phospholipid) so that the final lipid concentration ranged from 50 to 400 μ M. The resulting mixture was incubated for 15 min to allow NBD-Toc to equilibrate between α -TTP and acceptor SUVs or LUVs, the fluorescence spectrum of NBD-Toc from 475 to 600 nm was recorded, and the changes in the fluorescence at 520 nm were applied to the following equation [23, 26] to calculate partition coefficients:

$$1/\Delta F = 1/K_p(1/\Delta F_{\max})(\text{mol } \alpha\text{-TTP/mol PC}) + 1/\Delta F_{\max} \quad (1)$$

where ΔF is the difference between the initial fluorescence of NBD-Toc bound to α -TTP and the fluorescence at a given protein/PC ratio, and ΔF_{\max} is the maximum fluorescence change [15]. A plot of $1/\Delta F$ versus $(1/\Delta F_{\max})(\text{mol } \alpha\text{-TTP/mol PC})$ gave a straight line whose slope was equal to $1/K_p$.

Transfer of NBD-Toc to Lipid Vesicles Investigated by FRET

The rate of NBD-Toc transfer from α -TTP to lipid vesicles was investigated utilizing a FRET assay. Experiments were performed using a Photon Technologies, Inc. QuantaMaster-QM-2001-4 fluorometer (Photon Technologies International, Inc.) equipped with SPF-17 stopped-flow device which were used to determine the kinetics of NBD-Toc transfer to quencher TRITC-PE containing acceptor vesicles. The emission spectrum of NBD-Toc overlaps with the excitation spectrum of TRITC-PE, thus, upon mixing of donor (α -TTP bound NBD-Toc) and acceptor (TRITC-PE containing vesicles), the fluorescence intensity decreases with time. The excitation and emission wavelengths used were 466 and 526 nm, respectively. Standard transfer

experiments were performed by incubating 0.45 μ M NBD-Toc with 4 μ M α -TTP for 15 min prior to mixing with 200 μ M acceptor vesicles using the SPF-17 stopped-flow device. The final concentrations after mixing were 0.225 μ M NBD-Toc, 2 μ M α -TTP and 100 μ M vesicles. The ratio of α -TTP to NBD-Toc was kept at 9:1 to ensure that there was no free ligand and that the fluorescence signal was solely attributed to protein-bound NBD-Toc. A 50-fold excess of acceptor vesicle was used based on the partition coefficient of NBD-Toc between α -TTP and vesicles. All experiments were performed at 20 °C. The fluorescence quench was monitored over time and normalized to the starting fluorescent intensity of NBD-Toc bound to α -TTP as 100%. To study the intervesicular transfer of NBD-Toc, 1 mol% of NBD-Toc was incorporated into PC SUV or LUV, and the transfer of NBD-Toc from these vesicles to PC LUV or SUV were monitored. In our assay condition, after subtraction of the signal due to slight ligand photobleaching, the rate of NBD-Toc transfer was best fitted with a single exponential decay Eq. 2 provided by Prism software (version 5, GraphPad Software, Inc., El Camino Real, San Diego, CA, USA).

$$y = (y_0 - y_{\text{inf}}) * \exp(-k * x) + y_{\text{inf}} \quad (2)$$

where y_0 is the initial fluorescence when NBD-Toc bound to α -TTP, k is the rate constant, x is the half time, and y_{inf} is the remaining fluorescence signal after NBD-Toc has been transferred to the acceptor vesicle, which in our case is approximately 55% of the original fluorescence signal.

Results

A representative determination of the partition coefficient of NBD-Toc between α -TTP and vesicles of different size is shown in Fig. 1. The slopes of the lines for both LUVs and SUVs over this lipid concentration range are very similar and shallow. The average values of the determined partition coefficient, K_p , of NBD-Toc between α -TTP and bovine liver phosphatidylcholine unilamellar vesicles were determined to be 0.064 ± 0.026 ($n = 4$) for LUVs and 0.098 ± 0.035 ($n = 3$) for SUVs. These values are not significantly different from each other. As the units of K_p are (mol lipid-bound NBD-Toc/mol phospholipid)/(mol protein-bound NBD-Toc/mol protein) the magnitude of K_p shows that NBD-Toc binds to α -TTP with ~ 10 – 15 times greater affinity than to lipid. Thus, for our transfer assay conditions to reflect unidirectional movement from protein to vesicle, an excess of phospholipids must be provided. Our assays use a 50-fold molar excess of phospholipids over α -TTP and represent a convenient concentration that assures unidirectional transfer, is not wasteful of phospholipids, and maintains the rate of transfer within the

Fig. 1 Partitioning of NBD-Toc between α -TTP and SUVs or LUVs. Titration of NBD-Toc (0.225 μ M) bound to α -TTP (2 μ M) with PC SUVs (filled diamonds) or LUVs (filled squares) at a concentration of 50, 100, 200 and 400 μ M. The change in fluorescence intensity between NBD-Toc bound to α -TTP and vesicles at each lipid concentration is expressed as ΔF . The partition coefficients determined for this particular experiment are 0.122 and 0.082 for SUVs and LUVs, respectively

kinetic window of our stopped-flow device (mixing dead time \sim 20 ms). At equilibrium, the assays show a \sim 50% loss of the original fluorescence from protein-bound NBD-Toc.

However, it was observed that spontaneous intervesicular ligand transfer in the absence of α -TTP occurred at a higher rate for donor SUVs than donor LUVs (Fig. 2). Note that the fastest observed rate was for movement of NBD-Toc from donor SUV to acceptor SUV; when the donor vesicles were LUVs the rates were lowered by about 50%. This may represent a combination of the enhanced water-solubility of NBD-Toc (calculated $\log P = 7.34$) compared to natural α -tocopherol ($\log P = 9.60$), and the ease of ligand movement from the differing lipid packing of SUVs and LUVs. Our previous work with NBD-tocopherol in hepatocytes [17, 18] showed that this ligand partitions to membranes and that residence time in mainly endosomal membranes is dependent on the inducible expression of TTP that clears the fluorescence signal from the cell. This behavior completely mimics similar secretion assays done using 14 C- α -tocopherol. Furthermore, we recently reported on the effect of tocopherols on aspects of membrane curvature using differential scanning calorimetry (DSC) [27]. All of the tocopherols and tocotrienols lowered both the gel to liquid crystalline transition temperature (T_M) and the liquid crystalline to inverted hexagonal transition (T_H) of dielaidoyl phosphatidylethanolamine. We have repeated such measurements with NBD- α -tocopherol and found them to be more similar to natural α -tocopherol than any other tocopherol. In the above-cited work, the numbers for α -tocopherol were: ΔT_M ($^{\circ}$ C/mol fraction) = -41 ± 4 and ΔT_H

Fig. 2 Intervesicular transfer of NBD-Toc from donor vesicles to acceptor vesicles. 1 μ M NBD-Toc incorporated in 100 μ M donor PC SUVs or LUVs was transferred to 100 μ M acceptor bovine liver PC SUVs or LUVs containing 3% TRITC-PE. Data shown represent an average of six determinations \pm the standard deviation

($^{\circ}$ C/mol fraction) = -300 ± 35 . The values for NBD- α -tocopherol were $\Delta T_M = -33 \pm 4$ and $\Delta T_H = -262 \pm 17$, suggesting that NBD-tocopherol has the same effect on the physical attributes of a membrane as does α -tocopherol.

To test whether α -TTP uses a collisional mechanism of transfer where membrane binding is required [16], the concentration of acceptor phospholipids was increased while keeping the protein:ligand concentration constant. If protein-membrane collision is required then the rate of transfer should increase with increasing concentration of phospholipid. As shown in Fig. 3, the rate of transfer of NBD-Toc from α -TTP is quite insensitive to LUV concentration. However, the rates did increase about 50% (0.011 ± 0.0017 – 0.017 ± 0.005 s^{-1}) when the LUV concentration was increased from 50 to 750 μ M. When SUVs were the ligand acceptor the enhancement of transfer was much more dramatic as the lipid amount was raised, increasing \sim 4.5-fold from 25 to 625 μ M phospholipids. Indeed, we have noted a 4-nm red-shift of the intrinsic tryptophan fluorescence of α -TTP when bound to PC SUVs [28] suggesting that α -TTP binding to these vesicles is accompanied by a significant environmental change around tryptophan residues.

Supporting evidence for a collisional versus diffusional mechanism can be obtained if the rate of transfer is not affected by an increase in ionic strength of the medium. High ionic strength slows the rate of transfer if the ligand must first leave the protein and diffuse to a nearby membrane. Hydrophobic compounds such as α -tocopherol and NBD-Toc, which already have very low aqueous solubility, would be even less likely to exist free in buffer due to the increased solvent polarity of the high salt buffer. This has been demonstrated for the liver FABP [15]. Figure 4 shows

Fig. 3 Effect of lipid concentration on the rate of NBD-Toc transfer from α -TTP to PC SUVs and LUVs. Transfer of $0.125 \mu\text{M}$ NBD-Toc from $1.25 \mu\text{M}$ α -TTP to SUVs (open squares) or LUVs (filled squares) at the indicated concentration was monitored at room temperature. Results are the average of three curves \pm the standard deviation

that there is no transfer rate reduction for movement of NBD-Toc from α -TTP to SUVs (100% PC or 15 mol% PS in PC) up to 1.0 M salt.

We hypothesized that α -TTP would show enhanced rates of ligand transfer to membranes that contained anionic lipids, since this has been noted for other lipid transfer proteins such as the FABPs [26, 29–32], and cellular retinol binding protein I [33]. However, when SUVs were prepared containing 15% of anionic phospholipids such as bovine liver PI, DOPS, LBPA, or DOPA, rates of NBD-

Fig. 4 Effect of ionic strength on the rate of NBD-Toc transfer to PC or PS SUVs. $0.225 \mu\text{M}$ NBD-Toc transferred from $2 \mu\text{M}$ α -TTP to $100 \mu\text{M}$ PC SUVs (filled circles) or PC SUVs containing 15% PS (filled squares) in the presence of an increasing concentration of KCl. Data shown represents an average \pm the standard deviation, $n = 12$ for PC at 100 mM KCl, $n = 3$ for other conditions tested. The data shown are compiled from separate experiments with different protein and lipid preparations

Fig. 5 NBD-Toc transfer from α -TTP to anionic SUVs. Transfer of $0.225 \mu\text{M}$ NBD-Toc from $2 \mu\text{M}$ α -TTP to $100 \mu\text{M}$ bovine liver PC SUVs containing 15 mol% of PS, PI, LBPA and DOPA or 25 mol% of PS. Results are the average \pm the standard deviation, $n = 3$ for PI, PS, LBPA and DOPA and $n = 12$ for PC only controls. No statistical differences were observed between PC vesicles and those of variant lipid composition, as assessed by unpaired t tests

Toc transfer by α -TTP showed only minor rate variations (Fig. 5). An increase in the concentration of PS from 15 to 25% did not significantly increase the observed rate. Transfer rates from TTP to LUV were 4–10 times slower than for SUVs (data not shown). Inclusion of 15% cholesterol in bovine liver PC vesicles (both SUV and LUV) had no effect on the rate of transfer when compared to vesicles without cholesterol. The greater rate of transfer to SUV over LUV was, however, maintained (data not shown).

To explore further the effect of membrane surface curvature, vesicles of differing size were prepared by liposome extrusion through specific pore size filters and by sonication. The rates of NBD-Toc transfer to PC vesicles of 50-, 100-, or 200-nm diameters were similar ($k = \sim 0.017 \pm 0.0009 \text{ s}^{-1}$, Fig. 6). Sonicated vesicles, using either an immersion probe or bath sonicator, are generally accepted to yield SUVs of about $\sim 25 \text{ nm}$ in diameter [34, 35] and consistently showed 5–7 fold faster rates of ligand transfer than larger vesicles. For the probe-sonicated vesicles the rate was $0.114 \pm 0.023 \text{ s}^{-1}$ and for bath sonicated was $0.098 \pm 0.005 \text{ s}^{-1}$.

To assess the influence of lipid packing on the transfer process, the rate of NBD-Toc transfer to acceptor phospholipid vesicles of differing degrees of unsaturation is shown in Fig. 7. Three different sources of phosphatidylcholine were tested: soy PC (that has a saturated to unsaturated lipid ratio (S/U) of 0.30 and is composed predominantly 18:2 acyl chains; synthetic dioleoylphosphatidylcholine (DOPC); and bovine liver PC (which has a S/U ratio of 0.91). (Product data from Avanti Polar Lipids, Alabaster, AL). The rates of α -TTP mediated ligand transfer were faster to SUV than LUV acceptors, and soy

Fig. 6 Effect of vesicle size on the rate of NBD-Toc transfer from α -TTP. PC vesicles were prepared by probe sonication, bath sonication or extrusion. The transfer of NBD-Toc (0.225 μ M) from 2 μ M α -TTP to 100 μ M vesicles of various sizes was monitored. Data shown represents the average \pm the standard deviation $n = 12$ for the probe-sonicated PC SUV, $n = 18$ for 100 nm PC LUV, $n = 3$ for other conditions tested. Vesicles sizes represent the nominal pore size of the filters used for extrusion. For full details on the vesicles size distribution see “Materials and Methods”

PC lipids that contain a larger fraction of unsaturated acyl chains supported a transfer rate twice as fast as either DOPC or bovine liver PC.

Discussion

The α -tocopherol transfer protein is one important mechanism for the selective retention of α -tocopherol over other forms of vitamin E found in the diet. The selectivity of α -tocopherol binding to α -TTP [25, 36], coupled with

Fig. 7 Effect of lipid saturation on α -TTP mediated NBD-Toc transfer. Transfer of 0.225 μ M NBD-Toc from 2 μ M α -TTP to 100 μ M PC LUVs (closed bar) and SUVs (hatched bar) of soy PC, DOPC or liver PC was monitored. Data shown represents an average \pm the standard deviation, $n = 3$ for soy PC and DOPC, $n = 12$ for PC SUVs and $n = 18$ for PC LUVs

enhanced oxidative metabolism of non- α -tocols [37, 38], explains how plasma levels of α -tocopherol exceed those of γ -tocopherol for North Americans despite the dietary surplus of γ -tocopherol [39]. Once bound to α -TTP, α -tocopherol is secreted from hepatocytes by an as yet unknown mechanism, and carried in plasma by lipoproteins [1, 40, 41].

α -TTP is a soluble protein that is assumed to bind peripherally to membranes given its localization to late endosomes [18] and its ability to bind phospholipid vesicles in vitro [28]. The membrane-binding characteristics of peripheral membrane proteins are known to combine both electrostatic interactions and hydrophobic forces [42]. Proteins that depend chiefly on the presence of anionic phospholipids such as PS for favorable membrane binding include lipopolysaccharide binding protein (LBP) [43, 44], and bactericidal/permeability-increasing protein (BPI) [45, 46]. BPI (a family member along with PLTP and LBP) has a group of basic residues on its amino terminus that are responsible for recognition of acidic sites on bacterial endotoxin. The fatty acid binding proteins (FABPs) also have a cluster of basic residues on the loop capping the binding cavity that are key to their recognition of anionic membranes [16, 26, 29]. Figure 5 shows that when anionic lipids were incorporated at 15 mol% (and 25% PS) there was no effect on the rate of ligand transfer to SUV or LUVs. It remains possible that more significant differences might be apparent at much higher anionic lipid concentration, but we chose to use 15 mol% of these lipids since PI, PA, and LBPA rarely if ever occur in concentrations higher than this.

Other proteins have been shown to rely more on hydrophobic surface penetration into the lipid bilayer. The human phospholipid transfer protein (PLTP) uses a hydrophobic patch in the N-terminal tip of the protein for membrane binding. Mutations of these residues showed reduced binding [47]. Other contributions of hydrophobic residues for membrane binding have been noted for bee venom secreted PLA₂ [48] and human group \times secreted PLA₂ [49, 50].

A protein that uses predominantly hydrophobic interactions for membrane binding would presumably have difficulty arriving at any specific cellular bilayer membrane since all bilayers contain a hydrophobic core. Many proteins are directed to membranes that contain specific lipids such as the phosphatidylinositol phosphates (PIPs) through protein motifs such as the FYVE and PX domains that specifically recognize these anionic lipids [51–54]. Indeed, it has been recently noted that α -TTP may also have some specificity for membranes containing PIPs even though α -TTP does not contain a FYVE or PX domain [55].

Bilayer curvature is also a variable in membrane recognition and binding by proteins. Biological membranes

are in constant flux, undergoing fusion, exo- and endocytosis processes, all of which generate areas of high curvature and/or curvature stress [56–58]. The size of the organelle thus does not necessarily reflect local membrane curvature or curvature stress since such forces can occur in local portions of larger membranes [59].

α -TTP is known to localize to late endosomes [17, 60], structures that have complex membrane dynamics and topology [61–63]. Late endosomes occur in dense tubular, multi-lamellar, and multi-vesicular subclasses [64] and are reported to be 200–750 nm in diameter [64–66]. The endosome-specific phospholipid LBPA (lysobisphosphatidic acid, also known as bis(monoacylglycerol)phosphate, BMP) [67, 68] appears key to multivesicular body (MVB) structure and function. The interior vesicles of the MVB (called “exosomes” as they are destined for exocytosis) are “pinched” from the MVB limiting membrane at sites rich in LBPA and lysolipids that, at low pH, stabilize this highly curved membrane substructure [69]. The exosomes, however, are not enriched in LBPA [70]. α -TTP has been shown to co-localize with LBPA in rat McARH7777 cells transfected with α -TTP [71]. Our results suggest that this is not due to a specific attraction of α -TTP for LBPA, but rather the effect of LBPA on the properties of the endosomal membrane and the pH-dependent formation of the highly curved MVB [72–74]. The failure of LBPA to enhance α -TTP transfer of NBD-Toc in our assays may be due to lack of an internal acidic pH as in MVBs or, more likely, that SUVs—whether they contain LBPA or not—already have sufficient membrane curvature to enhance *in vitro* α -TTP binding and thus ligand transfer. Therefore, the co-localization of α -TTP with LBPA [71] may be a secondary effect (high curvature) rather than due to a direct interaction of α -TTP with LBPA. Contrarily, the Niemann-Pick-type C2 protein that also occurs in endosomes has recently been shown to exhibit enhanced cholesterol transfer in the presence of SUVs containing 25% anionic lipids such as PI and PS, but is most pronounced in the presence of LBPA [75].

The sensitivity of membrane binding proteins to bilayer curvature is common. For example, an increased rate of ligand transfer from protein to SUVs over LUVs has been observed previously for FABPs [30, 76, 77]. The binding of sterol carrier protein 2 [78], and the glycolipid transfer protein (GLTP) [79] have also been shown to favor more highly curved membranes. The lipid-packing sensor of Arf GTPase activating protein 1 (arfGAP1) known as ALPS2, also preferentially binds to the more highly curved surface of SUVs [80, 81].

Wootan and Storch [82] observed faster rates of fluorescent fatty acid transfer from adipocyte and heart fatty acid bind protein (A- and H-FABP) to SUVs. They noted that this may be due to the greater number of SUVs versus

LUVs prepared from an equal amount of lipid, and suggested that this could be the prime reason for the approximately ten-fold greater rate for transfer to SUVs than LUVs. We observed approximately the same increased rate of transfer to extruded 30 nm vesicles (~5-fold) and sonicated vesicles (~11-fold) as did Wootan and Storch. These authors also noted, however, that tighter packing of the phospholipid acyl chains in LUV due to their more flat lamellar structure may also have decreased rates of ligand transfer to LUVs. Our preparation of vesicles of different size used equal molar amounts of phospholipids. If we assume that vesicles are of uniform size and unilamellar, that the membrane thickness is ~5 nm, and that the area per phospholipid (here assumed to be DOPC) is 67.4 nm² [83], then the total available surface area for protein lipid interaction can be calculated (See Supplementary Material). The area available on the outer leaflet of vesicles increases by only 1.5 times when vesicle size is reduced from 200 to 20 nm when an equal amount of phospholipid is used for all samples. If the rate of ligand transfer was determined solely by the available surface area, we should have seen no more than an ~1.5 fold increase in transfer rate as vesicle size was varied from the larger 200 nm LUVs to smaller SUVs. However, we repeatedly saw transfer rate increases of ~11-fold on moving from extruded LUVs, to SUVs prepared by either extrusion or sonication, substantiating that TTP prefers to bind to SUV membranes of higher curvature.

It is worth noting that the spontaneous rates of NBD-tocopherol transfer between vesicles shown in Fig. 2 clearly shows that LUVs are both poorer donors and acceptors of NBD-tocopherol. Coupling this with our previous observation that TTP binds much better to SUVs than LUVs [28], suggests that in fact, the transfer of NBD-tocopherol to SUVs is faster due to the ease of both protein and ligand insertion into the membrane.

The collisional insertion of a ligand into a membrane by a protein can, in theory, be broken into two discrete steps: (1) binding of the protein-ligand complex to the acceptor membrane, and (2) insertion of the ligand into the bulk of the membrane. Our results do not rule out the possibility that ligand insertion occurs at different rates when the membrane structure is perturbed. However, the spontaneous rate of ligand movement from LUV donors to SUV or LUV acceptors suggests that NBD-Toc (as a model of α -tocopherol) inserts equally well into both membrane types. The presence of anionic lipids could enhance protein binding through electrostatic interactions between the protein and the phospholipid head group, or it might make ligand insertion easier if the anionic phospholipids have changed the packing density of the membrane. The present work cannot rule out packing density changes in the acceptor membrane, but the fact that each anionic

phospholipid supported near equal transfer rates whether they are present in SUVs or LUVs suggests that packing is not an important variable in rates of NBD-Toc transfer by α -TTP.

The only phospholipid composition that changed the rate of NBD-Toc transfer to vesicles by α -TTP were soy PC lipids. The higher degree of unsaturation in these plant lipid samples may provide a more receptive membrane environment for tocopherol as it is well-known that tocopherols prefer to partition into those phospholipid phases that are rich in polyunsaturated lipids [27].

In this report we have used only the wild type α -TTP to explore the variables that affect the rates of ligand movement from protein to membrane. The lack of effect of anionic phospholipids suggests that membrane recognition may rely more on hydrophobic forces, something that has been well interpreted by several comprehensive surveys [84–88]. We have now begun studies with mutant forms of α -TTP that perturb the putative hydrophobic face of the protein that is offered to membranes. We will soon report their ability to bind membranes and effect ligand transfer.

The α -TTP is selective for more highly curved membranes as observed by its fast transfer of NBD-Toc to small unilamellar vesicles of ~ 25 nm diameter versus vesicles of diameter larger than ~ 50 nm, but does not show any preference for anionic lipids when binding membranes. This preference for highly curved membranes may be linked to the localization of α -TTP to the late endosomes whose membranes are quite dynamic, and form small internal vesicles with the aid of the endosome-specific phospholipid LBPA. The degree of phospholipid unsaturation may also be a controlling feature for delivery of tocopherol to membranes since the plant-derived soy PC supported faster ligand transfer than did pure DOPC or bovine liver PC, both of which have a lower unsaturation content.

Acknowledgment We thank Richard and Raquel Epanand (Biochemistry, McMaster University) for the DSC measurements with NBD- α -tocopherol; Doug Keller and Yuguang Cui (Chemical Engineering, McMaster University) and Sigrid Kuebler (Wyatt Technology Corporation) for measurement of vesicle sizes. This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada to J.A. and, in part, by award DK067494 to D.M.

Abstract This study was designed to determine the nutritional lipid requirement of Manchurian trout and to investigate the effects of lipid concentrations on the antioxidant status in larvae with experimental diets with different lipid levels. Oxidative stress differences between different organs and tissues were also assessed. Manchurian trout larvae were fed for 35 days and, during that period, growth and survival, the activity of superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPX) and content of malondialdehyde (MDA) in viscera, muscle, gill and brain of four diets, lipid levels from 15 to 30%, and control treatment were measured. Growth rates were similar, but survival was low, between high and low dietary lipid levels. SOD activity was stimulated in viscera, muscle and brain in high lipid diets, but reduced in gills with increased lipid content. SOD was kept lower in the control group. GPX activity was inhibited in viscera and stimulated in gill, muscle and brain. CAT activities were enhanced by all treatments and showed the lowest values in the control. Lipid peroxidation of the diet was promoted in all organs, excluding the gill which showed no regular pattern. MDA content increased with increased dietary lipid levels in viscera, muscle and brain. Our results indicate that the most appropriate lipid requirement is probably 20–25% and a higher dietary level of lipids might induce oxidative stress in Manchurian trout larvae. The brain and

gill were probably the most sensitive organs to oxidative damage.

Keywords *Brachymystax lenok* · Lipid · Antioxidant enzyme · Stress · Larvae

Abbreviations

DLL	Dietary lipid level
SOD	Superoxide dismutase
CAT	Catalase
GPX	Glutathione peroxidase
MDA	Malondialdehyde
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid

Introduction

Reactive oxygen species (ROS) are free radicals and/or oxygen derivatives produced during normal cellular functions [1]. The biological handicap associated with oxidative stress could be estimated by a physicochemical condition in which an increase in the steady-state levels of oxidative species e.g. H_2O_2 , $HO\cdot$, O^{-2} , R^- and $ROO\cdot$ occurs [2]. At low concentrations, the ROS may be beneficial or even indispensable in processes such as defenses against microorganisms, contributing to phagocytic bactericidal activity. Cellular defense systems involving antioxidant enzymes; such as superoxide dismutase (SOD), glutathione peroxidase (GPX), catalase (CAT), and non-enzymatic scavengers—glutathione, vitamin A, and E—protect the organism against such oxyradical damages as DNA strand breaks, protein oxidation and the induction of lipid peroxidation [3]. An increase in the activated form of molecular oxygen

species due to overproduction and/or to inability to destroy them may lead to damage to the DNA structure and thus, cause mutations, chromosomal aberrations and carcinogenesis [4]. To counter the increase in superoxide radical levels, cells will increase activities of SOD and CAT. Free radicals may also stimulate cell growth by damaging specific genes that control the growth rate and differentiation during the promotion phase. In heavily polluted waters, an elevated activity of CAT and SOD among bivalves has been reported [5]. In the liver of the common carp, GPX activity is reduced under hypoxia and re-oxygenation, while CAT, SOD and Glutathione-S-transferase (GST) enzymes are unaffected [6].

In contrast, high doses and/or inadequate removal of ROS result in oxidative stress that may cause severe metabolic malfunctions and finally impair the health status of animal. Under a normal physiological state, the harmful effects of ROS are effectively neutralized by an antioxidant defense system which is an important mechanism to maintain the balance of ROS. As in higher vertebrates, fish also possess two major antioxidant defenses—the non-enzymatic system (vitamins and other molecules such as glutathione, etc.) and enzymatic system (SOD, CAT, GPX)—to protect the cells from damage by ROS. Most of the studies involving alteration of antioxidant defenses in aquatic animals have focused on stress induced by salinity changes, temperature fluctuations, hypoxia, aging, pollution of pesticide and heavy metal, etc. [7–11]. Only few have examined the influence of varying nutritional status on antioxidant enzymes in fish [12–14].

Little attention has been paid to evidence with regard to the influence of dietary lipids on the stress response [15, 16]; despite the facts that the production of prostaglandins is affected by dietary lipids and that prostaglandins may also play a role in stress hormone release [17, 18]. Dietary fatty acids can also influence the susceptibility of tissue lipids to peroxidative damage. Increasing dietary n-3 polyunsaturated fatty acids (PUFA) can elevate the unsaturation index of lipids in fish tissues and make them more prone to free radical attack [19]. High levels of dietary lipid and carbohydrate increase the growth and condition factor of an organism. However, high dietary fat also increases cholesterol concentration in blood plasma that, in turn, could influence the activity of the heart and other organs to weaken the physiological state and immune system [20, 21]. Nutrients misused, such as by high lipid intake, have been demonstrated to be harmful to animal health [22, 23]. Although high lipid diets had been fed to different species [24–27] and found to stimulate relevant metabolic enzymes [28, 29], the effect of antioxidant status in fish, especially in larvae is still unknown.

Being an endangered species in China, the population of Manchurian trout has declined in recent years [30, 31] and

has received increased attention through a program of artificial propagation for the purpose of restocking to a sustainable level since the 1990s. Few nutritional studies have been undertaken on this species.

This study attempted to establish a correlation between lipid nutrition and antioxidant stress of different organs in trout larvae, collating the data on physiological indicators and oxidative markers and evaluating possible effects on physiological status.

Materials and Methods

Fish and Diets

Brachymystax lenok (Pallas) larvae were propagated and maintained in an indoor water flow-through system at the BoHai experimental station of Heilongjiang Fishery Institute. Water temperature was regulated at $13 \pm 2^\circ\text{C}$ and the fish were fed a trial diet six times per day. At first, the larvae diet consisted exclusively of daphnia for 10 days. Then the larvae were divided into one control and four experimental groups (four tanks per group). The four groups were fed for 35 days with four formulated diets with an equal protein level (48%) with increasing fat levels (15, 20, 25, 30%) and decreasing carbohydrate levels (20–0%). The diets were designated as L15, L20, L25, and L30 (Table 1). The control groups were fed with daphnia and worm (*Branchiura sowerbyi* Beddard). In the added lipid, the soy lecithin/cod liver oil ratio was maintained at 0.8.

Diet formulation took into account the estimated requirements of salmonidae larvae in phospholipids and in the main highly unsaturated fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Table 2). Thiobarbituric acid reactive substances (TBARs) values were measured and diets should be under 0.3 mmol/kg as a standard. The size of the microparticulate diets was 125–200 μm during the first 5 days, then 200–400 μm . Fish were fed six times per day (6:00, 9:00, 12:00, 15:00, 18:00, 21:00) with excess. Food ingestion was monitored by observing the larvae digestive tract under a binocular microscope, as the dietary microparticles are visible in transparent tracts. Five hundred juvenile larvae were acclimated with diets for 3 days in each column. The prepared diets were kept in refrigerator until use.

Sample Collection

To monitor growth, ten larvae per tank each ($n = 4$ tanks for each dietary group) were taken in 10 days intervals. For this, water volume was lowered and ten larvae were collected at one time using an appropriate net at random. Before sampling, the larvae were starved for 24 h to

evacuate feces. These ten larvae were thus representative of the tank population. At the end of the experiment, larval survival rates were determined by counting individuals.

At days 0, 10, 20 and 30, 20 larvae were collected for enzymatic studies from each tank before morning food distribution; larvae were immediately stored at -80°C pending dissection and assays. Dissection under the microscope was conducted on a glass maintained at 0°C .

Individuals were cut into four parts: head, gill, viscera and trunk muscle, in order to limit the assay of enzymes to specific segments. This dissection of viscera produced a mixture of organs in each segment which containing liver, heart, intestine and pancreas.

All the segments were individually weighed and placed immediately in liquid nitrogen and stored at -80°C .

Tissues were homogenized into ten volumes (v/wt) in 0.25 M pH 7.4 sucrose buffer using a glass homogenizer for 1 min at 10,000 rpm/min and then centrifuged at 1,000g for 30 min in a Beckman centrifuge at 4°C , and the supernatant was used for biochemical analyses.

Enzyme Assay

SOD (EC 1.15.1.1) activity was determined immediately after centrifugation of the homogenates by measuring the inhibition of the auto-oxidation of pyrogallol using a modification of a published method [32]. Samples were assayed in a solution of 10 mL 50 mM phosphate buffer, pH 8.2, and 0.25 mL 20 mM pyrogallol (dissolved in 10 mM HCl). The rate of pyrogallol auto-oxidation was measured with a Shanghai UV-220 spectrophotometer at 325 nm. One unit of enzyme activity was defined as the amount of enzyme exhibiting 50% inhibition of the auto-oxidation rate of 0.1 mM pyrogallol in 1 mL solution at 25°C .

The assay of CAT (EC 1.11.1.6) followed that described by Abei [33] and involved monitoring the decrease in absorbance at 240 nm due to decomposition of 10 mM H₂O₂ (omitted for control) ($\epsilon = 0.0394 \text{ mmol L}^{-1} \text{ cm}^{-1}$). The reaction took place in 50 mM imidazole (pH 7.1 at 4°C).

GPX (EC 1.11.1.9) activity was measured following the method of Flohé and Günzler [34]. A freshly prepared glutathione reductase solution (2.4 U mL^{-1} in 0.1 M potassium phosphate buffer, pH 7.0) was added to a 50 mM potassium phosphate buffer (pH 7.0), 0.5 mM EDTA, 1 mM sodium azide, 0.15 mM NADPH and 0.15 mM H₂O₂. After the addition of 1 mM GSH (reduced glutathione), the NADPH consumption rate was monitored at 340 nm.

Protein was determined by the Bradford method [35] using bovine serum albumin as a standard.

Lipid Peroxidation

The MDA concentration, an index of lipid peroxidation, was measured following the method described by Esterbauer and Cheeseman [36] on homogenized tissues. The homogenized tissue (0.5 mL), previously treated with 25 μL of butylhydroxytoluene 1% v/v in glacial acetic, was mixed with 0.2 mL of sodium lauryl sulphate (8%), 1 mL

of acetic acid (20% v/v) and 1 mL of 0.8% thiobarbituric acid. This mixture was then heated at 95°C for 30 min. The resulting chromogen was extracted with 3 mL of *n*-butyl alcohol and, after centrifugation (1,500g for 10 min). The absorbance of the organic phase was determined at 532 nm. 1,1,3,3 tetramethoxypropane was used as a standard. Values were presented as $\mu\text{mol MDA/g tissue}$.

Statistical Analysis

For the comparison of various enzyme activities and lipid peroxidation products, one way ANOVA and LSD (used as a post hoc test) were performed by SPSS 10.1 (SPSS, Chicago). Differences were considered significant at $p = 0.05$ for all analyses. Values in the text are given as means \pm SD (standard deviation).

Results

Growth and Survival

Survival rate of L15, L20, L25, L30 and the control were as follows: 70, 75, 82, 64 and 80%. Final larval weights are shown in Fig. 1. Fish fed with control diet grew fast and steady. At day 10, fish fed with artificial diets exhibited lower weights than that with the control diet, but at 30th day, similar weights were obtained. Only L25 was heavier than that of control. Final survival rates changed greatly, 82% of L25 was the highest and similar as that of the control. The survival rate of L30 was the lowest at only 64%. Larval growth is similar with each other at different time interval, except at 10 day sampling, when the control group is better than those of other treatments, but there is no statistics difference. Due to acclimation to diets, larvae show less weight in the experiment groups than the control. Body weights (BW) of L30 at 20 and 30 day were similar as the control, but heavier than that of other three groups.

Fig. 1 Body weights at different time intervals

At 30 day, BW of L25 was the highest, but there were no significant difference with the others.

Antioxidant Enzyme

SOD

SOD activities of viscera and brain were maintained at 200–420 U/mg protein (Table 3; Fig. 2). The values in muscles were the lowest compared to other tissues. The highest activity was found in the gill.

In muscle, activities continued to increase steadily and the highest value achieved with L30. SOD activities were still low and steady in the control. But those larvae fed formulated diets showed an increase with time and L30 had the highest value. In the gill, the lowest activities were in the control, but there was no difference among those on different diets. The activities in brain remained steady among diets and showed a significant difference from that of the control.

CAT

The highest values were obtained in viscera compared with other tissues, but there was no consistency among organs (Table 3; Fig. 3).

In viscera, CAT activities of L30 exhibited higher value than other group, and declined with time, similar in this regard with L20 and L25 at the final experiment. The control group and L15 showed low activities from the beginning to the end (Fig. 3a).

CAT activities of muscle were the lowest among all tissues tested. L30 showed higher values compared with other treatments and increased with time. The highest value was determined at the end of experiment. The control groups were the lowest and showed significant differences to the others ($p < 0.05$) (Fig. 3b).

In gill and brain tissues, CAT activities of the control were lower compared to other treatments and showed significant differences ($p < 0.05$) except for the brain. Highest activities in gills were detected in L25 and showed significantly difference ($p < 0.05$) from the others. CAT in gill remained almost constant during the experiment and was higher than the other groups. CAT in gill of the control remained steady and that of L30 showed a decline. In brain, L30 showed the highest CAT values during the trial and appeared significantly different from the others (Fig. 3d).

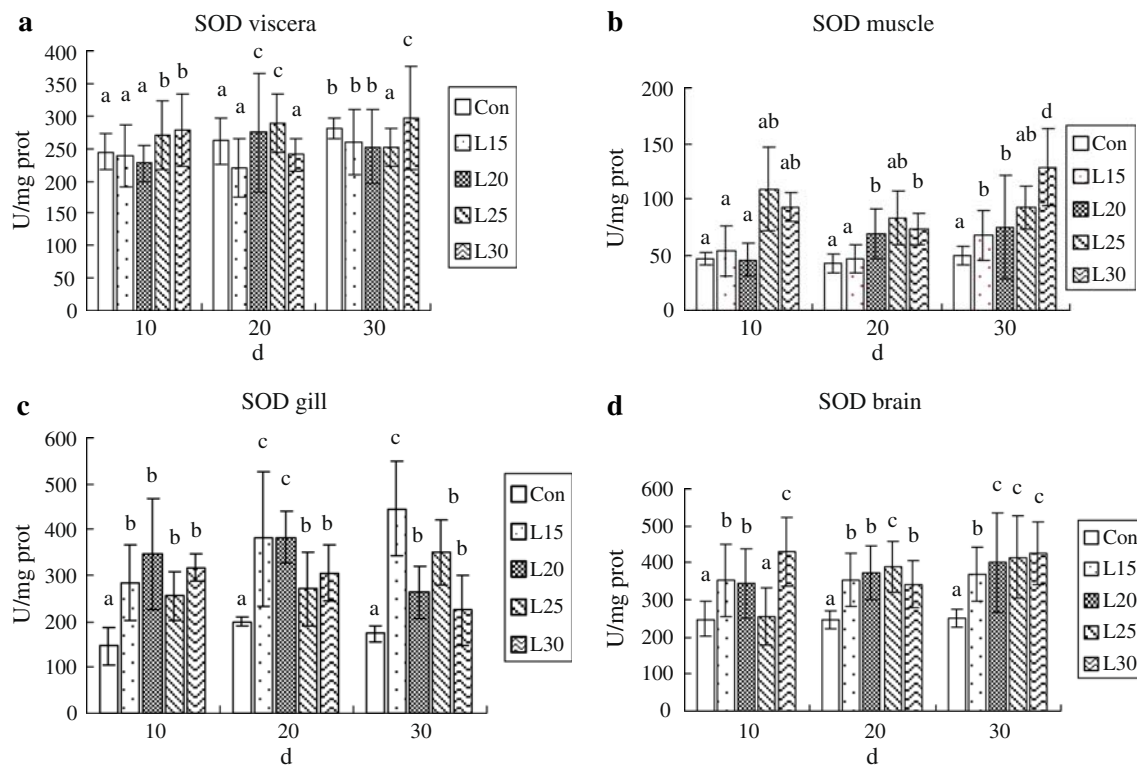

GPX

Activities of GPX in viscera showed higher values, compared with other tissues (Table 3; Fig. 4). GPX were significantly different among treatments and were lowered in

artificial diets. GPX in viscera of the L30 group was the highest and increased with dietary lipid levels, except the control.

In muscle, activities of moderate lipid diets showed higher than that of control and L30. Activities of L15 kept very steady from the start and was different to the others. The GPX of L30 declined and became the lowest at the end.

The values of gills were lower compared with those of the brain. There was no obvious tendency for treatment in gills except low activity of L15 in 10 days. GPX of L25 and L30 stayed at a higher level during the experiment in the gills. The GPX of the brain showed significant differences and decreased in the control. Activities of L30 remains at a high level and increased to the highest at 30 days. In the end, similar values were achieved except for

L25 and L30 and significant differences were found among treatments.

Lipid Peroxidation

MDA

The highest MDA contents were detected with an increase in dietary lipid level and time in viscera (Fig. 5a). Larvae with live food showed low values in tissues.

Compared with other treatments, the highest MDA content of viscera was found in L30 and showed a statistical difference ($p < 0.05$) to the others. The value of the control remained steady, under 0.8 nmol/mg protein, and significantly lower than experimental diets. The content of treatments from 0.8 to 1.2 $\mu\text{mol/mg}$ protein displayed no difference among treatments except for L30.

Values of artificial diets showed inclined pattern in muscle, but that of the control kept steady and maintained at low level. High values were found in low lipid diets, L15 and L20. Values of L15 increased sharply and were significant different with others. Content of L20 to L30 showed no difference and remained at a medium level.

There were significant differences among treatments and no tendency was found except for L30 in gill. From the start, the highest MDA content of L30 was observed and

higher than 0.4 nmol/mg protein, but no differences were found. Lower values obtained from L15 and significantly lower comparing with others.

MDA content in brain increased with time except that of the control. Results of L30 kept steady and significantly higher ($p < 0.05$). Values of the control remained constant. With increasing dietary lipid levels, high MDA production took place in the brain and maintained steady in L30.

Discussion

This study was to investigate relation between the dietary lipid requirements and the antioxidant status of fish larvae. The use of a compound diet as the only source is common in cold water fish, such as rainbow trout, and usually used to domesticate larvae. But there was no information on nutrition in Manchurian trout larvae, especially with regards to lipids. Indeed, larvae were carefully fed live prey, *Artemia* and crumbled worm at the developmental stage in previous feeding practices. A compound diet formulated to meet the specific nutritional requirements of fish larvae could replace live prey in larvae feeding and would lower the juvenile production costs and mortality in hatcheries. The lack of a compound diet available for the early larval stages explains the poor knowledge of larval nutritional requirements.

Lipids are very important for egg and larval development [24, 37, 38]. Research on lipid nutrition mainly focuses on the requirement of the total quantity and fatty acids, few studies have been conducted on physiological response of organs to dietary lipid levels, especially on antioxidant stress caused by poor diets in larvae [13, 14]. In sea bass (*Dicentrarchus labrax*) larvae, high DLL levels enhance digestive tract maturation and improve larval development [24].

In the experiment, the four diets were able to sustain some growth and survival in trout larvae. Final weight of L15 was the lowest. With dietary lipid concentration increasing from 15 to 30%, high growth gain was achieved. A maximal twofold increase was observed in the weight of fish larvae from day 10 to 30. With regard to the final body weight of experimental larvae, the highest weight of L25 showed that lipid contents can increase the growth rate and a high survival rate was achieved. It could be assumed that such a growth rate requires high energy diets, but DLL had a profoundly positive effect on Atlantic salmon growth and feed conversion, and gave fillets with nearly two times the fat content found in fish fed a low lipid diet [39].

In the same way, the increasing DLL positively affected the larval survival rate. The best survival rate in this study, 82% in the L25 group, was similar to that of the control, 80%. Survival rate increased with dietary lipid content and the lowest was 64% in L30, the highest lipid content group. Survival of control is 80% and only with L25 over 80%. These results indicated that the optimal lipid concentration in the diet for larvae might be 25%, higher than the 10–20%, generally adopted in other cold water species larvae diets (Fig. 6).

According to Panserat et al. [28] and Zambonino Infante and Cahu [24], high DLL could act on digestive physiology and to improve metabolism of nutrients. Our results indicated that appropriate DLL could alter growth and survival in trout larvae. Diet with 25% lipid might be appropriate to achieve better culture regime.

SOD is the first enzyme to respond to oxygen radicals [40] and is the one that offers the greatest response to oxidative stress [41]. Any situation that increases oxygen

consumption by the mitochondria proportionally increases the generation of O_2^- [42]. Experimental tests in animals demonstrate a correlation between SOD and tolerance to oxygen toxicity [43].

It is known that vertebrate liver exhibits a high metabolism and oxygen consumption, and it probably best represents the status of antioxidant defense in organisms, and therefore, it is frequently referred to in the literature [44]. Thus, the profile of SOD activities in tissues found in Manchurian trout larvae agreed with the literature in reference to the other fish [44–47].

In our study, the results were similar to rainbow trout [47] and SOD activity in muscle was the lowest compare with other tissues and indicated that fewer free radicals might take place. In muscle, lowest activities were found, which means lipid level cause less oxidative stress and whether lipid was accumulated is uncertain. In viscera, SOD showed significant difference and the control increased steady, but in L25 and L30, high values nearly always remained high and constant from the start to the end. The higher activities revealed that DLL played the key role in production of free radicals. Addition of fish oil in rat diet had been proved to alter the antioxidant status [48] and that might be helpful in explaining the results, which means that not only lipid level but fatty acids could alter fish antioxidant status, especially SOD.

The gills appear to be susceptible to oxidation, partly because of their defensive phagocytic activity [49] and partly for presenting fewer antioxidant resources in comparison with other tissues, such as liver [50]. In our results, SOD of artificial diets in gills showed higher values than that of the control. The high value indicated DLL might influence susceptibility in gills and induce responses to ROS to protect organ from damage.

Activities of SOD in brain showed different patterns unlike the organs mentioned above. Enzyme activities of larvae fed artificial diets were higher than that of the control. Rueda-Jasso et al. [51] found that juvenile Senegalese sole fed a high lipid diet had a different oxidation susceptibility. SOD activities increased with lipid level. Other experiments showed lipid levels and fatty acids influenced the species physiological status [22, 27, 52]. From our results, high SOD activities in the brain might be responses to free radicals derived from oxidation of lipids, but whether ROS could be removed completely is uncertain. Different fish with a different response to redox homeostasis might be helpful in explaining the harmful effects in larval development [53]. The response of SOD in the brain might indicate that neural system development could be influenced in Manchurian trout larvae in our experiment.

CAT is an enzyme present in nearly all animal and plant cells [54]. CAT combines rapidly with hydrogen peroxide to catalyze H_2O_2 , breakdown into oxygen and water. In

Fig. 6 Correlation between dietary lipid level and body weight

many cases, the enzyme is localized in subcellular organelles such as peroxisomes of the liver or in much smaller aggregates such as the microperoxisomes found in a variety of other cells. Chance et al. [54] documented that the physiological variation of CAT concentrations in different organs and tissues lead to different steady-state levels of hydrogen peroxide concentration for the same rate of hydrogen peroxide generation. Furthermore, CAT is uniquely fitted to provide a homeostasis for hydrogen peroxide concentrations in the cells [54].

CAT had been studied in many fish species with different situation [12, 55–57]. Tort et al. [55] reported that CAT activity in the livers of treated fish was not significantly different from the activity in control fish livers when hydrogen peroxide as a chemotherapeutant to treat walleye. However, CAT levels in the gills were significantly higher in the treated fish when compared to the control fish, indicating an induction of CAT activity in the gills of the fish treated with low concentration of hydrogen peroxide. Ozone and hyperoxic conditions increased SOD activity on red blood cell after exposure and CAT was only increase 10 min after exposure, suggesting other mechanisms rather than enzyme induction [56].

The increase of CAT in different tissues was obvious in L25 and L30 in our experiment. As in viscera and muscle, significant difference ($p < 0.05$) was found that might indicate antiperoxidative protection took place due to diets. As absorption and deposition of dietary lipid occurred mainly in viscera and muscle, high values were determined in L30 that might be indicator of oxidative reaction. Especially in brain, CAT of L30 maintained at high level indicated that brain was also a key organ influenced from start by DLL. Interestingly, among all groups, the control showed lower activity compared to the others. In *Solea senegalensis* larvae, Fernandez-Diaz et al. [16] found that larvae fed with both inert diets showed similar biomarker activities, but these activities were different ($p < 0.05$) from larvae fed with Artemia. SOD, CAT activities increased in inert diets and GPX showed a higher level in larvae fed with Artemia, but MDA did not markedly and was parallel with GPX. Varghese and Oommen [29] carried out a study that indicated that dietary lipids depress hepatic lipogenic activity in a teleost (*Anabas testudineus* Bloch) as well as lipid peroxidation products by maintaining high levels of antioxidant enzymes. All these demonstrated that dietary lipids in larvae might affected antioxidant enzymes and induced responses to artificial diet. In our experiment, DLL really induced an antioxidant response, especially in high lipid diets.

GPX catalyzes the reduction of H_2O_2 derived from oxidative metabolism as well as peroxides from oxidation of lipids and is considered the most effective enzyme against lipid peroxidation [41]. Its activity is considered

complementary to CAT activity, being especially suited for hydroperoxide detoxification at low substrate concentrations [43]. In our experiment, the determinations in viscera showed the highest levels, with similar values in other tissues (Fig. 3).

The increase of GPX activity observed in viscera is similar to the results reported by Li et al. [58], who studied the responses of the antioxidant systems in the hepatocytes of common carp (*Cyprinus carpio* L.) to microcystin-LR. Interestingly, THE GPX of the control in viscera remained at a high level during the experiment and that might be influenced by live prey's free radicals. An increasing tendency was found in muscle, especially significantly different was L30 with others. The increase in GPX activity probably reflects an adaptation to the oxidative conditions to which the fish had been exposed [59]. However, GPX activity increased in gills and brain after the longer exposure time, corroborating the ROS increase in this organ; this may be explained because gills and brain are less efficient than muscle and viscera at neutralizing the impact of peroxidative damage [50]. The fermented vegetable products (FVP)-fed fish showed a higher GPX activity of liver than the control fish which also demonstrated the influence of food on the tissues [57].

Estimation of lipid peroxidation in particular has been found to have high predictive importance as revealed by a credible number of research papers describing its use as a biomarker to great effect [60]. MDA is the main oxidation product of peroxidized PUFA and an increased MDA level is an important indicator of lipid peroxidation.

Similar to the Olsen et al. [61] and Rueda-Jasso et al. [51] results, MDA content in viscera and muscle increased with dietary lipid. The value of the controls was maintained at a low level and almost kept steady from start to finish in all groups, which might indicate that lipid from live prey could be assimilated well. Compared to the control fish, MDA in the viscera of fish fed supplemented diets achieved significant differences ($p < 0.05$).

In respiratory organs, a lower MDA concentration was determined than with other organs, which might be related to the excretion of the oxidative product and environmental stress [47, 49, 62, 63].

Studies on the addition of antioxidants to diets had been widely undertaken in animals [64, 65] and these may be beneficial to health. Our results showed that MDA in viscera and brain increased with dietary lipid levels and accumulated in the two organs with time. More peroxidative products produced meant that the protective mechanism could be operated to offset damaging effects caused by MDA.

However, it should be pointed out that more MDA is produced in the brain with higher dietary lipid level. In cold-temperature adaptive fish, high oxygen solubility and

a lipid diet might induce production of free radicals and stimulate the antioxidant defense mechanism [66]. The aging process might be related to DNA damage by oxidative stress in animals [67]. The accumulation of MDA in the brain with increased dietary lipid levels indicates that more oxidative stress might be induced and probably damage to the normal physiological function.

Lipids are an important energy store for larval metabolism [9, 11–13, 15, 26, 29] and play a role in digestive maturation [24, 25, 28]. In cultured fish, high dietary lipids may be utilized well and be beneficial to larval development and enhance survival [15, 16, 24–26, 28]. In our experimental diet, DLL increased and carbohydrate decreased. As a consequence, antioxidant enzyme activity showed variation in organs. With increased energy content in diets, high survival and growth were achieved, and the antioxidant status changed. As an energy resource, the lipid level might be more important than protein content in experimental treatments comparing with the control group (more than 80% protein in live organism, but a low lipid level, under 14%). For young animals, a high metabolism rate is a common phenomenon and more energy is needed to fuel development [42, 65], but fish species exhibited antioxidant differences to nutrients [16, 51] and few studies have focused in this area.

In recent studies, *Solea senegalensis* larvae fed on live and microencapsulated diets, these activities were different ($p < 0.05$) from larvae fed with *Artemia* [16]. That is, CAT and Hsp70 (stress protein) levels were lower in larvae fed with live prey and GPX and lipid peroxidation levels were lower in larvae fed with the inert food. Among the factors responsible for increased antioxidant defenses were the initiation of metamorphosis and the use of inert food. However, *Solea senegalensis* larvae in non-protein energy levels [51], lipid peroxidation was founded in fish with high lipid content diets and CAT, SOD activities were influenced by the type of dietary starch in the diet. These data suggest that lipid and carbohydrate energy sources affect the oxidative status of Senegalese sole. However, our results showed that decreased carbohydrate levels and increased lipid levels have been effective in regulating the antioxidant status in Manchurian larvae and improving growth.

In this study we have demonstrated that dietary lipid supplementation altered the antioxidant status in Manchurian trout larvae. Indices of oxidative stress directly measured in any organs indicated that the high DLL induced significant long-term oxidative stress due to antioxidant enzymes stimulated and peroxidative products increased, especially in brain and viscera, which were a key function in neuron regulation and the adsorption location. Our results demonstrated that trout larvae are susceptible to dietary components and these require appropriate lipid

contents. Moreover, if the high DLL did initially result in oxidative stress, then some organs adapted by increasing antioxidant defenses mechanism as demonstrated in this study. This may have been responsible for the protective effects against exogenous free radicals that are produced by absorbing and disposing them. Diet containing 20–25% lipid might meet larvae requirements and the antioxidant response would be moderate. The effects of fatty acids containing polyunsaturated bonds needs to be investigated in the future.

Acknowledgment The research was funded by Heilongjiang science and technology project, GC05B510, and national science supporting plan, 2006BAD03B08. The editorial help from Dr. Maynard Chen is appreciated.

Abstract The phospholipid fatty acid composition of the North-East Atlantic sponge *Polymastia penicillus* (South Brittany, France) was investigated. Sixty fatty acids (FA) were identified as methyl esters (FAME) and *N*-acyl pyrrolidides (NAP) by gas chromatography–mass spectrometry (GC/MS), including eight $\Delta 5,9$ unsaturated FA and three long-chain 2-hydroxylated FA. The major phospholipid FA were palmitic (14.3% of the total FA mixture), vaccenic (12.7%), 15(*Z*)-docosenoic (13.4%) and 5(*Z*),9(*Z*)-hexacosadienoic (13.3%) acids. In addition to the *iso*- and *anteiso*-branched saturated FA, several unusual short-chain branched saturated FA were identified. In addition to the known $\Delta 5,9$ FA, and interestingly regarding their identification by GC–MS as *N*-acyl pyrrolidides, was the co-occurrence of unusual FA possessing a $\Delta 3$, $\Delta 4$ and $\Delta 5$ double bond such as *iso*-4-pentadecenoic, *iso*-5-heptadecenoic, *anteiso*-5-heptadecenoic and two new compounds, not hitherto found in nature, namely 17-methyl-13-octadecenoic (0.8%) and 3,16-docosadienoic (1.1%) acids.

Keywords 3,16-Docosadienoic acid · Fatty acids · Phospholipids · *Polymastia* · Sponge ·

amu	Atomic mass unit
FA	Fatty acid(s)
FAME	Fatty acid methyl ester(s)
GC/MS	Gas chromatography–mass spectrometry
MS	Mass spectrum (spectra)
NAP	<i>N</i> -Acyl pyrrolidide(s)
NMI	Non-methylene-interrupted
TLC	Thin layer chromatography

Introduction

Marine sponges are primitive invertebrates with a remarkable ability to adapt to environmental changes. Thus, they have given rise to intensive investigations into the basic lipid components of their cell membranes since the pioneer studies [1, 2]. The phospholipid fatty acid composition is important for the functions of the cell membranes [3, 4]. In addition, sponge phospholipid classes have also been examined [3–5]. Moreover, sponges have proved to be a rich source of many unusual sterols and fatty acids (FA). Common polyunsaturated FA from the n-6 and n-3 series, such as eicosapentanoic acid EPA and docosahexaenoic acid DHA, are quite rare in sponge phospholipids, that instead usually contain very long-chain (C_{22} – C_{34}) non-methylene-interrupted (NMI) FA including the particular unsaturation pattern $\Delta 5,9$ [3, 4, 6–11].

Sponges from the genus *Polymastia* are known to contain secondary metabolites with biological activity but there have been, in comparison, few investigations of

their primary metabolites such as FA and sterols to date. Thus, organic extracts of *Polymastia janeirensis* demonstrated in vitro cytotoxicity against HT29 colorectal tumor cell lines [12]. *Polymastia croceus* has been farmed in order to produce quantities of bioactive compounds of medicinal interest [13, 14]. *Polymastia penicillus* is usually found in the North Atlantic in shallow waters and to depths of 600 m [15, 16]. The phospholipids of *P. gleneni*, collected around the Glenan Islands (South Brittany, France) were shown to contain a unique series of saturated 2-acetoxy long chain FA ranging from C₂₂ to C₃₀ chains [17].

As part of our ongoing investigations of sponge lipids [11, 18, 19], we present here the phospholipid FA composition of *P. penicillus* and the identification of several new and unusual Δ 3, Δ 4, Δ 5 and Δ 13 unsaturated FA.

Materials and Methods

Sponge Material

Samples of *Polymastia penicillus* were collected by hand (scuba) at a depth of 17 m, in the Etel River, Gulf of Morbihan, Brittany, France, in June 2005. Sponge identification was determined according to the recent classification [20, 21], and voucher specimens were deposited in the Marine Station of Endoume, Marseille, France. Like all Polymastiidae, this sponge is encrusting, hemispherical and cushion shaped, always with numerous papillae, but is characterized by the absence of a collagenous layer and by the absence of spicules in internal laminae, and spicules are tylostyles [15, 16].

Extraction, Isolation and Analysis of Phospholipids

The collected specimens were immediately transported to the laboratory for immediate lipid extraction. The sponges were washed in seawater, carefully cleaned, cut in small pieces and steeped twice in dichloromethane/methanol (1:1, v/v) for 24 h at room temperature. The combined extracts yielded the crude total lipids. Total lipid content (wt.%) was determined as the ratio total lipids versus sum of sponge dried residue plus total lipids. Total lipids were rapidly subjected to lipid class separation. Phospholipids were separated from other lipids by column chromatography on silica gel (70–230 mesh) successively eluted with dichloromethane (neutral lipids), acetone (glycolipids) and methanol (phospholipids) [10, 11]. The phospholipid classes were investigated by thin-layer chromatography on silica gel 60F₂₅₄ plates (0.2 mm thickness, SDS Carlo Erba, Val de Reuil, France) and dichloromethane/methanol

(70:30, v/v) was the eluent with phospholipid standards purchased from Sigma (Saint-Quentin Fallavier, France).

Preparation of Fatty Acid Methyl Esters and *N*-Acyl Pyrrolidides

Fatty acid methyl esters (FAME) were obtained by phospholipid transmethylation (40 min under reflux with 5% methanolic hydrogen chloride). *N*-Acyl pyrrolidide derivatives (NAP) were prepared by direct treatment of the FAME with pyrrolidine/acetic acid (10:1, v/v) for 2 h under reflux and purified by TLC on 0.5 mm silica gel layers using hexane/diethyl ether (1:2, v/v) [10, 22–26].

Fourier Transform Infrared Spectroscopy

Infrared spectra were recorded by means of a Bruker Vector-22 Fourier transform infrared spectrometer (Bruker Spectrospin, Karlsruhe, Germany) on liquid films between NaCl plates. Spectra were collected over the wavenumber range 4,000 to 600 cm⁻¹.

Gas Chromatography–Mass Spectrometry Analyses

Gas chromatography–mass spectrometry (GC/MS) coupling experiments were performed on a Hewlett-Packard HP-5890 chromatograph linked to a HP-5989-A mass spectrometer (70 eV) equipped with a HP-9000-345 integrator, and using a 30 m × 0.32 mm i.d. fused silica capillary column coated with HP-1 (0.25 μm phase thickness). The carrier gas was helium. The temperatures of injector and source were held at 240 °C, and the temperature of the GC–MS interface was held at 290 °C.

The column temperature was programmed for FAME and NAP from 180 to 310 °C at 3 °C/min. Equivalent chain length (ECL) were determined for FAME and for NAP in some cases since the observed ECL values have proved to be very similar for both derivatives except for highly branched FA [25].

Mass spectral data for the novel fatty acid structures are presented below.

Results and Discussion

Total lipids accounted for 5.3% of the dried sponge residues after extraction. Total phospholipids of *P. penicillus* accounted for 29.6% of the total lipids. As determined by thin layer chromatography, the most abundant phospholipids were phosphatidylserine, phosphatidylcholine and phosphatidylinositol, while phosphatidylethanolamine occurred at a significant level and phosphatidylglycerol was present at a lower amount. Acid methanolysis provided a complex phospholipid FA mixture. Sixty fatty acids (FA) were identified by gas chromatography–mass spectrometry (GC/MS) of their methyl esters (FAME) and *N*-acyl pyrrolidides (NAP) as shown in Table 1.

Many of the FA reported in Table 1 were identified by comparing their equivalent chain lengths (ECL) and their mass spectra (MS) with those of known standards. Unsaturated FA, mainly monoenes and dienes, accounted for almost 61% of the FA mixture. The Fourier transform infrared spectrum of the whole phospholipid FAME showed absorption at 3,004 cm⁻¹ (=C–H stretching), strong peaks at 2,923 and 2,852 cm⁻¹ (C–H stretching), 1,743 cm⁻¹ (C=O stretching, ester), significant peaks at 1,465 cm⁻¹ (CH₂ scissors deformation) and 720 cm⁻¹ (CH₂ rocking/C=C *cis*), and displayed no absorption in the region 940–980 cm⁻¹ (C=C–H out-of-plane), indicating the absence of (*E*)-unsaturation [27]. Thus, double bonds in major unsaturated phospholipid FA from *P. penicillus*, such as those at more than 1% have the (*Z*) configuration. It should be noted that the Δ^{5,9} FA have been generally reported to have the (*Z*) configuration [3, 4].

Five long-chain dimethylacetal derivatives occurred as minor compounds in the phospholipid FA mixture. All their MS displayed the fragmentation ion *m/z* 75 ([CH₃O)₂–CH]⁺ as the base peak, and a appreciable [M–MeO]⁺ ion [26, 28]. Unfortunately, complete identification

² Not previously found in nature

of these derivatives failed due to their very small amounts and that they were co-eluted with other compounds. It is known that they are obtained from particular phospholipids named plasmalogens (1-*O*-alk-1'-enyl-2-acyl-glycerophospholipids) of great biological interest, and were found in some sponges [29, 30]. Dimethylacetals are produced from fatty aldehydes, which are liberated from plasmalogen vinyl ether bonds on methanolic acid hydrolysis.

Saturated Fatty Acids

Twenty-five saturated FA of Table 1 were identified accounting for more than 32% of the total FA, including fourteen monobranched ones from C₁₄ to C₂₁ (almost 11%).

The highly branched phytanic acid present as trace was readily identified as methyl ester with an ECL value of 17.74 and diagnostic fragmentation ions including the molecular ion at *m/z* 326 and a base peak at *m/z* 101 (C-3 methyl branching), as previously described [25, 26]. It was the sole isoprenoid FA identified in the present mixture.

As usually, *iso*- and *anteiso*-branched FA were identified as FAME and NAP from their ECL values and their MS typical of saturated FA (*m/z* 74 base peak, McLafferty, *m/z* 87). The MS of their NAP displayed the corresponding molecular ion and a diminished peak for the ions [M-CH₃-CH₂]⁺ and [M-CH₃-2CH₂]⁺, respectively [10, 18, 19, 22, 24].

In addition to the *iso*- and *anteiso*-branched FA, seven various monomethyl-branched FA occurred in phospholipids of *P. penicillus*. Six of them with short-chains were

detected as FAME from their ECL values of 14.58, 15.52, 16.52, 16.56, 17.55 and 19.60, respectively, and from their MS that exhibited molecular ions at *m/z* 256, 270, 284 (two compounds) and 326, respectively. Thus, we dealt with branched pentadecanoic, hexadecanoic, heptadecanoic, eicosanoic acid structures. The MS of the 15:0 pyrrolidide showed a very low fragmentation ion at *m/z* 224 (C₁₀ fragment) and enhanced peaks at *m/z* 210 and 238 indicating a methyl branch at C-10 [10, 22, 24]. Thus, the unusual 10-methyltetradecanoic acid was identified. Another branched 17:0 acid was identified as FAME and as NAP. As FAME its MS showed the molecular ion at *m/z* 284 and an expected ion at *m/z* 227 of very low intensity, while the ions at *m/z* 213 and 241 were highly enhanced (methyl branch at C-13) [24, 29]. The branched 17:0 acid was then identified (FAME) as 13-methylhexadecanoic acid and this structure was confirmed by the MS of the NAP which showed a molecular ion at *m/z* 323. The expected ion *m/z* 266 was lacking, while the ions at *m/z* 252 and *m/z* 280 were highly enhanced (methyl branching at C-13). Mass spectra of NAP of 13-methyl- and 15-methyl-branched saturated FA were shown in a recent report [29]. The quite unusual 12-methylpentadecanoic, 14-methylheptadecanoic and 15-methylnonadecanoic acids were characterized as methyl esters since their MS showed the molecular ions at *m/z* 270, 298 and 326 (16:0, 18:0 and 20:0 structures) [24, 29]. Among these FA, the branched 20:0 acid (FAME) was identified as 15-methylnonadecanoic acid since the expected ion at *m/z* 255 was lacking, while the ions at *m/z* 241 and 269 were present (methyl branch at C-14) [22, 29].

Iso- and *anteiso* FA are typical for the occurrence of bacteria and the other monomethyl-branched short-chain FA probably have the same origin [31–34], although one of the most frequent bacterial phospholipids, namely phosphatidylglycerol, accounted here for a relatively low percentage [3, 4]. Branched-chain FA (*iso* and *anteiso*) are characteristic for gram-positive bacteria [34]. The 13-methylhexadecanoic acid was described in previous reports [22, 29]. Branched saturated FA (C₁₅–C₁₉) have been used as biomarkers for bacteria including anaerobic bacteria and the sulfate-reducing bacteria [33–37]. The 10-methyl-14:0, 10-methyl-15:0 and 10-methyl-16:0 acids were found in bacteria [33–35], and it was assumed that methyl branching on the tenth carbon atom in the acyl chain seems specific for actinomycetes [33, 38]. The 10-methylhexadecanoic acid was observed in a *Cinachyrella* sponge [10] and in a pioneering report on the sponge *Aplysina fistularis* [4]. The occurrence of bacteria in sponges has already been evidenced and studied in several reports [39, 40].

Fig. 1 Mass spectra of methyl ester (a) and pyrrolidide derivative (b) of 17-methyl-13 octadecenoic acid from *Polymastia penicillus*

2-Hydroxylated Fatty Acids

Three 2-hydroxylated FA (7.0% of FA mixture; C₂₄, C₂₅ and C₂₆) were readily identified by GC/MS as FAME since their MS displayed diagnostic fragmentation ions at *m/z* 90 (McLafferty) and 103, and the corresponding molecular ions at *m/z* 398, 412 and 426, respectively. Diagnostic ions of 2-hydroxy acids have been described in previous reports such as those on series of 2-hydroxylated FA found in two sponges of the family Suberitidae [29] and in two Caribbean sponges [31]. The M⁺ and *m/z* 90 and 103 ions were accompanied by the corresponding related ions [M–MeOH]⁺ at *m/z* 366, *m/z* 380 and *m/z* 394, respectively, and [M–COOMe]⁺ at *m/z* 339, *m/z* 353 and *m/z* 367, respectively. Mass spectra of NAP derivatives showed the corresponding molecular ions and the major ions at *m/z* 129 (McLafferty, base peak), *m/z* 113, *m/z* 100 and *m/z* 98, thus confirming the hydroxylated structures.

Monounsaturated Fatty Acids

Twenty-one monounsaturated FA listed in Table 1 were identified, accounting for more than 41% of the total FA, including four *iso*- and *anteiso*-branched FA. Three unusual short-chain monoenoic acids were readily identified in phospholipids of *P. penicillus*.

A short-chain acid was readily identified as a branched pentadecenoic acid (0.4%; ECL 14.28) since its NAP displayed a molecular ion at *m/z* 293 (15:1), and major fragment ions at *m/z* 126 and *m/z* 152, a peak at *m/z* 138 of low intensity, a very intense peak at *m/z* 166 (almost 70% of the base peak *m/z* 113; Δ4), and lacking the expected *m/z* 264, the ions at *m/z* 250 and *m/z* 278 being enhanced. Thus, we identified the *iso*-4-pentadecenoic acid, which was early observed in phospholipids from *Suberites massa* [29]. In addition, some examples of MS of NAP of Δ4 FA are shown in Christie's homepage "www.lipidlibrary.co.uk"

Fig. 2 Mass spectra of methyl ester (a) and pyrrolidide derivative (b) of 3,16-docosadienoic acid from *Polymastia penicillus*

[23, 24, 26]. Another $\Delta 4$ monounsaturated FA occurred in the freshwater sponge *Baicalospongia bacilifera*, namely *iso*-4-octadecenoic acid [41]. The latter sponge also contained $\Delta 5$ FA as shown with the use of the iodolactonization method [41].

Two closely related FA were identified as monounsaturated and monomethyl-branched FA since their MS showed a molecular ion (as FAME) at m/z 282, and that their ECL values were 16.28 and 16.40. Mass spectra of their NAP showed the expected molecular ion at m/z 321 and a gap of 12 amu between an appreciable m/z 140 and 152, while the ion at m/z 166 was enhanced, indicative of $\Delta 5$ unsaturation. The first br-17:1 acid was identified as 15-methylhexadecenoic (*iso*-17:1) acid because of the low relative intensity of the fragment ion at m/z 294 (C_{15}), while the ions at m/z 278 (C_{14}) and 306 (C_{16} ; M- CH_3) were enhanced. The second br-17:1 acid was identified as

14-methylhexadecenoic (*anteiso*-17:1) acid due to the low relative intensity of the fragment ion at m/z 278 (C_{14}), while the ions at m/z 264 (C_{13}) and 292 (C_{15}) were enhanced. Thus, we characterized two not-so-common FA, namely 15-methyl-5-hexadecenoic and 14-methyl-5-hexadecenoic acids. These *iso* and *anteiso* monounsaturated $\Delta 4$ or $\Delta 5$ FA probably originated from associated bacteria. Present at low growth temperatures in bacteria from the genera *Bacillus*, *Brevibacter* and *Streptomyces*, the *iso*- $\Delta 5$ -hexadecenoic, *anteiso*- $\Delta 5$ -pentadecenoic and *anteiso*- $\Delta 5$ -heptadecenoic acids were identified as methyl esters [42].

Another branched monoenoic FA was detected by GC-MS as FAME and characterized as NAP (Fig. 1).

This acid (FAME) showed a molecular ion at m/z 310, and a (M- CH_3O)⁺ at m/z 279, corresponding to a 19:1 acid structure, and an ECL value of 18.21, implying methyl branching (Fig. 1a). The usual peaks for FA methyl esters

at m/z 74 and m/z 87 were present as minor fragment ions. Other abundant fragments were not relevant for the characterization of structure. The molecular ion peak of the corresponding NAP was present at m/z 349 confirming the 19:1 structure (Fig. 1b). The gap of 12 amu between homologous fragment ions at m/z 252 (C_{12}) and m/z 264 (C_{13}) indicated $\Delta 13$ unsaturation. A diminished peak at m/z 320 (C_{17}) flanked by an elevated peak at m/z 306 (C_{16}), and an appreciable peak at m/z 334 (C_{18}), indicated a methyl branch at C-17. Thus, we identified the new 17-methyl-13-octadecenoic acid, which to our knowledge, has not been reported from any natural source.

Diunsaturated Fatty Acids

Ten dienoic FA were identified accounting for about 19% and including the 9,12-octadecadienoic acid (0.8%), a series of eight FA possessing the 5,9-unsaturation pattern common in sponges, and two other interesting NMI FA.

The FA with the 5(*Z*),9(*Z*)-unsaturation, ranged from C_{18} to C_{27} , were readily characterized by GC–MS. Mass spectra of all their methyl esters displayed the corresponding molecular ion and the ion at m/z 81 (base peak), while spectra of their NAP displayed a significant ion at m/z 180 arising from the activated double allylic cleavage. Mass spectra of both derivatives showed corresponding molecular ions. They had been already found in sponges [4, 6–11, 18, 19, 26, 29, 31, 32]. It is now well known that lipids of most sponge species contain various $\Delta 5$ olefinic FA mainly including $\Delta 5,9$ FA. Interestingly, $\Delta 5,9$ FA displayed antiprotozoal activity, antitumor activity, and topoisomerase I inhibitory activity [43, 44]. Only one triunsaturated FA occurred as a minor component in the FA mixture and was identified as 5,9,*x*-pentacosatrienoic acid since its methyl ester (ECL of 24.20) showed the molecular ion at m/z 390 and the base peak at m/z 81.

A first additional NMI FA (0.3%) had an ECL value of 19.60 as methyl ester and a molecular ion at m/z 322 indicative of a 20:2 acid structure. The MS of the NAP showed a molecular ion at m/z 361 (20:2 acid structure). The two double bonds were located by the 12 amu differences between the peaks at m/z 224 (C_{10}) and m/z 236 (C_{11}), indicating of $\Delta 11$ unsaturation, and between the peaks at m/z 278 (C_{14}) and m/z 290 (C_{15}), indicating $\Delta 15$ unsaturation. Thus, we dealt with the rare 11,15-eicosadienoic acid, which was firstly reported from the sponge *Amphimedon complanata* [45] and observed in *Stylissa carteri* [19]. This FA has been considered as a biosynthetic intermediate of the unusual dienoic FA 17,21-hexacosadienoic and 19,23-octacosadienoic acids [10].

The second interesting dienoic NMI FA (1.1%) as a methyl ester had an ECL value of 21.55 and a molecular ion at m/z 350, and elevated ions at m/z 319 ($[M-74]^+$) and

m/z 276 ($[M-31]^+$), indicative of a 22:2 acid structure (Fig. 2a).

The usual peaks for FA methyl esters at m/z 74 and m/z 87 were present as minor fragment ions. The relatively abundant ions at m/z 304 (C_{16}), m/z 290 (C_{15}), and m/z 276 (C_{14}) confirmed a 22:2 FA structure. The MS of the NAP showed a molecular ion at m/z 389 (22:2 structure) (Fig. 2b). A first double bond was readily located by the 12 amu gap between the peaks at m/z 292 (C_{15}) and m/z 304 (C_{16}), indicating of $\Delta 16$ unsaturation. The second double bond was located with the sequence of m/z 113 (base peak), m/z 126, m/z 139, m/z 152 (the second-most prominent ion at more than 60% of the relative intensity) and m/z 166, indicating a $\Delta 3$ unsaturation according to Andersson [23, 24]. It should be noted that the ion at m/z 152 was the second-most prominent ion in the MS of the NAP of the novel 3(*Z*),9(*Z*),12(*Z*)-octadecatrienoic acid that also exhibited the two appreciable m/z 126 and m/z 139 [26, 46]. Also available on the Christie's homepage, MS of the NAP of the 3(*E*),9(*Z*)-octadecadienoic acid allows another useful comparison [26]. Indeed, the m/z 152 ion is also the second-most prominent ion but there is a prominent ion at m/z 124 suggesting a probable isomerization to 2,9-18:2 during the derivatization step. Thus, MS of the NAP of 2,6-18:2 shows intense ions at m/z 124 without the m/z 126, and at m/z 139 (base peak) [26]. In addition, MS of 2-16:1 and 2-18:1 show similar features with a major ion at m/z 152, a prominent ion at m/z 124 and a minor ion at m/z 126 [26].

In the MS of the 22:2 (NAP), from *P. penicillus*, the ion at m/z 126 is intense in accordance with a $\Delta 3$ double bond. Nevertheless, the presence of the ion at m/z 124 with a lower intensity than the ion at m/z 126 in the SM depicted in Fig. 2 suggested a possible partial isomerization $\Delta 3$ to $\Delta 2$ [26]. Thus, we identified the new 3,16-docosadienoic acid, which to our knowledge, has not been reported from any natural source.

In summary, phospholipids from the sponge *P. penicillus* contained a lot of monomethyl-branched monoenoic FA, several $\Delta 5,9$ FA, and two novel FA, namely 17-methyl-13-octadecenoic and 3,16-docosadienoic.

Acknowledgments We express our thanks to scientists from the MMS research group (EA 2160, University of Nantes), Prof. Jean-François Biard and Dr. Karina E. Petit, for their help in collecting specimens of *P. penicillus*, and Mr. Denis Loquet for his help for additional GC/MS measurements. Mrs. Maryvonne Luçon, Faculty of Sciences and Techniques of Nantes, Department of Chemistry, is greatly acknowledged for FTIR measurements.

Abstract The present study demonstrated here for the first time that there are statistically significant differences in sterol composition between male and female gonads of the dominant limpets *Cellana grata* and *Cellana toreuma*, which are intertidal gastropods. Among 11 different sterols identified in this study, unusually high levels (11.2–19.8% of total sterols) of the Δ^8 -sterols 5 α -cholest-8-en-3 β -ol (zymostenol) and 5 α -cholesta-8,24-dien-3 β -ol (zymosterol), which have never been reported in aquatic invertebrate gonads, were present in only the male gonads.

Introduction

Our previous studies of male and female gonads of the dominant limpet species of intertidal gastropods are characterized by significant differences in their proportions of 16:0, 20:4n-6, and 20:5n-3 fatty acids and their composition of unusual nonmethylene-interrupted fatty acids, which differ widely in chain length and unsaturation [1, 2]. Furthermore, the female limpet gonads of *Cellana grata* had a wide range of unusual fatty acid isomers, including di-, tri-, tetra-, and pentaenoic fatty acids with a 5,9-double bond system in the triacylglycerols as one of the most usually abundant lipid classes [3, 4]. The previously observed sex-based differences in limpet gonad fatty acids stimulated us to characterize the sterols of these and other organs in limpets, although sterol composition has been reported from only whole bodies of the limpets *Lepetodrilus* spp. and *Patella vulgata* [5, 6]. Therefore, we characterized the occurrence and distribution of sterols in two representative dominant limpet species, *C. grata* and *C. toreuma*, which are widely distributed in northern Japan, using capillary GC and GC–MS, and further determined whether a sexual difference exists in the limpet gonads.

Experimental Procedures

Reagents

Most chemicals, cholesterol, desmosterol, and lathosterol were purchased from Sigma-Aldrich (St. Louis, MO, USA). Brassicasterol, 24-methylcholesterol, and sitosterol were kindly provided by Mr. K. Omata (Tama Biochemical Co. Ltd., Tokyo, Japan). Cholestanol, 24-methylenecholesterol,

and isofucosterol were prepared from the marine bivalve *Megangulus zyoensis* [7].

Sampling

The dominant limpets of the genus *Cellana*, *C. grata* and *C. toreuma*, were collected on intertidal rocky shores between June and August 2007. Specimens of *C. toreuma* ranging from 37.7 ± 0.6 ($n = 54$) mm in shell length and *C. grata* ranging from 39.2 ± 5.2 ($n = 54$) mm were collected from the coastal waters of Otsuchi and Funakoshi Bays, Iwate Prefecture, northern Japan.

Extraction of Lipids from Limpets

After collection, all limpets were immediately dissected in the laboratory. The gonads were distinguished as female or male by microscopic examination. The muscle, viscera, and gonads of males and females of each dominant limpet ($n = 54$) were dissected and separated. Each of group of muscles, viscera, or gonads (each of three pooled samples) was suspended in chloroform–methanol (2:1, v/v) and then homogenized for 1 min at 11,000 rpm by using an IKA Ultra Turrax[®] T25 Basic homogenizer (IKA Japan KK, Nara, Japan). Lipids were extracted by the method of Bligh and Dyer [8]. The different lipid classes were analyzed by thin-layer chromatography on silica gel 60 G plates (Merck, Darmstadt, Germany) as described previously [4, 9].

Preparation of Trimethylsilyl (TMS) Derivatives

Each sample of total lipids (2–5 mg) was saponified with 1.5 mL of 1.6 M KOH in 73% ethanol (v/v) at 90 °C for 1 h. After addition of 0.5 mL distilled water, the nonsaponifiables were extracted twice with 1.5 mL diethyl ether. The organic solvents were combined, dried over anhydrous sodium sulfate, filtered, and evaporated to dryness under a gentle stream of nitrogen at room temperature. The residue was converted to TMS derivatives of sterols by treatment with 0.3 mL of Sylon BFT, *N,O-bis* (trimethylsilyl) trifluoroacetamide containing 1% trimethylchlorosilane (v/v) (Supelco Inc., Bellefonte, PA, USA) at 80 °C for 1 h. The reaction mixture was evaporated under a gentle stream of nitrogen at 40 °C, and the derivatives were redissolved in 0.1 mL of *n*-hexane.

GC and GC–MS Analyses

The TMS derivatives of sterols were analyzed by GC using a Shimadzu GC-1700 chromatograph (Shimadzu Seisakusho Co., Kyoto, Japan) equipped with a flame ionization detector and an SACTM-5 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco Inc.). The injector and

detector temperatures were maintained at 290 °C, while the column temperature was isothermal at 270 °C for 30 min. The carrier gas was helium at a flow rate of 1.0 mL/min, and the injection split ratio was 1:36. GC–MS analyses of the TMS derivatives of sterols were performed in an electron impact mode at 70 eV with a scanning range 50–550 *m/z* using a Shimadzu GC-MS-QP2010 mass spectrometer (Shimadzu Seisakusho Co.) equipped with the same column used for in GC analysis. The column and injection temperatures were isothermal at 270 °C for 30 min, and the injection split ratio was 1:25. The carrier gas was helium at a flow rate of 1.0 mL/min, and pressure programming was used in a constant flow mode. Sterols were identified by comparison of their relative retention times, MS analysis of their free forms and TMS derivatives, published mass spectral data [10–12], and the Wiley Mass Spectral Library database (7th edition). All chromatographic analyses were performed within 48 h of sample preparation.

Statistical Analysis

The procedures were repeated three times for three different sets of pooled male or female muscle, viscera, and gonads. Data are expressed as means ± SD. Statistical comparisons between sterols of male and female limpets were made using Student's *t*-test. A value of $P < 0.05$ was considered significant.

Results and Discussion

Of 11 different sterols identified in this study, the two Δ^8 -sterols 5α -cholest-8-en- 3β -ol (zymostenol) and 5α -cholesta-8,24-dien- 3β -ol (zymosterol), which have never been reported in aquatic invertebrate gonads, were found to be the major sterol components (Fig. 1). The prominent and characteristic molecular ions were *m/z* 458 for zymostenol ($[M]^+$) and *m/z* 456 for zymosterol ($[M]^+$), but neither of these sterols gave the cleavage of the fragment ion *m/z* 129 due to the presence of a Δ^5 double bond in the B-ring structure of seven sterols (Δ^5 -sterols) identified in this study [7]. Although the mass spectra of lathosterol and zymostenol are rather similar, the intensity of the fragment ion *m/z* 255 ($[M-TMSOH\text{-side chain}]^+$) of lathosterol was about three times as much as that of zymostenol, and their relative retention times to cholesterol were markedly different (Fig. 1). These results are in accord with published studies [10, 11].

Although no statistically significant difference in sterol composition was found between male and female muscles or male and female viscera in either of the dominant limpets *C. grata* and *C. toreuma*, there were statistically significant

Fig. 1 Total ion current chromatogram of the TMS derivatives of sterols in male limpet gonads of *C. grata*. The chromatogram was obtained on an SACTM-5 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness) at 270 °C

differences between the levels of cholesterol and total Δ^5 -sterols in the male and female gonads of these limpets. In addition, there was also a statistically significant difference between the level of desmosterol in the male and female gonads in *C. toreuma*. In this study cholesterol was consistently the most abundant sterol in muscle, viscera, and gonad tissues, followed by desmosterol. However, high levels of zymostenol and zymosterol were present in only the male gonads of *C. grata* and *C. toreuma*, respectively, as shown in Table 1. The major sterols in the male limpet gonads of *C. grata* were cholesterol, desmosterol, and zymostenol, which were present at levels of 56.8, 15.3, and 15.0%, respectively, of total sterols. In contrast, the concentration of zymosterol as a major sterol, accounting for 9.0% of total sterols, in the male gonads of *C. toreuma* was nearly twice as high as that in *C. grata*, while that of zymostenol in the male gonads of *C. grata* was about eight times higher than in *C. toreuma*. The total sterol composition of whole bodies of *Patella vulgata* and *Lepetodrilus* spp. has been reported to contain the cholesterol levels of 79 and 90%, respectively. Although lathosterol was not found in *P. vulgata*, fucosterol and desmosterol accounted for 11 and 9%, respectively, of total sterols [5, 6]. In contrast, both desmosterol and lathosterol in *Lepetodrilus* spp. were less than 3% of total sterols, and fucosterol was not detected. In this study, a variety of unusual sterol components, including zymosterol and lathosterol, together with large amounts of cholesterol, desmosterol, and zymostenol, and other minor sterols, were found in the male gonads of *C. grata*, as compared with those of *C. toreuma*.

Interestingly, among the previously identified biologically active Δ^8 -sterols, zymosterol has also been reported to activate meiosis, which induced the maturation of rat oocytes and improved the formation of two-cell-preembryos in an in vitro maturation and fertilization mouse model [12–14],

although it has mainly been recognized as an important intermediate in ergosterol synthesis in both yeasts and fungi [15–18] and in cholesterol synthesis in mammalian cells [11, 19, 20]. However, the physiological function of zymostenol remains unclear. Cultures of human breast cancer cells, such as MCF-7 and MDA-MB-231, in the presence of tamoxifen, a selective estrogen-receptor modulator widely used for breast cancer treatment, or *N*-pyrrolidino-2-[4-(benzyl)-phenoxy]-ethanamine, a selective antiestrogen binding-site ligand that inhibits the growth of tumor cell lines in vitro and in vivo, produced massive accumulations of zymostenol as the most abundant sterol, together with minor amounts of zymosterol, desmosterol, and several other sterols [19]. This result suggests that the 3β -hydroxysterol- Δ^8 - Δ^7 -isomerase and 3β -hydroxysterol- Δ^7 -reductase involved in cholesterol biosynthesis were inhibited by these drugs [19]. In contrast, high levels of zymostenol (18% of total sterols) have been reported in cultures of a soil bacterium *Nannocystis exedens* Na e1 without any enzyme inhibitor [21], but both the major sterol components zymostenol and/or zymosterol and other sterols are most commonly present in *Nannocystis* strains that produce sterols [22].

Less is known about the biosynthesis of sterols by limpets than by marine bivalves [23–26]. The limpet *P. vulgata* is able to biosynthesize cholesterol *de novo* as well as produce cholesterol from phytosterols by a C-24 dealkylation process [6]. The results suggest that limpet gonads may be able to biosynthesize not only cholesterol but also the cholesterol precursors zymostenol and zymosterol detected in this study. Both the precursors may be biosynthesized by male limpet gonads rather than originating in their diets because these sterols were not detected in either muscle or viscera tissues of limpets. Although Δ^8 -sterols are converted into Δ^7 -sterols by 3β -hydroxysterol- Δ^8 - Δ^7 -isomerase, which is an essential enzyme on the sterol biosynthesis pathway in eukaryotes [16,

19, 27–31], and previous studies have provided evidence that this enzyme regulates the overall rate of cholesterol biosynthesis [31], the biosynthesis of both zymostenol and zymosterol by limpets is not well understood. Therefore, experimentation with inhibitors of 3β -hydroxysterol- Δ^8 - Δ^7 -isomerase and elucidation of the regulatory mechanism of related enzymes responsible for the accumulation of Δ^8 -sterols in limpets are necessary. The findings of this study may have important implications for clarification of the physiological roles and functions of unusual cholesterol precursors occurring in marine mollusk gonads rather than yeasts, fungi, and mammalian cells.

Acknowledgments This study was done as a cooperative research program (No. 104) with the International Coastal Research Center, Ocean Research Institute, The University of Tokyo.

Abstract The SREBP-2 transcription factor is mainly activated by low cellular cholesterol levels. However, other factors may also cause SREBP-2 activation. We have previously demonstrated activation of SREBP-2 by the polyunsaturated fatty acid docosahexaenoic acid (DHA) in SW620 colon cancer cells. Despite activation of SREBP-2, only a few target genes were induced and cholesterol biosynthesis was reduced. In the present study, gene expression analysis at early time points verified the previously observed SREBP-2 target gene expression pattern. Activation of SREBP-2 using siRNAs targeting Niemann Pick C1 protein (NPC1) led to increased expression of all SREBP target genes examined, indicating that activation of some SREBP-2 target genes is inhibited during DHA-treatment. Cholesterol supplementation during DHA treatment did not abolish SREBP-2 activation. We also demonstrate that activation of SREBP-2 is independent of ER stress and eIF2 α phosphorylation, which we have previously observed in DHA-treated cells. Thapsigargin-induced ER stress repressed expression of SREBP-2 target

genes, but with a different pattern than observed in DHA-treated cells. Moreover, oleic acid (OA) treatment, which does not induce ER stress in SW620 cells, led to activation of SREBP-2 and induced a target gene expression pattern similar to that of DHA-treated cells. These results indicate that DHA and OA may activate SREBP-2 and inhibit activation of SREBP-2 target genes through a mechanism independent of cholesterol level and ER stress.

Keywords SREBP-2 · Cholesterol biosynthesis · ER stress · Transcriptional regulation · eIF2 α

Abbreviations

ATF6	Activating transcription factor 6
DHA	Docosahexaenoic acid
DnaJA4	DnaJ (Hsp 40) homolog-subfamily A-member 4
ER	Endoplasmic reticulum
eIF2 α	Eukaryote translation initiation factor 2 alpha
FA	Fatty acid
FDFT	Farnesyl diphosphate farnesyltransferase
HMGCR	3-Hydroxy-3-methylglutaryl-coenzyme A reductase
IDI	Isopentenyl-diphosphate delta isomerase
Insig	Insulin induced gene
LDLR	Low density lipoprotein receptor
NPC1	Niemann Pick C1
OA	Oleic acid
PUFA	Polyunsaturated fatty acid
SCAP	SREBP cleavage activating protein
siRNA	Small interfering RNA
SRE	Sterol regulatory element
SREBP	SRE binding protein
mSREBP	Mature SREBP

Introduction

The sterol regulatory element binding proteins (SREBPs) are transcription factors regulating fatty acid (FA) and cholesterol synthesis. Three family members have been identified to date; SREBP-1a, SREBP-1c and SREBP-2. SREBP-1a and SREBP-1c are transcribed from the same gene using alternate promoters, while SREBP-2 is transcribed from a separate gene [1]. The SREBP-2 and SREBP-1c isoforms are expressed in liver and most other tissues, while in cultured cells SREBP-2 and SREBP-1a are the most dominant isoforms [2]. SREBP-1c mainly regulates genes involved in FA biosynthesis, while SREBP-2 activates genes involved in cholesterol biosynthesis [3]. SREBP-1a, which has a longer transcription activating domain than the SREBP-1c isoform, is able to induce expression of genes involved in both FA and cholesterol biosynthesis [1, 4].

The SREBP transcription factors are synthesized as inactive precursor proteins localized in the endoplasmic reticulum (ER) membrane [5]. The SREBP precursor protein forms a complex with another ER-localized protein, the SREBP cleavage activating protein (SCAP), which contains a cholesterol sensing domain [6]. Binding of cholesterol when ER cholesterol levels are high induces a conformational change in SCAP. This enables binding of the SCAP-SREBP complex to another ER resident protein; insulin-induced gene 1 (Insig1), which retains the SCAP-SREBP complex in the ER [7, 8]. When cells are depleted of sterols, SCAP dissociates from Insig-1, and the SCAP-SREBP complex is translocated to the Golgi where the SREBP precursor is cleaved by two proteases; site-1 protease (S1P) and site-2 protease (S2P) [5]. This releases the N-terminal fraction of the protein, termed mature SREBP (mSREBP), which contains the transcription factor domain. The active transcription factor is translocated to the nucleus where it induces expression of target genes, including the SREBP transcription factors themselves [3, 5]. SREBP target genes contain a sterol regulatory element (SRE) sequence or modified forms of this sequence in their promoters, while SREBP-1c target genes mainly contain E-boxes or E-box like sequences [9, 10]. The SREBP transcription factors have weak transcriptional domains, and require co-factors like NF-Y or Sp1 to activate target genes [9, 11].

In addition to cholesterol, unsaturated fatty acids (UFAs) have been shown to regulate mSREBP levels. A unified mechanism explaining the regulation of SREBP by UFAs has not yet been established. It has been demonstrated that UFAs may inhibit the proteolytic processing of the precursor protein [12–15], reduce SREBP-1 mRNA stability [16], as well as transcription [12, 17–19]. Studies performed on hepatic tissue *in vivo* or in hepatic cell lines have demonstrated that polyunsaturated FAs (PUFAs), but not the monounsaturated FA oleic acid (OA), reduce the levels of mSREBP-1 [15, 16, 19] or both SREBP-1 and -2 [20]. Other studies have demonstrated that OA as well as PUFAs, reduce the levels of both SREBP-1 and -2 [13, 14]. In a study using the non-hepatic 293T fibroblast-like cell line, both OA and arachidonic acid (AA) reduced SREBP-1 levels, while no alterations in SREBP-2 levels were found [12]. A similar response was seen when the CaCo-2 colon adenocarcinoma cell line was treated with PUFAs, while OA had no effect [18].

Regulation of the SREBP transcription factors independent of cholesterol and FA levels has also been reported. Several studies have demonstrated activation of the SREBP transcription factors by cellular stress like hypotonic shock [21], ER stress [21–23] or apoptosis [24].

ER stress is induced by disturbances in ER homeostasis and leads to initiation of the unfolded protein response (UPR). The response is mediated by three ER-localized transmembrane proteins; activating transcription factor 6 (ATF6), inositol-requiring enzyme 1 (IRE1) and the eukaryote translation initiation factor 2 alpha (eIF2 α) kinase 3 (EIF2AK3/PERK). Activated PERK phosphorylates eIF2 α [25], thereby inducing a global inhibition of translation resulting in reduced protein synthesis and depletion of short lived proteins like cyclin D1 [26].

We have previously demonstrated that treatment of SW620 human colon cancer cells with the PUFA docosahexaenoic acid (DHA; 22:6n-3) leads to reduced levels of SREBP-1 [27], while the SREBP-2 transcription factor is activated [28]. Despite increased levels of the activated transcription factor, only a few SREBP-2 target genes were up-regulated at mRNA level, and synthesis of cholesterol from acetate was reduced in DHA-treated cells [28]. In addition, DHA treatment induced accumulation of cholesteryl esters in SW620 cells without a corresponding increase in total cholesterol [27, 28]. These data made us hypothesize that free cholesterol was redistributed from the ER membrane to cholesterol esters, inducing local cholesterol depletion in the ER and activation of SREBP-2. DHA treatment also induced ER stress in SW620 cells [28], and it was hypothesized that depletion of cholesterol in the ER could lead to the observed ER stress and growth inhibition observed in DHA-treated SW620 cells.

In the present study we demonstrate that activation of SREBP-2 by DHA is not caused by cholesterol depletion or ER stress induction. Treatment of SW620 cells with OA, which does not induce cholesteryl ester accumulation [27] or eIF2 α phosphorylation [28], also lead to activation of SREBP-2, indicating that UFAs may have a common mechanism for SREBP-2 activation. Further, we observe that in DHA- and OA- treated cells, despite activated SREBP-2, expression of only a few target genes is increased. In cells where SREBP-2 is activated by cholesterol depletion all target genes examined are induced, indicating that activation of some SREBP-2 target genes is inhibited during DHA and OA treatment.

Experimental Procedures

Cell Culture

The human colon adenocarcinoma cell line SW620 was obtained from ATCC (Rockville, MD). Cells were cultured in Leibowitz's L-15 medium (Cambrex, BioWhittaker, Walkersville, MD) supplemented with L-glutamine (2 mM), FBS (10%) and gentamicin (45 mg/l) (complete growth medium) and maintained in a humidified atmosphere of 5% CO₂: 95% air at 37 °C.

Fatty Acid, Cholesterol and Thapsigargin Treatment

Stock solutions of DHA and OA in ethanol (Cayman Chemical, Ann Arbor, MI) were stored at –20 °C and diluted in complete growth medium before experiments (final concentration of ethanol <0.01% v/v). Cholesterol and Tg (both Sigma, St. Louis, MO) were dissolved in ethanol. Stock solutions were kept at –20 °C and diluted in complete growth medium before experiments. Complete growth medium with an equal volume of ethanol as for the treatment media was used as the control media in the experiments. For all treatments cells were plated at a density of 3.5×10^6 cells /175 cm² flask and allowed to attach over night, further FA, cholesterol or Tg was added and cells were treated for the indicated time periods. For DHA and cholesterol treatments, cells were also plated in triplicates in 6-well trays treated in parallel with the 175 cm² flasks to assay cell growth. Cells were harvested by trypsination and counted using a Coulter Counter (Beckman Coulter, Fullerton, CA).

Immunoblot Analysis

Preparation of total protein extracts was performed as described previously [27]. An equal amount of protein was separated on 10% precast denaturing NuPAGE gels

(Invitrogen, Carlsbad, CA) and transferred to PVDF membranes (Millipore, Billerica, MA). Membranes were blocked in PBS supplied with 5% nonfat dry milk and 0.1% Tween[®]-20 (BioRad, Hercules, CA) and further incubated over night at 4 °C with the indicated primary antibodies. The following primary antibodies were used to probe the membranes; LDLR (Progen, Germany), FDFT1/SQS (Abgent, San Diego, CA), Insig-1 (Santa Cruz, Santa Cruz, CA), SREBP-2 (BD Biosciences, San Jose, CA), IDI1 and β -actin (both AbCam, UK). Membranes were further incubated with HRP-conjugated secondary antibodies (DAKO, Carpinteria, CA) and detected by chemiluminescence using Super Signal West Femto Maximum Sensitivity Substrate (Pierce, Rockford, IL) and visualized by Kodak Image Station 4000R (Eastman Kodak Company, Rochester, NY). Quantification was performed using Kodak Molecular Imaging Software (version 4.0.1).

siRNA Transfection

siRNAs targeting Niemann Pick C1 protein (NPC1) (NCBI accession number NM_000271) and eukaryote translation initiation factor 2 alpha (eIF2 α) (NCBI accession number NM_004094) were purchased from Dharmacon (Lafayette, CO) (NPC1si#2, eIF2 α si#14) and Ambion (Austin, TX) (NPC1si#7). A non-targeting siRNA (Dharmacon, Lafayette, CO) was used as a control. siRNAs were dissolved in 1 \times siRNA buffer (Dharmacon, Lafayette, CO) and stock solutions were aliquoted and stored at –80 °C. For siRNA transfection experiments, 8.17×10^6 cells were plated in 175 cm² flasks in complete growth media without gentamicin. Cells were transfected 24 h after plating using siRNA (50 nM) and Dharmafect 1 transfection reagent (Dharmacon). The media was changed 24 h after transfection, and the cells were allowed to recover for 6 h before they were sub-cultured at a density of 3.5×10^6 cells/175 cm² flask for further growth or DHA treatment. Cells were harvested by scraping in ice cold PBS, and total cell extracts were prepared as described above.

RNA Isolation

For RNA isolation 3.5×10^6 cells were seeded in 175 cm² flasks and allowed to attach over night. The following morning, the growth medium was replaced with media supplemented with DHA (70 μ M) or an equal volume of ethanol (control). After 6 h, cells were harvested by scraping in ice cold PBS and stored at –80 °C. Total RNA was isolated using the High Pure RNA Isolation Kit (Roche, Mannheim, Germany) according to the instruction manual. RNase inhibitor rRNasin (40U/ μ l, 1 μ l) (Promega, Madison, WI) was added and RNA was up-concentrated on a speed vac and resuspended in RNase free distilled H₂O.

RNA concentration and quality were determined using the NanoDrop1000 (NanoDrop Technologies, Wilmington, Delaware) and agarose gel electrophoresis.

Gene Expression Profiling

A 5- μ g amount of total RNA was used for cDNA- and cRNA synthesis according to the eukaryote expression manual (Affymetrix, Santa Clara, CA). cRNA was hybridized to the Human Genome U133 Plus 2.0 Arrays (Affymetrix). Washing and staining were performed using the Fluidics Station 450 and the arrays were scanned using an Affymetrix GeneChip Scanner 3000 with autoloader (Affymetrix, USA). Expression profiling was performed in triplicate at all time points using RNA from independent biological replicates, except for the 1 h time point when only two control experiments were used. All experiments were submitted to ArrayExpress with accession number E-MEXP-2010. The statistical analysis was performed based on summary expression measures of the probe sets of the GeneChips, using the raw data (CEL) files and a linear statistical model for background-corrected, quantile normalized and log-transformed PM values, performed by the robust multiarray average (RMA) method [29, 30]. Data from all time points (0.5, 1, 3, and 6 h) were used in the statistical analysis.

For each transcript, a linear regression model including parameters representing treatment and time effects and treatment-time interactions was fitted to the RMA expression measures. Based on the estimated effects, tests for significant differential expression due to DHA treatment and time were performed using moderated *t* tests, in which gene-specific variance estimates are replaced by variance estimates found by borrowing strength from data on the remaining genes [31]. To account for multiple testing, adjusted *P* values controlling the false discovery rate (FDR) were calculated [32]. Differentially expressed genes were selected based on a threshold of 0.05 on the adjusted *P*-values.

The statistical analysis was performed in *R* (<http://www.r-project.org>), using the packages Limma and affy from Bioconductor [33]. Differentially expressed genes were annotated using the NetAffx Analysis Centre (<http://www.Affymetrix.com>) and NMC Annotation Tool/eGOn V2.0 (<http://www.GeneTools.no>).

Results

Expression of mSREBP-2 Target Genes at mRNA and Protein Level in DHA-Treated SW620 Cells

We have previously found that only some SREBP-2 target genes are up-regulated in SW620 cells after 12–48 h of

DHA treatment despite activation of SREBP-2 [28]. In the present study, gene expression analysis was performed on SW620 cells treated with DHA for short time periods using arrays covering the whole human genome. No SREBP-2 target genes were found differentially expressed at mRNA level after 0.5, 1 and 3 h treatment with DHA. However, after 6 h of DHA treatment up-regulation of some, but not all, SREBP-2 target genes was observed (Table 1), in agreement with our previous findings [28]. In addition, two SREBP-2 target genes that were not present on the Focus arrays previously used were found up-regulated at mRNA level; farnesyl-diphosphate farnesyltransferase 1 (FDFT1), encoding for squalene synthetase (SQS), an enzyme in the cholesterol biosynthetic pathway, and DnaJ (Hsp40) homolog, subfamily A, member 4 (DnaJA4), recently demonstrated to be a SREBP-2 target gene (Table 1) [34].

Several of the SREBP-2 target genes were also analyzed at protein level by Western blot. Increased protein levels of low density lipoprotein receptor (LDLR), SQS/FDFT1 and DnaJA4 were observed after 12 h of DHA treatment, and remained elevated up to 48 h of treatment (Fig. 1a). The level of the SREBP target gene isopentenyl-diphosphate delta isomerase 1 (IDI1), also an enzyme in the cholesterol biosynthetic pathway, was not changed by DHA treatment neither at mRNA nor protein level (Table 1, Fig. 1a).

Treatment of SW620 cells with OA, resulted in a similar protein expression pattern as for DHA-treated cells. Protein levels of mSREBP-2 and SQS were increased after 24 h of OA treatment, while IDI1 was unchanged (Fig. 1b).

Activation of SREBP-2 by NPC1 Knockdown Induces Expression of all Target Genes Examined in SW620 Cells

Activated SREBP-2 has been demonstrated to generally induce expression of all target genes [35–37]. In order to investigate whether activation of SREBP-2 by NPC1 knockdown would induce expression of target genes not activated during DHA treatment, SW620 cells were transfected with siRNAs targeting NPC1. The NPC1 protein is involved in intracellular cholesterol transport of LDLR-derived cholesterol from the lysosomes to the interior of the cell, and inhibition of NPC1 function leads to cholesterol depletion in the ER [38]. Significantly reduced NPC1 protein levels were observed in cells transfected with NPC1 siRNA, as well as increased levels of mSREBP-2 (Fig. 2a). Further, induction of both SQS and IDI1 was observed (Fig. 2a), in contrast to DHA-treated cells where only SQS was induced. These results demonstrate that SW620 cells are able to increase expression all target genes examined after activation of SREBP-2 by cholesterol depletion induced by NPC1 knockdown.

Fig. 1 Analysis of protein levels of mSREBP-2 and selected SREBP target genes after DHA and OA treatment. **a** Western blot analysis of mSREBP-2 target gene protein levels in total protein extracts from SW620 cells treated with DHA (70 μ M) for the indicated time periods (h). Controls were harvested at all time points, only 24 h control (C) is shown. **b** Western blot analysis of mSREBP-2 and SREBP target gene protein levels in total protein extracts from SW620 cells treated with OA (70 μ M) for 24 h. β -actin was used as a control for equal protein loading. The blots were quantified and protein band intensities

normalized relative to β -actin. For results in Fig. 1a, the β -actin adjusted band intensities from the DHA and control membranes were further normalized relative to the 24 h control band, present at all membranes, to adjust for differences in signal intensities between the membranes. The numbers under the blots represent mean fold change (with standard deviation(SD)) of DHA- or OA- treated samples relative to control at indicated time points for three independent experiments. *Significantly different from control (Student's *t* test, $P < 0.05$)

Cholesterol Supplementation During DHA Treatment Does Not Inhibit Activation of SREBP-2 or Relieve DHA-Induced Cell Cycle Arrest

We have previously observed increased cholesterol esterification in addition to reduced de novo cholesterol synthesis in SW620 cells treated with DHA [27, 28]. This may lead to depletion of cholesterol in the ER, which could lead to the observed activation of SREBP-2 [28] and possibly cause growth inhibition [39]. To further investigate this, we incubated SW620 cells with cholesterol alone or in combination with DHA. Cholesterol treatment alone reduced the level of mSREBP-2 compared to control, indicating uptake of sterols in ER and inhibition the proteolytic activation of the SREBP-2 transcription factor (Fig. 2b). When cells were treated with DHA in the presence of cholesterol, a significant increase in mSREBP-2 levels relative to control was observed (1.45 ± 0.16 relative to control with cholesterol only, $P < 0.05$), demonstrating activation of SREBP-2 by DHA in the presence of excess cholesterol. Further, the cell cycle arrest observed in SW620 cells after DHA treatment [27] was not rescued by co-incubation with cholesterol. Cholesterol treatment alone did not affect cell growth (results not shown). The data indicates that activation of mSREBP-2 and the growth arrest observed in SW620 cells after DHA treatment are not caused by depletion of cholesterol.

DHA Regulates mSREBP-2 and Target Genes Independent of ER Stress and eIF2 α Function

We have previously observed induction of ER stress and phosphorylation of eIF2 α in SW620 cells during DHA treatment [28]. Previous reports have demonstrated that ER stress activates SREBP-2 [22, 23], but may inhibit SREBP-2 target gene expression [40]. To investigate whether ER stress related mechanisms are causing the activation of mSREBP-2 and repression of target genes in our system, we used three different approaches; (1) induction of ER stress by thapsigargin (Tg), (2) measuring the level of the negative regulatory protein Insig-1 and (3) siRNAs targeting eIF2 α .

Thapsigargin Treatment Regulates mSREBP-2 and Target Genes

Tg induces ER stress by perturbing ER calcium homeostasis. Activation of SREBP-2 was observed when SW620 cells were treated with Tg for 6 h (Fig. 3a), but the level of mSREBP-2 was higher than in cells treated with DHA for the same time period [28]. The level of mSREBP-2 declined after 24 h of Tg treatment, but was still significantly higher than control (Fig. 3a). These results demonstrate that ER stress may lead to activation of SREBP-2 in SW620 cells, but that the response differs from the

Fig. 2 Analysis of protein levels of mSREBP-2 and selected SREBP target genes after induction of cholesterol depletion or cholesterol supplementation. **a** Western blot analysis of protein levels of NPC1, mSREBP-2 and mSREBP-2 targets in total protein extracts from SW620 cells transfected with NPC1 siRNAs. Cells were transfected with two siRNAs targeting independent sequences in the NPC1 transcript (NPCsi#2 and NPCsi#7), while control cells were transfected with a non-targeting siRNA. Cells were harvested for analysis 72 h after transfection. The blots were quantified and protein band intensities normalized relative to β -actin loading control. The numbers under the blots represent mean fold change (with SD) of

NPC1 siRNA transfected samples relative to control at indicated time points ($n = 3$). **b** Western blot analysis of mSREBP-2 levels in total protein extracts from SW620 cells after DHA treatment and cholesterol supplementation. Cells were incubated for 24 h in control media (C), DHA (70 μ M), 30 μ g/ml cholesterol (Chol), or both cholesterol (30 μ g/ml) and DHA (70 μ M); (Chol + DHA). The blots were quantified and intensities normalized relative to β -actin loading control. The numbers under the blots represent mean fold change (and SD) relative to control for three independent experiments. *Significantly different from control (Student's t test, $P < 0.05$)

response observed after DHA treatment, where the level of mSREBP-2 remained elevated up to 48 h of treatment [28]. The same response was also observed when using a tenfold lower concentration of Tg, indicating that the difference in response is not caused by high concentrations of Tg with a corresponding stronger ER stress response. The protein levels of selected SREBP-2 target genes were assayed after Tg-treatment of SW620. Unexpectedly, SQS and DnaJA4, both induced by DHA treatment, were down-regulated in Tg-treated cells (Fig. 3a). Furthermore, expression of IDI1, which was unchanged in DHA treated cells, was increased relative to control after 24 h of Tg-treatment (Fig. 3a).

mSREBP-2 Activation is not Caused by Depletion of the Regulatory Protein Insig-1

It has been suggested that activation of mSREBP-2 upon cellular stress may be caused by depletion of the negative regulatory protein Insig-1 due to eIF2 α phosphorylation and inhibition of protein translation [21]. However, the level of Insig-1 was not altered upon Tg nor DHA treatment in SW620 cells (Fig. 3a, b) demonstrating that SREBP-2 is not activated by Insig-1 depletion in these settings.

Inhibition of Protein Translation Using siRNAs Targeting eIF2 α

To investigate whether inhibition of protein translation would lead to activation of SREBP-2 through a mechanism other than reduced level of Insig-1, siRNAs targeting eIF2 α were used to deplete the protein from the cells. Transfection with siRNA significantly reduced the level of eIF2 α , and a significant reduction in cyclin D1 level was also observed, indicating inhibition of protein translation (Fig. 3c). Knockdown of eIF2 α did not result in increased levels of mSREBP-2, indicating that inhibition of protein translation does not lead to mSREBP-2 activation in SW620 cells. Instead decreased levels mSREBP-2 was observed (Fig. 3c). When eIF2 α siRNA transfected cells were treated with DHA for 24 h, increased level of mSREBP-2 relative to cells not treated with DHA was observed (Fig. 3d). These results indicate that activation of mSREBP-2 by DHA is independent of ER stress and eIF2 α function.

Discussion

Activation of the SREBP-2 transcription factor and induction of cholesterol biosynthesis are mainly regulated by cellular cholesterol levels [1]. However, cellular stress and ER stress have also been reported to activate SREBP-2,

independent of cholesterol levels [21, 22]. We have previously demonstrated that DHA treatment leads to activation of the SREBP-2 transcription factor in the human colon cancer cell line SW620, but that the activated transcription factor only induces expression of some SREBP target genes [28]. In the present study we demonstrate that activation of SREBP-2 by DHA occurs independent of cholesterol levels and ER stress induction, and that activation of some SREBP-2 target genes is inhibited during DHA treatment.

In our previous study, activation of the SREBP-2 transcription factor was observed as early as after 3 h of DHA treatment [28], and in the present study we demonstrate by gene expression analysis that increased mRNA levels of SREBP target genes can be observed after 6 h of DHA treatment. The gene expression analysis also verified the previously observed expression pattern in DHA-treated SW620 cells where activation of only a few SREBP-2 target genes was observed despite the activated transcription factor. In SW620 cells treated with OA, we observe a similar effect as for DHA on mSREBP-2 and target gene protein levels.

Previous studies have demonstrated that when SREBP-2 is activated by cholesterol depletion or by over-expression of the active transcription factor, expression of all known target genes is generally induced [35–37]. In line with this we demonstrate that SREBP-2 activated by knockdown of NPC1 is able to induce all target genes examined, unlike the response observed in DHA-treated cells. These results demonstrate that during DHA treatment activated SREBP-2 is not able to increase expression of all target genes.

Previously we have demonstrated increased protein levels of 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) and NPC1 in SW620 cells treated with DHA [28], and in the present study we demonstrate increased protein levels of LDLR. Together with the observed activation of mSREBP-2 [28], these results suggest an increased demand for intracellular cholesterol. However, our data demonstrate that activation of SREBP-2 is not inhibited by cholesterol supplementation to the cell culture media during DHA treatment. It has been suggested that cholesterol dissolved in ethanol added to cell culture media will not be efficiently absorbed by cells [41], and that observed effects could be caused by oxysterol impurities that are more easily absorbed. Thus, reduced levels of mSREBP-2 observed after cholesterol supplementation to SW620 cells could be caused by oxysterols present in the cholesterol. However, oxysterols are not able to substitute for the cellular functions of cholesterol [5, 41]. Also, others have demonstrated by using the same approach, that cholesterol supplementation may restore growth in cholesterol depleted cells [39, 42]. These results strongly indicate that SREBP-2 activation in DHA-treated cells is not caused by

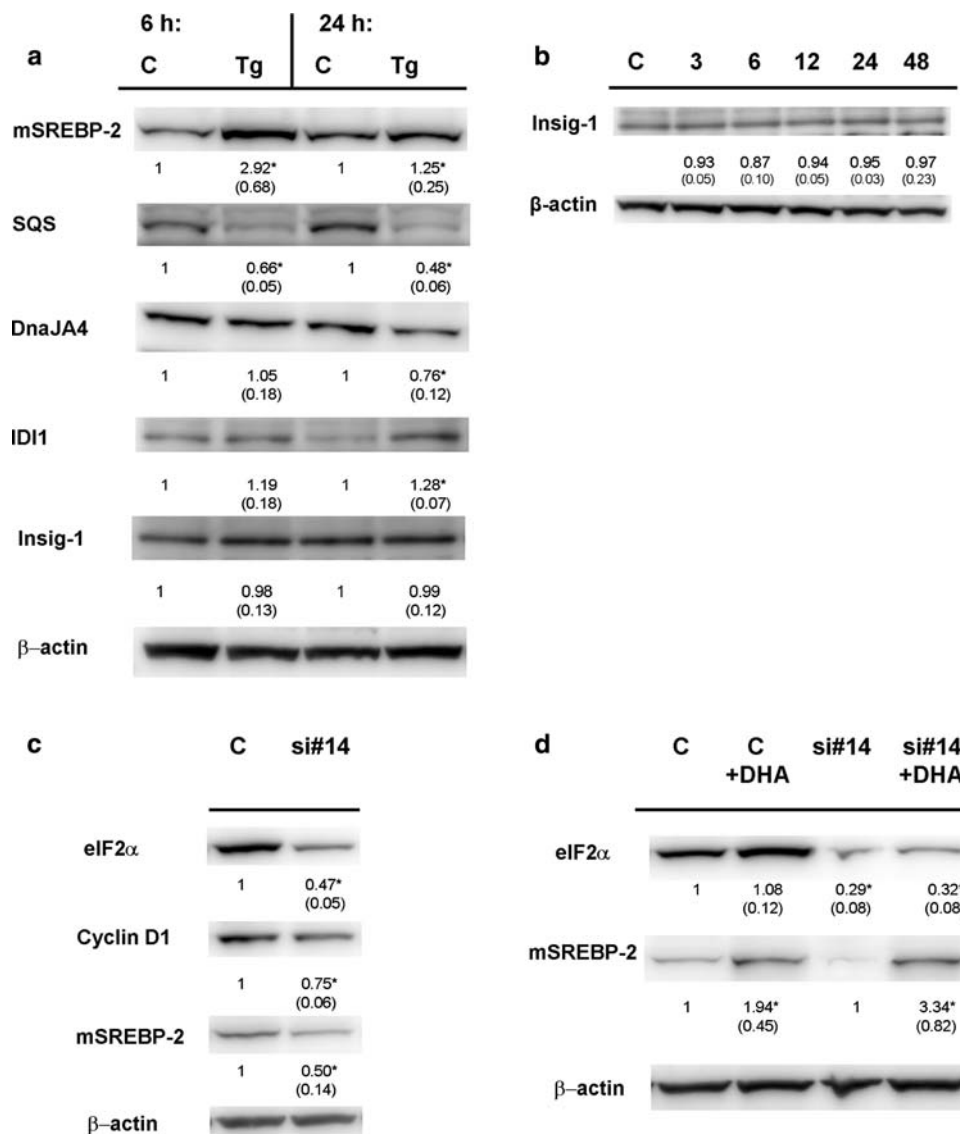

Fig. 3 Regulation of protein levels of mSREBP-2 and SREBP target genes by ER stress and eIF2 α knockdown. **a** Western blot analysis of the protein levels of mSREBP-2 and mSREBP-2 target genes in total protein extracts from SW620 cells treated with 0.2 μ M thapsigargin (Tg) for the indicated time periods (h). The blots were quantified and protein band intensities normalized relative to β -actin loading control. The numbers under the blots represent mean fold change (with SD) of Tg-treated samples relative to control at indicated time points for three independent experiments. **b** Western blot analysis of Insig-1 protein levels in total protein extracts from SW620 cells treated with DHA (70 μ M) for the indicated time periods (h). Controls were harvested at all time points; only 24 h control (C) is shown. The blots were quantified and protein band intensities normalized relative to β -actin. The β -actin adjusted band intensities from the DHA and control membranes were further normalized relative to the 24 h control band, present at all membranes, to adjust for differences in signal intensities

cholesterol depletion, despite the accumulation of cholesteryl esters and reduced cholesterol biosynthesis observed previously [27, 28]. Furthermore, OA treatment of SW620 cells does not induce cholesteryl ester

between the membranes. The numbers under the blots represent mean fold change (with SD) of DHA treated samples relative to control at indicated time points for three independent experiments. **c** Western blot analysis of the protein levels of eIF2 α , cyclin D1 and mSREBP-2 in total protein extracts from SW620 cells transfected with a siRNA targeting eIF2 α . Cells were harvested for analysis 48 h after transfection. **d** Western blot analysis of the protein levels of eIF2 α and mSREBP-2 in total protein extracts from SW620 cells transfected with a siRNA targeting eIF2 α and further treated with DHA for 24 h. For all eIF2 α experiments control cells were transfected with a non-targeting siRNA. The blots were quantified and protein band intensities normalized relative to β -actin loading control. The numbers under the blots represent mean fold change (with SD) of siRNA transfected cells relative to the corresponding control at indicated time points for three independent experiments. *Significantly different from control (Student's *t* test, $P < 0.05$)

accumulation [27], but we observe activation of SREBP-2 (this work). The data demonstrates that both DHA and OA may activate SREBP-2 independent of cellular cholesterol levels, possibly through a mechanism common for UFAs.

We further demonstrate that activation of SREBP-2 by DHA treatment is most likely not caused by ER stress or inhibition of protein translation, and that it is independent of Insig-1 protein levels and eIF2 α function. In SW620 cells treated with OA we observe activation of SREBP-2, but not induction of ER stress and eIF2 α phosphorylation [28]. These data further support a common mechanism for UFAs for activation of SREBP-2 independent of both cholesterol levels and ER stress.

Activation of SREBP-2 by induction of apoptosis has also been reported [24], but we have previously not detected induction of apoptosis or activation of caspases in DHA-treated SW620 cells [27, 28].

Inhibition of transcription of SREBP-2 target genes has previously been associated with ER stress-induced activation and cleavage of ATF6 [40]. Tg treatment activates both ATF6 [40] and mSREBP-2, as demonstrated in our study. The reduced protein levels of SQS and DnaJA4 observed after Tg treatment are most likely caused by ATF6 interaction with SREBP-2 transcription, since reduced levels of SQS after ATF6 activation have been demonstrated previously [40]. Unexpectedly, proteins that were repressed in Tg-treated cells were the same proteins found induced upon SREBP-2 activation in DHA treated cells. ATF6 activation was not assayed in this work, but it could be speculated that the ER stress response or activation of ATF6 in DHA-treated cells may be weaker than in Tg-treated cells, or that all the branches of the ER stress response are not equally activated upon DHA treatment [35]. In OA-treated cells, where no ER stress has been observed, the SREBP targets SQS and IDI1 display the same response as observed in DHA-treated cells. Together the data indicates that lack of activation of some SREBP-2 target genes during DHA or OA treatment is not caused by activation of ER stress and ATF6.

Regulation of the SREBP transcription factors by UFAs have been shown in several studies [12, 13, 17], but our study is the first to demonstrate increased levels of mSREBP-2 after UFA treatment. Why UFA treatment would cause activation of SREBP-2 in the SW620 colon cancer cell line is not known and remains to be investigated in our system. However, activation of SREBP-2 by DHA does not result in activation of all target genes and increased cholesterol biosynthesis. Instead, activation of some SREBP-2 target genes in DHA- and OA-treated cells seems to be inhibited, and a significant reduction in de novo cholesterol biosynthesis has previously been observed after DHA treatment [28].

Protein modification of the SREBP-2 transcription factor by phosphorylation, acetylation, sumoylation or ubiquitination may affect the binding affinity or activation of target promoters [43–45]. UFAs could also possibly affect co-factors or regulate repressors that are involved in

SREBP-2 target gene transcription [46, 47]. The SREBP-1a transcription factor has also been demonstrated to be involved in the regulation of genes involved in cholesterol biosynthesis [10, 36, 37]. We have previously observed reduced levels of mSREBP-1 in DHA-treated SW620 cells [27]. SREBP-1 levels were not altered in NPC1 siRNA transfected cells, where expression of all SREBP target genes examined were induced (results not shown). Whether the observed SREBP-2 target gene expression pattern induced by DHA and OA could be caused by reduced SREBP-1 levels, or if it is caused by other factors, remains to be investigated.

The liver is the main site for cholesterol biosynthesis in the body, but extra-hepatic tissue also synthesizes a significant amount of cholesterol (reviewed in [48]). In addition cancer cells and tumors display increased rates of cholesterol biosynthesis [49]. In spite of this, most studies investigating the effect of dietary fatty acids on cholesterol metabolism have been performed in fibroblasts or hepatic cell lines or tissues [14–16, 19, 20, 50]; only a few studies have addressed regulation of SREBPs or cholesterol biosynthesis in other tissues and cell types [18, 51]. The results from our study have revealed that UFAs may affect cholesterol homeostasis and reduce cholesterol biosynthesis in a colon cancer-derived cell line by interfering with induction of SREBP-2 transcription. This is in line with previous observations where UFA treatment reduced transcriptional levels of cholesterologenic enzymes or reduced cholesterol biosynthesis in both hepatic tissue and cells, as well as glioma cells [19, 20, 50, 51]. Altered levels of cholesterol biosynthesis in the liver may contribute to altered plasma cholesterol levels [48], and it has been suggested that the reduction in cholesterologenesis induced by UFAs may be a mechanism explaining the plasma cholesterol-lowering effect that has been observed in some studies after UFA treatment [20, 50]. In addition reduced levels of cholesterol biosynthesis in cancer cells may contribute to reduced cancer cell growth [52, 53]. However, further studies are needed to confirm our observations and investigate possible implications in other cancer cell lines.

Together the data presented in this report demonstrate that DHA and OA activate SREBP-2 independent of cholesterol levels and ER stress, possibly through a mechanism common for UFAs. Further, we show that activation of SREBP-2 by these FAs only increases expression of some SREBP target genes. The mechanisms by which DHA and OA increase the level of mSREBP-2, but inhibit induction of some SREBP target genes in SW620 human colon cancer cells remain to be investigated.

Acknowledgments Technical assistance from Caroline Hild Hakvaag Pettersen, Mari Sæther and Jens Erik Slagsvold is highly

appreciated. The project was financed by The Faculty of Medicine, NTNU, The Cancer Research Fund, Trondheim University Hospital and The Research Council of Norway through grants from the Functional Genomics Program (FUGE). Microarray experiments were performed at the microarray core facility at the Norwegian Microarray Consortium (NMC), Trondheim, which is supported by FUGE.

Abstract The ability to control the fatty acid content of the diet during early development is a crucial requirement for a one-generation model of docosahexaenoic acid (DHA; 22:6n3) deficiency. A hand feeding method using artificial rearing (AR) together with sterile, artificial milk was employed for feeding mice from postnatal day 2–15. The pups were fed an n-3 fatty acid adequate (3% α -linolenic acid (LNA; 18:3n3) + 1% 22:6n3) or a deficient diet (0.06% 18:3n3) with linoleic acid (LA; 18:2n6) as the only dietary source of essential fatty acids by AR along with a dam-reared control group (3.1% 18:3n3). The results indicate that restriction of n-3 fatty acid intake during postnatal development leads to markedly lower levels of brain, retinal, liver, plasma and heart 22:6n3 at 20 weeks of age with

replacement by docosapentaenoic acid (DPAn6; 22:5n6), arachidonic acid (ARA; 20:4n6) and docosatetraenoic acid (DTA; 22:4n6). A detailed analysis of phospholipid classes of heart tissue indicated that phosphatidylethanolamine, phosphatidylcholine and cardiolipin were the major repositories of 22:6n3, reaching 40, 29 and 15%, respectively. A novel heart cardiolipin species containing four 22:6n3 moieties is described. This is the first report of the application of artificially rearing to mouse pup nutrition; this technique will facilitate dietary studies of knockout animals as well as the study of essential fatty acid (EFA) functions in the cardiovascular, neural and other organ systems.

n-3 Def n-3 Fatty acid deficient group

Introduction

Nutritional studies during the early postnatal period are difficult to conduct since mammals are dependent upon maternal breast milk for nourishment and the breast milk composition cannot be controlled since it differs from the maternal diet. The artificial rearing (AR) method permits precise control of dietary essential fatty acids when used in combination with artificial milk and allows for a rapid induction of neural 22:6n3 deficiency in the newborn rat

[1–3]. Hoshiba has introduced a new type of nursing bottle for use in AR employing hand feeding that supports excellent pup survival [4] and recently it has been adapted for essential fatty acid research [3, 5]. This work has employed rats; however, mice are the most widely used animal in molecular biological work where genetic mutants are readily available. Thus, a practical method of artificially rearing mouse pups is desirable for neonatal nutrition.

Experimental animal, human and cell culture studies have reported anti-arrhythmic actions of omega 3 fatty acids [6]. Ku et al. [7] showed that the recovery of cardiac function after cold storage was impaired in hyperlipidemic rats fed a high-fat diet, but was restored in the presence of omega-3 fatty acids. The administration of a lipid preparation (medium chain-triacylglycerols (MCT): fish oil (FO) or MCT: triolein (OO)) improved cardiac function during aerobic reperfusion post-ischemia. In addition to the previous effect; the bolus injection of MCT:FO opposed the deleterious effect of long-term n-3 fatty acid deficiency and, in this respect, was superior to MCT:OO [8]. In a recent study by Porto et al. [9] the alteration of cardiac function in n-3 deficient rats and its improvement after injection of MCT:FO emulsion coincides with parallel changes in heart lipid fatty acid content and pattern.

In humans, Mori et al. [10] have also shown that compared with a placebo, heart rate was significantly reduced by 22:6n3 and increased by eicosapentaenoic acid (EPA; 20:5n3). The beat-to-beat variability correlated directly with the 22:6n3 content of platelet membranes in survivors of myocardial infarction [11]. The recent GISSI-Prevention study of 11,324 patients showed a marked decrease in the risk of sudden cardiac death as well as a reduction in all-cause mortality in the group taking omega-3 fatty acid ethyl esters, despite the use of other secondary prevention drugs, including beta-blockers and lipid-lowering therapy [12].

The fatty acid composition of myocardial membrane phospholipids is sensitive to the type of fatty acids consumed in the diet. Indeed, the myocardium and the myocardial membrane phospholipids are rich in n-3 PUFA after feeding fish oils [13–15]. Kramer [16] observed no effect of dietary lipids on the proportions of the major phospholipids of rat heart after feeding various plant oil supplements. These observations thus indicate that dietary lipid induced changes in the fatty acid composition of cardiac phospholipids are due primarily to changes in the fatty acid content of the lipids, rather than to altering lipid class profiles. Garg et al. [17] demonstrated for the first time that short-term supplementation with fish oil concentrate results in significant incorporation of long chain n-3 PUFA with a concomitant depletion of the eicosanoid substrate 20:4n6 in the human atrium.

In the present study, an AR system was employed to produce mice with lower levels of brain 22:6n3 in the first generation by feeding diets with only 18:2n6 as a source of essential fatty acids; a second group of mice were fed an identical diet to which 18:3n3 and 22:6n3 were substituted for a portion of the oleate (18:1n9). The fatty acid content of neural and peripheral tissues is presented.

Materials and Methods

Animals and Study Design

Time-pregnant, female ICR mice of 2-day gestational age were obtained from Harlan (Indianapolis, IN) and immediately placed on a diet (maternal diet) containing 3.1% 18:3n3 as the source of n-3 fatty acids (Table 1). They were maintained in our animal facility under conventional conditions with controlled temperature (23 ± 1 °C) and illumination (12 h; 06.00–18.00 h) and water was provided ad libitum. At postnatal day (PND) 2, one male pup was selected from various litters, born within a 48 h time window and randomly allocated into one of two experimental groups with the constraint that the groups had an equal mean body weight. A third male group served as another reference group and was allowed to suckle from dams fed on the maternal diet (dam-reared group; $n = 16$) containing 3.1 wt % 18:3n3. The two experimental groups were artificially fed one of the two artificial milks: n-3 fatty acid deficient (n-3 Def; $n = 14$) milk (18:2n6 only added as EFA) or an identical milk except that 3.1 wt % 18:3n3 and 1 wt % 22:6n3 were added (n-3 Adq; $n = 14$) in place of some of the monounsaturated fat (Table 2). All experimental procedures were approved by the Animal Care and Use Committee of the National Institute on Alcohol Abuse and Alcoholism, National Institute of Health.

Artificial Rearing System

The AR procedure used was a hand-feeding technique with a newly developed nursing bottle as described by Hoshiba [4] and recently adapted for essential fatty acid research [3, 5]. The AR system consisted of a custom made nursing bottle, container, cage, digital microprocessor incubator (Quincy Lab, Inc., Chicago, IL) with a thermo-hygrometer (Sper Scientific Ltd., Scottsdale, AZ).

Artificial Milk

The artificial milk formula was modified from the method of Yajima et al. [18, 19]. Table 2 shows the ingredients used as well as their commercial sources. Casein, whey

protein hydrolysate and whey protein were used as protein sources and lactose was used as the carbohydrate. The protein sources were carefully chosen so as not to introduce significant levels of n-3 fatty acids, as this is often the major source of introduction of these components into n-3 fatty acid deficient diets [25]. For complete dissolution, all ingredients were mixed in the order described by Kanno et al. [20] so as to minimize precipitation. The milk was then homogenized two times under high pressure (120 kg/cm²) using a homogenizer with a two-stage valve (Model #HP50–250 FES International, Pomona, CA) that had been cleaned by rinsing with 0.1 M NaOH and then neutralized with sterilized water. The homogenized milk was tyndalized twice at 63 °C for 30 min, 6 h apart. The complete

Component sources were as follows: ^a NZMP (North America) Inc, Santa Rosa, CA; ^b Sigma-Aldrich Corp. St. Louis, MO; ^c Harlan, Madison, WI; ^d Novartis Medical Nutrition, Fremont, MI; ^e Dyets, Bethlehem, PA; ^f Nu-Chek Prep. Inc. Elysian, MN; ^g Chicago Sweeteners, Chicago, IL

^h This fatty acid profile was analyzed by transmethylation of each artificial milk and GC analysis. Only trace quantities of the long-chain polyunsaturated fatty acids 20:4n6, 20:5n3, 22:5n3 were detected (i.e., <0.01%). Other minor peaks were not included

milk was poured into 50 mL sterilized polypropylene bottles (Falcon, San Jose, CA) and stored at -40°C . The milks contained 16 wt % lipids composed of saturated fat (medium chain triglycerides and hydrogenated coconut oil) and the ethyl ester form of purified unsaturated fatty acids (Nu-Chek Prep, Inc., Elysian, MN). The n-3 fatty acid deficient milk (n-3 Def) contained 16.7% of 18:2n6 and 0.06% of 18:3n3 and the n-3 fatty acid adequate (n-3 Adq) milk contained 16.9% of 18:2n6 and 3.1% 18:3n3 and 0.93% of 22:6n3 upon actual analysis (Table 2). The addition of the 18:3n3 and 22:6n3 to the n-3 Adq diet was substituted for an equal quantity of ethyl 18:1n9; this introduced only a 4% difference in 18:1n9 content between the two diets. Saturated, monounsaturated, and 18:2n6 were balanced leaving only the level of 18:3n3 and 22:6n3 as a dietary variable. Insulin-Like Growth Factor-I (IGF-I), (Fitzgerald Industries International, Concord, MA) was added to the milk as studies suggest that milk-borne IGF-I is important in modulation of somatic and gastrointestinal tract growth in the neonatal rat [21]. The IGF-I was added to the artificial mouse milk in the following manner: the IGF-I (10 μg in 0.5 mL of 0.1 M acetic acid) was added to Pyrex screw cap culture tubes (13 \times 100 mm, Corning). Tube contents were lyophilized and stored at -20°C until use. Each morning, 0.2 mL of Tris buffer (50 mM, pH 7.4) was added to each

tube and subjected to gentle mixing, then transferred into sterile polypropylene bottles with 20 mL of artificial milk to achieve a final IGF-I concentration of 500 ng IGF-I/mL of artificial milk.

Pelleted Diets

The three pelleted diets used were based on the AIN-93 [22] formulation with several modifications to obtain the extremely low n-3 fatty acid level required in this study (Table 1). The diets were obtained commercially and used a cold pelleting process to preserve unsaturated fats (Dyets, Bethlehem, PA). Pups were weaned to pelleted diets with a fat composition similar to that fed during the AR period; the dam-reared group was weaned onto the same diet as their dams and they were maintained on these diets until they were killed. All three diets contained 10 wt % fat and had a similar content of 18:2n6. The fatty acid data in Tables 1 and 2 represent actual gas chromatographic (GC) analyses of the entire diet (rather than theoretical values or analysis of just the lipid mixtures).

Lipid Extraction

The mice were killed by decapitation at 20 weeks of age, tissue samples including brain, liver, heart, plasma and retina were collected and stored at -80°C . The total lipid extracts of tissues were prepared according to the method of Folch et al. [23]. Aliquots of the lipid extracts were transmethylated with 14% BF_3 -methanol (Alltech Associates, Deerfield, IL) at 100°C for 60 min by a modification of the method of Morrison and Smith [24] with hexane addition [25]. The total lipids in the artificial milk and pelleted diets were transmethylated by the method of Lepage and Roy [26] as this is more accurate when shorter chain fatty acids (e.g. 8–12C) occur at appreciable levels. The fatty acid methyl esters were analyzed by a fast gas chromatographic method as previously described [27]. Data were expressed as a percentage of total fatty acid weight (% by wt) or referenced to an internal standard and expressed as an absolute concentration ($\mu\text{g}/\text{mg}$ tissue wet weight).

High Performance Liquid Chromatography (HPLC) Separations of Heart Lipid Classes

HPLC Procedures

Normal-phase HPLC was performed using a HP1100 consisting of a quaternary pump, online degasser, auto-sampler and variable wavelength detector (Agilent Technologies, Wilmington, DE). The column was an Advantage

silica 5 μm (60 \AA) 250 \times 4.6 mm purchased from Thomson Instrument Company (Clear Brook, VA). A guard column of 4.0 \times 10 mm packed with silica was used in conjunction with the analytical column.

An aliquot of 0.3–0.6 mg of the heart tissue lipid extract was dissolved in 20 μL chloroform and injected into the HPLC system. Phospholipid separations were achieved with a solvent system consisting of hexane:2-propanol:25 mM potassium acetate (pH 7.0):ethanol:glacial acetic acid (250:607:62: 100:0.6) (by volume) (Buffer A) and hexane:2-propanol:25 mM potassium acetate (pH 7.0):acetonitrile:glacial acetic acid (442:490:62:25:0.6) (by volume) (Buffer B) at 50 $^{\circ}\text{C}$ using a modification of the method of Lesnefsky et al. [28]. The first 65 min of the elution scheme was designed to separate various lipid classes, starting with Buffer A for 15 min for elution of neutral lipids (which included triacylglycerol, cholesterol, and cholesterol esters) and subsequently phosphatidylethanolamine followed by a linear gradient from A to B for elution of phosphatidylinositol and cardiolipin. The flow rate was increased from 1.0 to 1.25 mL/min at 26 min and then held constant until the end of the elution scheme for elution of phosphatidylserine and phosphatidylcholine. A 30 min period with Buffer A at the end of each run was used to reequilibrate the column prior to the next injection with a flow rate of 1 mL/min. Chromatographic peaks were identified using ultraviolet absorbance at 208 nm. Individual phospholipid peaks were identified by comparison of retention time to commercial standards. Phospholipid fractions were collected and stored at -80°C until later analysis for fatty acid content.

HPLC Materials

HPLC-grade hexane, water and potassium acetate were obtained from EMD Chemicals Inc. (Gibbstown, NJ), 2-propanol, acetonitrile and glacial acetic acid were obtained from J. T. Baker Inc. (Phillipsburg, NJ), ethanol was obtained from Pharmco products Inc. (Brookfield, CT). Phospholipid standards were obtained from Avanti Polar lipids (Alabaster, AL).

Transesterification and Gas Chromatography

The lipid fractions prepared by HPLC were transesterified as follows: 1 mL of hexane and 1 mL of 14% BF_3 -methanol was added and the mixture was incubated at 100 $^{\circ}\text{C}$ for 1 h. The fatty acid methyl esters were extracted with hexane and analyzed by gas chromatography as described above. A pulsed splitless mode was used for GC analysis of methyl esters from phosphatidylinositol, phosphatidylserine and cardiolipin due to the low concentration of these fractions. GC methodology was as previously described

[27] with the exception that ramp pressure was initially 55.5 psi with a 0.63 min hold; thereafter pressure was ramped at a rate of 50 psi/min to 14.50 psi, with a 60 min hold. The run time for a single sample was 74 min, with a sample injection-to injection time of 76 min.

Phospholipid Molecular Species Analysis of Cardiolipin

For phospholipid molecular species analysis, heart lipids were extracted in the presence of deuterium-labeled phospholipid standards and analyzed using reversed-phase high-performance liquid chromatography/electrospray ionization–mass spectrometry (HPLC/ESI–MS) with a C18 column (Prodigy, 150 \times 2.0 mm, 5 μm ; Phenomenex, Torrance, CA) as described previously [29]. The separation was accomplished using a linear solvent gradient (water:0.5% ammonium hydroxide in methanol:hexane), changing from 12:88:0 to 0:88:12 in 17 min after holding the initial solvent composition for 3 min at a flow rate of 0.4 mL/min [30]. An Agilent 1100 LC/MSD instrument (Palo Alto, CA) was used to detect the separated phospholipid molecular species. For electrospray ionization, the drying gas temperature was 350 $^{\circ}\text{C}$; the drying gas flow rate and nebulizing gas pressure were 11 L/min and 45 psi, respectively. The capillary and fragmentor voltages were set at 4,500 and 300 V, respectively. Identification of individual phospholipid molecular species was based on the monoglyceride, diglyceride and protonated molecular ion peaks [31].

Statistical Analysis

All data were expressed as the mean \pm SEM. Mouse growth was tested using repeated measures ANOVA (Statsoft, Tulsa, OK). Tissue fatty acid comparisons at 20 weeks of age were performed using a one-way ANOVA. The analysis was followed by Tukey HSD post hoc test for determination of statistical significance among the three dietary groups.

Results

Body and Organ Weights of Dam-Reared and Artificially Reared Mice

The AR pups had a significantly lower body weight than that of dam-reared pups from PND 2 to PND 21; Fig. 1 illustrates changes in body weight in the three groups. There was no significant difference in body weight at PND 21 and the mean body weights were 10.68 \pm 0.33 g for the n-3 Def, 10.73 \pm 0.19 g for the n-3 Adq, and 12.12 \pm 0.27 g for the dam-reared groups. After PND 21, the AR pups gained

Fig. 1 Growth curves of artificially reared and dam-reared mouse pups from PND2 through week 20. The body weight is presented as the mean \pm SEM, with an $n = 14$ or 16. Asterisk indicates $P < 0.001$ for Dam's group versus the artificially reared groups from PND2–PND21

weight rapidly so as to catch up and surpass the dam-reared pups. At 20 weeks of age, the mean body weights were 59.4 ± 1.5 g for the n-3 Def, 59.4 ± 1.0 g for the n-3 Adq, and 54.1 ± 1.4 g for the dam-reared groups. At 20 weeks of age there were no differences detected by one-way ANOVA in excised tissue weights between the AR and dam-reared groups except for the brain (the organ weights were for the brain (dam-reared group, 0.50 ± 0.01 g; n-3 Adq, 0.47 ± 0.01 g; n-3 Def, 0.460 ± 0.004 g), liver (dam-reared group, 2.66 ± 0.18 g; n-3 Adq, 3.13 ± 0.19 g; n-3 Def, 2.98 ± 0.24 g), heart (dam-reared group, 0.22 ± 0.01 g; n-3 Adq, 0.20 ± 0.01 g; n-3 Def, 0.21 ± 0.01 g), and retina (dam-reared group, 5.18 ± 0.42 mg; n-3 Adq, 5.64 ± 0.38 mg; n-3 Def, 5.43 ± 0.51 mg).

Fatty Acid Composition of Tissues

The 22:6n3 was significantly lower in the n-3 Def group as compared with the dam-reared and n-3 Adq groups in all tissues. In the n-3 Adq group, the 22:6n3 was similar to the dam-reared animals in all tissues, except liver. The decreased content of 22:6n3 for the n-3 Def group was largely replaced by a marked elevation in the percentage of 22:5n6 ($P < 0.0001$).

The 20:4n6 and 22:4n6 were also increased in the n-3 Def group compared with levels in the dam-reared and n-3 Adq groups except in heart tissue where there was no significant difference among the three dietary groups in the percentage of 22:4n6.

The brain, retina, and heart tissues had significantly lower docosapentaenoic acid (DPAn3; 22:5n3) in the n-3 Def group compared with the dam-reared and n-3 Adq groups whereas the plasma had significantly higher 22:5n3 in n-3 Def group compared with the dam-reared and n-3

Adq groups; the 22:5n3 was significantly different among the three dietary groups in the liver.

In the liver and retina, there were statistically significant differences in the ratio of 22:5n6/22:6n3 and n-6/n-3 between the dam-reared and n-3 Adq groups versus the n-3 Def group ($P < 0.0001$ for 22:5n6/22:6n3, $P < 0.0001$ for the n-6/n-3); for the liver, plasma and heart, there were significant differences in the ratio of 22:5n6/22:6n3 and n-6/n-3 in the n-3 Def group compared with those of the dam-reared and n-3 Adq groups ($P < 0.0001$ for 22:5n6/22:6n3, $P < 0.0001$ for n-6/n-3).

In brain, retina, heart and plasma the n-3 Def group showed a significantly higher percentage of total n-6 and a lower percentage of total n-3 compared with the n-3 Adq and the dam-reared group. In liver, the n-3 Def group showed a significantly lower percentage of total n-3 compared with those of the dam-reared, and n-3 Adq groups; there was no significant differences in total n-6 PUFA among the three dietary groups.

It must be noted that significant differences in weight percent do not necessary imply significant differences in absolute weight due to differences in some cases of absolute total fatty acid content. It should be noted in this regard that the absolute concentration of liver total fatty acid was significantly greater in the two controlled diets relative to the dam-reared control (Table 5) and this may suggest steatosis. This may be due to the very high content of saturated fatty acids (about 71–81%) in the two controlled diets due to the restriction in the use of vegetable oils in the basal fat that contained omega-3 fatty acids. Although the maternal diet also had a similarly high content of saturated fatty acids, the maternal milk composition could not be controlled in this regard. Since the two experimental diets (n-3 Adq and n-3 Def) had a similar liver total fatty acid content, the differences noted above in the weight percent data also correspond to differences in absolute concentrations.

When the results are presented on a relative percentage basis, the percentage of each fatty acid is influenced by changes in the other fatty acids. On the other hand, if the fatty acid results were reported as absolute concentrations, changes in fatty acids would be independent of each other. Detailed fatty acid compositions, including total fatty acid concentrations of each dietary group for each tissue, are included in Tables 3, 4, 5, 6, and 7.

Heart Lipid Classes

Since heart total lipid exhibited an extremely high 22:6n3 level when dietary 22:6n3 was supplied, a percentage much higher than that observed in any other tissue, it was of interest to further delineate the lipid pools within which the 22:6n3 resided. A non-uniform distribution of the major phospholipid classes in cardiac muscle has been reported

Table 3 Brain fatty acid composition of the two artificially reared groups and a dam-reared reference group at 20 week of age (wt % of total fatty acids)

Each parameter is presented as the mean (±SEM). Means with different alphabetical superscripts (a, b, c) indicate significant differences across diets by Tukey's HSD at $P < 0.05$

ND not detected (i.e., <0.01%), DMA dimethyl acetal

[32]. Both the distribution of the major heart phospholipid classes, as well as their fatty acid composition was determined, in order to more clearly define the extent of the diet-

induced changes. Significant changes in the distribution of phosphatidylcholine ($P < 0.01$), phosphatidylethanolamine ($P < 0.05$), neutral lipid ($P < 0.05$), cardiolipin

Table 8 Lipid class distribution in mouse heart of two artificially reared groups and a dam-reared reference group at 20 week of age

Phospholipids class	Diets		
	Dam-reared (<i>n</i> = 8)	n-3 Adq (<i>n</i> = 7)	n-3 Def (<i>n</i> = 8)
Phosphatidylcholine	43.0 ± 1.0 ^b	43.4 ± 0.9 ^b	39.0 ± 0.9 ^a
Phosphatidylethanolamine	21.8 ± 0.6 ^{ab}	19.9 ± 0.9 ^a	22.8 ± 0.6 ^b
Neutral lipids	20.8 ± 0.6 ^{ab}	19.5 ± 0.8 ^a	22.3 ± 0.6 ^b
Cardiolipin	5.8 ± 0.3 ^b	7.8 ± 0.5 ^a	5.9 ± 0.3 ^b
Phosphatidylserine	1.1 ± 0.2	1.6 ± 0.3	1.9 ± 0.2
Phosphatidylinositol	0.6 ± 0.1 ^a	1.4 ± 0.4 ^{ab}	2.0 ± 0.2 ^b

Values given are mean ± SEM for peak areas of HPLC chromatogram. Different alphabetical superscripts (a, b) indicate significant differences across diets by Tukey's HSD at $P < 0.05$. Neutral lipids included triacylglycerol, cholesterol, and cholesteryl esters

($P < 0.001$) and phosphatidylinositol ($P < 0.01$) were observed between the dietary groups (Table 8). The amount of the remaining material was below the level required for accurate determination of other lipid classes with the method employed.

When examining the fatty acid composition across the phospholipid classes under investigation, we find that, in general, there was no effect of the diet upon the distribution of the major saturated fatty acids (palmitic acid, 16:0; stearic acid, 18:0). 22:6n3 was concentrated in the phosphatidylethanolamine, phosphatidylcholine and cardiolipin fractions reaching 40, 29 and 15%, respectively, of total fatty acids in diets containing preformed 22:6n3. Again 22:5n6 replaced 22:6n3 in the n-3 Def case, and also 20:4n6 was very significantly elevated in all phospholipid classes relative to the n-3 Adq and dam-reared groups. While cardiac cardiolipin makes up only about 6–8% of the total phospholipid of cardiac muscle membranes, it contains a very high proportion of 18:2n6 compared with other phospholipid classes (See Tables 9 and 10).

In further investigation of the reservoirs for 22:6n3, a molecular species analysis of cardiolipins was performed. It was observed, for the first time, that the heart cardiolipin in the 22:6n3-supplemented group contained molecular species with four 22:6n3 moieties. HPLC/EIS-MS analysis of heart phospholipids indicated that cardiolipin in the n-3 Adq dietary group contained abundant 22:6 species, including 22:6,22:6/22:6,22:6, 22:6,22:6/18:2,22:6, 18:2, 22:6/18:2,22:6, 18:2,22:6/18:2,18:2, 18:2,22:6/18:2,18:1, 18:2,18:1/18:1,22:6, and 18:1,18:1/18:2,22:6 species. These assignments were based on the diglyceride ions detected at m/z 600, 648, 602, 650 and 696, representing 18:2,18:2 (di-linoleoyl), 18:2,22:6 (linoleoyl, docosahexaenoyl), 18:1,18:2 (oleoyl, linoleoyl), 18:1,22:6 (oleoyl, docosahexaenoyl) and 22:6,22:6 (di-docosahexaenoyl) species, respectively. Considering that cardiolipin contains

four fatty acyl chains, two diglyceride fragment peaks overlapping in the ion chromatogram indicated the presence of these cardiolipin molecular species, although positional information cannot be obtained using this approach. In contrast, in the n-3 Def diet group, 18:2,18:2/18:2,18:2 is the predominant molecular species in cardiolipin, with the 22:5-containing species 18:2,18:2/18:2,22:5 and 18:2,18:2/16:0,22:5 species as rather minor species. No 22:5,22:5 ion at m/z 700 was detected in the cardiolipin. These data suggested that 22:6n3 may be the preferred fatty acid incorporated into cardiolipin in comparison to 22:5n6.

Discussion

The AR technique has provided nutritionists with a powerful research tool. The main advantage of the AR technique is that it allows precise control of the amount and composition of milk-substitute that each pup receives. Historically, the species most studied using the AR technique is the rat. In addition to the obvious cost advantages of feeding and housing a smaller animal, the rat has emerged as a species of choice for these studies because of its well-defined nutritional requirements and long history of use in metabolic studies. The relatively large number of pups in a rodent litter also enables control and experimental animals to be chosen from the same litters. Finally, the small size of the rat makes its rearing apparatus easy to design and assemble. This work established that the Hoshiba [4] artificial rearing system could be applied to the mouse for studies of essential fatty acid nutrition throughout the neonatal period.

The body weight of the mice in the present study has the same pattern as reported previously [5, 33]; that is the AR groups showed lower weight gain than the dam-reared group until the time of weaning. No significant differences were detected between the growths of the two experimental diet groups. It should be noted that body weights were not reported beyond the weaning period in the above mentioned studies, hence comparison is not possible. From the later observation, it appears that the AR procedures may have induced some difference in ad libitum feeding behavior.

In our study, the mortality of pups was 12% in the artificially reared groups. Three pups in the n-3 Def group and one pup in the n-3 Adq group died after aspirating milk into the lungs. Different sizes of nipples were used that better fit the mouth of the pups as they aged so as to avoid bloating that can occur due to air aspiration through the gap between the incisors and nipple as we noted that this can lead to pup mortality.

Although the AR technique has several advantages, some limitations do exist, although future refinements will

likely overcome these. One such limitation is that it eliminates many of the maternal interactions experienced by naturally reared pups. Lack of these interactions may have profound effects on brain and behavioral development. Also, the presence or absence of some unknown factor(s) in the milk-substitute formula that are present in mother's milk may promote normal organ development, especially of the intestine [21, 34].

Other studies have used a mouse model for feeding a diet deficient in n-3 fatty acids including three [35]; two [36, 37]; and one generation models [38]. Because of the increasing availability of tools for genetic manipulation [39, 40], the mouse has become the most popular animal model; development of this technique will provide a means to perform studies involving nutritional manipulation of essential fatty acids in neonatal mice in conjunction with genetically derived enzymatic modifications of interest including desaturase knock out [41], fat1 [39] and SCD-1 [42] deficiency. In addition, it should be clear that any nutrient whose content can be controlled in the artificial milk can provide an independent variable for an AR experiment and so there should be many applications of this method for nutritional studies.

It was important initially to establish whether this "one generation" model can generate large enough losses in the nervous system as well as other organ levels of 22:6n3 so that functional changes can be observed. It must first be considered what the extent of brain/retinal DHA losses are necessary for behavioral/physiological parameters to be significantly altered. Lim et al. [43] have shown that adult rats with a 70% loss in brain 22:6n3 performed more poorly in spatial tasks. Weisinger et al. [44] showed that there was a loss in retinal sensitivity and b-wave implicit times in rats after three generations of n-3 deficiency. However, these rats had only a 55% loss of retinal 22:6n3, and showed no differences in α -wave amplitudes or in most of the phototransduction parameters measured. Moriguchi and Salem [45] have demonstrated, in a 22:6n3 repletion paradigm, that spatial task performance is altered when the brain level of 22:6n3 declines by 40% or more. Thus, a one generation model of n-3 fatty acid deficiency that better mimics the human situation but that still produces a substantial decline in brain and retinal 22:6n3 of 40–50% or more would be very valuable for the development of this field.

This method was shown to be an efficient means for inducing brain and peripheral organ n-3 fatty acid deficiency as the pups fed the n-3 Def formula exhibited a loss of 51% of their brain 22:6n3 by 20 weeks of age, replacing it primarily with 22:5n6. These changes were consistent with the proposal by Salem et al. [46] that reciprocal replacement of 22:6n3 with 22:5n6 should be extended to include other n-6 fatty acids like 20:4n6 and 22:4n6 since

for the case of the retina and brain, only when both 22:5n6 and 22:4n6 were summed together with 22:6n3 was reciprocal replacement of 22:6n3 complete at all time points when comparing n-3 fatty acid adequate and deficient diets. The liver, heart, plasma, and the retinal percentages of 22:6n3 were 91, 90, 86 and 29% lower, respectively, in the pups fed the n-3 Def milk formula relative to those fed the same formula to which 3.1% of 18:3n3 and 0.93% of 22:6n3 had been added. As expected then, the peripheral organ losses in 22:6n3 and other n-3 fatty acids was much more drastic than those observed in the nervous system. Thus, the present feeding method results in nutritional deficiencies comparable to those observed in multiple generational models and should prove useful for studies of 22:6n3 function in the nervous system as well as peripheral organs.

It must be noted here that the percentage of 22:6n3 in the n-3 Adq group in the heart reached 31%, a level much greater than that of the brain or retina, prompting us to investigate in which lipid classes the 22:6n3 was concentrated. Our data indicate that phosphatidylethanolamine and phosphatidylcholine were the major repositories of 22:6n3 in the mouse heart, with 22:6n3 contents of 40 and 29%, respectively. In a review by Wessels and Sedmera [47]; the authors concluded that, apart from the obvious differences in size, the mouse and human heart are anatomically remarkably similar throughout development. They also concluded that employing the mouse as a model system for the human heart is useful. This extremely high level of heart 22:6n3 in a diet containing 22:6n3 has not been previously noted, to our knowledge. It is also noteworthy that the level of 22:6n3 provided in our diet was less than 1 wt % of fatty acids, a level obtained in many modern diets. Perhaps the critical factor leading to a remarkably high 22:6n3 content in mouse heart is the feeding from the very beginning of life where fatty acid compositions are more malleable.

When comparing the level of 22:6n3 in the mouse heart versus that of the rat, the 22:6n3 content of the rat heart is much lower than the mouse heart reaching 10% for a diet containing only 18:3n3 (3.1% of 18:3n3 and no 22:6n3) and 15% for a diet containing 2.6% of 18:3n3 plus 1.3% of 22:6n3 (unpublished data). This then prompts the question of what this apparent species difference may be due to. The underlying differences in metabolism leading to this very significant response to dietary 22:6n3 between these species is unclear but it is noted that the murine heart has an elevated heart rate of 500–700 beats/min, whereas the rat has a heart rate of 300–400 beats/min [48]. It has previously been reported that 22:6n3 is concentrated in tissues, such as the hummingbird flight muscles, that have extremely high metabolic activity [49].

Observational, clinical, and experimental studies have demonstrated that long-chain n-3 PUFA supplementation reduces the risk of heart disease in humans including cardiac arrhythmias [50, 51]. In n-3 depleted rats, it was observed that within 2 h after intravenous bolus injection with medium chain-triacylglycerols: fish oil, the emulsion modifies several cationic events likely to be involved in contractile functions of aortic ring preparations [52]. A positive association between levels of circulating n-3 fatty acids derived from normal dietary variation and endothelial function was shown in young adults who smoked or had higher levels of fasting insulin, glucose or triglycerides. Given the central position of the endothelium in early atherogenesis, a protective influence of 22:6n3 may, in part, explain the epidemiological association between increased fish intake and reduced cardiovascular mortality and morbidity [53].

In a recent study by Garg et al. [17]; the authors demonstrated that short-term supplementation with a fish oil concentrate results in increased levels of 20:5n3 and 22:6n3, whereas the levels of the eicosanoid substrate, 20:4n6 decreased in the human atrium. However, more 22:6n3 than 20:5n3 is incorporated in the atrium total lipids (22:6n3/20:5n3 ratio of 2.54) and phospholipids (22:6n3/20:5n3 ratio of 2.78) despite the fish oil supplement supplying a higher amount of 20:5n3 than 22:6n3. The author also concluded that the enrichment of the phospholipid fraction with long-chain n-3 PUFA suggests that these fatty acids were readily available for release as non-esterified acids should an arrhythmic event occur. The accumulation of 20:5n3 and 22:6n3 was also observed during fish oil supplementation in myocardial fatty acids in humans [54] and that was at the expense of 20:4n6; 22:6n3 accumulated in atrial phospholipids more rapidly than did 20:5n3, even though 22:6n3 and 20:5n3 were present in equal proportions in the fish oil supplement used. The rapid accumulation of 22:6n3 was also reported in rat cardiac phospholipids without a similar increase in heart 20:5n3 content [13], and it was also confirmed in this mouse study; suggesting a specific mechanism for the uptake and/or retention of 22:6n3. The content of 20:5n3 in mouse cardiac muscle phospholipids was very low. This was apparent in both the total phospholipids (Table 7) and in all the major phospholipid classes examined in detail (Table 9). In the present study, consistent with these reports, the 20:5n3 content was very low in all tissues studied when dietary sources of 18:3n3 and 22:6n3 were provided.

In mammals, cardiolipin may contain up to 85 wt % of fatty acids as 18:2n6. However, this composition is known to be malleable as when the influence of maternal dietary fatty acids on the acyl composition of offspring cardiolipin was examined, feeding fish oil resulted in replacement of a substantial portion of 18:2n6 with 22:6n3 in 42-day-old

mice concomitant with a reduction in 18:2n6 from 62% (safflower oil fed) to 12% [55]. In the present study, the 18:2n6 content of the cardiolipin was 63% in the n-3 Def group and 41% in the n-3 Adq group. Watkins et al. [56] reported that cardiolipin did not accumulate more 22:6n3 than other phospholipid classes, and the mass of cardiolipin per g of heart did not change in response to a crocodile oil diet (containing 3% 22:6n3 and 1% 20:5n3) fed to weanling, 21-day-old mice until the 112th day of age. Heart phospholipids were enriched with the metabolic products of 18:3n3 in mice fed soybean oil suggesting that either 18:3n3 was converted to 22:6n3 within the heart itself or that the heart preferentially accumulated fatty acids from a plasma lipid pool enriched in 22:6n3. A novel observation in the present study was that in mice fed preformed 22:6n3, heart cardiolipin contained species with three and four 22:6n3 moieties. The occurrence of these rather extraordinary species has never been previously observed, to our knowledge. Together with phosphatidylcholine and phosphatidylethanolamine, the cardiolipin forms a repository for a high degree of 22:6n3 accretion in the mouse heart. This study lays the groundwork for studies of the unique biophysical role of tetra-22:6n3-cardiolipin species.

In conclusion, this study demonstrates the rather remarkable extent to which tissue fatty acid composition of internal organs, particularly the heart, but also nervous system tissues can be modified when the dietary fatty acid intake is controlled from the first days of life. The AR method employed here should be a boon to the study of EFA function, especially when combined with suitable genetically modified lines of mice. For example, desaturase knockout mice can be reared with or without particular essential fatty acids so that the relationship to physiological functions can be understood. It was notable that the mouse appeared to be a very responsive species in its organ fatty acid composition with respect to a diet containing preformed 22:6n3. Mouse heart phospholipids incorporated a very high level of 22:6n3 and a species of cardiolipin containing four 22:6n3 molecules were described for the first time.

Abstract The mechanism involved in the inhibition of testosterone (Te) biosynthesis after a sub-chronic exposure to low doses of dimethoate (D) was studied in rat interstitial cells (IC). Expression of COX-2 in IC isolated from D-treated rats increased by 44% over C data, while transcription of StAR decreased by approx. 50% and the expression of this protein was diminished by approximately 40%. PGE₂ and PGF_{2α} were increased by 61 and 78%, respectively. Te concentration decreased by 49% in IC homogenates. Concomitantly, plasma concentration of LH and FSH both increased. Arachidonic acid (ARA) and C₂₂ fatty acyl chains in phospholipids from IC mitochondrial fraction decreased by approx. 30% after D treatment. Protein carbonyls, lipoperoxides and nitrite content increased while α-tocopherol and the antioxidant capacity of the soluble cellular fraction decreased significantly. Stimulation with h-CG 10 nM overnight failed to overcome the inhibition caused by D on both Te biosynthesis and 3β- and 17β-hydroxysteroid dehydrogenases. Decreased Te biosynthesis may be attributed to (1) inhibition of StAR protein activity due to the stimulation of COX-2 and the overproduction of PGF_{2α}, (2) decreased stimulatory effect of ARA on StAR with a subsequent reduction in the availability of CHO for the androgenic pathway, and/or (3) indirect inhibition of steroidogenic enzymes by a lower transcriptional rate caused by elevated

PGF_{2α}. Rofecoxib administration prevents the deleterious effect(s) exerted by D.

Keywords Arachidonic acid · COX-2 · Dimethoate · Oxidative stress · Prostaglandins · Rat interstitial cells · StAR · h-CG · Rofecoxib · TROLOX

Abbreviations

C	Control group
CM	Cytoplasmic membrane
D	Dimethoate
FSH	Follicle-stimulating hormone
LH	Luteinizing hormone
LPO	Lipid peroxidation
MDA	Malonedialdehyde
N	Nucleus
OS	Oxidative stress
RNS	Reactive nitrogen species
PS	Protein synthesis
R	Rofecoxib
ROS	Reactive oxygenated species
StAR	Steroidogenic acute regulatory protein
T	TROLOX®
TBARS	Thiobarbituric acid-reactive substances
Te	Testosterone

Introduction

The growing amount of experimental evidence documenting endocrine dysfunction in male wildlife has led to the hypothesis that environmental contaminants adversely affect testosterone production and caused deleterious

effects on the male reproductive system [1]. In an interesting work, Carlsen et al. [2] reported that a significant worldwide decline in semen quality has occurred over the past 50 years. Retrospective studies performed in sperm banks from Paris [3] and London [4] have supported this conclusion. The hypothesis of environmental pollution as a causative factor is casually related to higher declines in sperm quality observed in developed countries characterized by important agrotechnical activities [5, 6]. Other authors reported that environmental chemicals can mimic estrogen action and also disrupt androgen signaling pathways [6]. Moreover, alterations were also observed not only in reproductive performance, but also in the incidence of cryptorchidism and testicular cancer [7]. Many contaminants demonstrated antiandrogenic activity both in whole animals and in receptor binding-in vitro assays [1]. Important evidence for this mechanism of action was obtained with the herbicide Linuron. This chemical agent binds to the androgen receptor with an affinity similar to that of flutamide, which is a potent antiandrogenic drug. As a result, feedback control to the pituitary is interrupted and serum LH and estrogen concentrations increase significantly. The ultimate outcome of Linuron exposure is Leydig cell cancer due to over-stimulation of steroidogenesis [8]. Several pesticides and their metabolites have similar effects [6, 9]. Currently, the levels of environmental exposure to these substances and their derivatives are completely unknown. Thus, predictions about alterations in male reproductive function or fertility cannot be made [6, 10]. This fact has generated considerable public and scientific concern about the relationship existing between environmental contaminants and alterations to the male reproductive system [11].

Some of the most used agrochemicals have been shown to disturb pro-oxidant/anti-oxidant balance in testicular cells and consequently decrease the androgen production [6]. Free radical generation in response to toxicants [12] plays different and complex roles in the Leydig cell physiology [6]. For example, high levels of corticosterone produced during oxidative stress may bring about, in part, the decline in testosterone biosynthesis since this steroid is able to induce Leydig cell apoptosis [13]. In addition, testosterone production is profoundly affected by the prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) level. The inducible enzyme cyclooxygenase-2 (COX-2) is responsible for the biosynthesis of $PGF_{2\alpha}$ from its precursor arachidonic acid (ARA). $PGF_{2\alpha}$ not only inhibits progesterone production but also activates its own biosynthetic pathway by induction of COX-2 via protein kinase C in an autoamplification cascade [14]. In this scenario it is possible to assume that pesticides induce oxidative stress (OS) and disturb the conversion of ARA into $PGF_{2\alpha}$ via COX-2. In addition, other laboratories have demonstrated that COX-2 and

$PGF_{2\alpha}$ are both inhibitors of Leydig cell steroidogenesis [14, 15].

In Leydig cells, cholesterol is converted to testosterone through various steps catalyzed by different enzymes [16]. The delivery of free cholesterol to the inner mitochondrial membrane is the true rate-limiting step of steroidogenesis and it is mediated mainly by the steroidogenic acute-regulatory protein (StAR) [16, 17]. The biological activity of this protein depends on many factors such as ARA, PGF levels, COX-2 activity, and free radical production in a complex interrelationship not fully understood yet [14, 15, 18–20]. StAR is also sensitive to various pesticides as demonstrated by Walsh et al. [21].

Some organophosphorus compounds are known to impair fertility, suppress libido, cause testicular degeneration, and a deterioration in semen quality [22]. Dimethoate (D; 2-dimethoxyphosphonylthio-*N*-methylacetamine) is an organophosphorus pesticide extensively used as a systemic insecticide and acaricide which proved to be neurotoxic [22] and to disturb StAR gene expression [21]. Toxicity of D on testicular Leydig cell function is still unexplored. Therefore, in the present study we aimed to investigate the action of a sub-chronic exposure of Wistar rats to low doses of D on Leydig cell steroidogenesis, free radical production, and StAR and COX-2 expression. The testis is the major site for testosterone production. It plays a crucial role in the development of secondary sexual characteristics and initiation, as well as regulation of spermatogenesis. Thus, reduction in testosterone production due to exposure to environmental toxicants (such as D) has the potential to adversely affect normal sexual development in humans.

Experimental Procedure

Chemicals

All chemicals used were of reagent grade and obtained from Sigma Chem. Co. (CA, USA, or Buenos Aires, Argentina) or Merck Laboratories (Darmstadt, Germany). Organic solvents were from Carlo Erba (Milano, Italy). α -Tocopheryl-diacetate (TROLOX[®], 98% pure) and rofecoxib (99% pure) were from Saporitti S.A., Buenos Aires, Argentina. Other chemicals employed were purchased from local commercial sources and they were of analytical grade. Dimethoate (2-dimethoxyphosphonylthio-*N*-methylacetamine) was obtained as a gift from INTA (Castelar, Argentina). Hormone measurements [luteinizing (LH), follicle-stimulating (FSH), total and free testosterone] were performed using commercial kits (KP7CT, KP6CT, KS24CT, and KS33CTN, respectively) from Radim (Radim SpA, Pomezia, Italy).

Animals and Treatments

Male Wistar rats weighing 190 ± 20 g with specific-pathogen free-certified status were used. Upon arrival, the rats were allowed to acclimatize for a week before starting the experiment. Rats were maintained under controlled conditions of temperature (25 ± 2 °C), and a normal photoperiod of 12 h dark and 12 h light. They were fed with standard Purina chow from Ganave S.A. (Santa Fe, Argentina) and water ad libitum. Clinical examination together with body weight evaluation was performed every week during the experiment. Animals were randomly divided into two groups of six rats each, assigned as control rats (C) injected i.p. with polyethylene-glycol 400 (PEG-400), or D-treated rats injected with 15 mg D/kg body weight dissolved in PEG-400. All animals were injected three times a week for 5 weeks. The dose used was in accordance with previous reports [23–26]. This model was chosen for simulation of a sub-chronic exposition to low doses of pesticide incorporated from the living environment [27]. Other experiment was designed to study the effect of the antioxidant α -tocopheryl diacetate (TROLOX[®]) and the COX inhibitor rofecoxib administered alone or in combination with dimethoate. In this experimental protocol TROLOX[®] (T) and rofecoxib (R) were dissolved in PBS with PEG-400 and administered i.p. to groups of 4 rats each at a doses of 12.5 and 5.0 mg/kg body weight, respectively. Two groups of rats received TROLOX[®] (CT) or rofecoxib (CR), other two groups were simultaneously injected with D and T (DT) or D and R (DR). Finally, other groups of animals were injected with the vehicle alone (C), dimethoate alone (D), or a combination of the three drugs (DTR). Animal maintenance and handling were in accordance with the NIH guide for the care and use of laboratory animals [28]. All procedures were approved by the local Laboratory Animal Bioethics Committee, Facultad de Ciencias Médicas, UNLP, Argentina.

Sample Collection

At the end of the treatment, the animals were decapitated. Blood was collected using heparin (10 UI/mL) as anticoagulant in graduated ice-cold polypropylene tubes. Plasma samples were immediately prepared by centrifugation ($4,000 \times g$, 10 min) and then stored at -80 °C until analyzed. Testes were rapidly excised, washed, weighed, and homogenized in ice-cold phosphate buffer 100 mM with 6 mM of EDTA pH 7.40 (3 ml of buffer to 1 g of tissue). Homogenates were stored at -80 °C until assayed.

Analytical Methods

Various biomarkers of oxidative stress and cell damage were measured in plasma and testicular interstitial cells.

Lipid peroxidation was assayed as authentic lipoperoxides (ROOHs) by the FOX assay [29]. ROOHs were expressed as nmol malondialdehyde (MDA)/mg protein. The sum of nitrates and nitrites ($[\text{NO}_x]$) was measured as the main end-metabolite products of nitric oxide (NO) and peroxy nitrite anion (ONOO^-) by the method of Miranda et al. [30]. Results were expressed as nmol of nitrites/mg protein. Protein carbonyls (nmol/mg of protein) were measured using the method of Reznick and Packer [31] as a biomarker of oxidative damage to proteins. We also measured parameters of the antioxidant defense system. The FRAP (ferric reducing ability of plasma) assay was determined by the method of Benzie and Strain [32] and the results were expressed as μM of equivalent TROLOX[®] or α -tocopheryl acetate. Vitamin E (α -tocopherol) was measured after extraction by the method of Buttriss and Diplock [33] using the HPLC technique of Bagnati et al. [34] which can detect and quantify both α - and γ -tocopherols. Total glutathione (GSH) was measured by the method of Anderson and Meister [35] and expressed as $\mu\text{mol}/\text{mg}$ of protein. Protein contents were determined according to the method of Bradford [36].

Cell Culture and Treatment

Technical procedure for Leydig cell isolation was described in detail in a previous report [37]. Briefly, Leydig cells were removed from the interstitial space of testicular tissue by mechanical shaking with collagenase (Sigma Chem. Co., type IV) in a metabolic incubator, at 34 °C, according to Suescon et al. [38]. Cells were suspended in Krebs Ringer bicarbonate glucose (KRBG) solution (pH 7.4), examined for viability (90%) by trypan blue exclusion [39], and counted in a hemocytometer to adjust cell concentration. Aliquots of cell suspensions were subjected to protein determination by the micromethod of Bradford [36]. Preparations of interstitial cells comprised a high percentage of Leydig cells. The homogeneity of cell preparations was assessed by means of the observation of smears fixed in acetone and stained with H&E. Interstitial cell preparations consisted of Leydig cells (79%) and 21% of spermatids, spermatocytes and small cytoplasmic fragments.

Functional Assay

The functional response of cultured interstitial cells was assayed by stimulation with chorionic gonadotrophin (h-CG, Ovusyn[®] from Syntex S.A., Buenos Aires, Argentina) 10 nM for 12 h. Cells were detached from the surface culture using mechanical harvesting, transferred to graduated polypropylene ice-cold tubes, and pelleted at $600 \times g$ for 10 min. The pellet was washed twice with sonication buffer (65 mM Tris-HCl, pH 7.0, containing 10% sucrose)

and resuspended in the same medium. Cellular homogenates were prepared by sonication (three 30-s bursts at medium power in a Heat Systems Ultrasonic sonicator model W-220F from Plainview, NY). Crude extracts were centrifuged at $2,000\times g$ for 15 min and the supernatants were used for hormone measurements.

Immunoblotting

Cells were homogenized by sonication as described above in Tris/HCl/sucrose buffer with a 1% antiprotease cocktail (Sigma Chem. Co, Bs. As., Argentina), and 2% SDS. After heating the samples (20 μ g) at 95 °C for 3 min with 10% mercaptoethanol, aliquots were supplemented with 10% glycerol and 0.01% bromophenol blue and loaded on 12% SDS-PAGE mini-slabs (Mini protean II, Bio-Rad, Hercules, CA). Proteins were electrophoretically transferred overnight to PVDF membranes (Bio-Rad, Hercules, CA) using a transfer buffer containing 25 mM Tris, 190 mM glycine and 20% methanol. COX-2 protein levels were analyzed using a polyclonal antibody (Santa Cruz Biotechnology Inc., CA) while StAR protein was detected with a rabbit polyclonal antibody generated against amino acids 88–98 of the 30 kDa StAR protein prepared according to Clark et al. [17]. Blots were re-analyzed for α -tubulin as the reference protein to control both loading and transfer processes. A polyclonal anti- α -tubulin antibody from Oncogene (San Diego, CA) was used. Immunocomplexes were revealed with peroxidase-labeled secondary antibodies from Amersham Pharmacia Biotech AB (Uppsala, Sweden). Semi-quantitation of Western blots was performed using the GeneGenius gel documentation system and GeneTools software from Syngene (Cambridge, UK). Results were normalized to α -tubulin signal and expressed as “fold change” relative to the control (basal assay) which was assigned a value of 1.

Northern Blot Analysis

To determine StAR mRNA expression, Leydig cells were collected by centrifugation at 2 °C ($3,000\times g$ for 10 min) and washed twice with PBS. Total RNA purification was performed with TRIzol reagent following the manufacturer's instructions (Gibco-BRL, Grand Island, NY). Quantification and purities were checked by determination of the absorbance ratio at 260/280 nm. Electrophoretic separation was performed in an agarose/formaldehyde gel with a linear gradient from 1 to 5%. Hybond-P membranes (Amersham, GE Healthcare Ltd., Buckinghamshire, UK) were used for blotting the slabs. Membranes were stripped with a buffer containing 15 mM NaCl, 15 mM Na citrate and 1% SDS (pH 7) for 40 min at 52 °C. StAR mRNA on the membrane was probed with biotin-labeled mouse StAR

cDNA and detected using the North2South Chemiluminescent Nucleic Acid Hybridization and Detection Kit from Pierce (Pierce Biotechnology Inc. Rockford, IL) following the manufacturer's instructions.

PGF_{2 α} and PGE₂ Assays

For assessment of PGF_{2 α} and PGE₂ contents in the incubation media of interstitial cells, samples were centrifuged at $15,000\times g$ for 20 min at 2 °C. Supernatants were filtered through Millipore 0.2 μ m filters and concentrated by lyophilization in a Telstar Lyobeta freeze drying unit (Madrid, Spain). The residues were dissolved with HCl 2 N adjusting the pH to 3.5. These solutions were injected into a 200-mg C₁₈ reverse phase Sep-columns (Peninsula Lab, Belmont, CA) and then eluted with ethyl acetate. The eluted fractions were evaporated to dryness under a nitrogen stream and reconstituted in buffers for enzyme-immuno assay (EIA) determinations. Prostaglandins were determined using commercially available kits Prostaglandin F_{2 α} EIA Kit and Prostaglandin E₂ Express EIA Kit from Cayman, Migliore Laclaustra S.R.L. (Buenos Aires, Argentina) with a minimum detection of 4 and 30 pg/mL, respectively. Intra- and inter-assay coefficients of variation were in the range of 8–12% for both kits.

Lipid Analysis

Total lipids were extracted by the method of Folch et al. [40]. The phospholipid fraction was separated from the Folch extracts by the micro-column chromatography method described elsewhere [41] and quantified as phosphorus content [42] after mineralization of an aliquot from the silicic acid partition. GLC of the FAME (fatty acid methyl esters) was performed as indicated in one of our previous papers [43] except that in this case we used a capillary column mounted on a Hewlett Packard HP 6890 Series GC System Plus (Avondale, PA) equipped with a terminal computer integrator and data station. The FAMES were identified by comparison of their relative retention times with authentic standards and mass distribution was calculated electronically by quantification of the peak areas. Eicosamonoenoic acid (20:1) was used as the internal standard. Cholesterol content was enzymatically measured according to Allain et al. [44] using a commercial kit from Wiener Lab. (Rosario, Argentina).

Steroidogenic Enzyme Activities

Appropriate aliquots of supernatants were employed to determine 3- β -hydroxysteroid-dehydrogenase (3 β HSD) and 17- β -hydroxysteroid-dehydrogenase (17 β HSD) [EC 1.1.1.51] enzyme activities following the method of

Marugesan et al. [45]. Sonicated interstitial cells were centrifuged (10,000 × g, 15 min, 1–2 °C). Supernatants were mixed with charcoal in order to remove the endogenous steroids and the samples were again centrifuged (10,000 × g 15 min, 2 °C). The reaction conditions were defined in preliminary experiments, in which the enzyme activities were tested by varying the incubation times and concentrations of substrates, protein, and cofactors. Assays were performed under initial velocity conditions in a reaction mixture (250 µL final volume) containing 10 µM of the steroid substrate (Δ^4 -androstenedione or pregnenolone for 17 β HSD and 3 β HSD, respectively), 1 mM NADPH (17 β HSD) or 0.2 mM NAD⁺ (3 β HSD), and 0.1 M phosphate buffer (pH 7.4). Mixtures were incubated under air in a spectrophotometric cell holder thermostated at 37 °C. The reactions were started by the addition of the supernatant aliquots and OD changes of the nicotinamide cofactor(s) were measured. The incubation mixture deprived of substrate(s) was used as control.

Statistical Analysis

Results were analyzed by one way analysis of variance (ANOVA) followed by the Tukey multiple comparison test. Data were expressed as means \pm standard deviation (SD) of six independent determinations. They were considered different with respect to control data at the level of significance of * $P < 0.05$ or ** $P < 0.01$. In some of the Figures or Tables where multiple comparisons can be done we used different superscript letters to indicate statistical significances among results. Correlation and regression analyses and data plotting were automatically performed with the aid of Systat (version 12.0 for Windows) from SPSS Science (Chicago, IL) or Sigma Scientific Graphing Software (version 8.0) from Sigma Chem. Co. (St. Louis, MO).

Results

Influence of Treatments on Growth Parameters

The influence of the treatments on feeding parameters is shown in Table 1. Dimethoate treatment did not influence significantly the water consumption (approximately 15 mL/day), the final body weights, the rate of body weight gain, or the food efficiency ratio. Similar conclusions were obtained for the other treatments assayed (R, T or combined administrations; data not shown). We did not find absolute and relative testicular weight changes. Pesticide exposure—alone or in combination with the other drugs—did not affect the animal behavior. Also, no visible signs of toxicity and/or cholinergic effects were observed during the entire experimental period.

Table 1 Main feeding parameters associated with experimental treatments

Parameters	Treatments	
	C	D
Initial body weight (g)	181.0 \pm 3.7	174.0 \pm 7.3
Final body weight (g)	307.5 \pm 13.7	288.8 \pm 20.9
Body weight gain (g)	126.5 \pm 3.4	114.8 \pm 5.5
Rate of body weight gain (g/day)	3.6 \pm 0.1	3.3 \pm 0.2
Food efficiency ratio ^a	9.5 \pm 0.2	8.7 \pm 0.3
Absolute testicular weight (g)	2.8 \pm 0.1	2.9 \pm 0.1
Relative testicular weight (mg/g) ^b	9.1 \pm 0.3	10.0 \pm 0.4

Values represent the means \pm SD ($n = 8$)

C control rats, D dimethoate-treated rats

^a Food efficiency ratio = [body weight gain (g)/food intake (g)] $\times 10^2$

^b Relative testicular weight = testis weight (mg)/body mass (g)

Testosterone Biosynthesis

Plasmas from dimethoate (D)-treated rats contained less free and bound testosterone compared to control animals (Table 2). In samples from dosed rats, a decrease of approximately 20% was observed in both parameters whereas the ratio free/bound testosterone was not modified. We observed a more significant decrease in testosterone levels (approximately 50%) when sonicated interstitial cells were analyzed. Plasma estradiol concentration was decreased in D-treated rats by approximately 30%, while LH and FSH were increased by 58 and 76%, respectively (Table 2).

Table 2 Hormone levels in plasma and interstitial cellular homogenates from control (C) or dimethoate-treated (D) rats

Determinations	C	D
Plasma		
Free testosterone (nM)	4.7 \pm 0.2	3.9 \pm 0.1**
Bound testosterone (nM)	22.2 \pm 1.5	17.1 \pm 3.0**
Free/bound testosterone $\times 10^3$	212 \pm 15	228 \pm 12
Estradiol (pg/mL)	15.1 \pm 0.6	11.0 \pm 0.4**
LH (mU/mL)	7.7 \pm 0.2	12.2 \pm 0.6**
FSH (mU/mL)	8.1 \pm 0.4	14.3 \pm 0.8**
Cellular homogenates		
Total testosterone (pmol/mg protein)	27.9 \pm 1.3	14.2 \pm 0.9**

Hormone levels were analyzed using RIA kits commercially available from Radim as indicated in the Experimental procedures. Data were expressed as the means \pm standard error of six independent determinations assayed in triplicate

Results significantly different to those of the corresponding control value are indicated with asterisks ($P < 0.01$)

Fig. 1 Testosterone production of interstitial cells isolated from control (*gray bars*) or dimethoate (D)-treated (*black bars*) rats incubated in the presence or not of h-CG 10 nM for 12 h. Results were the means \pm SD of six independent determinations performed by RIA as indicated in the “[Experimental procedure](#)”. Different superscript letters correspond to statistically significant differences at $P < 0.01$

Interstitial cell cultures from C or D rats exhibited a very different behavior after 12-h stimulation with 10 nM human chorionic gonadotrophin (h-CG) (Fig. 1). Cells isolated from C rats released four times the basal testosterone production after overnight stimulation. In contrast, the cells isolated from D-treated rats exhibited significantly decreased basal levels and they only doubled the concentration of testosterone after the functional test with h-CG. Thus, we observed a 50% reduction in androgen production in h-CG-stimulated cells from D rats (Fig. 1).

Direct measurement of the two key androgenic enzyme activities which regulate testosterone biosynthesis were performed in supernatants from interstitial cell sonicates after a h-CG stimulation assay (Fig. 2). Both enzymes activities, 3β - and 17β -hydroxysteroid dehydrogenases (3β HSD and 17β HSD, respectively) (Fig. 2A, B), were significantly lower (40–50%) after dimethoate treatment. Neither of the two enzymes exhibited a significant change after h-CG stimulation independent of the previous treatment of the animals and cells (Fig. 2).

Oxidative Stress Biomarkers

A condition of oxidative stress (OS) was clearly established in D-treated rats. This condition was characterized by a general failure of the antioxidant defense enzymes, a lower level of α -tocopherol and increased concentrations of oxidative damage biomarkers in plasma (data not shown). In interstitial cells of D-treated rats, a significantly higher level of ROOHs which are reliable biomarkers of lipid oxidative damage (Fig. 3A). Levels of protein carbonyls

Fig. 2 Steroidogenic enzyme activities in interstitial cells prepared from control (*gray bars*) or dimethoate (D)-treated (*black bars*) rats previously incubated or not with h-CG 10 nM for 12 h. Enzyme activities (A 3β HSD, B 17β HSD) were expressed as nmol of NAD or NADP/min mg protein and correspond to the means of six independent assays performed in duplicates \pm SD. See “[Experimental procedure](#)” for details. Different superscript letters correspond to statistically significant differences at $P < 0.01$

and $[\text{NO}_x]$ (nitrates + nitrites), which reflects the oxidative damage to proteins and the stimulation of NOS activity, respectively, were both increased by the administration of the pesticide (Fig. 3A). After dimethoate treatment, the total glutathione concentration increased (Fig. 3A) while α -tocopherol decreased (Fig. 3B). The FRAP assay was performed in sonicated interstitial cells from C and D rats as a biomarker of the total antioxidant ability. In cells from D-treated rats, FRAP was lower by approximately 30% compared with control animals (Fig. 3C).

StAR and COX-2 Expression

The level of StAR mRNAs was estimated by Northern blotting. A representative result is shown in Fig. 4A. Lanes 1 and 2 correspond to control interstitial cells while lanes 3 and 4 to cells isolated from D-treated rats. Chorionic gonadotrophin was added to the cultures analyzed in lanes 2 and 4. The same scheme was followed when the

Fig. 3 Oxidative stress biomarkers measured in interstitial cells from control (gray bars) or dimethoate-treated (black bars) rats. **A** Data for authentic lipoperoxides (ROOHs), protein carbonyls (PCs), nitrates + nitrites ([NO_x]), and glutathione (GSH) levels. **B** α-tocopherol concentration (α-Toc), **C** the assay of the total antioxidant capacity (FRAP). Each value was expressed as the mean of six independent determinations ±SD. Asterisks indicate significant difference with respect to control value **P* < 0.05 and ***P* < 0.01

expression of StAR or COX-2 proteins were tested by Western blotting (Fig. 4B). Relative quantification of the signals appeared in Fig. 5A and B. The h-CG stimulation provoked a significant increment of StAR at both transcriptional (Fig. 5A) and translational (Fig. 5B) levels. These increments were completely abolished by dimethoate treatment. Moreover, the pesticide evoked a reduction in the expression of StAR mRNAs, and also in its translation products (StAR protein). In contrast, dimethoate increased the biosynthesis of COX-2 protein at levels

Fig. 4 Expression of mRNA StAR (**A**) and protein level for StAR and COX-2 (**B**) in interstitial cells. Lanes were: 1 control cells, 2 control stimulated with hCG 10 nM for 12 h, 3 D-treated cells, 4 D-treated cells stimulated with h-CG. Results are representative of six different incubations run in duplicate. See details in the “Experimental procedure” part

which were very similar to those observed in both h-CG stimulated and non-stimulated cells (Fig. 5C).

Arachidonate Metabolism and Cholesterol Level

The analysis of interstitial cell phospholipids demonstrated that the content of total inorganic phosphate per mg protein was unaffected by dimethoate treatment (data not shown). However, the pesticide significantly modified the fatty acyl composition of membrane phospholipids (Fig. 6). Saturated palmitic and stearic acids were increased while arachidonic, docosapenta-, and docosahexaenoic acids were diminished. Similar alterations were observed in neutral lipids (data not shown).

The total lipid extract from the mitochondrial fraction was also analyzed by the absolute content of cholesterol and arachidonic acid (Table 3) using a coupled enzymatic procedure with cholesterol oxidase and quantitative capillary gas-liquid chromatography, respectively. Clear correlations between the androgen production and the content of these lipids were observed (Fig. 7). Testosterone concentrations in whole cells were linearly and positively correlated with cholesterol content ($r^2 = 0.92$) and arachidonate levels ($r^2 = 0.98$) in mitochondrial fractions from interstitial cells.

Cyclooxygenase-related metabolites of arachidonate were also studied in interstitial cells under basal or h-CG-stimulated conditions using EIA methods (Fig. 8). Prostaglandins F_{2α}, and its precursor (PGE₂), were both significantly higher in rats treated with dimethoate. Stimulation with h-CG provoked in both types of cellular cultures (control or D-treated) a slight—but not significant—change in the concentration of the prostaglandins analyzed compared with the corresponding reference culture (Fig. 8).

Fig. 5 Relative changes (RC) of the expression of StAR mRNA (A), StAR protein (B) or COX-2 protein (C), quantified by densitometry using the GeneGenius gel documentation system and GeneTools software from Syngene (Cambridge, UK). Results were normalized to α -tubulin signal and expressed as “fold change” relative to the control (basal assay) which was assigned a value of 1. Mean \pm SD. Different superscript letters correspond to statistically significant differences at $P < 0.01$

Antioxidant and COX-Inhibitor Effects

The effects of the antioxidant TROLOX[®] or the COX inhibitor rofecoxib on various experimental parameters

Fig. 6 Fatty acid composition of total phospholipids isolated from the mitochondrial fraction of interstitial cells prepared from control (gray bars) or dimethoate-treated (black bars) rats. Fatty acids were derivatized to methyl esters (FAMES) and analyzed by capillary gas-liquid chromatography under the conditions described in the “Experimental procedures”. FAMES were identified with authentic standards, quantified using eicosamonoenoic acid as internal standard and expressed as μ mol of fatty acid per mg cellular protein (mean of six independent analyses \pm SD). Double asterisks indicate significant difference with respect to control value at $P < 0.01$. Σ FA corresponds to the sum of other C₂₂ and C₂₄ fatty acids not identified in the chromatogram

measured on dimethoate-treated rats appear in Tables 4 (absolute values) and 5 (relative changes). Drugs were administered alone or in combination at dosages that effectively inhibited lipid peroxidation and COX-2 activity. TROLOX[®] produced a strong decrease in the formation of D-induced ROOHs. However, the hormonal alterations evoked by dimethoate administration (essentially decreased testosterone biosynthesis and raised levels of the main gonadotrophin) were not normalized by simultaneous treatment with D and T. The levels of ARA were not affected by the treatment with the antioxidant alone. In addition, the decreased level of ARA observed after D administration was not restored when the pesticide was associated with T. Injection of R raised the level of ARA and at the same time significantly decreased the biosynthesis of PGF_{2 α} . Interestingly, testosterone concentration in both plasma and cellular homogenates was slightly (but significantly) higher while LH was lower under R treatment. Simultaneous administration of D and R normalized hormonal disturbances induced by D; notwithstanding the production of ROOHs still persistent and markedly elevated (Table 4). The ARA and PGF_{2 α} D-induced changes were completely reverted by the opposite and proportional effects displayed by R (Table 5). When the three drugs were administered in combination (DTR) all the parameters of those of control rats were indistinguishable. From these

Table 3 Cholesterol and arachidonic acid levels of total lipids from the mitochondrial fraction isolated from interstitial cells from control or dimethoate-treated rats

Cells	Control		Dimethoate	
Treatment	None	+h-CG	None	+h-CG
Lipids				
Cholesterol (ng/ μ g protein)	27.1 \pm 5.0 ^a	63.6 \pm 15.0 ^b	20.4 \pm 5.2 ^c	16.2 \pm 5.6 ^c
Arachidonic acid (μ mol/mg protein)	36.2 \pm 6.6 ^a	57.3 \pm 3.2 ^b	25.5 \pm 5.0 ^c	31.2 \pm 4.3 ^c

Total lipids were extracted from the mitochondrial fraction of the interstitial cells prepared from control or dimethoate-treated rats after incubation with or without h-CG 10 nM for 12 h. Total lipid fractions were fractionated into neutral and polar lipids using silicic acid partition, and then analyzed for cholesterol and arachidonic acid levels using enzymatic and chromatographic methods as described in “[Experimental procedure](#)”. Results were expressed as the means of six independent determinations \pm 1 SD of the mean. Different superscript letters correspond to statistically significant differences at $P < 0.01$

Fig. 7 Linear regressions and linear correlation coefficients (r^2) for the relationship between cholesterol content of the mitochondrial fraction of interstitial cells and testosterone production (*upper panel*), or arachidonic acid level of the mitochondrial fraction of interstitial cells and testosterone production (*lower panel*). Data were obtained from basal or h-CG-stimulated cells from control or dimethoate-treated rats, and they were expressed as the means \pm SD of six independent measurements. Plots and r^2 were automatically generated by means of the statistical software described in the “[Experimental procedure](#)”

results, the main conclusion obtained is that there is an inverse proportionality between the changes induced by each drug assayed (D, T or R) that results in neutralization

Fig. 8 Prostaglandins (PG) production from interstitial cell suspension prepared from control (*gray bars*) or dimethoate (D)-treated (*black bars*) rats incubated in presence or absence of h-CG 10 nM for 12 h. PGE₂ (A) or PGF_{2 α} (B) were analyzed by EIA as described in the “[Experimental procedure](#)” section. Each datum is the mean \pm SD of six independent assays. Different *superscript letters* correspond to statistically significant differences at $P < 0.01$

of the effects when they are combined. For example, the decrease in testosterone or the increased biosynthesis of PGF_{2 α} produced by D were almost exactly compensated by simultaneous treatment with R. Also, it is evident that the generation of ROOHs does not parallel the changes of ARA concentrations suggesting that other fatty acids (in addition to ARA) are involved in the generation of free radicals.

Table 4 Main experimental parameters determined after dimethoate (D), TROLOX[®] (T), or rofecoxib (R) treatments to rats

Analytical parameters	Experimental groups						
	C	CT	CR	D	DT	DR	DTR
ARA ($\mu\text{mol}/\text{mg}$ cell protein)	15.5 \pm 0.7 ^a	16.2 \pm 0.8 ^a	19.4 \pm 0.9 ^b	9.8 \pm 0.1 ^c	10.1 \pm 0.5 ^c	15.3 \pm 0.6 ^a	14.9 \pm 0.8 ^a

Data are expressed as the means \pm SD (four independent determinations assayed in duplicate). C, control group (injected with vehicle alone). CT, CR and D were treated with TROLOX[®], rofecoxib or dimethoate, respectively. DT, DR, and DTR received combined administration of the drugs. Determinations were performed as described in the “[Experimental procedure](#).” Statistical comparisons (ANOVA plus Tukey’s test) among experimental groups within a same row were indicated with different superscript letters

Discussion

The increasing use for organophosphorus insecticides has introduced a serious and novel hazard for humans and livestock animals [22]. Dimethoate is one of the most used agrochemicals around the world. Experimental evidence indicates that it impairs fertility, suppresses libido, causes testicular degeneration, and deteriorates semen quality [22]. Despite its residual action, this drug is extensively used in horticulture as a systemic insecticide and acaricide for treating gardens, vineyards, and field crops, and it is also applied externally for the control of fly larvae in cattle [22]. Previous studies from other laboratories demonstrated its adverse effects on semen performance [22] which were attributed to the presence of the dimethyl group in the moiety [46]. In our experiments, the testes were macroscopically examined to find visible evidence of toxic effect(s). We observed considerable changes in appearance, volume, and consistence of both testes of treated rats that suggest tissue edema. However, we did not observe significant changes in absolute and/or relative weights such as those reported by Farag et al. [47]. This probably could be due to differences in animal species, time/route of treatment, and the dose of dimethoate administered. Since the wet weights were conserved, this finding may indicate loss of testicular-specific structural tissue. This was strongly supported by the aspects of the testes previously decapsulated, and it is in agreement with findings of Sayim et al. [48, 49] that revealed a dimethoate-dose depended histopathological features of rat testes. Alterations reported were characterized by moderate to severe seminiferous tubule degeneration as sloughing, atrophy, germ cell degeneration, and partial arrest of spermatogenesis [48, 49].

Dimethoate was also involved in hormonal unbalance. Thomas et al. [50] suggested that this pesticide could block

the uptake of steroid hormones at the interstitial cell receptor level. However, other research has previously proposed that dimethoate exerts a direct cytotoxic action not associated with alterations in LH, FSH, or other hormonal regulators implicated in androgen biosynthesis [51, 52]. The present work demonstrate that low doses of dimethoate administered i.p. chronically are able to produce significant alterations in the levels of circulating gonadotrophin hormones which raise in response to a decrease testosterone production. The LH and FSH increases may have important consequences in the differentiation status of Leydig cells. In fact, previous studies demonstrated that this chronic stimulation is closely related to increased cancer degeneration [8]. The estradiol level, which reflects testosterone metabolism, is also significantly reduced after dimethoate treatment. Our results agree with an early investigation by Afifi et al. [22] who reported a decrease testosterone level of rats dosed orally with dimethoate for 2 months. We are unaware of any other studies that have examined in more detail the hormonal profile after dimethoate intoxication.

Oxidative stress is a well-known consequence of intoxication with environmental contaminants. This condition was repeatedly observed under metal overload [14, 53–56] or after intoxication with agrochemicals [20, 57, 58]. Some of the detrimental effects produced by pesticides in the male reproductive system were explained as a consequence of the exacerbated free radical production caused by these drugs [59]. It was proposed that most pesticides may act as pseudosubstrates for the generation of free radicals, which in turn, can damage P450 enzymes [6]. However, this suggestion is not accepted for all researchers since antioxidant supplementation failed to restore testosterone biosynthesis after intoxication by, for example, octylphenols [57]. Our results indicate that cultures of interstitial cells isolated from D-treated rats have a clear

oxidative stress condition hallmarked by a general loss of the antioxidant capacity and elevation of biomarkers of OS damage. Interestingly, we observed an increased amount of the water-soluble antioxidant glutathione that could be ascribed to a compensatory mechanism of scavenging against the increased production of free radicals induced by dimethoate. This explanation is in agreement with previous experimental evidence indicating that γ -glutamyl-cysteinyl synthetase—which controls the biosynthesis of glutathione—is induced by a prolonged oxidative stress condition [60, 61]. At the same time, the decreased level of α -tocopherol could be the consequence of its increased rate of consumption within the lipophilic compartment of the interstitial cells. The loss of the lipid-soluble antioxidant capacity correlates well with the observed increase in the ROOHs production and the lower FRAP values. These findings led us to the idea that the testosterone level may be restored by antioxidant treatment. However, in agreement with the results reported by Muroño et al. [57] (for the octylphenol inhibitory effect on testosterone biosynthesis) we did not find any positive effect caused by concomitant administration of D and T (Tables 4, 5).

From this scenario, a first explanation for the decreased testosterone production could be proposed. Biosynthesis of this androgen in Leydig cells depends on the activities of two key enzymes (3β HSD and 17β HSD) which were inhibited in our experimental system in a clear correlation with the observed decrease in both the production of testosterone by Leydig cells and the plasma testosterone level. During the last years, free radical production has been linked to its possible role in reducing steroidogenesis [62–65]. In addition, studies from Murugesan et al. [20, 45, 66] and Kostic et al. [67] suggested that androgenic dehydrogenases could be significantly inhibited by free radical overproduction. Thus, we think that—as judged by the normalization of ROOHs—OS induced by dimethoate treatment can be reverted by T administration; however, this fact may not contribute at least crucially to the loss of the androgenic capacity via 3β - and 17β -dehydrogenase inhibition. These results support the assumption that D does not act as a pseudosubstrate that binds to the steroid-binding site of P450 enzymes (P450_{scc} and P450_{c17}) disrupting hydroxylation and leading to electron leakage and free radical production [57]. Also, it is unlikely that OS condition affects significantly the availability of NADPH that is required for the normal hydroxylation of steroids during P450 pathway for testosterone biosynthesis.

Another question concerning OS and steroidogenic activity can be discussed. It is well known that lipids can be destroyed by free radical attack. In particular, lipid peroxidation is now considered to be the main mechanism by which oxygen- or nitrogen-derived radicals can cause damage leading to impaired normal cellular function in

testis [68]. Mammalian spermatozoa, being rich in polyunsaturated fatty acids (PUFAs) are more susceptible to oxidative damage resulting in sperm deterioration [6, 49]. Similar consequences can be assumed for Leydig cells which are also very rich in PUFAs [69]. Induction of OS by pesticides has been a focus of research over the last decade as a possible mechanism for infertility [6, 70]. We observe that after intoxication with dimethoate a significant loss of PUFAs occurred in interstitial cells, specially arachidonic, docosapenta- and hexaenoic fatty acids (Fig. 6). C₂₂ PUFAs are involved in spermatogenesis [71] while arachidonic acid (ARA) is directly linked to the androgenic activity of Leydig cells [16, 19]. Thus, it is possible that chronic OS may be an important mechanism for the arachidonate-dependent loss of steroidogenic ability since this fatty acid is essential for the biological activity of the steroidogenic acute regulatory protein (StAR) [72]. ARA level in Leydig cells is controlled by a hormone-regulated mechanism which involves an acyl-CoA synthetase (ACS4) and a mitochondrial acyl-CoA thioesterase (Acot2). Recent findings have demonstrated that, in steroidogenic cells, ARA release does not operate through the activation of the phospholipase A₂ pathway [73]. Experimental evidence supports the idea that ARA is released from the cholesteryl-ester pool and immediately converted into arachidonoyl-CoA by ACS4 [19]. This thioester binds to the acyl-CoA binding protein (DBI), which in turn, binds to the translocator protein (TSPO) located in the outer mitochondrial membrane. This would possibly facilitate a direct transference of arachidonoyl-CoA into the mitochondria [72]. In addition, ARA is transformed into lipoxygenated products which induce the transcription of StAR gene [72]. Thus, the conversion of cholesterol to testosterone is limited by the transport of cholesterol from the outer to the inner mitochondrial membrane. This event is controlled by StAR activity [21] and also by the ARA level [73, 74]. We have demonstrated that both ARA and cholesterol concentration are decreased in cells isolated from dimethoate-treated rats. Reduction of ARA, which in turn leads to the reduction of mitochondrial cholesterol content, could be produced by oxidative destruction of PUFAs due to D-induced OS, by an increased utilization via the COX-2 pathway, or both. Previous studies with rat mitochondrial fractions subjected to peroxidative conditions support the assumption that PUFA content can be effectively depleted by overproduction of free radicals [75]. In addition, recent studies from our laboratory indicated that plasmalogen subfraction is particularly enriched in ARA and very sensible to oxidative damage [76]. In addition, another pathway for ARA metabolism which is very active in interstitial cells, is the cyclooxygenase route that converts the precursor ARA into prostaglandins G₂, H₂, E₂, D₂ and F_{2 α} [77]. Cyclooxygenase isoenzymes types

Table 5 Statistical comparisons and percent changes among experimental parameters determined after dimethoate (D), TROLOX® (T), or rofecoxib (R) treatments to rats

Data were obtained from Table 4 and assayed by ANOVA plus Tukey's test. Percentage changes (expressed as means ± SD) for a determined treatment were calculated as $[X - C] \times 100/C$, being X and C the tested and control paired data, respectively, within each group under comparison

ARA arachidonic acid, PGF_{2α} prostaglandin F_{2α}, ROOHs authentic hydroperoxides, Te testosterone

Statistical significances were indicated by asterisks (* $P < 0.05$ and ** $P < 0.01$), or with "n.s." (non-significant difference respect to the corresponding control group)

I (COX-1) and II (COX-2) are key enzymes that function coordinately and are controlled differentially by regulating the amount of ARA and lipid peroxides [78]. Previous studies from other laboratories suggested that COX-1 and COX-2 may not be important for male reproductive performance, at least in mice [77]. However, this early general view is being challenged by recent findings. COX-2 is overexpressed in human testis from men with impaired spermatogenesis, infertility, or degenerative disorders [79, 80]. Moreover, PGF_{2α} has been reported to significantly decrease StAR expression in porcine, rat, and human tissues [81–84]. In addition, Frungieri et al. [74] demonstrated that PGF_{2α} inhibition of h-CG-induced testosterone production in Leydig cells is accompanied by the down-regulation of both StAR and 17βHSD. Moreover, we observed elevated levels of trophic hormones in peripheral blood which failed to restore the androgenic capacity. This was in agreement with a previously demonstrated blockage of PGF_{2α} of the LH- or FSH-stimulatory pathway [85]. In vitro studies using MA-10 mouse Leydig cells further proved that inhibition of COX-2 activity significantly increased StAR protein expression and steroid production [86]. Our results strongly suggest that COX-2 is implicated in the inhibition of testosterone biosynthesis by dimethoate. We observed a significant increase in the level of COX-2 protein in cells isolated from dosed animals which correlated with the higher concentrations of both PGE₂ and PGF_{2α}. Concomitantly, StAR protein is diminished at both the gene expression and protein levels. These results also agree with those of Arakane et al. [87] who reported an inhibition of StAR gene expression by PGF_{2α}. Concerning the role of COX-2 in testosterone production, we demonstrated that simultaneous administration of rofecoxib and dimethoate normalizes the hormonal levels to control values although the COX inhibitor was not able to modify the

ROOHs production (Tables 4, 5). From these results, we assume that the main target of dimethoate effect on steroidogenic route is COX-2 activity that leads to the overproduction of PGE₂ and F_{2α} and subsequent inhibition of the StAR regulatory mechanism.

The status of androgenesis is usually tested (in vivo or in vitro) by the commonly accepted method of h-CG stimulation followed by the measurement of the testosterone production [12]. Interestingly, in our experimental system, the functional assay of stimulation with physiological concentration of h-CG does not normalize the changes induced by dimethoate, suggesting that the pesticide could act independently of gonadotrophin receptor-mediated events. This fact should be considered as another mechanism by which dimethoate can depress the pathway for androgen production. It remains to be explored whether this inhibitory response was initially triggered by overproduction of free radicals, and to what extent the overall effect can be attributed to the other(s) (synergistic) mechanism(s) involved. For example, previous studies by Diemer et al. [85] demonstrated that free radicals per se are able to inhibit StAR activity. However, results from Tables 4 and 5 suggest that OS may not have a crucial role in blocking StAR signal cascade directly or indirectly via gonadotrophin receptors. Whenever this crosstalk may (or not) occur, it seems quite possible that the ARA level was not (at least not entirely) depleted as a consequence of the oxidative stress condition since administration of D or R decrease and increase, respectively, the level of the acid in a clear correspondence with the COX-2 activity changes (Tables 4, 5). Thus, the increased production of PGE₂ and PGF_{2α} should be produced—as observed in our experiments—through an important stimulation of the COX-2 activity which is inversely associated to the concentration of its substrate (ARA). As a consequence, StAR activity

Fig. 9 Effects of chronic dimethoate intoxication on the steroidogenic status in rat testis. Dimethoate (*D*) evokes a general failure in the antioxidant system and exacerbates the production of lipoperoxides (*ROOHs*) which leads to an oxidative stress condition (*OS*). This effect is effectively blocked by administration of TROLOX® (*T*). The arachidonic acid (*ARA*) level decreases by conversion into peroxides principally due to exacerbated COX-2 activity rather than the destruction by free radicals. This condition diminishes the efficiency of the cholesterol transport complex (*CTC*) located at the mitochondrial membrane (*MM*). *ARA* is converted by the induced cyclooxygenase-2 (*COX-2*) into prostaglandin F_{2x} (*PGF_{2x}*) that inhibits the activity of the *CTC*. Rofecoxib (*R*) blocks the activity

of COX-2 and prevents the deleterious effect(s) of dimethoate (*D*). Administration of *D* also reduces the expression of the gene which encodes the steroid acute regulatory protein (*StAR*) and its translation into active protein. The decreased production of *StAR* further inhibits the input of cholesterol (*CHO*) by the mitochondria. All these effects act in concert to decrease the availability of *CHO* and its conversion into testosterone. Additional effects should be exerted on the activities of the 3 β - and 17 β -hydroxysteroid dehydrogenases (*HSD*), and on the signal transduction of LH and FSH which are increased by the pituitary–gonadal axis (*PGA*) in response to the decreased production of testosterone. *CM* cytoplasmic membrane, *N* nucleus, *PS* protein synthesis

would be inhibited indirectly by either a decreased availability of *ARA* or an increased concentration of PGF_{2x} . As reported previously, steroidogenesis is sensitive to small changes in *StAR* protein expression [21]. This question is important since *StAR* plays a key role in steroid production by gonads as well as in the steroidogenesis of adrenal glands. As a result, a disruption in *StAR* protein expression may impair more than just fertility. The biosynthesis of mineralo- and glucocorticoids may affect carbohydrate metabolism, immune system, and water balance. Such a general disturb may underline many of the toxic effects of environmental pollutants [21, 88].

As a conclusion, we propose that dimethoate inhibits testosterone biosynthesis by multiple mechanisms of action (Fig. 9). Chronic intoxication, even at the low doses used in our experiments, provokes an oxidative stress which in turn raises the level of lipoperoxides and the activity of COX-2. As a consequence, a decreased rate of the *StAR*-stimulated cholesterol transport into the mitochondria was observed. Dimethoate treatment also blocks the activities

of the hydroxysteroid dehydrogenases and impairs the LH- or FSH-dependent signal for stimulation of androgen biosynthesis by a mechanism(s) that do not depend crucially on the *ROOHs* level. At the same time, increased COX-2 protein decreases *StAR* transcription and translation. The subsequent elevation of PGF_{2x} further inhibits *StAR* protein action decreasing both the availability of cholesterol and the rate of testosterone biosynthesis probably by inhibition of the 17 β HSD mRNA transcription. The final biological effect suggests that the androgenesis status could provide a highly sensitive test for estimating the damage exerted by residual agrochemicals in chronically exposed populations. These conclusions should stimulate further research concerning the androgen functionality and the hormone level of men involuntarily exposed to dimethoate or others organophosphorus compounds. This fact also raised concern about the generality of the toxic action(s) of this kind of drugs on both the reproductive functions and the other metabolic pathways controlled by steroid hormones.

Acknowledgments This study was supported by a grant from Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina. We would like to thank Mrs. Agustina Zardis de Cobefias, Eva Illara de Bozzolo, and Norma Cristalli for their excellent technical assistance.

Abstract Recently, two polymorphisms (rs1884052 and rs3778099) of estrogen receptor α (ER-alpha) gene were identified as being associated with primary quantitative bone mineral density (BMD) in a genome-wide association (GWA) study in Framingham cohorts. In this study we aimed at investigating the association of rs1884052 and rs3778099, and another polymorphism (rs2234693) located at intron 1 of the ER-alpha gene with BMD, body mass index (BMI), glucose, triglyceride, and total cholesterol

(CHO) levels in Chinese Hans. We recruited 425 consecutive adult volunteers who had a physical examination in the Jinan Maternity and Child Care Hospital. We did not observe significant association of rs1884052 and rs3778099 with BMD, BMI, glucose, triglyceride, and total cholesterol (CHO) levels. For rs2234693, increased levels of BMD for hip, spine or whole-body regions were consistently observed in TT/TC genotype carriers than in CC genotype carriers, although the board line significance diminished after adjusting for age and gender. However, significant association of rs2234693 with glucose and CHO levels were observed in our sample. Subjects with TC/CC genotypes were associated with an increased level of glucose ($p = 0.013$) and CHO ($p = 0.032$) levels than subjects with TT genotypes. In conclusion, we did not confirm the association of rs1884052 and rs3778099 with BMD originally discovered in a GWA study; however, we made novel discoveries that rs2234693 was associated with glucose and CHO levels in Chinese Hans.

GWA	Genome-wide association
LD	Linkage disequilibrium
SD	Standard deviation
SNP	Single nucleotide polymorphism

Introduction

Bone mineral density (BMD), the major determinant and predictor of osteoporotic fracture risk [1], is a quantitative trait determined by multiple environmental, genetic, and metabolic factors. Despite years of hard research identifying major genetic variants, determining BMD in the general population remains elusive. The genes linked to BMD in one population have often been replicated inconsistently in other populations.

Recently, Kiel et al. [2] conducted a genome-wide association (GWA) study to examine genetic associations with ten primary BMD quantitative traits using the Affymetrix 100 K single nucleotide polymorphism (SNP) Gene Chip marker set in the Framingham cohort. Several genes (e.g., methylenetetrahydrofolate reductase, low-density lipoprotein receptor-related protein 5, vitamin D receptor, ER- α) were associated with BMD in this study. Among them, rs3778099 and rs1884052 in the ER- α gene were identified to be associated with femoral BMD and neck width, respectively.

The ER- α gene encodes an estrogen receptor, a ligand-activated transcription factor composed of several domains important for hormone binding, DNA binding, and activation of transcription. ER- α is expressed widely in human reproductive or non-reproductive tissues, including bone [3], cerebrovascular endothelial system [4], skeletal muscle [5], central nervous system [6], involved in several pathological processes in these tissues. ER- α knockout mice also exhibit insulin resistance, impaired glucose tolerance, and obesity, which support pleiotropic effects on metabolic phenotypes of ER- α [7].

In the present study, we aimed at investigating the association of rs1884052 and rs3778099, and another important polymorphism (rs2234693) located in intron 1 of the ER- α gene with BMD and metabolic phenotypes in Chinese Hans. China is composed of 56 ethnic groups. Among them the Han nationality accounts for about 92% (1.1367 billion) of the overall population, and the other 55 minority nationalities make up the remaining 8% [8].

Methods

Subjects

The study was performed at Jinan Maternity and Child Care Hospital from January to December of 2006. A total of 425 consecutive adult volunteers who had a physical examination (203 male and 222 female), aged 18–74 years (average 48.9 ± 12.5), were recruited. All the participants were of the same ancestry of the Jinan population. To

improve the representation of Jinan Han subjects, we recruited subjects from a variety of sources by advertisement (the relatives and friends of hospital workers, the relative and friends of the inpatients and outpatients at Jinan Maternity and Child Care Hospital, members of the social gathering, and blood donors). Participants were excluded if they reported to have chronic disease or were taking medication. Whole body scans were performed using a dual energy X-ray absorptiometry (DXA) scanner (Lunar Prodigy densitometer; Wisconsin, MA, USA), using the pencil beam mode to determine areal BMD (g/cm^2) of the total body, spine and hip. Body weight and height were measured to calculate BMI (the body weight in kilograms divided by the square of height in meters). The blood specimens were drawn after overnight fasting and subjected to centrifugation immediately and analyzed within 8 h for glucose, triglyceride, and CHO. Serum glucose, triglyceride, and CHO concentrations were measured using enzyme methods and commercial kits (Centronic, GmbH, Germany) on Advia 1650 Autoanalyzer (Bayer Diagnostics Leverkusen, Germany). Written informed consent was obtained from all subjects in this study. The Human Ethics Committee of Jinan Maternity and Child Care Hospital approved the research.

Genotyping

Blood was taken into EDTA-containing receptacles and DNA samples were prepared from blood, using a method described by Boom et al. [9]. Sample DNA (10 ng) was amplified by PCR following the recommendations of the manufacturer. Fluorescence was detected by using an ABI 7900HT and the alleles were scored by using Sequence Detection Software (ABI). The assay identifications of the Taqman probes of rs2234693, rs31884052 and rs3778099 were C_3163590_10, C_11918426_10 and C_2823740_10, respectively. Laboratory personnel were blinded to clinical status. In addition to quality control samples included in each batch by the laboratory, blinded quality control samples were included to monitor the reproducibility of the genotyping assays. The concordance of duplicate samples was >99%.

Statistical Analysis

Values are expressed as the means \pm standard deviation (SD). All rs2234693, rs1884052 and rs3778099 were divided into two genotype groups (TT vs. TC/CC; CC vs. CG/GG; TT vs. TC/CC). The differences between genotype groups were tested by using analysis of variance (ANOVA) and analysis of covariance (ANCOVA) including gender and age as covariates. For haplotype construction, genotype data were used to estimate

inter-marker Linkage Disequilibrium (LD) by measuring pair-wise D' and r^2 and defining LD blocks. Haplotype block structure was determined using Haploview version 3.32 [10].

Results

The genotype successful rates of rs2234693, rs1884052, and rs3778099 were 99.3, 99.6, and 98.4%, respectively. The frequencies of TT, TC, and CC genotypes and C allele of rs2234693 were 0.38, 0.46, 0.16, and 0.39, respectively. The frequencies of CC, CG, and GG genotypes and G allele of rs1884052 were 0.42, 0.46, 0.12, and 0.35, respectively. The frequencies of TT, TC, and CC genotypes and C allele of rs3778099 were 0.41, 0.45, 0.14, and 0.36, respectively. LD analysis revealed that the pair-wise LDs of the rs1884052, rs3778099, and rs2234693 were weak (r^2 ranged from 0 to 0.04) (data not shown).

Although the hip BMD, spine BMD, and total BMD were decreased in the CG/GG genotype carriers than in CC genotype carriers for rs1884052 and TC/CC genotype carriers than in TT genotype carriers for rs3778099, non-significant association were observed. Lack of association was also observed for BMI, glucose, triglyceride, and CHO with respect to rs1884052 and rs3778099 (Table 1).

For rs2234693, increased levels of hip BMD, spine BMD, and total BMD were consistently observed in TT/TC genotype carriers in comparison with CC genotype carriers, although the board line significance of spine ($p = 0.034$) and total BMD ($p = 0.040$) diminished after adjusting for age and gender. However, we observed a significantly higher level of glucose ($p = 0.013$) and CHO ($p = 0.032$) in TC/CC genotype carriers than in TT genotype carriers. The significant association of rs2234693 with glucose and CHO remained after adjusting for covariate age and gender ($p = 0.029$, and $p = 0.045$, respectively) (Table 2).

Discussion

In the present study, we did not find the association between rs1884052 and rs3778099 and BMD originally discovered in a GWA study conducted on Caucasians [2]. Nevertheless, we observed a significant association of rs2234693 with spine BMD, total BMD, glucose, and CHO levels in Chinese Hans. SNP rs2234693 is located in intron 1 of the ER-alpha gene. The functional significance of rs2234693 is still unknown. However, rs2234693 is located within a potential transcription factor binding site, in which subjects carrying CC genotype results in a relatively high level of ER-alpha transcription as compared with CT carriers [11]. Alternatively, rs2234693 is in strong LD with

Table 1 Clinical characteristics of subjects according to rs1884052 and rs3778099 genotypes in Hans

Variables	rs1884052		rs3778099

another TA repeat polymorphism in the promoter region of the ER-alpha gene in Caucasians [12].

Although the functional significance of rs2234693 remains to be elucidated, the relationship of this polymorphism with bone phenotypes was studied extensively. In women of four races/ethnicities who were premenopausal or in early perimenopause, Greendale et al. [13] observed that African American and Japanese women with the rs2234693 CC genotype had higher LS-BMDs than did their peers with the TT genotype ($p = 0.009$ and $p = 0.04$, respectively). In postmenopausal Japanese women, Kitamura et al. [14] discovered that the effect of lean tissue mass on femoral neck BMD was significantly larger for those with the TC/CC genotype than for those with the TT genotype for the rs2234693 polymorphism. In a cohort of 11-year-old European Caucasian girls, Tobias et al. [15] observed that differences in spinal area-adjusted bone mineral content in late puberty were two times greater in girls who were homozygous for the C alleles of rs2234693 ($p = 0.001$). However, In a meta-analysis of individual-level data involving standardized genotyping of 18,917 individuals in eight European centers, Ioannidis et al. [16] did not find a statistically significant effect of rs2234693 on BMD in adjusted or unadjusted analyses. Based on the above conflicting results and our observation on BMD in Chinese Hans, the role of rs2234693 polymorphism with regard to BMD needs further exploration.

There are also studies addressing the role of rs2234693 to cardiovascular or metabolic phenotypes. In a population-based offspring cohort of the Framingham Heart Study and in a meta-analysis including more than 7,000 whites in five cohorts from four countries, Individuals with CC genotype of rs2234693 were found to have a substantial increase in the risk of myocardial infarction [17, 18]. In an estrogen replacement and atherosclerosis trial with respect to 10 ER-alpha polymorphisms, Herrington et al. [19] discovered that the 18.9% of the women who had the rs2234693 CC genotype had an increased HDL cholesterol level with hormone-replacement therapy that was more than twice the increase observed in the other women. Interestingly, rs2234693 had been associated with lower waist circumference [20] and lower small LDL concentration [21, 22] in White Americans in the Framingham cohort, while this allele was associated with reduced insulin sensitivity index in multigenerational African-Americans and Hispanic Americans [23]. The C allele of rs2234693 was also associated with increased glucose and CHO concentration in our Chinese Hans. As far as we know, we are the first to report the association of rs2234693 with CHO concentration. However, in a recent study conducted in Framingham cohorts, Klos et al. [24] observed the association between other intron 1 genetic variants rs9322331 and rs9340799 and apoC-II, and TG concentrations in 15-year-olds

and younger. The relationship between rs2234693 and rs9322331 and rs9340799 needs further exploration.

The rs1884052 is located in intron 4 of the ER-alpha gene and 128 kb away from rs2234693. The rs1884052 is located in intron 7 of the ER-alpha gene and 255 kb away from rs2234693. The pair-wise LD constructed by rs2234693, rs1884052, and rs3778099 is weak in our Han population (D' ranged from 0 to 0.21, r^2 range from 0 to 0.04). Thus, rs2234693, rs1884052, and rs3778099 may represent different haplotype blocks in the Han population, and the effects of rs2234693 on BMD, glucose and CHO levels are independent of rs1884052 or rs3778099 in our samples.

In this study, we did not replicate the association of rs1884052, and rs3778099 with BMD originally discovered in a GWA study, which needs cautious explanation. To increase the representative of the Jinan Han general population, we examined a sample of adults of different ages. For females, we also included subjects before and after menopause. However, the sample size of the present study is relatively small which may decrease the statistical power to detect the genotype phenotype association, especially when the age spread of the subjects is broad. The negative results of rs1884052 and rs3778099 may be due to lack of statistical power owing to insufficient sample size. The differences in genetic background may be another explanation. As could be seen from the data released from the International Hapmap Project (http://www.hapmap.org/cgi-perl/gbrowse/hapmap26_B36/), the frequency of G allele of rs1884052 varies between Caucasians (10%), Chinese (31%), Japanese (35%), and Africans (2%). The frequency of C allele of rs3778099 are also varies between Caucasians (7%), Chinese (33%), Japanese (32%), and Africans (19%).

In summary, we did not confirm the association of rs1884052 and rs3778099 with the BMD originally discovered in a GWA study; however, we made novel discoveries that rs2234693 was associated with metabolic phenotypes in Chinese Hans. Due to the relative small sample size of our study and the novel observation that rs2234693 is linked to CHO levels in Chinese, the role of these polymorphisms on metabolic phenotypes needs further exploration in other large sample studies.

Abstract CHO-LY-B cells have been useful in studies of sphingolipid metabolism and function because they lack serine palmitoyltransferase (SPT) activity. Cloning and sequencing of the SPT1 transcript of LY-B cells identified the mutation as a guanine to adenine change at nucleotide 738, causing a G246R transformation. Western blots revealed low expression of the mutant SPT1 peptide, but activity was not detectable by mass spectrometric analysis of [¹³C]-palmitate incorporation into sphinganine, sphingosine, 1-deoxysphinganine, or 1-desoxymethylsphinganine. Treatment of LY-B cells with chemical chaperones (DMSO or glycerol) increased the amounts of mutant SPT1 as well as SPT2, but SPT activity was not restored. This study has established that G246R mutation in hamster SPT1 results in the loss of SPT activity.

Keywords Sphingolipid · Sphingoid base · Serine palmitoyltransferase · Mutant enzyme

Abbreviations

1-deoxy-Sa	1-Deoxysphinganine and 1-desoxymethylsphinganine
1-desoxymethyl-Sa	1-Desoxymethylsphinganine
BSA	Bovine serum albumin
CHO	Chinese hamster ovary
Cer	Ceramide
DMSO	Dimethyl sulfoxide
FBS	Fetal bovine serum
FB ₁	Fumonisin B ₁
GAPDH	Glyceraldehyde 3-phosphate dehydrogenase
HA	Human influenza hemagglutinin
HexCer	Hexosylceramide
HSN1	Hereditary sensory neuropathy type 1
LCB	Long-chain base
LCB1	Long-chain base subunit 1
LCB2	Long-chain base subunit 2
LC ESI-MS/MS	Liquid chromatography electrospray ionization mass spectrometry
LY-B	Chinese hamster ovary cells strain with defective SPT
LY-B/cLCB1	LY-B cells stably transfection with LCB1 cDNA
PBS	Phosphate buffer saline
PDB	Protein data bank
Sa	Sphinganine
SaP	Sphinganine 1-phosphate
SM	Sphingomyelin
So	Sphingosine
SoP	Sphingosine 1-phosphate

SPTLC2	Serine palmitoyltransferase long-chain base subunit 2
TBST	Tris buffered saline Tween-20

Introduction

Sphingolipids are a structurally diverse and important family of compounds [1] characterized by having a sphingoid base backbone [2]. Sphingoid base biosynthesis is initiated by serine palmitoyltransferase (SPT; EC2.3.1.50) [3], an activity that is essential for cells in culture unless the medium is supplemented with sphingolipids [4]. SPT is comprised of two [3], and possibly more [5, 6], subunits and homozygous deletion of two subunits (Sptlc1 and Sptlc2, also known as LCB1/LCB2 or SPT1/SPT2) in mice is embryonic lethal [7]. Mutations in *SPTLC1* are responsible for human hereditary sensory neuropathy type 1 (HSN1) [8, 9].

LY-B cells lack SPT activity due to mutation of *Sptlc1* [4], and have been useful tools for studies of de novo sphingolipid biosynthesis and the functions of sphingolipids [4]. This report describes the point mutation that results in the loss of SPT activity in LY-B cells, and notes that small amounts of SPT1 polypeptide can be detected by Western blotting, especially when the cells are treated with ‘chemical chaperones’ [10] such as DMSO and glycerol, but without restoration of activity.

Experimental Procedures

Materials

Chinese hamster ovary (CHO) derived lines LY-B and LY-B/cLCB1 (which are stably transfected with the Chinese hamster LCB1 cDNA to restore SPT activity) were available from previous studies [4]. Ham’s F12 medium was from Gibco (Carlsbad, CA) and fetal bovine serum was obtained from Hyclone (Logan, UT). The sources for the antibodies were BD Biosciences (San Jose, CA) for the anti-LCB1 monoclonal antibody, Cayman (Ann Arbor, MI) for the anti-SPT2 monoclonal antibody, Sigma (St. Louis, MO) for the anti-beta actin and anti-HA antibodies, Ambion (Austin, TX) for the anti-GAPDH antibody, and David Uhlinger (Johnson & Johnson Pharmaceutical Research & Development, Raritan, NJ) for another anti-

SPT1 antibody [11]. The enhanced chemifluorescence (ECF) Western blotting kit was purchased from GE healthcare (Piscataway, NJ). Mass spectrometry internal standards were obtained from Avanti Polar Lipids (Alabaster, AL) and [U-¹³C]-palmitic acid was purchased from Cambridge Isotope (Andover, MA). Fumonisin B₁ (FB₁) was obtained from Biomol (Plymouth Meeting, PA). All other reagents and solvents were of high quality.

Cell Culture and Treatments

LY-B and LY-B/cLCB1 cells were cultured in Ham’s F12 medium containing 10% fetal bovine serum, penicillin G (100 U/ml) and streptomycin sulfate (100 µg/ml) in 5% CO₂ at 37 °C. During stable isotope labeling studies, the media was supplemented with 0.1 mM [U-¹³C]-palmitic acid complexed with equimolar fatty acid free BSA (Calbiochem, Gibbstown, NJ). After 12 or 24 h, depending on the experiment, the incorporation of the stable isotope into sphingolipids was measured by liquid chromatography, electrospray ionization tandem mass spectrometry (LC ESI-MS/MS) as previously described [12] except as noted below.

To analyze whether LY-B and LY-B/cLCB1 cells produce both ‘typical’ (i.e., sphinganine and sphingosine) and ‘atypical’ sphingoid bases (1-deoxysphinganine and 1-desoxymethylsphinganine) [13, 14], 25-µM FB₁ was added to the medium 1 h before addition of 0.1 mM [U-¹³C]-palmitic acid–BSA complex to cause the sphingoid bases to accumulate [13].

For chemical chaperone treatment, the LY-B cells were grown to ~50% confluence and changed to media supplemented with different concentrations of DMSO (up to 3%) or glycerol (up to 1 M) for 24 h. To determine how this affected SPT amount, the SPT1 and SPT2 peptides were visualized by Western blotting as described below. GAPDH was used as the protein loading control because DMSO and glycerol influence actin expression [15–17]. To determine how SPT activity was affected, the cells were incubated for 12 h in the same medium supplemented with 0.1 mM [U-¹³C]-palmitic acid–BSA complex then analyzed by LC ESI-MS/MS.

Cloning and Sequencing of SPT1 from LY-B cells

Total RNA was extracted from LY-B cells by the Absolutely RNA Miniprep Kit (Qiagen, Valencia, CA) and reverse transcribed to cDNA using the cDNA Synthesis System Kit (TaKaRa, Mountain View, CA). PCR was performed to amplify the SPT1 transcript using primers (5′-atggcgatggcggcgaggca and 3′-ctacagcagcagcctgggca), which represent the start and stop codon for hamster SPT1 open reading frame. The amplified PCR transcript was

ligated into pUC18 cloning vector and restriction digested with EcoRI to determine the clones with the correct inserts. 15 selected clones were sequenced (Nevada Genomics Center, Reno, NV) and compared to wildtype CHO SPT1 mRNA by multiple sequence alignment using T-coffee [18].

Western Blotting

Cells were rinsed with PBS then scraped from the dishes using PBS containing complete mini protease inhibitor cocktail (Roche Diagnostics, Indianapolis, IN), lysed by brief sonication, incubated for 30 min at 25 °C with Benzonase Nuclease (Novagen, Madison, WI), then boiled briefly in Tris-HEPES-SDS (100 mM Tris, 100 mM HEPES, pH 8.0, 3 mM SDS) before loading onto a 12% SDS-PAGE (Pierce, Rockford, IL) minigel (40 µg of protein/well) and electrophoresed. The separated proteins were transferred onto a nitrocellulose membrane (Whatman, Florham park, NJ) and blocked with 5% milk-TBST (Tris buffered saline Tween-20) (20 mM Tris-HCl, pH 7.6, 137 mM NaCl, 0.1% Tween-20) solution. The membrane was incubated with primary antibodies (anti-LCB1, diluted 1:2,000; Anti-SPT1, diluted 1:3,000; anti-SPT2, diluted 1:1,000) overnight at 4 °C and washed with TBST solution before being probed with a secondary anti-fluorescein antibody (ECF kit) for 1 h. The protein bands were visualized by incubating the membrane with the ECF substrate for 30 min and imaged using FLA-3000 imager (Fujifilm, Stamford, CT). Pixel density was measured using Multi Gauge (Fujifilm) image analysis software. Statistical significance was defined at a *P* value of 0.05 using the Kruskal–Wallis rank sum test in R v2.61 (www.r-project.org).

LC ESI-MS/MS Analysis of Sphingolipids

The sphingolipids were analyzed in positive ionization mode by LC ESI-MS/MS [12] using ABI 3000 triple quadrupole and ABI 4000 quadrupole-linear ion trap mass spectrometers (Applied Biosystems, Foster city, CA). Since the major fragmentation products of ceramides (Cer) and ceramide monohexosides (HexCer) (e.g., ions with *m/z* 264.4 for sphingosine and *m/z* 266.4 for sphinganine) retain the carbon atoms originally derived from palmitoyl-CoA, the sphingolipids made de novo via incorporation of [^{13}C]-palmitate into the sphingoid base backbones were determined by adding 16 mass units to the precursor-product pairs for species labeled in only the sphingoid base backbone, and by adding 32 mass units to the precursor ion and 16 to the product for compounds labeled in both the fatty acid and the sphingoid base. Since these product ions are of very low abundance from sphingomyelins (SM) [12],

the incorporation of [^{13}C]-palmitate into the sphingoid base backbones of SM was determined by treatment of an aliquot of the lipid extract with the phospholipase D from *Streptomyces chromofuscus* (Sigma) to produce ceramide 1-phosphates [19, 20], which do provide definitive information about [^{13}C] labeling of the sphingoid base backbone [12, 21]. This treatment was conducted by incubating dried lipid extracts with 50 units of the enzyme suspended in 0.1 ml of 100 mM Tris-HCl, pH 8.0, and 3 mM decylglucopyranoside (Sigma), at 37 °C for 30 min. The reaction was dried by speedvac and analyzed by LC ESI-MS/MS.

Analysis of the biosynthesis of sphinganine (So), sphingosine (Sa), 1-deoxysphinganine (1-deoxy-Sa), and 1-desoxymethylsphinganine (1-desoxymethyl-Sa) [14, 22] from cells incubated [^{13}C]-palmitate and 25-µM FB₁ was conducted by LC ESI-MS/MS in positive ionization mode using multiple reaction monitoring with Q1 and Q3 set to pass the following precursor and product ions: 316.5/298.3 ([^{13}C]-So), 318.5/300.3 ([^{13}C]-Sa), 302.4/284.4 ([^{13}C]-1-deoxy-Sa), and 288.3/270.3 ([^{13}C]-1-desoxymethyl-Sa). The LC conditions were the same as described previously [13, 22], i.e., using a reverse phase LC column (Supelco 2.1 × 50 mm Discovery C18 column, Sigma, St. Louis, MO) and a binary solvent system at a flow rate of 0.6 mL/min; the binary system began with equilibration of the column with 60% mobile phase A (CH₃OH/H₂O/HCOOH, 58/41/1, v/v/v, with 5 mM ammonium formate) and 40% mobile phase B (CH₃OH/HCOOH, 99/1, v/v, with 5 mM ammonium formate), sample injection and elution for 1.3 min in the same mobile phase, followed by a linear gradient over 2.8 min to 100% B (then a column wash with 100% B for 0.5 min followed by re-equilibration with the original A/B mixture before the next run).

Homology Modelling of Mutant SPT1

Homology modelling was performed by comparing SPT with two POAS enzymes [23], with one being the SPT from *Sphingomonas paucimobilis* (PDB ID: 2JG2) [24]. The crystal structures of PDB ID: 2JG2 and 1FC4 were selected as templates because they were identified to have 30% sequence identity with hamster SPT1 by a blast search of the PDB database. The sequences of the templates and mutant SPT1 protein were aligned using T-coffee [18], refined manually into a PIR format alignment file that was used to generate the homology model with Modeller v6.1 [25], which provides a consensus structure of the target protein without a bias towards a single template [26, 27], and visualized by VMD v1.8.6 [28]. The 2JG2 template has 55% identity with hamster SPT1 for the amino acid residues located within a 5-Å radius of the mutated amino acid residue, R246, of SPT1 from LY-B cells.

Results and Discussion

Analysis of the Gene Sequence for Mutant SPT1 in LY-B Cells

Sequencing of the mutated SPT1 from LY-B cells revealed a guanine to adenine mutation at nucleotide residue 738, which would result in the substitution of Arg for Gly246, which is conserved across numerous species (*C. griseus*, *M. musculus*, *H. sapiens* and *S. cerevisiae*), as shown in Fig. 1a. To investigate the impact of G246R substitution on SPT1, a homology model was prepared and residues within 5 Å of G246R were compared to 2JG2 template by multiple sequence alignment, which revealed 55% sequence homology. The analysis revealed the presence of non-polar residues such as Val, Leu and Phe within 3–5 Å distance from the point mutation, while polar residues Glu and Ser were conserved between SPT1 and 2JG2, which may play a role in protein folding. The steric hindrance resulting from G246R substitution in a conserved region of SPT1 may destabilize the protein structure.

Analysis of Mutant SPT1 Polypeptide in LY-B Cells

Previous studies have not detected an SPT1 peptide in LY-B cells by Western blotting [4], however, a very faint

Fig. 1 Sequence comparison and homology model of the SPT1 mutant protein of LY-B cells. **a** Protein sequences of SPT1 were compared from LY-B cells, CHO, human, mouse and *S. cerevisiae* using T-coffee. The point mutation G246R in LY-B cells is indicated by an asterisk. **b** This homology model for mutant SPT1 from LY-B cells was prepared using Modeller v6.1. The illustrated figure shows the G246R mutation (indicated in a ball-and-stick representation) to be located in a pocket of hydrophobic residues (Phe279, Leu282, Val289, Leu247) was visualized by VMD

band is discernable when larger amounts of protein (40 µg) are examined using two antibodies (anti-LCB1 and anti-SPT1) (Fig. 2a, b) but not using an antibody to another polypeptide epitope not found in the cells (HA) (Fig. 2c). Also shown is the immunoblotting of SPT1 in LY-B/cLCB1 cells, which have been stably transfected with the wild-type SPT1 gene (Fig. 2a, b).

Analysis of Mutant SPT Activities in LY-B Cells

To ascertain whether this small amount of mutant SPT1 afforded detectable de novo sphingolipid biosynthesis, cells were incubated with [¹³C]-palmitic acid and analyzed for incorporation of [¹³C] into the sphingoid base backbone (with free sphingoid bases in Fig. 3a and complex sphingolipids in Fig. 3b–d); LY-B/cLCB1 cells were used as a positive control because they have SPT activities comparable to wild-type CHO cells [4]. When all of the subspecies are summed, the amounts of backbone [¹³C]-labeled sphingolipids in the LY-B/cLCB1 cells at 6 h were 62 ± 0.3 pmol Cer/mg protein, 54 ± 0.8 pmol

Fig. 2 Western blots of SPT1 in LY-B and LY-B/cLCB1 cells. Whole cell lysates of LY-B and LY-B/cLCB1 cells were prepared and equal amounts (40 µg) of protein were separated by an SDS-PAGE gel. Replicate membranes were probed with **a** a commercial LCB1 antibody; **b** an independent anti-SPT1 polyclonal antibody, and **c** an anti-HA antibody as a negative control. The detection of β-actin with an anti-β-actin antibody was used as a protein loading control

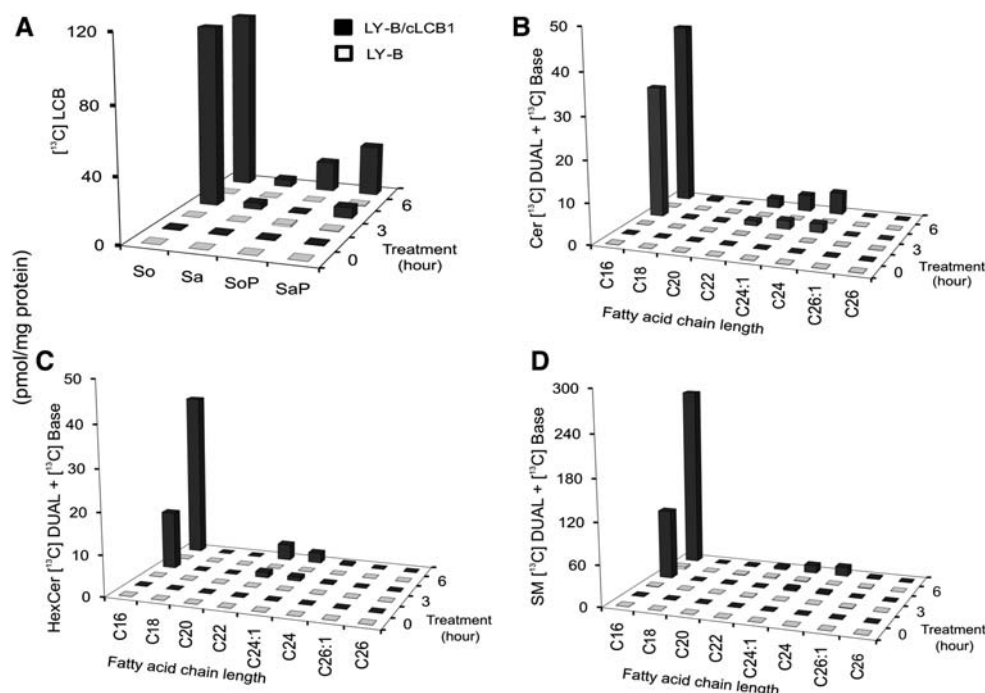

Fig. 3 Comparison of de novo sphingolipid biosynthesis in LY-B and LY-B/cLCB1 cells. LY-B and LY-B/cLCB1 cells were incubated with 0.1 mM [^{13}C]-palmitic acid for 0, 3 and 6 h and the sphingolipids labeled in the sphingoid base alone (BASE) plus the sphingoid base and fatty acid (DUAL) were measured by LC ESI-MS/MS. The *black bars* represent the sphingolipids in LY-B/cLCB1 cells while the *white bars* indicate the LY-B cells. **a** [^{13}C]-labeled long-

chain bases (LCB) sphingosine *So*, sphinganine *Sa*, sphingosine 1-phosphate *SoP*, and sphinganine 1-phosphate *SaP*. **(b–d)** provide the sum of the label in the BASE and DUAL subspecies of ceramide *Cer*, monohexosylceramides *HexCer*, and sphingomyelins *SM*, based on variation in the chain length of the amide-linked fatty acid (shown by chain length:number of double bonds)

HexCer/mg protein and 300 ± 14 pmol SM/mg protein, for a total of ~ 416 pmol/mg protein; for LY-B cells, the amounts were below the limits of detection for *Cer* and *HexCer* (~ 0.1 pmol/mg protein) and very low for *SM* (5.5 ± 16 pmol SM/mg protein) which, based on the high noise in the signal (reflected in the high SD), might be due to other compounds with similar ionization characteristics. Thus, even counting the possibility that this represents *SM*, the maximum amount of labeled backbone sphingolipids in the LY-B cells would only $\sim 1\%$ that in LY-B/cLCB1 cells. This is in agreement with a previous study [4] which has shown that SPT activity in the microsomal fraction of LY-B cells was less than 5% of that in CHO-K1 cells.

As has been shown before [4], although LY-B cells are defective in sphingolipid biosynthesis de novo, they contain appreciable amounts of sphingolipids if grown in medium that contains sphingolipids (e.g., from serum). In these studies, the pmol of unlabeled sphingolipids/mg protein for LY-B versus LY-B/cLCB1 cells (measured by LC ESI-MS/MS) were, respectively: 140 ± 18 versus $1,073 \pm 17$ for *Cer*; 122 ± 7 versus 447 ± 87 for *HexCer*; and $3,474 \pm 452$ versus $5,143 \pm 167$ for *SM* (data not shown).

As another way to assess sphingoid base biosynthesis, the cells were incubated with FB_1 to allow accumulation of the [^{13}C]-labeled sphingoid bases which are otherwise rapidly N-acylated to complex sphingolipids, and thus less easily tracked. These results are shown in Fig. 4 as the relative ion yields for the precursor/product pairs as they elute from the reverse phase column. Production of [^{13}C]-*So* (Fig. 4a), [^{13}C]-*Sa* (Fig. 4c), [^{13}C]-1-deoxy-*Sa* (Fig. 4b) and [^{13}C]-1-deoxy-methyl-*Sa* (Fig. 4d) were readily detected with the LY-B/cLCB1 cells, but the signal was not above background for the LY-B cells, which further confirms the conclusion from Fig. 3 that the LY-B cells do not synthesize detectable amounts of sphingoid bases de novo. The appearance of [^{13}C]-sphingosine in LY-B/cLCB1 cells was somewhat surprising because desaturation of sphinganine is thought to occur only after N-acylation [29], but it is possible that this concentration of FB_1 did not completely block [^{13}C]-*Cer* biosynthesis and this [^{13}C]-sphingosine arose from turnover.

Partial Stabilization of Mutant SPT in LY-B Cells

Some misfolded proteins can be stabilized by so-called chemical chaperones such as DMSO and glycerol [30–32].

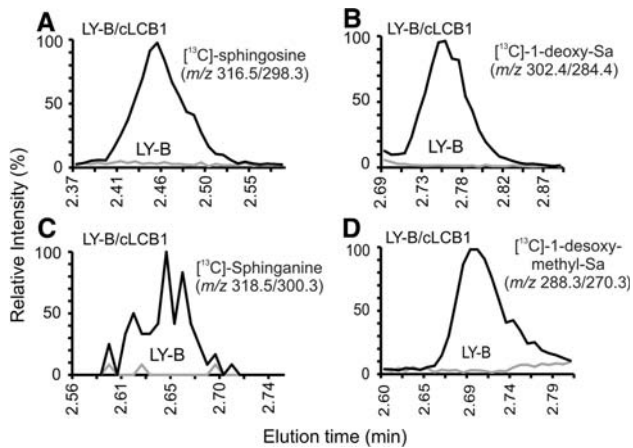

Fig. 4 Relative amounts of typical and atypical [^{13}C]-labeled sphingoid bases produced by LY-B and LY-B/cLCB1 cells upon co-treatment with FB_1 . Shown are the relative ion intensities of the shown precursor/product pairs in the LC ESI-MS/MS eluates. The LC retention times for these species matched that of standards for these compounds (not shown). The samples for these analyses were obtained by incubating LY-B and LY-B/cLCB1 cells with 0.1 mM [^{13}C]-palmitic acid and 25 μM FB_1 for 24 h; the *grey line* indicates LY-B cells and the *black line* represents LY-B/cLCB1 cells

When LY-B cells were treated for 24 h with DMSO or glycerol at concentrations where they have previously been effective [30, 32], there were noticeable increases in both SPT1 and SPT2 by Western blotting (Fig. 5, upper), with

Fig. 5 Elevation of the amounts of SPT1 and SPT2 in LY-B cells treated with chemical chaperones. LY-B cells were treated with DMSO (*left panels*) or glycerol (*right panels*) at the shown concentrations for 24 h then analyzed by Western blotting (*upper panels*), with GAPDH as the loading control. The lower panels are the relative differences in protein amounts as estimated from the pixel

the average increases in five experiments being between two and threefold (Fig. 5, lower). Lower concentrations had no effect, and higher were toxic (data not shown). In case these treatments also resulted in restoration of SPT activity, the incorporation of [^{13}C]-palmitate into sphingolipids was measured after LY-B cells had been treated with either 3% DMSO or 1 M glycerol for 24 h (the [^{13}C]-palmitate was added to the same medium and the cells were incubated for 12 h before extraction for sphingolipid analysis by LC ESI-MS/MS). As noted earlier, the ion yields for the [^{13}C]-labeled species were very low, but by manually averaging the ion counts in the samples versus the background, we would estimate that the amounts of newly made sphingolipids (i.e., [^{13}C]-labeled in the sphingoid base backbone) were 2.0 ± 0.5 pmol/mg protein for the LY-B cells in medium alone, 1.6 ± 0.2 pmol/mg protein for the LY-cells incubated with 3% DMSO and 2.3 ± 1.2 pmol/mg protein for LY-B cells in 1 M glycerol. Therefore, there was no evidence that the small amounts of SPT1 detected upon treatment of the cells with these chemical chaperones restored SPT activity.

Concluding Comments

The finding that the sequence of the SPT1 transcript from LY-B cells has a G246R substitution is not surprising because these cells were produced using ethyl methanesulfonate [4], a mutagen that causes the random replacement of

densities of the bands from five independent Western blots (*bottom panels*), with the standard error indicated by the *bars*. Ratios that were significantly different from the control (no treatment, 0) at $P \leq 0.05$, as determined by the Kruskal–Wallis rank sum test, are indicated by an *asterisk*

guanine(s) with adenine. Furthermore, the very low amounts of detectable mutant SPT1 polypeptide is consistent with the translated protein being unstable, which would be predicted upon localization of a positively charged Arg in a hydrophobic region of the enzyme, as suggested by the homology model [33]. It was worthwhile, nonetheless, to test for possible SPT activity given the recent discovery that SPT is able to produce not only sphinganine (and downstream sphingosine) but also the atypical sphingoid bases, 1-deoxysphinganine (from alanine) and 1-desoxymethylsphinganine (from glycine) [13, 22]; furthermore, it has been suggested that these are elevated in the mutated SPTLC1 found in human sensory neuropathy type 1 (HSN1) [14]. However, the LY-B cells produced no detectable sphingoid bases of any of these types.

Therefore, for most studies, the presence of small amounts of mutant SPT1 polypeptide is not likely to interfere with the investigation. Its presence should be kept in mind, nonetheless, during investigations where the residual protein might become stabilized and complicate interpretation of studies of protein–protein interactions or other phenomena.

Abstract HMG-CoA reductase (HMGCR) is an enzyme involved in cholesterol synthesis. To investigate the contribution of the *HMGCR* gene to lipids and lipoprotein subfractions in different ethnicities, we performed an association study in the Multi-Ethnic Study of Atherosclerosis (MESA). In total, 2,444 MESA subjects [597 African-Americans (AA), 627 Chinese-Americans (CHA), 612 European-Americans (EA), and 608 Hispanic-Americans

(HA)] without statin use were included. Participants had measurements of blood pressure, anthropometry, and fasting blood samples. Subjects were genotyped for 10 single nucleotide polymorphisms (SNPs). After excluding SNPs with minor allele frequency <5%, a single block was constructed. The most frequent haplotype was H1 (41–56%) in all ethnic groups except AA (H2a, 44.9%). Lower triglyceride level was associated with the H2a haplotype in AA and H2 in HA. In HA, H4 carriers had higher levels of triglyceride and small low-density lipoprotein (s-LDL), and lower high-density lipoprotein cholesterol (HDL-c), while carriers with H7 or H8 had associations with these traits in the opposite direction. No significant association was discovered in both CHA and EA. The total variation for triglyceride that could be explained by H2 alone was 2.6% in HA and 1.4% in AA. In conclusion, *HMGCR* gene variation is associated with multiple lipid/lipoprotein traits, especially with triglyceride, s-LDL, and HDL-c. The impact of the genetic variance is modest and differs greatly among ethnicities.

EA	European-Americans
HA	Hispanic-Americans
SNPs	Single nucleotide polymorphisms
BP	Blood pressure
DM	Diabetes mellitus
LD	Linkage disequilibrium
MAF	Minor allele frequency
HWE	Hardy-Weinberg equilibrium
GLM	General linear model
GWAS	Genome-wide association study

Introduction

Elevated triglyceride (TG), low levels of high-density lipoprotein cholesterol (HDL-c), and elevated small, dense low-density lipoprotein particles (s-LDL) have been established as important risk factors for cardiovascular diseases (CVD) [1]. Several studies have revealed ethnic differences in the variation in lipid/lipoprotein traits [2, 3]. Compared to other ethnic groups, despite a higher prevalence of hyperglycemia, hypertension, and obesity, the prevalence of hypertriglyceridemia and low HDL-c is lower in blacks [2–4]. In contrast, Asians had higher TG and lower HDL-c than whites despite the lower body mass index (BMI) [5]. The interethnic disparity in lipid/lipoprotein profile could not be solely explained by the differences in environmental or nutritional factors [2].

Genetic effects on lipid/lipoprotein phenotypes have been shown in numerous studies. Atherogenic lipoprotein phenotype was demonstrated to segregate in Caucasian families [6], and heritability of LDL particles was estimated to range from 0.34 to 0.60 in Caucasian and Hispanic families [7–10]. Linkage studies have reported several chromosome loci with lipid/lipoprotein traits in multiple ethnicities [11–15]. Two independent groups [11, 15] have reported a promising locus on 5q13–14, which suggests as a potential candidate gene the HMG-CoA reductase gene (*HMGCR*). This locus was linked to TG and total cholesterol (TC) levels in Turkish/Mediterranean families [15] and to LDL peak particle diameter and TG levels in Québec families [11].

HMGCR is the rate-limiting enzyme in cholesterol biosynthesis and is the target of statin therapy [16]. Pharmacokinetic studies have identified interethnic differences in statin responses [17, 18]. Previous studies [19, 20] have shown that the *HMGCR* gene contributed to the differences in response to statins. A major role of *HMGCR* alternative

splicing in influencing lipid response to statin therapy [21] and LDL-c variation [22] has been shown in the previous reports. Although the *HMGCR* gene was associated with the baseline LDL-c, it has not been clarified to what extent the *HMGCR* gene contributes to lipids and lipoprotein subfractions in multiple ethnic groups. To investigate the contribution of the *HMGCR* gene to the lipid/lipoprotein traits in different ethnicities, we utilized the Multi-Ethnic Study of Atherosclerosis study (MESA) to test the association between the *HMGCR* gene and a comprehensive profile of lipid and lipoprotein subfractions in African-Americans (AA), Chinese-Americans (CHA), European-Americans (EA), and Hispanic-Americans (HA). We used a tagged-single-nucleotide-polymorphisms (SNPs) approach to assess gene variation comprehensively.

Methods

Subjects

MESA is a prospective cohort study designed to study the progression of subclinical cardiovascular disease, consisting of 6,814 subjects who were free of clinical cardiovascular disease at entry. The participants were recruited from six communities (Baltimore, Chicago, Forsyth County, Los Angeles County, northern Manhattan, and St. Paul). The sampling procedures have been described in detail [23] and are available at <http://www.mesa-nhlbi.org>. A subcohort of 2,880 MESA subjects (720 in each ethnic group with matched age and gender) were randomly selected from subjects who gave informed consent for genetic studies. After excluding subjects with statin use, we included 2,444 subjects in the current study (597 AA, 627 CHA, 612 EA, and 608 HA).

Phenotyping

All data were collected at the first MESA examination (2000–2002), when participants had measurements taken of blood pressure (BP), anthropometry, and fasting blood samples. Three resting BP readings were recorded, and hypertension was defined as a mean systolic BP \geq 140 or diastolic BP \geq 90 mmHg, or use of antihypertensive medication. Diabetes mellitus (DM) was defined as a fasting glucose $>$ 6.88 mmol/L or use of antidiabetic medication.

Using CDC-standardized methods, lipid levels were measured on samples obtained after an overnight fast. LDL-c was calculated in plasma specimens having a TG value $<$ 400 mg/dL by the Friedewald equation. Measurements for lipoprotein particles have been previously described [24].

Genotyping

Genomic DNA was extracted from peripheral leukocytes isolated from packed cells of anticoagulated blood by use of a commercially available DNA isolation kit (Puregene; Gentra Systems, Minneapolis, MN). The DNA was quantified by determination of absorbance at 260 nm followed by PicoGreen analysis (Molecular Probes, Eugene, OR).

Because of linkage disequilibrium (LD) in the human genome, genotyping of chosen SNPs will provide sufficient information to assess the remainder of the common SNPs and to construct each of the common haplotypes in a specific region [25]. Using International HapMap data on NCBI Build 35 assembly for whites, Asian, and Yoruban populations, we selected 10 SNPs to tag major haplotypes with Haploview v4 [26]. Selection of single nucleotide polymorphisms (tagSNPs) in candidate gene loci was according to the following criteria: (1) location within the proximal and distal 10-kb regions 5' and 3' to the given candidate gene (NCBI Build 35); (2) compatibility with the Illumina GoldenGate technology [27, 28] as determined by the Assay Design Tool (TechSupport, Illumina, San Diego, CA, USA); (3) minor allele frequency (MAF) >0.05 or a tag (r^2 value >0.8) for another SNP with MAF >0.05 as determined by applying the multilocus or “aggressive” “Tagger” option of Haploview v3 [26, 29] using International HapMap project data for CEPH and Yoruban populations (release 19) (International HapMap Consortium 2003). All ten SNPs were used for haplotyping, except for the SNP rs5908, since its MAF was <0.05 in all MESA ethnic groups, and thus would provide little information in an association study.

The 10 SNPs were rs3761738 (G/A, mRNA untranslated region, UTR), rs3761739 (G/A, UTR), rs4704209 (A/G, intron), rs10038095 (A/T, intron), rs2303152 (G/A, intron), rs3846662 (G/A, intron), rs5908 (reference allele A/G, I637V), rs17238540 (A/C, intron), rs3846663 (G/A, intron), and rs5909 (G/A, UTR). As is well-known, G/A is the most common change in the human genome due to a methylation of the C on the opposite strand followed by deamination to a T. Although the MAF of the SNP rs5908 in CEPH shown in the International HapMap was 0.034, which is borderline lower than 0.05, it was still considered to be genotyped in this study because of its function as a nonsynonymous polymorphism (reference allele A, I637V).

Genotyping was performed by Illumina genotyping services (GoldenGate assay, Illumina, San Diego, CA). All 10 SNPs were successfully typed with a genotype calling rate of 100%. Each SNP was in Hardy-Weinberg equilibrium (HWE, significance level of 0.005) in each ethnic group. We utilized the SNPs with minor allele frequency (MAF) ≥ 0.05 to evaluate LD in each ethnic group and in the combined group with Haploview v4 [26]. Because the MAF of rs5908 was <0.05 in all ethnic groups, it was not included

in haplotype construction. In each ethnic group, there was a single block structure composed of a portion of the remaining nine SNPs. Because the MAF was different for each SNP between ethnicities, different ethnic groups had different portions of the nine SNPs for the same haplotype (see “Appendix”). For example, the H2 haplotype was separated into H2a and H2b in AA based on the variation of rs17238540, in which the MAF was 0.08 in AA but <0.05 in the others. Haplotypes were reconstructed based on the LD results in each ethnic group by PHASE 2.0 [30]. Haplotypes with frequency <1% were excluded and were numbered in the order of their frequency in the combined sample.

Statistical Analysis

Interethnic differences in the demographic/phenotypic characteristics and haplotype distribution were performed by ANOVA or the Pearson's χ^2 test where appropriate. We used haplotypes to examine the possible associations because it is expected that haplotype analyses will provide greater power than single SNPs since certain untyped SNPs may be in LD with a combination of typed SNPs [31]. Association tests for individual SNPs were only applied to those that differentiate the haplotypes with significant association results. We use a general linear model (GLM) to estimate association in each ethnic group. Covariates included age, gender, BMI, and DM. Dominant models for SNP analyses were used because the majority of the SNPs had minor allele homozygotes <10. Parameter estimates were derived from the same models. Permutation testing of 10,000 replicates was performed for empirical estimates to account for the multiple testing. To identify the interaction between significant haplotypes and ethnic groups, the multiplicative term of significant haplotypes and ethnic groups was examined by the GLM. R^2 was calculated to estimate the proportion of explained variation of the outcome variable as a function of independence in the GLM.

Under the sample of 600 independent individuals and a priori TC data in MESA, we tested the ability to detect an association between a SNP and TC. At the 0.005 significance level, for detectable effect size >0.4, we had sufficient power (>0.80) to identify the association under a dominant model with disease allele frequency >0.10.

Results

The prevalence of DM and hypertension, and the quantitative traits of BMI, waist circumference, and lipid/lipoprotein levels, significantly differed among ethnicities (Table 1), but age and gender did not. The prevalence of hypertension was higher in AA (52%) than the others (35–40%). BMI and waist circumference were higher in AA and HA, and lower in

Table 1 Mean values with standard deviations or percentage distributions of clinical, lipid, and lipoprotein variables in each MESA ethnic group

CHA. Compared to the other groups, AA had a more protective lipid/lipoprotein phenotype.

Haplotype structure and frequencies of the *HMGCR* gene in each ethnic group are shown in Table 2 and the Appendix. The frequency of each haplotype differed significantly among ethnic groups (χ^2 test, $P < 0.0001$). The H1 haplotype was the most frequent haplotype in every ethnic group except AA, in which 44.9% had H2a.

There was no significant association between any of the lipid traits and the *HMGCR* gene in both EA and CHA. However, lower TG was associated with H2a in AA ($P = 0.005$) and H2 in HA ($P = 0.021$) (Table 3). TG/HDL-c ratio was also lower in the H2a carriers in AA ($P = 0.023$). In HA, the H4 haplotype was associated with the lipid/lipoprotein traits, specifically, higher TG ($P = 0.012$), TG/HDL-c ratio ($P = 0.003$), s-LDL ($P = 0.016$), l-VLDL ($P = 0.012$), and m-VLDL ($P = 0.002$), and lower HDL-c ($P = 0.004$) and l-HDL ($P = 0.0004$) (Fig. 1). In contrast, H8 was associated with these traits in the opposite direction, including lower TG ($P = 0.002$), TG/HDL-c ratio ($P = 0.0005$), s-LDL ($P = 0.009$), l-VLDL ($P = 0.021$), and s-VLDL ($P = 0.039$), and higher HDL-c ($P = 0.002$)

and l-HDL ($P = 0.002$). In HA, the H7 haplotype was also associated with lower TG ($P = 0.013$), lower TG/HDL-c ratio ($P = 0.032$), and lower s-VLDL ($P = 0.017$), but to a lesser magnitude compared with H8. In addition, H7 was associated with lower TC ($P = 0.026$) and m-VLDL ($P = 0.012$), but not significantly associated with the subclasses of LDL and HDL. LDL-c was not associated with any of the examined haplotypes in any ethnic group. In HA, when combining the subjects carrying H7 or H8, carriers had lower TC ($P = 0.04$), lower TG ($P < 0.0001$), higher HDL-c ($P = 0.01$), lower l-VLDL ($P = 0.003$), and higher l-HDL ($P = 0.001$) than noncarriers (Fig. 1), and had lower TC ($P = 0.03$), TG ($P < 0.0001$), s-LDL ($P = 0.02$), and l-VLDL ($P = 0.0004$), and higher HDL-c ($P = 0.003$) and l-HDL ($P = 0.0003$) levels than the H4 carriers.

Examination of the interaction effect of H2 and the ethnicity of AA and HA on TG levels was performed to determine if the higher frequency of H2 in AA could explain their lower TG levels. The H2 haplotype was associated with lower TG in both AA and HA. However, compared to HA, both H2 carriers and noncarriers in AA had lower TG levels (Fig. 2). The differences in TG level

*Haplotypes that were not differentiated because of certain rare SNPs (MAF < 0.05)

^a Sum of haplotypes marked by *

between H2 carriers and noncarriers were similar in AA and HA ($P = 0.70$). The interethnic difference in TG thus could not be solely explained by the H2 effect only. The total variation for TG that could be explained by H2 alone was 2.6% in HA and 1.4% in AA when controlling for covariates.

Associations were examined for the SNPs that differentiated significant haplotypes, including rs3846662 (separating H2a and H1), rs17238540 (H2a and H2b), and rs10038095 (H2a and H7) in AA, and rs3846662 (H2 and H1), rs3846663 (H7 and H3), rs3761739 (H8 and H3), and rs4704209 (H4 and H8) in HA. All three selected SNPs in AA and rs3846662 and rs3761739 in HA showed no contribution toward the associations of the relevant haplotypes (data not shown). In contrast, the minor allele of rs3846663 was associated with higher TG ($P = 0.001$), higher TG/HDL-c ratio ($P = 0.006$), and higher m-VLDL ($P = 0.002$) in HA, which was consistent with the association and the direction of H7. The association with rs4704209 was entirely equivalent to that with the H4 haplotype in HA.

Discussion

To our knowledge, this is the first report regarding the interethnic differences in the distribution of *HMGCR*

haplotypes and the differential associations of *HMGCR* gene with lipid/lipoprotein levels. The significant associations occurred mainly in HA. In HA, the H4 haplotype was associated with higher TG, s-LDL, and VLDL and lower HDL-c; and the haplotypes H2, H7, and H8 were associated with lower TG, s-LDL, and VLDL and higher HDL-c. The H2 haplotype was associated with lower TG and lower VLDL in AA as well. The absence of H2 in CHA and the lack of distinct, separable H4 and H8 haplotypes in AA and EA could well have accounted for ethnic differences in the associations. In HA, SNP analyses suggested that the association of H7 and H4 could be attributed to rs3846663 and rs4704209, respectively (or any SNP in complete LD with the two SNPs). This study supports that AA have less proportion of hypertriglyceridemia and low HDL-c than the other ethnic groups. Although AA had a remarkably high frequency (44.9%) of H2a, this study revealed that the *HMGCR* H2a haplotype had only a modest effect on TG level and did not have a significant effect on the interethnic differences in TG levels. In summary, the *HMGCR* gene variation is associated with multiple lipid/lipoprotein traits. The impact of the genetic variance is modest and differs greatly among ethnicities.

The first published MESA genetic study [32] utilized a MESA sample ($n = 969$, white = 448, Chinese = 97, AA = 205, HA:219) from the overall baseline MESA cohort who were randomly selected from the 5,030 MESA

Parameter estimates (95% CI) derived from GLM models that included age, sex, BMI, and diabetes as independent variables show the difference in each trait in carriers (haplotype or genotype consisting at least one minor allele) compared to noncarriers. Definition for minor allele is based on the allele frequency of each SNP in all cohort subjects

* $P < 0.001$, † $P < 0.01$, ‡ $P < 0.05$

The *negative signs* mean the level of each trait in carriers is lower to that in noncarriers

To convert mg/dL to mmol/L, multiply LDL-C, HDL-C, and total cholesterol values by 0.02586 and triglycerides by 0.011

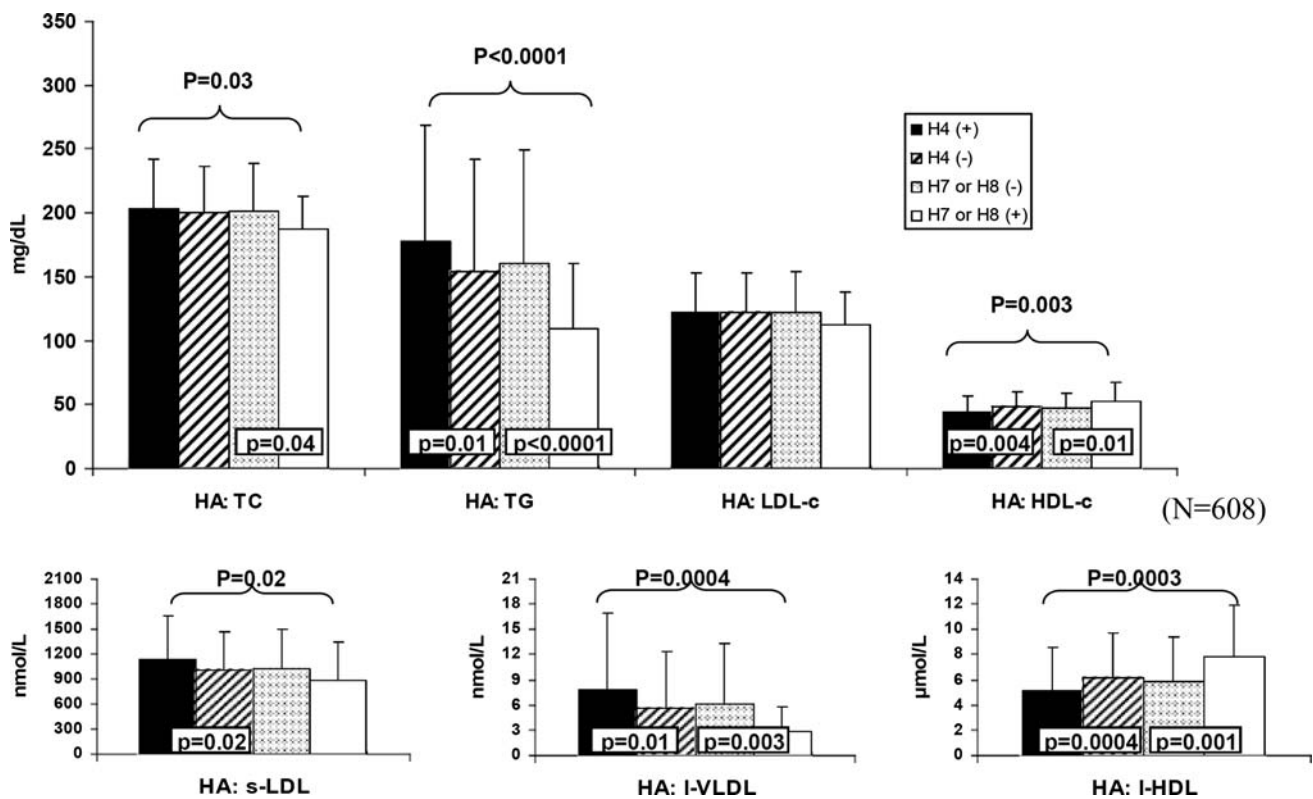

Fig. 1 Comparisons of lipid/lipoprotein levels between the carriers and noncarriers of the *HMGR* H4 and the combination of H7 and/or H8 in Hispanic-Americans. Data are presented as mean of the levels. Subjects carrying the H4 haplotype [H4 (+)] have significantly higher TG, lower HDL-c, higher s-LDL, higher l-VLDL, and lower l-HDL than noncarriers. In contrast, H7 or H8 carriers [H7/H8 (+)] have

lower total cholesterol (TC) and TG, higher HDL-c, lower l-VLDL, and higher l-HDL than noncarriers. H4 carriers have higher TC, TG, s-LDL, and l-VLDL, and lower HDL-c and l-HDL levels than H7/H8 carriers. To convert mg/dL to mmol/L, multiply LDL-c, HDL-c, and total cholesterol values by 0.02586 and TG by 0.011

participants enrolled prior to February 2002, before the completion of the overall recruitment. That study found ethnic differences in the association between *ABCA1* gene SNPs and HDL-c as well as subclinical atherosclerosis. The multi-ethnic composition of the MESA cohort is both a strength (analyses in multiple ethnicities) and a potential limitation (relatively small sample sizes) [32].

The limitations of the present study included moderate sample sizes of each population group, which could limit the capacity to reveal valid genetic information for the complex phenotype of lipoprotein levels. Independent confirmation or further replication is needed to verify these associations. The other potential limitation of this study was that the LDL-c level was calculated by the Friedewald equation instead of direct tests; therefore, LDL-c of subjects with TG value greater than 400 mg/dL was not included in the genetic analysis. However, there were only 1.4% (34 subjects) with elevated TG who were excluded from analyses. This study did not show any association between *HMGR* gene and lipid traits in EA and CHA. It is possible that lipids were associated with

other SNPs and haplotypes in the *HMGR* gene that have more potent associations with lipid/lipoprotein traits. In addition, the MESA subjects included only subjects free from known cardiovascular diseases at baseline, and this study has excluded subjects who took statins; both of the above selection criteria may lead to somewhat different results. The strengths of this study included the multiple samples of different ethnicities, extensive LD mapping and haplotyping of the locus, comparisons of haplotype frequency and genetic associations across ethnic groups, and the consistent associations between lower triglyceride level and the *HMGR* haplotype 2 in two ethnic groups, AA and HA.

The *HMGR* gene map locus is at 5q13.3–q14. Previous studies showed linkage evidence of this locus with several lipid/lipoprotein traits, mainly in whites [11, 15]. In AA, CHA, or HA, there were no promising data supporting this linkage [12–14]. In contrast to the linkage reports, the associations between *HMGR* gene and the lipid/lipoprotein traits in our study were most striking in HA and AA, but not in EA. In EA, the absence of association between

	β coefficient	P-value
H2 haplotype	-0.13	0.005
Ethnicity	0.35	<0.0001
Interaction of H2 and ethnicity	0.02	0.70

Fig. 2 Triglyceride levels in H2 carriers and noncarriers in African-Americans (AA) and Hispanic-Americans (HA). The H2 haplotype had lower TG level in both AA and HA. Both H2 carriers and noncarriers in HA had higher TG levels (142 ± 81 and 162 ± 90 mg/dL, respectively) than AA (101 ± 55 and 115 ± 75 mg/dL, respectively). The difference in TG level between H2 carriers and noncarriers was similar in AA and HA (14 and 20 mg/dL, respectively), without interaction between the H2 haplotype and ethnicity ($P = 0.70$)

the *HMGR* gene and lipid/lipoprotein traits was consistent with findings in previous studies [19, 20]. The Pravastatin Inflammation/CRP Evaluation (PRINCE) study and the Cholesterol and Pharmacogenetics (CAP) study have demonstrated that the *HMGR* gene contributed to the differences in response to statins [19, 20]. The PRINCE study did not find an association between the *HMGR* gene and the baseline LDL-c level in the studied population, which consisted mainly of whites (88.7%). The CAP study showed an association of their Hap2 (haplotype 2) and/or Hap7 (haplotype 7) with lower baseline LDL-c level in blacks, but not in whites. The CAP Hap2 and Hap7 are analogous to our H2a and H2b in AA, respectively; the combination of Hap2 and Hap7 is analogous to our H2 in the other ethnic groups. The study herein supports the association of H2 with lower TG in both AA and HA. In addition, the percentage of the designated Hap2 in the CAP study was higher in AA (32%) than EA (2%), which was similar to our results (H2a, 44.9% in AA; H2, 5.5% in EA). In AA, we observed the association of the H2 haplotype with lower TG instead of LDL-c level shown in the previous study [20]. In HA, this is the first association data that showed significant associations between *HMGR* haplotypes with multiple lipid/lipoprotein traits, especially with TG, s-LDL, and HDL-c. In CHA, we did not observe any association, although an association between the 8302A/C variation of the *HMGR* gene and lipids was

reported in one Chinese study [33]. It should be noted that the absence of H2 in CHA and the lack of the distinct, separable H4 and H8 haplotypes in AA and EA could well have accounted for the ethnic differences in the associations. Because the associations of the *HMGR* gene with lipid/lipoprotein traits were mainly in AA and HA, and the haplotype distribution was remarkably different among ethnicities, future studies of statin therapy will need to include adequate representation from several ethnic groups, such as AA and HA.

Recently, a genome-wide association study (GWAS) [34] using variance-weighted meta-analysis from up to four GWAS revealed an association between SNP rs12654264 of *HMGR* and LDL-c level in the European population ($P = 1 \times 10^{-20}$). A simultaneous GWAS [35] using similar study cohorts did not report this association (threshold $P = 5 \times 10^{-7}$). Based on the CEU data in HapMap, SNP rs12654264 is in LD with rs3846662 ($r^2 = 0.84$) and rs3846663 ($r^2 = 0.97$); however, in our white group, neither SNP exhibited any significant association with lipid levels in EA ($P > 0.05$). The SNP rs12654264 is in complete LD with rs3846662 and rs3846663 in HapMap's CHB and JPT data. In our CHA group, neither of the two SNPs was associated with lipid traits. The SNP rs12654264 is not in LD with any of our tagSNPs in the AA group, and the two SNPs rs3846662 and rs3846663 showed no association with lipid traits in AA. The only association discovered in our study between lipids and the two SNPs was rs3846663 with TG levels and l-VLDL and m-VLDL in HA. We had no LD information between rs3846663 and rs12654264 in our Hispanic groups. The inconsistency among the two GWAS and our reports might be caused by the different sample size and study/analysis methods. Independent study into this inconsistency is necessary. Further studies addressing the function related to the SNP and the intermediate phenotypes such as mevalonate and HMG-CoA reductase would increase the functional biochemical evidence for the association.

It is somewhat surprising that the *HMGR* gene was associated with TG and HDL-c because *HMGR* does not play a direct role in TG synthesis and hydrolysis. The association may be indirectly caused by the requirement of hepatic cholesterol for VLDL assembly [36], regulation of LDL receptor number, and the conversion of s-LDL from large TG-rich VLDL particles [36]. Several studies have also shown the effect of statins on lowering TG and increasing HDL-c [16]. The *HMGR* gene is thus a potential contributor, at least to some extent, to the differences in statin response of TG and HDL-c.

In summary, *HMGR* gene variations were associated with multiple lipid/lipoprotein traits in African-Americans and Hispanic-Americans. The impact of the *HMGR* gene

on lipid/lipoprotein levels appears modest and differs greatly among ethnicities.

Table 4 continued

Haplotype: <i>n</i> (%)	SNP MAF (%) in all								
	rs3761738 (G/A, UTR) (6.5)	rs3761739 (G/A, UTR) (16.9)	rs4704209 (A/G, intron) (8.6)	rs10038095 (A/T, intron) (41.0)	rs2303152 (G/A, intron) (8.2)	rs3846662 (G/A, intron) (40.9)	rs17238540 (A/C, intron) (3.6)	rs3846663 (G/A, intron) (38.4)	rs5909 (G/A, UTR) (6.5)
H7: 128 (2.6)	G	G	A	T	G	G	*	G	G
H8: 86 (1.8)	G	A	A	T	G	G	*	A	G

Haplotypes were constructed in the above SNP order. Haplotype frequency (%) shows the percentage for each haplotype in each race/ethnic group. The distribution of haplotypes was significantly different among the ethnic groups (χ^2 test, $P < 0.0001$)

– Absent or very rare (<1% frequency) haplotype

*SNPs with minor allele frequency (MAF) <5% were not included in haplotype construction

Abstract Two new natural compounds, a symmetrical disulfide dimer didodecyl 3,3''-dithiodipropionate (**1**) and a pregnane steroid 5,16-pregnadien-3 β -ol-20-one acetate (**2**), were isolated together with two known compounds, ergosta-4,6,8(14),22-tetraen-3-one (**3**) and ergosterol peroxide (**4**), from the ethyl acetate soluble extract of fermentation broth of an endophytic fungus, *Sphaceloma* sp. LN-15 isolated from the leaves of *Melia azedarach* L. and grown in pure culture. Their structures were determined on the basis of spectroscopic methods including 1D and 2D nuclear magnetic resonance spectroscopy (NMR) experiments and by mass spectrometric measurements (MS). These fungal metabolites were isolated for the first time from the genus *Sphaceloma*. The structure of **1** was also confirmed by chemical synthesis.

Keywords *Melia azedarach* L. · Endophytic fungus · *Sphaceloma* sp. · Disulfide dimer · Didodecyl 3,3''-dithiodipropionate · 5,16-Pregnadien-3 β -ol-20-one acetate · Fungal metabolites

Abbreviations

CC	Column chromatography
COSY	Correlation spectroscopy
DCC	<i>N,N'</i> -Dicyclohexylcarbodiimide
DEPT	Distortionless enhancement by polarization transfer
DMAP	<i>N,N</i> -Dimethylpyridin-4-amine
EI-MS	Electron impact-mass spectrometry
EC ₅₀	Effective concentration for 50% growth inhibition
ESI-MS	Electrospray ionization-mass spectrometry
FAB-MS	Fast atom bombardment-mass spectrometry
HMBC	Heteronuclear multiple bond correlation
HMQC	Heteronuclear multiple quantum correlation
HR	High resolution
MS	Mass spectrometric measurements
NMR	Nuclear magnetic resonance spectroscopy
PDA	Potato dextrose agar
TLC	Thin layer chromatography

Introduction

Endophytes are microorganisms that live in the intercellular spaces of the tissues of host plants without causing any discernible manifestation of disease [1, 2]. All higher plants seem to be hosts to one or more endophytic microbes. Of all the world's plants, however, only a few grass species were thoroughly studied for their endophytes [2]. As a result, the opportunity to find new and interesting endophytes among a variety of plants is enormous. Recent comprehensive studies have indicated that 51% of the biologically active substances isolated from endophytic fungi were previously unknown [3]. Most of these compounds have shown various interesting bioactivities such as

cytotoxic and antitumor, antimicrobial, phytotoxic and antileishmanial (active against *Leishmania aethiopica*, a parasitic trypanosome protozoa that is the causative agent of leishmaniasis) activities [3–5]. Hence, compared with only 38% of novel substances from soil microflora, endophytes have recently been recognized as prolific sources of structurally novel and biologically active secondary metabolites to be chemically explored [3–5].

Melia azedarach Linn (Meliaceae), also known as Chinaberry or Persian lilac tree, is a deciduous tree that is native to northwestern India and has long been recognized for its insecticidal properties [6]. This plant produces a class of low molecular weight metabolites, modified oxygenated triterpenoids, known as limonoids [7, 8]. However, little is known about secondary metabolites of endophytes harbored inside the healthy tissues of *M. azedarach* [9–12].

In the course of our ongoing study of biologically active metabolites from plant endophytes [13–15], we investigated the chemical constituents produced by an endophytic fungus *Sphaceloma* sp. found inside *M. azedarach* and isolated four compounds, including two new natural products, a fatty alcoholic disulfide dimer didodecyl 3,3''-dithiodipropionate (**1**) and a pregnane steroid 5,16-pregnadien-3 β -ol-20-one acetate (**2**), together with two known ergosterol derivatives ergosta-4,6,8(14),22-tetraen-3-one (**3**) and 5 α ,8 α -epidioxy-(22*E*,24*R*)-ergosta-6,22-dien-3 β -ol (**4**). In this paper, we describe the isolation and structural characterization of these two new natural products.

Materials and Methods

General Experimental Procedure

Melting points were obtained on an XRC-1 apparatus and uncorrected. Optical rotations were measured on a Perkin Elmer Model 341 polarimeter. NMR spectra were recorded on a Bruker DRX-500 instrument with TMS as an internal standard. Mass spectra were recorded on a VG Auto Spec-3000 spectrometer (Micromass, UK) and Thermo Finnigan LCQ Advantage. IR spectra were obtained in KBr pellets with a Bio-Rad FTS-135 infrared spectrophotometer. Column chromatography (CC) was performed over silica gel (200–300 mesh, Qingdao Marine Chemical Ltd., Qingdao, China) and Sephadex LH-20 (Pharmacia, Uppsala, Sweden). Silica gel 60 F₂₅₄ TLC plates (Qingdao Marine Chemical Ltd., Qingdao, China) and RP-18 F₂₅₄ TLC plates (Merck, Darmstadt, Germany) were used for analysis. Fractions were monitored by thin layer chromatography (TLC), and spots were visualized by spraying with 10% H₂SO₄ in ethanol, followed by heating. All other chemicals used in this study were of analytical grade.

Fungal Material

The endophytic fungal strain was isolated from the fresh leaves of the tree *M. azedarach* L. growing in the campus of Northwest A&F University, Yangling, Shaanxi province, China. The isolate was identified as *Sphaceloma* sp. LN-15 by morphological analysis and was deposited at the Research Centre for Natural Medicinal Chemistry, Northwest A&F University.

Cultivation

The fungal strain was cultured on the slants of potato dextrose agar (PDA) at 28 °C for 6 days. Then three pieces (size 8 mm², each) of mycelium were transferred to PDA liquid media. A suspension (1 ml) of the strain was inoculated aseptically to 500-ml Erlenmeyer flasks each containing 180 ml of PDA culture medium comprising potato (20%) and glucose (2%). The flask cultures were incubated at 28 °C for 7 days on a rotary shaker at 120 rpm.

Extraction and Isolation

The strain cultures (20 l) were filtered to collect mycelia. The filtrate was concentrated in vacuo at 45 °C, and then successively extracted four times with an equal volume of AcOEt to give a crude extract. The extract was fractionated by silica gel CC using petroleum ether–acetone gradient elution to provide seven fractions (Fr.1–Fr.7). Fr.3 (1.12 g) was subsequently fractionated by Silica gel CC using petroleum ether–AcOEt gradient elution to obtain Fr.3.1–3. Fr.3.2 was subsequently purified by Sephadex LH-20 column chromatography using acetone as solvents to yield compound **3** (10 mg). Fr.4 was chromatographed by RP-18 silica gel (40–75 μ m, 72 g) column using MeOH–H₂O (60:40–100:0) gradient elution to provide fr.4.1–4. Fr.4.3 eluted with MeOH–H₂O (90:10) was purified by Sephadex LH-20 using acetone to give compound **4** (8 mg). Fr.4.4 eluted with MeOH–H₂O (100:0) was subjected to CC over Silica gel using petroleum ether–AcOEt (95:5 and 85:15) to give Fr.4.4.1 and Fr.4.4.2; Fr.4.4.2 was separated by Sephadex LH-20 CC using MeOH, followed by Silica gel CC using petroleum ether–acetone (95:5 and 90:10) to afford compound **1** (4 mg). Fr.4.1 was separated by Sephadex LH-20 CC using MeOH, followed by Silica gel CC using petroleum ether–acetone (95:5, 90:10), and petroleum ether–AcOEt (87:13) to give compound **2** (6 mg).

Synthesis of Compound **1**

Method A. DCC (412.7 mg, 2 mmol) and DMAP (24.4 mg, 0.2 mmol) were added to a stirred solution of 3,3'-dithiodipropionic acid (210.3 mg, 1 mmol) and dodecanol (410 mg, 2.2 mmol) in dichloromethane (10 ml) at room temperature. The reaction was monitored by TLC. After about 6 h, the reaction mixture was then quenched by addition of several drops of acetic acid. After filtration, the mixture was washed with saturated aqueous sodium hydrogen carbonate, saturated NaCl solution and dried (MgSO_4) and the solvents evaporated. CC (SiO_2 , petroleum ether/acetone, 97:3) gave the crude product, which was crystallized from acetone–methanol to afford **1** (398.6 mg, 73%) as white plate-like crystals.

Method B. A catalytic amount of con. H_2SO_4 was added to a mixture of 3,3'-di-thiodipropionic acid (210.3 mg, 1.0 mmol) and dodecanol (2,490 mg, 13.36 mmol) at 60 °C under stirring. The reaction mixture was then heated to 120 °C under stirring. The reaction was monitored by TLC. After 5 h, the reaction mixture was then cooled to room temperature, and dichloromethane (5 ml) was added. The organic layer was washed with saturated aqueous sodium carbonate, saturated aqueous NaCl solution and dried (MgSO_4) and concentrated at reduced pressure. CC (SiO_2 , petroleum ether/acetone, 100:2) gave **1** (382 mg, 70%) as white plate-like crystals. Its NMR spectroscopic data were identical with those reported for the natural product (see “[Extraction and Isolation](#)”).

Antimicrobial Assays

In vitro antifungal activity was tested against the pathogenic fungi, *Alternaria solani*, *Fusarium oxysporium*, *Sclerotinia sclerotiorum*, *Exserohilum turcicum* and *Colletotrichum loeosporioides*, by the mycelial growth inhibitory rate method. These fungi were grown on PDA medium in Petri plates. All samples were dissolved in methanol.

The tested fungi (4 mm diameter) were inoculated at the centre of agar medium discs incorporating test samples. Three replicate plates for each fungus were incubated at 26 (± 2) °C for all test fungi. Control plates containing medium mixed with methanol (1 ml) were included. After incubation for 72–96 h, the mycelial growth of fungi (mm) in both treated (*T*) and control (*C*) Petri dishes were measured in three different directions (decussation method) until the fungal growth in the control dishes was almost complete. The growth inhibition rate (*I*) was calculated using the following formula $I (\%) = [(C - T)/C - 4] \times 100$.

Results and Discussion

The fungal strain was cultivated on PDA plates for 6 days at 28 °C. The extract of the culture was partitioned between AcOEt and water. The AcOEt extract was subjected to silica gel, RP-18 gel, and Sephadex LH-20 column chromatographic purification steps to yield four products **1–4** (Fig. 1), including a new fatty alcohol disulfur dimer **1** and a new pregnane steroid **2**.

In order to determine if any of the four isolated compounds in this study were derived from the medium as control, the AcOEt extract of the sterile medium treated equally but without inoculation of the microorganism was examined by LC-MS. This showed that all the isolates were produced by the endophytic fungus.

Compound **1** was obtained as a white needle-shaped crystal from acetone (m.p. 39–40 °C). It showed quasi-molecular ion peaks at m/z 569 $[M + Na]^+$, 570 $[M + Na + H]^+$, and 585 $[M + K]^+$, as well as at m/z 547 $[M + H]^+$ in the positive ESI-MS and in the positive

FAB-MS spectra, respectively, suggesting its relative molecular weight of 546. Its molecular formula was determined to be $C_{30}H_{58}O_4S_2$ by the positive high resolution ESI-MS (calc. for $[M + Na]^+$: 569.3674; found: 569.3681) and NMR data, indicating 2° of unsaturation. The IR spectrum of compound **1** suggested the presence of alkane ($2,920\text{ cm}^{-1}$, C–H stretch), ester carbonyl ($1,741\text{ cm}^{-1}$), methylene ($1,463\text{ cm}^{-1}$, $-\text{CH}_2$ bend), methyl ($1,376\text{ cm}^{-1}$, $-\text{CH}_3$ bend), ester ($1,264$, $1,188$, $1,125$, $1,099\text{ cm}^{-1}$, C–O), and di-sulfur (568 , 479 cm^{-1} , S–S) groups. The ^{13}C NMR (DEPT) and HMQC spectra further established the presence of 15 carbon signals, which were recognized as one methyl group [δ_{C} 14.1(*q*)], 13 methylenes [δ_{C} 22.7–65.8 (*t*)] including one oxygen-linked methylene [δ_{C} 65.8 (*t*)], one sulfur-linked methylene [δ_{C} 48.8(*t*)], and a carbonyl carbon [δ_{C} 170.4]. The ^1H NMR spectrum of **1** also supported the presence of one methyl [δ_{H} 0.89, (3H, t, $J = 8.2$ Hz)], 13 methylenes including three signals [δ_{H} 4.13 (2H, t, $J = 6.8$ Hz), 3.35 (2H, t, $J = 7.5$ Hz), 2.89 (2H, t, $J = 7.5$ Hz)] and ten ones [δ_{H} 1.58–1.66 (overlap) and 1.27–1.42 (overlap)]. These data indicate that this compound belongs to long chain fatty alcohol esters.

All these signals formed the partial structure moiety $-\text{S}(\text{CH}_2)_2\text{COO}(\text{CH}_2)_{11}\text{CH}_3-$. Taking the molecular formula and molecular weight into account, therefore, compound **1** should be a complete symmetric structure linked by a disulfur bond, which could match the molecular formula and mass of this molecule. Moreover, the proposed structure gained further reinforcement from its EI mass spectrum, which displayed prominent ion peaks at m/z 379, 361, 211, 193 (base peak), and 169, as shown in Fig. 2. Among them, this ion peak at m/z 193, consistent with the molecular composition of $C_6H_9O_3S_2$ (calc. for $[M + H]^+$:

Fig. 1 Chemical structures of four compounds isolated from *Sphaceloma* sp. Didodecyl 3,3''-dithiodipropionate (**1**). 5,16-Pregnadien-3 β -ol-20-one acetate (**2**). Ergosta-4,6,8(14),22-tetraen-3-one (**3**). Ergosterol peroxide (**4**)

Fig. 2 Proposed EI-MS fragmentation pathways of didodecyl 3,3''-dithiodipropionate (**1**). $[\text{HOOCCH}_2\text{CH}_2\text{SSCH}_2\text{CH}_2\text{CO}]^+$ at m/z 193 (base peak)

193.0032; found: 193.0024) was substantiated by high resolution EI-MS analysis. Further evidence to support the structure of **1** was obtained from ^1H - ^{13}C -long-range couplings observed in the HMBC and COSY spectra (Fig. 3). The HMBC and COSY spectra of compound **1** displayed the key correlations of H-3 (δ 3.35) with C-1 (δ 170.4) and C-2 (δ 27.0), and correlations of H-2 (δ 2.89) with C-1 (δ 170.4) and C-3 (δ 48.7); similarly, H-1' (δ 4.13) showed correlation to C-1 (δ 170.4), C-2' (δ 28.5) and C-3' (δ 29.6). Accordingly, the comprehensive analysis of MS, 1D and 2D NMR data led to the elucidation of compound **1** as didodecyl 3,3''-dithiodipropionate, which was synthesized [16] as sulfur-based antioxidant.

To the best of our knowledge, the structure of compound **1** has not previously been reported to occur naturally. Also, dithiopropionic acid, the “de-alcoholated” version of this natural product also has not been reported to occur naturally. Perhaps in *Sphaceloma* sp. dithiopropionic acid is biosynthesized by joining two cysteine molecules via an S-S bond, and both cysteines are also deaminated. Although it is reasonable to speculate that this fungus may also contain some of the mono-dodecyl form of the disulfide dimer, it was not detected in this study.

Compound **2** was obtained as an optically active white needle. Its molecular formula was deduced as $\text{C}_{23}\text{H}_{32}\text{O}_3$ by

Fig. 3 Selected H-H COSY and HMBC correlations of didodecyl 3,3''-dithiodipropionate (**1**) and 5,16-pregnadien-3 β -ol-20-one acetate (**2**)

the positive HR-ESI-MS at m/z 357.2432 $[\text{M} + \text{H}]^+$ (calc. 357.2430) and NMR data possessing 8 degrees of unsaturation. Its IR spectrum suggested the presence of an ester carbonyl ($1,728\text{ cm}^{-1}$) and a conjugated carbonyl ($1,659\text{ cm}^{-1}$) group. The ^{13}C -NMR spectrum of compound **2** showed resonances for 23 carbon atoms, and the DEPT spectrum indicated the presence of four methyl groups containing two tertiary ones, seven methylenes, six methines and six quaternary carbon atoms including two carbonyls [δ = 197.0 (C-20) and 170.5 (C-1')]. The ^1H - and ^{13}C -NMR spectra showed signals for two trisubstituted double bonds at δ = 6.72 (1H, dd, J = 2.3, 3.9 Hz, H-16), and 5.40 (1H, brd, H-6), and at δ = 140.2 (s, C-5) and 122.0 (d, C-6), and 144.4 (d, C-16) and 155.3 (s, C-17). The appearance of resonances for six sp^2 carbons including two carbonyl carbons in the ^{13}C -NMR spectrum indicated that 4 $^\circ$ of unsaturation were attributed to the presence of four double bonds and that the remaining degrees could be satisfied by the assignment of four rings in the molecule. In the ^1H -NMR spectrum, the multiplet at δ = 4.57–4.64 had a complexity normally seen for a 3 α -carbinol proton [17]. The ^1H -/ ^{13}C -NMR spectrum of **2** indicated resonances of two tertiary methyl groups [$\delta_{\text{H/C}}$ = 0.92 (3H, s)/15.7, 1.06 (3H, s)/19.2], which were assigned as 18- CH_3 and 19- CH_3 , respectively. These observations suggested that compound **2** has a steroidal skeleton. As a result of the HMBC correlations (Fig. 3) of H-3 and C-1' (δ 170.5), H-16 and C-20, and H₃-21 and C-17, one acetoxy and acetyl groups were clearly located at C-3 and C-17, respectively. In

addition, in comparison with NMR spectroscopic data of the synthetic known compound, 5,16-pregnadien-3 β -ol-20-one acetate, reported in the literature [18], compound **2** was thus assigned as 5,16-pregnadien-3 β -ol-20-one acetate, namely, 16-dehydropregnenolone acetate, belonging to a type of pregnane steroids. This compound, which is a well-known key intermediate in the synthesis of steroidal hormones in pharmaceutical industry, has been synthesized from a readily available natural product diosgenin via a sequence of fission of rings E and F in acetic anhydride–acetic acid and oxidative degradation [18].

In addition, two known compounds **3** and **4** were identified as ergosta-4,6,8(14),22-tetraen-3-one and 5 α ,8 α -epidioxy-(22*E*,24*R*)-ergosta-6,22-dien-3 β -ol, respectively, by comparison of their spectroscopic data with those in the literature [17]. They were isolated for the first time from this endophytic fungus, *Sphaceloma* sp.

The co-occurrence of two ergosterol-derived compounds **3** and **4**, typical and common metabolites of fungi, confirms that the pregnane steroid isolated from the culture broth is in fact of fungal origin. Biogenetically, the transformation of $\Delta^{5,7}$ -ergosterol compounds to the pregnane derivative **2** may be involved in the ergosterol side-chain cleavage, including sequential hydroxylation, and scission of the C-20–C-22 dihydroxylated bond in the presence of a family of oxidase enzymes like cytochrome P-450. This bioconversion is similar to that of cholesterol to pregnane steroids [19]. More recently, some new naturally occurring pregnane steroidal analogues, such as 3 β ,4 α -dihydroxy-5 α -pregnan-17(20)-(Z)-en-16-one and its *E*-isomer 3 β ,4 α -dihydroxy-5 α -pregnan-17(20)-(E)-en-16-one, were recorded in the genus *Melia* [20], but so far there is no evidence of this group of pregnane metabolites in *M. azedarach*. In the present study, the first discovery of compound **2** present in this endophytic fungus *Sphaceloma* sp. seems to further account for the established relationship between analogous secondary metabolites produced by the host and the endophytic fungus [3, 4]. Due to gene recombination during evolution, endophytic microorganisms have often developed biochemical abilities to produce compounds either similar or identical to those produced by their host plants [4]. On the other hand, it has been reported that the pregnane steroids are distributed not only in marine organisms such as corals, sponges, and gorgonians [19, 21–23], but also in terrestrial plants [24]; however, they are rare in fungi.

To verify the proposed structure of the disulfide compound **1** and to obtain further compounds for biological testing, we employed two synthetic methods to prepare compound **1**. The synthesis of the disulfide dimer **1** is based on the esterification reaction of a carboxylic acid with fatty alcohol. Dithiodicarboxylic acid was subjected to esterification reaction with dodecanol under the condition of H₂SO₄ or *N,N'*-dicyclohexylcarbodiimide (DCC) in the

Scheme 1 Reagents and conditions: method **a** DCC, DMAP, CH₂Cl₂, room temperature, 6 h (73%); method **b** H₂SO₄, 60–120 °C, 5 h (70%)

E. t *Exserohilum turcicum*, *C. l* *Colletotrichum loeosporioides*, *S. s* *Sclerotinia sclerotiorum*, *A. s* *Alternaria solani*, *F. o* *Fusarium oxysporium*, NA not active

presence of *N,N*-dimethylpyridin-4-amine (DMAP) in dichloromethane (Scheme 1) [25]. The residue was purified by silica gel CC to afford propanoate **1** in good yield. Its physicochemical, MS, and NMR data were in full agreement with those of the natural product.

The *in vitro* antifungal activities of the individual isolated metabolites **1–4** were examined using the reference agar dilution method using amphotericin B as a positive control. The inhibitory activities (the effective concentration for 50% growth inhibition, EC₅₀ values) were summarized in Table 1.

The results indicated that only compounds **1** and **2** displayed weak activities against several plant pathogenic fungi. Compound **1** showed growth inhibition against *Colletotrichum loeosporioides*, *Alternaria solani*, and *Fusarium oxysporium*. Compound **2** inhibited growth of *Colletotrichum loeosporioides* and *Alternaria solani*.

Two new natural fungal products **1–2** were isolated from an endophytic fungus, *Sphaceloma* sp. isolated from *M. azedarach* and their structures were confirmed by spectral data and chemical synthesis. To the best of our knowledge, this is the first report of these two metabolites from natural sources. Moreover, a naturally occurring symmetrical disulfide dimer lipid **1** containing a dithiodipropionic acid structure is rare in natural environment.

A limited number of symmetrical disulfide compounds have been previously isolated from marine sources [26, 27], a basidiomycete mushroom of the *Cortinarius* genus [28], and plants of the *Allium* genus [29, 30]. Interestingly, the isolation and structural elucidation of three co-metabolites, a pregnane derivative 5,16-pregnadien-3 β -ol-20-one acetate (**2**) and two ergosterol congeners appear to lend support for a shared steroidal nucleus produced via a biosynthetic pathway.

Overexpression of a FAD3 Desaturase Increases Synthesis of a Polymethylene-Interrupted Dienoic Fatty Acid in Seeds of *Arabidopsis thaliana* L.

Debbie Puttick · Melanie Dauk · Sharla Lozinsky · Mark A. Smith

Received: 7 April 2009 / Accepted: 15 May 2009 / Published online: 23 June 2009

Abstract A cDNA encoding the *Arabidopsis* extraplastidic linoleate desaturase (FAD3) was overexpressed in the seeds of wild-type *Arabidopsis* and in a mutant line that accumulates high levels of oleic acid. In the transformed wild-type plants, linolenic acid (18:3 Δ 9,12,15) increased from 19% to nearly 40% of total seed fatty acids, with a corresponding decrease in linoleate content (18:2 Δ 9,12). In the high oleate mutant, a large increase in the level of a fatty acid identified by gas-chromatography/mass-spectrometry as mangiferic acid (18:2 Δ 9,15) was observed. The results demonstrate that the polymethylene-interrupted dienoic fatty acid, mangiferic acid, can be produced in seed oil through the overexpression of a fatty acid n-3 desaturase.

Keywords Linoleate desaturase · Mangiferic acid · Polymethylene-interrupted dienoic fatty acid · *Arabidopsis* · Seed oil

FAMES Fatty acid methyl esters
PMIFA Polymethylene-interrupted fatty acid
PUFA Polyunsaturated fatty acid
VLCFA Very long chain fatty acid

Introduction

The predominant dienoic fatty acid of higher plants is linoleic acid (octadeca-9-*cis*,12-*cis*-dienoic acid, 18:2 Δ 9,12).¹ The methylene-interrupted (MI) *cis*-double-bond configuration of this fatty acid is characteristic of most plant polyunsaturated fatty acids. Polymethylene-interrupted fatty acids (PMIFA), where double bonds are separated by more than one methylene group, are uncommon but can be abundant within individual plant families. Seed oils of many conifer species, for example, are rich in Δ 5-polyunsaturated fatty acids and contain dienoic PMIFAs such as taxoleic acid (octadeca-5-*cis*,9-*cis*-dienoic acid, 18:2 Δ 5,9) and the very long chain fatty acid (VLCFA) eicosa-5-*cis*,11-*cis*-dienoic acid, 20:2 Δ 5,11. These species also produce a variety of polyunsaturated fatty acids containing double bonds in both MI and PMI configurations [1]. Fatty acids with Δ 5 unsaturation are also the major components of meadowfoam oil, obtained from the seeds of *Limnanthes alba* [2]. This oil contains an unusual VLC-PMIFA, docosa-5-*cis*,13-*cis*-dienoic acid (22:2 Δ 5,13), that accounts for up to 16% of total seed fatty acids [3, 4].

Biochemical studies have indicated that in *Limnanthes* species, 22:2 Δ 5,13 is synthesized by the action of a Δ 5 desaturase on the VLC-monounsaturated fatty acid erucic acid (22:1 Δ 13) [5]. The PMIFA therefore results from the activity of a desaturase that inserts a double bond at a

¹ Fatty acid nomenclature: X:Y Δ z, where X is chain length, Y is number of double bonds, and Δ z is double-bond position relative to the carboxyl end of the molecule. In fatty acids designated using n-x or ω x nomenclature, the position of the double bond is described relative to the methyl end of the molecule.

specific position in the fatty acid on the carboxyl side of an existing double bond. This activity is referred to as “front-end desaturation” and is distinct from the “methyl-end” desaturation catalyzed by the majority of plant desaturases [6]. It is likely that $\Delta 5$ desaturation of monounsaturated fatty acids in conifers also results in the formation of PMIFAs.

In addition to PMIFAs containing $\Delta 5$ unsaturation, a novel 18-carbon PMIFA, sometimes referred to as mangiferic acid, has been reported from the pulp of ripe mango fruit (*Mangifera indica* L.) grown in the Philippines [7], in the seed oil of *Arabidopsis* lines deficient in linoleate desaturase activities [8, 9], and in some high oleic lines of soybean [10]. In these reports, the fatty acid was suggested to be a result of low-level activity of an $\omega 3$ -desaturase, such as the plastidial or extraplastidial linoleate desaturases, acting on oleic acid (18:1 $\Delta 9$). The *ox* designation refers to a fatty acid desaturase that catalyzes double-bond formation at a specific position relative to the methyl end of a fatty acid [6]. Ectopic expression of a plant extraplastidial desaturase and an $\omega 3$ -desaturase from the nematode *Caenorhabditis elegans* in the yeast *Saccharomyces cerevisiae* confirmed the low-level activity of these enzymes on oleic acid and resulted in production of small amounts of 18:2 $\Delta 9,15$ [9, 11].

Polyunsaturated fatty acids (PUFAs) with double bonds that are not in methylene-interrupted positions are likely to have better oxidative stability and different physical properties compared to their MI isomers. Very little attention has been paid to these fatty acids as possible raw materials for industrial uses. To attempt to determine whether production of 18:2 $\Delta 9,15$ in a seed oil was possible by metabolic engineering, we overexpressed a gene encoding a linoleate desaturase in the seeds of *Arabidopsis*. Transformed plants accumulated this novel dienoid fatty acid in their seed oil to levels of up to 8% of total seed fatty acids.

Materials and Methods

Construction of the Plant Transformation Vector

A full-length cDNA encoding the *Arabidopsis* extraplastidial linoleate desaturase (Clone U11701, *FAD3*, At2g29980) was obtained from the Arabidopsis Biological Resource Center, DNA Stock Center (Ohio State University; www.arabidopsis.org). An expression cassette comprising the seed-specific *Lesquerella* hydroxylase promoter [12], the *FAD3* cDNA, and an *Arabidopsis* oleosin terminator (kindly provided by Prof. M. Moloney, SemBioSys, Calgary, Canada) was assembled in the binary vector pBar1 [13] to create the vector pDP5.

Arabidopsis Lines and Plant Transformation

Wild-type (Columbia ecotype) and *fad2/fae1* mutant *Arabidopsis* plants [14] were transformed with the binary vector pDP5 using the floral dip method [15]. For screening, T₁ seeds were sown onto moist potting soil, vernalized at 4°C for 72 h then transferred to a growth chamber at 23°C with constant light (fluorescent bulbs giving an intensity of 100 $\mu\text{E m}^{-2} \text{s}^{-1}$ at pot level), and allowed to grow until the first true leaves were clearly visible. Plants were sprayed three times at 2-day intervals with a solution containing 0.1 mL/L Silwet (Lehle Seeds, Round Rock, TX, USA) and 80 mg/L glufosinate ammonium (WipeOut herbicide, CIL Nu-Gro IP, Brantford, ON). Surviving plants were grown to maturity, and seeds (T₂ generation) were harvested from individual plants.

Gas Chromatography of Fatty Acid Methyl Esters

For determination of total seed fatty acid composition, three samples, each of approximately 100 seeds, collected from each individual *Arabidopsis* plant to be analyzed were placed in separate Pyrex screw-cap tubes with 2 mL 1 M HCl in methanol (Supelco) and 300 μL of hexane. The tubes were tightly capped and heated at 80°C for 2 h. After cooling, 2 mL of 0.9% NaCl was added, and fatty acid methyl esters (FAMES) were recovered by collecting the hexane phase. Gas chromatography of FAMES was conducted using an Agilent 6890N GC fitted with a DB-23 capillary column (0.25 mm \times 30 m, 0.25 μm thickness; J & W, Folsom, CA, USA) as described previously [16].

Identification of Fatty Acids by Mass Spectrometry

For identification of fatty acids by mass spectrometry, diethylamide derivatives were prepared, based on the method of [17]. Free fatty acids were generated from total seed lipids by grinding approximately 200 seeds in methanol and directly saponifying with 8.5% methanolic KOH. Fatty acids were dissolved in 400 μL of chloroform, 50 μL of pyridine was added, followed by the dropwise addition of 150 μL of acetyl chloride with continuous shaking. The mixture was diluted with 600 μL of chloroform, and 500 μL of diethylamine was added dropwise with continuous shaking. Excess reagent was removed by extracting twice with 1 mL of water, and the solvent phase was dried under a stream of nitrogen gas. The sample was dissolved in 200 μL of chloroform and 2 μL was directly injected (40:1 split ratio) onto a 30 m DB-23 capillary column in an Agilent 7890A GC equipped with a 5975C mass selective detector (ionizing energy of 70 eV). After an initial hold for 1 min at 160°C, the temperature was ramped at a rate of 4°C/min until reaching 240°C, and then held for 10 min.

Results

To demonstrate the activity of the FAD3 desaturase encoded by vector pDPP5, we transformed wild-type *Arabidopsis* plants with this vector. Transformed plants exhibited increased levels of linolenic acid (18:3 Δ 9,12,15) and reduced amounts of 18:2 Δ 9,12 in their seed oil (Fig. 1b), corresponding to the expected linoleate desaturase activity of the enzyme. Total C18-PUFA (18:2 + 18:3) levels, and the levels of other seed fatty acids were largely unchanged (Table 1). The vector was also used to transform a mutant line of *Arabidopsis* deficient in the activities of the extraplastidic oleate desaturase (FAD2) and seed-specific β -ketoacyl-CoA synthetase (FAE1) [14]. The seeds

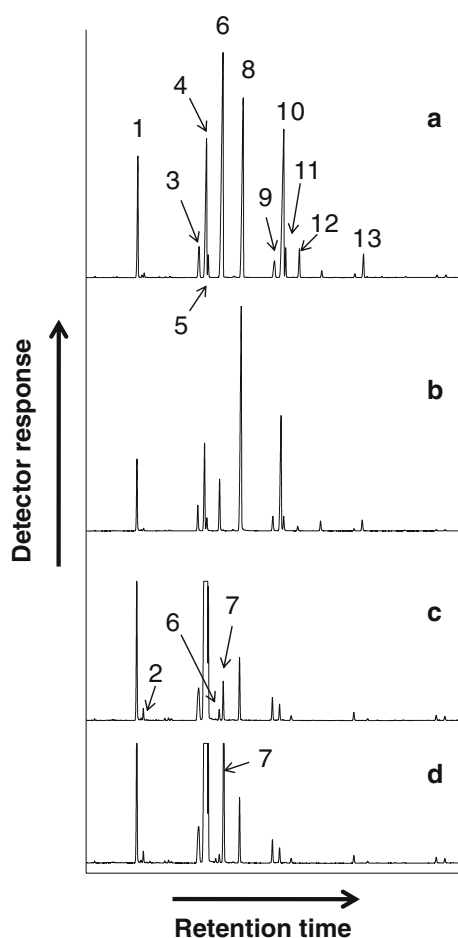

Fig. 1a–d Gas chromatogram traces of FAMES prepared from total seed lipids of *Arabidopsis*. **a** Wild-type. **b** Wild-type expressing the *Arabidopsis* FAD3 desaturase. **c** *Arabidopsis fad2/fae1* mutant. **d** *Arabidopsis fad2/fae1* mutant expressing the *Arabidopsis* FAD3 desaturase. Fatty acids: 1 palmitic acid (16:0); 2 palmitoleic acid (16:1 Δ 9); 3 stearic acid (18:0); 4 oleic acid (18:1 Δ 9); 5 *cis*-vaccenic acid (18:1 Δ 11); 6 linoleic acid (18:2 Δ 9,12); 7 mangiferic acid (18:2 Δ 9,15); 8 linolenic acid (18:3 Δ 9,12,15); 9 eicosanoic acid (20:0); 10 11-eicosenoic acid (20:1 Δ 11); 11 13-eicosenoic acid (20:1 Δ 13); 12 11,14-eicosadienoic acid (20:1 Δ 11, 14); 13 erucic acid (22:1 Δ 13)

of these plants contain over 82% oleic acid and less than 3% linolenic acid (Table 1, Fig. 1c). They also contain two 18-carbon dienoic fatty acids, linoleic acid (18:2 Δ 9,12) and mangiferic acid (18:2 Δ 9,15), at an average of 0.4 and 1.4%, respectively. Preliminary identification of 18:2 Δ 9,15 was based on the work of [9] who observed its presence in the seed lipids of a *fad2* mutant line of *Arabidopsis*. *Fad2/fae1* mutant lines expressing the FAD3 transgene showed increased levels of 18:2 Δ 9,15 and a reduction in 18:1 Δ 9. They also showed lower levels of 18:2 Δ 9,12 and an increase in 18:3 Δ 9,12,15 (Table 1, Fig. 1d). The highest level of PMIFA (18:2 Δ 9,15) observed in the transformed plants was 8.2% of total seed fatty acids. Total C18-PUFA (total 18:2 + 18:3) increased to 11.0% from an average of 4.1%, and a slight increase in total saturated fatty acid content was observed.

To confirm the identity of the putative PMIFA, GC/MS analysis was conducted using a diethylamide derivative of the fatty acid. The mass spectrum (Fig. 2) displayed a molecular ion at $m/z = 335$, suggesting a C18 dienoic fatty acid. Diagnostic ions differing by 12 amu at $m/z = 198$ and 210 and $m/z = 280$ and 292 locate the double bonds at the Δ 9 and Δ 15 (ω 9 and ω 3) positions, respectively. The 14-amu spacing of fragment ions at $m/z = 224$, 238, 252, and 266 demonstrates that there are no double bonds between the Δ 9 and Δ 15 positions. The abundant ion at $m/z = 115$ is suggested to be the McLafferty rearrangement ion, characteristic of fatty acid diethylamide derivatives [17]. An identical mass spectrum was obtained from the diethylamide derivative of the fatty acid identified as 18:2 Δ 9,15 in the seed oil of the untransformed *fad2/fae1* lines. Double-bond configuration (*cis/trans*) was not determined.

Discussion

Previous studies have observed the presence of an unusual dienoic acid in the seed oil of *Arabidopsis* linoleate desaturase-deficient lines. The fatty acid was identified by GC/MS as 18:2 Δ 9,15 and was suggested to result from the ω 3 desaturation of oleic acid [8, 9]. In soybean, low levels of mangiferic acid observed in certain *fad2-1* (oleate desaturase) mutant lines were not seen when plants were crossed with a line containing a suppressed FAD3 gene [10]. We have shown that overexpression of the *Arabidopsis* FAD3 extraplastidic linoleate desaturase in lines containing high 18:1 content results in a substantial increase in the amount of 18:2 Δ 9,15 accumulating in the seed oil. Plant FAD3 desaturases are considered to have ω 3 (methyl-end) rather than Δ 15 (carboxyl-end) regioselectivity. Preferred substrates have ω 6 double bonds, but low-level activity is observed on ω 9 unsaturated fatty acids [9].

Fig. 2 Mass spectrum of diethylamide derivative of 18:2Δ9,15

Overexpression of *FAD3* in seeds that have high levels of oleic acid (ω 9 unsaturation) and low levels of linoleic acid (ω 9 + ω 6 unsaturation) leads to the accumulation of the PMIFA 18:2Δ9,15. A corresponding decrease in 18:1Δ9 content was observed suggesting that the PMIFA results from ω 3 desaturation of oleic acid. To demonstrate the activity of the *Arabidopsis* FAD3 desaturase used in this work, we used the same construct to overexpress *FAD3* in wild-type *Arabidopsis*. Transformed plants synthesized increased amounts of linolenic acid with a corresponding decrease in the substrate fatty acid linoleic acid. Overall levels of PUFAs in these plants were largely unchanged, indicating that the limiting activity in C18 PUFA biosynthesis is likely to be the formation of linoleic acid.

A seed oil rich in dienoic PMIFAs would have novel chemical properties compared to existing oils in which dienoic acids have a MI configuration. Such fatty acids may serve as valuable chemical feed stocks. Recent advances in the development of catalysts for olefin metathesis chemistry, for example, could allow the production of novel hydrocarbon monomers such as α -olefins, α - ω -dienes, and short- to medium-chain ω -unsaturated methyl esters [18]. Metathetical cleavage using ethene (ethenolysis) of fatty acids from meadowfoam oil has been considered as a process for the production of 5-hexenoic acid for polymer biosynthesis [19]. A second product from this oil was 1,9-decadiene resulting from cleavage of 22:2Δ5,13. Ethenolysis of mangiferic methyl ester would

yield methyl-9-decenoate, 1,7-octadiene, and 1-butene. All of these compounds have potential industrial uses. The C18 PMIFA reported in this work results from the activity of an ω 3 desaturase on a suboptimal substrate. PMIFA levels of over 8% of seed fatty acids were however achieved in *Arabidopsis*. Molecular engineering of an ω 3 desaturase to improve its ability to utilize oleic acid offers intriguing possibilities for the generation of new plant oils suitable for use as industrial feed stocks.

During the course of this work, we determined the fatty acid profile of the pulp from ripe mangoes (*Mangifera indica* L., cultivar unknown) purchased from a local supermarket. Palmitic acid (30%) was the major fatty acid, 18:2 Δ 9,12 (25%) and 18:3 Δ 9,12,15 (19%) were also abundant, but no mangiferic acid was detected. The fatty acid profile was different from that reported previously for ripe fruit obtained from the Philippines [7] in which 18:2 Δ 9,12 was only present at levels close to 1% of total pulp fatty acids. It is likely that the material we analyzed is not from the same variety of mango, however, the very low levels of ω 6 unsaturation observed in the previous study may indicate that those fruit differ in oleate desaturase activity, resulting in low levels of 18:2 Δ 9,12. Endogenous ω 3 desaturase activity with 18:1 Δ 9, rather than 18:2 Δ 9,12, as substrate may account for the mangiferic acid previously observed in the fruit pulp.

Acknowledgments The authors would like to thank Dr. Alison Ferrie and Dr. Patrick Covello for critical review of the manuscript and Dr. Sue Abrams for advice on mass spectroscopy. NRC-PBI publication number 50144.

An Isomeric Mixture of Novel Cerebrosides Isolated from *Impatiens pritzellii* Reduces Lipopolysaccharide-Induced Release of IL-18 from Human Peripheral Blood Mononuclear Cells

Xuefeng Zhou · Lan Tang · Yonghong Liu

Received: 13 April 2009 / Accepted: 9 June 2009 / Published online: 17 July 2009

Abstract An isomeric mixture of two cerebrosides, soya-cerebrosides I and II, was isolated from an ethno drug, the rhizomes of *Impatiens pritzellii* Hook. f. var. *hupehensis* Hook. f., and their structures were identified by spectroscopic (NMR, MS) analysis. In order to determine the immunomodulatory activities of soya-cerebrosides I and II, the effects of the mixture of cerebrosides (MC) on cytotoxicity of human peripheral blood mononuclear cells (PBMC) and the inhibitory activities to lipopolysaccharide (LPS)-induced interleukin (IL)-18 in PBMC were studied. The MC at concentrations of 10 and 1 μ M, without toxicity to PBMC in 24 h, showed obvious inhibitory activity on IL-18 secretion. Because of this effect of modulating the cellular immune response, soya-cerebrosides I and II were considered to be the active substances of this ethno drug.

Introduction

The rhizomes of *Impatiens pritzellii* Hook. f. var. *hupehensis* Hook. f. (*I. pritzellii*) are used as an ethno drug for the treatment of rheumatoid arthritis in the northwest district of Hubei province and the Wan county of Chongqing, China [1]. In our previous study, the chemical constituents [2–4] and their immunomodulatory effect in the treatment of rheumatoid arthritis (RA) in mice were investigated [5].

Interleukin (IL)-18, which was formerly called as “IFN- γ -inducing factor”, is a novel cytokine with pleiotropic activities that is critical to the development of Th1 responses [6]. It can induce many other cytokines or components, which play important roles in RA, including IFN- γ , TNF- α , IL-1, GM-CSF, NO and PGE2 [7]. It has been reported that IL-18 is a potential therapeutic target in RA [8]. IL-18 could be secreted from monocytes or macrophages activated by lipopolysaccharide (LPS) [9].

Cerebrosides, a family of glycosphingolipids, are important components of a wide variety of tissues and organs in biological systems. Some cerebrosides have been proven to serve as structural support and texture determinants of cell membranes, and act as mediators of biological events such as activation, cell agglutination, intracellular communication and cell development. The biological activities of cerebrosides are very wide, for example, immunomodulatory, antitumor/cytotoxic, COX-2 and histidine decarboxylase inhibitory, anti-HIV-1, and so on [10].

Soya-cerebrosides I and II were isolated from the rhizomes of *I. pritzellii* and their chemotaxonomic significance were discussed in our previous study [3]. But their biological activities were not studied except their ionophoretic activity for Ca^{2+} ion [11, 12], and the antihepatotoxicity of soya-cerebroside II [13]. In order to discuss the immunomodulatory activities of soya-cerebrosides I and II, the isomeric mixture of these two cerebrosides was prepared and studied for the effect to lipopolysaccharide (LPS)-induced IL-18 in human peripheral blood mononuclear cells (PBMC).

Materials and Methods

General Experimental Procedure

$^1\text{H-NMR}$ and $^{13}\text{C-NMR}$ data were recorded on a Bruker AM-400 spectrometer. FABMS and HR-FABMS were conducted using a VG Auto Spec-3000 instrument. Optical rotation was determined on a Perkin–Elmer digital polarimeter. GC was carried out on a GC-14C gas chromatograph (Shimadzu, Japan) with a DB-17 fused silica capillary column (30 m \times 0.25 mm \times 0.25 μm) (J & W Scientific); FID detection; N_2 ; 230 $^\circ\text{C}$ for injector and detector; 150 $^\circ\text{C}$ for 1 min and then raised to 230 $^\circ\text{C}$ at the rate of 5 $^\circ\text{C}/\text{min}$. Silica gel (100–200, 200–300 mesh, Qingdao Marine Chemical Group Co., Qingdao, China) and Sephadex LH-20 (Amersham Pharmacia Biotech AB, Uppsala, Sweden) were used for column chromatography.

Plant Material

The rhizomes of *Impatiens pritzellii* Hook. f. var. *hupehensis* Hook. f. (Balsaminaceae) were collected in Enshi, Hubei province, China, and identified by Prof. Dingrong Wan (Hubei Province Institute for Drug Control, China). A voucher specimen (P 20020713) was deposited at the Faculty of Pharmaceutical Sciences, Tongji Medical College of Huazhong University of Science and Technology, Wuhan, China.

Extraction and Isolation

The extraction and isolation were briefly described previously [8], but this time compound **1** (soya-cerebroside I, 8 mg) and the mixture of cerebrosides (MC, soya-cerebrosides I and II, 36 mg) were isolated.

Preparation of Monocytes

Human PBMC were obtained from three healthy male volunteers after informed consent. Twenty milliliters of peripheral blood was withdrawn from the vein of the forearm. PBMC were isolated from the buffy coat of human peripheral blood by centrifugation on Nycoprep 1.077 (AXIS-SHIELD, Oslo, Norway) and then washed three times in RPMI 1640 medium (Nissui Co. Ltd., Tokyo, Japan). PBMC were suspended at a final concentration of 1×10^6 cells/mL in RPMI 1640 medium supplemented with 10% (v/v) heat-inactivated fetal calf serum.

Cytotoxicity Assay

The cytotoxicity of MC on PBMC was determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay.

Briefly, PBMC (1×10^6 cells/mL) were incubated with MC (1, 10, and 50 μM , with 1% DMSO) in 96-well plates to determine the cytotoxicity or proliferation effect of MC to PBMC. Meanwhile, PBMC were incubated together with MC and LPS (1 $\mu\text{g}/\text{mL}$, Sigma, MO, USA) to determine the effect of MC to LPS induced proliferation of PBMC [14]. PBMC incubated with 1% DMSO were used as control. All of these were prepared in three 96-well plates for different incubation periods (12, 24 and 48 h). After incubating in 37 $^\circ\text{C}$, 5% CO_2 and 90% humidity incubator for corresponding period (either 12, 24 or 48 h), 20 μL of MTT (Sigma, MO, USA) at 5 mg/mL was added into each well in the 96-well plate and incubated for 4 h at 37 $^\circ\text{C}$, 5% CO_2 and 90% humidity in an incubator. The solution was removed and 100 μL DMSO was added to dissolve the MTT formazan crystals. The plates were mixed on a microshaker for 10 min and then read the OD value on a microplate reader (Stat Fax-2100, USA) at 570 nm. Each concentration and control was assayed in triplicate three times. The cytotoxicity and cell survival were evaluated by the following formula:

$$\text{Cytotoxicity (\%)} = (\text{OD}_{\text{control}} - \text{OD}_{\text{sample}}) / \text{OD}_{\text{control}} \times 100\%$$

$$\text{Cell survival (\%)} = (\text{OD}_{\text{sample}} / \text{OD}_{\text{control}}) \times 100\%$$

Cytokine Assays

PBMC (1×10^6 cells/mL) were co-incubated with MC (1, 10, and 50 μ M, with 1% DMSO) and LPS (1 μ g/mL) at 37 $^{\circ}$ C, 5% CO₂ and 90% humidity in an incubator. PBMC incubated with LPS (1 μ g/mL) and 1% DMSO was used as model group and azothioprine (AZP, 1 and 10 μ M, Jiufu Drug Co., Shanghai, China) as positive control. After 24 h of culture, the cell suspensions were transferred into Eppendorf tubes and centrifuged. The cell-free supernatant fractions were assayed for IL-18 protein. IL-18 levels were measured using commercially available enzyme-linked immunosorbent assay (ELISA) kits (Human IL-18 INSTANT ELISA, BMS, Vienna, Austria) after standardization of the protein concentrations, and the detection limit was 10 pg/mL. The IL-18 level in untreated PBMC was also measured.

Statistical Analysis

Data are presented as means \pm SD. The results were statistically analyzed by one-way analysis of variance (ANOVA), followed by Dunnett's *t* test. *P* values < 0.05 were considered significant.

Results and Discussion

Compound **1** (soya-cerebroside I, 8 mg) and the mixture of cerebroside (MC, soya-cerebroside I and II, 36 mg) were isolated from the rhizomes of *I. pritzellii*. Compound **1** was obtained as white powder and had the molecular formula C₄₀H₇₅NO₉ as deduced from negative-ion HR-FABMS (*m/z* 712.5480 [M–H][–], calcd 712.5442) and ¹³C-NMR data. The signals of two long and branchless carbon chains, an amide group and a sugar moiety in ¹H and ¹³C-NMR spectrum suggested compound **1** was a cerebroside. Acid hydrolysis of **1** yielded D-glucose, as determined by TLC (EtOAc–MeOH–H₂O–HOAc, 6:1:1:1, *R_f* = 0.32), GC analyses (*R_t* = 23.37, D-glucose derivative) [15] and optical rotation (positive polarity), together with authentic sugar samples. The locations of hydroxyl groups and double bonds were determined by HMBC and ¹H–¹H COSY experiments. The configurations of two double bonds were determined to be *E* from the ¹³C-NMR chemical shift of the methylene carbon adjacent to the olefinic carbon as described in the literature [16]. The length of two long carbon chains, long-chain base (LCB) and fatty acid (FA), were determined by negative-ion FABMS: *m/z* 712 ([M–1][–]), 550 ([M–C₆H₁₀O₅–H][–]), 296 (LCB, [C₁₈H₃₄NO₂][–]) and 254 (FA, [C₁₆H₃₁O₂–H][–]). The ¹H and ¹³C-NMR spectrum and optical rotation of **1** ([α]_D²⁰ + 9.5 $^{\circ}$, *c* 0.1, MeOH) suggested that **1** has the same

Fig. 1 Chemical structures of soya-cerebroside I and II

absolute configuration as that of AS-1-4 (2*S*, 3*R*, 2'*R*) in the literature [16]. So, compound **1** was identified as 1-*O*- β -D-glucosyl-(2*S*, 3*R*, 4*E*, 8*E*, 2'*R*)-*N*-(2'-hydroxypalmitoyl)-2-amino-4,8-octadecadiene-1,3-diol (soya-cerebroside I) (Fig. 1).

The MC was obtained as white powder and the negative-ion FABMS showed the same molecular ion peak as compound **1** (*m/z* 712 [M–1][–]). The ¹H and ¹³C-NMR spectrum were similar with those of compound **1**, except the redundant signals of two olefinic carbons (δ 129.5, 130.7) and two methylene carbons (δ 27.4, 27.6). These redundant signals suggested there was another isomeric compound besides **1**. The *Z* configuration of double bond at C-8,9 was fit those four redundant carbon signals perfectly [16]. So, the other component in the mixture was determined as 1-*O*- β -D-glucosyl-(2*S*, 3*R*, 4*E*, 8*Z*, 2'*R*)-*N*-(2'-hydroxypalmitoyl)-2-amino-4,8-octadecadiene-1,3-diol (soya-cerebroside II). The ¹³C-NMR data of compound **1** and MC were showed in Table 1. MC was identified as isomeric mixture of soya-cerebroside I and II by comparing those NMR data in the literature [16].

The MTT assay was used to determine the cytotoxicity of MC on PBMC before evaluating the interleukin inhibitory activities (Fig. 2). MC showed obvious cytotoxicity to PBMC, at a concentration of 50 μ M, with survival of 86.67 ± 4.04 , 83.33 ± 6.66 , $72.67 \pm 7.57\%$ in 12, 24, 48 h, respectively. While MC at the concentration of 10 and 1 μ M showed no cytotoxicity. The proliferation effect of LPS (1 μ g/mL) to PBMC increased when the culture time was extended to 24 and 48 h, with a survival rate of 118.33 ± 7.57 and $141.33 \pm 7.64\%$, respectively. We found that MC had obvious inhibitory effect to LPS induced proliferation of PBMC at concentration of 50 μ M, which might be due to its cytotoxicity. At lower concentration (10 and 1 μ M), MC showed inhibitory effects to LPS-induced proliferation of PBMC when the co-culture time was extended to 48 h, and this revealed MC could effect the survival of PBMC activated by LPS when co-culture long enough.

The levels of IL-18 in PBMC co-cultured with MC and LPS were determined by ELISA kits (Fig. 3), and the

**Fig. 2** Effect of MC in different concentrations on cell survival of PBMC at 12, 24 and 48 h. The concentration of LPS is $1 \mu\text{g/mL}$. 1% DMSO was used in every group and each concentration was assayed in triplicate three times. The results are presented as means \pm SD

culture time was 24 h. The significant effect of MC, at the concentration of $50 \mu\text{M}$, to inhibit the production of IL-18 in vitro might be partly due to its cytotoxicity to PBMC.

**Fig. 3** Effects of MC on LPS-induced IL-18 level in PBMC at 24 h. AZP: azothioprine. The concentration of LPS is $1 \mu\text{g/mL}$. 1% DMSO was used in every group including model and untreated groups. IL-18 levels were measured by ELISA kits. The results were presented as means \pm SD ($n = 8$). One-way ANOVA revealed significant effects between model and treatment groups ($P < 0.001$). * $P < 0.05$ compared with model (Dunnett's t test)

However, MC at concentrations of 10 and $1 \mu\text{M}$, which showed no toxicity to PBMC in 24 h, were found inhibitory to IL-18 secretion. This result suggested MC might potentially modulate the cellular immune response in monocytes [17]. Moreover, the inhibitory activity of MC at concentration of $1 \mu\text{M}$ was somewhat higher than that for $10 \mu\text{M}$. Intracellular IL-18 represents a storage pool, which may be initially depleted by MC before their reduction in the excretion into the supernatant [18]. MC with the concentration of $1 \mu\text{M}$ could cause a marked decrease in extracellular levels of IL-18, as well as in intracellular. However, at the concentration of $10 \mu\text{M}$, MC might inhibit the intracellular IL-18 extremely, which was not seen by measuring cytokine level in cellular supernatants by ELISA technique. The toxicity of MC with $10 \mu\text{M}$, which were not observed by MTT measurement, affected the function of transportation of cytokines through the cell membrane. These results suggest that higher concentrations of MC result in a direct toxic or breaking the cellular function of PMBC compared with an immunosuppressive effect at lower concentration ($1 \mu\text{M}$). In addition, there is more than one mechanism of inhibitory of the IL-18 production of MC, as well as more than one pathway of the cytokine secretion [19]. The level of IL-18 and its effects on Th1/Th2 balance in immune cells were considered to be dependent on the coexisting cytokine and the state of activation of subsets [20]. So, the mechanisms of effects on the IL-18 secretion of MC might be much complicated and further study should be continued.

The IL-18 inhibitory activities of MC and its cytotoxicity on PBMC suggested MC could potentially modulate the cellular immune response. Because of the pleiotropic activities of IL-18 in the development of Th1 responses [6, 7], MC could be considered to modulate the cytokines levels in monocytes.

Our previously study revealed methanol extract of the rhizomes of *I. pritzellii* could modulate the cytokines levels, including down-regulation of the levels of IL-18, in serum of mice with RA model [5]. Soya-cerebrosides I and II, whose immunomodulatory effect was investigated in current study, were indicated to be the active substances in *I. pritzellii*.

Abstract We established a convenient assay method for measuring elongation of very long chain fatty acids (ELOVLs) using a Unifilter-96 GF/C plate. The Unifilter GF/C plate preferentially interacts with hydrophobic end products of ELOVLs (i.e., long chain fatty acid), with minimal malonyl-CoA (C2 unit donor for fatty acid elongation) interaction. This new method results in the quick separation and detection of [¹⁴C] incorporated end products (e.g., [¹⁴C] palmitoyl-CoA) from reaction mixtures containing excessive amounts of [¹⁴C] malonyl-CoA. In the Unifilter-96 GF/C plate assay, recombinantly expressed human ELOVLs (i.e., ELOVL1,-2,-3,-5 and -6) displayed appreciable assay windows (>2-fold vs. mock-transfected control), enabling us to conduct comprehensive substrate profiling of ELOVLs. The substrate concentration profile of ELOVL6 in the Unifilter-96 GF/C plate assay is consistent with that obtained from the conventional liquid extraction method, thus, supporting the reliability of the Unifilter-96 GF/C plate assay. We then examined the substrate specificities of ELOVLs in a comprehensive fashion. As previously reported, ELOVL1,-3 and -6 preferably elongated the saturated fatty acyl-CoAs while

ELOVL2 and ELOVL5 preferentially elongated the polyunsaturated fatty acyl-CoAs. This further confirms the Unifilter-96 GF/C plate assay reliability. Taken together, our newly developed assay provides a convenient and comprehensive assay platform for ELOVLs, allowing investigators to conduct high density screening and characterization of ELOVLs chemical tools.

Keywords ELOVL · Elongase · Long chain fatty acyl-CoA · Malonyl-CoA · Long chain fatty acid · Obesity · Diabetes · Metabolic disorder

Abbreviations

BSA	Bovine serum albumin
CoA	Coenzyme A
EDTA	Ethylenediaminetetraacetic acid
ELOVL	Elongase of long chain fatty acyl-CoA
LCFA	Long chain fatty acid
NADPH	Reduced nicotinamide adenine dinucleotide phosphate
SDS	Sodium lauryl sulfate
TBS	Tris-buffered saline

Introduction

Obesity, a complex condition associated with an increased risk of type 2 diabetes, hypertension, and cardiovascular diseases, is becoming a global epidemic. Accumulating evidence indicates that alternations in intracellular lipid metabolism play a prominent role in the pathology of obesity and diabetes [1]. An increase in fat storage in the nonadipose tissues such as the liver, leads to tissue

dysfunction, i.e., insulin resistance. Although it is unclear how increased intracellular lipid content exacerbates tissue and whole body insulin sensitivity, it has been suggested that increased levels of long chain fatty acyl-CoA antagonize the metabolic actions of insulin. Interestingly, recent reports have suggested that alternations of the specific fatty acid component (i.e., palmitoleate) have a significant impact on the insulin sensitivity of the liver and whole body [2, 3].

De novo lipogenesis plays a major role in maintaining energy storage and membrane fluidity. Fatty acid synthase (FAS), a cytosolic and multifunctional enzyme, is responsible for de novo synthesis of acyl-CoAs with fatty acid chains of C2 up to C16 (palmitoyl-CoA), while the elongation of very long chain fatty acids (ELOVL) family enzymes, microsome resident enzymes, are responsible for the elongation of fatty acids with longer chain fatty acids [4]. It is reported that fatty acid elongation in microsomal fractions occurs through four sequential steps: (1) condensation by ELOVL (elongase of long chain fatty acyl-CoA), (2) reduction by β -ketoacyl-CoA reductase, (3) dehydrogenase by β -hydroxyacyl-CoA dehydrogenase, and (4) reduction by trans-2,3-enoyl-CoA reductase [5, 6]. Given NADPH-dependent activity of β -ketoacyl-CoA reductase, the condensation activities of ELOVLs can be monitored in the absence of NADPH [7, 8].

In mammals, seven ELOVL enzymes (ELOVL1-7) have been identified [7, 9–13]. Accumulating evidence suggests that each ELOVL exhibits different fatty acid substrate preferences. In addition to the diverse substrate preference, it has been reported that ELOVLs are expressed in distinct tissues and their expressions were differently regulated. This suggests ELOVLs have distinct physiological roles [13–15]. Recent progress in this area revealed the potential physiological and pathological roles of ELOVLs. It was reported that overexpression of ELOVL2, but not ELOVL3, enhanced triglyceride synthesis and lipid accumulation in preadipocytes cells [16], suggesting ELOVL2 plays an important role in adipose tissues. ELOVL3 has been identified as a long chain fatty acid elongase that is highly expressed in brown adipocytes and skin. ELOVL3 is upregulated by cold-exposure in vivo. In addition, ELOVL3-deficient mice displayed a distinct skin phenotype including impaired barrier function, suggesting ELOVL3 plays a critical role in the regulation of thermogenesis and body temperature [17].

ELOVL6 has gained much attention in the field of metabolic disorders; Matsuzaka and his colleagues reported ELOVL6-deficient mice displayed improved insulin sensitivity and glucose homeostasis as compared with the wild-type mice when fed a high-fat diet. Therefore, ELOVL6 might serve as a therapeutic target for metabolic disorders [2].

In this study, we describe a convenient high density assay method (96-well format) for ELOVLs, which provides a comprehensive analysis of substrate specificities of ELOVLs.

Materials and Methods

Reagents

[2-¹⁴C] malonyl-CoA (1.92 GBq/mmol) was purchased from GE Healthcare Bioscience (Tokyo, Japan). [1-¹⁴C] palmitic acid, [1-¹⁴C] stearic acid, Unifilter-96 GF/C plate and MICROSCINT 0 were all purchased from PerkinElmer Japan (Kanagawa, Japan). [1-¹⁴C] behenic acid (C22:0), [1-¹⁴C] Δ -7,10,13,16-docosatetraenoic acid (C22:4), [1-¹⁴C] arachidic acid (C20:0) and [1-¹⁴C] Δ -11-eicosenoic acid (C20:1) were from Muromachi-Yakuhin (Tokyo, Japan). Other reagents were purchased from Sigma-Aldrich Japan (Tokyo, Japan).

Cloning of Human ELOVLs from Human Liver cDNA and Expression Vector Construction

The full-length human ELOVLs cDNAs were amplified by polymerase chain reaction (PCR) using gene specific primers from human liver cDNA (Clontech, Mountain View, CA) as the template. The primer sequence for cloning each elongase (Supplemental Table 1) was designed based on sequences obtained from GenBank and 5'-primers and 3'-primers introduced the *NotI* and *XbaI* sites in the 5'-end, respectively. The PCR products were subcloned into pEF1/V5-His vector (Invitrogen, Carlsbad, CA), which express C-terminal tag encoding V5-epitope and polyhistidine. The integrity of all PCR products and ligation was confirmed by DNA sequencing.

Cell Culture and Transfection

COS-7 cells (African green monkey kidney fibroblast cells) were grown in Dulbecco's modified Eagle's medium (DMEM; Invitrogen) containing 10% fetal bovine serum, supplemented with 100 units/ml penicillin and 100 μ g/ml streptomycin. For transfection, COS-7 cells were plated at a density of 5×10^7 cells/500 cm² square dish in DMEM. After overnight culture, cells were transfected with 240 μ g pEF1/V5-His plasmids harboring each ELOVL open reading frame (ORF) using 600 μ l Lipofectamine2000 reagent (Invitrogen), according to the manufacturer's instructions. After 48 h transfection, cells were washed three times with cold PBS and harvested in 10 ml of cold PBS. The cells were collected by centrifugation and stored at -80°C until use.

Preparation of Microsome Fractions Overexpressing Recombinant Human ELOVLs

The cell pellets were suspended in the homogenization buffer (10 mM Tris-HCl, pH 7.4, 1 mM EDTA, 0.25 M sucrose) containing protease inhibitor cocktail (Roche, Basel, Switzerland) and homogenized with POLYTRON homogenizer (Kinematica, Lucerne, Switzerland). Cell homogenates were centrifuged at 1,000g for 10 min at 4°C and the supernatant was centrifuged at 10,000g for 10 min at 4°C. The resulting supernatant was further centrifuged at 100,000g for 1 h at 4°C. The pellet was resuspended in buffer (50 mM Tris-HCl, pH 7.4, 1 mM EDTA, 20% glycerol) with protease inhibitor cocktail, and centrifuged again at 100,000g for 1 h at 4°C. The pellet was resuspended in buffer and used as microsomal protein. Concentration of the microsomal protein was determined by BCA protein assay kit (Pierce, Rockford, IL) and stored at -80°C until use.

Immunoblot Analysis

The expressions of V5 epitope-tagged human ELOVLs in microsomes from transfected COS-7 cells were examined by Immunoblot analysis using anti-V5-epitope antibody. In brief, cytosolic and microsomal protein (20 µg) were electrophoresed on a 10% SDS-polyacrylamide gel and transferred to PVDF membrane (Immobilon-P, Millipore) using the standard procedure. The membrane was blocked for 1 h at room temperature in TBS, 0.05% Tween-20 (TTBS) containing 1% dried non-fat milk, and then incubated with a 1:1,000 dilution of the horseradish peroxidase-conjugated anti-V5 monoclonal antibody conjugated (Anti-V5-HRP, Invitrogen) in TTBS for 1 h at room temperature. After 3 washes with TTBS, antibody-protein complexes were visualized using an ECL Plus kit (GE Healthcare Bioscience).

Binding of Malonyl-CoA and Long Chain Fatty Acids to the GF/C Filter

Radiolabelled C22:0, C22:4, C20:0, C20:1, C18:1 and malonyl-CoA (60 µM) were dissolved in the assay buffer containing 100 mM potassium phosphate buffer (pH 6.5), 200 µM BSA (fatty acid free), 500 µM NADPH, 1 µM rotenone and were applied to the Unifilter-96 GF/C plate. After three times washing with distilled water, the residual radioactivity values on the GF/C filter were measured by TopCount. The radioactivity values of fatty acids and malonyl-CoA on non-washed wells were also measured and defined as total radioactivity values. Remaining % of the respective fatty acids and malonyl-CoA are determined as follows;

$$\text{Remaining (\%)} = \left[\frac{\text{residual radioactivity after washing}}{\text{total radioactivity (non-wash)}} \right] \times 100$$

To compare the relative remaining (%) of fatty acids over malonyl-CoA, the remaining (%) of respective fatty acid was standardized by the remaining (%) of malonyl-CoA to yield the ratios of the respective fatty acids to Malonyl-CoA as follows:

$$\text{Remaining ratio} = \left[\frac{\text{remaining (\%)} \text{ of fatty acid}}{\text{remaining (\%)} \text{ of malonyl-CoA}} \right]$$

Fatty Acyl-CoA Elongation Assay

Reaction Step

Fatty acyl CoA elongation using the microsome fractions was performed by the method previously described [7] with slight modifications. Briefly, 30 µl reaction mixtures (100 mM potassium phosphate buffer (pH 6.5), 200 µM BSA (fatty acid free), 500 µM NADPH, 1 µM rotenone, 20 µM malonyl-CoA, 833 kBq/ml [2-¹⁴C] malonyl-CoA and 40 µM long chain fatty acyl-CoA) were used as the substrate mixture, and then the elongation reaction was initiated with the addition of 20 µl microsomal protein. The reaction step was performed on a 96 well plate with gentle shaking.

Separation Step

After 1 h incubation at 37°C, 50 µl of 5 M HCl was added to hydrolyze acyl-CoAs. The reaction mixtures were then filtered through the Unifilter-96, GF/C plate (Perkin Elmer) using FilterMate cell harvester (Perkin Elmer). The 96-well GF/C filter plate was subsequently washed with distilled water to remove the excess amount of [2-¹⁴C] malonyl-CoA. After drying the plate, 25 µl MICROSCINT 0 was added to each well and the residual radioactivity was measured by TopCount (Perkin Elmer). In order to compare the performance of our assay method with that of the conventional one, the separation step was conducted according to the previously described conventional method [7]. Briefly, after hydrolysis, the resulting mixtures were transferred into the glass tubes and extracted with 1 mL of n-hexane (3 times). The hexane layers were collected to a scintillation vial and dried up under nitrogen stream. The resulting materials were mixed with 3 mL of Clear-sol II (Nacalai tesque, Kyoto, Japan) and their radioactivity were measured by the liquid scintillation analyzer TRICARB 2300 (PerkinElmer).

Results

Expression of ELOVLs in Microsome Fraction of the Transfected COS-7 Cells

COS-7 cells were transfected transiently with a cDNA encoding V5 epitope-tagged human ELOVLs. Cytosolic fractions and microsome fractions from the transfected cells were prepared and subjected to western blot analyses with anti-V5 antibody (Fig. 1). We observed the specific bands showing the expected molecular weight (ca. 30 kDa) for each ELOVLs in microsome fractions but not in cytosolic fractions. This confirmed successful expression of recombinant ELOVLs in the microsomal fractions.

Different Binding Properties of Malonyl-CoA and Long Chain Fatty Acids to GF/C Filter

ELOVLs are rate-limiting enzymes for elongation of long chain fatty acid (LCFA) and catalyze the condensation between LCFA-CoA and malonyl-CoA, a C2 unit for elongation. Therefore, elongase activities are monitored by measuring the incorporation of [¹⁴C] into the reaction products (i.e., LCFA-CoAs) from [¹⁴C] malonyl-CoA after removing excessive [¹⁴C] malonyl-CoA from the reaction mixture. In the conventional assay, separation of radiolabelled hydrophobic products from reaction mixtures is achieved by organic solvent extraction or solid phase chromatography. We assumed that the GF/C filter could separate radiolabelled LCFAs from the reaction mixture by preferentially absorbing LCFAs while interacting to a lesser extent with malonyl-CoA, a more hydrophilic substance. Considering its potential application to the ELOVL

Fig. 1 Expression of V5-tagged human ELOVLs in microsomal fractions of transfected COS-7 cells. COS-7 cells were transiently transfected with the V5-tagged human ELOVLs cDNA expression vectors or the vector alone (mock). After 48 h transfection, the cells were harvested and the cytosolic and microsomal fractions were isolated according to the standard procedure. Twenty micrograms of cytosolic (C) and microsomal (M) protein were subjected to SDS-PAGE and immunoblot analysis

Fig. 2 Binding profiles of malonyl-CoA and long chain fatty acids to the GF/C filter. Radiolabelled fatty acids and malonyl-CoA (60 μM) were dissolved in assay buffer and applied to the Unifilter-96 GF/C plate. After washing, the residual radioactivity values on the GF/C filter were measured by TopCount. The horizontal axis indicates the fold of the residual radioactivity of respective fatty acids compared to that of malonyl-CoA. Data are expressed as means ± SD

assay, we evaluated the binding profiles of malonyl-CoA and the expected ELOVL end-products such as C22:0-, C22:4-, C20:0-, C20:1- and C18:0-fatty acids (for ELOVL1, -2, -3, -5 and -6, respectively) as described in the [Materials and Methods](#). LCFAs were retained on the GF/C filter by 5- to 20-fold as compared with malonyl-CoA following the washing step (Fig. 2).

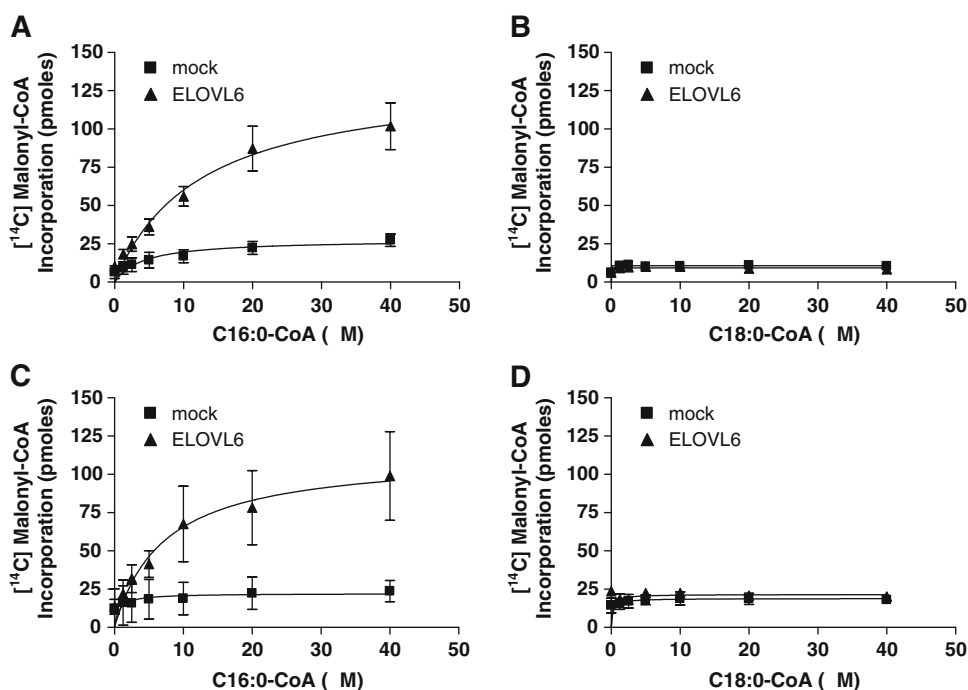

Assay Validation

In order to validate our new assay method, we examined the substrate specificity of ELOVL6 reported to elongate myristoyl-CoA (C14:0-CoA) and palmitoyl-CoA (C16:0-CoA), but not stearoyl-CoA (C18:0-CoA) [7]. As expected, we observed that human ELOVL6-transfected microsome fractions preferentially elongated myristoyl-CoA and palmitoyl-CoA with greater efficacy (4-fold) as compared with mock-transfected microsome fractions (Figs. 3a, 5e). In contrast, we could not see any differences in the elongation activities between the ELOVL6- and mock-transfected microsome fractions when stearoyl-CoA and other acyl-CoAs with longer, unsaturated fatty acids were used as substrates (Figs. 3b, 5e). Taken together, these results support the substrate specificity of ELOVL6 that was determined by the conventional assay method (Figs. 3c, 3d); thus demonstrating the reliability of the GF/C filter plate assay.

Application to Other Elongases

Since our newly developed assay method has been validated for ELOVL6, we have applied it to the other representative fatty acid elongases: ELOVL1, -2, -3 and -5. The

Fig. 3 Substrate concentration profiles for human ELOVL6 activity in microsomes from transfected COS-7 cells. Microsome fractions were prepared from COS-7 cells transfected with human ELOVL6 or mock vectors. The elongation activities against C16:0-CoA (**a, c**) or C18:0-CoA (**b, d**) were examined using the filtration assay method (**a, b**) and conventional assay method (**c, d**) as described in the [Materials and Methods](#). The elongation activities were represented by malonyl-CoA incorporation (pmol). Data are expressed as means \pm SEM from three independent experiments

microsome fractions overexpressing human recombinant ELOVL1, -2, -3 and -5 were prepared and used to test the elongase assays using the GF/C filter plates (Figs. 1, 4, 5). For the substrate concentration profile studies, representative substrates were used for each ELOVL: C20:0-CoA for ELOVL1, C20:4-CoA for ELOVL2, C18:0-CoA for ELOVL3 and C18:1-CoA for ELOVL5. As shown in Fig. 4, the ELOVL-transfected microsome fractions displayed dose-dependent activities that were 2.4-fold, 2.4-fold, 3.2-fold, and 3.2-fold higher than that of the mock transfected microsomes, respectively. These results suggest that under the current conditions, each ELOVL retains its own elongase activity and the GF/C filter assay plate assay is applicable to the measurement of these representative ELOVLs.

Comparison of the Substrate Preferences of Human ELOVLs

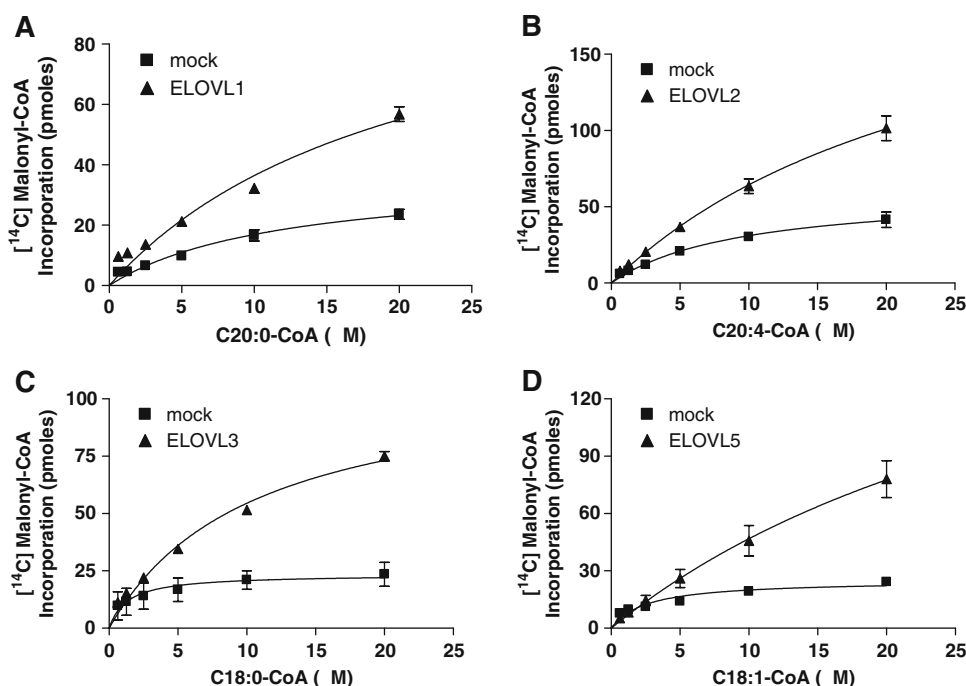

Up till now, seven ELOVLs (i.e., ELOVL1-7) have been genetically identified in mammals and characterized by several investigators using recombinantly expressed enzymes. To date, there have been no other studies using identical platforms for the expression and assay methods for ELOVLs. Since we observed significantly increased elongase activities of each recombinant ELOVL using the respective substrate (vs. mock-transfected controls), we have examined the substrate specificity of ELOVLs using a series of saturated and unsaturated fatty acyl-CoAs as substrates (Fig. 5a–e). ELOVL1, -3 and -6 preferably elongated the saturated fatty acyl-CoA (ELOVL1; C18:0,

C20:0 and C22:0, ELOVL3; C14:0, C16:0, C18:0 and C20:0, ELOVL6; C14:0, and C16:0), while ELOVL2 and -5 preferably elongated the mono- and poly unsaturated fatty acyl-CoA (ELOVL2; C20:4, ELOVL5; C16:1, C18:1, C18:2, and C20:4). These results are in good agreement with previous reports except that ELOVL5 also elongated the saturated acyl-CoAs (i.e., C14:0 and C16:0) in addition to the unsaturated acyl-CoAs.

Discussion

We have described our newly developed assay system for the measurement of long chain fatty acid elongases (i.e., ELOVLs) and its application in ELOVL primary characterization. This assay method is based on the findings that [14 C] malonyl-CoA (hydrophilic substance) and elongated long chain fatty acids (hydrophobic substance) are separated by the GF/C filter (Fig. 2). In conventional fatty acid elongase assays, the separation steps of radioactive products from reaction mixtures by organic solvent extraction or solid phase chromatography are required [7, 18] (Fig. 6). Although these methods are reliable and widely utilized, they are too labor intensive; meaning they are not suitable for screening a chemical library and head-to-head characterization or comparison of elongase activities. Regarding several cytosolic lipogenic enzymes such as FAS and farnesyl pyrophosphate synthase (FPPS), Glickman et al. reported that the FlashPlate assay provides investigators with robust assay windows, where the hydrophobic products preferably associate with a lipid-coated surface

Fig. 4 Substrate concentration profiles for human ELOVL1, -2, -3, and -5 activities in microsomes from transfected COS-7 cells. Microsome fractions were prepared from COS-7 cells transfected with human ELOVL1, -2, -3, -5 or mock vectors. The elongation activities of ELOVL1, -2, -3, or -5 were determined using C20:0-CoA (a), C20:4-CoA (b), 18:0-CoA (c) or C18:1-CoA (d) as the substrate and [14 C] malonyl-CoA as a C2 unit donor. The elongation activities were represented malonyl-CoA incorporation (pmol). Data are expressed as means \pm SEM from four or five independent experiments

[19, 20]. In the case of membrane enzymes such as ELOVLs, the enzyme fraction (i.e., microsome) provides a significant amount of lipid to the reaction mixture, which in turn interferes with the association of a hydrophobic end product and a lipid-coated surface. This gives rise to high background noise and increasing non-specific interactions of radioactive mixtures with the lipid-coated surface (data not shown).

Assay Development and Validation

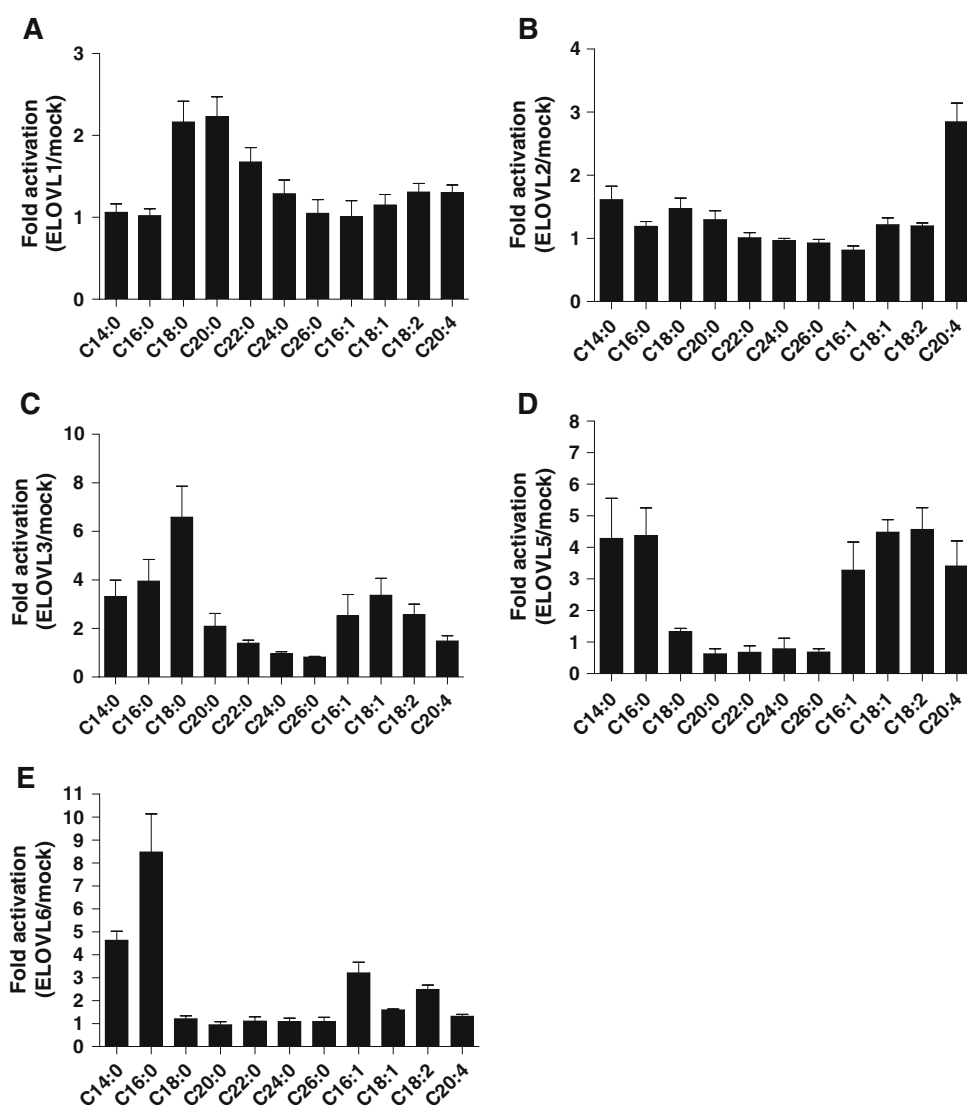

In our elongation assay, [14 C] malonyl-CoA was incorporated into long chain fatty acids and the excess amount of [14 C] malonyl-CoA was efficiently removed from the reaction mixtures by washing the GF/C filter. This resulted in the establishment of a quick and convenient ELOVL assay method in a 96-well format (Fig. 6). As expected from their hydrophobic properties associated with long chain fatty acid components (cLogP of C22:0, C22:4, C20:0, C20:1 and C18:0; >7.9 vs. cLogP of malonyl-CoA; -4.3 , cLogP was calculated by ACD software), long chain fatty acids corresponding to the representative end-products of each ELOVL enzyme remain on the GF/C filter with greater efficacy than malonyl-CoA after washing (Fig. 2). Among the long chain fatty acids tested, although C22:4, the end product of ELOVL2 (i.e., elongation of C20:4), displayed relatively low remaining efficacy, its remaining efficacy was still 5 times larger than that of malonyl-CoA. This enabled us to conduct the primary characterization of ELOVL2 (Figs. 4b, 5b). Although further research is necessary, the relatively low remaining

property of C22:4 (5-fold) may be associated with its higher desaturation degree as compared with the corresponding saturated fatty acid (vs. C22:0; 15-fold).

In order to validate our newly developed assay methods, we first examined the substrate profile of ELOVL6 because the substrate specificity of ELOVL6 has been well characterized with conventional assays [7]. Regarding the enzyme materials, immunoblot analysis has confirmed that recombinant ELOVL6 is successfully expressed in the microsome fractions without altering its intrinsic compartment location (Fig. 1). Furthermore, recombinant ELOVL6 displayed selective elongation activities against myristoyl-CoA (C14:0-CoA) and palmitoyl-CoA (C16:0-CoA), recapitulating the reported substrate profiles of ELOVL6. Taken together, this suggests C-terminally tagged recombinant ELOVL proteins and the GF/C-filter method are reliable for measuring ELOVL activities. In support of this, we similarly observed that the microsomes from ELOVL-transfected cells, but not mock-transfected cells, displayed dose-dependent increases in elongation activities against the acyl-CoA substrates, respectively, with appreciable assay windows (Fig. 4).

Because there had been no report that compares the substrate specificities of human ELOVLs using the same format, we further examined and compared the detailed substrate profiles of the representative ELOVLs; ELOVL1, -2, -3, -5 and -6. Consistent with previous reports [4, 7, 12, 21, 22], ELOVL1, -3, and -6 preferentially elongated the saturated acyl-CoAs while ELOVL2 and ELOVL5 elongated the unsaturated acyl-CoAs (Fig. 5). With regard to

Fig. 5 Comparison of the substrate specificity of human ELOVL enzymes. The substrate specificities of human ELOVL enzymes were assessed using a series of saturated (C14:0, C16:0, C18:0, C20:0, C22:0, C24:0 and C26:0), monounsaturated (C16:1 and C18:1), and polyunsaturated (C18:2 and C20:4) fatty acyl-CoAs. Data were expressed as fold activities of ELOVLs-transfected microsomes (a ELOVL1, b ELOVL2, c ELOVL3, d ELOVL5, e ELOVL6) compared to that of mock transfected microsomes. Data are expressed as means \pm SEM from three independent experiments for each ELOVL enzyme

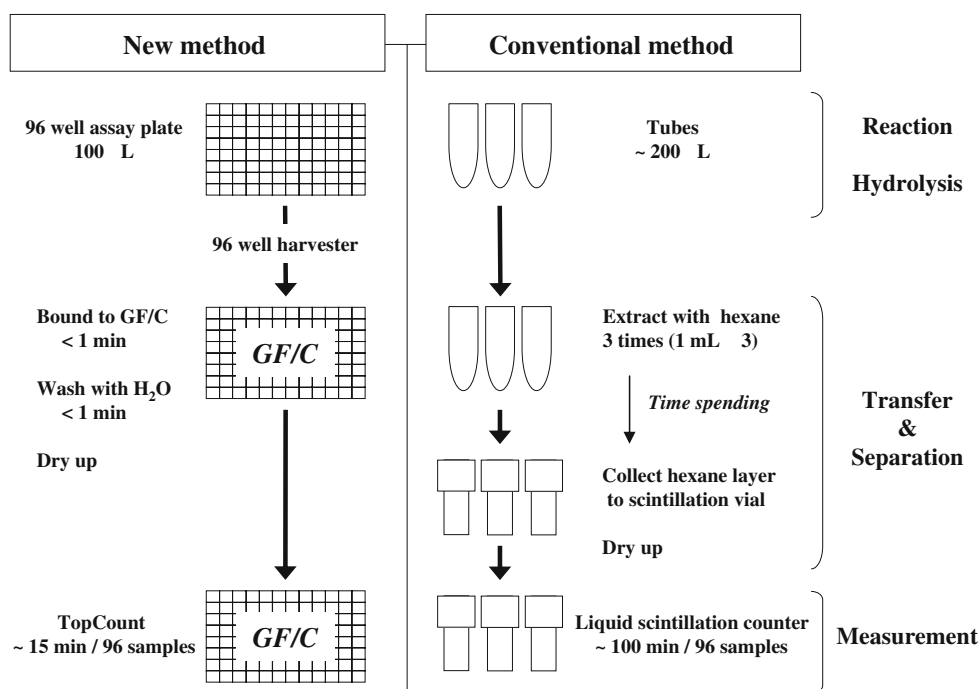

ELOVL3, there has been no study reporting the substrate specificity in a direct manner by using recombinantly expressed ELOVL3 so far. Under our assay conditions, ELOVL3 preferentially elongates C18:0 with relatively moderate-to-low elongation activities on other saturated fatty acids such as C14:0, C16:0 and C20:0. Although previous reports have not assessed ELOVL3 activity toward C14:0, we observed similar substrate specificity of ELOVL3 in the conventional assay (supplemental Fig. 2b), suggesting that ELOVL3 also elongates C14:0. Considering the highest sequence homology between ELOVL3 and ELOVL6 (46%) among the ELOVL family enzymes, it is not surprising that ELOVL3 and ELOVL6 show the overlapped substrate specificity for saturated fatty acids such as C14:0 and C16:0.

Under our assay conditions, ELOVL5 elongates the saturated acyl-CoAs such as myristoyl-CoA (C14:0-CoA)

and palmitoyl-CoA (C16:0-CoA); a 4-fold increase in elongation activities in the ELOVL5 transfected microsome versus the mock-transfected microsome (Fig. 5d). We observed the elongation activities of ELOVL5 for these acyl-CoAs under the conventional assay method, suggesting that the discrepancy between the current and previous reports is not due to the assay methods (data not shown). At present, we cannot exclude the possibility that the C-terminal tag may affect the substrate profile of ELOVL5. Further studies using recombinant ELOVL5 with no-tag will help us to understand the potential limits of using the modified recombinant enzymes for detailed profiling of ELOVLs. If this is the case, development of specific antibodies against native sequences of each ELOVL proteins might facilitate the confirmation of unmodified ELOVL expression and support our assay method when using unmodified enzymes.

Fig. 6 Scheme of elongation assay procedure (new vs. conventional method)

Drug Discovery

The lack of convenient ELOVL assay protocols keeps researchers from discovering new ELOVL drugs despite increasing interest. In order to establish an assay protocol that is amenable to high-throughput screening, we improved upon the 3 assay steps of the conventional assay by introducing 96-well-based devices (Fig. 6). (1) *Transfer step*: The 96-well harvester (FilterMate cell harvester: PerkinElmer) simplifies the transfer step as compared to the conventional method that requires time-consuming transfer of reaction mixtures to glass tubes. (2) *Separation step*: The use of the Unifilter-96 GF/C plate considerably reduced the experimental time needed for the separation procedure; now only 2–3 min are required to treat 96 samples (one plate). (3) *Measurement step*: We use the TopCount (PerkinElmer) to measure elongation activity. TopCount is capable of measuring 96 samples (one plate) within 15 min whereas the conventional method requires ~100 min when counting 96 samples.

Here we combined each step of the conventional assay using the Unifilter-96 GF/C filter plate, establishing a high-throughput assay that allows investigators to conduct (1) screening of a chemical library and further characterization of hit compounds and (2) a detailed characterization of ELOVL enzymes using the same format with reduced work load.

As demonstrated in this study, the respective ELOVLs have distinct substrate specificity. Furthermore, ELOVLs have different expression patterns in human tissues (Supplemental Fig. 1), suggesting ELOVLs have distinct

physiological roles. Recent studies using transgenic approaches strongly suggest that altered expressions of ELOVLs might be associated with diseases such as metabolic disorders and dyslipidemia [2, 23, 24]. We believe our 96-well format assay will help further ELOVL research, not only in industry but also in academic institutions. In turn, our new method will advance drug research.

© AOCS 2009

Lipids in aquatic ecosystems is a much needed and timely volume that encompasses how lipids progress in the food chain across freshwater and marine ecosystems. The book tries to cover the role of lipids from lower to higher trophic levels. In 14 chapters the editors have succeeded in gathering a nice compilation of very important and instructive chapters, by experts in the field, which should appeal to a broad audience of researchers and educators in the lipid ecological area. Each chapter starts with a well-drafted introduction to the topic, and finishes with a conclusion that opens the door for future research in the field.

Chapter one begins with a relatively short overview of the lipid composition of algae but the emphasis of the chapter is on how environmental factors such as temperature, salinity, pH, and nutrient effects affect algal glycerolipid biochemistry.

Chapter two describes the formation and transfer of fatty acids in aquatic microbial food webs with a special emphasis on the role of heterotrophic protists (unicellular eukaryotes). This chapter presents a precise summary of the biosynthetic pathways of polyunsaturated fatty acids (PUFA) in heterotrophic protists and tells us that many of the biosynthetic pathways found in protists can be understood based on their phylogenetic histories. We leave the chapter with the awareness that future research in this area is much needed and important.

Chapter three focuses on the ecological significance of sterols in aquatic food webs. After a relatively short introduction to sterols we get a quick and simplified scheme of the sterol biosynthetic capabilities of the

different taxa. The exploitation of sterols from aquatic microorganisms for nutritional purposes is highlighted and we are left with the idea that sterol limitation might be one important factor that could have a negative impact on aquatic food webs.

In Chapter four, probably my favorite in this book, fatty acids and oxylipins that can act as semiochemicals are reviewed and their potential to modify intra and extracellular aquatic processes is discussed. One plus of this chapter is that it nicely describes the mechanistic pathways resulting in the production of polyunsaturated aldehydes (PUA) and hydrocarbons, compounds that can be detrimental to plankton interactions with a multitude of mechanisms and consequences.

Chapter five successfully presents how lipids and xenobiotic chemicals (contaminants) interact and move in aquatic food webs. This is a very important chapter since lipids are ecotoxicologically important for determining the extent to which lipophilic organic contaminants are bioaccumulated in aquatic organisms. Chapter five should have great appeal to environmental chemists.

Chapter six describes how taxonomic affiliation, temperature, and diet influence the fatty acid composition of freshwater and marine zooplankton based on the fact that ocean and freshwater lakes have markedly different fatty acid compositions. The chapter ends with a series of unanswered questions in the field that should certainly spark much needed research in this area. Chapter six is certainly a good source of research ideas for aquatic ecologists.

Chapter seven defines specific optima between omega-3 and omega-6 fatty acids in freshwater fish, zooplankton and zoobenthos. This chapter is an excellent reference on n-3/n-6 ratios in marine biota (several reference tables with n-3/n-6 ratios are presented at the end of the chapter) and

N. M. Carballeira (✉)
Department of Chemistry, University of Puerto Rico,
Rio Piedras, PR, USA
e-mail: nmcarballeira@uprrp.edu

presents a good discussion on the physiological and ecological importance of these PUFA. When reading the chapter the reader can easily identify knowledge gaps in the field. We are told that there are large effects on these n-3/n-6 ratios when comparing wild vs. cultured fish and that diet has a strong influence on the PUFA composition.

Chapter eight gives an estimate of the transfer of omega-3 highly unsaturated fatty acids (HUFA) from aquatic to terrestrial ecosystems based on the available literature. We learn that the main flux of aquatic HUFA to terrestrial ecosystems originates from inland waters and estuaries rather than from the ocean. Algae are a main source of HUFA for many terrestrial animals but the role of birds and humans is also discussed.

Chapter nine is a good concise account of the biochemistry and molecular biology involved in the various pathways of polyunsaturated fatty acids and their inter-conversions in aquatic ecosystems. A well-referenced summary of the present knowledge of the biosynthesis of fatty acids in fish is presented and potential future directions of research are discussed. We are left with the message that fish will remain a major source of n-3 HUFA for humans, but fish will be cultivated using diets containing transgenic seed oils.

Chapter 10 is a short chapter dealing with the influence of lipids on membrane fluidity and immune response. The role that specific fatty acids play in maintaining the health and conditions of teleost cell membranes in terms of temperature adaptation is discussed. The author succeeds in conveying the message that biochemical methods are complimentary measures to assess the condition and underlying health of fish.

In Chapter 11, the emphasis now moves to global warming. The role of lipids in marine copepods is reviewed as the case study. The copepod lipid profiles have evolved in response to the specific habitats and temperature regimes

occupied by the various species. The copepods accumulate large resources of energy-rich lipids (as wax esters) and they play a key role in the transfer of energy through the food web. The lipid levels of zooplankton in polar regions can comprise more than half of the total carbon source and changes in temperature may have effects on these lipid profiles that may not be straightforward or predictable but it will have a decisive effect on future life in the oceans.

Chapter 12 emphasizes the need for a more quantitative method for using fatty acid trophic markers to explain food web dynamics. The author recognizes that fatty acids can be used as powerful trophic tracers of carbon flow and predator–prey interactions. The use of the statistical tool quantitative fatty acid signature analysis (QFASA) is discussed in detail and seems to be the way to go in the future. Therefore, chapter 12 is very important for those who want to move further in this field.

Chapter 13 questions what the essential fatty acids in aquatic food webs really are. The author states that it is time to reexamine whether the two fatty acids EPA and DHA are enough to describe adequately the essential fatty acid states in aquatic food webs. The last chapter in the book, Chapter 14, examines the position of humans in the global food web and calls for an urgent need to protect the aquatic food web → human connection.

The editors of *Lipids in Aquatic Ecosystems* correctly and clearly identify that this book should appeal to plankton ecologists, nutritionists, aquaculturists, toxicologists, environmental chemists and environmental managers. I would add that it should also appeal to lipid educators since the volume contains valuable material and information that could be incorporated in several sections of a course in lipid chemistry. Overall, this is a well-drafted and easy to read volume that should be in the shelves of most lipid chemists' libraries.

Marine Two-Headed Sphingolipid-Like Compound Rhizochalin Inhibits EGF-Induced Transformation of JB6 P⁺ Cl41 Cells

Abstract Rhizochalin [(2*R*,3*R*,26*R*,27*R*)-2,27-diamino-3-hydroxy-26-[(2*R*,3*R*,4*S*,6*R*)-3,4,5-trihydroxy-6-(hydroxymethyl)tetrahydro-2*H*-pyran-2-yl]oxy]octacosan-11-one], an antimicrobial and cytotoxic marine two-headed sphingolipid-like natural product, isolated from the sponge *Rhizochalina incrustata*, and some related compounds were studied as anticarcinogenic and proapoptotic agents. The corresponding effects were tested on the mouse skin epidermal JB6 P⁺ Cl 41 cell line, its stable transfectants, THP-1, HeLa, and SNU-C4 human tumor cells using a variety of assessments, including cell viability (MTS), flow cytometry, anchorage-independent soft agar, and luciferase assays. At 5–10 μM concentrations, rhizochalin was effective as an inhibitor of the malignant transformation of JB6 P⁺ Cl 41 cells or colony formation of human tumor cells, which exerted its action, at least in part, through the induction of p53-dependent apoptosis. Structure–activity relationship study showed aglycon of rhizochalin to be the most active while peracetylated aglycon was the least active among the compounds studied.

AP-1	Activator protein 1
TPA	12- <i>O</i> -Tetradecanoylphorbol-13-acetate
MAPK	Mitogen-activated protein kinase

Introduction

Since the isolation in 1989 of an unusual two-headed sphingolipid-like metabolite rhizochalin (**1**, Fig. 1) [1], a series of related natural products have been reported [2–10]. Two-headed sphingolipid-like compounds differ from classical sphingolipids in the presence of polar groups in α,ω -positions. These polar groups resemble a polar end of sphingoid bases, but contain often a terminal methyl group instead of hydroxymethyl group. Thus, these natural products represent a unique group of bipolar lipids.

Fig. 1 Structures of rhizochalin and its analogs and derivatives

Rhizochalin and analogs were reported to possess antibacterial, antifungal, and cytotoxic activities [2–10]. Beside preliminary data on blocking phytosphingolipid biosynthesis by the related metabolite oceanalin A [6], no information exists regarding the molecular mechanism that determines the physiological activities of rhizochalin and its analogs. In the present study we investigated the cancer-preventive and anticancer cytotoxic activities of rhizochalin (**1**) and its analogs (**5**, **6**) and derivatives (**2–4**).

Cancer chemopreventive agents are usually natural products or their synthetic analogs that inhibit either the transformation of normal cells to premalignant cells or the progression of premalignant cells to malignant cells [11–13]. Therefore, an effective chemopreventive agent should step in the process of carcinogenesis to eliminate premalignant cells before they become malignant [14–16]. Some chemopreventive agents (e.g. retinoids and antiestrogens) promote cytostatic effects in transformed cells by modulating cell proliferation or differentiation [11, 14, 16]. These agents should be long-term administered to healthy individuals who have an increased cancer risk. In this case long-term toxicity and the possibility of developing resistance to chemopreventive agents could limit the application of the substances [14]. An alternative chemopreventive approach calls for the use of agents that quickly eliminate premalignant cells by inducing them to undergo apoptosis. An increasing number of chemopreventive agents have been shown to stimulate apoptosis in premalignant and malignant cells in vitro and in vivo [17–22]. By using this approach, chronic exposure to a chemopreventive agent would not be necessary, thereby limiting the risk of long-term toxicity or the development of chemoresistance [14–16].

Herein, we report results of the study on rhizochalin and related compounds capability to inhibit the EGF-induced malignant transformation of JB6 P⁺ Cl41 and colony formation of several human cancer cell lines in anchorage-independent assay experiments. Some detailed data regarding the molecular mechanism of **1–6** action are also given. The JB6 cell system of clonal genetic variants, including promotion-sensitive (P⁺), promotion-resistant (P⁻), or malignantly transformed, enables the search of chemopreventive compounds and helps to study their cancer-preventive properties at the molecular level. The JB6 P⁺, P⁻, and transformed variants are a series of cell lines representing earlier-to-late stages of preneoplastic-to-neoplastic progression [23–27]. JB6 P⁺ cells transform when stimulated with EGF or TPA resulting in the formation of colonies in soft agar. The transformation involves the activation of the AP-1 nuclear factor which regulates the transcription of various genes related to inflammation, proliferation and metastasis [24, 28]. Cancer cells, in contradistinction from JB6 P⁺ Cl41 cells, do not need EGF or any other carcinogen for activation. The process of carcinogenesis initiated, promoted and perpetuated malignant phenotype in these cells. The colony formation of cancer cells in soft agar is a result of their phenotype expression [29, 30]. The investigation of rhizochalin and its analogs as anticancer agents requires the study of their activity against various human cancer cell lines. Anticancer activity of one and the same compound often differs significantly from one cancer cell line to another. We studied the anticancer activity of the substances using human THP-1 (acute monocytic leukemia), HeLa (cervical carcinoma), and SNU-C4 (colorectal

cancer) cell lines from the NCI panel. These cell lines are widely used in many laboratories all over the world, so the activities of rhizochalin and its analogs can be easily compared with those of a number of other anticancer agents.

Experimental Procedure

General Procedures

Cell colonies in the anchorage-independent transformation assay were scored using the LEICA DM IRB inverted research microscope (Leica Mikroskopie und Systeme GmbH, Germany) and Image-Pro Plus software, version 3.0 for Windows (Media Cybernetics, Silver Spring, MD, USA). The MTS reduction assay to determine cell viability was carried out using the μ Quant microplate reader (Bio-Tek Instruments, Inc, USA). The onset of apoptosis was analyzed by flow cytometry using the Becton-Dickinson FACSCalibur (BD Biosciences, San Jose, CA, USA). Data analysis was performed using CellQuest software (Becton-Dickinson, CA, USA). The luminescence assay for p53 nuclear factor-dependent transcriptional activity was measured using the Luminoscan Ascent Type 392 microplate reader (Labsystems, Helsinki, Finland).

Rhizochalin or Its Analogs and Derivatives

Rhizochalin and its analogs and derivatives were extracted, purified and prepared as described previously [1, 7–9] and were pure in accordance with NMR, MS, TLC, and HPLC data. Briefly, the fresh collection of the sponges *R. incrustata* was immediately lyophilized and kept at $-20\text{ }^{\circ}\text{C}$. The lyophilized material was extracted with EtOH (200 ml \times 3). The combined EtOH extract was concentrated under vacuum and dissolved in EtOH/H₂O (9:1, by vol). This solution was partitioned three times with equal volumes of *n*-hexane. The aqueous EtOH layer was evaporated in vacuo at $50\text{ }^{\circ}\text{C}$ to give a brown oil, which was purified from salts using reversed phase column chromatography. The rhizochalin-containing fraction (ninhydrine positive) was eluted with 50% EtOH and separated on a Si gel column [CHCl₃/EtOH/H₂O (3:2:0.2, by vol)] to give a rhizochalin-containing mixture. Preparative HPLC of the mixture using a C₁₈ reversed phase column [MeOH/H₂O/TFA (80:20:0.1, by vol)] gave rhizochalin or its analogs. Aglycons of rhizochalin or analogs were obtained after hydrolysis of the initial glycosides using 2 N HCl. Acetate of rhizochalin or peracetylated aglycon of rhizochalin were obtained after acetylation of rhizochalin or aglycon of rhizochalin in the mixture of pyridine/Ac₂O (1:1, by vol), rt for 12 h.

Reagents

Minimum essential medium (MEM), and RPMI medium were purchased from Gibco Invitrogen Corporation (Carlsbad, CA, USA). Fetal bovine serum (FBS) was from Gemini Bio-Products (Calabasas, CA, USA); penicillin/streptomycin and gentamycin were from Bio-Whittaker (Walkersville, MD, USA); and L-glutamine was from Mediatech, Inc. (Herndon, VA, USA). Epidermal growth factor (EGF) was obtained from Collaborative Research (Bedford, MA, USA). The luciferase assay substrate and Cell Titer 96 Aqueous One Solution Reagent [5-(3-carboxymethoxyphenyl)-2-(4,5-dimethylthiazolyl)-3-(4-sulfophenyl) tetrazolium, inner salt (MTS)] kit for the cell viability assay were from Promega (Madison, WI, USA). The Annexin V-FITC Apoptosis Detection kit was from Medical & Biological Laboratories (Watertown, MA, USA).

Cell Culture

The JB6 P⁺ Cl41 mouse epidermal cell line and its stable transfectants JB6 Cl41 DN-JNK1 mass1, JB6 Cl41 DN-p38 G7, JB6 Cl41 DN-ERK2 B3 mass1, JB6 Cl41-Lucp53 (PG-13) cells were cultured in monolayers at $37\text{ }^{\circ}\text{C}$ and 5% CO₂ in MEM containing 5% FBS, 2 mM L-glutamine, 100 U/ml penicillin and 100 $\mu\text{g/ml}$ streptomycin [23]. The human cancer cell lines THP-1, HeLa, and SNU-C4 were obtained from the American Type Culture Collection (Rockville, MD, USA) and were cultured at $37\text{ }^{\circ}\text{C}$ and 5% CO₂ in RPMI containing 10% FBS, 2 mM L-glutamine, 100 U/ml penicillin and 100 $\mu\text{g/ml}$ streptomycin. Information regarding the genetic background of these cell lines is available online.

Anchorage-independent Transformation or Phenotype Expression Assay

The cancer-preventive effect of rhizochalin or its analogs were evaluated using an anchorage-independent neoplastic transformation or phenotype expression assay. For evaluation of the anticancer effects of the substances in human cancer cell lines using a phenotype expression assay, no additional stimulus was required. EGF (10 ng/ml) was used for stimulating neoplastic transformation of JB6 P⁺ Cl 41 cells. The assay was carried out in six-well tissue culture plates. Human HeLa, THP-1, SNU-C4, or mouse JB6 P⁺ Cl 41 cells (8×10^3 per ml) were treated with various concentrations of the substances in 1 ml of 0.33% basal medium Eagle (BME) agar containing 10% FBS over 3 ml of 0.5% BME agar containing 10% FBS and various concentration of the substances. The cultures were maintained in a $37\text{ }^{\circ}\text{C}$, 5% CO₂ incubator for 1 week. Then cell colonies were scored.

Cell Viability Assay

The effect of the compounds on cell viability was evaluated using MTS reduction into its formazan product [31]. The cells were cultured for 12 h in 96-well plates (6,000 cells/well) in the corresponding medium (100 μ l/well) containing 10% FBS (5% for JB6 Cl 41 cells). The medium was then replaced with 10% FBS-medium (5% for JB6 Cl 41 cells) containing the indicated concentrations of the compounds, and the cells were incubated for 22 h. Then 20 μ l amount of MTS reagent was added into each well, and MTS reduction was measured 2 h later spectrophotometrically at 492 and 690 nm as background.

Apoptosis Assay

The onset of early and late apoptosis was analyzed by flow cytometry using Annexin V-FITC and propidium iodide (PI) double staining. THP-1 cells, 1×10^6 /10 cm dish, in 10% FBS-RPMI were treated with various concentrations of rhizochalin or its derivatives for 24 h. After incubation, cells were washed with PBS by centrifugation at 1,000 rpm (170 rcf) for 5 min, and processed for detection of apoptosis using Annexin V-FITC and PI staining according to the manufacturer's protocol. In brief, 1×10^5 to 5×10^5 cells were resuspended in 500 μ l of $1 \times$ binding buffer (Annexin V-FITC Apoptosis Detection Kit, Medical & Biological Laboratories). Then, 5 μ l of Annexin V-FITC and 5 μ l of PI were added, and the cells were incubated at room temperature for 15 min in the dark and were analyzed by flow cytometry.

Assay for p53-dependent Transcriptional Activity

The ability of rhizochalin or its aglycon to influence p53-dependent transcriptional activity in the mouse JB6 Cl 41 cell line was evaluated using the luciferase method. JB6 Cl41-Lucp53 (PG-13) cells (6×10^3) suspended in 100 μ l 5% FBS-MEM were added into each well of a 96-well plate. Plates were incubated for 12 h and then treated with various concentrations of the substances in 100 μ l of 10% FBS-MEM. After incubation with the substances for 24 h, the cells were extracted for 1 h at room temperature with 100 μ l/well of lysis buffer [0.1 M potassium phosphate buffer at pH 7.8, 1% Triton X-100, 1 mM dithiothreitol (DTT), 2 mM EDTA]. Then 30 μ l of lysate from each well was transferred in a plate used for luminescent analysis, and luciferase activity was measured using 100 μ l/well of the luciferase assay buffer [0.47 mM D-luciferin, 20 mM Tricin, 1.07 mM magnesium carbonate hydroxide pentahydrate ($\text{MgCO}_3)_4 \times \text{Mg(OH)}_2 \times 5\text{H}_2\text{O}$, 2.67 mM $\text{MgSO}_4 \times 7\text{H}_2\text{O}$, 33.3 mM DTT, 0.53 mM ATP, 0.27 mM CoA, and 0.1 mM EDTA (pH 7.8)].

Statistics

The statistical computer program Statistica 6.0 for Windows (StatSoft, Inc., Tulsa, OK, USA, 2001) was used for analysis of the data obtained. The value of the $n = 6$ (six samples of two independent experiments). Nonparametric Mann–Whitney U test was used to compare two independent groups of data. Method of regressions was used to compute IC_{50} , IAC_{50} or INCC_{50} in corresponding experiments.

Results

Cancer-preventive Properties

To assess whether rhizochalin or its derivatives can prevent tumor promoter-induced neoplastic transformation of mouse epidermal JB6 P⁺ Cl41 cells or inhibit phenotype expression of human cancer cell lines, we used the well-accepted anchorage-independent assay in soft agar and EGF (10 ng/ml) as a promoter of JB6 P⁺ Cl41 cells colony formation [24, 25, 32, 33].

Our experiments showed that rhizochalin (**1**) at 5–12 μ M concentrations, in a dose-dependent manner inhibited EGF-induced malignant transformation of JB6 P⁺ Cl41 cells (Fig. 2a–c). Specifically, a 50% inhibition of EGF-induced JB6 P⁺ Cl41 cells colony formation (INCC_{50}) by rhizochalin was achieved at a concentration of 8.6 μ M (Fig. 2a). Similar effects were observed for suppression of phenotype expression of several human tumor cell lines in a soft agar. For example, the INCC_{50} for phenotype expression of HeLa (cancer of cervix) cells (Fig. 2b) or THP-1 (monocytic leukemia) cells (Fig. 2c), were 12.6 and 5.4 μ M, respectively. Aglycon of rhizochalin (**3**) was significantly more active as inhibitor of SNU-C4 cells colony formation with $\text{INCC}_{50} = 1.7 \mu\text{M}$ (Fig. 2d).

Cytotoxic Activity and SAR Study

The MTS method [31] was applied to examine the cytotoxicity of rhizochalin or its analogs and derivatives against JB6 P⁺ Cl41, HeLa, or THP-1 cell lines. The results (Table 1) showed that the cytotoxic effect of the compounds (**1–6**) depends on their chemical structure. Thus, aglycon of rhizochalin (**3**) together with rhizochalinin A (**5**) and rhizochalinin C (**6**) were the most cytotoxic, while peracetylated aglycon of rhizochalin (**4**) was the least active among the compounds studied. Furthermore, peracetate of rhizochalin (**2**) was two times less active against THP-1 cells than rhizochalin (**1**). SAR study among the compounds **1–6** using MTS method (Table 1) indicated

Fig. 2 Rhizochalin inhibited EGF-induced malignant transformation of JB6 P⁺ Cl41 cells (a) or phenotype expression of human cancer HeLa (b) or THP-1 (c) cells. Aglycon of rhizochalin suppressed phenotype expression of human cancer SNU-C4 cells (d). Each bar represents the mean \pm SD from six samples of two independent experiments. * $p < 0.05$

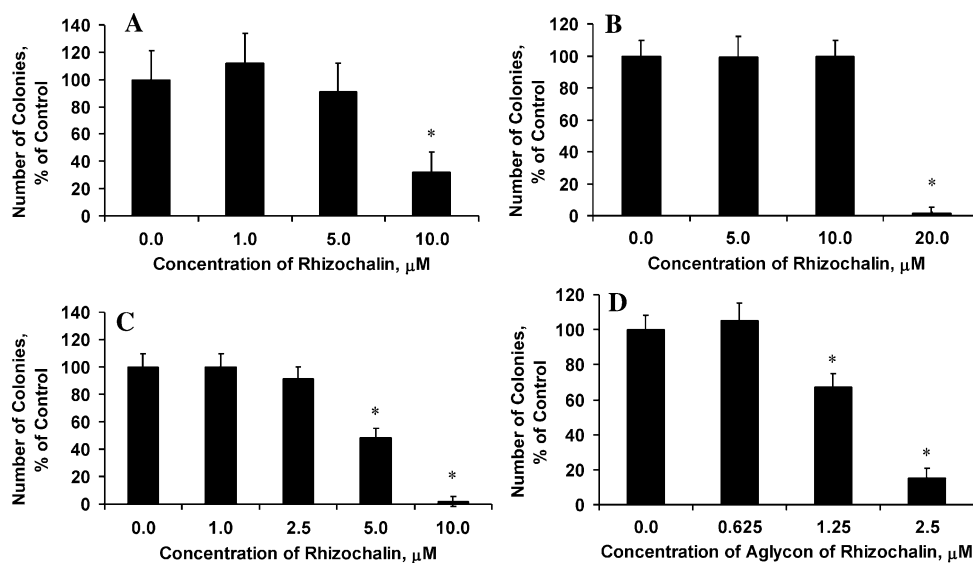

Table 1 Cytotoxic activity (IC₅₀, μ M) of the compounds (1–6)

Compound	JB6 P ⁺ Cl 41	HeLa	THP-1
Rhizochalin (1)	8.8	22.1	13.6
Peracetate of rhizochalin (2)	n/s	n/s	26.8
Aglycon of rhizochalin (3)	2.8	8.5	3.2
Peracetylated aglycon of rhizochalin (4)	>30	>30	63.3
Rhizochalinin A (5)	n/s	n/s	7.5
Rhizochalinin C (6)	n/s	n/s	6.7

n/s: Cytotoxicity was not studied

that unsubstituted hydroxyl groups at both α - and ω -ends of the molecule are important for the anticancer action of rhizochalin or its analogs and derivatives. Then, the results of the cell viability experiments were compared with the results of the soft agar experiments. As shown, rhizochalin (1) demonstrated cancer-preventive properties at non-cytotoxic concentrations against HeLa or THP-1 cells. In the case of JB6 P⁺ Cl 41 cells the active concentrations were about the same in both soft agar and cell viability experiments.

The dominant-negative mutant (DNM) JB6 Cl 41 cells and the MTS method were used to elucidate the effect of rhizochalin on the main MAPK signaling pathways in JB6 Cl 41 cells. The results (Fig. 3) demonstrated cytotoxic effect of rhizochalin to be different in respect to various DNM JB6 Cl 41 cells. Specifically, rhizochalin was significantly more active against JB6 Cl 41 DN-ERK2 or JB6 Cl 41 DN-JNK1 cells than against JB6 Cl 41 DN-p38 or non-transfected JB6 P⁺ Cl 41 cells (Fig. 3). Furthermore, JB6 Cl 41 DN-p38 and JB6 P⁺ Cl 41 cells showed the even sensitivity to the action of rhizochalin (Fig. 3). These

Fig. 3 Cytotoxic activity of rhizochalin against various JB6 Cl41 DNM cells. Each datapoint represents the mean \pm SD from six samples of two independent experiments. * $p < 0.05$

findings indicated that probably no one of the main MAPK kinases mediate the cytotoxic effect of rhizochalin.

Rhizochalin Induces Apoptosis in Human Leukemia Cells

Induction of apoptosis by rhizochalin was evaluated by flow cytometry using Annexin V-FITC and propidium iodide double staining. Rhizochalin was found to induce a dose-dependent apoptosis of human leukemia THP-1 cells with IAC₅₀ (induction of apoptosis C₅₀) 6.5 μ M (Fig. 4).

Rhizochalin Induces Basal p53 Transcriptional Activation in JB6 Cl41 Cells

The effect of the compounds 1 or 3 on p53 transcriptional activation was investigated in JB6 Cl41 p53 cells stably expressing a luciferase reporter gene controlled by a p53

Fig. 4 The induction of apoptosis by rhizochalin in human leukemia THP-1 cells as analyzed by flow cytometry. Representative experiment is shown

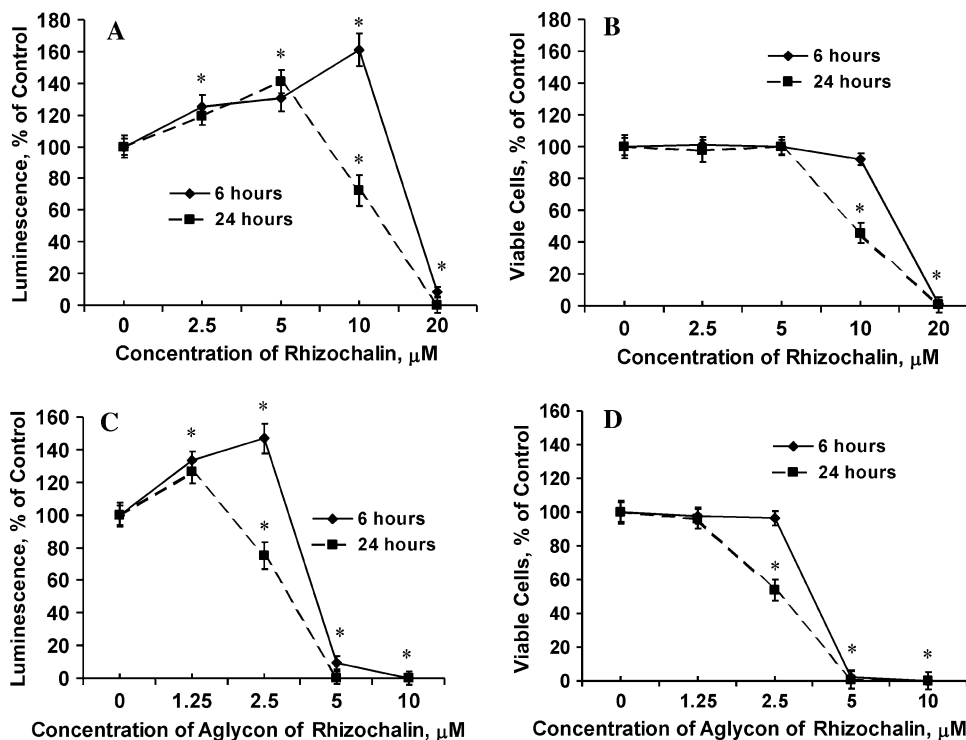

DNA binding sequence (Fig. 5a, c). Beside p53-dependent transcriptional activity, the effect of **1** or **3** on JB6 Cl41 p53 cells viability (Fig 5b, d) was also evaluated. Rhizochalin (Fig. 5a) or aglycon of rhizochalin (Fig. 5c) at active concentrations of 5–10 or 1.25–2.5 μM (Fig. 5b or d), respectively, and in a dose-dependent manner induced basal p53-dependent transcriptional activity in JB6 Cl 41 cells. It was demonstrated that about 100% of cells were still alive after 6 h of the treatment with the active concentrations of **1** or **3** (Fig. 5b, d). At these conditions, the p53-dependent transcriptional activity was induced 1.3–1.6 times more, when compared with untreated control cells (Fig. 5a, c). Only about 50% of cells were alive (Fig. 5b, d) after 24 h of the treatment with 10 μM of **1** or 2.5 μM of **3**. Nevertheless, luminescence was about 80% in comparison with that of untreated control cells (Fig. 5a, c) indicating thus the 1.6 times increase of p53-dependent transcriptional

activity in JB6 Cl 41 p53 cells treated with the active concentrations of rhizochalin (**1**) or aglycon of rhizochalin (**3**). These findings suggest that rhizochalin exerts its anticancer properties at least in part through the induction of p53-dependent pathway.

Discussion

The fact that most cancers are not of hereditary origin and that lifestyle factors, such as dietary habits, smoking, alcohol consumption, and infections have a profound influence on their development [34] provides major opportunities for cancer prevention. Natural products, including those of marine origin that show cancer-preventive and anticancer properties, attract more and more attention as probable candidates to be used in cancer-

Fig. 5 Rhizochalin (a) or aglycon of rhizochalin (c) induces basal p53-dependent transcriptional activity in JB6 Cl 41 p53 cells. The effect of rhizochalin (b) or aglycon of rhizochalin (d) on the cell viability of JB6 Cl 41 p53 cells evaluated after 6 or 24 h of incubation with the compounds. Each bar represents the mean \pm SD from six samples of two independent experiments. * $p < 0.05$

preventive or chemotherapeutic anticancer strategies [35–42]. The cancer-preventive effects of the most common natural chemopreventive compounds, such as resveratrol, caffeine, epigallocatechin-3-gallate were established using promotion-sensitive JB6 P⁺ Cl41 cells. All these compounds prevent EGF- or TPA-induced transformation of JB6 P⁺ Cl41 cells [43–45]. Our results also showed that rhizochalin (**1**) and its derivative, aglycon of rhizochalin (**3**), in a dose-dependent manner inhibited EGF-induced malignant transformation of JB6 P⁺ Cl41 cells and colony formation of human tumor HeLa or THP-1 cells in soft agar (Fig. 2). Rhizochalin and analogs also demonstrated the cytotoxic activity against various human cancer cells (Table 1). SAR study revealed that this activity depends on the chemical structure of the compounds **1–6** and that free hydroxyl groups at both α - and ω -ends of the molecule are important for the anticancer action of rhizochalin or its analogs and derivatives.

Three different MAPK signaling pathways have been identified in mammalian cells: ERKs, JNKs, and p38 kinase. In general, JNKs and p38 kinase are primarily activated by environmental stresses, whereas ERKs respond mainly to mitogenic and proliferative stimuli [46]. Many of the changes which drive the process of carcinogenesis in a cell occur in MAPK signaling pathways that regulate proliferation and apoptosis [47]. The chemopreventive compounds can modulate signaling by affecting MAP kinase activity. For example, antimutagenic effect of epigallocatechin-3-gallate depends on the ERKs pathway [48], flavonoid baicalein induces cancer cells death by the induction of p38 kinase activity [49], while novel flavonoid protoapigenone induces apoptosis in human prostate cancer cells through activation of JNKs and p38 kinase [50]. To determine effects of rhizochalin on the main MAP kinases in cells, the cytotoxic activity of rhizochalin in respect to dominant-negative ERK2, p38, or JNK1 JB6 Cl 41 cells was evaluated (Fig. 3). The results suggest that probably no one of three main MAPK signaling pathways, p38, ERKs or JNKs, mediate the effect of rhizochalin or its analogs. Moreover, JNKs and/or ERKs signaling pathways may counteract against cytotoxic action of the compounds **1–6**.

Apoptosis is a general mechanism for removal of unwanted cells from organisms playing a protective role against carcinogenesis [51]. Evidence from both in vivo and in vitro experiments shows that apoptosis is involved in successful cancer treatment using many drugs and other chemical substances [52]. A number of factors and signaling pathways in a cell can lead to apoptosis and one of the most important pathways extends through activation of the p53 tumor suppressor protein. The tumor suppressor protein p53 normally exists in cells as a short-lived protein and functions to negatively regulate cell growth following damage by inducing cell cycle arrest and apoptosis [53–55]. A plethora

of evidence exists that p53 is involved in the chemopreventive effects of many natural compounds. For example resveratrol, epigallocatechin-3-gallate, caffeine, and many other cancer-preventive substances suppress normal cell transformation or induce antiproliferative effects with subsequent apoptosis in cancer cells through a p53-dependent pathway [43, 45, 56–67]. To explore a possible mechanism of the cancer-preventive action of rhizochalin and analogs, we studied pro-apoptotic properties of rhizochalin and the effect of the compounds **1** or **3** on p53 transcriptional activation in JB6 Cl41 p53 cells stably expressing a luciferase reporter gene controlled by a p53 DNA binding sequence. As it was shown, rhizochalin also exerts its cancer-preventive properties at least in part through the induction of p53-dependent apoptosis (Figs. 4, 5).

In conclusion, our results indicate that rhizochalin (**1**) and some analogs (**2–6**) represent a new group of marine secondary metabolites having cancer-preventive and anticancer properties. These compounds induce also the apoptosis of human cancer cells and increase the p53-dependent transcriptional activity. Both cancer-preventive and cytotoxic effects of rhizochalin and its analogs may be explained, at least in part, by the induction of p53-dependent apoptosis. It was also found that aglycon of rhizochalin (**3**), rhizochalinin A (**5**), or rhizochalinin C (**6**) are the most active compounds while peracetate of rhizochalin aglycon (**4**) is the least active among the compounds studied. We conclude that free hydroxyl groups at the both α - and ω -ends of the molecule are important for the anticancer properties of rhizochalin and related compounds. Therefore, further search for cancer-preventive and anticancer two-headed sphingolipids and their synthetic analogs might be prospective to find new pharmaceutical leads and/or useful tools for the study on molecular mechanisms of anticancer action of different compounds.

Abstract Tocotrienols are powerful chain breaking anti-oxidant. Moreover, they are now known to exhibit various non-antioxidant properties such as anti-cancer, neuroprotective and hypocholesterolemic functions. This study was undertaken to investigate the anti-inflammatory effects of tocotrienol-rich fraction (TRF) and individual tocotrienol isoforms namely δ -, γ -, and α -tocotrienol on lipopolysaccharide-stimulated RAW264.7 macrophages. The widely studied vitamin E form, α -tocopherol, was used as comparison. Stimulation of RAW264.7 with lipopolysaccharide induced the release of various inflammatory markers. 10 $\mu\text{g/ml}$ of TRF and all tocotrienol isoforms significantly inhibited the production of interleukin-6 and nitric oxide. However, only α -tocotrienol demonstrated a significant effect in lowering tumor necrosis factor- α production. Besides, TRF and all tocotrienol isoforms except γ -tocotrienol reduced prostaglandin E_2 release. It was accompanied by the down-regulation of cyclooxygenase-2 gene expression by all vitamin E forms except α -tocopherol. Collectively, the data suggested that tocotrienols are better anti-inflammatory agents than α -tocopherol and the most effective form is δ -tocotrienol.

Keywords Tocotrienols · α -Tocopherol · Inflammation · RAW264.7 · Cyclooxygenase-2 · Vitamin E

Abbreviations

COX-1	Cyclooxygenase-1
COX-2	Cyclooxygenase-2
IL-6	Interleukin-6
LPS	Lipopolysaccharide
NO	Nitric oxide
PGE_2	Prostaglandin E_2
TNF- α	Tumor necrosis factor
TRF	Tocotrienol-rich fraction
αT	Alpha-tocopherol
αT_3	Alpha-tocotrienol
γT_3	Gamma-tocotrienol
δT_3	Delta-tocotrienol

Introduction

Inflammation is a complex response that protects the body from various harmful agents such as microbes and toxins [1]. Nevertheless, it is a known fact that unregulated inflammation is associated with many chronic diseases, contributing to the increase in worldwide morbidity and mortality rates. The relationship between cancer and inflammation was hypothesized in 1863 by Rudolf Virchow that cancer originates from sites of chronic inflammation where the inflammatory event serves as the cofactor in carcinogenesis [2]. The imbalance in inflammatory mediators during chronic inflammation causes damage to the cartilage and bone, leading to the debilitating rheumatoid arthritis [3]. Besides that, inflammation has also

This study was supported by Malaysian Palm Oil Board (MPOB).

been found to participate in all phases of the atherosclerotic process, from the initial atherogenesis through lesions progression and finally, the subsequent thrombotic complications [4]. In other words, inflammation plays a great role in the underlying mechanisms of almost all pathological states and diseases.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most widely prescribed drugs in inflammation therapy. Alleviation of pain and arrestment of the tissue-damaging process serve as the therapeutic strategies in patients with inflammation [5]. However, the short-coming of these drugs is their association with a wide range of adverse effects on the gastrointestinal tract, hematological, and renal functions [5, 6]. A study by Tomisato and colleagues shows that NSAIDs have the possibility of inducing gastric lesions through direct cytotoxic effects on the gastric mucosa [7]. Moreover, it has been put forward that a causal association exists between bowel perforation or hemorrhage and NSAIDs ingestion [8]. Hence, any alternatives to address the shortcomings of NSAIDs would be hailed.

Palm vitamin E comprising 30% tocopherols and 70% tocotrienols has been extensively studied for its nutritional properties and health benefits [9]. Both tocopherols and tocotrienols have different biological properties and are further separated into four isoforms, α -, β -, δ - and γ -, respectively. It is widely known that vitamin E possesses potent antioxidant properties as well as other beneficial values. It confers protection against peroxynitrite-induced lipid oxidation in vivo and prevents cholesterol-induced atherosclerotic lesions in rabbits [10, 11]. Besides, tocotrienols are shown to inhibit the growth of a human breast cancer cell line, ZR-75-1 [12]. Reactive oxygen metabolites are involved in the mediation of tissue injuries as well as amplifying the existing inflammatory response [13]. Therefore, it is possible that the use of antioxidants may have direct or indirect effects on inflammation. Moreover, some vitamin E forms have been shown to possess anti-inflammatory effects in vivo and in vitro [14, 15].

Materials and Methods

Chemicals and Reagents

Tocotrienol-rich fraction (TRF) was obtained from Golden Hope Plantations (Selangor, Malaysia). α -Tocopherol (α T) was purchased from Aldrich Chemical Company Inc. (Milwaukee, USA) whereas δ -, γ -, and α -tocotrienol (T_3) were acquired from Eisai Food & Chemical Co. Ltd. (Tokyo, Japan). All media and reagents for tissue culture were purchased from GIBCO BRL (Paisley, Scotland). A 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrasodium

bromide (MTT) kit for cell viability assay was purchased from Chemicon (Temecula, CA, USA). Lipopolysaccharide (LPS) from a *Escherichia coli* source was obtained from Sigma (St Louis, Missouri, USA). ELISA kit for tumor necrosis factor (TNF)- α and interleukin (IL)-6 was from eBioscience (San Diego, CA, USA) and the Amersham Prostaglandin E₂ Biotrak Enzyme immunoassay (EIA) System was from GE Healthcare Ltd. (Buckinghamshire, UK). Griess reagent for the determination of nitrite was purchased from Molecular Probes (Eugene, Oregon, USA). Meanwhile, TRI reagent was from the Molecular Research Center, Inc (Cincinnati, OH, USA) and reagents for polymerase chain reaction (PCR) applications were all from Invitrogen Life Technologies (Carlsbad, CA, USA). Protein assay dye reagent concentrate for the Bradford assay was from Bio-Rad (Hercules, CA, USA).

Cell Culture

RAW264.7 macrophages were purchased from American Type Culture Collection (ATCC) (Manassas, Virginia, USA) and grown in high-glucose Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 1% penicillin-streptomycin and 1% L-glutamine in a humidified atmosphere of 5% CO₂ at 37 °C. For treatment, cells were cultured in RPMI medium without phenol red, supplemented with 5% FBS, 1% penicillin-streptomycin and 1% L-glutamine. 1×10^5 cells/well were plated in 96-well plates and incubated overnight. The next day, treatments and stimulant were given accordingly and the cells were incubated for 24 h. Cell supernatant was collected for the measurement of cytokines (IL-6 and TNF- α), nitric oxide (NO) and prostaglandin E₂ (PGE₂).

Cell Viability Assay

RAW264.7 macrophages were cultured and left overnight in 96-well plates at a density of 1×10^5 cells/well. The next day, treatment with different concentrations of TRF, α T, and tocotrienol isoforms (δ -, γ -, and αT_3) in the presence of 10 ng/ml LPS were given. The cells were incubated for 24 h. MTT solution was added into the wells containing fresh RPMI medium and the cultures were returned to the incubator. Four hours later, the blue formazan crystals that had formed were dissolved in isopropanol-HCl and the optical density was measured at 570 nm using a microplate reader.

Cytokine Assays

1×10^5 cells/well of RAW264.7 macrophages were incubated overnight in 96-well plates. Next, 10 ng/ml of

LPS was added for stimulation, together with 10 µg/ml of vitamin E supplementation and the cells were incubated for 24 h. The levels of IL-6 and TNF- α in culture supernatants were determined using commercially available ELISA kits (eBioscience). Assays were carried out according to the manufacturer's instructions. Plates were read at 540 nm using a microplate reader.

Griess Assay

Determination of NO production was performed using a Griess reagent kit (Molecular Probes) which measures the levels of nitrite formed from the spontaneous oxidation of NO. Briefly, 1×10^5 cells/well of RAW264.7 were cultured overnight in DMEM in 96-well plates, and then subjected to their respective treatments for another 24 h in the presence of 10 ng/ml of LPS. To measure nitrite, supernatants were incubated for 30 min with an equal volume of *N*-(1-naphthyl)ethylenediamine dihydrochloride and sulfanilic acid against a nitrite standard. Absorbance was measured using a microplate reader at 548 nm.

Prostaglandin E₂ Enzyme Immunoassay

Measurement of PGE₂ in the cell culture supernatant of treated RAW264.7 was carried out using the Amersham Prostaglandin E₂ Biotrak Enzyme immunoassay (EIA) System according to the manufacturer's instructions. Optical density was read at 450 nm using a microplate reader.

RNA Extraction and Reverse Transcriptase-PCR

RAW264.7 macrophages were maintained in DMEM in culture flasks. Upon confluency, treatments were given in the presence of 10 ng/ml LPS and incubated for 24 h in 5% CO₂. Total RNA was extracted using TRI reagent (Molecular Research Center, Inc.) according to manufacturer's instructions. Next, the RNA was reverse transcribed into cDNA using reverse transcriptase and the resultant cDNA was subjected to PCR using gene-specific primers. The primers for β -actin was designed using Primer 3 software whereas the sequences for *COX-1* and *COX-2* have previously been reported [16, 17]. All the primers were purchased from Invitrogen (Carlsbad, CA, USA). The sequences and the product sizes are as follows: β -actin (forward: 5'-GTG GGGCGCCCCAGGCACCA-3', reverse: 5'-CTCCTTAAT GTCACGCACGATTTTC-3') 540 bps, *COX-1* (forward: 5'-CTTTGCACAACACTTCACCCACC-3', reverse: 5'-AG CAACCCAAACACCTCCTGG-3') 285 bps, and *COX-2* (forward: 5'-GCATTCTTTGCCAGCACTT-3', reverse: 5'-AGACCAGGCACCAGACCAAAGA-3') 299 bps. The amplified products were resolved on a 1.5% agarose gel

containing ethidium bromide and visualized using an imager. The bands were quantified using ImageJ software and results were expressed as the relative fold change after normalization against β -actin [18].

Real-Time RT-PCR

Total RNA was subjected to DNase treatment. Gene expression of *COX-2* was examined using SuperScript III Platinum SYBR Green kit (Invitrogen) which employs the ABI PRISM 7000 Sequence Detection System (Applied Biosystems, CA, USA). β -Actin was used as the endogenous control. Primers for β -actin and *COX-2* were purchased from Invitrogen (Carlsbad, CA, USA) and Bioneer (Korea), respectively. The primer sequences are: β -actin (forward: 5'-AGAAGGATTCCTATGTGGGGG-3', reverse: 5'-CAT GTCGTCCCAGTTGGTGAC-3') and *COX-2* (forward: 5'-CATACTCAAGCAGGAGCATCC-3', reverse: 5'-ACC GCTCAGGTGTTGCACGTAGTC-3'). The reactions were assayed as triplicates and performed in a final volume of 50 µl. Melting curve analysis was also done. The mRNA levels for *COX-2* were normalized against β -actin and expressed as fold change relative to control. The quantification was done using the delta-delta C_t method.

Western Blot

Total proteins were extracted from treated-RAW264.7 for Western blot analysis. Briefly, cells were trypsinized, washed with ice-cold PBS and resuspended in lysis buffer (10 mM Tris-HCl pH 7.4, 1.92 mM MgCl₂, 1 mM EDTA pH 8.0, 50 mM NaCl, 6 mM β -mercaptoethanol and 2% Triton X-100) containing 1% protease inhibitor cocktail (Calbiochem, San Diego, CA, USA) and incubated for 5 min on ice. Afterwards, the cells were passed through a 21G needle syringe twice, and sonicated for 5 min. The lysates were then centrifuged at 1,000g for 10 min and the supernatants were collected. Determination of protein concentration was done using the Bradford method. A 30-µg amount of the protein lysates were resolved on 10% SDS-PAGE gels and electroblotted onto nitrocellulose membranes using a semi-dry transfer system (Bio-Rad, CA, USA). The membranes were then incubated overnight at 4 °C with 5% blocking agent (Amersham, UK) in wash buffer (0.1% (v/v) Tween 20 in PBS). After the blocking step, membranes were probed with rabbit polyclonal COX-2 antibody (Santa Cruz, USA) for 1 h at room temperature. Subsequently, the membranes were incubated for another hour at room temperature with anti-rabbit secondary antibody (Amersham, UK). Detection was performed using an ECL detection kit from Amersham (UK), according to the manufacturer's instructions. Following that, the membranes

were stripped off from the probed antibodies, blocked, and re-incubated with mouse monoclonal actin (Sigma, USA) followed by horseradish peroxidase-labeled anti-mouse secondary antibody (Santa Cruz, USA). Bands on autoradiography films were quantified using ImageJ software and normalized against actin [18].

Statistical Analysis

All results were expressed as means \pm SD and analyzed using one way ANOVA. Dunnett's multiple comparisons test was applied to determine the significant differences between treatment groups. Results were accepted to be significant at $P < 0.05$.

Results

Effects of TRF, α T, and Individual Tocotrienol Isoforms (δ -, γ -, and α T₃) on the Viability of LPS-Stimulated RAW264.7

An MTT assay was performed to determine the viability of RAW264.7 following treatment with different vitamin E forms. Figure 1 shows the percent cell viability of LPS-stimulated RAW264.7 after 24 h incubation with different concentrations of TRF, α T and tocotrienol isoforms. It demonstrated that 10 ng/ml of LPS, the concentration used for RAW264.7 stimulation throughout the study, did not

cause any change in RAW264.7 viability. No cytotoxicity was observed in all treatment groups for up to 15 μ g/ml except for δ - and γ T₃. A significant decrease in the percentage cell viability was observed in these two groups at 15 μ g/ml.

TRF, α T and Tocotrienol Isoforms (δ -, γ -, and α T₃) Have Different Effects on Proinflammatory Cytokines (IL-6 and TNF- α)

IL-6 and TNF- α are two important proinflammatory cytokines that are released in various inflammatory conditions. The presence of 10 ng/ml of LPS stimulated the release of these cytokines in RAW264.7 (Fig. 2a, b). TRF and all tocotrienol isoforms (δ -, γ -, and α T₃) at 10 μ g/ml significantly reduced the release of IL-6 in LPS-stimulated RAW264.7 when compared to the untreated LPS-stimulated group (Fig. 2a). On the other hand, α T has no effect on this context. Of all the treatments, δ T₃ showed the best inhibitory effect, being able to reduce the production of IL-6 by more than 50%, followed by γ T₃, α T₃ and TRF. In contrast, co-treatment of vitamin E forms and LPS has different effects on the production of TNF- α in RAW264.7 (Fig. 2b). TNF- α levels were increased in TRF, α T and δ T₃-treated groups, remained unaltered in a γ T₃-treated group, but underwent a significant decrease in α T₃-treated RAW264.7. This decrease was equivalent to a 12% inhibition when compared to an untreated LPS-stimulated group. The significant increase in TNF- α production was

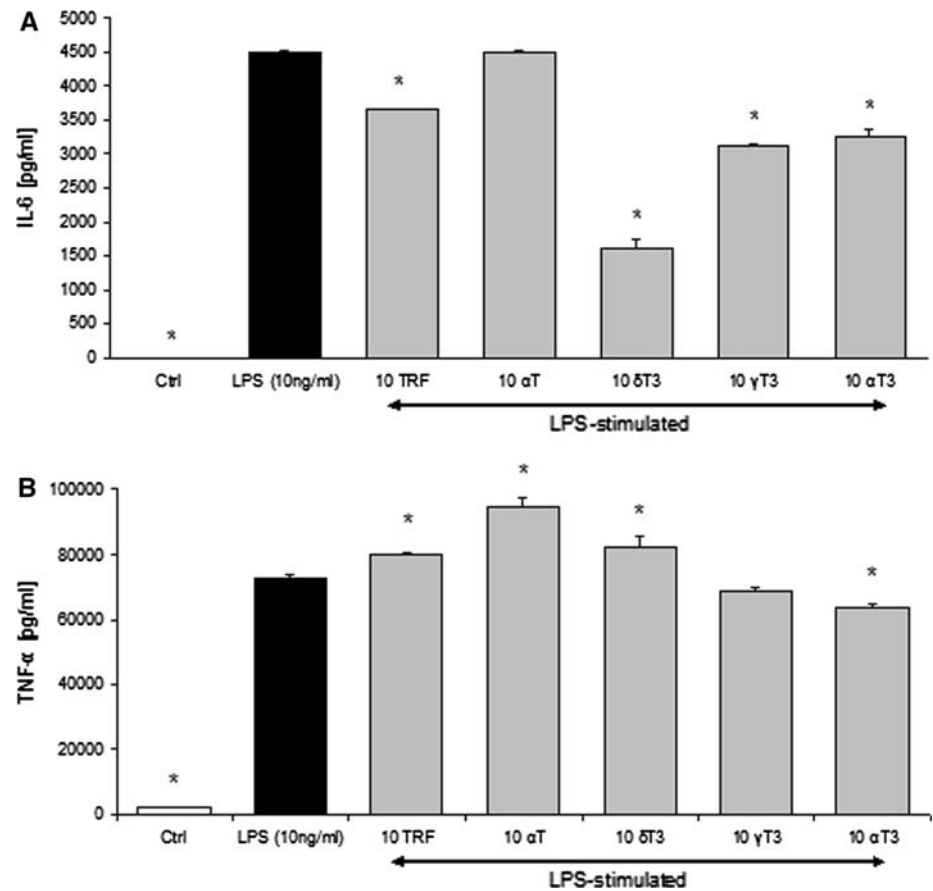

Fig. 1 Percentage cell viability of LPS-stimulated RAW264.7 following 24 h incubation with TRF, α T, and tocotrienol isoforms (δ -, γ -, and α T₃) as assessed using the MTT assay. Data are expressed as means \pm SD of triplicate wells. * $P < 0.05$ compared with control group

Fig. 2 The changes in (a) IL-6 and (b) TNF- α levels in LPS-stimulated RAW264.7 after 24 h treatment with various vitamin E forms. Supernatants were collected and assayed by ELISA. Data are presented as means \pm SD. * P < 0.05 compared with LPS group

highest in an α T-treated group, followed by δ T₃- and TRF-treated groups. Data suggested a possible proinflammatory effect of these vitamin E forms in LPS-stimulated RAW264.7.

All Vitamin E Forms Inhibited the Production of NO in LPS-Stimulated RAW264.7

The addition of 10 ng/ml LPS to RAW264.7 macrophages stimulated the production of NO from a baseline 0.2 μ M in the control to 37 μ M in the LPS group (Fig. 3). Treatment with 10 μ g/ml of all vitamin E forms showed a positive effect in inhibiting NO production. The best effect was observed in the δ T₃-treated group in which the level of NO was limited to 26 μ M which corresponds to a 31% inhibition when compared to the LPS-stimulated group. It was followed by γ T₃ which showed a 19% inhibition at 30 μ M, compared to the LPS group. Compared to δ - and γ T₃, other treatments also showed significant inhibitory effects in NO production although not as strongly. The levels of NO were detected at 33, 34, and 35 μ M in α T₃, TRF, and α T-treated groups, respectively. It is significant that α T treatment demonstrated the least inhibitory effect of only 5% when compared to the other vitamin E forms.

Tocotrienols Inhibited the Production of PGE₂ in LPS-Stimulated RAW264.7

Following LPS stimulation, the level of PGE₂ in the culture supernatant increased to approximately 1,000 pg/ml (Fig. 4). Treatment of LPS-stimulated RAW264.7 with TRF and tocotrienols, except γ T₃, significantly inhibited the level of PGE₂ when compared with the LPS group. The greatest inhibition was exerted by δ T₃, which showed approximately 55% reduction, followed by TRF and α T₃. No change in the level of PGE₂ was seen in the γ T₃-treated group. It was interesting that the PGE₂ level was significantly elevated in the α T-treated group when compared to the LPS group.

Effects of TRF, α T and Tocotrienol Isoforms (δ -, γ -, and α T₃) on COX-1 and COX-2 Gene Expression in LPS-Stimulated RAW264.7

COX-1 and COX-2 are two isoforms of the COX enzyme which regulate the synthesis of various prostanoids via the arachidonic acid pathway [19]. COX-1, being the constitutive isoform is important in the regulation of homeostasis whereas COX-2 is the inducible isoform that plays

The data are expressed as means \pm SD of triplicate wells. * $P < 0.05$ compared with LPS group

Fig. 4 The changes in PGE₂ release following treatment of LPS-stimulated RAW264.7 with different vitamin E forms. The PGE₂ levels in cell supernatants were measured using an enzyme immunoassay kit. The data are expressed as means \pm SD of triplicate wells. * $P < 0.05$ compared with LPS group

important roles in the pathophysiological aspects of inflammation (20). The expression of COX-2 can be initiated by a variety of stimuli and LPS is known to be a potent inducer for these enzymes [21, 22]. In order to elucidate the effects of different vitamin E forms on *COX-1* and *COX-2* gene expressions in LPS-stimulated RAW264.7, RT-PCR was performed using gene-specific primers. Data showed that gene expression of *COX-1* remained unaltered in all groups (Fig. 5b). This observation agrees with the fact that COX-1 remains a constitutive isoform of COX and being expressed equally in all samples. Meanwhile, 10 ng/ml of LPS up-regulated the expression of *COX-2* to a significant 6.4-fold relative to the control. Among the treated groups, δ T₃ showed the best inhibition in *COX-2* expression. δ T₃, at 10 μ g/ml down-regulated the expression of *COX-2* for 1.5-fold when compared with the LPS group but the change was not statistically significant.

TRF and Individual Tocotrienol Isoforms, but Not α T Down-Regulated the Expression of *COX-2* as Determined Using Semi-Quantitative Real-Time PCR

To ascertain the *COX-2* expression results obtained using the conventional RT-PCR method, semi-quantitative Real-Time PCR was applied. Real-Time PCR is a more sensitive method for direct detection of PCR product during the exponential phase of the reaction [23]. Data obtained showed a 145-fold increase in *COX-2* expression when compared to control (Fig. 6). Supplementation of LPS-stimulated RAW264.7 with all the vitamin E forms at 10 μ g/ml effectively reduced the expression of *COX-2*. However, the down-regulation was only statistically significant for TRF and other tocotrienol isoforms, but not α T. The most apparent change was seen in the δ T₃-treated group where the expression of *COX-2* was reduced 29-fold

Fig. 5 Gene expressions of *COX-1* and *COX-2* in LPS-stimulated RAW264.7. Total RNA was extracted from the treated macrophages and RT-PCR was carried out to study the gene expressions of *COX-1* and *COX-2*. (a) PCR bands as visualized from ethidium bromide-stained agarose gel. The images are representatives of three independent experiments. (b) Gene expressions are expressed as relative fold change following normalization against β -actin. Data are shown as means \pm SD of three replicates. * $P < 0.05$ compared with LPS group

Fig. 6 Relative *COX-2* mRNA expression in LPS-stimulated RAW264.7 after 24 h treatment with TRF, α T and tocotrienol isoforms (δ -, γ -, and α T₃) as determined by Real-Time PCR. Total RNA extracted using the TRIzol method was DNase-treated and subjected to Real-Time PCR to determine the expression of *COX-2*. Data represent expressional fold change relative to control after normalization against β -actin. Data are expressed as means \pm SD of triplicate wells. * $P < 0.05$ compared with LPS group

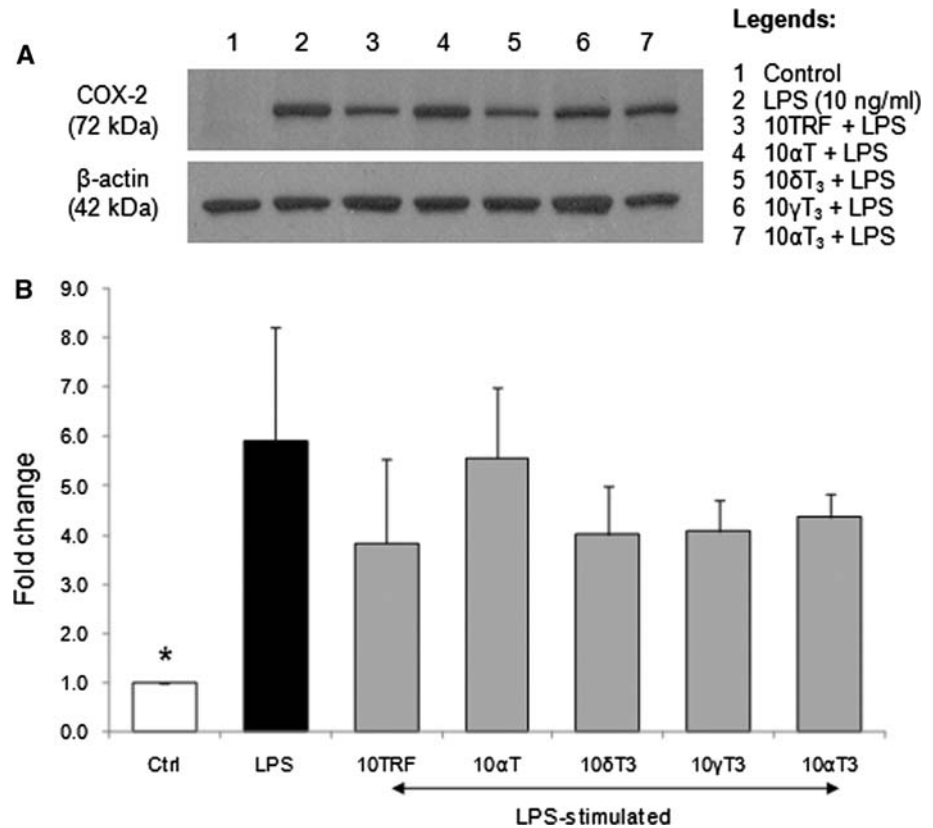

relative to the control, which was equivalent to a 116-fold difference from the LPS group. It was followed by α T₃, γ T₃, TRF and α T with *COX-2* expression levels at 51-, 55-, 79- and 129-fold relative to the control, respectively. In terms of differences from the LPS group, it corresponded to 94-, 90-, 66-, and 16-fold, respectively. Using this more sensitive approach to determine the expression of the *COX-2* gene, it showed that the most effective *COX-2* inhibitor was δ T₃ while α T has no effect.

Effects of TRF, α T and Tocotrienol Isoforms (δ -, γ -, and α T₃) on *COX-2* Protein Expression

Next, the effects of vitamin E forms on protein expression of *COX-2* were evaluated using Western blot analysis. Stimulation of RAW264.7 with 10 ng/ml of LPS significantly up-regulated the expression of *COX-2* protein to 5.9-fold relative to control (Fig. 7b). TRF, at the concentration tested showed the best effect in down-regulating the

Fig. 7 Protein expression of COX-2 in LPS-stimulated RAW264.7. Cell lysates from treated macrophages were obtained and analyzed for COX-2 protein expression by Western blot. (a) COX-2 and β -actin bands on autoradiography films following Western blotting. Images are representatives of three separate experiments. (b) Following densitometry analysis, data are expressed as the number of times the change is relative to the control group after normalization against β -actin. * $P < 0.05$ compared with the LPS group

expression of COX-2 protein. In the TRF group, COX-2 protein expression level was 3.8-fold relative to the control and this corresponded to a 2.1-fold difference from the LPS group. However, this down-regulation shown by TRF was not statistically significant. Other treated groups (δ -, γ -, and α T₃) also demonstrated a slight decrease in the number of times different compared to the LPS group but again, the changes were not significant. No obvious effect was seen in the α T-treated group.

Discussion

Recent studies have shown that tocotrienols possess powerful neuroprotective, anti-cancer, as well as hypocholesterolemic properties that are not seen in tocopherols [24]. The objective of the study was to investigate the anti-inflammatory effects of TRF and individual tocotrienol isoforms (δ -, γ -, and α T₃), using α T as comparison. RAW264.7, a transformed murine macrophages cell line was used as the in vitro model for the study. The cells were incubated for 24 h with 10 μ g/ml of one of the vitamin E forms together with 10 ng/ml of LPS as stimulation. The concentration of vitamin E form used, 10 μ g/ml, was selected based on the cell viability assay as the highest non-toxic concentration for all tested vitamin E forms. The levels of IL-6 in the culture supernatant were found to be

reduced in all treated groups except α T. The decrease was not due to the cytotoxic effects of the treatments because as shown by the MTT assay, cells were still viable at 10 μ g/ml for each treatment. On the contrary, treatment with vitamin E forms not only failed to reduce TNF- α levels, its production was increased in α T, δ T₃ and TRF-treated groups. When compared with the LPS group, only α T₃ was able to inhibit TNF- α significantly whereas its production was unaffected by γ T₃. NO, as estimated using Griess assay for the measurement of nitrite, was significantly reduced by all the vitamin E forms when compared with the LPS group. All the treatments, with the exception of α T and γ T₃ also inhibited the release of PGE₂. In addition, gene expression of COX-2 was found to be down-regulated in all treated group except α T. Of all the treatments, δ T₃ exhibited the best effect, followed by α T₃, γ T₃, and finally, TRF. No significant effect was observed in all the treated groups on the expression of COX-2 protein.

IL-6 and TNF- α are among the main cytokines produced by activated macrophages which are involved in both acute and chronic inflammation [25]. Many studies have used these two cytokines as important markers of inflammation [26, 27]. The up-regulation of IL-6 and TNF- α is seen in many disorders such as rheumatoid arthritis, multiple myeloma and chronic obstructive pulmonary disease [28–30]. Our findings on IL-6 release showed that all treatments except α T were able to reduce the production of

this cytokine significantly. This result contradicts a previous finding which showed a significant decrease in IL-6 level when 20 μ M of α T was supplemented [27]. The same report also demonstrated a reduction in TNF- α production at the same concentration of α T. This is in opposition to what we obtained where all the vitamin E forms except α T₃ failed to demonstrate a significant reduction in TNF- α production. The discrepancies in the results may be probably due to the use of different approaches in the experimental protocols as the effects caused by a particular mediator depend on the nature of the toxicant, target and quantities of the mediator produced [31].

NO is an important mediator that is involved in the regulation of homeostatic conditions and immune responses. Synthesis of NO requires the amino acid L-arginine as substrate and the process is catalyzed by a group of enzymes termed the nitric oxide synthases (NOS) [32, 33]. NOS co-exist in three isoforms, each with its own biological functions. The constitutive form of NOS, the cNOS, is important in maintaining homeostasis and it is further divided into the neuronal NOS (nNOS or type 1 NOS) and endothelial NOS (eNOS or type 3 NOS). The third isoform, the inducible NOS (iNOS or type 2 NOS) is the form that is involved in a wide range of pathophysiological events. Our findings showed that all vitamin E forms at 10 μ g/ml significantly reduced the generation of NO as assayed using Griess reagent that measures nitrite, the breakdown product of NO. This may be attributed to the antioxidant properties of vitamin E. NO is an effector molecule of innate immunity that forms the pro-oxidant and toxic peroxynitrite (ONOO⁻) in the presence of superoxide (O₂⁻) [34]. In addition, the data also agree with those reported by Berharka and colleagues stating that supplementation of vitamin E reduces the production of inducible NO in peritoneal macrophages derived from aged mice [35]. Study of *iNOS* gene expression was also carried out but none of the treatments showed a significant effect (results not shown). This suggested that vitamin E forms can only inhibit iNOS activity as demonstrated by the reduction in NO synthesis, and not at the gene level.

Being one of the most studied prostaglandins, PGE₂ is produced by fibroblasts, macrophages, and some types of malignant cells and its over-production is implicated in various pathophysiological and diseased states [36, 37]. Similar to NOS, the COX enzymes can be divided into the constitutive and inducible isoforms. COX-1, being the constitutive isoform plays important roles in the regulation of various physiological functions such as gastric cytoprotection, and the maintenance of kidney and platelet functions [20, 38]. On the other hand, COX-2 is the inducible isoform of COX, being expressed by immune cells and engages in the pathological aspects of inflammation [38]. The present study revealed that treatment of

LPS-stimulated RAW264.7 with TRF, δ -, and α T₃ suppressed the release of PGE₂ into the culture supernatant. On the other hand, study of gene expression demonstrated that treatment with 10 μ g/ml of TRF and tocotrienol isoforms (δ -, γ -, and α T₃) down-regulated the expression of COX-2. These levels of COX-2 expression were in accordance with the amount of PGE₂ measured in the cell supernatants. The expression level of COX-1, the constitutive isoform which is responsible for various housekeeping roles, remained unaffected in all groups. This shows that the changes of PGE₂, as shown in Fig. 4, have nothing to do with COX-1 activity. The down-regulation of the COX-2 gene suggested that vitamin E forms show an effect at the gene transcriptional level, subsequently affecting the levels of PGE₂ released. Although some marginal down-regulation was observed in the present study, treatment with all vitamin E forms seemed to have no significant effect on the protein translational level. Previous findings have shown that PGE₂ inhibition is accompanied by the down-regulation of the COX-2 gene and protein expression [39]. However, other findings also demonstrated that it does not necessarily follow in that manner as COX-2 enzymatic activity could be altered without any effects being shown at the transcription and translation levels [40, 41]. This suggests that each tocotrienol forms could modulate PGE₂ production through different mechanisms.

Tocotrienols, the vitamin E form which has previously been neglected, are now starting to gain attention due to their newly found properties. Besides their novel antioxidant functions, researchers have shown great interest in the non-antioxidant properties of this vitamin E form [42]. On top of that, studies are beginning to strengthen the notion that tocotrienols are superior to tocopherols in many aspects. TRF and individual tocotrienols, in particular δ - and γ T₃, are potent anti-proliferative agents, being able to induce apoptosis and cell cycle arrest in PC-3, a human prostate cancer cell line [43]. α T and α T₃ show no effect in that context. Besides, α T₃ is shown to provide the best neuroprotective effects in rat striatal cultures while α T failed to do so [44]. In the inflammation context, palm TRF has been shown to suppress the transcription of proinflammatory cytokines, and blocking the expression of COX-2 and iNOS in THP-1, a human monocytic cell line [45]. γ T₃ was found to inhibit the production of PGE₂ in human lung epithelial A549 cells activated by interleukin-1 β while no effect was seen in α T [46]. Meanwhile, another study has demonstrated that γ T₃, but not tocopherol, is a potent inhibitor of nuclear factor- κ B (NF- κ B) activation that leads to the down-regulation of various gene products including COX-2, as well as potentiating apoptosis [47]. NF- κ B is a principal transcription factor that modulates the expression of various cytokines, growth factors and

proinflammatory enzymes [48]. The activation of NF- κ B pathway is involved in the pathogenesis of many diseases such as those related to inflammation, enhanced cellular proliferation, infections and genetic diseases [49]. The expression of many proinflammatory genes including *COX-2* and *iNOS* is regulated by the activation of NF- κ B [50]. Therefore it is plausible that the inhibitory effects of vitamin E forms on *COX-2* expression in this study were due to the blockade of the NF- κ B pathway. Suppression of the NF- κ B pathway will eventually lead to a lower expression of proinflammatory enzymes and/or cytokines.

In conclusion, the results of this study showed that TRF and tocotrienol isoforms (δ -, γ -, and α T₃) possess anti-inflammatory properties with each displaying different levels of potency. It should be remembered that different effects might be observed if other cell types or different stimulation and incubation methods were used. Nevertheless, in this model of LPS-stimulated RAW264.7 macrophages, δ T₃ was demonstrated to be the most effective anti-inflammatory agent among all the vitamin E forms tested, being able to suppress the production of IL-6, NO, PGE₂, and at the same time inhibiting the expression *COX-2*. α T showed the least effect in alleviating an inflammatory response. It was suggested that individual isoforms of tocotrienol might have distinct and different effects, depending on the cell-type and on which parameters are being studied.

Abstract This study reports on the results of repeated gavages and dietary feeding of lutein dispersed either in phospholipids or fatty acid micelles or vegetable oils and the effects on lutein bioavailability and antioxidant enzymes in rats. For the gavage study, rats ($n = 5/\text{group}$) were intubated with lutein solubilized either in oleic acid (OLA, 18:1n-9) or linoleic acid (LNA, 18:2n-6) or phosphatidylcholine (PC) or lysophosphatidylcholine (LPC) or no phospholipid (NoPL) micelles for 10 days. For the dietary study, rats ($n = 5/\text{group}$) were fed a diet containing fenugreek leaf (lutein source), either with olive (OO) or sunflower (SFO) or groundnut (GNO, control) oil or L- α -lecithin (PL) for 4 weeks. The gavage study showed that the plasma, liver and eye lutein levels in OLA and LPC groups were higher by 23.9, 20.8 and 25.5% and 16.1, 28.5 and 14.0% than LNA and PC groups, respectively. The dietary study showed the plasma (35.0 and 43.5%) and eye (18.5 and 37.0%) lutein levels in OO were higher than SFO and GNO groups. The plasma and eye lutein levels in the PL group were higher by 20 and 31.3% than in the control. It is evident that OO and PL modulate lutein absorption, which in turn modulates antioxidant enzymes and fatty acids in plasma and tissues compared to SFO. Hence,

selection of the fat source may be vital to enhancing the lutein bioavailability.

Keywords Antioxidant enzymes · Bioavailability · Fatty acids · Lutein · Phospholipids

Abbreviations

GNO	Groundnut oil
LNA	Linoleic acid
LPC	Lysophosphatidylcholine
MDA	Malonaldehyde
OLA	Oleic acid
OO	Olive oil
PC	Phosphatidylcholine
PL	L- α -Lecithin
SFO	Sunflower oil
SOD	Superoxide dismutase

Introduction

Dietary ingestion is the only source of lutein, as humans cannot synthesize it. Consumption of lutein-rich food is associated with a lower risk of cataracts and age-related macular degeneration (AMD) [1]. Lutein is ingested along with other food matrices, reported to interfere with lutein absorption [2]. Herden et al. [3] reported that intestinal absorption of carotenoids depends on the concentration and origin of the dietary fat consumed. Dietary fat is reported to improve the absorption of β -carotene [4], by influencing the release of bile and the formation of mixed micelles in the intestine [5]. Plasma lutein response was improved after a meal with sufficient fat, but reduced when fat is absent or too

low [6]. Baskaran et al. [7] and others [8, 9] reported that a single oral dose of specific phospholipids in mixed micelles influenced the intestinal uptake of β -carotene and lutein in mice, rats and human intestinal Caco-2 cells, respectively.

There are studies which investigated the effects of vegetable fat on carotenoids bioavailability in animal and human subjects. Hu et al. [10] studied the effect of dietary sunflower oil and beef tallow on the level of β -carotene in plasma triacylglyceride-rich lipoproteins in women. Clark et al. [11] observed that lycopene and astaxanthin absorption in rats was greater with an orally administered emulsion with olive oil compared to corn oil. Despite the importance of dietary lipids as carriers for lutein, little is known with relation to their influence on lutein bioavailability in vivo. Hence, it is appropriate to study the role of dietary fat on lutein bioavailability. Earlier, we reported that a single oral dose of phospholipid micelles and olive oil significantly enhanced the plasma lutein level in rat and mice models [7, 12, 13]. This study appraises the effect of repeated gavages and dietary feeding of lutein with phospholipids, fatty acids and vegetable oils on its bioavailability, fatty acid profile and activity of certain antioxidant enzymes in rats. Although gerbils and monkeys are considered as being superior models for xanthophyll absorption studies, a rat model was chosen in this study because the results obtained can be considered valid and comparable with other animal models. Earlier, we had established by LC-MS that lutein and zeaxanthin are present in the rats' eye [13].

Materials and Methods

Chemicals and Materials

Lutein (99%), DL- α -tocopherol, monooleoylglycerol, sodium taurocholate, linoleic acid, oleic acid (~99%), phosphatidylcholine (99%) and lysophosphatidylcholine (99%) were purchased from Sigma-Aldrich (St. Louis, MO, USA). All other chemicals and solvents were of analytical reagent grade, unless otherwise mentioned, and were obtained from Sisco Research Laboratories (Mumbai, India). Food grade casein, cellulose, sucrose, methionine, vitamins, minerals, choline chloride and L- α -lecithin (L- α -phosphatidylcholine from soybean) were purchased from Himedia Laboratories Pvt. Ltd. (Mumbai, India). Refined olive, sunflower, and groundnut oils were obtained from a local super market.

Animals

Animal experiments were conducted after due approval from the Institutional Animal Ethics Committee. Male

albino rats [OUTB-, Wistar, IND-cft (2c)] weighing 42 ± 2 g were housed in individual steel cages at room temperature ($28 \pm 2^\circ\text{C}$) with a 12-h dark/light cycle in the institute's animal house facility.

Gavage Studies

Mixed micelles in phosphate buffered saline (pH, 7.0) containing monooleoylglycerol (2.5 mM), sodium taurocholate (12 mM), lutein (200 μM) either with 3 mM PC or LPC or no phospholipids (NoPL) or with 7.5 mM OLA or LNA was prepared separately [11]. Rats were divided into six groups ($n = 5/\text{group}$) and housed individually in metabolic cages for 7 days. Rats were fed orally a daily dose (0.2 ml/day) of micellar lutein containing NoPL (control) or PC or LPC or OLA or LNA for 10 days. Feed (Amrut feeds, Sangli, India) and water was made available ad lib throughout the experimental run. Feed samples were processed for lutein analysis before feeding to ascertain its level.

Urine was collected in amber bottles contained 0.5 ml of toluene (to prevent bacterial growth) and 0.2 ml of 2 mM α -tocopherol and faecal matter was collected separately from the individual rats for 6 days from days 2 to 8 and used for lutein analysis. At the termination of the experiment, the rats were anesthetized with diethyl ether, sacrificed; blood, liver and eyes were sampled and processed for lutein analysis.

Dietary Studies

The rats ($n = 5/\text{group}$) were fed an isocaloric diet [14] containing powdered fenugreek leaf (0.421%) as the source of lutein (2.69 mg/kg diet), 10% either olive oil (oleic acid source, OO group) or sunflower oil (linoleic acid source, SFO group) or groundnut oil (control, GNO group) or 10% soy lecithin (phospholipids source, PL group), casein (20%), DL-methionine (0.3%), sucrose (59.57%), cellulose (5%), vitamin mix (1%), mineral mix (3.5%) and choline bitartrate (0.2%), respectively, for 4 weeks. Rats had free access to food and water and the daily food intake and weekly gain-in-body weight were monitored. At the termination of experiment, rats were anesthetized with diethyl ether, sacrificed; blood, liver and eyes were sampled and processed for lutein analysis. Samples were handled on ice under dim yellow light to minimize isomerization and oxidation of lutein by light irradiation.

HPLC Analysis of Lutein

Lutein levels in the extracts of plasma, liver, eyes, urine, feces, fenugreek leaf powder and diet were analyzed by HPLC [12, 13]. In brief, lutein was separated under

isocratic condition at a flow rate of 1 mL/min on SGE C-18 (ODS) column, 25 cm × 4.6 mm id, 5 nm, 120A0 (SGE Co., India) using acetonitrile: methanol: dichloromethane (60:20:20, v/v/v) containing 0.1% ammonium acetate, as a mobile phase at 450 nm with UV–visible detector (Shimadzu, Japan). Peak identities, λ_{\max} and levels of lutein and zeaxanthin were confirmed and quantified by their retention time, characteristic spectra and peak area of reference standards, recorded with a Shimadzu model LC-10Avp series equipped with SPD-10AVP detector. In the case of eye samples, lutein and zeaxanthin levels are presented together as lutein + zeaxanthin, due to their unsatisfactory resolution.

Assay for Antioxidant Enzymes and Lipid Peroxides

Liver and eyes were homogenized separately in phosphate buffer (10%, pH 7.0), centrifuged at 600g for 15 min at 4 °C and the supernatant was used for enzyme assays. Superoxide dismutase (SOD, EC 1.15.1.1) activity was measured by the inhibition of cytochrome-C reduction mediated via superoxide anions generated by xanthine-xanthine oxidase and measured using spectrophotometer (Shimadzu-Japan, 1601) at 550 nm [15]. One unit of superoxide dismutase was defined as the amount-required to inhibit the reduction of cytochrome-C by 50%. Glutathione peroxidase (GSH-Px, EC 1.11.1.9) activity was measured by initiating reaction with *tert*-butyl hydroperoxide (100 μ l) and recorded decrease in absorbance at 340 nm for 5 min [16]. The activity is expressed as nmol of NADPH oxidized/min/mg protein (\sum 340–6.22 $\text{mM}^{-1}\text{cm}^{-1}$). The glutathione level was measured by monitoring the rate of 5-thio-2-nitrobenzoic acid formation at 412 nm [17]. Protein content and lipid peroxides (nmol MDA/mg protein) in plasma and tissue were estimated as per Lowry et al. [18] and a thiobarbituric acid reactive substances assay [19].

Analysis of Lipid Profile

Total lipids [20], triacylglycerides [21], cholesterol [22] and phospholipids [23] were analyzed from plasma and tissues by adopting standard procedures. Fatty acids were analyzed as methyl esters prepared using boron trifluoride in methanol [24] and analyzed by gas chromatography (Shimadzu 14B, fitted with FID) using a fused silica capillary column 25 cm × 0.25 mm (Parma bond FFAP-DF-0.25: Machery-Nagel GmbH co. Duren, Germany). The gas chromatography operating conditions were: initial column (160 °C), injector (210 °C) and detector temperature (250 °C) and the column temperature were programmed to rise at 6 °C/min to the final temperature of 240 °C. Nitrogen gas was used as the carrier. Fatty acids

were identified with their respective standards (Nu Chek Prep, Elysian, MN, USA).

Statistical Analysis

Data were tested for homogeneity of variances by the Bartlett test. When homogenous variances were confirmed, the data were tested by ANOVA and significant differences between the groups were evaluated by Tukey's test. Differences in means were considered significant at $P < 0.05$.

Results

Gavage Studies

Influence of Phospholipids on Lutein Bioavailability

The plasma lutein levels for the PC and LPC groups were higher by 19.2 and 32.3% than NoPL group, while the value for the LPC group was 16.1% higher than the PC group. The liver lutein levels in PC and LPC groups were 30 and 50% higher than the NoPL group, whereas in the LPC group it was 28.5% higher than the PC group. Similarly, lutein concentration in the eyes of PC and LPC groups were higher by 25.8 and 36.2% compared with the NoPL group, but it was 14.0% higher in the LPC than in the PC group (Table 1). Lutein excreted through the urine of the PC group was higher by 30.1 and 50.9% than the NoPL and LPC groups. However, lutein levels in feces of the PC group were higher by 8.3 and 38.8% than the NoPL and LPC groups (Table 1). The plasma TG response (mg/dl) on feeding PC was higher (257.3 ± 27.4) than LPC (183.6 ± 43.2) and NoPL (250.3 ± 25.2) groups.

Influence of fatty Acids on Lutein Bioavailability

The plasma, liver and eyes lutein response in the OLA group was higher by 23.9, 20.8 and 25.5% than in the LNA group (Table 1). The level of lutein excreted in urine was higher in the OLA group (25.2%) and its level in feces was slightly higher in the LNA group (Table 1). Likewise, a higher (44.8%) TG level was recorded in the plasma of the OLA in comparison to the LNA group.

Dietary Studies

The experimental diet had lutein (2.69 μ g/g diet) as the major carotenoid. No difference was noticed in mean food intake and gain-in-body weight among groups. Diet was analyzed for their fatty acid composition prior to use (Table 2). OLA (74.3%) and LNA (64.9%) are major fatty acids in olive oil and sunflower oil, whereas, lecithin

contained OLA as the major fatty acid (38.2%), followed by LNA (19.5%). Vegetable oils used in this study were chosen based on their fatty acid composition so as to compare with the results of specific fatty acids employed in the gavage studies.

Influence of Vegetable Oils and Lecithin on Lutein Bioavailability

At 0 day (baseline values), the plasma (nmol/l), liver and eyes (pmol/g) lutein levels were 4.7 ± 0.4 , 94.5 ± 17.4 and 32.7 ± 3.2 , respectively, and their levels were elevated after 4 weeks feeding of lutein dispersed in vegetable oils. The OO and SFO groups recorded higher plasma (43.5 and 13.1%) and eyes (37 and 22.7%) lutein levels than the GNO group. In comparison, the value for the OO group was 35 and 18.5% higher than the SFO group (Table 3). In contrast, no difference was noticed in the liver lutein levels

Table 3 Lutein levels in rats at 0 day and after 4 weeks feeding of a diet containing powdered fenugreek leaves as the lutein source either with vegetable oils or L- α -lecithin

Groups	Plasma (nmol/l)	Liver (pmol/g)	Eyes (pmol/g)*
Base line values	7.0 ± 0.4	94.5 ± 17.4	32.7 ± 3.2
GNO	28.5 ± 6.2 ^a	145.9 ± 18.5 ^a	88.4 ± 7.5 ^a
OO	50.5 ± 3.0 ^b	161.0 ± 4.0 ^a	140.5 ± 9.3 ^b
SFO	32.8 ± 4.5 ^{a,c}	177.5 ± 11.4 ^b	114.4 ± 13.5 ^c
PL	35.6 ± 2.4 ^c	183.3 ± 10.2 ^b	128.8 ± 12.8 ^b

* Lutein and zeaxanthin are expressed together due to their low resolution in eyes

among the groups. The plasma TG level was higher by 26.0 and 22.4% in the OO and SFO groups compared with the GNO group. The plasma, liver and eye lutein level in the PL group was higher by 19.9, 20.4 and 31.3% compared to the GNO group (Table 3).

Antioxidant Enzymes

The activity of SOD in plasma was higher by 17.4% (SFO group) and lower by 38% (OO group) compared with the GNO group, wherein its activity in the OO group was lower by 40% compared to the SFO group. In contrast, no significant difference was noticed in the liver of the SFO group compared with the GNO and OO groups. Similarly, no difference was noticed in SOD activity in eyes between SFO and OO groups and plasma, liver and eye of the PL group compared to the GNO group (Table 4).

The activity of GSH-Px in plasma of the SFO group increased slightly and it was lower (32%) in the OO than in the GNO group in comparison, the OO group displayed 30.6% lower activity than the SFO group. Activity of GSH-Px was higher by 15.4 and 37.4% in liver and eyes of the SFO group and it was non-significantly lower in the OO group than in the GNO group. Data further reveal that the activity of enzyme in liver and eyes of the OO group was

* Per ml of 10% tissue homogenate

lower by 28.9 and 37.4% than in the SFO group. The activity of GSH-Px in the PL group was higher in plasma (21.4%), while no difference was noticed in liver and eyes compared with the GNO group (Table 4).

Plasma glutathione levels in the SFO and OO groups increased by 26.6 and 20% over the GNO group. In case of liver and eyes, the levels of glutathione was 17.1, 24.7 and 24.4, 5.0% higher in SFO and OO groups than in the GNO group, wherein its level was slightly lower in the OO group than in the SFO group. Glutathione level in plasma, liver and eyes of the PL group were non-significantly higher than the control group (Table 4).

Lipid Peroxides

Elevated levels (39.1 and 9%) of MDA were recorded in the plasma of the SFO and OO groups compared to the GNO group, wherein it was lower by 33% in the OO group in comparison to the SFO group. Similarly, the MDA level in the liver of the SFO group was higher (40 and 15.4%) and in eyes not much difference was observed compared to the OO and GNO groups. The plasma, liver and eyes MDA level in the PL group was higher by 29, 47.2 and 10.1% compared to the GNO group (Table 4).

Plasma and Tissues Lipid Profile

In the OO group, the plasma TG level was higher by 21.1 and 35.9% and cholesterol level was lower by 29.1 and 55.0% than in the SFO and GNO groups, respectively. No significant difference was found in plasma phospholipids levels among groups (Table 5). OLA and LNA levels (%) in plasma, liver and eye of 0 weeks (base line value) were recorded as 16.3 ± 2.7 and 23.9 ± 0.5 , 18.4 ± 2.1 , 19.2 ± 1.1 and 16.3 ± 4.5 and 18.8 ± 2.3 , respectively. The plasma fatty acid profile of the OO, SFO and GNO groups show that the OLA and LNA levels were 54 and 21.5% in the OO and SFO groups. However, the proportion of OLA and LNA levels in the GNO group were 42.6 and 17.9%, respectively (Table 6).

The triacylglyceride level in the liver of the OO group was 22.5 and 12.7% higher than those of the SFO and GNO groups, while cholesterol and phospholipids levels were not altered significantly (Table 5). Feeding OO and SFO resulted in elevated levels of OLA (28.4%) and LNA (29.6%) in the liver. There was non-significant alteration in the lipid profile studied in the eyes of the OO and SFO groups compared with the GNO group while, fatty acid profile show that the OLA is a major fatty acid in the OO (36.1%) and SFO (21.4%) groups (Table 5). The plasma, liver and eyes lipid profile of the PL group was not significantly changed compared with the control group, whereas the fatty acid profile showed higher OLA

FA fatty acid; ND not detected

accumulation in plasma (36.2%), liver (31.3%) and in eyes (28.3%) (Table 6).

Feeding vegetable oils resulted in altered plasma, liver and eyes fatty acid composition (Table 6). Rats fed on SFO and OO diets had 25 and 45% lower level of LNA in the plasma compared to those fed on a GNO diet. Plasma of the SFO group had 15% of total fatty acid as LNA, whereas, LNA was not detected in the GNO group. OLA and LNA were present only in rats fed on the OO diet and they were 1.3 and 1.4% of total fatty acids. Rats fed with the SFO diet contained LNA to the extent of 2.9% of total fatty acids in liver. The basal level of LNA and OLA in the GNO group was 9.6% of total fatty acids and it increased to 12.7 and 14.4%, respectively, in the SFO and OO groups. The eyes of rats fed with the SFO diet contained 4.9% of LNA of total fatty acids, whereas, it was not detected in other dietary groups.

Discussion

The plasma response of lutein was considered as a measure of intestinal absorption. This study indicates that repeated gavages of lutein solubilized in LPC micelles resulted in an enhanced plasma lutein level compared to PC micelles in rats. This is inconsistent with our earlier single dose studies [7, 9], reported that PC inhibited β -carotene and lutein absorption in rodents and Caco-2 cells, indicating that incomplete hydrolysis of PC in the intestine may affect the rate of solubilization and transfer of lutein from mixed micelles to the enterocytes [12]. Evidence has been reported [25] showing that the presence of intact PC in mixed micelles slows the transfer of cholesterol and α -tocopherol from the micellar matrix. This could be a reason for a higher level of lutein excreted in the feces of rats fed with PC compared to LPC micelles. In contrast, the present study shows that the plasma, liver and eyes lutein levels of the PC group were higher compared with the NoPL group. Repeated intake of PC may stimulate the phospholipases [9], which hydrolyses PC to LPC in the intestine resulting in an increased lutein absorption suggesting that the hydrolysis of phospholipids in the intestinal tract is vital, although PC plays a significant role in the solubilization of carotenoids in lipid emulsions [26]. PC with two long-chain acyl moieties is more hydrophobic than LPC, which has one acyl moiety and a free hydroxyl group, may slow the intestinal uptake of PC more than LPC [25]. Thus, PC can strongly retain the hydrophobic lutein in the mixed micelles thereby suppressing its intestinal uptake [9]. These properties of phospholipids could make it possible to modify the lutein bioavailability.

The dietary study revealed that the plasma lutein level was higher in the OO group than in the SFO group. The

differences in plasma triglycerides and the fatty acids profile indicate that the ingested dietary lipid readily altered the plasma TG. Hollander and Ruble [27] reported that oleic acid in micellar perfusate enhanced the β -carotene absorption more than linoleic acid indicating that the rate of transport depends upon the hydrophobicity of the fatty acids. A more elevated lutein level in the eyes of the OLA group than in the LNA group suggests that, OLA not only influences the intestinal accessibility but also sways the transport of newly absorbed lutein to target tissue. An elevated level of plasma TG further supports the above hypothesis, it being a carrier molecule for lutein. A lower level of plasma lutein after 10 days of intubation and its higher level in eyes further suggests the basis for clearance of absorbed lutein as being via TG (Table 1).

The lipid sources used in this study differ in TG and fatty acid composition (Table 4). OO is rich in oleic acid whereas, SFO is rich in linoleic acid. Borel et al. [28] and Odeberg et al. [29] reported that incorporation of β -carotene and astaxanthin into chylomicrons in human subjects was lower with emulsions containing medium-chain than long-chain triglycerides and suggested that medium-chain triglycerides are mainly transported by portal blood and do not favor the lymphatic transport of lipoproteins. In fact, the higher levels of plasma TG recorded in this study after repeated gavages and dietary feeding support the above mechanism.

Although, specific fatty acids or vegetable lipids play a vital role in lutein bioavailability, they are found to be involved in the regulation of oxidative mechanism. The present results demonstrate that OLA-rich OO is found to protect tissue from lipid peroxidation more than LNA-rich SFO [30]. The effect of a feeding diet with olive oil on tissue lipid composition and the activity of SOD and GSH-PX were comparatively lower than SFO while slightly higher than in the control rats. This could be the reason for lower MDA levels in the OO group. Changes in the liver fatty acid composition may be due to unsaturated lipids in SFO; in turn they may enhance the efficiency of the SOD and GSH-Px [31, 32]. Since lutein is an antioxidant, it may be involved in the protective action against oxidative reactions [1]. This has been supported by the fact that retinal cells treated with lutein had decreased oxidative stress-induced lipid peroxidation and apoptosis [32]. The present data suggest that high levels of dietary unsaturated fat as a carrier for lutein may be avoided if oxidative stress is a critical issue in nutrition-related degenerative diseases like AMD.

In conclusion, the choice of carrier lipid and its fatty acid profile is critical to achieving an enhanced bioavailability of dietary lutein. The relative bioavailability of lutein could be improved either by single, repeated and dietary feeding of lutein either with OLA micelles or

dispersed in olive oil which, in turn, may help in modulating the activity of antioxidant molecules.

Abstract Lipase-catalyzed transesterification of flaxseed oil with cinnamic acid (CA) or ferulic acid (FA) using an immobilized lipase from *Candida antarctica* (E.C. 3.1.1.3) was conducted to evaluate whether the lipophilized products provided enhanced antioxidant activity in the oil. Lipase-catalyzed transesterification of flaxseed oil with CA or FA produced a variety of lipophilized products (identified using ESI-MS-MS) such as monocinnamoyl/feruloyl-diacylglycerol, dicinnamoyl-monoacylglycerol and monocinnamoyl-monoacylglycerol. The free radical scavenging activity of the lipophilized products of lipase-catalyzed transesterification of flaxseed oil with CA or FA toward 2,2-diphenyl-1-picrylhydrazyl radical (DPPH·) were both examined in ethanol and ethyl acetate. The polarity of the solvents proved important in determining the radical scavenging activity of the substrates. Unesterified FA showed the highest free radical scavenging activity among all substrates tested while CA had negligible activity. The esterification of CA or FA with flaxseed oil resulted in significant increase and decrease in the radical scavenging activity compared with the native phenolic acid,

respectively. Based on the ratio of a substrate to DPPH· concentration, lipophilized FA was a much more efficient free radical scavenger compared to lipophilized CA and was able to provide enhanced antioxidant activity in the flaxseed oil. Lipophilized cinnamic acid did not provide enhanced radical scavenging activity in the flaxseed oil as the presence of natural hydrophilic antioxidants in the oil had much greater radical scavenging activity.

Keywords Lipase-catalyzed transesterification · Cinnamic acid · Ferulic acid · Free radical scavenging activity · Antioxidant

Abbreviations

CA	Cinnamic acid
DPPH·	2,2-Diphenyl-1-picrylhydrazyl radical
ESI-MS	Electrospray ionization-mass spectroscopy
ESI-MS-MS	Electrospray ionization-mass spectroscopy-mass spectroscopy
FA	Ferulic acid
HPLC	High performance liquid chromatography

Introduction

Flaxseed oil is rich in alpha linolenic acid (ALA), an essential n-3 fatty acid. The oil usually contains greater than 50% of ALA [1]. The high content of ALA in flaxseed oil, however, renders the oil susceptible to oxidation. Flaxseed oil is not recommended to be used for frying, pan-heating or preparation of food when heat is involved [2]. Today, flaxseed oil is usually cold-pressed from the seed and is increasingly sold as a health food.

There is growing interest in modifying fats and oils to form structured lipids with specific properties for nutritional and pharmaceutical applications [3, 4]. Modification of natural lipids can be achieved by enzymatic means. Long et al. [5] investigated the effect of enzymatic transesterification of palm stearin and palm olein with flaxseed oil on the melting behaviour of palm stearin and palm olein with the objective of expanding the application of the oils. Phenolic acids are natural antioxidants that occur ubiquitously in fruits, vegetables, spices and aromatic herbs [6]. Phenolic acids are hydrophilic in character, which may reduce their antioxidant effectiveness in stabilizing fats and oils. Lipophilization of phenolic acids, which involves the esterification of the phenolic acid with a lipophilic moiety resulting in new molecules with modified hydrophilic/lipophilic balance is a way to utilize their antioxidative properties [7–9]. The lipophilized phenolic acids should maintain its original functional properties such as antioxidant, antimicrobial and UV filtering ability [10, 11].

The esterification of phenolic acids with non-triacylglycerol structures such as alcohol have been previously investigated [12–15]. Literature pertaining to studies involving direct esterifying of phenolic acids on oils has been mainly limited to studies conducted by two groups of researchers. Compton and Laszlo [16], Laszlo et al. [17], Laszlo and Compton [18], and Compton et al. [19] focused mainly on using lipase-catalyzed reactions of vegetable oils such as soybean oil to synthesize structured lipids with properties suitable for use as possible sunscreen reagents. These structured lipids were examined for their ultraviolet-absorbing efficacy but not their free radical scavenging activity. Sabally et al. [20, 21] and Karboune et al. [22] investigated lipase-catalyzed reactions using fish liver oil or flaxseed oil with phenolic acids to synthesize nutraceutical phenolic lipids.

The objectives of this research were to characterize the lipophilized products from lipase-catalyzed transesterification of flaxseed oil with cinnamic acid or ferulic acid, to evaluate the antioxidant activity of the lipophilized products and to investigate whether the lipophilized products provided enhanced antioxidant activity in the flaxseed oil.

Experimental Procedure

Materials

An organic, unrefined, cold-pressed flaxseed oil (abbreviated as OSELO) was obtained from Oil Seed Extractions Ltd, Ashburton, New Zealand. The triacylglycerol profile of OSELO was as follows: trilinolenoylglycerol,

dilinolenoyl-linoleoylglycerol, dilinolenoyl-oleoylglycerol, dilinolenoyl-stearoylglycerol, dioleoyl-linolenoylglycerol, dioleoyl-linoleoylglycerol and trioleoylglycerol. The percentage of free fatty acids was determined as $0.30 \pm 0.05\%$. Peroxide value and *p*-anisidine value were 0.91 ± 0.12 milliequivalent peroxide/kg sample and 0.70 ± 0.05 , respectively. Commercially available immobilized lipase B from *Candida antarctica* [E.C. 3.1.1.3; Novozym 435, with an activity of 10,000 propyl laurate units per solid gram (PLU)], was a gift from Novozymes (Bagsværd, Denmark). CA, FA and DPPH \cdot were purchased from Sigma Chemicals Co. (St. Louis, MO, USA). All the chemicals and solvents used were of analytical or HPLC grade.

Enzymatic Transesterification

The enzymatic transesterification of OSELO with CA or FA was carried out according to a modified method of Karboune et al. [23]. OSELO (1,000 mg) was dissolved in 10 mL of *n*-hexane in a 50-mL Erlenmeyer flask. CA (170 mg) or FA (56 mg) was added to the reaction mixture followed by Novozym 435 (234 mg for CA system; 211 mg for FA system). The mol ratio of OSELO:CA and OSELO:FA was 1:1 and 4:1, respectively. The flask was incubated under nitrogen at 50 °C, with continuous shaking, in an orbital shaker at 120 rpm (Model SS70, Chiltern Scientific, Auckland, New Zealand) for 2 weeks. The enzymatic reaction was stopped by termination of contact with immobilized lipase by filtration using Whatman glass microfibre filter paper C. The removal of unreacted CA/FA by aqueous solvent washing of reaction components and hydrolysis of lipophilized products for quantification were carried out according to the method of Choo and Birch [24]. Briefly, the reaction components in *n*-hexane were washed with four volumes of acetone:methanol:water (7:7:6). Each volume was 6 mL. This was followed by drying the recovered hexane fraction under nitrogen at room temperature. Lipophilized products free from unreacted CA or FA (2.0–7.0 mg) were weighed into a glass tube (15.0 cm \times 1.3 cm with Teflon-lined screw cap). One mL of 4 N methanolic NaOH was added and the hydrolysis was carried out under nitrogen at 50 °C for 3 h, followed by acidification with concentrated HCl. Acidity was checked using litmus paper. This solution was then evaporated to dryness. The dried sample was dissolved in 2 mL isopropanol:hexane (4:1) prior to HPLC analysis. The conversion of CA or FA was calculated as w/w ratio of CA or FA released from the hydrolysis of lipophilized products to its initial amount. Quantification was based on an external standard method where a calibration curve [25, 50, 75, 100, 125 and 150 μ g CA or FA dissolved in 1 mL of isopropanol:hexane (4:1)] was prepared.

HPLC Analysis of Reaction Components

The enzymatic reaction components were monitored by HPLC analysis, according to the method of Sabally et al. [25]. The separation of reaction components was performed on a C-18 Phenosphere-Next column (250 × 4.6 mm, 5 μm; Phenomenex, Torrance, CA, USA) using a Varian 9010 solvent delivery system (Varian Associates, Inc., Walnut Creek, CA, USA), a SPD-M10AV diode array detector (Shimadzu, Kyoto, Japan) and an analyzing software, Shimadzu Class-M10A. Detection of reaction components was achieved at 215 and 280 nm (CA system) and 215 and 290 nm (FA system). These wavelengths, 280 and 290 nm, were selected from the absorption spectrum of CA and FA, respectively. Elution of a 20-μL injected sample was carried out with a gradient system using an acetonitrile/methanol mixture (7:5, vol/vol) as solvent A and isopropanol as solvent B; the elution was initiated by a flow of 100% solvent A for 10 min, followed by a 20-min linear gradient to 100% solvent B, which was maintained for an additional 5 min. The flow rate was 1 mL/min. Typically, a 10-min equilibration period was used between samples, requiring about 45 min/sample.

Electrospray ionization-mass spectroscopy (ESI-MS) and electrospray ionization-mass spectroscopy-mass spectroscopy (ESI-MS-MS) were used for the analysis of reaction components.

The reaction components were recovered by HPLC and analyzed using an ESI-MS system, Bruker microTOFQ (Bruker Daltronics, Bremen, Germany). Samples were introduced using direct infusion into the ESI source in a positive mode with a collision energy of 10 eV. Capillary voltage of −4.5 kV and a dry gas of 99% N₂ at 180 °C were employed. Sampling was averaged for 3 min over a *m/z* range of 100–1,000 amu. The mass was calibrated using an external calibrant of sodium formate clusters. Spectra were processed using Compass software version 1.3 (Bruker Daltronics, Bremen, Germany). Selected ions that were tentatively identified were chosen to undergo further analysis by ESI-MS-MS with collision energy between 20 and 40 eV. High resolution MS data (to five decimal points) was obtained but all the MS data was presented to the nearest mass unit for simplicity.

Determination of Radical Scavenging Activity

The free radical scavenging activity of compounds was measured using a modified DPPH· radical method of Silva et al. [6]. The concentration of sample and DPPH· solution was modified to suit the rate of reactivities of the samples analyzed here. All assays were carried out in triplicate. For the evaluation of free radical scavenging activity of the CA/FA system, five samples were tested (Fig. 1). OSELO

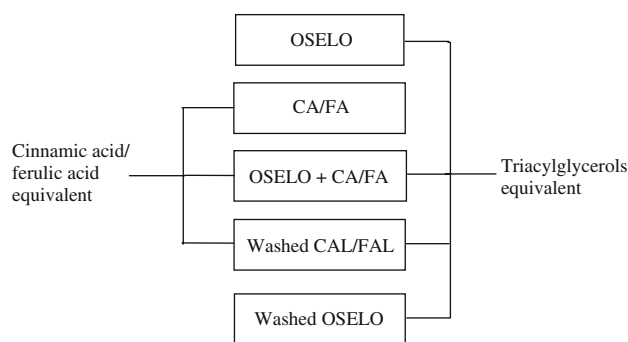

Fig. 1 Samples for evaluation of free radical scavenging activity of the CA/FA system. Lipophilized product including unreacted OSELO from lipase-catalyzed transesterification of OSELO and CA/FA was abbreviated as CAL/FAL. As CAL/FAL underwent aqueous solvent washing to remove unreacted CA/FA, it was labelled as ‘washed CAL/FAL’. Washed OSELO underwent the same aqueous solvent washing. The mixture of OSELO and CA/FA without transesterification was abbreviated as OSELO + CA/FA

concentration was set at 25.0 mM. The amount of CA/FA tested was equivalent to the amount of CA/FA esterified to the acylglycerols of OSELO in CAL/FAL. Taking into consideration the unreacted triacylglycerols (calculated using percentage of conversion) in the CAL/FAL fraction, the amount of CAL/FAL was estimated and set at 25.0 mM. The sample for analysis was mixed with 2×10^{-4} M DPPH· solution in ethanol or ethyl acetate. The ratio of a substrate to DPPH· concentration was $1:8 \times 10^{-3}$. The reduction of DPPH· radical was monitored spectrophotometrically at 517 nm over a period of 30 min against a blank assay. The percentage of the remaining radical was calculated as the absorbance of the sample at 517 nm, divided by that of the DPPH· control at the same time, multiplied by 100.

Results and Discussion

Figure 2 shows a chromatogram of reaction components of the lipase-catalyzed transesterification of OSELO and CA after removal of the enzyme followed by aqueous solvent washing. Unreacted CA was removed from the reaction components by aqueous solvent washing for the quantification of the amount of CA that has been converted to lipophilized products. The average percentage conversion of CA in this lipase-catalyzed transesterification of OSELO and CA was 44.6%. Lipophilized product and CA were detected at both $\lambda = 215$ and 280 nm. Unreacted OSELO triacylglycerols were detected at $\lambda = 215$ nm as trilinolenoylglycerol (25.133 min), dilinolenoyl-linoleoylglycerol (26.150 min), dilinolenoyl-oleoylglycerol (27.254 min), dilinolenoyl-stearoylglycerol (28.252 min), dioleoyl-linolenoylglycerol (29.181 min) and dioleoyl-linoleoylglycerol

Fig. 2 HPLC chromatogram at 215 nm and 280 nm of reaction components of the lipase-catalyzed transesterification of OSELO and CA after removal of the enzyme followed by aqueous solvent washing. Peaks were identified as follows: monocinnamoyl-linolenoylglycerol (5.207); dicinnamoyl-linolenoyl-glycerol (7.393); dicinnamoyl-linoleoylglycerol (9.440); dicinnamoyl-oleoylglycerol (12.841); monocinnamoyl-dilinolenoylglycerol (19.342); monocinnamoyl-oleoyl-

linolenoylglycerol (20.964); monocinnamoyl-linoleoyl-linolenoylglycerol (22.582); monocinnamoyl-oleoyl-linoleoylglycerol (23.862); trilinolenoylglycerol (25.133); dilinolenoyl-linoleoylglycerol (26.150); dilinolenoyl-oleoylglycerol (27.254); dilinolenoyl-stearoylglycerol (28.252); dioleoyl-linolenoylglycerol (29.181); dioleoyl-linoleoylglycerol (30.117)

(30.117 min), respectively. The first peak at 5.207 min at 280 nm in Fig. 2 was found to be monocinnamoyl-linolenoylglycerol, with two positions on the glycerol having acyl groups (one CA and one linolenic acid) and one position having a hydroxyl (–OH) group (Table 1). Peaks at 7.393, 9.440 and 12.841 min at 280 nm in Fig. 2 were found to be dicinnamoyl-monoacylglycerols whereas peaks at 19.342, 20.964, 22.582 and 23.862 min were found to be monocinnamoyl-diacylglycerols. The identification of lipophilized products for peaks 25.224 and 26.494 min at 280 nm in Fig. 2 was not successful. This was most likely due to the unreacted OSELO triacylglycerols co-eluting at the same retention times, detected at 215 nm. As shown in Fig. 2, the lipophilized products peaks at 25.224 and 26.494 min at 280 nm were minor peaks as compared to the larger respective peaks at 25.133 and 26.150 min at 215 nm.

Figure 3 shows a chromatogram of the reaction components of the lipase-catalyzed transesterification of OSELO and FA after removal of the enzyme followed by aqueous solvent washing. Unreacted FA was removed from the reaction components by aqueous solvent washing for the quantification of the amount of FA that has been converted to lipophilized products. The average percentage conversion of FA in this lipase-catalyzed transesterification of OSELO and FA was 23.7%. Lipophilized products and FA are detected at both $\lambda = 215$ nm and 290 nm.

Unreacted OSELO triacylglycerols were detected at $\lambda = 215$ nm. The four lipophilized product peaks at 15.933, 18.084, 19.987 and 21.383 min at 290 nm in Fig. 3 were found to be monoferuloyl-diacylglycerols (Table 2). Diferuloyl-monoacylglycerol was not detected in this study although Compton et al. [26] reported the presence of diferuloyl-monoacylglycerol in their study of lipase-catalyzed transesterification of soybean oil with ethyl ferulate. This is most likely due to the use of different transesterification conditions and substrates in this study. Unreacted OSELO triacylglycerols (peak 25.064, 26.082, 27.182, 28.113, 29.103, 30.027 and 30.912 min at 215 nm in Fig. 3) were trilinolenoylglycerol, dilinolenoyl-linoleoylglycerol, dilinolenoyl-oleoylglycerol, dilinolenoyl-stearoylglycerol, dioleoyl-linolenoylglycerol, dioleoyl-linoleoylglycerol and trioleoylglycerol, respectively.

The free radical scavenging activity of the lipophilized products of lipase-catalyzed transesterification of OSELO with CA or FA toward DPPH \cdot were examined both in ethanol and ethyl acetate. To examine the comparative free radical scavenging activity of the lipophilized products (CAL and FAL), four control samples were examined (Figs. 4, 5). CA showed very limited free radical scavenging activity in ethanol and ethyl acetate. This is in agreement with the free radical scavenging activity of CA found by Karboune et al. [23] and Choo and Birch [24]. Although Sabally et al. [20] and Karboune et al. [22]

Table 1 Summary of ESI-MS data of lipophilized products of the lipase-catalyzed transesterification of OSELO with CA

Lipophilized products	HPLC (280 nm; Fig. 2) retention time (min)	Molecular weight	ESI-MS	ESI-MS-MS fragmentation
Monocinnamoyl-linolenoylglycerol	5.207	482	505 (M + 23) ⁺	357 [-CA] 227 [-C18:3]
Dicinnamoyl-linolenoylglycerol	7.393	612	635 (M + 23) ⁺	487 [-CA] 357 [-C18:3]
Dicinnamoyl-linoleoylglycerol	9.440	614	637 (M + 23) ⁺	489 [-CA] 357 [-C18:2]
Dicinnamoyl-oleoylglycerol	12.841	616	639 (M + 23) ⁺	491 [-CA] 357 [-C18:1]
Monocinnamoyl-dilinolenoylglycerol	19.342	742	765 (M + 23) ⁺	617 [-CA] 487 [-C18:3]
Monocinnamoyl-oleoyl-linolenoylglycerol	20.964	746	747 (M + 1) ⁺	599 [-CA] 469 [-C18:3] 465 [-C18:1]
Monocinnamoyl-linoleoyl-linolenoylglycerol	22.582	744	745 (M + 1) ⁺	597 [-CA] 467 [-C18:3] 465 [-C18:2]

Fig. 4 Time course for DPPH· radical scavenging activity of CA system tested in ethanol (a) and ethyl acetate (b). All standard deviations values were below 3.6%. The lipophilized product including unreacted OSELO and CA from the lipase-catalyzed transesterification of OSELO and CA was abbreviated as CAL. Washed CAL and washed OSELO refer to the aqueous solvent washing that CAL and OSELO underwent. The mixture of OSELO and CA without transesterification was abbreviated as OSELO + CA

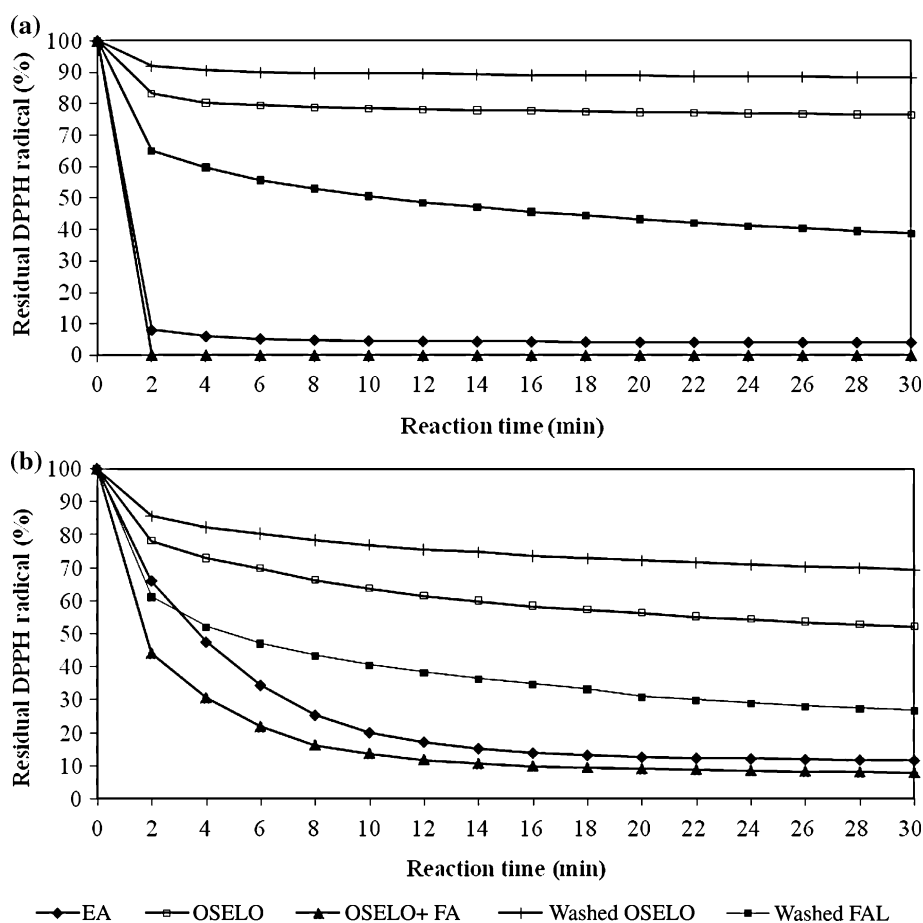

as phenolic acids and tocopherols in OSELO. OSELO showed higher free radical scavenging activity in ethyl acetate than that in ethanol and this indicates that the polarity of the solvent and solubility of substrate may have affected the free radical scavenging activity. When CA was added to OSELO and mixed without transesterification, no significant change in free radical scavenging activity was found for this mixture (OSELO + CA) as compared with

OSELO (Fig. 4). This result reaffirmed that CA has limited free radical scavenging activity at the level tested.

As CAL underwent aqueous solvent washing to remove unreacted CA, a control OSELO was subjected to the same aqueous solvent washing. The aqueous solvent washing removed not only unreacted CA from CAL, it also removed hydrophilic antioxidants present in the oil. This resulted in a loss of free radical scavenging activity in washed OSELO as

Fig. 5 Time course for DPPH· radical scavenging activity of FA system tested in ethanol (a) and ethyl acetate (b). All standard deviation values were below 3.4%. Lipophilized product including unreacted OSELO and FA from lipase-catalyzed transesterification of OSELO and FA was abbreviated as FAL. As FAL underwent aqueous solvent washing to remove unreacted FA, it was labelled as 'washed FAL'. Washed OSELO underwent the same aqueous solvent washing. The mixture of OSELO and FA without transesterification was abbreviated as OSELO + FA

compared with unwashed OSELO (Fig. 4). However, lipophilic tocopherols were not removed by the aqueous solvent washing and contributed to the free radical scavenging of washed OSELO in ethanol (11.8%) and ethyl acetate (30.6%). There was no significant difference in the free radical scavenging activity of OSELO, OSELO + CA and washed CAL tested in ethanol (Fig. 4a). However, a difference was observed among the three samples tested in ethyl acetate (Fig. 4b). The free radical scavenging of OSELO tested in ethyl acetate was 8.9% units higher than that of washed CAL whereas the free radical scavenging activity of washed CAL was 8.3% units higher than that of washed OSELO. These results indicate the esterification of the carboxyl group of CA resulted in a slight increase of its free radical scavenging activity. Alkyl substituents in the carboxylic ethylene side chain of lipophilized CA may have donated electrons inductively to the benzene ring and increased the rate of hydrogen atom transfer reactions and hence an increase in the free radical scavenging activity [24]. However, the radical scavenging activity of natural antioxidants in unwashed OSELO was much greater. The increase in the free radical scavenging activity of CAL was in agreement with the findings of Karboune et al. [23]

and Choo and Birch [24]. For CAL to provide higher enhancement of free radical scavenging activity in OSELO, a higher level of lipophilized CA may be needed, however the conversion to lipophilized CA was already high.

Figure 5 shows the time courses for DPPH· scavenging of the FA system tested in ethanol and ethyl acetate, respectively. The free radical scavenging activity of FA tested in ethanol and ethyl acetate was 96.0 and 88.3%, respectively. The higher free radical scavenging activity obtained for FA in ethanol than that in ethyl acetate was in agreement with the study of Choo and Birch [24]. When FA was added to OSELO and mixed without transesterification, the free radical scavenging activity obtained for this mixture (OSELO + FA) was higher than that of OSELO (Fig. 5). The OSELO activity was due to the contribution of free radical scavenging activity of naturally occurring antioxidants in OSELO. These results were in agreement with that of Warner and Laszlo [27] who reported that ferulic acid acted as an antioxidant when added to soybean oil used for frying potato chips and those of Nag [28], Bera et al. [29, 30] and Jaswir et al. [31, 32] who used natural antioxidants such as capsicum extract, ajowan extract, oleoresin rosemary extract and sage extract

to improve the oxidative stability of flaxseed oil. Like washed CAL, FAL underwent aqueous solvent washing to remove unreacted FA. The free radical scavenging activity of washed FAL tested in ethanol and ethyl acetate was 61.3 and 73.2%, respectively. The higher free radical scavenging activity obtained for washed FAL in ethyl acetate than that in ethanol again indicates that the polarity of the solvent and solubility of substrate may have affected the free radical scavenging activity of washed FAL. The free radical scavenging of washed FAL tested in ethanol and ethyl acetate was 34.7 and 15.1% units lower than those of FA, respectively. The decrease in free radical scavenging activity after esterification of the carboxyl group of FA was in agreement with the findings of Safari et al. [33] and Choo and Birch [24]. The electron-donating alkyl group in the carboxylic ethylene side chain of lipophilized FA may have decreased the reactivity of the phenolic hydroxyl group toward electron transfer reactions and hence a decrease in the free radical scavenging activity [24]. The free radical scavenging of washed FAL tested in ethanol and ethyl acetate was 37.8 and 25.6% units higher than those of OSELO, respectively, and much higher than those of washed OSELO. These results indicate that FAL provided enhanced antioxidant activity in the flaxseed oil.

Conclusions

FAL was a much more efficient free radical scavenger compared to CAL and was able to provide enhanced antioxidant activity in OSELO. The level of CAL required to achieve a noticeable change in antioxidant activity of OSELO would be extreme due to the presence of natural antioxidants in OSELO. Nevertheless, CAL may be useful for unsaturated oils with a small amount of natural antioxidants in them. CAL and FAL demonstrated higher free radical scavenging activities in ethyl acetate than those in ethanol. FA demonstrated a higher free radical scavenging activity in ethanol than that in ethyl acetate. These results strongly suggest that the most suitable polarity medium with respect to the hydrophilicity or lipophilicity of a substrate should be sought in evaluating the free radical scavenging activity of the substrate as it controls the ability of the substrate to reach the true site of free radical attack.

The Hypolipidemic Effect of an Ethyl Ester of Algal-Docosahexaenoic Acid in Rats Fed a High-Fructose Diet

Abstract Preclinical and clinical studies demonstrate that the omega-3 fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) as a triacylglycerol (TAG) or an ethyl ester are protective against cardiovascular disease. Both have significant TAG-lowering effects. We developed a concentrated ethyl ester of DHA (MATK-90, 900 mg/g) using microalgae as its source. This study evaluated the effects that different doses of MATK-90 had on lipid levels and clinical parameters in male Wistar rats fed a high-fructose diet used to induce hypertriglyceridemia ($\text{TAG} \geq 300 \text{ mg/dL}$). Effects of MATK-90 were compared to those produced by a pharmaceutical product (Lovaza, formerly Omacor, P-OM3; 465 mg EPA + 375 mg DHA), a TAG oil used in food (DHASCO, algal-DHA, 40% DHA by weight), and a control (corn oil). Doses of MATK-90 (0.6, 1.3, 2.5, 5.0 $\text{g kg}^{-1} \text{ day}^{-1}$), algal-DHA (2 g DHA $\text{kg}^{-1} \text{ day}^{-1}$), and P-OM3 (5.0 $\text{g kg}^{-1} \text{ day}^{-1}$) were administered by oral gavage for 28 days. A significant dose-related decrease was observed in TAG and cholesterol levels in all but the lowest dose of MATK-90 treatment group vs. control. The high-dose group of MATK-90 and the P-OM3 group produced similar reductions in TAG levels.

Abbreviations

Apo E-KO Apolipoprotein E-knockout mice
CHOL Cholesterol

DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
GRAS	Generally recognized as safe
HDL-C	High-density lipoprotein cholesterol
HTG	Hypertriglyceridemia
LC-PUFAs	Long-chain polyunsaturated fatty acids
LDL-C	Low-density lipoprotein cholesterol
LSMEAN	Least square means
P-OM3	Lovaza TM , formerly Omacor [®]
RANCOVA	Repeated measure analysis of covariance
TAG	Triacylglycerol

Introduction

The omega-3 long-chain polyunsaturated fatty acids (LC-PUFAs), particularly docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), are known to have many cardiovascular benefits in animals and humans. Both DHA and EPA not only lower triacylglycerol (TAG) levels but may also reduce the risk of sudden death [1, 2], decrease the risk of arrhythmia and atherosclerosis [3–5], increase plaque stabilization [6], and reduce blood pressure and heart rate in both normotensive and mildly hypertensive individuals [7–9]. The TAG-lowering effects of DHA and EPA appear to be due to the combination of decreased hepatic TAG secretion and enhanced clearance of TAG from the plasma [10] that can occur in the fasting state or post-prandially [11, 12].

Several animal studies have considered the effects of DHA and EPA on plasma lipid levels and metabolism, but the findings have been inconsistent [13, 14]. In Wistar rats fed a standard diet, a cholesterol (CHOL) diet (2% CHOL),

A. S. Ryan (✉) · E. Bailey-Hall · E. B. Nelson · N. Salem Jr

e-mail: alryan@martek.com

or a pelleted chow diet with highly purified DHA (92% pure) at different doses (0.5, 1, 1.5 g kg⁻¹ day⁻¹), there was no significant decrease in hepatic and plasma concentration of TAG after 10 days of treatment [13]. However, a TAG-lowering effect was reported after 1 day in Wistar rats fed a standard diet after receiving 1.5 g kg⁻¹ day⁻¹ of EPA [14].

Highly purified ethyl esters of EPA (93%) and DHA (91%) were added at a 3% level to a hypercholesterolemic diet (52.5% sucrose, 5% lard, 0.5% CHOL, and 25% sodium cholate) and administered to male Sprague–Dawley rats [15]. In addition to the hypercholesterolemic diet, four experimental diets were considered (5% olive oil, 2% olive oil + 3% ethyl-linoleate, 2% olive oil + 3% EPA, and 2% olive oil + 3% DHA). The animals were fed the experimental diets for up to 20 days. Serum total CHOL level was significantly lower in the rats fed the diet that included DHA, whereas serum TAG level was significantly lower only in the rats fed the diet that included EPA.

The mechanisms and degree of suppression of postprandial hypertriglyceridemia (HTG) resulting from a fish oil diet rich in DHA (6.7 g/100 g EPA, 20.5 g/100 g DHA) were considered in a study of Sprague–Dawley rats [12]. TAG levels were significantly lower in animals fed the DHA-rich fish oil diet than in those fed safflower oil for 3 weeks. The authors reported that the TAG-lowering was due to the suppression of hepatic fatty acid and TAG synthesis [12].

To investigate the effect that fish oil had on serum lipid levels and atherosclerotic lesions in apolipoprotein E-knockout (Apo E-KO) mice, 1% dietary fish oil was added to a mouse chow containing 9% (w/w) fat and 0.2% (w/w) CHOL for 14 days [16]. Apo E-KO mice develop spontaneous atherosclerosis and high plasma TAG and CHOL levels. Aortic atherosclerosis was assessed by histological and morphological techniques. Although levels of DHA and EPA increased significantly in plasma free fatty acids and plasma TAG, phospholipid, and cholesteryl ester fractions, there were significant increases in plasma TAG levels, and the development of atherosclerotic plaque was not prevented. The authors suggested that the lack of the effect of fish oil on TAG levels may be related to the role that Apo E has on metabolism of fatty acids and TAG-rich lipoprotein particles [16]. Apo E is needed for clearance of TAG-rich particles and therefore the lack of Apo E was probably responsible for the absence of the TAG-lowering effect typically reported for fish oil.

Studies in animals have shown that insulin resistance can be improved with diets containing LC-PUFAs [17, 18]. Results from human studies have been less conclusive [19, 20]. In a study of insulin-resistant mice fed a lipid modified diet with DHA and/or DHA blends, TAG levels significantly decreased by ~40%, but insulin sensitivity and

fasting plasma glucose were not altered [21]. In a study that compared a diet with EPA to one containing safflower oil, EPA-fed diabetic-prone rats had lower TAG and CHOL levels and improved insulin resistance [22].

The effects of dietary fish oil (17.6 g of DHA and 7.7 g of EPA per 100 g of fatty acid, respectively) on lipid peroxidation and serum TAG levels were considered in a study of psychologically stressed female BALB/c mice [23]. The animals were initially group-housed (four mice/cage) and fed a diet containing fish oil, soybean oil, or olive oil for 3 weeks. The animals were then housed under the same conditions or individually housed to generate psychological stress for 2 weeks. In the fish-oil-fed mice, a significant reduction in serum TAG levels was observed versus the soybean-oil- or olive-oil-fed mice. The reduction was more profound in the isolation stress group. The authors suggested that dietary intake of LC-PUFAs could exert more beneficial effects against the onset of cardiovascular disease under conditions of isolation stress [23]. The isolation stress group had increased levels of LC-PUFAs in the liver and serum when compared with the group-housed animals. This increase may account for the more profound reduction in the serum TAG levels in the fish-oil-fed mice subjected to isolation stress compared with their group-housed counterparts.

Cardiovascular benefits of LC-PUFAs also have been observed in large animals. Thirteen thoroughbred or standard bred horses were assigned to diets with fish oil or corn oil for 63 days [24]. The fish-oil diet contained 10.8% EPA and 8% DHA. The oils were added to timothy hay and a mixed-grain concentrate at rates necessary to maintain body weight (324 mg/kg of body weight). Compared with horses receiving corn oil, those receiving fish oil had significantly lower TAG levels after 63 days. Serum CHOL, platelet number, prothrombin and partial prothrombin time, red blood cell number, and lymphocyte percentage did not change with either diet.

In humans, DHA and EPA are obtained primarily from marine mammals and fatty fish that have consumed microalgae containing these LC-PUFAs. However, the consumption of DHA and EPA from fatty fish is relatively low, particularly in Westerners, and normal dietary intake is unlikely to provide a significant TAG-lowering effect in individuals with relatively high TAG levels. Consequently, DHA and EPA can be provided through a pharmaceutical product. Lovaza (formerly Omacor, P-OM3) was approved by the U.S. Federal Drug Administration to reduce elevated TAG levels in adult patients with very high (≥ 500 mg/dL) TAG levels. Each gram capsule of P-OM3 contains 900 mg of ethyl esters of omega-3 fatty acids including EPA (approximately 465 mg) and DHA (approximately 375 mg). The U.S. recommended daily dose of P-OM3 is 4 g per day.

As discussed above, most studies in humans and animals have considered experimental diets that contain mixtures of EPA and DHA. However, there is growing evidence that DHA alone provides cardioprotective benefits similar to those seen with products containing both EPA and DHA [25]. A microalgal source of DHA, which contains only trace amounts of EPA and other omega-3 fatty acids, is available for food use and for dietary supplements. The DHA is derived from the microalga *Cryptocodinium cohnii* in a controlled fermentation process to produce a TAG oil (DHASCO, algal-DHA, Martek Biosciences, Columbia, MD, USA). Algal-DHA oil naturally contains approximately 40–50% DHA by weight. Algal-DHA is generally recognized as safe (GRAS) for use in food products and dietary supplements. A highly concentrated ethyl ester of DHA derived from algal-DHA (~900 mg/g DHA) was manufactured for clinical evaluation (MATK-90, Martek Biosciences).

To date, it is not known whether a highly concentrated ethyl ester of DHA from algae devoid of EPA affects plasma lipids in a similar fashion as algal-DHA triacylglycerol oil or the combination of DHA and EPA ethyl esters from fish oil. However, highly purified ethyl esters of DHA and EPA from fish oil each decrease TAG levels in humans [26]. These ethyl esters from fish oil are not 100% pure; each may contain up to 5–10% of the corresponding LC-PUFA [26]. In the present study, we evaluated the effects that different doses of MATK-90 had on plasma lipid levels, fatty acid levels, and clinical parameters in male Wistar rats fed a hyperlipidemic (high fructose) diet. The effects of MATK-90 were compared with those produced by P-OM3, algal-DHA, and a control (corn oil modified with vitamin E).

Materials and Methods

Animals and Experimental Design

Male Wistar rats, 41–44 days of age, were provided by Charles River Laboratories, Montreal, Quebec, Canada, and were maintained in their testing facility in Shrewsbury, MA. The study was conducted according to Good Laboratory Practices standards. The animals were examined for signs of disease or injury upon receipt, and 84 males were assigned to the study. On the day of receipt, animals (including spare animals) weighed 168–236 g. The animals were individually housed in clear polycarbonate cages with contact bedding, as recommended by the National Research Council [27]. Environmental controls maintained temperatures at 18–26 °C (64–79°F) with a relative humidity of 30–70%. A 12-h light/12-h dark cycle was maintained (lights on at approximately 0300 h and lights

off at approximately 1500 h). At least 10 air changes per hour were maintained in the animal room.

Charles River Laboratories is accredited by the Association for the Assessment and Accreditation of Laboratory Animal Care, International, and registered with the United States Department of Agriculture to conduct research in laboratory animals. The study was conducted in conformity with the Public Health Service Policy on Humane Care and Use of Laboratory Animals and was approved by the Institutional Animal Care and Use Committee at the facility.

All animals were fed a high-fructose diet (Research Diet D07121202, Research Diets, New Brunswick, NJ, USA) (Table 1) ad libitum for approximately 5 weeks before the initial dose administration (designated here as week -5). The high-fructose diet was used to induce HTG. Animals with a pretreatment TAG level of <299 mg/dL were excluded from the study. Thirty-three animals were excluded based on the TAG-level study entry criterion.

Animals enrolled into the study were fed the high-fructose diet continuously throughout the study except during times of fasting.

Test materials for the treatment groups are described in Table 2. Doses were prepared by diluting the MATK-90, P-OM3, and algal-DHA with corn oil stripped of tocopherol (item #401101, Dyets, Bethlehem, PA). α -Tocopherol (0.4%) was added to MATK-90, algal-DHA, and control oil to match the level found in P-OM3. Eighty-four animals were assigned to one of seven treatment groups, and each group contained 12 animals. The experimental design is provided in Table 3. Animals were 10–11 weeks of age at

the time of dosing. Doses were administered once daily via oral gavage, within 3 h of the onset of the dark cycle, for 28 consecutive days. The animals were dosed at a volume of 10 mL/kg.

The first day of dosing was day 1. The doses were given at approximately the same time each day and were based upon the most recently collected body weight. Doses were rounded to the nearest 0.1 mL.

Clinical Observations

Clinical observations were performed at least once daily starting before the initiation of the high-fructose diet and continuing until the completion of the study. Body weights were measured before the initiation of the high-fructose diet and at least three times per week during the pretreatment time period. After group assignment, body weights were measured before the initial dose administration (day -1); on day 1, 3, 5, 8, 10, 12, 15, 17, 19, 22, 24, and 26; and before necropsy on day 29.

Food consumption was quantitatively measured before the initiation of the high-fructose diet (pretreatment) and at least three times per week before the treatment administration. After group assignment and treatment, food consumption was measured on day 1, 3, 5, 8, 10, 12, 14, 15, 17, 19, 22, 24, 26, and 28.

Biochemical Analyses

Blood samples to determine TAG entry levels were collected 1 and 3 weeks prior to dosing. Serum samples were also collected before the high-fructose diet initiation (week -5), before initial dose on day -1, and on day 14 and 28 to determine levels of glucose, urea nitrogen, creatinine, total protein, albumin, calculated globulin and albumin/globulin ratio, calcium, phosphorus, electrolytes, total CHOL, total albumin, TAG, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and gamma glutamyltransferase. Levels

Table 3 Experimental design

Group number	Number of animals	Test material	Dose level (g kg ⁻¹ day ⁻¹)	Dose volume (mL/kg)	Dose DHA (g/kg) ^a	Dose EPA (g/kg) ^a
1	12	Vehicle (corn oil)	0.0	10.0	0.00	0.00
2	12	Algal-DHA	5.0	10.0	2.18	0.00
3	12	P-OM3 ^b	5.0	10.0	1.99	2.53

5	12	MATK-90	1.3	10.0	1.26	0.00
6	12	MATK-90	2.5	10.0	2.34	0.00
7	12	MATK-90	5.0	10.0	4.38	0.00

^a Based on actual analysis of DHA and EPA. Assumes the specific gravity conversion factor of 0.9

^b Each gram of P-OM3 contains 465 mg EPA and 375 g DHA

of high-density lipoprotein cholesterol (HDL-C) and low-density lipoprotein cholesterol (LDL-C) were measured before the initial treatment on day -1 and on day 28.

Whole blood samples collected into serum separator tubes were centrifuged. Serum chemistry parameters were determined at Charles River Laboratories using the Olympus AU640 chemistry immune analyzer (Center Valley, PA, USA). Blood samples for fatty acid analysis (DHA and EPA) were collected on day 14 and 29 before necropsy. Plasma total lipid fatty acids were analyzed as described previously [28]. The fatty acid profiles were expressed as area percent of fatty acids.

Fasting (specified as a minimum of 6 h, not to exceed 8 h) was conducted before all blood collections, including the terminal blood collection. Water was provided *ad libitum* during times of fasting.

Statistical Analysis

Statistical analysis was performed on body weights, food consumption, and serum chemistry parameters. Each analysis endpoint was analyzed with a repeated measure analysis of covariance (RANCOVA). Factors in the model included treatment, duration of treatment, and the treatment \times duration interaction. The baseline measurement was included as a covariate. Least square means (LSMEAN) and their standard deviations were produced. Initially, the control and the MATK-90 dose groups were included in the statistical analysis. The monotonic dose–response relationship was evaluated for the control and four MATK-90 groups using sequential linear trend tests based on ordinal spacing of dose levels [29]. The trend tests were conducted at the 0.05 significance level for each post-dose day as well as across the pooled post-dose days.

To evaluate responses that occurred in a non-dose-related fashion, non-monotonic dose responses were evaluated whenever no significant linear trends were detected, but when either treatment or the treatment \times duration interaction was significant at the 0.01 level. Within the framework of the RANCOVA, pairwise comparisons were made for each individual MATK-90 group with the control group through linear contrasts. The comparisons were conducted at the 0.01 significance level for each post-dose day as well as across the pooled post-dose days.

Pairwise comparisons were made using Dunnett's test at the 0.05 significance level to compare the MATK-90 dose groups to P-OM3. The pairwise comparisons were conducted for each post-dose day as well as across the pooled post-dose days.

To compare algal-DHA to P-OM3 and to the control, if either the treatment or treatment \times duration interaction was significant, Duncan's multiple range test was used to make all possible pairwise comparisons of the three groups for each

post-dose day as well as across the pooled post-dose days. Both the Dunnett's test and Duncan's multiple range test were adjusted for multiple comparisons. All statistical analyses were conducted with SAS software (Cary, NC, USA).

Results

Clinical Observations, Body Weights, and Food Consumption

Treatment-related mortality was not observed during the study. No unusual clinical signs were observed. One accidental death was observed for an animal in the P-OM3 group; this animal died immediately after the day 14 blood collection. A comprehensive necropsy revealed that the death was related to the blood collection procedure.

Before the initiation of the high-fructose diet, mean body weights in each group were comparable, ranging from 249 ± 6.2 to 262 ± 11.4 g; during week -1, mean body weights in each group ranged from 405 ± 19.8 to 431 ± 23.6 g. Over time, body weight trends were similar among the control, algal-DHA, MATK-90, and P-OM3 treatment groups.

Throughout the approximately 5-week high-fructose diet prestudy feeding period, all groups demonstrated a similar food intake pattern. Upon initiation of treatment, all groups exhibited an immediate 1.4- to 1.8-fold decrease in food intake, relative to baseline, that remained until the completion of study. After the initiation of treatment, over time, food intakes were similar between groups. The decrease in food consumption was attributed to the higher caloric density of the test diets.

Triacylglycerols and Other Serum Chemistry Parameters

Before the initiation of the high-fructose diet (approximately week -5), serum chemistry values were comparable among groups and within expected ranges for the Wistar rat. During the high-fructose diet prestudy feeding period, TAG levels were evaluated for progressive increases over time to gauge the induction of HTG. Mean TAG levels increased 3.4- to 4.8-fold relative to the baseline diet levels after approximately 4 weeks of the high-fructose diet (approximately week -1), demonstrating successful induction of HTG. Before the initiation of treatments (day -1), baseline serum chemistry values were comparable among groups, and serum chemistry values were within expected ranges for the Wistar rat, with the exception of the TAG levels. Changes in CHOL and HDL-C were also observed as anticipated with diet induction. The pretreatment (day -1) mean values for TAG, CHOL, and HDL-C

levels were 476 ± 179.3 , 127 ± 22.3 , and 43 ± 6.9 mg/dL, respectively.

Overall Trends in TAG Levels vs. Control

MATK-90 treatment at 0.6, 1.3, 2.5, or 5.0 g kg⁻¹ day⁻¹ resulted in an overall significant ($p < 0.05$) trend for reduced TAG levels during the dosing phase, relative to the control group. On day 14, mean (LSMEAN) TAG levels in the 0.6, 1.3, 2.5, and 5.0 g kg⁻¹ day⁻¹ MATK-90 treatment groups were significantly ($p < 0.05$) decreased and were 65, 67, 47, and 43% of the control group (Fig. 1). Mean (LSMEAN) TAG values for the 1.3, 2.5, and 5.0 g kg⁻¹ day⁻¹ MATK-90 treatment groups on day 28 were 60, 60, and 47% of the control group ($p < 0.05$), respectively. On day 28, the mean (LSMEAN) TAG value for the 0.6 g kg⁻¹ day⁻¹ MATK-90 treatment group was not significantly different from that of the control group.

Mean (LSMEAN) TAG levels in both the algal-DHA- and P-OM3-treated animals were significantly ($p < 0.05$) lower overall compared to the control-treated animals. On day 14, mean (LSMEAN) values were 47 and 48% of the control in the P-OM3- and algal-DHA-treated animals, respectively ($p < 0.05$). On day 28, mean (LSMEAN) TAG levels in the P-OM3-treated but not the algal-DHA-treated animals were significantly lower (35%, $p < 0.05$) than that in the control group.

Fig. 1 Mean (LSMEAN) TAG levels in Wistar rats at day 14 and 28 after treatment with MATK-90, algal-DHA, or P-OM3. Different letters indicate significant differences ($p < 0.05$) between treatment groups vs. the control. On day 28, asterisks indicate significant differences ($p < 0.05$) between 0.6 g kg⁻¹ day⁻¹ of MATK-90 vs. P-OM3. On day 14, mean TAG levels in the 0.6, 1.3, 2.5, and 5.0 g kg⁻¹ day⁻¹ MATK-90 treatment groups were significantly ($p < 0.05$) decreased vs. the control. On day 28, the mean TAG level in the 0.6 g kg⁻¹ day⁻¹ MATK-90-treated animals was 2.7 times greater ($p < 0.05$) than that of the P-OM3 group. The high-dose group of MATK-90 and the P-OM3 group produced similar reductions in TAG levels at day 14 and 28

TAG Levels of MATK-90 and Algal-DHA vs. P-OM3

There were no significant differences in the mean (LSMEAN) TAG levels between the 1.3, 2.5, and 5.0 g kg⁻¹ day⁻¹ MATK-90 and P-OM3-treated animals at day 14 and day 28. However, on day 28, the mean (LSMEAN) TAG level in the 0.6 g kg⁻¹ day⁻¹ MATK-90-treated animals was 2.7 times greater ($p < 0.05$) than that of the P-OM3 group. There were no differences overall in TAG levels between the DHASCO-treated and P-OM3-treated animals.

Overall Trends in CHOL Levels vs. control

There was an overall significant trend ($p < 0.05$) toward reduced CHOL levels, relative to the control, in all of the MATK-90 dose groups. Significantly reduced mean (LSMEAN) CHOL levels were observed on day 28, relative to the control, in the 1.3 (62%), 2.5 (71%), and 5.0 (61%) g kg⁻¹ day⁻¹ MATK-90-treated animals (Fig. 2). There was a statistically significant ($p < 0.05$) overall trend for reduced mean (LSMEAN) CHOL levels, relative to the control, in the P-OM3-treated animals but not the algal-DHA-treated animals. However, there was no statistically significant difference in mean (LSMEAN) CHOL levels between the P-OM3-treated and the control-treated animals on days 14 and 28.

CHOL levels of MATK-90 and algal-DHA vs. P-OM3

Mean (LSMEAN) CHOL levels were similar at day 14 and 28 in the MATK-90-, algal-DHA, and P-OM3-treated animals.

Fig. 2 Mean (LSMEAN) CHOL levels in Wistar rats at day 14 and 28 after treatment with MATK-90, algal-DHA, or P-OM3. Different letters indicate significant differences ($p < 0.05$) between treatment groups vs. the control. Significantly reduced mean CHOL levels were observed on day 28, relative to the control in the 1.3, 2.5, and 5.0 g kg⁻¹ day⁻¹ MATK-90-treated animals

Overall Trends in HDL Levels vs. Control

There were no significant trends for HDL-C levels relative to the control in any of the MATK-90, algal-DHA, or P-OM3 treatment groups. On day 28, the mean HDL-C level in the control-treated animals was 68% (44.7 ± 8.6 vs. 30.5 ± 3.1 mg/dL) of the day -1 baseline level. Similar decreased mean (LSMEAN) values (53–65%) on day 28 in HDL-C, relative to baseline, occurred in the algal-DHA-treatment group (41.9 ± 8.4 vs. 25.0 ± 5.6 mg/dL), the MATK-90 treatment groups (0.6 g kg⁻¹ day⁻¹: 42.5 ± 6.1 vs. 27.8 ± 3.6 mg/dL; 1.3 g kg⁻¹ day⁻¹: 42.8 ± 7.4 vs. 25.0 ± 3.6 mg/dL; 2.5 g kg⁻¹ day⁻¹: 44.0 ± 8.4 vs. 26.1 ± 4.2 mg/dL; 5.0 g kg⁻¹ day⁻¹: 42.0 ± 5.0 vs. 23.5 ± 6.2 mg/dL) and the P-OM3-treated animals (42.0 ± 4.5 vs. 22.1 ± 3.5 mg/dL).

LDL-C Levels

A large percentage of LDL-C samples were below the lower limit of detection (< 7 mg/dL) at approximately week -5, day -1, and day 28 (20, 59, and 66%, respectively). These values were not included in the statistical analyses, and the data for LDL-C are not presented here.

Other Serum Chemistry Values

After the initiation of the high-fructose diet (approximately week -5), except for the serum lipid values considered above, the other chemistry values were comparable among groups and within expected ranges for the Wistar rat.

Fatty Acid Analysis

The administration of MATK-90 (0.6–5.0 g kg⁻¹ day⁻¹), algal-DHA (2.0 g DHA kg⁻¹ day⁻¹), or P-OM3 (5 g kg⁻¹ day⁻¹) resulted in a statistically significant ($p < 0.05$) increase in DHA levels in plasma (day 29) compared with baseline (day -1) values (Fig. 3). On day 14 and 29, in the MATK-90 groups, there was a dose-dependent response in DHA levels. Also observed was a significant ($p < 0.05$) increase in EPA levels, with the greatest increase in animals that were administered P-OM3 (5 g kg⁻¹ day⁻¹), which contained ~55% EPA. Algal-DHA and MATK-90 contained only traces of EPA, yet animals treated with the algal-DHA or MATK-90 exhibited significant increases in EPA levels (Fig. 4). This increase in EPA level was thus attributed to the retroconversion of DHA to EPA. The increases in EPA with MATK-90 treatment were dose-related, and retroconversion of DHA to EPA demonstrated that saturation was not achieved at the highest dose of 5.0 g kg⁻¹ day⁻¹ in this animal model.

Fig. 3 Mean DHA fatty acid area percent levels in Wistar rats prior to treatment (day -1) and after treatment (day 29) with MATK-90, algal-DHA, or P-OM3. Administration of MATK-90 (0.6–5.0 g kg⁻¹ day⁻¹), algal-DHA (2.0 g DHA kg⁻¹ day⁻¹), or P-OM3 (5 g kg⁻¹ day⁻¹) resulted in a statistically significant ($p < 0.05$) increase in DHA levels in plasma compared with baseline (day -1) values

Fig. 4 Mean EPA fatty acid area percent levels in Wistar rats prior to treatment (day -1) and after treatment (day 29) with MATK-90, algal-DHA, or P-OM3. There was a significant ($p < 0.05$) increase in EPA levels vs. baseline (day -1), with the greatest increase in animals that were administered P-OM3 (5 g kg⁻¹ day⁻¹), which contained ~55% EPA. Algal-DHA and MATK-90 contained less than 1% EPA, yet animals treated with algal-DHA or MATK-90 exhibited significant increases in EPA levels vs. baseline. This increase in EPA level was attributed to the retroconversion of DHA to EPA

Discussion

This study was designed to evaluate the potential TAG-lowering effects of a highly purified ethyl ester of algal-DHA (MATK-90) in male Wistar rats fed a high-fructose diet to induce HTG. Different doses of MATK-90 were administered (0.6–5.0 g kg⁻¹ day⁻¹) for 28 days and the results were compared to those observed in animals fed a high dose of a commercially available algal-DHA triacylglycerol oil (DHASCO; 2 g DHA/kg per day), a

prescription formulation of omega-3-fatty acid ethyl esters of DHA and EPA (Lovaza;P-OM3, 5 g kg⁻¹ day⁻¹), and a placebo (corn oil). Results indicated that MATK-90 at 1.3, 2.5, or 5.0 g kg⁻¹ day⁻¹ was effective at reducing TAG levels relative to the control group at day 14 and 28. There were no significant differences in the mean TAG levels between the 1.3, 2.5, and 5.0 g kg⁻¹ day⁻¹ MATK-90-treated and the P-OM3-treated animals at day 14 and day 28.

There may be concern that the degree of TAG-lowering observed with DHA might not have resulted had a high-fat diet been used rather than the high-fructose diet used in the present study. A high-fructose diet may allow for a better evaluation of the inhibitory effect of DHA on hepatic conversion of fructose to fatty acid and then esterification to TAG. However, in a recent study of mice fed high-fat diets (18% fat wt/wt) with different fatty acid compositions (soy vs. a high-DHA fish oil) for 4 months, the fish-oil diet significantly reduced plasma TAG concentration by ~50% both in fasting and postprandial states [30]. Further, in humans who consume a typical “western” diet, which may be high in fat, moderate amounts of DHA (1–2 g/day) have been shown to lower TAG levels significantly in subjects with both normal and elevated TAG levels [25].

In humans, LC-PUFAs typically do not affect total CHOL levels, although significant reduction in the level of total CHOL has been observed in subjects who have received both LC-PUFAs and statins [31, 32]. As demonstrated here with Wistar rats, MATK-90 at 1.3 g kg⁻¹ day⁻¹ or greater, but not P-OM3, was effective in markedly reducing total plasma CHOL. It is unclear why MATK-90 reduced total CHOL in this animal model.

LC-PUFAs modestly increase HDL-C levels in humans [25, 33]. However, in the present study, there were no significant trends for HDL-C levels, relative to the control, in any of the treatment groups considered. In all groups, levels of HDL-C declined relative to baseline and the changes were of similar magnitude. This finding suggests that the decline in HDL-C levels may be specific to the animal model considered.

DHA was clearly bioavailable based on the dose-dependent increase in the level of DHA in plasma. Administration of DHA also led to a dose-dependent increase in EPA. The increase in EPA was probably related to retroconversion of DHA to EPA [34]. These results corroborate earlier findings from a 28-day Sprague–Dawley rat study with algal-DHA [35]. The retroconversion of DHA to EPA is also observed in other tissues such as heart and liver [36]. In humans receiving 280 mg of DHA, a retroconversion rate of ~1.4% has been reported [34], but rates as high as 12% have also been noted in subjects who received 1.62 g DHA [37, 38].

No safety issues were identified with MATK-90 even at the relatively high concentrations administered in this study. In the present study, the dose of DHA per kilogram of body weight was up to 100-fold higher than the DHA doses found to lower TAG levels in humans (i.e., 1–2 g/day). As in many preclinical studies, doses of investigational product administered to animals are typically much higher than those given to humans. Higher doses are needed to account for increased metabolic rates in small animals; they may also shed light on any issues with toxicity. The safety of DHA, as contained in algal-DHA, has been evaluated in several animal studies [36, 39–44]. These studies included tests for genetic, acute, subchronic, and developmental toxicity. Many of these studies considered pregnant, lactating, and/or neonatal animals. Results demonstrated that algal-DHA is not a genetic, reproductive, or developmental toxicant, and the effects of acute toxicity are negligible. Rat subchronic toxicology studies documented doses of algal-DHA of up to 500 and 1,250 mg kg⁻¹ day⁻¹. Higher doses than would normally be consumed in a diet or as a supplement or drug have been considered in studies of healthy human volunteers (up to 6 g DHA or 15 g algal-DHA oil per day) [45]; no adverse events were reported. Algal-DHA is used in capsule form as a dietary supplement or as oil in infant formulas and food products throughout the world. The findings from the present study suggest that MATK-90, the concentrated ethyl ester form of DHA, is well tolerated in this animal model. Further research is needed to demonstrate efficacy and safety of MATK-90 in humans.

From studies in healthy volunteers, and those with dyslipidemia, it is clear that DHA and EPA lower blood TAG levels. Many factors related to the development of atherosclerosis and its complications are positively influenced by DHA and EPA [46]. These factors include TAG levels, platelet aggregation, hemostatic parameters, blood pressure, and endothelial aggregation. In 16 clinical studies in humans [25], it was unexpectedly shown that supplementation of 1–2 g/day of algal-DHA alone as a TAG oil is associated with a marked reduction in serum TAG levels (up to 26%) in normal individuals and in those with HTG or combined hyperlipidemia. Algal-DHA devoid of EPA was also associated with increased HDL-C levels, increased LDL-C particle size, and a modest reduction in blood pressure and heart rate in many subjects. This study demonstrated that the benefits of TAG reduction accomplished using combined ethyl esters of DHA and EPA from fish oil may also be attainable with an ethyl ester of algal-DHA alone.

Acknowledgments The authors are grateful to Dr. Joan F. Flanagan from at Charles River Laboratories who provided thoughtful discussions relating to this study.

Abstract As meat is a rich source of the omega-3 fatty acid docosapentaenoic acid (DPA) and Australians consume six times more meat than fish, investigation of the potential health benefit of DPA is warranted. The aims were to compare the effects of seal oil supplementation with fish oil, on measures of plasma lipids and blood pressure in hypertriglyceridaemic subjects. Forty-eight volunteers were recruited from the Wollongong community and were randomly allocated to one of three groups either receiving 1 g/day of long-chain omega-3 polyunsaturated fatty acids (LC n-3 PUFA) using one of three oils: seal oil capsules (340 mg eicosapentaenoic acid (EPA), 230 mg DPA, 450 mg DHA), fish oil capsules (210 mg EPA, 30 mg DPA, 810 mg DHA) or placebo capsules (containing sunola oil) for 6 weeks. Plasma triglycerides remained unchanged in the placebo group, whilst reductions of 7 and 14% ($P < 0.05$) were seen in the fish oil and seal oil groups respectively. Systolic blood pressure improved by 8 and 5 mmHg with

seal oil and fish oil respectively ($P < 0.05$). The mean arterial pressure was significantly lower after seal oil supplementation ($P < 0.005$) compared with the placebo group. These results indicate that seal oil is as effective as fish oil in lowering plasma triglycerides and blood pressure.

Keywords Docosapentaenoic acid · Omega-3 polyunsaturated fatty acids · Cardiovascular disease · Blood pressure · Dyslipidaemia

Abbreviations

ANOVA	Analysis of variance
ARA	Arachidonic acid
BMI	Body mass index
CVD	Cardiovascular disease
DBP	Diastolic blood pressure
DHA	Docosahexaenoic acid
DPA	Docosapentaenoic acid

Introduction

Cardiovascular disease (CVD) is the greatest single cause of mortality in Australia, accounting for 34 and 39% of male and female deaths, respectively [1]. Numerous clinical trials have shown that highly unsaturated long-chain omega-3 polyunsaturated fatty acids (LC n-3 PUFA) such as eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3) benefit cardiovascular disease outcomes in primary and secondary prevention [2]. Risk factors for CVD include hypertension and dyslipidaemia, with increased plasma triglycerides emerging as an independent risk factor [3]. EPA and DHA are effective in lowering plasma triglyceride levels [4]. Yet there is almost no data available regarding the potential health benefits of the only other common highly unsaturated LC n-3 PUFA, docosapentaenoic acid (DPA; 22:5n-3).

Epidemiological evidence indicates that intakes of all three of the LC n-3 PUFA (EPA, DHA, DPA) are significantly and inversely related to carotid intimal-medial thickness (IMT) [5]. The quartiles of gram EPA intakes (0.00–0.15; 0.16–0.29; 0.30–0.41; 0.42+); of gram DHA intakes (0.01–0.27; 0.28–0.45; 0.46–0.63; 0.64+) and of gram DPA intakes (0.02–0.04; 0.05–0.07; 0.08–0.10; 0.11+) all correlated negatively with IMT, which suggests that the cardiovascular benefits attributed to LC n-3 PUFA are not just attributable to EPA and DHA, but also to DPA [5]. Furthermore, the Kuopio Ischaemic Heart Disease Risk Factor Study showed that the men with the highest quintile of serum DHA plus DPA (>3.58% of total fatty acids) had a 44% reduced risk of acute coronary events compared with men in the lowest quintile (<2.38% of total fatty acids), and there were no associations with EPA levels [6]. The significance was due to DHA plus DPA, not just DHA alone. Hence there is scientific evidence that DPA has cardiovascular health benefits but this evidence is limited.

DPA can be found in relative abundance in most red meat. Australian grass fed beef contains 32 mg EPA, 49 mg DPA and 6 mg DHA per 100 g lean beef, as opposed to grain fed beef which contains much lower values (16 mg EPA, 37 mg DPA and 5 mg DHA per 100 g) [7]. This is consistent with beef from USA with range fed beef containing 0.62% EPA, 0.71% DPA and 0.09% DHA as percent of total fatty acids compared with only 0.13% EPA, 0.26% DPA and 0.04% DHA in feed-lot (grain fed) beef [8]. Hence meat contains more DPA and EPA, whereas fish/seafood contains more DHA and much less DPA.

Actual DPA intakes have been reported as 90 mg/day for men and 52 mg/day for women in Australia [9] which is comparable to that of France (75 mg/day for men and 56 mg/day for women, [10]) and Japan (90 mg/day for both men and women in Japan [5]), but both France and Japan consume more fish/seafood than Australians and

hence their EPA and DHA intakes are higher than Australian intakes [5, 9, 10]. As Australians consume more meat than fish/seafood, in the Australian diet, meat contributes up to 42.7% of LC n-3 PUFA intake which is similar to the new estimate of fish and seafood of 48% [9, 11]. This would indicate that DPA intakes are threefold higher than previously thought [9, 11]. Importantly, DPA intakes contribute up to 30% towards the intakes of LC n-3 PUFA in the Australian adult diet [9]. Given this level of DPA in the Australian diet, it is pertinent to understand its potential health benefit.

However for research studies on DPA, no purified or enriched form is commercially available. The richest commercial source of DPA is seal oil. There have been limited trials assessing the effect of seal oil supplementation on cardiovascular disease risk factors. One study showed a significant reduction in plasma triglycerides after seal oil supplementation for 6 weeks in healthy people [12], whilst another similar study showed no significant lowering of plasma triglycerides [13]. However these studies were conducted in people with normal plasma triglyceride levels. Therefore the aim of this study was to assess the ability of seal oil supplementation to lower plasma triglyceride levels and blood pressure in people with hypertriglyceridaemia in comparison to fish oil containing similar levels of EPA and DHA in a placebo controlled double blind intervention trial.

Experimental Procedures

Notification of Clinical Trial and Ethics Approval

The study on the cardiovascular effects of DPA was registered with the Australian Clinical Trial Register, number ACTRNO. 12605000641695 and notification forwarded to the Therapeutics Goods Administration. Ethics approval was granted by the University of Wollongong (UoW) Human Research Ethics Committee and informed consent was obtained from all study participants prior to the commencement of the clinical trial.

Recruitment and Study Population

Hypertriglyceridaemic subjects were recruited via newspaper advertisements, email to UoW community, social clubs and on local ABC radio. The UoW media release unit also generated interest from the media. Fifty-six volunteers were recruited and eligible for the study (i.e. plasma triglycerides >1.5 mmol/l) and 48 completed the study. Reasons for dropping out of the study included suffering from diarrhoea, forgetting to come to their 6-week appointment, losing their job and not being contactable for

their 6-week appointment or no discernable reasons. People already taking fish oil supplements were excluded from the study.

Seal Oil, Fish Oil and Placebo Capsule Supplementation

The capsules were 500 mg in weight and their composition is shown in Tables 1A and 1B. All three groups were provided with two separate bottles of capsules and they were asked to take 10 capsules per day; four capsules before breakfast and six capsules before dinner, such that all three groups were taking the same number of capsules per day. The target LC n-3 PUFA intake of the Seal Oil (BGI Atlantic Marine Product Inc, Canada) and Fish Oil (NuMega Ingredients Ltd, Sydney) groups was 1 g/day. Therefore the Seal Oil group took 10 Seal Oil capsules per day (which provided 340 mg EPA, 230 mg DPA, 450 mg DHA per day); the Fish Oil group took four placebo capsules and six Fish Oil capsules per day (which provided 210 mg EPA, 30 mg DPA, 810 mg DHA per day). The third group took 10 placebo capsules per day (Sunola oil, NuMega Ingredients Ltd, Sydney, which provided no LC n-3 PUFA but did provide approximately 4 g monounsaturated oil per day). The placebo group intake of monounsaturated oil in quantity is trivial compared to the dietary intake of monounsaturated fat. Furthermore as the seal oil capsules contained squalene (12.5 mg/500 mg capsule), the fish oil and placebo groups took one squalene capsule (875 mg) per week for 6 weeks equivalent to 125 mg/day, an identical intake to the seal oil group. Seal oil provided a 7.6-fold increase in the amount of DPA; a 1.6-fold increase in the amount of EPA and a 1.8-fold decrease in the amount of DHA compared to fish oil (Table 1B).

Seal oil also contains 0.3 mg/100 g vitamin A and 4.5 mg/100 g alpha-tocopherol [14]. Tuna oil contains less than 10 International Units of vitamin A and 0.21% of mixed natural tocopherols (NuMega Ingredients Ltd, Sydney).

Table 1A Individual capsule composition by principal fatty acid (mg per 500 mg capsule)

Fatty acid	Sunola oil capsules (mg/500 mg)	Fish oil capsules (mg/500 mg)	Seal oil capsules (mg/500 mg)
C18:1n-9	425	61	142
C20:5n-3	0	35	34
C22:5n-3	0	5	23
C22:6n-3	0	135	45

Study Design

A randomised, parallel, placebo-controlled, double-blind study was conducted in 56 hypertriglyceridaemic subjects, 48 of whom completed the study. They were randomly allocated to one of three groups and all three groups took ten 500-mg capsules per day for a 6 week intervention trial. Blood pressure and fasting blood samples were taken at baseline and at 6-week post intervention. Blood samples were assessed for erythrocyte fatty acids and plasma lipids (triglycerides, total cholesterol, LDL-cholesterol and HDL-cholesterol).

Erythrocyte Fatty Acids

Fasting blood samples were collected in tubes containing ethylenediamine tetra-acetic acid (EDTA) and placed on ice. The erythrocytes were separated from the plasma by centrifugation (10 min, 2,000×g, 4 °C). Erythrocyte and plasma samples were stored at −80 °C until analysed.

Erythrocyte membranes were isolated from 400 µl of packed erythrocytes and prepared for fatty acid analysis. The erythrocytes were lysed in 10 ml TRIS buffer (10 mM TRIS buffer, 2 mM EDTA, pH 7.2) and the membranes were pelleted after ultracentrifugation (200,000×g, 4 °C, 30 min). The erythrocyte membrane pellets were resuspended in 200 µl water and 150 µl was transferred into glass tubes for direct transesterification as described by Lepage and Roy [15]. Briefly, 2 ml of methanol:toluene (4:1) was added to each sample. While vortexing, 200 µl of acetyl chloride was added dropwise to each sample using a positive displacement pipette. Samples were then heated for 60 min at 100 °C in a heating block. After the tubes had been cooled in cold water, 3 ml of potassium chloride (10%) and 100 µl of toluene were added to each tube before centrifugation for 10 min (2,000×g, 4 °C). The fatty acid methyl esters, contained in the upper toluene phase, were removed and placed in GC vials. The fatty acid methyl esters were analysed by flame-ionisation gas chromatography (model GC-17A, Shimadzu) using a 30 m × 0.25 mm internal diameter capillary column (Varian). Individual fatty acids were identified upon comparison with known fatty acid standards (NuChek, Sigma, Australia, mix C10–C24 plus added DPA).

Plasma Lipids

HDL was isolated from plasma by precipitation of the apoB containing lipoproteins using dextran sulphate and magnesium chloride according to Warnick et al. [16]. All lipid analyses (plasma triglyceride, total cholesterol, HDL-cholesterol) were carried out using enzymatic colorimetric assays using the Konelab autoanalyser. LDL-cholesterol was calculated using the Friedewald calculation [17].

Table 1B Amount of principal fatty acids supplemented per group per day (mg per day)

Fatty acid	Sunola oil group (placebo) (mg per day)	Fish oil group (mg per day)	Seal oil group (mg per day)
C18:1n-9	4,250	1,944	1,420
C20:5n-3	0	210	340
C22:5n-3	0	30	230
C22:6n-3	0	810	450
Total LC n-3 PUFA	0	1,050	1,020

The placebo group consumed 10 placebo capsules per day; the fish oil group consumed six fish oil capsules per day plus four placebo capsules per day; the seal oil group consumed 10 seal oil capsules per day

Blood Pressure

Systolic blood pressure (SBP), diastolic blood pressure (DBP) and mean arterial pressure (MAP) were measured using the Omron blood pressure instrument (Medisave Australasia). These measurements were taken in triplicate at baseline (duplicate days) and after 6 weeks intervention (duplicate days). An average of the six baseline readings were obtained for each study participant and similarly after 6 weeks intervention.

Statistical Analysis

Statistical analysis was carried out using a JMP statistical analysis package (SAS Institute Inc Windows NT v5.1) and where variables were not normally distributed (plasma triglycerides), log transformation was used prior to analysis. One-way ANOVA was used to assess the change in plasma triglycerides and blood pressure between the three groups. One-way ANOVA was also used to assess the change in erythrocyte EPA and DHA levels and the change in plasma triglycerides per group. Pearson correlation analyses were conducted using Microsoft Excel. Statistical significance was set at $\alpha = 0.05$ for all analyses.

Results

Study Participant Characteristics and Baseline Blood Pressure and Plasma Lipids

The study participant baseline characteristics and baseline blood pressure and plasma lipids are shown in Table 2. There were no significant differences in age, sex, weight, body mass index (BMI) and blood pressure lowering medication used, between the three groups at baseline. On average, the study population was overweight, and ranging from middle age to elderly. All subjects were hypertriglyceridaemic, but with relatively normal plasma

cholesterol levels. Systolic blood pressures were greater than 140 mmHg in 23% of the study population whilst diastolic blood pressures were greater than 90 mmHg in 10% of the study population. The study volunteers did not change their body weight throughout the intervention (results not shown) (Table 2).

Erythrocyte Fatty Acids

The main erythrocyte LC PUFA measured at baseline (0 weeks) and after 6 weeks of intervention (week 6) in all three groups are shown in Table 3. The placebo group showed no changes over the 6 weeks period. In comparison to its own baseline value (0 weeks), fish oil supplementation resulted in decreases in arachidonic acid (ARA, 20:4n-6 ($P < 0.01$), adrenic acid (22:4n-6, $P < 0.05$) and DPA (22:5n-3, $P < 0.05$) and an increase in DHA (22:6n-3, $P < 0.01$). In comparison to its own baseline value (0 weeks), seal oil supplementation significantly decreased levels of ARA ($P < 0.05$) and adrenic acid ($P < 0.05$) and significantly increased the mean levels of EPA ($P < 0.001$), DPA ($P < 0.001$) and DHA ($P < 0.0005$) (Table 3, Fig. 1).

Figure 1 shows the comparison of the percentage changes in erythrocyte fatty acids in the three groups after 6 weeks supplementation. In comparison to the change in the placebo group (0–6 weeks), there were no significant difference in ARA, EPA and DPA in the fish oil group (0–6 weeks), but there were significant decreases in adrenic acid ($P < 0.05$) and increases in DHA ($P < 0.0005$). In comparison to the change in the placebo group (0–6 weeks), there was no significant difference in ARA in the seal oil group (0–6 weeks), but there were significant decreases in adrenic acid ($P < 0.05$) and significant increases in EPA ($P < 0.001$), DPA ($P < 0.001$) and DHA ($P < 0.0001$).

Plasma Lipids

The change in plasma lipids (mmol/l) from baseline (0 weeks) to 6 weeks for all three groups are shown in Fig. 2. Plasma triglycerides remained unchanged in the placebo group (2.31 vs. 2.36 mmol/l), but were reduced by 7% in the fish oil group (2.24 vs. 2.09 mmol/l, $P > 0.05$) and 14% in the seal oil group (2.54 vs. 2.19 mmol/l) ($P < 0.05$) and these changes were significantly different to the changes in the placebo group. No differences were seen in the total cholesterol, LDL-cholesterol or HDL-cholesterol between any of the groups (Fig. 2).

Blood Pressure

The changes in blood pressure results are shown in Fig. 3. Systolic blood pressure (SBP) decreased significantly in both the fish oil (-5.3 mmHg, $P < 0.05$) and the seal oil

Table 2 Study participant characteristics, plasma lipids and blood pressure at baseline ($n = 48$)

^a Values are means ± SEM

groups (−7.7 mmHg, $P < 0.01$) in comparison to the placebo group (6 mmHg). The mean arterial pressure (MAP) was significantly reduced (−8.3 mmHg, $P < 0.01$) in the seal oil group and tended towards a reduction (−3.5 mmHg, n.s.) in the fish oil versus the placebo group (3.9 mmHg). There were no statistical differences in diastolic blood pressure (DBP) in the three groups (Fig. 3).

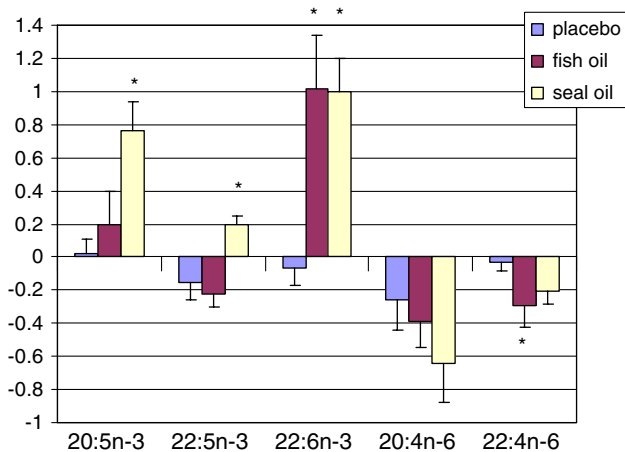

Correlations between the Change in Erythrocyte EPA and DHA Levels and the Change in Plasma Triglycerides and Blood Pressure

The change in erythrocyte EPA + DHA levels correlated with the change in plasma triglycerides in the seal oil group, $r = 0.52$ ($P < 0.05$) but there were no correlations in the fish oil or placebo oil groups with the change in plasma triglycerides (Table 4).

There were several significant correlations (see Table 4) between the change in erythrocyte EPA and DHA levels and the change in SBP, DBP and MAP in the fish oil groups with correlation coefficients ranging from 0.56 to 0.76 ($P < 0.05$). As expected there were no correlations with erythrocyte LC n-3 PUFA and blood pressure in the placebo group (Table 4).

Discussion

The supplementation of 1 g of LC n-3 PUFA per day supplied by fish oil capsules for 6 weeks resulted in a significant increase in erythrocyte DHA levels, which is in agreement with previous studies using similar doses of fish oil and similar duration of intervention [18, 19]. However, the supplementation of 1 g of LC n-3 PUFA per day

* significantly different from the change in the placebo group ($p < 0.05$)

Fig. 1 The percent change in erythrocyte fatty acids (6 weeks minus baseline) from the three groups from left to right: placebo, fish oil and seal oil group. The fatty acid abbreviations: *20:5n-3* is eicosapentaenoic acid, *22:5n-3* is docosapentaenoic acid, *22:6n-3* is docosahexaenoic acid, *20:4n-6* is arachidonic acid and *22:4n-6* is adrenic acid. *Significantly different from the change in the placebo group ($P < 0.05$)

* significantly different from the change in the placebo group ($p < 0.05$)

Fig. 2 The change in plasma lipids (mmol/l) in the three groups from left to right: placebo, fish oil and seal oil group. supplied by seal oil capsules for 6 weeks differed to that of fish oil, in that DPA and EPA in addition to DHA were significantly increased, which is in agreement with a previous study using the same 1 g dose of seal oil for 6 weeks [12].

It has been shown previously that intakes of EPA and DHA correlate significantly with erythrocyte EPA and DHA levels respectively [20]. However, there was no correlation between DPA intakes and erythrocyte DPA

* significantly different from the change in the placebo group ($p < 0.05$)

Fig. 3 The change in blood pressure (mmHg) in the three groups from left to right: placebo, fish oil and seal oil group. levels (correlation coefficient $r = 0.05$, $P = 0.71$), despite quite reasonable correlations between dietary intakes and erythrocyte levels of EPA, DHA and total LC n-3 PUFA [20]. Since that publication, another study assessed the validity of a PUFA questionnaire by comparison to 3 day weighed food record and erythrocyte fatty acids using the methods of triads [21]. In that triangulation of DPA intakes from PUFA questionnaire versus DPA intake from 3 day weighed food record versus DPA in erythrocytes (or plasma)—a validity co-efficient could not be determined as the estimate was >1 for erythrocytes and negative for plasma. This lack of correlation between dietary intake of DPA and circulating levels of DPA has been shown by another group [22] who assessed a different questionnaire. Using the methods of triads they found a similar negative validity co-efficient when assessing plasma DPA to their questionnaire and weighed food records [22]. Hence whilst there is a direct correlation between EPA and DHA intakes and EPA and DHA erythrocyte levels respectively, this does not hold true for DPA as there is no direct correlation between DPA intake and erythrocyte or plasma levels of DPA.

Therefore to interpret the DPA results in this study it is probably better to look at DPA intakes rather than erythrocyte levels of DPA. In this study the fish oil group consumed 210 mg/day EPA, 30 mg/day DPA and 810 mg/day DHA, whilst the seal oil group consumed 340 mg/day EPA, 230 mg/day DPA and 450 mg/day DHA. The difference between the fish oil and seal oil groups is the seal oil group consumed 130 mg/day more EPA; 200 mg/day more DPA and 360 mg/day less DHA than the fish oil group. This difference corresponds to a 1.6-fold increase in

EPA; a 7.6-fold increase in DPA and a 1.8-fold decrease in DHA, where the magnitude of dietary change is greatest in DPA.

This study showed a trend towards a 7% reduction plasma triglyceride levels with 1 g LC n-3 PUFA per day fish oil supplementation, which is less than a recently published study that assessed a dose response with DHA rich fish oil supplementation which showed 6% (n.s.), 20 and 25% reductions with approx 0.7, 1.3 and 2 g of fish oil supplementation per day for 6 weeks [19]. The seal oil 1 g LC n-3 PUFA per day supplementation for 6 weeks resulted in 14% reduction in plasma triglyceride which was also less than 21% reduction previously reported [12], however another seal oil study showed no significant lowering of plasma triglycerides [13]. Both Bonefeld-Jorgensen et al. [12] and Conquer et al. [13] were conducted in healthy people with normal plasma triglyceride levels which could explain the lack of effect in the latter study. The Bonefeld-Jorgensen et al. study [12] was not a placebo-controlled study and the reductions in plasma triglyceride seen could have been due to other factors.

In terms of the mechanism in plasma triglyceride lowering effect, a decrease in hepatic VLDL output has been attributed to increased hepatic fatty acid oxidation and a decreased rate of lipogenesis [23, 24]. EPA and DHA have been shown to be ligands for nuclear receptors such as PPAR-alpha [23–25] and sterol regulatory element binding proteins [23, 26], which modulate the expression of key genes in these metabolic processes. Now DPA may also be involved in these processes. Certainly in a well controlled rat study (where seal oil and fish oil supplemented rat groups had constant PUFA/MUFA/SAFA levels and the control rat group had linoleic acid as their sole PUFA in the diet), the seal oil was more effective than fish oil in lowering serum triglyceride levels [27]. In this rat model the activities of fatty acid synthase, glucose-6-phosphate dehydrogenase and hepatic lipase were all lower in the seal oil group compared to the control group, whereas only the activity of hepatic lipase was lower in the fish oil group compared to the control group. However, the activities of peroxisomal beta-oxidation and lipoprotein lipase in adipose tissue were significantly higher in the fish oil group compared to the controls [27]. Hence the hypotriglyceridaemic effect of the seal oil was attributed to suppression in fatty acid synthesis. As the main difference between seal oil and fish oil is the eightfold increased level of DPA in seal oil, the authors surmised that this higher DPA content could be the primary agent responsible for triglyceride lowering.

Moreover, a study comparing the effects of EPA rich oil versus DHA rich oil on circulating plasma triglyceride levels in humans found that the DHA rich oil was more effective than EPA rich oil and remained significant when

compared to the olive-oil placebo group, whereas the EPA rich oil did not [28]. Interestingly, the authors pointed out that the DHA rich oil contained a sixfold greater amount of DPA than the EPA rich oil, but the hypotriglyceridaemic effect of DPA was unknown and that it warranted further study [28].

In the present study, both fish oil and seal oil supplementation resulted in improvements in blood pressure. The reduction in blood pressure as a result of fish oil supplementation is well documented with several meta-analyses showing benefits as described in the review by Mori [29]. However, most of these trials required doses of 3–4 g per day to achieve the blood pressure lowering benefits. This study showed significant reductions in SBP (fish oil and seal oil groups) and MAP (seal oil group) but no significant reductions in DBP (all groups) using a 1-g dose of LC n-3 PUFA per day for 6 weeks. There was an increase in SBP in the placebo group, however, upon re-analysis with estimating zero change in SBP in the placebo group, the changes in SBP in the seal oil and fish oil groups remained significantly lower compared to placebo.

However the increase in erythrocyte EPA + DHA after fish oil but not seal oil supplementation correlated with the change in blood pressure. EPA correlated with SBP whilst DHA correlated with DBP (Table 4). Mori et al. [30] showed that purified DHA capsules lowered 24-h ambulatory blood pressure in mild hyperlipidaemic subjects, whilst purified EPA capsules had no effect. Even though similar study populations were assessed, it is not clear why the differential effect of EPA on SBP and DHA on DBP is seen in this current study. However, other studies have shown limited effect of EPA and DHA on blood pressure in normotensive people [31] and in study populations taking multiple medications [29].

Even though there was no correlation between the changes in erythrocyte EPA + DHA levels and the change in blood pressure in the seal oil treated group, in this study, seal oil resulted in a significant 8 mmHg reduction in SBP. Usually high doses of EPA + DHA of 3–4 g per day are needed to reduce blood pressure as shown by meta-analyses [32, 33]. It is conceivable that the significant reduction in SBP in the current study could be due to (1) the study population having an average blood pressure of 130/75 mmHg of which 23% had SBP greater than 140 mmHg and 10% had DBP greater than 90 mmHg and (2) less than 20% of the study population were taking medication to lower their blood pressure, thereby allowing the omega-3 PUFA to be effective. A study by Vericel et al. [34] showed that supplementation for 42 days with 150 mg DHA and 30 mg EPA per day in an elderly un-medicated population resulted in 14 mmHg reduction in SBP, which is consistent with the current study showing the effect of low dose omega-3 PUFA and reduction in SBP.

Table 4 Correlations between the changes in erythrocyte LC n-3 PUFA and changes in plasma triglyceride and changes in blood pressure

The mechanisms of action of LC n-3 PUFA on blood lowering effects have been described by Mori et al. [29]. The mechanisms include (1) the LC n-3 PUFA having vasodilatory effects by increasing the release of nitric oxide; (2) modifying the release of ADP, vasoactive prostanoids (such as thromboxane A₂ and prostacyclin I₂) (3) and the LC n-3 PUFA incorporation into plasma and cellular membranes, altering the physicochemical structure of the membrane and leading to changes in fluidity, permeability and function of the membrane and membrane-bound proteins [29].

Given the health benefits of seal oil containing DPA, what are some DPA rich containing foods? Australian red meat is a relatively rich source of DPA [9, 11] and Australians consume six times more meat (158 g per day [35], 164 g per day [36]) than fish/seafood (26 g per day [35], 28 g per day [36]). Abalone is another DPA rich food [37] but the consumption is also much lower than meat. The National Health and Medical Research Council (NHMRC)

in Australia has released Nutrient Reference Values (NRV) for LC n-3 PUFA intakes which includes EPA, DPA and DHA [38]. However, DPA is not included in the LC n-3 PUFA nutrient claim in the current Food Standards Australia and New Zealand (FSANZ) Code [39]. The exclusion of DPA precludes many cuts of meat qualifying for this LC n-3 PUFA nutrient claim. Hence these standards favour fish and seafood as well as fortified foods containing LC n-3 PUFA over those with intrinsic DPA content [40]. The rationale for the exclusion of DPA is a lack of scientific evidence. Hence more research is warranted to ascertain the potential health benefits of DPA. Therefore larger trials with more pure forms of DPA are warranted.

In conclusion, 1 g/day of LC n-3 PUFA from seal oil is just as effective as 1 g/day of LC n-3 PUFA from fish oil in reducing plasma triglyceride levels and SBP in hypertriglyceridaemic subjects; however, studies using (as yet unavailable) purified DPA are warranted.

Acknowledgments The authors would like to acknowledge the time and effort of all the study participants as well as funding from the Meat & Livestock Australia.

Abstract Imaging mass spectrometry (IMS) has been developed as a method for determining and visualizing the distribution of proteins and lipids across sections of dissected tissue. Although lipids play an important role in mammal development, their detailed distributions have not been analyzed by conventional methods. In this study, we tried to determine and visualize lysophosphatidylcholine (LysoPtdCho) and triacylglycerol (TAG) in a mouse embryo by matrix-assisted laser desorption/ionization (MALDI) hybrid quadrupole time-of-flight (TOF) mass spectrometer. Many peaks were detected from a raster scan of the whole embryonic sections. The peaks at m/z 496.33, 524.36, 879.72, 881.74, and 921.74 were identified by MS/MS analyses as [LysoPtdCho (16:0) + H]⁺, [LysoPtdCho (18:0) + H]⁺, [TAG (16:0/18:2/18:1) + Na]⁺, [TAG (16:0/18:1/18:1) + Na]⁺, and [TAG (16:0/20:3/18:1) + K]⁺, respectively. The ion images constructed from the peaks revealed that LysoPtdCho were distributed throughout the body and TAGs were distributed around the brown adipose tissue and in the liver at embryo day 17.5. Thus, IMS system based on MALDI hybrid quadrupole TOF MS revealed the distribution of LysoPtdCho and, more importantly, the organ-specific distribution of TAGs

in the embryonic stages of mammals for the first time. We can conclude that this technique enables us to analyze the roles of various lipids during embryogenesis and gives insight for lipid research.

Keywords Lysophosphatidylcholine · Triacylglycerol · Phosphatidylcholine · Mouse · Embryo · Imaging mass spectrometry · Matrix-assisted laser desorption/ionization · Time of flight

Abbreviations

ARA	Arachidonic acid
Da	Dalton
DHA	Docosahexaenoic acid
DHB	2,5-Dihydroxybenzoic acid
H&E	Hematoxylin and eosin
IMS	Imaging mass spectrometry
ITO	Indium-tin-oxide
LPA	Lysophosphatidic acid
LysoPtdCho	Lysophosphatidylcholine
LPLD	Lysophospholipase D
MALDI	Matrix-assisted laser desorption/ionization
MW	Molecular weight
NL	Neutral loss
OCT	Optimal cutting temperature
PtdCho	Phosphatidylcholine
PL	Phospholipid
PLA2	Phospholipase A2
PUFA	Polyunsaturated fatty acid
SM	Sphingomyelin
TAG	Triacylglycerol
TFA	Trifluoroacetic acid
TOF	Time of flight
TRPV	Transient receptor potential vanilloid

Introduction

The techniques of metabolomics [1], proteomics [2, 3], and transcriptomics [4, 5] have been used for detailed analyses of metabolites, proteins, and RNAs. In these techniques, distributional information for the biomolecules of interest is lost due to the homogenization during sample preparation. In methods used to visualize the distribution of proteins in a living organism, antibodies [6, 7] and various fluorescent proteins [8, 9] are used to label target proteins. However, the antibodies and fluorescent proteins are not usually able to identify detailed structural differences, such as the posttranslational changes in protein and fatty acid composition in lipids [10]. Recently, imaging mass spectrometry (IMS) has been used to directly reveal the distribution of these biomolecules, such as phospholipids (PLs) [11–13], proteins [11, 14], and glycolipids [15, 16]. In IMS, a tissue section sprayed with matrix solution is directly raster-scanned by matrix-assisted laser desorption/ionization (MALDI) [17, 18]. The biomolecules in the section are ionized by MALDI and separated by time of flight (TOF) [19, 20]. The distribution of a biomolecule is two-dimensionally visualized as the relative signal intensities among the measurement points on the tissue section [11]. In this way, a great number of signals can be analyzed using a single IMS measurement.

In parallel with other groups [13, 21–27], our research group has contributed to the development of IMS [11, 28]. A large number of signals can now be detected from a tissue section because the detection sensitivity has been improved by the introduction of pretreatment techniques [14, 29–32] and new approaches for the processing and analysis of IMS data have been developed [33, 34]. The improved IMS has been applied to the imaging of various samples, such as the organs of various animals [11, 12, 14, 30–33, 35], human pathological samples [36–38], the brains of knock-out mice [39], and drug-treated animals [40]. Moreover, a MALDI-TOF-based IMS system has enabled us to perform structural analyses of PLs and peptides in tissue sections by MS/MS analysis [11, 12]. When the biomolecules are well-known lipid species, MS/MS analysis can easily figure out its detailed structure, including the difference of fatty acids, using other MALDI-TOF instruments, such as the QSTAR XL system used in the present study. With this technique, the distributions of phosphatidylcholine (PtdCho), lysophosphatidylcholine (LysoPtdCho), and triacylglycerol (TAG) are now able to be visualized by IMS.

Polyunsaturated fatty acids (PUFA), in particular arachidonic acid (ARA; 20:4) and docosahexaenoic acid (DHA; 22:6), are important structural components of membrane PLs and are required for normal development. Responding to nutritional intake, mammal development

has mainly been analyzed for lipids and/or the fatty acid composition in the liver [41], heart [41], endothelium [42], kidney [42], adipose [43], red blood cell [44], brain [41], plasma [41], and retina [45]. The important roles of PUFA in neural development have been reported not only in mammals but also in other invertebrate model animals. In *C. elegans*, for example, a subset of PUFA is implicated for the chemosensory and nociceptive behavior through transient receptor potential vanilloid (TRPV) channel signaling [46]. These results indicated that the synthesis and/or intake of nutritional sources rich in PUFA contributed to normal development and prevented several diseases associated with PUFA deficiency. However, distributional information was completely lost due to the homogenization during sample preparation in the previous analyses.

When PtdCho is hydrolyzed by phospholipase A2 (PLA2), it is changed to LysoPtdCho. LysoPtdCho is a signal mediator. LysoPtdCho possesses a charged head-group like PLs with only a single fatty acid as a consequence of the hydrolytic cleavage of one of the two fatty acids of PtdCho [47]. As an intermediate in the metabolism of PtdCho, LysoPtdCho is present in a variety of mammalian tissues and accumulates rapidly in diseases such as cardiac ischemia and diabetic cardiomyopathy [48]. However, the distribution of LysoPtdCho has not been well characterized by IMS. The characterization of accumulated LysoPtdCho would be of great significance for the analysis of diseases. TAGs are important long-term fuel-storage molecules that contain three fatty acid substituents esterified to a glycerol backbone. These three substituents may consist of one type, or may consist of two or three distinct types, each of which can have varying chain lengths, degrees of unsaturation, and locations of double bonds. Although TAGs have long been viewed as passive storage molecules, recent evidence suggests that TAGs are present at certain levels within cells, and that accumulation of excessive levels of TAGs impairs cellular functions [49]. With respect to IMS, TAGs have very recently been detected and visualized using TOF secondary-ion mass spectrometry [21]. This method allowed the detection of precise m/z values from a tissue section, and TAGs were identified by the m/z values and the result that fatty acid and TAGs were colocalized in the ion images. However, there are many kinds of lipids in the mass range of m/z 700–1,000. Moreover, the distribution of TAG was constructed from multiple peaks [21]. We believed that MS/MS analysis is preferable for discriminating the different kinds of lipids.

In this study, we identified and visualized PtdCho, LysoPtdCho, and TAGs in a mouse embryo with a MALDI hybrid quadrupole TOF-based IMS system. Embryogenesis is an important process for most organisms to generate the body plan specific for every species. During this dynamic

event, cells are dividing, migrating, and differentiating to form the mature tissue structures. The mechanism of development has been studied genetically and biochemically through the regulation of proteins thus far. On the other hand, the nature of other components, such as sugars and lipids, is not well known. Considering the dynamic change of morphology and migration of embryonic cells, lipids—important signaling mediators as well as the main component of plasma membrane—are expected to change their distribution and composition according to the stage of development. Many regulatory genes during development are known to be reactivated in abnormal involved tissues in adult, which means that analysis of embryogenesis can reveal not only the mechanism of development but also the nature of human diseases. To study the roles of lipids during embryogenesis, we prepared mouse embryos, which are most commonly used for developmental analysis. Sagittal sections of a mouse embryo at embryonic age of 17.5 days (E17.5) were analyzed by IMS. Based on the MS/MS analyses, we were able to perform IMS-based identification of LysoPtdCho, PtdCho, and TAG. Moreover, our IMS analyses also demonstrated the distributions of these lipids in the mouse embryos. This is the first finding of the specific distribution of LysoPtdCho, PtdCho, and TAG in mouse embryos.

Experimental Procedure

Reagents

Trifluoroacetic acid (TFA) and methanol were purchased from Kanto Chemical Company (Tokyo, Japan). 2,5-Dihydroxybenzoic acid (DHB) matrix was purchased from Bruker Daltonics (Bremen, Germany). Human angiotensin II and human bradykinin fragment 1–7 were purchased from Sigma Aldrich (St. Louis, MO). Ultrapure water was purchased from Kanto Chemical Company and used for the preparation of all buffers and solvents. All the chemicals used in this study were of the highest purity available.

Sample Preparation

The care and use of laboratory animals were in accordance with the Animal Experiment Regulations at Hamamatsu University School of Medicine, which follow the Guidelines for the Proper Conduct of Animal Experiments by the Science Council of Japan. Pregnant ICR mice were purchased from SLC (Shizuoka, Japan). The mice were euthanized and the embryos were isolated immediately. The embryonic age was 17.5 days. After washing twice with 0.1 M phosphate buffer, the embryos were frozen on dry-ice powder and stored at -80°C . Before sectioning, the

embryos were left for 30 min at -20°C . Frozen whole-body sagittal sections of the mouse embryo were sliced to a thickness of 8 μm using a cryostat (CM 1950; Leica Microsystems, Wetzlar, Germany). Sections were thaw-mounted onto an indium-tin-oxide (ITO)-coated glass slide (Bruker Daltonics) and dried at room temperature. The glass slide was cut to the proper size by a thin-layer chromatography (TLC) plate cutter (OM laboratory, Kanagawa, Japan) before thaw-mounting. The sections were placed in a polycarbonate tube and stored at -80°C until their analysis. An optimal cutting temperature (OCT) compound (Sakura Finetek, Torrance, CA) was used only to fix each mouse embryo body onto the support stand of the cryostat, and was not used for embedding the embryo body, because the residual polymer on the sections might have degraded the mass spectra. The sections were thawed in their tubes at room temperature for 20 min. A thin matrix layer was applied to the surface by a 0.2-mm nozzle caliber airbrush (Procon Boy FWA Platinum; Mr. Hobby, Tokyo, Japan). Spraying with 500 μL DHB matrix solution (50 mg/mL DHB in 70% methanol/0.1% TFA) was performed and each section was allowed to dry at room temperature. During spraying, the distance between the nozzle and the tissue surface was kept at 15 cm. After drying, the ITO-coated glass slide was adhered to an MS target plate with double-sided conductive adhesive tape to facilitate electrical conduction.

IMS System

A MALDI hybrid quadrupole TOF-type mass spectrometer (QSTAR XL; Applied Biosystems/MDS Sciex, Foster City, CA) equipped with an orthogonal MALDI source was used to acquire MALDI-MS and MALDI-MS/MS spectra. All analyses were performed in positive-ion and reflector modes after external calibration with human angiotensin II ($[\text{M} + \text{H}]^+$, m/z 1,046.54) and human bradykinin fragment 1–7 ($[\text{M} + \text{H}]^+$, m/z 757.40 Da). The laser shot was run at 100 Hz. The MS method was optimized on biological molecules on the tissue surface coated with DHB matrix to maximize the sensitivity of the tissue analysis. MALDI-MS spectra were obtained from an Nd:YAG laser per image spot with a 1 s accumulation time. The instrument is equipped with an oMALDI Server application. oMALDI Server version 4 includes a graphical user interface that allows the user to specify the area to be imaged and the step size between laser shots (lateral resolution). The oMALDI Server then directs the acquisition software (Analyst QS version 1.1) to acquire data, treating each laser spot as one sample in a batch run. Analyst QS allows the user to specify the instrument acquisition method to be used, the time to be accumulated in a spectrum, and the mass ranges of interest to monitor. As the profiles are being

acquired, the sample stage is moved from spot to spot, creating a raster of desorbed areas over the tissue surface. A spectrum is acquired at each spot, and the intensity of each signal from all of the mass ranges specified is stored in “wiff” format file. In the present study, when the “wiff” format file was converted to an “analyze” format file using the function of oMALDI Server version 5.1, the interval value of m/z was set to 0.2. The ion density maps were constructed by BioMap software (Novartis, Basel, Switzerland) and highlighted the signal intensities obtained from each area of interest within the tissue. The images from mouse whole-body sections were acquired from a raster scan with a step size of 200 μm . After raster-scanning, the section was soaked in 100% methanol for 30 s to wash off the DHB matrix and then stained with hematoxylin and eosin (H&E) for anatomical visualization. The optical images were taken with a microscope (LMD6000; Leica Microsystems) to adjust the ion images constructed by BioMap.

MS/MS analysis

In the MS/MS analysis, collisional activation of selected ions was carried out using the relative collision energy from 20 to 35 V with argon as the collision gas. The selectivity of precursor ions was increased by selecting a high mass selection mode. In the product-ion spectrum, when the fragment peaks were identical to the specific neutral loss (NL) of trimethylamine $[(\text{CH}_3)_3\text{N}]$ and/or the cyclophosphane ring $[(\text{CH}_2)_2\text{PO}_4\text{H}]$ and to specific ions of the headgroup $[(\text{CH}_3)_3\text{N}(\text{CH}_2)_2\text{PO}_4\text{H}]$ from LysoPtdCho and PtdCho and of each fatty acid from TAG, the m/z value of the precursor ion was transferred to the Lipid Search (http://lipidsearch.jp/manual_search/) and the Metabolite MS Search (<http://www.hmdb.ca/labm/jsp/mlims/MSDbParent.jsp>). These websites provide information on the carbons and unsaturated bonds included in LysoPtdCho, PtdCho, and TAG. In this study, to reveal the detailed composition of fatty acids, the NL of fatty acids from LysoPtdCho, PtdCho, and TAG was detected by MS/MS analysis.

Results

Mass Spectra Obtained from Mouse E17.5 Sections

After raster-scanning, the sections were stained with H&E (Fig. 1a). Eight organs were selected from the whole body and the name of each was indicated on the optical image (Fig. 1a). The spectra recorded for each of the organs are presented in the panels of Fig. 1 as follows: b, brain; c, brown adipose tissue; d, lung; e, liver; f, hypoglossitis; g,

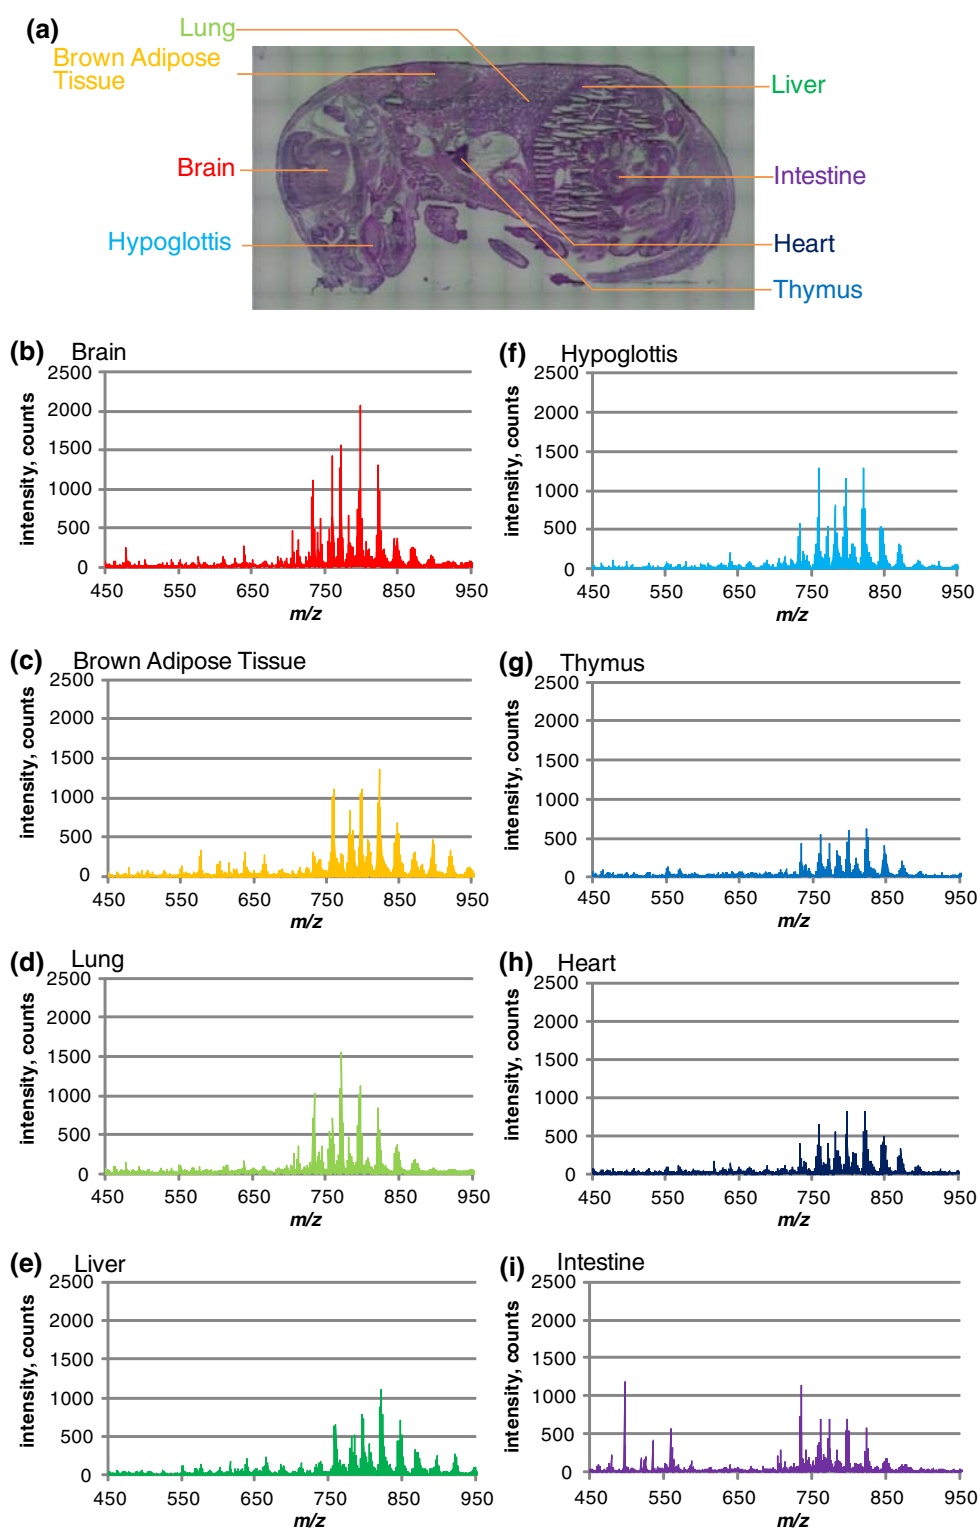

thymus; h, heart; i, intestine. The mass spectra were obtained from representative points in each organ using BioMap software, and displayed in the mass range of m/z 450–950. The intensity counts were highest in the spectrum of the brain (Fig. 1b). The spectrum in the intestine was different from the other spectra (Fig. 1i). The peaks detected from the intestine had higher intensities at m/z 490–570. In each organ, the top ten peaks with higher intensity were selected. The peaks were identified by MS/MS analysis to be revealed as major lipids. The representative molecular species are presented in Table 1. Although four peaks, m/z 558.25, 786.58, 794.46, and 846.48, could not be identified, we speculated that they were $[\text{LysoPtdCho (18:2) + K}]^+$, $[\text{PtdCho (18:1/18:1) + H}]^+$, $[\text{PtdCho (16:0/18:3) + K}]^+$, and $[\text{PtdCho (18:1/20:4) + K}]^+$, respectively, based on previous reports. In the results, almost all biomolecules were PtdCho and had at least one unsaturated fatty acid. There was only one PtdCho composed of two saturated fatty acids, i.e., PtdCho (16:0/16:0).

Distribution of LysoPtdCho and PtdCho

The product-ion spectra were obtained by MS/MS analysis (Fig. 2a, b). In the product-ion spectrum of m/z 496.33 (Fig. 2a), fragment peaks at m/z 184.08 and 313.28 were detected. In the MS/MS analyses for PtdCho and sphingomyelin (SM), a NL of 183 Da from a precursor peak was detected. The NL corresponds to the headgroup $(\text{CH}_3)_3\text{N}(\text{CH}_2)_2\text{PO}_4\text{H}$ of PtdCho and SM. So, the fragment peaks at m/z 184.08 and 313.28 correspond to $[(\text{CH}_3)_3\text{N}(\text{CH}_2)_2\text{PO}_4\text{H} + \text{H}]^+$ and an NL of 183 Da from a precursor peak, respectively. The product-ion spectrum even indicated peaks at m/z 104.11 and 125.00. These peaks correspond to $[(\text{CH}_3)_3\text{N}(\text{CH}_2)_2\text{O} + \text{H}]^+$ and $[(\text{CH}_2)_2\text{PO}_4\text{H} + \text{H}]^+$ from the headgroup, respectively. The m/z value of 496.33 is too small for PtdCho and SM because they are detected as the m/z value at the range of m/z 600–900. In addition, the ions of SM are detected as the odd number by the nitrogen rule. Therefore, the biomolecule may be LysoPtdCho. Moreover, the m/z value of 496.33 was retrieved from Lipid Search and we identified the biomolecule as $[\text{LysoPtdCho (16:0) + H}]^+$ from the results of the retrieval. In the same way, the peak at m/z 524.36 was identified as $[\text{LysoPtdCho (18:0) + H}]^+$. Although the NL of 183 Da does not appear in the MS/MS analysis of LysoPtdCho using electrospray-ionization MS, the spectrum in the MS/MS analysis of $[\text{LysoPtdCho (18:0) + H}]^+$ also showed the peak corresponding to the NL. Therefore the discrepancy was deemed to be due to the kind of ionization.

In the MS/MS analysis for m/z 782.59 (Fig. 2b), fragment peaks at m/z 599.52 and 723.51 were detected. PtdCho adducted with a cation often has these two fragment peaks

Fig. 1 Mass spectra obtained from mouse E17.5 sections. The analyzed section was stained with H&E: **a** the spectra recorded for each of the organs are presented in the panels as follows: **b** brain, **c** brown adipose tissue, **d** lung e liver, **f** hypoglottis, **g** thymus, **h** heart, and **i** intestine. The mass spectra were obtained from representative *points* in each organ using BioMap software, and displayed in the mass range of m/z 450–950

corresponding to NLs of 59 Da [trimethylamine, $(\text{CH}_3)_3\text{N}$] and 183 Da [headgroup, $(\text{CH}_3)_3\text{N}(\text{CH}_2)_2\text{PO}_4\text{H}$] from a precursor peak [50]. Because the two peaks from m/z 782.59

were also consistent with the NLs, the biomolecule is a PtdCho with a cation. The kind of cation adducted to a biomolecule is usually considered to be a sodium ion or a

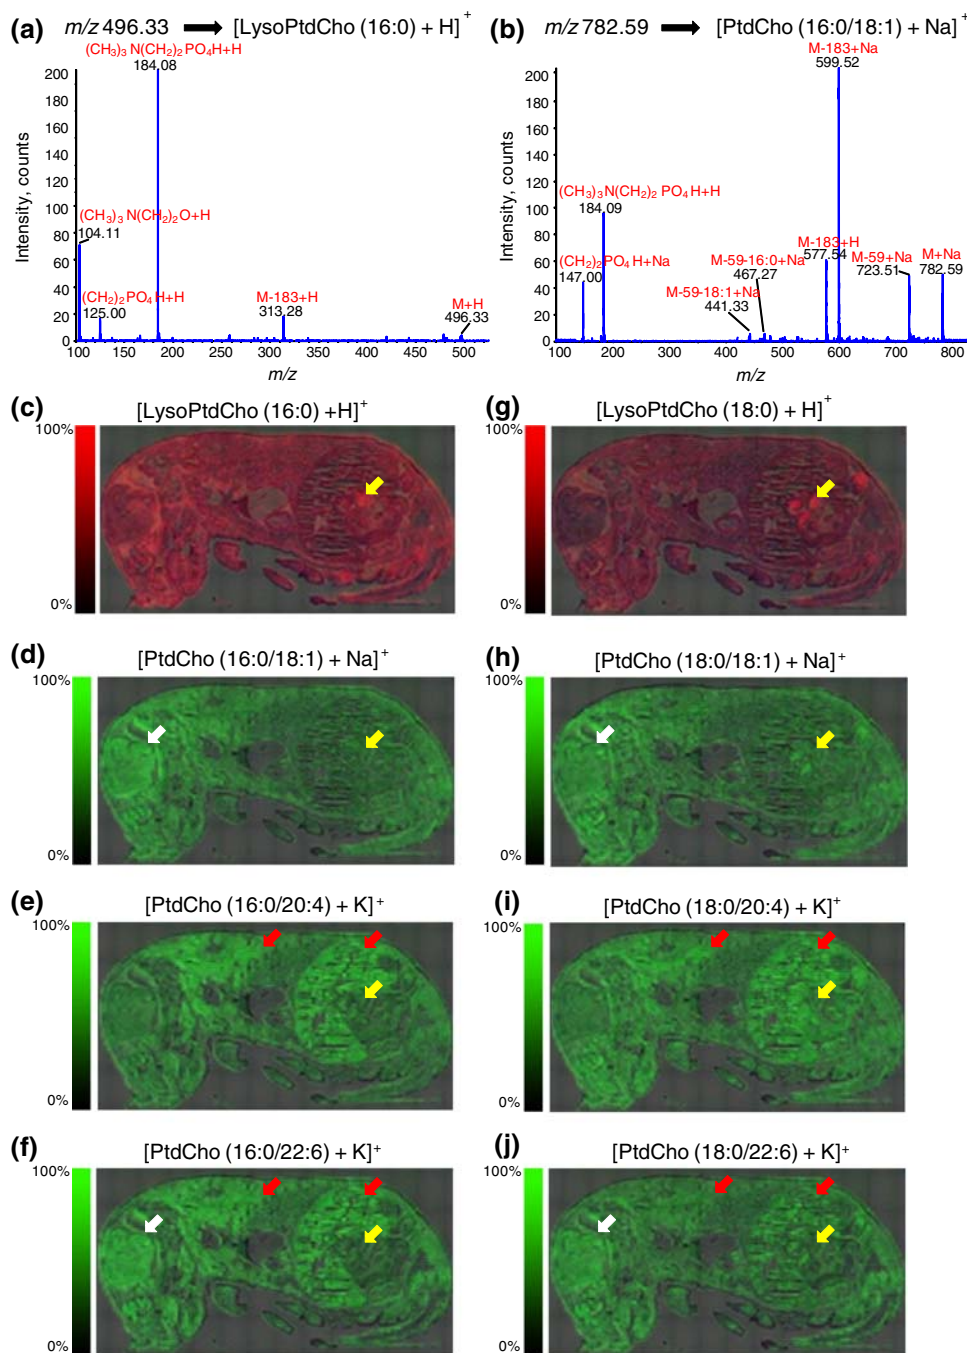

Table 1 The representative molecular species for the top ten peaks in each organ

	PtdCho(16:0/18:1) + Na	782.54	782.57	0.03		PtdCho(16:0/18:3) + K	794.46	794.51	0.05

potassium ion from the biological tissue. The product-ion spectrum of m/z 782.59 indicated peaks at m/z 577.54. The value of 577.54 is 21.98 away from 599.52. In the MS/MS analysis for PtdCho with a cation, such a characteristic fragment peak is often detected [12, 50]. The fragment peak is produced when a cation replaces a proton. In this case, the value of 21.98 Da was consistent with the replacement of a

sodium ion [molecular weight (MW) 23 Da] with a proton (MW 1 Da). This consideration is supported by the fact that the peak at m/z 147.00 corresponded to $[(\text{CH}_2)_2\text{PO}_4\text{H} + \text{Na}]^+$. The results of the retrieval from Lipid Search also indicated that the biomolecule is PtdCho (1-acyl 32:1). Moreover, there are two minor peaks, m/z 441.33 and 467.27, in the product-ion spectrum. We considered that

Fig. 2 Distributions of LysoPtdCho and PtdCho. The structural analyses of two peaks as respective biomolecules were performed. The product-ion spectra from **a** m/z 496.33 and **b** m/z 782.59 as precursor ions were obtained by MS/MS analyses on a mouse embryonic section. Their biomolecules were identified by the production and the neutral loss as follows: **a** [LysoPtdCho (16:0) + H]⁺ and **b** [PtdCho (16:0/18:1) + Na]⁺. In the same way, six more biomolecules were identified. The ion images constructed from the peaks showed the distribution of biomolecules as a relative difference in signals detected in the mouse embryo: **c** [LysoPtdCho (16:0) + H]⁺, **d** [PtdCho (16:0/18:1) + Na]⁺, **e** [PtdCho (16:0/20:4) + K]⁺, **f** [PtdCho (16:0/22:6) + K]⁺, **g** [LysoPtdCho (18:0) + H]⁺, **h** [PtdCho (18:0/18:1) + Na]⁺, **i** [PtdCho (18:0/20:4) + K]⁺, and **j** [PtdCho (18:0/22:6) + K]⁺. The ion images were merged with the optical image of a section stained with H&E

these peaks were consistent with NLs of (59 + 282 Da) and (59 + 256 Da) from the precursor peak. The values of 282 and 256 Da corresponded to fatty acids 18:1 and 16:0. There are many lipids in the range of m/z 700–850. Our IMS system, which directly detects the ions on the biological tissue, cannot separate the peak completely and the productions are not sufficiently abundant. However, we could identify each lipid as a major biomolecule by MS/MS analysis. In general, saturated fatty acids are esterified at the *sn*-1 position while unsaturated fatty acids are esterified at

the *sn*-2 position [51, 52]. We determined *sn*-1 and *sn*-2 positions based on previous works. Therefore, in this experiment, we identified the biomolecule of m/z 782.59 as [PtdCho (16:0/18:1) + Na]⁺. In the same way, the peaks at m/z 810.4, 820.48, 844.48, 848.51, and 872.50 were identified as [PtdCho (18:0/18:1) + Na]⁺, [PtdCho (16:0/20:4) + K]⁺, [PtdCho (16:0/22:6) + K]⁺, [PtdCho (18:0/20:4) + K]⁺, and [PtdCho (18:0/22:6) + K]⁺.

We constructed the ion image from the peaks identified as above on the embryonic section using the BioMap

software (Fig. 2c–j). The ion images showed the relative difference of signals detected on the mouse embryonic section. The ion images of LysoPtdCho (16:0) and LysoPtdCho (18:0) showed that both biomolecules were distributed throughout the body, and were especially prominent in the intestines (yellow arrows in Fig. 2c, g). The ion images of PtdCho (16:0/18:1) (Fig. 2d), PtdCho (16:0/20:4) (Fig. 2e), and PtdCho (16:0/22:6) (Fig. 2f), which have the same fatty acid of 16:0 at *sn*-1, indicated a specific disappearance in the intestine (yellow arrows in Fig. 2d–f). In the same way, the specific distribution of LysoPtdCho (18:0) (Fig. 2g) was also compared with the distributions of PtdCho (18:0/18:1) (Fig. 2h), PtdCho (18:0/20:4) (Fig. 2i), and PtdCho (18:0/22:6) (Fig. 2j). All four molecules had similar distributions in the intestines (yellow arrows in Fig. 2g–j).

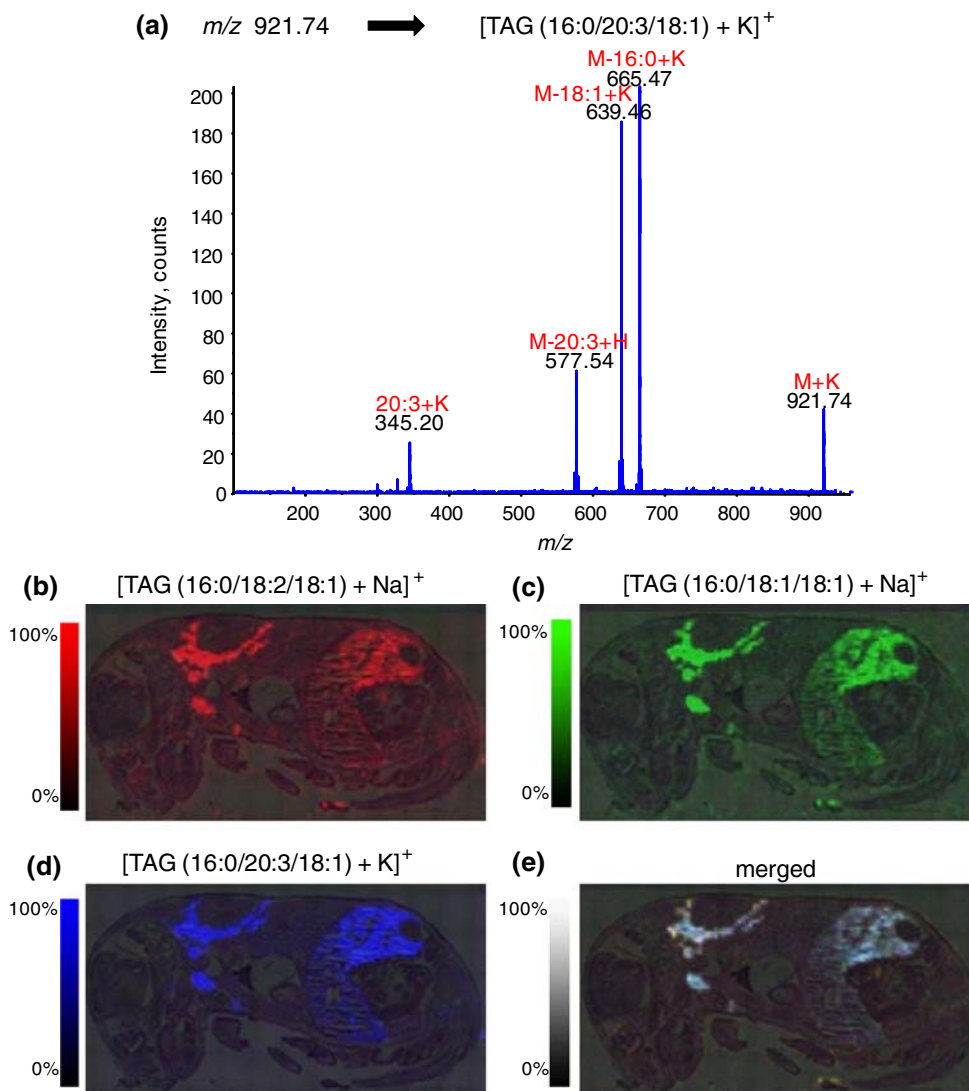

There was heterogeneity of the distribution among PtdCho. PtdCho (16:0/18:1) and PtdCho (16:0/22:6) were

strongly distributed in the brain (white arrows in Fig. 2d, f). PtdCho (16:0/20:4) and PtdCho (16:0/22:6) were distributed around brown adipose tissue and in the liver (red arrows in Fig. 2e, f). Similarly, PtdCho with the same fatty acid at *sn*-2, such as PtdCho (16:0/18:1) and PtdCho (18:0/18:1), showed the same distribution (white arrows in Fig. 2d, h).

Distribution of TAG

The product-ion spectrum of m/z 921.74 was markedly different from the other spectra that were identified as LysoPtdCho and PtdCho (Fig. 3a). The major peaks were m/z 639.46 and 665.47, which corresponded to NLs of 282 Da (18:1) and 256 Da (16:0) from a precursor ion. These NLs have been reported [53] and are characteristic of the MS/MS analysis for TAG. Moreover, there are two abundant peaks, m/z 345.20 and 577.54, in the product-ion

Fig. 3 Distribution of TAG. The structural analysis of one peak was performed. The product-ion spectrum from **a** m/z 921.74 as a precursor ion was obtained by MS/MS analysis on a mouse embryonic section. The biomolecules were identified by neutral loss as TAG (16:0/20:3/18:1). In the same way, two more biomolecules were identified. The ion images constructed from the peaks showed the distribution of biomolecules on the mouse embryo: **b** [TAG (16:0/18:2/18:1) + Na]⁺, **c** [TAG (16:0/18:1/18:1) + Na]⁺, and **d** [TAG (16:0/20:3/18:1) + K]⁺. The ion images were merged with the optical image of a section stained with H&E. The three merged TAG images demonstrate the same distribution

spectrum. We considered that these peaks were consistent with the ion of $[20:3 + K]^+$ and NL of 344.20 Da from the precursor ion. The product-ion reflecting neutral loss of the *sn*-2 fatty acid substituent was less abundant than the corresponding ions reflecting such losses of either *sn*-1 or the *sn*-3 fatty acid substituent [54]. Therefore, we identified this biomolecule as $[TAG (16:0/20:3/18:1) + K]^+$. In the same way, the peaks at *m/z* 879.72 and 881.74 were identified as $[TAG (16:0/18:2/18:1) + Na]^+$ and $[TAG (16:0/18:1/18:1) + Na]^+$. Three ion images of TAG demonstrated the same distribution, which is illustrated by the merged image (Fig. 3b–e).

Discussion

In this study, we aimed to identify and visualize biomolecules in the mouse embryo. E17.5 embryo was chosen because the embryonic organs are highly similar to those of adult mice at this age. Since different organs should be compared in the same slide, we can visualize all the tissues at the same time. Late stage of embryo is suitable for this purpose. We are also able to obtain detailed information about the identity and distribution of embryonic metabolites, which can be compared with those of adults. The ion image constructed from the peaks is often merged with the optical image to reveal the detailed distribution of biomolecules in IMS. This method was also used in the present study: all sections analyzed by IMS were stained, and the optical images were merged with the ion images (Figs. 2c–j, 3b–e).

Whole-body sections were prepared from a mouse E17.5, and raster-scanned by a QSTAR XL system. The spectra recorded for each of the organs are presented in the panels of Fig. 1b–i. The intensity counts in the mass spectra obtained from representative points in each organ indicated the abundance of PLs in the brain (Fig. 1b). Therefore, the intensity counts which we detected in the brain are reasonable. However, the characteristic spectrum was detected in intestine (Fig. 1i). The peaks had higher intensities at the range of low molecules. The results of MS/MS analyses indicated that some of the low molecule was LysoPtdCho (Fig. 2a and Table 1). Moreover, the ion images of LysoPtdCho (16:0) and LysoPtdCho (18:0) showed that both biomolecules were especially prominent in the intestines (yellow arrows in Fig. 2c, g). It is known that PLs are hydrolyzed to lyso-PLs with any phospholipase. The detected peaks suggest that the enzyme exists and acts in the intestine. LysoPtdCho is produced by the hydrolysis of PtdCho with an enzyme such as PLA2 and is changed to lysophosphatidic acid (LPA) by an enzyme such as lysophospholipase D (LPLD) [55]. These results

imply two different aspects. One is that most PLA2 acted on PtdCho at this location because PLA2, especially pancreatic PLA2, is prominent in the intestines. However, the ion images of PtdCho did not show the specific disappearance in the intestine (Fig. 2d–f). Therefore, we thought that the increase of LysoPtdCho in the intestine was not dependent on the nonspecific action of pancreatic PLA2. Another is that LPLD activity was lower in the intestines and LysoPtdCho accumulated before changing to LPA. Anyway, IMS enabled us to screen the distribution of LysoPtdCho as well as PtdCho.

The distribution among PtdCho indicated heterogeneity (Fig. 2d–f, h–j). These results suggest that the fatty acids at *sn*-2 play specific roles in the normal development and function of each organ. Both fatty acids of 20:4 (ARA) and 22:6 (DHA) were minor species in this study. However, these fatty acids are important structural components of membrane PLs and are required for normal development. Deficiencies in these fatty acids result in abnormal development and several diseases [41, 44, 56]. For example, the amount and composition of fatty acids are controlled precisely; complete loss of fatty acid synthesis results in early embryonic lethality [57]. Therefore, we thought that the detection of these fatty acids by IMS analysis would be more useful for many researchers.

In a previous report, TAG was identified by its exact *m/z* value, without MS/MS analysis [21]. In addition, Murphy et al. [58] visualized the peak at *m/z* 879.7 on the mouse kidney section and identified the peak as $[TG (16:0/20:4/18:1) + H]^+$ in their previous report [59], which revealed product-ions at *m/z* 623.5, 597.5, and 575.5 from the extraction of RAW 264.7 cells using electrospray mass spectrometry. However, since there are numerous lipids in the mass range of *m/z* 700–1,000 and the main composition of fatty acids is different for a biological sample, it is preferable that MS/MS analysis be performed for the same kind of sample. Thus, we proved that the identification can be performed fairly accurately by detecting the NLs of fatty acids in the product-ion spectrum for TAG on the whole-body mouse embryonic sections, which produce specific signals (Fig. 3a).

We demonstrated the merged image from three ion images of TAG (Fig. 3b–d). This merged image showed a distinctly different distribution from the LysoPtdCho and PtdCho images (Fig. 3d). It is clear from the image merged with the optical image stained with H&E that the distribution was localized around brown adipose tissue and in the liver. Intriguingly, the signals hardly existed in other areas. Moreover, the image merged from the distribution of three TAG highlighted the complete correspondence of their distributions (Fig. 3e). This fascinating localization pattern probably reflects functional difference of each TAG

during embryogenesis, which was not established by conventional methods.

Thus, we identified and visualized the lipid species in a mouse embryo with a MALDI hybrid quadrupole TOF-based IMS system. The IMS system detected a number of peaks in the analysis of the whole embryonic sections, and the spectra were different in each organ. Eleven specific peaks were analyzed with MS/MS analyses. The biomolecules were identified as LysoPtdCho (16:0), LysoPtdCho (18:0), PtdCho (16:0/18:1), PtdCho (16:0/20:4), PtdCho (16:0/22:6), PtdCho (18:0/18:1), PtdCho (18:0/20:4), PtdCho (18:0/22:6), TAG (16:0/18:1/18:1), TAG (16:0/18:2/18:1), and TAG (16:0/20:3/18:1). In addition, the ion images constructed from the peaks of the biomolecules showed their distribution in the whole body. Interestingly, the distributions of the three PtdCho were different from one another, which is dependent on the fatty acid at *sn*-2. In contrast, the distributions of TAG were the same, with a predominance around the brown adipose tissue and in the liver. TAG might accumulate in such organs to maintain body temperature or to supply TAG for other organs. This is the first successful visualization of LysoPtdCho and TAG localization in the embryonic stage of a mammal using an IMS system based on MALDI hybrid quadrupole TOF. In the future, this method will help to combine developmental biology and lipid research.

Acknowledgments We are grateful to Masako Suzuki (Hamamatsu University School of Medicine) for technical support with the operation of the QSTAR XL system. This work was supported by a Grant-in-Aid for SENTAN from the Japan Science and Technology Agency (to M.S.) and a Grant-in-Aid for Young Scientists B (to T.H.).

Abstract Four new fatty acid esters have been isolated from Feces *Trogopterus*. Their structures were determined by spectroscopic and chemical methods to be bis(7-hydroxyheptyl) icosanedioate (**1**), bis(7-hydroxyheptyl) heptadecanedioate (**2**), bis(7-hydroxyheptyl) decanedioate (**3**), and bis(7-hydroxyheptyl) octanedioate (**4**). In the anticoagulative assay, compounds **3** and **4** had significant antithrombin activity.

Keywords Feces *Trogopterus* · Fatty acid ester · Antithrombin activity

Abbreviations

COSY	Correlation spectroscopy
ESI	Electrospray ionization
FAME	Fatty acid methyl ester
HMBC	Heteronuclear multiple bond correlation
HMQC	Heteronuclear multiple quantum correlation
HR	High resolution
IR	Infrared
MS	Mass spectrometry
NMR	Nuclear magnetic resonance
Tris	Trishydroxymethylaminomethane
TT	Thrombin time

Introduction

Feces *Trogopterus*, called “Wulingzhi”, are the dry excrement of *Trogopterus xanthipes* Milne-Edwards (Petauristidae).

Feces *Trogopterus* promote blood circulation and remove stasis, and in traditional Chinese medicine are often used for treatment of amenorrhea, dysmenorrhea, menses pain, and retained lochia due to stasis. The literature reports that the chemical constituents of Feces *Trogopterus* are mainly terpenoids, phenolic acids, and sterols, and these have the pharmacological activity of anticoagulation, enhancing immunity, and anti-inflammation [1]. Different solvent extracts of Feces *Trogopterus* were screened in our current study, which showed that the ethyl acetate extract was the important active part. The ethyl acetate extract was, therefore, investigated chemically and contained four new fatty acid esters. Fatty alcohols, fatty acids, and their esters are important lipid compounds reported to have many biological and pharmacological functions, including inhibiting cholesterol synthesis, increasing low-density lipoprotein processing, and anti-thrombosis and anti-platelet aggregation activity [2–4]. In this study we deal with the isolation and structure elucidation of four new fatty acid esters, bis(7-hydroxyheptyl) icosanedioate (**1**), bis(7-hydroxyheptyl) heptadecanedioate (**2**), bis(7-hydroxyheptyl) decanedioate (**3**), and bis(7-hydroxyheptyl) octanedioate (**4**), and a new natural product, bis(7-hydroxyheptyl) hexanedioate (**5**) (Fig. 1), and report some of their anticoagulative activity. Their structures were elucidated by means of chemical and extensive spectroscopic analysis.

Materials and Methods

General Experimental Procedures

Melting points were determined with a WRS-IB melting point apparatus (Shanghai Precision and Scientific Instrument, Shanghai, P.R. China) and are uncorrected. Optical

rotation was measured on a Perkin–Elmer 341 polarimeter. IR spectra were taken on a Nicolet IR-100 FT-IR spectrometer in KBr discs. NMR spectra were measured on a Bruker AV-500 MHz (500 MHz for ^1H NMR and 125 MHz for ^{13}C NMR), using TMS as internal standard; chemical shifts were recorded as δ values. ESI-MS and HR-ESI-MS spectra were obtained on a Micromass Q/TOF mass spectrometer. Anticoagulative assay was performed on an LG-PABER-I coagulation-analysis instrument. The blood sample was treated on an Anke TDL-40B centrifuge.

Materials and Chemicals

Feces Trogopterus were collected in June 2008 from Hebei province of China, and identified as the dry feces of *T. xanthipes* by Associate Professor Nianyun Yang of Nanjing University of Traditional Chinese Medicine. A voucher specimen (GS-20080610) was kept in the Herbarium of Nanjing University of Traditional Chinese Medicine.

Silica gel for column chromatography (CC) (200–300 mesh) and TLC plates (10–40 μm) were the products of Qingdao Marine Chemical (Qingdao, P.R. China). All solvents used were of analytical grade (Nanjing Chemical Plant, Nanjing, P.R. China). Thrombin was purchased from Xisen Sanhe (Leling, P.R. China). Trishydroxymethylaminomethane (Tris) was the product of Shanghai Jingxi Chemical Industry (Shanghai, P.R. China). Sodium citrate was purchased from Shanghai Lingfeng Chemical Reagent (Shanghai, P.R. China). Heparin sodium (biotech grade, 150 U mg^{-1}) was purchased from Amresco (Solon, USA). A rabbit (3.8 kg) was supplied by Shanghai Sikelai Experimental Animal (Shanghai, P.R. China).

Extraction and Isolation

Air-dried and powdered Feces Trogopterus (3 kg) were extracted with 60% $\text{C}_2\text{H}_5\text{OH}$ (2 \times 50 L) for 2 h under reflux, and the combined extracts were concentrated under reduced pressure. The resulting extract (370 g) was suspended in H_2O and extracted successively with ethyl acetate and *n*-butanol to give the respective extracts after solvent removal. The combined ethyl acetate extracts were evaporated under reduced pressure to leave a residue (277 g) which was chromatographed on silica gel (2 kg) eluting with a CHCl_3 – CH_3OH stepwise gradient (100:0 \rightarrow 5:1); five fractions were collected. Fraction 1 (10 g) was separated on silica gel (CH_2Cl_2) to yield compounds **1** (50 mg) and **2** (55 mg). Fraction 2 (15 g) was separated on silica gel (CH_2Cl_2 – CH_3OH 20:1) to yield compounds **3** (300 mg), **4** (550 mg), and **5** (500 mg).

white powder, m.p. 127–128°C, IR (KBr) λ_{\max} 3210, 2909, 1624, 1535, 1471 1270, 1060, 1015, 722 cm^{-1} ; ^1H NMR (CD_3OD , 500 MHz) δ 4.07 (4H, t, $J = 6.6$ Hz, H-1', 1''), 3.53 (4H, t, $J = 6.7$ Hz, H-7', 7''), 2.29 (4H, t, $J = 7.4$ Hz, H-2, 16), 1.62 (12H, m, H-3, 15, 2', 2'', 6', 6''), 1.28–1.30 (34H, br s, H-3'-5', 3''-5'', 4–14); ^{13}C NMR (CD_3OD , 125 MHz) δ 177.7 (C-1, 17), 66.0 (C-1', 1''), 63.6 (C-7', 7''), 35.8 (C-2, 16), 34.2 (C-6', 6''), 30.9–31.2 (C-4–14, 4', 4''), 30.7 (C-2', 2''), 27.4 (C-3', 3'', 5', 5''), 26.5 (C-3, 15); ESI-MS: m/z 529 $[\text{M}+\text{H}]^+$, 551 $[\text{M}+\text{Na}]^+$; HR-ESI-MS: m/z 551.4305 $[\text{M}+\text{Na}]^+$ ($\text{C}_{31}\text{H}_{60}\text{O}_6\text{Na}$, calc. 551.4288).

Bis(7-hydroxyheptyl) decanedioate (3)

white powder, m.p. 118–120°C, IR (KBr) λ_{\max} 3211, 2905, 1626, 1535, 1473 1271, 1062, 1015, 721 cm^{-1} ; ^1H NMR (CD_3OD , 500 MHz) δ 4.06 (4H, t, $J = 6.6$ Hz, H-1', 1''), 3.53 (4H, t, $J = 6.7$ Hz, H-7', 7''), 2.29 (4H, t, $J = 7.4$ Hz, H-2, 9), 1.60 (12H, m, H-3, 8, 2', 2'', 6', 6''), 1.27–1.29 (20H, br s, H-3'-5', 3''-5'', 4–7); ^{13}C NMR (CD_3OD , 125 MHz) δ 176.2 (C-1, 10), 66.0 (C-1', 1''), 63.6 (C-7', 7''), 35.7 (C-2, 9), 34.2 (C-6', 6''), 30.9–31.2 (C-4–7, 4', 4''), 30.7 (C-2', 2''), 27.4 (C-3', 3'', 5', 5''), 26.6 (C-3, 8); ESI-MS: m/z 431 $[\text{M}+\text{H}]^+$, 453 $[\text{M}+\text{Na}]^+$; HR-ESI-MS: m/z 453.3203 $[\text{M}+\text{Na}]^+$ ($\text{C}_{24}\text{H}_{46}\text{O}_6\text{Na}$, calc. 453.3192).

Bis(7-hydroxyheptyl) octanedioate (4)

white powder, m.p. 103–104°C, IR (KBr) λ_{\max} 3210, 2906, 1624, 1533, 1469 1268, 1060, 1012, 722 cm^{-1} ; ^1H NMR (CD_3OD , 500 MHz) δ 4.06 (4H, t, $J = 6.6$ Hz, H-1', 1''), 3.55 (4H, t, $J = 6.7$ Hz, H-7', 7''), 2.28 (4H, t, $J = 7.4$ Hz, H-2, 7), 1.60 (12H, m, H-3, 6, 2', 2'', 6', 6''), 1.27–1.29 (16H, br s, H-3'-5', 3''-5'', 4, 5); ^{13}C NMR (CD_3OD , 125 MHz) δ 177.9 (C-1, 8), 66.0 (C-1', 1''), 63.7 (C-7', 7''), 35.7 (C-2, 9), 34.2 (C-6', 6''), 30.9–31.2 (C-4, 5, 4', 4''), 30.7 (C-2', 2''), 27.4 (C-3', 3'', 5', 5''), 26.6 (C-3, 6); ESI-MS: m/z 403 $[\text{M}+\text{H}]^+$, 425 $[\text{M}+\text{Na}]^+$; HR-ESI-MS: m/z 425.2890 $[\text{M}+\text{Na}]^+$ ($\text{C}_{22}\text{H}_{42}\text{O}_6\text{Na}$, calc. 425.2879).

Bis(7-hydroxyheptyl) hexanedioate (5)

white powder, m.p. 100–102°C, IR (KBr) λ_{\max} 32109, 2903, 1624, 1535, 1470 1269, 1061, 1011, 722 cm^{-1} ; ^1H NMR (CD_3OD , 500 MHz) δ 4.06 (4H, t, $J = 6.6$ Hz, H-1', 1''), 3.55 (4H, t, $J = 6.7$ Hz, H-7', 7''), 2.28 (4H, t, $J = 7.4$ Hz, H-2, 5), 1.60 (12H, m, H-3, 4, 2', 2'', 6', 6''), 1.27–1.29 (12H, br s, H-3'-5', 3''-5''); ^{13}C NMR (CD_3OD , 125 MHz) δ 177.9 (C-1, 6), 66.0 (C-1', 1''), 63.6 (C-7', 7''), 35.7 (C-2, 9), 34.2 (C-6', 6''), 31.0 (C-4', 4''), 30.7 (C-2', 2''), 27.4 (C-3', 3'', 5', 5''), 26.6 (C-3, 4); ESI-MS: m/z 375

$[\text{M}+\text{H}]^+$, 397 $[\text{M}+\text{Na}]^+$; HR-ESI-MS: m/z 397.2576 $[\text{M}+\text{Na}]^+$ ($\text{C}_{20}\text{H}_{38}\text{O}_6\text{Na}$, calc. 397.2566).

Methanolysis of 1–5

Compounds 1–5 (ca. 1 mg) were heated with 10% HCl in MeOH (1 mL each) at 80°C for 14 h. The reaction mixtures were then extracted with *n*-hexane. The upper and lower layers were analyzed by ESI-MS to identify the chemical structures of the reaction products.

Anticoagulative Assay

The anticoagulative activity of the different solvent extracts and pure compounds 1–5 was evaluated by use of the thrombin time (TT) method. All samples were dissolved in ethanol. A sample of blood was taken from the rabbit common carotid artery and mixed with anticoagulant (3.8% sodium citrate) in the proportion 9:1. The mixture was centrifuged at 2,500 rev min^{-1} for 15 min to collect the plasma. The plasma (50 μL) was placed in a plastic cup for 3 min at 37°C, and 100 μL thrombin solution (15 U mL^{-1}) diluted with 0.1 mol mL^{-1} pH 7.4 Tris-HCl buffer was also placed in the plastic cup, with 10 μL sample solution. The coagulation analysis instrument was then started and the thrombin clotting time was recorded. The same experiment was done for the positive control drug heparin sodium and the blank solvent ethanol. Each analyte was tested several times, and an average value was calculated. TT prolongation rate and lgTT prolongation rate were calculated to assess the anticoagulative activity of the samples.

Results and Discussion

The anticoagulative ethyl acetate extract of *Feces Troglodytes* was separated by CC on silica gel to give two fractions and further purified by silica gel to yield compounds 1–5. Their structures were elucidated as follows.

Compound 1 was isolated as a white powder. The molecular formula of 1 was established as $\text{C}_{34}\text{H}_{66}\text{O}_6$ by HRESI-MS (m/z 593.4775 $[\text{M} + \text{Na}]^+$). The positive ESI-MS showed quasi molecular ion peaks at m/z 571 $[\text{M} + \text{H}]^+$ and 593 $[\text{M} + \text{Na}]^+$. The ^1H and ^{13}C NMR spectra were typical of a fatty acid ester, but the ^1H and ^{13}C NMR spectra did not reveal any methyl signals, which suggested that 1 is a symmetric dibasic acid diester [5]. The proton signals at δ 4.06 (4H, t, $J = 6.5$ Hz) and 3.53 (4H, t, $J = 6.7$ Hz) and the carbon signals at δ 66.0 and 63.6 indicated that 1 is a terminal diol ester. When 1 was methanolized with methanolic HCl, a fatty acid methyl ester (FAME) was obtained together with a fatty alcohol. On the

Fig. 2 Key ^1H - ^1H COSY and HMBC correlations of compound **1**

basis of ESI-MS analysis, the FAME was characterized as dimethyl icosanedioate from a quasi molecular ion peak at m/z 371 $[\text{M} + \text{H}]^+$, and the fatty alcohol was identified as 1,7-heptanediol from a quasi molecular ion peak at m/z 133 $[\text{M} + \text{H}]^+$. Assignments of all protons and carbons in **1** were also made on the basis of ^1H - ^1H COSY, HMQC, and HMBC spectra (Fig. 2). Thus, the structure of compound **1** was determined as bis(7-hydroxyheptyl) icosanedioate.

Compound **2** was isolated as a white powder. The molecular formula of **2** was established as $\text{C}_{31}\text{H}_{60}\text{O}_6$ by HRESI-MS (m/z 551.4305 $[\text{M} + \text{Na}]^+$). The positive ESI-MS showed quasi molecular ion peaks at m/z 529 $[\text{M} + \text{H}]^+$ and 551 $[\text{M} + \text{Na}]^+$. The ^1H and ^{13}C NMR spectra were very similar to that of **1**. The quasi molecular ion peak at m/z 529 $[\text{M} + \text{H}]^+$ indicated a deficiency of 42 Da in comparison with that of **1**, which suggested lack of three CH_2 units in **2**. When **2** was methanolized with methanolic HCl, a fatty acid methyl ester (FAME) was obtained together with a fatty alcohol. On the basis of ESI-MS analysis, the FAME was characterized as dimethyl heptadecanedioate from a quasi molecular ion peak at m/z 329 $[\text{M} + \text{H}]^+$, and the fatty alcohol was identified as 1,7-heptanediol from a quasi molecular ion peak at m/z 133 $[\text{M} + \text{H}]^+$. Thus, the structure of compound **2** was determined as bis(7-hydroxyheptyl) heptadecanedioate.

Compound **3** was isolated as a white powder. The molecular formula of **3** was established as $\text{C}_{24}\text{H}_{46}\text{O}_6$ by HRESI-MS (m/z 453.3203 $[\text{M} + \text{Na}]^+$). The positive ESI-MS showed quasi molecular ion peaks at m/z 431 $[\text{M} + \text{H}]^+$ and 453 $[\text{M} + \text{Na}]^+$. The ^1H and ^{13}C NMR spectra were very similar to that of **1**. The quasi molecular ion peak at m/z 431 $[\text{M} + \text{H}]^+$ indicated a deficiency of 140 Da in comparison with that of **1** which suggested lack of ten CH_2 units in **3**. When **3** was methanolized with methanolic HCl, a fatty acid methyl ester (FAME) was obtained together with a fatty alcohol. On the basis of ESI-MS analysis, the FAME was characterized as dimethyl decanedioate from a quasi molecular ion peak at m/z 231 $[\text{M} + \text{H}]^+$, and the fatty alcohol was identified as 1,7-heptanediol from a quasi molecular ion peak at m/z 133 $[\text{M} + \text{H}]^+$. Thus, the structure of compound **3** was determined as bis(7-hydroxyheptyl) decanedioate.

Compound **4** was isolated as a white powder. The molecular formula of **4** was established as $\text{C}_{22}\text{H}_{42}\text{O}_6$ by HRESI-MS (m/z 425.2890 $[\text{M} + \text{Na}]^+$). The positive

ESI-MS showed quasi molecular ion peaks at m/z 403 $[\text{M} + \text{H}]^+$ and 425 $[\text{M} + \text{Na}]^+$. The ^1H and ^{13}C NMR spectra were very similar to that of **1**. The quasi molecular ion peak at m/z 403 $[\text{M} + \text{H}]^+$ indicated a deficiency of 168 Da in comparison with that of **1** which suggested lack of twelve CH_2 units in **4**. When **4** was methanolized with methanolic HCl, a fatty acid methyl ester (FAME) was obtained together with a fatty alcohol. On the basis of ESI-MS analysis, the FAME was characterized as dimethyl octanedioate from a quasi molecular ion peak at m/z 203 $[\text{M} + \text{H}]^+$, and the fatty alcohol was identified as 1,7-heptanediol from a quasi molecular ion peak at m/z 133 $[\text{M} + \text{H}]^+$. Thus, the structure of compound **4** was determined as bis(7-hydroxyheptyl) octanedioate.

Compound **5** was isolated as a white powder. The molecular formula of **5** was established as $\text{C}_{20}\text{H}_{38}\text{O}_6$ by HRESI-MS (m/z 397.2576 $[\text{M} + \text{Na}]^+$). The positive ESI-MS showed quasi molecular ion peaks at m/z 375 $[\text{M} + \text{H}]^+$ and 397 $[\text{M} + \text{Na}]^+$. The ^1H and ^{13}C NMR spectra were very similar to that of **1**. The quasi molecular ion peak at m/z 375 $[\text{M} + \text{H}]^+$ indicated a deficiency of 196 Da in comparison with that of **1** which suggested lack of fourteen CH_2 units in **5**. When **5** was methanolized with methanolic HCl, a fatty acid methyl ester (FAME) was obtained together with a fatty alcohol. On the basis of ESI-MS analysis, the FAME was characterized as dimethyl hexanedioate from a quasi molecular ion peak at m/z 175 $[\text{M} + \text{H}]^+$, and the fatty alcohol was identified as 1,7-heptanediol from a quasi molecular ion peak at m/z 133 $[\text{M} + \text{H}]^+$. Thus, the structure of compound **5** was determined as bis(7-hydroxyheptyl) hexanedioate, which has been reported in the literature [6].

The in-vitro anticoagulative activity of the different solvent extracts and of compounds **1**–**5** was tested using the thrombin time method assay with heparin sodium as a positive control. As can be appreciated from the results summarized in Table 1, compounds **3** and **4** significantly prolonged thrombin time with a good dose–effect relationship.

The thrombin time is a coagulation assay which is usually performed in order to detect for the therapeutic level of the anticoagulant heparin, and it is one of the most procedurally simple methods for screening potential thrombin inhibitors [7]. A bioassay called the optimized thrombin time was successfully developed in our laboratory for determining the anti-thrombin activity of a series of Chinese blood-activating medicines and some active components [8]. The isolated fatty acid esters **1**–**5** from *Feces Troglodytes* might be metabolic products of *T. xanthipes*. The coagulative assay results suggested that these fatty acid esters are the important anticoagulative constituents of *Feces Troglodytes*. The antithrombin

Abstract First studies on the occurrence of nitrated fatty acids in plasma of healthy subjects revealed basal concentrations of 600 nM for free/nonesterified nitro-oleic acid (NO₂-OA) as measured by liquid chromatography tandem mass spectrometry (LC–MS/MS). We recently showed by a gas chromatography tandem mass spectrometry (GC–MS/MS) method the physiological occurrence of two isomers, i.e., 9-NO₂-OA and 10-NO₂-OA, at mean basal plasma concentrations of 880 and 940 pM, respectively. In consideration of this large discrepancy we modified our originally reported method by replacing solid-phase extraction (SPE) by solvent extraction with ethyl acetate and by omitting the high-performance liquid chromatography (HPLC) step for a more direct detection and with the potential for lipidomics studies. Intra-assay imprecision and accuracy of the modified method in human plasma were 1–34% and 91–221%, respectively, for added NO₂-OA concentrations in the range 0–3,000 pM. This method provided basal plasma concentrations of 306 ± 44 pM for 9-NO₂-OA and 316 ± 33 pM for 10-NO₂-OA in 15 healthy subjects. Nitro-arachidonic acid and nitro-linolenic acid were not detectable in the plasma samples. In summary, our studies show 9-NO₂-OA and 10-NO₂-OA as endogenous nitrated fatty acids in human plasma in the pM range; HPLC is recommendable as a sample clean-up step for reliable quantification of nitro-oleic acids by GC–MS/MS.

Introduction

Nitrated fatty acids are a newly discovered class of biologically active nitro-compounds [1–12]. For the first time, the nonesterified nitro-oleic acid (NO₂-OA) has been found by LC–MS/MS in human plasma, at a basal concentration of about 600 nM [5]. Recently, our group has reported on the development, validation, and application of a highly specific GC–MS/MS method for the quantification

of NO₂-OA in human plasma [13]. In order to avoid potential interferences we incorporated in this GC–MS/MS method a HPLC step for separation and isolation of NO₂-OA. In freshly obtained plasma from 15 healthy subjects we identified by GC–MS/MS two isomers of nitro-oleic acid, namely 9-NO₂-OA and 10-NO₂-OA, and determined their concentration to be on the threshold of the pM-to-nM range [13]. The 9-NO₂-OA and 10-NO₂-OA concentrations measured by us are about three orders of magnitude lower than those firstly reported by Freeman and co-workers by using the LC–MS/MS methodology [5]. The large discrepancy between the findings of our and other groups is difficult to reconcile because the analytical performance of the LC–MS/MS method in terms of accuracy, precision, and specificity has not been reported [5]. A recent study [14], in which nitro-oleic acid could not be found in mouse plasma, argues against the originally reported concentration of nitro-oleic acid and supports our findings that 9-NO₂-OA and 10-NO₂-OA occur in human plasma in the pM-to-nM range [13].

In consideration of this contradiction, we have performed additional work to verify our originally reported data on 9-NO₂-OA and 10-NO₂-OA. For this, we have made two modifications, i.e., we performed solvent extraction instead of SPE and omitted the HPLC step (Fig. 1). These modifications were aimed at simplifying and making the method more direct, with the potential for lipidomics studies. The modified method reported here revealed plasma 9-NO₂-OA and 10-NO₂-OA concentrations of 300 pM, which support our previous findings [13]. On the basis of the new analytical facts, this article discusses the importance of nitro-fatty acids with regard to their physiological and pathological roles.

Experimental Procedures

Materials

2,3,4,5,6-Pentafluorobenzyl bromide (PFB-Br) was obtained from Sigma–Aldrich (Steinheim, Germany). *cis*-9-Nitro-9-octadecenoic acid (9-NO₂-OA) and *cis*-10-nitro-9-octadecenoic acid (10-NO₂-OA) were obtained from Cayman Chemical (Ann Arbor, MI, USA) and were stored at –20°C. The preparation, isolation, characterization, and standardization of the ¹⁵N-labeled 9-NO₂-OA (9-¹⁵NO₂-OA) and 10-NO₂-OA (10-¹⁵NO₂-OA), which were used as internal standards in the present study, have been described in detail elsewhere [13]. Toluene was purchased from Baker (Deventer, The Netherlands). Acetonitrile, ethyl acetate, and *N*-ethyl-diisopropylamine were from Merck (Darmstadt, Germany).

Solvent Extraction of Free 9- and 10-Nitro-oleic Acid from Human Plasma

For the present work we used plasma samples that were generated and analyzed for nitro-oleic acid using GC–MS/MS and HPLC (Fig. 1, procedure A) in a previous work of our group [13]. Healthy adults had volunteered to donate blood and had given written consent to the use of their blood samples for analytical examination in the frame of scientific experiments only. Blood had been drawn from antecubital veins of healthy volunteers using 9-mL syringes containing ethylenediamine tetraacetic acid (EDTA), put immediately on ice, and centrifuged (4,240 × *g*, 4°C, 5 min). Plasma samples had been proportioned into 1-mL fractions and stored at –80°C until further analysis.

Only once-thawed plasma samples were placed in an ice bath and spiked with a mixture of 9-¹⁵NO₂-OA and 10-¹⁵NO₂-OA as specified in the respective studies, mixed by vortexing, and allowed to condition for 30 min in the ice bath (Fig. 1). Then, plasma samples were acidified to pH 5 by using 20 vol% acetic acid (HAc). Substances were extracted by solvent extraction with ethyl acetate (750 μL) by vortex-mixing for 2 min (Fig. 1, procedure B). After centrifugation (4,240 × *g*, 4°C, 5 min) the upper ethyl acetate phase (600 μL) was decanted and dried over anhydrous Na₂SO₄, and the solvent was evaporated under a stream of nitrogen. The residue was reconstituted in molsieve-dried acetonitrile (MeCN, 100 μL) and methanol (MeOH, 10 μL), and fatty acid pentafluorobenzyl (PFB) esters were prepared using PFB-Br (30 vol% in MeCN) as the derivatization agent and *N*-ethyl-diisopropylamine as the catalyst [13]. After incubation for 60 min at 30°C, solvents and reagents were evaporated to dryness under nitrogen and the residue was reconstituted in toluene (50 μL) from which 1-μL aliquots were injected into the GC–MS/MS instrument in the splitless mode by means of the autosampler.

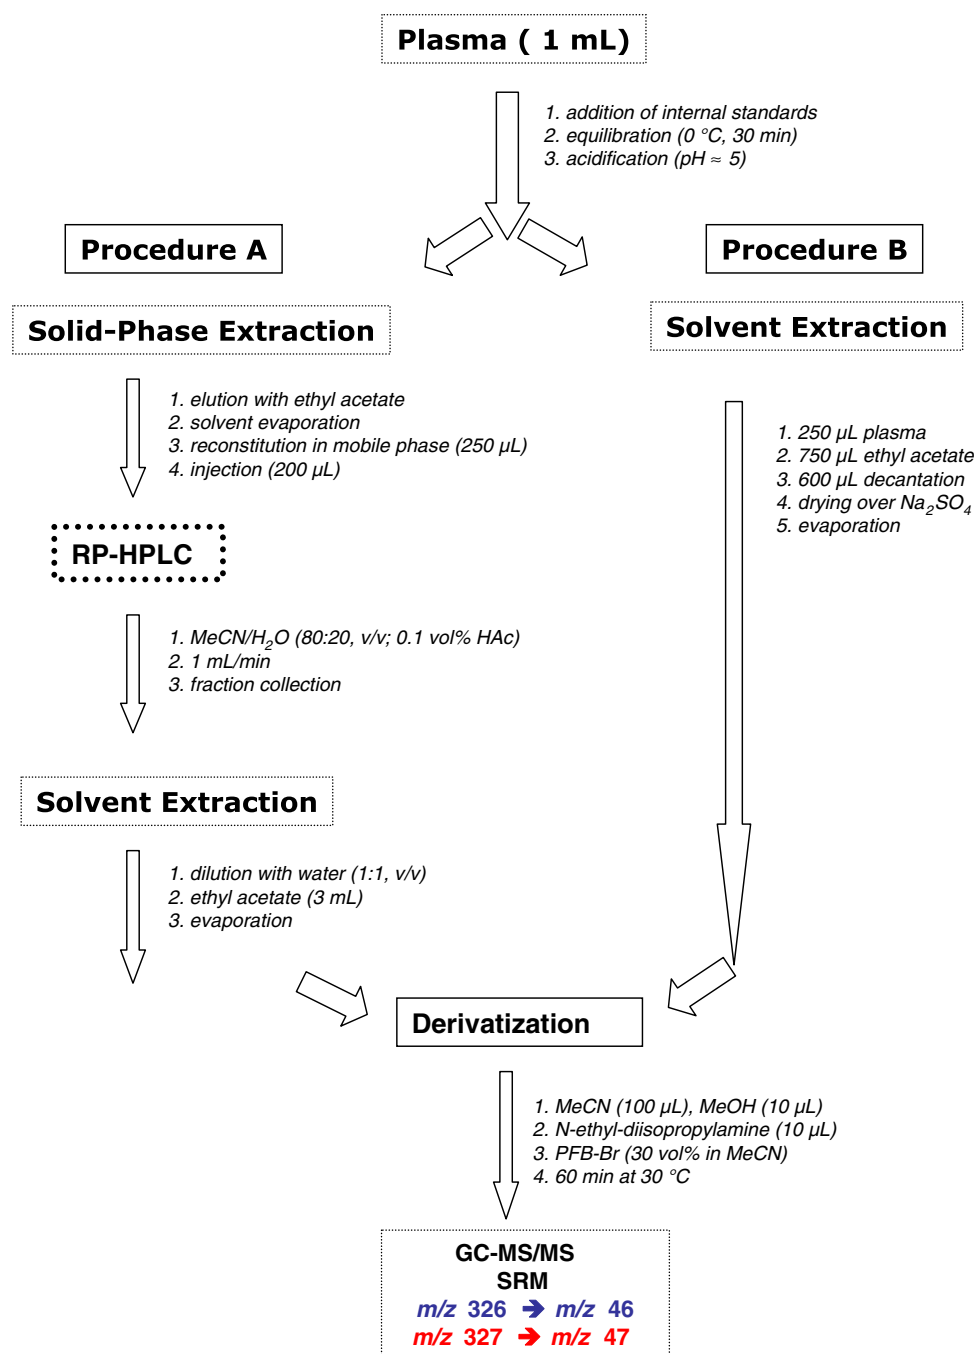

HPLC Conditions

HPLC with ultraviolet (UV) absorbance detection at 263 nm was carried out on a Summit apparatus from Dionex (Idstein, Germany) as described elsewhere [13]. A Nucleodur C18 Gravity column (250 mm × 4.6 mm i.d., 5 μm particle size) from Macherey-Nagel (Düren, Germany) was used. The mobile phase was 80 vol% MeCN and 0.1 vol% acetic acid and was pumped at a flow rate of 1 mL/min.

GC–MS/MS Conditions

The GC–MS/MS conditions used in the present study were essentially the same as described elsewhere [13]. Analyses were carried out on a triple-stage quadrupole (TSQ)

Fig. 1 Schematic of the GC–MS/MS method for the quantification of free 9- and 10-nitro-oleic acid (9-NO₂-OA and 10-NO₂-OA) in human plasma. In procedure A (*left panel*), SPE and HPLC are used [13]. Procedure B was used in the present work to measure nitro-oleic acid in human plasma. *HAc* acetic acid

ThermoQuest TSQ 7000 mass spectrometer (Finnigan MAT, San Jose, CA, USA) directly interfaced with a Trace 2000 series gas chromatograph equipped with an autosampler AS 2000 and a BEST programmable temperature vaporizer (PTV) injector (CE Instruments, Austin, TX, USA). A 15-m-long fused-silica DB-5ht capillary column (0.25 mm i.d., 0.25-μm film thickness) from Agilent (Santa Clara, CA, USA) was used. The following oven temperature program was used with helium as the carrier gas at constant flow rate of 1 mL/min: 1 min at 90°C, then increased to 225°C and 320°C at a rate of 15°C/min and

30°C/min, respectively. Interface and ion source were kept at 280°C and 180°C, respectively.

In quantitative analyses, sample injection was performed by PTV starting at an injector temperature of 70°C, which was increased to 280°C at 10°C/s. Electron energy and electron current were set to 200 eV and 300 μA, respectively. Methane (530 Pa) and argon (0.13 Pa collision pressure) were used as reagent and collision gas, respectively. The collision energy was 15 eV. Quantification was performed by selected reaction monitoring (SRM) of the product ions *m/z* 46 ([¹⁴NO₂]⁻) and *m/z* 47

($[^{15}\text{NO}_2]^-$) produced by collision-induced dissociation (CID) of the parent ions $[\text{M}-\text{PFB}]^-$ at m/z 326 and m/z 327 for endogenous nitro-oleic acids and the internal standards, respectively. The dwell time was 100 ms for each mass transition.

Results

Intra-assay Precision and Accuracy of the Method

Intra-assay imprecision (relative standard deviation, RSD, %) and accuracy (recovery, %) were determined by analyzing in duplicate 9-NO₂-OA and 10-NO₂-OA in human plasma before and after their addition at 300, 900, and 3,000 pM each. The results from the intra-assay validation are summarized in Table 1. Figure 2 shows chromatograms from the GC–MS/MS analysis (procedure B) of the plasma sample before and after addition of 300 pM of 9-NO₂-OA or 10-NO₂-OA. The respective basal concentrations of 9-NO₂-OA and 10-NO₂-OA in the plasma used to validate the method was determined to be 102 and 205 pM.

Basal Plasma Concentrations of 9-NO₂-OA and 10-NO₂-OA in Healthy Humans

The results from the quantitative analysis of 9-NO₂-OA and 10-NO₂-OA in plasma samples of 15 healthy subjects by GC–MS/MS without preceding HPLC separation, i.e., by using procedure B, are summarized in Table 2. The results previously obtained by analyzing the same plasma samples by using procedure A that includes HPLC separation [13] (Fig. 1) are also presented in Table 2 for comparison. The samples in the present study were worked up and analyzed within a single run. The quality of these analyses was evaluated by co-processing four 250- μL aliquots of a pooled plasma which served as a quality control (QC). In both the 15 study plasma samples and the

QC plasma sample analyzed by the present method we identified the two isomers of nitro-oleic acid, i.e., 9-NO₂-OA and 10-NO₂-OA. The concentration of 9-NO₂-OA and 10-NO₂-OA in the QC plasma sample was determined to be 288 ± 11 and 334 ± 40 pM with an intra-assay precision (RSD) of about 4% and 12%, respectively, indicating satisfactory analytical precision.

Representative chromatograms from the GC–MS/MS analysis of 9-NO₂-OA and 10-NO₂-OA in two aliquots of the same plasma sample worked up by the two procedures (Fig. 1) are shown in Fig. 3. These GC–MS/MS chromatograms clearly show how effective the HPLC step is from the analytical point of view. HPLC analysis of the ethyl acetate eluate from the SPE step of procedure A: (1) separates potentially interfering substances co-extracted from plasma, (2) improves the gas chromatography of the PFB ester derivatives of the isomeric 9-NO₂-OA and 10-NO₂-OA, and (3) enhances the sensitivity of the method by improving the signal-to-noise (S/N) ratio as compared with the rather rough and not further purified extract from solvent extraction of the plasma sample in procedure B. To quantitate this effect we used the S/N ratios observed for the internal standards 9-¹⁵NO₂-OA and 10-¹⁵NO₂-OA. Without the HPLC step the mean S/N ratio was determined to be 667:1 (RSD, 8.7%) for 9-¹⁵NO₂-OA and 949:1 (RSD, 15%) for 10-¹⁵NO₂-OA. With the use of the HPLC step the mean S/N ratio was determined to be 25,400:1 (RSD, 57%) for 9-¹⁵NO₂-OA and 28,000:1 (RSD, 58%) for 10-¹⁵NO₂-OA. Considering the spike of 40 pmol of 9-¹⁵NO₂-OA or 10-¹⁵NO₂-OA in procedure A with HPLC (1 mL plasma) and 6.25 pmol of 9-¹⁵NO₂-OA or 10-¹⁵NO₂-OA in procedure B without HPLC (0.25 mL plasma) (Fig. 1), it is calculated that the internal standards were analyzed with about five to six times more sensitivity when the HPLC step was implemented. Presumably, this factor also applies to the endogenous 9-NO₂-OA and 10-NO₂-OA (Fig. 3).

Incorporation of the HPLC step into the method always provided symmetric GC peaks of very similar peak areas

Table 1 Intra-assay imprecision (RSD, %) and accuracy (recovery, %) of the GC–MS/MS method for 9-NO₂-OA and 10-NO₂-OA in human plasma without the use of HPLC

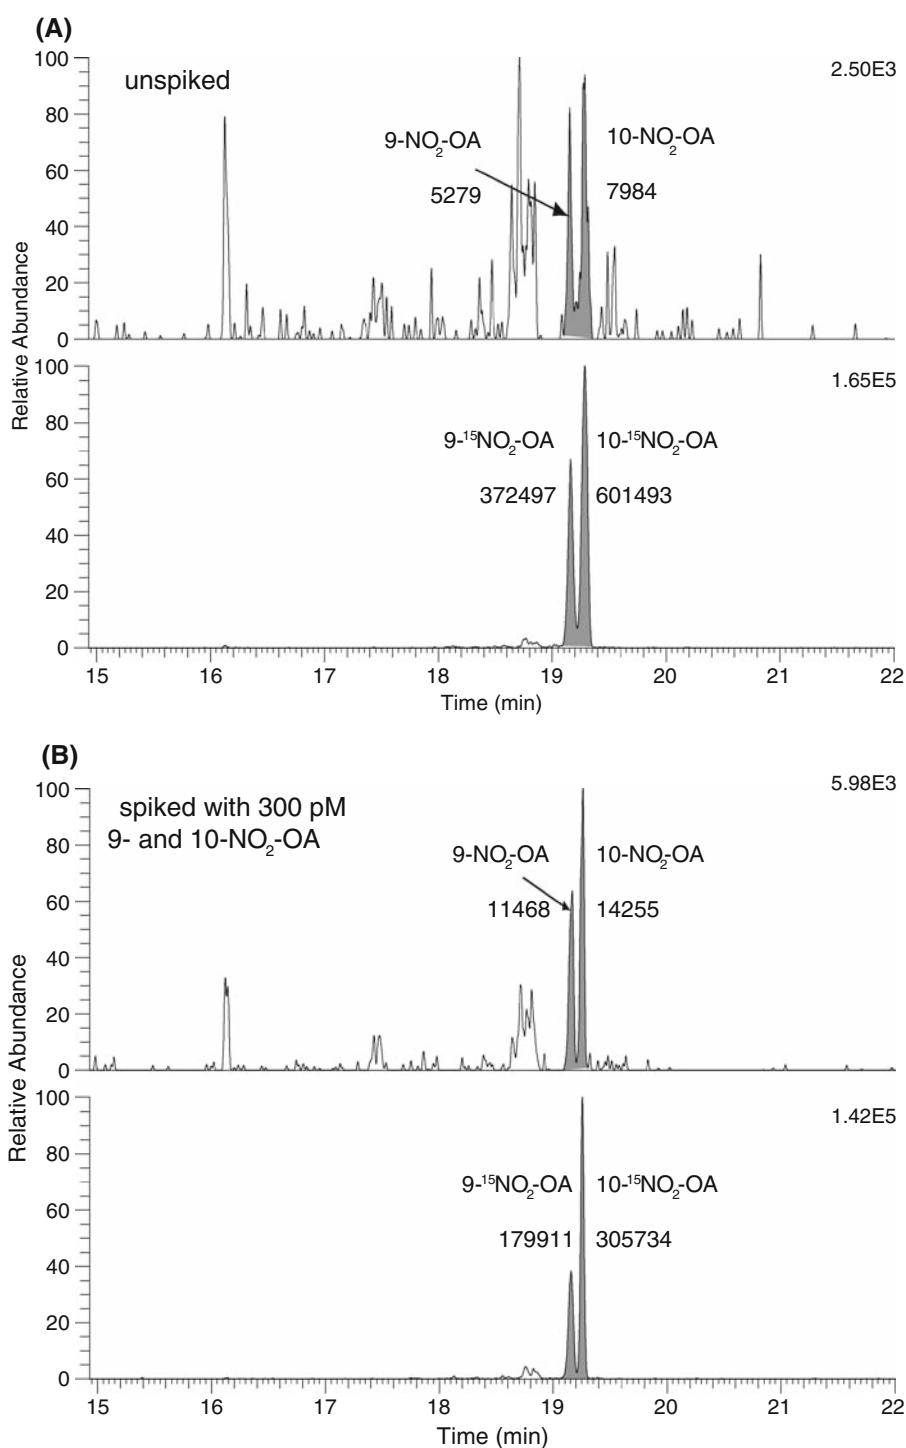

Added (pM)	Measured (pM) ^a		Imprecision (%)		Recovery (%) ^b

^a The internal standards 9-¹⁵NO₂-OA and 10-¹⁵NO₂-OA were used at final concentrations of 6,400 and 19,500 pM, respectively. Data are presented as mean ± standard deviation from duplicate analyses

^b Recovery was calculated by using the formula: recovery = [(measured concentration – basal concentration)/added concentration] × 100

Fig. 2 Partial chromatograms from simultaneous quantitative GC–MS/MS analysis of 9-NO₂-OA and 10-NO₂-OA in a plasma sample from a healthy volunteer using procedure B (no use of HPLC) before (a) and after (b) addition of 300 pM of 9-NO₂-OA or 10-NO₂-OA. ¹⁵N-Labeled 9- and 10-nitro-oleic acid were used as the internal standards at final added plasma concentrations of 6.37 and 19.5 nM, respectively. SRM of *m/z* 46 and *m/z* 47 produced by CID of the parent ions at *m/z* 326 for unlabeled 9-NO₂-OA and 10-NO₂-OA (*upper traces*) and *m/z* 327 for the internal standards (*lower traces*). Endogenous 9-NO₂-OA and 10-NO₂-OA and internal standards were analyzed as their PFB derivatives. The numbers beside the peaks provide the peak areas. The longer retention times of these derivatives in this figure as compared with those shown in Fig. 3 and reported in the *text* are due to the use of a new GC column. See also Fig. 1 and Table 1

and peak heights for both isomers (Fig. 3b). By contrast, omission of the HPLC step resulted in chromatographically considerably differing GC peaks, with the 9-NO₂-OA peak being always wider than that of 10-NO₂-OA (Fig. 3a). However, our analyses show that the internal standards 9-¹⁵NO₂-OA and 10-¹⁵NO₂-OA behave obviously identically to their endogenous analogs from the chromatography point of view, so that quantification of 9-NO₂-OA and

10-NO₂-OA extracted from plasma by ethyl acetate is possible with reasonable precision and accuracy nevertheless (see also Table 1). Thus, within the whole study group, 9-NO₂-OA and 10-NO₂-OA basal plasma concentrations were fairly close and of the order of 0.3 nM and their molar ratio was close to unity (Table 2). This order of magnitude is about 1,000 times lower than that reported initially by others for free, i.e., nonesterified, NO₂-OA [5].

^a Data from using procedure A are taken from a previous study of our group [13]. The concentration of the internal standards 9-¹⁵NO₂-OA and 10-¹⁵NO₂-OA was 50 nM in procedure A and 25 nM in procedure B

^b Molar ratio of 9-NO₂-OA to 10-NO₂-OA

Interestingly, the concentrations determined by the present method (procedure B, without HPLC) are consistently three times lower than those measured by procedure A utilizing the HPLC step (Table 2) [13]. Also, it is worth mentioning that the molar ratio of 9-NO₂-OA and 10-NO₂-OA varied considerably more in the procedure without HPLC as compared with that using the HPLC clean-up step, i.e., by 20.4% versus 8.3% (RSD). Another interesting and unexpected finding of the present study is that there was no correlation between 9-NO₂-OA and 10-NO₂-OA when they were quantitated without preceding HPLC separation, in contrast to the procedure that uses the HPLC clean-up step (Fig. 4) [13].

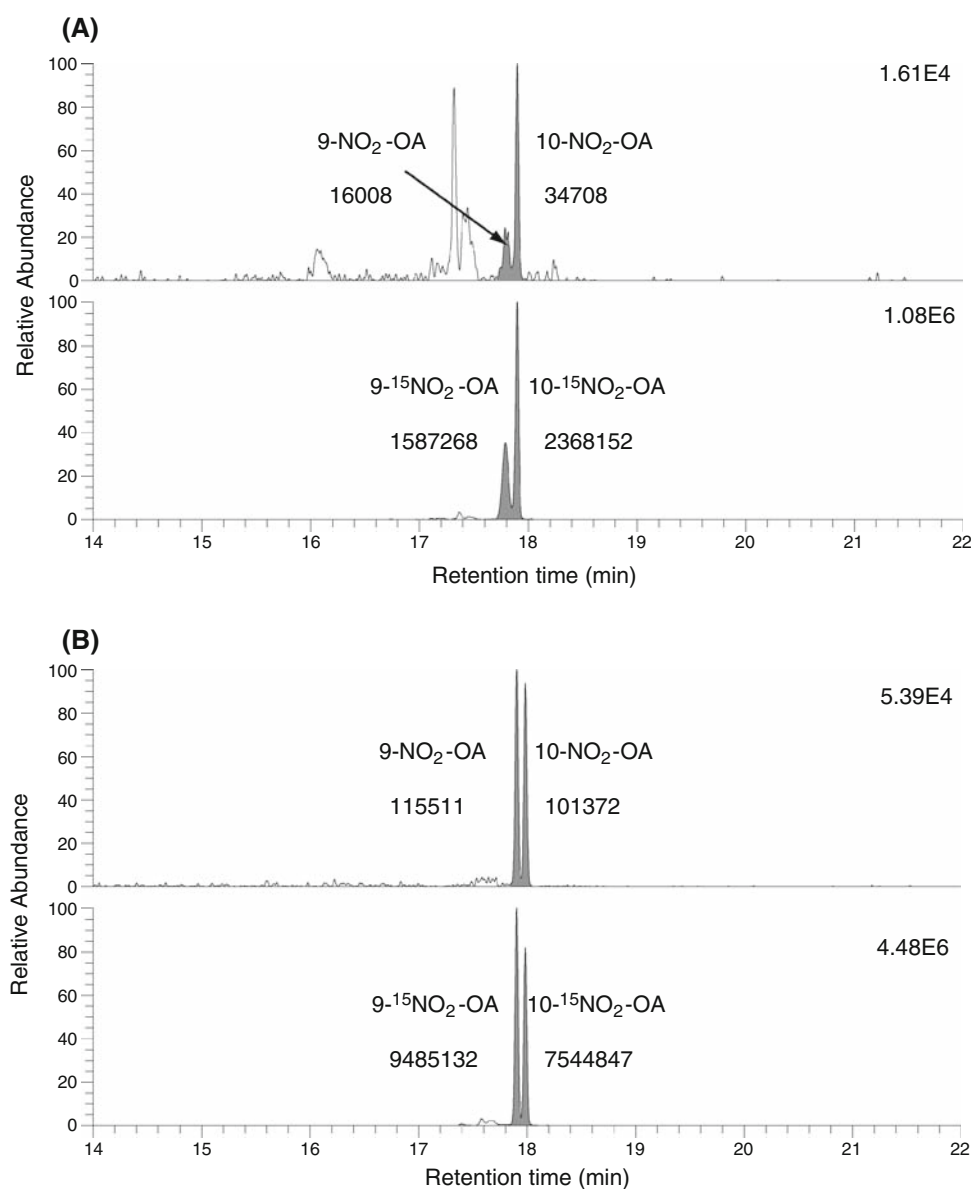

Nitro-lipidomics of Human Plasma

Leaving out the HPLC step after the extraction of plasma with water-immiscible organic solvents such as ethyl acetate as used in the present study allows performance of lipidomics studies on nitrated fatty acids in plasma. On the reasonable assumption that the PFB esters of the expected nitrated fatty acids undergo ionization to the parent ions [M–PFB][–] and that their CID fragmentation in GC–MS/MS occurs analogously to 9-NO₂-OA and 10-NO₂-OA and produces the common characteristic product ion nitrite at *m/z* 46 ([¹⁴NO₂][–]), we searched for the appearance of endogenous nitro metabolites of various unsaturated fatty acids in human plasma samples by SRM of the calculated mass are summarized in Table 3.

Figure 5 shows representative GC–MS/MS chromatograms from the nitro-lipidomics analysis of the PFB esters of nitro-fatty acids extracted by solvent extraction with

ethyl acetate from a plasma sample of a healthy subject. As expected, both endogenous nitro-oleic acid isomers and their externally added synthetic ¹⁵N-labeled analogs were identified on the basis of their retention time at 17.78 min for 9-NO₂-OA/9-¹⁵NO₂-OA and at 17.87 min for 10-NO₂-OA/10-¹⁵NO₂-OA. The tracing for nitro-arachidonic acid is very poor in peaks at relevant retention times and suggests that no nitro-arachidonic acid is endogenously present in the plasma sample analyzed. However, because the limits of detection (LOD) and limits of quantitation (LOQ) of the present method have not been determined for nitro-arachidonic acids, the physiological occurrence of nitro-arachidonic acids at concentrations below about 100 pM in human plasma cannot be excluded. This may also apply to nitro-linolenic acid and nitro-palmitoleic acid, the PFB esters of which are expected to elute in front of the nitro-oleic acid derivatives (Table 3). With regard to nitro-linoleic acid we obtained two groups of peaks, of which only the earlier-eluting group at about 16.5 min and 16.7 min deserves consideration, because the PFB esters of nitro-linoleic acids are expected to elute in front of the PFB esters of nitro-oleic acids. These findings are supportive of the physiological occurrence of nitro-linoleic acid in plasma of healthy humans at concentrations presumably not higher than those of the nitro-oleic acids. Nitro-linoleic acid concentrations of the order of 300 pM would be greatly contradictory to previous reports on the physiological occurrence of nitro-linoleic acid in human plasma at about 80 nM for the free form and 550 nM for the esterified form [2]. However, unequivocal identification and quantification of nitro-linoleic acids and other nitro-fatty

Fig. 3 Partial chromatograms from simultaneous quantitative GC–MS/MS analysis of 9-NO₂-OA and 10-NO₂-OA in the same plasma sample from a healthy volunteer. **(a)** Procedure B (no use of HPLC) was applied as described in the present work. **(b)** Procedure A (use of HPLC) was applied as described elsewhere [13]. ¹⁵N-labeled 9- and 10-nitro-oleic acid were used as the internal standards (50 nM each in procedure A, and 25 nM each in procedure B). SRM of *m/z* 46 and *m/z* 47 produced by CID of the parent ions at *m/z* 326 for unlabeled 9- and 10-nitro-oleic acid (*upper traces*) and *m/z* 327 for ¹⁵N-labeled 9- and 10-nitro-oleic acid (*lower traces*). 9-NO₂-OA and 10-NO₂-OA and internal standards were analyzed as their PFB derivatives. The numbers beside the peaks provide the peak areas. See also Figs. 1 and 2

acids in human plasma require use of well-characterized stable-isotope-labeled internal standards and preceding separation by HPLC, as described by us for the nitro-oleic acid isomers [13].

Discussion

First publications on nitro-fatty acids reported physiological occurrence of nitro-oleic acid in human plasma at concentrations of the order of 600 nM [5]. Based on our experience on quantitative analysis of nitrated biomolecules and fatty acids, a plasma concentration of 600 nM for nitro-oleic acid in healthy humans appeared to us as very high. Our first goal was, therefore, to develop a GC–MS/MS method for the unequivocal identification and accurate

quantification of nitro-oleic acid in human plasma. This goal was achieved by incorporating a HPLC step for the isolation of two expectable nitro-oleic acid isomers, i.e., 9-NO₂-OA and 10-NO₂-OA. After adequate validation we applied the method to determine their concentration in plasma of 15 healthy subjects in the basal state. This method, i.e., procedure A in Fig. 1, revealed mean plasma concentrations of 880 pM for 9-NO₂-OA and 940 pM for 10-NO₂-OA, which are almost three orders of magnitude lower than that initially reported by others [5]. In consideration of this discrepancy we performed additional studies to verify our initial findings and to examine whether the HPLC step might have led to loss of nitro-oleic acid despite the use of synthetic ¹⁵N-labeled analogs as internal standards. Expectedly, this quite “rough” method, i.e., procedure B in Fig. 1, provided analyses at considerably lower

Fig. 4 Relationship between 9-NO₂-OA and 10-NO₂-OA in plasma of 15 healthy volunteers as measured by GC–MS/MS using two different procedures. This figure was constructed with data generated in the present work (i.e., procedure B, without use of HPLC) and with those previously reported by our group (i.e., procedure A, with use of HPLC) [13]

S/N values and poorer chromatography (Figs. 2, 3) due to co-extracted “background,” but allowed quantification with satisfactory precision and accuracy, as reported in the present work. These analyses provided even lower concentrations than the method using HPLC separation [13], presumably as a result of suboptimum gas chromatography. On the other hand, an advantage of leaving out the HPLC step in the GC–MS/MS method for nitro-fatty acids is that the sample obtained is suitable for rather qualitative lipidomics studies. Technological advancements in mass chromatography and improvements in chromatographic techniques in the area of lipidomics research and biomarker discovery have been recently reviewed [15].

Figures 2, 3, and 5 and Table 1 clearly indicate that renunciation of the HPLC step in nitro-fatty acid

quantification by GC–MS/MS is not recommended due to deterioration of the analytical performance, notably in terms of loss of accuracy, precision, and sensitivity. This especially applies to 10-NO₂-OA, which can be measured by GC–MS/MS using procedure B with acceptable accuracy in human plasma only if present at the very high concentration of 3,000 pM, which is about 15 times higher than its putative basal concentration (Table 1). In addition, use of “rough” yellow-colored ethyl acetate extracts for “shotgun” GC–MS/MS would inevitably require much more frequent need for maintenance of the whole GC–MS/MS apparatus, unlike the “pure” colorless HPLC fractions provided by procedure A.

Because the ethyl acetate extract of human plasma in procedure A contains many more compounds than the ethyl acetate extract of the HPLC fraction in procedure B, it is likely that some of the co-extracted compounds aggravate the gas chromatography of the PFB ester derivatives of 9-NO₂-OA and 10-NO₂-OA, as can be seen in Figs. 3–5. The presence of a much higher number of analytes in the ethyl acetate fraction in procedure B enhances the baseline, so that the S/N ratio decreases and consequently the LOD and LOQ values of the method increase. In LC–MS/MS, ion suppression and ion enhancement effects are very well recognized and investigated, and methods have been developed for their identification, quantification, and exclusion or minimization [16, 17]. Theoretically, such effects may also have occurred in our GC–MS/MS method for nitro-oleic acid using procedure B, but to a much lesser degree using procedure A (with HPLC). Use of stable-isotope-labeled analogs may attenuate such effects. However, because we used the internal standards 9-¹⁵N-NO₂-OA and 10-¹⁵N-NO₂-OA in high molar excess over their endogenous counterparts (about 80-fold), it may be that their high concentration was suboptimal, unlike in procedure A in which the molar excess was about 60-fold [13]. In addition, during gas chromatography, *trans*-nitration may occur [18]. Together with the use of high molar excess of the internal standards over the endogenous nitro-oleic acids and with the presence of numerous other compounds in the ethyl

Table 3 Calculated mass-spectrometry-related data for pentafluorobenzyl (PFB) esters of putative vinylic nitro-fatty acids from major unsaturated fatty acids

Parent fatty acid	Molecular mass	Putative nitro-fatty acid	Molecular mass	[M–PFB] [–]	Mass transition (<i>m/z</i> → <i>m/z</i>)	Relative retention time
Palmitoleic acid	254.4	Nitro-palmitoleic acid	299.4	298.4	298.4 → 46.0	<1.0
Linoleic acid	280.5	Nitro-linoleic acid	325.5	324.5	324.5 → 46.0	<1.0
Linolenic acid	278.4	Nitro-linolenic acid	323.4	322.4	322.4 → 46.0	<1.0
Oleic acid	282.5	Nitro-oleic acid	327.5	326.5	326.5 → 46.0	1.0
Oleic acid	282.5	[¹⁵ N]-Nitro-oleic acid	328.5	327.5	327.5 → 47.0	≈ 1.0
Arachidonic acid	304.5	Nitro-arachidonic acid	349.5	348.5	348.5 → 46.0	>1.0

Fig. 5 Representative partial chromatograms from targeted nitro-lipidomics GC–MS/MS analysis of a plasma sample from a healthy subject. 9-NO₂-OA and 10-NO₂-OA, their internal standards added to plasma (at 25 nM each), and other putative nitro-fatty acids were analyzed using procedure B (Fig. 1). The mass transitions monitored are summarized in Table 3. A dwell time of 100 ms was used for each mass transition

acetate extract of procedure B, these unfavorable circumstances may have resulted in lower 9-NO₂-OA and 10-NO₂-OA concentrations in plasma as compared with procedure A involving the HPLC step. In consideration of the potential importance of matrix effects and ion suppression/enhancement in GC-based methods, these phenomena deserve thorough investigation.

Our previous study [13] and the present work suggest that presumably nitro-oleic acid is the most abundant nitrated unsaturated fatty acid in human plasma. It occurs as two isomers with basal plasma concentrations in the pM range. With regard to other nitrated fatty acids our present study only allows a rough estimation of their concentration in human plasma. Thus, nitro-linoleic acid seems to occur physiologically at concentrations in the lower pM range. On the other hand, nitro-linolenic acid and nitro-arachidonic acid, i.e., the nitro-derivatives of higher unsaturated fatty acids, are to be expected at much lower concentrations in plasma of healthy humans. Validated GC–MS/MS methods and use of stable-isotope-labeled analogs of these nitro-fatty acids are required for accurate determination of their basal concentrations in human plasma.

Endogenous nitrated fatty acids, first and foremost nitro-oleic acid, have been proposed as a new class of cell-signaling molecules, storage and transport forms of NO bioactivity within the vasculature, and anti-inflammatory

mediators [2–7, 10]. Presumably, the basis for these proposals has been the finding by LC–MS/MS that the sum of nitro-fatty acids and their esterified forms occur at concentrations of the order of almost 1,000 nM in human blood [2, 5]. These reports have initiated much scientific work in the field of NO research. However, the findings of our group (present study and [13]) and the results reported in a recent paper [14] challenge the originally reported concentrations of nitro-fatty acids [2, 5].

As discussed by us recently [13], the reasons for this discrepancy and for the inability of Freeman's group to confirm originally reported concentrations for nitro-oleic acid and other nitro-fatty acids are unknown at present. The analytical performance of the LC–MS/MS method originally used for quantitative analyses has not been described adequately [5]. Thus, from the quantitative perspective the reliability of the LC–MS/MS method used in previous studies cannot be properly evaluated. Theoretically, differences may also be due to the different species investigated, i.e., mouse [5] versus human (present study and [13]). However, given the fair comparability between mouse and human with regard to fatty acid [19] composition and quantity in blood and urine, as well as to the nitric oxide (NO) pathway [20], it is unlikely that species differences may account for a three-order-of-magnitude discrepancy. Indeed, pointing out the discrepancies between

initial and recent reports, Rudolph et al. discussed in their recent paper that “We and others have detected nitro-oleate in rodents and humans in other instances, as well as metabolites reported herein” [14]. Unlike other nitrosated and nitrated biomolecules such as *S*-nitrosothiols [21] and 3-nitrotyrosine [22, 23], artifactual formation of nitro-fatty acids is unlikely [13]. We can therefore only hypothesize that mainly analytical factors, such as lack of specificity of the LC–MS/MS method used, have resulted in severe artefacts. The large discrepancy and the inadequate description of the analytical performance of the LC–MS/MS method used in previous studies [2, 5] underscore the pressing need for validation of analytical methods and reporting of their analytical performance in detail prior to their use in quantitative analyses. The discrepancy seen in reported nitro-fatty acid plasma concentrations emphasizes the observation that the L-arginine/NO area of research is highly susceptible to analytical difficulties [24].

Freeman and co-workers have recently provided the following two explanations for their failure to detect nitro-oleic acid unlike in their previous studies [14, 25]: (1) “The initial report of ~500 nM nitro-oleate in human plasma (1) is now viewed to be higher than current measurements, with the original value complicated by non-covalent complexes of nitrite and oleate.”; and (2) “These previous estimates of free and esterified *cis*-nitroalkenes derivatives are now viewed to be overestimated in concentration due to electrophilic adduction of biological nucleophiles [100] and the co-elution of an isobaric molecule that is not covalently nitrated.¹”. These explanations are not clear and not likely from the chemical and analytical point of view, in our opinion, and deserve clarification.

Very recently, Schopfer et al. reported that nitro-oleic acid forms protein adducts, with endogenous protein-adducted nitro-oleic acid being, however, not detectable in plasma of untreated mice as measured by LC–MS/MS [25]. This finding argues against the assumption that “electrophilic adduction of biological nucleophiles” might have interfered [26]. Furthermore, this finding suggests that the fraction of non-protein-adducted nitro-oleic acid should be considered rather minor due to the rather inert vinyl functionality of nitro-oleic acid against nucleophiles such as sulfhydryl groups. For example, the cyclopentenone ring of prostaglandins such as 15-deoxy-prostaglandin J₂ (15-d-PGJ₂) is highly reactive towards nucleophiles, so that the non-protein-adducted and nonconjugated forms are practically not detectable in human plasma and urine (≤ 150 pM) as measured by us using GC–MS/MS (unpublished results). As stated above for nonadducted nitro-fatty acids, it may also be concluded for adducts of nitro-fatty acids that analytical methods need to be validated and proven prior to their use in quantitative analyses of such adducts which require additional analytical steps.

So far, there are no *in vivo* studies to indicate any involvement of endogenous nitro-fatty acids such as nitro-oleic acid in physiology and pathology based on the use of reportedly really reliable analytical quantitative methods. In consideration of the likely analytical inadequacy one may also question results generated by the same LC–MS/MS method [14, 26], which is now assumed to be not free of artefacts. Also, biological effects seen in association with nitro-fatty acids, such as anti-inflammatory actions and NO signaling, originate from the use of synthetic nitro-fatty acids at extraordinarily high concentrations [26] compared with their basal plasma concentrations. In this context, it is worth mentioning that nitro-arachidonic acid had to be used at concentrations of 1,000–5,000 nM in order to achieve any appreciable biological response [10, 27]. Presumably, and on a rather conservative basis, the concentration of nitro-arachidonic acid used *in vitro* is 10,000–50,000 times higher than the concentration of endogenous nitro-arachidonic acids in tissue. This may equally apply to nitro-oleic acid and nitro-linoleic acid [28–30]. Such concentrations are most likely beyond any pathophysiological relevance. With regard to a potential pharmacological relevance of nitro-fatty acids several factors need to be considered, including their rather very low potency, for instance regarding NO-dependent vasorelaxation, their rapid and extensive metabolism [14], and presumably their very high protein binding. In synergy, these factors may make mandatory the administration of very high doses with the potential risk of severe adverse effects.

To conclude, in view of the possibly lacking occurrence of nitro-arachidonic acid and nitro-linolenic acid and of the most likely pM concentrations of the simply unsaturated nitro-oleic acid in human blood, the physiology, pathology, and pharmacological potential of nitro-fatty acids demand thorough revision and consideration of the new analytical facts (present study and [13, 14]). Reliable, thoroughly validated, and adequately reported analytical methods are required and are the key to achieving reliable scientific results and to progress.

Abstract Gangliosides are a large family of glycosphingolipids that are abundant in the brain, and have been shown to affect neuronal plasticity during development, adulthood, and aging. We developed a fast, efficient, and sensitive liquid chromatography–mass spectrometry method to quantify eight different classes of gangliosides (GM₁, GM₂, GM₃, GD₃, GD_{1a}, GD_{1b}, GT_{1b}, GQ_{1b}) in the brains of 2-day-old and 80-day-old Wistar rats. The gangliosides were extracted from rat brain using a modified Svennerholm and Fredman method. After ganglioside class separation using a hydrophilic high performance liquid chromatography (HPLC) column, the resolving power of the LTQ-OrbitrapTM mass spectrometer was used to extract and sum the major species of each ganglioside class, generating fully resolved extracted ion current peaks for both standards and samples. The flexibility and the specificity of this method are such that it can be applied to the analysis of other ganglioside species/classes not discussed in this paper, provided appropriate standards are available. The method had good repeatability (coefficient of variation 4.8–12.3%) and mean recoveries in the range 92–107%.

Introduction

Gangliosides, a large family of complex lipids that are abundant in the brain, have been shown to affect neuronal plasticity during development, adulthood, and aging and are considered to be possible therapeutics [1–3]. Gangliosides in human milk and infant milk formula are considered to be bioactive components in human infant nutrition and have an important role during early infancy, modifying the intestinal microflora and promoting the development of intestinal immunity in the neonate [4].

Thin layer chromatography (TLC) coupled with densitometry detection [5, 6] and high performance liquid chromatography (HPLC) [7–12] methods have traditionally been used to measure ganglioside levels in tissues.

More recently, liquid chromatography–mass spectrometry (LC–MS) methods have been used for the quantification of selected gangliosides. LC–MS offers improved sensitivity and selectivity over the more traditional TLC and HPLC methods for ganglioside detection. For example, Sorensen [13] used an LC–electrospray tandem MS method (LC–MS/MS) for the quantification of two ganglioside classes (GM₃ and GD₃) in bovine milk and in infant formulae using a standard addition technique. Gu et al. [14]

used an LC–MS/MS method for the quantification of a single species of both GM₁ and GM₂ in cerebrospinal fluid, using isotope dilution techniques. Sommer et al. [15] also used an LC–MS method to measure four gangliosides (GM₃, GM_{1a}, GD_{1a}, and GT_{1b}) in human lipoprotein lipids. Quantification was based on the signal area of single ion chromatograms at the appropriate retention time.

In this study, we used the resolving power of an LTQ–OrbitrapTM mass spectrometer to extract and sum the major ganglioside species [16, 17] present within eight classes of ganglioside (GM₁, GM₂, GM₃, GD₃, GD_{1a}, GD_{1b}, GT_{1b}, and GQ_{1b}) in order to quantitatively determine the amount of these ganglioside classes present in rat brain samples. The advantage of this LC–MS method is its ability to measure eight individual ganglioside classes simultaneously and to give detail on the relative proportions of the molecular species present within each ganglioside class.

The described method was used to compare the ganglioside composition in the brains of 2-day-old and 80-day-old rats. Although a large number of gangliosides are present in rat brain, many are minor. The eight classes were chosen for analysis by LC–MS, based on the reported abundance [18] and the availability of commercial standards.

Experimental Procedure

Standards and Chemicals

Ganglioside standards were obtained from Matreya, LLC (Pleasant Gap, PA). All solvents used were of LC grade (Merck, Darmstadt, Germany), except for chloroform which was analytical grade (ethanol stabilized).

Sample Preparation

Rat brains were obtained from 2-day-old and 80-day-old Wistar rats. The brain lipids were extracted using a modified Svennerholm and Fredman extraction protocol [19]. This method was used to remove the phospholipids present in the tissue, as we found that the presence of high levels of phospholipids in the extract suppresses ionization of the gangliosides.

Briefly, the left hemisphere of rat brain was homogenized in 3 ml of water for 1–2 min in an ice bath using an ultrasonicator probe. A portion of the rat brain homogenate (0.5 ml) was weighed into a 10-ml Kimax tube. Water (0.5 ml) was added to the homogenate, followed by methanol (2.7 ml) and chloroform (1.35 ml) at room temperature. The mixture was allowed to rock gently for 30 min on a rocker before centrifugation at 2,000g for 30 min. The supernatant was transferred to a 15-ml Kimax

tube and the pellet was re-extracted using water (0.5 ml) and chloroform/methanol (1:2, 2 ml). After mixing and centrifugation (30 min at 2,000g), the supernatants were pooled and the pellet was discarded. Solvent partition of the supernatant was achieved by the addition of water (1.3 ml) and gentle inversion three to four times, followed by centrifugation (2,000g for 30 min). The upper phase was transferred to a 10-ml volumetric flask. KCl (0.01 M, 0.5 ml) was added to the remaining lower phase and any interfacial fluff (minimal) and was centrifuged (2,000g, 20 min). The upper phase was pooled into the 10-ml volumetric flask without disturbing any interfacial fluff, and the flask was made up to the mark with methanol (50%). The upper phase was used for ganglioside analysis.

Standard Preparation

Ganglioside stock standards [GM₁ (bovine brain), GM₂ (human brain), GM₃ (bovine buttermilk), GD_{1a} (bovine brain), GD_{1b} (bovine brain), GD₃ (bovine buttermilk), GT_{1b} (bovine brain), and GQ_{1b} (bovine brain)] were obtained from Matreya, LLC (Pleasant Gap, PA) and were prepared at 1 mg/ml or 0.5 mg/ml in methanol (50%). An intermediate mixed standard solution was prepared from each stock solution into a 5-ml volumetric flask, and was serially diluted further in methanol (50%) to give a seven-point calibration curve (Fig. 1). All solutions were stored at –80 °C.

High Performance Liquid Chromatography

The HPLC analysis was performed on an Agilent 1100 series HPLC system (Santa Clara, CA) consisting of a quaternary pump, binary pump, degasser, column heater (60 °C), and refrigerated auto-sampler (5 °C). Samples or standards (10 µl) were initially loaded (0.5 ml/min; 50%

Fig. 1 Ganglioside calibration curve. The correlation coefficient r for every ganglioside is >0.9 . Amount (ng) refers to the ng of each ganglioside loaded onto the HPLC column

Table 1 HPLC mobile phase solvent gradient for separation of the gangliosides

Time (min)	Trap valve position	A (%)	B (%)	C (%)
0	Waste	95	5	0

25		95	5	0

Solvent A consisted of acetonitrile (100%), solvent B consisted of 50:50 acetonitrile/50 mM ammonium acetate buffer, pH 5.6, and solvent C consisted of 50:50 methanol/water. The flow rate was 0.5 ml/min

methanol) on to a wide pore, reversed-phase trap (C18, 4 mm × 2.0 mm, 5 μm, Phenomenex, CA) for pre-concentration/desalting. After 8 min, the trap was switched in-line with an APS-2 hypersil hydrophilic column (150 mm × 2.1 mm, 3 μm, Thermo Electron Corporation, Waltham, MA) coupled to an APS-2 guard column (10 mm × 2.1 mm inner diameter). The gangliosides were separated with an acetonitrile/ammonium acetate buffer gradient as described in Table 1.

Mass Spectrometry

The eluate from the HPLC system was introduced into an LTQ-OrbitrapTM mass spectrometer (Thermo Electron Corporation, Waltham, MA) using an ESI probe inlet. Ions were generated and focused using an ESI voltage of −3,750 V, a sheath gas flow of 30 L/min, an auxiliary gas flow of 10 L/min, and a capillary temperature of 300 °C. MS data acquisition was carried out with the LTQ-OrbitrapTM mass spectrometer scanning in negative ion mode over 700–1,650 *m/z*, with a resolution of 30,000 @ 400 *m/z*. The system was calibrated with ganglioside standards obtained from Matreya, LLC (Pleasant Gap, PA) as described above. The HPLC run was diverted to waste for the first 9 min and after 18 min. The total run time was 25 min.

The resolving power of the LTQ-OrbitrapTM mass spectrometer was used to filter post analysis for known masses of ganglioside species present within each class of ganglioside measured. Three factors were considered when compiling our extract mass lists for filtering post analysis.

Sphingosine group and fatty acid side chains

The exact ganglioside masses extracted (including three carbon 13 isotopes) were based on sphingosine d18:1 and

d20:1, and dihydrosphingosine d18:0 with fatty acid side chains C16:0, C18:0, C18:1, C20:0, C21:0, C22:0, C23:0, and C24:0. These ganglioside species represent the major proportion of the ganglioside species present in rat brain [17, 20].

Sugar moiety

Only gangliosides containing *N*-acetylneuraminic acid (NANA), and not *N*-glycolylneuraminic acid (NGNA), were included in the mass list calculations, as these species make up the majority of gangliosides observed in rat brain [18].

Charge state

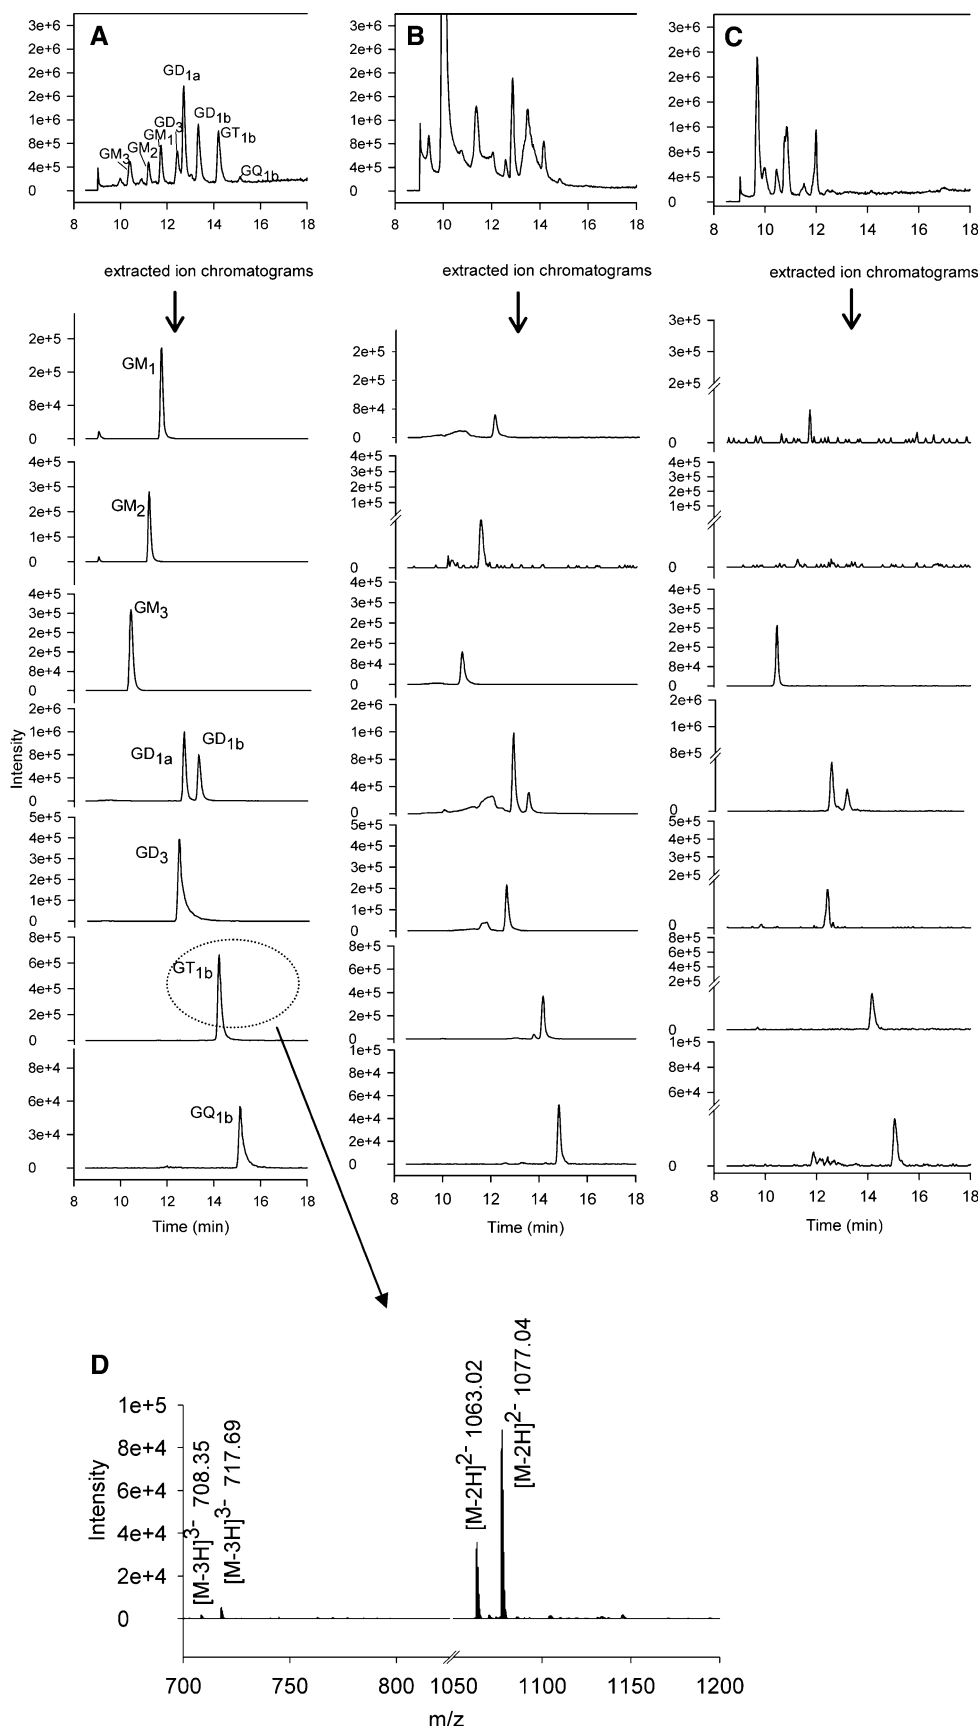

The number of NANA residues present on a ganglioside molecule determines the number of possible charge states that may be observed in the (electrospray) mass spectra of that ganglioside. Where more than one charge state existed for a given class of ganglioside, the charge state(s) observed in the greatest intensity were those used for compiling our mass lists. Figure 2d shows an extracted ion spectrum of calibration standard GT_{1b} displaying prominent species (most likely dC18:1/C18:0 and dC20:1/C18:0) in their −2 and −3 charge states [16]. The charge state(s) selected for each ganglioside class were as follows: (GM₁ [M−H][−], GM₂ [M−H][−], GM₃ [M−H][−], GD_{1a} [M−2H]^{2−}, GD_{1b} [M−2H]^{2−}, GD₃ [M−2H]^{2−}, GT_{1b} [M−2H]^{2−}, [M−3H]^{3−}, and GQ_{1b} [M−2H]^{2−}, [M−3H]^{3−}).

The excellent specificity of the method allowed us to use it confidently to quantify gangliosides in rat serum samples (extracted using the modified Svennerholm and Fredman extraction protocol where the serum samples were treated the same as homogenised brains), which have proportionally much lower levels of gangliosides than brain extracts (Fig. 2). The flexibility of this technique may also allow for quantification of other ganglioside species (e.g., NGNA-containing or *O*-acetylated gangliosides) or classes such as GM₄ that are present in tissue or serum samples and that are not discussed in this paper, provided that appropriate standards are available. Qualitative comparison using theoretical molecular masses could also be undertaken when standards are not available.

Accuracy and Repeatability

The accuracy and the repeatability of the method were evaluated by performing recovery studies, the between-day precision, and the within-day precision using an 80-day-old rat brain.

Fig. 2 Total ion current of the calibration mix (20 ng, **a**), rat brain extract (**b**), and rat serum (**c**) followed by the extracted ion chromatograms of each ganglioside class analyzed. The extracted ion spectrum of calibration standard GT_{1b} (**d**) shows the two dominant species present in the mix (most likely dC18:1/C18:0 ([M–2H]^{–2} 1063.02, [M–3H]^{–3} 708.35) and dC20:1/C18:0 ([M–2H]^{–2} 1077.04, [M–3H]^{–3} 717.69). The quantification of each class of ganglioside was carried out using the peak areas obtained from each extracted ion chromatogram

Results and Discussion

HPLC–MS

Figure 2 shows a separation of the gangliosides in a standard mixture, and in sample (rat brain and serum). We used a hydrophilic HPLC column because of its ability to separate gangliosides largely by sugar moiety or class, as opposed to reversed-phase columns which separate gangliosides largely by carbon number, leading to multiple peaks for each class of ganglioside [21]. It was important to condition the column before use to stabilize the retention time, particularly for GT_{1b} and GQ_{1b}. Conditioning was achieved by repeated injection of the standards and samples overnight. Adequate blanks were run prior to analysis to avoid any carryover issues.

Calibration Curve

The HPLC–MS method used an external standard to quantify the relative amounts of gangliosides present in rat brain. A typical calibration curve obtained by the method is given in Fig. 1. The linear calibration range used routinely in this study was up to 40 ng on-column but could be extended to twice that magnitude. The variation in response between different ganglioside classes observed in Fig. 1 may in part be explained by the size of the glycan portion of the ganglioside and the position of NANA on the ganglioside molecule, bound to the internal or terminal galactose. The possibility of NANA loss from the gangliosides due to front end collision induced dissociation (CID) causing this reduction in response was investigated. No fragments arising from the loss of NANA were observed in the spectra.

The current method was used to compare samples derived from the same sample matrix, i.e., 2-day-old and 80-day-old rat brains, and results were not corrected for any variation in ionization efficiencies of species within a given ganglioside class that may exist. Consequently the results may not be absolute. Variation in ionization efficiency has been corrected by the use of internal standards for the quantification of other classes of lipids, e.g., phospholipids [22–24]. The need for this correction for ganglioside analysis is currently being investigated in our laboratory.

Accuracy and Precision

Matrix Effects

The brain extracts were serially diluted and compared with their respective standard curves. Only GQ_{1b} showed any matrix effects; at high concentration, suppression of the

Fig. 3 Response of gangliosides in standards and sample (*control*) solutions. All gangliosides, except GQ_{1b}, showed the same response over the measured concentration range

response was observed at above approximately 20 ng loaded. Dilution of the extract to below 20 ng/10 μ l loaded was required to eliminate this matrix effect (Fig. 3). It is unclear what components in the matrix were affecting the GQ_{1b} response.

Spiked Recovery

Recovery experiments were conducted using homogenized rat brains spiked with a mixed ganglioside standard. The spiking solutions were measured into 10 ml Kimax tubes and were evaporated to near dryness under a stream of nitrogen at 25 °C. Homogenized brain (1 ml) or water (1 ml) was added and extraction proceeded as outlined previously. Given the nature of the method, solvent/solvent extraction, the recoveries (Table 2) were extremely good, ranging from 84 to 110%. Higher than 100% recovery can be explained by the coefficients of variance of the method measuring the endogenous gangliosides.

Method Repeatability

The repeatability of the method was calculated using the pooled standard deviation determined from 48 samples analyzed in duplicate across the control, low treatment, and

Table 2 Recovery (%) of gangliosides after spiking into a water blank and into rat brain homogenate

	GM ₁	GM ₂	GM ₃	GD ₃	GD _{1a}	GD _{1b}	GT _{1b}	GQ _{1b}
Water	95	95	102	90	93	89	No data	No data
	92	96	84	94	103	104		
Rat brain	94	94	96	103	96	92	101	94
	102	93	104	110	97	97		
	111	101	92		98	102		

Table 3 Repeatability percentage coefficient of variation (CV) for gangliosides, determined from the pooled standard deviation of 48 duplicate analyses of rat brain across the control, low treatment, and high treatment groups

Ganglioside	Mean ($\mu\text{g/g}$)	CV (%)
GM ₃	47.2	8.8
GM ₂	13.9	12.3
GM ₁	383.1	7.2
GD ₃	21.9	4.8
GD _{1a}	531.1	5.7
GD _{1b}	324.1	5.0
GT _{1b}	615.9	5.1
GQ _{1b}	814.9	6.0

high treatment groups. The coefficients of variation ranged from 4.8 to 12.3% (Table 3).

Limit of Detection (LOD) and Limit of Quantification (LOQ)

The LOD was estimated by loading decreasing amounts of ganglioside standard on to the HPLC–MS system until the peak was three times the noise level. The LOQ was estimated as three times the LOD. The LODs were determined to be 0.34, 0.08, 0.16, 0.09, 0.08, 0.16, 0.17, 0.84 and LOQs 1.00, 0.25, 0.50, 0.30, 0.25, 0.50, 0.50, 2.50 ng on column for GM₁, GM₂, GM₃, GD_{1a}, GD_{1b}, GD₃, GT_{1b} and GQ_{1b}, respectively. Sensitivity could be further improved by using a hydrophilic column with a smaller column diameter as they become available.

Gangliosides in the Brains of 2-Day-Old and 80-Day-Old Rats

The distributions of the individual ganglioside classes in 2-day-old and 80-day-old rat brains are shown in Fig. 4

Fig. 4 Ganglioside distribution in 2-day-old ($n = 22$) and 80-day-old ($n = 11$) rat brain

(as μg ganglioside/g brain (wet weight)) and Table 4 (as percentage of total ganglioside). Figure 4 shows an increase in the amount of ganglioside as the rat brain developed, consistent with results reported by Vanier et al. [25]. The substantial decrease in GQ_{1b} and the substantial increase in GT_{1b}, as a percentage of total ganglioside shown in Table 4, are consistent with trends outlined by Rosner et al. [26] as the rat brain ages, but disagree with those reported by Yu et al. [18], where the GQ_{1b} percentage of lipid-bound sialic acid (LBSA) remained the same and the GT_{1b} (percentage of LBSA) decreased with age. The gangliosides GM₁, GM₃ and GD_{1a} increase in concentration between the two ages (Fig. 4) as the concentration of total gangliosides increases. The significant rise in the percentage of GM₁ between the day 2 and day 80 tissues (Table 4) is consistent with both Rosner et al. [28] and Yu et al. [27] but GD_{1a} and GM₃ do not increase as a percentage of LBSA which is consistent with Yu et al. [18], but not Rosner et al. [26].

We compared our 2-day-old and 80-day-old rat brain ganglioside results (percentage ganglioside) with similar results (newborn and adult rat brain) reported by Yu et al. [27] (Table 4). Whereas the 80-day-old and adult rat brain analyses compared very well for all the measured ganglioside classes (Table 4), the 2-day-old and newborn rat brain analyses compared well for all ganglioside classes except GQ_{1b}, GD₃, and GT_{1b}. The difference in age between the newborn and the 2-day-old rat brain samples may go some way to explaining the discrepancies observed between the two sets of data, as, just after birth, the rat brain is developing rapidly [25]. The influence of the different methods of analysis, the strain of rat and the number of individuals sampled in this study and that of Yu et al. [27] may also help to explain the discrepancies between the results. Certainly, Rosner et al. [26] indicated a small increase in the relative concentration of GD₃ just after birth and there is also an increasing percentage of GT₁/GD_{1b}

Table 4 Ganglioside distribution in newborn and adult rats

	Molecular weight ^a	Lipid-bound sialic acid (%) Newborn ^b	Ganglioside (%)		Lipid-bound sialic acid (%) Adult ^b	Ganglioside (%)	
			Newborn ^c	2-day-old ^d		Adult ^c	80-day-old ^d
GM ₁	1,546.87	5.4	10	10	12.9	22	25
GM ₂	1,383.82	1	2	0	0.4	1	0

Comparison of results obtained from this study with those reported in the literature

^a The molecular weight of the most dominant ganglioside class species (dC18:1/C18:0) was used to convert lipid-bound sialic acid to ganglioside equivalent

^b Lipid-bound sialic acid data obtained from Yu et al. [27]

^c Lipid-bound sialic acid results from Yu et al. [27] converted to percentage ganglioside equivalent to allow direct comparison with our data

^d Total ganglioside levels were estimated by summing the amounts of the eight ganglioside classes measured in this study

around this time. The small number of studies that have investigated the ganglioside levels at this rapidly changing developmental stage of the rat brain makes it difficult to compare in detail this method and others with our 2-day-old rat brain analysis. With respect to the analysis of young adult rat brains (day 80) for gangliosides the results obtained using this study's methodology are consistent with those previously published [25, 27, 28] for adult rat brain ganglioside levels and individual ganglioside species distribution using this study's methodology are consistent with those previously published.

In conclusion, an LC–MS method for the simultaneous measurement of gangliosides in rat brain was developed. The flexibility of this method is such that it can be applied to the analysis of ganglioside classes not presented in this paper. This method could also be extended to measure the ganglioside (GM₁, GM₂, GM₃, GD₃, GD_{1a}, GD_{1b}, GT_{1b}, GQ_{1b}) content in other tissues or serum.

Acknowledgments The authors would like to thank Kathleen Schoeman for technical support, Charles Yang and Alastair MacGibbon for LC–MS discussions, Claire Woodhall for editing this manuscript, and Mark Vickers (Liggins Institute, Auckland University) for providing the rat brains.

Abstract In animals and plants, fatty acids with at least three double bonds can be oxidized to prostaglandin-like compounds via enzymatic and non-enzymatic pathways. The most common fatty acid precursor in mammals is arachidonic acid (C20:4) (AA) which can be converted through the cyclooxygenase pathway to a series of prostaglandins (PG). Non-enzymatic cyclization of arachidonate yields a series of isoprostanes (IsoP) which comprises all PG (minor compounds) as well as PG isomers that cannot be formed enzymatically. In contrast, in plants, α -linolenic acid (C18:3) (ALA) is the most common substrate for the allene oxide synthase pathway leading to the jasmonate (JA) family of lipid mediators. Non-enzymatic oxidation of linolenate leads to a series of C18-IsoPs termed dinor IsoP or phytoprostanes (PP). PP structurally resemble JA but cannot be formed enzymatically. We will give an overview of the biological activity of the different classes of PP and also discuss their analytical applications and the strategies developed so far for the total synthesis of PP, depending on the synthetic approaches according to the targets and which key steps serve to access the natural products.

Introduction

In animals and plants, fatty acids with at least three double bonds can be oxidized to prostaglandin-like compounds via enzymatic and non-enzymatic pathways [1]. The most common fatty acid precursor in mammals is arachidonic acid (C20:4) (AA) which can be converted through the cyclooxygenase pathway to a series of prostaglandins (PG). Non-enzymatic cyclization of arachidonate yields a series of isoprostanes (IsoP) which comprises all PG (minor compounds) as well as PG isomers that cannot be formed enzymatically. In contrast in plants, α -linolenic acid (C18:3) (ALA) is the most common substrate for the allene oxide synthase pathway leading to the jasmonate (JA) family of lipid mediators. Non-enzymatic oxidation of linolenate leads to a series of C18-IsoPs termed dinor IsoP or phytoprostanes (PP). PP structurally resemble JA but cannot be formed enzymatically.

PG and JA are short lived, local mediators that have important functions in animal and plant development, respectively. In both kingdoms, these mediators are essential for reproduction. Moreover, PG and JA can be rapidly formed by *de novo* synthesis in response to a variety of biotic (microorganisms) and abiotic (UV-light, wounding) stresses. In the acute stress response, PG and JA induce a massive defense response on a cellular level by reprogramming cellular metabolism through binding to extracellular receptors (PG) and through binding to intracellular receptors (JA, cyclopentenone prostanoids). As discussed below, IsoP and PP display some but not all biological activities of PG and JA. It is generally assumed that chemically synthesized isoprostanooids are accidentally formed by autoxidation and may incidentally bind to receptors involved in PG/JA signaling.

From an evolutionary point of view, PG and JA pathways evolved rather late and separately in the animal and plant kingdom. Although PG and JA can be found in some lower organisms, they are only common and display essential functions in mammals and higher land plants. In contrast, non-enzymatic formation of isoprostanooids takes place *in vivo* in all aerobic organisms that use polyunsaturated fatty

acids as membrane modules. Hence, isoprostanooids are an evolutionary ancient class of compounds which occur in most organisms.

Biosynthesis and Nomenclature of Phytoprostanes

IsoP have been well established as markers of oxidative stress in animals [2]. In plants, PG and IsoP cannot be formed, since higher plants generally lack the enzymatic capacity to form arachidonic acid.

α -Linolenic acid (C18:3 ω 3) is beside linoleic acid (C18:2 ω 6), the predominant polyunsaturated fatty acid in plant membranes [3]. α -Linolenate can be released from membrane lipids and metabolized via an enzymatic pathway to prostaglandin-like compounds of the JA family. The best studied jasmonates are 12-oxo-phytodienoic acid (OPDA), JA and its isoleucine conjugate (JA-Ile) [4]. However, the autoxidation of fatty acids that have more than two double bonds yields a series of oxylipins for which no enzymatic biosynthetic pathways have yet evolved in plants. Since α -linolenic acid is a major unsaturated fatty acid in plants and only a trace fatty acid in animals, these compounds have been termed phytoprostanes.

The free radical-initiated peroxidation of ALA and its esters generates mixtures of primary hydroperoxides and cyclic peroxides. Two regioisomeric series are formed from the oxidation of linolenate depending on the site of initial hydrogen abstraction and subsequent oxygen insertion (Fig. 1). Hydrogen atom abstraction at C-14 generates type I PP whereas hydrogen abstraction at C-11 yields type II PP, according to the nomenclature by Rokach et al. [5].

Each series is composed of 16 isomers and 32 PPG₁ can be formed in total. These PPG₁ are major products of linolenate peroxy radicals and are thought to be formed in situ in membrane lipids, similar to the corresponding IsoPs in animals. Unstable PPG₁ spontaneously rearrange and/or are reduced to D₁-, E₁- and F₁- ring compounds (Fig. 2). Finally, D₁- and E₁-PP may further dehydrate and isomerize to J₁-, deoxy-J₁, A₁ and B₁- PP.

Analytical Applications of Phytoprostanes

First evidence for the formation of PP in plants was discovered by Parchmann and Mueller in 1998 [6]. Highly sensitive and specific analysis methods were needed to overcome the daunting task of the sheer numbers of primary and secondary metabolites present in plant materials. Initially, gas chromatography-mass spectrometry (GC-MS) and HPLC coupled to a fluorescent detector were the instruments of choice for analysis quantification. However as detailed below, GC-MS methods require extensive and laborious sample preparation and derivatization procedures. More recently, HPLC-ESI-MS/MS has become the method of choice for the analysis of all classes of PP since this analytical method can be applied to simple methanol extracts of plant materials without further purification or derivatization. In any case, internal standard are required for accurate analysis. The best internal standards are oxygen-18 labeled PP which could be obtained by two methods. In the first procedure [¹⁸O₃]PPE₁ and [¹⁸O₃]PPF₁ standards were obtained by autoxidation of linolenate in oxygen-18 atmosphere. While PPB₁ was synthesized from [¹⁸O₃]PPE₁ by base-catalyzed dehydration [6, 7]. The

Fig. 1 Non-enzymatic phytoprostane biosynthesis from α -linolenic acid

Fig. 2 The Phytoprostane pathway in plants

second method, that can be generally applied to oxylipins, is the lipase- or base-catalyzed exchange of the two oxygen atoms in the carboxyl group by oxygen-18 using H₂¹⁸O [8].

Within the PPE₁ series, comprised of 32 possible isomers, quantification was achieved by chromatographic separation (HPLC or solid phase extraction, SPE) of PPE₁ from PPB₁. Next, the pre-purified crude mixture of PPE₁ was converted to PPB₁ (comprising only two regioisomers) by brief exposure to KOH followed by another SPE purification step. PPB₁ were subsequently derivatized into pentafluorobenzyl ester and trimethylsilyl ether derivatives. GC–MS analysis in the negative chemical ionization mode against [¹⁸O]₁PPB₁ internal standard permitted quantification of the two regioisomers of PPB₁ representing the endogenous PPE₁ regioisomers (type I and type II). Both regioisomers can be well chromatographically separated and quantified [6].

PPF₁ quantification required another method to separate the large amount of acyclic triols (derived from both enzymatic and non-enzymatic oxidation of linolenate in plants) to cyclic triols of the PPF₁ type. Although acyclic and cyclic compounds have similar chromatographic and mass spectrometric properties and the same molecular weight, they differ by their number of double bonds. However after hydrogenation, PPF₁ could be differentiated from the acyclic compounds by their molecular weight. Thereafter, another step of SPE purification was necessary followed by derivatization of the hydrogenated PPF₁ to their corresponding pentafluorobenzyl ester and trimethylsilyl ether derivatives. PPF₁ isomers could only be partially resolved on the GC column and were quantified by GC–NICI–MS [9].

Table 1 Prostaglandin-like oxylipins in tomato leaves

Cyclopentane phytoprostanes (ng/g DW)	
PPD ₁ -I (459 ± 130)	PPD ₁ -II (698 ± 161)
PPE ₁ -I (35 ± 8)	PPE ₁ -II (35 ± 12)
PPF ₁ -I (75 ± 25)	PPF ₁ -II (75 ± 25)
Cyclopentenone phytoprostanes (ng/g DW)	
PPA ₁ -I (3.3 ± 2.0)	PPA ₁ -II (1.2 ± 2.0)
PPB ₁ -I (1.2 ± 1.1)	PPB ₁ -II (0.75 ± 1.5)

Jasmonates (ng/g DW)	
12-Oxo-phytodienoic acid (212 ± 51)	Jasmonic acid (20 ± 5)

Levels of non-enzymatically formed Phytoprostanes and enzymatically biosynthesized jasmonates in tomato leaves (*Lycopersicon esculentum* cv. moneymaker) were quantitated by GC–MS or HPLC/fluorescence detection. Data are means ± SD of leaves collected from three different plants

PPD₁ and deoxy-J₁-phytoprostane (dPPJ₁) were analyzed using a novel method based on the unique capability of dPPJ₁ to bind covalently to thiol groups. After separation of PPD₁ and dPPJ₁ by SPE, dPPJ₁ were covalently linked to 7-mercapto-4-methyl-coumarin and analyzed by HPLC coupled with a fluorescence detector. All regioisomers eluted in one peak and 15-deoxy-Δ^{12,14}-PGJ₂ was used as the internal standard. PPD₁ were converted to dPPD₁ by acid dehydration and analyzed as above using PGD₂ as internal standard (transformed into PGJ₂ by acid treatment) [10].

The analysis of cyclopentenone PPA₁ and B₁ had to be accomplished by the combination of two different analyses. After extraction of PPA₁/PPB₁ by SPE and derivatization (see PPE₁), GC–NICI–MS analysis revealed that PPA₁ had isomerized into PPB₁. Quantification of the sum was performed using [¹⁸O]PPB₁ as an internal standard (added prior to work-up). Furthermore, methoxime derivatization of the carbonyl group to prevent isomerization of PPA₁ into PPB₁ into the GC injector revealed the endogenous ratio of PPA₁ to PPB₁. From both analyses, levels of PPA₁ and PPB₁ could be calculated indirectly [11].

Non-enzymatic peroxidation of ALA produces a large spectrum of PP in plant tissues. In plant species studied to date (more than 20 from taxonomically different plant species) all types of free PP and dPPJ₁ have been found to occur ubiquitously at greater levels than their mammalian congeners, the IsoP [6, 7, 10, 12]. The relative abundance of all the aforementioned PP classes has been established in tomato leaves (*Lycopersicon esculentum* cv. moneymaker) (see Table 1) [11].

PPE₁ and PPF₁ are for instance at least 2 to 3 orders of magnitude higher in plants tissues than IsoP in mammalian tissues. Furthermore, PPD₁ and dPPJ₁ are the most abundant PP in most plant species [10]. Free PPA₁ and PPB₁ are

also found in vivo to the contrary of their mammalian congeners which are apparently below the limit of detection at basal levels [13–15]. Moreover, glutathione conjugates of PPA₁ dramatically accumulate after pathogen infection in *Arabidopsis thaliana*.

High levels of isoprostanoids in plants could be the cause of enhanced formation (arachidonates are more reactive toward autoxidation but are prone to further polyoxygenation) or slower metabolism of PP in plants. However, oxygenic photosynthesis in chloroplasts has been shown to be a major source of reactive oxygen species, especially singlet oxygen. In green plant tissues, lipid peroxidation is predominately dependent on singlet oxygen and leads to the accumulation of fatty acid hydroperoxides esterified in chloroplast galactolipids. It is assumed that the pool of lipid peroxidation products is prone to further free radical-catalyzed peroxidation of chloroplast membranes, hence leading to the accumulation of PP. In contrast, levels of lipid peroxidation products in plant roots (that do not form singlet oxygen) are about 10-fold lower than in leaves and comparable to levels found in mammalian tissues. Hence, singlet oxygen formed during photosynthesis in the plant specific chloroplast organelle may accelerate free radical driven lipid peroxidation [16].

Investigation of PP in human diet showed that levels increase when plants are dried and stored after harvest. Indeed, up to a 250-fold of free and esterified PPF₁ (in the range of 3,000–20,000 and 10,000–55,000 ng/g of dry weight, respectively) were found in fresh plant parts [9]. An impressive high amount of free PPF₁ (more than 32,000 ng/g) was also found in fresh birch pollen [9], and *Betula alba* L. (*Bet*-APE) pollen were found to contain E₁, F₁, A₁, and B₁ PP, of which PPE₁ levels were eightfold more abundant than the others [17].

A recent investigation showed that PPF₁, PPE₁, PPA₁, and PPB₁ are found in vegetable oils and parenteral nutrition (intralipid) in remarkably high levels (0.09–99 mg/L) [18]. It was demonstrated that PPF₁ were absorbed after oral consumption, and found to circulate in plasma in an unknown conjugated form. They were excreted in free form in urine. Because cyclopentenone-PP display potent anti-inflammatory and apoptosis-inducing activities similar to PGA₁, deoxy-PGJ₂, A₂-IsoP, and J₂-IsoP, this study indicates that PP may contribute to the beneficial effects of the Mediterranean diet. In addition, a study by Barden et al. show that after 4 weeks supplementation with flaxseed oil, plasma phospholipid ALA was significantly increased and PPF₁ were elevated in plasma and urine, in men [19].

Similar to IsoP in mammals, PP have been shown to represent a reliable marker of oxidative stress in vivo [9, 12].

Levels of free PPF₁ transiently increased by more than 15- and 30-fold, respectively, after treatment of *Eschscholzia californica* cell cultures with butyl hydroperoxide

(10 mM) or copper ions (500 μM) with maximum levels of 1.7 and 2.7 μg/g of dry weight, respectively. Wounding which causes an increase in endogenous reactive oxygen species generated a 4- to 5-fold increase in both free and esterified PPF₁, showing that PPF₁ is clearly inducible by oxidative stress in plants [7]. A recent study showed that levels of free and esterified PPF₁ increased after pathogen treatment. The fact that the increase in esterified compounds occurred earlier than in free compounds suggests that non-enzymatic lipid oxidation occurs predominantly in membranes from which oxidized lipids can be released [20].

Other PP are also produced during oxidative stress, and indeed butyl hydroperoxide treatment of tobacco cell cultures resulted in an accumulation of E₁-, A₁- and B₁-PP [12]. Furthermore, necrotrophic plant fungi like *Botrytis cinerea* induced an oxidative burst in infected tomato leaves and triggered a three- to four-fold increase of E₁-, A₁- and B₁-PP, reflecting generation of ROS by the necrotrophic plant fungus. It was interesting to notice that the PP pathway can be triggered independently of the JA pathway (hydroperoxide treatment) or simultaneously (*Botrytis cinerea*) depending on the environmental conditions [12].

Biological Activity of Phytoprostanes

PP have been reported to possess a broad spectrum of biological activities in different plant species. The best studied compounds are the cyclopentenone-PP of the A and B classes. In several studies it was shown that exogenous application of these classes of PP regulates gene expression in *Arabidopsis thaliana* and tomato [12, 15, 21]. A whole genome transcriptome analysis of *A. thaliana* treated with 75 μM PPA₁ for 4 h revealed that the expression of 157 genes was up-regulated by a factor of three or more while the expression of 211 genes was repressed [15]. 28% of the up-regulated genes were related to detoxification, stress responses and secondary metabolism. In agreement with gene regulation, the levels of secondary metabolites increase upon PP treatment. This accumulation in response to PPB₁ was shown for different classes of phytoalexins in different plant species: the indole-alkaloid camalexin in *A. thaliana*, the coumarin scopoletin in tobacco, the isobavachalcone in *Crotalaria cobalticola* and the alkaloid sanguinarine in *Eschscholzia californica* [21].

Detoxification genes which were up-regulated by PPA₁ and PPB₁ comprised genes involved in the xenobiotic response in animals such as phase I enzymes (CytP450 enzymes, aldehyde dehydrogenases, OPDA-reductases), phase II conjugating enzymes (glutathione-S-transferases and glycosyltransferases) and putative phase III xenobiotica transporters (ABC transporters) [21]. Enhanced

activities of these enzymes might be useful in the deactivation of xenobiotics as well as endogenous compounds such as peroxidized lipids [22]. Also, the increased expression of stress-related genes encoding heat shock proteins and heat shock factors indicate the activation of mechanisms which might help to improve cellular metabolism under stress conditions. Recently, Dueckershoff et al. [23] reported the impact of PPA₁ on the proteome of *A. thaliana* showing that the PPA₁-regulated proteins were localized in chloroplast and mitochondria—locations where internal oxidative stress is generated.

These results suggest that cyclopentenone PP may be archetypal mediators of oxidative stress: they trigger the first adaptive responses thus limiting the consequences of oxidative stress by inducing several plant-protection mechanisms [19, 24].

In agreement with this hypothesis, it has been shown that PPB₁ may induce cell protection genes which enables plant cells to survive subsequent, otherwise lethal stress [21]. Pretreatment of a tobacco cell culture with PPB₁ decreased cell death caused by a severe oxidative stress generated by CuSO₄ [21].

PP also display inhibitory effects on gene regulation and on the physiological level. In *A. thaliana*, PPA₁ down-regulate the expression of genes related to cell division and growth. In accordance with gene regulation, treatment with PPA₁ resulted in inhibition of root growth and of cell cycle progression. With respect to inhibition of root growth, it has been found that the cyclopentenones OPDA and PPA₁ mediate their activities through the COI1 complex, an established receptor for the JA-isoleucine conjugate (JA-Ile). Most biological activities of PPA₁ and OPDA, however, are independent of the JA-COI1-signaling pathway and are mediated through TGA transcription factors [15]. It is assumed that cyclopentenone prostanoids exert their biological activities by covalently binding to free thiol groups of target proteins such as transcription factors and redox-regulated enzymes. While several target proteins such as NF- κ B and PPAR γ have been identified in animals, little is known about the primary cyclopentenone target proteins in plants [25].

For most biological activity studies, mixtures of various PP isomers have been used. Only in a few studies, the effect of different regioisomers was investigated with interesting results. In tomato cell culture (*Lycopersicon esculentum*), exogenous application of PPA₁-I/II, deoxy-PPJ-I/II and PPB₁-II activated significantly the mitogen-activated protein kinases (MAPK) whereas PPB₁-I did not [12, 26]. In the same system, PPB₁-I/II but not PPA₁ led to an increase in the mRNA levels of *Lin6* (encoding an extracellular invertase) after 3 h. PPB₁-I/II also induced the expression of *PAL* (phenylalanine ammonia lyase) in tomato cell suspension cultures in 30 to 60 min. PPA₁ did

not up-regulate the expression of *PAL* in tomato cells but induced strongly expression of the orthologous gene in tobacco [12]. In addition, the regulation of gene expression by PPB₁ in an *A. thaliana* cell suspension culture was dependent on the regioisomer: the spectrum of induced genes was similar but the response to PPB₁-I was stronger than to PPB₁-II. In contrast, the induction of phytoalexins in three different models (tobacco, *C. cobalticola*, *E. californica* cell culture) was stronger with PPB₁-II in comparison to PPB₁-I. The allylic alcohol configuration, the free acid or the esterified form did not affect phytoalexin formation [21]. These results clearly demonstrate the importance of investigating the response to specific, defined stereoisomers. The comparison of different stereoisomers is necessary to learn more about the mechanisms involved in mediating the effects of PP.

PP also display several biological activities in animal models. PPE₁ inhibit in vitro dendritic cell interleukin-12 (IL-12) production and increase Th2 cell polarization [17, 27]. In contrast, in vivo, PPE₁ and PPF₁ inhibit partially the Th1 and Th2 cytokine production [28].

Finally, Mueller and coworkers reported that the cyclopentenones PPA₁ and dPPJ₁, displayed an anti-inflammatory activity at the same concentration (10–50 μ M) similar to PGA₁ and dPGJ₂ in human embryonic kidney (HEK) cells and RAW264.7 murine macrophages by down-regulating NF- κ N and inhibiting nitric oxide synthesis, respectively. Moreover, the authors reported that PPA₁-I induced apoptosis in leukemia Jurkat T cell, at the same concentration as PGA₁ (10–40 μ M) but at a higher degree (60 vs. 33% apoptosis). dPPJ₁-I, dPPJ₁-II showed the same activity at a concentration range of 20–40 μ M, whereas PPA₁-II, PPB₁-I and -II were completely inactive [18]. This indicates that biological activities exerted in animals also depend on the stereochemistry of the compound.

Synthetic Approaches to Phytoprostanes and Analogs

Many efforts towards the total synthesis of IsoPs and analogs, metabolites derived from peroxidation of arachidonic acid and other polyunsaturated fatty acids (PUFA) have been made in the last 15 years [29, 30]. Since the discovery of IsoP [31], neuroprostanes (NeuroP) [32, 33] and more recently, the PP [7] there has been a growing interest in the total synthesis of such molecules in order to supply sufficient amounts for their identification, quantification as well as their biological properties.

Without the synthetic strategies developed so far, the field of IsoP and PP would not have advanced to its current status. However, as can be seen in the following section, only selected members of some PP families have been

synthesized. One of the greatest needs is the development of novel synthetic approaches that are more efficient with respect to number of steps and time to execute them. Approaches to synthetic PP and analogs have been reported by several groups during the last 5 years. Nevertheless, much remains to be learned concerning the functions of these new bioactive lipids. We will concentrate our review on the outline of the general strategies and the involved key steps to assemble the respective intermediates.

Most of the published total syntheses use one of three basic synthetic strategies of the PP skeletons.

1. The side chains were introduced at the same time or subsequently to suitably functionalized cyclopentane rings. This strategy is very flexible for the synthesis of more than one member of different regioisomeric series of PP. Since the configuration of cyclopentane stereocenters directs the incoming side chains strongly, a potential limitation is the accessibility of diastereomeric structures.
2. Precursors containing the fully assembled PP chain with the desired functionality were assembled first. The key step was a cyclization reaction to afford the natural products. Potential limiting factors of this strategy are a considerable synthetic effort to prepare the cyclization precursors and a low flexibility to apply the methodology to a largest range of substrates.
3. An approach via a two component coupling process, where at first one of the side chains is disconnected. The cyclopentane ring with the other side chain in place is available by a number of cyclization reactions. Here, the methodology can be rather easily developed, divergent stereochemical control opportunities exist, albeit precursor's synthesis may be somewhat more difficult than the other strategies pointed above.

Synthesis of Phytoprostanes by Attachment of the Side Chains to a Suitably Functionalized Cyclopentane Ring

Synthesis from Functionalized Cyclopentenones

In 2007, Boland and coworkers developed a very short and general strategy for the synthesis of B₁-PP, dinor-IsoP and several analogs (Scheme 1) [34]. Their approach is based on five key operations to introduce the two side chains. Starting from 1,3-cyclopentanedione **1**, a three-step procedure consisting of *O*-acylation with acyl chlorides to **2**, subsequent 1,3-*O,C*-acyl shift with acetone cyanohydrin/*N*Et₃ and reduction of the exocyclic keto function by triethylsilane yielded the desired C-alkylated 3-hydroxyenones **3a–c** with the first lateral chain in place. Reaction with the iodine-triphenylphosphine complex gave access to 2-alkyl-3-iodocyclopentenones **4a–c**, which served as

precursors for the introduction of the second side chains by Heck-type cross-coupling reactions employing a 2:1 mixture of PPh₃ and Pd(OAc)₂ as the catalyst in the presence of Et₃N. THP-protected 1-alken-3-ols proved to be the coupling substrates of choice. THP-deprotection completed the total synthesis of 16-PPB₁ **5a**, of 9-PPB₁ **5b** and of 5,6-dihydro-2,3-dinor-15-B₂-IsoP **5c** in good overall yield. The flexibility of this approach was also demonstrated by the synthesis of acetylenic and *O*-alkylated PP analogs (not shown).

Cyclization Reactions Followed by Attachment of the Remaining Side Chain

Radical Cyclizations Since radical cyclizations are well-suited to approach cyclopentane rings with *cis*-oriented substituents [35], they are attractive to synthesize IsoP intermediates. At the beginning of the 1990s, the Durand/Rossi group along with Rokach's team reported the synthesis of key intermediate **6**, a diastereomer of Corey's formyl-lactone, via an acyclic thionocarbonate [36]. Durand and Rossi developed subsequently radical carbocyclizations of functionalized iodo precursors **8** and **9** (Scheme 2) [37], which replace the thionocarbonate precursors initially proposed advantageously. The synthesis of **6** started with commercially available 1,2,5,6-di-*o*-isopropylidene- α -D-glucufuranose **10**, which was transformed to the corresponding 3-deoxy-sugar **11** in 85% yield using the Barton-McCombie procedure. A selective deprotection of the isopropylidene group at 5,6-position to diol **12** was accomplished in the presence of 70% aqueous acetic acid in good yield. Protection of the primary alcohol using 1.1 equiv. of *tert*-butyldiphenylsilyl chloride in

Scheme 1 Total synthesis of PPB₁ according to Boland et al. [34]

DMF and imidazole led to the pure mono silyl ether **13**. Introduction of iodine at C5 to **14** was accomplished in 96% yield by using I₂, Ph₃P and imidazole in xylene in a procedure developed earlier by our group [37].

Hydrolysis of the isopropylidene group at 1,2-position was achieved in the presence of 10% aqueous sulfuric acid in THF-dioxane (3:1) to afford the diol **15** in 86% yield. The next step was a Wittig reaction with methyl triphenylphosphoranylidene acetate affording the cyclization precursor **8** in 75% yield. Protection of the two hydroxy groups in **8** with triethylsilyl chloride in pyridine gave **9** in 96% yield. The crucial radical 5-*exo* cyclizations were conducted in the presence of tributyltin hydride initiated by triethylborane/oxygen under ambient conditions. The factors controlling the cyclization diastereoselectivity of these polyhydroxylated hex-5-enyl radicals were carefully examined and shown to be strongly dependent on the protecting group pattern of the two secondary hydroxy groups in **8** and **9** [38]. Compound **8** with free hydroxy groups cyclizes preferentially via hydrogen-bonded transition state **16** to all-*cis*-**6**. The bis(TES) derivative **9**, in contrast, cyclizes via a Beckwith-Houk transition state **17** to *syn-anti-syn*-**7**. All reactions shown for D-glucose were also performed with

Scheme 2 Synthesis of cyclopentane key intermediates according to Durand, Rossi and co-workers [37]

L-glucose to make all stereoisomers of the *syn-anti-syn* and all-*cis* cyclopentane families accessible.

Compounds **6** and **7** were converted to a large set of enantiomerically pure IsoP, NeuroP, and PP by the following standard methods: (a) sequential appendage of the side chains by Wittig and/or HWE reactions; (b) protection/deprotection reactions; (c) regioselective oxidation; and (d) enantioselective reduction.

This is illustrated by the first total synthesis of PPF₁ type II methyl ester **18**, which was achieved in 2004 starting from *syn-anti-syn* cyclopentane **7** (Scheme 3) [39]. After the reduction of the methyl ester **7** and activation of the hydroxy group with toluenesulfonyl chloride, followed by reduction, once again, by LAH the methyl group of the α chain is obtained in 83% yield.

Introduction of the ω chain in *syn-anti-syn* derivative **19** was achieved by a HWE reaction with dimethyl [9-(ethoxycarbonyl)-2-oxononylphosphonate/NaHMDS and afforded the enone β -**21**. Diastereoselective reduction of the C9 keto group in **21** with the chiral reducing agent [40] (*R*)-BINAL-H gave the desired pure 9(*R*) derivative in 82% yield. Finally, deprotection of the benzoyl groups, in presence of 1 N NaOH, followed by excess of CH₂N₂, afforded the desired *ent*-PPF₁ type II methyl ester **18** in ten steps and 38% yield from the cyclopentane **7**.

Using this radical pathway, starting from D- and L-glucose, all diastereomers of PPF₁ summarized in Scheme 4 were synthesized [41].

Transition Metal-Catalyzed Cyclization Reactions Leading to Phytoprostanes The Evans group reported an interesting Pauson-Khand strategy for the synthesis of J-type IsoP or PP (Scheme 5) [42, 43]. The reaction between Co₂(CO)₆-complexed trimethylsilylacetylene **29** and norbornadiene **30** led to racemic key intermediate **31**. The yield of this cyclization step was optimized by using thermal microwave heating. The following key step represents an adaption of the well-known three-component coupling for PG synthesis consisting of copper(I)-catalyzed conjugate addition of 7-silyloxyheptylmagnesium bromide to **31** followed by an aldol addition of *trans*-oct-2-enal. The construction of the cross-conjugated dienone unit **32** was achieved by subsequent Peterson olefination under acidic conditions and gave an initial 1:3 13*E*/13*Z*-diene mixture.

After removal of the silicon protecting group and separation, the individual diene isomers (12*Z*)-**32** and (12*E*)-**32** were isolated in 25 and 28% yield, respectively. The authors named this procedure conjugate addition-Peterson olefination reaction. Conversion of the primary alcohol **22** into the methyl ester **33** was achieved using a three-step protocol. Alcohol (12*E*)-**32** was oxidized with Dess-Martin periodinane and subsequently sodium chlorite to the

Scheme 3 Total synthesis of PPF₁ type II according to Durand, Rossi and co-workers [41]

Scheme 4 Four diastereoisomers of PPF₁ synthesized by Durand/Rossi group [41]

corresponding carboxylic acid, which was esterified with (trimethylsilyl)diazomethane in good yield. The total synthesis was completed by retro-Diels–Alder reaction of the cyclopentadienyl-protected methyl ester **33** with MeAlCl₂ and maleic anhydride under microwave conditions to give 52% of (\pm)-*trans*- $\Delta^{12,14}$ -15-deoxy-PGJ₁ methyl ester **34** and 14% of its *cis*-isomer (not shown).

In 2005, Evans' group associated with Riera's group published the synthesis of optically pure 13,14-dehydro-12-oxophytodienoic acids **37** and **38** (dPPJ₁) using an asymmetric version of their earlier approach (Scheme 6) [26]. This was achieved by ligand exchange of **29** with bidentate chiral ligand **35** in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO) in toluene to give the two diastereomeric cobalt complexes **36a** and **36b** in good yield, which were separated by crystallization and/or

chromatography. The Pauson–Khand reaction of **36a** with norbornadiene **30** in the presence of *N*-methylmorpholine *N*-oxide (NMO) in dichloromethane furnished (+)-**31** in excellent yield and enantiomeric excess.

Using similar conditions as in the synthesis of racemic compound **34** (cf. Scheme 5), the synthesis of (+)-*trans*,-*trans*-dPPJ₁ type I **37** as a single isomer was accomplished from (+)-**31** in a six-step sequence including 1,4-conjugate addition using 7-(silyloxy)heptylmagnesium bromide, a Peterson olefination with *trans*-pent-2-enal and finally the removal of the cyclopentadienyl-protecting group with MeAlCl₂ and maleic anhydride under microwave irradiation conditions. A similar sequence with lithium diethyl cuprate and the appropriate functionalized α,β -unsaturated aldehyde provided (+)-*trans*,*trans*-dPPJ₁ type II **38** in good yield (Scheme 6).

Scheme 5 Total synthesis of J-type IsoP and PP according to Evans and co-workers [42, 43]

In 2009, Riera and coworkers developed a new approach using an intermolecular Pauson–Khand reaction of internal alkynes (Scheme 7) for the synthesis of PGB₂ and PPB1 [44].

The synthesis required internal alkynes **39**, easily prepared from propargylic alcohol and the corresponding bromo acid. The alkynes were treated with octacarbonyl dicobalt to give the related cobalt complexes. The Pauson–Khand reaction was performed at room temperature in a pressure reactor under ethylene, NMO and powered 4-Å molecular sieves with good yield. After a quantitative silyl group removal using HF.Pyr. , the Pauson–Khand adduct **41** was converted into an aldehyde **42** under Swern conditions in an excellent yield.

The first attempt of Riera's group to introduce the ω chain by a Wittig reaction on the aldehyde **42** afforded a mixture of stereoisomers in low yield. Finally, they succeeded in their approach by using a Julia olefination to introduce the chiral ω chain.

Mikolajczyk et al. reported the synthesis of a key intermediate (Scheme 8), the 3-(phosphorylmethyl)cyclopent-2-enone **46** which turned out to be an excellent building block in the synthesis of naturally cyclopentenone derivatives [45].

The cyclopentenone **46** was obtained in the reaction between the α -phosphonate carbanions and dicarboxylic

Scheme 6 Synthesis of optically pure dPPJ₁ type II according to Riera, Evans and co-workers [26]

acid esters **44** to afford the bis- β -ketophosphonates **45**. Under basic conditions, this latter yielded through an intramolecular HWE reaction the desired cyclopentenones **46**.

Recently, by a controlled combination of the alkylation and Horner reaction of the anion generated from **46** the authors were able to reach the PPB₁ type I (Scheme 9). The anion of **46** generated from NaH in DMSO reacts with the 8-bromooctanoate to afford the corresponding C2-alkylated derivative **47**. Then, the Horner reaction of **47** with the enantiopure (–)-*S*- α -benzyloxybutanal yielded the olefination product **48** which after saponification of the methyl ester afforded the enantiopure PPB₁ **49** in a 25% overall yield [46]. Starting from (+)-*R*- α -benzyloxybutanal, the authors reported the synthesis of the enantiomer of PPB₁ type I.

Scheme 7 Synthesis of PPB₁ type I according to Riera et al. [44]**Scheme 8** Synthesis of 3-(phosphorylmethyl)cyclopent-2-enone according to Mikolajczyk [45]**Scheme 9** Synthesis of PPB₁ type I according to Mikolajczyk [46]

Phytosteranes Syntheses Based on Furan Ring Transformations

Spur and coworkers developed very efficient syntheses of the PPE₁ via a two components coupling process typically used for the synthesis of PG and analogs [47–49]. By simply modifying “work-up” conditions using chelating proton sources, a switch from PG *trans*-dialkyl stereochemistry to PP *cis*-dialkyl stereochemistry was accomplished. The synthesis of chiral cyclopentenone component **55** started with a Friedel–Crafts acylation of furan and the mixed anhydride of azelaic acid monoester to give furyl ester **51** (Scheme 10) [50]. NaBH₄ reduction followed by

rearrangement with ZnCl₂ in dioxane/water at reflux afforded 4-hydroxycyclopentenone **53**, probably via ring opening of intermediate **52** and subsequent intramolecular aldol addition. Treatment of **53** with chloral yielded the more stable 4-hydroxycyclopentenone **54** in 70% overall yield.

Enzymatic resolution and TBS protection gave **55**, which was subjected to conjugate addition with a chiral component, obtained by lithium-iodine exchange of the corresponding vinyl iodide **56**. The resulting 2,3-dialkylcyclopentanone enolate intermediate was then added to a cool solution of methyl acetoacetate to provide a *cis*-2,3-dialkylcyclopentanone with 72% selectivity. Finally,

**Scheme 10** Synthesis of PPE₁ according to Spur et al. [50]

Scheme 11 Synthesis of PPB₁ according to Durand et al. [54]

deprotection and ester hydrolysis gave 16-*epi*-16-E₁-PP **57**. *ent*-16-E₁-PP was also synthesized starting from the enantiomer of **55** [51, 52].

Since 2004, Durand's group became interested in developing new and flexible routes to B-, D-, E-IsoP and -PP starting from two common intermediates reported by Freimanis, namely the 4-hydroxy-2-cyclopentenone precursors **60a,b** (Scheme 11) [53]. The synthesis started with a Vilsmeier formylation reaction at 5-position of the furans **58a,b**. A selective rearrangement of **59a,b** yielded the 4-hydroxy-2-cyclopentenones **60a,b** after four steps. The two 4-hydroxycyclopent-2-enone acetals **60a,b** were transformed to 3-oxocyclopentenecarbaldehydes **61a,b** in three steps and served as precursors for the synthesis of both enantiomers of PPB₁ type I methyl ester **62** as well as of PPB₁ type II methyl ester **63** by Wittig reactions using chiral β-hydroxy phosphonium salts [54].

In another synthetic venture (Scheme 12), methyl *trans*-3-(2-furyl)acrylate **64** was transformed in six steps to racemic 4-hydroxycyclopentenone **65** using the above procedure. An efficient enzymatic resolution for this compound to the two enantiomerically pure hydroxycyclopentenones (*R*)-**65** and (*S*)-**65** using CAL-B was developed [55]. Following a similar strategy, but applying **64** as a starting material and different coupling partners, other PP, such as all diastereomers of PPE₁ type II (**67** and **68**) were obtained [56].

Scheme 12 Synthesis of PPE₁ type II according to Durand et al. [55, 56]

Conclusion

During the last 10 years the chemistry, analysis, biology, and application of PP has undergone significant developments.

PP are generated by free radical-catalyzed oxidation of esterified linolenate in membranes in situ, from which they may be released preformed by lipases similar to IsoP in mammals. PPF₁ have been shown to occur predominantly esterified in plant lipids, presumably in plastidic galactolipids.

Pure synthetic PP are necessary as analytical standard for the unequivocal structure determination, the quantification and the exact elucidation of their potential biological properties. Without the synthetic strategies developed so far, the field of PP would not have advanced to its current status.

In parallel to these synthetic and analytical achievements, recent studies indicate that several PP display similar biological activities as OPDA which are mediated to a large part through TGA-transcription factors. In addition, PP also share biological activities with JA which are in part mediated through the COI1 signaling pathway such as induction of phytoalexin biosynthesis in plants and root growth inhibition. Cyclopentenone PP rapidly activate mitogen activated protein kinase (MAPK) and trigger activation of genes involved in stress responses and detoxification, hence, resembling the mammalian xenobiotic response. The Pollen-derived PPE₁ modulate DC function via PPAR γ -gamma dependent pathways that lead to inhibition of NF- κ B activation and result in reduced DC IL-12 production and consecutive T(H)2 polarization. Work is in progress to elucidate the signal transduction mechanisms of phytoprostanes in humans and animals in more detail.

A recent investigation showed that PPF₁, PPE₁, PPA₁, and PPB₁ are found in vegetable oils and parenteral nutrition (Intralipid) in remarkably high levels (0.09–99 mg/L). In addition, a study by Bardeen et al. show that after 4 weeks supplementation with flaxseed oil, plasma phospholipid ALA was significantly increased and PPF₁ were elevated in plasma and urine (data not shown). Since PP are contained in the human diet the profile of their pharmacological activities in humans and animals needs also to be explored.

Acknowledgment We are deeply grateful to Pr. Jean-Yves Lallemand and the ICSN for their generous financial support and a part of this work was supported by the University Montpellier I grant (BQR-2008).

Abstract Cyclooxygenase-2 (COX-2) is intimately involved in symptoms of arthritis while dietary n-3 polyunsaturated fatty acids (PUFA) are thought to be beneficial. In these experiments, using both bovine and human in vitro systems that mimic features of arthritis, we show that the n-3 PUFA eicosapentaenoic acid (EPA) is able to reduce mRNA and protein levels of COX-2. Activity, as assessed through prostaglandin E₂ formation, was also reduced in a dose-dependent manner. These effects of EPA contrasted noticeably with the n-6 PUFA, arachidonic acid. The data provide direct evidence for a molecular mechanism by which dietary n-3 PUFA, such as EPA, can reduce inflammation and, hence, associated symptoms in arthritis.

Keywords Cyclooxygenase-2 (COX-2) expression · COX-2 activity · Arthritis · n-3 Polyunsaturated fatty acids

Abbreviations

ARA	Arachidonic acid
BCIP	5-bromo-4-chlorindolyl phosphate
COX	Cyclooxygenase
DHA	All <i>cis</i> - Δ 4, 7, 10, 13, 16, 19-docosahexaenoic acid
DMEM	Dulbecco's modified Eagle's medium
EPA	All <i>cis</i> - Δ 5, 8, 11, 14, 17-eicosapentaenoic acid
FCS	Foetal calf serum

FGF	Fibroblast growth factor
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
IL-1	Interleukin-1
NBT	Nitroblue tetrazolium
NSAIDs	Non-steroidal anti-inflammatory drugs
OA	Osteoarthritis
PDGF	Platelet-derived growth factor
PG	Prostaglandin
PUFA	Polyunsaturated fatty acid
RA	Rheumatoid arthritis
TNF- α	Tumour necrosis factor- α
TSA	TRIZMA saline azide

Introduction

There are two classes of essential polyunsaturated fatty acids (PUFA), the n-3 compounds such as α -linolenic acid and the n-6 series such as linoleic acid. Both types of PUFA are needed in a healthy diet [1] but there has been a continuous debate about the amounts and the ratio of n-3/n-6 PUFA which are required [2]. Although the plant-derived PUFA, linoleate and α -linolenate, are the main dietary components it is their 20C metabolites, arachidonate (ARA) and eicosapentaenoate (EPA), respectively, which are the direct precursors of the biologically-active eicosanoids. Moreover, the n-3 PUFA, EPA and docosahexaenoate (DHA), can also give rise to newly-discovered mediators such as resolvins and neuroprotectins [3]. One complication when considering dietary requirements for n-3 and n-6 PUFA is the relatively poor conversion of the 18C precursors into the respective 20C (or 22C) PUFA [4]. For that reason, acids such as EPA or DHA, as present in oily fish,

are often considered important for a healthy diet [5] and are regarded in some circumstances as conditionally-essential [6].

It is accepted generally that dietary n-3 PUFA can have a beneficial effect on the etiology and progression of chronic inflammatory complaints [7], such as cardiovascular disease [8], Alzheimer's disease [9] or arthritis [10]. This is in contrast to the n-6 PUFA which are usually regarded as pro-inflammatory [11] and the predominance of such acids in the Western diet has led to calls for an urgent adjustment of the ratio of dietary n-3/n-6 PUFA in order to help with the prevention and management of chronic diseases [2].

The molecular mechanism(s) by which n-3 PUFA can exert their beneficial effects is uncertain but may include actions on membranes (and membrane rafts) [12], competition with n-6 PUFA in metabolism [13, 14], the production of anti- or less-inflammatory metabolites [3, 11] and effects on gene expression [15].

Arthritis, particularly osteo- and rheumatoid arthritis, is a major problem world-wide with an estimated 30% of the W. Europe or US populations having symptoms and up to 10% experiencing disability [16]. A beneficial effect for fish oil was first noted in 1783 [17] and, in the last twenty years there have been many clinical studies (e.g. [18–20]) showing clear clinical benefits for n-3 PUFA which mainly relate to reduction of the inflammatory response associated with arthritic conditions [10, 11, 21]. Overproduction of pro-inflammatory and immunoregulatory cytokines is associated with chronic inflammatory diseases [22] and both TNF- α and IL-1 have been implicated as mediators of arthritic joint pathology [4, 10]. The production of such cytokines may be modulated by eicosanoids [22] or n-3 PUFA may influence their expression via the NF- κ B pathway [15].

A key enzyme in mediating the effects of n-3 and n-6 PUFA is cyclooxygenase (COX) [23]. Indeed, non-steroidal anti-inflammatory drugs (NSAIDs), which inhibit cyclooxygenase, are widely prescribed to alleviate symptoms of arthritis (e.g. [24]) and can show chondroprotective effects in vitro [25]. There are two main isoforms of COX; COX-1 and COX-2. These enzymes are the products of different genes although their protein products are highly homologous [26]. COX-1 is present in most cell types and is usually expressed constitutively. In contrast, COX-2 expression is typically transient and is often induced by inflammatory factors such as endotoxin or cytokines. Not only is COX-2 expression under control by multiple factors but the degradation of its protein is rapid due, in particular, to a unique 27 amino acid sequence near its C-terminus. Thus, while COX-1 degradation is slow or undetectable, the $T_{1/2}$ for COX-2 protein degradation varies from 2 to 7 h [26].

n-3 PUFA have been implicated in the reduction of COX-2 expression in a number of tissues [27–29] particularly in relation to malignant cells [30–33]. Moreover, a short report suggested beneficial effects of α -linolenic acid on inflammation and prostaglandin E_2 production in horse joint tissue [34]. Because of the persuasive evidence for a central role for COX-2 activity in the pathogenesis of arthritis, we decided to examine the effect of PUFA on expression and activity of COX-2 using in vitro tissue culture model systems that mimic cartilage matrix degradation in degenerative joint diseases. The results show that, while the n-6 PUFA arachidonate had no beneficial effect in lowering the IL-1 induced levels of COX-2, the n-3 PUFA EPA reduced mRNA and protein levels down to control values. Activity, as measured by PGE $_2$ production, was also reduced in a dose-dependent manner by EPA. These data provide evidence for a molecular mechanism underlying the beneficial effect of dietary n-3 PUFA in arthritis patients.

Experimental Procedures

Materials

Collagenase Type II, isolated from *Clostridium histolyticum* was from Worthington, pronase (*Streptomyces griseus*) from Boehringer and Dulbecco's modified Eagle's medium (DMEM) and foetal calf serum (FCS) from Gibco-BRL (now Invitrogen). Fatty acid standards were from Nu-Chek Prep. or Sigma-Aldrich and recombinant human interleukin-1 α (IL-1 α) or IL-1 β from Totam Biologics. Other chemicals were of the best available grades and were from Sigma-Aldrich or Boehringer-Mannheim (now Roche Diagnostics).

Isolation and Culture of Bovine Chondrocytes

Bovine metacarpo- or metatarsophalangeal joints from 7 day-old calves were obtained from the local abattoir. Human tissue was obtained from patients undergoing total knee replacement surgery for osteoarthritis (Llandough Hospital, S. Wales, UK). All procedures had Local Ethical Committee Approval. Cartilage tissue slices were obtained in sterile conditions and placed in DMEM before subjecting them to pronase and collagenase digestion to isolate the chondrocytes [35]. Monolayer cultures were established in 60 mm culture dishes by plating 1 ml/dish of a suspension of 6×10^6 chondrocytes/ml of DMEM. In the case of human chondrocytes these had to be passaged several times to obtain enough cells for analysis. Cultures were maintained overnight in the absence or presence of 1–10 μ g/ml (for bovine cultures) or 10–30 μ g/ml (for human cultures)

of the n-3 polyunsaturated fatty acid (PUFA), eicosapentaenoic acid (all *cis* Δ5, 8, 11, 14, 17–20:5, EPA) or the n-6 PUFA arachidonic acid (all *cis* Δ5, 8, 11, 14–20:4, ARA). Previous experiments had established that these were appropriate concentrations to observe changes in gene expression in these two tissues (see e.g. [36]). Prior to addition to the cultures, all PUFA were incubated for 16 h at 37 °C in Tyrode-HEPES buffer (20 mM HEPES, 140 mM NaCl, 4.5 mM KCl, 1 mM MgCl₂, 2.5 mM CaCl₂, 11 mM glucose, pH 7.4) containing 3.5 mg/ml fatty acid-free bovine albumin. Following incubation with the PUFA, the culture medium was removed, the cells washed in fresh DMEM and new media (without PUFA) added with supplementation with or without 10 ng/ml IL-1 α or IL-1 β for bovine or human cultures, respectively. The cells were further incubated at 37 °C for 4 days before harvesting.

Explant Cultures

Cartilage explants were obtained from both bovine metacarpal- and metatarsophalangeal joints (7 day-old calves) and from human patients undergoing total knee replacement surgery for OA as described above. The explant cultures were established by taking diced cartilage (20–70 mg wet weight) and maintaining them in 1 ml of DMEM containing 10% FCS (plus 50 μ g/ml gentamicin, 0.5% antibiotic/antimycotic solution 100 \times for the human cultures) for 72 h at 37 °C, with aeration using 5% CO₂/95% air. Following pre-culture, the explants were washed (3 \times 10 min) in serum-free DMEM and maintained for 24 h in individual wells of 24-well plates with 1 ml of serum-free DMEM with or without 1–10 μ g/ml (for bovine cultures) or 10–30 μ g/ml (for human cultures) n-3 or n-6 PUFA. After this culture period, the medium was removed and explants washed and fresh medium (no PUFA) added with or without 10 ng/ml IL-1 α (for bovine tissue) or IL-1 β (for human tissue) and cultured for a further 4 days before harvesting.

RNA Extraction and PCR Analysis

Total RNA was extracted from intact cartilage explants. Explants were snap-frozen in liquid nitrogen and then

subjected to pulverisation with a Braun Mikro-Dismembrator for 1 min at 2000 rpm. Tri-reagent (Sigma-Aldrich) was added to the powdered cartilage (1 ml for samples up to 100 mg) prior to RNA isolation using the Qiagen RNeasy miniprep kit. To 1 ml of Tri-Reagent, 0.2 ml of CHCl₃ was added and the mixture left at room temperature for 15 min. Following centrifugation at 13200 rpm for 15 min, the upper phase was transferred to a sterile 1.5-ml tube containing 375 μ l of 70% ethanol and mixed by inverting. The mixture was applied to a spin column and RNA was isolated following the manufacturer's protocol (Qiagen).

Reverse transcription-polymerase chain reactions (RT-PCR) were performed using an RNA PCR kit (Perkin-Elmer) as described previously [37] using oligonucleotide primers specific to cyclooxygenase cDNA sequences (see Table 1). Following an initial denaturation step of 1 min at 95 °C, amplification consisted of 30–45 cycles of 1 min at 95 °C, 45 s at the individual annealing temperature of the primers (Table 1), 30 s at 72 °C, followed by a final extension step of 5 min at 72 °C. The PCR products were visualised on 3% agarose gels (containing 0.5 μ g/ml ethidium bromide) under UV light.

The Wizard PCR Preps DNA Purification System (Promega) was used to purify the PCR products following the manufacturer's guidelines. The PCR products were sequenced to check the template specificity of each primer by using an Applied Biosystems AB1310 Genetic Analyser. This was followed by alignment of nucleotide sequences using the MacDNASIS sequence analyser software package (Hitachi).

Individual gels were scanned using a Kodak Digital IB Image Analysis apparatus to provide densitometric values for the PCR products. These densitometric values were normalised to those for GAPDH (used as a constitutive gene) from the same cDNA samples.

SDS-PAGE and Western blot Analysis of Cyclooxygenase Protein

Monolayer cultures were washed twice with cold phosphate-buffered saline (PBS) and, using a rubber cell

Table 1 Oligonucleotide primers used in RT-PCR

	Target	PCR Primer sequence (5'-3')	Annealing Temp (°C)	Product size (bp)

scraper, the chondrocytes were scraped from their plates into 1 ml of cold lysis buffer (40 mM Tris, 1 mM EDTA, 250 mM sucrose, 5 mM DTT, 0.2 M Na_3VO_4 , 0.5 mM phenylmethylsulphonyl fluoride (PMSF), 10 $\mu\text{g}/\text{ml}$ leupeptin, 1 $\mu\text{g}/\text{ml}$ anitpain, 1 $\mu\text{g}/\text{ml}$ pepstatin A), placed into tubes and kept on ice. The suspension was subjected to homogenisation by 30 passages through a narrow gauge needle and syringe. The homogenate was centrifuged at 13,000 rpm for 10 min and the supernatant kept as the protein source [38]. Samples were then dialysed and lyophilised.

The lyophilised sample was initially prepared by diluting with 2 \times Sample Buffer (0.125 M Tris HCl, pH 6.8, 4% SDS, 20% glycerol, 0.01% bromophenol blue) and Milli-Q water. The samples were reduced by adding β -mercaptoethanol at 10% of the final loading volume and the mixture heated for 10 min at 70 °C prior to gel loading. The samples were separated on 10% polyacrylamide gels (poured using acrylagel and bisacrylagel from National Diagnostics) in SDS. After electrophoresis, the fractionated proteins were transferred electrophoretically to nitrocellulose membranes (Schleicher and Schuell), blocked with 5% BSA (w/v) in TRIZMA saline azide (TSA) (50 mM TRIZMA, 200 mM NaCl, 0.02% (w/v) NaN_3 , pH 7.4 with HCl (1 h) and immuno-blotted with a polyclonal primary antibody specific to the 72 kDa COX-2 protein (Santa Cruz Biotechnology). Anti-COX-2 was used at 1:1000 dilution, overnight. The primary antibody was poured off and a secondary antibody, alkaline-phosphatase conjugated anti-goat (Sigma-Aldrich), was added at a concentration of 1:10,000 for 1 h. All antibodies were diluted with 1% BSA/TSA. The membrane was subjected to three 10 min washes in TSA and developed in alkaline phosphatase substrate; 10 ml of buffer (100 mM Tris, 100 mM NaCl, 5 mM MgCl_2 , pH 9.55) with 66 μl of nitroblue tetrazolium (NBT) (50 mg/ml in 70% dimethylformamide and 33 μl of 5-bromo-4-chloro-1-indolyl phosphate (BCIP; Promega) for 10–15 min until the optimum colour had developed.

Quantification of Prostaglandin E_2 (PGE_2)

The PGE_2 immunoassay kit from R & D Systems is a competitive enzyme immunoassay designed to measure PGE_2 concentrations in cell culture supernatants and other biological samples. This kit shows some cross-reactivity with a few eicosanoids (mainly PGE_3 and PGE_1) but no interference at mid-range PGE_2 concentrations, such as found in present study (Manufacturer's brochure). Explant culture medium was harvested and either frozen at -20 °C or assayed immediately. The assay was carried out following the manufacturer's protocol and absorbance was read at 405 nm prior to statistical analysis using Statview 4.02 package for Macintosh (Abacus Concepts Inc.).

Results

Metabolic Activity of Explant Cultures

Previous experiments with model in vitro culture systems for arthritis [38] demonstrated that fatty acids could be added as a complex with BSA, which is the natural way in which they are supplied in vivo. Such complexes have been shown to allow transport of fatty acids through the cartilage matrix at measurable rates [39].

Explant cultures of tissue from joints have been shown, when cultured appropriately, to mimic many of the features of matrix degradation found in arthritic tissues [40]. Lactate production by explants from both bovine and human joints was unaffected by the addition of IL-1, by the n-3 PUFA, EPA or the n-6 PUFA, ARA (Fig. 1a, b). These results show that general metabolism, as measured by lactate production, was not affected by any of the additions performed.

In contrast, degradation of matrix components was monitored by glycosaminoglycan (GAG) release and this was increased significantly by IL-1 α challenge in bovine explants (Fig. 1c). In control cultures, the level of GAG release was low as expected for healthy tissue. However, the level of GAG release, which was raised by IL-1 α addition, was reduced successively by increasing amounts of EPA but not by ARA (Fig. 1c). For the explants of human joint tissues, the control samples showed high levels of GAG release which fitted well with the fact that these samples were obtained from patients with advanced osteoarthritis. The amount of GAG release in these tissues was only slightly increased by IL-1 β challenge and the addition of fatty acids had no significant effect (Fig. 1d).

Effect of PUFA on COX-2 Expression

We now used these in vitro explant cultures to examine cyclooxygenase expression and activity. In control bovine tissues which had not been pre-treated with PUFA or stimulated with IL-1 α , low levels of COX-2 mRNA were found (Fig. 2a). Expression was stimulated by exposure to the inflammatory cytokine IL-1 α and this was abrogated by previous incubation of the explants with the n-3 PUFA EPA but not by the n-6 PUFA ARA (Fig. 2a).

In contrast, for the human explant cultures, COX-2 expression was significant in controls (Fig. 2b). This was indicative of the pathological state of the osteoarthritic cartilage which had been obtained from patients awaiting knee-replacement surgery. Nevertheless, expression levels of COX-2 were increased further by exposure to IL-1 β . Furthermore, COX-2 mRNA levels were reduced significantly by pre-incubation with EPA but not by

Fig. 1 Lactate production and glycosaminoglycan (GAG) release in healthy bovine (a, c) or osteoarthritic human (b, d) cartilage explant cultures. Cultures were supplemented with 1–30 μg (as shown) fatty acid/ml medium for 24 h followed by culture in the presence or absence of 10 ng/ml IL-1 for 4 days. Data show means \pm SDs ($n = 3-4$) each carried out in triplicate. * Data significantly (t test, $P < 0.05$) different from control; + Significantly different from IL-1 treated explants. The upper histograms (a, b) show lactate levels and the lower histograms (c, d) are for GAG release. Open bars without IL-1 challenge and the shaded bars for incubations in the presence of IL-1

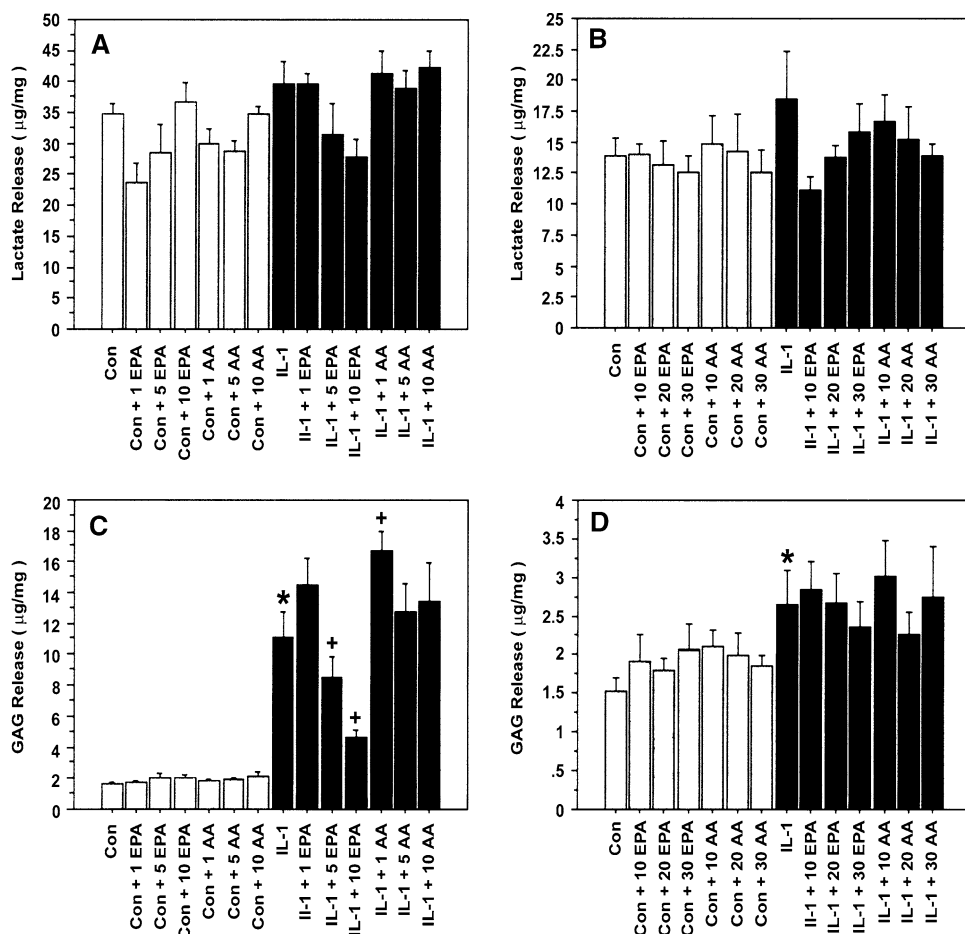

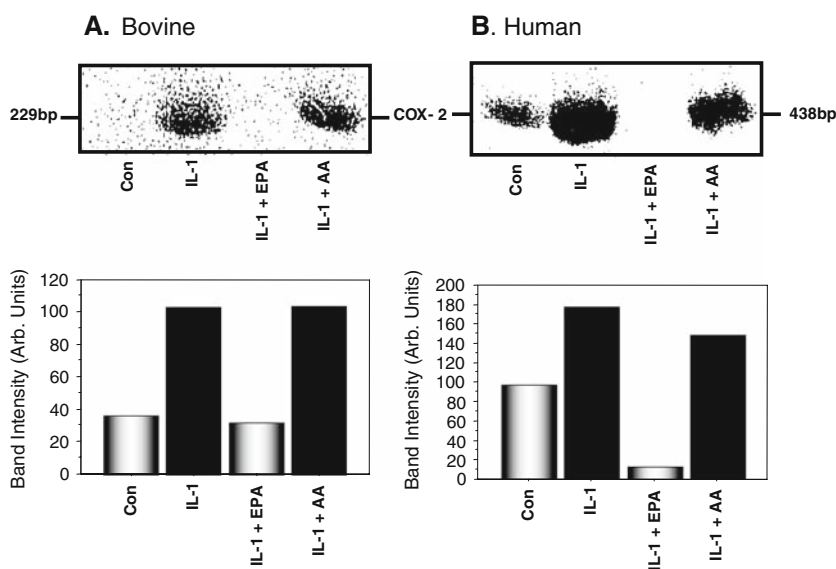

Fig. 2 mRNA levels for cyclooxygenase-2 (COX-2) in bovine (a) and human (b) cartilage explant cultures. Cultures were supplemented with 10 $\mu\text{g}/\text{ml}$ (bovine) or 30 $\mu\text{g}/\text{ml}$ (human) EPA or ARA for 24 h followed by culture in the presence or absence of 10 ng/ml IL-1 α (bovine cultures) or IL-1 β (human cultures) for 4 days. RT-PCR was carried out using specific primers (Table 1) and the Figure shows gel images in the upper portion and quantification using the NIH Image and Statview 4.02 software packages in the lower part. Representative experiments are depicted

pre-incubation with ARA (Fig. 2b). Thus, in both human and bovine cartilage explants, COX-2 mRNA was increased by the inflammatory cytokine IL-1 and this increase was strongly inhibited by the n-3 PUFA, EPA but not by the n-6 PUFA, ARA.

EPA and ARA have Opposite Effects on COX-2 Protein Levels

Because changes in gene expression are not necessarily paralleled by similar alterations in protein levels (and

Fig. 3 Western blot analysis to show the effects of 10 $\mu\text{g/ml}$ EPA or ARA on COX-2 protein levels in bovine chondrocyte cultures. Cultures were pre-incubated with fatty acids and treated with IL-1 α as described in Fig. 2

activity), we examined the effect of PUFA on COX-2 protein in IL-1 challenged bovine tissues (Fig. 3). As expected for tissue preparations from young, healthy animals, little COX-2 protein was detected in controls. Pre-incubation with EPA caused a small (non-significant) reduction in protein levels whereas ARA increased COX-2 protein more than 5-fold (Fig. 3). Incubation with IL-1 α caused a moderate increase in COX-2 protein and this was clearly abrogated by pre-incubation with EPA. In contrast, pre-incubation with ARA resulted in elevated COX-2 protein levels (Fig. 3). Similar experiments using chondrocyte preparations from the human osteoarthritic tissue were attempted several times but could not be achieved because of the small numbers of viable cells available.

Cyclooxygenase-2 Activity

Having shown beneficial effects of EPA on COX-2 expression (at both mRNA and protein levels), we quantified prostaglandin E₂ (PGE₂) as a measure of COX-2 activity. This eicosanoid is also thought to be particularly relevant to the etiology of arthritis (see [10]).

In Fig. 4, the effect of pre-incubation with different concentrations of EPA is shown. For control bovine explants there were very low concentrations of PGE₂ detected—as expected given the low levels of COX-2 expression (Fig. 2) in such preparations. Pre-incubation

Fig. 4 Prostaglandin E₂ (PGE₂) production in bovine explant cultures is stimulated by IL-1 α and reduced dose-dependently by EPA. Cultures were supplemented with or without 1–10 $\mu\text{g/ml}$ EPA for 24 h and then challenged with 10 $\mu\text{g/ml}$ IL-1 α for 4 days. Means (pg PGE₂/mg fresh wt. of tissue) \pm SD ($n = 4$) shown. ***/** Significantly different (t test, $P < 0.05/P < 0.01$) from IL-1-treated alone

with EPA did not change the amount of PGE₂ released. Exposure to IL-1 α caused a large elevation in PGE₂ levels and these were progressively reduced by pre-incubation of the tissue with increased amounts of EPA (Fig. 4).

For human explant cultures, significant PGE₂ release was found in controls, due to the pathological state of the original tissue. This varied between 4 and 31 pg/mg fresh wt. tissue for preparations from different patients. In order to allow comparisons, results (Fig. 5) are expressed as a percentage of the level of PGE₂ which was induced by incubation with IL-1 β . On average this caused about a five-fold increase in the PGE₂ detected relative to control. However, pre-incubation with EPA was able to reduce PGE₂ back to control levels whereas pre-incubation with ARA had no effect on the IL-1 β -induced PGE₂ concentrations (Fig. 5).

Discussion

In arthritis it is well accepted that inflammatory changes are critical to the development and exacerbation of the disease. IL-1 and TNF- α are the main cytokines involved [10] and here we have used IL-1 to induce molecular changes in model systems that mimic cartilage degradation in arthritis. IL-1, which is raised in arthritic tissue [33], also increases expression of COX-2 in a variety of cell types such as cardiac [41] or venous epithelial cells [28] and our experiments (Figs. 2, 3) are consistent with these findings. While dietary n-6 PUFA increase inflammatory cytokines,

Fig. 5 Prostaglandin E₂ (PGE₂) production in human osteoarthritic joint explant cultures is reduced by EPA but not by ARA. Treatments as in Fig. 2. The data are expressed as % of the +IL-1 β value which had a mean of 400 pg/mg fresh wt. of tissue for the 8 patients. Means \pm SD ($n = 8$) shown. Significant differences (t test) shown

such as IL-1 and TNF- α , as well as COX enzymatic products [2], dietary n-3 PUFA reduce inflammatory gene expression [42, 43] including that of COX-2 [15]. Some of the effects of the n-3 PUFA may be via resolvins [44] in addition to the classic eicosanoids [23]. In addition, the n-3 and n-6 PUFA have antagonistic effects on TNF receptors [45].

Here we show that the n-3 PUFA, EPA, is able to reduce COX-2 expression, protein levels and activity in both bovine and human tissue cultures, which act as models for cartilage degradation in arthritis. These effects suggest a functional manifestation of the benefit of dietary n-3 PUFA. These data parallel other experiments showing that n-3 PUFA reduce COX-2 expression and/or activity in several other systems [28, 46], especially neoplastic tissues [29, 31–33]. Furthermore, in chondrocyte cultures (as used in this work) we showed that EPA was the most effective n-3 PUFA [36].

The molecular basis for the dietary benefits of n-3 PUFA is not yet resolved and it is probably multifactorial [23]. Such dietary components may affect the expression of COX-2 via Toll-like receptors [47] and inflammatory signalling pathways such as NF κ B [48]. Indeed, the latter has been proposed as a potential therapeutic target for arthritis [49]. Here we have been able to show that the reduction of PGE₂, which is a therapeutic goal for the use of COX-2 inhibitors in arthritis treatment [24], is dose-dependent on the n-3 PUFA, EPA, and that this, in turn, is due to a reduction in both COX-2 gene and protein expression.

Whether the alterations in gene expression are mediated through NF κ B, such as has been proposed from work related to cardiovascular disease using venous epithelial cells [28], requires further experiments. Nevertheless, our data indicate interesting parallels between the two chronic inflammatory conditions, cardiovascular disease and arthritis [7], both of which benefit from dietary n-3 PUFA.

Acknowledgments This investigation was supported financially by the Arthritis Research Campaign and the Biotechnology and Biological Sciences Research Council (Grant D16961) for which we are grateful.

Abstract Ezetimibe inhibits cholesterol absorption in the intestine. Sphingomyelin has strong interactions with cholesterol. We investigated the effects of ezetimibe on Sphingomyelinase (SMase) expression in intestine and liver. After feeding rats with ezetimibe (5 mg/kg per day) for 14 days, acid SMase activities in the liver and in the proximal part of small intestine were reduced by 34 and 25%, respectively. Alkaline SMase (alk-SMase) was increased in the proximal part of the small intestine. Administration of lower doses of ezetimibe reduced acid SMase only in the liver by 14% ($P < 0.05$). In cell culture studies, ezetimibe decreased acid SMase activity in Hep G2 and Caco-2 cells dose-dependently. The reductions were more rapid for Hep G2 cells than for Caco-2 cells. Western blot showed that acid SMase protein was decreased in both Hep G2 and Caco-2 cells by 100 μ M ezetimibe. The SM content was increased in Hep G2 cells but not Caco-2 cells, and total cholesterol content was increased in both cell lines 24 h after stimulation with 100 μ M ezetimibe. Mevastatin, the inhibitor of cholesterol synthesis, induced a mild increase in acid SMase activity in Hep G2 cells but not Caco-2 cells. Following the reduction of acid SMase, ezetimibe at high dose slightly increased alk-SMase activity. In conclusion, the study demonstrates an inhibitory effect of ezetimibe on acid SMase activity and expression in both liver and intestine.

NPC1	Niemann–Pick C1
NPC1L1	Niemann–Pick C1 like 1 protein
SM	Sphingomyelin
SMase	Sphingomyelinase

Introduction

Ezetimibe is an effective drug that inhibits the absorption of biliary and dietary cholesterol from the small intestine. In the intestinal tract, ezetimibe is glucuronidated, transported to the liver, and in turn secreted in the intestine in response to diet [1]. The glucuronide form is more potent than ezetimibe itself. Studies using Niemann–Pick C1 like 1 (NPC1L1) protein deficient mice indicated that NPC1L1 is the target of ezetimibe [2, 3]. NPC1L1 is a membrane protein that shares 42% identity with Niemann–Pick C1 (NPC1) protein [4]. NPC1L1 is expressed in the intestine and also several other organs including liver, and plays important roles in mediating cholesterol absorption and uptake. Besides the effect on absorption of cholesterol in the intestine, ezetimibe has also been shown to affect the metabolism of lipoproteins, such as to increase HDL levels, and enhance clearance of LDL via upregulation of LDL receptors [1]. In addition, ezetimibe may have other effects such as to improve insulin resistance in obese mice, improve the liver function in non-alcohol fatty liver disease

[5], and reduce the formation of gallstones [6]. The mechanisms underlying these effects are largely unknown.

Sphingomyelin (SM) is a type of sphingolipid, which interacts strongly with cholesterol to form a stable complex. Previous studies have shown that hydrolysis of membrane SM by sphingomyelinase (SMase) affects cholesterol metabolism. Treating the fibroblasts with exogenous SMase increases the mass cholesterol ester in the cells associated with an increase in ACAT [7] and HMG-CoA reductase activities [8], whereas in the cells isolated from Niemann–Pick diseases, the trafficking of cholesterol into the cells is impaired [9]. SM levels in the intestine may also affect cholesterol absorption. Chan et al. [10] showed that treating Caco-2 cells with exogenous SMase reduces the uptake of cholesterol. We previously showed that when animals were fed cholesterol together with SM, the cholesterol absorption decreased with increasing the amount of SM in the diet [11]. In the intestinal tract, the levels of SM are mainly regulated by two types of SMases: acid SMase and alkaline SMase (alk-SMase) [12, 13]. Acid SMase activity is relatively high in the proximal part of the intestine and liver. The main function of acid SMase is to degrade the internalized SM associated with endocytosis. Genetic lack of acid SMase causes Niemann–Pick disease, which is characterized by an accumulation of both SM and cholesterol in lysosomes [14]. Alk-SMase is distributed mainly in the middle part of the intestine and is the main enzyme for hydrolyzing dietary SM and also affects the membrane bound SM of the mucosal cells.

The present study investigated whether ezetimibe changes activity and expression of SMases in the intestine and liver both *in vivo* and *in vitro*. Our results disclosed an inhibitory effect of ezetimibe on acid SMase expression.

Materials and Methods

Materials

Female Sprague–Dawley rats weighing about 225 g were obtained from Mollegaard, Denmark and kept under normal housing conditions with free access to drinking water. The Hep G2 and Caco-2 cells were obtained from American Tissue Culture Collection. SM was purified from bovine milk and labeled with [^{14}C -CH $_3$] choline ([^{14}C -SM]). Antibody against acid SMase was purchased from Santa Cruz and antiserum against alk-SMase was generated as described earlier [15]. The cell culture media and other chemical agents used were purchased from Sigma Co. (Stockholm, Sweden). Ezetimibe tablets (10 mg/tablet) and purified ezetimibe were obtained from Schering–Plough Research Institute (Kenilworth, NJ, USA). ^{14}C -cholesterol

(0.1 mCi/ml) was purchased from American Radiolabeled Chemicals (Malmö, Sweden).

Preparation of Ezetimibe for Animal Study

Two types of animal studies were performed. In type 1, the tablets of ezetimibe (10 mg/tablet) were ground, dissolved in distilled water, and then given to the animals by gavage according to Deushi [5]. In the second type of experiment, dietary chows containing ezetimibe were prepared based on the method of Lillienau et al. [16]. Briefly, standard chow R34 (Lactamin AB, Sweden) was soaked in 100 ml 99.5% ethanol containing 9 mg ezetimibe. After saturation, the reduction of the solution volume was measured and the amount of ezetimibe incorporated into the pellets was calculated. The pellets were air-dried at room temperature overnight. Using this procedure, a chow containing 0.001% (w/w) ezetimibe was obtained. The diet was stored at 4 °C, and given to the animals daily.

Animal Study

In the type 1 study, six rats were given ezetimibe by gavage once a day at a dose of 5 mg/kg in a volume of 1 ml for 14 days. Those in the control group ($n = 6$) were given distilled water only. In the type 2 study, six rats were provided with 25 g pellets containing ezetimibe per day for 14 days, and another six rats in the control group were given 25 g normal pellets. The remaining food was weighed everyday and the food intake was recorded. After feeding, all the animals were anesthetized with an intramuscular injection of ketamine (60 mg/kg body weight) and xylazine (8 mg/kg body weight), and killed by puncture of the aorta. The liver and whole gastrointestinal tract were removed. A part of the liver was homogenized in 0.15 M NaCl containing 6 mM taurodeoxycholate and 1 mM benzamidine. The homogenate was centrifuged at 12,000g for 10 min and the supernatant was saved for biochemical analysis. The small intestine was cut into three segments in equal length, representing the proximal, middle and distal parts of the organ. The intestinal content was washed out with ice cold 0.15 M NaCl, and the intestinal mucosa was scraped and homogenized as previously described [17]. After centrifugation, the supernatant was saved for biochemical analysis. The colon was used as a single segment and one piece of feces was collected. The research was conducted in conformity with PHS policy and was approved by the animal ethical committee of Lund University, Sweden.

Cell Culture Study

Hep G2 cells and Caco-2 cells were cultured in RPMI-1640 medium and DMEM medium, respectively, containing

4.5 g/l glucose, 2 mM glutamine, 100 IU/ml penicillin, 10 µg/ml streptomycin, and 10% heat inactivated FBS. Pure ezetimibe was dissolved in DMSO as a stock. After culturing with ezetimibe at different concentrations, the cells were scraped, lysed, sonicated and centrifuged as described previously [15]. The supernatant was used for biochemical analysis. For a time-course study, the cells were incubated with ezetimibe (50 µM) for 8, 16, 24 and 48 h. The cells in control groups were incubated with the vehicle DMSO only. At each time point, the cells in both control and experimental groups were lysed and the activities of acid and alkaline SMase were determined. The changes of the activities were expressed as percentage of the values in control group at each time point.

Assay Cholesterol Absorption and Cholesterol Content in the Cells

The efficiency of ezetimibe used was checked by examining its effect on cholesterol absorption in Caco-2 cells according to Chen et al. [10]. The cells were cultured with micelles contained ^{14}C -cholesterol (50 µCi) for 4 h in the presence of different concentrations of ezetimibe. After treatment, the cells were washed, scraped and lysed in 0.2 M NaOH, and the absorbed ^{14}C -cholesterol was determined by liquid scintillation. For measuring the total cholesterol content in the cells, both Hep G2 and Caco-2 cells were treated with ezetimibe at different concentrations for 24 h. The total cholesterol in the cells was extracted by sonication of the cells in 0.5 ml of isopropyl alcohol according to Heider and Boyett [18]. After centrifugation at 8,000g for 10 min, the cholesterol in the supernatant was measured fluorometrically using a cholesterol assay kit purchased from Cayman (Ann Arbor, USA). The final concentration of isopropyl in the assay system is 1.7 µl in 1 ml assay buffer for both control and ezetimibe-treated samples. The cell pellet was dissolved in 0.2 M NaOH and the protein content was determined. The total cholesterol levels were expressed against the protein levels.

Sphingomyelinase Assay

The activities of different types of SMase activity were analyzed with different buffers as described [19]. The assay buffers used were 50 mM Tris–maleate buffer pH 5.0 containing 0.15 M NaCl and 0.12% Triton 100× for acid SMase, 50 mM Tris–HCl buffer pH 7.5 containing 4 mM Mg^{2+} and 0.12% Triton 100× for neutral SMase, and 50 mM Tris–HCl pH 9.0, containing 2 mM EDTA, 0.15 M NaCl, and 6 mM taurocholate for alk-SMase. Each sample in 10 µl was mixed with 90 µl of the corresponding buffer containing 80 pmol [^{14}C]-SM (~8,000 dpm) and

incubated at 37 °C for 30 min. The reaction was terminated by adding 0.4 ml of chloroform/methanol (2/1, v/v) followed by centrifugation at 10,000g for 5 s. An aliquot of the upper phase was taken and the production of ^{14}C -phosphocholine was determined by liquid scintillation. The preparation of the fecal samples for SMase assay was described previously [20].

Western Blot

Seventy micrograms of proteins in cell lysate were subjected to 7.5% SDS-PAGE for acid SMase or to 10% SDS PAGE for alk-SMase. The resolved proteins in the gel were transferred to a nitrocellulose membrane electrophoretically overnight. The membranes were either incubated with anti acid SMase (1:5,000) or anti alk-SMase antibody (1:2,500), and then with the second antibody (1:50,000) conjugated with horseradish peroxidase. The specific acid SMase and alk-SMase bands were identified by enhanced chemiluminescence advance reagent. The membranes were then stripped and re-probed with anti-actin antibody as a loading control. The details of the methods have been described elsewhere [15]. The densities of the bands were quantified by use of the software Scion Image (www.scioncorp.com).

Changes of SM in Cells after Ezetimibe Treatment

The changes of SM in the cells were determined as described [15]. In brief, the cells were first incubated with [^3H]-choline chloride (0.5 µCi/ml) for 48 h to label the endogenous SM. After that, the excess ^3H -choline chloride was removed and the cells were then treated with ezetimibe for 24 h in the absence of ^3H -choline chloride. The cell-free extract was prepared as described above and the protein concentration in the lysate was determined. The total lipids in the lysate were extracted according to Bligh and Dyer [21] and applied to the 60F Silica Gel plate (0.25 mM) for TLC. The plates were developed with chloroform/methanol/ammonium hydroxide (65/25/4 v/v/v) and stained with iodine vapor. The bands of SM were scraped according to the authentic standards and the radioactivity in the various bands was counted by liquid scintillation. The levels of SM were adjusted to the protein concentrations of the cell lysate.

Direct Effects of Ezetimibe on SMase Activity

To investigate whether ezetimibe has a direct effect on acid SMase activity, 30 µl of cell-free extract from Hep G2 or Caco-2 cells was incubated with ezetimibe at 0, 50 and 100 µM at 37 °C for 1 h or with DMSO as a control. The enzyme activities were then determined. The changes of

enzyme activity were expressed as percentage of control. For investigating the direct effect of ezetimibe on alk-SMase, purified alk-SMase (15 nmol/h per ml) was incubated with ezetimibe in a way similar to that above.

Other Biochemical Determinations

The acid and alkaline phosphatase activities were analyzed as described previously [20] using *p*-nitrophenylphosphate as a substrate. Proteins were determined with a kit from Bio-Rad using bovine albumin as a standard.

Results

Ezetimibe Administration Reduced Acid SMase Activities in Rat Accompanied by a Slight Increase in Alk-SMase Activities

After feeding rats with ezetimibe in either high or low doses, there were no great differences in body weight and food intake between the control and the treated animals (data not shown). When SMase activities were determined, the acid SMase activity in the liver of the rats fed high dose of ezetimibe was significantly decreased by 34% (Fig. 1, upper panel). Neutral SMase activity was not changed and alk-SMase activity was not detectable in rat liver. Feeding animals with the low dose of ezetimibe also decreased hepatic acid SMase activity, but to a lesser extent (lower panel). When the activities in the intestine were examined, a significant reduction of acid SMase activity by 25% (Fig. 2a) and an increase in alk-SMase by 52% (Fig. 2b) were identified by high dose, but not low dose of ezetimibe (Fig. 2c, d). The changes were observed only in the proximal part of the small intestine. There was also no change of SMase in either colonic mucosa or stool of the rats in both high and low dose experiments (data not shown).

Changes of Acid and Alk-SMase Activity in Hep G2 and Caco-2 Cells after Ezetimibe Treatment

For further characterizing the effects of ezetimibe on SMases found in vivo, we examined the effects of ezetimibe on SMases in Hep G2 liver cells and Caco-2 intestinal cells. Before starting such experiments, the efficiency of ezetimibe was checked by measuring its inhibitory effects on cholesterol absorption in Caco-2 cells. We found that ezetimibe ranging from 12.5 to 100 μ M dose-dependently inhibited cholesterol absorption (data not shown). In these concentrations, we found that ezetimibe inhibited acid SMase activities in both cell lines (Fig. 3 upper panel). The effects occurred at concentrations higher than 25 μ M. The Caco-2 cells appeared less sensitive than

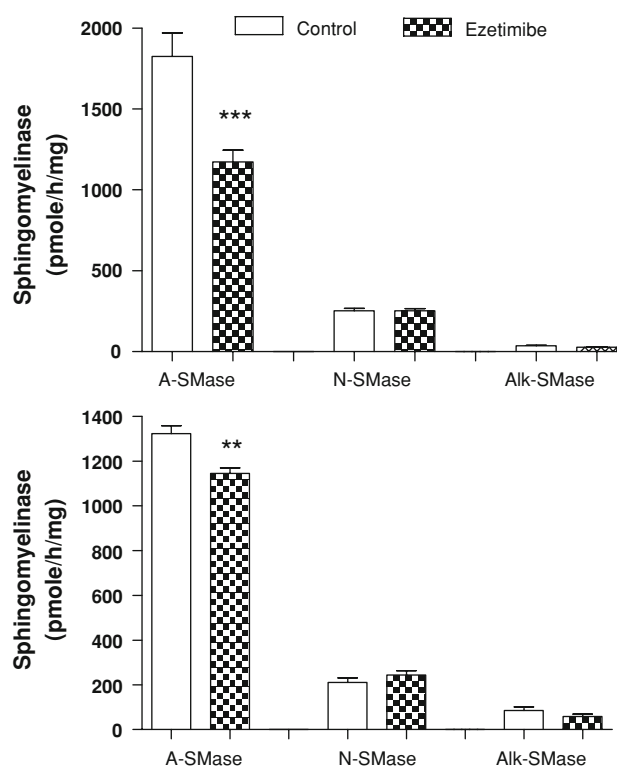

Fig. 1 Changes of SMase activity in rat liver after ezetimibe administration. In the *upper panel*, rats were fed ezetimibe by gavage at a dose of 5 mg/kg for 14 days. In the *lower panel*, the animals had free access to chow pellets containing 0.001% ezetimibe for 14 days. The activities of three types of SMase in the liver were determined. Results are mean \pm SE, $n = 6$. ** $P < 0.01$, *** $P < 0.001$ compared with control

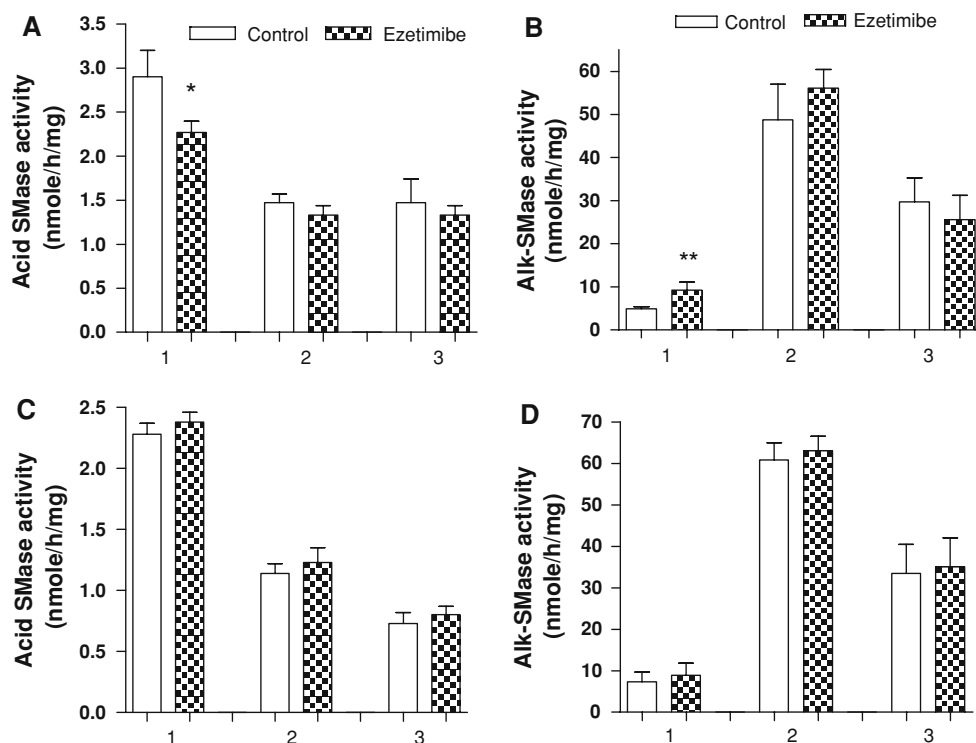

that of Hep G2 cells. As for alk-SMase (lower panel), the basal activity was higher in Caco-2 cells than in Hep G2 cells. Ezetimibe appeared increasing alk-SMase activity, but a statistically significant increase was demonstrated only after stimulation with ezetimibe at 100 μ M.

The time courses for the changes of SMases were shown in Fig. 4. The ezetimibe-induced reduction of acid SMase was more rapid in Hep G2 cells than in Caco-2 cells, with the maximal reduction occurred earlier in Hep G2 cells than in Caco-2 cells. For the changes of alk-SMase, a significant increase was demonstrated 48 h after incubation in both cell lines.

Mevastatin Mildly Increased Acid SMase Activity in Hep G2 Cells

When we identified the changes of SMase in the cells after ezetimibe treatment, we also examined whether mevastatin, the inhibitor of cholesterol biosynthesis had a similar effect on SMases activity. We treated the cells with mevastatin at the same concentrations as ezetimibe for 24 h.

Fig. 2 Changes of SMase activity in rat intestine after ezetimibe administration. Rats were either fed ezetimibe at a dose of 5 mg/kg by gavage or had free access to chow pellets containing 0.001% ezetimibe for 14 days. The small intestine was removed and cut into three parts, representing proximal, middle and distal small intestine. The acid and alkaline SMase activities in the mucosa were determined. **a** Acid SMase, high dose of ezetimibe, **b** alk-SMase, high dose of ezetimibe, **c** acid SMase, lower dose of ezetimibe, and **d** alk-SMase, low dose of ezetimibe. Results are mean \pm SE $n = 6$. * $P < 0.05$, ** $P < 0.01$ compared with control

A mild increase of acid SMase activity in Hep G2 cells was identified (Table 1).

Western Blots Showed a Reduced Expression of Acid SMase by Ezetimibe in Hep G2 and Caco-2 Cells

To examine whether the changed SMase activities were associated with changes of the enzyme proteins, Western blots were performed. A representative result is shown in panel a and b in Fig. 5. Ezetimibe decreased the expression of acid SMase in both Hep G2 and Caco-2 cells. However, the effects were obvious in the cells treated with 100 μ M of ezetimibe. Density determination of six samples in three separate experiments found that ezetimibe decreased acid SMase mass by 57.2 ± 10.3 ($P < 0.001$) and $74.4 \pm 5\%$ ($P < 0.0001$) in Hep G2 and Caco-2 cells, respectively. As to alk-SMase, ezetimibe at 100 μ M showed 43 and 23% increases in the protein in Caco-2 and Hep G2 cells, respectively.

Changes of SM and Cholesterol Levels in Hep G2 and Caco-2 Cells by Ezetimibe

Whether the changed acid and alkaline SMase expression affects the SM levels in the cells is shown in Fig. 6. We found that incubating the cells with 50 μ M ezetimibe for 24 h did not induce significant changes of SM content in

both Hep G2 and Caco-2 cells, whereas incubating the cells with 100 μ M ezetimibe increased the SM content in Hep G2 cells, but not in Caco-2 cells. Incubating the Caco-2 cells even for 48 h with ezetimibe did not induce an accumulation of SM levels (data not shown). Ezetimibe up to 50 μ M had no effects on total cholesterol levels in both Hep G2 and Caco-2 cells. However, 100 μ M ezetimibe increased total cholesterol levels in both cell lines, the effect being greater in Hep G2 cells than in Caco-2 cells (Table 2).

Other Effects of Ezetimibe

In order to assess the specificity of the changes of SMases found in this study, we determined acid and alkaline phosphatase activities in the cells treated with ezetimibe. Ezetimibe up to 50 μ M had no effects on acid phosphatase activity in both Hep G2 and Caco-2 cells. At the highest concentration (100 μ M) ezetimibe only decreased acid phosphatase activity by 20%. No change of alkaline phosphatase activity was identified by ezetimibe.

We also examined whether ezetimibe can directly affect the acid and alkaline SMase activities. Pre-treating the cell lysate with ezetimibe up to 100 μ M in test tubes at 37 $^{\circ}$ C for 1 h did not change the acid and alkaline SMase activity (data not shown). Incubating the purified alk-SMase with ezetimibe also did not affect the enzyme activity.

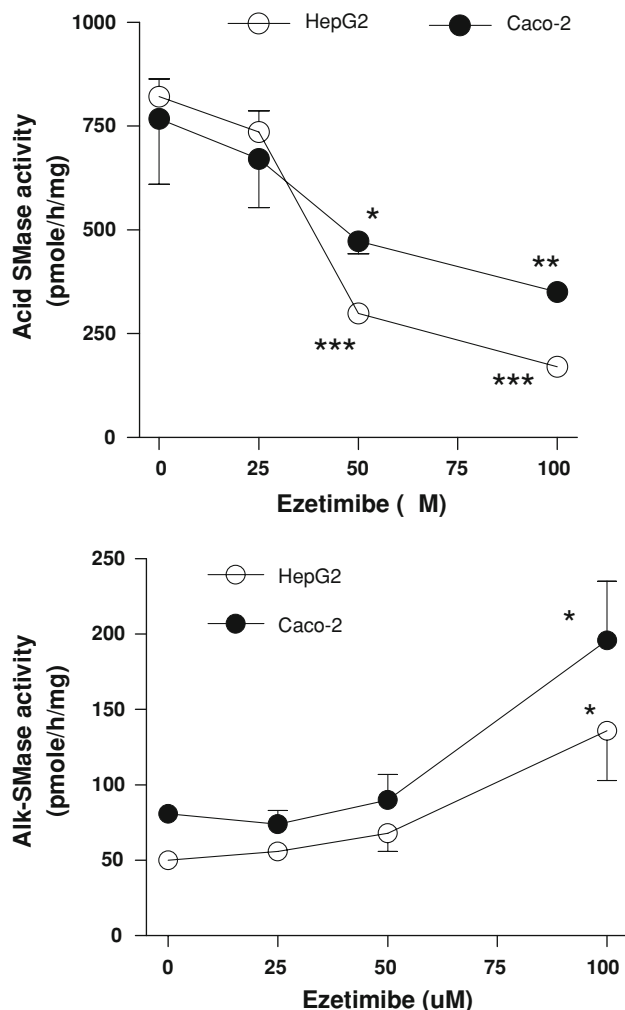

Fig. 3 Changes of acid SMase (*upper panel*) and alk-SMase (*lower panel*) in Hep G2 and Caco-2 cells. The cells were treated with ezetimibe for 24 h and the activities of acid and alkaline SMases were determined. Discussion

Ezetimibe is a well known inhibitor of cholesterol absorption and is used in the treatment of patients with hypercholesterolemia. The effects are believed to be mediated by interference of a specific intestinal sterol transporter NPC1L1, which is located on the apical membrane of absorptive mucosal cells [2]. The present study discovered a novel effect of ezetimibe, i.e., to inhibit acid SMase expression both in the intestinal tract and liver, and both in animal studies and human cell cultures. The effects showed a dose-dependent pattern, and the effective concentration was higher than 25 μ M in culture studies after 24 h incubation. Although the effective concentration in vitro was higher than that measured in the peripheral blood of human beings [22], the portal concentration reaching the

liver and the luminal concentration in the small intestine could be much higher. Particularly, our in-vivo study showed that a low dose of ezetimibe (chows containing 0.001% ezetimibe w/w) did decrease acid SMase in the liver of the rat, indicating that a clinical relevance should be considered. The effect is likely to be specific, as ezetimibe had no similar effect on acid phosphatase, another lysosomal enzyme.

Comparing the reduction of acid SMase activity with the levels of enzyme protein on Western blot, we found that the reduction of activity occurred earlier than the reduction of the enzyme protein. When 50 μ M ezetimibe decreased acid SMase activity by about 50%, no similar reduction of acid SMase protein could be found in Western blot examination. This discrepancy may not be explained by a direct inhibition of ezetimibe on the enzyme, as pre-incubation of cell lysate with ezetimibe in vitro did not change acid SMase activity. The hypothesis is that ezetimibe at lower doses can affect post-translational regulation of acid SMase and at high doses, the translation or transcription of the acid SMase gene. It has been demonstrated that post-translational modification which involves glycosylation, phosphorylation, and proteolytic processing, as recently reviewed [23], is an important step for maturation of acid SMase and therefore its activity. Further study may be required to examine whether ezetimibe could affect any process of the maturation of acid SMase.

Of interest is that liver appears more sensitive than the intestine in response to ezetimibe. Feeding high doses of ezetimibe to rats decreased acid SMase activity to a greater extent in the liver than in the small intestine, and feeding low doses of ezetimibe only reduced acid SMase in the liver, not in the small intestine. Time course experiments also showed that the reduction of acid SMase in Hep G2 cells occurred more rapidly than in Caco-2 cells. The reason for such differences is not known. The effect of ezetimibe on cholesterol absorption is thought to be mediated by an inhibition of NPC1L1. Whether the inhibitory effect on acid SMase is also mediated by NPC1L1 inhibition is unknown. Our result, that reduction of acid SMase occurs only in the proximal part of small intestine, may indicate an involvement of NPC1L1, as NPC1L1 is highly expressed in this part of the small intestine [2]. However, regarding the different sensitivities between liver and intestine, there is no evidence indicating that the level of NPC1L1 is higher in liver than in the small intestine in rats [24]. The involvement of other mechanisms secondary or independent of the effects on NPC1L1 cannot be excluded. In fact, such a hypothesis was indicated previously by several studies [25].

Acid SMase has been considered to play important roles in the lysosomal degradation of SM that is internalized by endocytosis. Niemann–Pick disease, a genetic disease due

Fig. 4 Time course of the changes of acid and alkaline SMases induced by ezetimibe in Hep G2 (left) and Caco-2 (right) cells. The cells were treated with or without ezetimibe (EZ) (50 μ M) for different times. After treatment, the cells were lysed and the enzyme activities were determined in comparison with the control group in each time points. The activities in the control group were taken as 100%. Results were means \pm SE from duplicate culture flasks in three separate experiments (six samples)

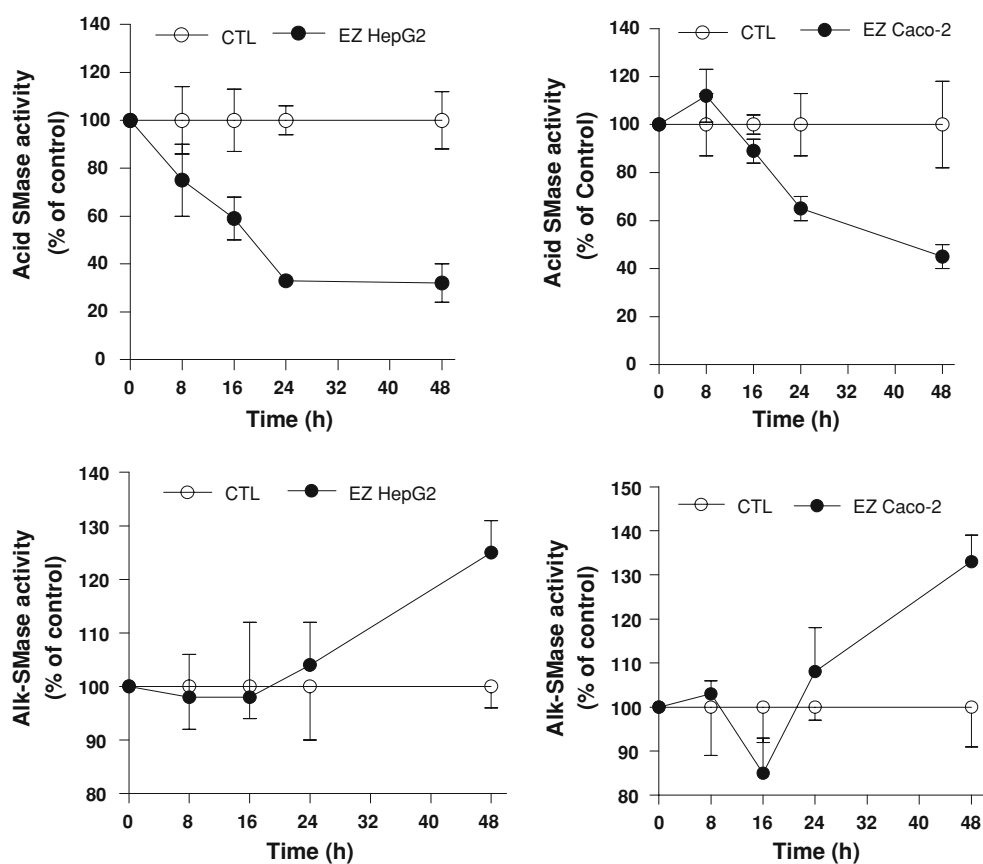

Table 1 Effects of mevastatin on SMase activity (pmol/mg per h) in Hep G2 and Caco-2 cells

	0	25	50	100 (μ M)
Hep G2

to deficiency of acid SMase, causes a mass accumulation of SM and cholesterol in the lysosomes [14]. Under the conditions studied in this paper, we found increases of total SM and cholesterol in Hep G2 cells and increased cholesterol in Caco-2 cells by ezetimibe at 100 μ M. High levels of cholesterol in the cells have been shown to inhibit acid SMase expression in NPC1 mutant cells [26]. Whether the increase in cholesterol found in this study is responsible for reduced acid SMase expression is tempting to

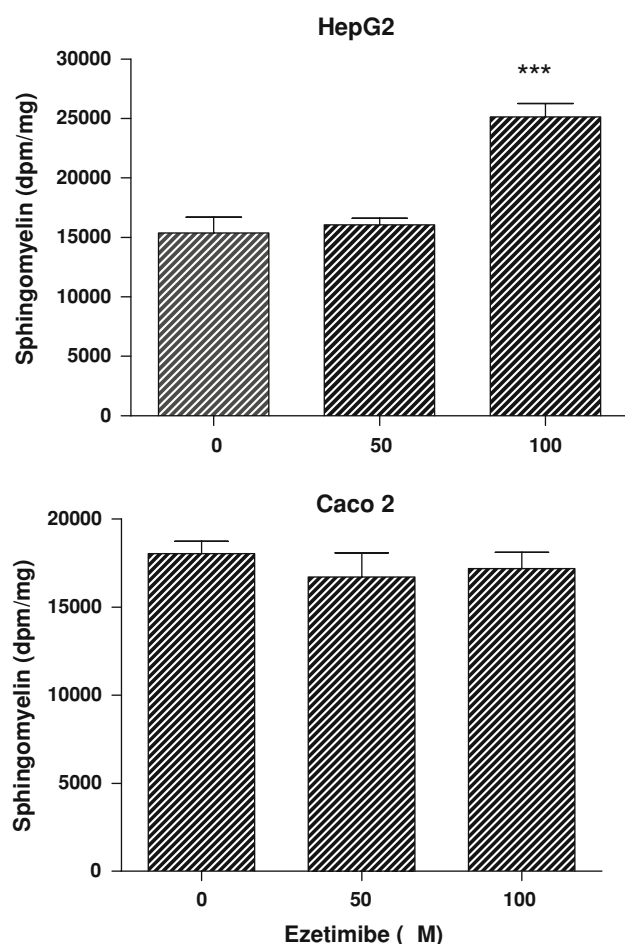

Fig. 6 The changes of SM content in Hep G2 cells and Caco-2 cells after treatment of ezetimibe. The endogenous SM was labeled with ^3H -choline chloride for 48 h before stimulation with ezetimibe for 24 h. The lipids in the cell lysate were extracted and separated by TLC. The radioactivity in the SM band was counted by liquid scintillation counting. Results were obtained from triple cell culture flasks in two separate experiments (six samples). *** $P < 0.005$ as compared with the 0 concentration of ezetimibe

speculate. Our results that mevastatin increased acid SMase activity support the hypothesis. How ezetimibe increases the cholesterol content in the cells was not examined in detail in the present work. Previous studies showed that, in NPC1L1 deficient mice, the expression of HMG-CoA synthase was significantly increased in both liver and

intestine [3], and treating the LDL receptor deficiency mice with ezetimibe resulted in a significant increase of hepatic cholesterol [27]. On the other hand, the increase in cholesterol found in this study may also be a consequence secondary to the changed SM and acid SMase activity, since high SM levels may increase the biosynthesis of cholesterol [28]. Further kinetic characterizations of the changes of SM, cholesterol, and the enzymes involved are required to address such questions.

The present study also identified an increase of alk-SMase activity in the intestinal tract by ezetimibe. Alk-SMase is the major enzyme in the intestinal tract that hydrolyzes dietary SM to form ceramide, which in turn to be degraded by ceramidase to sphingosine [29]. Previous studies have shown that alk-SMase may have anticancer and antiinflammatory effects in the gut through its ability to generate ceramide and to inactivate platelet activating factor [13]. Alk-SMase may also inhibit cholesterol uptake, because hydrolysis of membrane SM has been shown to reduce cholesterol uptake [10, 13]. However, the increase of alk-SMase induced by ezetimibe is relatively mild and occurred only in the proximal part of small intestine where alk-SMase is not high. The importance of such changes in cholesterol absorption may be questionable.

Finally it should be emphasized that our finding that ezetimibe significantly reduced acid SMase activity has clinical relevance. Acid SMase not only functions as a lysosomal enzyme, but also has signaling effects. In response to stress and pathogen stimuli, acid SMase can be relocated to the outer leaflet of the plasma membrane to hydrolyze SM and generate ceramide, a key molecule in favor of apoptosis [30]. Acid SMase activity is relatively high in the liver and has been shown to be an important enzyme for hepatic functions and liver diseases [31], such as in apoptosis induced by $\text{TNF-}\alpha$ [32] and CD95 [33]. Deficiency of acid SMase in hepatic cells may increase the risk of inflammation and proliferation, due to the resistance to apoptosis. Although ezetimibe is considered as a safe drug, case reports recently showed that it may induce liver swelling, hepatitis, and abnormal changes in liver enzymes [34–37]. How the reduction of acid SMase by ezetimibe may be involved in these phenomena is unknown. On the other hand, high levels of acid SMase in some organs

Table 2 Changes of total cholesterol (nmol/mg protein) after ezetimibe treatment in Hep G2 and Caco-2 cells

Ezetimibe	0	25	50	100 (μM)
Hep G2	140.7 \pm 11.2	135.7 \pm 13.2	137.5 \pm 14.1	313.5 \pm 58.3**
Caco-2	113.0 \pm 5.6	129.0 \pm 9.4	118.5 \pm 4.3	130.3 \pm 4.9*

The cells were cultured with ezetimibe for 24 h and then suspended in 0.5 ml isopropanol followed by sonication for 10 s. After centrifugation, the cholesterol in the supernatant was determined fluorometrically using a kit purchased from Cayman Chemical Company. The cell pellets were dissolved in 0.5 ml 0.2 M NaOH and the protein concentration was determined. The levels of cholesterol are expressed as nmol/mg cell proteins. Results are means \pm SE in triple samples in two separate experiments (six samples). * $P < 0.05$, ** $P < 0.01$ compared with 0 concentration

particularly the endothelial cells in blood vessels may have important implications in the pathogenesis of atherosclerosis, heart failure, insulin resistance and obesity, as recently reviewed [23]. It was recently shown that acid SMase could promote lipoprotein retention within early atheromata and thus accelerate the lesion progress [38]. Whether ezetimibe, by inhibiting the expression of acid SMase in endothelial cells and thus reducing the risk of cardiovascular disease would be of interest to explore. Improvement of insulin resistance after intravenous administration of ezetimibe has already been reported [5]. Our results raise questions for further investigations.

Acknowledgments The work was supported by grants from Albert Pålsson Foundation, Swedish Cancer Foundation, Swedish Research Council, and the Research Foundation of Lund University Hospital. Merck Sharp & Dohme (Sweden) AB is thanked for providing ezetimibe and financial support for this study.

Abstract Octacosano-10,19-dien-1-ol is a newly synthesized long-chain alcohol, an unsaturated analogue of 1-octacosanol, the major component of policosanol, the purified natural mixture of different higher aliphatic alcohols obtained from sugarcane wax. Our efficient synthetic protocol (five steps with 50% overall yield) is well suited for gram scale preparations and a rapid generation of analogues with different degrees of unsaturation. Beneficial effects of policosanol in the prevention of atherosclerosis and thromboembolic disorders have been reported and related to the inhibition of sterol biosynthesis possibly by the regulation of the activity of HMGCoA reductase mediated by AMP-dependent kinase AMPK. We have compared the effect of octacosadienol and policosanol on the regulation of HMGCoA reductase in HUVEC and HepG2 human hepatoma cells. Octacosadienol was as effective as policosanol in inhibiting the upregulation of HMGCoA reductase, in inducing the phosphorylation of AMPK and in downregulating the HMGCoA reductase mRNA.

Keywords Long-chain alcohols synthesis · Octacosadienol · Octacosanol · HMGCoA reductase · Policosanol · AMPK phosphorylation

Abbreviations

AMPK	AMP-activated protein kinase
DMEM	Dulbecco-modified Eagle medium
EDTA	Ethylenediaminetetraacetic acid
EGTA	Ethylene glycol tetraacetic acid
HMGR	HydroxyMethylGlutaryl-Coenzyme A reductase
HUVEC	Human endothelial cells from umbilical cord veins
LDL	Low density lipoproteins
LDM	Lipid-depleted medium
PBS	Phosphate-buffered saline
RT-PCR	Real time-polymerase chain reaction
SDS	Sodium dodecyl sulfate
THF	Tetrahydrofurane

Introduction

For many years, higher aliphatic primary alcohols have been a subject of research. Early works were mainly focused on the biological activities of 1-triacontanol ($C_{30}H_{61}OH$) and 1-octacosanol ($C_{28}H_{57}OH$) [1–7]. The former was mainly isolated from beeswax [8], whereas 1-octacosanol from germ oils, wax sources (sugarcane, rice bran) and *Euphorbiaceae* [8–10]. 1-Triacontanol was highlighted as a plant growth promoter and an anti-inflammatory substance [1–3], while 1-octacosanol showed ergogenic, neurological and antioxidant properties [4, 5]. The C_{28} linear aliphatic

primary alcohol is the major component (60–70%) of policosanol, the purified natural product, was first described by Cuban researchers [11], and consists of a mixture of eight higher aliphatic alcohols obtained from the wax of sugarcane (*Saccharum officinarum* L.). Policosanol was found to inhibit cholesterol biosynthesis by indirect regulation of the activity of HydroxyMethylGlutaryl-Coenzyme A reductase (EC: 1.1.1.34) (HMGR) and by an enhancement of receptor-dependent LDL processing [12–15]. The relevant literature dealing with cholesterol and serum lipids lowering, antiplatelets and antioxidant properties of policosanol has been extensively reviewed [16, 17]. More recently, several authors have raised doubts on the cholesterol and serum lipids lowering, as well on the antioxidant properties of policosanol, on the basis of clinical studies on hypercholesterolemic patients [18–21].

In spite of the recent negative results as a cholesterol and lipid-lowering drug in clinical practice, policosanol seems able to affect some interesting cellular targets. The most important biochemical effect observed is the downregulation of HMGR activity, the regulatory enzyme of cholesterol biosynthesis, in homogenates of Vero fibroblasts grown for 24 h in lipid-depleted medium (LDM) in the presence of policosanol [13]. The decrease of HMGCoA reductase activity parallels the decrease of incorporation of labeled acetate in cholesterol (Scheme 1). Similar results have been observed in rat hepatoma cells grown in the presence of policosanol [22]. In a recent metabolic study, the possibility of a reduced cholesterol synthesis in the liver has been suggested to explain the observed decrease of fecal cholesterol end products after treatment with policosanol [23]. In neither Vero fibroblasts nor hepatoma cells could a direct inhibition of HMGR be found. Therefore the suppression of the upregulation of HMGR that occurs when the cells are grown in LDM [24] could be caused by the interference

of policosanol with the regulation of HMGR. One of the mechanisms of negative regulation of HMGR is the phosphorylation by the AMP kinase (AMPK) [25]. In rat hepatoma cells grown in the presence of policosanol, the decrease of sterol biosynthesis and HMGR activity was accompanied by a significant increase in phosphorylated AMPK, detected by immunoblot [22] (Scheme 1). The increase in phosphorylated AMPK is very close to the one obtained in the presence of metformin, a glucose-lowering drug which activates AMPK phosphorylation. Phosphorylation by AMP kinase also inactivates acetylCoA carboxylase, the enzyme catalyzing the first and regulatory step in fatty acid synthesis, suggesting the possibility of a coordinated regulation of cholesterol and fatty acid biosynthesis [25]. As a more general function, AMPK is involved in the control of the energy balance within the cell, acting as a metabolic sensor of the cellular AMP/ATP ratio [25, 26].

Owing to the involvement in the regulation of important signalling cascades controlling the cell proliferation and differentiation, AMPK has been suggested as a therapeutic target for atherosclerosis and cancer [27, 28]. An effect of policosanol on the activity of AMPK could interfere with the complex regulatory net of this kinase and explain the controversial results obtained in different experimental models or clinical trials. Moreover an effect on the regulation of sterol or fatty acid biosynthesis can open very important therapeutic opportunities in different fields, such as angiogenesis control. The antiangiogenic activity of the HMGR inhibitors statins is known [27, 29] and recently some common inhibitors of enzymes of the late steps of sterol biosynthesis such as itraconazole, an inhibitor of sterol C-14 demethylase, and naftifine, an inhibitor of squalene epoxidase, were shown to inhibit both the growth of HUVEC cells and angiogenesis [30, 31]. More recently octacosanol purified from the medicinal plant *Tinospora cordifolia*, showed antiangiogenic and antitumoral activity both in vitro and in vivo [32].

In an attempt to study a possible effect of analogues of policosanol mixture on the angiogenic process, we synthesized octacosano-10,19-dien-1-ol, a new unsaturated derivative of octacosanol. The effect on HMGR activity and expression of this synthetic compound was studied in HUVEC cells and, for comparison, in hepatoma cells and compared to the effect, in the same experimental condition, of a commercial mixture of policosanol (Source Naturals, Inc., Scotts Valley, CA). Our results showed that, in both cell types, in the presence of octacosadienol the upregulation of HMGR is decreased and the phosphorylation of AMP kinase increased. In HUVEC cells we could also observe by RT-PCR a decrease in HMGR mRNA. Octacosano-10,19-dien-1-ol showed almost the same activity as the natural policosanol mixture.

Scheme 1 Sterol biosynthesis and HMGCoA reductase activity are upregulated in cells grown in a delipidated medium (LDM). In the presence of policosanol the upregulation of HMGCoA reductase and the incorporation of acetate into sterols is decreased [13] and the phosphorylated form of AMPK is increased [22]

Experimental Procedures

Chemistry

Chemicals were purchased from Carlo Erba Reagenti and Acros Organics.

Buffers and cultural media were obtained from Sigma–Aldrich (Milan, Italy) unless otherwise specified.

3-Hydroxy-3-methyl[3-¹⁴C]glutaryl-coenzyme A (57 mCi/mmol) were obtained from Amersham Biosciences (UK). Policosanol 10-mg tablets were manufactured by Source Naturals, Inc. (Scotts Valley, CA) and purchased from a local health food store. Two 10-mg policosanol tablets were dissolved in 10 ml of absolute ethanol with the aid of a mortar and pestle. The insoluble excipients were removed by low-speed centrifugation (5000×g for 5 min), and the supernatant was aliquoted and stored at –20 °C or added directly to media upon use. Extracts were analysed by GC/MS using an Agilent 6850 gas chromatograph equipped with a 5973 MS detector and fitted with an HP-5 MS fused silica column (length 30 m; i.d. 0.25 mm; film thickness 0.25 mm).

Reactions were monitored by TLC on Fluka F₂₅₄ (0.25 mm) plates, which were visualized by spraying with a molybdic acid and heating.

Silica gel Merck 60 was used for column chromatography (CC). IR: Shimadzu FT-IR 8001 spectrophotometer. NMR: Bruker 300 Avance spectrometer (for ¹H NMR CDCl₃ was used as solvent, CHCl₃ at δ = 7.27 as reference. Low-resolution mass spectra: Finnigan-MAT TSQ70 in chemical ionization (CI-MS) with isobutane as reactant gas; ESI-MS were recorded on a Waters Micromass ZQ.

Methyl undec-10-enoate (**1**)

A solution of undecylenic acid (1.5 g, 8.14 mmol), anhydrous methanol (8 ml) and *p*-toluenesulfonic acid (50 mg, 0.29 mmol) in anhydrous toluene, placed in a 100-ml, two-neck, round-bottomed flask was heated under reflux for 5 h using a Dean-Stark apparatus and a condenser to remove esterification water. All glassware had been previously dried in an oven at 120 °C. The reaction progress was monitored by TLC on silica gel plates with hexane/ethyl acetate 7:3 as eluent (*R*_f ester = 0.64). Work-up: the product was diluted with ethyl acetate, washed twice with a 1:1 NaHCO₃/H₂O mixture, then with H₂O and brine; finally dried over Na₂SO₄. **1** was isolated as a transparent oil (1.5 g, 7.57 mmol, 93% yield). Residual traces of undecylenic acid were able to be removed by filtration on a pad of basic alumina. FT-IR (neat, cm⁻¹): ν = 2926, 1740, 1466, 1180, 1037, 742, 721, 669. ¹H NMR (300 MHz, CDCl₃): δ = 1.30 (m, 10 H, H-4-8), 1.68 (m, 2 H, H-3), 1.96 (m, 2 H, H-9), 2.31 (t, 2 H, *J* = 7.5 Hz, H-2), 3.6 (s, 3

H, -COOCH₃), 4.99 (m, 2 H, H-11), 5.70 ppm (m, 1 H, H-10). CI-MS *m/z* 199 [M + H]⁺ C₁₂H₂₂O₂.

Methyl 10-oxodecanoate (**2**)

A two-neck 250-ml round-bottomed flask containing methyl undec-10-enoate (2.43 g, 12.27 mmol) and H₂O/acetone 1:1 (50 ml) was placed in a high-power ultrasound bath (with ice-water) with an emitting titanium surface fixed to two sonotrodes (19.0 kHz). A 0.2-M solution of OsO₄ in toluene (305 μl; 0.061 mmol) and *N*-methylmorpholine-*N*-oxide (1.44 g, 12.27 mmol) were added to the mixture under sonication (70 W). After 5 min NaIO₄ (7.59 g, 35.46 mmol) was added in small portions over a time of 20 min at 20 °C. The reaction course was monitored by TLC on silica gel plates with hexane/ethyl acetate 7:3 as eluent (*R*_f of **2** = 0.5). After 3 h sonication the conversion was complete. Work-up: the reaction mixture was filtered on a porous sintered glass funnel, washing the residue with ethyl acetate. The filtrate was washed with brine, dried over Na₂SO₄ and evaporated under vacuum. The product was purified by column chromatography using hexane/ethyl acetate 9:1 as eluent. **2** was obtained as a pale yellow oil (2.11 g, 10.55 mmol, yield 86%). FT-IR (neat, cm⁻¹): ν = 2928, 2675, 1745, 1464, 1242, 1047, 943, 725. ¹H NMR (300 MHz, CDCl₃): δ = 1.29 (m, 8 H, H-3, 4, 5, 6), 1.56 (m, 2 H, H-8), 1.42 (m, 2 H, H-7), 2.31 (t, *J* = 7.5 Hz, 2 H, H-2), 2.4 (td, *J*_t = 8.1 Hz, *J*_d = 1.8 Hz, 2 H, H-9), 3.60 (s, 3 H, -OCH₃), 9.74 ppm (t, *J* = 1.8 Hz, 1 H, -CHO). CI-MS *m/z* 201 [M + H]⁺ C₁₁H₂₀O₃.

(*E*) Octadec-9-en triphenylphosphonium bromide (**3**)

The phosphonium salt was prepared from (*E*)-1-bromooc-tadec-9-ene (1.3 g, 3.9 mmol) heated under reflux overnight (N₂ atmosphere) in a toluene (30 ml) solution with triphenylphosphine (1.02 g, 3.9 mmol). After cooling down to 0 °C and addition of diethyl ether (30 ml), the precipitate of phosphonium salt was collected on a paper filter. **3** was obtained as a whitish-pink powder (1.87 g, 3.16 mmol, 81% yield). ¹H NMR (300 MHz, CDCl₃): δ = 0.87 (t, *J* = 6.4 Hz, 3H, H-18), 1.24 (m, 30 H, H-3-17), 1.65 (m, 4 H, H-1, 2), 7.85 ppm (m, 15 H, -ArH). CI-MS (*m/z*): 593 [M + H]⁺ C₃₆H₅₀BrP.

Methyl octacos-10,19-dienoate (**4**)

Glassware was previously dried at 120 °C for 2 h. The phosphonium bromide (**3**) (3.32 g, 5.6 mmol) was dissolved in 30 ml of anhydrous THF in a 100-ml, two-neck, round-bottomed flask. To the stirred solution under N₂ atmosphere 1.6 N BuLi (3.4 ml; 1.05 equiv) in hexane was

added dropwise. Due to the formation of phosphorus ylide the mixture turned orange-red. After 20 min, 5 ml of a solution of **2** (1.07 g, 5.35 mmol) were added dropwise and the solution turned yellow-orange. After the addition was complete, the mixture was allowed to stir overnight. TLC with hexane/ethyl acetate 9:1 as eluent (R_f **4** = 0.69). The crude product (**4**) was diluted with a 0.1 N solution of HCl, extracted with ethyl acetate, washed with brine and dried over sodium sulfate. Methyl octacosadienoate (**4**) was obtained in good yield as an oil (90%) (2.09 g, 4.82 mmol, 90% yield). FT-IR (neat cm^{-1}): 3005, 2926, 1709, 1288, 1120, 964, 721. ^1H NMR (300 MHz, CDCl_3): δ = 0.87 (t, J = 6.0 Hz, 3 H, H-28), 1.31 (m, 34 H, H-3-8, 13-17, 22-27), 2.01 (m, 8 H, H-9, 12, 18, 21), 2.36 (t, J = 6.5 Hz, 2 H, H-2), 3.5 (s, 3 H, $-\text{COOCH}_3$), 5.35 ppm (m, 4 H, H-10, 11, 19, 20). ^{13}C NMR (300 MHz, CDCl_3): δ = 13.77 (C-28), 22.48 (C-27), 27.14 (C-9,11,18, 21), 29.05 ($(\text{CH}_2)_n$), 31.50 (C-26), 34.17 (C-2), 51.4 ($-\text{OCH}_3$), 130.03 (C-10, 11, 19, 20), 174.3 ppm (C-1). CI-MS m/z 435 $[\text{M} + \text{H}]^+$ $\text{C}_{29}\text{H}_{54}\text{O}_2$. ESI-HRMS (m/z): 435.4117 ($\text{M} + \text{H}^+$), (calcd. 435.4124).

Octacosadienol (**5**)

To a suspension of LiAlH_4 (0.51 g, 13.4 mmol, 3eq) in anhydrous THF (30 ml) under N_2 , a solution of **4** (2.0 g, 4.6 mmol) in THF (10 ml) was added at 0 °C. The reaction was stirred at room temperature for 3 h and monitored by TLC with hexane/ethyl acetate 80:20 (R_f **5** = 0.4). Work-up: 1 N H_2SO_4 (15 ml) was added and the organic phase extracted with CH_2Cl_2 washed with brine and dried over sodium sulfate. The solvent was removed under vacuum and a white powder was obtained (1.59 g, 3.91 mmol, yield 85%). FT-IR (neat cm^{-1}): 3510, 2926, 1464, 1290, 1174, 1034, 965, 731. ^1H NMR (300 MHz, CDCl_3): δ = 0.88 (t, J = 6.0 Hz, 3 H, H-28), 1.28 (m, 34 H, H-3-8, 13-17, 22-27), 1.61 (m, 2 H, H-2), 2.02 (m, 8 H, H-9, 12, 18, 21), 3.64 (t, J = 6.0 Hz, 2 H, H-1), 4.45 (br, 1 H, OH), 5.35 ppm (m, 4 H, H-10, 11, 19, 20). ^{13}C NMR (300 MHz, CDCl_3): δ = 13.77 (C-28), 22.48 (C-27), 27.14 (C-9,11,18, 21), 29.05 ($(\text{CH}_2)_n$), 31.50 (C-26), 32.64 (C-2), 63.02 (C-1) 130.03 ppm (C-10, 11, 19, 20). CI-MS m/z 407 $[\text{M} + \text{H}]^+$ $\text{C}_{28}\text{H}_{54}\text{O}$. ESI-HRMS (m/z): 407.4160 ($\text{M} + \text{H}^+$), (calcd. 407.4175).

Cell Culture

Human hepatoma HepG2 cells (ATCC HB-8065, HepG2) were routinely maintained as monolayers in Dulbecco-modified Eagle medium (DMEM) supplemented with 10% v/v adult bovine serum, 0.03% of glutamine, penicillin 100 U/mL and streptomycin 0.1 mg/mL. Human endothelial cells from umbilical cord veins (HUVEC) were

prepared, characterized and grown as previously described [33]. HUVEC were routinely maintained as monolayers in M199 medium supplemented with 20% v/v adult bovine serum, 0.03% of glutamine, penicillin 100 U/mL, streptomycin 0.1 mg/mL and heparin 8.5 USP unit/mL. Cells were grown at 37 °C in a humidified atmosphere (air 95%/CO₂ 5%).

HMGR Assay

The HMGR activity was determined in HepG2 and HUVEC cells seeded in 24-well plastic clusters. Each well received 25,000 cells suspended in 1,000 μL of complete medium. After 24 h, cells were rinsed twice with phosphate-buffered saline (PBS) and the medium was replaced with 987.5 μL of fresh growth medium containing lipid-depleted serum [34] to induce the upregulation of HMGR. Cells were divided into three experimental groups and grown 24 h after addition of 12.5 μL of absolute ethanol (control wells) or 12.5 μL of an ethanolic solution of octacosadienol or policosanol (final concentration 50 $\mu\text{g}/\text{mL}$). In this range of concentration octacosadienol, policosanol and absolute ethanol had no effect on cell viability. As a control of the upregulation obtained in the above conditions, the HMGR activity was determined also in cells grown in parallel but in a medium supplemented with normal serum plus absolute ethanol. Cells were then washed with ice-cold PBS and lysed in ice for 20 min with 100 $\mu\text{L}/\text{well}$ of ice-cold phosphate buffer, pH 7.4, containing 0.1 M sucrose, 40 mM KH_2PO_4 , 30 mM EDTA, 50 mM KCl, 5 mM dithiothreitol, 0.25% (v/v) Brij 96. Cell debris was removed by centrifugation at 12,000 $\times g$ for 3 min and the protein concentration of the supernatant was determined with a SIGMA Protein assay Kit based on the method of Lowry modified by Peterson [35]. In order to measure the HMGR activity 80 μL of supernatant were added with 10 μL of NADPH-generating system and 10 μL of labeled substrate hydroxy-3-methyl[3- ^{14}C]glutaryl-coenzyme A. The final mixture assay (100 μL) contained 2.5 mM NADP, 20 mM glucose 6-phosphate, 1.5 units of glucose 6-phosphate dehydrogenase and 0.01 μCi of hydroxy-3-methyl[3- ^{14}C]glutaryl-coenzyme A. The enzymatic reaction was stopped after 60 min at 37 °C by addition of 10 μL of 5 M HCl. After an additional incubation for 30 min at 37 °C to allow for complete lactonisation of the product, the mixture was centrifuged at 12,000 $\times g$ for 2 min. The aqueous supernatant was applied to a silica column that was primed with 2 ml of eluting solvent mixture toluene/acetone (3:1, v/v). The mevalonolactone was eluted from the column with 6 ml of the eluting solvent mixture and the eluate collected in a scintillation vial for measuring ^{14}C radioactivity (2500 TR Liquid Scintillation Analyzer—Packard BioScience, Waltham,

MA—USA). TLC analysis (toluene/acetone, 1:1 as eluent) of the eluate with a System 200 Imaging Scanner (Canberra Packard, USA) showed that all the recovered radioactivity was in correspondence of the reference of mevalonolactone. The HMGR activity was expressed as dpm of [^{14}C]mevalonate formed per milligram of protein incubated.

RT-PCR

HepG2 and HUVEC cells were seeded in 100-mm diameter dishes and incubated in 5 ml of complete medium. At 70% confluence, cells were rinsed twice with phosphate-buffered saline (PBS) and the medium was replaced with fresh growth medium containing lipid-depleted serum [34]. At this point, cells were divided into three experimental groups and a further 24 h treatment was carried out in the presence of 62.5 μl of absolute ethanol (control wells) or 62.5 μl of an ethanolic solution of octacosadienol or policosanol (50 $\mu\text{g}/\text{mL}$). A further group of cells was grown in a medium supplemented with normal serum plus absolute ethanol to check the upregulation of HMGR after incubation with lipid-depleted serum. After 24 h cells were washed twice with phosphate-buffered saline, and total RNA was extracted using NucleoSpin[®] RNA II Kit (Machery-Nagel). The cDNA was synthesized with the RevertAid TM H Minus First Strand cDNA synthesis Kit (Fermentas). TaqMan[®] RT-PCR reactions (25 μl) were set up in 96-well reaction plates using a TaqMan[®] Gene Expression Assay Mix specific for human HMGR or a TaqMan[®] Endogenous Control TBP (TATA-box binding protein) Mix and a TaqMan[®] Universal Master Mix (Applied Biosystems). Real-time PCR was performed using an ABI Prism 7900 Sequence Detection System (Applied Biosystems), using generic cycling conditions.

Immunoquantitation of AMP-Kinase

HepG2 and HUVEC cells were seeded in 100-mm diameter dishes and incubated in 5 ml of complete medium. Cells were grown to 70% confluence and then maintained overnight in serum-free medium containing 1.5% bovine serum albumin. Cells were then divided into three experimental groups for a further 6 h culture in the presence of 62.5 μl of absolute ethanol (control wells) or 62.5 μl of an ethanolic solution of octacosadienol or policosanol (50 $\mu\text{g}/\text{mL}$). As a positive control cells were cultured as described above in the presence of metformin (360 $\mu\text{g}/\text{mL}$) and 62.5 μl of absolute ethanol. The treatment of HepG2 and HUVEC cells with metformin did not show any detectable cell toxicity. After 6 h cells were washed twice with phosphate-buffered saline, and lysed in ice-cold buffer (20 mM Tris-HCl, pH 8.0, 1% Nonidet P-40, 1 mM EDTA, 1 mM EGTA, 1 mM sodium orthovanadate, 1 mM

dithiothreitol, 1 mM phenylmethyl sulfonyl fluoride and 1 mM protease inhibitor cocktails (Sigma-Aldrich) [36]. Cells were scraped from the plates and collected in a micro-centrifuge tube. Cells debris was removed by centrifugation at 12,000 $\times g$ for 10 min and the resulting supernatant was used for Western Blotting. Protein concentration in cell lysate was measured using a BCA protein assay kit (Pierce). For Western Blotting, 20–50 μg of protein was separated by 10% SDS-polyacrylamide gel electrophoresis and electroblotted to a nylon membrane in a transfer buffer containing 125 mM Tris-HCl, 960 mM glycine, 0.5% SDS and 20% methanol. The membrane was blocked with 10% nonfat dry milk in PBS buffer and then incubated in the same buffer containing 0.1% Tween 20 with rabbit antibody to total AMP-kinase (anti-AMPK α -pan, 1:2,000; Upstate Biotechnology) or to phosphorylated AMP-kinase (anti-phospho-AMPK α , 1:1,000; Upstate Biotechnology). The immunoblot was developed with a secondary antibody conjugated to horseradish peroxidase and visualized and quantified by chemiluminescence (Western LightningTM Plus-ECL, Medical Imaging, PerkinElmer Life Sciences) on Molecular Imager Chemidoc XRS System, Quantity One software (Biorad).

Statistical Analysis

Data of HMGR activity (% of delipidated controls) were compared by the Kruskal–Wallis rank test [37], while RT-PCR data ($2^{\Delta\Delta\text{Ct}}$) were analyzed by ANOVA.

Results

Synthesis of Octacosadienol

In the search of a more active synthetic analogue of policosanol and with the aim to study the effect of unsaturations on C-28 fatty alcohol, we planned the synthesis of octacosadienol. Our synthetic approach was studied for gram-scale production of long chain unsaturated fatty alcohols [38]. The key step was a Wittig olefination to bind two relatively cheap building blocks: the methyl ester of the 10-oxodecanoic acid and the phosphorus ylide obtained from oleyl bromide. The whole synthetic procedure is depicted in Scheme 2.

HMGR Activity Regulation

The effect on HMGR of the octacosadienol, the synthetic unsaturated derivative of octacosanol, was studied in HUVEC and hepatoma cells and compared with the effect of the natural policosanol mixture extracted from commercial tablets. The composition of ethanolic extracts of

Scheme 2 a MeOH, PTSA_{cat}, toluene, rfx. 5h. b H₂O/acetone, OsO₄, NMMO, NaIO₄, US 19 kHz. c toluene rfx., PPh₃ d **2**, BuLi, THF; e LiAlH₄, THF

tablets, analysed by GC/MS after extraction and purification [39] was the same found by Singh, Li and Porter [22]. Octacosanol content was about 60%.

In agreement with previous results from different authors [13, 22], we could not observe a direct inhibition of the enzyme after the addition of octacosadienol or policosanol to cell lysates from both cell lines.

However after a 24-h incubation of the cells grown in a delipidated medium with either octacosadienol or the commercial policosanol, the activity of HMGR measured in cell lysates was significantly reduced with respect to the controls grown in the same conditions in the absence of octacosadienol or policosanol. Figure 1 shows the HMGR activity measured in lysates of cells grown in a complete medium, compared to cells grown in a delipidated medium, in the absence or in the presence of octacosadienol or policosanol. As shown in the figure, the HMGR activity of cells grown in a delipidated medium was significantly increased by 50% in hepatoma and by 80% in HUVEC cells ($P < 0.01$), compared with cells grown in a normal medium. In hepatoma the addition of 50 $\mu\text{g/ml}$ of octacosadienol to the delipidated medium caused a 30% decrease in HMGR activity. In HUVEC cells the effect of octacosadienol was even higher and the enzymatic activity dropped by 50%. In both cell types octacosadienol was almost as effective as policosanol. The enzymatic activity did not drop to the level found in the not induced cells grown in a complete medium, but in both cell types the presence of policosanol or octacosadienol significantly reduced ($P < 0.01$) the induction of the enzymatic activity caused by the absence of uptake of sterols from the medium.

In order to find out if the decrease of the activity of HMGR in the presence octacosadienol or policosanol in

Fig. 1 Effect of octacosadienol and policosanol on the activity of HMGR of HUVEC and HepG2 hepatoma cells grown in a delipidated medium. The HMGR activity was measured in lysates prepared from HepG2 or HUVEC cells grown either in a delipidated or in a complete medium and compared with the activity of lysates of cells incubated with 50 $\mu\text{g/ml}$ of octacosadienol or policosanol in LDM. The HMGR activity is expressed as % of the activity found in control cells grown in LDM. Each value represents the mean and SE of at least two separate experiments in duplicate. **a** Control cells grown in LDM. **b** Control cells grown in a complete medium. **c** Cells grown in LDM with 50 $\mu\text{g/ml}$ octacosadienol. **d** Cells grown in LDM with 50 $\mu\text{g/ml}$ policosanol

HUVEC cells could be explained with an inactivation of the enzyme induced by AMPK we analyzed HUVEC cell lysates in western blot to evidence the phosphorylated form of AMPK by a specific antibody. As shown in Fig. 2 the increase of 2.5–3.5 fold of the phosphorylated form of AMPK in lysates of HUVEC cells grown in a delipidated medium in the presence of the same amount of octacosadienol or policosanol used to measure the activity of HMGR, is comparable to that obtained in the presence of metformin, a well known activator of the phosphorylation of AMPK [40]. A comparable increase of phosphorylated

Fig. 2 Immunoblot of total and phosphorylated AMPK in HUVEC cell lysates. Cell lysates untreated (controls) or incubated with 360 $\mu\text{g}/\text{mL}$ of metformin (+met) or 50 $\mu\text{g}/\text{mL}$ of policosanol (+pol) or octacosadienol (+oct) were fractionated by electrophoresis and transferred to nylon membranes for immunodetection with an antibody specific for total AMPK or for phosphorylated AMPK (P-AMPK). The band density determined as arbitrary units are expressed as ratio versus the untreated control. Bars represents SE of duplicate experiments

AMPK was observed in hepatoma cells treated with policosanol and octacosadienol in the same conditions. From these experiments the efficacy of octacosadienol is comparable to that of the natural mixture of policosanol.

Furthermore, in order to study the occurrence of an alternative or additional mechanism based on a decrease of the expression of the enzyme, we determined by quantitative RT-PCR the relative amount of the HMGR mRNA present in HUVEC cells grown in a delipidated medium in absence or in presence of octacosadienol. RNA was extracted from both cells grown in a complete medium and cells grown in a delipidated medium with or without the addition of 50 $\mu\text{g}/\text{mL}$ of octacosadienol. The cDNA from all the samples was obtained by RT-PCR using the same starting amount of RNA. The relative amount of cDNA was determined in real time PCR with the $2^{-\Delta\Delta\text{Ct}}$ method [41], using as housekeeping gene the TBP gene cDNA and as a calibrator the HMGR mRNA of HUVEC cells grown in a complete medium. By using this method the value of $2^{-\Delta\Delta\text{Ct}}$ of the calibrator (cells grown in a complete medium) is 1 and the $2^{-\Delta\Delta\text{Ct}}$ value of the cells grown in a delipidated medium in the presence or in the absence of octacosadienol or policosanol represents the fold change in mRNA in a delipidated medium. As shown in the histogram of Fig. 3, the increase of HMGR mRNA in HUVEC cells grown in a delipidated medium is almost six fold. The addition of octacosadienol reduces this increase by 50%, ($P < 0.05$). By comparing in the same experiment the $2^{-\Delta\Delta\text{Ct}}$ obtained in the presence of octacosadienol and of the mixture of policosanol we have shown that octacosadienol alone has the same activity of the mixture of policosanol, as can be seen in Fig. 4. A degree of variability among the experiments was observed mainly in the amount of the induction of the expression of HMGR in a delipidated medium. The higher the induction in the control cells, the more evident was the reduction effect of the octacosadienol. In hepatoma

Fig. 3 Effect of octacosadienol on the HUVEC cells expression of HMGR. The cDNA obtained after extraction of total RNA from cell lysates was amplified in the presence of a TaqMan probe specific for HMGR in real-time PCR and quantified relatively to untreated controls grown in a complete medium. **a** Lysates from cells grown in LDM. **b** Lysates from cells grown in LDM with octacosadienol. Each value represents the mean and SE of six separate experiments

cells, we could not observe a significant effect of octacosadienol. In two different experiments we obtained no or very little (18%) reduction in the HMGR mRNA with respect to the control cells grown in a delipidated medium.

Discussion

The present paper describes an efficient synthetic procedure to obtain octacosadienol on a gram scale, starting from commercially available cheap building blocks, namely oleyl bromide and undecylenic acid. The method is extremely versatile because by varying the chain length of the alkenyl halide as well as the number/position of the double bonds, a wide number of analogues can be

Fig. 4 Effect of octacosadienol and policosanol on the HUVEC cells expression of HMGR. prepared. The simplicity of this protocol and the excellent overall yield (about 50%) are worthy of mention.

Our results show that the naturally occurring policosanol is able to downregulate the HMGR activation that occurs when the cells are grown in a delipidated medium also in cell types different from the previously studied fibroblasts and hepatoma cells [13, 22], i.e. the angiogenic HUVEC cells. Moreover, the synthetic unsaturated long-chain alcohol octacosadienol has the same activity as the natural product in both hepatoma and HUVEC cells. Both policosanol and octacosadienol increased the phosphorylation of AMPK, a kinase that phosphorylates several downstream substrates including HMGR, having the overall effect of switching off ATP-consuming pathways such as fatty acid and cholesterol synthesis and switching on ATP-generating pathways [25]. An increased phosphorylation of HMGR by AMPK could explain the downregulation of HMGR observed in hepatoma and HUVEC cells, since the phosphorylated HMGR is inactive [25]. The increased phosphorylation of AMPK can affect the activity of HMGR either by the direct phosphorylation and consequent inactivation of the enzyme, or by an indirect downregulation, mediated by transcription factors. SREBP-1, a transcription factor involved in the regulation of several lipogenic enzymes, included HMGR [27], has been recently shown to be downregulated following the activation of AMPK [26, 40]. Our quantification of HMGR mRNA by RT-PCR shows that in HUVEC cells both policosanol and octacosadienol affect the regulation of HMGR activity also at the transcription level, causing a decrease of mRNA. In hepatoma cells we could not detect a significant decrease of the level of the HMGR mRNA, and the observed downregulation of the enzyme could be mainly explained with the phosphorylation by AMPK and consequent inactivation.

Therefore, the induction of the phosphorylation of AMPK seems to be a general mechanism by which

policosanol, and also synthetic analogues of these natural compounds, contrast the upregulation of HMGR by activating different cell-specific mechanisms of regulation. The downregulation of HMGR, besides affecting cholesterol biosynthesis, could influence cell cycle progression as a consequence of the decreased synthesis of nonsterol mevalonate derivatives as farnesyl, geranyl and geranylgeranyl intermediates which are necessary for the prenylation of proteins as Ras and Rho, involved in the signal transduction cascades controlling cell proliferation and differentiation. Antitumor properties such as induction of growth arrest and apoptosis, inhibition of metastasis and inhibition of angiogenesis, have been observed in various cell lines and in experimental animals after treatment with statins, the most known inhibitors of HMGR. The mechanism that mediates the antitumoral effects of statins, originally related to the inhibition of Ras farnesylation, is still being discussed and possibly dissimilar in different cell lines [42]. Recently, the involvement of a long chain aliphatic alcohol in the control of cell proliferation has been described in a paper studying the effect of octacosanol purified from *Tinospora cordifolia*, on the proliferation of HUVEC and tumor cells. In this study, octacosanol has been shown to inhibit the proliferation of HUVEC and Ehrlich ascites tumor cells (EAT) [32]. Moreover, angiogenesis decreased in the peritoneum of EAT-bearing mice treated with octacosanol. The antiangiogenic activity was accompanied by a decrease in the secretion of VEGF in ascites fluid, a decreased activity in the collagenase MMP2, and the inhibition of nuclear translocation of NFκB, a transcription factor involved in the control of the inflammatory response and apoptosis and controlled by different, complex activation pathways [43, 44].

The regulation of the HMGR activity and AMPK phosphorylation in HUVEC cells by a synthetic long-chain alcohol such as octacosadienol opens promising perspectives for the design of new antiangiogenic compounds. Pathological angiogenesis is a hallmark of cancer and various ischemic and inflammatory diseases and anti-angiogenic therapy is one of the most promising approaches to cancer treatment, making the discovery of new anti-angiogenic molecules very attractive.

Abstract The exchange of lipids with cells and other lipoproteins is a crucial process in HDL metabolism and for HDL antiatherogenic function. Here, we tested a practical method to quantify the simultaneous transfer to HDL of phospholipids, free-cholesterol, esterified cholesterol and triacylglycerols and to verify the lipid transfer in patients with coronary artery disease (CAD) or undergoing statin treatment. Twenty-eight control subjects without CAD, 27 with CAD and 25 CAD patients under simvastatin treatment were studied. Plasma samples were incubated with a donor nanoemulsion prepared by ultrasonication of the constituent lipids and labeled with radioactive lipids; % lipids transferred to HDL were quantified in the HDL-containing supernatant after chemical precipitation of non-HDL fractions and the nanoemulsion. The assay was precise and reproducible. Increase of temperature (4–37 °C), of incubation period (5 min to 2 h), of HDL-cholesterol concentration (33–244 mg/dL) and of mass of nanoemulsion lipids (0.075–0.3 mg/ μ L) resulted in increased lipid transfer from the nanoemulsion to HDL. In contrast, increasing pH (6.5–8.5) and albumin concentration (3.5–7.0 g/dL) did not affect lipid transfer. There was no difference between CAD and control non-CAD with regard to the lipid transfer, but statin treatment

reduced the transfer to HDL of all four lipids. The test herein described is a valid and practical tool for exploring an important aspect of HDL metabolism.

Introduction

Plasma lipoproteins constantly exchange lipids, both those that make-up the lipoprotein surface monolayer, namely phospholipids and free cholesterol and the core lipids, triacylglycerols and cholesteryl esters. This process is facilitated by transfer proteins, namely cholesteryl ester transfer protein (CETP) [1] and phospholipid transfer protein (PLTP) [2]. In addition to the action of transfer proteins, other factors such as the composition and concentration of the lipoproteins and of some plasma constituents may affect the ability of the lipoprotein particles to receive and donate lipids [3–6].

Different from the other lipoprotein classes that are synthesized into the liver or intestinal cells, high-density

lipoprotein (HDL) is formed in the intravascular compartment. In the plasma, apolipoprotein A-I (apo A-I), which is synthesized by the liver or by the small intestine, receives phospholipids and cholesterol from cell membranes and from apoB-containing lipoproteins. This results in the formation of discoidal HDL that is converted to larger, spherical HDL by esterification of free cholesterol by lecithin:cholesterol acyltransferase (LCAT), using apo A1 as co-factor. The interaction of spherical HDL with CETP transfers HDL cholesteryl ester to apoB-containing lipoproteins. Cholesterol transported in HDL is taken-up by the liver, either via the selective uptake of HDL cholesteryl ester by scavenger receptor class B type I (SR-BI) or via the uptake of whole low-density lipoprotein (LDL) by the LDL receptor in the liver [7, 8]. HDL is thus constantly being remodeled by lipid transfers which are essential for the role of the lipoprotein in cholesterol esterification and in reverse cholesterol transport, whereby cholesterol from peripheral tissues is shuttled to the liver and excreted in bile, as described above. Because the lipid transfer process is determinant for HDL composition and thereby for the adhesion of proteins to the lipoprotein surface, it is possible that other atheroprotective functions of the lipoprotein, such as antioxidative, anti-inflammatory, antiapoptotic, vasodilatory, antithrombotic and anti-infectious may also be affected by this process.

Because the transfer of lipids to HDL is conceivably important for the maintenance of HDL structure, stability and function, the current study was designed to establish a practical method to evaluate the ability of the lipoprotein to simultaneously receive its main constituent lipid classes, namely phospholipids, free cholesterol, esterified cholesterol and triacylglycerols. This approach had not been previously explored. The studies in the literature have been focused on the transfer of isolated lipids to estimate the action of the transfer proteins. The novel method consists of the incubation of whole plasma with a cholesterol-rich artificial nanoemulsion as the donor of the four radioactive lipids. After chemical precipitation of the apo B-containing lipoproteins and the artificial nanoemulsion, the % of lipids that transferred to HDL is determined by radioactive counting of the supernatant. Lipid transfer to HDL was studied in subjects with or without coronary artery disease (CAD) and under simvastatin treatment.

Experimental Procedure

Study Subjects

Three groups of subjects grouped for age, body mass index (BMI) and HDL-cholesterol were studied: 28 control subjects without CAD, 27 with CAD and 25 CAD patients under simvastatin treatment (20 mg/day for at least 1 year).

Table 1 Clinical characteristics and blood biochemistry analyses of the three groups of participant subjects: non-CAD, CAD and CAD under simvastatin treatment

Parameters	Non-CAD (n = 28)	CAD (n = 27)	CAD + simvastatin (n = 25)
Age (years)	58 ± 5	57 ± 6	58 ± 7
BMI (kg/m ²)	29 ± 6	26 ± 3	28 ± 4
Glucose (mg/dL)	98 ± 10	98 ± 8	98 ± 10
Triacylglycerols (mg/dL)	145 ± 63	164 ± 34	146 ± 50
Cholesterol (mg/dL)			
Total	182 ± 42	212 ± 23*	180 ± 56
LDL	108 ± 35	145 ± 25*	108 ± 53
HDL	45 ± 11	46 ± 11	45 ± 13

Data are expressed as means ± SD

BMI body mass index, HDL high density lipoprotein, LDL low density lipoprotein

* $p < 0.001$ when compared to non-CAD and CAD under simvastatin treatment groups

The participants were of both genders and the presence or absence of CAD was confirmed by cineangiocoronariography performed over the last 6 months before they were studied. Exclusion criteria were diabetes, alcoholism, liver, renal, metabolic, inflammatory or neoplastic diseases. Their physical characteristics and plasma laboratorial profile are shown in Table 1. The Ethics Committee of the Medical School Hospital of the University of São Paulo approved the study and a written informed consent was obtained from all subjects after a complete description of the study.

Plasma Lipids

Total cholesterol (CHOD-PAP; Roche, Basel, Swiss) and triacylglycerols (Triglyceride Rapid; Roche) were determined by enzymatic methods on a Cobas Bio analyzer from plasma samples collected after a 12-h fast. HDL-cholesterol was measured by the same method used for total cholesterol after lipoprotein precipitation with magnesium phosphotungstate. LDL-cholesterol was estimated by the Friedewald formula [9].

HDL Particle Size Determination

The diameter of the HDL fraction particles was measured in fresh plasma collected after a 12-h fast as described by Lima and Maranhão [10], using a ZetaPALS Zeta Potential Analyzer (Brookhaven Instruments, Holtsville, NY).

Preparation of the Nanoemulsion

The lipid donor nanoemulsion was prepared from a lipid mixture composed of 40 mg cholesteryl oleate, 20 mg egg

phosphatidylcholine, 1 mg triolein and 0.5 mg cholesterol purchased from Sigma Chemical Company (St. Louis, MO). Emulsification of lipids by prolonged ultrasonic irradiation in aqueous media and under N₂ stream, and the procedure of two-step ultracentrifugation of the crude emulsion with density adjustment by addition of KBr to obtain the nanoemulsion was carried out by the method described previously by Ginsburg et al. [11] and modified by Maranhão et al. [12]. The fraction containing the nanoemulsion was dialyzed against 0.9% NaCl solution. Trace amounts of cholesteryl [1-¹⁴C] oleate and glycerol tri [9, 10(n)-³H] oleate or [7(n)-³H] cholesterol and L-3-phosphatidylcholine, 1-stearoyl-2-[1-¹⁴C] arachidonyl (Amersham, Little Chalfont, Buckinghamshire, UK) were added to the initial solution. The approximate specific activities of the isotopes (in cpm/mg of lipid) in the nanoemulsions were 10,000 for ¹⁴C-phospholipids, 20,000 for ³H-cholesteryl esters, 800,000 for ³H-cholesterol and 400,000 for ¹⁴C-triglycerides.

The lipid mixtures that originated the nanoemulsion and the final nanoemulsion preparation were tested in duplicate samples for lipid peroxidation by the TBARs method [13]. The malonaldehyde concentration was 9.5 in the lipid mixture and 7.3 nmol/mL in the resulting nanoemulsion, which implies that the emulsification procedure by prolonged ultrasonication does not increase the content of peroxides. The average diameter of the nanoemulsion particles, as measured by laser light scattering (Zeta Pals Analyser 90Plus, Brookhaven Instruments) was 43 nm.

Lipid Transfer from the Nanoemulsion to HDL

The assay consisted of the incubation of the radioactively labeled nanoemulsion with whole plasma followed by chemical precipitation of the apo B-containing lipoproteins and the nanoemulsion and radioactive counting of the supernatant for the lipids that shifted from the nanoemulsion to HDL. Plasma with EDTA that was stored at -80 °C in a 200 µL volume was incubated with 50 µL of the nanoemulsion labeled with ¹⁴C-cholesterol and ³H-triacylglycerols or with ³H-cholesteryl esters and ¹⁴C-phospholipids. After 1 h in a shaking bath at 37 °C, 250 µL of dextran sulfate/MgCl₂ was added as precipitation reagent. The mixture was mixed for 30 s, centrifuged for 10 min (3,000g) and 250 µL of the supernatant were immediately transferred to counting vials containing 5 mL scintillation solution (Packard BioScience, Groenigen, Netherlands). Radioactivity was then measured with a Packard 1600 TR model Liquid Scintillation Analyzer (Palo Alto, CA). The blank samples consisted of 200 µL TRIS solution with added labeled nanoemulsion with addition of the precipitation reagent after the incubation as described above. The results of radioactive transfer from the nanoemulsion to

plasma HDL were expressed as % of the total incubated radioactivity, determined in a plasma sample without the addition of precipitation reagent. One percent of ¹⁴C-phospholipids corresponded to a 0.217 µM transfer of this lipid from the nanoemulsion to HDL, 1% ³H-cholesteryl esters to 0.149 µM, 1% ³H-cholesterol to 0.006 µM and 1% ¹⁴C-triglycerides to 0.006 µM.

To demonstrate that chemical precipitation stops the lipid transfer to HDL, the supernatant radioactivity was measured 30 min after the addition of dextran and subsequent centrifugation, in a quadruplicate experiment. No further increase in the supernatant radioactivity counting was observed, which confirms that the lipid transfer was indeed interrupted.

Lipid Transfer under Different Conditions

The lipid transfer was analyzed under different conditions of temperature, pH, incubation time and albumin concentration. To evaluate the influence of temperature, the lipid transfer assay was performed at temperature range of 4–50 °C. The pH effect was evaluated at plasma pH 6.5–8.5 that was obtained by addition to the assay of Tris HCl or Tris NaOH buffer. To test the influence of incubation time, the assays were carried out at different incubation periods, ranging from 5 min to 6 h. The effect of the concentration of albumin in the plasma was tested at the range of 3.6–7.2 g/dL. It was also tested the effect on the lipid transfer of increasing the mass of nanoemulsion lipids (0.075–1.50 mg/µL) and HDL-cholesterol (33–244 mg/dL) in the plasma.

Lipid Transfer and Storage of Plasma and Nanoemulsion

The effect of the period of storage of the nanoemulsion and of the plasma samples on the lipid transfer to the HDL plasma fraction was tested. The transfer assay was performed using aliquots of the same labeled nanoemulsion or the same plasma sample in predetermined intervals over a 30-day or 1-year period, respectively.

Intra- and Inter-Assay Validation Parameters

The transfer assay method was validated for precision according to the FDA guidelines [14] in which the upper limit is 5%. Intra-assay precision studies included ten replicates of samples. Inter-assay precision was calculated based on three assays of ten replicates, run on three different days.

Statistical Analysis

Results are expressed as means and standard deviations (means ± SD). Differences of $p < 0.05$ were considered

significant. The Student's *t* test was used for normally distributed data and the Mann–Whitney test for those with non Gaussian distribution. The correlation between lipids transfer ratio with the other parameters was made by using analysis of variance and the Pearson's test.

Results

Figure 1 shows the effects of several variables on the results of the assay of the transfer of the four lipids from the nanoemulsion to HDL. In this respect, temperature, pH, incubation time, mass of the donor nanoemulsion, concentration of the recipient HDL and concentration of albumin in the incubate were tested. Increasing the temperature of the incubate resulted in progressive increase in the transfer of all lipids from 4 to 37 °C, when a plateau was reached until the last observation point, at 50 °C (Fig. 1a). Between 4 and 37 °C, the transfer values of phospholipids, free cholesterol, esterified cholesterol and triacylglycerols positively correlated with temperature ($r = 0.9212, 0.8709, 0.8656$ and 0.7983 , respectively, $p < 0.0001$). However, the correlation did not continue beyond the 37 °C temperature point.

The variation of the pH in the incubation from 6.5 to 8.5 did not affect the transfer of all lipids (Fig. 1b).

With respect to the effect of incubation time on lipid transfer, as shown in Fig. 1c the transfer of all lipids significantly increased ($p < 0.001$) up to 15 min incubation time. After this time, from 30 to 360 min, the apparent increase observed mainly in phospholipid transfer was not statistically significant. It can be stated that, between 2 and 4 h incubation time, a plateau of all lipid transfer was reached (Fig. 1c).

As shown in Fig. 1d, when the mass of nanoemulsion was increased in the assay, the transfer of phospholipids and free cholesterol pronouncedly increased from 0.075 to 0.3 mg/μL ($p < 0.001$). Regarding the transfer of the core lipids, the increase of both was statistically significant ($p < 0.001$) at increase from 0.075 to 0.1 mg/μL.

The variation of the recipient HDL mass in the assay resulted in increase of the transfer of all lipids in almost all tested HDL-cholesterol concentration intervals, from 33 to 244 mg/dL (Fig. 1e). Exceptions were free cholesterol transfer in HDL cholesterol concentration from 33 to 47 mg/dL and the esterified cholesterol transfer from 185 to 244 mg/dL HDL cholesterol concentration interval. Interestingly, the surface lipid transfer curves seem to show a linear shape while the transfer of core lipids looks like a sigmoidal curve. In addition, a positive correlation between HDL-cholesterol and transfer of the four lipids was found (phospholipids $r = 0.9508$,

free cholesterol $r = 0.9530$, esterified cholesterol $r = 0.8822$ and triacylglycerols $r = 0.8995$, $p < 0.002$ for all comparisons).

Finally, the transfer of the lipids to HDL was not affected by the albumin concentration in the assay (Fig. 1f).

The storage of nanoemulsion up to 15 days before the performance of the assay did not affect the results of the transfer of the four lipids to HDL. By day 30, however, there was a difference between the transfer values when compared to day 0 or day 1 ($p < 0.05$ for all four lipid transfer). The storage of the plasma sample for up to 1-year had no effect on the lipid transfer results ($p > 0.05$).

The coefficient of variation (C.V.) from intra-assay (phospholipids = 0.83; free cholesterol = 0.56; esterified cholesterol = 1.49; triacylglycerols = 0.51%) and inter-assay (phospholipids = 0.78; free cholesterol = 0.59; esterified cholesterol = 1.32; triacylglycerols = 0.58%) indicated that the method is reproducible.

Table 1 shows the physical characteristics and data of laboratorial analysis of 28 non-CAD controls, 27 CAD and 25 CAD patients under simvastatin treatment. As established in the inclusion criteria, the three groups did not differ regarding their age, BMI and HDL-cholesterol, but LDL-cholesterol was higher in the CAD group compared with the non-CAD controls. In Table 2, it is shown that the HDL particle size was equal in the three study groups. Transfer of phospholipids, free cholesterol, esterified cholesterol and triacylglycerols did not differ between CAD and non-CAD subjects. However, simvastatin treatment administered to CAD patients diminished the transfer of all four lipids.

A correlation analysis was performed between the transfer of the four lipids and the different clinical and laboratorial parameters of the three study groups. The only correlation found in this analysis was a positive correlation between free cholesterol transfer and HDL-cholesterol concentration observed in the non-CAD group. The HDL size did not correlate with any of the lipid transfers.

Discussion

Although it is well established that HDL-cholesterol levels inversely correlate with the incidence of CAD, it has been increasingly perceived that HDL-cholesterol does not necessarily reflect the qualitative and functional aspects of the lipoprotein that are important for its anti-atherogenic actions [15–17]. In this regard, subjects with apo A1 Milano mutation are protected from cardiovascular events [18, 19] despite their low HDL cholesterol levels. On the other hand, high HDL levels consequent to CETP or hepatic lipase mutations are not necessarily protective against CAD [4]. In a rather unexpected

† $p < 0.001$ when compared to the CAD group

outcome, when HDL levels were increased by use of the CETP inhibitor Torcetrapib, there were excessive deaths and increases in CAD events, leading to discontinuation of the clinical trial [20].

The ability to receive lipids is a fundamental feature of HDL metabolism [4]. HDL function in cholesterol esterification is essential for the stabilization of this compound in the organism, and in reverse cholesterol transport, by which cholesterol from peripheral tissues is transported to the liver and excreted in bile [4], depends on lipid exchanges [21]. Hypertriglyceridemia is a typical condition in which lipid transfers are determinants of HDL metabolism. Accumulation in the plasma of very low-density lipoprotein (VLDL) leads to an increased transfer of cholesteryl esters from HDL to VLDL and HDL enrichment with triacylglycerols, as a result of combined mass action and CETP. This destabilizes HDL particles that tend to disappear faster from the plasma leading to decreased HDL-cholesterol [6].

By determining the composition of HDL, lipid exchanges are conceivably influential on the array of proteins that can be accommodated on the lipoprotein particle and that trigger the series of anti-inflammatory, antioxidant and anticoagulation properties of the lipoprotein. The *in vitro* assay described in this study was shown to be reproducible and precise. Among the tested factors, duration of the incubation period, temperature, and HDL concentration can affect the results and should be carefully monitored in the performance of the assay. In contrast, plasma pH, concentration of albumin and of the donor nanoemulsion were not determinants of the results.

The set-up of the assay described here permits a comparative analysis, not yet explored in the literature, of the transfer of the four main lipid constituents of the lipoproteins, as performed simultaneously, with the same lipid

donor particle and under identical experimental conditions. As expected [22, 23], lipid transfers increased as function of the incubation time and subsequently tended to reach a plateau indicative of the equilibrium state. Nonetheless, two distinct time-course behaviors clearly appeared: the transfer curve of core lipids—esterified cholesterol and triacylglycerols—were nearly identical and with much smaller perceptual transfer rates than those of surface lipids, namely phospholipids and free cholesterol. This can be ascribed to the location of surface lipid molecules that facilitates their dissociation from the donor nanoparticles and the incorporation into the surface monolayer of the recipient HDL. In addition, phospholipids are transferred not only by PLTP action but also by CETP, differently to esterified cholesterol and triacylglycerols [24], and free cholesterol may at least in part be transferred without the action of transfer proteins. In this respect, about half the phospholipids and free cholesterol had already transferred to HDL within the first 5 min of incubation, whereas the transfer of core lipids occurred pronouncedly slower. This is conceivably due to the fact that transfer of surface lipids depends on mechanisms that are different from those of the transfer of core lipids.

Variation in temperature of the incubation from 4 to 37 °C may have affected the lipid transfer by changing the fluidity of the lipoprotein structure and the rate of collisions among lipoprotein particles [3]. It is noteworthy, however, that between 37 and 50 °C increasing the temperature no longer increased the lipid transfer.

The positive correlation found in this study between the transfer of the four lipids and the HDL-cholesterol concentration in the incubation (Fig. 1e) was expected because the rate of collisions between donor and recipient particles increase with the concentration of the latter. Likewise, a positive correlation between lipid transfers and the concentration of the donor nanoemulsion in the assay would also be expected. Indeed there was an initial increase in lipid transfers, notably in the transfer of surface lipids (Fig. 1d), but a plateau was reached already at the third tested point (0.3 mg/μL nanoemulsion concentration). This indicates that the transfer assay was largely performed at saturation range of the donor nanoemulsion. By taking this finding into account, in all subsequent experiments, a saturating concentration of the nanoemulsion (1.5 mg/μL) was standardized to avoid interference of this variable on the results [25].

The fact that the variation of pH in the assay did not affect the lipid transfer to HDL was expected in view of data in the literature showing that CETP and PLTP are not affected by pH variation at a similar range [26–28]. In respect to albumin, other authors also observed that the concentration of this protein does not influence lipid transfer, regardless transfer proteins were present or not in

the assays [29–31]. In contrast, Sammet et al. [26] found that albumin could affect CETP action, depending on the amount of fatty acids associated with HDL in the mixtures and Lagrost et al. [30] found that albumin influenced the transfer of cholesteryl esters from HDL to VLDL.

Plasma samples can be stored for at least 1 year, when we last tested, without change in the lipid transfer results. Storage of plasma samples for a long period of time offers a great advantage for planning long-term clinical trials. Under the conditions when it was prepared, the donor nanoemulsion can be stored for 2 weeks only but this is not a drawback for the design of clinical trials of long duration. At any rate, the storage period of the nanoemulsion can eventually be prolonged with the use of antioxidants and stabilizers, but this procedure was not attempted in the current study.

The *in vitro* transfer of the four lipids to HDL was not different in CAD and non-CAD subjects. Many factors could have been influential in the results of this clinical study. One of the most important, HDL cholesterol levels, that is usually found to have decreased in CAD patients, was excluded by our pairing of CAD with non-CAD subjects by HDL cholesterol. LDL was increased in the CAD group; as LDL competes with HDL to receive lipids from the nanoemulsion, the higher levels of LDL-cholesterol would favor diminution of lipid transfer in the CAD group, which was ultimately not observed. CETP and PLTP action would also be major factors intervening in the process; however, it has been reported that mass and activity of CETP were not altered in CAD patients [32, 33]. Furthermore, as shown in the prospective study by Boekholdt et al. [34], CETP did not predict CAD development, unless triglyceride concentrations were increased, which is not the case of the study subjects. Data from the literature on the status of PLTP action in CAD patients are contradictory [35, 36]. Therefore, this overview on CETP and PLTP status in CAD is in agreement with the similar lipid transfer rates between CAD and non-CAD observed in our study subjects.

The diminished transfer of the four lipids to HDL by simvastatin treatment of the CAD patients may be ascribed to the diminished action and mass of CETP elicited by this hypocholesterolemic drug [37–40]. It can be hypothesized that a decrease in lipid transfer to HDL could also be observed with treatment with other statins, since atorvastatin also induces reduction in total CETP-dependent cholesterol ester transfer [41]. In contrast, the hypolipidemic resin cholestyramine did not change CETP action in hypercholesterolemic individuals [38]. In normolipidemic subjects, simvastatin administration also decreased the transfer of esterified cholesterol [37]. By increasing the clearance of LDL from the plasma and eliciting secondary changes in HDL metabolism, statins may change the

composition of those lipoprotein classes that could affect the lipid exchange that were reflected here by the decrease in lipid transfer to HDL.

Although not tested in this study, the concentration of free fatty acids has been documented as modifying CETP action [26] and may eventually change the transfer of lipids to HDL. This and other factors that influence the action of CETP or PLTP should be considered to interpret future results of studies using the currently described assay in disease states.

In conclusion, this practical *in vitro* assay designed to evaluate the lipid transfer to HDL described and validated here can be a useful tool for exploring the HDL metabolism in large populations and in several clinical conditions. The issue of how these transfer rates relate with the several HDL specific functions and HDL subclasses should be addressed in future studies.

Abstract Statins directly inhibit 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGR) activity, while γ -tocotrienol, an isoform of vitamin E, enhances the degradation and reduces cellular levels of HMGR in various tumor cell lines. Since treatment with statins or γ -tocotrienol alone induced a dose-responsive inhibition, whereas combined treatment with subeffective doses of these agents resulted in a synergistic inhibition in +SA mammary tumor cell growth, studies were conducted to investigate the role of the HMGR pathway in mediating the antiproliferative effects of combined low dose statin and γ -tocotrienol. Treatment with 8 μ M simvastatin inhibited cell growth and isoprenylation of Rap1A and Rab6, and supplementation with 2 μ M mevalonate reversed these effects. However, the growth inhibitory effects of 4 μ M γ -tocotrienol were not dependent upon suppression in mevalonate synthesis. Treatment with subeffective doses of simvastatin (0.25 μ M), lovastatin (0.25 μ M), mevastatin (0.25 μ M), pravastatin (10 μ M), or γ -tocotrienol (2 μ M) alone had no effect on protein prenylation or mitogenic signaling, whereas combined treatment with these agents resulted in a significant inhibition in +SA cell growth, and a corresponding decrease in total HMGR, Rap1A and Rab6 prenylation, and MAPK signaling, and mevalonate supplementation reversed these effects. These findings demonstrate that the synergistic antiproliferative effects of combined low dose statin and γ -tocotrienol treatment are directly related to an inhibition in HMGR activity and subsequent suppression in mevalonate synthesis.

Abbreviations

HMGR	3-Hydroxy-3-methylglutaryl-coenzyme A reductase
MAPK	Mitogen-activated protein kinase
FPP	Farnesyl pyrophosphate
GGPP	Geranylgeranyl pyrophosphate
ERK	Extracellular signal-regulated kinase
BSA	Bovine serum albumin
DMEM	Dulbecco's modified Eagle's medium
PBS	Phosphate buffered saline
MTT	3-(4,5-Dimethylthiazol-2yl)-2,5-diphenyl tetrazolium bromide
SDS	Sodium dodecyl sulfate
PVDF	Polyvinylidene fluoride
TBST	10 mM Tris-HCl containing 50 mM NaCl and 0.1% Tween 20, pH 7.4
TBS	0.05 M Tris-buffered saline (TBS) pH 7.6
PI3K	Phosphatidylinositol 3-kinase

Introduction

3-Hydroxy-3-methylglutaryl-coenzyme A reductase (HMGR) is the rate limiting enzyme in the mevalonate biosynthetic pathway and is involved in the synthesis of sterol and non-sterol intermediates essential for cell survival and growth [1]. Specifically, HMGR catalyzes the conversion of 3-hydroxy-3-methylglutaryl-coenzyme A to mevalonate, which subsequently produces isoprenoid intermediates

such as farnesyl pyrophosphate (FPP) and geranylgeranyl pyrophosphate (GGPP) that are required for posttranslational modification (isoprenylation) of various small GTP-binding proteins including Ras, Rap, Rab, Rho, nuclear lamins, and heterotrimeric G-protein γ -subunit [1–3]. Isoprenylation is needed for anchoring these signaling proteins to the cell membrane in close proximity to growth factor receptors so that these signaling proteins can be activated following receptor activation, and subsequently participate in turning on downstream mitogenic signaling pathways such as MAPK and Akt [2–4].

HMGR activity is characteristically elevated and/or unregulated in many forms of cancer and thereby acts to promote cancer cell survival and proliferation by providing an abundance of non-sterol intermediates [5]. As a result, a great deal of attention has been focused on the development of agents that target and inhibit HMGR activity for use in cancer chemotherapy. Statins represent a class of such agents that act as competitive inhibitors of HMGR and display potent anticancer activity in a variety of cell culture and animal tumor models [6, 7]. However, clinical use of statins in the treatment of cancer has been greatly limited by their high-dose toxicity that includes severe myotoxicity, liver toxicity, gastrointestinal dysfunction, and even death [8, 9].

γ -Tocotrienol, a naturally occurring isoform within the vitamin E family of compounds, displays potent anticancer activity [10] and has been shown to reduce HMGR activity through the post-transcriptional down-regulation of this enzyme [11]. The vitamin E family of compounds is divided into two subgroups called tocopherols and tocotrienols. Tocopherols are commonly found in high concentrations in a wide variety of foods, whereas tocotrienols are relatively rare and found in appreciable levels only in a few specific vegetable fats, such as palm oil [10]. Although chemically very similar, tocopherols have a saturated, whereas tocotrienols have an unsaturated phytyl chain attached to a chroman ring structure. It is now clearly established that tocotrienols, but not tocopherols, display potent antiproliferative and apoptotic activity against mammary tumor cells at treatment doses that have little or no effect on normal cell growth and viability [10].

Previous studies demonstrated that combined treatment of subeffective doses of statins with subeffective doses of γ -tocotrienol, synergistically inhibited the growth of highly malignant +SA mammary epithelial cells in culture, and these effects were associated with a suppression in MAPK and Akt mitogenic signaling [12]. Other studies showed that similar combination therapy induced G1 cell cycle arrest in +SA mammary tumor cells and these effects were associated with an increase in p27 expression, decreased cyclin D1 expression, and hypophosphorylation of Rb [13]. However, the specific intracellular target responsible for

mediating the antiproliferative effects of combined statins and γ -tocotrienol treatment remains unclear. Since statins and γ -tocotrienol have both been shown to suppress HMGR activity, it was hypothesized that inhibition of mevalonate synthesis may be ultimately responsible for mediating the growth inhibiting effects of combined therapy with these agents. Therefore, studies were conducted to characterize the growth inhibitory effects of combined low dose statins and γ -tocotrienol treatment on mevalonate synthesis, isoprenylation of small G-proteins Rap1A and Rab6, and mitogenic signaling in +SA mammary tumor cells.

Experimental Procedures

Chemicals and Antibodies

All materials were purchased from Sigma Chemical Company (St. Louis, MO, USA), unless otherwise stated. Isolated γ -tocotrienol (>98% purity) was generously provided as a gift by First Tech International Ltd. (Hong Kong). Antibodies for cyclin D1, phospho-p44/42 ERK, phospho-p38, total p44/42 ERK, and total p38 were purchased from Cell Signaling Technology (Beverly, MA, USA). Antibodies for Ki-67 antigen, unprenylated Rap 1A and isoprenylated Rab 6 were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Antibodies for HMGR and Ras were obtained from Upstate Biotechnology (Lake Placid, NY, USA) and BD Biosciences (San Jose, CA, USA), respectively. Anti- α -tubulin antibody was obtained from EMD Biosciences (La Jolla, CA, USA). Horseradish peroxidase-labeled goat anti-rabbit and anti-mouse secondary antibodies were purchased from PerkinElmer Biosciences (Boston, MA, USA) and donkey anti-goat secondary antibody was purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Alexa Fluor 594 donkey anti-goat secondary antibody was obtained from Molecular Probes (Eugene, Oregon, USA).

Cell Line and Culture Conditions

Experiments conducted in the present study represent a logical continuation of previous studies that have extensively characterized the antiproliferative and apoptotic effects of γ -tocotrienol in the highly malignant +SA mammary epithelial cell line [10]. The +SA mammary tumor cell line was derived from an adenocarcinoma that developed spontaneously in a BALB/c female mouse [14, 15]. +SA cells display anchorage-independent growth when cultured in soft agarose gels, and when injected back into the mammary gland fat pad of syngeneic female mice, +SA cells form anaplastic adenocarcinomas that

metastasize to the lung [15]. Cell culture conditions have been previously described in detail [12, 16, 17]. Briefly, +SA cells were maintained in serum-free defined medium consisting of Dulbecco's modified Eagle's medium (DMEM)/F12 containing 5 mg/mL bovine serum albumin (BSA), 10 $\mu\text{g}/\text{mL}$ transferrin, 100 U/mL soybean trypsin inhibitor, 100 U/mL penicillin, 0.1 mg/mL streptomycin, 10 $\mu\text{g}/\text{mL}$ insulin, and 10 ng/mL epidermal growth factor. For subculturing, cells were rinsed twice with sterile Ca^{2+} and Mg^{2+} -free phosphate buffered saline (PBS) and incubated in 0.05% trypsin containing 0.025% EDTA in PBS for 5 min at 37°C. The released cells were centrifuged, resuspended in serum-free media and counted using hemocytometer.

Experimental Treatments

To dissolve highly lipophilic γ -tocotrienol in aqueous culture media, a stock solution of γ -tocotrienol was first prepared by binding it to bovine serum albumin (BSA) as described previously [12, 13, 16, 17]. Simvastatin, lovastatin or mevastatin exist in their inactive lactone forms that do not inhibit HMGR, but are active as their corresponding open-ring hydroxy-derivatives [18, 19]. Hence,

these statins were activated prior to addition to treatment media as described previously [12, 13]. Briefly, statins were dissolved in a 70% ethanol solution containing 0.1 N NaOH and then incubated at 50°C for 1 h. The alkaline statin solution was then neutralized by the addition of 70% ethanol solution containing 0.1 N HCl to form a stock solution that was then used to prepare treatment media. Pravastatin has an active open ring structure and was therefore, directly dissolved in 70% ethanol to form a stock solution. All media was adjusted so that the final ethanol concentration was same in all the groups within a given experiment and never exceeded 0.05%, and all cells were fed fresh control or treatment media every day.

Growth Studies and Viable Cell Number

In growth studies (Figs. 1, 4), +SA cells were initially seeded at a density of 5×10^4 cells/well (6 wells/group) in 24-well culture plates in serum-free defined control media and allowed to attach overnight. Cells were then, exposed to respective experimental treatments containing simvastatin, lovastatin, mevastatin, pravastatin, γ -tocotrienol, mevalonate alone or in various combinations for 4 days. During this period, cells were fed fresh treatment or control

Fig. 1 Effects of simvastatin and γ -tocotrienol treatment on +SA cell growth, HMGR and Ras levels, and Rap1A and Rab6 isoprenylation. Cells were plated at a density of 5×10^4 cells/well (6 wells/group) in 24-well culture plates and exposed to 0–8 μM simvastatin treatment alone or the combined treatment of 8 μM simvastatin with 2 μM mevalonate (a), 0–4 μM γ -tocotrienol treatment alone or the combined treatment of 4 μM γ -tocotrienol with 2 μM mevalonate (b) for 4 days in culture. Afterwards, viable cell count was determined using MTT assay. Vertical bars indicate the mean cell count \pm SEM in each treatment group. * $P < 0.05$ as compared with

8 μM simvastatin-treated group. For Western blot studies (c, d), cells were plated at a density of 1×10^6 cells/100-mm culture dishes and treated with the above doses of simvastatin and mevalonate (c), or γ -tocotrienol and mevalonate (d) for a 4-day culture period. Afterwards, whole cell lysates were prepared for subsequent separation by polyacrylamide gel electrophoresis, followed by Western blot analysis to measure total HMGR, Rap1A (unprenylated), Rab6 (isoprenylated), total Ras and α -tubulin levels. α -Tubulin was visualized to ensure equal sample loading in each lane

media every day. At the end of the treatment exposure period, the viable cell number was determined by using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) colorimetric assay as described previously [16, 17]. Briefly, cells in 24-well plates were incubated at 37°C with fresh defined control media containing 0.42 mg/mL MTT. After a 4-h incubation period, the media was removed and MTT crystals were dissolved in isopropanol (1 mL/well), and the optical density of each sample was measured at 570 nm on a microplate reader (SpectraCount, Packard BioScience Company). The number of cells/well was calculated against a standard curve prepared by plating various concentrations of cells, as determined by hemocytometry, at the beginning of each experiment.

Western Blot Analysis

For Western blot analysis, +SA cells were plated at a density of 1×10^6 cells/100-mm culture dish and grown in serum-free defined control or treatment media. After a 4-day treatment period, cells were isolated with trypsin, washed with PBS, and the whole cell lysates were then prepared as previously described [13, 16, 20]. Protein concentration in each sample was determined using the Bio-Rad protein assay kit (Bio-Rad, Hercules, CA, USA). Equal amounts (25 µg/lane) of each sample were subjected to electrophoresis through 7.5 to 15% SDS–polyacrylamide minigels. Minigels within a given experiment were run simultaneously using a AccuPower model 500 power supply unit (VWR, Suwanee, GA). Proteins separated on minigels were transblotted at 30 V for 12–16 h at 4°C onto a polyvinylidene fluoride (PVDF) membrane (PerkinElmer Lifesciences, Wellesley, MA, USA) in a Trans-Blot Cell (Bio-Rad Laboratories, Hercules, CA, USA) according to the methods of Towbin and these PVDF membranes were used for subsequent Western blot analyses as previously described [13, 16, 20, 21]. Briefly, membranes were then blocked with 2% BSA in 10 mM Tris–HCl containing 50 mM NaCl and 0.1% Tween 20, pH 7.4 (TBST) and then, incubated with specific primary antibodies against HMGR, Rap1A, Rab6, Ras, phospho-p44/42 ERK, phospho-p38, total p44/42 ERK, total p38, cyclin D1, and α -tubulin, diluted 1:2,000–1:10,000 in TBST/2% BSA for 2 h. Membranes were washed five times with TBST and then incubated with respective horseradish peroxidase-conjugated secondary antibodies diluted 1:5,000 in TBST/2% BSA for 1 h followed by rinsing with TBST. Chemiluminescence (Pierce, Rockford, IL, USA) was used to visualize the antibody bound proteins. Images of protein bands from all treatment groups within an experiment were acquired using Kodak Gel Logic 1500 Imaging System (Carestream Health Inc, New Haven, CT, USA). The visualization of α -tubulin was used to ensure equal sample

loading in each lane. All experiments were repeated at least three times and a representative Western Blot image from each experiment is shown in Figs. 1, 3 and 5.

Ki-67 Immunofluorescence

+SA cells were initially plated at a density of 2×10^5 cells/chamber in single chamber slides (Nalge Nunc International, Rochester, NY, USA) and allowed to attach overnight. Afterwards, cells were divided into different groups that fed their respective treatment media. After 4 days of treatment exposure, cells were rinsed with 0.05 M Tris-buffered saline (TBS) pH 7.6, and fixed with methanol previously cooled to -20°C . Fixed cells were blocked with 2% donkey serum in TBS for 1 h, followed by overnight incubation with Ki-67 primary antibody at 4°C. Cells were washed five times with TBS followed by 45 min incubation with fluorescent labeled anti-goat secondary antibody at room temperature in dark. After washing the cells five times with TBS, cells were embedded with Vectashield Mounting Medium (Vector Laboratories Inc., Burlingame, CA, USA) containing DAPI as the counterstain, followed by imaging by confocal microscopy (LSM Pascal confocal microscope, Carl Zeiss Microimaging Inc., Thornwood, NY, USA). Quantification of Ki-67 labeling was achieved by counting the number of +SA cells displaying positive staining versus the total number of cells within five randomly selected 80,000- μm^2 areas of each slide in each treatment group using LSM software ZEN 2007 (Carl Zeiss Microimaging Inc., Thornwood, NY).

Statistical Analysis

Differences among the various treatment groups in +SA cell growth studies were determined by analysis of variance (ANOVA) followed by Dunnett's *t* test. A difference of $P < 0.05$ was considered to be statistically significant as compared with vehicle-treated controls or as defined in the figure legends.

Results

Effects of Simvastatin and γ -Tocotrienol on +SA Cell Proliferation, HMGR Levels and Protein Prenylation

Treatment with 0–0.5 μM simvastatin or 2 μM mevalonate had no effect, whereas treatment with 1–8 μM simvastatin significantly inhibited +SA mammary tumor cell growth in a dose-dependent manner as compared with vehicle-treated controls (Fig. 1a). Simvastatin-induced growth inhibition was reversed in cells given 2 μM mevalonate

supplementation (Fig. 1a). Treatment with 1–8 μM simvastatin had little or no effect on the relative levels of HMGR, while treatment with 2 μM mevalonate decreased HMGR levels as compared with vehicle-treated controls (Fig. 1c). The anti-HMGR antibody used in these Western blots specifically detects two adjacent protein bands in +SA cell lysates and this doublet possibly indicates two isozymes of HMGR that have been reported previously [22]. Treatment with 1–8 μM simvastatin was also found to reduce the level of protein prenylation as evidenced by a marked increase in unprenylated Rap1A and a marked decrease in isoprenylated Rab6 as compared with their respective vehicle-treated controls (Fig. 1b). Simvastatin-induced inhibition of Rap1A and Rab6 prenylation was blocked by 2 μM mevalonate supplementation (Fig. 1c). Total Ras levels were similar in all treatments groups (Fig. 1c).

Treatment with 0–3 μM of γ -tocotrienol had no effect, whereas treatment with 3.5–4 μM γ -tocotrienol treatment significantly inhibited +SA cell growth in a dose-responsive manner (Fig. 1b). However, simultaneous administration of 4 μM γ -tocotrienol and 2 μM mevalonate did not reverse the growth inhibitory effects of γ -tocotrienol treatment (Fig. 1b). Treatment with 1–4 μM γ -tocotrienol or 2 μM mevalonate alone decreased HMGR levels, and combined treatment of these agents further decreased HMGR levels as compared with vehicle-treated controls (Fig. 1d). Treatment with 4 μM γ -tocotrienol or 2 μM mevalonate alone or in combination had no effect on Rap1A and Rab6 prenylation or total Ras levels as compared to vehicle-treated controls (Fig. 1d).

Combined Treatment Effects of Individual Statins and γ -Tocotrienol on +SA Cell Proliferation

It has been established that combined treatment with low dose statins and γ -tocotrienol results in a synergistic inhibition in +SA mammary tumor cell growth [12, 13]. Figure 2a shows the effects of statins and γ -tocotrienol alone or in combination on the ratio of +SA cells demonstrating positive Ki-67 immunofluorescent staining versus the total number of cells within each treatment group. The Ki-67 protein is specifically expressed and localized in the nucleus of proliferating cells and can be used as a marker for cell proliferation. More than 88% of cells displayed positive Ki-67 staining (pink) in the vehicle-treated control group (C) and groups treated with subeffective doses of simvastatin (S; 0.25 μM), lovastatin (L; 0.25 μM), mevastatin (M; 0.25 μM), pravastatin (P; 10 μM) or γ -tocotrienol (T; 2 μM) alone (Fig. 2a). However, combined treatment with subeffective doses of individual statins with a subeffective dose of γ -tocotrienol displayed <26% positive Ki-67 staining (Fig. 2a). Fluorescent

Fig. 2 Effects of low dose statin and γ -tocotrienol treatment on Ki-67 expression in +SA mammary tumor cells. +SA cells were initially plated at a density of 2×10^5 cells/chamber in single-well chamber slides and exposed to media containing vehicle (C), 0.25 μM simvastatin (S), 0.25 μM lovastatin (L), 0.25 μM mevastatin (M), 10 μM pravastatin (P), 2 μM γ -tocotrienol (T) or the combination of individual statins (S, L, M, or P) with 2 μM γ -tocotrienol (T) for a 4-day culture period. Afterwards, cells were fixed with methanol and stained with fluorescent Ki-67 antibody and counterstained with DAPI, and images were visualized by confocal microscopy. **a** Vertical bar graph shows percent of malignant +SA mammary epithelial cells displaying positive Ki-67 fluorescent staining in each treatment group. Numbers presented over each vertical bar represent the number of cells displaying positive Ki-67 staining over the total number of cells counted in each treatment group. Cells were counted in five squares of area equivalent to 80,000 μm^2 . **b** Confocal fluorescent images of positive Ki-67 staining in +SA mammary tumor cells. The pink color indicates positive Ki-67 staining in individual nuclei of +SA cells. Magnification of each image is $200\times$

confocal images of +SA cells in the vehicle-treated control (C), 0.25 μM simvastatin (S), 2 μM γ -tocotrienol (T), and combined 0.25 μM simvastatin and 2 μM γ -tocotrienol (S + T) treatment groups are shown in Fig. 2b. The majority of +SA cells in control (C), simvastatin alone (S) or γ -tocotrienol alone (T) treated groups showed abundant positive (pink) Ki-67 staining in their nuclei. In contrast, Ki-67 positive staining was greatly reduced in the +SA cell nuclei treated with the combination of simvastatin and

γ -tocotrienol (S + T; Fig. 2b). Similar results were obtained when +SA cells were exposed to 0.25 μ M lovastatin, 0.25 μ M mevastatin, or 10 μ M pravastatin alone or in combination with 2 μ M γ -tocotrienol (images not shown).

Effects of Combined Statin and γ -Tocotrienol Treatment on HMGR Levels, Protein Prenylation and Mitogenic Signaling

Figure 3 shows that treatment with 0.25 μ M simvastatin (S), 0.25 μ M lovastatin (L), 0.25 μ M mevastatin (M) or 10 μ M pravastatin (P) alone did not alter the relative levels of HMGR. However, treatment with 2 μ M tocotrienol (T) alone or in combination with the various statins caused a relatively large decrease in HMGR levels as compared to vehicle-treated controls (Fig. 3). Similar treatment with

Fig. 3 Effects of statin and γ -tocotrienol treatment on the intracellular levels of HMGR, isoprenylated small G-proteins, MAPKs and cyclin D1 in +SA mammary tumor cells after a 4-day culture period. +SA cells were plated at a density of 1×10^6 cells/100 mm culture dishes and exposed to control (C) simvastatin (S), 0.25 μ M lovastatin (L), 0.25 μ M mevastatin (M), 10 μ M pravastatin (P), or 2 μ M γ -tocotrienol (T) alone, or the combination of individual statins (S, L, M or P) with 2 μ M γ -tocotrienol (T). Afterwards, cells in all treatment groups were isolated and whole cell lysates were prepared and electrophoresed through polyacrylamide minigels, transblotted to PVDF membrane, followed by Western blot analysis to measure relative levels of total HMGR, Rap1A (unprenylated), Rab6 (isoprenylated), total Ras, phospho-p44/42 ERK, phospho-p38 levels, total p44/42 ERK, total p38, cyclin D1 and α -tubulin levels. α -Tubulin was visualized to ensure equal sample loading in each lane

simvastatin, lovastatin, mevastatin, pravastatin, or γ -tocotrienol alone had no effect on the relative levels of unprenylated Rap1A, but combined treatment of γ -tocotrienol with individual statins dramatically increased unprenylated Rap1A levels as compared with vehicle-treated controls (Fig. 3). Likewise, the relative intracellular levels of isoprenylated Rab6, total Ras, phospho-p44/42 ERK, total ERK, phospho-p38, total p38 and cyclin D1 were unaffected by treatment with individual statins or γ -tocotrienol alone, whereas combined treatment of γ -tocotrienol with individual statins resulted in a reduction in the levels of isoprenylated Rab6, phospho-p44/42 ERK, phospho-p38 and cyclin D1, as compared with vehicle-treated controls (Fig. 3). These same combination treatments did not alter the relative levels of total Ras, total ERK, and total p38 (Fig. 3). The antibodies used to detect total and phosphorylated p44/42 ERK detect two bands at 44 and 42 kDa corresponding to the two protein kinases ERK1 and ERK2, respectively.

Effects of Mevalonate Supplementation on +SA Cell Growth

Treatment with 0.25 μ M simvastatin (S), 0.25 μ M lovastatin (L), 0.25 μ M mevastatin (M), 10 μ M pravastatin (P), 2 μ M γ -tocotrienol (T), 1 μ M (m1) mevalonate, or 2 μ M (m2) mevalonate alone had no effect on +SA mammary tumor cell growth as compared with vehicle-treated controls (C) following a 4-day culture period (Fig. 4). Combined treatment with similar doses of individual statins with γ -tocotrienol markedly suppressed growth of +SA cells. However, these growth inhibitory effects of combined statin and γ -tocotrienol treatment were partially reversed with 1 μ M mevalonate supplementation and completely reversed with 2 μ M mevalonate supplementation (Fig. 4). Interestingly, supplementation with 0–50 μ M FPP or GGPP was unable to reverse the inhibitory effect of combined statin and γ -tocotrienol treatment on the +SA mammary tumor cell growth (data not shown).

Effects of Statins, γ -Tocotrienol, and Mevalonate Supplementation on HMGR, Protein Prenylation and Mitogenic Signaling

Figure 5 shows that combined treatment of 0.25 μ M simvastatin (S), 0.25 μ M lovastatin (L), 0.25 μ M mevastatin (M) or 10 μ M pravastatin (P) with 2 μ M γ -tocotrienol (T) resulted in a large increase in unprenylated Rap1A levels and a corresponding decrease in the levels of HMGR, isoprenylated Rab6, phospho-p44/42 ERK, phospho-p38 and cyclin D1, as compared with vehicle-treated controls (C). In contrast, +SA cells receiving 2 μ M mevalonate supplementation (m) alone or together with combined

Fig. 4 Effects of mevalonate supplementation on the growth of +SA mammary tumor cells. Cells were plated at a density of 5×10^4 cells/well (6 wells/group) in 24-well culture plates and exposed to control (C), 0.25 μ M simvastatin (S), 0.25 μ M lovastatin (L), 0.25 μ M mevastatin (M), 10 μ M pravastatin (P), 2 μ M γ -tocotrienol (T), 1 μ M mevalonate (m1) or 2 μ M mevalonate (m2) alone, or combination

with individual statins (S, L, M or P) and/or γ -tocotrienol (T) for a 4-day culture period. Afterwards, viable cell count was determined using the MTT assay. Vertical bars indicate the mean cell count \pm SEM in each treatment group. * $P < 0.05$ as compared with respective combination statin and γ -tocotrienol treatment groups not exposed mevalonate supplementation

statins and γ -tocotrienol treatment showed no change in the relative levels of unprenylated Rap1A, isoprenylated Rab6, phospho-p44/42 ERK, phospho-p38 and cyclin D1 levels, as compared with vehicle-treated controls (Fig. 5). However, all groups receiving mevalonate supplementation displayed a decrease in HMGR levels as compared with vehicle-treated controls. The relative levels of total Ras, total ERK, and total p38 did not differ among any of the treatment groups (Fig. 5).

Discussion

Results in this study demonstrate that the growth inhibitory effects of statins on +SA mammary tumor cells are directly related to suppression in HMGR activity, mevalonate synthesis, small G-protein prenylation and mitogenic signaling. In contrast, the antiproliferative effects of γ -tocotrienol are not dependent on a reduction in HMGR activity, as evidenced by the finding that treatment with growth inhibiting doses of γ -tocotrienol has little effect on protein prenylation, and mevalonate supplementation does not reverse the antiproliferative effects of this form of vitamin E. However, the synergistic suppression of +SA mammary tumor cell growth that occurs with combined treatment of subeffective doses of individual statins with subeffective doses of γ -tocotrienol appears to result from the action of γ -tocotrienol to potentiate statin-dependent inhibition of HMGR activity. This suggestion is supported by the finding that mevalonate supplementation was able to reverse

the inhibitory effects of combined low dose statin and γ -tocotrienol treatment on +SA cell growth, protein prenylation and mitogenic signaling. These findings demonstrate that the synergistic antiproliferative effects of combined low dose statin and γ -tocotrienol treatment result directly from an inhibition in HMGR activity and subsequent suppression in mevalonate synthesis.

Previous investigations have indicated that the anticancer effects of statins are mediated by both HMGR-dependent and -independent mechanisms [18, 23]. However, the growth inhibitory effects of statins were reversed by mevalonate supplementation and indicate that inhibition of HMGR activity is the primary mechanism mediating the antiproliferative effects of statins in +SA mammary tumor cells. It was also found that mevalonate supplementation alone and in combination with individual statins decreased HMGR levels in +SA cells. This observation agrees with earlier findings that showed mevalonate supplementation induces a down-regulation in HMGR through both transcriptional and post-transcriptional mechanisms [1, 24].

The HMGR pathway plays an essential role in the synthesis of isoprenoids which are required for the isoprenylation of key signaling proteins such as Rap1A and Rab6. Rap and Rab family members are small G proteins similar to Ras that are involved with activating signal transduction pathways important in regulating cellular proliferation, differentiation, adhesion and cancer progression [25–27]. Rap1 activates the MAPK pathways through the interaction with B-Raf [28]. Rab proteins are characteristically elevated in prostate, bladder, ovarian and

Fig. 5 Effects of mevalonate supplementation on intracellular levels of HMGR, isoprenylation of small G-proteins, MAPKs and cyclin D1. +SA cells were plated at a density of 1×10^6 cells/100 mm culture dishes and exposed to control media (C) or 2 μ M mevalonate (m) containing media, or treatment media containing the combination of 0.25 μ M simvastatin (S), 0.25 μ M lovastatin (L), 0.25 μ M mevastatin (M), or 10 μ M pravastatin (P), with 2 μ M γ -tocotrienol (T) alone or in combination with 2 μ M mevalonate (m) for a 4-day culture period. Afterwards, whole cell lysates were prepared and electrophoresed through polyacrylamide minigels, transblotted to PVDF membrane, followed by Western blot analysis to measure relative levels of total HMGR, unprenylated Rap1A, isoprenylated Rab6, total Ras, phospho-p44/42 ERK, phospho-p38, total p44/42 ERK, total p38, cyclin D1 and α -tubulin. α -Tubulin was visualized to ensure equal sample loading in each lane

breast cancers, and suppression of Rab6 prenylation can initiate apoptosis in many types of cancer cells [29, 30]. In contrast to statins, the growth inhibitory effects of γ -tocotrienol treatment alone occurs independently of HMGR activity and is not associated with a reduction in small G-protein prenylation. The reduction in HMGR levels observed following γ -tocotrienol treatment alone is apparently insufficient to decrease HMGR activity enough to block the prenylation of Rap1A and Rab6. However, combined low dose treatment of statins and γ -tocotrienol greatly reduced prenylation of Rap1A and Rab6, and this effect was reversed by mevalonate supplementation. Studies also found that unlike mevalonate, supplementation of FPP or GGPP did not reverse the inhibitory effects of combined low dose statin and γ -tocotrienol treatment (data not shown). It is possible that non-sterol products synthesized downstream of mevalonate, but upstream of FPP and

GGPP, such as isopentenyl pyrophosphate (IPP) and geranyl pyrophosphate (GPP), play an important role in the prenylation of Rap1A and Rab6 in +SA cells. Additional studies are required to determine the exact enzymatic step downstream of mevalonate that is targeted by combined statin and γ -tocotrienol treatment to prevent the prenylation of Rap1A and Rab6.

Previous studies have established that γ -tocotrienol decreases cellular levels of HMGR by accelerating the degradation of this enzyme [11]. However, the present findings clearly indicate that when given alone, the growth inhibitory effects of γ -tocotrienol are not dependent on its action to down regulate HMGR levels. The antiproliferative effects of γ -tocotrienol have been previously reported to be associated with a suppression in ErbB3/PI3K/Akt mitogenic signaling [31, 32]. ErbB/PI3K/Akt signaling pathway is important for cell survival and growth, and plays a pivotal role in tumorigenesis. Since Akt phosphorylates and stimulates the function of many intracellular proteins involved in proliferation and survival, enhanced Akt signaling has been shown to be associated with the development of breast cancer in humans [33]. The ability of subeffective doses of γ -tocotrienol to synergistically enhance the growth inhibitory effects of individual statins can be explained, at least in part, by the finding that statin inhibition of HMGR activity is associated in triggering a compensatory feedback mechanism that results in an up-regulation in HMGR expression [34, 35], and this self-limiting effect of statins is blocked when given in combination with γ -tocotrienol.

Mitogenic activation of small G-proteins like Ras, Rap and Rab stimulates MAPK pathways and promotes cell cycle progression [36–38]. MAPK signaling cascades such as Erk, p38, and JNK control the fundamental cellular processes of growth, proliferation, differentiation, migration and apoptosis, and elevated or unregulated MAPK signaling can play a critical role in the development and progression of cancer [39]. Over expression or enhanced Ras activation and MAPK signaling can result in enhanced expression of cyclin D1 and stimulate unregulated cell cycle progression in many types of human cancers [40]. Combined treatment of γ -tocotrienol with individual statins caused a reduction in Rap1A and Rab6 prenylation, decreased phosphorylation (activation) of p44/42-ERK and p38, and decreased expression of cyclin D1 which regulates cell cycle transition from G1 to S phase, and these effects were reversed by mevalonate supplementation. Although this same treatment was found to have no effect on total Ras levels, it is very likely that prenylated Ras levels were also reduced and contributed to the reduction in phosphorylated-MAPKs that was observed in these +SA mammary tumor cells. Further studies are necessary to determine the effects on combined low dose statin and γ -tocotrienol treatment on Ras prenylation.

HMGR activity and expression is characteristically elevated and often resistant to feedback regulation by sterols in many types of cancer cells [1, 41, 42]. Fortunately, HMGR activity has also been found to be highly sensitive to the feedback inhibition by non-sterol isoprenoids, and exogenous administration of plant derived isoprenoids such as α -limonene, perillyl alcohol, and β -ionone has been shown to induce a down-regulation of HMGR in various types of cancer cells [5, 22, 43]. Chemically, γ -tocotrienol is also classified as an isoprenoid and this property might explain the mechanism involved in mediating γ -tocotrienol-induced down-regulation of HMGR levels in +SA mammary tumor cells [11, 22].

In conclusion, the present findings demonstrate that suppression in HMGR activity and mevalonate synthesis is primarily responsible for mediating the antiproliferative effect of combined low-dose statin and γ -tocotrienol treatment in +SA mammary tumor cells. The synergistic antiproliferative activity of these agents appears to be due to the cooperative action of γ -tocotrienol to cause a down-regulation in HMGR levels and statins to directly inhibit HMGR activity. These findings also suggest that combined low-dose statin and γ -tocotrienol treatment may greatly improve therapeutic responsiveness in the treatment of breast cancer, while at the same time greatly reduce or eliminate the severe myotoxicity and other adverse side effects associated with high-dose statin monotherapy.

Abstract A kinetic study of the prooxidant effect of α -tocopherol was performed. The rates of allylic hydrogen abstraction from various unsaturated fatty acid esters (ethyl stearate **1**, ethyl oleate **2**, ethyl linoleate **3**, ethyl linolenate **4**, and ethyl arachidonate **5**) by α -tocoperoxyl radical in toluene were determined, using a double-mixing stopped-flow spectrophotometer. The second-order rate constants (k_p) obtained are $<1 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **1**, $1.90 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **2**, $8.33 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **3**, $1.92 \times 10^{-1} \text{ M}^{-1} \text{ s}^{-1}$ for **4**, and $2.43 \times 10^{-1} \text{ M}^{-1} \text{ s}^{-1}$ for **5** at 25.0 °C. Fatty acid esters **3**, **4**, and **5** contain two, four, and six $-\text{CH}_2-$ hydrogen atoms activated by two π -electron systems ($-\text{C}=\text{C}-\text{CH}_2-\text{C}=\text{C}-$). On the other hand, fatty acid ester **2** has four $-\text{CH}_2-$ hydrogen atoms activated by a single π -electron system ($-\text{CH}_2-\text{C}=\text{C}-\text{CH}_2-$). Thus, the rate constants, $k_{\text{abstr}}/\text{H}$, given on an available hydrogen basis are $k_p/4 = 4.75 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ for **2**, $k_p/2 = 4.16 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **3**, $k_p/4 = 4.79 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **4**, and $k_p/6 = 4.05 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **5**. The $k_{\text{abstr}}/\text{H}$ values obtained for **3**, **4**, and **5** are similar to each other, and are by about one order of magnitude higher than that for **2**. From

these results, it is suggested that the prooxidant effect of α -tocopherol in edible oils, fats, and low-density lipoproteins may be induced by the above hydrogen abstraction reaction.

Introduction

It is well known that vitamin E (α -tocopherol, α -TocH) is localized in biomembranes and functions as an antioxidant

Fig. 1 Molecular structures of fatty acid ethyl esters (LH) (ethyl stearate **1**, ethyl oleate **2**, ethyl linoleate **3**, ethyl linolenate **4**, and ethyl arachidonate **5**), α -tocopherol (α -TocH), α -tocopheroxyl (α -Toc•), 5,7-di-isopropyl-tocopheroxyl (5,7-Di-iPr-Toc•), and aroxy (ArO•) radical

by protecting unsaturated lipids from peroxidation [1–4]. The antioxidant actions of the α -tocopherol have been ascribed to the scavenging reaction of active free radicals (LOO• and LO•), producing corresponding α -tocopheroxyl (α -Toc•) radicals (see Fig. 1 and reaction 1) [5, 6]. The α -Toc• radicals produced may combine with another peroxy (LOO•) radical (reaction 2) [6]. If α -tocopherols exist in biomembranes and oils, the α -Toc• radicals may react with unsaturated lipids (LH) (reaction 3) and lipid hydroperoxides (LOOH) (reaction 4). These reactions 3 and 4 are known as prooxidant reactions, which induce the degradation of unsaturated lipids [7–10]. α -Toc• radicals may be regenerated by vitamin C (ascorbate anion, AsH⁻) (reaction 5) [1] and/or ubiquinol-10 [11] in biomembranes, to protect the above prooxidant effects. Further, α -Toc• radicals disappear by bimolecular reaction with another α -Toc• to give non-radical products (NRP) (reaction 6) [6].

As described above, α -Toc• radical is an important key radical, which appears in the process of the antioxidant and prooxidant actions of α -TocH. Detailed kinetic studies have been performed for the reactions 1 [2, 6], 4 [12, 13], 5 [14–17] and 6 [6, 18–20], and the mechanisms involved have been studied extensively. However, the examples of the measurements of the rate constants (k_2 and k_p) for the reactions 2 [21] and (3) [21, 22] are limited, because of the instability of α -Toc• radicals. The reaction of LOO• with α -Toc• radical (reaction 2) is very fast with a rate constant (k_2) of $3 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ [21]. The reaction rates (k_p) were measured by using more stable 5,7-di-isopropyl-tocopheroxyl (5,7-Di-iPr-Toc•) radical (see Fig. 1), and the structure–activity relationship was discussed for the reaction 3 [23, 24].

In the present work, in order to clarify the mechanism of prooxidant action of vitamin E (α -TocH) in biological systems, a kinetic study of the reaction of α -Toc• radical with saturated and unsaturated fatty acid esters (LH) (ethyl stearate **1**, ethyl oleate **2**, ethyl linoleate **3**, ethyl linolenate **4**, and ethyl arachidonate **5**) (Fig. 1) has been performed in toluene, using a double-mixing stopped-flow spectrophotometer.

Experimental Procedure

α -TocH was obtained from Calbiochem. Ethyl stearate **1** (>99%) was obtained from the Tokyo Chemical Industry Co. Ltd. Ethyl oleate **2** (>98%) was obtained from Aldrich. Ethyl linoleate **3** (>99%), ethyl linolenate **4** (>98%), and ethyl arachidonate **5** (>99%) were purchased from the Sigma Chemical Co. Aroxy radical (ArO•, 2,6-di-*t*-butyl-4-(4'-methoxyphenyl)phenoxyl) (see Fig. 1) was prepared according to the method of Rieker et al [26].

The measurement of the second-order rate constant (k_s) for the reaction of ArO• with α -TocH (reaction 7) was performed with a Unisoku single-mixing stopped-flow spectrophotometer (Model RSP-1000) by mixing equal volumes of toluene solutions of ArO• and α -TocH under a nitrogen atmosphere [25].

The measurement of the k_p value (reaction 3) was performed with a Unisoku double-mixing stopped-flow spectrophotometer (Model RSP-1000-03F). By mixing first equal volumes of toluene solutions of α -TocH with $\text{ArO}\cdot$, $\alpha\text{-Toc}\cdot$ radical was prepared (reaction 7), and after 2 s the second-mixing of equal volumes of $\alpha\text{-Toc}\cdot$ solution and LH 1–5 solutions (reaction 3) was performed, using double-mixing unit of the RSP-1000. The rate constants (k_p) were determined by analyzing the decay curve of $\alpha\text{-Toc}\cdot$ as described later. The time between mixing two solutions and recording the first data point (that is, dead time) was 10–20 ms. The reaction was monitored with either single wavelength detection or photo-diode array detector attached to the stopped-flow spectrophotometer. All measurements were performed at 25.0 ± 0.5 °C.

Results

Rate Constant (k_s) for the Reaction of α -Tocopherol with Aroxyl Radical in Toluene

The reactions studied in the present work are the following ones:

In order to determine the rate constant (k_p) for the reaction 3 of LH with $\alpha\text{-Toc}\cdot$, the measurements of the rate constants (k_s and $2k_d$) for the reactions 7 and 6 are necessary, as described later [20, 22].

The $\text{ArO}\cdot$ radical is stable in the absence of $\alpha\text{-TocH}$, and shows absorption peaks at $\lambda_{\text{max}} = 377$ nm ($\epsilon = 15,700$ M⁻¹ cm⁻¹), 528 nm ($\epsilon = 3,030$ M⁻¹ cm⁻¹), and 573 nm ($\epsilon = 3,450$ M⁻¹ cm⁻¹) in toluene solution, as shown in Fig. 2a. By adding the toluene solution of $\alpha\text{-TocH}$ (1.10×10^{-3} M) to the solution of $\text{ArO}\cdot$ (9.20×10^{-5} M) (1:1 in volume) at 25.0 °C, the absorption peak of $\text{ArO}\cdot$ disappeared quickly, and the spectrum was changed to that of $\alpha\text{-Toc}\cdot$ with four absorption peaks at $\lambda_{\text{max}} = 423$, 403, 382sh, and 341 nm (see Fig. 2a, b) [20, 25]. $\alpha\text{-Toc}\cdot$ is unstable at 25.0 °C, and its absorption peaks decreased gradually, after passing through the maximum (see Fig. 2b).

The decay rate of $\text{ArO}\cdot$ radical was determined by following the decrease in absorbance at 377 and/or 573 nm of

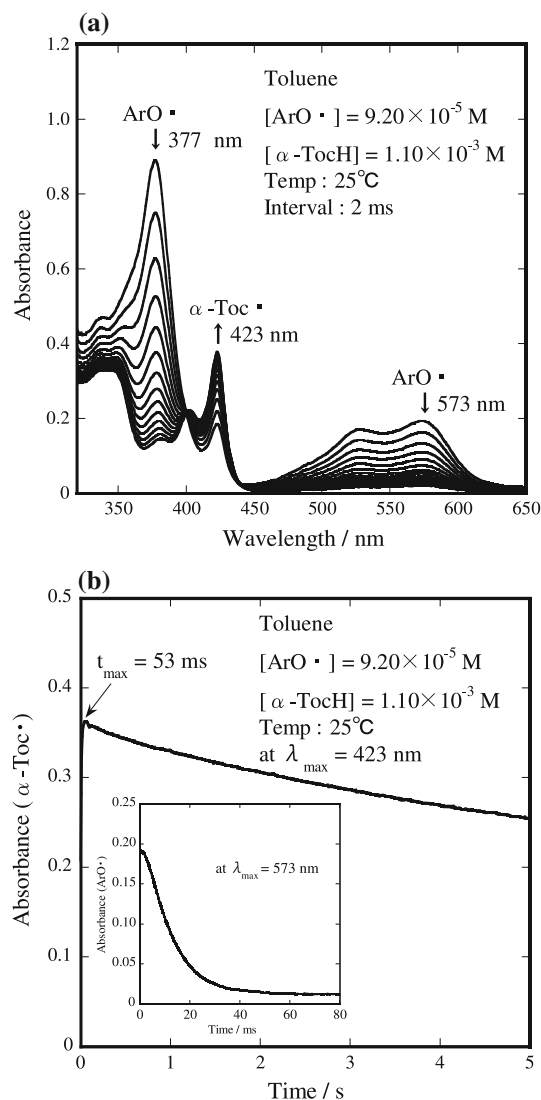

Fig. 2 **a** Change in electronic absorption spectrum of aroxyl ($\text{ArO}\cdot$) and $\alpha\text{-Toc}\cdot$ radical during the reaction of $\text{ArO}\cdot$ with $\alpha\text{-TocH}$ in toluene at 25.0 °C. $[\alpha\text{-TocH}]_{t=0} = 1.10 \times 10^{-3}$ M and $[\text{ArO}\cdot]_{t=0} = 9.20 \times 10^{-5}$ M. The spectra were recorded at 2-ms intervals. The arrow indicates a decrease ($\text{ArO}\cdot$) and an increase ($\alpha\text{-Toc}\cdot$) in an absorbance with time. **b** Time dependence of the absorbance of $\text{ArO}\cdot$ (at 573 nm) (inset) and $\alpha\text{-Toc}\cdot$ (at 423 nm) radicals produced by the reaction of $\text{ArO}\cdot$ with $\alpha\text{-TocH}$ in toluene at 25.0 °C. The values of $[\text{ArO}\cdot]_{t=0}$ and $[\alpha\text{-TocH}]_{t=0}$ are shown in Fig. 2b

the $\text{ArO}\cdot$ (see Fig. 2) [20, 25]. The pseudo-first-order rate constants (k_{obsd}) at 377 and/or 573 nm were linearly dependent on the concentration of $\alpha\text{-TocH}$ ($[\alpha\text{-TocH}]$), and thus the rate equation is expressed as

$$-d[\text{ArO}\cdot]/dt = k_{\text{obsd}}[\text{ArO}\cdot] = k_s[\alpha\text{-TocH}][\text{ArO}\cdot] \quad (8)$$

The rate constants (k_s) were obtained by plotting k_{obsd} against $[\alpha\text{-TocH}]$ (data are not shown). The k_s value obtained is 7.10×10^4 M⁻¹ s⁻¹.

Rate Constant ($2k_d$) for the Self-Bimolecular Reaction of α -Tocopheroxyl Radical in Toluene

By reacting $\text{ArO}\cdot$ with α -TocH in toluene (reaction 7), α -Toc \cdot radical is produced rapidly, and disappears by the bimolecular reaction (reaction 6) [6, 18–20], as shown in Fig. 2b. Independent reaction equations included in the reactions 7 and 6 are as follows:

$$-d[\text{ArO}\cdot]/dt = k_s[\alpha\text{-TocH}][\text{ArO}\cdot] \quad (9)$$

$$d[\alpha\text{-Toc}\cdot]/dt = k_s[\alpha\text{-TocH}][\text{ArO}\cdot] - 2k_d[\alpha\text{-Toc}\cdot]^2 \quad (10)$$

Recently, Eqs. 9 and 10 were solved numerically using the fourth-order Runge–Kutta method [18], and the $2k_d$ value was determined for several solvents [20]. Similar analysis was performed in the present work. The simulation of the formation and decay curves of α -Toc \cdot at $\lambda_{\text{max}} = 423$ nm in toluene was performed by varying the rate ($2k_d$) of bimolecular reaction and the molar extinction coefficient (ε) at 423 nm, where the concentration of α -Toc radical, $[\alpha\text{-Toc}\cdot]_t$, was calculated from the absorbance, by using Lambert–Beer's equation (absorbance (A_t) = $\varepsilon[\alpha\text{-Toc}\cdot]_t$). The value of k_s ($=7.10 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$) in toluene was used for the calculation. The results of the analysis performed for α -Toc \cdot are shown in Fig. 3.

The good agreement between the observed and simulation curves was obtained for the concentration of α -TocH ($[\alpha\text{-TocH}] = 1.10 \times 10^{-3} \text{ M}$) at $t = 0$ –10 s, when we used the values of k_s ($=7.10 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$), $2k_d$ ($=8.00 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$), and ε ($=3,820 \text{ M}^{-1} \text{ cm}^{-1}$ at $\lambda_{\text{max}} = 423$ nm) (see Fig. 3). As shown in Fig. 3, the concentration of α -Toc \cdot ($[\alpha\text{-Toc}\cdot]_t = 9.49 \times 10^{-5} \text{ M}$) at $t_{\text{max}} = 53$ ms is similar to

Fig. 3 Time dependence of the concentrations of α -Toc \cdot radical observed at λ_{max} (at 423 nm) during reaction of $\text{ArO}\cdot$ with α -TocH in toluene at 25.0 °C (solid line). The dotted line is a simulation curve. The values of $[\text{ArO}\cdot]_{t=0}$ and $[\alpha\text{-TocH}]_{t=0}$ are shown in Fig. 3

the initial concentration of $\text{ArO}\cdot$ ($[\text{ArO}\cdot]_{t=0} = 9.20 \times 10^{-5} \text{ M}$), if the concentration of α -TocH is high ($[\alpha\text{-TocH}] = 1.10 \times 10^{-3} \text{ M}$) and, thus, $\text{ArO}\cdot$ and α -Toc \cdot rapidly disappears and appears, respectively.

Rate Constants (k_p) for the Hydrogen Atom Abstraction by α -Tocopheroxyl Radical from Fatty Acid Ethyl Esters 1–5

As described above, measurements of the rate constant (k_p) for the reaction of α -Toc \cdot radical with LH 1–5 (reaction 3) were performed in toluene solution, using a double-mixing stopped-flow spectrophotometer. For example, the α -Toc radical was prepared by first-mixing of equal volumes of $\text{ArO}\cdot$ ($9.20 \times 10^{-5} \text{ M}$) and α -TocH ($1.10 \times 10^{-3} \text{ M}$) solutions (reaction 7), and after 2 s, the second-mixing of equal volumes of α -Toc \cdot solution and ethyl linolenate 4 solutions ($0, 1.81 \times 10^{-2}, 3.61 \times 10^{-2}, 5.42 \times 10^{-2}, 9.03 \times 10^{-2} \text{ M}$) (reaction 3) was performed. The decay curves of the absorbance of α -Toc \cdot at 423 nm in toluene were shown in Fig. 4b, indicating that the decay rates increase with increasing the concentration of 4. The decay of the absorbance of α -Toc \cdot at 423 nm without 4 is due to a bimolecular reaction 6 of α -Toc \cdot radicals. The rate constants (k_p) were determined by analyzing the decay curve of α -Toc \cdot as described later.

Similar measurements were performed for ethyl stearate 1, ethyl oleate 2, ethyl linoleate 3, and ethyl arachidonate 5. As shown in Fig. 4a, c and d, the reactions of α -Toc radical with ethyl oleate 2, ethyl linoleate 3 and ethyl arachidonate 5 in toluene were observed, respectively. On the other hand, the reaction of α -Toc \cdot with ethyl stearate 1 was negligible (data are not shown).

In the presence of LH 1–5, the rate of decay of α -Toc radical is given by Eq. 11, where k_p and $2k_d$ are the rate constants for reactions 3 and 6, respectively.

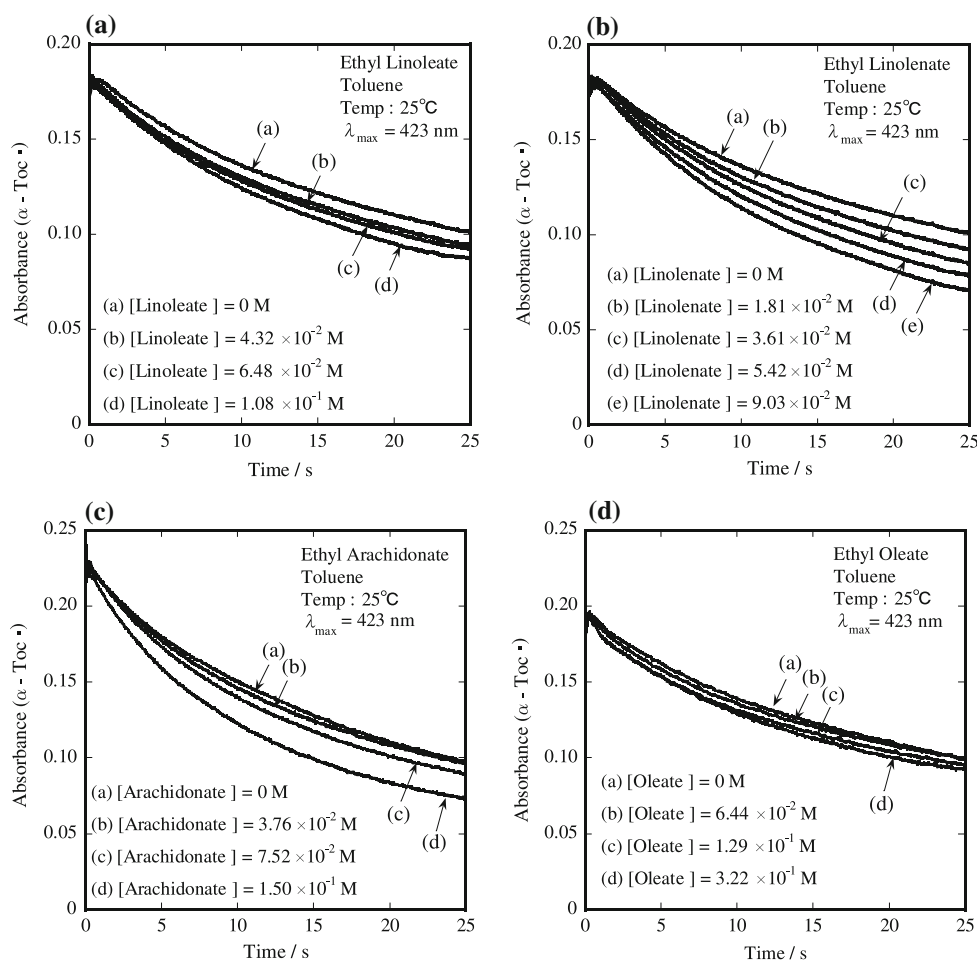

$$-d[\alpha\text{-Toc}\cdot]/dt = k_p[\text{LH}][\alpha\text{-Toc}\cdot] + 2k_d[\alpha\text{-Toc}\cdot]^2 \quad (11)$$

$$[\alpha\text{-Toc}\cdot]_{t=t} = \frac{\frac{k_p[\text{LH}][\alpha\text{-Toc}\cdot]_{t=0}}{2k_d[\alpha\text{-Toc}\cdot]_{t=0} + k_p[\text{LH}]} \exp(-k_p[\text{LH}]t)}{1 - \frac{2k_d[\alpha\text{-Toc}\cdot]_{t=0}}{2k_d[\alpha\text{-Toc}\cdot]_{t=0} + k_p[\text{LH}]} \exp(-k_p[\text{LH}]t)} \quad (12)$$

Equation (12) is obtained by an integration of Eq. 11, where $[\alpha\text{-Toc}\cdot]_{t=0}$ and $[\alpha\text{-Toc}\cdot]_{t=t}$ denote the concentrations of $[\alpha\text{-Toc}\cdot]$ at time $t = 0$ and $t = t$, respectively, [22]. The concentration of α -Toc radical, $[\alpha\text{-Toc}\cdot]_t$, (see Fig. 4) was calculated from the absorbance, by using Lambert–Beer's equation (absorbance (A_t) = $\varepsilon[\alpha\text{-Toc}\cdot]_t$). The values of ε ($=3,820 \text{ M}^{-1} \text{ cm}^{-1}$ at 423 nm) and $2k_d$ ($=8.00 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$) [20] obtained in toluene were used for the calculation.

The experimental decay curve for α -Toc radical in the presence of ethyl linolenate 4 ($[\text{LH } 4] = 9.03 \times 10^{-2} \text{ M}$)

Fig. 4 The decay of α -Toc· radical for the reaction of α -Toc· with fatty acid ethyl esters (a) LH 3, (b) LH 4, (c) LH 5, and (d) LH 2 observed at 423 nm in toluene at 25.0 °C. The values of $[\text{LH } 2\text{--}5]_{t=0}$ are shown in Fig. 4

is shown in Fig. 5b, as an example. The simulation of the decay curve of α -Toc· at $\lambda_{\text{max}} = 423 \text{ nm}$ in toluene was performed by varying the value of k_p . The calculated curves obtained by assuming various values for the rate constant k_p are also included in Fig. 5b. The good agreement between the observed and simulation curves was obtained for the four kinds of concentrations of **4** ([LH **4**] = 1.81×10^{-2} , 3.61×10^{-2} , 5.42×10^{-2} , and $9.03 \times 10^{-2} \text{ M}$) at $t = 0\text{--}15 \text{ s}$, when we used the values of k_p ($=1.82 \times 10^{-1}$, 2.03×10^{-1} , 1.98×10^{-1} , $1.84 \times 10^{-1} \text{ M}^{-1} \text{ s}^{-1}$), respectively. The four k_p values obtained and the average value ($k_p^{\text{av}} = 1.92 \times 10^{-1} \text{ M}^{-1} \text{ s}^{-1}$) of k_p are listed in Table 1. Experimental errors are estimated to be less than 10%.

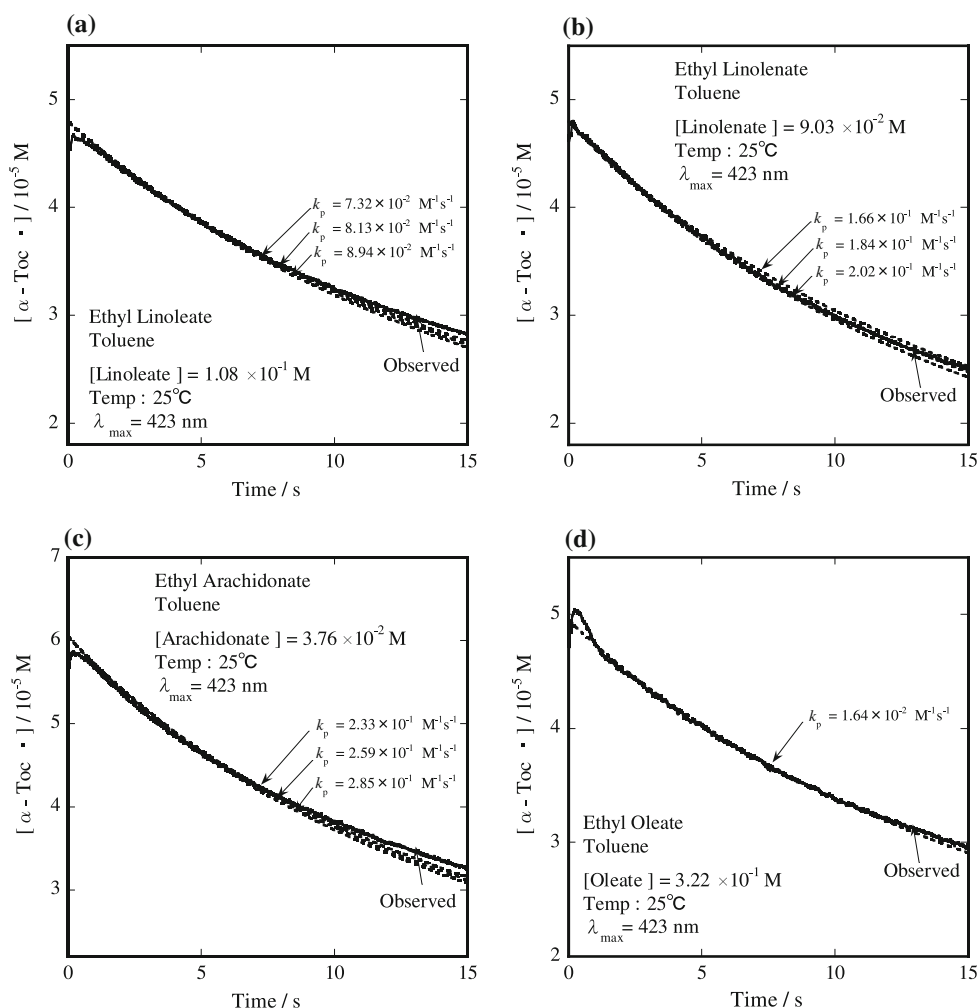

Similar analyses were performed for **2**, **3** and **5**, using the values of $2k_d$ ($=8.00 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$), and ε ($=3,820 \text{ M}^{-1} \text{ cm}^{-1}$ at $\lambda_{\text{max}} = 423 \text{ nm}$). As shown in Fig. 5, the good agreement between the observed and simulation curves was obtained for the four kinds of concentrations of LH (see Table 1) at $t = 0\text{--}15 \text{ s}$. On the other hand, in the case of ethyl stearate **1** containing no double bond, we could not determine the rate constant, because the hydrogen-atom abstraction reaction between α -Toc· and ethyl stearate **1** is

very slow and negligible. The k_p and k_p^{av} values obtained are summarized in Table 1. The rate constants (k_p^{av}) of hydrogen atom abstraction from the five kinds of **1**–**5** by α -Toc· radical decreased in the order of ethyl arachidonate **5** > ethyl linolenate **4** > ethyl linoleate **3** > ethyl oleate **2** > ethyl stearate **1**.

Discussion

In a previous work, we measured the reaction rate constants (k_p) for the hydrogen abstraction reaction of fatty acid ethyl esters **1**–**5** by 5,7-Di-*i*Pr-Toc· radical, because this radical is stable and we can easily obtain correct second-order rate constants without considering the decay of the radical, using usual UV-Vis spectrophotometer [23]. The values are $\ll 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$ for **1**, $1.04 \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$ for **2**, $1.82 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **3**, $3.84 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **4**, and $4.83 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for **5** in benzene solution at 25.0 °C. In order to interpret the observed features of the rate constants, ab initio molecular orbital calculations of models for the fatty acid esters were carried out [23]. From the calculation results, it was shown that the observed

Fig. 5 Time dependence of the concentrations of α -Toc \cdot radical observed at $\lambda_{\max} = 423$ nm during reaction of α -Toc \cdot with (a) LH 3, (b) LH 4, (c) LH 5, and (d) LH 2 in toluene at 25.0 °C (solid line). The Dotted line is a simulation curve. The values of $[\text{LH } 2\text{--}5]_t=0$ are shown in Fig. 5

features of the rate constant can be explained in terms of the pseudo- π -conjugation between the --C=C-- double bond and the active hydrogen-carbon bond of $\text{--CH}_2\text{--}$ group bound with --C=C-- double bond ($\text{--C=C--CH}_2\text{--C=C--}$).

The k_p value for the reaction of linoleic acid with α -Toc \cdot radical in benzene was also determined by using UV-Vis spectrophotometer; the k_p value tentatively obtained is $\sim 5 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ [24]. The measurement of the k_p values for the reaction of fatty acid methyl esters with α -Toc \cdot was performed by Remorova and Roginskii, using a ESR technique [21]. The k_p values reported are $7.5 (\pm 0.6) \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for methyl linoleate, $8.2 (\pm 0.3) \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for methyl linolenate, and $< 3 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ for methyl oleate in benzene at 50 °C. The measurement of the k_p value for the reaction of methyl linoleate with α -Toc \cdot in ethanol at 37 °C was performed by Watanabe et al., using a stopped-flow ESR technique [22]. The k_p value ($2.7 (\pm 0.4) \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$) was determined by the simulation of the decay curve of α -Toc \cdot using Eq. (12). These values are summarized in Table 1. When ESR technique is used for the measurement, the estimation of the initial concentration of

α -Toc \cdot ($[\alpha\text{-Toc}\cdot]_t=0$) in Eq. (12) will be accompanied by a large experimental error, because α -Toc \cdot radical is unstable. In the present work, the concentration (that is, the value of ε_1) and decay rate ($2k_d$) of α -Toc \cdot in toluene were determined exactly, using a stopped-flow spectrophotometer and by the simulation of a kinetic model (see Fig. 3).

As listed in Table 1, the rate constants (k_p) in toluene decrease as the number of the double bond in fatty acid ethyl esters decreases in the order of $5 > 4 > 3 > 2 > 1$. The k_p values obtained for the reaction of 3, 4, and 5 with α -Toc \cdot radical in the present work are 4.6, 5.0, and 5.0 times as large as the corresponding those with 5,7-Di-*i*-Pr-Toc \cdot reported in a previous work, respectively. These ratios (4.6, 5.0, and 5.0) are similar to each other, suggesting that the values obtained by a simulation of the decay curve of α -Toc \cdot are correct ones. This substitution effect is likely due to the steric hindrance by the substituent groups at the 5- and 7-positions of the tocopheroxyl radical [24]. The bulkier the substituent groups at the 5- and 7-positions, the smaller the rate constant of the hydrogen abstraction. The reaction rate for 1 without --C=C-- double bond

(without π -electron system) is negligibly small for both the radicals (α -Toc \cdot and 5,7-Di-*i*Pr-Toc \cdot). On the other hand, the k_p value of **2** for α -Toc \cdot is still 1/4.4 of that of **3**, although the k_p value of **2** for 5,7-Di-*i*Pr-Toc \cdot is by about three orders of magnitude smaller than that of **3**. Recently, we measured the second-order rate constants (k_s) for the reaction of **2** and **3** with ArO \cdot in toluene solution, in order to compare with those for carotenoids. The k_p value ($2.86 \times 10^{-4} M^{-1} s^{-1}$) of **2** for ArO \cdot is also still 1/4.4 of that ($1.25 \times 10^{-3} M^{-1} s^{-1}$) of **3**. The reason is not clear at present why the ratio of the rate constants for **2** and **3** changes drastically, depending on the kinds of free radicals.

By comparing the k_p values obtained for ethyl oleate **2** and ethyl linoleate **3**, it was found that the k_p value ($1.90 \times 10^{-2} M^{-1} s^{-1}$) of the former is 1/4.4 of that ($8.33 \times 10^{-2} M^{-1} s^{-1}$) of the latter, as described above. The ethyl oleate **2** has four $-CH_2-$ hydrogen atoms activated by a single π -electron system ($-CH_2-C=C-CH_2-$). Therefore, the rate constant, k_{abstr}/H , given on an available hydrogen basis, are $k_p/4 = 4.75 \times 10^{-3} M^{-1} s^{-1}$ for **2**. On the other hand, the ethyl linoleate **3** has two $-CH_2-$ hydrogen atoms activated by two π -electron systems ($-C=C-CH_2-C=C-$).

Consequently, these two hydrogen atoms will contribute to the high reactivity of ethyl linoleate **3** [23]. In fact, the polyunsaturated fatty acid esters **3**, **4**, and **5** show the same order of reactivity with α -Toc \cdot (k_{abstr}/H), as listed in Table 1. These fatty acid esters **3**, **4**, and **5** have two, four, and six hydrogen atoms activated by two π -electron systems, respectively, and thus the rate constants, k_{abstr}/H , given on an available hydrogen basis, are $k_p/2 = 4.16 \times 10^{-2} M^{-1} s^{-1}$ for **3**, $k_p/4 = 4.79 \times 10^{-2} M^{-1} s^{-1}$ for **4**, $k_p/6 = 4.05 \times 10^{-2} M^{-1} s^{-1}$ for **5**, if we neglect the contribution from the oleate-type four $-CH_2-$ hydrogen atoms activated by a single π -electron system in **3**, **4**, and **5**. These values are similar to each other, and by one order of magnitude larger than that ($4.75 \times 10^{-3} M^{-1} s^{-1}$) of ethyl oleate **2**. Since ethyl stearate **1**, which does not contain allylic hydrogens, negligibly react with α -Toc \cdot radical, we estimated that k_p of ethyl stearate **1** will be $\lesssim 1 \times 10^{-2} M^{-1} s^{-1}$. The results suggest that α -Toc \cdot radicals produced in edible oils and biomembranes mainly react with polyunsaturated lipids by abstracting hydrogen atoms activated by two π -electron systems, and induce the peroxidation of lipids.

As described in Introduction, the rate constant (k_4) for the reaction of methyl linoleate hydroperoxide (LOOH)

with α -Toc \cdot radical (reaction 4), i.e., the reverse of reaction 1 was reported [12]. The k_4 value was $5.0 \times 10^{-1} \text{ M}^{-1} \text{ s}^{-1}$ in benzene at 25.0 °C. On the other hand, the k_p values obtained for the reaction of LH 3, 4, and 5 with α -Toc \cdot radical are 0.833×10^{-1} , 1.92×10^{-1} , and $2.43 \times 10^{-1} \text{ M}^{-1} \text{ s}^{-1}$ in toluene at 25.0 °C, respectively, as listed in Table 1. The value of k_4 is 6.0, 2.6, and 2.1 times larger than those of k_p for 3, 4, and 5, respectively. However, the concentration of LOOH is much lower than that of LH in the initial stage of LH peroxidation. Consequently, the contribution of the reaction 4 is considered to be small and negligible. The initial prooxidant effect of α -TocH is induced by the hydrogen abstraction from LH by α -Toc \cdot (reaction 3). When the autoxidation proceeds and the concentration of LOOH increases, reaction 4 will contribute to the prooxidant effect of α -TocH.

It is well known that α -TocH is the major endogenous lipid-soluble antioxidant in human plasma [27], low-density lipoprotein (LDL) [24, 28] and edible oils, and acts as an antioxidant by protecting polyunsaturated fatty acids and lipids from peroxidation. However, for instance, if “antioxidant” α -TocH in high concentrations exists in edible oils, lipid peroxidations are accelerated, and further, the rate of lipid peroxidation increases by increasing the concentration of α -TocH [7, 8, 10]. Similarly, α -TocH acts as a prooxidant to oxidize polyunsaturated lipids in LDL in the absence of other endogenous antioxidants such as vitamin C and ubiquinol-10, as reported by Bowry et al. [9, 29]. They proposed that this prooxidant activity of α -TocH is caused by reaction of the α -Toc \cdot with active LH groups in LDL. It has been reported that, not only vitamin C and ubiquinol-10, but also many polyphenols (such as flavonoids [30], catechins [31], and caffeic acids [32]) function as antioxidants by regenerating α -Toc \cdot to α -TocH in LDL system. Similar tocopherol-mediated peroxidation and α -tocopherol regeneration reactions might take place in other biological systems.

The rate constants (k_r) for the regeneration reaction 5 from α -Toc \cdot to α -TocH have been reported for many natural antioxidants. For instance, the values are $2.73 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for vitamin C (sodium ascorbate) in ethanol:water (=5:1, v/v) solution [17], $3.74 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ for ubiquinol-10 in benzene [15], and $2.39 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ for epigallocatechin gallate (EGCG) in ethanol:water (=5:1, v/v) solution [33]. These values are ca. 10^5 – 10^7 times larger than those ($k_p = 8.33 \times 10^{-2}$ – $2.43 \times 10^{-1} \text{ M}^{-1} \text{ s}^{-1}$) for 3, 4, and 5 in toluene. The k_r value for caffeic acid is $2.31 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$ in ethanol [33], and by two to four orders of magnitude smaller than those for vitamin C, ubiquinol-10, and EGCG. However, it is by three orders of magnitude larger than those (k_p) for 3, 4, and 5. The results suggest that these antioxidants may contribute to the prevention of the prooxidant effect of α -TocH in many biological systems.

Summary

The hydrogen abstraction reaction of α -Toc \cdot radical from lipids is considered to be a key reaction for the prooxidant effect of α -TocH. However, a detailed kinetic study for the reaction between α -Toc \cdot radical and lipids (unsaturated fatty acids) (reaction 3) has not been performed so far, because α -Toc \cdot radical is unstable, showing the large self-bimolecular reaction rate constant ($2k_d = 8.00 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$) (reaction 6). In the present work, we have succeeded in determining the second-order rate constants (k_p) for the reaction of five kinds of saturated and unsaturated fatty acid ethyl esters (ethyl stearate 1, ethyl oleate 2, ethyl linoleate 3, ethyl linolenate 4, ethyl arachidonate 5) with α -Toc \cdot radical (reaction 3), using a double-mixing stopped-flow spectrophotometer. The k_p values obtained are $< \sim 1 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for 1, 1.90×10^{-2} for 2, 8.33×10^{-2} for 3, 1.92×10^{-1} for 4, and 2.39×10^{-1} for 5 in toluene, indicating that the rate constants decrease as the number of the double bond in fatty acid ethyl esters decreases in the order of $5 > 4 > 3 > 2 > 1$. The rate constants (k_p) for 2–5 were compared with the rate constants for the regeneration reaction (k_r) of α -Toc \cdot radical to α -TocH by natural antioxidants (such as vitamin C, ubiquinol-10, polyphenols), suggesting that the prooxidant effect of α -tocopherol may be prevented by these antioxidants.

Abstract The wild type (Wt) and mutant form of yeast (sphingolipid compensation) genes, *SLC1* and *SLC1-1*, have been shown to have lysophosphatidic acid acyltransferase (LPAT) activities (Nageic et al. in *J Biol Chem* 269:22156–22163, 1993). Expression of these LPAT genes was reported to increase oil content in transgenic *Arabidopsis* and *Brassica napus*. It is of interest to determine if the TAG content increase would also be seen in soybeans. Therefore, the wild type *SLC1* was expressed in soybean somatic embryos under the control of seed specific phaseolin promoter. Some transgenic somatic embryos and in both T2 and T3 transgenic seeds showed higher oil contents. Compared to controls, the average increase in triglyceride values went up by 1.5% in transgenic somatic embryos. A maximum of 3.2% increase in seed oil content was observed in a T3 line. Expression of the yeast Wt LPAT gene did not alter the fatty acid composition of the seed oil.

Introduction

Different plant species vary greatly in seed storage reserves with some grain seeds having >85% starch, while 50–70% oil in oil seeds, and legumes such as soybeans with 40% protein and 20% oil of the seed dry weight [2]. Soybeans are the largest oil seed crop in the world followed by Brassica, peanut, sunflower and cotton seeds [3, 4]. There is a significant amount of vegetable oil that is used for industrial purposes. For example, of the ~380 million tons of oilseeds produced in 2005, about 85% of the extracted oil is used for food and cooking applications, while nearly 15% is put to use in industry for, among others, lubricants, inks, coatings, plasticizers and biodiesel [5]. Since oil production has such tremendous importance, conventional and genetic engineering strategies are being applied to improve oil quantity and quality in oil seed crops [6].

The Kennedy pathway is the major TAG pathway of plants [7, 8] with the three acyltransferases the glycerol-3-phosphate acyltransferase (GPAT, EC 2.3.1.15), the lyso-phosphatidic acid acyltransferase (LPAT, EC 2.3.1.51) and the diacylglycerol acyltransferase (DGAT, EC 2.3.1.20) operating in a sequential manner. The other enzymes that directly participate in the DAG to TAG conversion are DAG transacylase and phospholipid-DAGAT [9]. Over-expression of Kennedy pathway enzymes, GPAT [10]; yeast LPAT [11, 12]; DAGAT [13, 14] have reportedly

increased oil content in plants and yeast. Maize high oil QTL (Qho6) encodes a mutated DAGAT1-2 allele [15]. Besides the Kennedy pathway, other pathway enzymes like glucose metabolism enzymes like glycerol-3-phosphate dehydrogenase (GPDH, EC 1.1.1.8) [16] and Dof-type transcription factors [17] were also implicated in the seed oil increase. *Arabidopsis* transcriptional factor FUSCA3 (FUS3) was implicated in the increased oil content in *Arabidopsis* seeds [18].

Saccharomyces cerevisiae sphingolipid suppressor gene, *SLC1-1* and the wild type *SLC1* gene proved to be acyltransferases with LPAT activity [1, 11]. Transforming plants with wild type (*SLC1*) and mutated (*SLC1-1*) forms of yeast genes resulted in increased triglyceride levels [11, 12, 19]. So far there are no reports on soybean seed oil enhancement except the high oil cultivar N88–480 developed by [20] through conventional breeding though several strategies were successfully reported for seed oil increase in plants [10, 14–16, 21]. Soybean seed expressing a diacylglycerol acyltransferase 2A from the soil fungus *Umbelopsis* (formerly *Mortierella*) *ramanniana* showed a 1.5% increase in oil levels [22].

An important method of soybean regeneration is somatic embryogenesis. Embryogenic tissues can be proliferated by subculture on a solid proliferation (MSD20) medium or a liquid suspension culture medium [23, 24]. Through somatic embryogenesis, genetic engineering of soybean has proved to be a powerful technique for improving seed compositions including the oil for enhanced edible and industrial purposes [25–27]. Furthermore, somatic embryo proliferation can result in a higher number of somatic embryos [24] thus probably increasing the rate of recovery. Another potential advantage of the somatic embryos system is that they are good targets in many cases of seed specific traits since they can be analyzed at the mature soybean somatic embryo stage prior to the zygotic embryonic stage, thus saving labor and time [28–33].

Here in this paper we report the generation of transgenic soybean somatic embryos (SS embryos) expressing the yeast *SLC1* gene with increased total lipids. We also report the generation of fertile transgenic soybean plants with seeds showing increased oil content.

Materials and Methods

Plant Material

Soybeans [*Glycine max* (L.) Merrill cv. ‘Jack’] were grown in a greenhouse at the University of Kentucky, Lexington under a 16 h photoperiod at 35 °C day and 25 °C night temperature. Pods with immature seeds were surface sterilized by immersing for 30 s in 70% 2-isopropyl alcohol

followed by a 10 min immersion in 25% bleach solution (with 1.5% final hypochlorite concentration) with a few drops of Liquinox (detergent). The pods were then rinsed three times in sterile water for 5 min each time. Immature seeds 3–6 mm in length were removed from the pods. The end containing the embryonic axis was cut off and discarded. Then the two cotyledons were pushed out from the seed coat, separated and placed with abaxial side (round side) down on MSD40 (Murashige and Skoog salts, 40 mg/l 2,4-dichlorophenoxyacetic acid, B5 vitamins, sucrose (3% wt/vol) with 0.2% gelrite) medium [34]. Cultures were then incubated at 25 °C at a 23 h photoperiod (low light intensity, 5–10 μE). Globular staged somatic embryo clusters were harvested from the explant tissues 4–6 weeks after induction and then placed on MSD20 (MS salts, B5 vitamins, sucrose (3% wt/vol), 20 mg/l 2,4-D with 0.2% gelrite) solid medium for a period of 1 month for proliferation. Embryogenic tissues were then transferred from MSD20 to FNL (Finer and Nagasawa “lite”) “liquid medium” [24] for further proliferation. Suspension cultures were agitated at 100 rpm and maintained with a 2 week subculture period at 25 °C with a 23 h photoperiod. The T1 and T2 generation transgenic plants were grown in the green house under the same conditions as described above for the Jack control plants.

Vector Construction

The amplified *SLC1* gene product was cloned into the PGEM T-vector. The product was sequenced using T7 and SP6 vector sequencing primers to confirm the sequence of the ligated product. A 0.9-kbp *NcoI/HpaI* T-Vector digested *SLC1* fragment was cloned into a pPHI472 vector [29] digested with the same enzymes to put the *SLC1* gene under the seed specific phaseolin promoter and phaseolin terminator. The whole cassette was digested with *EcoRI/PstI* and ligated to a pCAMBIA 1201 (Genbank accession number AF234293) plant transformation vector digested with the same restriction enzymes. The pCAMBIA 1201 binary vector has a chloramphenicol resistance gene for bacterial selection and a hygromycin resistance gene for plant selection. The GUS reporter gene was driven by the constitutive CaMV 35S promoter.

Microprojectile Bombardment

Green embryo clumps were slightly pressed with a spatula to partially separate them and were placed in the center of a moist filter paper in sterile petri plates (approximately 100–150 mg of somatic embryos per plate) and partially desiccated in a laminar flow hood for 15 min prior to bombardment. Transformation was carried out via particle bombardment with a gene gun (Dupont PDS1000; Bio-Rad Laboratories, Hercules, and CA) by gold/DNA

microprojectile preparations as described by [34]. Briefly, for 9 shots, 25 µg of plasmid DNA was used to coat 7.5 mg of 0.6 µm gold particles. Cultures were bombarded at 10,687 kPa (1,550 psi) helium gas pressure under 91 kPa (27 in) of Hg vacuum, at a shooting distance of 11 cm from the rupture disk to the target tissue. Immediately after bombardment, embryogenic cultures were placed on D20 proliferation media without any selective agent for 7 days.

Selection and Regeneration of Transformants

Bombarded globular SS embryos that were cultured on D20 were transferred (approximately 100 clumps of 0.3–0.4 cm diameter per plate) to FN Lite medium Samoylov et al. [35] containing 25 mg/l hygromycin. After 3–4 weeks, visibly growing clumps were moved to fresh selection medium. After approximately 12 weeks, green looking hygromycin resistant SS embryo clumps were transferred from FN Lite into 500-ml Erlenmeyer flasks containing 100 ml of liquid MS0 (MS salts, B5 vitamins and 3% sucrose) medium as described by Samoylov et al. [24]. Prior to transfer into flasks, each embryogenic cluster was gently pressed with a spatula to partially separate the individual globular-stage embryos. At 4 weeks, the resulting cotyledon-stage embryos were analyzed for GUS staining (β -glucuronidase) and RNA isolation. Some of the embryos were desiccated as described in [24]. Ten to twelve matured embryos were placed in a 100 × 15 mm Petri dish and sealed with Nescofilm. To allow gradual desiccation of embryos over a period of 5–7 days, a small piece (approximately 1 cm³) of solid MS0 medium (MSO medium with 0.2% Gelrite) was placed in the middle of the plate away from the embryos. Desiccated embryos were germinated on 1/5th MS medium (1/5th concentration of MS salts, B5 vitamins, 0.4% Gelrite without sucrose).

Yeast DNA Isolation and *SLC1* Gene Amplification

A pellet from a 10-ml culture of Yeast strain *InVsc1* (Invitrogen, Carlsbad, CA) was homogenized with mortar and pestle. Total DNA was isolated from the homogenized yeast following the procedure described by [36]. The *SLC1* gene [1] was directly amplified from yeast genomic DNA since no introns sequences were found. With 100 ng of yeast genomic DNA as template, PCR was done to amplify the *SLC1* gene using the primers 5'-CCATGGATGAGTG TGATAGGTAGGTTTC-3' and 5'-GTTAACAATGCATCT TTTTACAGATGA-3' for the sense and antisense strand, respectively. *NcoI* restriction site was added to the forward primer while the reverse primer was designed with a *HpaI* site. The PCR conditions were 94 °C for 2 min; 30 cycles at 94 °C, 30 s; 55 °C, 30 s; 72 °C, 1 min and a final extension at 72 °C for 8 min.

Plant DNA Isolation

Genomic DNA was isolated from soybean leaves and embryos as described by Reddy et al. [36]. Screening of transgenic soybean lines was done by PCR of the *SLC1* gene using 200 ng of the genomic DNA in 50-µl reactions. The primers and the PCR conditions for *SLC1* gene amplification were as described above.

Southern Blotting

Five micrograms of DNA was digested overnight with *EcoRI*, fractionated on a 0.8% agarose gel, and blotted onto a Zetaprobe membrane (Bio-Rad). Hybridization was done overnight at 42 °C in a hybridization solution containing 50% formamide, 0.12 M Na₂HPO₄, 0.25 M NaCl, and 1 mM EDTA with a *SLC1* gene-specific fragment random prime labeled with [α ³²P]-dCTP (Prime-It II Random Primer Labeling Kit; Stratagene, La Jolla, CA) as a probe. The membrane was washed three times at room temperature in 0.1 × SSC (1 × SSC is 0.15 M NaCl plus 0.015 M sodium citrate) and 0.1% SDS and exposed in a phosphorImager cassette (Molecular Dynamics, Sunnyvale, CA). The intensity of hybridized DNA bands was estimated using the ImageQuant software program (Molecular Dynamics).

RT-PCR

Total RNA was extracted from the hygromycin resistant matured soybean somatic embryos using the Trizol reagent as advised by the manufacturer (Invitrogen Corporation, Carlsbad, USA). Using the isolated total RNA as a template, reverse transcription was performed for the synthesis of the first-strand cDNA using oligo dT as prescribed by manufacturers of the Kit (Sigma-Aldrich Corporation, St. Louis, MO, USA) in a 20-µl reaction at 48 °C for 45 min. A 2-µl aliquot of the RT reaction was used in a 50-µl PCR reaction with the following profile: 94 °C for 2 min; 30 cycles at 94 °C, 30 s; 55 °C, 30 s; 72 °C, 1 min and a final extension at 72 °C for 8 min. The primers used were the same as in the PCR reaction described for *SLC1* gene amplification.

Lipid Analysis

Lipids were isolated as described in [37]. Total lipids were extracted independently from seed chips (~2 mg) cut from ten different matured seeds for each line. For fatty acid analysis of matured somatic embryos ten individual 5 week old (matured on 6% maltose containing MS medium plates) somatic embryos of a clone were used. The somatic embryos were desiccated before lyophilization. To allow

gradual desiccation of embryos over a period of 5 days a small piece (approximately 1 cm³) of solid MS0 medium was placed in the middle of the plate away from the embryos. The desiccated embryos were freeze dried and weighed. TAG (triacylglycerol) contents were calculated from the addition of known amounts of tri -17:0 (1,2,3-Triheptadecanoylglycerol, Sigma-Aldrich Corporation, St. Louis, MO, USA) internal standard added to the somatic embryos and seed chips before lipids were extracted. The lipids were methylated with 0.5 ml of sodium methoxide (4.2%, wt/vol) with shaking at 800 rpm for 45 min. The fatty acid methyl esters were extracted with 1 ml of hexane twice. The hexane extracts were combined and then washed with 1 ml of 0.9% KCl. The fatty acid methyl esters in hexane were analyzed by gas chromatography (Hewlett Packard 5890 with a flame ionization detector) on FFAP column of 14 m × 0.25 mm, 0.33 μm film thickness. The temperature program started from 140 °C for 1 min, then increased to 235 °C at a rate of 10 °C/min and held at this temperature for 20 min.

Additionally oil and protein content of the zygotic seeds were analyzed using a near infrared (NIR) analyzer as described by [38]. NIR analyses were performed in triplicate compared to the known oil and protein content of control soybean cultivar Jack [39] and high oil seeds, N88–480 [20].

Results

PCR, GUS staining and Southern blot hybridization techniques were used to identify the transgenic nature of the embryos and plants obtained by hygromycin selection. Thirteen transgenic lines were PCR positive for the introduced *SLC1* gene [S1 (supplementary SFig. 1)] when analyzed at the embryo stage. Only nine of those lines were further regenerated. The expected fragment size of 0.9 kbp was amplified in the transgenic samples but not in the negative control embryos. As a positive control, a *SLC1* expression cassette containing pCAMBIA 1201 vector DNA was used. Genomic DNA from empty pCAMBIA 1201 vector transformed embryos and the untransformed Jack embryos were used as negative controls. A strong PCR band was observed in the positive controls. No *SLC1* amplification was seen in the negative controls.

Southern blot hybridization was done for the first five independent transgenic lines (SFig. 1) for the presence of the *SLC1* gene. Southern blot hybridization (Fig. 1) analysis of these transgenic plants indicated the integration of the *SLC1* gene into the soybean genome. As expected, Southern blot hybridization bands from the transgenic plants were much larger than the size of the *SLC1* fragment. Southern blot analysis also revealed that the

Fig. 1 Southern blot hybridization of yeast *LPAT* (*SLC1*) transgenic plants. Each lane represents a different transgenic line. Genomic DNA was digested with *EcoRI*. Since the yeast *SLC1* gene has no internal *EcoRI* restriction sites total DNA was digested with *EcoRI* restriction enzyme. As a positive control the PCR amplified 0.9 kb *SLC1* fragment was used. Lane 1 has two hybridization bands while other transgenic lines have single copy insertions of the transgene. The bands representing the *SLC1* transgenic lines are larger in size than the positive control. Molecular weights are given on the sides. Letters “P” and “C” represents positive and negative controls. “E” indicates an empty lane

introduced gene copy number varied from one to two. Four of the five transgenic plants analyzed have varying sized single insertions of the introduced *SLC1* cassette. A single transgenic plant (Plant 1) had two copies of the introduced gene. All the transgenic plants regenerated grew normal and set flowers and pods (SFig. 2). Except plant 3 all other southern positive plants are turned out to be GUS positive (SFig. 3). GUS expression among different transgenics lines varied with the blue GUS stain was visible in the leaves and flowers of some lines while it was visible only in the flowers in others (SFig. 3). The reasons for such variation are not clear since the GUS gene was expressed under a constitutive CaMV 35S promoter. GUS staining was also visible in the cotyledons and in the axis of matured somatic embryos (SFig. 4).

Total lipid content was analyzed in matured *SLC1* transgenic and vector control transformed soybean somatic embryos (Fig. 3). On average the total lipid content of the *SLC1* transgenic embryos was found to be 1.5% higher than the transgenic vector controls and Jack control embryos. In addition to GUS analysis (SFig. 4) RT-PCR was done to determine the expression of the introduced *SLC1* gene in matured somatic embryos (SFig. 5). Transgenic plant line 8 was established from the somatic

Table 1 Percentage oil content in T2 seeds of transgenic plants

Plant line	% oil
Control	20.7 ± 0.5
1	21.0 ± 1.8
2	22.7 ± 1.3
3	23.3 ± 0.9
4	22.4 ± 0.9
5	23.2 ± 1.5
6	21.6 ± 0.8
7	21.3 ± 0.9
8	21.8 ± 2.2
9	18.8 ± 1.7

embryos analyzed for total lipid content. As shown in Table 1 the seeds of transgenic line 8 also had a similar increase in total lipid content.

The total seed lipid content was analyzed from the seeds of greenhouse grown T1 and T2 plants. PCR was done to identify the presence of the *SLC1* gene in the T2 generation transgenic plants. The TAG content of vector transformed Jack control seeds was ~20% on a dry weight basis (Table 1) while some of the T2 transgenic seeds had increased total lipid contents that varied from 0.6 to 2.5% (Table 1). The average total lipid content of T2 generation *SLC1* transgenic line 9 were found to be lower than the vector-transformed Jack controls while transgenic line 1 had similar values (Table 1). TAG analysis of T3 seeds have shown that lines 1–11, 3–4, 3–9 and 6–20 have oil content increases of 1.6–3.2% compared to the vector control (Fig. 2). The T3 seeds of plants 1–11, 3–4, 3–9 and 6–20 represents the progeny of T1 transgenic lines 1, 3, and 6, respectively. The high oil cultivar N88–480 [20] showed TAG content of 22.5% by seed dry weight and the untransformed Jack plant 20.2%. The increase in lipid

content of these *SLC1* transgenics was accompanied by a decrease in protein content (Fig. 2).

Discussion

Some *Brassica* and *Arabidopsis* seeds that expressed the *SLC1* and its mutant form, *SLC1-1* genes with LPAT activity in yeast [1, 11, 19] showed increased oil levels. The present investigation examined the impact of the wild type *SLC1* gene on total fatty acid levels in soybean somatic embryos and seeds. Some transgenic soybeans thus developed showed high oil in the T2 and T3 seeds. The initial aim behind transforming *Brassica* with yeast *SLC1-1* gene was to increase erucic acid content though the transgenics also showed higher oil content [11]. As explained by Zou et al. [11] for *Brassica* and *Arabidopsis*, endogenous LPAT regulation might be one of the controlling steps in the TAG accumulation in soybeans also. Yeast LPAT with no significant homology to plant LPATs is likely not recognized by regulatory systems in plants thus creating a sink towards TAG accumulation in soybean seeds. Currently, there are at least 53 QTLs (quantitative trait loci) associated with oil content in different soybean cultivars, however, most of the QTLs are not confirmed [40]. As the accumulation of different storage components needs the coordination of several genes that encode the enzymes of the respective pathways [2] it will be interesting to know if any of the high oil QTLs encode for LPATs or for that matter any of the three Kennedy pathway acyltransferases. Besides yeast LPAT, safflower GPAT (glycerol-3-phosphate acyltransferase,) [10], *Mortierella* GPAT [41] and DGAT (Diacylglycerol acyltransferase) from *Arabidopsis* [21] have been reported to increase oil content in plants and yeast. A maize high oil QTL (Qho6) was recently analyzed [15] and known to encode DGAT.

Although larger seed sizes and ~40% increase in seed oil content have been reported for *Brassica* and *Arabidopsis* that expressed the yeast *SLC1* gene [11, 19] no such dramatic results were noticed in the case of soybean seeds by us. The highest increases observed were similar in values reported for high oil line N88–480 [20]. Maybe the smaller increase in seed oil might be a reason for regular seed sizes in case of *SLC1* transgenic soybean. To date the only soybean gene reported to have increased seed oil content when over-expressed are the two Dof-type transcription factor genes *GmDof4* and *GmDof11* [17]. When over-expressed in *Arabidopsis* these genes increased oil content. Over-expression of these genes activated the acetyl CoA carboxylase (ACC, EC 3.1.3.44) and long-chain-acyl CoA synthetase (ACS, EC 6.2.1.3). So one of the 58 reported QTLs of soybean oil enhancement might include these transcription factors also.

Fig. 2 Mean percentages oil and protein ± standard errors (SE) in T3 seed of some of the high oil transgenic plant lines, vector controls and high oil line N88–480 (*Hi*). Compared to the vector controls all the other lines had higher oil and lower protein levels. Line 3–9 showed the highest oil content

There is typically a negative correlation between protein and oil concentration in soybean seed [42]. Wilcox [43] showed that increased protein amounts led to a decrease in oil content in soybeans. Interestingly the two soybean transcription factors *GmDof4* and *GmDof11* that elevated the activity of lipid biosynthesis enzymes also down regulated the seed storage protein gene *CRA1* in *Arabidopsis* [17]. In the case of *SLC1* transgenics also we have noticed that an increase in oil content was associated with reduced protein amounts (Fig. 2). Our results also indicate that the oil increase in soybean seeds expressing this yeast gene with LPAT activity was at the expense of protein content [44].

Somatic embryos mimic zygotic embryos in developmental and physiological aspects [45, 46]. Confirming the expected transgenic trait at the somatic embryo stage itself saves time and effort in soybean transgenic research. If a desired trait is observed in somatic embryos different clones can be screened for better producers of the end product and further taken to germination. Transgenic soybean somatic embryos were screened for fatty acid modification traits. Liu et al. [29] were the first to show palmitoleic acid in the soybean somatic embryos by over-expressing a mammalian Δ^9 desaturase (SCD, EC 1.14.19.1). Cahoon et al. [32] produced vernolic acid and 12-epoxy-octadeca-9,15-dienoic acid; Δ^5 -eicosenoic acid and Δ^5 -hexadecenoic acid [31]; α -eleostearic acid and α -parinaric acids [30] in soybean somatic embryos by over-expressing the transgenes responsible for the synthesis of these compounds. As mentioned in the introduction several embryos can be generated and proliferated from a single clone of transgenic embryo. On an average when 10 embryo clones were analyzed the *SLC1* expressing embryo line has 1.5% increase in oil content compared to the vector control and untransformed Jack embryos (Fig. 3). In the T2 seeds of the transgenic line 8 produced from these embryos the TAG content increase was found to be similar

Fig. 3 Total lipid content of freeze dried *SLC1* transgenic soybean somatic embryos, Jack control and vector control embryos. The data represents three independent experiments. The bars represent standard errors

(Table 1). Besides the hygromycin resistance we have confirmed the transgenic status of the embryo line by RT-PCR by amplifying the introduced the *SLC1* gene and GUS analysis. This is the report on the total fatty acid content of transgenic somatic embryos being correlated with an increase in oil content of transgenic soybean seeds.

In conclusion, expression of the yeast *SLC1* gene that codes for a yeast lyso-phosphatidic acid acyltransferase led to an increase in soybean seed oil content. The increase in seed oil was accompanied by a reduction in seed protein content.

Analysis of soybean somatic embryos over-expressing the yeast *SLC1* gene led to an increase in total fatty acid content. Soybean somatic embryos can be used for analyzing quantitative changes in oil content before germinating and growing plants thus saving time and effort.

Abstract The first total syntheses of the naturally occurring acetylenic fatty acids—6-heptadecynoic acid (59% overall yield) and 6-icosynoic acid (34% overall yield)—was accomplished in four steps. Using the same synthetic sequence the naturally occurring fatty acids (6*Z*)-heptadecenoic acid (46% overall yield) and (6*Z*)-icosenoic acid (27% overall yield) were also synthesized. The Δ^6 acetylenic fatty acids displayed good antiprotozoal activity towards *Leishmania donovani* promastigotes (EC_{50} = 1–6 $\mu\text{g/mL}$), but the 6-icosynoic acid was the most effective in the series. In addition, the (6*Z*)-icosenoic acid was a much better antiprotozoal compound (EC_{50} = 5–6 $\mu\text{g/mL}$) than the (6*Z*)-heptadecenoic acid (EC_{50} > 25 $\mu\text{g/mL}$). The saturated fatty acids *n*-heptadecanoic acid and *n*-eicosanoic acid were not effective towards *L. donovani*, indicating that the Δ^6 unsaturation in these fatty acids is necessary for leishmanicidal activity. In addition, both the 6-icosynoic acid and the (6*Z*)-icosenoic acid were inhibitors of the *Leishmania* DNA topoisomerase IB enzyme (EC_{50} 's = 36–49 μM), a possible intracellular target for these compounds. This is the first study assessing fatty acids as inhibitors of the *Leishmania* DNA topoisomerase IB enzyme.

Keywords Acetylenic fatty acids · Antiprotozoal activity · *Leishmania donovani* · Synthesis · Topoisomerase IB

Abbreviations

DNA	Deoxyribonucleic acid
EC_{50}	Effective concentration 50%
GC–MS	Gas chromatography–mass spectrometry
HRMS	High resolution mass spectrometry
IC_{50}	Inhibitory concentration 50%
IR	Infrared spectroscopy
LdTOPIB	<i>Leishmania</i> DNA topoisomerase IB
MIC	Minimum inhibitory concentration
NMR	Nuclear magnetic resonance
PDC	Pyridinium dichromate

Introduction

Many acetylenic fatty acids are natural plant constituents, but those with a C-6 triple bond, such as the 6-nonadecynoic acid, have displayed strong antifungal activity [1]. Recently, the novel 6-heptadecynoic acid (**1a**) and 6-icosynoic acid (**1b**) were isolated from the plant *Sommeria sabiceoides* [1]. While **1a** is a new natural product, **1b** has been known for sometime as a trace constituent of *Alvaradoa amorphoides* seed oil [2]. Neither of these two acetylenic fatty acids **1a** and **1b** have been explored for antiprotozoal activity nor their olefinic analogs (6*Z*)-heptadecenoic acid (**6a**) and (6*Z*)-icosenoic acid (**6b**), which are also natural products. The (6*Z*)-heptadecenoic acid (**6a**) was identified in the opisthobranch *Haminaea templadoi* as well as in a marine *Micrococcus* bacterium [3, 4], while **6b** is also a minor constituent of some seed oils [2].

Some fatty acids display antiprotozoal activity, in particular against *Leishmania donovani*, the causative agent of leishmaniasis [5]. Visceral leishmaniasis is a very serious

disease characterized by the invasion of spleen and liver macrophages, anaemia, fever and ultimately death if not diagnosed in time and left untreated. Visceral leishmaniasis is mostly found in India, Bangladesh, Indonesia [6] and Sudan [7] and in many cases is associated with an opportunistic infection in immunocompromised AIDS patients [8]. Pentavalent antimonials (meglumine antimoniate and sodium stibogluconate) have been used as first-line drugs despite the early reported resistances [9]. An emerging alternative to these compounds are the oral chemotherapy drugs, such as the alkylphosphocholine derivatives (miltefosine and edelfosine) and the antibiotic paromomycin [10, 11]. Miltefosine—originally developed as an anticancer drug—was confirmed as a major advance against visceral leishmaniasis since it was the first oral drug with high healing rates in phase IV studies, including pentavalent antimonials relapsing cases [12]. However, reproductive toxicity, its arbitrary use and its serious tendency to select resistant strains in the laboratory [13], suppose a high risk of emerging resistances during treatment with this drug, making it necessary to continue the search of new drugs for the treatment of this disease.

The toxicity of fatty acids towards *L. donovani* promastigotes is known, but it has not been thoroughly studied. Probably, the most representative work is that of Chaudhuri et al. [5] where the growth inhibition of a series of C₄–C₁₈ fatty acids towards *L. donovani* promastigotes was investigated. It was found that the longest fatty acids (up to 18 carbon atoms) were the most inhibitory and that unsaturated fatty acids were more toxic than their corresponding saturated analogs. For example, oleic acid displayed a MIC of 0.09 μmol/mL against *L. donovani* promastigotes, while octadecanoic acid resulted in a MIC of 0.18 μmol/mL [5]. *n*-Decanoic acid was less effective against *L. donovani* with a MIC of 1.39 μmol/mL. No conclusions regarding the inhibitory mechanism of these fatty acids could be drawn, but the Chaudhuri group found that growth inhibition was not due to leakage of metabolites from the protozoan cells or from the potential ability of these molecules to affect the surface tension of the growth medium. However, it was found that the studied fatty acids inhibited the uptake of glucose and leucine by *L. donovani*. An earlier work by Kuwahara et al. [14] reported that *n*-decanoic, *n*-dodecanoic, and *n*-hexadecanoic acids, at levels of 100 μg/mL, inhibited the motility of *L. donovani* promastigotes, but oleic acid had no effect.

The aim of the present study was to synthesize, for the first time, the naturally occurring 6-heptadecynoic acid (**1a**) and 6-icosynoic acid (**1b**), as well as the (6*Z*)-heptadecynoic acid (**6a**) and (6*Z*)-icosenoic acid (**6b**), and assess their antileishmanial activity against *L. donovani* promastigotes. The objective of the investigation was to determine, by keeping the chain length fixed, if a higher degree of

unsaturation favors a better antileishmanial activity. In addition, we also studied the inhibition of the Leishmania DNA topoisomerase IB enzyme by these fatty acids as a possible intracellular target.

Materials and Methods

General Experimental Procedures

¹H NMR (300 or 500 MHz) and ¹³C NMR (75 or 125 MHz) were either recorded on a Bruker DPX-300 or a Bruker DRX-500 spectrometer. ¹H-NMR chemical shifts are reported with respect to internal (CH₃)₄Si, ¹³C-NMR chemical shifts are reported in parts per million relative to CDCl₃ (77.0 ppm). GC/MS analyses were recorded at 70 eV using either a Hewlett Packard 5972A MS ChemStation or an Agilent 5975C MS ChemStation coupled to an Agilent 7890A GC where both instruments were equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) of polymethyl siloxane crosslinked with 5% phenyl methylpolysiloxane. IR spectra were recorded on a Nicolet Magna 750 FT-IR spectrophotometer (Thermo-Nicolet, Madison, WI, USA). High resolution mass spectral data was performed at the Emory University Mass Spectrometry Center on a thermo LTQ-FTMS using APCI as the probe.

5-Bromo-1-[(tetrahydropyran-2-yl)oxy]pentane (**2**)

To 5-bromo-1-pentanol (4.0 g, 23.9 mmol) in 20 mL of CHCl₃ was added dropwise 2,3-dihydro-2*H*-pyran (DHP) (4.4 mL, 47.9 mmol) and catalytic amounts of *p*-toluenesulfonic acid (*p*-TSA). The reaction mixture was stirred for 90 min at room temperature. The organic layer was washed with water (1 × 50 mL), NaHCO₃ (1 × 50 mL), water (1 × 75 mL) and dried over Na₂SO₄. The crude product was purified using silica gel column chromatography eluting with hexane:ether (9:1) affording 5.93 g of **2** as a colorless oil for a 99% yield.

General Procedure for the Acetylide Coupling Reaction

Into a 100 mL round-bottomed flask at 0 °C containing dry THF (5.0–7.0 mL) was added the terminal alkyne (6.0–7.2 mmol) followed by the dropwise addition of 2.5 M *n*-BuLi (12.0–14.4 mmol). The mixture was stirred at 0 °C for 80 min. The temperature was then lowered to –60 °C and HMPA (10.0–14.0 mL) was added followed by the addition of **2** (6.0–7.2 mmol). The mixture was stirred for 24 h and then washed with brine (2 × 15 mL), extracted with hexane (2 × 15 mL) and the organic phase dried over Na₂SO₄ and evaporated in vacuo affording **3a**

(1.47 g, 54% yield) or **3b** (1.60 g, 79% yield) after purification by Kugelrohr distillation at 170 °C/3 mm Hg.

2-(Heptadec-6-ynyloxy)-tetrahydro-2H-pyran (**3a**)

This was obtained as a pale yellow oil in a 79% yield from the reaction of 1-dodecyne (1.3 mL, 6.0 mmol) with *n*-BuLi in dry THF (5.0 mL) and **2** (1.510 g, 6.0 mmol) according to the general procedure described above; IR (neat) ν_{\max} : 2,923, 2,853, 1,455, 1,440, 1,351, 1,136, 1,120, 1,077 cm^{-1} ; ^1H NMR (CDCl_3 , 300 MHz) δ 4.56 (1H, m), 3.85–3.73 (2H, m), 3.48–3.37 (2H, m, H-1), 2.12 (4H, m), 1.69–1.35 (6H, m), 1.26 (22H, brs, $-\text{CH}_2-$), 0.87 (3H, t, $J = 6.8$ Hz, $-\text{CH}_3$); ^{13}C NMR (CDCl_3 , 75 MHz) δ 98.8, 80.4 (C-7), 79.9 (C-6), 67.5, 62.3, 31.9, 30.7, 29.6, 29.5, 29.3, 29.3, 29.2, 29.0, 28.9, 26.9, 25.5, 22.7, 19.6, 18.7, 18.7, 14.1; GC–MS (70 eV) m/z (relative intensity) 336 (M^+ , 4), 265 (3), 264 (3), 263 (12), 252 (2), 251 (2), 195 (5), 181 (6), 167 (4), 135 (2), 125 (2), 95 (17), 93 (11), 86 (6), 85 (100), 81 (17), 79 (19), 69 (9), 67 (25), 57 (14), 55 (25); HRMS calcd for $\text{C}_{22}\text{H}_{40}\text{O}$ [$M + \text{H}$] $^+$ 337.3101, found 337.3102.

2-(Icos-6-ynyloxy)-tetrahydro-2H-pyran (**3b**)

This was obtained as a pale yellow oil in a 54% yield from the reaction of 1-pentadecyne (1.9 mL, 7.2 mmol) with *n*-BuLi in dry THF (7.0 mL) and **2** (1.82 g, 7.2 mmol) according to the general procedure described above; IR (neat) ν_{\max} : 2,922, 2,853, 1,464, 1,351, 1,322, 1,136, 1,120, 1,077 cm^{-1} ; ^1H NMR (CDCl_3 , 300 MHz) δ 4.57 (1H, m), 3.91–3.68 (2H, m), 3.55–3.34 (2H, m, H-1), 2.14 (4H, m), 1.90–1.40 (6H, m), 1.25 (28H, brs, $-\text{CH}_2-$), 0.87 (3H, t, $J = 6.8$ Hz, $-\text{CH}_3$); ^{13}C NMR (CDCl_3 , 75 MHz) δ 98.8, 80.4 (C-7), 79.9 (C-6), 67.5, 62.3, 31.9, 30.7, 29.7, 29.7, 29.6, 29.5, 29.4, 29.3, 29.2, 29.0, 28.9, 26.9, 25.5, 22.7, 19.7, 18.7, 18.7, 14.1; GC–MS (70 eV) m/z (relative intensity) 378 (M^+ , 1), 305 (4), 293 (2), 195 (6), 125 (2), 101 (10), 97 (4), 95 (11), 93 (6), 86 (5), 85 (100), 83 (7), 67 (19), 57 (12), 55 (18); HRMS calcd for $\text{C}_{25}\text{H}_{46}\text{O}_2$ [$M + \text{H}$] $^+$ 379.3571, found 379.3573.

General Procedure for the Tetrahydropyranyl Deprotection

To a mixture of methanol (10 mL) and either **3a** or **3b** (0.91–1.46 g, 2.7–3.9 mmol) was added catalytic amounts of *p*-toluenesulfonic acid (*p*-TSA) and the reaction mixture was stirred at 60 °C for 24 h. After this time the solvent was evaporated and then the organic extract was washed with a saturated solution of sodium bicarbonate (3 \times 25 mL), dried over Na_2SO_4 , filtered, and evaporated in vacuo, affording 0.68–0.95 g (83–99% yield) of the

alkynols **4a** and **4b**. The products were deemed sufficiently pure so as to be used as such for the next steps without further purification.

6-Heptadecynol (**4a**)

This was obtained as a pale yellow oil in a 99% yield from the reaction of **3a** (0.91 g, 2.7 mmol) with catalytic amounts of *p*-TSA in methanol (10 mL) according to the general procedure described above; IR (neat) ν_{\max} : 3,355, 2,923, 2,853, 1,460, 1,377, 1,333, 1,119, 1,047, 1,010, 724 cm^{-1} ; ^1H NMR (CDCl_3 , 300 MHz) δ 3.63 (2H, t, $J = 6.5$ Hz, H-1), 2.13 (4H, m), 1.40–1.61 (6H, m), 1.24 (16H, brs, $-\text{CH}_2-$), 0.87 (3H, t, $J = 6.8$ Hz, $-\text{CH}_3$); ^{13}C NMR (CDCl_3 , 75 MHz) δ 80.5 (C-7), 79.8 (C-6), 62.9 (C-1), 32.3, 31.9, 29.7, 29.6, 29.6, 29.3, 29.2, 29.1, 28.9, 24.9, 22.7, 18.7, 18.7, 14.1; GC–MS (70 eV) m/z (relative intensity) 252 (M^+ , 1), 152 (2), 135 (5), 124 (6), 108 (30), 98 (45), 97 (32), 95 (37), 93 (62), 91 (22), 84 (22), 83 (37), 82 (100), 81 (62), 80 (62), 79 (85), 70 (36), 69 (38), 67 (91), 65 (13), 57 (31), 55 (86); HRMS calcd for $\text{C}_{17}\text{H}_{32}\text{O}$ [$M + \text{H}$] $^+$ 253.2526, found 253.2527.

6-Icosynol (**4b**)

This was obtained as a semi solid in a 83% yield from the reaction of **3b** (1.46 g, 3.9 mmol) with catalytic amounts of *p*-TSA in methanol (10 mL) according to the general procedure described above; IR (neat) ν_{\max} : 3,321, 2,922, 2,852, 1,461, 1,376, 1,350, 1,120, 1,055, 721 cm^{-1} ; ^1H NMR (CDCl_3 , 300 MHz) δ 3.63 (2H, t, $J = 6.5$ Hz, H-1), 2.12 (4H, m), 1.51 (4H, m), 1.24 (24H, brs, $-\text{CH}_2-$), 0.86 (3H, t, $J = 7.0$ Hz, $-\text{CH}_3$); ^{13}C NMR (CDCl_3 , 75 MHz) δ 80.5 (C-7), 79.8 (C-6), 62.9 (C-1), 32.3, 31.9, 29.6, 29.6, 29.4, 29.2, 28.9, 24.9, 22.7, 19.7, 18.7, 14.1; GC–MS (70 eV) m/z (relative intensity) 292 (M^+ , 1), 194 (2), 135 (9), 126 (5), 111 (26), 108 (47), 98 (60), 97 (39), 95 (43), 93 (74), 91 (27), 82 (100), 81 (67), 80 (69), 79 (95), 69 (37), 68 (33), 67 (96), 57 (43), 55 (98); HRMS calcd for $\text{C}_{20}\text{H}_{38}\text{O}$ [$M + \text{H}$] $^+$ 295.2995, found 295.2998.

General Procedure for the Oxidation of the Alcohols

To a solution of pyridinium dichromate (PDC) (5.6–11.9 mmol) and 2 mL of dimethylformamide (DMF) was added under argon a solution of the alcohol (1.11–2.38 mmol) in 6.6 mL of DMF and the reaction mixture was left being stirred at room temperature for 48 h. The mixture was washed with water (3 \times 25 mL), extracted with hexane (1 \times 25 mL), the organic phase was dried over Na_2SO_4 , and the solvent removed in vacuo affording the corresponding carboxylic acids **1a** (0.26 g) and **1b** (0.48 g) in 76% yields.

6-Heptadecyanoic acid (**1a**)

This was obtained as a white solid (mp 38–40 °C, lit [1] mp 39 °C) in a 76% yield from the reaction of **4a** (0.6 g, 2.38 mmol) and PDC (4.5 g, 11.9 mmol) in DMF according to the general procedure described above. Compound **1a** presented spectral data similar to the one reported in the literature [1].

6-Icosynoic acid (**1b**)

This was obtained as a white solid (mp 52–54 °C, lit [1] mp 53 °C) in a 76% yield from the reaction of **4b** (0.3 g, 1.11 mmol) and PDC (2.1 g, 5.6 mmol) in DMF according to the general procedure described above. Compound **1b** also presented spectral data similar to the one reported in the literature [1].

General Procedure for the Catalytic Hydrogenation of the Alkynes

Into a 25-mL two-neck round-bottom flask were placed dry hexane, the alkynes **4a** (0.056 g) or **4b** (0.295 g), quinoline (0.18–0.8 mL), and 10% palladium on activated carbon (Pd/C). One of the necks was capped with a rubber septum and the other was connected via tygon tubing to a 25-mL graduated pipet ending in a 150-mL beaker with distilled water. While stirring at room temperature a 20-mL syringe with needle was used to withdraw air from the system and to draw water up into the graduated pipet to the 0.0 mL mark. Hydrogen was then introduced into the system using a balloon filled with hydrogen attached to a hose barb-to-luer-lock adapter with a stopcock and a needle. The reaction mixture consumed 5.4–24.6 mL of hydrogen in 1 h. The mixture was filtered and the solvent removed in vacuo obtaining the desired alkenols **5a** (0.046 g, 70% yield) and **5b** 0.208 g (82% yield) after purification by Kugelrohr distillation at 110 °C/3 mm Hg.

(6Z)-Heptadecenol (**5a**)

This was obtained as a colorless oil (0.046 g, 0.18 mmol) in a 82% yield from the catalytic hydrogenation described in the general procedure above; IR (neat) ν_{\max} : 3,328, 3,004, 2,922, 2,853, 1,658, 1,461, 1,377, 1,074, 1,053, 720 cm^{-1} ; ^1H NMR (CDCl_3 , 300 MHz) δ 5.32 (2H, m, H-6, H-7), 3.61 (2H, t, $J = 6.6$ Hz, H-1), 2.00 (4H, m), 1.55 (3H, m, $-\text{CH}_2-$, $-\text{OH}$), 1.24 (20H, brs, $-\text{CH}_2-$), 0.87 (3H, t, $J = 6.8$ Hz, $-\text{CH}_3$); ^{13}C NMR (CDCl_3 , 75 MHz) δ 130.2 (C-7), 129.5 (C-6), 63.0 (C-1), 32.7, 31.9, 29.8, 29.7, 29.6, 29.5, 29.4, 29.3, 27.2, 27.1, 25.4, 22.7, 14.1; GC–MS (70 eV) m/z (relative intensity) 254 (M^+ , 1), 236 (6), 208 (2), 180 (2), 123 (13), 97 (25), 96 (65), 95 (61), 82 (100),

81 (64), 69 (40), 68 (54), 67 (92), 57 (32), 55 (69); HRMS calcd for $\text{C}_{17}\text{H}_{34}\text{O}$ [$M + \text{H}$] $^+$ 255.2682, found 255.2684.

(6Z)-Icosenol (**5b**)

This was obtained as a semi solid (0.21 g, 0.71 mmol) in a 70% yield from the catalytic hydrogenation described in the general procedure above; IR (neat) ν_{\max} : 3,346, 3,002, 2,919, 2,850, 1,460, 1,363, 1,062, 724 cm^{-1} ; ^1H NMR (CDCl_3 , 500 MHz) δ 5.35 (2H, m, H-6, H-7), 3.63 (2H, m, $J = 6.6$ Hz, H-1), 2.02 (4H, m), 1.57 (2H, m), 1.25 (26H, brs, $-\text{CH}_2-$), 0.88 (3H, t, $J = 6.5$ Hz, $-\text{CH}_3$); ^{13}C NMR (CDCl_3 , 125 MHz) δ 130.2 (C-7), 129.5 (C-6), 63.0 (C-1), 32.7, 31.9, 29.8, 29.70, 29.67, 29.6, 29.5, 29.4, 29.3, 27.3, 27.2, 25.4, 22.7, 14.1; GC–MS (70 eV) m/z (relative intensity) 296 (M^+ , 1), 279 (2), 278 (9), 250 (2), 222 (2), 138 (6), 124 (10), 123 (11), 97 (26), 96 (61), 95 (52), 82 (100), 81 (59), 69 (41), 68 (55), 67 (89), 57 (41), 55 (77); HRMS calcd for $\text{C}_{20}\text{H}_{40}\text{O}$ [$M + \text{H}$] $^+$ 297.3152, found 297.3154.

General Procedure for the Oxidation of the Alkenols

To a solution of pyridinium dichromate (PDC) (1.27–1.77 mmol) and 2 mL of dimethylformamide (DMF) was added under argon a solution of the alcohol (0.25–0.35 mmol) in 5.0 mL of DMF and the reaction mixture was left being stirred at room temperature for 48 h. The mixture was washed with water (3 \times 25 mL), extracted with hexane (1 \times 25 mL), the organic phase was dried over Na_2SO_4 , and the solvent was removed in vacuo affording the carboxylic acids **6a** (0.067 g, 73% yield) and **6b** (0.069 g, 86% yield).

(6Z)-Heptadecenoic acid (**6a**)

This was obtained as a viscous oil in a 73% yield from the reaction of **5a** (0.09 g, 0.35 mmol) and PDC (0.69 g, 1.77 mmol) in DMF according to the general procedure described above; IR (neat) ν_{\max} 3,264, 3,005, 2,922, 2,853, 1,708 (C = O), 1,459, 1,412, 1,378, 1,342, 1,201, 1,119, 935, 720 cm^{-1} ; ^1H NMR (CDCl_3 , 500 MHz) δ 5.37 (2H, m, H-6, H-7), 2.37 (2H, t, $J = 7.6$ Hz, H-2), 2.14 (4H, m), 1.67 (2H, m), 1.27 (18H, brs, $-\text{CH}_2-$), 0.89 (3H, t, $J = 7.0$ Hz, $-\text{CH}_3$); ^{13}C NMR (CDCl_3 , 125 MHz) δ 179.6 (C-1), 130.5 (C-7), 128.9 (C-6), 33.9, 31.9, 29.7, 29.6, 29.5, 29.32, 29.29, 29.2, 29.1, 27.2, 26.7, 24.3, 22.7, 14.1; GC–MS (70 eV) m/z (relative intensity) 268 (M^+ , 4), 250 (15), 208 (7), 206 (6), 166 (6), 165 (3), 152 (5), 151 (5), 138 (6), 137 (7), 123 (11), 111 (17), 110 (15), 97 (35), 96 (27), 95 (29), 81 (47), 69 (45), 67 (59), 57 (36), 55 (100); HRMS calcd for $\text{C}_{17}\text{H}_{32}\text{O}_2$ [$M - \text{H}$] $^-$ 267.2330, found 267.2334.

(6Z)-Icosenoic acid (6b)

This was obtained as a white solid in a 86% yield from the reaction of **5b** (0.075 g, 0.25 mmol) and PDC (0.48 g, 1.27 mmol) in DMF according to the general procedure described above; mp 31–34 °C; IR (neat) ν_{\max} 3,200–3,095, 3,002, 2,922, 2,852, 1,709 (C = O), 1,462, 1,411, 1,377, 1,348, 1,120, 1,075, 936, 797, 719 cm^{-1} ; ^1H NMR (CDCl_3 , 500 MHz) δ 5.33 (2H, m, H-6, H-7), 2.34 (2H, m, $J = 7.2$ Hz, H-2), 2.10 (4H, m), 1.63 (2H, m), 1.38 (4H, m), 1.24 (20H, brs, $-\text{CH}_2-$), 0.86 (3H, t, $J = 7.1$ Hz, $-\text{CH}_3$); ^{13}C NMR (CDCl_3 , 125 MHz) δ 179.5 (C-1), 130.8 (C-7), 129.2 (C-6), 34.0, 32.2, 29.94, 29.91, 29.88, 29.8, 29.6, 29.5, 29.4, 29.3, 29.2, 27.5, 27.0, 24.5, 22.9, 14.3; GC–MS (70 eV) m/z (relative intensity) 310 (M^+ , 4), 292 (25), 211 (7), 208 (4), 250 (5), 249 (4), 248 (4), 194 (3), 165 (4), 164 (4), 152 (4), 151 (5), 123 (11), 122 (8), 111 (18), 110 (14), 109 (12), 97 (34), 95 (27), 85 (17), 81 (46), 67 (51), 55 (100); HRMS calcd for $\text{C}_{20}\text{H}_{36}\text{O}_2$ [$M - \text{H}$] $^-$ 309.2799, found 309.2802.

Cell Cultures

L. donovani (MHOM/ET67/L82 strain) promastigotes were propagated in a completely defined medium 199, supplemented with 10% heat inactivated fetal calf serum (FCS) and penicillin/streptomycin cocktail (containing 50 U/ml penicillin, 50 $\mu\text{g}/\text{ml}$ streptomycin). The IC_{50} values were determined after 48 h incubation with different concentrations of the fatty acids dissolved in DMSO (ranging from 0.6 to 25 $\mu\text{g}/\text{ml}$) added to cultures and cell population assessed by Coulter.

Murine macrophages (RAW 264.7) were grown at 37 °C in RPMI 1640 medium, supplemented with 10% FCS antibiotics (containing 50 U/ml penicillin, 50 $\mu\text{g}/\text{ml}$ streptomycin). Toxicity IC_{50} values were determined after 48 h incubation with different concentrations of the compounds dissolved in DMSO (0.3 to 100 $\mu\text{g}/\text{ml}$) using vital alamar-Blue[®] dye (Invitrogen, Carlsbad, CA, USA), according manufacturer recommendations.

Purification of Recombinant Leishmanial TopIB

Expression of a recombinant topoisomerase IB from *Leishmania donovani* (LdTopIB) in a topoisomerase IB-deficient *Saccharomyces cerevisiae* strain has been described elsewhere [15]. Purification of recombinant LdTopIB was done according to Diaz-González and coworkers [16]. Briefly, LdTopIB overexpressing yeasts were disrupted with one freeze/thaw cycle at -80 °C, with the purpose of weakening the yeast wall; after lysis with 425–600 μm acid-washed glass beads, the extracts were cleared by centrifugation at 15,000 $\times g$ for 30 min at 4 °C. The protein suspension was

loaded onto a phosphocellulose (P-11) column, previously equilibrated as manufacturer indications. LdTopIB was eluted at 4 °C with a discontinuous gradient of KCl (0.2, 0.4, 0.6, 0.8 and 1 M) in TEEG buffer, supplemented with 0.1 mg/ml sodium bisulphite, 0.8 mg/ml NaF and the protease inhibitors cocktail. Active fractions were further loaded onto a phenyl-sepharose column (Sigma-Aldrich, St Louis, USA), eluted with a discontinuous inverse gradient of ammonium sulphate (1, 0.8, 0.6, 0.4 and 0.2 M) and then concentrated by Microcon YM-30 (Millipore) before use.

DNA Relaxation Assays

DNA topoisomerase I activity was assayed by the relaxation of negatively supercoiled plasmid DNA. The reaction mixture in a total volume of 20 μl contained 0.2 μg of supercoiled pHOT plasmid, 10 mM Tris–HCl buffer pH 7.5, 5 mM MgCl_2 , 0.1 mM EDTA, 15 $\mu\text{g}/\text{ml}$ bovine serum albumin, 50 mM KCl and various extracts containing altered proteins or wild type enzyme, starting with 1 unit LdTopIB. The reaction mixtures were incubated for 30 min at 37 °C. The enzyme reactions were stopped by the addition of up to 1% SDS—final concentration—and digested by 2 mg/mL proteinase K with 1 h incubation to remove protein bonded to the DNA fragment. The extent of plasmid DNA relaxation was assessed by electrophoresis in a 1% agarose gel in 0.1 M Tris acetate EDTA (TAE) buffer pH 8.0 at 2 V/cm for 14 h. The gels were visualized under UV illumination after being stained with ethidium bromide (0.5 mg/ml) and a posterior electrophoresis in the presence of 0.1 mg/ml ethidium bromide, in order to separate the nicked DNA from the relaxed topoisomers. One unit of LdTopIB is defined as the amount of purified protein able to relax 0.2 μg of pHOT supercoiled DNA per 30 min at 37 °C.

Results and Discussion

Our approach towards the total synthesis of either 6-heptadecynoic acid (**1a**) or 6-icosynoic acid (**1b**) started with commercially available 1-dodecyne or 1-pentadecyne which were successfully alkylated with 2-(5-bromopentyloxy)tetrahydropyran (**2**) in the presence of *n*-BuLi in THF–HMPA at 0 °C affording the tetrahydropyranyl protected alkynes **3a** (79% yield) and **3b** (54% yield) (Scheme 1). Deprotection of either **3a** or **3b** was achieved with *p*-toluenesulfonic acid (PTSA) in methanol at 60 °C, which yielded the desired 6-heptadecynol (**4a**) (99% yield) or 6-icosynol (**4b**) (83% yield). Final oxidation of either **4a** or **4b** with pyridinium dichromate (PDC) in DMF afforded the desired 6-heptadecynoic acid (**1a**) or 6-icosynoic acid (**1b**) in 76% yields. The overall yields for the last three steps of the syntheses of **1a**

i) DHP, p-TSA, CHCl_3 , rt, 90 min; ii) 1-dodecyne or 1-pentadecyne, *n*-BuLi, THF-HMPA, 0 °C, 80 min; iii) p-TSA, MeOH, 60 °C, 24h; iv) PDC, DMF, 48 h; v) H_2 , Pd/C (10%), quinoline, hexane; vi) PDC, DMF, 48 h.

Scheme 1 Synthesis of the acetylenic acids **1a** and **1b** and the olefinic acids **6a** and **6b**

Table 1 Antileishmanial activities (in $\mu\text{g/mL}$) of the studied fatty acids

Fatty acids	<i>L. donovani</i> promastigotes EC_{50}	Murine macrophages IC_{50}	Therapeutic index $\text{IC}_{50}/\text{EC}_{50}$
6-Heptadecynoic (1a)	6.67 ± 1.42	5.66 ± 0.92	0.85
(6 <i>Z</i>)-Heptadecenoic (6a)	>25	11.86 ± 1.63	n/a
Heptadecanoic (17:0)	>25	14.18 ± 7.48	n/a
6-Icosynoic (1b)	1.11 ± 0.28	5.35 ± 2.14	4.82
(6 <i>Z</i>)-Icosenoic (6b)	5.67 ± 1.07	28.20 ± 7.54	4.97
Icosanoic (20:0)	>25	21.93 ± 2.61	n/a

As a positive control we determined that miltefosine displays an IC_{50} of $0.79 \pm 0.14 \mu\text{M}$ against *L. donovani* and an EC_{50} of $1.95 \pm 0.37 \mu\text{M}$ against murine macrophages

n/a not assessed

(59% yield) and **1b** (34% yield) favored the shorter chain acid **1a**. The syntheses shown in Scheme 1 represent the first synthesis for both **1a** and **1b**.

Taking advantage of the same synthetic methodology (Scheme 1) we synthesized the naturally occurring fatty acids (6*Z*)-heptadecenoic acid (**6a**) and (6*Z*)-icosenoic acid (**6b**). For example, diverting the alkyne intermediates **4a** or **4b** to a catalytic hydrogenation under Lindlar's conditions resulted in the (6*Z*)-heptadecenol (**5a**) (82% yield) or the (6*Z*)-icosenol (**5b**) (70% yield) with a 100% *cis* stereochemistry for the double bonds. Oxidation of either **5a** or **5b** with pyridinium dichromate (PDC) in DMF afforded the desired (6*Z*)-heptadecenoic acid (**6a**) (73% isolated yield) and (6*Z*)-icosenoic acid (**6b**) (86% isolated yield). The overall yields for the four-step synthesis of **6a** (36%) and **6b** (21%) from **2** again favored the shorter chain acid **6a**. Surprisingly, this is also the first reported synthesis for either the alkenoic acids **6a** or **6b**.

Aiming at exploring the antiprotozoal activity of the acetylenic fatty acids **1a** and **1b** as well as that of the olefinic fatty acids **6a** and **6b** we studied their toxicity

towards *L. donovani* promastigotes. The results of our investigation are shown in Table 1. As the table shows, the acetylenic fatty acids **1a** and **1b** as well as the olefinic fatty acid **6b** displayed good antileishmanial activities towards *L. donovani* promastigotes ($\text{EC}_{50} = 1\text{--}7 \mu\text{g/mL}$). Surprisingly, the (6*Z*)-heptadecenoic acid (**6a**) was not effective against *L. donovani* ($\text{EC}_{50} > 25 \mu\text{g/mL}$). The saturated fatty acids *n*-heptadecanoic acid and *n*-icosanoic acid were tested as a control and they were also not effective towards *L. donovani* promastigotes ($\text{EC}_{50} > 25 \mu\text{g/mL}$), thus corroborating the previous literature report that unsaturation is an important factor for the antileishmanial activity of fatty acids [5]. From the results with the *L. donovani* promastigotes we can conclude that the C_{20} fatty acids were the more effective antileishmanial compounds since both acids **1b** and **6b** displayed a better therapeutic index ($\text{IC}_{50}/\text{EC}_{50} \approx 5$) over either **1a** or **6a**. Among the C_{17} fatty acids the acetylenic acid **1a** was the most efficient antiprotozoal compound, thus corroborating the importance of the C-6 triple bond in the antileishmanial activity of these compounds. Therefore, these results tend to indicate that

Fig. 1 Inhibition of the relaxation activity of recombinant LdTopIB by the 6-icosynoic acid (**1b**) (top) and the 6-heptadecynoic acid (**1a**) (bottom). One unit of recombinant LdTop1 was assayed in a plasmid DNA relaxation assay for 30 min at 37 °C (as described under “Materials and Methods”) in the presence of 12.5–1,000 μM compounds **1a** and **1b**. Reaction products were resolved in agarose

gel and subsequently visualized by ethidium bromide staining. The relative position of the negatively supercoiled DNA substrate is indicated by Sc, N is the nicked DNA, whereas the ladder of relaxed DNA topoisomer bands is labeled R. Reactions were stopped with a mixture of 1% SDS and 6.1 μg of proteinase K. Lane 1 contains 0.2 μg of pHOT plasmid DNA and lane 2 is a relaxed marker

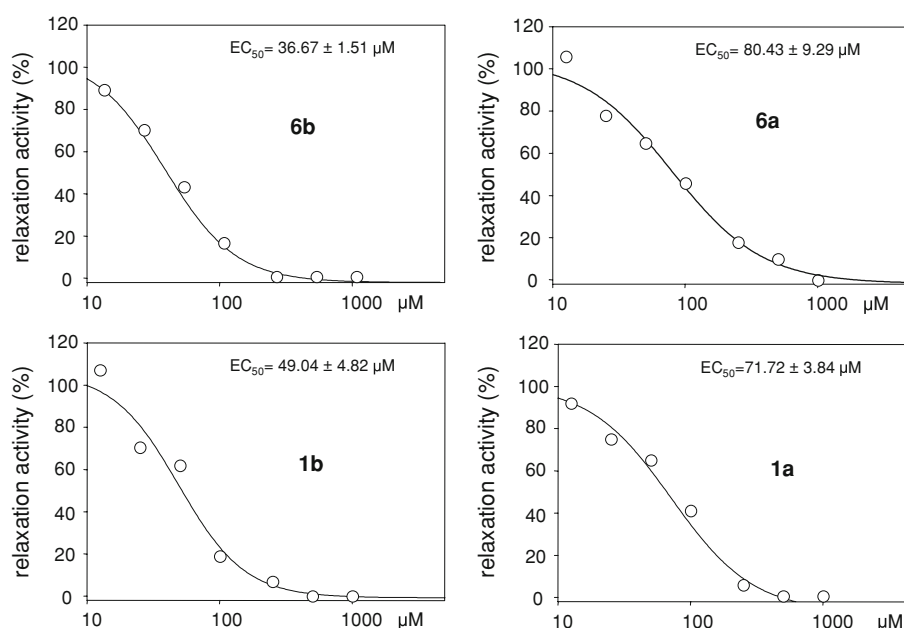

Fig. 2 Inhibition of the relaxation activity of recombinant LdTopIB by the (6Z)-icosenoic acid (**6b**) (top) and the (6Z)-heptadecenoic acid (**6a**) (bottom). One unit of recombinant LdTop1 was assayed in a plasmid DNA relaxation assay for 30 min at 37 °C (as described under “Materials and Methods”) in the presence of 12.5–1,000 μM compounds **6a** and **6b**. Reaction products were resolved in agarose

gel and subsequently visualized by ethidium bromide staining. The relative position of the negatively supercoiled DNA substrate is indicated by Sc, N is the nicked DNA, whereas the ladder of relaxed DNA topoisomer bands is labeled R. Fig. 3 Plots of relaxation activities (%) of the LdTOPIB enzyme versus concentration (μM) of the acetylenic fatty acids **1a** and **1b**, and the olefinic fatty acids **6a** and **6b**. The EC_{50} values are shown at the top of each graph

naturally occurring Δ^6 acetylenic fatty acids could be valuable fatty acids that can be optimized for developing more potent antileishmanial agents and thus merit further scrutiny in the search for better analogs.

As a possible mechanism of toxicity we also studied the inhibition of these Δ^6 fatty acids towards the Leishmania DNA topoisomerase IB (LdTOPIB) enzyme since nothing is known in the literature as to the interaction of fatty acids with this particular enzyme. One aim here was to determine a possible selectivity of the studied fatty acids towards the LdTOPIB enzyme as a function of the level of unsaturation. The LdTOPIB enzyme is substantially different from the human topoisomerase I enzyme since the LdTOPIB enzyme is a heterodimer resulting from two separate genes encoding for the core and catalytic domains of the enzyme [9]. Our results with the acetylenic acids **1a** and **1b** are shown in Fig. 1 and with the alkenoic acids **6a** and **6b** in Fig. 2, while the corresponding inhibition plots are shown in Fig. 3. As can be seen from Figs. 1 and 3 the 6-icosynoic acid (**1b**) was more efficient ($\text{EC}_{50} = 49.04 \pm 4.82 \mu\text{M}$) than the 6-heptadecynoic acid (**1a**) ($\text{EC}_{50} = 71.72 \pm 3.84 \mu\text{M}$) in inhibiting the LdTOPIB enzyme. On the other hand, the (6Z)-icosenoic acid (**6b**) also displayed reasonably good inhibition of the enzyme ($\text{EC}_{50} = 36.67 \pm 1.51 \mu\text{M}$) (Figs. 2, 3), but the (6Z)-heptadecenoic acid (**6a**) displayed a weak inhibition of the enzyme ($\text{EC}_{50} = 80.43 \pm 9.29 \mu\text{M}$), which seems to explain its lack of toxicity towards the *L. donovani* promastigotes. The saturated fatty acids *n*-heptadecanoic acid and *n*-icosanoic acid did not inhibit the enzyme, even at concentrations as high as 1 mM (gel not shown). Therefore, the 6-icosynoic acid (**1b**) and the (6Z)-icosenoic acid (**6b**) were among the best inhibitors in the series of the LdTOPIB enzyme indicating that both

unsaturation and chain length are important factors when considering inhibition of the LdTOPIB enzyme by fatty acids. Therefore, the LdTOPIB enzyme seems to be a likely intracellular target for these C_{20} unsaturated fatty acids. We believe that our results should pave the way for the development of more potent antileishmanial fatty acids towards *L. donovani* and similar protozoa such as the trypanosomes, who share a similar topoisomerase IB enzyme.

Acknowledgments The project described was supported by Award Number SC1GM084708 from the National Institutes of General Medical Sciences of the NIH. M. Cartagena thanks the UPR RISE program for a graduate fellowship. We thank Dr. Fred Strobel (Emory University) for the high resolution mass spectral data. This research was also partially supported by a grant (Gr238) from Junta de Castilla y León and the Tropical Diseases Network (RICET) from Ministerio de Salud y Consumo (SPAIN).

oils, several strategies to increase TAG production in plants have been explored [4–6].

The two major pathways leading to TAG production in humans, proposed many years ago, converge in the last step catalyzed by acyl-CoA:diacylglycerol acyltransferase (DGAT, EC 2.3.1.20) [7]. DGAT utilizes *sn*-1,2-diacylglycerol (DAG) and acyl-CoA as substrates to form TAG [8, 9] and at least two distinct membrane-bound polypeptides, referred to as DGAT1 [10, 11] and DGAT2 [12–14] have been identified. In yeast TAG can be also formed through the catalytic action of phospholipid:diacylglycerol acyltransferase (PDAT, EC 2.3.1.158) which is encoded by the *LRO1* gene and uses a phospholipid as the acyl donor and DAG as the acceptor [15]. Orthologues of PDAT have been found in plant genomes, but their contribution to overall TAG biosynthesis remains unclear [16, 17]. In addition yeast possesses two other enzymes with minor DGAT activity. These enzymes, encoded by *ARE1* and *ARE2* genes, are mainly responsible for the biosynthesis of sterol esters [18].

Standard methods to measure the enzyme activity of DGAT and PDAT, here referred to as TAG synthesizing enzymes (TAG-SE), require a sensitive but rather laborious assay with radio-labeled substrates [19]. Due to the hydrophobic nature of TAG, their analysis entails time-consuming techniques such as solvent extraction and/or thin layer chromatography (TLC). In addition, TAG synthesizing enzymes are usually associated with membranes and therefore, enzyme assays typically use microsomal fractions obtained through ultracentrifugation, further decreasing the throughput of the assay. These factors contribute to the delay of fundamental and applied research involving TAG-SE. Moreover, a relatively small number of known genes, mostly identified by homology-based cloning, limit our understanding of this group of enzymes.

In the present work, we developed an activity-based screening method capable of identifying yeast clones expressing a functional DGAT. The method uses a eukaryotic heterologous expression system and a modified baker's yeast (*Saccharomyces cerevisiae*) strain H1246. This strain is particularly suitable for heterologous expression of *DGAT*, as it is free of TAG and sterol esters as a result of knockouts in four genes (*DGA1*, *LRO1*, *ARE1* and *ARE2*) [18]. To further evaluate the DGAT clones and quantitatively measure the enzyme activity we applied an additional method to determine the amounts of TAG accumulated in intact living cells using Nile red, a fluorescent dye commonly used to stain neutral lipids [20]. The changes in fluorescence caused by the interaction of the dye with TAG correlate with DGAT activity as demonstrated for several *DGAT1* mutants. The simple nature of the assay makes it amenable to higher throughput experimental designs. We discuss several applications for these

two methods applied independently or in combination. Siloto et al. [21] have presented a preliminary account of some of this work.

Experimental Procedures

Yeast Cell Culture and Reagents

Yeast nitrogen base without amino acids (YNB), glucose, raffinose, galactose and amino acid drop-out supplement were obtained from BD Difco (Oakville, Canada). Oleic acid and tergitol were purchased from Sigma–Aldrich (Oakville, Canada) and other FAs were from Nu-Chek Prep (Elysian, USA). Nile red (7-diethylamino-3,4-benzophenoxazine-2-one) was obtained from Molecular Probes (Invitrogen, Carlsbad, USA). Oligonucleotides were synthesized by Integrated DNA Technologies (Coralville, USA).

The *S. cerevisiae* strain H1246 (*MAT α are1- Δ ::HIS3, are2- Δ ::LEU2, dga1- Δ ::KanMX4, lro1- Δ ::TRP1 ADE2*) containing knockouts of the *DGA1*, *LRO1*, *ARE1* and *ARE2* genes, was kindly donated by Drs. S. Stymne and U. Ståhl. The strain 12501 (*MAT α dga1- Δ ::KanMX4*) was obtained from Open Biosystems (Thermo Fisher Scientific, Huntsville, USA). Yeast transformation was performed according to Gietz and Schiestl [22] using heat-shock at 42 °C for 12 min. After transformation, the yeast culture was cultivated in minimal medium with dextrose (YNBD) containing 0.67% (w/v) of YNB, 2% (w/v) dextrose, 20 mg/L of adenine, arginine, tryptophan, methionine, histidine, and tyrosine, 30 mg/L of lysine and 100 mg/L of leucine. The cultures were grown at 30 °C, 250 rpm.

Cloning and Expression of DGAT in Yeast

For expression of *Brassica napus DGAT1* (*BnDGAT1*) in yeast, the coding region of *BnDGAT1* was amplified using a cDNA clone previously isolated in our laboratory (unpublished) using forward primer 5'-gaccatggggattttggattctg gagg-3' and reverse primer 5'-ctgatgaccggaaaggggtccatgt cc-3'. The amplified DNA was cloned into the yeast expression vector pYES DEST52 (Invitrogen) under the control of GAL1 promoter to yield pYESBnDGAT1. Flax (*Linum usitatissimum*) and castor bean (*Ricinus communis*) *DGAT1* (*LuDGAT1* and *RcDGAT1*, respectively) were similarly cloned to generate pYESLuDGAT1 and pYESRcDGAT1. The *LuDGAT1* coding region was amplified using forward primer 5'-gaccatggggcgtgctgcacactcctgacaatc-3', reverse primer 5'-caggaatgggaaagatggaatcaagcttaaa-3', and a cDNA template previously isolated in our laboratory (Siloto et al., unpublished data). The *RcDGAT1* coding region was amplified using forward primer 5'-gaatcgcca

tggaacaagcttaa-3', reverse primer 5'-caggaatgggaaagatggaatcaagctt-3', and a cDNA clone template [23]. pYES-LacZ, used as a negative control, was obtained from Invitrogen. The variants of *RcDGAT1* were similarly obtained by PCR. N1, N2 and N3, are N-terminus truncations while C1 and C2 are C-terminus truncations. Y302F, Y199F, S226A and S168A are point mutants of *RcDGAT1* obtained by site-directed mutagenesis.

Expression of the recombinant genes in yeast was induced using minimal medium containing 2% (w/v) galactose and 1% (w/v) raffinose (YNBG). Prior to induction, cultures were centrifuged for 5 min at 3,000g at room temperature and washed twice with water.

FA Supplementation

FAs were dissolved in ethanol at 0.5 M with the exception of palmitic and stearic acids that were dissolved at 0.25 M in hot ethanol. FA solutions were diluted in a warm medium containing 0.01% (v/v) tergitol immediately before yeast inoculation. Tergitol is a nonionic surfactant that was used to assist the dispersion of the FA in the medium. Control experiments without FAs contained the same volume of ethanol and 0.01% (v/v) of tergitol.

Yeast Lipid Analysis

Induced yeast cultures at the stationary growth stage, cultivated in 50 mL medium, were washed twice with water and resuspended in 2 mL of methanol. Glass beads (0.5 mm) were added and the suspension was vigorously vortexed. Lipids were extracted by adding 4 mL of chloroform and 1 mL of 0.9% (w/v) of sodium chloride. The sample was vortexed and centrifuged at 2,000g for 2 min. The lower phase was recovered and the remaining lipids were re-extracted twice with an additional 4 mL of chloroform. Chloroform fractions were pooled, dried under nitrogen, resuspended in 20 μ L of chloroform, and spotted on a TLC plate (SIL G25, 0.25 mm, Macherey–Nagel, Germany). The plate was developed with hexane/diethyl ether/acetic acid (80:20:1, v/v/v) and lipids visualized with 8% (w/v) copper sulfate and 5% (v/v) phosphoric acid followed by charring at 350 °C for 1 h.

In Vitro Measurement of Microsomal DGAT Activity in Yeast

Induced yeast cultures were collected at 3,000g for 5 min and washed twice with 1 mL of buffer containing 20 mM Tris–HCl pH 7.5, 10 mM MgCl₂, 1 mM EDTA, 5% (v/v) glycerol, 300 mM ammonium sulfate and 2 mM dithiothreitol. Yeast cells were resuspended in 1 mL of the same buffer and homogenized with a bead beater (Biospec,

Bartlesville, USA) using 0.5 mm glass beads. The homogenate was centrifuged at 10,000g, at 4 °C for 10 min and the supernatant was recovered. The microsomal fraction was recovered through centrifugation at 100,000g, at 4 °C for 1 h. The pellet was resuspended in 50 μ L of 3 mM imidazole buffer (pH 7.4) containing 125 mM sucrose. The crude protein concentration in the microsomal fraction was normalized using the BCA assay (Pierce, Rockford, USA) with a BSA standard curve. DGAT assays were conducted with 15 μ g of microsomal protein in the presence of 25 mM sucrose, 0.1 mM EDTA, 15 mM Tris–HCl pH 7.4, 125 μ g/mL BSA (FA-free), 320 μ M *sn*-1,2-diolein and 15 μ M [¹⁴C] oleoyl-CoA in a total volume of 60 μ L in a similar fashion to a previously described method [24]. The reaction was allowed to proceed at 30 °C for 15 min and quenched with 10 μ L of sodium dodecyl sulfate 10% (w/v). The reaction was spotted on a TLC plate (SIL G25, 0.25 mm, Macherey–Nagel), along with 100 μ g of triolein standard. The plate was developed with hexane/diethyl ether/acetic acid (80:20:1, v/v/v). TAG spots were detected with iodine, scraped, and measured in a Beckman-Coulter LS6500 liquid scintillation counter. The assays were performed in three technical replicates.

Nile Red Assay

Nile red assay and optical density determination were performed in 96-well polystyrene flat-bottom microplates (UNIPLATE, Whatman, UK). The Nile red fluorescence assay was performed by placing 95 μ L of yeast culture in a 96-well dark plate. The background fluorescence was measured using a multi-well plate fluorimeter (Fluoroscan Ascent, Thermo, Milford, USA) for 100 ms with excitation and emission filters of 485 and 538 nm, respectively. Five microliters of freshly prepared methanolic Nile red solution were added to the culture using a built-in automatic dispenser. Different concentrations of Nile red in methanol were used as described in the “Results” section and the optimal concentration was determined as 0.8 mg/mL. The mixture was then briefly mixed and incubated for 5 min at room temperature. A second fluorescence measurement was performed using the same conditions. The assays were performed with four technical replicates. Nile red was protected from light to avoid photo-bleaching.

Results

Positive Selection of Yeast Cells Expressing DGAT

Most yeast expression systems use the galactokinase (GAL1) promoter to control the expression of the heterologous gene [25]. The induction of the heterologous

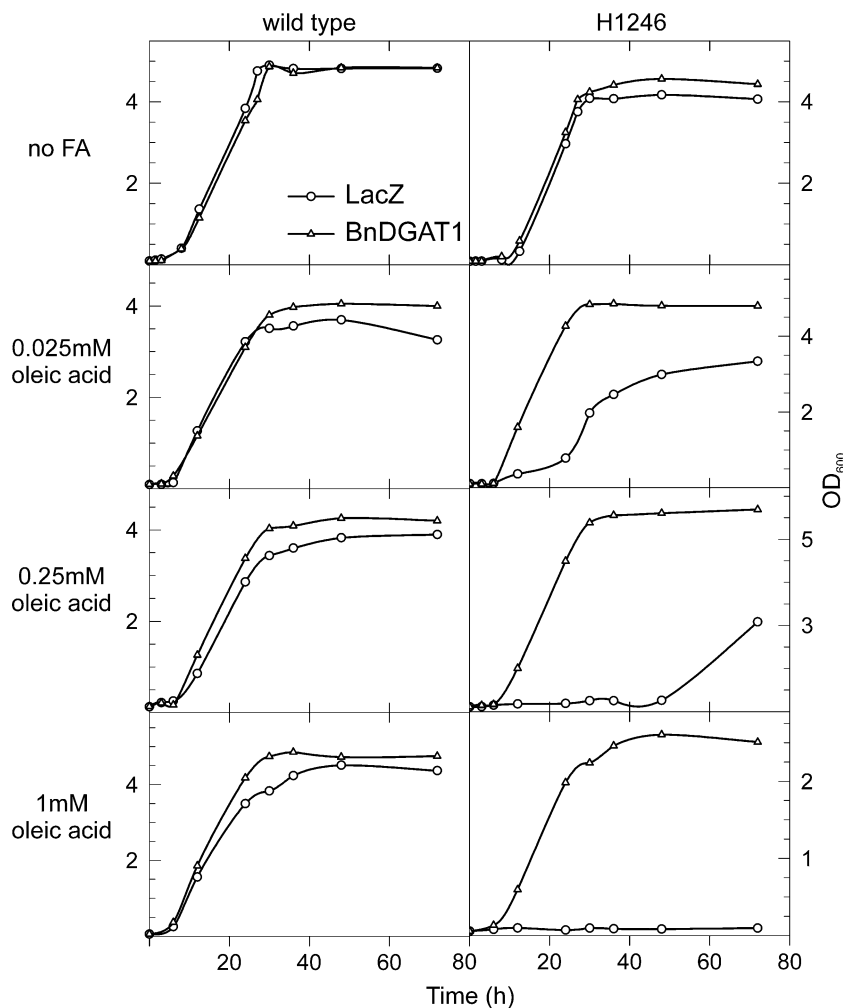

expression is achieved by changing the carbon source in the medium from glucose (medium YNBD) to galactose (YNBG) which activates the GAL1 promoter [26]. The quadruple knockout yeast strain H1246 is suitable for expression and characterization of DGAT genes as it is devoid of DGAT activity and does not accumulate storage lipids [18]. Since yeast is able to import exogenous FAs and convert them to respective acyl-CoA derivatives, supplementation of the medium with FA can further enhance the TAG accumulation conferred by the recombinant DGAT gene.

In our experiments we routinely use the pYES vector coding for the bacterial protein LacZ as a negative control. We noticed that H1246 cultures transformed with pYES-LacZ grew normally in YNBD, but displayed a reduced growth rate in the FA-containing induction medium when compared to *DGAT*-expressing cells. Growth curve experiments confirmed this observation and revealed dependence of this phenotype on the FA concentration (Fig. 1). Interestingly, expression of *BnDGAT1* in the H1246 background was able to reverse the effect of FA and the growth curve of

the *BnDGAT1*-expressing culture was similar to that of the *wild type* yeast even at the highest tested FA concentration that entirely inhibited the growth of *LacZ*-expressing strain. In fact, expression of *BnDGAT1* in *wild type* host slightly favored yeast growth. To eliminate the possibility that growth was adversely affected by the *LacZ* expression, we repeated the experiments with yeast harboring an empty pYES vector with results similar to those of *LacZ* control strain (Fig. 2a). Additionally we observed only a partial FA-induced growth inhibition using the *S. cerevisiae* mutant 12501 which contains a single knockout in *DGAI1* gene that encodes yeast DGAT (Fig. 2a).

In another experiment we inoculated H1246 cultures expressing *LacZ* and *BnDGAT1* on YNBG solid medium with and without FA supplement. Similarly to the liquid medium, the plates containing 1 mM oleic acid distinguished the two cultures (Fig. 3a). To investigate the nature of the growth effect and assess broader applicability of the selection system, we inoculated both *LacZ*- and *BnDGAT1*-expressing cultures on YNBG plates supplemented with a range of FA differing in the carbon-chain length as

Fig. 1 Exogenous FAs inhibit growth of yeast cells devoid of TAG synthesizing enzyme activity. Cultures of *S. cerevisiae* strain H1246 (right column) and the corresponding parental strain (left column) transformed with pYESLacZ or pYESBnDGAT1 were inoculated in YNBG at a final OD₆₀₀ of 0.1. Oleic acid, dissolved in ethanol at 0.5 M, was supplemented to the cultures at the final concentrations indicated. The cultures were incubated at 30 °C, 250 rpm and the growth was monitored for 72 h. Cultures expressing *LacZ* or *BnDGAT1* are denoted by circles or triangles, respectively

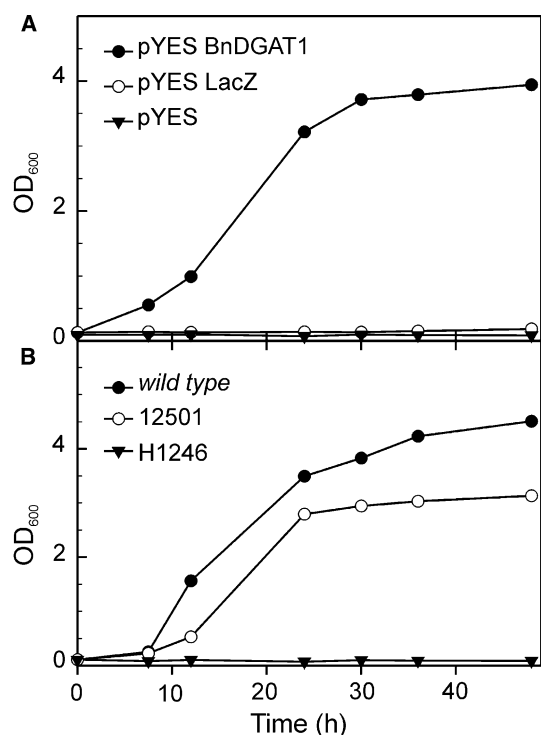

Fig. 2 Effect of yeast genetic background in FA-growth inhibition. **a** *S. cerevisiae* strain H1246 transformed with pYESBnDGAT1, pYESLacZ or pYES were inoculated in YNBG at a final OD₆₀₀ of 0.1 and oleic acid was supplemented to the cultures at a final concentration of 1 mM. The cultures were incubated at 30 °C, 250 rpm and the cell growth was monitored for 48 h. **b** *S. cerevisiae* wild type, 12501 (*DGA1* knockout) or H1246 (*DGA1*, *LROI*, *ARE1* and *ARE2* knockout) were transformed with pYESLacZ. The recombinant yeast strains were inoculated in YNBG at final OD₆₀₀ of 0.1 and oleic acid was supplemented to the cultures at a final concentration of 1 mM. The cultures were incubated at 30 °C, 250 rpm and the cell growth was monitored for 48 h

well as in the degree of saturation (Fig. 3b). The growth of the control strain was inhibited in most cases except when palmitic, stearic and erucic acids were supplemented, most likely due to their lower dispersion in the aqueous medium. Lowering the concentration of these FAs to 0.5 mM seemed to help their dispersion in the medium, but it did not substantially improve the selectivity of the media. Media containing 1 mM linoleic, α -linolenic or docosahexaenoic acids, on the other hand, inhibited the growth of both cultures. In view of the results obtained with liquid media supplemented with different amounts of oleic acid, we tested a range of lower concentrations and found that plates with 0.5 mM concentrations of α -linolenic or docosahexaenoic acids were suitable for selection (Fig. 3c).

Taken together, these results suggested that the growth inhibition of the H1246 yeast strain in the presence of FA could provide a basis for a functional complementation assay capable of identifying recombinant genes encoding a

functional DGAT. To test this hypothesis we transformed H1246 with a mixture of plasmids consisting of 0.9 μ g of pYESLacZ and 0.1 μ g of pYESBnDGAT1 along with controls consisting of 1 μ g of each vector. The transformed cells were spread on YNBG plates with or without 1 mM oleic acid. In the presence of FA, the number of colonies growing on the plates with mixed vectors represented 10.1% of those formed by the pYESBnDGAT1 transformation. As expected, pYESLacZ did not produce any colonies on plates containing oleic acid (Fig. 3d).

In Situ Quantification of TAG Synthesizing Enzyme Activity in Yeast Cells

The functional complementation assay allowed for easy identification and isolation of yeast cells expressing a functional TAG-SE or other free FA-detoxifying enzymes. Since H1246 yeast strain is essentially devoid of neutral lipids, the TAG produced and accumulated is directly attributable to the activity of the expressed heterologous DGAT. We used this relationship to extend the previously described system of qualitative selection, adding a quantitative dimension in a simple in situ fluorescent assay. To quantify the amount of TAG that accumulated in transformed yeast cells, we used Nile red, a fluorescent dye commonly applied in microscopy to stain lipid particles [20]. The emission maximum of Nile red conjugated with neutral lipids differs from that of the dye-polar lipid complex. Moreover, the intensity of fluorescence caused by the interaction of the dye with neutral lipids is much higher than it is with polar lipids, making Nile red suitable for our purpose. Nile red dye moves freely across cellular membrane and thus makes it possible to perform the quantitative neutral lipid assay in living cells, eliminating the need for sample preparation.

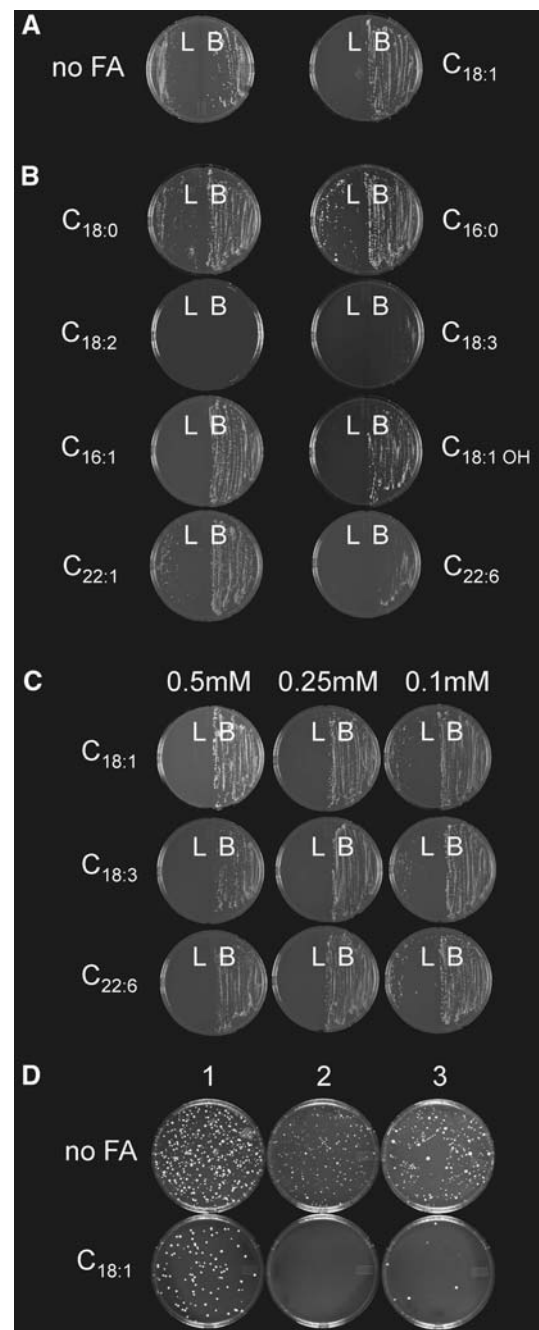

An example of NRA is illustrated in Fig. 4. The fluorescence increase (ΔF) is significantly higher in yeast cultures expressing *BnDGAT1* and *LuDGAT1* than in the culture deficient in the biosynthesis of neutral lipids (expressing *LacZ*) (Fig. 4a). The results of NRA correlated well with DGAT activity quantified by a standard in vitro radioactive assay. Thin layer chromatography of neutral lipids extracted from the three cultures confirmed the presence of TAG only in cultures expressing heterologous DGATs (Fig. 4b). We therefore concluded that the fluorescent NRA can be used to rapidly estimate the activity of the recombinant DGAT in living yeast cells without the need for extensive sample preparation.

Optimization of the Fluorescent NRA

To optimize NRA and investigate factors influencing fluorescence values, we conducted several experiments

Fig. 3 Growth phenotype is observed on solid medium supplemented with FAs. H1246 yeast strain expressing *LacZ* (L) or *BnDGAT1* (B) were inoculated on the corresponding YNBG solid medium and incubated at 30 °C for 6 days. **a** Plates of YNBG with and without supplement of 1 mM oleic acid (18:1^{*cis*Δ9}) dissolved in ethanol. The plate without FA contained the same volume of ethanol only. **b** Plates of YNBG supplemented with 1 mM palmitoleic (16:1^{*cis*Δ9}), linoleic (18:2^{*cis*Δ9,12}), α-linolenic (18:3^{*cis*Δ9,12,15}), docosahexaenoic (22:6^{*cis*Δ4,7,10,13,16,19}), ricinoleic (18:1^{12-OH *cis*Δ9}), erucic (22:1^{*cis*Δ13}) and 0.5 mM palmitic (16:0) and stearic (18:0) acids. The FAs were dissolved in ethanol at 0.5 or 0.25 M and added to the YNBG prior to plating. **c** Plates supplemented with oleic, α-linolenic and docosahexaenoic acids at the final concentrations indicated. **d** Selection of yeast cells in medium with FA after transformation. H1246 cells were transformed with 1 μg of pYESBnDGAT1 (column 1), 1 μg of pYESLacZ (column 2) and 0.1 μg of pYESBnDGAT1 mixed with 0.9 μg of pYESLacZ (column 3). After transformation, yeast cells were recovered in liquid YNBD medium for 6 h, inoculated in YNBG plates with or without supplement of 1 mM oleic acid and incubated at 30 °C for 6 days

using *BnDGAT1*- or *LacZ*-expressing cultures cultivated to stationary growth phase in YNBG. Initially, we prepared Nile red solution in methanol at different concentrations and conducted the NRA by mixing 5% of the dye in the yeast cultures, normalized to a range of cell densities (OD₆₀₀). The highest Δ*F* values were obtained using Nile red at final concentration of 0.04 mg/mL of yeast culture (Fig. 5a). The difference between Δ*F* values obtained for *LacZ*- and *BnDGAT1*-expressing cultures was clearly observed with concentrations up to 0.2 mg/mL. Although the cell density did not affect the concentrations at which maximal Δ*F* values were observed, it did alter the measured fluorescence values. In order to investigate the effect of cell density on Δ*F* values, NRA was performed with *BnDGAT1*- or *LacZ*-expressing cultures adjusted to a range of OD₆₀₀ values using plain YNBG medium as a diluent. As illustrated in Fig. 5b, there was a clear distinction between the fluorescence increases due to the cell density in the culture accumulating TAG (*BnDGAT1*-expressing cultures) and the increase of background fluorescence in the control (*LacZ*-expressing cultures). The results further indicated that Δ*F* values are not affected by the medium itself and correlate linearly with the cell density within the studied OD₆₀₀ range. Consequently, it is possible to normalize Δ*F* values by calculating the Δ*F*/OD ratio rather than trying to achieve the same cell density across samples, which can be impractical. To test the reliability of the assay over a range of possible amounts of TAG produced by the yeast culture, we performed NRA with mixtures of *BnDGAT1*- and *LacZ*-expressing cultures, both adjusted to the same cell density (Fig. 5c). As expected, the observed Δ*F* increased with the proportion of the *BnDGAT1*-expressing culture in the mixture in a linear fashion, indicating that NRA provides a good estimate of TAG accumulated in yeast cells and, in conjunction with the quadruple knockout

strain H1246, also an estimate of the heterologous DGAT activity.

Validation of the Methods with DGAT Mutants

To evaluate the efficacy of the DGAT screening system we tested the selection by functional complementation and the NRA with mutants of a castor bean *DGAT1* (*RcDGAT1*) prepared and characterized in our laboratory. Several mutants of *RcDGAT1* were constructed by truncation of the N-terminus (N1, N2 and N3), C-terminus (C1 and C2) as

Fig. 4 NRA correlates with DGAT activity and TAG accumulation in yeast. **a** NRA and DGAT enzyme assays performed with H1246 yeast cultures expressing *LacZ*, *BnDGAT1* or *LuDGAT1*. Fluorescence was measured with 95 μ L of cultures in YNBG at the stationary phase using 485 (excitation) and 538 nm (emission) before and after the addition of Nile red, and expressed in arbitrary units (a.u.). DGAT activity was measured with the microsomal fraction extracted from

the same cultures induced for 16 h in YNBG. DGAT activity in the H1246 yeast culture expressing *LacZ* was not detected. **b** Lipid profile of the same cultures in YNBG at the stationary growth phase. Total yeast lipids were extracted with methanol/chloroform, resolved by TLC and visualized by charring in the presence of copper acetate. The position of TAG is indicated

well as by the substitution of single residues (Y302F, Y199F, S226A and S168A) through site-directed mutagenesis (unpublished). These mutants display a wide range of DGAT activity, providing us with a useful model for validation of the novel methods. Briefly, the mutation Y302F produced no significant effect on the enzyme activity while other mutations resulted in lower degrees of activity compared to the *wild type RcdGAT1*. We used the selection on FA-containing plates to verify the phenotype of each mutant (Fig. 6a). As expected, *RcdGAT1*-expressing cells displayed normal growth on YNBG with FA. The mutants Y302F, Y199F, S226A and S168A also grew normally while no growth could be detected for N1, N2, N3, C1 and C2 over the same period of incubation. We also performed NRA and the radioactive *in vitro* assay with liquid cultures expressing *RcdGAT1* variants. Briefly, the relative comparison of DGAT activity of the *wild type* and the modified *RcdGAT1* variants measured by NRA resembled the results of the *in vitro* enzyme assay for most of the mutants analyzed here (Fig. 6a). Positive correlation between the fluorescent *in situ* and the conventional *in vitro* enzyme assay (Fig. 6b) suggests that NRA can be used to measure recombinant DGAT activity in yeast, especially in large-scale experiments.

Discussion

DGAT plays a pivotal role in TAG accumulation and homeostasis in eukaryotes [8, 9]. It had been suggested that in plants DGAT activity may be the rate-limiting step for TAG biosynthesis in developing seeds [27], a hypothesis confirmed by several independent genetic studies [28–30].

The growing demand for vegetable oil worldwide has stimulated research in the area of TAG synthesis and DGAT is at the center of multiple genetic engineering efforts to modify the amount and quality of oil accumulated in seeds [6, 31]. In mammals, a fat-rich diet combined with a sedentary lifestyle results in an excessive accumulation of TAG associated with obesity and other metabolic disorders. One of the possible strategies for the treatment of obesity is to restrict TAG synthesis and DGAT has been considered a potential target [32]. In spite of the continuing advances in our understanding of TAG biosynthesis, many questions related to the roles of enzymes involved and their regulation remain to be addressed.

Most DGAT studies rely on some type of heterologous expression followed by an enzyme assay. The conventional DGAT activity assay is laborious and requires radio-labeled substrates. Commonly, phase separation and/or TLC are employed to isolate the reaction product before liquid scintillation [19]. The low throughput of such assays considerably limits the choice of applicable experimental designs. Here we describe the NRA method that can be used to rapidly estimate accumulated TAG and hence DGAT activity in genetically altered yeast cultures. This live-cell-based assay is versatile and particularly suitable for high-throughput applications. Similar methods to estimate neutral lipid content in oleaginous microorganisms such as *Umbelopsis ramanniana* [33] or mammalian cultured cells [34] have been previously devised. By combining a Nile red-based fluorescent assay with the *S. cerevisiae* H1246 strain, the NRA method described here estimates the activity of a single recombinant DGAT in live yeast cells. Such estimates are biologically relevant, even though some of the tested *RcdGAT1* mutants appear to

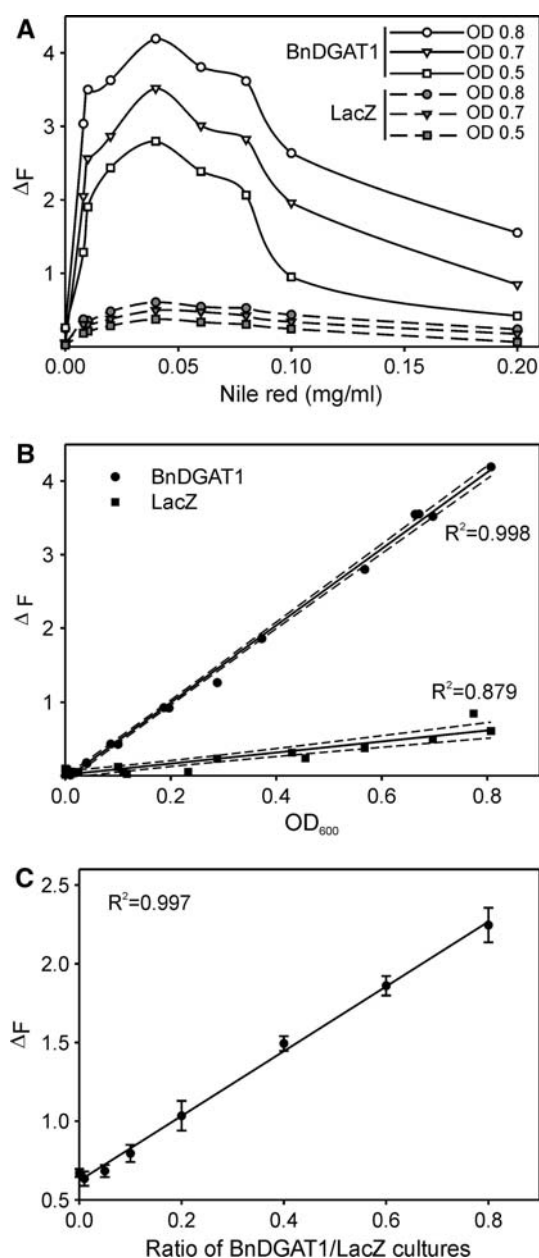

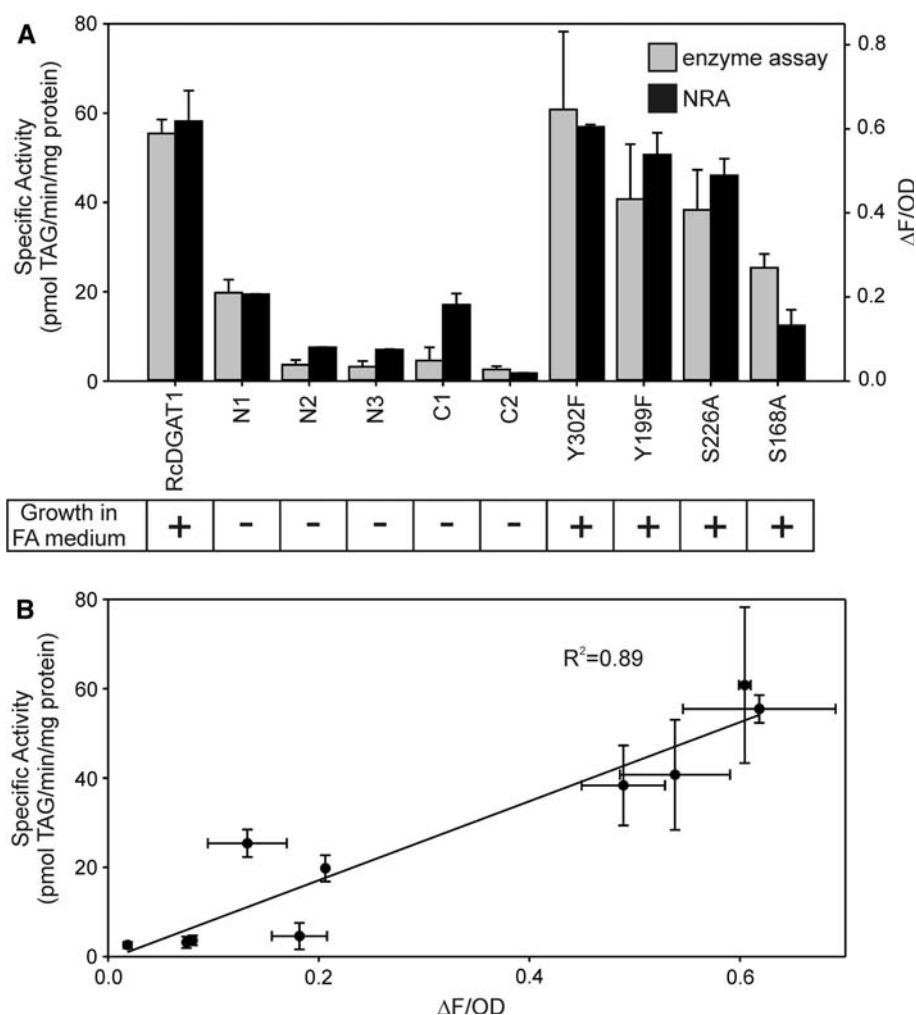

Fig. 5 Characterization of factors influencing NRA. **a** Optimization of Nile red concentration. NRA was performed with 95 μ L of H1246 cultures expressing *LacZ* (dashed lines) or *BnDGAT1* (full lines) at stationary phase and diluted at different cell densities as described. After measuring the background fluorescence, 5 μ L of methanolic solution of Nile red at different concentrations were added and followed by the second measurement with 5-min interval from the first measurement. The difference between the first and second measurement is denoted in *Y* axis as ΔF in arbitrary units (a.u.) and the final concentration of Nile red in the culture is denoted in the *X* axis as ΔF in arbitrary units (a.u.). **b** NRA of the same cultures at stationary phase plotted as a function of cell density (OD_{600}). Full lines denote linear regression with dashes corresponding to intervals of 99% confidence. **c** NRA performed with mixtures of *BnDGAT1*- and *LacZ*-expressing cultures normalized to the same cell density. The full line represents the linear regression with the error bars representing standard deviation

deviate from the linear relationship between the two assays. One of the possible reasons for such deviation is that the radio-active assay is performed *in vitro* in a controlled environment, typically with relatively high substrate content in the reaction mixture under linear initial reaction velocity conditions, while NRA is subject to a limited availability of substrates controlled by multiple endogenous cellular mechanisms. The protein stability can affect the read-out since the *in vitro* assay reflects the conversion of labeled substrates into TAG during a relatively short time period. NRA, however, quantifies the accumulation of storage lipids over the course of individual cell lives. Consequently, while standard assays provide an accurate quantification of the enzyme activity in the controlled environment, NRA might better reflect the performance of a DGAT under study in the live cell context.

Motivated by the pharmaceutical importance of DGAT inhibitors, Seethala et al. [35] recently developed an improved radioactive method based on scintillation proximity assay. The method uses DAG and tritium-labeled acyl-CoA substrates with the resulting TAG being bound by scintillant-containing microsphere beads. The proximity of a radioactive atom causes the bead to emit signal detected by a fluorescent imaging system or a microplate scintillation counter. The assay uses a microsomal fraction as a source of DGAT and is therefore amenable for high throughput experiments which evaluate interactions of an array of chemical compounds with TAG-SE from a single biological source. In contrast, the methods described here are suitable for experimental designs studying a large number of individual gene products. Since NRA does not require sample preparation, it is possible to assess the activity of an array of enzymes, for instance, an expressed cDNA library or a mutagenized population of a single gene. NRA could equally well serve in specific DGAT inhibitor screens, providing additional information regarding the cytotoxicity and ability of compounds to move across the cellular membrane.

The combination of the functional complementation assay and NRA can be used as a unique high throughput screening system, an essential element for optimizing directed evolution of proteins [36]. Such an approach might produce DGATs with enhanced catalytic efficiency or modified substrate selectivity [21]. In addition, information obtained from large mutagenized cDNA populations would advance our understanding of the structure–function relationship in DGAT. Few studies investigating the influence of specific amino acid residues on DGAT enzyme activity have been conducted [37, 38] and most of the information available on the structure and function of DGATs has been derived from comparisons of homologous enzymes. Application of the methods described here could enhance

Fig. 6 Validation of the selection system and NRA with mutants of *RcDGAT1*. **a** NRA and DGAT microsomal activity. Enzyme activity was determined by radioactive assay for each *RcDGAT1* variant and NRA results were expressed as ΔF (a.u.) divided by OD_{600} . The table below indicates the selection system results for H1246 cultures expressing *RcDGAT1* and the respective variants. *Negative* (–) and *positive* (+) indicate the ability to produce colonies in solid YNBG supplemented with 1 mM oleic acid. **b** Relationship between $\Delta F/OD$ and the specific activity measured by radioactive assay. The line denotes linear regression; error bars represent standard deviation

our knowledge of the molecular mechanisms involved in DGAT activity.

Yeast cultures are routinely analyzed at a single-cell level by flow cytometry [39]. The nature of NRA, based on the detection of fluorescent signal in individual cells, offers an exciting possibility to significantly bolster the throughput of the technique by employing fluorescence-activated cell sorting (FACS). This method has been used, for instance, in yeast viability assessment [40] and Muller and Losche [41] have used Nile red staining of neutral lipids as one of the parameters in their characterization of brewing yeast subpopulations.

There is substantial data showing that yeast internalizes FAs via a process known as vectorial acylation, where an acyl-CoA is formed upon crossing the plasma membrane. Genetic studies have identified the key elements of the protein complex that involve acyl-CoA synthetases [42, 43]. The import of FAs by yeast is tightly coupled to their utilization, and the size of the internal sink is limited under glucose repression [44]. Harnessing the natural capability of yeast to import FA and to convert them to their

acyl-CoA equivalents constitutes one of the main advantages of the described cell-based methods. Any FA that can be made available to yeast cells in the medium and undergoes efficient vectorial acylation can be used for selection and activity evaluation. In contrast to conventional in vitro assays, where substrates have to be presented in an acyl-CoA form, supplementing growth medium with FA is simple, inexpensive and more flexible. The spectrum of FAs that can be used in such experiments extends far beyond the typical yeast lipid profile. Different FA, however, displayed varying efficacy for triggering the restricted growth phenotype. The most efficient were oleic, palmitoleic and the polyunsaturated α -linolenic and docosahexaenoic acids, probably due to their relatively good dispersion in the medium and consequently their availability for yeast internalization. In contrast, saturated FAs (palmitic and stearic) were much more difficult to disperse in the solid medium. Lowering their concentration to 0.5 mM prevented the formation of visible aggregates on the surface of the solid medium. Such plates, however, were not effective in FA-induced selection. Similarly, the selection was more

efficient with long-chain (16–18 carbons) than with very-long-chain monounsaturated FAs (22 carbons). Finally, docosahexaenoic acid at 1 mM concentration prevented even the growth of *DGAT*-expressing cultures, suggesting that Bn*DGAT1* might not efficiently utilize very-long-chain and/or polyunsaturated substrates (Fig. 3).

Although we did not investigate the biochemical mechanism of growth inhibition on FA-containing media, Zhang et al. [45] have demonstrated the inhibitory role of cellular DAG accumulation in a fission yeast strain (*Schizosaccharomyces pombe*) lacking the main TAG-synthesizing enzymes. Unlike *S. cerevisiae*, where FA exposure apparently led to a prolonged lag phase in a concentration-dependent manner, similar treatment in *S. pombe* caused apoptosis of cells in their stationary phase. We did not observe an FA-induced growth inhibition in the *S. cerevisiae* mutant 12501 where PDAT, another enzyme using DAG as acyl-acceptor encoded by *LROI*, was intact (Fig. 2b). It is therefore likely that the FA-induced growth inhibition in baker's yeast is also a result of the accumulation of DAG which is indeed considered an important regulator of many metabolic networks [46].

In summary the methods described here have broad applicability for studies involving *DGAT* and possibly other TAG-SE. Most genes encoding these enzymes have been isolated by usual DNA or polypeptide homology-based cloning. The functional complementation assay on FA-containing media could accelerate the identification of novel genes involved in TAG synthesis from genomes or tissues that have not been yet explored. Moreover, the combination of FACS with heterologous expression of target cDNAs in the H1246 background could also provide efficient tools for identifying enzymes involved in the biosynthesis of other neutral lipids, directed evolution of such enzymes and identification of their potential modulators. Experiments exploring these possibilities have been initiated in our laboratory.

Acknowledgments We thank S. Szymne and U. Ståhl for providing the yeast strain H1246 and the corresponding parental line and C. Snyder for reviewing the manuscript. This research was supported by AVAC Ltd., the Natural Science and Engineering Research Council of Canada and the Canada Research Chairs Program.

Abstract Conjugated linoleic acid (CLA) reduces body weight and adipose mass in a variety of species. The mechanisms by which CLA depletes adipose mass are unclear, but two independent microarray analyses indicate that in white adipose tissue (WAT), uncoupling protein 1 (UCP1) was among genes most changed by CLA. The objective of this study was to determine whether CLA induces ectopic expression of UCP1 in WAT, which may contribute to increased energy expenditure and weight loss. Six-week old, male *ob/ob* mice were fed either a control diet (CON) or a diet supplemented with 1.5% mixed isomer CLA (CLA) for 4 weeks. A third group of mice (LEPTIN) was fed the control diet and received daily injections of recombinant leptin as a positive control for adipose depletion in *ob/ob* mice. CLA did not alter several mRNA markers of lipid oxidation in epididymal white adipose

tissue (eWAT), but significantly increased carnitine palmitoyltransferase-1b (CPT1b) and PPAR gamma coactivator-1 α (PGC1 α) expression. Notably, CLA increased both mRNA and protein expression of uncoupling protein-1 (UCP1). β 3-adrenoceptor mRNA and phosphorylated-p38 mitogen activated protein kinase (MAPK) protein levels were not affected by CLA, but were upregulated by LEPTIN. These data suggest the increased CPT1b, PGC1 α , and UCP1, in WAT of CLA-fed mice may contribute to the depletion of adipose, and CLA does not appear to increase UCP1 through β 3-adrenergic signaling. Future studies will focus on understanding how CLA increases mitochondrial oxidation and energy dissipation in white adipose tissue.

WAT	White adipose tissue

Introduction

Conjugated linoleic acid (CLA) is a group of dietary fatty acids that has received considerable attention due to its ability to significantly reduce adipose mass in a variety of species [1–4]. While these dienoic isomers of linoleic acid are naturally found in products derived from ruminants, such as dairy and beef, CLA is also commercially available as a mixed isomer, weight loss supplement. CLA, specifically the *trans*-10, *cis*-12 isomer, probably reduces adipose through a combination of mechanisms including apoptosis, decreased preadipocyte differentiation and lipogenesis, and increased fatty acid oxidation and energy expenditure [5]. However, the data are conflicting, and therefore, the mechanisms by which CLA depletes adipose remain unclear. Several studies report CLA decreases adipose mass concomitant with increased energy expenditure [6–10], but the results are inconsistent as to whether CLA increases energy expenditure through increased fatty acid oxidation or by another mechanism. Several groups have postulated that increased energy expenditure by CLA may be due to increased thermogenesis, yet CLA does not change, or in some reports, decreases uncoupling protein 1 (UCP1) expression in brown adipose tissue (BAT) [7, 8, 11–13].

UCP1 mediates adaptive thermogenesis in brown adipose tissue (BAT) by uncoupling respiration, generating heat instead of ATP. Under normal physiological conditions, UCP1 is expressed almost exclusively in BAT, which, unlike white adipose tissue (WAT), is rich in mitochondria and has a high oxidative capacity, thereby contributing to energy expenditure [14, 15]. In addition to thermogenesis, the roles of UCP1 and BAT have expanded to include preventing or reducing adiposity. Mice with genetic ablation of BAT become hyperphagic and obese [16]. Mouse strain differences in susceptibility to diet-induced metabolic syndrome can be partly attributed to increased ectopic expression of UCP1 [17]. Notably, treating rodents with a β 3-adrenergic receptor agonist [18–23] or leptin [24, 25] stimulates ectopic expression of UCP1 in WAT and prevents or reduces adiposity. Two independent microarray analyses of WAT from mice fed CLA report that UCP1 was among genes most differentially expressed [26, 27]. An increase in ectopic UCP1 in WAT by CLA may have a significant role in the CLA-mediated reduction of adiposity. Therefore, the objective of this study was to determine whether CLA induces ectopic expression of UCP1 in WAT.

Research Design and Methods

Experimental Design

In this study, we continued our analyses of mice described previously [28]. Six-week old, male B6.V-*Lepob/OlaHsd*

(*ob/ob*) mice (Harlan, Indianapolis, IN) were housed 4/cage at 22 ± 0.5 °C on a 12-h light/dark cycle. Diets were isocaloric, modified AIN-93G diets (Bio-Serv, Frenchtown, NJ) containing 6.5% fat by weight. Mice received either a control diet that contained 6.5% soybean oil (CON; $n = 8$) or a CLA-supplemented diet containing 5% soybean oil and 1.5% CLA mixed triglycerides (CLA; $n = 8$). CLA mixed triglycerides (Tonalin TG 80, Cognis Corp., Cincinnati, OH) were ~80% CLA composed of 39.2% *c9t11*- and 38.5% *t10c12*-CLA isomers. Leptin increases energy expenditure through induction of UCP1 expression in WAT via a β -3 adrenoceptor mediated pathway [25], therefore, a third group of mice received the control diet and an intraperitoneal injection of 1 mg/kg BW recombinant mouse leptin (R&D Systems, Minneapolis, MN) (LEPTIN; $n = 8$). CON and CLA mice received injections of similar volumes of the vehicle (PBS). Mice were injected daily, 2 h before the onset of the dark cycle. Food intake between mice treated with LEPTIN or CLA was similar (13.5 vs. 12.4 g/day per 4 mice, respectively; $P = 0.56$). At 4 weeks, after an overnight (12 h) fast, mice were anesthetized with isoflurane and blood was collected via cardiac puncture. Epididymal adipose was quickly harvested, weighed, snap-frozen with liquid nitrogen, and stored at -80 °C until analyses. All procedures were in accordance with institution guidelines and approved by the Institutional Animal Care and Use Committee of The Ohio State University.

Analysis of Serum Lipids

Serum free fatty acids, glycerol, and triglyceride were determined using colorimetric kits (NEFA C, Wako Chemicals, Richmond, VA and Free-Glycerol and triglyceride reagents, Sigma, St. Louis, MO, respectively).

Real-time RT-PCR

RNA was extracted from epididymal adipose tissue using the RNeasy® Lipid Tissue Mini kit (Qiagen, Valencia, CA) according to manufacturers' protocols. RNA was reverse transcribed with High Capacity cDNA Archive Kit (ABI, Foster City, CA) according to directions and then amplified by real-time PCR using pre-designed and validated primers (FAM probes) under universal cycling conditions defined by ABI (TaqMan Gene Expression Assays, ABI, Foster City, CA). Target gene expression was normalized to the endogenous control 18S (VIC probe) amplified in the same reaction and expressed as $2^{-\Delta\Delta Ct}$ relative to the CON group [29] for each gene.

Western Blot Analyses

Epididymal adipose tissue was homogenized in 3 volumes of ice cold lysis buffer (20 mM Trizma base, 50 mM NaCl,

250 mM sucrose, 50 mM NaF, 5 mM $\text{Na}_4\text{P}_2\text{O}_7 \cdot 10\text{H}_2\text{O}$, 1% Triton-X100, and protease inhibitors). Protein concentrations were measured by the bicinchoninic acid (BCA) method (Pierce, Rockford, IL). Either 40 (AMPK and p38 MAPK) or 80 μg (UCP1) of protein was mixed and boiled for 5 min with 4 \times loading buffer (125 mM Tris HCl at pH 6.8, 50% glycerol, 4% SDS, 0.02% Bromophenol Blue) and β -mercaptoethanol and subjected to SDS-PAGE using 10% gels for 1 h. Protein was then transferred to 0.45 μm nitrocellulose membranes for 1 h at 120 V on ice. Membranes were probed for P-AMPK, P-p38 (Cell Signaling Technology, Inc., Danvers, MA), or UCP1 (AbCam Inc., Cambridge, MA) according to manufacturer's protocol. Membranes were incubated in SuperSignal West Femto Maximum Sensitivity Substrate (Pierce, Rockford, IL) for 5 min. Densities of bands were detected and measured by Kodak ImageStation 2000RT using 1D Kodak software. Membranes were stripped with RestoreTM Western Blot Stripping Buffer (Pierce, Rockford, IL) for 30 min at RT and reprobed with total-AMPK, -p38, or β -actin (Cell Signaling).

Statistical Analyses

Data are expressed as least square means (LSM) \pm standard error (SE). Data were analyzed by one-way ANOVA using the GLM procedure of Statistical Analysis System (SAS v9.1; SAS Institute Inc., Cary, NC) with Dunnett's adjustment for post hoc analysis using CON as the control. Differences of $P < 0.05$ were considered significant.

Results

CLA Did Not Induce Markers of Lipolysis

As we previously reported [28], mice from both LEPTIN (34.79 g \pm 0.99) and CLA (28.98 g \pm 0.99) treatments had significantly lower final body weights compared to CON mice (42.20 g \pm 0.9). LEPTIN (2.16 g \pm 0.14) and CLA (1.71 g \pm 0.14) treatments also significantly decreased epididymal adipose masses compared to CON (2.96 g \pm 0.14). Elevated serum non-esterified fatty acids (NEFA) and glycerol concentrations may indicate increased adipose lipolysis. After 4 weeks of treatments, neither CLA nor LEPTIN altered serum NEFA or glycerol concentrations (Table 1). Expression of adipose triglyceride lipase (ATGL) and hormone sensitive lipase (HSL), two prominent lipases involved in lipolysis in adipose tissue, was measured in eWAT. CLA did not change ATGL but decreased HSL mRNA expression (Table 1). LEPTIN did not change HSL but increased ATGL mRNA expression.

Table 1 Effects of CLA on markers of lipolysis

	CON	LEPTIN	CLA
Serum triacylglycerol (mg/dl)	88.1 \pm 16.2	122.9 \pm 14.0	131.4 \pm 16.2
Serum NEFA (mequiv/L)	0.90 \pm 0.09	0.83 \pm 0.09	1.03 \pm 0.09
Serum glycerol (mg/dl)	5.9 \pm 0.9	5.8 \pm 0.8	3.8 \pm 1.1
eWAT ATGL mRNA ^a	1.05 \pm 0.09	1.39 \pm 0.09*	1.03 \pm 0.09
eWAT HSL mRNA ^a	1.07 \pm 0.09	1.18 \pm 0.09	0.6 \pm 0.09*

Values represent LSM \pm SE ($n = 7-8$) with significant differences ($P < 0.05$) from CON denoted by *

^a mRNA was measured from eWAT of fasted mice by real time RT-PCR. Data are expressed as $2^{-\Delta\Delta\text{Ct}}$ relative to the 18S endogenous control and the CON group

CLA Increased mRNA Expression of Markers of Fatty Acid Uptake and β -Oxidation in eWAT

Figure 1a shows that both CLA and LEPTIN decreased lipoprotein lipase (LPL), whereas, CLA and LEPTIN increased fatty acid transporter (FAT/CD36) mRNA, a marker of fatty acid uptake. Both CLA and LEPTIN decreased mRNA of sterol receptor element binding protein-1 (SREBP-1), a marker of lipogenesis, but only LEPTIN decreased mRNA of its downstream target, fatty acid synthase (FAS). Both CLA and LEPTIN also reduced expression of peroxisome proliferator activated receptor- γ (PPAR γ) by approximately 60%. CLA and LEPTIN did not alter mRNA levels of several markers of fatty acid oxidation: PPAR α , acyl-coA oxidase-1 (ACOX1), and carnitine palmitoyltransferase-1a (CPT1a) (Fig. 1a). However, CLA significantly increased CPT1b mRNA by nearly 25-fold (Fig. 1b).

To determine the involvement of signaling upstream of β -oxidation, we examined levels of phosphorylated (P-) and total-AMPK in eWAT. CLA, but not LEPTIN, significantly increased the ratio of P-AMPK relative to total-AMPK (Fig. 2) in eWAT. However, neither CLA nor LEPTIN increased P-ACC/total ACC, the downstream target of AMPK (data not shown).

CLA Increased Ectopic Expression of UCP1 mRNA and Protein in eWAT

After 4 weeks of treatments, CLA significantly increased ectopic expression of UCP1 mRNA by 89-fold (Fig. 3a) and protein by approximately 7.8-fold (Fig. 3b) in eWAT. As expected, LEPTIN increased UCP1 mRNA expression \sim 57-fold over CON (Fig. 3a; $P = 0.055$). However, LEPTIN did not alter protein levels of UCP1 in eWAT (Fig. 3b). CLA also significantly increased UCP2, but not UCP3 mRNA expression (Fig. 3c, d, respectively).

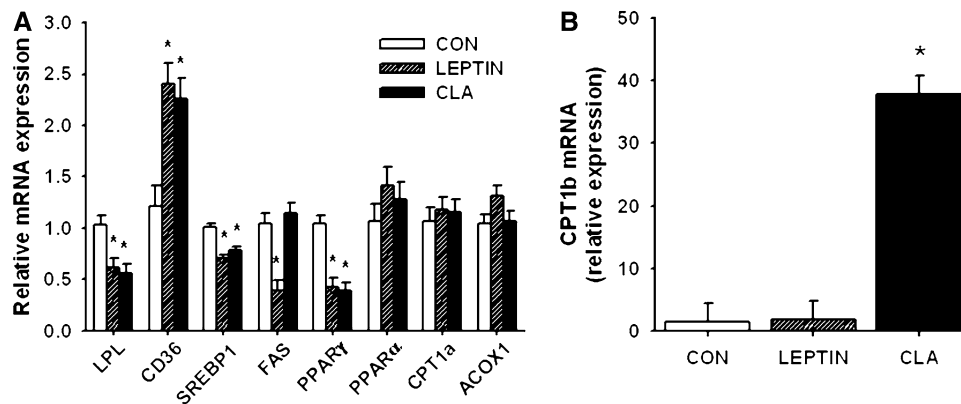

Fig. 1 Effects of CLA on markers of lipid metabolism in eWAT. **a** mRNA expression of markers of lipid uptake (*LPL* and *CD36*), lipogenesis (*SREBP1* and *FAS*), and lipid oxidation (*PPARα*, *CPT1a*, and *ACOX1*). **b** *CPT1b* mRNA expression. Mice were fed a control diet and treated with vehicle (*CON*) or leptin (*LEPTIN*) or fed a CLA-supplemented diet and treated with vehicle (*CLA*). After 4 weeks,

mRNA was measured from eWAT of fasted mice by real-time RT-PCR. Data are expressed as $2^{-\Delta\Delta Ct}$ relative to the 18S endogenous control and the *CON* group for each gene. Values represent LSM \pm SE ($n = 8$) with significant differences ($P < 0.05$) from *CON* denoted by asterisks

Conversely, *LEPTIN* did not change *UCP2* expression, but significantly increased *UCP3* mRNA expression in eWAT (Fig. 3c, d, respectively).

Effects of CLA on the Regulation of *UCP1*

Increased *UCP1* transcription may be mediated through induction of *PGC1α* and β_3 adrenergic signaling [30]. We, therefore, measured transcript levels of *PGC1α* and β_3 adrenoceptor (β_3AR). Both *CLA* and *LEPTIN* significantly increased expression of *PGC1α* in eWAT (Fig. 4a). Unlike *LEPTIN*, which increased β_3AR mRNA expression 4.3-fold, *CLA* did not alter levels of β_3AR (Fig. 4b). Phosphorylation of p38 mitogen activated protein kinase (*MAPK*) is a critical signaling step in β_3 adrenergic induction of *PGC1α* and *UCP1* [30]. Similar to the trend in β_3AR expression, *LEPTIN*, but not *CLA*, increased P-p38/total-p38 *MAPK* protein expression (Fig. 4c). *CLA*, but not *LEPTIN*, decreased mRNA expression of *RIP140*, a repressor of *UCP1* transcription [31]; however, the decrease was not statistically significant (Fig. 4d). Because *UCP1* is highly expressed in *BAT*, but was induced by *CLA* in eWAT, we measured mRNA expression of *Cidea* (cell-death-inducing DFF45-like effector), which is expressed in several tissues at low levels but at high levels in *BAT* and is therefore considered a *BAT*-specific marker [32]. While *LEPTIN* did not affect levels of *Cidea*, *CLA* significantly increased *Cidea* mRNA expression by 2.5-fold (Fig. 4e).

Discussion

The ability of *CLA* to reduce adipose mass dramatically in a variety of species has received considerable attention.

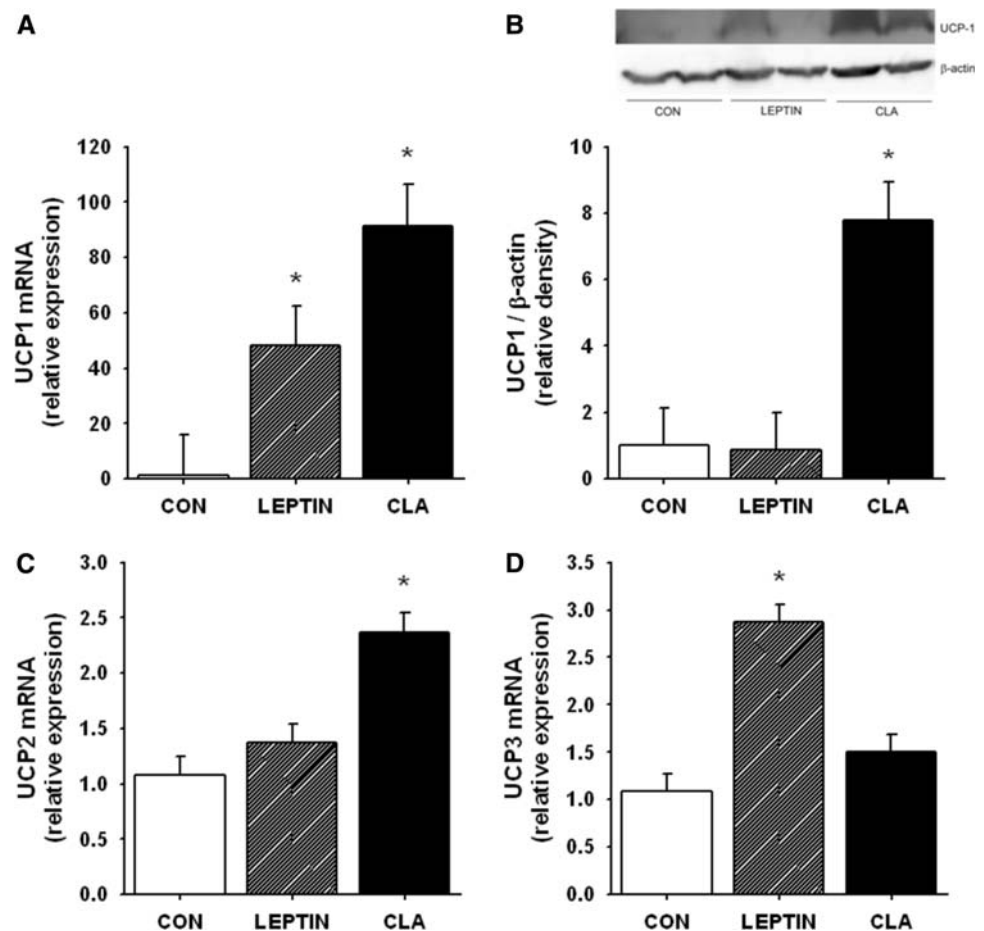

Fig. 2 Effect of *CLA* on activation of *AMPK* in eWAT. Mice were fed a control diet and treated with vehicle (*CON*) or leptin (*LEPTIN*) or fed a *CLA*-supplemented diet and treated with vehicle (*CLA*). After 4 weeks, expression of P-*AMPK* and total-*AMPK* were measured from eWAT of fasted mice by Western blot analysis. A representative blot is shown. Values represent LSM \pm SE ($n = 8$) with significant differences ($P < 0.05$) from *CON* denoted by asterisks

However, the mechanisms by which *CLA* induces *WAT* loss remain unclear. Previously, we reported that in *ob/ob* mice, *CLA* decreases body weight and adipose mass [28]. In the present study, we report that in these same mice, *CLA* increased both *UCP1* mRNA by 89-fold and protein expression by over 7-fold in eWAT. These observations suggest that *CLA* depletes adipose mass by inducing ectopic uncoupled oxidation in *WAT*.

Fig. 3 Effect of CLA on UCP expression in eWAT. **a** UCP1 mRNA; **b** Analysis of UCP1 protein expression in eWAT of fasted mice by Western blot with β -actin to show equal loading. A representative blot is shown; **c** UCP2; and **d** UCP3 mRNA expression. mRNA was measured from eWAT of fasted mice by real time RT-PCR. Data are expressed as $2^{-\Delta\Delta Ct}$ relative to the 18S endogenous control and the CON group for each gene. Values represent LSM \pm SE ($n = 7-8$) with significant differences ($P < 0.05$) from CON denoted by asterisks

CLA rapidly and significantly reduces body weight and adipose mass in as little as 6 days in C57Bl/6J mice [33, 34]. However, hepatomegaly and hepatic lipid accumulation [13, 35, 36] also occurs with CLA-induced weight loss, resulting in lipodystrophy. The redistribution of lipid, coupled with increased lipolysis, as observed in several in vitro studies [3, 37, 38] may partially account for the loss of WAT mass. We previously reported that compared to CON, both CLA and LEPTIN reduce body weight by 33 and 18%, respectively. Additionally, CLA and LEPTIN decrease epididymal adipose mass by 54 and 27%, respectively [28]. However, as opposed to LEPTIN, the changes in body weight and adipose mass induced by CLA were not accompanied by decreased lipid accumulation in other tissues or altered molecular markers of lipogenesis and fatty acid oxidation in liver or skeletal muscle. LEPTIN decreased both hepatic [28] and muscle (unpublished data) TAG, whereas, CLA did not change TAG contents of either liver [28] or gastrocnemius muscle (unpublished data). In this study, we report that CLA did not increase HSL and ATGL expression in eWAT or serum NEFA or glycerol concentrations, supporting previous in vivo data [39, 40]. These data suggest that lipids were not being mobilized from adipose and accumulating or being

oxidized in non-adipose tissues. However, CLA increased FAT/CD36 mRNA expression, suggesting fatty acid uptake was increased into eWAT. The fate of this assumed increase in lipid uptake in eWAT was unclear, as it was obviously not being stored. While others have shown CLA generally reduces markers of lipogenesis, [13, 26, 27, 41, 42], the slight changes in markers of lipogenesis in eWAT of this study suggests decreased lipogenesis in adipose does not play a significant role in CLA depletion of adipose, especially in a system which ectopic lipid accumulation does not seem to occur.

Previous studies have demonstrated that CLA increases fatty acid oxidation in adipose in both in vitro and in vivo models, but the results are somewhat contradictory. McIntosh's group reported that CLA increased fatty acid oxidation in 3T3-L1 preadipocytes [38] but later showed CLA decreased fatty acid oxidation in human adipocytes derived from primary stromal vascular cells [43]. Others [44, 45] have reported increased CPT activity in rats fed CLA, and analyses of differential gene expression in WAT of CLA-fed mice show a general increase in mRNA expression of genes involved in fatty acid oxidation, most notably, CPT1a and CPT1b [26, 27]. We did not find significant differences in either PPAR α or downstream targets,

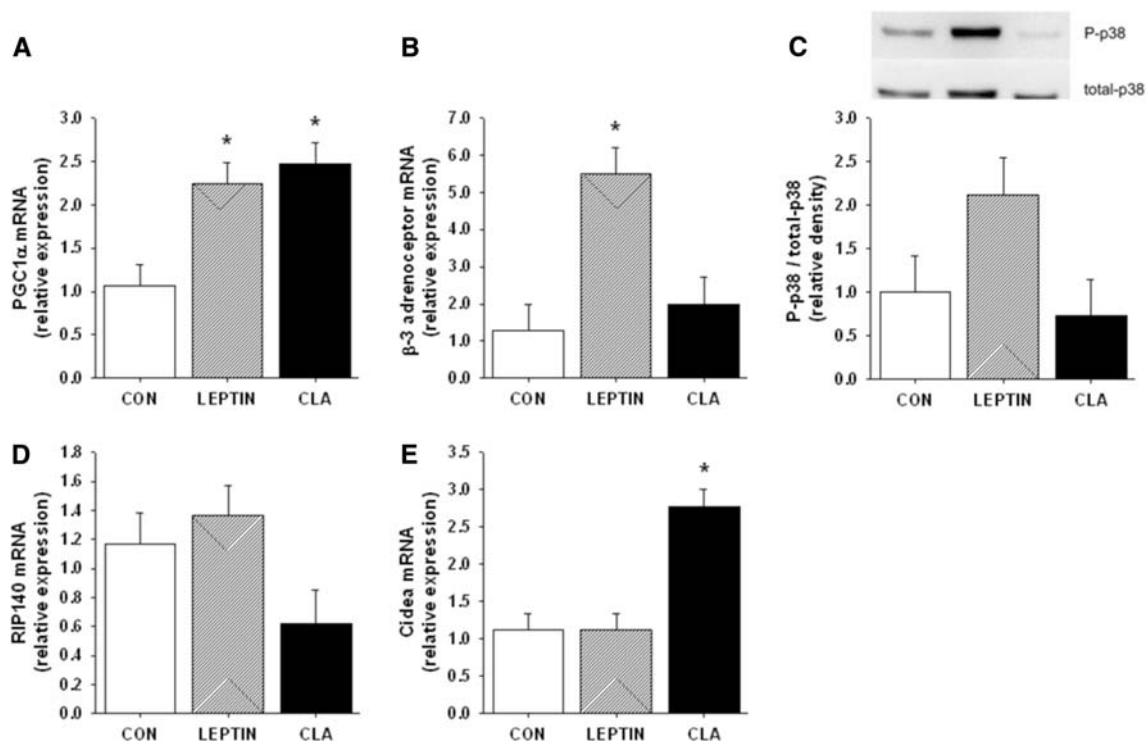

Fig. 4 Effects of CLA on the regulation of UCP1. **a** PGC1 α mRNA; **b** β -3 adrenoceptor mRNA; **c** Analysis of p38 MAPK protein activation. P-p38 and total-p38 MAPK were measured by Western blotting. A representative blot is shown; **d** RIP140 mRNA; and **e** Cidea mRNA. mRNA was measured from eWAT of fasted mice by

real time RT-PCR. Data are expressed as $2^{-\Delta\Delta Ct}$ relative to the 18S endogenous control and the CON group for each gene. Values represent LSM \pm SE ($n = 7-8$) with significant differences ($P < 0.05$) from CON denoted by asterisks

CPT1a and ACOX1, genes involved with mitochondrial and peroxisomal fatty acid oxidation, respectively, in eWAT. However, CLA greatly increased CPT1b, which is highly expressed in muscle and BAT [46]. The combined increases in FAT/CD36 and CPT1b expression implied that fatty acids were being taken up into adipocytes and mitochondria for oxidation.

The protons created from the influx and subsequent oxidation of fatty acids in the mitochondria usually drive ATP generation, as in normal oxidative phosphorylation. Alternatively, uncoupling proteins can dissipate the proton gradient, producing heat instead of ATP and increasing energy expenditure [14]. While UCP1 clearly mediates adaptive thermogenesis and increases energy expenditure [47], the contributions of UCP2 and UCP3 to thermogenesis and energy expenditure is controversial. Rather, UCP2 seems to have a role in preventing reactive oxygen species generation and inflammation [48]. In this study, CLA increased eWAT UCP2 expression over twofold and was associated with increased eWAT macrophage infiltration (previously reported [28]). This is consistent with other reports that CLA increases UCP2 in WAT [11–13, 49]. The increased UCP2 and associated WAT inflammation and apoptosis [13] likely contribute to the mechanism by which CLA induces insulin resistance.

While uncoupled energy expenditure is generally used for non-shivering thermogenesis, the role of ectopic UCP1 in WAT depletion is strengthening. Both overexpressing UCP1 in WAT [23] and stimulation with β_3 -adrenergic agonists [18–22] prevents or reverses obesity in rodents. Furthermore, upon stimulation with β_3 AR agonists or with leptin, WAT adopts brown adipose-like characteristics, including increased UCP1 expression [18–20, 50], increased mitochondrial biogenesis [50, 51], and a multilocular morphology [18–20, 50, 51]. Additionally, transgenic expression of UCP1 in white adipose has been associated with activation of AMPK and increased fatty acid oxidation [52]. Previous studies report that CLA does not change or decreases UCP1 expression in BAT [7, 8, 11–13], suggesting CLA does not increase energy expenditure through thermogenesis in BAT. Nevertheless, two independent microarray analyses of WAT from mice fed CLA report that UCP1 was among genes most differentially expressed [26, 27]. Peters et al. [49] has also reported that UCP1 mRNA expression is increased in gonadal WAT. In the present study, CLA robustly increased both UCP1 mRNA and protein expression in eWAT. This was accompanied by increased eWAT expression of genes associated with an oxidative phenotype, CPT1b and PGC1 α . These data suggest that CLA increases energy expenditure by increasing uncoupled oxidation in WAT.

UCP1 transcription is mediated through β_3 adrenergic signaling and PGC1 α , a cofactor for PPAR- α and - γ that target the enhancer region of UCP1 [53]. The β_3 AR-mediated stimulation of UCP1 is dependent on a cascade of events, notably activation of p38 MAPK [30, 54] and subsequent phosphorylation of transcription factors that act directly at the UCP1 promoter region as well as indirectly by regulating PGC1 α . Stimulation of the sympathetic nervous system by leptin increases transcription of UCP1 through β_3 AR signaling [55]. Appropriately, LEPTIN increased both β_3 AR mRNA expression and P-p38 MAPK protein expression. CLA, conversely, did not alter expression of either of these markers, suggesting CLA did not increase UCP1 expression through β_3 AR signaling. However, CLA increases serum noradrenaline and adrenaline levels 2 h after administration concomitant with increased oxygen consumption and fat oxidation, possibly by stimulating sympathetic nervous activity via β_3 AR signaling [56]. The lack of effect after 4 weeks of CLA-supplementation, therefore, does not rule out possible β_3 AR stimulation in earlier events.

In summary, this study demonstrates that, in *ob/ob* mice, CLA-induced depletion of adipose is accompanied by increased WAT expression of markers of uncoupled energy dissipation, CPT1b, PGC1 α , and UCP1. Furthermore, CLA does not appear to increase UCP1 through β_3 AR signaling, but perhaps by some other mechanisms. Understanding the mechanisms by which unique fatty acids, such as CLA, enhance energy expenditure in WAT will contribute to the development of therapeutic prevention and treatment of obesity and type 2 diabetes.

Acknowledgments We thank all of the members of the Belury lab for their assistance with care and feeding of mice and discussions of the work in this manuscript. Abstract Conjugated linoleic acid (CLA) is a popular supplement believed to enhance immune function, body composition and insulin sensitivity, but results of scientific studies investigating its effects are conflicting. The isomer- and tissue-specific effects of CLA may explain these conflicting results. Therefore, this study quantified the incorporation of the *c9t11* and *t10c12* CLA isomers into adipose tissue and skeletal muscle in response to supplementation in healthy, regularly-exercising, non-obese persons. The CLA group ($n = 14$) ingested 3.9 g per day CLA (50:50 *t9c11*:*c10t12*) and the placebo group ($n = 11$) 3.9 g per day high-oleic-acid sunflower oil for 12 weeks. Following supplementation, the *t10c12* isomer was incorporated into adipose tissue triacylglycerol ($P < 0.001$), and the *c9t11* isomer tended to increase in skeletal muscle phospholipids ($P = 0.056$). Therefore, human adipose tissue and skeletal muscle are enriched with CLA in an isomer-specific manner.

Keywords CLA supplementation · Isomer-specific fatty acid incorporation · Adipose tissue triacylglycerol · Skeletal muscle phospholipids

CLA Conjugated linoleic acid
TAG Triacylglycerol

Introduction

Conjugated linoleic acid (CLA) is the generic name for the mixture of isomers of linoleic acid, an 18-carbon polyunsaturated fatty acid. The most common CLA isomers contain double bonds in the 9 and 11, 10 and 12 and 11 and 13 positions, in either the *cis* or *trans* positions. This fatty acid, which is primarily obtained from the food products of ruminant animals, but can also be manufactured, is a popular supplement believed to enhance immune function [1, 2], body composition [3–6] and insulin sensitivity. However, the numerous clinical trials conducted in humans to investigate the effects of CLA supplementation have produced varying, and sometimes conflicting results [4, 5, 7–13].

Each CLA isomer is thought to have a distinct mode of action [14–17], and in some instances these actions are antagonistic. For example, cell culture studies have shown that the *c9t11* CLA isomer appears to be more effectively incorporated in tissue membranes and lipid droplets, and may in fact increase triglyceride content in humans; while the *t10c12* CLA isomer may be better metabolised in the β -oxidation pathway and is thought to be anti-adipogenic in nature [11, 18–20]. Since most of the studies to date

have used CLA preparations containing varying amounts and ratios of up to four isomers, the unique and sometimes opposing actions of the isomers may, in part, explain the inconsistent results.

A first step towards understanding the clinical effects of CLA supplementation in humans is to determine which tissues may be enriched with CLA in response to supplementation. We propose that incorporation of CLA isomers into human tissue is both tissue and isomer-specific. Therefore the result of any given trial might be a reflection of the quantity of a specific isomer present in the supplement as well as its site of incorporation and subsequent effect within the target tissue. Adipose tissue and skeletal muscle are regarded as important tissues with respect to adipogenesis and insulin sensitivity, two factors believed to be altered by CLA supplementation. Therefore, changes in their fatty acid profile, specifically the CLA isomers, may provide the basis for understanding the clinical effects of CLA supplementation. Accordingly, the aim of this study was to measure the incorporation of the *c9t11* and *t10c12* CLA isomers into adipose tissue and skeletal muscle in apparently healthy, non-obese, exercising individuals supplementing with a commercially available 50:50 *c9t11:t10c12* CLA preparation.

Experimental Procedures

This experiment formed part of a larger study, the detailed design of which has been reported previously [21], and was approved by the Research and Ethics Committee of the Faculty of Health Sciences, University of Cape Town. All volunteers signed consent forms agreeing to participate in the trial. Briefly, in this double-blind study, 25 non-obese, regularly exercising, apparently healthy white male and female volunteers, aged 21–45 years, were randomly assigned to either the experimental (CLA, $n = 11$) or control (placebo, $n = 14$) groups. Only individuals who were exercising at least three times per week at the time of the study and had been doing so for the past six months, were not obese ($\text{BMI} < 30 \text{ kg m}^{-2}$), had maintained a stable weight ($\pm 2\text{--}3 \text{ kg}$) for the three months preceding the trial, did not suffer from any chronic illness, and were not taking any medication or nutritional supplements (other than a general multi-vitamin) were included in this study. Lactating women, or those planning on becoming pregnant, were excluded.

All volunteers underwent a two week placebo ‘run-in’ period, followed by baseline testing, 12 weeks of supplementation and follow-up testing, as described previously [21]. They were asked to keep their training and diet constant throughout the trial and met with registered dietitians every two weeks who monitored any adverse

responses to supplementation, changes in training, lifestyle or eating patterns, and pill compliance.

The 3.9 g daily CLA supplement, taken each morning in the form of four capsules, consisted primarily of the *c9t11* (29.7%) and *t10c12* (30.9%) isomers, as well as other CLA isomers (2.9%) and oleic (18:1 *n*-9; 24.7%), palmitic (16:0; 3.5%), linoleic (18:2 *n*-6; 1.9%) and stearic (18:0; 1.3%) acid (Formule Naturelle Ltd., France, containing Clarinol™ from Lodders Croklaan, Lipid Nutrition, The Netherlands). The placebo capsules contained 3.9 g of high oleic acid sunflower oil.

Fasting (10–12 h) gluteal adipose tissue biopsies were obtained prior to and after the 12-week supplementation period. Biopsies of the vastus lateralis muscle [22] were also obtained from a sub-sample of participants (6 CLA, 6 Placebo). The samples were stored at $-80 \text{ }^{\circ}\text{C}$ and subsequently used to determine the fatty acid composition of the adipose tissue and muscle triacylglycerols (TAG), and the muscle membrane phospholipids.

The frozen muscle samples were thawed and homogenised using a mortar and pestle [23]. Total lipids were extracted from approximately 20 mg (wet weight) portions of the muscle tissue and from 10 mg of the frozen adipose tissue using chloroform:methanol (2:1 v/v) according to a modified method of Folch et al. [24]. All the extraction solvents contained 0.01% butylated hydroxytoluene (BHT) as an antioxidant. Heptadecanoic acid (C17:0) was used as an internal standard to quantify the individual fatty acids. TAG were separated from total phospholipids by thin-layer-chromatography (TLC) on pre-coated silica gel 60 plates (10 × 10 cm) without a fluorescent indicator (Art. 1.05721; Merck, Darmstadt, Germany) using the solvent system petroleum benzene (bp 40–60 °C):diethyl ether (peroxide free):acetic acid (90:30:1 v/v/v). The lipid bands were visualised with long wave ultraviolet light after spraying the plates with chloroform:methanol (1:1 v/v) containing 2,5-bis-(5'-*tert*-butylbenzoxazolyl-[2'])thiophene BBOT (10 mg/100 ml) (Sigma Chemical Co.).

The TAG and the total phospholipid bands from muscle tissue and the TAG band from adipose tissue were scraped off and analysed for fatty acid composition. The different lipid classes were transmethylated using 5% H_2SO_4 /methanol at 70 °C for 2 h. After cooling, the resulting fatty acid methyl esters (FAMES) were extracted with 1 ml of water and 2 ml of *n*-hexane. The FAME were purified by TLC and analysed by gas liquid chromatography (Varian Model 3300 equipped with flame ionisation detection) using 60 m BPX70 capillary columns of 0.25 mm internal diameter (SGE, Australia). The gas flow rate for hydrogen was 25 ml min^{-1} and $2\text{--}4 \text{ ml min}^{-1}$ for the hydrogen carrier gas. The initial column temperature was held at 150 °C for 18 min, followed by a linear programming at $3 \text{ }^{\circ}\text{C min}^{-1}$ with a final temperature of 220 °C, an injector temperature

of 240 °C and a detector temperature of 250 °C. The FAME were identified by comparison of the retention times to those of a standard FAME mixture (Nu-Chek-Prep Inc., Elysian, MN, USA). The fatty acid composition of the different lipid classes was expressed as a percentage of the total fatty acids identified.

Baseline characteristics of the CLA and placebo groups were compared using an independent *t* test. Two-way repeated measures ANOVA was used to examine the effects of supplementation on all measured variables. Correlations were performed using a Pearson product moment test. Statistical significance was accepted at $P < 0.05$. All results are presented as mean \pm SD.

Results

The groups had similar baseline body composition, fasting glucose and insulin levels, and insulin resistance [as estimated by the Homeostasis Assessment Model (HOMA) and the Insulin Sensitivity Index (ISI)] prior to supplementation (Table 1). All participants completed this trial, pill compliance was above 90% for both groups, and of the few adverse events reported both groups tolerated the supplements equally [21]. Following 12 weeks of supplementation, significantly higher levels of the *t10c12* isomer ($P < 0.001$) and oleic acid ($P = 0.019$) were present in adipose tissue TAG in the CLA group than in the Placebo group (Table 2). The *c9t11* isomer, linoleic acid, total saturated, monounsaturated and polyunsaturated fatty acid (Table 2) and all other fatty acid (data not shown) levels measured did not change over the supplementation period.

There was a trend for the *c9t11* isomer ($P = 0.056$) and oleic acid ($P = 0.055$) to be incorporated into the skeletal muscle phospholipids of the CLA group, however, there was no evidence of incorporation of CLA isomers into skeletal muscle TAG (Table 2). The *t10c12* isomer was not present in the phospholipids and supplementation did not change the levels of linoleic acid, total saturated, mono-unsaturated or polyunsaturated fatty acids (Table 2) or any of the other fatty acids (data not shown) measured.

Twelve weeks of CLA supplementation did not alter body composition, glucose or insulin parameters (Table 1), or the serum lipid profiles (data not shown) of the two groups. Dietary analysis indicated that the contributions of saturated (CLA: $13.4 \pm 9.1\%$, placebo: $11.4 \pm 5.7\%$, $P = 0.570$), monounsaturated (CLA: $9.4 \pm 3.5\%$, placebo: $7.4 \pm 2.5\%$, $P = 0.094$) and polyunsaturated (CLA: $6.5 \pm 3.0\%$, placebo: $6.4 \pm 2.7\%$, $P = 0.900$) fats to the diet were similar in both groups prior to the trial and remained constant during the trial (data not shown). Lastly, reported physical activity energy expenditure remained constant throughout the trial for all subjects ($P = 0.433$).

Discussion

Few studies have investigated the in vivo effects of CLA supplementation in humans on tissue-specific CLA isomer incorporation. This is the first study, to the best of our knowledge, to show that 12 weeks of supplementation with a 50:50 *c9t11*:*t10c12* CLA preparation results in incorporation of the *t10c12* isomer into adipose tissue TAG in humans.

Table 1 Baseline characteristics (pre) and subsequent changes (post) in response to 12 weeks of supplementation

	CLA ($n = 11$)		Placebo ($n = 14$)		<i>P</i> value

The significance of this finding may lie in adipose tissue's role in lipid storage and/or insulin resistance. The *t10c12* isomer of CLA is believed to inhibit the actions of lipoprotein lipase and stearoyl-CoA-desaturase, which would inhibit the uptake of lipids into adipocytes (reviewed in Pariza 2001) [25]. The *t10c12* CLA isomer has also been proposed to increase insulin resistance in human adipocytes, possibly by antagonising peroxisome proliferator-activated receptor γ signalling, which in turn may indirectly reduce the expression of insulin-stimulated glucose transporter 4 and insulin-stimulated glucose uptake in adipocytes ([14] and reviewed in [19]).

Whether there is an association between the incorporation of the *t10c12* isomer into adipose tissue and its

subsequent effect on lipid uptake or insulin sensitivity in humans supplementing with CLA remains to be determined, since we did not see any change in insulin sensitivity in this group of individuals. Thrush et al. [26] have, however, shown that 12 weeks of supplementation with CLA (50:50, *t10c12:c9t11*) increases the content of the *t10c12* and *c9t11* isomers in skeletal muscle and this is accompanied by a decrease in insulin sensitivity in overweight, but non-diabetic individuals. Furthermore, the extent of the increase in the *t10c12* isomer was similar to that which we found in adipose tissue TAG (~0.01%) [26]. Therefore, it is possible that a very small enrichment of a tissue with the *t10c12* isomer may be sufficient to result in a functional change in the tissue.

In contrast to our results, Benito et al. [27], failed to detect the *t10c12* isomer in the adipose tissue of healthy females following 63 days of supplementation with a 4-isomer mixture of CLA (*c9t11*, *t8c10*, *c11t12* and *t10c12*) [27]. One explanation for this discrepancy might be that the supplement used in our study contained more than twice of the *t10c12* isomer (30.9%, 1.885 g) than that used by Benito et al. [27] (14.7%, 0.882 g).

There was also a trend towards significant incorporation of the *c9t11* isomer into the skeletal muscle phospholipids. While this study could not determine the functional implications of this, it warrants further investigation as fatty acid incorporation into the muscle phospholipids has been shown to result in various sequelae including changes in muscle cell membrane permeability, an increase in the number of insulin receptors [28, 29], insulin resistance and excessive accumulation of body fat (reviewed in [30]), depending on the proportions of the fatty acids. Indeed, Thrush et al. [26] showed that incorporation of both the *c9t11* and *t10c12* isomers in skeletal muscle lipids (TAG, diacylglycerol and ceramide) following 12 weeks of supplementation with CLA (50:50 *c9t11*:*t10c12*) was associated with a reduction in insulin sensitivity in nine overweight, non-diabetic individuals.

We also found that CLA supplementation was associated with increased oleic acid content of adipose tissue TAG and a trend for increased incorporation in skeletal muscle phospholipids. The CLA supplement contained 24.7% oleic acid and the placebo supplement was made up purely from high oleic sunflower oil. Therefore, one would expect oleic acid levels to increase in both groups. While oleic acid has been shown to be absorbed into plasma lipids following supplementation with CLA and a sunflower oil placebo [31], the location and extent of oleic acid incorporation into either adipose tissue or skeletal muscle following supplementation is not clear, making these observations difficult to explain. From a functional perspective, however, these changes in oleic acid levels were not differentially associated with any changes in body composition or insulin sensitivity.

The tissue-specific incorporation of the CLA isomers and oleic acid observed in this study were not accompanied by changes in variables such as body composition or insulin sensitivity. One explanation may be related to the antagonistic actions of the *c9t11* and *t10c12* CLA isomers. Given that our CLA supplement contained equal amounts of the two isomers, it is possible that any anti-adipogenic effect of the *t10c12* isomer was negated by the *c9t11* isomer, which appears to increase adipocyte triglyceride content in humans [19]. Alternatively, the relatively small sample size used in this study may not have been sensitive enough to detect physiological changes which typically have a large degree of inter-individual

variance. Another explanation may be that a longer supplementation period may be required for the observed fatty acid changes to be translated into physiological changes. Finally, the gender, body composition, activity level or health status of the individuals studied might have influenced such changes.

In conclusion, the fatty acid composition of adipose tissue TAG and skeletal muscle phospholipids may be altered in an isomer-specific manner with CLA supplementation in healthy, non-obese, regularly exercising individuals. The functional significance of these findings has yet to be elucidated.

Acknowledgments We thank the participants who gave of their time to participate in this study; Ryan Jankelowitz for his expert medical assistance; Jack Bergman and Debbie Steele of Symington Radiology, and Tobie de Villiers for performing the CT and DXA scans, respectively. We are also grateful to Judy Bolojne for her expert technical assistance and Jenny Ann Smuts for her assistance in dietary analysis. This study was funded in part by Loders Crokiaan, The Netherlands; RP Schere, UK; Aspen Pharmacare, South Africa; and Technology and Human Resources for Industry Programme, South Africa.

activate fatty acids of C12–C20 in chain lengths [1]. Since the rat ACSL1 cDNA was first cloned in 1990, to date, five distinct isoforms of ACSL that share a common structure have been identified and characterized in mammals [2–6]. Based on amino acid identity, these isoforms can be further divided into two subfamilies. The first subfamily consists of ACSL1, 5 and 6, which share about 60% amino acid sequence homology with each other and ~30% with the second subfamily made up by ACSL3 and ACSL4 that have 68% identity to each other [2–6]. In addition, all five ACSL isoforms differ in tissue distribution [2–7] and subcellular organelle location (reviewed in [1]). For instance, rat ACSL3 and ACSL6 mRNA expression is most abundant in brain followed by testis [3, 6, 7]. Recent studies also found ACSL3 protein, together with ACSL4, in a lipid droplet-enriched fraction isolated from the human hepatoma-derived Huh7 cell line [8, 9] as well as in lipid droplets from lipolytically stimulated 3T3-L1 adipocytes [10].

Despite the fact that our knowledge of the ACSL family has advanced greatly in recent years, the functional role of the individual isoforms in lipid metabolism is yet to be fully understood. It has been hypothesized that individual ACSL isoforms could channel fatty acids into different metabolic pathways. Evidence supporting this idea initially came from *in vitro* studies using ACSL inhibitors particularly triacsin C, a specific inhibitor of ACSL1, 3 and 4 [11–13]. For example, triacsin C was shown to block *de novo* synthesis of glycerolipids while had very little inhibition on the incorporation of oleate or arachidonate into phospholipids in human fibroblasts [14]. Subsequent studies in which some isoforms of ACSL were overexpressed through adenoviral-mediated gene delivery provided direct evidence for the role of ACSL in fatty acid partitioning within the cell [15–17]. Overexpression of ACSL1 in HepG2 cells, for instance, increased both cellular long-chain acyl-CoAs and oleate incorporation into extractable lipids without altering fatty acid oxidation, and caused a TG level increase in mouse liver [17]. It was also shown that ACSL1 directed fatty acids into diacylglycerol and phospholipids synthesis and away from cholesterol esterification and β -oxidation in primary rat hepatocytes [15].

To date, only limited information regarding the regulation of ACSL isoforms under hyperlipidemic conditions is available. For instance, one report investigating the regulation of ACSL isoforms and cytosolic thioesterase 1 (CTE1) in rodent heart has shown that while streptozotocin-induced diabetes and fasting both induced CTE1 and repressed ACSL6 mRNA, high-fat feeding only induced CTE1 expression without affecting all five ACSL isoforms [18].

We previously identified ACSL3 and ACSL5 as novel genes regulated by oncostatin M (OM), a lipid-lowering

cytokine, in liver cells [19]. We showed that OM upregulated mRNA expression of both ACSL3 and ACSL5 in HepG2 cells through ERK signaling pathways. More importantly, we demonstrated that overexpression either ACSL3 or ACSL5 led to fatty acid partitioning into β -oxidation. These *in vitro* data suggest that ACSL3 might regulate hepatic fatty acids metabolism under normal physiological or pathological conditions. In this report, we extend our initial *in vitro* study to *in vivo* investigation by examining ACSL3 expression and regulation under both physiological and disease conditions, particularly hyperlipidemia.

It is well established that the hamster is an attractive animal model for the study of lipid metabolism [20, 21]. With regard to their lipid metabolism profiles, hamsters share more characteristic features of those found in humans than do other rodents such as mouse and rat. In addition, hamsters quickly develop hyperlipidemia when fed high-fat diets. Therefore, in the present studies, we utilized hyperlipidemic hamsters as our *in vivo* model to investigate the effects of HFHC feeding as well as changes in nutritional status on ACSL3 expression in various tissues. Our study revealed that expression of ACSL3 was upregulated specifically in liver of HFHC-fed hamsters. Furthermore, the abundance of ACSL3 mRNA was differentially affected by fasting and refeeding in livers of hamsters fed normal chow or HFHC diet. These new findings suggest that ACSL3 may have an important role in hepatic FFA metabolism.

Experimental Procedure

Cloning of Hamster ACSL3 Complete Coding Sequence

To clone the hamster ACSL3 complete coding sequence (cds), we first compared mRNA sequences from human, mouse and rat ACSL3 genes and selected regions that are highly conserved across these species for primer sets design. Using primers identified by this approach, hamster ACSL3 cds was amplified from a cDNA pool generated from hamster liver samples and TA cloned into pCR2.1-Topo (Invitrogen, Carlsbad, CA, USA) and sequenced. Primers were 5'-ATGAATAACCACACACCTTC-3' (forward) and 5'-TTACTTCCTCCCATACATCCGCTC-3' (reverse).

Animal Diet Study

Six-week old male Golden Syrian hamsters were purchased from Harlan Sprague–Dawley and caged (3 animals/cage) under controlled temperature (22 °C) and lighting

(12 h light/dark cycle). Animals had free access to autoclaved water and food. The hamsters were randomly allocated to receive either a standard rodent diet (SD group, $n = 15$) or a high-fat and high-cholesterol rodent diet containing 35% calories from fat and 1.25% cholesterol (#D12336, Research Diets, Inc., New Brunswick, NJ, USA) (HFHC group, $n = 15$) for 2 weeks before the experiments. For the fasting and refeeding experiments, animals within each diet group were further randomly divided into three subgroups of five animals each: fed, fasted and refed. The fed subgroup remained on chow diet and were sacrificed at 7:00 am. The fasted subgroup was fasted for 24 h (from 7:00 am to 7:00 am next day), and the refed subgroup was fasted for 24 h and then refed for 10 h before sacrifice. At the time of dissection, the liver was removed, rinsed in $1 \times$ PBS buffer, weighed, cut into small pieces, immediately frozen in liquid nitrogen and stored at -80°C . All other tissues were collected at the same time. Serum was isolated by low speed centrifugation and aliquots were stored at -80°C . All animal procedures were approved by the Institutional Animal Care and Use Committee of the VA Palo Alto Health Care System.

Serum Lipid Measurement

Serum total cholesterol (TC), triglyceride (TG), free fatty acid (FFA), low-density lipoprotein-cholesterol (LDL-C), and high-density lipoprotein-cholesterol (HDL-C) levels were determined using kits obtained from Stanbio Laboratory (Boerne, TX, USA) and Wako Chemical GmbH (Neuss, Germany).

RNA Isolation and Real-Time RT-PCR

Total RNA was isolated from flash-frozen hamster tissues using an RNeasy kit (Qiagen, CA, USA). RNA integrity was confirmed by agarose gel electrophoresis and ethidium bromide staining. Two microgram of total RNA was reverse transcribed with a high-capacity cDNA reverse transcription kit (Applied Biosystems, Foster City, CA, USA) using random primers according to the manufacturer's instructions. Real-time PCR was performed on the ABI PRISM[®] 7900HT Sequence Detection System (Foster City, CA, USA) with SYBR PCR master mix (Applied Biosystems, Foster City, CA). Each cDNA sample was run in duplicate. Primer sequences used were: ham-ACSL3: forward: GGGCACCATTAGTTTGCTGT, reverse: CCGC TGTCATTTTCATCTT; ham-GAPDH: forward: ACCC AGAAGACTGTGGATGG, reverse: CGACATGTGAGA TCCACGAC; ham-18S rRNA: forward: TTCCGATA ACGAACGAGACTCT, reverse: TGGCTGAACGCCACT TGTC [22].

Generation of ACSL3-Specific Antibodies and Immunoblotting

Rabbit polyclonal antibodies against ACSL3 were raised commercially by GenScript Corporation (Piscataway, NJ, USA). Briefly, a peptide corresponding to the C-terminal end of hamster ACSL3 that is 100% identical to human, mouse and rat ACSL3 (THYQADIERMYGRK) was synthesized, purified and conjugated to keyhole limpet hemocyanin (KLH). Rabbit antiserum against ACSL3 peptide antigen was obtained using a standard immunization protocol and subject to affinity-purification. For immunoblotting experiments, an equal amount of protein (unless otherwise indicated) was separated on 10% SDS-PAGE, transferred to a PVDF membrane and probed with the anti-ACSL3 antibody (1:5,000), an anti-FLAG M2 antibody (Sigma, St Louis, MO, USA), an anti- β -Actin AC-15 antibody (Sigma, St Louis, MO), or an anti- γ -tubulin DQ-19 antibody (Sigma, St Louis, MO). Immunoreactive bands were visualized using an ECL plus kit (GE Healthcare life Sciences, Piscataway, NJ, USA) and quantified with the KODAK Molecular Imaging Software (Kodak, New Haven, CT, USA).

Statistical Analysis

Data were analyzed by two-way ANOVA (diet and feeding status) followed by post hoc LSD tests and by Student's two-tailed t test. A p value less than 0.05 is considered statistically significant.

Results

Cloning of the Hamster ACSL3 Coding Region

It is well known that hamsters are a very useful species for studying lipid metabolism because the hamster responds to dietary lipids in a fashion that is comparable to humans [20, 21]. The ACSL3 gene has been identified and characterized in mammals including human, mouse and rat. However, to date, no sequence data are available for the hamster ACSL3 gene. In order to study the role of ACSL3 in lipid metabolism of hyperlipidemic hamsters, we cloned the ACSL3 entire coding region from a hamster liver cDNA pool. The hamster ACSL3 cDNA coding sequence is 2,060 base pairs in length that is 88, 92 and 91% identical to human, mouse and rat sequences, respectively (Fig. 1a). It encodes the hamster ACSL3 protein of 720 amino acids with a calculated molecular weight of 80.57 kDa. The overall homology of hamster ACSL3 amino acids to human, mouse and rat is 91, 95 and 93%, respectively (Fig. 1b). Moreover, protein sequence analysis

Fig. 1 Comparison of hamster, human, mouse and rat ACSL3 cDNA coding regions and protein sequences. **a** The hamster ACSL3 cDNA complete coding sequence (cnds) was cloned and shows an open reading frame of 2,163 nucleotides. It was aligned with the human, mouse or rat cnds by using the DNASTAR software (DNASTAR, Inc., Madison, WI, USA). Boxes indicate nucleotides of the human, mouse or rat ACSL3 cnds that differ from those of the hamster sequence. **b** Alignment of hamster, human, mouse and rat ACSL3 protein sequence. Amino acid residues of the human, mouse or rat ACSL3 that differ from those of the hamster sequence are boxed. The *open box* at the end indicates stop codon. Two luciferase-like regions (LR) 1 (133–389) and 2 (434–686) are shown as *underlined*

showed that hamster ACSL3 protein also contained two similar putative conserved luciferase-like regions (LS) (Fig. 1b) as found in human, mouse and rat ACSL3 [3, 23].

Generation and Characterization of Anti-ACSL3 Antibody

To facilitate current and future studies on ACSL3, we generated a rabbit polyclonal antibody against hamster ACSL3 residues 707–720 at the C-terminus, a peptide sequence that is identical to that in human, mouse and rat, but not conserved in other ACSL isoforms. To test whether the antibody can specifically recognize the ACSL3 protein, we performed western blot analysis on protein extracts prepared from HepG2 cells and HepG2 cells overexpressing a C-terminal Flag-tagged hamster ACSL3 recombinant protein (Ad-hams-Acs13-Flag) or a control GFP (Ad-GFP). A single band with an approximate molecular weight of 80 kDa was observed in HepG2 (Fig. 2a, lane 1). In addition, the antibody also detected a higher molecular weight band around 83 kDa in HepG2 overexpressing the hamster ACSL3 recombinant protein (Fig. 2a, lane 3) but not in the cells expressing the plasmid control protein GFP (Fig. 2a, lane 2). Immunoblotting on the same extracts with an anti-FLAG M2 antibody showed a single band at the same position as the higher band detected by the ACSL3 antibody (Fig. 2b, left panel), confirming that the higher band found in transduced HepG2 cells is indeed correspondent to the overexpressed recombinant hamster ACSL3 protein with a Flag tag. Furthermore, co-incubation of the ACSL3 antibody with the immunizing peptides completely eliminated the ACSL3 signal (Fig. 2a, lanes 4–6). Additionally, a single band was also observed in

human Huh7 and rat McA-RH777 cells in a dose-dependent manner (Fig. 2c). Together, these data demonstrate that the anti-ACSL3 antibody can specifically recognize the ACSL3 protein from various species. With both the coding sequence and specific antibody on hand, we next investigated the effects of HFHC diet and food consumption on ACSL3 mRNA and protein expression in hamsters.

Upregulation of Hepatic ACSL3 Expression by a Fat and Cholesterol-Enriched Diet

We first examined tissue expression of ACSL3 mRNA in standard diet (SD)-fed hamsters. As shown in Fig. 3a by black bars, ACSL3 mRNA is highly expressed in brain and testis, with moderate expression in white adipose tissue, liver and heart. In addition, muscle also expresses low levels of ACSL3 mRNA. Detection of ACSL3 protein in these tissues using the specific ACSL3 polyclonal antibody confirmed this tissue-specific expression pattern of the ACSL3 gene at the protein level (Fig. 3b).

Next, we examined the ACSL3 mRNA levels in tissues of hamsters fed the HFHC diet. Two weeks of feeding with a HFHC diet induced hyperlipidemia in hamsters as evidenced by a marked increase in plasma levels of triglycerides (TG), cholesterol (TC) and free fatty acids (FFA) (Table 1). Strikingly, compared to the mRNA levels in SD-fed hamsters, HFHC feeding specifically increased ACSL3 mRNA abundance 2.3-fold ($p < 0.001$) in liver and 1.8-fold ($p < 0.05$) in muscle without an effect on other tissues including white adipose tissue, brain, heart, and testis. Moreover, the ACSL3 protein levels in livers of SD-fed and HFHC-fed hamsters, as determined by Western blot analysis, were firmly correlated with the results seen at

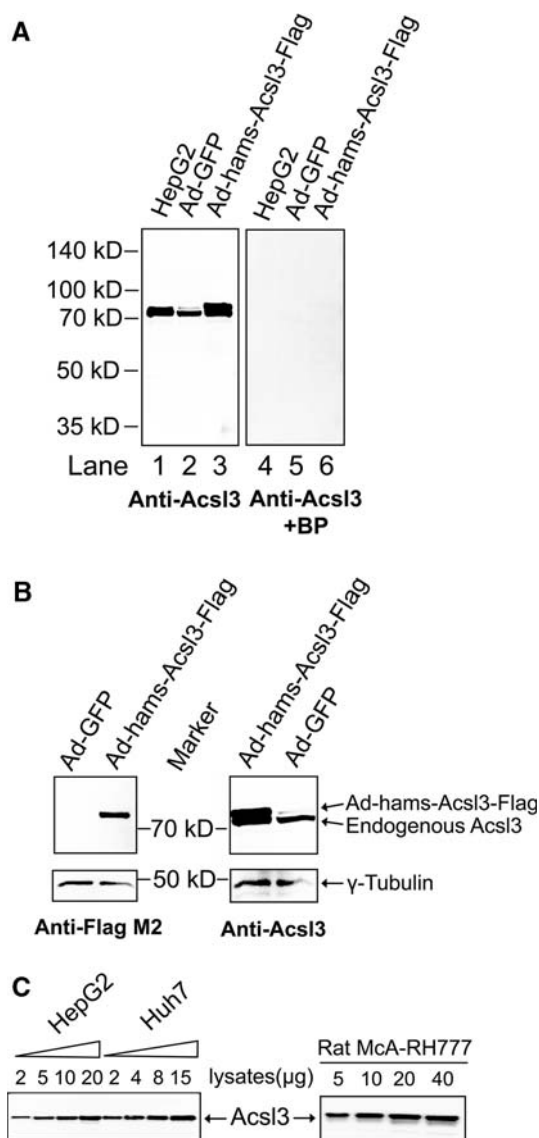

Fig. 2 Characterization of anti-ACSL3 polyclonal antibody. **a** Extracts from regular HepG2 cells and HepG2 cells infected with recombinant adenoviruses expressing either a GFP control or a C-terminal Flag-tagged hamster ACSL3 recombinant protein were separated on 10% SDS-PAGE gel, transferred to PVDF membranes and immunoblotted using a rabbit polyclonal anti-ACSL3 antibody or the antibody plus the immunizing blocking peptides (BP, THY-QADIERMYGRK) at a final concentration of 100 μ g/mL. Protein markers are shown on the left to indicate the protein molecular weights. **b** Western blot analysis of the overexpressed recombinant hamster ACSL3 and endogenous ACSL3 protein in HepG2 cells using either an anti-Flag M2 antibody or the anti-ACSL3 antibody. γ -tubulin was used as a loading control. **c** Western blot analysis using anti-ACSL3 antibody in HepG2, Huh7 and rat McA-RH777 cells

the mRNA level (Fig. 3c). We could not verify the HFHC diet-induced increase in ACSL3 protein expression in muscle due to the extremely low level of expression.

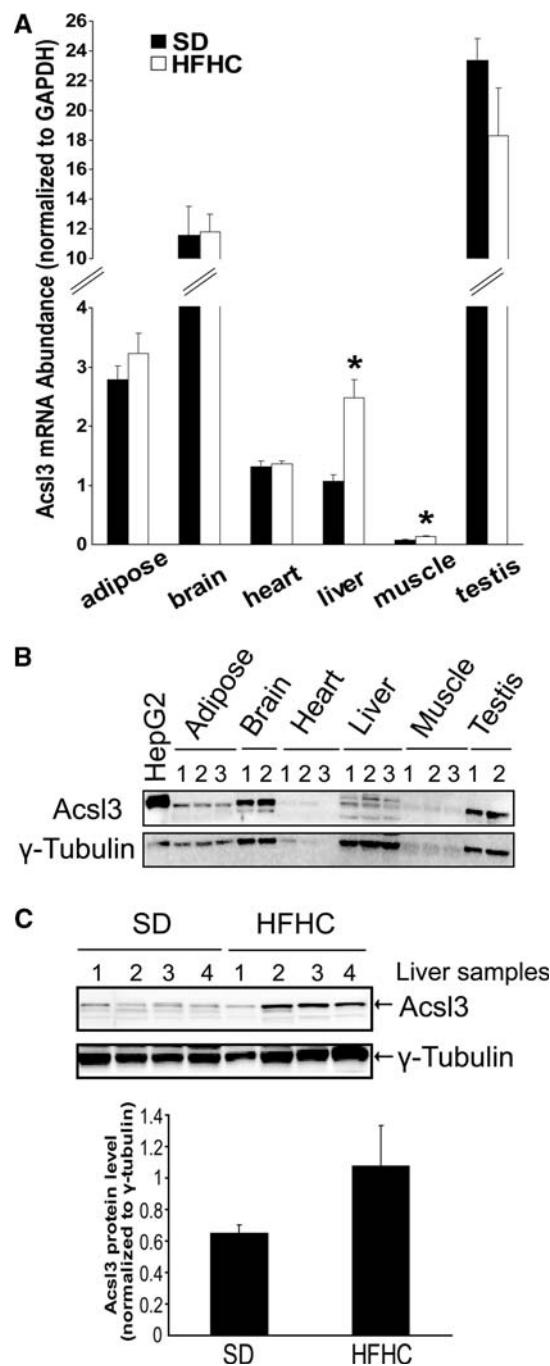

Fig. 3 ACSL3 expression in SD- and HFHC-fed hamster tissues. **a** ACSL3 mRNA expression in various tissues from SD-fed (black bars) and HFHC-fed (white bars) hamsters. Abundance of mRNA was determined by real-time RT-PCR and normalized to GAPDH. Data represent means \pm SEM ($n = 5$). * $p < 0.05$ versus SD. **b** Western blot analysis of ACSL3 protein in representative tissue samples from SD-fed hamsters. HepG2 extracts were included as a control to indicate the position of the ACSL3 protein. γ -Tubulin was used as a loading control. **c** Comparison of ACSL3 protein levels in liver samples from hamsters fed SD and HFHC diets. Expression levels were quantified with the KODAK Molecular Imaging Software and normalized to γ -tubulin

Table 1 Serum lipid profile of normal and hyperlipidemic hamsters

Diet	SD			HFHC		
	Fed	Fasted	Refed	Fed	Fasted	Refed
Triglyceride (mg/dL)	139 (13)	55 (7)*	105 (12)	317 (37)*	76 (17) [§]	132 (33)
Cholesterol (mg/dL)	94 (11)	81 (12)	67 (6)	387 (35)*	274 (27) [§]	337 (18)
Free fatty acids (mequiv/ml)	0.54 (0.03)	0.65 (0.11)	0.42 (0.04)	0.95 (0.06)*	0.92 (0.1)	0.56 (0.05) ^{§§}
LDL-C (mg/dL)	63 (10)	47 (8)	43 (5)	125 (6)*	174 (14) [§]	190 (13)
HDL-C (mg/dL)	86 (12)	68 (9)	55 (6)	168 (8)*	142 (6)	154 (8)

Values shown are means (\pm SEM)

* $p < 0.05$ versus SD fed

[§] $p < 0.05$ versus HFHC fed

^{§§} $p < 0.05$ versus HFHC fasted as determined by ANOVA and post hoc LSD tests

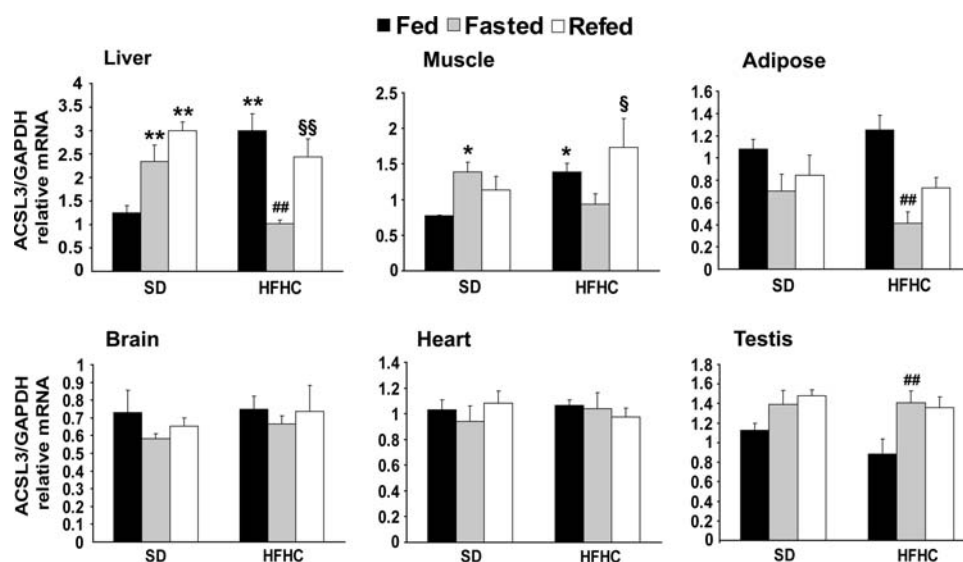

Fig. 4 Regulation of ACSL3 mRNA expression by food consumption in healthy and hyperlipidemic hamsters. ACSL3 mRNA expression, as quantified by real-time RT-PCR and normalized to GAPDH, in various tissues from fed hamsters, hamsters fasted for 24 h, and hamsters fasted for 24 h and refed for 10 h under healthy (SD) and

hyperlipidemic (HFHC) conditions. Data show as means + SEM. ($n = 5$ or 4). * $p < 0.05$ versus SD fed, ** $p < 0.01$ versus SD fed, ## $p < 0.01$ versus HFHC fed, [§] $p < 0.05$ versus HFHC fasted, and ^{§§} $p < 0.05$ versus HFHC fasted by two-way ANOVA and post hoc LSD tests

Changes in Nutritional Status Differentially Affected ACSL3 mRNA Expression in SD- and HFHC-Fed Hamsters

To further investigate the influence of HFHC diet on ACSL3 expression, we examined ACSL3 mRNA abundance in tissues of fed, fasted, and refed hamsters from both SD and HFHC groups. As shown in Fig. 4, the most significant changes of ACSL3 mRNA expression caused by different nutritional status were again observed in liver. In SD-fed hamster livers, fasting significantly increased the level of ACSL3 mRNA by 88% ($p < 0.01$), and refeeding led to a further 28% elevation ($p < 0.01$). Interestingly, in contrast to the change seen in the SD group, in livers of HFHC-fed hamsters, the mRNA for ACSL3 declined by

almost 70% upon fasting ($p < 0.01$) and returned to slightly reduced levels after refeeding ($p < 0.01$). We further validated these results by normalizing ACSL3 mRNA expression to another reference gene 18S rRNA and obtained similar results (data not shown).

In addition to liver, we observed a similar pattern in muscles but to a lesser extent. In white adipose tissue, fasting caused ACSL3 mRNA expression to decline by 35% ($p > 0.05$) in SD group and 67% ($p < 0.01$) in HFHC group. In both dietary groups, ACSL3 mRNAs showed only minor or insignificant changes in brain, heart and testis after fasting and refeeding.

To determine whether ACSL3 protein expression correlated with changes in ACSL3 mRNA abundance caused by the fasting and refeeding regimen, we measured ACSL3

Fig. 5 Regulation of ACSL3 protein expression by food consumption in hamster liver, brain and testis tissues. **a** Western blot analysis of ACSL3 protein expression in tissue extracts from pooled livers of HFHC-fed hamsters (four to five hamster livers per feeding group). β -actin was used as a loading control. Western blot analysis of ACSL3 protein expression in tissue extracts from pooled brains (**b**) and testis (**c**) of both SD and HFHC-fed hamsters (four to five samples per group were pooled). β -actin was used as a loading control

protein in all tissues (pooled samples) in which mRNA levels were quantified. Due to the low protein expression, we were unable to measure ACSL3 protein abundance using our ACSL3 polyclonal antibody in muscle, adipose and heart tissues of both diet groups, and liver samples of SD group. In HFHC-fed hamster livers, fasting resulted in a decline in ACSL3 protein and refeeding increased ACSL3 protein abundance (Fig. 5a), which was consistent with the changes seen at the mRNA levels. Interestingly, fasting notably decreased ACSL3 protein levels in brain and testis of SD-fed animals but not in brain or testis of HFHC-fed hamsters (Fig. 5b, c). These data suggest that ACSL3 protein expression might be regulated at the level of translation in brain and testis of healthy but not hyperlipidemic animals.

Discussion

We previously reported the identification of two members of the ACSL family, ACSL3 and ACSL5, as OM-regulated genes in HepG2 cells and suggested that the TG-lowering effect of OM observed in hamsters could be mediated through the stimulation of the transcription of ACSL specific isoforms in the liver [19]. To further understand the

role of ACSL in fatty acids metabolism in vivo, in the current study we investigated the nutritional regulation of ACSL3, one of the least characterized members of the ACSL family with only few known functions [9, 19, 24], in normolipidemic and hyperlipidemic hamsters.

Through the cloning of coding region, we demonstrate that hamster ACSL3 has a high degree of sequence homology to human, mouse and rat ACSL3 at both nucleotide and amino acid levels, which is in line with the notion that this enzyme is highly conserved among different species. We show that hamster ACSL3 mRNA, consistent with rat ACSL3 data previously reported [3, 7], is predominantly expressed in both brain and testis, suggesting physiological importance of this ACSL isoform in the regulation of lipid metabolism during the development of the central nervous and reproductive systems. In addition, it's also been shown that the mRNA abundance of ACSL3 changes during the development of mouse heart, suggesting that ACSL3 may play a critical role during the development of the fetal heart [25]. However, the detailed mechanism by which ACSL3 functions in these specific tissues still remains to be elicited. With the specific antibody developed in this current study, for the first time, the tissue expression of ACSL3 protein was determined and the results mirror the data from mRNA detection.

One of the important findings of this study is the demonstration of the distinct elevation of hepatic ACSL3 expression by a HFHC feeding at both mRNA (2.3-fold increase) and protein (1.7-fold increase) levels compared to those in livers of SD-fed hamsters. These data suggest that, at least in hamsters, ACSL3 is actively involved in hepatic fatty acid metabolism and its increased expression in HFHC-fed hamster livers might reflect the demand of body to metabolize excessive FFAs in a feed-forward regulatory mechanism.

In addition to the HFHC-induced upregulation, a functional role of ACSL3 in liver fatty acid metabolism can be further inferred from the fact that the most significant alteration of ACSL3 mRNA levels caused by changes in food consumption was in the liver, and the different patterns between SD-fed and HFHC-fed hamsters. Fasting increased ACSL3 mRNA level by 88% and refeeding led to a further 28% elevation in SD-fed hamster liver, whereas in hyperlipidemic hamster liver the mRNA level declined by almost 70% upon fasting and returned to slightly reduced levels after refeeding. It is also worth noting that the same pattern of changes under two different diets was recaptured in muscle but not in other tissues. Liver and muscle are recognized as major organs of FFA utilization for energy production or for lipid synthesis. Thus, it is plausible to speculate that these two organs might share similar regulatory mechanisms for ACSL3 gene transcription.

Previous studies in rodent models have shown that the expression of some isoforms of the ACSL family is regulated by food consumption under both physiological and pathological conditions [2, 4, 7, 18]. Our results here also indicate that ACSL3 expression is differentially regulated in normal chow-fed versus HFHC diet-fed hamsters in a tissue-specific manner. This warrants further studies to examine the expression and regulation of other ACSL isoforms under pathological conditions, which may help to better understand the causes of dyslipidemia and its related diseases, especially in the liver, such as NASH.

Currently, the transcriptional network involving in ACSL3 gene expression in liver tissue is largely uncharacterized. Possible candidates might include members of the PPAR transcription factor family, since it's been shown that both ACSL1 and ACSL4 expression increased after the treatment with PPAR α agonist GW9578 in rat liver [26]. Indeed, a PPAR responsive element (PPRE) has been identified on the ACSL1 gene promoter [27, 28]. In addition, ACSL1 and ACSL5 mRNA increase in adipose tissue upon PPAR γ agonists stimulation [29]. Moreover, a recent report investigating the regulation of ACSL isoform gene expression in rat heart concluded that ACSL1 is a PPAR α -regulated gene whereas ACSL6 is an insulin-regulated gene [18]. In the same study, it has also been shown that insulin significantly increased the expression of ACSL3, as well as ACSL1 and ACSL6, in adult rat cardiomyocytes. Therefore, further work is needed to determine whether the PPAR and/or insulin are involved in the regulation of ACSL3 in the liver under different diet conditions.

Acknowledgments This study was supported by the Department of Veterans Affairs (Office of Research and Development, Medical Research Service) and by grants (1R01 AT002543-01A1, 1R21AT003195-01A2) from the National Center for Complementary and Alternative Medicine.

such as meat tenderness, juiciness and taste [1]. IMF tissue which is present in connective tissue surrounding muscle fibers and muscle fiber bundles, is composed of adipocytes interspersed between fiber fascicule (intramuscular adipocytes) [2].

In general, adipocytes arise from preadipose cells recruited from a population of mesodermal origin stem cells [3]. And the increase of adipose tissue mass is due to a combination of an increase in adipocyte number (hyperplasia) and in size (hypertrophy) [4], but the ratio between both processes varies among tissues [5]. The hyperplasia of intramuscular adipocytes may play a more important role in the deposition of IMF than other adipose tissues [6].

Adipogenesis is the process by which mesodermal precursor cells (preadipocytes or stem cells) differentiate into adipocytes, which store lipid and serve as central regulators of metabolism [7]. The adipogenesis process is documented as being controlled by both positive and negative regulators [7]. Transcription factor peroxisome proliferator-activated receptor γ (PPAR γ) is the chief positive and central regulator of adipogenesis to trigger hyperplasia of adipocytes, and is both necessary and sufficient for preadipocytes and stem cells differentiation [8–10]. On the other hand, Wnt/ β -Catenin signaling is considered as the main negative regulator of adipogenesis [11]. Wnts are an evolutionarily conserved family of secreted lipidated glycoproteins and Wnt/ β -Catenin signaling functions as an adipogenic switch, when it is on, adipogenesis is repressed [11, 12].

It is worth mentioning that another transcription factor PPAR δ is also involved in adipogenesis but playing different roles from PPAR γ [13]. PPAR δ is demonstrated to be not directly involved in the regulation of adipose terminal differentiation, but to be implicated in the initial steps of the adipogenic program by inducing PPAR γ gene expression in response to various adipogenic nutrients which are ligands of PPAR δ , especially long chain fatty acids [13–15].

The n-3 polyunsaturated fatty acids (n-3 PUFA) which belong to one of the major classes of long chain fatty acids are potential activators of PPAR δ [16]. Activating PPAR δ by n-3 PUFA may in turn induce PPAR γ to stimulate adipogenesis. There was also evidence by which n-3 PUFA exerted inhibition on Wnt/ β -Catenin signaling pathway in cell cultures [17]. So it is likely that n-3 PUFA could induce adipogenesis through affecting both positive and negative regulators.

Hsu et al. [18] pointed out that effective regulation of the expression of a certain gene such as adipocyte determination and differentiation-dependent factor 1 (ADD1) in adipose tissue may need much n-3 PUFA enrichment, so it is reasonable to assume that the same case may also exist in skeletal muscle. The n-3 PUFA level can be increased in pork by feeding linseed, which contains about one-third oil,

of which more than 50% is α -linolenic acid (18:3n-3, ALA), and duration of linseed feeding could increase n-3 PUFA enrichment in tissues [19]. In the current study, experiments were designed by feeding pigs with a diet containing 10% linseed for 0, 30, 60 and 90 days before slaughter to test the hypothesis that increasing the n-3 PUFA enrichment in the skeletal muscle of growing-finishing pigs by feeding linseed, could activate PPAR δ , which may subsequently upregulate the expression of PPAR γ to promote adipogenesis. Meanwhile, n-3 PUFA enriched in the skeletal muscle could also decrease Wnt/ β -Catenin signaling to release the inhibition of adipogenesis, consequently to increase IMF deposition.

Experimental Procedures

Animals and Diets

The study was carried out according to Huazhong Agriculture University Animal Care and Use Committee guidelines. Two isoenergetic, isonitrogenous and isolipidic diets were formulated: a basal diet containing saturated fat powder and a linseed diet containing 10% (wt%) linseed. Diet composition is presented in Table 1. The fatty acid composition of the diets was analyzed and listed in Table 2. Twenty-four Landrace \times NewDamLine barrows weighing 35 ± 3.7 kg were randomly assigned to four treatment groups with six pigs per group. The NewDamLine is a cross-bred pig bred at Huazhong Agriculture University containing 25% blood of a Chinese breed “Taihu pig”. Throughout the experimental period of 90 days, pigs in treatment group 1 (T1), T2, T3 and T4 were respectively fed first the control diet for 90, 60, 30 and 0 days and then the linseed diet for 0, 30, 60 and 90 days, respectively. Pigs were housed individually and fed ad libitum. At the end of the trial the pigs were humanely slaughtered at the age of 170 days by electrical stunning coupled with exsanguinations. Tissue samples were rapidly removed, wrapped in foil, and frozen in liquid nitrogen to be stored at -70 °C. Skeletal muscle samples (separated from adhering adipose tissue) were removed from longissimus muscle between the 10th and the last rib, and then collected for subsequent RNA extraction. Another set of longissimus muscle samples were also collected from each pig and stored at -20 °C for fatty acid analysis. And the longissimus muscle samples used for meat quality evaluation were also collected.

Meat Quality Evaluation

Drip loss (wt%) was calculated as fluid loss after storage of longissimus muscle in plastic bags at 4 °C for 24 h. Water

^b Saturated fatty acids (SFA) percentage is the sum of 14:0, 16:0, 18:0, 20:0, and 22:0; polyunsaturated fatty acids (PUFA) percentage is the sum of 18:2n-6, 18:3n-3 (α -linolenic acid)

holding capacity (wt%) was measured by the press technique [20] using a 2.523 cm diameter 1 cm high columnar meat sample pressed for 5 min between 36 medium-speed

filter papers (Xinhua Paper Industry Co. Ltd., China) using a swelling press (Qinchuan Electric Apparatus Factory, China) and an applied force of 35 kg [21]. The pH₄₅ (portable pH meter, model 3071, Jenway, England) of the longissimus muscle was directly measured 45 min after slaughter at the level of the first lumbar vertebra using a combined glass electrode (P19/BNC). Water moisture content (wt%) was measured in a drying oven at 102 °C for 18 h [22]. The intramuscular fat content (wt%) of the last thoracic vertebral longissimus muscle was determined by chloroform-methanol extraction and expressed as the weight percentage of wet muscle tissue [23].

Fatty Acid Analysis

Lipids were extracted from the diet and longissimus muscle samples by the chloroform:methanol procedure as described by Folch et al. [24]. Fatty acid methyl esters (FAME) were prepared for gas chromatography determination using KOH/methanol [25].

The CP-3800 gas chromatography (Varian Inc., USA) equipped with a 1177 injector, a flame ionization detector and a capillary chromatographic column CPSi188 (Varian, Inc. USA) for FAME (50 m × 0.25 mm id × 0.20 µm) was used in this experiment. The injector and detector

temperature were kept at 250 and 270 °C, respectively. Nitrogen was used as carrier gas with a flow rate of 1.0 ml/min, split ratio was 1:100. The column was programmed as follows: 100 °C at first, increase to 200 °C (5 °C/min) and held constant for 5 min. Subsequently, the temperature was increased to 225 °C (2 °C/min) and kept constant for 2 min. The total analysis time was 39.5 min. The fatty acids were identified by comparing the retention times of the peaks with those of known standards (Sigam Chemical Co., St. Louis, MO, USA). Response factors for the fatty acids were calculated using the same standard mixtures plus an internal standard [26]. Peaks were identified using standards where available (Sigma Chemical Co. Ltd, Poole).

RNA Isolation

Total RNA was extracted from skeletal muscle samples using the TRIzol reagent (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's specifications. RNA samples were then treated with a DNA-free kit (Applied Biosystems, Foster City, CA, USA) to remove any contamination with genomic DNA. The RNA samples were quantified spectrophotometrically at 260 and 280 nm. The ratio of light absorbance at 260 nm to that at 280 nm was between 1.8 and 2.0, indicating that they were pure and clean. The quality of RNA was also checked by 1.0% agarose gel electrophoresis and staining with 1 µg/mL ethidium bromide.

Reverse Transcription and Real-Time PCR Analysis

Oligo-(dT)_{20n} (Toyobo, Japan) was used as the primer in cDNA synthesis. The reverse transcription reaction solution (20 µL) consisted of 4 µL of total RNA (1 µg/µL),

100 U of Moloney Murine Leukemia Virus reverse transcriptase (Toyobo, Japan), 20 U of an RNase inhibitor (Toyobo, Japan), 0.5 mmol/L of deoxyribonucleotide triphosphate, and 2.5 µL oligo-(dT)_{20n} primers. The reverse transcription reaction parameters were as follows: reverse transcription at 42 °C for 60 min followed by denaturation at 99 °C for 5 min. The cDNA stock was stored at -20 °C.

Relative mRNA levels of *PPAR*δ, *PPAR*γ, *adipocyte fatty acid-binding protein (aP2)*, *lipoprotein lipase (LPL)*, *wingless related MMTV integration site 10b (Wnt10b)*, *myogenic differentiation 1 (MyoD)* and *α-actin* were quantified using real-time PCR with an iQTM5 Real Time PCR Detection System (BioRad). The *β-actin* mRNA levels were similarly measured and served as the reference gene. Of each cDNA, 0.1 µg were added to PCR reagent mixture, SYBR[®] Green Master Mix (Applied Biosystems), with the sense and antisense primers (500 nM each) (Table 3). Specific primers were synthesized commercially (Shanghai Sangon Biological Engineering Technology & Services Co, Ltd., Shanghai, China).

The PCR parameters were as follows: denaturation at 95 °C for 3 min followed by 40 cycles of denaturation at 94 °C for 20 s, annealing for 20 s (annealing temperatures in Table 3), extension at 72 °C for 20 s and reading plate for 10 s. All sample mRNA levels were normalized to the values of *β-actin* and the results expressed as fold changes of threshold cycle (Ct) value relative to controls using the 2^{-ΔΔCt} method [27]. All samples were measured in triplicate.

Statistical Analysis

Experimental animals were assigned to different treatments in a completely randomized design. Statistical analysis was

performed using SAS software package (version 8.2; SAS Institute, Cary, NC, USA). The basic variable was linseed addition time (days). Linear and quadratic relationships were determined for parameters collected from treatment groups. The data variances were analyzed using a general linear model (PROC GLM, SAS, 1985). The equations which describe quadratic relations were generated by iterative nonlinear least-squares regression. And the equations which describe linear relations were generated by linear regression. The correlations between enrichment of fatty acids and IMF content were also assessed. Data are presented as least squares means. Means were considered statistically different at $P < 0.05$.

Results

Meat Quality

The effects of linseed supplementation in the diets on meat quality in growing-finishing pigs are presented in Table 4. The content of IMF increased linearly ($P < 0.05$) as the time of feeding linseed diet prolonged, whereas no significant difference ($P > 0.05$) was observed for drip loss, water holding capacity, pH₄₅ and moisture in longissimus muscle among treatment groups. In addition, the significant difference ($P < 0.05$) compared with group T1 (0 days) was observed in group T3 (60 days) and group T4 (90 days), but not in group T2 (30 days).

Tissue Fatty Acid Composition

Fatty acids profile of total fat in longissimus muscle was shown in Table 5. Fatty acid analysis of longissimus muscle showed a linear increase ($P < 0.01$) in PUFA and n-3 PUFA content. 18:3n-3, 20:5n-3 and 22:5n-3 content

Gene Expression in Longissimus Muscle

The genes having a positive effect (*PPAR*δ, *PPAR*γ, *aP2* and *LPL*) and a negative effect (*Wnt10b*) on adipogenesis were determined using real-time PCR. The genes involved in myogenesis (*MyoD* and *α-actin*) were determined as well. Relative mRNA levels of the genes were all normalized to *β-actin* signals. The results are presented in Table 6 and show that relative expression levels of *PPAR*δ, *PPAR*γ, *aP2* and *LPL* were all increased (*P* < 0.01) linearly with increasing duration of feeding linseed diet. And the relative expression level of *Wnt10b* linearly decreased (*P* < 0.01), while the relative expression level of *α-actin* quadratically decreased (*P* < 0.01) with the increasing time on linseed diet. No significant difference (*P* > 0.05) was observed for the relative expression level of *MyoD* among groups. In addition, the significant changes (*P* < 0.05) in expression levels of *PPAR*δ, *PPAR*γ, *aP2* and *Wnt10b* occurred after 60 days of feeding a 10% linseed diet, while those of *LPL* and *α-actin* occurred after 30 days of treatment (Table 6).

Correlations between Enrichment of Fatty Acids and Intramuscular Fat Content

The simple correlation analysis was conducted to evaluate the correlations between enrichment of fatty acids in longissimus muscle and intramuscular fat content. As shown in

Table 7 Correlations between enrichment of fatty acids and intramuscular fat content

^a Correlation coefficient between two items

Table 7, 18:2n-6, 18:3n-3, 20:5n-3, 22:5n-3, 22:6n-3, n-3 PUFA and PUFA enrichment were all positively correlated with IMF content (*P* < 0.01), and the greatest correlation coefficient was observed between n-3 PUFA enrichment and IMF content, whereas no significant correlation of n-6 PUFA to IMF content was found (*P* = 0.138).

Regressions between n-3 PUFA Enrichment and Intramuscular Fat Content or Gene Expressions

The results of regressions between n-3 PUFA enrichment and IMF content or gene expressions are presented in Table 8. A significant (*P* < 0.01) quadratic relation was found between n-3 PUFA enrichment and IMF content (Table 8; Fig. 1). There was a statistically significant (*P* < 0.01) linear relation between n-3 PUFA enrichment and the expression of *PPAR*δ or *LPL*, while significant (*P* < 0.01) quadratic relation was found between n-3 PUFA enrichment and the expression of *PPAR*γ, *aP2*, *Wnt10b* or *α-actin* (Table 8).

Regressions between Gene Expressions and Intramuscular Fat Content

The results of regressions between gene expressions and IMF content were presented in Table 9. There was

^a In the regression analysis, n-3 PUFA enrichment was used as independent variable (X), while IMF content and the expression of *PPAR*δ, *PPAR*γ, *aP2*, *LPL*, *Wnt10b* and *α-actin* were used as dependent variables (Y)

^b E effect of two items; L and Q are significant linear and quadratic effect of two items, respectively; ** $P < 0.01$

statistically significant ($P < 0.01$) quadratic or linear relation between the expression of *PPAR*γ, *aP2*, *Wnt10b* or *α-actin* and IMF content in longissimus muscle (Table 9; Figs. 2, 3, 4 and 5), whereas no significant linear or quadratic relation was found between the expression of *PPAR*δ or *LPL* and IMF content in longissimus muscle (Table 9).

Discussion

Intramuscular adipose site is a later developing tissue [6, 28]. The major increase in IMF begins after 16 weeks of age in pigs and the number of intramuscular adipocytes does not reach a plateau even at 24 weeks but continues to increase [6]. It is well known that traits of animals are developed in a specific growth and development period and the traits are more likely to be influenced during this period. Based on these facts, the trial period (from 80 to 170 days of age) of pigs was designed in the current study. The result of the present study showed that IMF content increased linearly ($P < 0.05$) along with the increasing time on a linseed diet without affecting drip loss, water holding capacity, pH₄₅ and moisture in longissimus muscle among treatment groups (Table 4). In addition, average daily feed intake was also not affected by the treatment [29]. Noteworthy, the significant difference ($P < 0.05$) in IMF content compared with group T1 (0 days) was observed in group T3 (60 days) and T4 (90 days), but not in group T2 (30 days), suggesting that a certain length of duration of feeding linseed diet has to be reached in order

Fig. 1 The quadratic relation between n-3 PUFA content and intramuscular fat content in longissimus muscle. The inclusion of linseed in diets was initiated at the last 0 days (open circles), 30 days (filled circles), 60 days (open triangles) and 90 days (filled triangles) before slaughter, respectively. These data were represented in Table 4 (for the intramuscular fat content), Table 5 (for the n-3 PUFA content). The fatty acid results were presented as g/100 g fatty acids (wt%)

to influence the IMF content. However, the current result of intramuscular fat was inconsistent with other studies where no significant change was found by feeding a linseed diet [30–37]. As Zhan et al. [29] pointed out, the stimulatory effect of linseed on growth may not be significant when the level added is less than 5% or the feeding duration is shorter than 60 days in growing-finishing pigs, the effect of linseed on IMF content may exhibit a similar pattern. The inconsistent results of those studies might be due to differences in trial designs, such as: lower dietary linseed or ALA level [30–34]; short linseed feeding duration [33, 35] and not adopting isoenergetic, isonitrogenous and isolipidic diets [36, 37].

In the present study, n-3 PUFA content in longissimus muscle of pig was raised linearly by feeding linseed diet

Fig. 2 The quadratic relation between expression of *peroxisome proliferator-activated receptor γ* (*PPAR γ*) and intramuscular fat content in longissimus muscle. The inclusion of linseed in diets was initiated at the last 0 days (*open circles*), 30 days (*filled circles*), 60 days (*open triangles*) and 90 days (*filled triangles*) before slaughter, respectively. These data are presented in Table 4 (for the intramuscular fat content), Table 6 (for the expression of *PPAR γ*)

Fig. 3 The linear relation between expression of *adipocyte fatty acid-binding protein* (*aP2*) and intramuscular fat content in longissimus muscle. The inclusion of linseed in diets was initiated at the last 0 days (*open circles*), 30 days (*filled circles*), 60 days (*open triangles*) and 90 days (*filled triangles*) before slaughter, respectively. These data are presented in Table 4 (for the intramuscular fat content), Table 6 (for the expression of *aP2*)

Fig. 4 The linear relation between expression of *wingless related MMTV integration site 10b* (*Wnt10b*) and intramuscular fat content in longissimus muscle. The inclusion of linseed in diets was initiated at the last 0 days (*open circles*), 30 days (*filled circles*), 60 days (*open triangles*) and 90 days (*filled triangles*) before slaughter, respectively. These data are presented in Table 4 (for the intramuscular fat content), Table 6 (for the expression of *Wnt10b*)

(Table 5), which was in general agreement with other studies [35]. Among 18:2n-6, 18:3n-3, 20:5n-3, 22:5n-3, 22:6n-3, n-3 PUFA and PUFA enrichment which were all positively correlated with IMF content, the greatest

Fig. 5 The linear relation between expression of α -actin and intramuscular fat content in longissimus muscle. The inclusion of linseed in diets was initiated at the last 0 days (*open circles*), 30 days (*filled circles*), 60 days (*open triangles*) and 90 days (*filled triangles*) before slaughter, respectively. These data are presented in Table 4 (for the intramuscular fat content), Table 6 (for the expression of α -actin)

correlation coefficient with IMF content was observed in n-3 PUFA enrichment, implying the highest correlation between n-3 PUFA enrichment and IMF content (Table 7). Moreover, regression analysis showed that enhancement of the IMF content was quadratically related to n-3 PUFA enrichment and n-3 PUFA enrichment could explain 79% of IMF content variation through the regressive equation (Table 8; Fig. 1). These results suggested that, of all the fatty acids, n-3 PUFA enrichment in muscle may play the most important role for IMF deposition extent in the context of our trial, coinciding with its dramatic fold change (from 1.11 to 7.13%, 6.42 times) in longissimus muscle. Moreover, the significant difference ($P < 0.05$) in IMF content was first found in group T3 (60 days) with an n-3 PUFA enrichment of 5.16%, implying certain n-3 PUFA enrichment may be required for efficiently affecting IMF deposition. It seems confusing that the present result was inconsistent with other studies where a negative correlation was found between PUFA enrichment and IMF content [34, 38]. However, in those studies, the PUFA enrichment especially n-3 PUFA enrichment in muscle was much lower than that of present study. And the low level of the n-3 PUFA enrichment in muscle may not be sufficient to affect IMF deposition. And the increase of IMF content in those studies is probably due to the increase of neutral lipids in the intramuscular adipocytes which lead to a dilution of phospholipids rich in PUFA and result in the decrease in PUFA content [39]. In contrast, the increase of IMF content in present study might be caused by the stimulatory effect of high enrichment of PUFA, especially n-3 PUFA.

Dietary n-3 PUFA has been demonstrated to affect diverse physiological processes such as the regulation of plasma lipid levels, cardiovascular and immune function, insulin action, neuronal development and visual function

[40]. However, the influence of IMF deposition by n-3 PUFA is seldom documented.

PUFA including n-3 PUFA or its derivatives can directly act at the level of nucleus to influence the transcription activity of transcription factors and in turn the transcription of their target genes responding to diverse cellular processes including adipogenesis [41]. Therefore, the expression levels of the genes involved in adipogenesis were assessed and the result showed that the expression of *PPAR δ* , *PPAR γ* , *aP2*, *LPL* and *Wnt10b* all exhibited a significant ($P < 0.01$) linear response to the duration of feeding linseed diet (Table 6), implying a time-dependent manner. Meanwhile, a significant ($P < 0.01$) quadratic or linear relation was observed between the n-3 PUFA enrichment and the expression of these genes (Table 8), suggesting that the expression of these genes were influenced by the n-3 PUFA enrichment in longissimus muscle in a dose-dependent manner. In addition, the significant changes in expression levels of *PPAR δ* , *PPAR γ* , *aP2* and *Wnt10b* occurred after 60 days of feeding 10% linseed diet, while that of *LPL* occurred after 30 days (Table 6), suggesting that affecting certain genes expression may need certain duration of feeding linseed diet and certain enrichment of n-3 PUFA as well.

Peroxisome proliferator-activated receptors (PPARs) belong to the steroid hormone nuclear receptor superfamily of ligand-activated transcription factors [42]. Two isoforms of PPARs, *PPAR δ* and *PPAR γ* are documented as positive regulators involved in adipogenesis [13]. *PPAR δ* is a widely expressed in all tissues and is the main PPAR isoform expressed in skeletal muscle [43, 44]. Although *PPAR δ* was described for its role in fatty acid oxidation in several tissues [45], gain-of-function experiments suggested that both *PPAR δ* and *PPAR γ* isoforms are required to facilitate maximal lipid accumulation and differentiation during adipogenesis [14]. Furthermore, *PPAR δ* is demonstrated not directly involved in the regulation of adipose terminal differentiation, but is implicated in control by long chain fatty acids of *PPAR γ* gene expression [13]. In the current study, a linear relation between n-3 PUFA enrichment and *PPAR δ* mRNA abundance suggested that *PPAR δ* was directly upregulated by n-3 PUFA which may be good ligands of *PPAR δ* , which corresponded with other studies [46, 47]. A quadratic relation was also observed between n-3 PUFA enrichment and the expression of *PPAR γ* (Table 8). However, fatty acids including n-3 PUFA are proved to be poor activators of *PPAR γ* [47–49], thus, the inducing expression of *PPAR γ* seemed not to be direct action by n-3 PUFA. Instead, it could be due to the effect of *PPAR δ* which was directly activated by n-3 PUFA. Similar result was reported by Kronberg et al. [50] that feeding linseed diet to increase n-3 PUFA enrichment in bovine muscle upregulated *PPAR γ* expression in muscle tissue.

PPAR γ which is predominantly expressed in adipose tissues, is a central regulator during adipogenesis [9], and activation of *PPAR γ* can promote stem cells or preadipocytes to differentiate into adipocytes [51]. A relative high expression of *PPAR γ* was detected in the current study, revealing high adipogenesis in the skeletal muscle, which was consistent with the high amount of IMF content. However, the expression of *PPAR γ* in skeletal muscle failed to be detected in pigs of 30 kg weight [52]. This may be due to the fact that development of IMF was not predominant in the 30-kg weight stage, coinciding with the result that the major increase in IMF begins after 16 weeks of age in pigs [6]. Moreover, a statistically significant ($P < 0.01$) quadratic relation was observed between the expression of *PPAR γ* and IMF content in longissimus muscle (Table 9; Fig. 2), suggesting that the increasing of IMF content was directly related to the enhancement of adipogenesis and the expression of *PPAR γ* in skeletal muscle would be an important determinant of the extent of the IMF deposition. However, no significant ($P > 0.05$) linear or quadratic relation was found between the expression of *PPAR δ* and IMF content (Table 9), which implies that *PPAR δ* may act as an activator of *PPAR γ* , rather than directly affecting adipocytes differentiation, and the action of *PPAR δ* was different from that of *PPAR γ* which is the direct factor that determines the differentiation of adipocytes from preadipocytes or stem cells [51].

Due to the increasing expression of *PPAR γ* , the expression of two target genes of *PPAR γ* , *aP2* and *LPL* were also linearly increased ($P < 0.01$) along with increasing time on linseed diet. *aP2* is adipocyte specific fatty acid binding protein, directly participates in fatty acid uptake and transport process of intramuscular adipocytes [53]. And the *LPL* can hydrolyze the lipoprotein triacylglycerols from cycling and release free fatty acid for skeletal muscle uptake [54], so *LPL* directly participates in IMF deposition. The increasing expression of the two genes indicated that the ability to uptake exogenous fatty acid and afterward synthesize triacylglycerols could be increased, which could increase IMF deposition. Furthermore, statistically significant ($P < 0.01$) linear relation was observed between the expression of *aP2* and IMF content in longissimus muscle (Table 9; Fig. 3), corresponding with other results [55], but no significant ($P > 0.05$) linear or quadratic relation was observed between the expression of *LPL* and IMF content (Table 9). This may be because *aP2* is an adipocyte-specific gene which is known to be a later marker of adipogenesis, whereas *LPL* is widely expressed in most cell types not only functioning in adipocytes [53, 54].

Wnt/ β -Catenin signaling is demonstrated as the main negative regulator to repress adipogenesis and maintain the undifferentiated state of preadipocytes [11, 56]. Activation

of Wnt/ β -Catenin signaling is mediated by paracrine and/or autocrine production of members of Wnt family of secreted polypeptides [56]. Wnt10b is one of the main endogenous Wnt signaling molecules, and is highly expressed in stromal vascular cells, which are enriched in preadipocytes, but not in mature adipocytes [12]. Suppressing the expression of Wnt10b is needed for adipogenesis [11]. It has been demonstrated that skeletal muscle is an endocrine tissue, capable of expressing a wide range of molecules with endocrine actions [57]. Wnt10b mRNA was detected in the present study, suggesting that Wnt10b may serve as an endogenous inhibitor of adipogenesis in skeletal muscle, i.e. as the inhibitor of the IMF deposition. The Wnt10b expression level was quadratically decreased with the enhancement of n-3 PUFA enrichment in the present study (Table 8), implying that the transcription of Wnt10b was inhibited by n-3 PUFA. Similar result was reported that n-3 PUFA could inhibit Wnt/ β -Catenin signaling in cell cultures, but without mention about Wnt10b [17]. It is not surprising that Wnt10b could be inhibited by n-3 PUFA. It was demonstrated that Wnt10b expression can be upregulated by proinflammatory cytokine tumor necrosis factor- α (TNF- α) [58]. Meanwhile, dietary n-3 PUFA was reported to decrease the production of TNF- α in different animal species [59–61]. Previous work of our research team also revealed that the serum concentration of TNF- α as well as the expression level of TNF- α in skeletal muscle both linearly decreased with duration of linseed diet [29], therefore, the downregulation of Wnt10b expression may be due to the inhibition on production of TNF- α by dietary n-3 PUFA. Interestingly, a linear relation was observed

between expression of Wnt10b and IMF content (Table 9; Fig. 4), suggesting that extent of inhibition of Wnt10b expression was another determinant of the extent of the IMF deposition.

Two genes involved in myogenesis were also assessed in the present study. The expression of MyoD which is expressed in the early stages of myogenesis [62] was not affected by the treatment (Table 6), implying that n-3 PUFA might not influence the early myogenesis processes. However, it was interesting that the relative expression level of α -actin which is a late marker of myogenesis quadratically decreased ($P < 0.01$) with the increasing of n-3 PUFA enrichment (Table 8), suggesting that myogenesis might be inhibited by n-3 PUFA during the late growing-finishing period of pigs. In addition, the linear relation between expression level of α -actin and IMF content suggested that the enhancement of adipogenesis might be accompanied by decrease in myogenesis (Table 9; Fig. 5). Similar result was observed that the expression of α -actin decreased with the IMF content increasing in cattle between early and late fattening stages [63]. Several studies also reported that inhibition myogenesis could induce adipogenic process in myogenic cell lines [64–66], which implicated that the decrease in myogenesis might to some extent be involved in the enhancing of adipogenesis by n-3 PUFA enriched in skeletal muscle in the present study.

In conclusion, increasing the n-3 PUFA enrichment in the skeletal muscle of growing-finishing pigs by feeding linseed could activate PPAR δ , which may subsequently upregulate the expression of PPAR γ to promote

Fig. 6 The pathways of adipogenesis potential to be affected by n-3 PUFA in skeletal muscle. n-3 PUFA enrichment in the skeletal muscle could activate peroxisome proliferator-activated receptor δ (PPAR δ), which may subsequently upregulate the expression of PPAR γ and then the target genes of PPAR γ (such as adipocyte fatty acid-binding protein (aP2) and lipoprotein lipase (LPL)) to promote adipogenesis; n-3 PUFA could also inhibit the producing of tumor necrosis factor- α (TNF α) and then decrease the expression of wingless related MMTV integration site 10b (Wnt10b), so as to release the inhibition of adipogenesis by Wnt signaling

adipogenesis. Meanwhile, n-3 PUFA enriched in the skeletal muscle could also decrease the expression of *Wnt10b* and *Wnt/β-Catenin* signaling to release the inhibition of adipogenesis, consequently increasing IMF deposition (Fig. 6). Sufficient n-3 PUFA enrichment (5.16% in the present study) in skeletal muscle may be required for efficiently affecting the expression of genes involved in adipogenesis, and further influencing IMF deposition.

Implication

IMF content is an important determinant of meat eating quality. In the present study, we revealed that including linseed (rich in n-3 PUFA) in the diet could increase the IMF content of pigs, which might then enhance the eating quality of pork. The result indicates that IMF content could be manipulated by dietary nutrients. Dietary nutrients can regulate metabolism and genes expression in tissues, the investigation of nutritional regulation pathways and mechanisms of IMF deposition would provide a basis for nutritional manipulation of IMF, and also facilitate successful regulation of improving IMF content and meat eating quality.

Acknowledgments This research was supported by the National High Technology R & D Program of China (No. 2006AA10Z140), National Natural Science Foundation of China (No. 30871779) and Major Science & Technology Industrialization Projects in Wuhan City of China (No. 200720112026). Introduction

Numerous studies have been performed on the effects of dark chocolate or cocoa in relation to public health [1, 2]. Improved immune function [3, 4], cardiovascular status [5] and insulin sensitivity [6, 7] are among the reported positive health effects of cocoa. Cocoa contains flavonoids, which are believed to mediate the beneficial effects of dark chocolate. Flavan-3-ol has recently received much attention due to its cardioprotective properties [1]. However, the lipid content of chocolate and cocoa is relatively high, and with a high percentage of saturated fatty acids (SFA).

Epidemiological studies have shown that intake of excess SFA is the principal lifestyle-related cause of insulin resistance and obesity-related diseases in humans [8]. Carbohydrate tolerance and whole-body insulin sensitivity have been shown to be impaired with consumption of diets enriched with SFA in healthy human subjects [9, 10] and experimental animals [11–13]. The concept that dietary SFA produces hypercholesterolemia is also widely accepted. However, cocoa butter has been shown to have little or no effect on plasma cholesterol levels and the development of atherosclerosis when fed to animals [14–16] and humans [17, 18]. It has been suggested that this neutral effect of cocoa butter might be related to its relatively low digestibility [19] and lymphatic absorption [20]. Furthermore, stearic acid, which is the main saturated fatty acid in cocoa butter, has been shown to have a neutral effect on the plasma lipid profile [21]. Ingested cocoa has also been shown to reduce de novo lipid synthesis in rat liver [22], which might explain some of the positive health

effects of cocoa. Whether cocoa butter would exert similar effects on the liver is not known.

It is well accepted that hepatic fat accumulation is linked to insulin resistance [23], and that fatty liver is an independent predictor of type 2 diabetes, the metabolic syndrome and cardiovascular disease [24, 25]. Since fatty liver leads to failure of insulin to suppress hepatic glucose production, subjects with a fatty liver have an increased risk of developing hyperglycemia, glucose intolerance and peripheral insulin resistance. Furthermore, hepatic insulin resistance includes the decreased ability of insulin to suppress triglyceride-rich VLDL particle production in the liver [26], leading to hypertriglyceridemia and low HDL cholesterol concentration [27]. Hepatic insulin resistance is thus likely to be an important factor of the metabolic syndrome.

Short term (3 days) high-fat feeding in rats results specifically in hepatic fat accumulation and has been used as a model to study the mechanisms underlying hepatic insulin resistance [28, 29]. Three days of high-fat feeding, using safflower oil as lipid source, is sufficient to cause a threefold increase in hepatic lipid content and to suppress insulin sensitivity [29]. Safflower oil is rich in linoleic acid (18:2n-6) and has been shown to increase oxidative and inflammatory stresses [30–32], which are thought to be involved in the development of e.g. hepatic insulin resistance. Since hepatic insulin signaling results in increased de novo lipogenesis, suppressed hepatic insulin sensitivity might be protective for the liver during situations of increased dietary fat. Short-term oxidative stress, in the absence of lipotoxicity and inflammation, might thus be part of a cellular defense system where reduced insulin signaling protects the liver from further lipid loading. It has been proposed that insulin resistance is good when viewed in its original evolutionary context, but becomes pathological upon persistent stimulation by oxidative stress [33].

In contrast to the neutral effect of cocoa butter on plasma cholesterol levels, linoleic acid-enriched diets have beneficial effects on circulating cholesterol levels [34–36]. The aim of this study was to get clues as to whether this difference can be attributed to differences at the level of hepatic metabolism. The lipid content of chocolate and cocoa is relatively high, but the effects of ingested cocoa butter on markers for hepatic lipid metabolism and insulin signaling have to our knowledge not been addressed before. In the present study we sought (1) to answer whether short-term cocoa butter feeding is neutral, beneficial or detrimental regarding hepatic lipid metabolism, and (2) to identify similarities as well as differences between cocoa butter and safflower oil regarding effects on plasma lipoproteins, hepatic gene expression, lipid metabolism and insulin sensitivity using short-term high-fat feeding in rats.

Experimental Procedure

Animal Experiments

Seven week old male Sprague–Dawley rats (Scanbur BK AB) were maintained on standard chow (R36, Lactamin, Sweden) for a week before start of the experiment. Rats were thereafter fed for 3 days with either standard, cocoa butter- or safflower oil-enriched R36 diets. The compositions of these diets are shown in Table 1. The fatty acid compositions of the high-fat diets were the following; the safflower-enriched diet contained 77% linoleic, 15% oleic, 6% palmitic and 2% stearic acid; whereas the cocoa butter-enriched diet contained 36% stearic, 33% oleic, 25% palmitic and 3% linoleic acid. Food was removed late in the evening (11 p.m.), so that the animals were without food for 12 h before they were sacrificed.

Four rats from each group were injected intraperitoneally with insulin (Actrapid, Novo Nordisk), at a dose of 5 mU/g body weight, and four with saline only. Immediately before and 40 min after the injection, a drop of blood was collected from the tip of the tail and analyzed for blood glucose, using a Precision Xtra glucometer and test strips (Abbot Scandinavia AB). The rats were sacrificed and tissues removed and frozen in liquid nitrogen. The animal experiments were approved by the regional Ethics Committee on Animal Experiments.

Plasma Analysis

Blood was collected from the vena cava in 10-ml tubes containing 17.5 mg EDTA (B&D). Plasma was obtained by centrifugation at 3,000 g for 10 min. The resulting supernatants were removed and analyzed for insulin (RIA kits from Millipore) and lipids. Lipoprotein separation, by size-exclusion chromatography on individual samples from each animal, and lipid content calculations

were performed as described previously [37]. Plasma levels of cytokines (IL-1 β , IL-6, IL-17 and TNF α) were determined using Rat Cytokine/Chemokine Milliplex Kit (Millipore) and a Luminex instrument (LABScan 100, Luminex), according to the manufacturer's instructions.

Hepatic Lipid Content

Cellular lipids were extracted from the rat liver using chloroform and methanol (2:1 v/v), using the Folch method [38]. The extracts were dried, dissolved and analyzed for triacylglycerides and total (free and esterified) cholesterol, using kits from Roche and Calbiochem, respectively. Samples were analyzed in triplicate and the results expressed as microgram lipid per milligram liver weight.

Fatty Acid Oxidation

Hepatic β -oxidation was assayed by monitoring the palmitoyl-CoA-dependent reduction of NAD to NADH in sub-fractionated liver homogenates, as described previously [39]. Liver tissues (300 mg) were homogenized in 3 ml ice-cold sucrose-solution (0.25 M sucrose, 10 mM HEPES, 1 mM EDTA) using a Potter–Elvehjem glass-Teflon homogenizer. The homogenates (1 ml) were centrifuged for 10 min at 500 g, the supernatants withdrawn and centrifuged for 10 min at 10,000 g, and the resulting pellet re-suspended in sucrose-solution. The samples were added to the reaction buffer to a final concentration of 30 mM phosphate buffer pH 7.5, 0.2 mM NAD, 0.1 mM coenzyme A, 12 mM DTT, 0.15 mg/ml BSA (fatty acid free) and 0.01% triton X-100 (Sigma–Aldrich, Inc). The initial rate of NADH production was determined upon addition of palmitoyl-CoA (Sigma–Aldrich, Inc) (10 μ g/ml) at 37 °C. The absorbance at 340 nm was measured spectrophotometrically.

Table 1 Diet compositions

	R36 standard		Safflower oil-enriched		Cocoa butter-enriched	
	Component (g/100 g diet)	Energy (%)	Component (g/100 g diet)	Energy (%)	Component (g/100 g diet)	Energy (%)
Moisture	10	–	10	–	10	–
Ash	6	–	6	–	6	–
Fiber	3.5	0.8	2.7	0.5	2.7	0.5
Carbohydrate	58	67.8	40.1	36.3	40.1	36.3

Total calories (kJ/100 g)	128.8		166.1		166.1	

Analysis of Gene Expression by Quantitative Real-Time PCR

Total RNA was isolated by homogenization of frozen rat livers using a polytrone PT-2000 (Kinematica AG) and TRIzol[®] Reagent (Invitrogen Life Technologies) according to the protocol supplied by the manufacturer. The RNA concentration was determined spectrophotometrically at 260 and 280 nm. The quality of the RNA samples was examined using a RNA 6000 Nano Bioanalyzer according to the manufacturer's instructions (Agilent Technologies).

5 µg total RNA was treated with DNase (RQ1) and reverse transcribed using iScript[™] reverse transcriptase and 5× buffer for a First Strand cDNA synthesis (Bio-Rad Laboratories AB). The purity of the synthesized cDNA was checked by agarose gel electrophoresis. Subsequently, 2 µl of each first strand cDNA served as a template in a 20 µl PCR reaction mix containing the primers for the gene of interest (see Table 2) and iQ SYBR Green Supermix (Bio-Rad Laboratories AB). Quantification of gene expression was performed according to the manufacturer's protocol using DNA Engine Opticon[™]2 real-time PCR detection system (MJ Research). A relative standard curve was constructed with serial dilutions (1:1, 1:5 and 1:25) using a pool of the cDNA generated from all animals used in the study. The amplification program consisted of 1 cycle of 95 °C for 10 min, followed by 45 cycles of 95 °C for 15 s, annealing temperature for 10 s, 72 °C for 30 s; fluorescent intensity was measured at a specific acquisition temperature for each gene. The protocol was validated for each gene of interest by checking melting curves for the absence of primer-dimers or other unwanted amplicons. The level of individual mRNAs was normalized with the level of the housekeeping gene ribosomal protein long-chain protein P0 (RPLP). Results are expressed in arbitrary units.

Immunoblotting

Whole liver cell lysates were obtained by homogenizing 100 mg of liver in 1 ml RIPA buffer (50 mM Tris-HCl, pH 7.4, 1% Triton X-100, 150 mM NaCl, 5 mM EDTA,

1 mM PMSF, 1 mM Na₃VO₄, 10 mM NaF, 1 µg/ml of aprotinin, leupeptin, and pepstatin), using a polytrone PT-2000 (Kinematica AG), followed by 20 min of centrifugation (12,000g). The resulting supernatants were collected and proteins resolved by SDS-PAGE and transferred to PVDF membranes. The membranes were blocked for 1 h in Tris-buffered saline (TBS; 10 mM Tris pH 8.0, 150 mM NaCl) containing 0.1% (v/v) Tween-20 and 5% (w/v) milk powder or 5% (w/v) bovine serum albumin, incubated overnight at 4 °C with the antibody of interest diluted in TBS-T with 1% milk or bovine serum albumin. Antibodies for detecting IGFBP1 (1:500) were from Abcam; p-STAT3-Tyr705, STAT3, p-STAT5-Tyr694 (1:500), SOCS2, STAT5, p-AMPK-Thr172 and AMPK (1:1,000) were from Cell signaling; SCD-1 (1:500), SREBP-1, IRS (1:2,000), p-IRS1-Ser307 (1:1,000) and β-actin (1:50,000) were from SantaCruz. The membranes were washed and incubated with secondary antibody for 1 h in room temperature according to the data sheet provided by the company. After additional washing steps antibody binding was visualized using an ECL detection system (Pierce Biotechnology, Inc). Densitometry analysis was performed using the software Quantity One 4.6.5 Basic (Bio-Rad) to compare the amount of the antibody of interest to β-actin.

Akt Phosphorylation

Whole liver cell lysates were obtained by homogenizing 1 g of liver in 3 ml RIPA buffer, as described above). The resulting supernatants were collected and the degree of insulin signaling was analyzed by measuring the degree of insulin-dependent phosphorylation of Akt and GSK3β. Akt activation was determined by analyzing the amount of phosphorylated Akt (p-Akt-Ser473) in relation to total Akt, using commercially available ELISA kits (Biosource). Samples were analyzed in triplicate and the results determined as unit p-Akt per ng total Akt.

Expression Profiling Using Microarrays

Microarrays containing 70-mer oligonucleotide probes for 27,649 rat protein-coding genes were fabricated and used

Table 2 Primers

to obtain transcript profiles, essentially as described previously [40]. A 40- μg amount of the total RNA from each sample were DNase-treated using RNeasy MiniElute Cleanup kit (QIAGEN) according to the supplied protocol and RNA concentrations measured using a NanoDrop ND-1000 Spectrophotometer (NanoDrop Technologies Inc.). The microarray experiments were performed using the Pronto!TM Plus Direct Systems (Corning Incorporated and Promega Corporation, NY), according to the manufacturer's instructions using 5 μg total RNA from each sample. In the first set of experiments, each hybridization compared Cy3-labeled cDNA reverse transcribed from RNA isolated from rats fed the standard diet with Cy5-labeled cDNA isolated from rats fed the high-fat diets. Each experiment was analyzed using individual samples and dye-swapping. The Cy3-labelled cDNA was mixed with Cy5-labelled cDNA and purified using the Chip-ShotTM Membrane Clean-Up System. The probes were next mixed with 45 μl hybridization solution, added to the arrays and placed in sealed hybridization chambers at 42 °C. After an overnight incubation (18–19 h), arrays were washed, dried and scanned to create images, using a Genepix 4200A laser scanner (Axon Instruments, Union City, CA, USA). For each array, the photomultiplier tubes and power of the laser were adjusted so that the overall count ratio of Cy5 to Cy3 signal was approximately 1. Image analysis was performed using the GenePix 6.0 software (Axon Instruments). Automatic flagging was used to localize absent or very weak spots, which were excluded from further analysis.

The analyzed image files were filtered for spots showing signals at least two times above background. The fluorescence ratios of the spots were further normalized with the Lowess (Locally Weighted Scatter Plot Smoother) method using the statistical language R (R 1.3.1 software). Identification of differentially expressed genes (due to high-fat feeding) was performed using the SAM 1.21 (Significance Analysis for Microarray) software incorporated in Microsoft office Excel program. A 5% false discovery rate was used as a first cut-off. Genes with a greater than 1.5-fold increase or decrease were considered as being regulated, even though smaller changes in gene expression may also have important biological consequences. The results are represented as the mean of at least three independent determinations. All data are available from the NCBI Gene Expression Omnibus database (GEO; <http://www.ncbi.nlm.nih.gov/geo/>) using the series entry GSE13936.

Statistical Analysis

All data were subjected to analysis of variance (one-way ANOVA) followed by Fisher's post-hoc analysis and expressed as means \pm SE. Differences between groups

were considered statistically significant when the probability that they occurred by chance was <0.05 .

Results

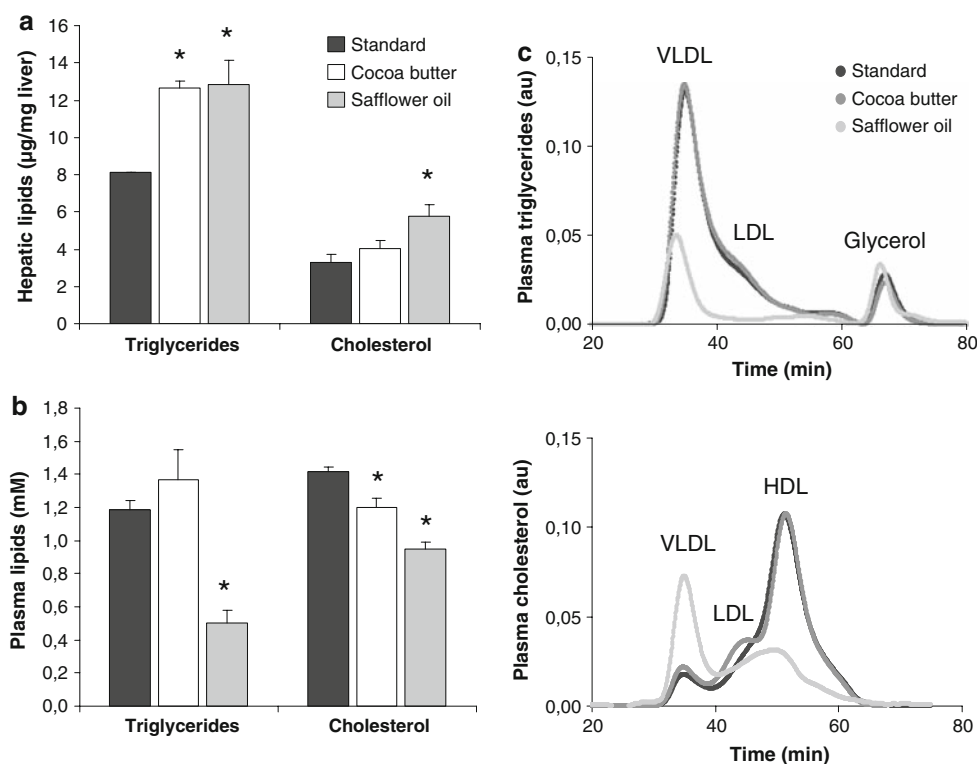

High-Fat Diet-Mediated Effects on Lipid Profiles and Hepatic Gene Expression

Rats fed a cocoa butter-enriched diet (CBD; 52% of the energy from cocoa butter) for 3 days were compared to rats fed safflower oil-enriched diet (SOD; 52% of the energy from safflower oil) or standard diet (StD; 9% of the energy from cocoa butter). Hepatic triglyceride (TG) content was increased in animals fed high-fat diets, as compared to those fed StD (Fig. 1a). No difference in TG content was observed between the two different high-fat diets. In contrast, only SOD-fed rats had increased levels of hepatic cholesterol. Safflower oil exerted the biggest effects on plasma lipids. As illustrated in Fig. 1b, the SOD-fed rats had the lowest plasma levels of TG and cholesterol. CBD-fed rats had similar plasma TG content as the rats on StD, but lower levels of plasma cholesterol.

To determine the effects of the different high-fat diets on lipoproteins, plasma lipid profiles were generated from the three diet groups. Again, SOD had the greatest impact on plasma lipids. As shown in Fig. 1c, ingested safflower oil decreased TG-rich VLDL particles and increased cholesterol-rich VLDL particles. At the same time, HDL cholesterol was reduced. No difference was observed between the rats fed CBD and StD. Thus, in spite of similar hepatic lipid content, the two different high-fat diets elicited different effects on plasma lipoprotein particles. The results are in line with previous publications [34], and indicate lipid-specific effects (i.e. dependent on lipid source) on hepatic lipid and lipoprotein metabolism.

To get an overview of high-fat diet-mediated alterations within the liver, whole-genome rat oligo microarrays were used to generate hepatic transcript profiles (using livers from StD-fed animals as control). Surprisingly, the CBD had a much greater impact on gene expression than the SOD. With a 5% false discovery rate and a cut-off at 1.5-fold difference, 822 transcripts were significantly different between CBD- and StD-fed animals, whereas only 151 transcripts were altered in response to SOD-feeding. Most effects were lipid-specific (i.e. dependent on lipid source), but 73 transcripts were similarly altered in the two high-fat groups (Fig. 2a). The high-fat-regulated transcripts were grouped according to cellular functions and some interesting results are listed in Table 3. All data are available from the NCBI Gene Expression Omnibus database (GEO; <http://www.ncbi.nlm.nih.gov/geo/>) using the series entry GSE13936.

Data are represented as means \pm SE, and * indicates significant differences compared to standard diet ($n = 4$). The chromatograms represent the average from determinations performed on individual samples

High-Fat Diet-Mediated Changes in Gene Expression Independent on Lipid Source

As mentioned above, hepatic TG content was increased to the same extent in the two high-fat groups, which might elicit a similar response on certain genes. Among the gene products similarly altered in the two high-fat groups, the biggest changes (more than 2.5-fold) were observed for stearoyl-CoA desaturase 1 (SCD-1) and 2 (SCD-2), fibroblast growth factor 21 (FGF21), nuclear protein 1 (p8) and serine dehydratase (Table 3). Reduced levels of serine dehydratase might indicate reduced amino acid catabolism. Similarly, increased levels of glucokinase (Table 3) indicate enhanced capacity for hepatic glucose uptake and enhanced activity through anabolic pathways.

The p8 protein is a transcription factor that regulates the expression of genes involved in cell defense against adverse effects of stress [41]. Such stress-mediated survival mechanisms within the liver involve protein kinase C delta binding protein (DIG-1) and insulin-like growth factor-binding protein 1 (IGFBP-1) [42]. Both DIG-1 and IGFBP-1 mRNA were increased in our high-fat fed animals (Table 3). Based on microarray data IGFBP-1 mRNA levels were only increased in CBD-fed rats, but quantitative RT-PCR showed increased IGFBP-1 mRNA levels in both fat-fed groups (Fig. 2b). However, IGFBP-1 protein was increased in CBD-fed rats only (Fig. 3a).

As shown in Fig. 2b, the high-fat-mediated induction of FGF21 mRNA was confirmed using RT-PCR. Since FGF21-treatment in animals has been shown to increase fat utilization and to reduce hepatosteatosis [43], the rate of β -oxidation was compared between the groups. As shown in Fig. 4a, the SOD-fed rats had a 2.7-fold increase in fatty acid (FA) turnover rate. A trend ($p = 0.07$) towards increased β -oxidation was also observed in the CBD-fed rats.

Among the lipid-induced effects on gene products from metabolic pathways, the biggest changes were observed for SCD-1 and 2. The high-fat-mediated reduction of SCD-1 mRNAs was confirmed using RT-PCR (Fig. 2b) and reduced SCD-1 protein levels were demonstrated using immunoblotting (Fig. 3b). This is an interesting finding since SCD-1 deficiency leads to activation of lipid oxidation, reduced TG synthesis and storage within the liver [44]. The lowest levels of both mRNA and protein were observed in the SOD-fed rats. Increased AMP-activated protein kinase (AMPK) activity has been shown to mediate SCD-1 dependent effects on hepatic β -oxidation [45]. We analyzed the degree of AMPK activation, i.e. the degree of phosphorylation, but the higher rate of β -oxidation in the SOD group was not paralleled by increased AMPK phosphorylation (Fig. 4b).

Both PUFA and monounsaturated fatty acids (MUFA) activate farnesoid X receptor (FXR), and thereby decrease the mature form of sterol regulatory element binding

Fig. 2 Effects of short-term high-fat feeding on hepatic gene expression. **a** Overview of results obtained from microarray analysis comparing the effects of cocoa butter and safflower oil on hepatic gene expression. Whole-genome rat oligo microarrays were used to generate transcript profiles from rats fed a standard diet (StD) or either cocoa butter- (CBD) or safflower oil- (SOD) enriched diets ($n = 4$). StD-fed animals were used as control. A 5% false discovery rate was used and transcripts with a greater value than 1.5-fold increase or decrease (compared to StD) were considered differentially expressed. The total number of hepatic gene products affected by CBD (no fill), SOD (black fill), or both (gray fill) are indicated. **b** Effects of short-term high-fat feeding on selected hepatic transcript levels. Hepatic mRNA was isolated from rats fed standard or high-fat diets. Expression levels were quantified by real-time PCR and normalized to the housekeeping gene RPLP. Data are represented as means \pm SE, and * indicates significant differences compared to standard diet ($n = 4$)

protein-1c (SREBP-1c), as well as the expression of its target lipogenic genes such as SCD-1 in liver [46]. We therefore compared the content of hepatic SREBP-1 between the three diet groups. Surprisingly, the mature form of SREBP-1 (68 kDa) was elevated at the expense of unprocessed SREBP-1 (125 kDa) in both CBD- and SOD-fed rats (Fig. 4c). This observation suggests that SCD-1 expression can be repressed upon high-fat feeding through a mechanism that does not depend on reduced SREBP-1 maturation.

Taken together, these results indicate that a lipid-induced program for hepatic lipid disposal and cell survival might be operating upon 3 days of high-fat feeding. The former might involve increased levels of FGF21 and reduced levels of SCD-1 and SCD-2, whereas the latter includes increased levels of p8, DIG-1 and IGFBP-1.

Cocoa Butter Diet-Mediated Changes in Gene Expression

As summarized in Table 3, cocoa butter had a greater impact on hepatic genes from all functional groups listed, as compared to safflower oil. Rats fed CBD had increased levels of gene products from anabolic pathways, including biosynthesis of amino acids and lipids with cholesterologenesis being represented by the largest number of transcripts (Table 3). Several genes from the glycolytic pathway and de novo lipid synthesis were increased about twofold, including transketolase, pyruvate kinase, malic enzyme 1, ATP citrate lyase and spot 14. ATP citrate lyase catalyzes the formation of acetyl-CoA and oxaloacetate, and acetyl-CoA serves several important biosynthetic pathways such as fatty acid, cholesterol and bile acid synthesis. However, the biggest changes in expression levels (more than fivefold) were observed for 3-phosphoglycerate dehydrogenase (3-PGDH), phosphoserine aminotransferase 1 (PSAT1), asparagine synthase and early growth response 1 (EGR1). Higher levels of 3-PGDH and PSAT1 indicate a greater capacity for serine synthesis and serine-dependent pathways, such as the biosynthesis of phosphatidylserine and glutathione.

The effect on EGR1 might be related to a CBD-specific effect on inflammatory mediators, including the observed increase in expression of macrophage migration inhibitory factor and interleukin 17 receptor B (Table 3). This is in line with previous reports on EGR1 as a master switch to trigger the expression of inflammatory genes involved in e.g. atherosclerosis [47]. Since EGR1-negative mice have been shown to exhibit decreased expression of hepatic IL-6 mRNA [48], this and other cytokines (IL-1 β , IL-17, and TNF α) were measured in plasma from the different rats. However, only one animal (from the SOD group) had detectable levels of inflammatory cytokines (IL-6, 945 pg/ml; IL-1 β , 168 pg/ml). We further measured the degree of activation (phosphorylation) of the transcription factor STAT3, which is known to be activated in response to IL-6 and other cytokines [49]. There was no indication of enhanced STAT3 signaling in these rats, as determined by immunoblotting (data not shown).

Within the group of transcripts for signaling molecules, suppressor of cytokine signaling 2 (SOCS2) showed the greatest response to CBD-feeding. Reduced expression of SOCS2 mRNA was confirmed using RT-PCR (Fig. 2b),

Total hepatic RNA was extracted from rats fed different diets ($n = 4$) and the effect of cocoa butter or safflower oil on gene expression was studied using rat whole-genome oligo arrays. The data were obtained using SAM at a false discovery rate of 5% and are represented as mean fold changes. All data are available from the NCBI Gene Expression Omnibus database (GEO; <http://www.ncbi.nlm.nih.gov/geo/>) using the series entry GSE13936

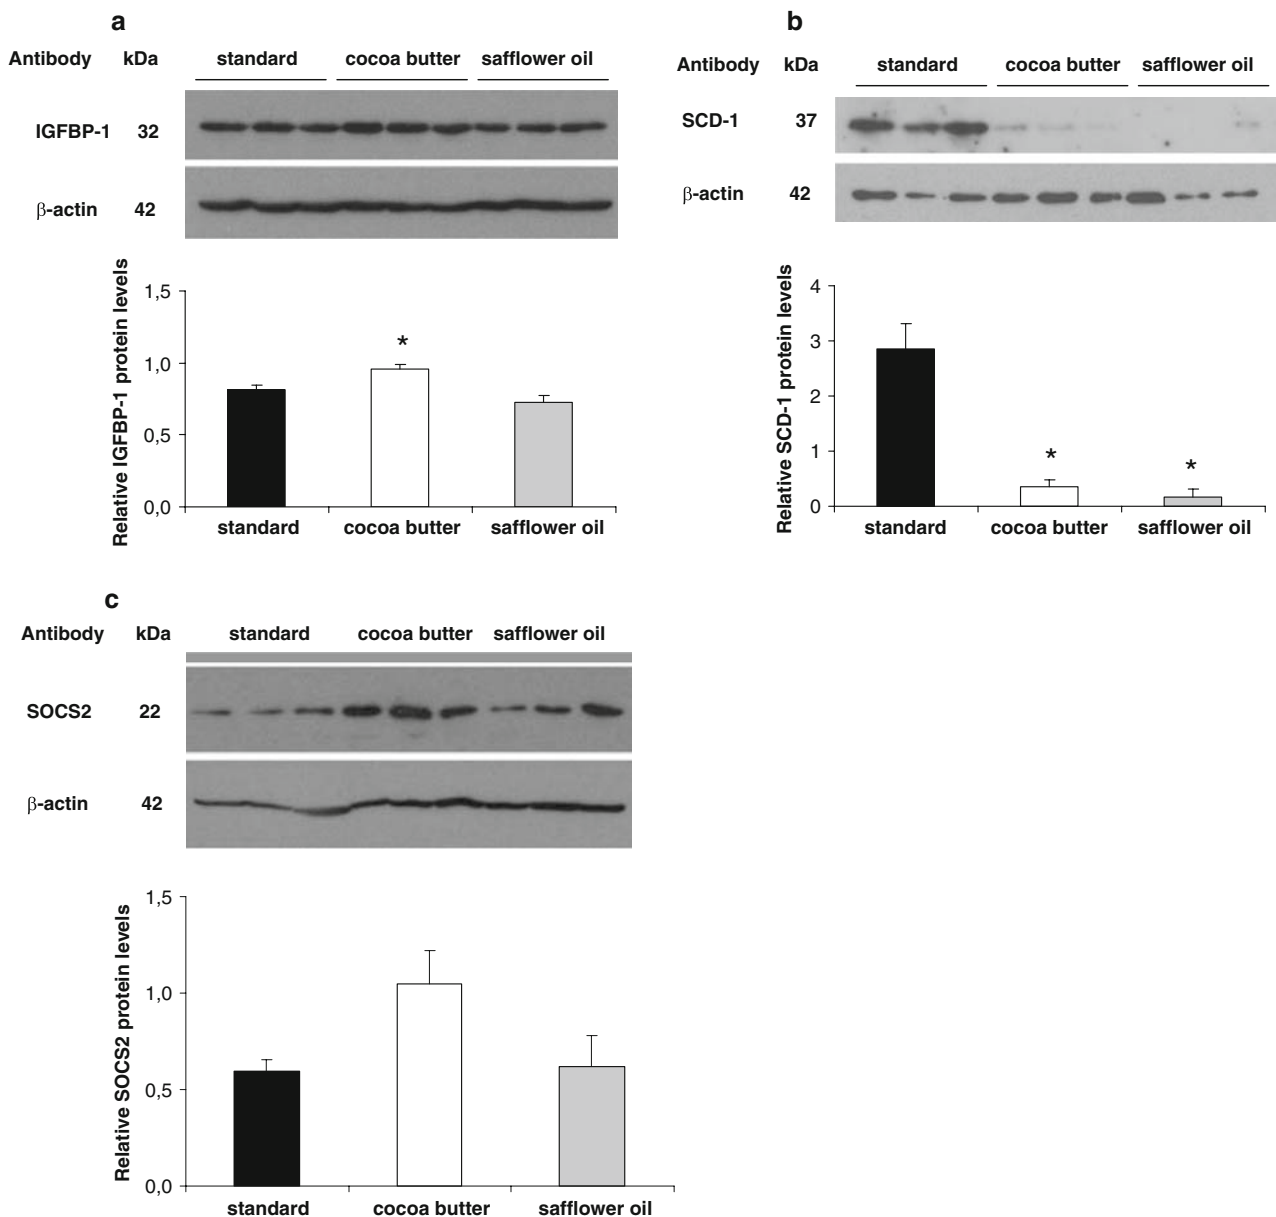

Fig. 3 Effects of short-term high-fat feeding on selected hepatic protein levels. Livers from rats fed standard or high-fat diets were used to extract whole-cell lysates. Protein levels of **a** IGFBP-1, **b** SCD-1 and **c** SOCS2 were analyzed by immunoblotting (*upper*

section) and quantified by densitometry analysis in relation to β -actin (*lower section*). Data are represented as means \pm SE, and * indicates significant differences compared to standard diet ($n = 3$)

but a trend ($p = 0,112$) towards increased SOCS2 protein levels were demonstrated using immunoblotting (Fig. 3c). SOCS2 is a negative regulator of growth hormone (GH)-mediated signaling and gene regulation, which includes down-regulation of its own GH-dependent expression [50, 51]. Reduced GH signaling, supposedly due to increased SOCS2 protein in the CBD group, might thus explain the reduced expression of SOCS2 mRNA as well as the observed effects on other GH-regulated transcripts in these animals (Table 3). Those include IGFBP1 [52], insulin-like

growth factor binding protein acid labile subunit [53], prolactin receptor [54], CYP2C7 [55], SCD-1 [40, 56] and SCD-2 [51].

Taken together, the results described above suggest that rats fed a cocoa butter-enriched diet for 3 days might have a higher capacity to synthesize fatty acids, phospholipids, cholesterol and bile acids, as compared to rats fed safflower oil. Altered GH-signaling and expression of GH-regulated genes in the CBD-fed rats might lead to further perturbations in hepatic lipid metabolism.

Fig. 4 Effects of short-term high-fat feeding on hepatic fatty acid oxidation rates and SREBP-1 protein levels. **a** Fatty acid oxidation rates were determined in liver homogenates ($n = 4$), whereas **b** AMPK phosphorylation ($n = 4$) and **c** SREBP-1 maturation ($n = 3$) were

determined in whole-cell lysates by immunoblotting (*upper section*) and quantified by densitometry analysis in relation to total AMPK or β -actin (*lower section*). Data are represented as means \pm SE, and * indicates significant differences compared to standard diet

High-Fat Diet-Mediated Effects on Hepatic Insulin Sensitivity

Finally, hepatic insulin sensitivity was compared between the three diet groups. The effect of insulin treatment (i.p. injection) was investigated using the degree of Akt-activation (phosphorylation at Ser473) as a measure of insulin receptor signaling [57]. All rats responded to insulin through increased Akt-phosphorylation, but the safflower oil-fed rats were only half as sensitive as the other animals (Fig. 5a). This indicates that, in spite of a similar degree of hepatic lipid content, hepatic insulin signaling was more efficient in the CBD-fed rats as compared to those fed with safflower oil. Cellular stress and free fatty acids (among other things) are known to induce insulin resistance through the activation of several serine/threonine kinases that phosphorylate and inactivate IRS1. In the liver, phosphorylation of IRS1 at Ser307 has been suggested to play a role in the development of high-fat feeding-induced insulin resistance [58]. To find an explanation for the lipid-dependent differences in Akt-phosphorylation we next compared the degree of IRS1-phosphorylation. There was

no indication of enhanced phosphorylation of IRS1 at Ser307 in the SOD-fed rats, as determined by immunoblotting (data not shown).

One important function of hepatic insulin signaling is to suppress TG-rich VLDL particle production [24]. Comparing rats on StD with those on CBD, a similar reduction in both plasma TG levels (Fig. 5c) and TG-rich VLDL particles (Fig. 5d) were observed. The SOD-fed rats did not respond, which might reflect reduced hepatic insulin sensitivity or alternatively be due to the already low levels of TG-rich VLDL in these rats. All rats responded equally well to insulin at the level of blood glucose lowering, and their basal glucose levels were the same (Fig. 5b). Basal insulin levels were also similar between the groups (StD 1.57 ± 0.15 ng/ml; CBD 1.10 ± 0.07 ng/ml; SOD 1.62 ± 0.23 ng/ml).

Discussion

In the present study, short-term cocoa butter feeding in healthy rats was neutral regarding serum lipids and hepatic

Fig. 5 Effects of short-term high-fat feeding on effects of insulin treatment. Rats fed standard or high-fat diets were subjected to 40 min of saline or insulin treatment. **a** The ratio between phosphorylated and unphosphorylated Akt was determined in whole liver cell lysates using ELISA. Levels of **b** glucose in blood and **c** TG in plasma were

determined, and **d** plasma lipoprotein profiles were generated. Data are represented as means \pm SE, * indicates significant differences compared to standard diet, and \square indicates significant differences compared to saline treatment ($n = 4$). The chromatograms represent the average from determinations performed in individual samples

insulin sensitivity, but changes in hepatic gene expression were induced that might lead to increased lipid synthesis, lipotoxicity, inflammation and insulin resistance if maintained. Safflower oil increased hepatic β -oxidation, was beneficial in terms of circulating TG-rich VLDL particles, but led to reduced hepatic insulin receptor signaling. The effects of safflower oil on hepatic gene expression were partly overlapping with those exerted by cocoa butter, but fewer transcripts from anabolic pathways were altered.

Increased hepatic cholesterol levels and increased expression of hepatic CYP7A1 and ABCG5 mRNA, important gene products in bile acid production and cholesterol excretion, were specific effects elicited by safflower oil only. Common effects on gene expression included increased levels of p8, DIG-1, IGF1BP-1 and FGF21, as well as reduced levels of SCD-1 and SCD-2. This indicates that a lipid-dependent program for hepatic lipid disposal and cell survival was induced by 3 days of high-fat

feeding, independently of the lipid source. The observation that cocoa butter exerted a similar degree of SCD-1 reduction as did safflower oil has to our knowledge not been described before. The mechanism behind this effect is as yet unknown, but data presented herein suggest that it is independent of reduced SREBP-1 maturation.

The diet-specific effects on plasma lipids are in agreement with previous studies [34], and might partly be explained by differences in hepatic FA oxidation rates. The level of TG in plasma is most often related to VLDL production in the liver, and this in turn is dependent on whether FA are being used for FA oxidation or re-esterification [27]. The enhanced FA oxidation rate in the SOD-fed rats indicates that both de novo FA synthesis [45] and lipoprotein formation was reduced [59], leading to lowered levels of plasma TG. Another explanation might be provided by diet-specific FA compositions in combination with reduced hepatic expression of SCD-1.

SCD-1 is a microsomal enzyme required for the biosynthesis of oleate and palmitoleate, which are the major MUFA of membrane phospholipids, TG, and cholesteryl esters (CE). SCD-1 gene expression is highly regulated by dietary factors; induced by carbohydrates or cholesterol but repressed by PUFA to maintain lipid homeostasis [60, 61]. Cholesterol has been shown to override PUFA-mediated repression of the SCD-1 gene [62], which might redistribute FA from FA oxidation to esterification, CE formation and VLDL production. SCD-1 deficiency has been linked to reduced plasma VLDL secretion [63], lending further support to the notion that oleoyl-CoA and palmitoleyl-CoA produced by SCD-1 are necessary to synthesize CE targeted to hepatic VLDL secretion. In the present study, low expression of SCD-1 might thus contribute to the reduced plasma levels of TG-rich VLDL particles observed in the SOD-fed rats. Cocoa butter has a higher content of MUFA compared to safflower oil (33 vs. 15%). Since MUFA (mainly oleate) are supplied to a greater extent by the CBD, reduced synthesis of oleoyl-CoA and palmitoleyl-CoA might not affect VLDL secretion to the same extent as in the SOD-fed rats. Supposedly, the higher rate of β -oxidation upon SOD-feeding might in part be a consequence of reduced VLDL secretion and re-esterification of FA into CE.

Hepatic cholesterol was increased, VLDL cholesterol increased and HDL cholesterol reduced after 3 days SOD-feeding, whereas there were no such changes due to CBD-feeding. Since reduced reverse cholesterol transport is well-known to promote atherosclerosis, this indicates a potential proatherogenic effect of the former dietary regimen. The SOD-mediated increase in hepatic cholesterol might lead to liver X receptor (LXR) stimulation and thus explain the increased expression of CYP7A1 [64] and the sterol transporter ABCG5 [65]. This effect of safflower oil

on gene products involved in hepatic cholesterol turnover has to our knowledge not been described before but might be related to the reduced expression of SCD-1 and capacity to export CE in VLDL particles in the SOD-fed rats.

Although it is well accepted that inhibition of SCD-1 prevents many aspects of the metabolic syndrome (diet-induced obesity, hepatic steatosis, insulin resistance, hypertriglyceridemia), it was recently shown that low levels of SCD-1 might promote aortic atherosclerosis in a mouse model of hyperlipidemia and atherosclerosis [66]. It was suggested that inhibition of SCD-1 in the liver results in secretion of VLDL particles that are highly enriched in SFA-rich CE, giving rise to SFA-CE-rich LDL particles. Increased delivery of SFA to macrophages leads to accumulation of SFA, enhanced inflammatory cytokine secretion and a proinflammatory phenotype. In the present study, reduced expression of SCD-1, in the absence of sufficient levels of dietary MUFA (i.e. in the SOD group only), was paralleled by increased hepatic cholesterol, increased VLDL cholesterol and reduced HDL-cholesterol. Whether this effect would persist upon longer periods of high dietary intake of safflower oil is not known and should be addressed.

The finding that SOD exerted a greater effect on FA oxidation as compared to CBD is in accordance with previous studies and might be related to its higher content of PUFA, which are known to be potent activators of PPAR α and modulators of lipid metabolism [67]. Upon PPAR α activation, CPT-I and II, peroxisomal and mitochondrial β -oxidation enzymes, enzymes of ketogenesis, and omega-oxidation enzymes are induced and create an increased capacity for FA oxidation [59]. However, none of these gene products were induced in the SOD-fed rats in this study (see GEO; <http://www.ncbi.nlm.nih.gov/geo/>). Increased β -oxidation has also been shown to be an effect of SCD-1 deficiency [44], but the CBD-fed rats had almost equally reduced SCD-1 expression without the same increase in FA oxidation. Increased AMPK activity has been shown to mediate the SCD-1 dependent effects on hepatic β -oxidation [45]. This pathway involves AMPK-dependent repression of acetyl-CoA carboxylase (ACC), reduced ACC-mediated formation of malonyl-CoA, and thereby de-repression of CPT-Ia enzymatic activity, leading to enhanced transfer of FA into the mitochondria [45, 68]. However, a higher rate of β -oxidation was not paralleled by an increased degree of AMPK phosphorylation in the SOD-fed rats.

The high-fat diet-mediated increase in FGF21 mRNA is interesting in this regard, since FGF21 has been shown to increase β -oxidation. FGF21, a hormone induced by fasting, is predominantly expressed in the liver and has beneficial effects on glucose homeostasis and insulin sensitivity both in rodents [69], monkeys [70] and man [71]. Furthermore, FGF21-treatment in animals was recently

shown to mediate increased energy expenditure, fat utilization and lipid excretion, to reduce hepatosteatosis and improve glycemia [43]. The mechanisms behind these effects were recently shown to include peroxisome proliferator-activated receptor gamma coactivator protein-1 α [72]. Whether there is any link between increased FGF21 levels and reduced SCD-1 expression has to await further studies.

It has also been shown that FGF21 induces SOCS2, blocks GH-dependent STAT5b signaling and alters the expression of GH-regulated genes during starvation [73]. Among other GH-suppressed gene products [74, 75], hepatic IGFBP-1 expression was found to be induced by FGF21 [73]. Our finding that FGF21 was induced by high-fat feeding in parallel with increased IGFBP-1 and increased FA oxidation is in line with the reports cited above, and adds to the picture of FGF21 as a sensor of FA availability, during starvation as well as during hepatic fatty infiltration. In the present study, 3 days of cocoa butter feeding seemed to induce the level of hepatic SOCS2 protein and altered the expression of genes previously shown to be under the regulation of GH, such as IGFBP1, insulin-like growth factor binding protein acid labile subunit, prolactin receptor, CYP2C7, SCD-1, SCD-2 as well as SOCS2. A down-regulation of SOCS2 mRNA in the CBD-fed rats indicates that GH sensitivity might become normalized with time and, since GH has lipogenic effects in the liver [76–78], lead to enhanced fatty infiltration if the high-fat feeding is maintained.

Circulating fasting levels of IGFBP-1 were recently shown to reflect hepatic lipid content and insulin sensitivity in non-diabetic humans, with IGFBP-1 levels being positively correlated with hepatic insulin sensitivity and inversely related to liver fat content [79]. Furthermore, low circulating IGFBP-1 concentrations have been linked with increased risk of macrovascular disease in humans [80]. Although the cause and effect relationship has not been proven, increased hepatic lipid content might lead to elevated levels of hepatic and circulating IGFBP-1, beneficial for metabolic health. Furthermore, stress-mediated survival mechanisms within the liver of rodents have been shown to involve IGFBP-1 [42]. In this study, we have shown that the p8 protein, DIG-1 and IGFBP-1 were induced by short-term high-fat feeding. The p8 protein is a transcription factor that regulates the expression of genes involved in cell defense, whereas DIG-1 is a protein kinase C delta binding protein that increases the protein stability of p53. When the expression of p53 target genes such as IGFBP-1 is increased, a survival pathway is initiated, which is thought to give the cell an opportunity to repair low-level damage. Since high levels of lipids within the hepatocyte are toxic to the cell, this high-fat response might include ways to reduce the hepatic lipid content. Another

interesting gene product of importance during situations of nutrient overload, and induced by high-fat feeding in the present study, is the eukaryotic translation initiation factor 4E-binding (eIF4E-binding) protein 1 (4E-BP1). The combined disruption of 4E-BP1 and 4E-BP2 in mice has been shown to increase their sensitivity to diet-induced obesity and insulin resistance [81]. It was suggested that 4E-BP1 and 2 play important roles as metabolic brakes in the development of obesity and type 2 diabetes. 4E-BP1 was induced to the same extent (more than twofold) in both CBD- and SOD-fed rats (Table 3).

The notion that SOD-feeding reduces hepatic insulin sensitivity has been described before [28, 29]. Our finding that 3 days on SOD reduces insulin-mediated phosphorylation of Akt in the absence of any detectable change in p-IRS1-Ser307 verifies the results presented by Samuel et al. [29]. In the same study, reduced activation of Akt was paralleled by blunted insulin-mediated suppression of hepatic glucose output (HGO). This important measure of hepatic insulin sensitivity was not investigated in the present study, and it can not be ruled out that cocoa butter feeding would lead to the same detrimental effect. The possibility that short-term HGO regulation is independent of Akt-phosphorylation should be investigated, but it would also be interesting to compare the impact of different high-fat feeding protocols on other hepatic effects of insulin, such as lipid and glycogen synthesis. Furthermore, there are Akt-independent signaling pathways that might have been differently affected by the high-fat diets. Further studies are required to address this and to find the SOD-mediated mechanism that blocks insulin receptor signaling up-stream of Akt. Specifically, the hypothesis that a greater FA oxidation rate, as a consequence of high dietary intake of safflower oil or similar fat sources, might lead to enhanced oxidative stress and insulin resistance should be tested.

As indicated above, the difference in insulin sensitivity at the level of Akt and GSK3 β between CBD- and SOD-fed rats does not exclude that hepatic insulin resistance might develop upon excess intake of cocoa butter. On the contrary, our transcript profiles could be interpreted as an increased capacity for lipid synthesis within the liver of CBD-fed rats, which might increase the risk of developing steatosis and insulin resistance. This is in contrast to the effects of cocoa ingestion, which was reported to suppress the expression of genes for enzymes involved in fatty acid synthesis in rat liver [22]. This beneficial effect of cocoa might therefore depend on lipophobic molecules absent in the butter fraction of cocoa.

Taken together, we have described short-term effects of high-fat feeding on hepatic gene expression in relation to lipid profiles and insulin signaling. Three days of a high dietary intake of cocoa butter led to changes within the

liver that might be part of a defense program triggered by the increase in hepatic TG. This included reduced expression of SCD-1, which could result in reduced synthesis of oleoyl-CoA and palmitoleyl-CoA of importance for VLDL secretion. However, the high content of oleate in cocoa butter (i.e. provided by the diet) might explain why there were no changes in plasma lipoproteins or hepatic cholesterol levels, in spite of reduced SCD-1. Thus, 3 days on this diet might not be a metabolic problem, but since there were other changes in transcript levels indicative of increased activity through anabolic pathways, it might be speculated that longer treatment duration would lead to steatosis and insulin resistance. In comparison, 3 days on a safflower oil-enriched diet resulted in similar defense-related changes, but this was paralleled by reduced TG-rich VLDL and HDL cholesterol in plasma, increased hepatic cholesterol, increased FA oxidation and reduced insulin signaling. The low expression of SCD-1 in the absence of sufficient MUFA supplied by the diet might result in a reduced ability to produce CE and VLDL, leading to reduced TG-rich VLDL in the circulation, increased cholesterol and fatty acids in the liver, and as a consequence of the latter, increased FA oxidation, ROS formation and insulin resistance. In summary, we speculate that increased hepatic TG leads to reduced expression of SCD-1, which might mediate either neutral, beneficial or unfavorable effects on hepatic metabolism upon high-fat feeding, depending on which fatty acids were provided by the diet.

local pigs than in other commercial pigs [3–5]. The Wujin pig is one of the Chinese local pigs, which is regarded as fatty genotype [6, 7]. The Landrace pig is considered a lean breed. Therefore, the underlying mechanism of fat deposition in fatty and lean pigs could be elucidated using these two pig models.

Triacylglycerol (TAG), the major component of IMF in muscles, is stored within the myofibers and mostly within the intramuscular adipocytes [8]. From a physiological perspective, lipid metabolism could theoretically contribute to the variation of fat deposition content [9–11]. Previous studies have investigated the difference of muscle lipid metabolism between fat and lean pig lines. However, these studies were mainly limited to lipogenesis and did not consider other aspects of lipid metabolism [12]. The extent of fat deposition in skeletal muscles depends on the balance of synthesis and degradation of TAG, which includes TAG synthesis, fat mobilization, fatty acid transport as well as fatty acid oxidation [13]. This fact implies that not only lipogenesis, but also lipolysis and fatty acid transport are involved in IMF deposition. Thus, the hypothesis is that higher IMF deposition may be attributed to increasing fat catabolism or diminishing endogenous fatty acid synthesis or both processes.

Therefore, the objective of this study is to investigate the expression of genes involved in lipogenesis, lipolysis and fatty acid transport in muscle, to compare the expression pattern of lipid metabolism associated genes in pigs with different fat deposition capacity, and then to elucidate the mechanism of IMF deposition between fatty and lean pigs.

Materials and Methods

All experiment procedures were performed according to the Guide for Animal Care and Use of Laboratory Animals in the Institutional Animal Care and Use Committee of Yunnan Agricultural University. The experimental protocol was approved by the Department Animal Ethics Committee of Yunnan Agricultural University.

Animals and Samples

Twelve Wujin and 12 Landrace pigs were used. All pigs had free access to water from nipple drinkers. The diets were not isonitrogenous or isoenergetic because the growth rate of the two breeds was so divergent (Table 1) and were provided ad libitum. Pigs were weighed individually for the calculation of average daily gain. When the pigs reached 100 kg body weight, they were transported to Yunnan Agricultural Center Meats Laboratory and slaughtered after electrical stunning. Longissimus muscle samples from the last ribs were collected from every animal.

Table 1 Composition of diets (% , as fed basis)

	Wujin pigs	Landrace pigs
Corn	68.90	75.70
Wheat bran	22.40	7.30
Soybean meal	5.60	11.80
Fish meal	0.50	1.20
Limestone	0.97	0.40
Monocalcium phosphate	0.10	0.70
Salt	0.30	0.30
Premix ^a	1.00	1.00
Calculated nutritional composition		
Crude protein	11.42	13.20
Total lysine	0.69	0.60
Digestive energy (MJ/kg)	13.11	13.56
Calcium	0.46	0.45
Total phosphorus	0.37	0.40
Available phosphorus	0.14	0.15

^a A vitamin premix provided the following per kilogram of diet: vitamin A, 8,267 IU; vitamin D2, 2,480 IU; vitamin E, 66 IU; menadione (as menadione pyrimidyl bisulfite complex), 6.2 mg; riboflavin, 10 mg; Ca D-pantothenic acid, 37 mg; niacin, 66 mg; vitamin B12, 45 µg; D-biotin, 331 µg; folic acid, 2.5 mg; pyridoxine, 3.31 mg; thiamine, 3.31 mg; vitamin C, 83 µg; Trace mineral premix provided the following per kilogram of diet: Zn, 127 mg; Fe, 127 mg; Mn, 20 mg; Cu, 12.7 mg; I, 0.80 mg, as zinc sulfate, ferrous sulfate, manganese sulfate, copper sulfate, ethylenediamine dihydride, respectively, with calcium carbonate as the carrier. Provided 0.3 mg Se per kilogram of diet

Determination of Adipocyte Diameter

Adipocytes were obtained by collagenase treatment. Adipocyte diameters were determined in five serial cross sections (10 µm thick at 40 µm intervals) of frozen tissues cut with a cryostat (2800 Frigocut Reichert-Jung, Francheville, France). Results corresponded to the mean of determinations performed on the five sections of each sample and were expressed as the diameter (µm) of visible adipocytes [14].

Measurement of IMF Content

Muscles were sampled for IMF content evaluation 24 h after slaughtering by following the Soxhlet petroleum-ether extraction method.

Determination of Fatty Acid Composition

Lyophilized muscle samples were methylated using methyl sulfate solution. Briefly, 0.5 g muscle was added in 5 ml methyl sulfate solution and backed on the 70 °C water bath pan for 1 h, then cooled and extracted using 10 ml extraction solution. After centrifugation, supernatant was dehydrated

over film and measured on the machine. Fatty acid profile was determined on an HP 1100 gas chromatograph (GC, USA), with a flame ionization detector (FID), and an automatic sample injection operating a septum-equipped programmable injector operating. Inlet temperature was 240 °C and detector temperature was 250 °C. Programmed temperature start at 195 °C for 2 min, 195 °C for 6 min, 215 °C for 5 min, 225 °C for 10 min and ended at 235 °C. Fatty acid methyl esters were identified according to peak retention times using standards (Sigma–Aldrich). C21:0 was used as the internal standard. The response factors of the individual FA were previously calculated. Selected abbreviations are saturated fatty acid (SFA) = C14:0 + C16:0 + C18:0 + C20:0; monounsaturated fatty acid (MUFA) = C16:1 + C18:1; and polyunsaturated fatty acid (PUFA) = C18:2 + C18:3 + C20:4 + C20:5 + C22:5. Results are expressed as weight percentages of total fatty acid.

Muscle Tissue Enzyme Activity Analyses

Approximately 1 g muscle tissue was homogenized using an Ultra-Turrax T8 (IKA Laboratory Technics; Vienna, Austria) in 3 mL of 10 mmol/L HEPES buffer containing 0.25 mol/L sucrose, 1 mol/L EDTA, and 1 mmol/L dithiothreitol, and then centrifuged at 100,000g for 30 min at 4 °C. Supernatants were collected and used for enzyme activity assays. Spectrophotometric assays were used for FAS [15]. The assay for HSL activity was based on a cholesterol esterase assay described by Osterlund et al.

[16]. The whole mitochondrial was isolated using the method of Beiber et al. [17]. The CPT-1B activity was assayed directly using whole mitochondrial isolates which were resuspended in 0.3 mmol/L sucrose containing 10 mmol/L Tris–HCl (pH 7.4 at 0 °C) and 1 mmol/L EDTA and sonicated to obtain a mitochondrial supernatant after centrifugation at 20,000g for 40 min at 4 °C [17]. Microsome was extracted from muscle tissue and SCD enzyme activity was determined as described by Archibeque et al. [18]. All assays were conducted in the range of linearity with respect to the amount of enzyme and time. Soluble protein concentration in the tissue supernatants was measured according to the method of Bradford [19], using bovine serum albumin as the standard. Except otherwise mentioned, all reagents were obtained from Sigma Chemical.

Real-Time PCR Analysis

Total RNA was isolated from muscle tissues using Trizol reagent according to the manufacturer's protocol (Invitrogen, USA). RNA was stored at –80 °C prior to use. Two micrograms of total RNA was used for RT in a final volume of 25 µL according to the manufacturer's instructions (Promega, America). Each primer (Table 2) was designed according to porcine nucleotide sequences in GenBank using Primes Premier 5, and synthesized by Shanghai Shengong Biological Company (Shanghai, China).

Real-time PCR was performed to quantitate mRNA expression of *A-FABP*, *H-FABP*, *FAS*, *SREBP-1*, *HSL*, *CPT-1B*, *SCD* and *ATGL* genes. Each 25 μ L PCR mixture contained 12.5 μ L of 2 \times iQTM SYBR Green Supermix, 0.5 μ L (10 mmol/L) of each primer and 1 L of cDNA. As an internal control, the same reverse transcription products were also subjected to PCR in the presence of a second pair of primers specific to pig β -actin RNA. Mixtures were incubated in an iCycler iQ Real-time Detection system (Bio-Rad, USA). Optimal PCR conditions for 40 cycles were shown in Table 2. Quantitation of the transcripts was performed using a standard curve with 10-fold serial dilutions of cDNA. A melting curve was constructed to ensure that only a single PCR product was amplified. Samples were assayed in triplicate, and each experiment was repeated at least twice. Negative and positive control reactions (without template or Taq enzyme) were performed for each sample.

Western Blotting

Whole frozen muscle samples (0.5 g) were homogenized on ice in 700 μ L buffer A [50 mmol/L Tris-HCl (pH 7.5), 50 mmol/L NaF, 5 mmol/L sodium pyrophosphate, 1 mmol/L EDTA, 1 mmol/L DTT, 0.1 mmol/L phenylmethyl sulfonyl fluoride, 10% glycerol] containing 1% Triton X-100, 5 μ mol/L aprotinin, leupeptin and pepstatin. The lysates were centrifuged at 6,000g for 20 min at 4 $^{\circ}$ C to remove insoluble material. Thereafter, the supernatant extracts were collected and protein concentration was determined using the method of Bradford [19]. The extracts were frozen at -80 $^{\circ}$ C until the western blot analyses were performed.

A-FABP, H-FABP, SREBP-1c and ATGL protein expression was measured according to the method described by Doran et al. [20]. Briefly, 50 μ g of total whole cell protein extract were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (12% resolving gel), transferred to a nitrocellulose membrane and probed respectively (1:500, 1:800, 1:1,000 and 1:2,000 dilution) with a rabbit polyclonal anti-A-FABP (HPA002188), H-FABP(AV33823) (Sigma, USA), SREBP-1c (SC-367) and ATGL (SC-67355) (Santa Cruz, USA) antibody overnight. The membranes were then probed with a goat anti-rabbit IgG-horseradish peroxidase conjugate (1:20,000) (Sigma, USA) for 1 h at room temperature. Blots were developed using the SuperSignal West Pico Chemiluminescent Substrate system (Bio-Rad, Hercules, CA, USA) and imaged onto microfilm for image analysis and densitometry. Signal intensity was quantified using Quantity One 1-D analysis software (Bio-Rad, Hercules, CA, USA).

Statistical Analysis

The results were expressed as means \pm SE and differences were considered significant when $P < 0.05$ tested by one

Table 3 Growth performance

	Wujin pigs	Landrace pigs
Daily gain (g/day)	0.59 \pm 0.02	0.77 \pm 0.01*
Feed intake (g/day)	1.86 \pm 0.14	1.87 \pm 0.14
Gain: feed (g/g)	0.32 \pm 0.01	0.41 \pm 0.01*

Values are expressed as means \pm SE and values in the same row with asterisks differ significantly ($P < 0.05$)

way analysis of variance (ANOVA) with Statistical Packages for Social Science 12.0 and Excel 2003 in Microsoft.

Results

Growth Performance

Table 3 showed growth performance of Wujin and Landrace pigs. Average daily gains for Wujin and Landrace pigs were 0.59 and 0.77 kg, respectively ($P < 0.05$). There was no significant difference of daily feed intake between both pigs. The feed conversion ratio for Wujin and Landrace pigs was 0.32 and 0.41 ($P < 0.05$), respectively.

Adipocyte Diameter, IMF Content and Fatty Acid Composition

Figure 1 showed adipocyte diameters in Wujin and Landrace pigs. The results showed that adipocyte diameter in Wujin pigs was significantly higher than in Landrace pigs ($P < 0.05$). IMF content and fatty acid composition of muscle tissue in Wujin and Landrace pigs are shown in Table 4. IMF content in Wujin pigs (6.58%) was significantly higher than in Landrace pigs (3.90%) ($P < 0.05$). Wujin pigs possessed higher contents of C16:1, C18:2, C18:3, C20:4 and C20:5 than Landrace pigs ($P < 0.05$).

Table 4 Fatty acid composition and IMF content

	Wujin pigs	Landrace pigs
C14:0	2.06 ± 0.09	1.99 ± 0.08
C16:0	27.11 ± 0.72	27.22 ± 0.57
C16:1	4.99 ± 0.09*	4.06 ± 0.08
C18:0	10.11 ± 0.24	14.43 ± 0.28*
C18:1	40.81 ± 0.73	40.98 ± 0.96
C18:2	12.16 ± 0.28	9.39 ± 0.13*
C18:3	0.94 ± 0.03	0.62 ± 0.05*
C20:0	0.92 ± 0.03	0.80 ± 0.05
C20:4	0.38 ± 0.03	0.20 ± 0.04*
C20:5	0.28 ± 0.03	0.11 ± 0.01*
C22:5	0.24 ± 0.02	0.20 ± 0.03
SFA	40.20 ± 0.68	44.44 ± 0.73*
MUFA	45.80 ± 0.74	45.04 ± 0.96
PUFA	14.00 ± 0.30	10.52 ± 0.12*
IMF	6.58 ± 0.13*	3.90 ± 0.10

Data are expressed as means ± SE and values in the same row with asterisks differ significantly ($P < 0.05$)

Table 5 Enzyme activities

Items	Wujin pigs	Landrace pigs
FAS ^a	8.23 ± 3.45 ^{e*}	4.41 ± 2.84
HSL ^b	0.21 ± 0.04	0.73 ± 0.02*
CPT-1B ^c	10.94 ± 0.62	16.12 ± 0.04*
SCD ^d	9.21 ± 0.02*	4.43 ± 0.06

Units are:

^a nmol reduced nicotinamide adenine dinucleotide phosphate (NADPH) min⁻¹ mg protein⁻¹

^b mU mg protein⁻¹

^c nmol palmitate min⁻¹ mg protein⁻¹

^d nmol/(7 min⁻¹ mg of tissue)

^e Values are expressed as means ± SE and values in the same row with asterisks differ significantly ($P < 0.05$)

However, the percentage of C18:0 in Wujin pigs was significantly lower than in Landrace pigs ($P < 0.05$). In addition, Wujin pigs had a higher percentage of total PUFA ($P < 0.05$). However, the UFA percentage in Wujin pigs was significantly higher compared with Landrace pigs ($P < 0.05$).

Enzyme Activity

The activities of FAS, SCD, HSL and CPT-1B enzymes were shown in Table 5. The enzyme activities of FAS and SCD were significantly higher ($P < 0.05$) in Wujin pigs than in Landrace pigs. However, the activities of HSL and

CPT-1B enzymes in Wujin pigs were significantly lower ($P < 0.05$) compared with Landrace pigs.

Gene Expression

Results are presented as numerical relative gene expression values (using β -actin as a housekeeping calibrator) (Fig. 2). The expression of lipogenetic genes, *SREBP-1c* and *FAS*, were significantly higher in Wujin pigs than in Landrace pigs ($P < 0.05$). Wujin pigs exhibited significantly higher mRNA abundance of fatty acid transportation genes, *H-FABP* and *A-FABP*, than Landrace pigs ($P < 0.05$). However, the expression intensity of genes involved in fatty acid oxidation and fat mobilization, *ATGL*, *CPT-1B* and *HSL*, was lower in Wujin pigs than in Landrace pigs ($P < 0.05$). Wujin pigs have a significantly higher mRNA abundance of the desaturase gene, *SCD*, compared with Landrace pigs ($P < 0.05$).

Protein Expression

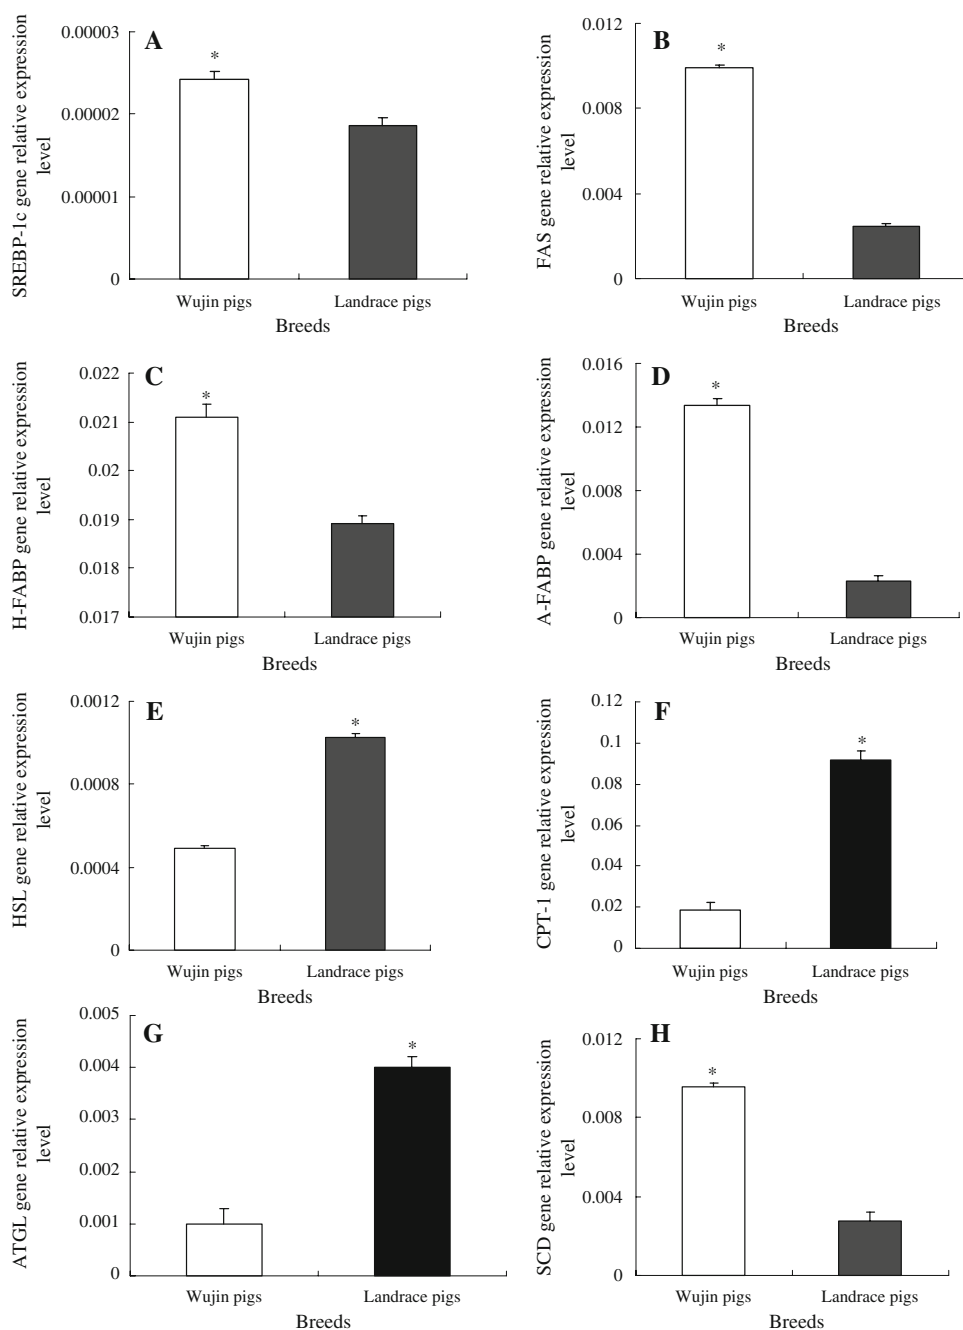

Figure 3 showed the expression of H-FABP, A-FABP, SREBP-1c and ATGL proteins in Wujin and Landrace pigs. Wujin pigs exhibited the higher expression of A-FABP compared with Landrace pigs, but the difference was not significant. The expression of H-FABP and SREBP-1c proteins in Wujin pigs was significantly higher ($P < 0.05$) than in Landrace pigs. The expression of ATGL protein in Wujin pigs was lower ($P < 0.05$) compared with Landrace pigs.

Discussion

Previous data indicated that local Chinese pigs deposit more fat than other commercial pigs, especially higher IMF content which can reach up to 6–7% [3–5]. Mersmann et al. [21] and Campion et al. [22] reported that the plasma and muscle of obese pigs had a greater triglycerides percentage than the lean pigs. TAG, the major component of IMF in muscles, is stored within the intramuscular adipocytes [8]. Hauser et al. [23] indicated that intramuscular adipocytes appeared to be larger in Meishan than Pietrain pigs. In this study, IMF content (6.58%) in Wujin pigs was significantly greater than in Landrace pigs (3.90%). Moreover, the average adipocyte diameter in Wujin pigs was higher than that in Landrace pigs. This suggested that the fatty Wujin pigs possessed the higher capacity to deposit TAG in muscle tissue compared with the lean Landrace pigs.

Additionally, not only the amount of IMF has to be considered, but also the composition of fatty acid is of great interest because of its association with human health [24–26]. This study showed that contents of C16:1, C18:2,

Fig. 2 Relative mRNA abundance of muscle tissue in Wujin and Landrace pigs. Data are expressed as means \pm SE of specific mRNA: β -actin for 12 pigs. Asterisks show significant differences between two pig breeds ($P < 0.05$). A, B, C, D, E, F, G and H represented *SREBP-1c*, *FAS*, *H-FABP*, *A-FABP*, *HSL*, *CPT-1B*, *ATGL* and *SCD* genes, respectively

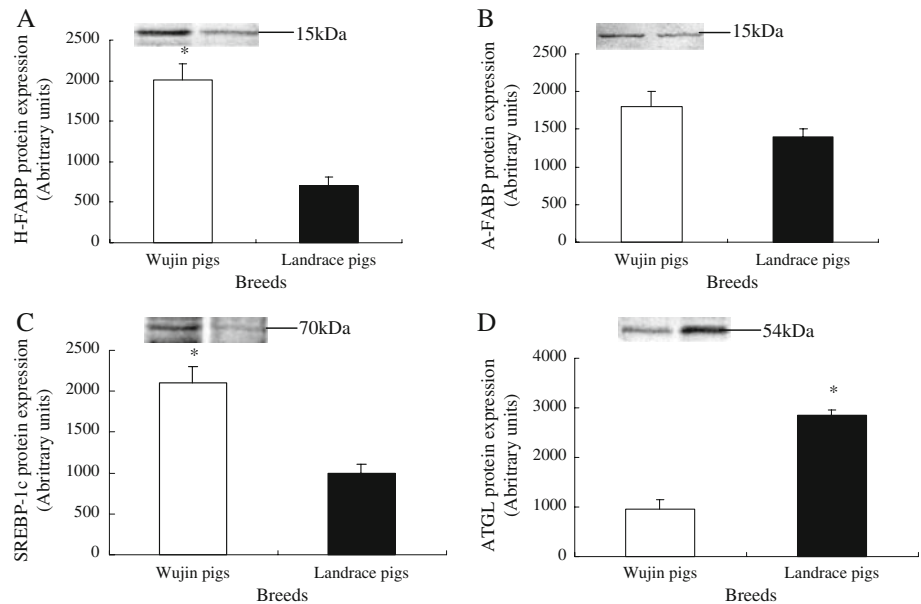

C18:3, C20:4 and C20:5 were higher in Wujin pigs than in Landrace pigs. Wujin pigs possessed a higher UFA concentration compared with Landrace pigs, which means that muscle UFA percentage was higher in fatty pigs than in lean pigs. This result indicated that the fatty acid composition in muscle tissue was different in fatty and lean pigs. The difference of fatty acid composition between both genotypes may be due to the variance of SCD, because SCD is a rate-limiting enzyme in the biosynthesis of unsaturated fatty acid [20]. SCD or Δ^9 -desaturase catalyzes the conversion of C16:0 and C18:0 to C16:1 and C18:1, the

2 major MUFA of muscle lipids [26]. Smith et al. [27] indicated that *SCD* gene expression would be greater in obese pigs than in crossbred, contemporary pigs. The present study showed that mRNA abundance of *SCD* gene and enzyme activity in Wujin pigs was higher compared with Landrace pigs. Therefore, the results suggested that the different expression of SCD between Wujin and Landrace pigs may result in the variation of muscle fatty acid composition.

The intramuscular adipose tissue possesses adequate levels of lipogenic enzymes [12] and was markedly

Fig. 3 Protein expressions of muscle tissues in Wujin pigs and Landrace pigs. Data are expressed as means \pm SE. Letters with asterisks differ significantly between the two pig breeds ($P < 0.05$). A, B, C and D represent A-FABP, H-FABP, SREBP-1c and ATGL

influenced by the animal breed [28, 29]. FAS is transcriptionally regulated and a key enzyme in fatty acid synthesis [30]. SREBP-1c has been shown to be the principal regulatory transcription factor for fatty acid synthesis in animals [31]. Thus FAS and SREBP-1 have been shown to be critical to lipogenesis. Our results showed that the fatty Wujin pigs showed higher mRNA abundance and enzyme activity of FAS and higher expression of *SREBP-1c* gene and protein compared with the lean Landrace pigs. Muscle lipogenic enzyme activities were generally higher in fatty pigs than in lean pigs [12]. This suggested that the muscle lipid synthesis in fatty Wujin pigs was higher compared with the lean Landrace pigs.

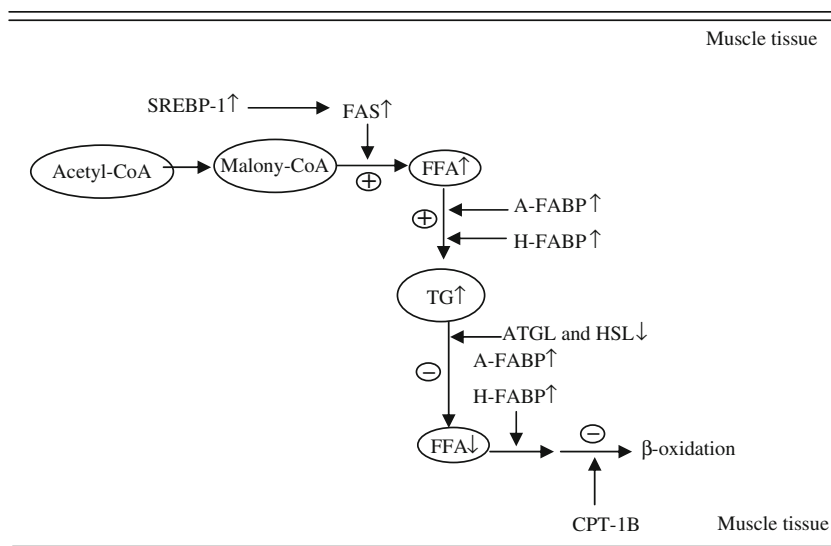

Although lipogenesis appears to be more important than lipolysis in regulating backfat thickness in the breeds of swine [11] and adipose tissue lipolysis does not appear to be a major metabolic factor leading to the excessive fat accretion in the obese pigs [32]. Fat deposition is determined by a complex balance between lipogenic and lipolytic enzymes [9–11]. Adipose tissue of obese pigs had lipolytic rates expressed on a cellular basis or per 100 mg adipose tissue in vitro that were greater than those from lean pigs [33–35]. The present study compared the expression of muscle lipolysis related gene and protein as well as enzyme activities between the fatty Wujin pigs and the lean Landrace pigs. ATGL is a newly identified lipase and its expression reacts to hormonal stimuli and plays a role in catecholamine-induced lipolysis in porcine adipose tissue [36]. HSL cleaves fatty acid from intracellular triacylglycerol for oxidation and exportation [37]. CPT-1B is involved in regulating mitochondrial fatty acid oxidation [13]. Our results showed that the fatty Wujin pigs exhibited lower mRNA abundance, enzyme activities or protein

expression for ATGL, CPT-1B and HSL compared with the lean Landrace pigs. For our knowledge, this is the first report to compare porcine muscle lipid catabolism between the fatty and lean pigs. Previous reports focused on the muscle lipogenes independent of the muscle lipolysis [12]. This data suggested that the mRNA and protein expression of genes related to oxidative metabolism and fat mobilization were lower in Wujin pigs contrasted with Landrace pigs.

Previous studies revealed the role of FABPs. Of them, A-FABP and H-FABP play a critical role in intracellular trafficking of fatty acid and have been elucidated as candidate genes related to fat deposition in pigs [38–42]. Additionally, H-FABP is critical for fatty acid uptake as well as trafficking in heart and in brain in *H-FABP* gene-ablated mice [43]. Furthermore, L-FABP facilitates fatty acid uptake and disposition into L-cell phospholipids whereas I-FABP did not facilitate uptake and targeted the fatty acids to TAG [44–47]. However, Damon et al. [48] indicated that there was no difference of A-FABP mRNA or protein levels between low fat and high fat groups, but H-FABP content may be a valuable marker of lipid accretion [49]. In our study, mRNA abundance and protein expression level of A-FABP and H-FABP in Wujin pigs was higher than in Landrace pigs. This data suggested Wujin pigs could transport more fatty acid into intracellular trafficking compared with Landrace pigs.

In conclusion, this study demonstrated the different expression patterns of muscle lipid anabolic and catabolic genes and fatty acid transporting genes in the pigs with different IMF deposition. The cause underlying higher IMF content in Wujin pigs appear to be that Wujin pigs possessed a higher capacity of lipogenesis and fatty acid

Fig. 4 The causes of higher IMF content in Wujin pigs comparing with Landrace pigs. ↑ Represents up-regulated gene expression. ↓ Represents down-regulated gene expression. ⊕ Represents the metabolism pathways being strengthened. ⊖ Represents the metabolism pathways being weakened

transport, lower potential of fat mobilization and fatty acid oxidation (Fig. 4).

Remarkably, studies performed on various cell systems have shown that administration of short-chain ceramides may also induce accumulation of the long-chain forms of this molecule [4–7]. Although the latter phenomenon has been appreciated for a long time, only recently have its metabolic bases and biological implications started being investigated [8–10]. In the above-reported setting, a previous study from this laboratory showed that administration of *N*-hexanoylsphingosine (C6-Cer) to CHP-100 human neuroepithelioma cells induces both apoptosis and LC-Cer accumulation [7]. In the present study, we experimentally addressed the issue of whether, in the above-mentioned cell system, LC-Cer generation is relevant to the apoptotic response evoked by administration of its short-chain analogue.

Experimental Procedures

Materials

Material for cell culture, phosphatidylcholine, natural ceramide from bovine brain, *D*-erythro-C6-Cer, *D*-erythro-sphingosine, *L*-cycloserine (L-CS) and fumonisins B1 (FB1) were from Sigma-Aldrich Chemical Co. The anti-poly-(ADP)ribose polymerase (PARP) mouse monoclonal antibody was from Biomol. Res. Lab. The mouse monoclonal anti-cytochrome *c* antibody was from Pharmingen. The DNA fluorescent dye Hoechst 33342, the fluorescein isothiocyanate (FITC)-conjugated anti-mouse antibody and Mitotracker Red were from Invitrogen. The caspase-9 fluorogenic peptide substrate *acetyl*-Leu-Glu-His-Asp-amido-4-trifluoromethyl-coumarin (*Ac*-LEHD-AFC) was from Calbiochem. Silica gel 60 high-performance thin layer chromatography (HPTLC) plates were from Merck. The chemiluminescence ECL detection system was from Amersham Corp.

Cell Culture and Treatments

CHP-100 cells were grown at 37 °C in RPMI 1640 medium, supplemented with 10% (v/v) heat-inactivated foetal calf serum, 2 mM glutamine, 100 i.u./ml penicillin and 100 µg/ml streptomycin, in a humidified atmosphere with 5% CO₂. C6-Cer, sphingosine and FB1 were administered to cells from dimethylsulfoxide stock solutions (30, 10 and 50 mM, respectively); L-CS was administered from a 1 M aqueous stock solution. After treatments, adherent cells were mechanically removed from the substrate directly in the culture medium, containing already detached cells; total cells were then washed three times with phosphate-buffered saline (PBS, pH 7.4) prior to further processing.

Lipid Analysis

Lipids were extracted by the method of Folch et al. [11]. For ceramide analysis, the Folch lower phase was dried under vacuum, lipids resuspended in 0.1 M methanolic KOH, subjected to mild alkaline hydrolysis for 1 h at 37 °C and re-extracted by Folch's method. Ceramide was resolved by HPTLC in chloroform/acetic acid (9:1, by vol) and visualized after charring with 3% cupric acetate in 8% phosphoric acid [12, 13]. Bands were quantitated by densitometric analysis, referring to known amounts of lipid standards (C6-Cer and natural ceramide from bovine brain) developed along with samples, using a computerized image processing system (Gel-Pro Analyzer). Phosphatidylcholine was resolved from the Folch lower phase by two-dimensional HPTLC, using chloroform/methanol/25% ammonia/water (6.4:9.8:1:1, by vol) and chloroform/methanol/acetone/acetic acid/water (15:5:6:3:1.5, by vol) as solvent systems. Phosphatidylcholine spots were identified by co-migration with authentic standards, visualized by plate exposure to iodine vapour and scraped off. Phosphate content was measured according to Marinetti [14].

Immunofluorescence Microscopy

Cells were grown on coverslips and incubated in a medium containing 30 µM C6-Cer for 24 h. Mitotracker Red (40 nM) was added overnight to the cell medium before washing and fixing in 4% paraformaldehyde. Cells were then subjected to immunocytochemistry by using an anti-cytochrome *c* antibody, followed by incubation with a FITC-conjugated anti-mouse antibody. Cellular nuclei were stained with Hoechst dye (0.5 µg/ml) and the samples analyzed by confocal microscopy. Confocal microscopy images were acquired using a laser scanning microscope (model LSM 510 Combi; Carl Zeiss MicroImaging, Inc.) equipped with a visible and infrared Ti-Sa pulsed laser (Tsunami/Millenia Spectra-Physics). Post-acquisition processing was performed with Adobe Photoshop software.

Apoptosis Evaluation and PARP Cleavage Analysis

Cells were fixed in 4% paraformaldehyde in PBS and incubated for 15 min with a solution of 0.5 µg/ml Hoechst 33342 in PBS. Nuclei were visualized with a Zeiss fluorescence microscope; condensed or fragmented elements were scored as apoptotic. In parallel, apoptosis was monitored by flow cytometric analysis, after evaluation of the fluorescence of propidium iodide-stained nuclei, as reported in detail elsewhere [15]. The two methods gave similar results. For Western blot analysis of PARP, cells were lysed in 62 mM Tris-HCl, pH 6.8, containing 2% SDS, 2 mM EDTA, 20 µg/ml aprotinin, 10 µg/ml leupeptin,

1 mM phenylmethylsulfonyl fluoride and 1 mM sodium vanadate. After sonication, aliquots of the lysates were saved for protein determination [16] and, after addition of 0.05% β -mercaptoethanol, samples were boiled for 10 min. Proteins from cell lysates (40 μ g) were resolved by 10% SDS-PAGE, transferred onto nitrocellulose paper and probed by Western blot, as previously described [15]. Immunoreactivity was revealed by an ECL detection kit, according to the manufacturer's instructions.

Evaluation of Caspase-9 Activity

Caspase-9 activity was monitored by a fluorogenic assay, using *Ac-LEHD-AFC* as a substrate [17]. Briefly, CHP-100 cells, either left untreated or treated for 24 h with 30 μ M C6-Cer, were harvested directly in the culture medium and washed three times in PBS. The final pellets were resuspended in lysis buffer (150 mM NaCl, 50 mM Tris-HCl, pH 8.0, 0.1% SDS, 1% Nonidet P-40, 0.5% sodium deoxycholate) and incubated for 30 min at 4 °C. Aliquots of the lysates corresponding to 50 μ g or 100 μ g of protein were incubated in an assay buffer (100 mM HEPES, pH 7.0, 1 mM EDTA, 0.1% CHAPS, 10% glycerol, 20 mM dithiothreitol), in the presence of 75 μ M *Ac-LEHD-AFC*, for 1 or 2 h, at 37 °C. Substrate cleavage by caspase-9 resulted in the release of the free fluorochrome (AFC), producing a yellow–green fluorescence that was monitored using a Perkin-Elmer LS-5 luminescence spectrometer, by setting λ_{ex} at 400 nm and λ_{em} at 505 nm. Under the above-reported conditions, enzymatic activity assays were linear with respect to time and protein content. Fluorescence intensity values were normalized to protein amount and to incubation time, and used to estimate the relative changes in caspase-9 activity.

Statistical Analysis

Statistical significance was determined by unpaired Student's *t* test. Differences were considered significant at $P < 0.05$.

Results

CHP-100 Cells Rapidly Accumulate LC-Cer in Response to C6-Cer: Evidence that the Phenomenon is Inhibited by FB1, but not by L-CS

Accumulation of LC-Cer in response to C6-Cer administration has been previously demonstrated in CHP-100 cells after equilibrium labeling with radioactive palmitic acid [7]. In this study, cells were exposed to 30 μ M C6-Cer for different periods and changes in LC-Cer and C6-Cer mass

simultaneously estimated by densitometric analysis, after lipid separation by HPTLC and staining by charring [12, 13]. As shown in Fig. 1, C6-Cer was rapidly incorporated by CHP-100 cells and its levels were already sub-maximal after 2 h of incubation, maintaining at steady-state throughout the remaining period examined. Remarkably, a rapid increase of LC-Cer levels was also observed, albeit with slower kinetics than those occurring for the short-chain counterpart: as shown in Fig. 1, LC-Cer accumulation was already evident after 2 h from the beginning of cell treatment with C6-Cer, reaching, by 8 h, a 5-fold elevation over the basal level and remaining at this steady-state at later times. As expected, LC-Cer migrated as a doublet, reflecting the heterogeneous length of the fatty acids linked to the sphingosine backbone.

To get insight into the mechanism driving C6-Cer-evoked LC-Cer accumulation, we investigated the sensitivity of the phenomenon to L-CS (1 mM), a serine-palmitoyltransferase inhibitor [18], or to FB1 (50 μ M), an inhibitor of CoA-dependent dihydroceramide/ceramide synthase [18, 19]. As shown in Fig. 2(a, b), neither basal LC-Cer levels nor C6-Cer-evoked LC-Cer accumulation were significantly affected by L-CS; on the other hand, Fig. 2(c, d) shows that FB1, beside attenuating basal LC-Cer levels, potently inhibited LC-Cer accumulation in response to C6-Cer. Altogether, the above-reported results strongly suggested that LC-Cer might be predominantly produced via the salvage pathway, namely by C6-Cer deacylation and sphingosine reacylation with a long-chain fatty acid [20].

Fig. 1 Time-course of intracellular ceramide accumulation in cells exposed to C6-Cer. CHP-100 cells were incubated with 30 μ M C6-Cer for the indicated times; thereafter, aliquots of the lower phase of the Folch extracts from the different samples, corresponding to equal amounts of protein, were resolved by HPTLC and LC-Cer and C6-Cer levels analysed as reported in the text. The *upper panel* shows data obtained from four different experiments, expressed as means and SD. A representative HPTLC analysis is shown in the *lower panel*

Apoptosis Induced by C6-Cer Administration Associates with Cytochrome *c* Release from Mitochondria and Caspase-9 Activation and is not Inhibited by FB1

It has been reported that exposure of CHP-100 cells to 30 μM C6-Cer also evokes caspase-dependent apoptosis [7, 21]. Notably, Fig. 3 now shows that apoptotic nuclear condensation and fragmentation associate with cytochrome *c* release into the cytosol. Moreover, in line with the possibility that mitochondrial permeabilization might provide a relevant mechanism for the apoptotic response evoked by C6-Cer administration, Fig. 4 shows that caspase-9 was also activated [22]. To test whether C6-Cer-evoked LC-Cer accumulation was instrumental to apoptosis induction, we investigated whether apoptosis was attenuated by impairing LC-Cer accumulation by co-treatment with FB1. In this respect, we observed that 50 μM FB1 was neither toxic by itself to CHP-100 cells, nor did it affect the apoptotic response induced by cell exposure to 30 μM C6-Cer over a 24 h-period, as monitored by evaluation of apoptotic nuclei (Fig. 5a) and cleavage of the caspase substrate PARP (Fig. 5b).

Exogenously Administered Sphingosine Evokes Elevation of LC-Cer Levels Without Inducing Apoptosis

As mentioned above, the differential inhibitory effect displayed by FB1 and L-CS on C6-Cer-evoked LC-Cer

Fig. 3 Apoptosis induced by C6-Cer in CHP-100 cells associates with cytochrome *c* release from mitochondria. CHP-100 cells were grown on coverslips and incubated in medium containing 30 μM C6-Cer for 24 h. Nuclei were stained with Hoechst, mitochondria with Mitotracker Red, and cytochrome *c* with a specific antibody, followed by treatment with a FITC-conjugated secondary antibody, as reported

in the text. Cells were then analyzed by phase contrast and confocal microscopy. The *upper* and *lower* rows, respectively, show typical alive and apoptotic cells. Note the fragmented nucleus and condensed chromatin, as well as the different localization of mitochondria and cytochrome *c*, in the apoptotic cell

Fig. 4 C6-Cer administration induces caspase-9 activation in CHP-100 cells. Cells were either left untreated or treated for 24 h with 30 μ M C6-Cer. Thereafter, aliquots of cell lysates corresponding to equal amounts of protein were probed for caspase-9 activity, by measuring release of the free fluorochrome AFC, after hydrolysis of the enzyme fluorogenic substrate Ac-LEHD-AFC, as described in the text. Data are expressed as relative fluorescence units (r.f.u.) and are means and SD from four independent experiments. Statistical significance: * $P = 0.0001$, as compared to untreated cells, after Student's t test

accumulation strongly suggested that the latter phenomenon might occur along the sphingosine salvage pathway [20]. To study whether CHP-100 cells efficiently acylate free

Fig. 5 FB1 does not affect the apoptotic response evoked by C6-Cer administration. **a** Cells were incubated for 24 h either in the presence (+) or absence (-) of 30 μ M C6-Cer, in media enriched (+) or devoid (-) of 50 μ M FB1. Cells were then collected and the percentage of apoptotic elements determined as described in the text. Data are from four different experiments and are expressed as means and SD; *ns* difference not statistically significant, as by Student's t test. **b** Cells were incubated for 24 h either in the presence (+) or absence (-) of 30 μ M C6-Cer, in media enriched (+) or devoid (-) of 50 μ M FB1. Equal amounts of protein from total lysates were then resolved by SDS-PAGE and probed for the native (116 kDa) and the cleaved form (85 kDa) of PARP

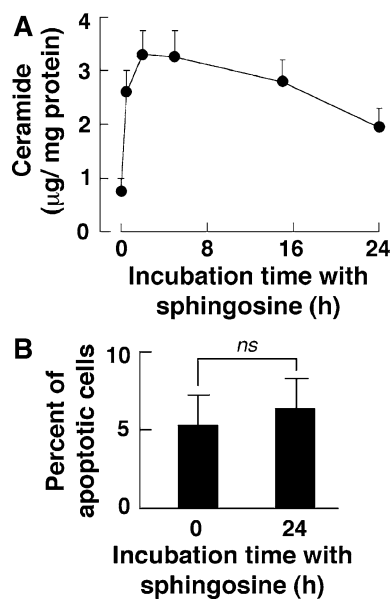

Fig. 6 Exogenously administered sphingosine evokes elevation of LC-Cer levels but not apoptosis. **a** CHP-100 cells were incubated with 10 μ M sphingosine for the indicated times; aliquots of the lower phase of the Folch extracts corresponding to equal amounts of cell protein were then analyzed for LC-Cer content, by HPTLC separation and densitometric analysis, as reported in the text. Data are from four different experiments and are expressed as means and SD. **b** Cells were either left untreated or incubated for 24 h in the presence of 10 μ M sphingosine and apoptosis determined as described in the text. Data are from four different experiments and are expressed as means and SD; *ns* difference not statistically significant, as by Student's t test

sphingosine, this lipid was administered in the medium at a 10 μ M concentration and intracellular LC-Cer levels monitored. As shown in Fig. 6a, LC-Cer levels promptly increased in response to sphingosine administration, reaching by 2 h a more than 4-fold increase over the basal level. On prolonging the incubation period, LC-Cer levels maintained initially at this high steady-state, to slowly decrease thereafter: however, by 24 h, LC-Cer levels were still two to three times the basal level (Fig. 6a). On the basis of this result we monitored whether LC-Cer accumulation, as evoked by sphingosine administration, associated with apoptosis induction. We observed that sphingosine, administered at a 10 μ M concentration for 24 h, caused cell rounding, associated with detachment of a minor fraction of the total cell population from the substrate (not shown); however, as reported in Fig. 6b, cell viability was not significantly affected.

Discussion

The above-reported results support the notion that LC-Cer accumulation, as observed in CHP-100 neuroepithelioma cells exposed to C6-Cer, is dispensable for apoptosis

induction. In this respect, the first key evidence is provided by the finding that LC-Cer synthesis can be severely impaired by the ceramide synthase inhibitor FB1, with no effect on the apoptotic response. We also observed that LC-Cer produced in response to C6-Cer, albeit potently inhibited by FB1, was insensitive to the palmitoyl-transferase inhibitor L-CS, a result strongly suggesting that LC-Cer is synthesized through the sphingosine salvage pathway [20]. In line with this possibility we have shown that CHP-100 cells markedly accumulate LC-Cer after administration of exogenous sphingosine: however, LC-Cer accumulation did not induce an apoptotic response. It can be argued that exogenously administered free sphingosine might not be functionally equivalent to sphingosine derived from C6-Cer deacylation, due to the fact that the two pools of the sphingoid base are expected to follow different intracellular traffic and processing, prior to be acylated [8, 23]. However, we observe that, in any case, the latter reaction is expected to occur in the endoplasmic reticulum, where the members of the ceramide synthase family reside [24]. It cannot be excluded that LC-Cer synthesis after administration of either C6-Cer or sphingosine is operated by ceramide synthase isoforms with a different sub-location within the endoplasmic reticulum and/or different fatty acid specificity. Nevertheless, it is evident from our results that, in the cell system presently employed, LC-Cer produced via the sphingosine salvage pathway displays no apoptotic potential.

The reasons as to why, in CHP-100 cells, apoptosis appears to be selectively triggered by C6-Cer over LC-Cer remain to be elucidated; nevertheless, an important clue may be provided by the evidence that apoptosis associates with cytochrome *c* release into the cytosol and caspase-9 activation, thus lending support to the notion that the phenomenon might occur, at least partly, via the mitochondrial pathway [22]. Indeed, studies on isolated mitochondria have shown that both short- and long-chain ceramides can induce organelle permeabilization and cytochrome *c* release [25]: however, in intact cells, the picture is made more complex by the fact that ceramide must efficiently accumulate in mitochondria to exert its cytotoxic activity. On the one hand, internalized C6-Cer, due to its property to form water-soluble micellar aggregates [3], may be expected to freely diffuse to mitochondria, possibly via the cytosolic milieu; in this respect, a study performed with a fluorescent C6-Cer analogue demonstrated that this exogenous sphingolipid rapidly labels mitochondria over other membrane compartments, prior to accumulation in the Golgi complex [26]. On the other hand, there is evidence that LC-Cer, due to its high hydrophobic characteristics, must be produced at the mitochondrial level to be cytotoxic [27, 28] or therein efficiently transported from its site of production [29]. On this basis, an issue deserving further investigation is

whether, in CHP-100 cells, LC-Cer produced via the sphingosine salvage pathway remains compartmentalized outside mitochondria. With respect to this point, it is also worth mentioning that studies on neural systems have shown that ceramide synthase activity localized in the endoplasmic reticulum is FB1-sensitive, whereas mitochondria harbor a reverse ceramidase activity able to acylate sphingosine that, however, is not inhibited by FB1 [30]. Of course it remains to be elucidated whether loss of mitochondrial integrity is the sole mechanisms through which C6-Cer induces apoptosis in the cell system presently investigated: in fact, short-chain ceramide ability to target various membrane compartments and to affect their physical and biological properties, leaves open the possibility that it might exert its cytotoxic effect through pleiotropic mechanisms.

Remarkably, it has been shown that short-chain ceramides may inhibit enzymes involved in phosphatidylcholine biosynthesis [31, 32]. Based on the notion that severe downregulation of phosphatidylcholine levels may induce apoptosis [33], this might provide a further mechanism through which short-chain ceramides exert their apoptotic effect [31, 32]. However, in an additional set of experiments, we observed that the phosphatidylcholine mass was 68 ± 12 nmol/mg protein ($n = 4$) in untreated CHP-100 cells and 62 ± 10 nmol/mg protein ($n = 4$) in cells exposed for 24 h to 30 μ M C6-Cer ($n = 4$) (not statistically significant, as shown by Student's *t* test). On the one hand, this result indicates that, in the system presently investigated, and under the experimental conditions employed, apoptosis is not accounted for by a general and dramatic downregulation of phosphatidylcholine levels. On the other hand, the possibility that the apoptotic effect of C6-Cer might also impact on reduction of phosphatidylcholine synthesis cannot be presently ruled out: in fact, it remains to be elucidated whether the rate of phosphatidylcholine turnover is reduced by C6-Cer treatment and/or whether a reduction of phosphatidylcholine mass locally occurs at the level of particular membrane compartments.

As our results are consistent with the notion that C6-Cer, but not LC-Cer synthesized via the salvage pathway, has pro-apoptotic properties, a study performed on human keratinocytes showed that C6-Cer efficiently induces apoptosis through LC-Cer production [10]; in addition, a study performed on HeLa cells demonstrated that apoptosis observed after C6-Cer administration was indeed due to elevation of the intracellular levels of sphingosine produced through the salvage pathway, that caused Golgi fragmentation [34]. Altogether, these observations underscore the important notion that short-chain ceramides may cause apoptosis through multiple mechanisms, depending on the cell system and, possibly, on the specific apoptotic pathway(s) involved.

Indeed, in line with the notion the LC-Cer produced through the salvage pathway may be dispensable for apoptosis induction, it has been shown that both *D-erythro-* and *L-erythro-C6-Cer* are equally effective in inducing apoptosis in leukemia HL-60 cells [8]. In the same study, it was shown that neither *D-erythro-* nor *L-erythro-C6-Cer* induced apoptosis in A549 lung adenocarcinoma cells; on the other hand, *D-erythro-*, but not *L-erythro-C6-Cer*, was able to modulate telomerase activity and to suppress cell growth, in a FB1-sensitive fashion. Intriguingly, we previously demonstrated that C6-Cer also causes growth inhibition and retinoblastoma protein dephosphorylation in CHP-100 cells [35]: thus it will be interesting to investigate whether, different to apoptosis, these phenomena are dependent on LC-Cer production through the salvage pathway.

As it is widely recognized that endogenous ceramide plays important roles in the control of a variety of cell functions, the present study lends support to the notion that caution must be exercised when investigating its biological effects by use of exogenously administered short-chain analogues. Indeed, short-chain ceramides may still provide useful research tools, provided the awareness that their peculiar chemico-physical properties might not invariably mimic the behavior of the endogenous counterparts.

Acknowledgments This work was partly supported by MIUR (Ministero dell'Istruzione dell'Università e della Ricerca) funds (60%) to Angelo Spinedi.

Traditionally, thin layer chromatography (TLC) and high performance liquid chromatography (HPLC) with evaporative light scattering or ultraviolet detection [4–7] methods have been used to quantitatively profile PL levels in tissues. However, these identification techniques are limited in their ability to identify PL species within each class.

Electrospray ionization-mass spectrometry (ESI-MS) offers sensitivity and selectivity over these more traditional TLC and HPLC methods for PL detection, identification, and quantification [8–13]. Chromatographic separation of PLs prior to MS can help to avoid the ion suppression effects that are often observed in the analysis of complex PL mixtures by MS, and also simplifies the analysis of very complex samples by separation of the components to be measured [14, 15]. HPLC-ESI-MS is now widely used for lipid analysis and has been used for the analysis of selected PL classes, qualitatively by comparing peak intensities without a calibration curve [16] and quantitatively using peak areas obtained from the total ion current (TIC) with an external standard curve [14–17].

In this study, we describe the development of an LC-MS/MS method that utilizes PL-class-specific fragmentations to measure changes in the relative concentration of five prominent classes of PLs in the brain tissues of 80-day-old Wistar rats [Choline glycerophospholipid ((ChoGpl) consists of phosphatidyl choline (PtdCho) and plasmeyl choline (PlsCho)), Ethanolamine glycerophospholipid ((EtnGpl) consist of phosphatidyl ethanolamine (PtdEtn) and plasmeyl ethanolamine (PlsEtn)), phosphatidyl serine (PtdSer), phosphatidyl inositol (PtdIns), and sphingomyelin (CerPCho)]. Neutral loss or precursor ion scanning was used to generate, in the extracted ion chromatogram, a discrete peak for each PL class analysed based on head group identification. The advantage of a headgroup detection system is that the complexity within the PL class is able to be accommodated. This complexity is due to the large combination of fatty acids present which means a large range of molecular masses which must be quantified. Calibration curves were generated based on these peak areas. This approach, as opposed to using the TIC peak areas obtained from the LC-MS methods discussed above, allows much improved specificity, has a shortened analysis time, and relies less heavily on the efficiency of chromatographic separation for the effective analysis of the PLs.

Materials and Methods

Standards and Chemicals

PL standards were obtained from Avanti Polar Lipids, (Alabaster, AL, USA). All solvents used were of liquid

chromatography grade (Merck, Darmstadt, Germany), except for chloroform which was analytical grade (ethanol stabilized).

Sample Preparation

At 80 days of age, the Wistar rats were sacrificed and the brain lipids were extracted using the Svennerholm and Fredman extraction protocol [18].

Briefly, the left hemisphere of rat brain was homogenized in 3 mL of water for 1–2 min in an ice bath using an ultrasonicator probe (5 Watts, Misonic Incorporated, Farmingdale, NY, USA). A portion of the rat brain homogenate (0.5 mL) was weighed into a 10 mL Kimax tube. Water (0.5 mL) was added to the homogenate, followed by methanol (2.7 mL) and chloroform (1.35 mL) at room temperature. The mixture was allowed to rock gently for 30 min on a rocker before centrifugation at 2,000g for 30 min. The supernatant was transferred to a 15 mL Kimax tube and the pellet was re-extracted using water (0.5 mL) and chloroform/methanol (1:2, 2 mL). After mixing and centrifugation (30 min at 2,000g), the supernatants were pooled and the pellet was discarded. Solvent partition of the supernatant was achieved by the addition of water (1.3 mL) and gentle inversion 3–4 times, followed by centrifugation (2,000g for 30 min). The upper phase was removed. KCl (0.01 M, 0.5 mL) was added to the remaining lower phase and any interfacial fluff (minimal) and was centrifuged (2,000g, 20 min).

The lower phase was used for PL analysis. Samples were aliquoted into HPLC vials and stored under nitrogen at -80°C prior to analysis. Sample analysis was completed within 2 weeks of extraction and samples were analyzed immediately upon thawing to reduce any degradation of the PLs.

Standard Preparation

PL standards [PtdCho (porcine brain), PtdEtn (bovine heart), PtdSer (porcine brain), PtdIns (bovine liver), and CerPCho (bovine brain)] were purchased from Avanti Polar Lipids (Alabaster, AL, USA). Stock solutions were prepared at 1 mg/mL in chloroform/methanol (1:2) and stored at -80°C under nitrogen, for no longer than 2 months. An intermediate mixed standard solution was prepared from each stock solution into a 10 mL volumetric flask, and was serially diluted further in chloroform/methanol (1:2) to give a six-point calibration curve for each PL class (Fig. 1). Standards were selected based on availability and similarity of fatty acid distribution to the phospholipids identified in the samples.

Fig. 1 Typical phospholipid calibration curve. The regression coefficient (r^2) is typically >0.9 . *PtdCho* phosphatidyl choline, *CerPCho* sphingomyelin, *PtdSer* phosphatidyl serine, *PtdEtn* phosphatidyl ethanolamine, *PtdIns* phosphatidyl inositol

High Performance Liquid Chromatography

An Alliance HPLC (Model 2690, Waters, Milford, MA, USA) system, consisting of an ultraviolet–visible detector and a refrigerated auto-sampler (set to 5 °C), was used for this work. The samples were loaded on to an APS-2 Hypersil (aminopropyl group stationary phase) column (150 mm × 2.1 mm, 3 μm, Thermo Scientific, Waltham, MA, USA) protected by a guard column containing the same column packing (10 mm × 2.1 mm inner diameter). The column temperature was set to 50 °C. Ten microliters of sample or standard was loaded on to the column. The PLs were separated with an acetonitrile/ammonium acetate buffer gradient, as described in Table 1. The flow rate was set at 0.5 mL/min.

Mass Spectrometry

The eluate from the HPLC system was introduced into a Thermo Scientific TSQ Quantum triple quadrupole mass spectrometer using a heated electrospray ionization (HESI) probe, except for the first 4 min and the last 6 min of the run, which were diverted to waste. Ions were generated and focused using an ESI voltage of 3,750 V, a sheath gas flow of 30 L/min, an auxiliary gas flow of 10 L/min, and a capillary temperature of 300 °C.

Common ions (precursor ions) or neutral losses that occur when each PL class [11, 19, 20] is fragmented in the collision cell were detected with the appropriate mass range selected, as outlined in Table 2. The mass distribution of the PL species within a class determined the mass window range used and to some extent the mass spectrometer tube lens voltage.

The excellent specificity of the method also allowed us to use it confidently to quantify phospholipids in rat serum samples (extracted using the modified Svennerholm and Fredman extraction protocol where the serum samples were treated the same as homogenised brains), which have

Table 1 HPLC mobile phase solvent gradient for separation of the phospholipids

Time (min)	Divert valve	Flow rate (mL/min)	%A	%B
0	To waste	0.5	100	0
4	To detector			
7.5		0.5	50	50
8.5		0.5	50	50
9		0.5	50	50
11		0.5	0	100
12		0.5	0	100
14	To waste	0.5	0	100
15			100	0
20			100	0

proportionally much lower levels of some phospholipids than brain extracts (Fig. 2).

Accuracy and Precision

The accuracy of the method was evaluated by performing recovery studies. The between-day precision and the within-day precision were assessed by repeated analysis of a quality control sample.

Results and Discussion

HPLC–MS

A typical separation of PLs on the aminopropyl HPLC column is shown in Fig. 2. We used a hydrophilic HPLC column because of its ability to separate PLs largely by their polar head group or class, as opposed to reversed-phase

Table 2 Summary of the phospholipid-class-specific scan events in positive ion mode

Scan event	Phospholipid specificity	Scan mode	Phospholipid fragment detected	Mass window (m/z)	Tube lens (volts)	Collision energy (volts)
1	Lyso-PtdCho	Precursor 184	Phosphoryl choline	470–550	125	26
2	Lyso-PtdEtn	Neutral loss 141	Phosphoryl ethanolamine	450–550	110	18
	EtnGpl	Neutral loss 141	Phosphoryl ethanolamine	730–830	150	18
3	PtdSer	Neutral loss 185	Phosphoryl serine	650–750	150	20
		Neutral loss 185	Phosphoryl serine	750–850	165	20
4	PtdIns	Neutral loss 277	Phosphoryl inositol (+NH ₄)	800–900	130	20
		Neutral loss 277	Phosphoryl inositol (+NH ₄)	900–1000	130	20
5	CerPCho,ChoGpl	Precursor 184	Phosphoryl choline	650–850	125	26

ChoGpl choline glycerophospholipid, *EtnGpl* ethanolamine glycerophospholipid, *PtdSer* phosphatidyl serine, *PtdIns* phosphatidyl inositol, *CerPCho* sphingomyelin

columns, which separate PLs largely by carbon number, leading to multiple peaks for each class of PL [10, 21–23]. Our method, based on the head group characteristics of each PL, could not resolve PtdEtn from PlsEtn, both of which are present in approximately equal amounts in adult rat brain, and could not resolve PtdCho from PlsCho, which is present in negligible amounts in rat brain [24–26]. Consequently, both ethanolamine and choline species present in the rat brain were quantified as EtnGpl and ChoGpl, respectively (the sum of the two components) using PtdEtn and PtdCho standards. In contrast to the other PL classes measured, it was important to keep PtdCho and CerPCho baseline resolved because they were detected using the same head group (phosphoryl choline) and the scan mode, in the same scan event. In order to keep this baseline resolution, the guard column was changed frequently (50–75 sample injections as prepared in this study). In general, the peaks were of reasonable resolution, with peak widths at base between 0.5 and 0.7 min, except for the PtdSer peak, which was significantly wider (1.8 min) due to the acidic nature of this PL. The extracted ion chromatograms shown in Fig. 2d, e and f demonstrate the selectivity and sensitivity of this technique compared to using the TIC peak areas (Fig. 2a, b and c) for quantification, allowing this method to be extended to other tissue samples such as serum (Fig. 2).

The parent ion spectra under each extracted PL peak could be viewed. PtdSer, ChoGpl, CerPCho, and EtnGpl were detected as $[M + H]^+$ ions in the spectra whereas PtdIns, negatively charged at pH 5.6, was detected as the ammonium adduct $[M + NH_4]^+$ ions in the spectra.

Positive ion mode ESI-MS/MS was chosen as the research focus was on the quantification of CerPCho and PtdCho in rat brains.

Calibration Curve

The HPLC-MS method used an external standard to quantify the relative amounts of PLs present in 80-day-old

rat brains. The linear calibration range used routinely in this study was up to 100 ng on-column but could be extended to twice that magnitude if required. The variation in response observed between the PL classes (Fig. 1) was not unexpected because, in positive ion mode, PtdCho and CerPCho ionize the most effectively and PtdIns ionizes the least effectively [10, 27]. PtdIns would be more effectively detected in negative ion mode. Unfortunately, it was not possible to switch between positive ion mode and negative ion mode during analysis on the mass spectrometer used in this study.

The current method was used to compare samples derived from the same sample matrix, i.e., 80-day-old rat brains. As the results were not corrected for variation of the ionization and/or fragmentation efficiencies within a given PL class, [11, 22, 28], they may not be absolute. However, as was the case in this study, the selection of standards with a fatty acid profile similar to the fatty acid profiles of the PLs in rat brain should eliminate some of these variations.

Precision and Accuracy

Matrix Effects

Matrix effects are a potential problem with most analytical methods. The components in the sample matrix may either suppress or enhance the analytical signal, leading to an under- or over-estimation of the analytical results.

In this study, the samples were evaluated for matrix effects. The brain extracts were serially diluted and compared with their respective standard curve. This resulted in close to parallel lines between the standard and the sample for EtnGpl, PtdSer, CerPCho, and ChoGpl indicating the effect of matrix on the analysis was minimal. However, considerable matrix effects were observed for PtdIns at all concentrations studied. It is unclear what components in the matrix were affecting the PtdIns response, but the low sensitivity of the PtdIns response would mean that it would

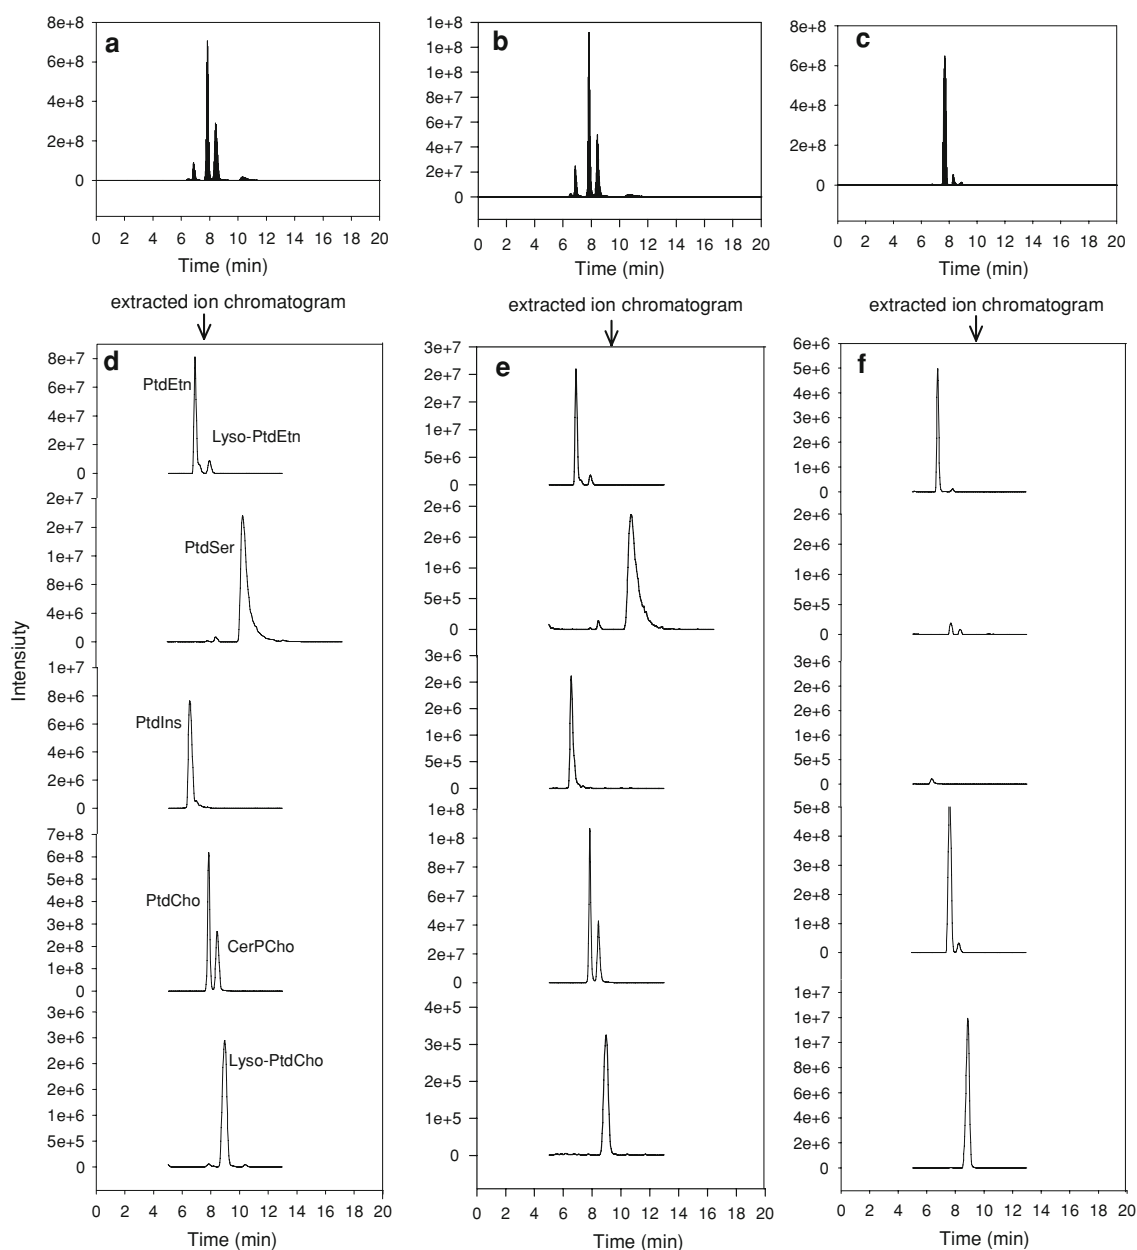

Fig. 2 TSQ Quantum triple quadrupole mass spectrometer total ion current trace of phospholipid standard mixture (10 ng load, **a**) and 80-day-old rat brain extract (**b**) and rat serum (**c**). The lower traces are their respective extracted ion chromatograms for each phospholipid

class—phospholipid standard (**d**), 80-day-old rat brain extract (**e**) and rat serum (**f**). The phospholipid classes are *PtdCho* phosphatidyl choline, *CerPCho* sphingomyelin, *PtdSer* phosphatidyl serine, *PtdEtn* phosphatidyl ethanolamine, *PtdIns* phosphatidyl inositol

be more affected by the matrix. This may explain the high variations observed for *PtdIns* (Table 3).

Spiked Recovery

Recovery experiments were conducted using homogenized rat brains spiked with a mixed phospholipid standard. Given the nature of the method, solvent/solvent extraction, the recoveries, ranging from 87 to 107% (Table 4) gave a good indication that the extraction protocol recovered

almost all of the PLs. Higher than 100% recovery can be explained by the coefficients of variance of the method measuring the endogenous phospholipids.

Repeatability and Reproducibility

The repeatability standard deviation was determined by analyzing the same sample over several days, whereas reproducibility was established over a longer period, over several months, by pooling the standard deviation of 48

Table 3 Repeatability and reproducibility coefficient of variation (CV) for the HPLC–MS phospholipid method

	ChoGpl	EtnGpl	PtdSer	PtdIns	CerPCho
Repeatability CV (%)	3	7	8	32	9
Reproducibility CV (%)	11	10	11	14	12

Repeatability was determined from analysis of the quality control sample between days whereas reproducibility was determined from duplicate extractions of 48 samples over several months using pooled standard deviation calculations

ChoGpl choline glycerophospholipid, *EtnGpl* ethanolamine glycerophospholipid, *PtdSer* phosphatidyl serine, *PtdIns* phosphatidyl inositol, *CerPCho* sphingomyelin

Table 4 Recovery of phospholipids spiked into rat brain

Phospholipid	Recovery (%)
PtdCho	107, 101
PtdEtn	97, 99
PtdSer	101, 103
PtdIns	102, 87
CerPCho	98, 104

ChoGpl choline glycerophospholipid, *EtnGpl* ethanolamine glycerophospholipid, *PtdSer* phosphatidyl serine, *PtdIns* phosphatidyl inositol, *CerPCho* sphingomyelin

samples analyzed in duplicate. Upon thawing, samples were analyzed immediately to reduce degradation of the PLs, which would have contributed to the assay variation. Degradation of the PLs in the sample was able to be monitored in part by observation of an increase in the lyso-PtdCho and lyso-PtdEtn peak areas (Fig. 2).

The repeatabilities and reproducibilities for EtnGpl, PtdSer, ChoGpl, and CerPCho (repeatability CV of 3–9%

and reproducibility CV of 10–12%, Table 3) were acceptable for such LC–MS/MS analyses. However, the PtdIns data had higher variation than expected. This may have been because PtdIns is not as effectively or reproducibly ionized under positive ion mode as discussed above. It could also have been related to the low response of PtdIns and the matrix effect issues observed as discussed above.

PLs in the Brains of 80-day-Old Rats

The total amount of PL in the 80-day-old rat brain (42 ± 1.3 mg/g brain, wet weight, $n = 9$) was derived from the sum of the individual PLs measured in this study (EtnGpl, ChoGpl, PtdIns, PtdSer, and CerPCho). This result was expected to account for greater than 95% of the total PL present in rat brain (minor PLs, e.g., lysophospholipid, phosphoglycerols, phosphatidic acid were not measured) [29] and showed excellent comparison with the PL results (44 ± 1.7 mg/g brain, wet weight mg, $n = 4$) converted from the total amount of phosphorus (54 ± 2.2 μ mol/g brain, wet weight) measured from the same rat brains. Total phosphorus determined as described by Vogel [30] provides an estimate of the amount of PL present in a sample based on multiplying the measured phosphorus value by a factor of 25, which is derived by dividing the average PL molecular weight of 754 by the phosphorus molecular weight of 31 [31].

The distributions of the individual PL classes were also consistent with literature data (Fig. 3), with ChoGpl and EtnGpl making up approximately 80% of the total PL in the rat brains. The results from Wells and Dittmer [25], Metz and Dunphy [24], and this study measured EtnGpl as the sum of PtdEtn and PlsEtn present in the samples

Fig. 3 Phospholipid distribution in 80-day-old rat brain (this study) compared with literature data. The rat strain and the rat age were Sprague–Dawley (42 days) for Wells and Dittmer [25], ACI/Seg-Hsd (70–84 days) for Metz and Dunphy [23], and Sprague–Dawley (no age given) for Lutzke and Braugler [30]. Standard deviation error bars are given where available. In this figure, PtdEtn and PlsEtn were

combined as a single EtnGpl value for the results presented for Wells and Dittmer [25], Metz and Dunphy [24], and this study. * Converted from total phosphorus results using a factor of 25 [29]. *EtnGpl* ethanolamine Glycerophospholipid, *ChoGpl* choline glycerophospholipid, *PtdSer* phosphatidyl serine, *PtdIns* phosphatidyl inositol, *CerPCho* sphingomyelin

(Fig. 3). It was assumed that this was also the case for the Lutzke and Braughler [32] results, as the values compared well, although the authors did not specifically define this. The differences in the amounts observed (Fig. 3) may in part be explained by differences in the rat strain and the age of the rat brain [29], and differences in the analytical methods used, i.e., both Wells and Dittmer [25] and Metz and Dunphy [24] used phosphorus as an indirect measure of PL amount, in comparison with the Lutzke and Braughler [32] study and this study, which quantified PLs directly using HPLC-ELSD and HPLC-MS/MS, respectively. It is also possible that the amount of EtnGpl has been underestimated in our analysis. Berry et al. [33] identified a reduced efficiency for the neutral loss of the ethanolamine head group (141 Da) from PlsEtn compared to PtdEtn. This potential problem could be rectified by using a EthGpl standard from a brain source (which contain around 50% PlsEtn). Furthermore, the lower PtdIns results obtained in this study may have been caused by the inefficiency of PtdIns ionization in positive ion mode as discussed earlier.

In summary, a rapid, selective and sensitive LC-MS/MS method, using an external calibration curve, has been developed to provide quantitative or comparative data for five PL classes in rat brain. The use of headgroup detection in this method overcame the complexities of the wide range of molecular masses within a class of phospholipids. This method could be extended to samples other than brain as illustrated by the serum sample in Fig. 2.

Acknowledgments The authors would like to thank Kathleen Schoeman for technical support, Charles Yang (Thermo Fisher Scientific, San Jose, CA, USA) for LC-MS discussions, Claire Woodhall for editing, and Mark Vickers (Liggins Institute, Auckland University, New Zealand) for providing the rat brain samples.

intermediates in the isoprenoid biosynthetic pathway (Fig. 1). This pathway is responsible for the production of a vast array of products which have very diverse cellular activities [1]. Both FPP and GGPP are positioned at branch-points leading to the synthesis of longer-chain isoprenoids. Head-to-head condensation of two FPP units, catalyzed by squalene synthase (SQS), leads to the first precursor in the sterol pathway [2]. In addition, FPP is used for the synthesis of dolichols, ubiquinone and heme A. FPP and GGPP also serve substrates for protein isoprenylation reactions [3]. Farnesylation and geranylgeranylation, catalyzed by farnesyl transferase (FTase) and geranylgeranyl transferase (GGTase) I and II respectively, ensure proper membrane localization and function of a number of key proteins including members of the Ras small GTPase superfamily [4].

In plants, GPP is a direct precursor for monoterpenes, which represent a large family of natural products. Monoterpenes play roles in repelling or attracting animals or insects, resisting microbial attack, and interfering with the growth of other plants [1]. In addition, monoterpenes are utilized in a diverse array of commercial products, including insecticides, cosmetics, and flavorings. In plants, GPP is produced by geranyl diphosphate synthase via the condensation of isopentenyl diphosphate (IPP) with dimethylallyl diphosphate (DMAPP) [5]. In animal cells however, farnesyl diphosphate synthase (FDPS) catalyzes the synthesis of both GPP and FPP via sequential addition reactions (Fig. 1) [6]. First, GPP is produced via condensation of IPP and DMAPP. GPP then reacts with IPP to yield FPP. Little is known about the role of GPP in mammalian cells, aside from serving as an intermediate in the synthesis of FPP.

The isoprenoid biosynthetic pathway has been targeted extensively by numerous therapeutic agents [7]. The statins, widely used to manage hyperlipidemia, inhibit

HMG-CoA reductase (HMGR), the rate-limiting enzyme in the pathway, and thus deplete cells of all downstream isoprenoid products including cholesterol [8]. The nitrogenous bisphosphonates (NBS), used to treat osteoporosis and metastatic bone disease, inhibit FDPS [9–11] and likewise deplete downstream products [12]. We have developed a series of GGPP synthase (GDPS) inhibitors which deplete cells of GGPP [13]. Inhibitors of SQS [14], FTase [15], and GGTase I [16] are currently at varying stages of clinical development.

In general, the effects of inhibitors of the isoprenoid biosynthetic pathway have been considered to be a consequence of depletion of key isoprenoid-derived species. However, there is increasing evidence to suggest that accumulation of upstream products may also be of importance. Accumulation of IPP/DMAPP in human peripheral blood monocytes following zoledronic acid administration has been shown to activate $V\gamma 9V\delta 2$ T cells, which in turn, have been linked to anti-tumoral activity as well as a flu-like acute-phase reaction [17]. Treatment of mice with inhibitors of SQS leads to large increases in urinary excretion of FPP derivatives [18]. Additionally, we have shown that SQS inhibitors dramatically increase intracellular levels of FPP [19]. This is relevant because farnesol, a derivative of FPP, can induce apoptosis [20, 21]. Therefore, as more drugs that target downstream isoprenoid biosynthesis become available it will be necessary to understand their concomitant effects on the upstream species.

Several methods for measuring FPP and GGPP in biological samples have been reported [22–25]. Unfortunately, issues such as limited sensitivity, heavy instrument requirement (e.g., LC–MS–MS), or complex procedures (e.g., column switching) have limited their routine application. Recently, we reported an analytical method to quantify FPP or GGPP in biological samples by HPLC [19]. This method is based on the ability of FPP or GGPP to be incorporated into fluorescent peptides by FTase or GGTase I, respectively. Using this method, cellular levels of FPP and GGPP have been determined in cultured cells and in animal tissues [19, 26]. Importantly, this method is sensitive enough to measure the changes of FPP and GGPP in cultured cells upon treatment with isoprenoid pathway inhibitors [27, 28].

Previously published GPP quantification methods have relied on radioactive tracing or HPLC–MS/MS [25, 29]. The major challenges in developing a method for GPP quantification in biological samples have been the low basal concentrations of GPP as well as its instability [25, 30]. We have developed a non-radioactive and sensitive method for measuring GPP levels in mammalian cells which is based on the ability of GPP to serve as a substrate for FTase *in vitro* [31]. This methodology allows for the

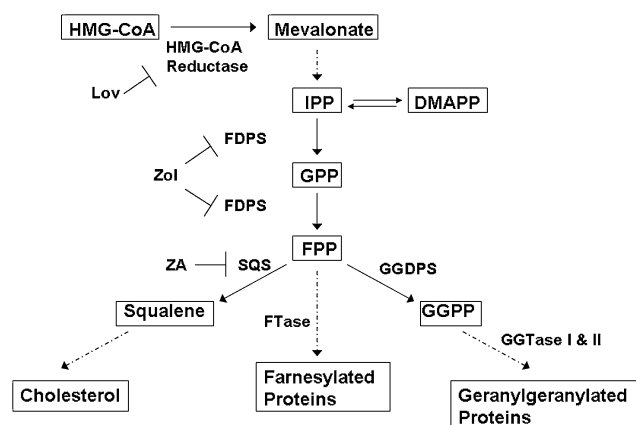

Fig. 1 The isoprenoid biosynthetic pathway. Key substrates, products, enzymes, and pharmacological inhibitors [lovastatin (*Lov*), zaragozic acid (*ZA*), and zoledronic acid (*Zol*)] are shown

measurement of basal levels of GPP as well as induced changes following treatment with isoprenoid biosynthetic pathway inhibitors. Furthermore, this methodology allows for the simultaneous measurement of GPP, FPP and GGPP levels.

Experimental Procedure

Cell Culture and Reagents

RPMI-8226, U266, H929 and K562 cells were obtained from the American Type Culture Collection (Manassas, VA). RPMI-8226, U266, H929 cell lines are human myeloma lines while the K562 cell line is a human erythroleukemia line that was established from a patient with chronic myelogenous leukemia [32]. Cells were grown in RPMI-1640 medium supplemented with fetal bovine serum, penicillin/streptomycin, and glutamine. GPP, FPP, GGPP, *n*-octyl β -glucopyranoside, and lovastatin were purchased from Sigma (St. Louis, MO). Zoledronate was purchased from Novartis (East Hanover, NJ). D*-GCVLS and D*-GCVLL (dansyl-labeled peptides) were obtained from Bio-Synthesis (Lewisville, TX). Rat recombinant FTase and GGTase-1 were purchased from EMD Biosciences (La Jolla, CA) or Jena Biosciences (Jena, Germany). HPLC-grade water was prepared with a Milli-Q system (Millipore, Bedford, MA). All solvents were optima or HPLC grade.

Extraction of GPP from Cultured Cells

RPMI-8226, U266 and H929 cells ($5\text{--}10 \times 10^6$) were incubated in the absence or presence of lovastatin or zoledronic acid for 24 h. Cells were collected and counted using a hemocytometer and Trypan blue staining. Cells were pelleted by centrifugation at 4 °C for 10 min at 2,800 rpm. The cell pellet was resuspended in 1 ml ice-cooled $1 \times$ PBS and then centrifuged at 20,000 $\times g$ 4 °C for 2 min. The PBS was aspirated and the cell pellet was again washed with 1 ml of ice-cold $1 \times$ PBS. Extraction solvent (isopropanol/75 mM ammonium hydroxide/acetone 1:1.5:5) (1.2 mL) was added to the cell pellet and vortexed for 1 min. The mixture was then centrifuged at 20,000 $\times g$ at 15 °C for 2 min. The supernatant was saved and the protein pellet was re-extracted in 1.2 ml of extraction solvent. After repeating the centrifugation step (20,000 $\times g$ at 15 °C for 5 min), the supernatants were combined and the volume was reduced to approximately 150 μ l via a stream of nitrogen at 30 °C. The samples were then dried using a speed vacuum (Savant SpeedVac Concentrator). The residue was dissolved in 50 mM Tris–HCl assay buffer (40 μ l, pH 7.5) containing 5 mM DTT,

5 mM MgCl₂, 10 μ M ZnCl₂, and 1.0% octyl- β -D-glucopyranoside.

Enzymatic Reaction

An appropriate amount of GPP (or FPP), D*-GCVLS (0.25 nmol), and FTase (1 μ l, 61 μ g/ml protein) were added to 50 mM Tris–HCl assay buffer (40 μ l). For GGPP, the reaction mixture contained GGPP, D*-GCVLL (0.25 nmol), and GGTase-1 (1 μ l). The assay mixture was incubated at 38 °C for up to 120 min. The reaction was terminated by addition of acetonitrile (60 μ l). The reaction products are stable over 24 h at 4 °C. Denatured proteins were removed by centrifugation at 20,000 $\times g$ at 15 °C for 5 min and the supernatant was analyzed by HPLC. For cross-reactivity studies, enzyme reactions were performed in which GPP (0.2 or 0.5 ng) was added to the FTase assay mixture containing tenfold FPP (2 or 5 ng) and D*-GCVLS (0.25 nmol). Likewise, FPP (0.2 or 0.5 ng) was added to the FTase assay mixture containing tenfold GPP (2 or 5 ng) and D*-GCVLS (0.25 nmol). For simultaneous measurement of GPP, FPP, and GGPP, the reaction mixture contained 0.25 nmol of each dansylated peptide (D*-GCVLS and D*-GCVLL) and 1 μ l of each enzyme (FTase and GGTase-1).

Quantification of GPP in Cell Extracts

HPLC analysis was carried out on a Beckman Gold system (126 solvent module, 168 detector, and 508 autosampler from Beckman Coulter, Inc., Ontario, CA) connected to a FP-920 intelligent fluorescence detector (Jasco Co., Tokyo, Japan). The sample analysis was performed on a C18 reverse phase analytical column (250 \times 3.0 mm, 5 μ m, Luna, C18 (2), Phenomenex) protected by a guard cartridge system (4 \times 3.0 mm, 5 μ m, Phenomenex). To separate prenylated peptides (G-D*-GCVLS, F-D*-GCVLS and GG-D*-GCVLL), two solvent systems were used: solvent A, 20 mM ammonium acetate in 40% acetonitrile and solvent B, 20 mM ammonium acetate in 90% acetonitrile. The program was initiated at 26% B for 0.8 min, and then solvent was brought to 60% B by a linear gradient in 3 min. At 9 min, the solvent was raised to 100% in 1 min. An isocratic 100% solvent B was run at 19 min, then the solvent was brought back to 26% B by a linear gradient in 4 min. The total run time was 28 min. The flow rate of 0.5 ml/min was kept throughout the analysis. The peptide and geranyl- and farnesyl- (or geranylgeranyl-) adducts were monitored by a fluorescence detector at the excitation wavelength of 335 nm and the emission wavelength of 528 nm. The entire procedure was performed at ambient temperature. The retention time for the G-D*-GCVLS, F-D*-GCVLS and the GG-D*-GCVLL peaks were 7.5, 12.8 and 21.8 min, respectively.

Determination of Extraction Efficiency

The assay mixture was incubated at 38 °C for 2 h. A modified external calibration curve was constructed for the calculation of GPP in cultured cell extracts using the previously described method [19]. In brief, 0, 100, 250, 500, 1,000, 1500 or 2,000 pg of standard GPP was added to K562 cells pellets (5×10^6) which had been depleted of GPP via incubation at 4 °C for 24 h. The standard was extracted, incorporated and analyzed as described above.

Results

Sample Preparation

Measurement of intracellular GPP has historically been limited by low levels and poor stability. GPP hydrolysis has previously been demonstrated to rapidly occur in the presence of Mn^{2+} and/or at high temperatures [30]. In particular, at pH 7.0 in the absence of Mn^{2+} , the rate of GPP hydrolysis increases 13-fold as the temperature increases from 25 to 46.5 °C [30]. We observed that GPP rapidly disappears from samples even at 4 °C and that GPP is much less stable than FPP and GGPP during sample processing (data not shown). Our preliminary studies showed that the overall recovery of GPP from GPP-spiked cell samples is approximately 20% when using the previously published solvent system (butanol/75 mM ammonium hydroxide/ethanol 1:1.25:2.75) and sample processing procedure [19]. We found that sample processing at relatively low temperatures, as compared with the 70 °C utilized in the previously published methodology, allows for a better recovery and more accurate determination of GPP in cell samples.

The newly developed method includes a different solvent system (isopropanol/75 mM ammonium hydroxide/acetone 1:1.5:5), low temperature (4 °C) sample processing and drying, as well as a new HPLC program which allows for complete resolution of geranyl-conjugated dansyl peptide (G-D*-GCVLS) from farnesylated (F-D*-GCVLS) or geranylgeranylated (GG-D*-GCVLL) peptide peaks on a C18 column in less than 30 min (Fig. 2).

Conjugation of GPP to Dansylated Peptide by Enzymatic Reaction

Pompliano et al. [31] previously demonstrated that GPP may be utilized as a substrate by FTase to prenylate Ras-CVLS in vitro. To determine whether GPP is incorporated into D*-GCVLS as quickly as FPP, a reaction time study was performed using a fixed concentration of GPP with D*-GCVLS and FTase via our previously established methodology [19]. Figure 3a demonstrates that the incorporation of GPP into D*-GCVLS occurs within 2 h. As shown in Fig. 3b, GPP and FPP can be simultaneously incorporated into D*-GCVLS in the same reaction mixture within 2 h. Interestingly, although the initial reaction rate of FPP incorporation is faster than that of GPP, the GPP reaction rate was not decreased in the presence of FPP. In this selected reaction system, we chose to use an excess of peptides, relatively large amounts of FTase (or GGTase I), and a long incubation time (2 h) to ensure complete conversion of GPP, FPP and GGPP to the fluorescent derivatives. The potential mutual interference between GPP and FPP on FTase-mediated reactions was further investigated under conditions in which tenfold of the assumed interfering isoprenyl diphosphate (GPP or FPP) was added to the FTase reaction mixture. As shown in Table 1, excess

Fig. 3 Effects of reaction time on FTase-mediated product formation. The enzymatic reaction was performed as described in “[Experimental Procedure](#)” using 1 ng of GPP alone **a** or in the presence of 1 ng FPP **b**

Table 1 GPP (or FPP) recovery in the presence of tenfold excess FPP (or GPP)

Measured isoprenoid	Quantity of spiked isoprenoid	
	0.2 ng (% Recovered)	0.5 ng (% Recovered)
GPP (with tenfold FPP) ($n = 5$)	105 ± 10	98 ± 8
FPP (with tenfold GPP) ($n = 5$)	100 ± 15	102 ± 2

levels of FPP or GPP did not interfere with the measurement of either GPP or FPP, respectively. Additional experiments demonstrated that FTase does not transfer GPP to D*-GCVLL and that GGTase I cannot use GPP as a substrate (data not shown).

Calibration Curves and Method Validation

An external calibration curve was constructed for the determination of GPP levels in cell samples (Fig. 4). To mimic the condition of tissue samples, K562 cells were used as a carrier for the analytical procedure. In brief, K562 cell pellets were incubated at 4 °C for 24 h to deplete endogenous GPP. Different amounts of GPP were then

Fig. 4 GPP calibration curve. Known quantities of GPP were extracted from K562 cells as described in the text and a calibration curve was determined. Data are shown as mean ± SEM ($n = 3$)

added to the washed cell pellets and isolated and analyzed following the procedure described in “[Experimental Procedure](#)”. Under these conditions, a linear response was established over a range of 0–2,000 pg (Fig. 4). The lower limit of detection was approximately 5 pg. To fully validate the method, GPP-spiked K562 cells were used to determine the overall recovery for the procedure. The average recoveries of GPP at the 250, 500, and 1,000 pg levels were 92.5 ± 5.1%, 95.0 ± 8.2% and 95.8 ± 4.1%, respectively ($n = 3$).

This method also allows for simultaneous measurement of FPP and GGPP levels. To determine whether this method is as sensitive as our previously established method [19], FPP and GGPP levels were measured in various cell lines using both methods. In all cases, the measured levels of FPP and GGPP were slightly higher (by 5–10%) using the previously established method (Table 2).

Determination of GPP Levels in Cultured Cells

Using the method described above, levels of GPP in RPMI-8226, H929 and U266 cells were determined (Table 3). Detectable basal GPP levels were found in all tested cell lines, with a range of 0.029–0.101 pmol/million cells. To determine whether this methodology could be used to measure changes in GPP levels following treatment of cells with drugs known to inhibit the isoprenoid biosynthetic pathway, experiments were performed in which cells were treated with either lovastatin or zoledronic acid. Lovastatin, an HMGCR inhibitor, prevents mevalonate synthesis and thus depletes cells of downstream isoprenoid intermediates, including GPP. As shown in Table 3, treatment of cells for 24 h with lovastatin resulted in a decrease in GPP levels by over 50% in all tested cell lines. In contrast, when cells were treated with zoledronic acid, an FDPS inhibitor, it was found that GPP levels markedly increased (16 to 107-fold) in all tested cell lines.

Table 2 FPP and GGPP levels in human cell lines, as determined by the newly developed method and the previously established method

Cell line ($n = 3$)	FPP (pmol/10 ⁶ cells)		GGPP (pmol/10 ⁶ cells)	
	New method ^a	Established method ^b	New method	Established method

^b Established method: as previously reported by Tong et al. [19]

Discussion

In these studies we present a simple and sensitive method for the determination of GPP levels in cultured mammalian cells. This method involves the extraction of GPP from cells followed by incorporation into a dansyl-labeled peptide via enzymatic reaction. The fluorescent product is then analyzed by HPLC (Fig. 2). This method is significantly more sensitive than a previously published method [25] and is the first to allow for detection of basal levels of GPP (Table 3). In addition, this method allows for concomitant measurement of GPP, FPP, and GGPP. Although FPP and GGPP levels measured with this methodology are slightly lower (by 5–10%) than those obtained from our established method, the results may likely be acceptable for some studies. In particular, simultaneous determination of GPP, FPP, and GGPP in the setting of limited sample size (e.g., patient samples) is advantageous and allows for conservation of time and resources.

This methodology relies on the ability of GPP to serve as a substrate for FTase in an *in vitro* enzyme reaction [31]. We have demonstrated that the presence of FPP does not interfere with the utilization of GPP (Fig. 3b; Table 1), thereby

allowing for the determination of both GPP and FPP levels in one enzymatic system. GPP has not previously been demonstrated to serve as a substrate for prenylation reactions *in vivo* under standard conditions, although geranyl-cysteine has been detected in radiolabeling experiments involving mevalonate starvation [33]. This is presumably due to low basal levels of GPP and to FTase preferring FPP as a substrate; the K_M is 6,200 nM for GPP versus 390 nM for FPP when using Ras-CVLS as the peptide acceptor [31]. However, we have demonstrated that GPP levels markedly increase following zoledronic acid treatment (Table 3). It is interesting to speculate that in this setting, the induced changes in GPP and FPP levels may allow for FTase utilization of GPP. Further studies will be necessary to determine whether geranylation of proteins occurs in this setting. Protein geranylation, as compared with farnesylation or geranylgeranylation, could have significant impact on prenylated protein localization and/or function.

These studies represent the first time that basal GPP levels have been determined in mammalian cells. To our knowledge, the male bark beetle is the only animal which has been shown to synthesize GPP for monoterpene-derived pheromones [34, 35]. Otherwise, it has been assumed that in animals, GPP exists only as a transient intermediate in the FDPS-catalyzed synthesis of FPP. That we have been able to measure basal levels of GPP raises the hypothesis that there are mechanisms in place which regulate GPP pool size and that GPP may have additional functions within the cell. The consequences of markedly increasing GPP levels, as seen when cells were treated with zoledronic acid, are unknown. Geraniol, the alcohol version of GPP, has been demonstrated to inhibit colon cancer cell growth [36] and to have chemopreventative properties in a rat model [37]. A GPP pyrophosphatase activity has been described in cockerels [38]. Thus excess levels of GPP may result in geraniol production. Aminobisphosphonates have been recognized to have anti-neoplastic properties which have been largely attributed to the inhibition of protein prenylation [39]. Our results raise the hypothesis that intracellular accumulation of GPP may also contribute to these cytotoxic effects.

Table 3 GPP levels in human myeloma cell lines following 24 h incubation in the presence or absence of lovastatin or zoledronic acid

Cell line ($n = 5$)	GPP (pmol/10 ⁶ cells)
RPMI-8226	
Control	0.101 ± 0.016
Lovastatin (10 μM)	0.033 ± 0.018
Zoledronic acid (50 μM)	10.846 ± 1.519
H929	
Control	0.073 ± 0.029
Lovastatin (10 μM)	0.035 ± 0.017
Zoledronic acid (50 μM)	1.915 ± 0.391
U266	
Control	0.029 ± 0.011
Lovastatin (10 μM)	0.014 ± 0.011
Zoledronic acid (50 μM)	0.473 ± 0.121

It has been well-documented that aminobisphosphonates induce an increase in IPP levels and lead to the production of the ATP analog ApppI (triphosphoric acid 1-adenosin-5'-yl ester 3-(3-methyl-but-3-enyl) ester) [40–42]. However, an induced increase in GPP has not been previously demonstrated following alendronate treatment [9, 25]. Whether this is secondary to the loss of GPP during the analytical procedures or is due to differences between alendronate- and zoledronic acid-FDPS interactions remains to be determined. The aminobisphosphonates have been shown to bind to the allylic (i.e., DMAPP or GPP) substrate site, leading to the partial closure of the active site [43, 44]. Subsequent binding of IPP further stabilizes the inhibitor-enzyme complex in the fully closed position [44]. Thus it would be predicted that both GPP and FPP synthesis would be inhibited. However, our findings reveal that zoledronic acid treatment leads to an increase in GPP levels in all tested cell lines (Table 3). This suggests a complex relationship between IPP/DMAPP/GPP levels and flux through the pathway, regulation of FDPS activity, and inhibitor. Further studies will be needed to delineate the mechanism underlying the observed increase in GPP levels.

In summary, we have established a sensitive nonradioactive method for the measurement of GPP in mammalian cells. We have reported the first basal measurements of GPP in mammalian cells and have demonstrated that this method can be used to quantify the effects of isoprenoid pathway inhibitors on GPP levels. There is still much to be learned with regard to the role of GPP, the flux of isoprenoid intermediates through the biosynthetic pathway, regulation of isoprenoid concentration, and hierarchy of utilization under conditions of isoprenoid precursor deprivation. Furthermore, given the interest in isoprenoid biosynthetic pathway inhibitors [45, 46] and isoprenyl transferase inhibitors [47] for the treatment of cancer and other diseases, as well as the emerging role of isoprenoids as regulators of protein expression [48, 49], there are a wide variety of applications for which measurement of GPP, FPP and GGPP levels will be important.

minor constituent in human bile [6] and is used as a drug to dissolve cholesterol gallstones, to treat biliary cirrhosis, bile reflux gastritis, treatment of colorectal cancer and a range of other adult cholestatic conditions [7, 8]. Several instrumental approaches have been described for the analysis of bile acids in bulk or in pharmaceutical preparations, including potentiometry, voltammetry, micellar electrokinetic chromatography (MEKC), supercritical fluid chromatography (SFC), gas chromatography and HPLC. However, the procedures are generally quite onerous and involve difficult or time-consuming extraction procedures [9, 10]. The extensive use of bile acids in the pharmaceutical formulations for aesthetics clinics and pharmacies shows the need for biotechnological studies to develop alternative methods for fast analysis of these products, making it easier to implement the government health policy (ANVISA and FDA) to control the illegal commerce of these products.

In this context, cyclodextrins (CDs) are a group of naturally occurring cyclic oligosaccharides with six (α -), seven (β -) or eight (γ -) glucose residues linked by α -(1–4) glycosidic bonds [11, 12]. In aqueous solution, they possess a truncated cone shaped structure with a hydrophilic exterior and a hydrophobic interior [13] capable of forming inclusion complexes with a wide variety of substrates such as dyes, drugs, small anions, carboxylic acids and alcohols [14]. The inclusion complexes formed are often able to promote enhancements or perturbations of the photophysical and photochemical properties of included guest molecules [15]. Hence, investigation of the inclusion mechanisms can be accomplished using a great variety of methods including molecular absorption spectrophotometry and fluorometry, HPLC, surface tension, electrochemistry and calorimetry [16]. However, reports of the use of CDs as analytical reagents in UV–Vis spectrophotometry are scarce. Xie et al. [17] used the absorption spectra of the dibenzoyl peroxide- β -cyclodextrin complex in the analysis of benzoic acid concentrations. Yanez et al. [18] proposed the use of β -CD to directly quantify the furnidipine through of the inclusion complex formed and Yuexian et al. [15] resorted to the methyl orange- α -cyclodextrin inclusion complex to determine aromatic amino acids. More commonly, CDs have been used in UV–Vis spectrophotometry mainly to improve the solubility and stability of colored compounds and to increase the sensitivity and selectivity of colorimetric reactions [19].

Phenolphthalein (PHP) is a typical acid/base indicator that forms a colorless 1:1 inclusion complex with β -CD and can be used for the determination of colorless compounds through competitive complexation reaction [20, 21]. In this context, the objective of this work is the proposal of the colorimetric determination of deoxycholic and ursodeoxycholic acid based on competitive complexation reaction

with phenolphthalein- β -cyclodextrin inclusion complexes. Two factorial designs were developed to identify the constraints and study the experimental conditions to accomplish optimized determination procedures. Good figures achieved for the proposed procedures enable one to envisage low costs and simple application in large scale monitoring and control tasks.

Experimental

Materials

Absorption spectra and data were collected by means of a Pharmacia Ultraspec 3000pro UV–Vis spectrophotometer using 1-cm path length quartz cells. Statistical evaluations were carried out by means of the Statistica software (StatSoft Inc., Tulsa, OK, USA).

Double deionized water and analytical grade chemicals were used without further purification. β -cyclodextrin was obtained from Fluka (Steinheim, Germany). Phenolphthalein, deoxycholic (sodium salt) and ursodeoxycholic acids were obtained from Sigma (St. Louis, MO, USA). Under acidic conditions, the measurements were performed using a 150 mM KCl–HCl buffer solution, pH 2.0. A 150 mM carbonate buffer solution was prepared to provide measurements at basic conditions [20].

Methods

The co-precipitation technique [22] was used to prepare the inclusion complexes. Therefore, solutions were mixed in the following order: 1.0 mL of the indicator solution, 1.0 mL of buffer, 1.0 mL of β -CD solution. The mixture was stirred vigorously after the addition of each solution (the order did not interfere in the results). After, this the initial mixture was homogenized with 1.0 mL of the bile acid sample. The blank solution was composed of 1.0 mL of buffer and 3.0 mL of water.

The ratio between the concentrations of β -CD and indicator (6:1) was recorded to find the best indicator inclusion complex to accomplish the bile acids determinations. Thus, the following concentrations of indicators were tested: bromophenol blue (4×10^{-5} M), bromocresol blue (1.85×10^{-5} M), methyl orange (5.1×10^{-5} M at pH 2.0 and 4.0×10^{-4} M at pH 9.5), methyl red (3.1×10^{-4} M), phenol red (7.5×10^{-5} M), phenolphthalein (3.1×10^{-4} M, only in basic conditions) and thymol blue (1.3×10^{-4} M). All the concentrations referred were in the linear range of spectrophotometric response for the respective indicator.

The equilibrium constants of the β -CD-PHP inclusion complex was measured using solutions of 3.1×10^{-4} M

phenolphthalein in different amounts of β -CD (5.17×10^{-5} – 1.86×10^{-3} M) at pH 9.5 or of 1.55×10^{-4} M phenolphthalein in the 2.58×10^{-5} – 9.3×10^{-4} M β -CD range at pH 10.5, were respectively prepared. The equilibrium constants of the β -CD-DCA inclusion complex was determined mixing DCA to final concentrations between 1.56×10^{-5} and 6.25×10^{-3} M to the β -CD-PHP (1.24×10^{-3} : 3.1×10^{-4} M) solution. The same experimental conditions were performed for measuring the β -CD-UDCA equilibrium constant, utilizing UDCA concentrations in the interval of 4.84×10^{-5} – 3.1×10^{-3} M prepared with a constant ratio of β -CD-PHP (6.2×10^{-4} : 1.55×10^{-4} M).

Applications

The study was performed by the addition of known amounts of the DCA and UDCA standards to a sample with a known amount of pharmaceutical formulations such as, injectable phosphatidylcholine formula [23] (phosphatidylcholine 5% w/v, deoxycholic acid sodium salt 4.75% w/v, benzyl alcohol 0.9% v/v, and water up to a volume of 100 mL) and injectable deoxycholate formula [24] (Deoxycholic acid 2.5% w/v, Benzyl alcohol 1% v/v, propylene glycol 10% v/v, Water 100 mL) for the DCA and Ursacol (labeled with 300 mg of ursodeoxycholic acid per pill) for the UDCA.

Results

Evaluation of the Inclusion Complexes Between β -Cyclodextrin and Different Indicators

Figure 1 shows the spectral changes of different common pH indicators after addition of β -CD up to a concentration ratio of 6:1 at pH 2.0 and 9.5 media. For bromocresol blue, bromophenol blue, thymol blue and phenol red, no significant changes were observed in the respective spectra when β -CD was added. However, the phenolphthalein (PHP) showed a strong interaction with the β -CD in alkaline pH since there was a decrease in the absorption peak (at a wavelength of 553 nm) (Fig. 1a) of more than 95%. Inclusion complexes between methyl orange and the β -CD were observed on both pH conditions tested (Fig. 1b). At pH 2.0, the absorption peak at 506 nm decreased slightly, whereas at pH 9.5 the formation of two isobestic points at 400 and 456 nm and a blue shift of the absorption band of about 6 nm were registered. Methyl red also formed inclusion complexes with β -CD at the two pH values (Fig. 1c), evidenced by the appearance of two isobestic points in acid (484 nm and 579 nm), basic pH (335 nm and 433 nm) and a blue shift of 8 nm in the wavelength corresponding to the absorption maxima.

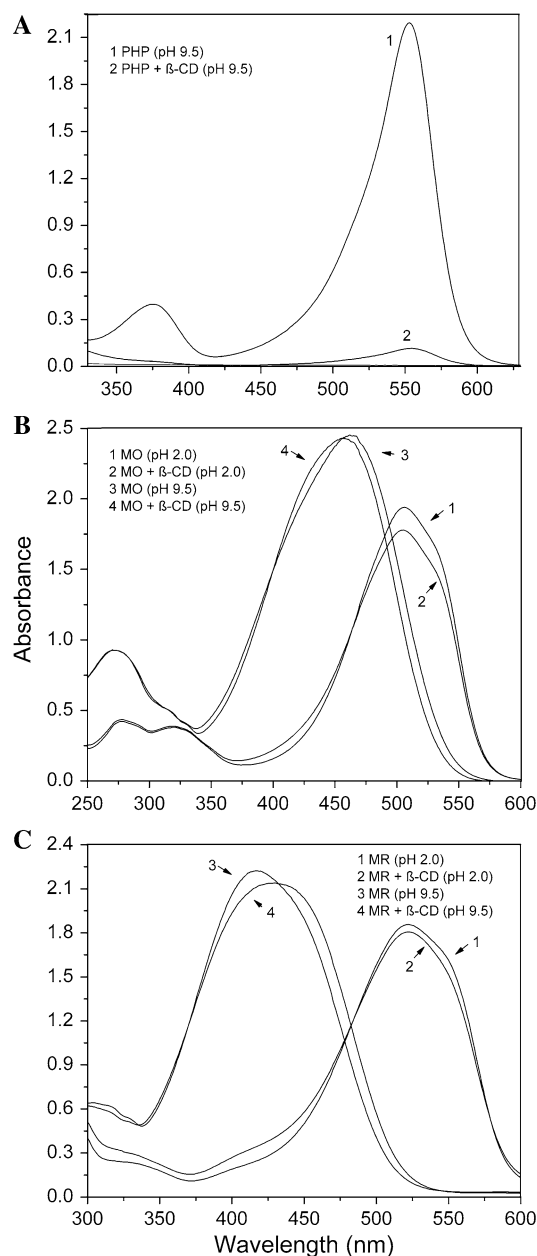

Fig. 1 Absorption spectra at acid (2.0) and alkaline pH (9.5) of **a** phenolphthalein (3.1×10^{-4} M, only in basic solution), **b** methyl orange (5.1×10^{-5} M at pH 2.0 and 4.0×10^{-4} M at pH 9.5), **c** methyl red (3.1×10^{-4} M), at a ratio of 1:6 with β -CD

Based on previous observations, it is clear that inclusion complexes are formed with particular forms of the indicators, but the spectral changes are more pronounced in the case of the β -CD-PHP complex. When the PHP is forced to leave the cavity of β -CD by a competitive colorless guest which it will again confer the red color to the solution. Thus, the extent of the solution color change can then be easily determined against a calibration curve of the free indicator and the corresponding amount related with the amount of the host substance. The absorption spectra of

PHP solutions with concentrations of β -CD ranging from 5.17×10^{-5} – 1.86×10^{-3} M revealed a proportional decrease in the free PHP up to a concentration of 1.24×10^{-3} M at pH 9.5 and up to 6.2×10^{-4} M at pH 10.5, showing a concentration ratio of 4:1 (β -CD:PHP). Higher concentrations of β -CD did not cause an additional observable decrease in absorption under both pH values. Some reports have been established the premise that under the assay conditions, phenolphthalein is only capable of forming 1:1 inclusion complexes with β -cyclodextrin as in Eq. 1 [20, 22, 25], a double reciprocal plot shows a linear relationship corresponding to the equilibrium constant (K_c), which can be obtained from Eq. 2. The equilibrium constant (K_c) for the formation of the inclusion complex was determined from the ratio of the intercept to the slope in the linear Benesi–Hildbrand plot [26, 27]:

$$\frac{1}{A - A_0} = \frac{1}{a} + \frac{1}{aK_c[\beta\text{-CD}_0]} \quad (2)$$

where A and A_0 are the absorbance of PHP in the presence and absence of β -CD, respectively, K_c is the equilibrium constant for the formation of a 1:1 inclusion complex, a is a constant related to the molar absorption coefficients changes, and $[\beta\text{-CD}_0]$ is the initial concentration of β -CD. The equilibrium constants (K_c) were then determined both at pH 9.5 and pH 10.5 from the linear plots experimentally obtained. The respective values of $1.65 (\pm 0.98) \times 10^4$ and $5.10 (\pm 0.37) \times 10^4 \text{ M}^{-1}$ demonstrated that the smaller amount of free PHP found at the higher pH is congruent with the higher value of the complex equilibrium constant.

Determination of Deoxycholic Acid and Ursodeoxycholic Acid by Their Competitive Complexation Reaction with β -Cyclodextrin-Phenolphthalein inclusion complex

The inclusion complex formation was instantaneous and could be seen without any equipment. Figure 2 shows the absorption spectra of the β -CD-PHP inclusion complex under different concentrations of DCA (Fig. 2a) and the UDCA (Fig. 2b). It is clear that with the addition of DCA or UDCA, an increase in the monitored absorbances occurred. This behavior indicates competition of the DCA or of the UDCA with PHP to form the inclusion complex with the β -CD. However, at pH 9.5 the spectral changes of the solution with the increasing amounts of UDCA were absent. For the studies of the conditions for the determinations of both acids and simultaneous evaluation of the robustness of the experimental conditions, two independent factorial designs were developed considering the pH

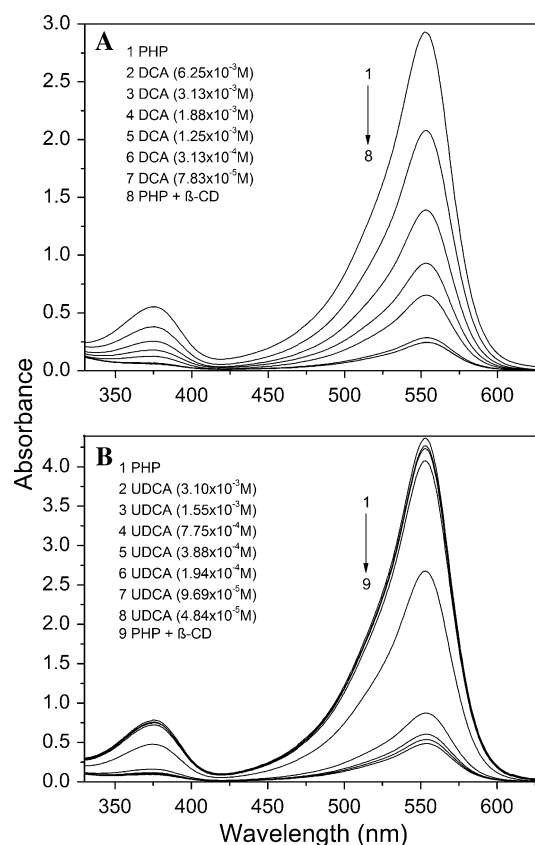

Fig. 2 Determination of various concentrations of DCA (a) by the β -CD-PHP inclusion complex at pH 9.5 (β -CD-PHP: 1.24×10^{-3} ; 3.1×10^{-4} M) and UDCA (b) at pH 10.5 (β -CD-PHP: 6.2×10^{-4} ; 1.55×10^{-4} M)

changes, the temperature, the concentration of the inclusion complex and the buffer concentration (Table 1). The central points of both designs were also assayed in quadruplicate for determination of the pure error.

The results obtained through a 2^3 full factorial design for the study of the variables that influence the determination of DCA demonstrated that the pH had the main statistically significant positive effect ($p < 0.05$). In fact, there was an increase of about 73.2% in the result for DCA (1.88×10^{-3} M) for the pH values 9.2 and 10.7 (Fig. 3), and only of 2.85% between the pH values 10.5 and 10.7 (increase not significant according to the Tukey test ($p < 0.05$)). Thus, the adoption of the higher pH conditions provided the larger variation in the absorbance of the sample under the conditions studied. The second order interactions between the pH and β -CD-PHP concentration values and between temperature and β -CD-PHP concentration values also presented positive effects, meaning that the main pH effect was slightly enhanced by raising the levels of the other two variables. The other main effects and third order interactions were not statistically significant ($p < 0.05$). To calculate the equilibrium constants of the β -CD-DCA inclusion

complexes with a 1:1 stoichiometry, the modified Benesi–Hildbrand [26, 27] equation (Eq. 3) can be resorted to, since the β -CD-PHP complex is colorless at the monitoring wavelength and any absorbance of the solution is due to the free PHP₀ displaced from the complex and thus proportional to the bile acid concentration.

$$\frac{1}{A - A_0} = \frac{1}{a} + \frac{1}{aK_c[\text{PHP}_0]} \quad (3)$$

The values of K_c of 8.65×10^3 and $2.58 \times 10^4 \text{ M}^{-1}$ were found at the pH values of 9.5 and 10.5, respectively.

The results obtained through the 2^4 full factorial design for the study of the variables with significant influence in the determination of UDCA are presented in the Table 1.

The concentration of the β -CD-PHP complex had a negative and highly significant effect ($p < 0.05$), indicating that smaller inclusion complex concentrations lead to larger absorbance values under the studied conditions. The pH (positive effect) and buffer concentration (negative effect) variables used in the solution of UDCA presented low statistically significant effects. Only a second-order interaction was significant, namely the interaction between temperature and β -CD-PHP concentration, indicating a positive effect of those variables on the absorbance. As can be seen on Fig. 4, and settling a constant 4:1 ratio between β -CD and PHP concentrations, the absorbance of the complex remained stable above 7.75×10^{-5} : $1.94 \times 10^{-5} \text{ M}$. However, the studies of these

Fig. 3 pH effect in the β -CD-PHP inclusion complex (6.2×10^{-4} : 1.55×10^{-4} M) formation and your interaction with DCA (1.88×10^{-3} M)

Fig. 4 Concentration effects of PHP, β -CD-PHP inclusion complex without UDCA and with UDCA (3.88×10^{-4} M) in the absorbance values

inclusion complexes in the presence of 3.88×10^{-4} M of UDCA, showed an increase in the response of 43.2% (difference statistically significant according to the Tukey test, $p \leq 0.05$) at the concentration of β -CD-PHP complex, 3.1×10^{-4} : 7.75×10^{-5} M, compared to that previously used (6.2×10^{-4} : 1.55×10^{-4} M).

Under these conditions, the straight line obtained from the Benesi–Hildbrand plot enabled us to obtain the value of $2.22 \times 10^4 \text{ M}^{-1}$ for K_c .

Analytical Parameters

From the measurements performed under the optimum conditions described above, the calibration graph was linear in the range 6.1×10^{-6} – 3.13×10^{-3} M of DCA allowing the establishment of a regression line of equation: $A = 698(\pm 10)\text{DCA}_M - 0.005(\pm 0.012)$ with a correlation coefficient of 0.9995. For UDCA a quadratic relationship

was found in the range 6.05×10^{-6} – 3.88×10^{-4} M, but translated in a linear regression line if this is established in the form of $A^{0.5} = 3,814(\pm 133)\text{UDCA}_M + 0.03(\pm 0.01)$ with a correlation coefficient of 0.9991. The limits of detection were of 3.94×10^{-5} M for DCA and of 4.08×10^{-5} M for UDCA. The corresponding limits of quantification were respectively of 1.31×10^{-4} and 1.36×10^{-4} M.

Based on Tukey's test there were no significant differences between the standards and the pharmaceutical formulations (three replicates, $p < 0.05$), according to the method described in the experimental section (variation: injectable phosphatidylcholine 4% and injectable deoxycholate 2.6% for DCA and 1% for UDCA). Table 2 shows a summary of the analytical parameters for the determination of DCA and UDCA.

Discussion

CDs are the most important and widely studied examples of host molecular receptors due to their high affinity for hydrophobic molecules in aqueous media. In particular, herein we report the preparation, characterization and application of the inclusion complexes with β -cyclodextrin and indicators to determine bile acids spectrophotometrically in pharmaceutical formulations.

In this work, we tested β -CD with nine different indicators, in which it was not possible to detect spectral changes for six of them, obtaining the best inclusion complexes with phenolphthalein (PHP), methyl orange, and methyl red.

The strong interaction between phenolphthalein (PHP) and β -CD at alkaline pH values shown in the Fig. 1a can be explained because under this pH condition, the ionized red form of PHP becomes enclosed in the β -CD cage, where it is forced into its colorless lactone structure without, however, protonating the phenolic groups [20]. However, the results obtained with the inclusion complexes between methyl orange and the β -CD observed on Fig. 1b, showed that the decrease in absorbance values, according to the literature, can be justified due to the lack of coplanarity of methyl orange caused by the constrained conformation of methyl orange in the cyclodextrin cavity [15, 28]. The same authors reported a similar behavior between the methyl orange and α -CD. In the basic pH, the formation of an isosbestic point was also noted by Sueishi and Miyakawa [29]. While the inclusion complexes obtained with methyl red and β -CD at the two pH values (Fig. 1c) showed two isosbestic points (acidic and basic pH). The isosbestic point's appearance characterizes the formation of the azonium tautomer inclusion complex, one of the cationic protonated forms of methyl red. Similar findings were previously described by Tawarah and Khouri [30] and

Table 2 Summary of the best analytical parameters for the determination of deoxycholic and ursodeoxycholic acids using an inclusion complex

Analytical parameters	Deoxycholic acid	Ursodeoxycholic acid
β -CD-PHP inclusion complex (M)	6.2×10^{-4} : 1.55×10^{-4}	3.1×10^{-4} : 7.75×10^{-5}
Temperature (°C)	20–30	20–30
pH	10.5	10.5
Solubility	Water	Carbonate buffer 50 mM
Reaction time	Instantaneous	Instantaneous
Wavelength (nm)	553	553
Linearity range (M)	6.1×10^{-6} – 3.13×10^{-3}	6.05×10^{-6} – 3.88×10^{-4}
Limit of detection (M)	3.94×10^{-5}	4.08×10^{-5}
Limit of quantification (M)	1.31×10^{-4}	1.36×10^{-4}

Kuwabara et al. [31] concerning the inclusion complexes with γ -CD and β -CD, respectively.

According to Del Valle [22], the measurements of stability or equilibrium constants (K_c) or the dissociation constants (K_d) of the guest–cyclodextrin complexes are important since this is an index of changes in the physicochemical properties of a compound upon inclusion. Then, if the K -value is high, it means that the inclusion complex is stable, as is the case of the β -CD-PHP, a colorless 1:1 inclusion complex [20, 21] at pH 10.5 and 25 °C, obtained in this work which is the method reagent proposed. In this way, only hydrophobic molecules with high affinity to the cyclodextrin cavity will be able to replace the PHP in the β -CD cavity, causing spectral changes in the visible spectrum. In addition, in the concentrations studied, the excipients used in the formulations and water type did not interfere with the results using the reagent complex (β -CD-PHP) (data not shown).

Based on the results reported here, it is clear that inclusion complexes were formed with particular forms of the indicators, but the spectral changes were more pronounced in the case of the β -CD-PHP complex at a concentrations ratio of 4:1 β -CD-PHP for determination of the DCA and UDCA. The proposed method is capable of determining the bile acid concentration using the visible spectrum, eliminating the sample preparation steps of the methods using UV detectors such as HPLC that can exhibit problems due to bile acids absorbing weakly at about 200 nm, where it is possible to function only after oxygen removal, otherwise a derivatization must be performed [32].

The other advantages of the procedure proposed herein are the short time for the analysis completion, qualitative analysis in commercial facilities, use of low cost reagents and the low concentrations which can be used for determinations. The best pH condition found for determining DCA was 10.5 and similar to that proposed for fluoxetine and tetrahydrofuran by Afkhami et al. [20] and Zarzycki and Lamparczyk [33], respectively. The development of low cost methods for determining DCA is important in quality control of pharmaceutical formulations, for

example, in deoxycholate-hydrogels [34] to prevent misuse when considering aesthetic usage purposes. The limit of detection of 3.94×10^{-5} M and a linearity varying the order of 6.1×10^{-6} – 3.13×10^{-3} M makes possible the determination of its content in samples of phosphatidylcholine injections (50 mg/mL) indiscriminately used in injection lipolysis [5, 23]. The limit of detection for the UDCA determinations is more than ten times lower than the concentrations found in liver $5\text{--}6 \times 10^{-4}$ M [35] and the typical pattern provided by the European Pharmacopoeia for tablets is 60 mg.

DCA and UDCA were satisfactorily determined in the pharmaceutical formulations by a competitive complexation reaction with a color indicator to form β -cyclodextrin-inclusion complexes. The proposed method can be used for qualitative and fast pre-examination at commercial facilities (aesthetics clinics and pharmacies), which would be useful for health policies in testing pharmaceutical formulations containing DCA and UDCA. Furthermore, the products can be submitted to quantitative analysis by this technique we have developed which is characterized by simplicity, high stability over a large temperature range, instantaneous reaction, high sample throughput and low cost for reagents and instrumentation.

Acknowledgments The authors would like to thank FACEPE, CAPES-GRICES, LIKA/UFPE, CNPq. Dr. Benício B. Neto provided assistance in the statistical analysis of the manuscript.

Introduction

The role of nutrition in the management of diseases has often centered on correcting apparent nutrient deficiencies or meeting estimated nutritional requirements of patients. Recently, further understanding of the underlying mechanisms of various disease processes and how certain nutrients possess pharmacological properties have fueled an interest in exploring how nutritional therapies themselves could modify the behavior of various conditions. Nutrients such as n-3 PUFA have been demonstrated to have at least the potential to modulate diseases. Eicosapentaenoic (C20:5n-3, EPA) and docosahexaenoic acid (C22:6n-3, DHA), the n-3 PUFA present in marine foods, have an important role in the prevention of many diseases, particularly cardiovascular diseases (CVD) [1, 2] and the American Heart Association and the European Society of Cardiology recommend a higher fish consumption and/or the daily intake of 1 g n-3 PUFA for primary and especially for secondary prevention [3].

n-3 PUFA preventive activity is related to their hypocholesterolemic, hypotriglyceridemic and anti-inflammatory effect, to the reduction of platelet aggregation and blood viscosity, to the antithrombotic and fibrinolytic activities [4, 5] and to the protection from ischemia/reperfusion-induced cellular damage and arrhythmias [6]. Among the different mechanisms considered at the basis of PUFA effects, the modulation of gene expression [7] is of particular interest. Actually, in a recent work [8] we demonstrated that EPA and DHA supplementation to cultured neonatal rat cardiomyocytes is able to modulate the expression of more than 100 genes, many of them related to cardiac hypertrophy.

The fatty acids regulate gene expression binding directly to nuclear receptors or affecting SREBP, ChREBP and NF kappa B protein content. PPAR are considered important effectors of fatty acid regulation of gene transcription, and recent studies have identified that PPAR have some new effects in CVD [9]. PPAR belong to a ligand-activated nuclear receptor super-family that includes three members (α , β/δ , and γ) encoded by distinct genes, which bind to sequence-specific target elements as an hetero-dimer with the retinoid X receptor (RXR) in the promoter region of target genes [10].

The first aim of the present study was to elucidate if EPA and DHA act simply by increasing PPAR/RXR DNA binding or if they can also increase the biosynthesis of PPAR themselves, so regulating the nuclear abundance of these nuclear factors.

The second aim of this work was to establish a new link between the modification of fatty acid composition induced by n-3 PUFA and their molecular effects.

Experimental Procedure

Material

Fatty acids, Ham F10 medium, fetal calf serum (FCS), horse serum (HS), gentamicin, amphotericin B, BSA, pentadecanoic acid, CelLytic™ M, protease inhibitor cocktail, DTNB, palmitoyl coenzyme A lithium salt, anti-rat β -actin IgG were from Sigma (Milan, Italy). Anti-rat α , β/δ , γ PPAR, nucleophosmin and HRP-conjugated goat anti-rabbit IgG were from Santa Cruz Biotechnology (Milan, Italy). All other chemicals and solvents were of the highest analytical grade.

Methods

Cell Cultures

Primary cultures of neonatal cardiomyocytes were obtained from the ventricles of 2–4 day old Wistar rats according to Yagev et al. [11]. The research was conducted in conformity with the Public Health Service Policy on Human Care and Use of Laboratory Animals, and the study protocol was approved by The Animal Care Committee of the University of Bologna (Italy). Cells were seeded at a density of 1.5×10^6 cells/ml in 100-mm i.d. Petri dishes in Ham F10 nutrient mixture supplemented with 10% v/v FCS, 10% v/v HS, gentamicin (1%), amphotericin B (1%), and grown at 37°C, 5% CO₂ and 95% humidity. Forty-eight hours from seeding, cardiomyocytes were randomly divided into control and fatty acid supplemented groups. EPA and DHA were dissolved in ethanol and supplemented at 60 μ M concentration. Control medium was added with the same volume of ethanol ($\leq 0.1\%$ v/v), to avoid interference due to the vehicle. Media were changed every 48 h and on day 8 from seeding, after a 6-day exposure to fatty acids and at complete confluence, cardiomyocytes were washed three times with 0.9% NaCl and the cells scraped off. Whole cell lysate (WCL) was obtained using CelLytic™ M plus protease inhibitor cocktail (1 μ M AEBSF, 0.8 μ M aprotinin, 20 μ M leupeptin, 40 μ M bestatin, 15 μ M pepstatin A and 14 μ M E-64) while the nuclear (NF) and cytoplasmic fraction (CF) were obtained by differential centrifugations as previously reported by Wright et al. [12].

PPAR DNA Binding

The degree of DNA binding of the three PPAR isoforms was determined by an immunosorbent assay (ELISA) utilizing PPAR α , β/δ and γ transcription factor assay kits (Cayman Chemicals, USA) following the manufacturer's instructions. Briefly, a specific double stranded DNA sequence containing the peroxisome proliferator responsive

element (PPRE) was immobilized onto the bottom of the wells of 96-well plates. Aliquots of NF diluted to obtain 50 μg protein in each assay were added to each well, so that PPAR contained in the extract bind specifically to the PPRE. Different PPAR isoforms were detected by the addition of specific primary antibodies directed against PPAR α , β/δ , or γ . A secondary antibody conjugated to HRP was added to provide a sensitive colorimetric readout at 450 nm. DNA binding of all the three isoforms was evaluated in each NF.

Western Blot Analysis

Western blotting was performed on WCL, CF and NF. Aliquots corresponding to 30 μg of proteins were analyzed by SDS-PAGE (12% gel). Proteins were transferred onto a nitrocellulose membrane and probed at room temperature for 60 min with the specific primary antibody anti- α , anti- β/δ , anti- γ PPAR, anti-nucleophosmin (B23) (1:1,000) or anti- β -actin (1:20,000). After further washing, the membrane was incubated with HRP-conjugated goat anti-rabbit IgG for 30 min. Final detection was performed with an enhanced chemiluminescence (ECL AdvanceTM) Western blotting detection kit (Amersham Biosciences, UK). β -Actin was used in WCL and CF [13, 14], and B23 in NF [15] as loading control.

Fatty Acid Composition

Total lipids were extracted from CF and NF according to Folch et al. [16] and methyl esterified according to Stoffel et al. [17]. Prior to methyl esterification, pentadecanoic acid (C15:0) was added as the internal standard. Fatty acid composition (as methyl esters) was determined by gas chromatography (GC 8000, Fisons, Milan, Italy) using a capillary column (SP 2340, 0.2 μm film thickness) at a programmed temperature gradient (160–210 $^{\circ}\text{C}$, 8 $^{\circ}\text{C}/\text{min}$) as previously reported [18]. The gas chromatographic peaks were identified on the basis of their retention time ratio relative to methyl stearate and predetermined on authentic samples. Gas chromatographic traces and quantitative evaluations were obtained using a Chrom Card Software (Thermo Electron Scientific, Milan, Italy) computing integrator.

Acyl-CoA Thioesterase Activity

Acyl-CoA thioesterase (EC 3.1.2.2, ACOT) activity was determined spectrophotometrically according to Ofman et al. [19] by measuring the cleavage of the free thiol group of palmitoyl coenzyme A, used as the substrate. The reaction mixture contained 50 mM HEPES, 50 mM KCl, 1 mg/ml BSA and 100 μM palmitoyl coenzyme A lithium

salt. Reactions started with the addition of 100 μl of WCL, and after 15 min at 37 $^{\circ}\text{C}$ were stopped by the addition of DTNB at a final concentration of 0.5 mM. DTNB reacted with CoA-SH, and the TNB formed was measured at 412 nm using a spectrophotometer (Beckman Coulter DU730, Milan, Italy). Substrate blanks were run in order to correct for aspecific TNB formation. ACOT activity was calculated from the TNB molar extinction coefficient ($\epsilon = 13,600 \text{ M}^{-1} \text{ cm}^{-1}$) and normalized for protein content in the same sample.

Protein Content

The protein content in the samples was determined according to Bradford [20] using BSA as standard.

Statistical Analysis

Data are reported as means \pm SD of results obtained in at least three independent cell cultures. Differences were tested for statistical significance by one way ANOVA using Tukey's test.

Results

The evaluation of DNA binding of the three PPAR isoforms revealed a significant increase in EPA and DHA supplemented cardiomyocytes for the β/δ isoform only (Fig. 1).

As evidenced by western blotting analysis, all three PPAR isoforms appeared expressed in WCL (Fig. 2a), and PUFA supplementation did not apparently modify protein

Fig. 1 PPAR binding to DNA in control and EPA or DHA supplemented cardiomyocytes. PPAR binding was measured using aliquots of NF as described in “Methods”, and is expressed as percentage of control cells, assigned as 100%. Data are mean \pm SD of five samples obtained in independent cell cultures. Statistical analysis was by one way ANOVA (PPAR β/δ $P < 0.01$) with Tukey as post-test ($\#P < 0.05$ and $^{\circ}P < 0.01$ vs. control)

Fig. 2 PPAR α , β/δ and γ protein expression and subcellular localization in control, EPA and DHA supplemented cardiomyocytes. PPAR protein expression was analyzed in whole cell lysate (a), cytosolic fraction (b), and nuclear fraction (c) using SDS-PAGE as described in “Methods”. Pictures are representative of three different western blotting experiments

expression, regardless of the isoform considered. Western blotting analysis in CF (Fig. 2b) and NF (Fig. 2c) clearly showed that all PPAR isoforms were present almost exclusively in the nucleus, while at the cytoplasmic level, a very mild appearance was noted only for the γ subtype. Differences due to PUFA supplementation were not apparent either in WCL nor in NF.

The fatty acid composition of CF is reported in Fig. 3a. EPA supplementation led to an enhanced EPA and n-3 docosapentaenoic (C22:5n-3, DPA) relative molar content, without any increase in DHA content. DHA relative molar content increased in CF of DHA supplemented cardiomyocytes. In both cases, incorporation of n-3 PUFA was paralleled by a reduction in C18:1, C18:2n-6, and C20:4n-6 relative molar content. Total concentration of fatty acids in CF was unaffected by PUFA supplementation (Fig. 3b).

Even in NF, supplementation with EPA led to an enhanced EPA and n-3 DPA relative molar content, without any increase in DHA content, while supplemented

DHA was significantly incorporated without any appreciable retro conversion to n-3 DPA and EPA (Fig. 4a). Supplementation with both PUFA caused a reduction in C16:0, C18:0, C18:1, and C20:4n-6 relative molar content, more evident in EPA supplemented cells. Furthermore, both n-3 PUFA supplementations increased fatty acid concentration in NF (Fig. 4b).

As shown in Fig. 5 n-3 PUFA supplementation, particularly DHA one, significantly increased ACOT activity.

Discussion

The evaluation of PPAR α , β/δ and γ protein mass confirmed that all PPAR isoforms are expressed in neonatal rat cardiomyocytes, according to Takano et al. [21] and Planavila et al. [22], and that they are almost exclusively localized at the nuclear level, as reported by Takano et al. [21] and Cheng et al. [23] in neonatal and adult rat cardiomyocytes, respectively. The mild expression of γ isoform in CF is in agreement with Burgermeister and Seger [24], who reported the export to and retention in cytosol of this isoform due to its interaction with mitogen-activated protein kinase/extracellular signal-regulated kinase (MEK1) [25]. The enhanced PPAR β/δ DNA binding observed in n-3 PUFA supplemented cells could be due to both a PPAR enhanced activity state or to a higher PPAR concentration. Although immunoblotting did not reveal any modification in PPAR protein mass it is difficult to exclude it, since ELISA assays are most sensitive.

EPA and DHA supplementation deeply changed the acyl composition of both CF and NF. In the NF the increase in n-3 PUFA relative content occurred at the expense of saturated C16:0 and C18:0, indicating that supplementation had a stronger effect on the PUFA/SFA ratio in the nucleus than in the cytosol. The high content of total FA, and in particular of EPA and DHA, and its increase following supplementation suggests a selective accumulation of n-3 PUFAs in the nucleus. This is in agreement with Brochot et al. [26], who observed a particularly high incorporation of n-3 PUFAs in the nuclear membrane of cardiac cells after feeding rats an α -linolenic supplemented diet, and supports a direct interaction of EPA and DHA with PPAR, since, in order to act as a bona fide ligand, a compound has to be present within the nucleus in sufficient amounts.

Obviously, for acting within the nucleus, EPA and DHA have to get into the nucleus. In this study, EPA and DHA were delivered as non-esterified fatty acids (NEFA) to the cell from extracellular sources, and CF composition clearly show that they were taken up from media. Once within the cell, free EPA and DHA may continue to diffuse into the nucleus, but more likely they are modified by enzymes for acylation into membrane phospholipids, or they are bound

Fig. 3 Fatty acid percent composition and concentration of cytoplasmic fraction in control, EPA and DHA supplemented cardiomyocytes. Cytosolic fraction was separated by centrifugation, lipids were extracted, methylesterified and analyzed by gas chromatography as described in “Methods”. Data are expressed as mol/100 mol (a) and $\mu\text{g}/\text{plate}$ (b), and are mean \pm SD of at least six samples obtained in three independent cell cultures. Statistical analysis was by one way ANOVA (18:1 $P < 0.001$; 18:2n-6 $P < 0.05$; 20:4n-6 $P < 0.001$; 20:5n-3 $P < 0.001$; 22:5n-3 $P < 0.001$; 22:6n-3 $P < 0.001$) with Tukey as post-test ($^{\circ}P < 0.01$ and $*P < 0.001$ vs. control)

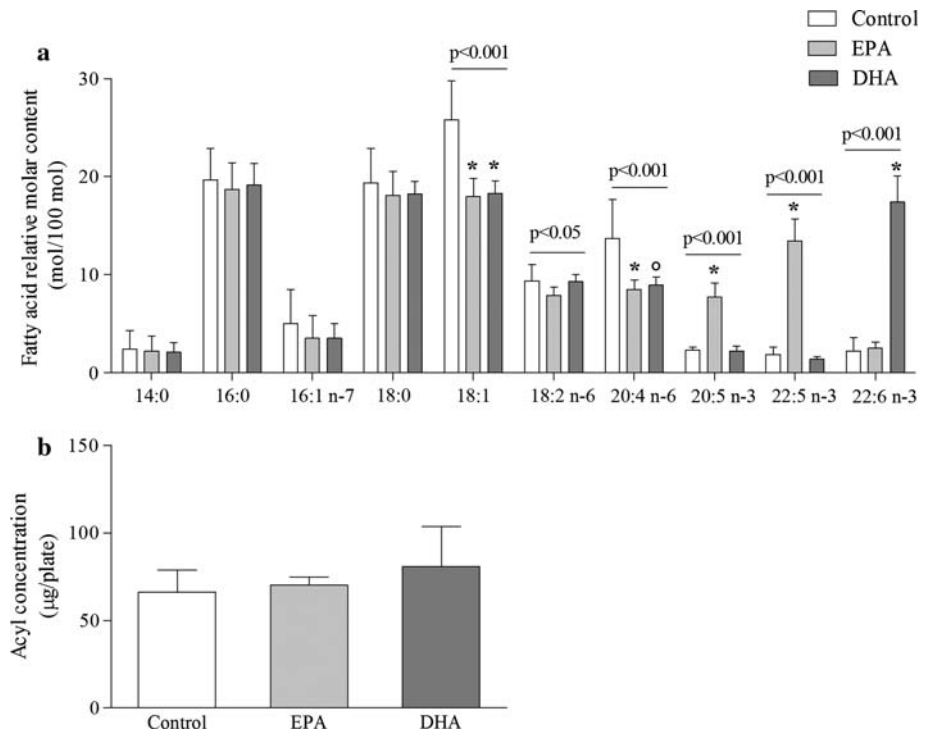

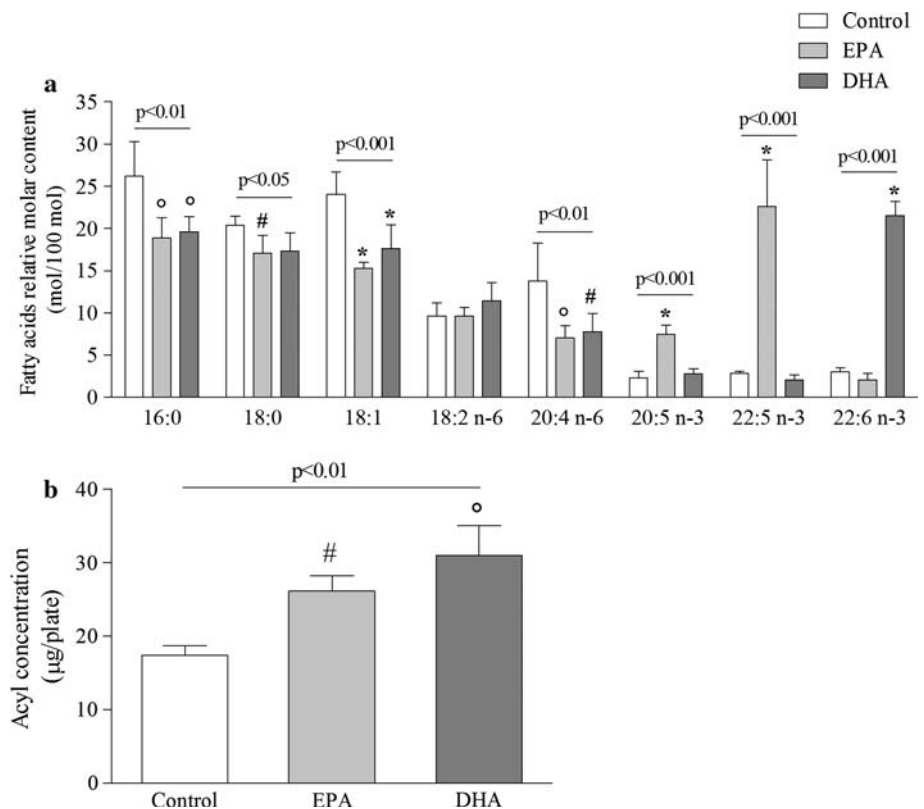

Fig. 4 Fatty acid percent composition and concentration of nuclear fraction in control, EPA and DHA supplemented cardiomyocytes. Nuclear fraction was separated by centrifugation, lipids were extracted, methylesterified and analyzed by gas chromatography as described in Methods. Data are expressed as mol/100 mol (a) and $\mu\text{g}/\text{plate}$ (b), and are mean \pm SD of at least six samples obtained in three independent cell cultures. Statistical analysis was by one way ANOVA (16:0 $P < 0.01$; 18:0 $P < 0.05$; 18:1 $P < 0.001$; 20:4n-6 $P < 0.01$; 20:5n-3 $P < 0.001$; 22:5n-3 $P < 0.001$; 22:6n-3 $P < 0.001$) with Tukey as post-test ($\#P < 0.05$; $^{\circ}P < 0.01$ and $*P < 0.001$ vs. control)

by fatty acid binding proteins (FABP). FABP have been shown to strongly bind medium- and long-chain FA [27, 28]. Binding of FA to FABP within the cytoplasm results in the rapid movement of the lipid-protein complex through

the nuclear pores into the nucleus [29, 30]. Since FABP bind NEFA with higher affinity than acyl-CoAs [31, 32], and long-chain acyl-CoA esters act as antagonists while long-chain NEFA as agonists for the PPAR [32, 33],

Fig. 5 Acyl-CoA thioesterase (ACOT) activity in control, EPA and DHA supplemented cardiomyocytes. ACOT activity was measured in whole cell extract as described in “Methods”. Data are expressed as nmol/min/mg protein, and are mean \pm SD of at least six samples obtained in three independent cell cultures. Statistical analysis was by one way ANOVA ($P < 0.001$) with Tukey as post-test (# $P < 0.05$; * $P < 0.001$ vs. control)

the NEFA/acyl-CoA ratio is an important determinant in fatty acid transport to the nucleus and in the regulation of gene transcription. The activity of ACOT, catalyzing the reaction leading to NEFA from acyl-CoA, increased in n-3 PUFA supplemented cells, in agreement with Ramos and Colquhoun [34]. Although ACOT activity is not the only parameter for NEFA/acyl-CoA ratio, it is conceivable that it is important for the control of the NEFA pool composition, as also suggested by Pawar and Jump [35] and Mandard et al. [36]. Recently, Dongol et al. [37] reported the presence of a functional PPRE in the promoter region of ACOT gene. Since EPA and DHA are PPAR ligands, they could upregulate ACOT gene transcription, creating a self-maintaining loop that guarantees a high cytosolic NEFA concentration. NEFA are then transferred to the nucleus by FABP, where they can exert their activity as PPAR ligands.

The selective activation of PPAR β/δ is difficult to explain. Tentatively, we can suggest the intervention of FABP. Within the nucleus, FABP may interact with PPAR [28] and apparently donate the fatty acid to activate the PPAR [38]. Tan et al. [38] provided evidence that in adipocytes some FABP act in concert with PPAR and that this activity is highly selective for particular FABP-PPAR pairs: A-FABP specifically enhances the activity of PPAR γ , while K-FABP activates PPAR β/δ . Although further studies are needed to verify if similar pairs are also present in cardiomyocytes, and eventually if they have preferential ligands, this hypothesis could explain the preferential PPAR β/δ activation.

Although the original concept that ligand availability is the sole and primary factor controlling the activity of PPAR has been replaced in recent years, due to the

recognition of different control mechanisms of PPAR activity (competition for the dimerization partner RXR and for PPRE sites, recruitment of co-activators and repressors, degree of phosphorylation), it remains the sine qua non of the event. Our data further clarify what happens in cardiomyocytes following n-3 PUFA supplementation, linking the modification of acyl composition to ACOT activity and PPAR activation. This may contribute to the understanding of the protective mechanisms of n-3 PUFA in CVD.

involved in the absorption of dietary fats and subsequent postprandial metabolism of the dietary-derived TRLs [3]. Studies in humans, examining the short-term effects of dietary fatty acids on postprandial lipaemia, have suggested that the fatty acid composition of the test meal may influence the absorption, synthesis and secretion of dietary TAG, as well as chylomicron (CM) particle size. However, mechanisms responsible for the qualitative and quantitative differences in postprandial TRLs following meals of different fatty acids are limited. We have previously shown marked differences in the composition of TRLs within the Svedberg flotation rate (S_f) > 400 fraction, in response to meals of differing fatty acid composition in middle-aged men. Although greater numbers of apolipoprotein (apo) B-48 containing lipoproteins were present in the circulation following the monounsaturated fatty acid (MUFA)-rich meal, there was a greater TAG to apoB ratio and enrichment of the TRLs with apos C-III and E following a single meal containing predominately saturated fatty acids (SFAs) [4]. These unexpected findings raise questions as to the origin of these compositional differences, in particular whether differences in TRL composition originate in the enterocyte or result from differences in their metabolic processing in the circulation.

Whilst the majority of *in vitro* studies have examined the impact of single fatty acids on CM synthesis and secretion by enterocytes [5–10], very few studies have used mixtures of fatty acids similar to those found in the diet. van Greevenbroek et al. [11] incubated Caco-2 cells for 24 h with mixtures of palmitic acid (PA), oleic acid (OA) and linoleic acid (LA) to represent: (a) western type dietary fat, (b) olive oil, (c) corn oil and (d) cream fat. Even though the fatty acid composition of the incubates did not influence cellular TAG levels, secreted apoB or TAG levels, the secreted TAG to apoB ratio and the incorporation of newly synthesised lipids into lipoproteins was shown to be increased after incubation with the ‘olive oil’ compared with ‘corn oil’ mixture. Interestingly, incubation of cells with all of the dietary fatty acids, including the SFA-rich mixture led to the secretion of TRL-sized lipoproteins similar to CM/very low density lipoprotein (VLDL), a finding which contrasts with experiments using single SFAs, where intermediate density lipoprotein (IDL)/low density lipoprotein (LDL) density particles are found to be secreted [10, 11].

In the present study, we examined the effects of mixtures of PA, stearic acid (SA), OA and LA resembling the SFA-, polyunsaturated fatty acid (PUFA)- and MUFA-rich meals used in our human postprandial study [4], on lipoprotein synthesis and secretion using the Caco-2 cell line. Our findings reveal there was some concordance between our cell studies and the composition of TRLs isolated in our previous postprandial study, and indicate that some of

the differences in the postprandial response to meal fatty acids could originate in the enterocyte.

Methods

Cell Culture

Caco-2 cells (European Collection of Cell Culture, Centre for Applied Microbiology and Research, UK), passage 39–58, were seeded at 5×10^5 cell/ml on Transwell (Corning Inc., USA) permeable polyester filters (0.4 μ m pore size and 4.7 cm² surface area) and grown to confluence in complete medium as previously described [10]. Prior to the start of the fatty acid treatments, Caco-2 cells were incubated for 24 h with serum-free complete medium. In the apical compartment, monolayers were incubated with 1.5 ml of complete medium containing 20% lipid-depleted serum (First Link (UK) Ltd.) and the 0.5 mM fatty acid mixtures for a period of 4 days. The fatty acid mixtures were formulated to be as close as possible to the composition of the SFA-, PUFA- and MUFA-rich meals from our previously reported human study [4]. The composition of the mixtures was as follows: (1) SFA-rich mixture contained 0.2 mM PA, 0.1 mM SA and 0.2 mM OA, (2) the PUFA-rich mixture 0.325 mM LA, 0.1 mM OA, 0.05 mM PA and 0.025 mM SA and (3) the MUFA-rich mixture 0.35 mM OA, 0.075 mM PA and 0.075 mM LA. All of the fatty acid mixtures were emulsified with taurocholate to form micelles as previously described [10]. The basolateral compartment contained 2.6 ml of serum-free complete medium. The media in the apical compartment were changed and refreshed every 24 h for a period of 4 days while the basolateral media were collected, aliquoted and stored at -20°C with the addition of a preservative to prevent the proteolytic degradation of apoB [12] for subsequent analysis of secreted lipoproteins. Transepithelial electrical resistance (TER) measurements, an index of tight junction formation and Caco-2 cell growth, were taken daily during the post-confluent experimental period.

Experiments were conducted in Caco-2 cells to determine effects of SFA-, PUFA- and MUFA-rich mixtures on Caco-2 cell: (1) integrity, by measurements of cytotoxicity and TER, (2) functional capacity for lipid and lipoprotein synthesis and secretion, by measurement of cellular and basolateral accumulation of lipids, apos B-100 and B-48, TRL ($d < 1.016$ g/ml) and IDL/LDL-density ($d = 1.016$ – 1.049 g/ml) lipoproteins, (3) fatty acid profile of the cellular and secreted (basolateral) lipids and (4) cellular morphology by electron microscopy.

Cytotoxicity of Fatty Acid Mixtures

The release of lactate dehydrogenase (LDH; a sensitive indicator of cell-membrane damage) in the apical medium was determined after each 24 h incubation with the 0.5 mM concentrations of the fatty acid mixtures using a colorimetric cytotoxicity assay (Biogeneis, UK).

Transepithelial Electrical Resistance Measurements

TER was determined with a Millicell-ERS apparatus (Millipore Corp., USA). Measurements of two Transwells without a cell monolayer, but containing media, were used as blanks. Data are expressed as $\Omega \times \text{cm}^2$.

Total Lipid Extraction from the Basolateral Medium and Cell Monolayers

Basolateral medium samples from 4 successive 24-h incubations from each monolayer were pooled and concentrated in Vivaspin tubes (Sartorius Ltd., UK) for the analysis of secreted lipid as previously described [10]. TAG and cholesterol concentrations were measured with an ILAB 600 (Instrumentation Laboratory (IL), UK) using enzyme-based colorimetric kits supplied by IL. Cellular lipids were extracted as previously described [10] and analysed as above.

Fatty Acid Profile of the Cell Monolayers and Basolateral Medium

Gas chromatography was used for the determination of the fatty acid profile of the cellular and secreted lipids. Cell monolayers were trypsinised and centrifuged at $100 \times g$ for 5 min. Lipids in the cell pellets and concentrated basolateral medium were extracted using chloroform:methanol (2:1, by v/v) containing butylated hydroxytoluene (50 mg/ml) and saponified and methylated in methanol containing 2% (v/v) H_2SO_4 at 70 °C for 1 h. Fatty acid methyl esters (FAME) were recovered by extraction into hexane and analysed in a gas chromatograph as previously described [13]. FAME were identified by comparison of retention times against known standards, Supelco 37 component FAME mix and PUFA-3 menhaden oil (Supelco, Dorset, UK).

Isolation of Lipoprotein Particles

Lipoproteins of different densities secreted by Caco-2 cell monolayers were isolated from self-generating gradients of iodixanol [14, 15] as previously described [10]. Each tube was fractionated based on density of the lipoprotein fractions, where the top 0.8 ml corresponded to TRL-density

fraction ($d < 1.016 \text{ g/ml}$) while the next 2.08 ml corresponded to the IDL/LDL-density fraction ($d = 1.016\text{--}1.049 \text{ g/ml}$). The fractions were assayed for TAG concentration as before.

Apolipoprotein B-100 and B-48 Determination

Basolateral medium samples from four successive 24-h incubations from each monolayer were pooled and concentrated in Vivaspin tubes for the analysis of apoB-100 and B-48 using specific ELISAs, adapted from methods developed to assay human TRL samples [4].

Electron Microscopy

Caco-2 cells, grown on Transwell membranes, were incubated for 24-h periods over 3 days with 0.5 mM fatty acid mixtures before being fixed and prepared for electron microscopy according to Curry et al. [16] as previously described [10]. Sections were examined with a Phillips CM10 transmission electron microscope and magnifications are stated in the individual figure legends.

Statistical Analysis

Data were analysed using SPSS version 14 (SPSS Inc., Chicago, USA) and presented in the tables and figures as means \pm SD. Two-way ANOVA was used to determine the effects of the fatty acid treatments over time on TER measurements and LDH release. The effects of the SFA-, PUFA- and MUFA-rich mixtures on lipid and lipoprotein parameters were analysed using one-way ANOVA. A Tukey post hoc test was used to determine significant pairwise differences. The apoB-100 and fatty acid profile data which could not be normalised was analysed using the Kruskal–Wallis test and Mann–Whitney test. $P < 0.05$ was taken as being significant.

Results

TER Measurements and Cytotoxicity Data

On day 0, prior to the cell monolayers being supplemented with specific fatty acid mixtures, TER measurements were not significantly different between wells. Incubation with the SFA-rich mixture lowered TER measurements compared to the PUFA- and MUFA-rich mixtures (Fig. 1a). Monolayers supplemented with the PUFA- and MUFA-rich mixtures released significantly lower amounts of LDH into the cell culture media compared with the SFA-rich mixture during the experiment ($P < 0.05$; Fig. 1b).

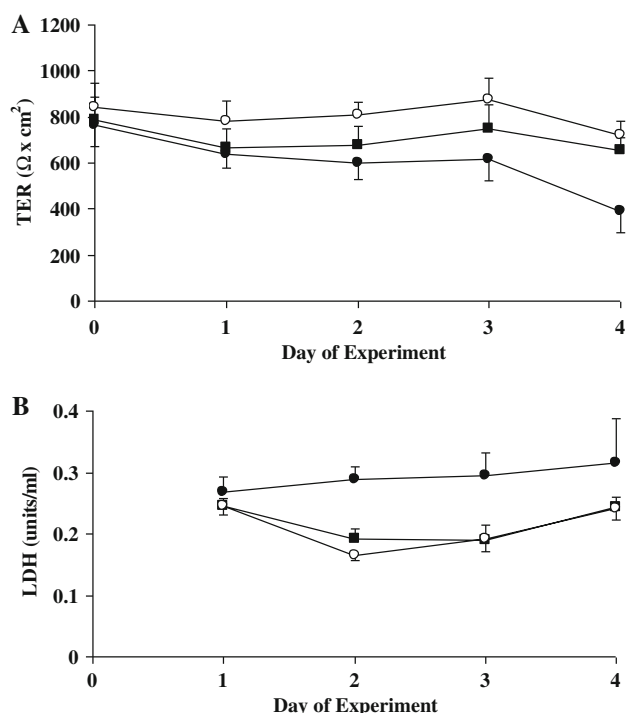

Fig. 1 **a** TER measurements across Caco-2 cells and **b** LDH release from cells during incubation with the SFA- (closed circles), PUFA- (open circles) and MUFA-rich (closed squares) mixtures for 4 days. Data are mean \pm SD for $n = 12$ experiments. LDH release was determined in the apical medium samples collected on days 1–4 and calculated relative to a standard curve of the LDH enzyme standard. For the TER measurements and LDH release, there was a significant effect of treatment ($P < 0.02$), time ($P < 0.001$) and a time \times treatment interaction ($P < 0.05$)

Cellular and Secreted Lipids

Monolayers exposed to the SFA-rich mixture had the lowest cellular TAG content compared with the PUFA- or MUFA-rich mixtures over the 4-day treatment period ($P < 0.001$). Cellular cholesterol contents were significantly greater in monolayers exposed to the MUFA compared with the PUFA-rich mixture, but not the SFA mixture ($P < 0.05$; Table 1). There were no differences in the cellular cholesterol content of monolayers treated with either the SFA- or PUFA-rich incubates.

TAG secretion from cells exposed to the MUFA-rich mixture was greater than from cells exposed to the SFA- or PUFA-rich mixtures ($P < 0.005$) whereas cholesterol secretion was greater compared with the SFA-rich mixture only ($P < 0.05$; Table 1). Lipid secretion from monolayers supplemented with the SFA- and PUFA-rich mixtures was similar.

The fatty acid profiles of the cellular and secreted lipids are shown in Table 2. As expected, the proportions of PA and SA were greater in the monolayers treated with the SFA-rich mixture ($P < 0.004$), LA greater in the monolayers exposed to the PUFA-rich mixture ($P = 0.005$) and OA greater in the cells treated with the MUFA-rich mixture ($P < 0.0001$). The proportions of arachidonic acid, eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA) and docosapentaenoic acid (DPA) were greater in the cells treated with the SFA-rich compared with the unsaturated fatty acid-rich mixtures.

Table 1 Effects of SFA-, PUFA- and MUFA-rich mixtures on cellular and secreted lipids, apoB concentrations and TAG to apoB ratio of lipoproteins secreted by Caco-2 cells

Parameter	Fatty acid mixtures						ANOVA
	SFA		PUFA		MUFA		
	Mean	SD	Mean	SD	Mean	SD	
Cellular							
TAG	0.32 ^a	0.06	0.60	0.12	0.54	0.09	$P < 0.0001$
Cholesterol	0.12	0.02	0.12 [*]	0.02	0.15	0.02	$P = 0.021$
Secreted							
TAG	25.28 ^{**}	2.2	26.60 ^{**}	2.0	36.60	1.0	$P = 0.003$

Values represent means SD for $n = 6$ experiments. *DHA*, docosahexaenoic acid; *DPA*, docosapentaenoic acid; *EPA*, eicosapentaenoic acid

* $P < 0.05$, ** $P < 0.005$, significantly different to MUFA-rich mixture

^a $P < 0.03$, significantly different to the SFA and MUFA-rich mixtures

^b $P < 0.03$, ^c $P < 0.005$, significantly different to PUFA- and MUFA-rich mixtures

A similar fatty acid profile was observed in the lipids secreted into the basolateral medium from the cells treated with the different fatty acid mixtures (Table 2).

Lipoprotein Secretion from Caco-2 Cells

The MUFA-rich mixture led to a greater apoB-100 secretion by Caco-2 cells than the PUFA-rich mixture ($P < 0.05$) whereas apoB-100 secretion from cells exposed to the SFA-rich mixture did not differ significantly from cells exposed to either the MUFA- or PUFA-rich mixtures (Table 1). Although the secretion of apoB-48 by Caco-2 cells followed a similar trend to that of apoB-100, there was no significant effect of the fatty acid composition of the mixtures. The ratio of TAG to apoB has been previously used as an indicator of particle size [11]. There was a tendency for the MUFA-rich mixture to lead to a greater TAG to apoB ratio (apoB-48 and B-100 data combined) in secreted lipoproteins than the SFA- and PUFA-rich mixtures (Table 1).

As expected, TAG concentrations were greater in the TRL ($d < 1.016$ g/ml) compared with the IDL/LDL ($d = 1.016$ – 1.049 g/ml) fraction in cells exposed to the fatty acid treatments ($P < 0.005$; Fig. 2). Incubation of the cell monolayers with the MUFA-rich mixture led to significantly greater TAG concentrations in both the TRL- and

IDL/LDL-density fractions compared with the SFA- and PUFA-rich mixtures ($P < 0.05$; Fig. 2).

Caco-2 Cellular Morphology

Treatment of cells with the SFA-rich mixture led to detrimental effects on cellular morphology compared with the PUFA- and MUFA-rich mixtures. The microvilli at the apical membrane were numerous and relatively mature in cells exposed to the unsaturated fatty acid-rich mixtures (Fig. 3a, b) and to a lesser extent, in cells exposed to the SFA-rich mixture (Fig. 3c; Table 3). The tight junctions of cells exposed to the MUFA- and PUFA-rich mixtures were also relatively mature and showed interdigitation and desmosomes (Fig. 3a, b) whilst the junctions of cells exposed to the SFA-rich mixture were disrupted, immature and lacking desmosomes (Fig. 3c). Ribosomes and mitochondria were numerous in cells exposed to the MUFA- and PUFA-rich mixtures indicating a high level of metabolic activity and the nuclei showed no sign of chromatin degradation. Glycogen-rich areas were also observed in these cells but not in those exposed to the SFA-rich mixture. Lipid-dense organelles were present in all cells but whereas these organelles were often surrounded by mitochondria, multivesicular bodies and other membrane-bound organelles in the MUFA- and PUFA-treated cells, in the cells

Fig. 2 Effects of SFA-, PUFA- and MUFA-rich mixtures on the secretion of TRL (black bars) and IDL/LDL (white bars) density lipoproteins by Caco-2 cells. Data are mean \pm SD for $n = 6$ experiments. * $P < 0.05$, compared with the SFA- and PUFA-rich mixtures, † $P < 0.005$, compared with the TRL density TAG concentration

exposed to the SFA-rich mixture, they appeared to be crystallised and surrounded by white degraded areas. Mitochondria and endoplasmic reticulum membranes surrounded these lipid-dense organelles, suggesting some metabolic activity in these SFA-treated cells (Fig. 3c).

Figure 4 indicates the endocytosis of a lipid-rich particle, probably a MUFA-rich mixture micelle at the apical membrane of the MUFA-treated Caco-2 cells.

Discussion

In a recent human study, we reported marked differences in both the number and lipid composition of $S_f > 400$ fraction

TRL particles (predominantly CMs) following meals enriched in SFA (a mixture of palm oil and cocoa butter), PUFA (safflower oil) and MUFA (olive oil). In order to determine if these meal fatty acid-induced differences in TRL number and composition could originate in the enterocyte, we incubated Caco-2 cells with mixtures of fatty acids representative of the test meals used in our human study to determine their effects on lipoprotein synthesis and secretion.

The fatty acid profile of the cells and secreted lipids reflected the quantities of PA, SA, LA and OA used to prepare the SFA, PUFA and MUFA-rich mixtures. The proportions of arachidonic acid, EPA and DHA were also different between the fatty acid treatments, with higher amounts in the cells exposed to the SFA-rich mixture. However, the changes in these fatty acids were less dramatic compared with those of PA, SA, OA and LA and most likely secondary effects of the overall fatty acid composition and a result of expressing the data as percentage weight of total fatty acids.

The MUFA-rich mixture promoted greater TAG and apoB-100 secretion and a tendency for increased apoB-48 secretion. Previous findings in the literature, including our own, have shown lipoprotein secretion to vary in the order OA > LA > PA = SA [5, 8, 10, 11], yet our current data indicates similar levels of TAG secretion after the SFA- and PUFA-rich mixtures, even though the PUFA-rich mixture promoted greater intracellular TAG accumulation than did the SFA-rich mixture. These findings are consistent with our hypothesis that MUFA increase the number of intestinally derived lipoproteins, rather than that MUFA-

Fig. 3 Electron micrographs of Caco-2 cells after supplementation with **a** the MUFA-rich mixture (magnification 15,300 \times), **b** the PUFA-rich mixture (magnification 8,750 \times) and **c** the SFA-rich mixture (magnification 29,500 \times) for three successive 24 h periods. Microvilli are numerous and mature (white arrows) after all treatments. With the MUFA- and PUFA-rich mixtures, tight junctions between cells are mature, well formed and desmosomes are present

(small black arrows). There are large lipid dense organelles (LDO) which are surrounded by mitochondria (M) and rough endoplasmic reticulum. There are also areas rich in glycogen (G). With the SFA-rich mixture, the junctions are disrupted and immature (large black arrows). There are crystallised lipid dense organelles (LDO) present associated with mitochondria (M) and endoplasmic reticulum

Fig. 4 Electron micrograph of the endocytosis of MUFA-taurocholate micelles at the apical membrane of a Caco-2 cell (magnification 71,250 \times). The micrograph clearly shows the formation of membranes around the endocytosed micelles (white arrows)

containing TRL particles are less effectively cleared from the circulation.

As well as greater numbers of secreted apoB-containing particles, we also observed incubation of the Caco-2 cell monolayers with fatty acid mixtures to lead to increased secretion of lipoprotein particles of TRL-density compared with IDL/LDL-density. There was also a tendency for the ratio of secreted TAG to apoB to be increased when Caco-2 cells were exposed to MUFA compared with PUFA-rich mixtures. Van Greevenbroek et al. [11] proposed that olive oil promoted the production and secretion of larger lipoproteins and hypothesised that TAG synthesised during incubation with the ‘olive oil’ mixture was more efficiently translocated to the preformed lipoprotein particle. In the present study, incubation with the MUFA-rich mixture led to significantly greater TAG concentrations within both the TRL- and IDL/LDL-density fractions compared with the PUFA-rich mixtures. Although van Greevenbroek and co-workers hypothesised that unsaturated fatty acids were required in the mixtures for the secretion of lipoproteins of TRL-density [17], our present findings are suggestive that OA is the key fatty acid involved in the ‘core expansion’ stage of CM synthesis, at least in Caco-2 cells.

The electron micrographs obtained from cells exposed to the different fatty acid mixtures may also shed further

light on possible mechanisms underlying the promotion of TRL secretion by the MUFA-rich mixture. In the case of both the MUFA- and PUFA-rich mixtures, the electron micrographs demonstrate appearance of many lipid-dense bodies, termed ‘secondary TAG-rich particles’ [18]. The presence of ‘secondary TAG-rich particles’ is consistent with the proposal of a two-step mechanism of CM formation [19] in which a ‘first-step’ primordial lipid-poor apoB-48-containing particle is synthesised before fusing with a large TAG-rich ‘second-step’ particle to produce a CM particle. Hamilton et al. [18] observed that secondary TAG-rich particles would increase in size if they did not fuse with ‘first-step’ particles to produce large viable lipoproteins that can be secreted, suggesting that the capacity for production of primordial lipid-poor apoB-containing particles is rate limiting in the secretory pathway. Our previous study [10] showed OA (major fatty acid in the MUFA mixture) to upregulate the gene expression of apoB together with proteins involved in the recruitment of apoB for TRL synthesis and secretion, suggesting greater capacity for primordial particle formation with OA than other fatty acids.

One interesting, unexpected and novel feature of the cells treated with MUFA-rich mixture, is the observation from the electron micrographs of evidence for endocytosis of lipid micelles at the apical membrane. How this mechanism occurs in the Caco-2 cells cannot be determined from these electron micrographs. It has been proposed that fatty acid uptake by enterocytes is a carrier mediated process, possibly involving caveolin, a protein involved in the endocytosis of LDL. Baba et al. [20] reported that in the middle segment of the small intestine in suckling rats, the absorptive cells had apical coated pits, apical invaginations, coated vesicles, tubules, early endosomes, late endosomes and a large homogeneous electron dense lysosome at the supranuclear region. It was suggested that the endocytic membrane system in the absorptive cells were specialised for quick and active intracellular digestion. However, Baba et al. [20] did not observe the actual endocytosis of lipid. In the present study, coupled with the apparent endocytosis of fatty acid micelles, there are numerous multivesicular bodies and other membrane-bound organelles consistent with the findings of Baba and

co-workers. This novel and unexpected finding warrants further investigation as the mechanisms by which the absorption of dietary fatty acids occur remain controversial.

The Caco-2 cell line is generally regarded as an acceptable model for the study of lipoprotein production. However, we have recently highlighted the cytotoxic effects of SFAs, in particular PA when incubated as a single fatty acid, and proposed that mixtures of fatty acids may provide a more physiological model for studying impact of dietary fatty acids on lipoprotein synthesis and secretion [10]. However, the inclusion of 0.2 mM OA in the SFA-rich mixture used in the present study failed to prevent cytotoxicity or detrimental effects on cellular morphology. Our data indicate that within 3 days of supplementing cells with the SFA-rich mixture, fully differentiated cells apparently regress to a less polarised state (reflected by the lower TER measurements) which may partially explain why there is a lower capacity for lipid synthesis compared with the predominately unsaturated fatty acid mixtures. The novel observation of crystalline lipid-dense organelles in the cells suggests that solidified tripalmitoylglycerol may actually be formed in the cells, resulting in failure to translocate TAG from lipid droplets to primordial particles and thereby failure in CM secretion. In addition, recent evidence in liver and pancreatic cell lines has suggested that incubation with single SFAs may induce endoplasmic reticulum stress and apoptosis independently of the formation of ceramide [21, 22], a finding yet to be confirmed in Caco-2 cells. However, it is not as yet clear to what extent the effects of SFA on (a) the structural integrity of the cells and (b) CM synthesis and secretion resemble those which occur *in vivo*.

In conclusion, our cell studies have shown the MUFA mixture (rich in OA) to stimulate a greater secretion of TRLs, of larger particle size than the PUFA-rich mixture. Furthermore, the MUFA- and PUFA-rich mixtures were shown to be able to maintain cell membrane integrity and cellular morphology over the period of incubation, whereas the SFA-rich mixture was not. In both Caco-2 cells and our human study, MUFA stimulated greater TRL secretion, highlighting the importance of OA in the formation and secretion of viable CMs by the enterocyte. The electron micrographs provide evidence that, in Caco-2 cells at least, there appears to be some endocytotic uptake of large lipid-containing micelles which we suggest may increase lipoprotein formation by promoting recruitment of a greater number of primordial apoB-containing particles.

Acknowledgments The authors thank Dr. Esti Olano-Martin and Dr. Paul Sharpe for advice on the Caco-2 cell line and Dr. Ian Davies and Dr. John Graham for helpful discussions regarding iodixanol gradient ultracentrifugation. We are grateful to Dr. Alan Curry for his expertise in providing the electron microscopy images and Dr. Caroline Childs for her time and advice on the GC analysis. This

work was supported by the Biotechnology and Biological Sciences Research Council (BBSRC, UK; Project No: 45/D15215).

Introduction

Highly unsaturated fatty acids (HUFAs) have a well-known, essential role as components of structural phospholipids of cell membranes in animals. HUFAs are crucial to the nutritional health, physiology and reproductivity of higher vertebrates [1]. Diseases arising from HUFAs deficiency are well documented in many species [2, 3]. Freshwater fish, such as salmonids, can generally synthesize HUFAs from C18 precursors, 18:3n-3 and 18:2n-6. However, marine fish, which lack or have a very low activity of Δ 5-desaturase and Δ 6-desaturase, cannot convert 18:3n-3 and 18:2n-6 to their corresponding HUFAs at a rate of permitting their normal growth and development. Therefore, marine fish require dietary HUFAs for normal growth, reproduction and health [4, 5]. Of HUFAs, EPA and DHA are the most important [6–9] and must be supplied in the diet of marine fish, especially in larvae and juveniles [10–12].

DHA and EPA function completely differently in their metabolism in marine fish juveniles [13–15]. Thus, on the one hand, DHA and EPA should be simultaneously supplied in the diet of marine fish juvenile [14, 16–18]; on the other hand, their suitable quantity and ratio should be investigated at the same time since increasing dietary DHA/EPA ratios enhanced growth [15]. Sargent et al. [19] suggested that the optimal DHA and EPA ratio was 2:1 in the diet of sea bass larvae. However, the requirement of DHA and EPA varies in different stages and species attributable to differences in their environments and metabolisms [20].

The optimal amount and ratio of DHA and EPA is one of the hottest topics for fish studies, especially in new species [8, 21, 22]. Cobia is a new cultured species and a fast developing marine fish which is important in industrial fishery. Although the amount of DHA and EPA was reported from 0.8 to 1.2% of the dried diet in cobia [23], little is known about the optimal amount and ratio of DHA and EPA in cobia juveniles.

The present paper reports on the effect of different ratios of DHA and EPA on the growth, nucleic acid and fatty acids of cobia juveniles fed for 8 weeks in the laboratory.

Materials and Methods

Main Feed Materials

Mixed fish-meal containing protein 65% was bought from Gaolong Feed Ltd. Co. of Shunde City, Guangdong

Province, China. Three kinds of fish oils were from Yuwang Company in Shandong Province, China and their contents were as follows: (1) DHA 62.40%, EPA 14.11%; (2) EPA 33.86%, DHA 30.93%; (3) DHA 14.51%, EPA 25.85%, respectively. Vitamin mixtures, mineral mixtures and taste attractant were bought from Biotechnological Ltd. Co. of Chengyi, Guangzhou City, China.

Fish and Diets

Two thousand cobia juveniles, 30 days old with around 5-g body weight, were from a fish breeding farm in Shanyia City, Hainan Province, China, in July 2005. The juveniles were reared in floating sea net cages at Shen Ao Bay, near the Nan Ao Marine Biology Station of Shantou University, China. The water temperature was 26.0–30.0 °C, salinity 25.35–33.00‰ and pH 7.82–7.99. The cobia juveniles were fed a fish-diet for 2 weeks and a control diet (D-0) for one more week. Then the juveniles were moved and kept in glass-steel tanks (200-l volume) in the Laboratory of the Seashore at Shen Ao Bay and fed D-0 for 7 days. Through the tanks flowed filtered-seawater of Shen Ao Bay at a rate of 2–2.5 L min⁻¹ and compressed air. The laboratory was lit from 6 a.m. to 6 p.m. every day during the experiment.

After acclimatizing to the glass-steel tank, 380 cobia juveniles (age 56-day, body weight 6.86 ± 0.03 g, body length 9.23 ± 0.06 cm) were selected and 20 of them were randomly selected and their initial body weight, length, and the biochemical analysis of their livers, muscle and blood in the week 0 were measured. A further 360 cobia juveniles were randomly assigned into eight groups in triplicate, in total 24 tanks with 15 fish in each. The juveniles were reared in glass-steel tanks using the same climatic conditions and fed D-0–D-7 for 8 weeks from August to October 2005. D-1–D-7 contained the same amount of DHA and EPA (1.5 ± 0.1% of dried diet) but varying DHA/EPA ratios (0.90, 1.10, 1.30, 1.50, 1.70, 1.90, 2.10, respectively) differing from those of D-0 (DHA + EPA = 0.8% of dried diet, DHA/EPA = 1.30) (Tables 1, 2). The juveniles were fed twice a day at 8:00–9:00 a.m. and 4:00–5:00 p.m. using different diets at around 5% (dried diet) of body weight. The diets delivered were completely ingested aided by mixing an additive, namely, 0.1% of taste attractant and controlling the feeding amount. The juveniles were weighed every other week and washed with freshwater once a week to prevent parasites.

Sampling

Five (5) fish per tank were randomly selected, their body weight and length measured, then the biochemical analysis of their livers, muscle and blood at the end of weeks 4 and 8, respectively was carried out. Before sampling, the juveniles

were starved for 1 day and then anaesthetized one by one using MS-222 (1/10,000–15,000). The fish body weight was measured immediately after being anaesthetized. Blood was sampled from the anaesthetized fish and kept for 4 h at room temperature. Then the blood was centrifuged for 10 min at 3,000×g and the serum was taken for freezing in liquid nitrogen and then stored at –80 °C for analyzing later. The anaesthetized fish was then killed by being struck on the head and the liver and muscle dissected out. The liver and muscle were immediately frozen in liquid nitrogen and then stored at –80 °C for analyzing later.

Reagents and Determination of Samples

Reagents

A DNA-extracting kit was purchased from Shanghai Biotechnological Company, Shanghai, China and TaKaRa RNAiso reagent from the Bao Biotechnological Company,

Dalian, Liaoning, China. Standard fatty acids (>98% purity) were bought from the Sigma Chemical Company, USA. Ethanol, methanol, hexane, acetone and isopropanol were high performance liquid chromatography (HPLC) grade and bought from Fair Lawn New Jersey, USA. Potassium permanganate, BFCI₃, sodium citric acid, sodium chloride, potassium hydroxide, sodium hydroxide and ether were of analytic grade and bought from Qanyi Trade Ltd. Co. of Shantou City, Guangdong Province, China. H₂SO₄ was of analytic grade and bought from Guanghua Chemical Factory of Shantou City, Guangdong Province, China.

Extraction and Determination of DNA

DNA was extracted from the tissues of the cobia juveniles using a DNA-extracting kit. A tissue sample (30 mg) of the cobia juvenile was ground into powder after immersion in liquid nitrogen (DNA extraction from serum without this

step) and then placed in a 1.5-mL centrifuge tube. Twenty μ L of proteinase K after having been pre-activated for 1 h at 37 °C and 300 μ L of antimicrobial catheter lock (ACL) solution were added to the above-mentioned centrifuge tube and mixed with the tissue powder to extract DNA for 1–3 h at 55 °C and stirred at intervals. The mixed tissue sample was cooled to room temperature and centrifuged for

5 min at 12,000 \times g. A volume of 300 μ L of supernatant with DNA were applied to a UNIQ-10 column (from Shanghai Biotechnological Company, Shanghai, China) to be absorbed. Then, 300 μ L of AB solution was placed in the column, shaken two to three times inversely and allowed to stand for 3 min. The column-supernatant-AB solution (with UNIQ-10 column) mixture was centrifuged

for 3 min at 2,500–3,000×g and the solution in the column-collecting tube was discarded. A wash solution (500 µL) (with UNIQ-10 column) was added to the above-mentioned column and centrifuged for 0.5 min at 8,000×g at room temperature. The step was repeated again and the solution in the column-collecting tube was discarded. The UNIQ-10 column was centrifuged for 0.5 min at 10,000×g to remove the superfluous wash solution. The contents of the column were placed in a newly cleaned 1.5-mL centrifuge tube and DNA eluted for 2 min by the addition of 50 µL of elution buffer (with UNIQ-10 column) at 55 °C. The column was centrifuged for 1 min at 10,000×g at room temperature and the DNA in the elution buffer was immediately tested on a NanoDrop 1000 instrument (NanoDrop Technologies Co., USA) according to the User's Manual or stored at –20 °C for determination later.

Extraction and Determination of RNA

RNA was extracted from the tissues of the cobia juvenile using a TaKaRa RNAiso reagent (from Bao Biotechnological Company, Dalian, Liaoning, China). About 100 mg of a tissue from the cobia juvenile was ground into powder after immersion in liquid nitrogen (RNA extraction from serum without this step) and then placed in a 5-mL of centrifuge tube. One milliliter of RNAiso reagent was added to the centrifuge tube, mixed and allowed to stand for 5 min. The mixed sample in the centrifuge tube was centrifuged for 5 min at 12,000×g at 4 °C. The upper supernatant layer was carefully moved to a new centrifuge tube and centrifuged for 15 min at 12,000×g at 4 °C. The upper supernatant that had a white color was carefully moved to another new centrifuge tube. The same volume of iso-propanol was added to the supernatant in the centrifuge tube, mixed by inversion and allowed to stand for 10 min at 15–30 °C. The mixture of supernatant and iso-propanol was centrifuged for 10 min at 12,000×g at 4 °C and the upper supernatant layer was carefully removed. One milliliter of 75% ethanol was slowly added to the centrifuge tube down the tube wall and the deposit was gently washed by inversion. The washed deposit was centrifuged for 5 min at 12,000×g at 4 °C. The ethanol was removed and the deposit (RNA) in the centrifuge tube was allowed to evaporate naturally for 2–5 min at room temperature. The deposit (RNA) was dissolved in a volume of RNase-free water and immediately tested on a NanoDrop 1000 instrument (NanoDrop Technologies Co., USA) according to the User's Manual or stored at –80 °C for determination later.

Determination of Lipids

Crude lipids were extracted with chloroform and methanol 2:1 (v/v) and then estimated gravimetrically [24].

Determination of Fatty Acids

The composition of fatty acids in the samples was analyzed by comparing with standard fatty acids using a gas chromatograph (GC, Agilent 6890 N, Agilent Company, USA) with a hydrogen flame ionization detector (FID) and an HP-5 column (30 m × 0.32 mm). A sample was injected at 1 µL and analyzed at a speed of 40 mL min⁻¹ for hydrogen, which was used as the carrier. The column temperature was initially held at 140 °C for 5 min, then 200 °C for 5 min, 240 °C for 15 min and 260 °C for 15 min with all the temperature ramps increasing at a rate of 4 °C min⁻¹.

Determination of Protein

Crude protein was determined by the Kjeldahl method (Association of Official Analytical Chemists 1980) [25]. Put simply, nitrogen contained in the sample was extracted and determined. And then the protein was calculated according to the amount of nitrogen using the following formula:

$$\text{Protein (\%)} = \text{Nitrogen (\%)} \times 6.25$$

Data Analysis and Statistics

Data were analyzed by analysis of variance with Fisher's Protected l.s.d. Post hoc Test (Super ANOVA V1.11 Folder) (Abacus Concepts, Inc., 1984 Bonita Avenue, Berkeley, CA, USA) followed by Tukey's multiple comparison test. The effects of diets on all of the data were determined by two-way ANOVA and differences were regarded as significant when $P < 0.05$.

Results

The body weight (BW) of juveniles fed D-0–D-7 increased significantly by the end of experiment (from 6.86 ± 1.64 in week 0 to 58.52 ± 16.45 g at the end of week 8 on average, $P < 0.05$) (Table 3).

The RNA levels and RNA/DNA ratios in the muscle (Table 4) and liver (Table 5) of cobia juveniles were much higher than those of the serum (Table 6) although all of them were markedly higher at the end of experiment than at the beginning ($P < 0.05$). The ratio of RNA to DNA in the muscle and liver of cobia juveniles increased with their growth and this demonstrates an obvious positive relationship, especially in the muscle of the cobia juveniles, based on regression analysis (Fig. 1).

The RNA level was the highest in the muscle of cobia juveniles fed D-0 (297.41 ± 11.84 µg mg⁻¹) and the lowest in those fed D-5 (232.26 ± 26.30 µg mg⁻¹)

Fig. 1 Regression relationship between body weight and RNA/DNA ratio in the muscle of cobia juveniles fed for 8 weeks (total average, $n = 3 \times 3$). $Y = -12.04 \times 3 + 264.84 \times 2 - 1932.1x + 4703.5$, $R^2 = 0.8839$

(Table 4); however, there were no significant differences between those fed D-0 and D-1–D-7 ($P > 0.05$). The amounts of DNA in the muscles of cobia juveniles fed D-0 were higher than in the muscles of those fed D-1–D-2 and D-5–D-7; however, there was no significant difference among each of these others ($P > 0.05$) (Table 4). The amounts of RNA and the RNA/DNA ratios in the liver of cobia juveniles fed D-0 were lower than those fed D-1–D-7, but there was no significant differences among the others ($P > 0.05$) (Table 5).

Compared to the beginning, lipid content increased significantly in the liver (from 29.82 ± 0.99 to $37.47 \pm 3.25\%$) and in muscle (from 6.74 ± 0.25 to $10.63 \pm 0.23\%$) of cobia juveniles at the end of week 8 ($P < 0.05$). However, no significant differences were found in the lipid contents of juveniles fed different diets for 8 weeks ($P > 0.05$) (Table 7).

The effect of different ratios and amounts of DHA and EPA on the fatty acid composition of the muscle, liver and serum in cobia juveniles at the end of week 8 is shown in Tables 8, 9 and 10. Generally, in the muscle and liver of juveniles, the EPA decreased with its reduction in the diet; DHA, DHA/EPA ratios and PUFAs usually increased with their increment in the diet; while these parameters varied in the serum. The amounts of DHA were higher in the tested tissues of the cobia juvenile than in the corresponding diet and those of EPA were lower ($P > 0.05$).

Table 7 Comparison of lipid contents (%) in the muscle and liver of cobia juveniles fed different ratios of DHA and EPA for 8 weeks

Diet	Muscle	Liver	N

All above data are means \pm SD. Different superscript letters in the same column indicate significant differences ($P < 0.05$)

*Initial means in the week 0 ($n = 8 \times 3$)

**Total mean is an average datum of eight diets ($n = 8 \times 3$)

Discussion

With our experimental diets consisting of 67% mixed fish-meal and 17% lipids (Table 1), the amount (0.8%) and ratio (1.30) of DHA and EPA in D-0 met with the requirement of cobia juveniles, resulting in our obtaining the highest growth (Table 3). The content, 0.8% of DHA and EPA, is in the range of 0.8–1.2% of DHA and EPA required by cobia [23]. The amount ($1.50 \pm 0.1\%$ of dried diet) of DHA and EPA as well as their ratios (0.90, 1.10, 1.30, 1.50, 1.70, 1.90, 2.10) in the treatment diets did not benefit the growth of cobia juveniles, actually resulting in less growth. The result is consistent with previous reports in that a negative effect of HUFAs excess can be encountered for higher HUFAs levels or at low lipid levels in some species [26–28]. Higher n-3 HUFAs were reported to be unavailable in the growth of *Platichthys flesus* larvae [29, 30] since higher n-3 HUFAs influenced the balance of the membrane phospholipids, resulting in dysfunction of the cell membrane [29, 31]. In our experiment, the ratio of DHA to EPA in D-3 and D-0 was the same, 1.30, however, the amounts of DHA and EPA in D-3 were almost twofold that in D-0, resulting in poor growth in cobia juveniles fed D-3 (Tables 1, 3). This is consistent with the report by Rodriguez et al. [28] in that a suitable ratio of DHA to EPA was 1.3:1 in the diet of gilt-head bream (*Sparus aurata*) larvae; over EPA or lack of DHA could result in lower effectiveness of the diet and slowing down of the growth of the larvae.

Nucleic acid analysis has provided a useful tool for studying recent growth and mortality of young fishes and their responses to environmental variability. The ratio of RNA–DNA (R/D) has been shown to respond to changes in feeding conditions and growth after periods as short as

Table 8 Effect of different ratios of DHA and EPA on the fatty acid composition (%) of muscle in cobia juveniles fed for 8 weeks

1–3 days in a variety of fish species [32, 33]. RNA:DNA, a surrogate measure of growth and feeding condition, corroborated somatic growth trends [34]. The ratio of tissue RNA to DNA (R/D) has proven to provide a reliable indicator of recent growth and nutritional conditions of larvae and juvenile fish [35–39]. Therefore, the ratio of tissue RNA to DNA (R/D) is a widely used index of recent growth and nutritional conditions in larvae and juvenile fish [40, 41].

In experiments, the RNA levels and RNA/DNA ratios in the muscle and liver of cobia juveniles fed D-0–D-7 were significantly higher at the end of the 8-week period than at the beginning ($P < 0.05$, Tables 4, 5) The RNA/DNA ratio in the muscle and liver of cobia juveniles increased with their growth and appeared to be an obvious positive relationship, especially in the muscle, based on regression analysis (Fig. 1). Fish growth is mainly performed by synthesizing proteins, while proteins are translated by rRNA. In other word, the amount of proteins is determined by the level of RNA, therefore, the synthesis of proteins and fish growth can be predicted by determining the quantity of RNA [42]. Speed of growth of a fish can be calculated by the ratio of RNA to DNA in the fish even though the fish is in its initial growth stage. The amount of DNA is fixed in a cell of a fish and the total amount of DNA in a fish is related to the number of cells in the fish [43]; whereas the ratio of RNA to DNA is determined by the RNA concentration in the cell of the fish [44]. Therefore, the ratio of RNA to DNA is a better indicator of RNA concentration in a fish and can exactly indicate the metabolism of the growing-fish.

Fish grow by a change in the RNA/DNA ratio and/or rapid synthesis of proteins. Compared to the liver of the cobia juvenile, the RNA/DNA ratio in the muscle appeared a better positive indicator of its growth based on regression analysis (Fig. 1), therefore, the RNA/DNA ratio in the muscle can more exactly indicate the growth of the cobia juvenile. The results are consistent with a previous report [45] in that an obvious positive relationship existed in the ratio of RNA to DNA in the muscle of shrimps based on regression analysis.

The RNA/DNA ratio in the liver and serum of cobia juveniles fed D-0 was lower than that in juveniles fed D-1–D-7. While the RNA level was the highest in the muscle of cobia juveniles fed D-0 from among the experimental groups (Tables 4, 5, 6). However, no significant differences were found in the RNA/DNA ratio and/or RNA level between juveniles fed D-0 and D-1–D-7 ($P > 0.05$). These results imply that there was no significant effect of different ratios and the amounts of DHA and EPA on the RNA/DNA ratios as well as the RNA levels of cobia juveniles under our experimental conditions.

The lipid contents, amounts of DHA, DHA/EPA ratios and amounts of PUFAs generally increased in the liver and muscle of cobia juveniles with increasing amounts and

Table 10 Effect of different ratios of DHA and EPA on the fatty acid composition (%) of serum in cobia juveniles fed for 8 weeks

higher ratios of DHA and EPA in their diets, while EPA decreased in the experiment (Tables 7, 8, 9).

Different ratios and amounts of DHA and EPA could directly influence the composition of fatty acids in the tissues of cobia juvenile. In the muscle and liver of cobia juveniles, the amount and ratio of DHA and EPA increased with their increase in the diet since cobia juveniles absorbed n-3 HUFAs in the diet to increase the contents in their tissues. Dietary nutrients have been proved to be effectively incorporated into the tissues of fish, resulting in the change of biochemical composition and growth performance of the fish [19, 46–49]. HUFAs, especially DHA and EPA, have effects not only on biological and physiological conditions, but also on fatty acid profiles of the fish tissues [50, 51]. Fatty acid composition of fish muscle lipids usually reflects that of the lipids in their feed [19, 52–55]. Our results are in agreement with previous reports that dietary EPA and DHA concentrations show good correlations with tissue concentrations of DHA and EPA [56].

In addition, the DHA/EPA ratio could be increased by conversion of EPA to DHA, by a greater reduction of EPA relative to DHA in the effects of selective HUFA deposition in the tissues or higher oxidation of EPA relative to DHA. These changes resulted in no significant differences being found among the lipid contents in the same organ of cobia juveniles fed different diets ($P > 0.05$).

The fact that PUFAs, including the amount and the ratio of DHA to EPA, varied in the serum implied that the composition of fatty acids was unstable in the serum and was sensitively influenced by diets and free endogenesis fatty acids. This might relate to the difference in the functions and enzymes in the serum in comparison to those of the muscle and liver in cobia juveniles [15, 57].

Acknowledgments Authors would like to give thanks for the help given by the staff of the institutes involved. This research was financially supported by a grant from the National Natural Science Foundation of China (30571448), a NSFA-RSE international grant fund (30711130272), a Ph.D. station fund from the Education Ministry (20060560001), natural science funds of Guangxi (Gui-ke-zi 0728014, 0728011) and key funds of Guangxi University (CC 150008, 150009).

The intention in this work is to study the chemical changes taking place in glycerides containing 18:2 fatty acids, namely trilinolein and trilinoelaidin during thermal induction in inert atmosphere. This study would give understanding of the quantities of the isomers formed, the chemistry of isomerization and the relative stability of the fatty acid molecules towards isomerization. Reports involving the analysis of products formed from the glycerides containing 18:2 fatty acids during thermal induction are scarce in the literature. Furthermore, there are no reports in the literature regarding thermal induction of 18:2 fatty acids with *trans*, *trans* configuration. The published literature only deals with the chemical analysis of the mixture formed during heating of edible fats in the temperature range 240–265 °C [15–17]. The analysis in one of the reports [15] was carried out for the purpose of determining kinetic parameters for the *cis*–*trans* isomerization of linoleic acid. The acids analyzed were only 9t12t, 9c12t and 9t12c. There was no mention about the other products formed during heating. Here, the assumption was that the formation of 9t12t, 9c12t and 9t12c were purely from 9c12c fatty acid. The second paper [16] reports the appearance of the individual isomers during heat induced isomerization of α -linolenic acid. The effect of temperature and heating time were study parameters in this report. In both reports, the identification of isomers was carried out from the total chromatogram of the fatty acid methyl esters (FAME) of the fatty acids in the samples. The third report [17] deals with the quantification of *cis*/*trans* isomerization in triolein, trilinolein, trilinolenin during heat induction. The maximum heating time was 8 h and the *trans* isomer formation in trilinolein was not significant. Furthermore, there was no attempt to look at the chemistry of the formation of the *trans* isomers in the heated mixture.

When the fatty acids in the glyceride molecules are identical, then analysis of the glyceride for products after heating becomes comparatively easy. Trilinolein and trilinoelaidin are glycerides of 18:2 (9, 12) fatty acids with *cis*, *cis* and *trans*, *trans* configurations respectively. The acid molecules in the glyceride backbone are of definitive structure and the products formed should originate from these acid molecules. This will give understanding of the changes taking place and how the molecules behave under thermal stress.

The major products formed during thermal induction of the triglyceride samples were mixtures of isomers with *cis* or *trans* hydrogens on the double bonds in trilinolein and trilinoelaidin. These were analysed by two different techniques namely gas chromatography and infrared spectroscopy. The use of infrared spectroscopy and gas chromatography to determine the *trans* content in edible oils and fats have been extensively investigated and they are standardized by The American Oil Chemists Society

(AOCS) [18]. The quantitative determination of *trans* fatty acid concentration in fats and oils is based on the fact that the *trans* isomers of monounsaturated fatty acids and *trans* isomers of the polyunsaturated fatty acids containing isolated *cis*–*trans*, *trans*–*cis* and *trans*–*trans* double bonds give rise to one specific absorption at 969 cm^{-1} [19–22]. Conjugated linoleic acids (CLAs) with *cis*, *trans* and *trans*, *cis* configurations give rise to two specific absorptions around 986 and 946 cm^{-1} . These absorptions arise due to the =CH out of plane deformation vibration [23]. The =CH out of plane deformation vibration of the *tt* (*trans*, *trans*) isomers absorb around 982 cm^{-1} and, *cis*–*cis* isomers do not absorb in this region. This characteristic difference in the absorptions makes it possible to quantify methylene interrupted *trans* isomers and CLA isomers with *cis*, *trans* and *trans*, *cis* configurations using infrared spectroscopy. Christy et al. [24] have utilized this fact in simultaneous quantification of isolated *trans*, and CLAs in oils and fats. Furthermore, the presence of absorption peaks at 986 and 946 cm^{-1} of the fatty acids formed during the isomerization is a clear indication of the formation of CLA isomers containing *cis*, *trans* and *trans*, *cis* configurations.

Gas chromatography involves saponification and derivatization of the oil or fat involved and the separation of the methyl esters using a high resolution capillary column that is suitable for the separation of isomers. Quantification of different isomer components is carried out using Standards of fatty acids methyl esters and literature references [25].

Experimental

Samples and Methods

The triglycerides of 9t12t and 9c12c fatty acids and the methyl esters of the same fatty acids were purchased from Sigma-Aldrich. The methyl esters containing the 9c11t and 10t12c (99%) fatty acids were purchased from Larodan Chemicals, Sweden.

The heating experiments were carried out in micro glass ampules with a length of 4 cm. These were made from glass tubes of 1.5 mm internal diameter and a wall thickness of 1 mm. The triglyceride samples containing the 9c12c fatty acid were injected in the tubes using a plastic syringe and each sample was flushed by a weak nitrogen flow. The open end of the glass tubes were melted and sealed. In the presence of air, the samples undergo oxidation and polymerization. The ampules containing the samples were then placed in a short glass vial and placed in a chromatographic oven set at 250 °C. Thermally induced samples were removed from the oven at regular intervals, cut open, their infrared spectrum recorded, sealed again by paraffin film and stored in darkness for the analysis by gas

chromatography at the end of the thermal induction experiment. The experiments were repeated with the triglyceride of the 9t12t fatty acid.

Infrared Spectroscopic Measurements

Each of the samples removed from the oven was subjected to infrared measurements. A Perkin Elmer Spectrum One FT-IR spectrometer equipped with a Harrick single reflectance attenuated total internal reflectance (ATR) accessory and lead glycine sulfate detector was used in measuring the infrared spectra. Each sample was spread on the ATR crystal using a capillary glass tube. The blunt side of the capillary tube was used to pick up a small amount of the sample and spread on the ATR plate. A background spectrum was scanned in the range of 4,000–600 cm^{-1} before the application of a sample. A total of 30 scans at a resolution of 4 cm^{-1} were then measured on each sample. The ATR crystal was washed with dichloromethane and acetone after each measurement. The same procedure was repeated for the thermally induced 9t12t LA samples. All the infrared spectra were saved in absorbance format. The spectra were then doubly derived and used in the quantitative analysis.

Gas Chromatographic Analysis

The remaining glyceride samples containing 9c12c and 9t12t fatty acids after the infrared analysis were subjected to derivatization. Each glass tube containing the sample was cut just above the liquid mark and crushed inside a 15-ml test tube. To each test tube was then added 2 ml of 0.5 M sodium methanolic sodium hydroxide and placed in a water bath at 60 °C for 15 min. After cooling, 2-ml portions of BF_3 /methanol were added to the solutions in the test tubes and placed in the water bath again for 10 min. To the solutions in each test tube was then added a 2-ml portion of a saturated solution of NaCl followed by a 1-ml portion of heptane and the resultant mixture well shaken to aid separation and dissolution of the FAMES in the heptane layer. After a few minutes standing, anhydrous magnesium sulphate powder was added to the top heptane layers in the test tubes. The heptane layers from the test tubes were extracted, placed in small brown vials and stored in dark for gas chromatographic analysis.

The GC analysis of the methyl esters of the fatty acids resulting from the thermal induction was carried out by using a Hewlett Packard 5890 gas chromatograph equipped with a 100-m capillary column with 0.25 mm internal diameter coated with a 0.20- μm thick 90%-bis-(cyano-propyl)-methyl polysiloxane stationary phase (HP 88). A temperature program involving two step gradients was used. The program started with 1 min at an initial

temperature of 150 °C and followed by a temperature gradient of 5 °C min^{-1} to reach a temperature of 180 °C. After 50 min at 180 °C another temperature gradient of 5 °C min^{-1} was used to bring the final temperature to 220 °C. The temperature was held at 220 °C for 30 min giving a total running time of 95 min for each sample.

Results and Discussion

Infrared Spectroscopy

The thermal induction of 9c12c fatty acid is expected to give 9c12t, 9t12c and 9t12t isomers. In addition to these, decomposition and formation of CLA isomers can also be expected [26, 27]. The positional isomers containing *trans* configurations are expected to absorb at 969 cm^{-1} in the infrared because of the =CH *trans* bending vibrations. The infrared spectra measured on the thermally induced samples of trilinolein and trilinoelaidin are given in Fig. 1. The figures clearly show that the peak at 969 cm^{-1} increases with time in the case of trilinolein samples and decreases with time in the case of trilinoelaidin samples. The transformation of fatty acid chains is clearly evident in both cases. The trilinolein has a weak absorption around 3,004 cm^{-1} because of the =CH stretching modes. This absorption decreases as the fatty acid moieties in the trilinolein molecules isomerize.

The formation of CLAs in the heated samples of 9c12c fatty acid has been demonstrated by Destailats and Angers [26]. There is also evidence in the infrared spectra of the

Fig. 1 Infrared spectra of heated samples of trilinolein and trilinoelaidin. The spectra are scale adjusted for clarity

heated samples for the formation of CLAs. There are humps on both sides of the peak at 969 cm^{-1} which become clearly evident in the fourth derivative spectra of the heated samples of trilinolein (Fig. 2). The peaks at 987 and 946 cm^{-1} are characteristic to CLAs. The formation of CLAs in the heated samples of trilinoelaidin has been shown by Christy [8] in a recent report. The fourth derivative spectrum of the heated sample of trilinoelaidin shows absorptions at 989 , 969 and 946 cm^{-1} . The peaks at 989 and 946 cm^{-1} indicate the presence of CLAs in the heated sample. The slight shift in the peak at 989 cm^{-1} indicates the presence *trans, trans* isomers in the mixture of the CLAs formed. The CLAs in the heated sample are a mixture of *c,tt,c* and *t,t* isomers of CLAs with a high percentage of *t, t* isomers. The peak at 969 cm^{-1} indicates the presence of *t, c* or *c, t* or *t, t* LAs or mixture of these isomers.

Gas Chromatography

The gas chromatograms of the FAME of the heat-treated trilinolein and trilinoelaidin are shown in Figs. 3 and 4, respectively. The concentrations of the isomers from both trilinolein and trilinoelaidin are presented in Fig. 5. The FAME profiles are very different for these samples. The 9c12c fatty acid readily isomerizes to 9c12t and 9t12c isomers. Furthermore, isomerization into 9t12t isomer seems to be very slow. In contrast to this, the isomerization of 9t12t fatty acid into the 9c12t, 9t12c and 9c12c isomers is much slower.

The 9c12t and 9t12c isomers in heat-treated trilinolein are equal in concentration. This fact proves that the isomerization of the 9,12 double bonds in 9c12c fatty acids are equally probable. However, heat-treated trilinoelaidin gives different concentration profiles for 9c12t and 9t12c isomers with relatively higher concentrations of 9t12c

compared to 9c12t isomers in all the heated samples of trilinoelaidin. Formation of different concentrations of 9t12c and 9c12t isomers imply that the double bonds in the 9t12t molecules are perturbed by the neighboring molecules or groups. The absolute lower concentrations of 9t12c, 9c12t and 9c12c isomers in the heated samples of trilinoelaidin show the stability of 9t12t double bonds towards isomerization.

These results enable the depiction of an energy diagram for the isomerization (Fig. 6). The isomerization of 9t12t fatty acid into 9c12t and 9t12c isomers requires higher activation energy. Furthermore, the isomerization of 9t12t fatty acid into 9t12c requires relatively lower activation energy compared to the isomerization into 9c12t. It is not clear why the isomerization of 9t12c requires lower activation energy. A theoretical approach is necessary to resolve this question.

Apart from positional isomerization, heat induction of trilinolein and trilinoelaidin also forms CLAs [8, 26, 27]. The CLA profiles produced in these thermal induction reactions are identical [8]. The top parts of the Figs. 3 and 4 show the CLA isomers produced in trilinolein and trilinoelaidin during thermal induction. The concentrations of total CLAs and the concentration of *trans, trans* CLAs within the total CLAs are shown in Fig. 7. The bar diagrams show the increase in concentration of CLAs during thermal induction of trilinolein and trilinoelaidin. The relative total concentration of CLAs in the heated samples approaches a maximum of around 5%. When the degradation of the trilinoelaidin (Fig. 8) is taken into account, the concentration of the total CLA in the heated trilinoelaidin amounts to around 2.2%. At the same time when the degradation of trilinolein (Fig. 8) is taken into account, the concentration of CLAs in the heated glyceride samples of 9c12c fatty acids amounts to around 3.3%. The relative concentration of *t, t* CLA isomers which elute together amounts to around 60% in all the heated samples.

The mechanism of formation of CLAs from heat induced 9c12c fatty acids has been described in detail elsewhere [26]. The same mechanisms can also be applied to the formation of CLAs from heat induced isomerization of 9t12t fatty acids [8]. Conjugated 9t11t and 10t12t fatty acids are formed as primary products through either (1) A free radical chain reaction mechanism or (2) An intramolecular [1, 3] sigmatropic rearrangement mechanism. All the other isomers of the CLAs are formed from these primary products through a series of positional isomerization and [1, 5] sigmatropic rearrangements [8].

Gas Chromatography and Infrared Spectrometry

As mentioned earlier, the acid molecules in the trilinolein and trilinoelaidin undergo degradation and a part of the

Fig. 2 Fourth derivative spectra of trilinoelaidin and trilinolein

Fig. 3 Gas chromatograms of FAMES of the heated trilinolein samples. The *top window* shows the elution order of CLAs formed during heating (Reprinted from Christy [8] with permission from Elsevier)

Fig. 4 Gas chromatograms of FAMES of the heated trilinoelaidin samples. The *top window* shows the elution order of CLAs formed during heating (Reprinted from Christy [8] with permission from Elsevier)

molecules will not be available for the isomerization reaction. The remaining trilinoelaidin can be quantitatively determined by using a pure trilinoelaidin standard. The use

of peak at 969 cm^{-1} in quantifying the concentrations of rest trilinoelaidin in the mixtures is reasonable. Heat-treated trilinoelaidin yields around 6–7% 9c12t and 9t12c

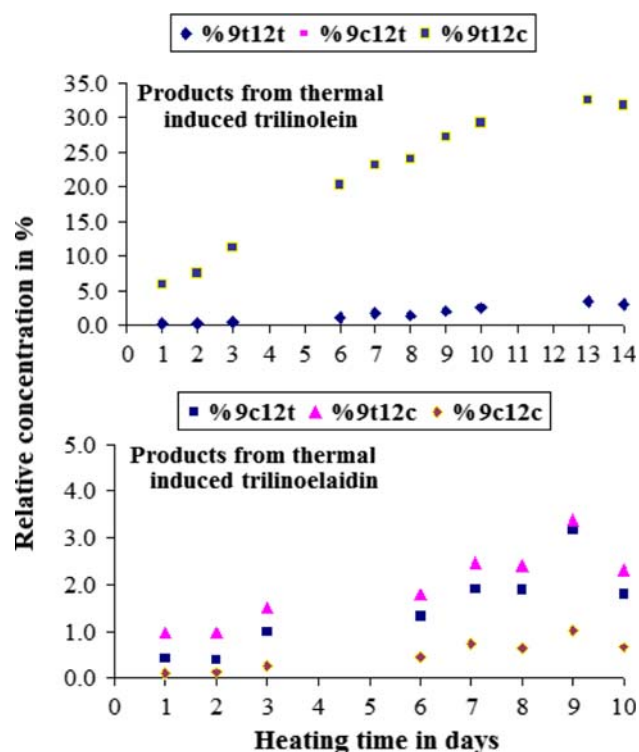

Fig. 5 Concentration profiles of the isomers formed during heating. The concentrations of 9t12c and 9c12t are identical in the heat induced trilinolein

isomers and therefore the error in the determination of rest trilinoelaidin will be in that range. In the case of trilinolein, the formation of 9t12t is around 3% and therefore the total concentration of 9c12t and 9t12c in each sample can be determined by comparing the peak height at 969 cm^{-1} with trielaidin peak height at the same wavenumber. Rest trilinolein can then be calculated by relative comparison of the percentages.

Fig. 6 Energy level diagram for the isomerization into mono *trans* isomers following a diradical mechanism

Fig. 7 Concentration profiles of conjugated linoleic acids in the heated trilinolein and trilinoelaidin

The concentration of rest trilinoelaidin and trilinolein in the heat-treated samples determined by infrared spectrometry and gas chromatography are given in Fig. 8. The plots clearly show the difference between the concentrations determined by GC and infrared spectroscopy. The analysis of fatty acids in the thermally induced mixtures was carried out after derivatization into FAMES. This derivatization reaction involves only the acidic components formed during thermal induction in the mixture and excludes all the other organic components formed from the

Fig. 8 Concentration of remaining trilinolein and trilinoelaidin in the heated samples as estimated by gas chromatography and infrared spectroscopy

thermal degradation. That is the concentrations of fatty acids determined as FAME profiles by gas chromatography are overestimated. The calculations show that both trilinolein and trilinoelaidin decompose during heating in addition to isomerization. Around 50% of trilinoelaidin decomposed after 10 days of heating and at the same time around 30% trilinolein decomposed after 10 days of heating. Differences in the decomposition characteristics are not difficult to understand. The concentration profiles of the products formed during the heat induction of trilinolein suggest that the activation energy for the isomerization is low and most of the fatty acid molecules in the molecule isomerize before decomposition into various products. In the case of trilinoelaidin, the molecule is very stable and the activation energy for the isomerization is very high and decomposition of trilinoelaidin may take place under thermal stress. These characteristics support the energy diagram shown in Fig. 6.

The decomposition products are mostly saturated and unsaturated aldehydes and shorter fatty acids [7]. Some of these aldehydes are carcinogenic [28]. These products were not analyzed for their chemical composition. However, there is evidence in the infrared spectra of the trilinolein and trilinoelaidin for oxidation during thermal induction. Infrared spectra of the heated sample of trilinolein and trilinoelaidin are given in Fig. 9. The absorption at $3,470\text{ cm}^{-1}$ is due to the overtone of the -C-O stretching in the glyceride molecules [29]. As the sample is being heated, some molecules are oxidised and hydroperoxide molecules formed. These hydroperoxide groups give a

Fig. 9 Infrared spectra of heat-treated trilinolein and trilinoelaidin samples in the region $4,000\text{--}3,000\text{ cm}^{-1}$

broad band which overlaps with the -C-O overtone. Several aldehydes are formed depending on the position of the peroxide group in the molecules [30, 31]. A detailed mechanism for the formation of different aldehydes during the oxidation process can be found in Ref. 31.

Conclusion

In this paper, I have shown the transformation of trilinolein and trilinoelaidin under thermal stress. The fatty acids in the triglyceride molecules undergo decomposition and isomerization. The concentration profiles of the positional isomers and CLAs have been acquired. These profiles give clear indications of the behavior of the molecules under thermal stress. The 9c12c fatty acids lead to isomerization easily compared to the 9t12t fatty acids. These findings confirm the stability of the 9t12t isomer compared to 9c12c.

The thermal decomposition of 9c12c and 9t12t also follow different patterns. Because of the molecular stability of the 9t12t fatty acid, the molecule undergoes decomposition easily instead of isomerization. Almost 50% of the trilinoelaidin decomposes in 10 days and at the same time 30% of trilinolein decomposes in 10 days. The products of the decomposition include peroxides and aldehydes.

The 9c12c and 9t12t fatty acids isomerize also into CLAs. The maximum concentration of CLAs in the heated

samples reaches around 5% both in trilinolein and trilinolein. All the *trans*, *trans* isomers except 11t13t co-elute under a large peak which comprises about 60% of the total CLAs in the sample. The concentration of CLAs formed from the 9t12t fatty acid is almost 66% of that yielded by 9c12c fatty acid. This again reaffirms the stability of 9t12t fatty acid toward transformations.

These findings suggest that linoleic acids in oils and fats transform into other products in the same way as the mono-unsaturated fatty acids. Because of these changes, oils and fats turn into a mixture of complex organic molecules that may have implications for human health.

Introduction

In marine environments, heterotrophic bacteria play a predominant role in particulate and dissolved organic matter (OM) transformations [1–4]. They control most OM fluxes since they are the main trophic level able to use dissolved OM efficiently. However, OM is made up of diverse chemicals, including proteins, peptides, polysaccharides, lipids, nucleic acids and other organic acids, phosphoric esters and humic substances [5]. Moreover, although bacterial abundance is regulated around a relatively constant value (10^5 to 10^6 cell ml^{-1}) [6], the bacterial species making up the pool of marine bacteria, are very diverse and have structures/functions/physiological conditions that may vary considerably, depending on the substrate and environmental conditions. One important bacterial function is hydrolysis that enables them to cleave the biopolymers into monomers before assimilation. Thus, protease, lipase and carbohydrase activity are fundamental to the carbon cycle. Understanding the specific and functional diversity of bacteria required to transform these targeted chemical substances is an important challenge in environmental research.

Lipids represent 3 to 55% of the OM in aquatic environments [7, 8]. They are natural substances derived from biological production, and are good tracers of the carbon cycle. Lipid hydrolysis, by lipases produced by heterotrophic bacteria, is essential for lipid assimilation by the bacteria. Studies regarding the specific relationships between lipids and lipase positive bacteria are uncommon [9] and lipid hydrolysis rates are poorly documented. Current methods used to measure lipase activity are the use of analog fluorogenic substrates as 4-methylumbelliferyl (MUF) fatty acyl esters [10], or radiolabelled triglycerides [11]. Lipase activities have been reported in the range 0.9–5.8 nM h^{-1} (using 12.5 nM MUF-oleate as the substrate), in a New-Caledonia lagoon [11] and Goutx et al. (unpublished results) measured lipase activities in the range of 5–7 nM h^{-1} (using 30 μM saturating MUF-oleate concentration) in the 0–60 m layer at the DYFAMED site (north-western Mediterranean Sea).

Using also MUF-oleate analog substrate (20 μM), specific lipase activity ranged over 3 orders of magnitude on pure cultures (0.2–584 $\text{amol cell}^{-1} \text{h}^{-1}$) and 20–70 $\text{amol cell}^{-1} \text{h}^{-1}$ in Coastal Californian waters [12], i.e. higher values than obtained at DYFAMED site (mean sd 3.3 ± 2.7 $\text{amol cell}^{-1} \text{h}^{-1}$).

Although lipid hydrolysis rates can be obtained by measuring lipase activities, it is still not known which organisms are responsible for the activities measured. To date, the potential capacity of the various bacterial communities to process a substrate have been estimated by comparing specific activities (activities per cell), based on

the misplaced assumption that all cells i) express the targeted enzyme and ii) exhibit the same activities. However, in order to focus on relationships between the targeted chemical substances (such as lipids) and the bacterial species able to process these substrates (named lipase + throughout the text), it is necessary to identify the bacteria responsible for the measured lipase activities.

Current methods used to measure lipase activity cannot detect the source of the activity measured. However, another analog fluorescent substrate, ELF-palmitate, may be used as a probe to target lipase + bacteria. Unlike MUF, which is soluble in water, ELF Alcohol (ELFA), the fluorescent product of the substrate hydrolysis, is insoluble in water and precipitates at the enzymatic site responsible for its hydrolysis. Thus, the walls of the bacteria having lipase activity are marked by ELF fluorescent crystals, enabling them to be detected by microscopy.

This method has been developed using ELF-phosphate substrate for detecting alkaline phosphatase and was first used on natural populations of marine and lake plankton [13–16]. The method was then adapted to marine heterotrophic bacteria [17]. ELF-palmitate has also been used for lipase detection on filamentous bacteria in wastewater treatment [18–21] and in rotifers digestive tracts in lakes [22]. However, no specific methodological developments have been reported in the literature on the use of ELF-palmitate, or its use in detecting lipase activities in free marine heterotrophic bacteria. The kinetics of ELF-palmitate hydrolysis and the mechanisms leading to the formation of fluorescent precipitates at the enzymatic sites are still poorly understood.

In this study, we used diverse techniques for measuring lipase activities of marine bacteria. Lipid substrate consumption and lipase activities were measured using both a chemical and an enzymatic approach (using the fluorogenic analogs MUF-palmitate and ELF-palmitate). Finally, we observed the accumulation of ELFA fluorescence over time but no precipitates were clearly associated with bacteria on prepared slides, neither for pure cultures of *Alteromonas macleodii* nor for natural samples from the Bay of Marseille, France. Possible factors controlling ELFA precipitation are discussed.

Experimental Procedure

Control of the Lipase + Properties of *Alteromonas macleodii*

The Gram-negative marine strain was obtained from the collection of the Observatoire Océanologique de Banyuls-sur-mer, in France, isolated from Mediterranean coastal

waters. This strain, named *Alteromonas infernus* in previous studies [17, 23] was recently reclassified as *Alteromonas macleodii*. On thawing, the strain was incubated at 25 °C on nutrient agar. The lipase + property was tested using a medium containing Tween 80, which is easily hydrolyzed by lipases, and calcium which reacts with the products of the Tween 80 hydrolysis. The reaction was characterized by an opaque halo around the colonies. The strain was then cultured in a triglyceride (TG) enriched medium in which lipase activities were measured.

Culture Media

Experiments were conducted in artificial sea water, based on f/2 Lyman & Fleming composition [24], in which we added excess NH_4Cl (6.7 mM N) and KH_2PO_4 (165 μM P) as sources of N and P, as well as traces of iron and vitamins. In the PYR medium, pyruvate was the single carbon source, supplied at low concentration (330 μM C) to obtain less dense cultures. The TG medium was a triglyceride-enriched medium (i.e. PYR medium + 1.2 μM tripalmitate, corresponding to 63 μM C of tripalmitate) which can theoretically induce lipase activity.

Bacterial Culture

Different experiments were performed. Whatever the final objectives of the experiments (synthesized in Table 1), all cultures were conducted in a reproducible manner as follows: prior to each culture, 48 h-colonies were inoculated into 100 ml pre-cultures of the PYR medium, allowing the bacteria to adapt to their new growth conditions. Following

24 h incubations at 25 °C, an inoculum was provided so that bacterial abundance was around 1×10^6 cell ml^{-1} in the cultures. The 300-ml cultures were continuously shaken, left growing in an incubated chamber at 25 °C in the dark until the stationary phase had been reached (generally lasting 50 h or more). PYR cultures and TG cultures are the cultures grown in PYR and TG media, respectively.

First, a series of three successive experiments were conducted to define the most propitious growth phase for ELFA labelling (experiments 1, 2, 3, Table 1). Bacterial abundance and lipase activities measured with the MUF-palmitate substrate were monitored over a period of 50 h in PYR and TG cultures. As these successive experiments showed reproducible patterns (see results), we thus felt confident enough to compare data acquired during experiments that were not run simultaneously (Table 1). Secondly, a duplicate experiment was performed on TG cultures (experiment 4, Table 1) to follow the tripalmitate decay over 144 h during bacterial growth. Then, experiments were performed on TG cultures, during the exponential phase (20 h) to verify the ectoenzymatic property of lipases (experiment 5, Table 1), test the effect of the ELF-palmitate solvent on lipase activities (experiment 6, Table 1), the competitive inhibition between MUF-palmitate and ELF-palmitate (experiment 7, Table 1) and ELF-palmitate labelling (experiment 8, Table 1).

Bacterial Counts

Bacterial abundance was estimated using epifluorescence microscopy counts following 4',6-diamidino-2-phénylindole (DAPI) staining. Samples (1 ml for pure cultures and

Table 1 Aims of the different experiments performed during this study

10 ml for the natural environment) were fixed with 2% final concentration of buffered formaldehyde (pre-filtered through 0.2 μm membrane). Then, bacteria were incubated with a DAPI solution ($\sim 2.5 \mu\text{g ml}^{-1}$ final concentration) for 10–15 min in the dark and at room temperature. Samples were then filtered onto black polycarbonate membranes (0.2 μm) and mounted onto glass slides using an Olympus immersion oil for fluorescence (nd 1.404). DAPI stained cells were counted with an Olympus BH2 microscope equipped with a long pass cube type U (dichroic mirror DM 400, barrier filter L420). Bacterial abundance was calculated from thirty fields with a minimum of thirty cells counted per field.

MUF-Palmitate Lipase Activity Measurement

Lipase activity was measured fluorometrically using 4-methylumbelliferyl-palmitate (MUF-palmitate) analog substrate [25]. The hydrolysis of MUF-palmitate releases a fluorochrome (MUF) that is soluble in the aqueous phase and can be detected spectrofluorometrically. Samples of pure culture (20 ml) were incubated with MUF-palmitate (50 μM final concentration), in the dark (25 °C). The linear increase in sample fluorescence was followed over an appropriate time period, with a spectrofluorometer Kontron SFM 25 calibrated with standard solutions of MUF (in the range 0.05–10 μM , excitation 365 nm, emission 450 nm). The MUF-palmitate concentration was chosen in order to reach saturating conditions as verified in previous concentration kinetic experiments (data not shown). Briefly, the parameters V_{max} (maximum hydrolysis rate) and K_m (Michaelis constant which reflects enzyme affinity for the substrate) were determined by fitting the data using a non-linear regression on the Michaelis–Menten equation.

Controls were performed in a sterile medium. Lipid hydrolysis rates were determined from the regression slope of the MUF fluorescence and calibration factors. Specific lipase activity was calculated by the ratio rates to abundances.

Chemical Monitoring of the TG Substrate Degradation

The decrease in tripalmitate concentration was estimated over time in duplicate experiments in the TG medium, using chemical analysis (experiment 4, Table 1).

Samples were collected regularly, over the 144 h of culture monitoring, to measure the concentration of dissolved lipids and bacterial abundance. A control was carried out in sterile TG medium to evaluate the abiotic decomposition of the substrate.

Lipids were extracted by liquid–liquid extraction, using dichloromethane: two extractions at natural pH followed by one extraction following acidification at pH <2 using HCl.

An internal standard (hexadecanone) was used to take into account the loss of lipid material during the analytical protocol.

Lipid extracts were analyzed by thin layer chromatography–flame ionization detection (TLC–FID). Depending on their polarity, lipids were separated into classes of compounds, on chromarods SIII (0.9 mm diameter, 150 mm length, 75 μm thick silica) and quantified using an Iatrosan TH10 apparatus model MK-IV (Iatron, Japan; hydrogen flow, 160 ml min^{-1} ; air flow, 2,000 ml min^{-1}) coupled to a Borwin integration system (Bionis, Paris). The complete elution scheme has been described previously [26]. It allows reliable separation and quantification of twelve classes of compounds, including triglycerides and their hydrolysis products, the free fatty acids (FFA) [27]. In this study, we reported on TG and FFA patterns only.

Verification of the Ectoenzymatic Property of Lipases

Experiments were conducted in triplicate in TG enriched cultures (experiment 5, Table 1). The control was performed in a sterile TG medium. The MUF-palmitate hydrolysis rate was measured in TG cultures and in the 0.2 μm filtrate of TG cultures in order to measure activity in the dissolved phase.

Lipase + Bacteria Labelling by the ELF-Palmitate Fluorescent Probe, Principle of Reaction

The ELF-palmitate substrate is a lipid analog substrate, as is MUF-palmitate. It consists of a lipid residue (palmitate) bound by an ester bond to the fluorochrome ELF. The product of ELF-palmitate hydrolysis, a brightly fluorescent ELF97 alcohol (ELFA), is water insoluble and precipitates theoretically at the site of its origin, labelling the cells that develop lipase activity with a more or less bright yellow staining that is detected under UV light by using epifluorescence microscopy.

The ELF-palmitate was purchased from Molecular Probes, in powder form (5 mg) and was solubilized in dimethylsulfoxide (DMSO). The solubility limit was reached at a concentration of 2.5 mM. Aliquots of stock solutions (150 μl) were kept at $-18 \text{ }^\circ\text{C}$. After thawing, one aliquot was filtered through 0.2- μm spin-filters before being used for bacteria labelling.

Effect of the Solvent of ELF-Palmitate (DMSO) on Bacterial Activity

The influence of DMSO on bacterial activity was tested by measuring the MUF-palmitate hydrolysis rate in the presence of increasing concentrations of DMSO (0.5, 1, 2, 5, 7 and 10% of the final volume) (experiment 6, Table 1).

Inhibition Kinetics Experiments

The ability of ELF-palmitate to saturate the sites of the enzymes responsible for the cleavage of MUF-palmitate was tested (experiment 7, Table 1). The effect of ELF-palmitate, added in a series of concentrations (0.1–184 μM), on the hydrolysis rate of MUF-palmitate, applied at a single low concentration (0.5 μM) was examined. The concentration of MUF-palmitate was close to K_m , the Michaelis constant for MUF-palmitate hydrolysis by extracellular lipases present in the sample examined, determined in previous saturation experiments, using a concentration range of 0.05–100 μM .

The MUF-palmitate hydrolysis rate in presence of ELF-palmitate was expressed as a percentage of the control value (occurring in the absence of ELF-palmitate), and plotted on a semilogarithmic graph, as a function of ELF-palmitate concentrations. The IC_{50} , which corresponds to the ELF-palmitate concentration giving a 50% inhibition of MUF-palmitate hydrolysis, was calculated using nonlinear regression by fitting data with a decelerating 3-parameter sigmoid function (displacement curve), assuming competitive inhibition (as in previous study, [28]):

$$v = \text{Min} + (\text{Max} - \text{Min}) / (1 + I/\text{IC}_{50}),$$

where v is the substrate (MUF-palmitate) hydrolysis rate (% of control), Max and Min are the upper and lower plateaus of displacement curve, respectively (% of control), and I is inhibitor concentration (i.e. final ELF-palmitate concentration). The Prism 4 (GraphPad Software, San Diego, USA) statistical package was used to perform nonlinear regressions.

Standard Protocol for ELF-Labeling in a Liquid Medium

Labelling tests were conducted in triplicate on TG cultures, based on existing protocols used for alkaline phosphatase labelling [16] (experiment 8, Table 1).

Samples (2,640 μl) were incubated with 60 μl of a 2.5 mM stock solution of ELF-palmitate in DMSO for a final substrate concentration of 50 μM for 1–5 h. 300 μl of a 100 mM Tris-HCl (pH 7.5) was added in order to provide pH stability during incubation. Indeed, a high pH would lead to the formation of a non-fluorescent and soluble form of ELF [29].

During the incubations, hydrolysis of ELF-palmitate was measured using spectrofluorimetry in order to compare with the activity measured using MUF-palmitate. The increase in fluorescence of ELFA was measured as a function of time (excitation 365 nm, emission 530 nm). As for MUF, the spectrofluorometer was calibrated using a concentration range of ELFA from 0.05 to 2 μM to

determine the conversion factor of fluorescence units to nmol of ELFA product released.

Aliquots were also taken at different incubation times for microscopy observation. The reaction was stopped by formalin tetraborate (2% final concentration). The samples were then stained with DAPI before being filtered onto a black polycarbonate membrane (0.2 μm). Then the filter was mounted on a glass slide for epifluorescence microscopy observation. Dual staining (combining ELFA and DAPI) enables us to discriminate between the total bacterial abundance and ELFA labelled cells [17, 30, 31].

Tests in the Natural Environment

Sea water was sampled from April to July 2007 at two stations in the Bay of Marseille, France: Riou (43°09'N, 5°24'E) and Cortiou (43°12'N, 5°24'E). Lipase activity was measured using MUF-palmitate (kinetic concentrations 0.05–50 μM), along with the measurement of bacterial abundance. The proportion of ELFA-labelled cells was investigated in the natural bacterial community, following the same protocol as for pure cultures, except that we tested different concentrations of ELF-palmitate (12–50 μM).

Results

Growth of *Alteromonas macleodii*

In cultures, bacterial growths (Fig. 1) were initiated with an average concentration of $1.6 (\pm 0.2) \times 10^6$ cell ml^{-1} in PYR cultures and $1.5 (\pm 0.4) \times 10^6$ cell ml^{-1} in TG cultures. During bacterial growth, a lag phase of approximately 6 h was systematically observed, followed by a log phase, the time period of which depended on the substrate. The stationary phase was reached after 30–40 h of culture with final concentrations of $2.5 (\pm 0.5) \times 10^8$ cell ml^{-1} and $3.0 (\pm 0.4) \times 10^8$ cell ml^{-1} in PYR and TG cultures, respectively. There were no significant differences between PYR and TG cultures, shown by non-significant differences between growth rates (test t , $p > 0.05$, slopes compared with data from log phase) and between abundances reached at stationary phase (ANOVA, $p > 0.05$). Although the four experiments were successive, there were no statistical differences between each other (test t and ANOVA, $p > 0.05$). We thus considered that they were comparable and that following experiments were also comparable.

Lipase Activity in *Alteromonas macleodii* Cultures: The Enzymatic Approach

During experiments 1, 2 and 3, bacterial counts were associated with MUF-palmitate hydrolysis rates measurements

Fig. 1 Evolution of bacterial abundances (cell ml^{-1}) in four successive experiments. *Triangle*: PYR cultures, *square*: TG cultures. Experiment 1: *black*, experiment 2: *light grey*, experiment 3: *white*, experiment 4: *dark grey*

(Table 1). The latter varied in a larger range than abundances between the three successive experiments. Potential MUF-palmitate hydrolysis rates ($50 \mu\text{M}$ additions) ranged between $2.8\text{--}9.3 \mu\text{M h}^{-1}$ after 20 h of culture and $4.3\text{--}21.4 \mu\text{M h}^{-1}$ at the stationary phase (47 h) in the PYR cultures (Fig. 2). In the TG cultures, lipase activities ranged between $4.6\text{--}9.4 \mu\text{M h}^{-1}$ at 20 h and $5.5\text{--}18.2 \mu\text{M h}^{-1}$ at the stationary phase. In a given experiment, MUF-palmitate hydrolysis rates measured in a PYR culture were always close to and occasionally higher than those measured in a TG culture. The same was observed for specific potential activities ranging between $2.0\text{--}11 \times 10^{-2} \text{fmol cell}^{-1} \text{h}^{-1}$ at 20 h and $2.1\text{--}8.0 \times 10^{-2} \text{fmol cell}^{-1} \text{h}^{-1}$ at the stationary phase in PYR cultures. In TG cultures specific activities were $3.2\text{--}14.0 \times 10^{-2} \text{fmol cell}^{-1} \text{h}^{-1}$ at 20 h and $2.0\text{--}6.9 \times 10^{-2} \text{fmol cell}^{-1} \text{h}^{-1}$ at the stationary phase. The growth phase where specific potential activities were the highest was difficult to determine using the enzymatic approach. Specific activities were clearly highest during the

Fig. 2 Evolution of MUF-palmitate hydrolysis rates measured with $50 \mu\text{M}$ MUF-palmitate final concentration ($\mu\text{M h}^{-1}$) in the successive experiments 1, 2, 3. *triangles*: PYR cultures, *squares*: TG cultures. Experiment 1: *black*, experiment 2: *grey*, experiment 3: *white*

Table 2 Specific activity during bacterial growth

Experiments	Log phase		Stationary phase	
	PYR	TG	PYR	TG
1	2.0	3.2	2.1	2.0
2	11.0	14.0	3.4	2.3
3	9.9	8.0	8.0	6.9

Specific activities ($\times 10^{-2} \text{fmol cell}^{-1} \text{h}^{-1}$) measured at the log and stationary phases with MUF-palmitate ($50 \mu\text{M}$ final concentration) in PYR and TG cultures, during three successive experiments

early log phase in both PYR and TG cultures in only two of the three experiments performed (Table 2).

Lipase Activity in *Alteromonas macleodii* Cultures: the Chemical Degradation of the TG Substrate

Tripalmitate concentrations decreased (Fig. 3), from $1.2 (\pm 0.3) \mu\text{M}$ at the beginning of the experiments to $0.1 (\pm 0.02) \mu\text{M}$ after 144 h of culture. About 90% of the tripalmitate was degraded during the experiment. There were no free fatty acids (FFA) at the beginning of the cultures in either of the 2 experiments. They appeared after 19 h of culture with a concentration of $0.4 (\pm 0.04) \mu\text{M}$. Their concentration increased to $0.9 (\pm 0.6) \mu\text{M}$ after 27 h of growth then fell to $0.5 (\pm 0.03) \mu\text{M}$ after 144 h of culture. Two phases of tripalmitate decay can be distinguished: a short first phase, from 0 to 19 h, and a longer second phase, between 19 and 144 h, that fitted into linear regressions. Between 0 and 19 h, $0.6 \mu\text{M}$ of the triglycerides were consumed. Using these chemical data, we calculated a tripalmitate hydrolysis rate that we considered to be the real lipase activity (Table 3). It was 30nM h^{-1} during the first phase. During the second phase, between 19 and 144 h, the same substrate quantity was consumed, $0.6 \mu\text{M}$, which was equivalent to a lipase activity of 5nM h^{-1} . During these two phases, a range of specific activities was estimated, based on the smaller and highest values of bacterial abundance during each phase. Values were $0.4\text{--}2.1 \times 10^{-2} \text{fmol cell}^{-1} \text{h}^{-1}$ for the first phase and $1.2\text{--}5.7 \times 10^{-5} \text{fmol cell}^{-1} \text{h}^{-1}$ for the second one.

Verification of the Ecto enzymatic Property of Lipases

In the fifth experiment, the average MUF-palmitate hydrolysis rate was $2.5 (\pm 0.2) \mu\text{M h}^{-1}$ in the unfiltered culture, while no activity was detected in the dissolved phase of the culture or in the sterile medium. Lipases were thus firmly attached to bacteria, which was a prerequisite condition for labelling the membrane enzymatic sites with the ELF-palmitate.

Fig. 3 Evolution of tripalmitate (*black squares*) and fatty acids (*white squares*) concentrations (μM) during bacterial growth in TG cultures. *Error bars* represent the standard deviation between duplicates. Note that one molecule of tripalmitate contains three fatty acids chains (experiment 4)

Table 3 Real lipase activity

Growth phase	Lipase activity ($\mu\text{M h}^{-1}$)	Specific activity ($\text{fmol cell}^{-1} \text{h}^{-1}$)
Phase 1	0.03	$0.4\text{--}2.1 \times 10^{-2}$
Phase 2	0.005	$1.2\text{--}5.7 \times 10^{-5}$

Tripalmitate decay rates ($\mu\text{M h}^{-1}$) and specific activity ($\text{fmol cell}^{-1} \text{h}^{-1}$) during phase 1 (phase where triglycerides decay was high) and phase 2 (phase where triglycerides decay was low), during bacterial growth in TG cultures

Solvent of ELF-Palmitate Effect

MUF-palmitate hydrolysis rates were measured with different DMSO proportions. Without DMSO, the measured activity was considered to be 100%. With up to 2% DMSO of the final volume, lipase activity did not decrease by more than 6%. Lipase activity decreased from 35 to 72% when DMSO represented 5% or more of the final volume. Hence, we considered that lipase activity was not influenced by the presence of DMSO as long as its proportion was less than 2% of the final volume.

Inhibition Kinetics Experiments

Measured data on the inhibition of MUF-palmitate hydrolysis by ELF-palmitate fitted well with the competitive inhibition model ($R^2 = 0.91$). The IC_{50} value obtained with the model was $44.7 \mu\text{M}$. So, the maximum ELF-palmitate concentration ($184 \mu\text{M}$) was only 4 times the IC_{50} . Inhibition of MUF-palmitate hydrolysis reached 80% (Fig. 4).

Although 100% inhibition of MUF-palmitate hydrolysis was not reached, the competitive inhibition experiment showed that more than 80% of enzymatic sites that

Fig. 4 Inhibition of MUF-palmitate hydrolysis by ELF-palmitate applied at different concentrations, in samples from TG cultures. MUF-based activity is given as a percentage of MUF-based activity measured without ELF-palmitate

hydrolyzed the MUF-palmitate also hydrolyzed the ELF-palmitate.

ELF-Labeling Tests

Prior to any labelling, the presence of both MUF-based and ELF-based activities was checked by spectrofluorometry in TG cultures, with a $50\text{-}\mu\text{M}$ final concentration for both substrates. The experiment was performed in triplicate (experiment 8, Table 1). The average MUF-based activity was $2 (\pm 0.2) \mu\text{M h}^{-1}$. The average ELF-based activity was about 5 times greater $10 (\pm 1) \mu\text{M h}^{-1}$. There was no MUF-based or ELF-based activity in the abiotic control. The ELFA fluorescence increased linearly as a function of time up to 5 h, after a lag time of about 1 h (result not shown). Specific ELF-based activities were in the range of $7\text{--}10 \times 10^{-2} \text{fmol cell}^{-1} \text{h}^{-1}$.

In the natural environment, MUF-based activities ranged from 1.5 to 7.5nM h^{-1} corresponding to $1.8\text{--}8.6 \times 10^{-3} \text{fmol cell}^{-1} \text{h}^{-1}$. ELF-based activities ranged from 30.4 to 88.1nM h^{-1} and corresponded to $2.4\text{--}9 \times 10^{-2} \text{fmol cell}^{-1} \text{h}^{-1}$. Comparing MUF- and ELF-based activities with the same substrate concentrations, no correlation was found between the two substrates in the natural environment.

During incubation in the presence of the ELF-palmitate substrate, samples from pure cultures and sea water were periodically taken to observe under the microscope, to look for any ELFA stained cells. For most replicates and at most incubation times, the labelling was not conclusive. Only yellow-green halos were spread on filters, not clearly associated with bacteria (Fig. 5).

However, at only one occasion in the pure cultures, for one of the replicates, we observed ELFA spots associated with bacteria. In this case, about 3% and 7% of bacteria were labelled with the ELFA, after 1 and 2 h of incubation,

Fig. 5 Heterotrophic bacteria from the natural community of the Bay of Marseille stained with DAPI. ELFA halos (yellow-green) are observed but no ELFA grains are associated with bacteria. Composite image obtained from two digitalized images: one with a narrow DAPI-filter (for blue, total bacteria) and one with a large DAPI filter combined with a low level of intensity of excitation (for yellow-green, ELFA halos)

Fig. 6 *Alteromonas macleodii*. ELFA labelled cells (yellow-green) counterstained with DAPI (blue) in TG cultures. Composite image obtained from two digitalized images: one with a narrow DAPI-filter (for blue, total bacteria) and one with a large DAPI filter combined with a low level of intensity of excitation (for yellow-green, ELFA-labeled bacteria)

respectively (Fig. 6). After 3 h of incubation, the staining was no longer visible and this result was never reproduced in other tests.

In the natural bacterial community, in order to verify that lipase activity was responsible for the appearance of such halos, we determined when possible the surface of these halos on the filters, over time (Fig. 7). At station Riou, there was no clear trend over time. At station Cortiou, the area occupied by the ELFA halos did not change during the first hour, but there were a sharp increase after about 2 h of incubation, particularly in June. In filtered samples (0.2 µm), there were only few halos and no trend over time.

Discussion

Reports in the literature state that lipases are mostly inducible enzymes [32]. Their production is greatly influenced by environmental parameters such as carbon and nitrogen sources, inorganic nutrients, temperature, dissolved oxygen concentration, pH [33] and the presence of lipids generally enhance their production [34–37].

As lipase synthesis represents an energetic cost for cells, we expected an enhancement of lipase activity in TG cultures at the stationary phase, when the most available substrate (pyruvate) should be limiting. However, in TG cultures, differences in specific MUF-based activities were not significant between the exponential growth phase and the stationary phase. Based on a bacterial yield of $2\text{--}3.4 \times 10^8$ cell ml⁻¹ and assuming a bacterial carbon

Fig. 7 Effect of incubation time on the surface area of filters occupied by ELFA halos (mm²), with 25 µM of ELF-palmitate added. Tests made in natural samples from the Bay of Marseille

content between 12.4 and 20 fg C cell⁻¹ [38, 39] and a bacterial growth efficiency between 0.14 and 0.38 for *Alteromonas macleodii* growing on pyruvate [40], the bacterial carbon demand would range between 540 and 4,000 µM C. This theoretical value is higher than the available carbon in our cultures (330 and 393 µM C in PYR and TG cultures, respectively). However, while the cell number increased, microscopic observations showed a decrease of the cell size over time. This “fragmentation phenomenon” [41] reflects a situation of carbon starvation which seems to take place very quickly in our cultures (approximately 20 h). Because of carbon limitation, the

rapid utilization of lipids (see Fig. 3) would explain why no difference was observed between the exponential growth phase and the stationary phase.

Finally, our results did not show the expected contrast “no lipase activity in PYR cultures/induced lipase activity in TG cultures”.

All these results suggest that lipases were constitutive for this *Alteromonas macleodii* strain. Phosphatases were reported to be in part constitutive for the same strain [17]. Other studies show that lipid enrichment does not systematically induce the enzyme synthesis [42] in natural microbial assemblages of deep marine sediments. Constitutive lipases were also reported for psychrotrophic bacteria [43].

The chemical measurement of lipid concentrations in TG cultures showed the disappearance of tripalmitate and the appearance of its hydrolysis products (free fatty acids) over time, thus ensuring the use of the lipidic substrate by bacteria. Another result concerned the lipolytic capacity of *Alteromonas macleodii* that was found in the range of previously reported real lipid hydrolysis rates. The tripalmitate hydrolysis rate that we obtained by the chemical approach corresponded to 2.0×10^{-5} to 2.1×10^{-2} fmol cell⁻¹ h⁻¹. Using trace concentrations of a radiolabelled triglyceride substrate, which (as for the chemical approach) was assumed to measure real rates, hydrolysis rates were measured in the Mediterranean Sea, ranging from 1.1×10^{-5} to 1.8×10^{-3} fmol cell⁻¹ h⁻¹ (with 0.13 to 0.26 nM of [³H]-triolein, at seawater temperature between 13 and 26 °C) [9]. Consequently, these rates obtained in lipid enriched cultures were on the same order of magnitude than in natural samples, suggesting efficient potentialities for lipid hydrolysis in the marine environment.

Comparison between MUF-based and ELF-based activities measured fluorometrically suggest that ELF-palmitate may be used to measure the potential hydrolysis rate of lipids: the increase in the ELFA fluorescence as a function of time was linear. However, ELF-based activities were four times greater than MUF-based activities with the same concentration of substrate added (50 μM) in pure cultures and no correlation was found with MUF-based activities in the natural environment. In a study of the ELF-phosphate kinetics on phytoplankton populations in freshwater lakes, similar results were found with 2–4 times more activity measured with the ELF-phosphate than with the MUF-phosphate [16]. In our experiment, the ELFA fluorescence appeared to increase linearly from the beginning of the ELF-palmitate incubation. However, the first two fluorescence measurements were separated by an important time step (1 h) that did not necessarily allow the observation of a possible shorter lag time. Indeed, other tests (data not shown) showed that the ELFA fluorescence increase may occur after a lag time of 30 min to 1 h. This

observation was well consistent with previous work [16] where a lag time ranging from a few minutes to more than 4 h was obtained in samples from lakes incubated at 25 °C.

The study of the ELF-palmitate kinetics required using varying and high substrate concentrations. However, we were limited by the proportion of DMSO, which we observed, should not exceed 2% of the final volume. Through inhibition experiments, this problem could be partly resolved. The maximum ELF-palmitate concentration used in this experiment was determined by the maximum amount of DMSO usable without modification of the lipase activity. To achieve it, we have however exceeded 2% of DMSO and reached a maximum of 4% of DMSO. Thus, the maximum concentration in ELF-palmitate (184 μM) represented only 4 times IC₅₀ (ELF-palmitate concentration causing 50% inhibition of the MUF-based activity). However, the inhibitor concentration is expected to exceed IC₅₀ by at least two orders of magnitude to observe 100% inhibition. This explains why only 80% of the maximum inhibition was reached. The experiment using ELF-palmitate as the inhibitor of MUF-palmitate showed that at least 80% of the enzymes interacting with ELF-palmitate hydrolyzed MUF-palmitate as well. We assumed that both substrates were in competition for the same enzymatic sites.

Finally, three substrates were used for measuring lipase potential and real activity. It was therefore interesting to compare them. Although bacterial abundances showed a very stable pattern, lipase activities measured with MUF-palmitate and tripalmitate showed a high variability between the successive experiments performed (see Figs. 2, 3). It may be due to the insoluble property of lipids and their capacity to form micelles that are not always homogeneously spread in culture media. Nevertheless, potential activity measurements, obtained with MUF-palmitate added at saturating concentrations were in the range of 3–25 μM h⁻¹ and thus far exceeded the real activities (5–30 nM h⁻¹), measured by following the tripalmitate decay chemically. The initial MUF-palmitate concentration was at saturating concentration (50 μM) while the TG concentration was approximately 1.2 μM, about 40 times less, which may partly explain the observed differences. We calculated MUF-palmitate hydrolysis rate based on a substrate addition of 1.2 μM and using the terms of Michaelis-Menten equation (based on MUF-palmitate kinetics) as described previously [44]. These “apparent real rates” were still much higher (7–57 times) than tripalmitate hydrolysis rate. The difference in structure between MUF-palmitate and tripalmitate, used to measure hydrolysis rates may be partly responsible for the differences found in our study. Indeed the quantity of esters bonds is different for the two molecules: the MUF-palmitate contains only one while the tripalmitate contains three bonds. At the same

substrate concentrations, and assuming that the two substrates are recognized in the same way by lipase, there should be a difference of a factor of three between the measured activities. As far as we know, there is no other comparison between MUF-palmitate and the natural corresponding triglyceride (tripalmitate). However, other studies reported comparison between MUF-oleate and triolein. Oleate is a long unsaturated fatty acid (18:1) compared to palmitate (16:0) and probably behaves somewhat differently (when combined to MUF-or p-nitrophenyl fluorogenic derivatives) in tests on pure enzymes [45] and environment [46]. Lipases do not behave the same way with the MUF-oleate analog and their natural substrate: triglycerides [47, 48]. The fluorogenic analog, whose structure differs from that of the natural substrate, is not necessarily recognized by the targeted enzyme [49] and may undergo a non-specific hydrolysis by various carboxylesterases [47, 48], for example. In addition, a comparison of two methods for enzymatic activity measurements showed that the MUF-oleate was probably more labile and more easily hydrolyzed by lipases than the radiolabelled ^3H -triolein [11]. Although MUF- and ELF-palmitate were hydrolyzed by the same enzymes, these substrates were probably not hydrolyzed specifically by lipases (defined as triacylglycerol acylhydrolase, E.C. 3.1.1.3) but rather by “lipolytic enzymes”.

Before testing ELFA labelling on bacteria, we checked that the enzymes responsible for the measured potential enzymatic activities were attached to bacteria. This verification ensured that ELFA insoluble crystals could precipitate at the enzymatic site responsible for the substrate hydrolysis. The early log phase of *Alteromonas macleodii* growth (between 5 and 20 h) exhibited the highest specific activity (measured chemically) and was most suitable for the ELFA staining of *Alteromonas macleodii* cells. Therefore we carried out the labelling tests at this growth phase. Theoretically, all conditions were met to observe the ELFA labelling of bacteria under microscopy.

Yet, in most cases only a yellow-green halo was spread over the filter's surface (absent at the beginning of incubation). In only one case spots of ELFA, as those observed in previous study ([17], see their Fig. 1) were obtained, and only in that case we were able to associate ELFA spots with bacteria. But this result was not reproducible in both cultures and in situ samples.

Many factors control ELFA precipitation. The non-fluorescent water-soluble phenol form of ELFA converts into its fluorescent water-insoluble form due to the spontaneous formation of an intramolecular hydrogen bond, and only subsequently precipitates. A pH > 10 would lead to inhibit the formation of this intramolecular hydrogen bond of the ELFA molecule [50]. An increase in local ELFA concentration over a certain level is also required to initiate

its precipitation [16]. Adding ELFA in certain conditions has been found to promote fine structure resolution [51]. The undissolved alcohol could promote precise crystallization of the reaction product at the site of enzymatic activity (serving as crystal nucleation sites) but also maintain its localized precipitation. We did not add ELFA in samples during incubation with ELF-palmitate. We ensured that the level of specific activities was sufficient for observing ELFA precipitation. A $0.17 \text{ fmol cell}^{-1} \text{ h}^{-1}$ minimum phosphatase activity was recommended to observe ELFA spots formation in bacterial samples from acidified mountain lakes [31]. However, 30% ELFA labelled cells were reported in pure cultures of *Alteromonas macleodii* with an alkaline phosphatase activity of $0.01\text{--}0.16 \text{ fmol cell}^{-1} \text{ h}^{-1}$ [17]. In our cultures, specific activities varied in a similar range ($0.07\text{--}0.10 \text{ fmol cell}^{-1} \text{ h}^{-1}$ measured with ELF-palmitate). Thus, the low percentage of labelled bacteria that we obtained in our samples cannot be inferred onto the level of specific activities. Salt concentrations can also be involved in the formation of fine precipitates [51]. To detect alkaline phosphatase, the use of a salt-rich reactive (B reactive of the ELF-97 Endogenous Phosphatase Detection kit E6601) with ELF-phosphate is proposed by Molecular Probes. However, alkaline phosphatase was stained by ELF on marine bacteria without the use of this component [16].

It has been previously suggested that a kind of nucleation (e.g. on hydrophobic structures) may trigger ELFA precipitation [16]. Lipid-enriched target sites were found to form large crystals [51].

The specificity of hydrophilic/hydrophobic interactions and the complex mechanisms underlying the precipitates formation might explain the difficulty in obtaining ELFA spots in lipid-enriched media. Instead, we obtained a rather diffuse staining in our preparations. ELFA spots attached to filaments of filamentous bacteria were observed in studies of wastewaters from different treatment plants after incubation with ELF-palmitate [19, 20]. Another study [21] also reported ELFA spots attached to the filaments of filamentous bacteria. In these studies, the signal was never observed on free cells. However, filamentous bacteria in wastewater often have a hydrophobic surface, whereas free cells have rather a hydrophilic surface [19, 52, 53]. ELFA labelling was also observed on *Alteromonas macleodii* strain in pure cultures [17, 23]. In these cultures, the strain formed aggregates, which could characterize cells with hydrophobic surface. The ELF-phosphate substrate dissolved in milli-Q water could behave differently than ELF-palmitate dissolved in DMSO. In our study, the strain never formed aggregates and no clear ELFA signal was observed. The growing conditions in these previous experiments may promote the increase of the hydrophobicity degree on the site of ectoenzymatic activities of *Alteromonas macleodii*,

while the growing conditions of our experiments may have tended to favor its decline. Indeed, the degree of hydrophobicity of the cell surface may change depending on environmental conditions (degree of starvation, [54]) and a strong correlation between the adhesion of cells to sludge flocs and cell surface hydrophobicity was demonstrated [53].

In highly eutrophicated aquatic environments (wastewater treatment plants), free cells are rather hydrophilic [52]. This may explain the lack of significant bacterial labelling in an eutrophicated marine environment in this study. Among the three stations, Cortiou is the nearest station to the Marseille wastewater discharge outflow. Our hypothesis was that the presence of enhanced concentrations of glycerides, previously recorded in wastewater [55], would trigger bacterial lipolytic activity and, thus, the number of ELFA labelled cells, capable of developing lipase activity, among the natural bacterial community. Activities were measured with the MUF-palmitate substrate and were enhanced at the different stations, depending on the season (Duflos et al. in prep). Although we observed an increase in ELFA halos spread on filters at Cortiou, suggesting a biological origin for the ELF-palmitate hydrolysis, we never observed any ELFA labelled cells on the filters, for natural communities. This problem has also been encountered for the detection of alkaline phosphatase of heterotrophic bacteria in the Mediterranean Sea [17].

In conclusion, this study uses the first assay of ELF-palmitate for marine bacteria staining. We saw clear evidence that ELF-palmitate was cleaved by bacterial enzymatic activity but that cell labelling cannot be obtained routinely, even on a small percentage of cells. Although several conditions for the assay were set up (growth phase, solvent solubilization), it is likely that assay conditions have to be optimized before routine use.

However, other alternatives should be sought to identify the organisms which are responsible for the measured lipase activity in the marine environment. Indeed, this method seems selective and ELFA labelling of lipolytic bacteria seems influenced by the degree of hydrophobicity of the cell surfaces. This study therefore suggests that prior to proving that the ELFA can precipitate indiscriminately on hydrophobic and hydrophilic surfaces, this substrate must be used with extreme caution.

Acknowledgments We acknowledge the anonymous reviewers for their helpful comments. We also thank Tracy Bentley and Rose Campbell for improving the English. This study was supported by a graduate research fellowship from the Conseil Régional Provence-Alpes-Côte d'Azur. Funding was obtained from the "Agence de l'eau" de Marseille in the framework of the IBISCUS project (Indicateurs Biologiques et chimiques de Contaminations Urbaines).

high density lipoprotein (HDL) cholesterol levels and small, dense low-density lipoprotein (LDL) particles. These alterations in plasma lipoprotein-lipid metabolism have been shown to increase the risk for cardiovascular disease in both men and women [2].

The state of dyslipidemia is influenced by the body fat distribution with central obesity leading to a higher risk for cardiovascular disease [3]. Both, transfer proteins such as cholesteryl ester transfer protein (CETP) and phospholipid transfer protein (PLTP), and lipases such as lipoprotein lipase (LPL) and hepatic lipase (HL) are candidates to mediate the higher risk for cardiovascular disease [4].

Adipose tissue is a prominent source of CETP and obesity is associated with elevated plasma CETP concentrations [5, 6]. CETP is an important determinant of lipoprotein composition due to its capacity to mediate the transfer of cholesteryl esters (CE) from CE-rich lipoproteins to TG-rich lipoproteins in exchange for triglycerides. It has been suggested that CETP plays a key role in the reversibility of the atherogenic lipoprotein profile seen in obese subjects [7]. During marked reduction in fat mass the serum levels of both CETP-mass and CETP-activity are reduced in parallel [8, 9].

PLTP circulates bound to HDL and mediates the transfer of phospholipids from apo B-containing lipoproteins into HDL, thus modulating HDL size and lipid composition. PLTP activity generates pre-beta HDL, the major acceptor of cholesterol in the reverse-cholesterol transport route [10]. Liver, adipose tissue and lung are presumably the major sources of circulating PLTP [11]. PLTP-knockout mice have been shown to have markedly reduced HDL levels due to defective transfer of phospholipids from triglyceride-rich lipoproteins into HDL [12]. In a cross-sectional study elevated PLTP levels were associated with an increased risk for coronary artery disease [13]. Furthermore, it has been hypothesized that reduction of PLTP activity and increase of HDL particle size are important component factors in converting the atherogenic lipoprotein profile of obese subjects into a less atherogenic profile with weight loss [14].

The HL plays a role in the metabolism of chylomicrons and very low-density lipoprotein (VLDL) remnants, LDL, and high-density lipoproteins (HDL), which are all implicated in atherosclerosis [15–17]. A decrease in the activity of postheparin HL was found in 21 obese older men after weight loss, suggesting that the reduced HL concentrations might mediate the improvement in the lipoprotein profile [18].

LPL is a rate-limiting enzyme that hydrolyzes circulating triglyceride (TG)-rich lipoproteins, such as VLDL and chylomicrons [19]. A decrease in LPL activity is associated with an increase in plasma TG levels and a decrease in HDL-cholesterol [19].

As compared to previous weight loss studies, which evaluated either lipid transfer proteins or lipolytic enzymes, we determined—to our knowledge for the first time—the influence of weight reduction on both the lipid transfer proteins CETP and PLTP and the lipolytic enzymes LPL and HL in parallel and in a prospective study design.

Subjects and Methods

Subjects

Nineteen morbidly obese women defined by a BMI of more than 40 kg/m² participated in this prospective study. Subjects desiring surgical intervention for the treatment of obesity were referred from the surgical department to the outpatient clinic for metabolism, where they were consecutively screened for eligibility. Exclusion criteria were secondary causes of adiposity, diabetes mellitus, pregnancy, intake of lipid lowering drugs or other medically significant illness. Examinations of the study subjects were undertaken within 2 months prior to Laparoscopic Adjustable Gastric Banding (LAGB) and 1 year post LAGB. Informed consent was obtained from each participant before entering the study, and all procedures were performed in accordance with institutional guidelines at the Internal Department of the medical faculty of the University of Innsbruck. The study protocol was approved by the Ethical Committee of the Medical University Innsbruck.

Surgical Procedure

The surgical procedure was performed as described by Forsell [20] at the Department of Surgery, University of Innsbruck [21]. The Swedish Adjustable Gastric Band was used in all of the study patients (SAGB Obtech Medical AG, Zug, Switzerland).

Analysis of Body Composition

BMI was calculated as body weight in kilograms divided by height in meters squared. Body composition was determined by impedance analysis using InBody 3.0 Body Composition Analyzer from Biospace Europe (Dietzenbach, Germany). Measurements were taken in the morning in the fasted state.

Glucose Metabolism, Leptin and Lipoprotein Analysis

Blood was collected after an overnight fast. Plasma was separated from erythrocytes by centrifugation at 3,000 rpm for 10 min at 4 °C immediately after collection. Plasma samples were stored frozen at –80 °C until assayed. Plasma

TG, cholesterol, apo-AI and apo-B concentrations were quantified using a commercially available enzymatic kit (Roche Diagnostic Systems, Basel, Switzerland) on a Cobas Mira analyzer. HDL-cholesterol and HDL₃-C concentrations were determined using precipitation procedures with polyethylene glycol (Immuno, Vienna, Austria) [22]. HDL₂-C concentrations were calculated by subtracting HDL₃-C from HDL-C. LDL-C was calculated according to the formula of Friedewald et al. [23]. Plasma glucose was measured by the hexokinase method on a Cobas MIRA analyzer. Plasma insulin was determined by a micro particle enzyme immunoassay from Abbott (Wiesbaden, Germany). The homeostasis model of assessment of insulin resistance (HOMA-IR) was calculated by the following formula: fasting serum insulin concentration ($\mu\text{IU mL}^{-1}$) \times blood glucose concentration (mmol L^{-1})/22.5. Leptin concentrations were measured using an ELISA (R&D Systems, Wiesbaden, Germany).

CETP Mass

CETP concentrations were determined by capture enzyme-linked immunosorbent assay. Wells were coated with recombinant single-chain antibody fragments 1CL8 [24]. CETP was detected using a polyclonal anti-CETP antibody conjugated directly to alkaline phosphatase [25, 26].

PLTP Activity

The ability of plasma PLTP to transfer [³H]-dipalmitoyl-phosphatidylcholine (NEN Life science Products, Boston, MA, USA) from phosphatidylcholine vesicles to HDL₃ was measured as described previously [27].

LPL- and HL-Activity

LPL activity and HL activity were measured as described previously [28, 29]. Briefly, postheparin plasma was collected 15 min after an intravenous heparin dose of 50 Units per kg body weight into cold tubes to maintain the enzyme activity. For HL activity, we used a gum arabic emulsion of [³H]-glycerol-trioleate, under these conditions LPL is inactivated. To measure LPL activity we used an emulsion of Intralipid[®] into which [³H]-glycerol-trioleate was incorporated by sonication. HL activity was inhibited by goat immunoglobulins to human HL, that was a kindly provided by Thomas Olivecrona, University of Umea, Sweden.

Statistical Analysis

Descriptive data are expressed as mean values \pm SD. Normal distribution was estimated using a Shapiro–Wilk

Table 1 Anthropomorphic measures of the study participants at baseline and after weight loss induced by LAGB

	Pre LAGB	Post LAGB	Test probability
Age (years)	37.2 \pm 11.6	38.5 \pm 11.7	
Height (cm)	167 \pm 6		
Weight (kg)	116.8 \pm 12.2	94.6 \pm 14.4	<0.001
BMI (kg/m^2)	41.7 \pm 2.9	33.7 \pm 4.3	<0.001
Fat mass (kg)	57.5 \pm 8.1	37.0 \pm 8.4	<0.001

Data are expressed as means \pm SD. Statistical significance was estimated by paired-samples *t* test

test. Normally distributed data from the pre- and post-gastric banding group were compared using a paired-samples *t* test. Not normally distributed data from the pre- and post-gastric banding group were compared using a Wilcoxon test for paired samples. Associations between PLTP activity and CETP mass were assessed using the Spearman *r* correlation coefficient. Statistical significance was inferred at a two-tailed *P* value of less than 0.05. Statistical analyses were calculated using SPSS release 11.5 for Windows (SPSS, Chicago, USA).

Results

Clinical Characteristics

Anthropomorphic measures of the study subjects are shown in Table 1. The mean age was 37.2 \pm 11.6 years in pre-gastric banding subjects. In this group the mean body weight was 116.8 \pm 12.2 kg and the BMI was 41.7 \pm 2.9 kg/m^2 . Mean body weight loss after the surgical procedure was 22.2 kg ($P < 0.001$), respectively. Mean BMI decreased in parallel by 8 kg/m^2 after 1 year ($P < 0.001$). The body fat mass was 57.5 \pm 8.1 kg in the subjects undergoing surgical intervention. After bariatric surgery body fat mass decreased to 37.0 \pm 8.4 kg, corresponding to a loss of 20.5 kg fat mass ($P < 0.001$). Thus, in these study subjects weight loss mainly due to loss of fat mass.

Lipids and Apolipoproteins

Lipid parameters at baseline and after LAGB are shown in Table 2. Mean triglyceride levels decreased by 0.45 mmol L^{-1} after weight loss ($P = 0.027$). HDL-cholesterol tended to increase from 1.37 \pm 0.31 mmol L^{-1} in the pre-gastric banding group to 1.43 \pm 0.28 mmol L^{-1} in the post-gastric banding group. Mean HDL₂-C concentrations increased significantly by 0.02 mmol L^{-1} ($P = 0.009$). Further mean Apo-B levels decreased 4 mg dL^{-1} from baseline concentrations 1 year after LAGB, respectively.

Table 2 Lipid parameters and apolipoproteins at baseline and after weight loss induced by LAGB

Lipid Transfer Proteins and Lipolytic Enzymes

The CETP mass was 1.81 ± 0.5 μg mL⁻¹ at baseline. After a weight loss of 20.5 kg in fat mass, CETP mass decreased by 8.3% ($P = 0.043$; Table 3). Baseline PLTP activity of 7.15 ± 1.0 (μmol mL⁻¹ h⁻¹) decreased by 14.4% ($P = 0.002$; Table 3). In univariate analysis CETP mass and PLTP activity were significantly associated at baseline ($r = .539$, $P = 0.026$), but not after weight loss ($r = .248$, $P = 0.338$). The correlation coefficient for Δ CETP and Δ PLTP was not significant ($r = .074$, $P = 0.787$). LPL activity tended to decrease from baseline levels of 297 ± 96 to 248 ± 74 nmol mL⁻¹ h⁻¹ ($P = 0.139$) and, also, the HL activity tended to decrease from 371 ± 148 to 319 ± 151 nmol mL⁻¹ h⁻¹ ($P = 0.170$).

Discussion

Obesity is associated with a higher risk for morbidity and mortality from atherosclerotic disease [1]. Bariatric surgery is an efficient method for reducing body weight and thereby reducing mortality and morbidity [30]. Weight loss leads to beneficial metabolic effects such as lowering serum triglycerides, improving the insulin sensitivity and increasing HDL-cholesterol. The Swedish Obese Subjects Study represents the first prospective controlled intervention study

on overall mortality after bariatric surgery [31]. After an observation period of 10 years several lipid parameters ameliorated in the bariatric surgery group: triglycerides decreased by 16%, HDL-cholesterol increased by 24% and total cholesterol decreased by 5.4% [31]. Changes in lipid transfer proteins and lipolytic enzymes could account for these improvements.

Consequently, we evaluated the influence of weight reduction by bariatric surgery on the lipid transfer proteins CETP and PLTP and the lipolytic enzymes LPL and HL in parallel in a prospective study. The study cohort comprised healthy obese women to minimize potential confounding factors.

One year post gastric banding fat mass decreased by 35.7% and, in parallel, CETP mass and PLTP activity decreased significantly by 8.3% and by 14.4%, respectively. We previously reported that CETP mass and activity decreased in subjects undergoing weight loss after bariatric surgery leading to a more favorable lipoprotein profile. After the bariatric procedure a consistent increase in LDL particle diameters was found in parallel to the plasma CETP diminution [8]. PLTP is another lipid transfer protein that plays a crucial role in improving the atherogenic lipoprotein profile of obese subjects during weight loss. In a previous study we found a significant reduction of PLTP activity and a concomitant increase in HDL₂ particle size during weight loss, whereas no

alteration of HDL₃ particle size was observed [14]. We hypothesized that a reduction in PLTP activity and an increase in HDL particle size are important component factors in converting the atherogenic lipoprotein profile of obese subjects into a less atherogenic profile with weight loss [14]. Furthermore, decreased PLTP activity was positively correlated with the change in subcutaneous fat after weight loss, but there was no significant relationship between the change in PLTP activity and the change in intraabdominal fat and insulin sensitivity [32]. Parallel CETP and PLTP plasma level reduction has already been found after slight weight loss induced by caloric restriction in obese women [33]. CETP and PLTP showed to correlate positively in obese females before weight reduction [33]. After weight loss the positive relationship between CETP and PLTP disappeared [33]. Both lipid transfer proteins seem to play a favorable role in the variances of lipids after weight reduction.

In contrast, postheparin HL activity and LPL activity did not change significantly after LAGB induced weight loss in the present study. However, we noted a tendency to decrease in both lipolytic enzymes. The role of HL and LPL in weight loss associated improvements of the lipid profile has been explored in previous studies. Pardina et al. [34] recently reported a significant reduction of plasma and liver HL activity after gastric bypass surgery. Purnell et al. [18] observed a reduction in postheparin HL activity after weight loss which contributed to the observed increase in LDL size and HDL₂-C, especially in those subjects with pattern B LDL particles before weight loss. A recently published study postulated that the lowering of plasma lipids following a weight reduction program was due to increased expression of both LPL and LDL receptor mRNA [35]. However, in another study by Berman et al. [36] regional adipose tissue LPL did not change after weight loss. The different weight loss inducing interventions investigated in the above-mentioned trials may be responsible for the conflicting results. In our study, HL and LPL activity seem to be unaffected by LAGB, a caloric intake restricting procedure.

A major limitation of this study is the restriction to women and the limited number of subjects. The latter could explain that, although we found a decrease in both LPL and HL activity, these differences were not significant in the respective statistical analysis.

In conclusion weight loss induced by bariatric surgery results in amelioration of TG and HDL-2 concentrations in normolipidemic obese women. These improvements may be attributable to decreased mass and action of the adipocyte tissue derived lipid transfer proteins CETP and PLTP, while the modest increase in HDL-2 could be the consequence of the change in TG independent of, or in combination with, the changes in the transfer proteins.

Introduction

The link between high serum low-density lipoprotein (LDL) cholesterol concentrations and cardiovascular disease (CVD) has been clearly established [1]. However, evidence is accumulating that high serum concentrations of triacylglycerols (TAG)—also known as hypertriglyceridemia—and low serum concentrations of high-density lipoprotein (HDL) cholesterol are also causally related to CVD [1]. TAG are major lipids in chylomicrons and very-low-density lipoprotein (VLDL) particles. These particles are closely related to the metabolism of other lipoproteins, including HDL. High TAG and low HDL often occur together, frequently with normal concentrations of LDL cholesterol, increased concentrations of small dense (sd) LDL and apoB, and insulin resistance [1]. This lipid abnormality is a fundamental characteristic of patients with the metabolic syndrome, a condition strongly associated with the risk to develop type II diabetes (DM2) and CVD [1].

Interestingly, a recent meta-analysis has indicated that consumption of plant stanol esters (PSE) not only lowers serum LDL cholesterol, but also serum TAG concentrations, in particular in subjects with high baseline TAG concentrations [2]. This meta-analysis was based on five trials carried out in our department and included almost 400 subjects. The reason that these effects have not been observed in individual studies may have been due to a lack of statistical power, as effects were only marginal in subjects with normal serum TAG concentrations. We therefore decided to design for the first time a study to specifically evaluate the effects of PSE on the serum lipoprotein profile in a population with elevated fasting serum TAG concentrations.

Subjects and methods

Subjects

Subjects, aged between 18 and 70 years, were recruited among an already existing cohort of patients diagnosed with familial combined hyperlipidemia (FCHL) at the Academic Hospital Maastricht (AZM). Patients were characterized by a specific phenotype, i.e. serum total cholesterol concentrations >6.5 mmol/L and/or elevated serum TAG concentrations (>2.3 mmol/L) at different visits before taking medication. Also subjects, who had serum TAG concentrations between 1.7 and 4.0 mmol/L, as indicated in earlier studies at our department, were approached. A fasting serum TAG concentration >1.7 mmol/L was chosen as lower boundary as this concentrations is considered to be elevated [3], while subjects with concentrations >4.0 mmol/L frequently need to be treated with medication [4].

Participants were further selected for the study according to the following inclusion criteria: no history of CVD such as congestive heart failure or recent (<6 months) event (acute myocardial infarction, CVA), type I and II diabetes mellitus, epilepsy, asthma, COPD (chronic obstructive pulmonary disease), inflammatory bowel diseases, cancer, or rheumatoid arthritis; no use of diuretics; no abuse of drugs and/or alcohol; willing to abstain from alcohol 3 days before blood sampling; no pregnant or breast-feeding women; and no use of an investigational product 30 days before the study. The Medical Ethical Committee of the University of Maastricht had approved the study. Participants were given a detailed description of the experimental protocol and purpose of the study before they gave their written informed consent. Twenty-nine volunteers were selected for the study. One subject withdrew in the third week of the study because of difficulty in performing venipuncture. All other 28 volunteers, 16 men and 12 women, completed the study. Baseline characteristics did not differ between the treatment groups, except for the number of smokers (Table 1).

Experimental design

The study had a randomized, double-blind, placebo-controlled, parallel design. Two weeks before the start of the actual study and during the 4 weeks of the study, subjects had to stop [in consultation with their general practitioner (GP)] the intake of their regular cholesterol-lowering medication (statins or cholesterol-absorption inhibitors) when appropriate. No other classes of cholesterol-lowering drugs were used. Besides serum LDL and HDL cholesterol concentrations, this medication can also lower serum TAG concentrations. During the first 2 weeks of the study (before the run-in period), subjects were given a control margarine containing 60% absorbable fats. After these 2 weeks, the volunteers returned for blood sampling to the university. Further participation (and thus continuation of the medication-free period) was allowed only if serum total cholesterol concentrations were <8.0 mmol/L and TAG concentrations <4.0 mmol/L. Otherwise, subjects were sent back to their GP and were advised to (re)start lipid-lowering medication according to the Dutch Cholesterol Consensus [4]. When serum cholesterol concentrations were <8.0 mmol/L and TAG concentrations between 1.7 and 4.0 mmol/L, subjects continued to consume daily 20 g of the control margarine for one more week. At the end of this run-in period, subjects were randomly divided over two groups, stratified for gender. The following 3 weeks (experimental period), one group continued to consume the control margarine, while the other group consumed daily 20 g of the experimental margarine, which had a similar fat content and fatty acid composition as the control

PSE plant stanol esters

^a Data were analyzed by the independent Student's *t* test. Differences were considered statistically significant at *P* < 0.05

^b Subjects had to stop the intake of their lipid-lowering medication 2 weeks before the actual start of the study and during the 4 weeks of the study

margarine, but provided 2.5 g plant stanols. Plant stanols were made by saturation of plant sterols from tall oil, with a distribution of sitostanol (77.7%), campestanol (16.7%), sitosterol (2.2%), campesterol (1.8%), brassicasterol (0.1%), stigmaterol (0.1%), and other phytosterols (1.4%) (Raisio Group, Finland). The free plant stanols were esterified with fatty acids derived from sunflower oil before incorporation into the margarine. The margarine was packed in tubs of 140 g, equivalent to margarine for 7 days. Subjects had to divide the content of one tub into seven equal pieces of 20 g of margarine. One piece of 20 g had to be used on bread/crackers each day. All products were coded with a color label to blind the subjects and the investigators. All margarine leftovers had to be returned to the department and were weighed for the calculation of average daily margarine intake.

Participants recorded in diaries any signs of illness, medication used, menstrual phase, alcohol consumption, any deviations of the study protocol, and any of the following experienced complaints: headache, stomach complaints, nausea, bloated feeling, flatulence, diarrhea, constipation, itching, eruptions/rashes, fatigue and dizziness. Other possible side effects were monitored at the end of the run-in (day 21) and experimental period (day 42) by assessing parameters reflecting liver function.

Subjects also recorded their food intake for the previous 3 weeks at days 21 and 42 by completing food-frequency questionnaires (FFQ) to estimate their energy and nutrient intakes (Table 2). FFQ were checked by a registered dietician in the presence of the subjects. Body weight without shoes or heavy clothes was recorded at each visit.

Blood sampling

Five fasting blood samples were drawn during the study. All venipunctures were generally carried out by the same person, at the same location, and at the same time of the day (between 07:45 and 11:00 a.m.) on days 14, 21, 32, 37, and 42. Blood samples were taken from a forearm vein using vacutainers under minimal stasis with the subject in a supine position. On the morning of sampling, subjects were not allowed to smoke, to eat or to drink (except water). Volunteers had been fasting since 10 p.m. on the day preceding blood sampling. In addition, subjects were not allowed to drink alcohol 3 days before sampling.

Blood was collected in a 10-mL serum tube (Becton–Dickinson Vacutainer Systems, Breda, The Netherlands) for analysis of lipids (total cholesterol, HDL cholesterol, TAG), apolipoproteins (apoA-I, apoB-100), plant sterols and stanols, insulin, hs-CRP, and indices of liver function. Serum tubes were kept at room temperature after blood sampling. At least 1 h after venipuncture, serum was obtained by centrifuging at 2,000×*g* for 30 min at 4 °C. Serum was aliquoted and thereafter stored at –80 °C. At the same time, 4 mL of blood was also collected in a NaF tube (Becton–Dickinson Vacutainer Systems, Breda, The Netherlands) for analysis of glucose. Plasma was obtained immediately by centrifugation at 2,000×*g* for 30 min at 4 °C. Plasma was then divided into aliquots, snap-frozen, and stored at –80 °C. At days 21 and 42, blood was also collected in a 10-mL EDTA tube (Becton–Dickinson Vacutainer Systems, Breda, The Netherlands) for analysis of the plasma lipoprotein profile (lipoprotein particles).

Table 2 Nutrient composition of the two diets according to food frequency questionnaires

PSE plant stanol esters

^a The difference between the change in the control versus the change in the PSE group was considered statistically significant at *P* < 0.05. Data were analyzed by the independent Student's *t* test

EDTA plasma was obtained directly by centrifugation of the EDTA tube at 2,000×*g* for 30 min at 4 °C. Plasma was then divided into aliquots, snap-frozen, and subsequently stored at −80 °C until analysis.

Side effects

Serum samples from days 21 and 42 were analyzed to determine parameters of liver function (alanine transaminase, aspartate aminotransferase, γ -glutamyl transpeptidase, alkaline phosphatase, and total bilirubin). Measurements were carried out on a Beckman Coulter Synchron LX20 PRO Clinical System (Beckman Coulter Inc., Fullerton, CA, USA). All samples from one subject were analyzed in the same analytical run.

Inflammation

Serum samples from days 21 and 42 were analyzed to determine hs-CRP with a highly sensitive immunoturbidimetric assay (Kamiya Biomedical Company, Seattle, WA, USA). All samples from one subject were analyzed in the same analytical run.

Lipid metabolism

Concentrations of total cholesterol (ABX Diagnostics, Montpellier, France), HDL cholesterol (precipitation method; Roche Diagnostics Corporation, Indianapolis, IN, USA), and TAG corrected for free glycerol (Sigma–Aldrich Chemie, Steinheim, Germany) were analyzed enzymatically in all serum samples. Apolipoprotein concentrations (apoA-I, apoB-100) were analyzed in serum samples from days 14, 21, 37, and 42 using an immunoturbidimetric method (ABX Diagnostics, Montpellier, France). Serum LDL cholesterol concentrations were calculated by the formula of Friedewald et al. [5]. The plasma lipoprotein profile (lipoprotein particles) was analyzed with NMR by Liposcience (NMR LipoProfile test, Liposcience Inc., Raleigh, NC, USA). All samples from one subject were analyzed in the same analytical run.

Glucose metabolism

Plasma samples from days 14, 21, 37, and 42 were analyzed enzymatically to determine glucose concentrations by using the hexokinase method (Roche Diagnostic Systems, Hoffmann-La Roche Ltd., Basel, Switzerland). Insulin was measured using an ELISA method (DRG Instruments GmbH, Germany). The HOMA index, a measure of insulin sensitivity, was calculated [6]. All samples from one subject were analyzed in the same analytical run.

Serum plant sterols and stanols

Plant sterols and stanols (campestanol, sitostanol, campesterol, sitosterol, lathosterol) were determined in serum samples from days 21 and 42 as described [7]. All samples from one subject were analyzed in the same analytical run.

Statistics

The sample size was calculated at 14 subjects per group to provide 80% statistical power to detect a true difference in fasting serum TAG concentrations equal or greater than 0.50 mmol/L between both groups.

Before the statistical analyses were carried out, serum lipid and lipoprotein concentrations from days 14 and 21 and days 37 and 42 were averaged for each subject. Plasma glucose and insulin concentrations from days 14 and 21 and days 37 and 42 were averaged as well. Normality was tested by the Shapiro–Wilk test. Hs-CRP concentrations and indices of liver function were not normally distributed and analyzed accordingly by the non-parametric Mann–Whitney test. Differences in baseline characteristics between the control and intervention groups, and differences in changes in dietary intakes were analyzed by the independent Student's *t* test. Metabolic parameters were analyzed by ANCOVA. To answer the question whether baseline subject characteristics influenced response-to-treatment, the baseline value of that variable was included (as a covariate) into the model together with an interaction term (baseline value \times treatment). The interaction term was only included in the final statistical model if statistically significant. Values are presented as means \pm SD. Pearson correlation coefficients were determined for the relationship between the PSE-induced changes in TAG and the changes in the different lipoprotein particles. Differences were considered statistically significant at a $P < 0.05$. Statistical analyses were performed using SPSS 11.0 (version 11.0.3) for Macintosh OS X (version 10.3.9).

Inspection of the diaries revealed that five subjects had consumed alcohol during the 3-day period before blood sampling. For this reason, their corresponding TAG values for that particular day were omitted from the analyses. In addition, one subject had to be excluded from the statistical analyses, because of alcohol consumption on days 14, 37, and 42. Another subject was excluded, because he confirmed that he had continued his use of lipid-lowering medication during a part of the study, as indicated by a questionnaire filled out at the end of the study. Therefore in the final statistical analyses, the data of 26 subjects were used.

Results

Side effects

Liver function was assessed to monitor side effects. Throughout the study, all variables remained within the normal range for all subjects and no treatment effects were present (data not shown).

Dietary intake and body weight

As calculated from the returned tubs, average daily consumption of margarine on the control and PSE diets was 19.3 ± 1.9 and 19.3 ± 1.8 g, respectively. Average daily plant stanol intake was therefore 2.41 ± 0.23 g. Changes in daily energy intake and nutrient composition of the diets did not differ among the treatment groups (Table 2). Changes in body weight were similar for the control and PSE groups ($P = 0.579$), and were -0.10 ± 0.92 and 0.11 ± 0.74 kg, respectively.

Inflammation

Concentrations of hs-CRP, a marker for inflammation, also did not change during the study. Five subjects had, unrelated to the dietary treatments, on one or more occasion hs-CRP concentrations >9 mg/L [8]. When these subjects were excluded from the analysis, conclusions did not change (data not shown).

Lipid metabolism

Compared to the control diet, consumption of PSE significantly decreased serum total and LDL cholesterol concentrations by 6.7% ($P = 0.015$) and 9.5% ($P = 0.041$), respectively. In addition, serum apoB-100 concentrations were significantly lowered by 7.1% ($P = 0.007$). Changes in serum HDL cholesterol and apoA-1 concentrations did not differ among the diet groups (Table 3). A significant interaction between baseline TAG value and PSE intake was found ($P = 0.009$). PSE consumption lowered TAG concentrations by 11% in subjects with high baseline TAG concentrations (>2.3 mmol/L). For subjects with lower baseline serum TAG concentrations (<2.3 mmol/L), PSE consumption did not affect serum TAG concentrations.

Further, a significant interaction between the baseline number of the total LDL particles (LDL-P) and PSE intake was found ($P = 0.020$; Table 4). Supplementation of PSE lowered the total number of LDL-P, primarily in subjects with elevated baseline values. This decrease was reflected by a reduction of similar magnitude in the number of sdLDL particles, but this decline did not reach statistical significance ($P = 0.150$).

Serum sterols and stanols

Cholesterol-standardized serum sterol and stanol concentrations are presented in Table 5. A significant interaction between baseline concentrations of cholesterol-standardized sitostanol and response-to-treatment was found ($P = 0.011$). Consumption of PSE increased cholesterol-standardized sitostanol concentrations, in particular in subjects

Table 3 Effects of PSE consumption on serum lipids and lipoproteins

PSE diet	1.42 ± 0.19	1.41 ± 0.19			

Values are means ± SD and are expressed in mmol/L, except for apoB-100 and apoA-1 which are expressed in mg/L. Days 14 and 21 were averaged for the end of the run-in period. Days 37 and 42 were averaged for the end of the experimental period

n.a. not applicable, PSE plant stanol esters

^a The difference between the change in the control versus the change in the PSE group was considered statistically significant at $P < 0.05$. Data were analyzed by ANCOVA. To answer the question whether baseline subject characteristics influenced response-to- treatment, the baseline value of the variable of interest was included (as a covariate) into the model together with an interaction term (baseline value × diet). The interaction term was only included in the statistical model if statistically significant. For the control group, diet was coded with a “0” and for the intervention group with a “1”

with elevated baseline values. Additionally, eating the PSE-enriched margarine significantly increased cholesterol-standardized serum campestanol concentrations ($P < 0.001$). Plant stanol concentrations increased in every subject receiving the PSE-enriched margarines, which demonstrates good compliance with the study protocol.

Compared to the control diet, cholesterol-standardized serum sitosterol ($P = 0.008$) and campesterol ($P = 0.020$) concentrations significantly decreased after PSE consumption, indicating decreased intestinal cholesterol absorption [9]. A significant interaction between baseline cholesterol-standardized lathosterol concentrations and plant stanol intake was found ($P = 0.043$). Daily intake of PSE increased this marker for endogenous cholesterol synthesis, especially in subjects with elevated baseline values.

Glucose metabolism

Changes in plasma glucose and insulin concentrations, and HOMA index did not differ among the diet groups (data not shown).

Correlations

Significant correlations were found between PSE-induced changes in concentrations of TAG and large VLDL particles ($r = 0.713$, $P < 0.001$), large LDL-P ($r = -0.575$, $P = 0.002$), and sdLDL particles ($r = 0.438$, $P = 0.025$). Further, PSE-induced changes in TAG significantly correlated with medium HDL particle concentrations ($r = 0.394$, $P = 0.047$). Regarding the remaining lipoprotein particles, no significant correlations were found with the PSE-induced changes in TAG (data not shown).

Discussion

This study was specifically designed to examine the effects of PSE on serum TAG concentrations in subjects with elevated serum concentrations of TAG. In line with our recent meta-analysis [2], a significant interaction between baseline TAG concentrations and PSE intake was found. Also, we have recently shown that plant stanols lowered

serum TAG concentrations in subjects with the metabolic syndrome [10]. Based on the meta-analysis [2], the expected decrease in serum TAG concentrations was on average 0.09 mmol/L for “borderline high” baseline TAG

concentrations (1.7–2.2 mmol/L; [3]) and a daily plant stanol intake of 2.5 g. At a similar intake, the expected decline in serum TAG concentrations at “high” baseline TAG values (2.3–4.0 mmol/L; [3]), was on average

n.a. not applicable, PSE plant stanol esters

^a The difference between the change in the control versus the change in the PSE group was considered statistically significant at $P < 0.05$. Data were analyzed by ANCOVA. To answer the question to whether baseline subject characteristics influenced response-to-treatment, the baseline value of the variable of interest was included (as a covariate) into the model together with an interaction term (baseline value × diet). The interaction term was only included in the statistical model if statistically significant. For the control group, diet was coded with a “0” and for the intervention group with a “1”

0.19 mmol/L. Compared to these predicted effects, our results are slightly different since a reduction in serum TAG concentrations was hardly present at baseline TAG values <2.3 mmol/L. In contrast, at “high” baseline TAG concentration, the average decrease was larger than anticipated, i.e. 0.35 mmol/L. It is possible that the estimates from the meta-analysis for subjects selected on disturbances in TAG metabolism are less precise, because most of the subjects in the meta-analysis had serum TAG concentrations <2.0 mmol/L.

As TAG in the fasted state are mainly transported by VLDL particles, it can be suggested that VLDL metabolism is changed after consumption of PSE. However, plasma concentrations of VLDL particles (large, medium, small) were not significantly altered after the PSE diet. TAG-rich lipoproteins (TRL), such as chylomicrons, VLDL (small, large), and TRL remnants play a significant role in the pathogenesis of atherosclerosis, the main cause of CVD [1]. It has been proposed that the potential atherogenicity of the large VLDL particles resides in their susceptibility to oxidation, which promotes foam cell formation by a mechanism analogous to that of oxidized LDL [11]. In support, however, of an effect on VLDL metabolism, a significant correlation was found between the PSE-induced changes in TAG and large VLDL particle

concentrations. Regarding medium and small VLDL particles, no significant correlations were found between the change in these particle numbers and the change in TAG concentrations. Possibly, the variation in response of the different VLDL particles was too large to reach statistically significant dietary effects.

Daily consumption of 2.4 g plant stanols also significantly decreased serum LDL cholesterol concentrations by 9.5%. This change is consistent with the estimated mean change in LDL cholesterol concentrations of –8.9% for daily intakes of 2.0 to 2.4 g plant sterols or stanols [12]. Serum apoB-100 concentrations were lowered by 7.1%, which is in the same range as the reductions for total and LDL cholesterol. As expected, no effects on serum HDL cholesterol and apoA-1 concentrations were found. Plant sterols and stanols lower serum LDL cholesterol by interfering with the absorption of cholesterol in the intestine [13]. As a consequence, endogenous cholesterol synthesis and LDL receptor-mediated cholesterol uptake will increase, which will lead to decreased serum LDL cholesterol [14]. In support of this working mechanism and in agreement with previous studies [15, 16], consumption of PSE significantly lowered concentrations of markers reflecting cholesterol absorption and increased concentrations of a marker reflecting endogenous cholesterol

synthesis. In our study, the serum LDL cholesterol-lowering effect was mainly related to a decrease (−11.2%) in the atherogenic sdLDL particles, but this effect was not statistically significant. A significant positive correlation however was found between the plant stanol-induced changes in TAG and sdLDL particle concentrations. sdLDL particles are particularly considered to be atherogenic, since these particles are retained preferentially by the artery wall and are readily oxidized [1, 17]. Generation of small, dense LDL occurs by intravascular lipoprotein remodeling as a result of metabolic disturbances, which are frequently present in patients with DM2 and the metabolic syndrome [17]. The common underlying predisposing factor may be the development of a fatty liver resulting in hypertriglyceridemia, due to in particular large VLDL particles. Large VLDL particles are a precursor for the synthesis of sdLDL by LPL mediated processes [18].

Hypertriglyceridemia is also associated with an overproduction of other cardiovascular risk factors, such as glucose, hs-CRP, plasminogen activator inhibitor-1 (PAI-1), fibrinogen, and coagulation factors [1]. We therefore looked into the effects of the PSE diet on glucose metabolism in our hypertriglyceridemic study population. However, consumption of PSE did not favorably alter glucose and insulin concentrations, and consequently the HOMA index (insulin resistance measurement) was also unchanged. These effects are in line with earlier findings in healthy subjects, where glucose concentrations were not changed after supplementation of a reduced-calorie orange juice beverage enriched with plant sterols (2 g/day) [19]. In addition, daily consumption of plant sterol ester (1.9 g plant sterols) and PSE (2.0 g plant stanols)-enriched spreads for 10 weeks did not change plasma glucose and serum insulin concentrations in hypercholesterolemic subjects [20].

There are some limitations of this study. First, we did not measure effects on postprandial TAG concentrations. As PSE consumption interferes with intestinal cholesterol absorption, it can be suggested that effects on postprandial lipid metabolism are even more pronounced. Studies on the postprandial effects of phytosterols are however scarce. In healthy subjects, 2-week PSE consumption (3 g/day plant stanols) only tended to diminish postprandial TAG concentrations [21]. In addition, the use of PSE (3 g/day plant stanols)-enriched margarine did not decrease postprandial triglyceridemia in statin patients [22]. Another limitation is the generalization of our findings to different etiologies of hypertriglyceridemia. Like hypercholesterolemia, hypertriglyceridemia has a broad genetic base and cannot be extrapolated depending on the mechanism.

To summarize, consumption of PSE significantly lowered serum LDL cholesterol in subjects with elevated TAG concentrations, primarily by a decrease in the atherogenic

sdLDL particles. The PSE-induced TAG-lowering in these subjects was related to their baseline TAG concentrations, and was particularly evident in subjects with high serum TAG concentrations. Taken together, these findings show that functional foods enriched with PSE are not only of benefit to lower increased serum LDL cholesterol concentrations, but also those of TAG in subjects with overt hypertriglyceridemia.

Acknowledgements We thank the study participants for their cooperation and enthusiasm. We also thank the technical and dietary staff from our department for their support. The study was supported financially by the Raisio Group Finland.

makes it possible to transform such molecules into alcohol. MP is used in China in the treatment of lipid disorders. In Western countries, the use is mainly limited to the pigmentation of meat, fish, cheese, alcoholic drinks and cured meats [1–4]. The hypocholesterolemic efficacy of MP was evaluated through experimental [5–8] and clinical [9–13] trials. By acting through the direct inhibition of 3-hydroxy-3-methylglutaryl coenzymeA reductase, MP could partially have the same effect as statins [14]. In order to enhance agent safety by giving the lowest dose without losing its hypocholesterolemic effect, MP was combined with Linear aliphatic alcohols (LAAs). LAAs show a synergic effect with MP as they induce the down-regulation of 3-hydroxy-3-methylglutaryl coenzymeA reductase [15]. MP and LAAs seem to have lowering effect on cholesterol, but not on TG. Niacin (N) was added because of its well-known hypotriglyceridemic effect. If given in high doses, N also induces an increase in HDLC [16, 17]. In this study Dif1stat[®] effects have been evaluated on a long-term basis in patients with primary moderate hypercholesterolemia.

Aim of the Study

Experimental Design

The target of this randomized trial for parallel groups was to evaluate the efficacy of adding MP–LAAs–N (Dif1stat[®]), 1 capsule/day [Composition: MP, dry extract, 200 mg (corresponding to 3 mg of mevinolin) + LAAs, 10 mg + N, 27 mg] to the treatment of patients with primary moderate hypercholesterolemia (lipoprotein phenotype IIa). One group (A) was treated with hypolipidemic diet according to adult treatment panel III (ATPIII) criteria [18]. In the second group (B) diet was supplemented with Dif1stat[®]. The study lasted 8 months.

Patients

The trial included 240 patients randomly assigned into two groups. The first group (group A # 130) was treated with diet only. In the second group (group B # 110) a capsule of Dif1stat[®] a day was added to the diet (Fig. 1). The average patient age was 56.5 ± 9 years. The average BMI was 22.3 ± 8.5 kg/cm² (Table 1). All the patients were under primary prevention with an overall coronary risk lower than 20% according to the Framingham algorithm [19]. All the patients were given an hypocholesterolemic diet in accordance with ATPIII guidelines (30% of total calories represented by lipids, less than 10% of them being saturated fats, 19% of proteins, 52% of carbohydrates for a

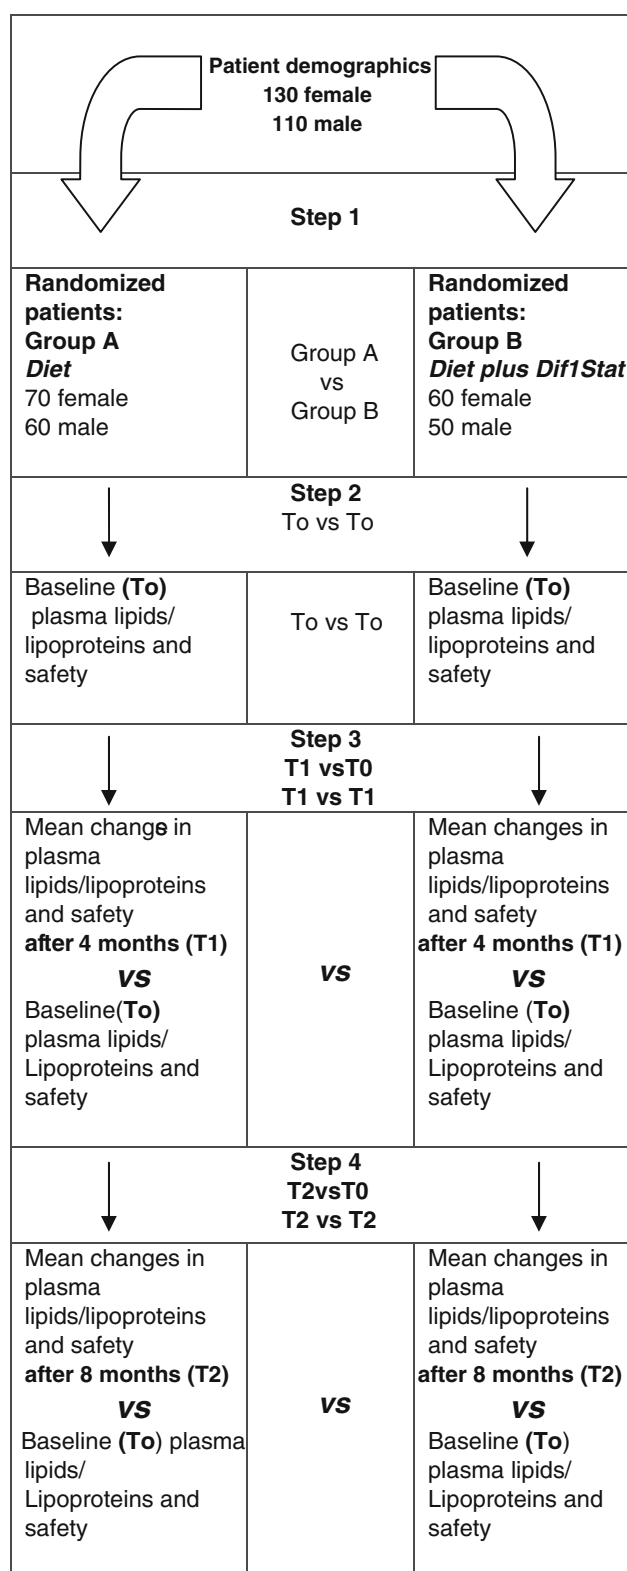

Fig. 1 Study design and schedule

total amount of 1,500/1,800 Kcal a day). The compliance to the diet was assessed every 2 months by two dieticians by way of 24-h dietary recall.

Table 1 Patient demographics

NS not significant

Exclusion Criteria

The subjects involved in the trial did not show clinical and hematological evidence of hepatic, kidney or thyroid disorders. There was no clinical evidence of cardiovascular disease, hypertension, diabetes or obesity. The patients were not taking lipid-lowering agents or drugs affecting lipid metabolism such as: β -blockers, diuretics, and corticosteroids.

Laboratory Methods

Clinical laboratory measurements were performed in a certified central university hospital laboratory. Blood samples for lipid measurements were taken from peripheral veins after overnight fasting (12 h). Plasma TC and TG levels were determined by enzyme assay (Cholesterol and Triglycerides Tests TM Instrumentation Laboratory Company-Lexington, MA, USA). The plasma HDLC level was determined with a combined immune and enzymatic assay (HDL Cholesterol Test TM Instrumentation Laboratory Company-Lexington, MA, USA). The plasma LDLC level was calculated according to the formula of Friedewald: $LDLC = TC - (HDLC + TG/5)$ [20]. The plasma non-HDLC level was calculated according to the following formula: $non-HDLC = TC - HDLC$. Laboratory safety parameters were determined by usual enzymatic and chemical methods. The blood cell count was determined with a Beckman Coulter ACT Diff. (Beckman Coulter, S.p.A, Milan, Italy-EU).

Ethics

Informed consent was obtained from all patients, according to the recommendations of the declaration of Helsinki guiding physicians in biomedical research involving human subjects. Adopted by the 18th World Medical Assembly, Helsinki, Finland, June 1964, amended by the 29th World Medical Assembly, Tokyo, Japan, October 1975, the 35th World Medical Assembly, Venice, Italy,

October 1983, and the 41st World Medical Assembly, Hong Kong, September 1989. The work was approved by the ethical panel of our institution.

Statistical Analysis

Statistical analysis was performed according to parametric tests, depending on parameters under evaluation. All results are expressed as means \pm SD. Within group and between groups differences were tested for statistical significance using Student's *t* test for paired data. The percent variation ($\Delta\%$) of mean lipid and lipoprotein levels in plasma was also estimated. Patients were randomized according to a list created by a random number generator included in the statistical package (SPSS version 15.0—Statistical Product and Services Solutions, SPSS Inc., Chicago, IL, USA).

Results

Plasma TC, LDLC, HDLC, TG, non-HDLC, ALT, AST, γ GT, CK, creatinine, urea and the fibrinogen profile at T0, are shown in Table 2. Between groups, statistically significant differences at baseline were not observed. Neither significant changes in lipid nor lipoprotein levels in plasma were observed after 4 months (T1) in group A. After 8 months (T2), significant reductions in plasma TC ($\Delta\%$: -22), LDLC ($\Delta\%$: -30) and non-HDLC ($\Delta\%$: -27) ($P \leq 0.001$) levels were observed in the same group; TG ($\Delta\%$: -8.4) and HDLC ($\Delta\%$: -5.5) were only slightly lower (Table 3; Fig. 2). Table 3 and Fig. 3 show the results obtained after Dif1stat[®] addition to the diet in group B. After 4 months (T1), the addition of Dif1stat[®] to the diet had induced a significant reduction in TC ($\Delta\%$: -21.3), LDLC ($\Delta\%$: -29) and non-HDLC ($\Delta\%$: -26) ($P \leq 0.001$). Significant differences in TG ($\Delta\%$: -6) and HDLC ($\Delta\%$: -2) were not observed. After 8 months (T2), the change of TC ($\Delta\%$: -29.4), LDLC ($\Delta\%$: -38), non-HDLC ($\Delta\%$: -37%) and TG ($\Delta\%$: -33%) in plasma showed a further increase ($P \leq 0.001$). HDLC was only slightly increased

Differences are calculated as follows diet (group A): T0 versus T1; T0 versus T2. Diet plus Dif 1Stat (group B): T0 versus T1; T0 versus T2

($\Delta\%$: +2) when compared to T0. The variation of safety parameters in plasma in both groups is shown in Table 4. A change in plasma profile of AST ($\Delta\%$: -29.6; $\Delta\%$: -59) and γ GT ($\Delta\%$: 25; $\Delta\%$: 33) was observed in group A after 4 (T1), and 8 (T2) months of treatment, respectively. The above mentioned variations were statistically significant when compared to the basal values ($P \leq 0.001$). Statistically significant reductions of ALT ($\Delta\%$: -21), AST ($\Delta\%$: 43) and γ GT ($\Delta\%$: -33%) ($P \leq 0.001$) levels were observed also in group B, but only after 8 months of treatment (T2). The change of lipid and lipoprotein profile between groups (A vs. B) after 4 (T1) and 8 (T2) months,

is shown in Table 5, and Fig. 4. After 8 months (T2), the addition of Dif1stat[®] to the diet in group B had induced a significant reduction in TG: (B) $\Delta\%$ -33 versus (A) $\Delta\%$ -8.4 ($P \leq 0.001$). Side effects were not observed in either of the groups.

Discussion

Available studies have highlighted that statins have a good lowering effect on C-reactive protein but not on lipoprotein (a) [Lp(a)] [21–24]. The extract of MP seems to be able to

Comparison between groups (Diet vs. Diet + Dif 1Stat)

Differences are calculated as follows Diet (group A) versus Diet plus Dif 1Stat (group B): T1 versus T1; T2 versus T2

Fig. 4 Mean change in plasma (*TC*), triglycerides (*TG*), low-density lipoprotein-cholesterol (*LDLC*), high-density lipoprotein-cholesterol (*HDLC*) and non-HDLC levels, in patients with mild hypercholesterolemia after 8 months (*T2*) of treatment with Diet and Diet plus Dif 1Stat

reduce the level of Lp(a) [25]. However, the effects of Dif1stat® on the above mentioned inflammatory and lipid parameters were not taken into account in our study. A trial with 60 patients affected by coronary heart disease assigned to two groups (extract of MP 1,200 mg/day vs. placebo for 6 weeks) showed that the extract of MP can significantly inhibit the postprandial increase of TG in blood [26]. The effect of MP on postprandial TG is more evident than the presence of LAAs could suggest. MP seems to be able to reduce TG by 32, 38, and 43%, after 2, 4, and 6 h, respectively. Some authors suggested that the effect of MP is not related only to the presence of LAAs but probably to a synergy between the various therapeutic agents. Some studies have demonstrated that the combination of MP, LAAs and N induces a significant decrease of TC, LDLC and TG. Castaño et al. [10] have carried out a randomized, double blind, controlled trial on patients affected by hypercholesterolemia with lipoprotein phenotype IIa. Two different doses of policosanol were given: 20 mg/day (# 29 patients) and 40 mg/day (# 30 patients). After 24 weeks, the two groups showed a reduction in LDLC of 27.1 and 28.1%, respectively. HDLC showed a

statistically significant increase of 17.6 and 17.0%, respectively. The LDLC/HDLC ratio changed by 37.2 and 36.5%. Lastly, TG decreased by 12.7 and 15.6%, respectively. The authors concluded that their trial failed to highlight any difference possibly related to the dosages, at least for the cholesterol-lowering effect of policosanol. In other words, the 40 mg/day dose given, did not demonstrate any further significant cholesterol-lowering effect. In the trial carried out by Cicero et al. [12] 111 patients with low cardiovascular risk profile (<20% acc. to the Framingham algorithm) treated with Dif1stat, were compared to 20 patients taking pravastatin at low doses. The first group showed a significant reduction in TC, LDLC and TG, without side effects. In particular, the reduction of LDLC was 20%; the same observed in the group with moderate hypercholesterolemia treated with pravastatin. An interesting meta-analysis by Chen JT highlighted the efficacy and safety of vegetable sterols and stanols versus policosanol in terms of taking advantage of both lipid-lowering and anti-atherogenic effects [11]. The impact on LDLC was evaluated as a primary endpoint in 4,596 patients belonging to 52 randomized and controlled trials. The weighed average of the percentage differences underlined the following variations: -11% for the vegetable sterols and stanols given at a dosage of 3.4 g/day (range 2–9 g/day; # 893 patients) in 23 trials, versus -23.7% for policosanol given at a dosage of 12 mg/day (range 5–40 mg/day; # 1,528 patients). The differences in both groups versus the placebo group were statistically significant. The absolute decrease in LDLC was higher in the group treated with policosanol: -24 versus -10% ($P \leq 0.0001$). The activity of policosanol was also more pronounced on TC, HDLC and TG, inducing a significant improvement in the LDL/HDL ratio. The authors concluded that not only policosanol, but also vegetable sterols and stanols were effective and safe. However, policosanol showed a greater LDLC-lowering effect. A multicenter, randomized, double-blind controlled trial versus placebo

carried out by Berthold HK on 143 patients with hypercholesterolemia, was reported in 2006 [13]. The patients had levels of LDLC \geq 150 mg/dL with no one or only 1 cardiovascular risk factor, or with a documented coronary heart disease, or with baseline levels of LDLC between 150 and 189 mg/dL and two or more cardiovascular risk factors. The patients were treated with policosanol at dosages of up to 80 mg/day. They were assigned to five groups, and the figures analyzed according to the intention-to-treat statistical model. The study failed to demonstrate a decrease of LDLC greater than 10% compared to the values at the baseline. Moreover, TC, HDLC, TG, Lp(a) and the LDLC/HDLC ratio did not demonstrate statistically significant change. The authors concluded that policosanol given at a usual or higher dose, failed to show any substantial effect in terms of reduction of lipids and lipoproteins in plasma compared to the patients on placebo. In our study, the administration of Diflstat[®] with a controlled diet induced a significant decrease in plasma of TC, LDLC, non-HDL and TG, in patients with moderate hypercholesterolemia compared to those treated only with the diet. Interestingly, the diet had positive effects on both groups (A and B). The result regarding the reduction in cholesterolemia in group A after 4 months, goes beyond every possible expectation considering that the control group underwent only dietetic treatment. Nevertheless, it is necessary to observe that the patients were extremely motivated by the investigators and the dieticians who administered the 24-h dietary recall, strongly stimulating the connection with diet. There was much insistence on the modification of life-style and dietary habits. A preventive operation on the consumption of alcoholic beverages was also carried out. The above mentioned recommendations and a hypocaloric diet—1,500/1,800 kcal/day—containing cholesterol equal to 200 mg/day, achieved not only the reduction in the plasmatic concentration of cholesterolemia, but also a discreet ponderal reduction, although not statistically significant. The reduction in weight also contributed to the hypolipidemic effects of the diet. The patients did not have any input concerning the consumption of functional foods, neither from doctors nor dieticians. Moreover, the good result obtained is likely attributed to the detailed operation put into direct action to modify life-style and above all, dietary habits. As reasonably expected, Diflstat[®] had better results in terms of reduction of lipids and lipoproteins, and particularly of TG, when both groups were compared after 8 months of treatment. Diflstat[®], in association with a suitable diet, was well tolerated in the long-term and induced an anti-atherogenic plasma profile of lipids and lipoproteins in patients with moderate hyperlipidemia.

It is to be emphasized that up to now, only one patient treated with cyclosporine after a kidney transplantation

developed a modest asymptomatic rhabdomyolysis while taking MP [27]. However, it is well known that cyclosporine enhances the cytotoxicity of many drugs by strongly inhibiting the liver CYP3A4 enzymatic system. It will be interesting to study the effect of Diflstat[®] with a longer administration (>1–2 years) to definitely assess if it may be considered as a valuable lipid-lowering agent for primary prevention of cardiovascular risk, or if it may be preferably used as a therapeutic alternative for statin-intolerant patients with moderate hypercholesterolemia, [28], or not.

double-blind placebo-controlled intervention study in normolipidemic subjects in which no effects of plant stanol esters consumption on serum TAG concentrations were found [6].

Methods

Study 1: Metabolic Syndrome Subjects, Diets and Design

Subject characteristics of this study have been reported before [5]. In short, we included 18 subjects, who had the metabolic syndrome according to the ATP III criteria [7]. All subjects gave their written informed consent before the start of the study. The study was approved by the medical ethical committee of Maastricht University. During a 3-week run-in period, all subjects were instructed to consume with the meals (lunch or diner, but not breakfast) a low-fat yogurt drink (Emmi, Lucerne, Swiss) containing no plant stanol esters. At the beginning of the experimental period, subjects were randomly allocated to one of the two treatment groups, stratified for gender and age. Baseline characteristics of the groups are listed in Table 1. The control group continued to use the placebo yogurt drink for another 8 weeks, while a second group used the same low-fat yogurt drink to which a vegetable oil based stanol ester mixture was added. Daily intake of plant stanols was 2 g provided as a one-shot yogurt drink. All products were coded with a coloured label to blind the subjects and the investigators.

Study 2: Normolipidemic Subjects, Diets and Design

As described earlier [6], 112 non-hypercholesterolemic apparently healthy subjects participated in a double-blind placebo-controlled trial in which we compared the effects of vegetable oil based and pine-wood based plant stanol esters versus placebo. In brief, during a 4-week run-in period subjects were instructed to use margarines and shortenings with breakfast, lunch and for the preparation of dinner. At the beginning of the experimental period, subjects were randomly allocated to one of the three treatment groups, stratified for gender and age. Since there were no differences between the two plant stanol ester sources in their effects on cholesterol metabolism [6, 8, 9], the vegetable-oil based and pine-wood based groups were combined into one plant stanol ester group for further analysis. For the current analysis, we randomly selected 25 subjects from the control and 25 subjects from each plant stanol ester group, hereby taking gender distributions into account. Baseline characteristics of the control versus the intervention groups are listed in Table 1. The control group continued to use the placebo margarines and shortenings for another 8 weeks, while a second group used the same margarines and shortenings to which the plant stanol ester mixtures were added. Total daily plant stanol intake was 3.8–4.1 g/day, which is higher than the currently recommended intake. All products were coded with a coloured label to blind the subjects and the investigators. As in study 1, all subjects gave their written informed consent before the start of the study, and the study was approved by the medical ethical committee of Maastricht University.

Table 1 Baseline population characteristics of metabolic syndrome (study 1) and normolipidemic (study 2) subjects

	Metabolic syndrome subjects		Normolipidemic subjects	
	Controls (<i>N</i> = 9)	Plant stanols (<i>N</i> = 9)	Controls (<i>N</i> = 25)	Plant stanols (<i>N</i> = 50)
Age (years)	60 ± 7	60 ± 4	35 ± 17	34 ± 15
BMI (kg/m ²)	30.2 ± 1.9	28.1 ± 2.6	23.0 ± 3.2	22.9 ± 3.0
Blood pressure (mm Hg)				
Systolic BP	142 ± 14	138 ± 11	119 ± 12	123 ± 12
Diastolic BP	92 ± 10	94 ± 8	74 ± 8	75 ± 8
Serum lipid (mmol/L)				
Total cholesterol	6.50 ± 1.59	6.29 ± 1.19	4.81 ± 0.79	5.02 ± 0.69
Non-HDL cholesterol	5.47 ± 1.29	5.32 ± 1.29	–	–
LDL cholesterol	–	–	2.82 ± 0.73	2.89 ± 0.71
HDL cholesterol	1.03 ± 0.26	0.97 ± 0.15	1.61 ± 0.32	1.58 ± 0.39
Triacylglycerol	2.24 ± 1.26	2.21 ± 0.98	0.83 ± 0.34	1.02 ± 0.61

Values are means ± SD. To convert values for total, HDL and LDL cholesterol to mg/dL × 38.67. To convert values for triacylglycerols to mg/dL × 88.54

Blood Sampling and Analyses

Blood Sampling

In both studies, blood samples obtained at the end of the run-in period and at the end of the 8 weeks experimental periods, were used for further analysis. All blood samples were taken after an overnight fast; i.e., subjects were not allowed to eat and drink (except water) after 10 p.m. in the evening preceding blood sampling, to drink alcohol the day preceding blood sampling, or to smoke on the morning of blood sampling. Blood was sampled into clotting tubes (CORVAC, integrated serum separator tube, Sherwood Medical Company, St. Louis, USA). Serum was obtained by centrifugation of the clotting tubes at $2,000\times g$ for 30 min at 4 °C, minimally 1 h after venipuncture. All serum samples were immediately stored in small portions, snap-frozen, and stored at -80 °C until further analysis.

Lipids, Lipoproteins and Lipoprotein Profiles

Serum lipids and lipoproteins were analysed as described [5]. All samples from one subject were analysed within the same run at the end of the study. In study 1, we reported serum non-HDL cholesterol concentrations instead of serum LDL cholesterol concentrations because we could not use the Friedewald equation to calculate serum LDL cholesterol, because of the increased serum TAG concentrations of our population. Lipoprotein profiles at the end of the run-in period and at the end of the 8 week intervention period were evaluated by NMR (Liposcience, Raleigh, USA). Before NMR analysis, two blood samples at the end of the run-in period and at the end of the experimental period (at least three and maximally 7 days between both blood sampling moments) were pooled to minimise the noise due to normal day-to-day variation in lipoprotein particle concentrations. Although the two intervention studies were performed 8 years apart, all NMR analysis were performed in samples stored at -80 °C in retrospect for both studies at the same time.

Statistics

Changes for all parameters were calculated for each subject as the difference between values of the intervention period and run-in periods and reported as means \pm SD. The differences in changes between the groups were tested with an unpaired *t* test in which a $P < 0.05$ was considered significant. All statistical analyses were performed with Statview 4.5.

Results and Discussion

Serum Lipid and Lipoproteins

In both studies, plant stanol ester consumption improved serum lipoprotein profiles. Compared with the control group, consumption of plant stanol esters for 8 weeks lowered serum non-HDL cholesterol concentrations by 0.73 ± 0.52 mmol/L or 13.8% ($P = 0.012$) in the metabolic syndrome subjects. In addition, plant stanol esters lowered TAG concentrations by 0.23 ± 0.36 mmol/L or 27.5% ($P = 0.044$). No effects on serum HDL cholesterol concentrations were found.

In normolipidemic subjects, plant stanol esters also significantly lowered serum LDL cholesterol concentrations. Compared with the control group, this decrease was 0.44 ± 0.29 mmol/L or 13.7% ($P < 0.001$) for the plant stanol ester group. There were no effects on serum TAG and HDL cholesterol concentrations. The finding that serum TAG concentrations were unchanged in this study is in line with all other studies in normolipidemic subjects [1].

We now aim to find an explanation for the observed effects on serum TAG concentrations and here postulate the hypothesis that the TAG lowering effect of plant stanol esters originates from a reduced hepatic production of large TAG-rich VLDL-1 particles. We had earlier excluded that the effects of plant stanol ester consumption on serum TAG concentrations could be explained by changes in serum apoCII and apoCIII concentrations, which are both determinants of lipoprotein lipase (LPL) activity [5]. In line with the unaffected HDL cholesterol concentrations, we have also shown that CETP activity was not changed [5]. The hypothesis postulating effects on hepatic VLDL-1 production is based on the present finding that in metabolic syndrome subjects plant stanol esters significantly reduced concentrations of large (>60 nm) and medium (35–60 nm) VLDL particles, as compared to the control group. We are aware of the fact that we did not measure hepatic VLDL particle production and VLDL kinetics (i.e., referring to LPL activity) by using stable isotope approaches. Therefore it remains speculative whether the suggested hypothetical mechanism is correct. No effects were found on small (27–35 nm) VLDL particles or any of the other lipoprotein fractions (Table 2). The fact that there was no change in the number of small sized LDL particles was somewhat unexpected, since the large VLDL-1 particles—of which the numbers were strongly reduced after plant stanol ester consumption—are precursors for the smaller denser LDL particles. This might also imply that the effects on VLDL-1 concentrations are not caused by a reduced hepatic VLDL-1 production.

In the normolipidemic subjects we also found a reduction in the number of large VLDL-1 particles (Table 2) in serum from the plant stanol ester group, as compared to controls. The reduction was however, smaller as compared to the reduction observed in subjects with the metabolic syndrome, which is in line with the lack of effects on serum TAG concentrations. There are however, substantial differences between both studies (i.e., plant stanol intake, age,

etc.) not allowing a direct comparison between the outcomes from both studies.

Assuming that plant stanol esters lower hepatic VLDL-1 production in humans, the mechanism underlying this effect is still open. In this respect, Ikeda et al. [11] have recently shown that campest-5-en-3-one (campestenone), an oxidised derivative of campesterol, was a potent hepatic PPARα activator in mice. Consumption of this plant

sterol derivative resulted in a lower concentration of TAG in serum and liver. These changes in mice fit very well with our suggestion of a lowered hepatic large TAG-rich VLDL particle production after plant stanol ester consumption. However, in our studies we provided plant stanol esters and not plant sterol esters. This introduces the question whether intermediates with similar effects can be formed from plant stanol esters *in vivo* in humans.

In apoE*3-Leiden mice, Volger et al. [10] have shown that plant stanol ester consumption lowered hepatic TAG (−38%), free cholesterol (−31%), and cholesterol ester (−62%) content. Since hepatic TAG concentrations are thought to be a driving force behind large sized VLDL particle production—at least in humans—[12], the observed reduction in hepatic TAG in these mice suggest that the number of larger sized VLDL particles was probably lowered. However, only cholesterol incorporation into nascent VLDL particles was lowered, while total VLDL-TAG and total VLDL-apoB production rates were surprisingly unchanged. Unfortunately, VLDL production rates of the different VLDL-particle subpopulations were not measured.

This data also introduces a final discussion point: the functional consequences of a lowered VLDL-1 production. In humans, it is generally recognised that the amount of fat in the liver is an important factor determining hepatic VLDL-1 production [12]. Therefore, the lowered hepatic VLDL-1 production may indicate a reduced ectopic fat accumulation in the liver. If this is indeed true, plant stanol ester consumption may be even more beneficial than currently anticipated. This latter assumption warrants, however, further study.

In conclusion, we have earlier reported that plant stanol esters not only lower serum LDL cholesterol concentrations, but also serum TAG concentrations in subjects with elevated TAG concentrations at baseline. We here present data supporting the hypothesis that the effect is caused by a reduction in the hepatic production of large TAG-rich VLDL-1 particles. Effects are most pronounced in metabolic syndrome subjects, resulting in subsequent reductions in serum TAG concentrations.

Acknowledgments We are indebted to the members of our dietary and technical staff, and to all volunteers for their cooperation and interest. The studies were sponsored by RAISIO Life Sciences, Raisio, Finland (study 2), and McNeil, UK (study 1).

As part of a program aimed at the search for new marine natural products [14], including minor ones, we have continued to study the ethanol extract of lyophilized sponge *Rhizochalina incrustata*, collected near the northern point of the island of Madagascar [1, 3, 4] in the hope of finding new trace bipolar metabolites whose structures may be of interest for illuminating biogenetic aspects of this intriguing group of lipids.

Herein, we wish to report isorhizochalin (**1**), a new two-headed sphingolipid from *R. incrustata*, which is a minor C-2 epimer of rhizochalin, the major component of the sponge. The structure elucidation of isorhizochalin including absolute configuration is the subject of this paper.

Experimental Procedure

General Experimental Procedures

Optical rotations were measured using a Perkin–Elmer 343 polarimeter. CD spectra were recorded on a Jasco J810 spectrometer using quartz cells (0.2-mm pathlength) at a scan rate of 50 nm/s. The ^1H - and ^{13}C -NMR spectra were recorded on a Bruker DPX-500 spectrometer at 500 and 125 MHz, respectively, with Me_4Si as an internal standard. ESI mass spectra were obtained on an Agilent 6510 Q-TOF LC–MS spectrometer by direct infusion in MeOH containing HCOOH (0.1%). MALDI-TOF mass spectra were obtained on a Bruker Biflex III laser desorption spectrometer coupled with delayed extraction using an N_2 laser (λ 337 nm) on 2,5-dihydroxybenzoic acid (DHB) and α -cyano-4-hydroxycinnamic acid (CCA) as matrix. Low-pressure column liquid chromatography was performed using Polichrome I (powder Teflon[®], Biolar, Latvia). Low-pressure column liquid chromatography was performed using silica gel L (50/160 μm ; Sorbopolymer, Russia). Silica gel plates, 4.5 \times 6.0 cm (5–17 μm ; Sorbfil, Russia), were used for thin layer chromatography. HPLC was performed using an Agilent Series 1100 Instrument equipped with the differential refractometer RID-DE14901810.

Animal Material

The sponge *Rhizochalina incrustata* (phylum Porifera, class Demospongiae, subclass Ceratinomorpha, order Haplosclerida, family Phloeodictyidiidae) was collected using SCUBA (depth 3–5 m) during the 3-d scientific cruise on-board R/V “Akademik Oparin”. A voucher specimen is kept under the registration number PIBOC #03-98 in the marine invertebrate collection of the Pacific Institute of Bioorganic Chemistry (Vladivostok, Russia).

Extraction and Isolation

The fresh collection of the sponge *R. incrustata* was immediately lyophilized and kept at -20°C . The lyophilized material (300 g) was extracted with EtOH (200 ml \times 3). The combined EtOH extract was concentrated under reduced pressure and redissolved in EtOH– H_2O (9:1). This solution was partitioned three times with equal volumes of *n*-hexane. The aqueous EtOH layer was evaporated in vacuo at 50°C to give brown oil (44.2 g) which was separated over a Polichrome I by elution with gradient of $\text{H}_2\text{O} \rightarrow \text{EtOH}$. The two-headed sphingolipid fraction (ninhydrin positive) was eluted with 40% EtOH.

Peracetylation

A portion of the two-headed sphingolipid fraction, obtained by chromatographic separation over Polichrome I (182.0 mg) was dissolved in pyridine (1.0 ml) and acetic anhydride (1.0 ml) and allowed to stand at 25°C for 18 h. Removal of the volatile materials give a residue with peracetates of rhizochalin and isorhizochalin (**1**) (191.0 mg). The latter was separated by preparative HPLC (YMC-Pack ODS-A column, 80% aqueous EtOH) followed by rechromatography on an YMC-Pack ODS-A HPLC column (75% aqueous EtOH) to yield rhizochalin peracetate (90 mg, 0.02% dry weight) and isorhizochalin peracetate (**1a**) (2.0 mg, 0.0005% dry weight).

Isorhizochalin Peracetate

Colorless solid; $[\alpha]_{\text{D}} +6.7$ (c 0.33, CHCl_3); HRMS-ESI: m/z $[\text{M} + \text{H}^+]$ calcd for $\text{C}_{48}\text{H}_{83}\text{N}_2\text{O}_{15}$: 927.5788; found: 927.5779; $[\text{M} + \text{Na}^+]$ calcd for $\text{C}_{48}\text{H}_{82}\text{N}_2\text{O}_{15}\text{Na}$: 949.5607; found: 949.5614. MALDI-TOF m/z 949 $[\text{M} + \text{Na}^+]$; NMR (CDCl_3 , see Table 1).

Methanolysis of Isorhizochalin Peracetate

A solution of **1a** (1.8 mg) in mixture of 5% HCl in MeOH (0.5 ml) was heated in a sealed vial at 75°C for 24 h. The mixture was cooled, concentrated, and subjected to chromatography on silica gel column to provide two fractions.

Fraction 1, eluted with CHCl_3 –MeOH (4:1) and gave an anomeric mixture of D-1-*O*-methyl galactopyranosides (0.4 mg) HRMS-ESI: m/z $[\text{M} + \text{H}^+]$ calcd for $\text{C}_7\text{H}_{15}\text{O}_6$: 195.0863; found: 195.0987; calcd for $\text{C}_7\text{H}_{14}\text{O}_7\text{Na}$: 217.0683; found: 217.0683.

Fraction 2, eluted with CHCl_3 –MeOH– NH_4OH (16:4:1) gave a heterogeneous mixture of amino lipid and partially deacetylated analogs (0.5 mg). The mixture was dissolved

in pyridine (0.2 ml) and acetic anhydride (0.2 ml) and allowed to stand at 25 °C for 18 h. Removal of the volatile materials gave isorhizochalinin peracetate **2** (0.6 mg); $[\alpha]_D^{25}$: +7.0 (*c* 0.06, MeOH); HRMS-ESI: m/z [$M + Na^+$] calcd for C₃₆H₆₆N₂O₇Na: 661.4762; found: 661.4731; [$M + Na^+$]; NMR (CDCl₃, see Table 2).

Isorhizochalinin

Isorhizochalinin peracetate (**2**) (0.6 mg) in 5% HCl in MeOH (500 μ l) was heated at 80 °C for 48 h in a sealed vial. The solution was cooled, concentrated under reduced pressure, and the residue subjected to microcolumn silica gel chromatography with successive elution by 9:4:1 CHCl₃/MeOH/NH₄OH to provide a mixture of aglycone and aglycone acetates (0.5 mg).

Preparative HPLC of the mixture (80:20:0.1% MeOH–H₂O–TFA) gave **2a** (0.4 mg). HRMS-ESI: m/z [$M + Na^+$] calcd for C₂₈H₅₉N₂O₃: 471.4520; found: 471.4591; [$M + Na^+$]; NMR (CD₃OD, see Table 2).

Isorhizochalinin Perbenzoate

A mixture of isorhizochalinin **2a** (0.1 mg, 0.2 μ mol), DMAP (dimethylaminopyridine, 1 mg), benzoic acid (9.2 mg, 0.075 mmol), and EDC (1-ethyl-3 [3-dimethylaminopropyl] carbodiimide hydrochloride, 12.2 mg, 0.067 mmol) in CH₂Cl₂ (1 ml) was stirred at room temperature for 6 days. The product was purified by silica gel column chromatography (20:1 CHCl₃/EtOAc) followed by preparative HPLC (93:7 EtOH–H₂O) to obtain isorhizochalinin perbenzoate (**2b**, 0.1 mg): CD (MeOH) λ 221 ($\Delta\epsilon$ + 4.4), 239 (–5.8). HRMS-ESI: m/z [$M + H^+$] calcd for C₅₆H₇₃N₂O₇: 887.5569; found: 887.5570; [$M + Na^+$] calcd for C₅₆H₇₂N₂O₇Na: 909.5388; found: 909.5385. ¹H NMR (500 MHz, CDCl₃): 8.09 (2 H, *d*, *J* = 7.6, *O*-PhCOO for *erythro* terminus); 8.03 (2 H, *d*, *J* = 7.6, *O*-PhCOO for *threo* terminus); 7.77 (2 H, *d*, *J* = 7.6, *ortho*-PhCONH for *erythro* terminus); 7.72 (2 H, *d*, *J* = 7.6, *ortho*-PhCONH for *threo* terminus); 7.39–7.61 (*m*, 12H; aryl H); 2.355 (2H, *t*, *J* = 7.0, 17-H); 2.349 (2H, *t*, *J* = 7.0, 19-H); 1.26 (*bs*, 38H, 4–16H);

Baeyer–Villiger Oxidation of Isorhizochalin Peracetate

A mixture of TFA (>99%) and H₂O₂ (30% v/v aq.) [TFA/H₂O₂, 3:1 (60 μ l)] was added to a solution of **1a** (0.2 mg) in MeOH (50 μ l). The mixture was heated at 60 °C for 2 h, left for 72 h at room temperature. The volatiles were removed under reduced pressure and the residue acetylated with Ac₂O/pyridine (1:1, 100 μ l). The resulting mixture of peracetates, **3a** and **3b**, was analyzed by MALDI-TOF-MS: *m/z* 724 [M + Na]⁺.

Cytotoxicity Assay

Cell culture: HL-60 (human promyelocytic leukemia) and THP-1 (human monocytic leukemia) cell lines were

cultured in monolayers at 37 °C and 5% CO₂ in RPMI containing 10% FBS, 2 mmol/l L-glutamine, 100 units/ml penicillin, and 100 μ g/ml streptomycin.

The effect of the compounds on HL-60 or THP-1 cells viability was evaluated using MTS reduction into its formazan product [15]. The cells were cultured for 12 h in 96-well plates (6,000 cells/well) in RPMI medium (50 μ l/well) containing 10% FBS. Then 50 μ l of the fresh RPMI/FBS medium containing the indicated concentrations of the compounds was added into each well and the cells were incubated for 22 h. Next, 20 μ l of the MTS reagent was added into each well, and MTS reduction was measured 2 h later spectrophotometrically at 492 and 690 nm as background using the μ Quant microplate reader (Bio-Tek Instruments, Inc.). Data were obtained as the mean \pm SD from six samples of two independent experiments. The statistical computer program Statistica 6.0 for

Results and Discussion

The EtOH extract of *R. incrustata* was concentrated and partitioned between *n*-hexane and aqueous EtOH. The aqueous EtOH-soluble materials were further separated by column chromatography on Polychrome-1 to obtain a crude mixture of two-headed sphingolipids. Part of the mixture was acetylated, and the products of the reaction were separated by preparative HPLC to give rhizochalin peracetate and the minor compound, isorhizochalin peracetate (**1a**, 0.0005%, based on dry weight of the sponge). The molecular formula of **1a**, C₄₈H₈₂N₂O₁₅, was derived from HRMS-ESI (*m/z* 927.5779 [M + H⁺], calculated 927.5788). The ¹H and ¹³C NMR data of **1a** were similar to those of rhizochalin peracetate [1]. These included signals of two secondary methyl groups (δ_{H} 1.07; 1.10; δ_{C} 13.4; 18.5), two *N*-substituted CH carbons (δ_{H} 3.99, m; 4.20, m; δ_{C} 47.1, CH; 47.2, CH), two hydroxymethines (δ_{H} 3.60, m; 4.85, m; δ_{C} 83.4, CH; 76.5, CH), and a ketone carbonyl group (δ_{C} 211.6), flanked by two α -CH₂ groups (δ_{H} 2.369, t, 2.374, t; δ_{C} 42.8, 42.9). The remainder of the signals was assigned to long CH₂ chains (δ_{H} 1.27–1.29; δ_{C} 29.1–29.7) and a sugar moiety. In contrast with the NMR data of rhizochalin peracetate, the amide doublet (C₂-NH) and hydroxymethine multiplet were shifted down-field from δ_{H} 5.87 to 6.41 ppm and from δ_{H} 3.49 to 3.60 ppm, respectively. The signal of one of two secondary methyl groups was shifted up-field from δ_{H} 1.17 to 1.07 ppm. Consequently, the structure of **1a** was suggested as an analogue of rhizochalin with a stereochemical modification from *threo* to *erythro* at the α -terminus (defined as the glycosylated end group) that was revealed by analyses of ¹³C

NMR, COSY and HMBC data. In fact, the down field shift of the amide NH is a characteristic difference in the NMR spectra of *N*-acyl *erythro*-sphingosines compared to the corresponding *threo*-derivatives [16, 17] (Fig. 1).

The HMBC spectrum of **1a** showed a cross peak from H-1' (δ_{H} 4.46) to C-3 (δ 83.4), confirming the attachment of the *O*-galactopyranosyl residue at C-3. The ³*J*-coupling constant of the anomeric proton H-1' (d, *J* = 7.8 Hz) and other NMR data indicated that isorhizochalin is a β -galactoside.

Methanolysis of **1a** (5% HCl in MeOH, 75°C, 24 h) gave two fractions that were separated by silica gel column chromatography, the first-eluting fraction was a mixture of anomeric *O*-methyl *D*-galactosides (C₇H₁₅O₅, *m/z* 195.0987, M + H⁺), confirmed by the positive specific rotation. The second fraction, eluted from the column with NH₃-MeOH-CHCl₃ represented a mixture of aglycone and aglycone acetates that was re-acetylated (Ac₂O/pyr) to provide the peracetylated aglycone, isorhizochalinin peracetate (**2**). A molecular formula for **2**, C₃₆H₆₆N₂O₇, was derived from HRMS-ESI (*m/z* 661.4731 [M + Na⁺], $\Delta m\mu$ 3.1). The ¹H and ¹³C NMR data of **2** were similar to those of rhizochalinin peracetate [1], with the exception of the amide doublet (C-2-NH) which was shifted downfield from δ_{H} 5.51 to 5.78 ppm and the C-3 hydroxymethine multiplet that was shifted upfield from δ_{H} 4.20 to 4.16 ppm. The signal of one secondary methyl group was shifted upfield from δ_{H} 1.10 to 1.09 ppm. Consequently, the structure of **2** was formulated as an analogue of rhizochalinin peracetate with a stereochemical modification at one terminus.

Methanolysis of **2** (5% HCl in MeOH, 80 °C, 48 h) gave a mixture of aglycone and aglycone peracetates which were purified by preparative HPLC to provide the pure isorhizochalinin (**2a**). The molecular formula C₂₈H₅₈N₂O₃ of **2a** was derived from HRMS-ESI (*m/z* 471.4491 [M + H⁺], $\Delta m\mu$ = 3). The ¹H NMR data of **2a** were similar to those

Fig. 1 Structures of isorhizochalin and its derivatives

of rhizochalinin. In contrast with the NMR data of rhizochalinin, one hydroxymethine multiplet was shifted downfield from δ_{H} 3.08 to 3.27 ppm. The signal of one secondary methyl group was shifted upfield from δ_{H} 1.26 to 1.21 ppm. The foregoing evidence confirmed the structure of isorhizochalin as a glycosylated two-headed sphingolipid, having a ketone group embedded at C-18 in a long-chain but with a C-2,3 *erythro* configuration at the α -terminus instead of *threo* found in rhizochalin.

Interpretation of spectroscopic data could not establish the position of the carbonyl group of these natural products. As in our previous studies of ketosphingolipids, we applied a procedure for localization of the C=O group based on in situ MS analysis of Baeyer–Villiger oxidation products obtained from the ketone [3]. Treatment of peracetate **1a** with TFA-H₂O₂ in MeOH, followed by acetylation (Ac₂O, pyridine) of the oxidation-solvolysis products gave **3a,b** as shown by MALDI-TOF-MS (principal ion at m/z 724 [M + Na⁺]), and permitted placement of the C=O group at the C-18 position in **1a** (Fig. 2).

The foregoing ¹H-NMR analysis failed to distinguish *S,R* or *R,R* stereoisomers from their antipodes at either terminus. Consequently, the absolute configuration of isorhizochalin was assigned from deconvolution of the CD spectrum of the corresponding perbenzoyl aglycone **2b** following a procedure we developed specifically for two headed-sphingolipids, including rhizochalin [18] and oceanapaside [17]. The method has been applied recently by Kingston and coworkers to calyxoside [9], and by Molinski and co-workers to leucettamol A [19].

Perbenzoyl compound **2b** was prepared using a conventional procedure (benzoic acid, EDC, CH₂Cl₂) and purified by HPLC. When the CD spectrum of the natural product-derived perbenzoyl aglycone was compared with ‘hybrid CD spectra’ generated from all eight possible linear combinations of terminal group configurations [17] a unique solution to the absolute configurations at the four stereocenters emerged, but only when interpreted in combination with NMR data as follows. The CD spectrum of **2b** (Fig. 3) shows a split Cotton effect with negative signal

Fig. 2 Structures of degradation products from isorhizochalin

Fig. 3 CD spectrum of isorhizochalin perbenzoate (**2b**, dashed line) (MeOH, 23 °C, $c = 2.8 \times 10^{-5}$ M) overlaid with ‘hybrid’ CD spectra generated from linear combinations of **a** *ent-threo-4a* + *erythro-4b* and **b** *ent-threo-4a* + *ent-threo-4a*

at $\sim \lambda$ 239 ($\Delta\epsilon - 5.8$) and a positive signal at λ 221 ($\Delta\epsilon + 4.4$) that corresponds closely to two ‘hybrid’ spectra that are similar and consistent with either *2S,3R,26R,27R* (Fig. 3a) or *2R,3R,26R,27R* (Fig. 3b). Since the latter configuration had already been assigned to the *pseudo-C*₂ symmetric epimer, perbenzoyl rhizochalinin [18], the non-symmetrical *C*₁ epimer **2b** must have the *2S,3R,26R,27R* configuration,¹ however, we independently corroborated this assignment as follows. Comparative analysis of the ¹H-NMR spectrum of **2b** with those of the perbenzoyl rhizochalinin and *N,O*-dibenzoyl model compounds (**4a**, **4b**) [17] (Fig. 4), as shown in Tables 3 and 4 revealed similar chemical shifts and coupling constants for the α -terminus of isorhizochalinin perbenzoate (**2b**) to those of the *erythro*- model compound **4b**. Therefore, isorhizochalinin perbenzoate (**2b**) and isorhizochalin (**1**) share the *erythro* configurations at C-2, C-3 of the α -terminus (Table 3) and isorhizochalin (**1**) is the C-2 epimer of rhizochalin [1] (Fig. 1).

Compound **1** differs from earlier reported rhizochalins A, B and D [2, 3, 5], and oceanalin A [10] which possess the *threo* configuration at each α -terminus. The ¹H-NMR chemical shifts and coupling constants for the ω -terminus

¹ Of all 16 possible diastereomers of ‘two-headed’ sphingolipids, the two most difficult to discriminate by the CD deconvolution method are those represented by rhizochalinin and isorhizochalinin (*ent-threo/ent-threo* and *erythro/ent-threo* end groups). The differences in the hybrid CD spectra constructed from CD spectra of models **4a** and **4b** measured in MeOH are small, but somewhat differentiated when measured in CH₃CN.

Fig. 4 Structures of *N,O*-dibenzoyl model compounds

of isorhizochalinin perbenzoate (**2b**) and ω -termini of rhizochalinin, rhizochalinins C, D perbenzoates [3], oceanin perbenzoate [8] and calyxinin perbenzoate [9], and model compound (**4a**) are identical (Tables 3 and 4).

Taking into consideration that biosynthesis of the both termini in **1** and related metabolites most likely proceeds by pyridoxal phosphate-dependent, sphingolipid synthase catalyzed condensation of alanine (or serine in the case of oceanapiside and other C-1 hydroxylated analogs) with fatty acyl CoA ester followed by NADPH-dependent reduction of the incipient ‘ketosphingosine-like’ intermediate. The biosynthesis of the mycotoxin fumonisin B₁-like B₂, a (2*S*,3*S*)-sphingolipid [20], has been shown by ²H- and ¹³C-labeling studies to involve incorporation of L-alanine [21] with loss of CO₂ and retention of the C-2 configuration at the condensation step, similar to sphingosine biosynthesis. The absolute stereochemistry of **1** and its C-2 epimer rhizochalin, both found in the same sponge, now suggests two possible pathways that may explain their stereochemical heterogeneity. The α -terminus of **1** may be biosynthesized from L-alanine, while the ω -terminus derives from D-alanine, each with C-2 retention and the same ketoreductase stereospecificity for C-3 and C-26. D-alanine may derive from a host-derived epimerase, or a symbiotic bacterium in the sponge. Alternatively, both head group configurations, *ii*, and *iii*, could originate from L-alanine, with *inversion* of C-2 at the condensation step, and high 3*R* stereospecificity of the ketoreductase for both

termini. The *erythro* terminus *iii* could arise from a second C-2 inversion (not retention) in the 3-ketosphingosine-like intermediate 2*R-i* to *ent*-2*S-i* through enolization-reprotonation (Fig. 5). Since the all-*R*-configured rhizochalin is the predominant metabolite in the sponge and (2*S*,3*R*)-**1** is a very minor epimer, the latter compound may represent ‘leakage’ of C-2 stereofidelity in the canonical pathway. The second pathway has a certain appeal since it explains the plasticity of the C-2 configuration throughout the family of sponge-derived two-headed sphingolipids, but conservation of C-3. It is of special interest that so far only one similar *erythro*-, *threo*- bipolar metabolite has been described: oceanapiside, the major two-headed sphingolipid from the sponge *Oceanapia phillipensis* [17]: with termini that formally derive from D-alanine and L-serine configurations, respectively.

Both isorhizochalinin (**2a**) and rhizochalinin show same prominent cytotoxicities against human leukemia HL-60 cells with IC₅₀ values of 2.90 and 2.57 μ M as well as against human leukemia THP-1 cells with IC₅₀ values of 2.20 and 1.70 μ M, respectively. Thus, it appeared that the stereochemistry at position C-2 was not important structural requirement for cytotoxic activities of these two-headed sphingolipids. In addition, isorhizochalin is the first representative of essentially constitutionally symmetric two-headed sphingolipid natural product that lacks *pseudo*-C₂ symmetry. Structure identification of isorhizochalin reveals that the position of the keto group is conserved at C-18 in all known two-headed ketosphingolipids, but the stereochemistry for the α -termini can be *threo* (the majority of lipids in this group) or *erythro* (less common). It is possible, that a unified biosynthetic pathway may yet link these natural compounds to a common, but as-yet unidentified biosynthetic C₂₈ lipid intermediate, however the details of two-headed sphingolipid metabolism remain to be elucidated.

Fig. 5 Alternative biosynthetic hypotheses for stereochemical heterogeneity of long-chain base head groups of **1** and rhizochalin [1, 2]

Acknowledgments This investigation was supported by the Fogarty International Center and NIH (TWO06301-01) and the NIH (AI039987 and CA122256 to T.F.M.).
