CL 316,243 (1 μM) administration down-regulated ATGL protein and potently activated Akt ex vivo and in vitro. Activation of Akt by the β_3AR signaling is non-classical and involves crosstalk between G-protein coupled receptors (GPCR) and the PI3 K signaling pathway. In order to determine if PI3 K signaling caused the decrease in ATGL protein levels, we blocked Akt activation with the PI3 K inhibitor LY294002. However, blocking Akt activation did not prevent ATGL down-regulation in vitro (Fig. 4b, c). In addition, insulin treatment potently activated PI3 K but did not result in decreased ATGL protein levels in differentiated primary brown adipocytes (Fig. 4b). These findings led us to conclude that the PI3 K/Akt signaling pathway does not antagonize PKA signaling as it does in other tissues. From this point, we focused on classical β_3AR-signaling as a putative ATGL regulatory mechanism in BAT.

β_3AR Signaling-Mediated Degradation of ATGL is PKA Dependent in Brown but not White Adipocytes

We show that inhibition of PKA signaling by H89 rescues the down-regulation of ATGL (Fig. 4a, b). An H89 dose curve with CL (1 μM) shows that 10 μM H89 was most effective at rescuing ATGL (Fig. 4a). This is also a commonly used dose in the literature for inhibition of PKA

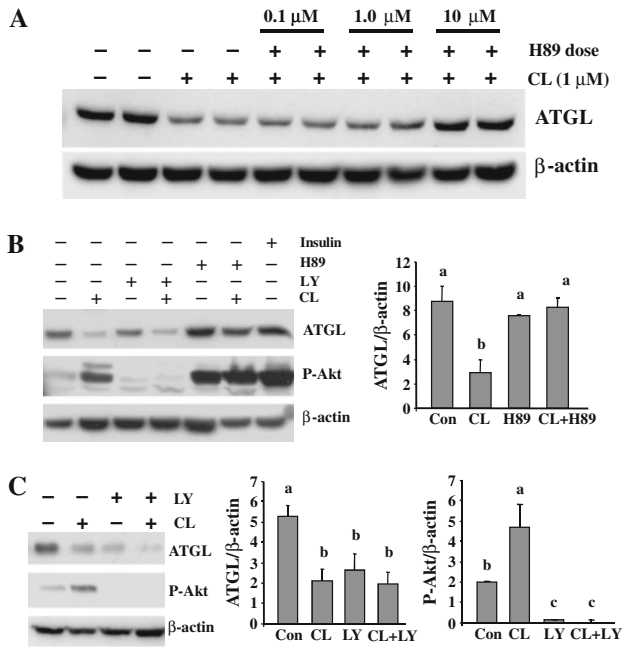

Fig. 4 Inhibition of PKA signaling, not Akt signaling, rescues ATGL protein levels in a dose-dependent manner. **a** The PKA inhibitor, H89, rescues the CL-mediated decrease in ATGL protein in a dose-dependent manner at 3 h in primary brown adipocytes as shown in this immunoblot. **b**, **c** CL as well as 100 nM insulin potently activated Akt, however, blockage of Akt signaling did not rescue ATGL protein levels. The letters (*a, b*) represent a significant difference among groups by using one-way ANOVA at $P < 0.05$. Statistical values are derived from three independent experiments ($n = 3$) using primary brown adipoctyes cultured from separate isolations/differentiations of primary mouse preadipocytes isolated from interscapular brown adipose (2 mice per 12 well dish—see "Materials and Methods")

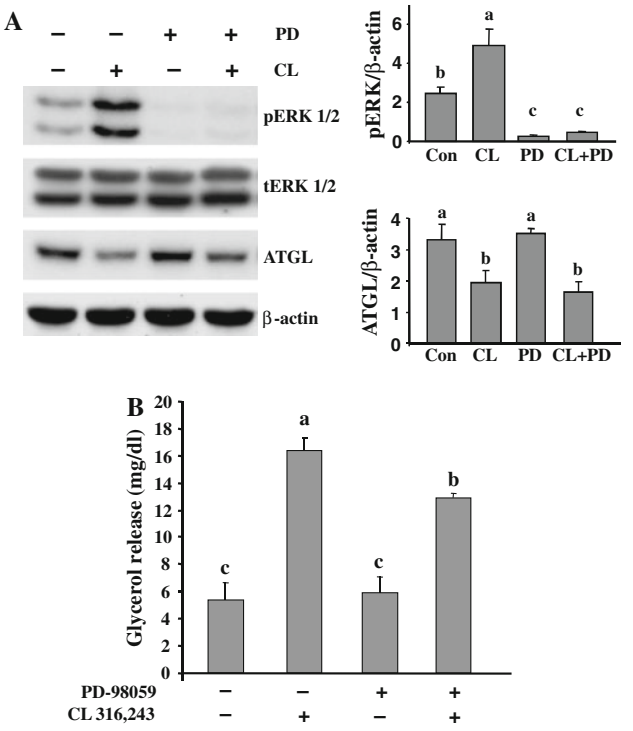

Fig. 5 Activation of ERK 1/2 in brown adipocytes by CL; ERK 1/2 are not downstream of CL-PKA-mediated ATGL downregulation. **a** CL potently activated ERK 1/2, which correlates with a decrease in ATGL protein levels; however, blocking ERK 1/2 with PD 98059 (50 μM) does not rescue ATGL expression ($n = 3$). **b** CL potently induces lipolysis in brown adipocytes as measured by glycerol release. ERK 1/2 inhibition resulting in a significant ($P < 0.01$) decrease, approximately 20%, in β_3AR-stimulated lipolysis ($n = 3$). The letters (*a*, *b*, *c*) represent a significant difference among groups by using one-way ANOVA at $P < 0.05$

signaling. Interestingly, CL and H89 treatment did not modulate ATGL protein levels in differentiated 3T3-L1 adipocytes at 3 h (data not shown).

Adipose triglyceride lipase can exist as a phosphoprotein, although it has been reported that ATGL is *not* a direct substrate of PKA [23, 29]. Due to the rapid decrease in ATGL levels after β_3AR agonism, we hypothesized that ATGL phosphorylation leads to degradation via an intermediate downstream of PKA. In order to identify this intermediate, we focused on known signaling pathways downstream of β_3AR-mediated lipolysis, including ERK 1/2 and p38 signaling [33]. CL administration potently activated ERK1/2 (Fig. 5a). The inhibition of ERK 1/2 by PD 98059, however, did not rescue ATGL protein levels. We do show that inhibition of ERK 1/2 by PD 98059 led to a significant inhibition of CL-mediated lipolysis. This shows that ERK1/2 signaling is important in β_3AR-mediated BAT lipolysis. Also, brown adipocytes are capable of increased lipolysis concurrent with significant decreases in ATGL protein levels. H89 attenuated CL-mediated upregulation of UCP1 gene expression by blocking PKA-mediated phosphorylation of p38 [34]. Therefore, we assessed the role of p38 signaling on ATGL expression. CL treatment results in p38 activation; however, the p38 blockade by 10 and 25 μM of SB 203580 did not rescue ATGL protein expression in cultured primary brown adipocytes (data not shown).

Adipose triglyceride lipase protein levels decreased significantly after only 30 min of CL treatment and reached maximal downregulation by 1 h which was maintained to the 3 h time point (Fig. 6a). H89 pretreatment rescued ATGL protein levels 1 and 3 h after CL treatment. In order to determine if the decrease in ATGL protein was due to decreased transcription of ATGL gene expression, we treated the primary mouse brown adipocytes with 1 μM of CL over a time course. ATGL gene expression showed a downward trend which became significant after 3 h as in the in vivo study (Fig. 6b). CL administration results in decreased ATGL transcription, however, ATGL protein levels decrease at a greater rate than can be attributed to transcriptional effects. Our data suggest that the decrease in ATGL protein is partially due to the protein degradation via PKA signaling. Thus, we hypothesized that ATGL was

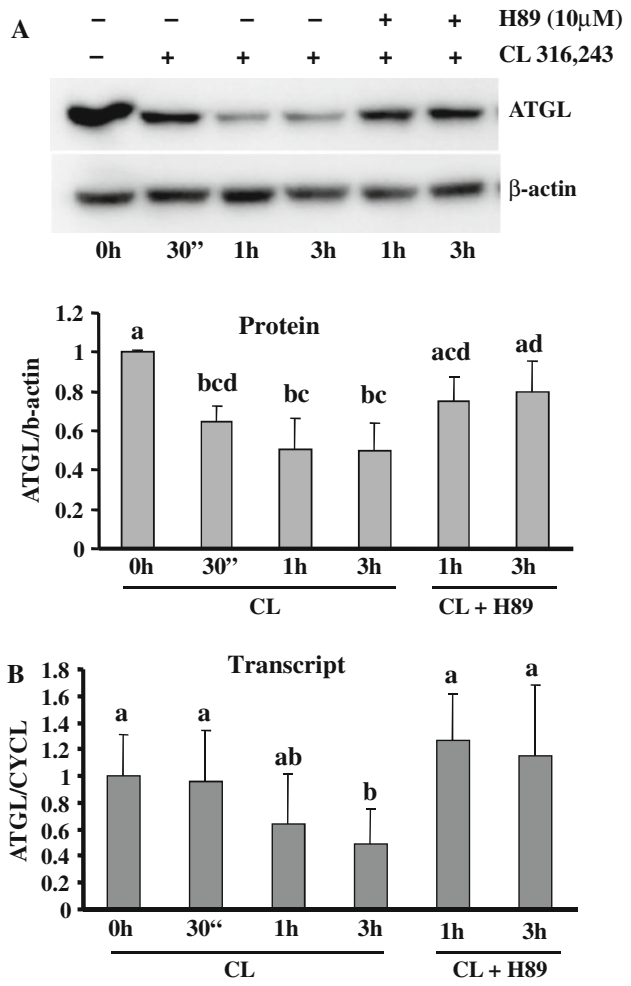

Fig. 6 CL-PKA-mediated ATGL protein degradation occurs rapidly while effects on transcript lag. **a** Immunoblotting ($n = 3$) shows that CL administration results in a significant decrease in ATGL protein levels in as little as 30 min ($P < 0.05$). H89 pretreatment rescues ATGL protein. **b** ATGL gene expression is significantly reduced only at 3 h post CL administration and is rescued by H89 at 1 and 3 h ($n = 3$). The letters (*a*, *b*, *c*, *d*) represent a significant difference among groups at various time points by using one-way ANOVA at $P < 0.05$

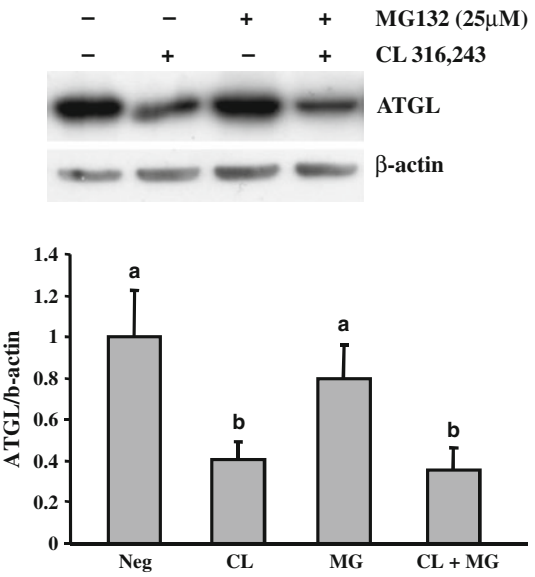

Fig. 7 ATGL protein level decrease in CL 316,243-treated cells is not due to 26S proteasomal degradation. **a** Inhibition of the proteasome by MG 132 (25 μM) does not rescue CL-mediated ATGL protein degradation at 3 h as shown in this representative immunoblot ($n = 3$). The letters (*a, b*) represent a significant difference among groups by using one-way ANOVA at $P < 0.05$

being degraded by 26S proteasome hydrolysis. In order to test this hypothesis, we pretreated primary brown adipocytes with the proteasome inhibitor MG 132 (25 μM) for 1 h then stimulated the cells with CL. The cells were collected at 3 h. However, blockade of the proteasome did not prevent ATGL degradation (Fig. 7), suggesting degradation by an alternative pathway.

Discussion

The nine currently identified cytoplasmic fatty acid binding proteins ($FABP_C$) belong to the superfamily of lipid binding proteins. $FABP_C$ all possess similar protein structures but show tissue specific expression [35]. This tissue specific expression pattern suggests unique or specialized functions for the various $FABP_C$. H- and A-FABP proteins are $FABP_C$ that function to increase cytoplasmic diffusion and transport of FFA from the plasma membrane [36, 37]. A-FABP is exclusively expressed in adipose tissue where it has been shown to be involved in increasing the solubility and aiding in trafficking of free fatty acids between cellular compartments. Whereas, H-FABP is mainly expressed in cardiac and skeletal muscles where fatty acid oxidization is a major source of energy. For example, H-FABP increased in rat heart and skeletal muscle tissues in conditions of increased fatty acid oxidation, such as diabetes and fasting, respectively [38, 39]. In humans, increased H-FABP expression is correlated to increased fatty acid oxidation in type two diabetic individuals undergoing dietary and exercise interventions [40]. In the current studies, the dramatic increase in H-FABP transcription contrasted by the decrease in A-FABP transcription suggests that cold shock alters the fatty acid trafficking within the brown adipocytes. We propose that the FFA flux into the BAT has a direct or indirect affect upon the transcription of A- and H-FABP. While H-FABP's precise role in intracellular trafficking and fat metabolism is undefined, our study suggests that H-FABP may function to transport/direct the influx of intracellular FFAs to the mitochondrial FFA transport system (CPT1) for oxidation thus fueling non-shivering thermogenesis. Finally, the FFA influx and

trafficking in BAT has a direct/indirect affect upon the transcription of A- and H-FABP.

Nonshivering thermogenesis requires the up-regulation of β-oxidation and uncoupled oxidative phosphorylation in BAT. Cold stress-induced NE release stimulates the β_3 and α_2-adrenergic receptors and has profound effects on BAT including upregulation of lipolysis and UCP1 expression, promotion of proliferation and differentiation, and inhibition of apoptosis [17]. It has been shown recently that in vitro stimulation of the β_3-adrenergic receptor by NE, isoprenaline, and CL induced glucose uptake in brown adipocytes in culture by increasing GLUT1 gene expression with decreasing GLUT4 expression [41]. Adams and colleagues showed that cold exposure from 1 to 48 h increased glucose uptake and de novo lipogenesis while increasing β-oxidation [42]. Our in vivo cold exposure data show phosphorylation of GSK-3β, suggesting an increase in glycogen synthesis in BAT during cold exposure. This finding complements the work of others [41, 42] showing increased glucose uptake in brown adipocytes upon NE or cold exposure. PI3 K/Akt signaling is the main regulator of GLUT4 translocation to the plasma membrane due to the effects of insulin [43]. Thus, β_3AR mediated activation of PI3 k/Akt may function to increase glucose uptake in the tissue as well as increase sensitivity to circulating insulin levels. This response appears to be specific to BAT, as PI3 K/Akt signaling normally antagonizes the lipolytic pathway. In addition, muscle and WAT exhibit reduced sensitivity of PI3 K/Akt signaling to insulin in the rat during cold exposure [44].

Current studies show in cold exposure that ATGL is transiently down-regulated with a corresponding increase in Akt signaling in vivo. During cold exposure, changes in ATGL expression were more sensitive and occurred before the decrease in the other lipases, HSL and Carb3. Also, supporting the sensitivity of ATGL to metabolic stress are data from mouse fasting and refeeding studies where ATGL expression changes in the WAT according to positive or negative energy balances [26]. A recently published article shows that noradrenaline-induced lipolysis was positively correlated with HSL protein levels, but not with ATGL protein levels in the WAT of women [45]. In agreement with this, CL treatment did not affect ATGL protein levels in 3T3-L1 adipocytes or in WAT treated ex vivo. However, defective cold adaptation of ATGL knockout mice clearly indicates an important role of ATGL-mediated lipolysis in WAT to supply BAT with free fatty acids. Considering no change in expression of ATGL protein in response to CL, ATGL activity can be regulated by other interacting proteins. The recent discovery of two proteins, comparative gene identification-58 (CGI-58) and the G0/G1 switch gene 2 (G0S2) that physically interact with ATGL protein, increases the complexity of ATGL regulation. CGI-58 functions as an activator of ATGL without affecting HSL activity, increasing lipolysis [46]. In contrast to CGI-58, interaction of G0S2 with ATGL decreased ATGL-mediated lipolysis, acting as a negative regulator of ATGL [47]. Up-regulation of G0S2 by anti-lipolytic hormone insulin and drastic down-regulation by β-adrenergic agonist isoproterenol or another lipolysis-inducing hormone, tumor necrosis factor α, demonstrated the importance of G0S2 as a regulator of ATGL activity in response to metabolic hormones [47]. This implicates possible mechanisms by which alteration of G0S2 amounts affect ATGL activity without changing ATGL protein levels in WAT in response to CL.

It has been reported that the ATGL gene is a target for PPARγ transactivation [27]. Decreases in PPARγ levels have been shown in primary brown adipocytes treated with NE as well as in white adipocytes treated with β_3AR agonists, leading to its degradation and lowered transcription of PPARγ mediated genes [48, 49]. Thus, the decreases in ATGL levels during cold-stress in vivo may be due to decreases in PPARγ levels. ATGL gene expression has been shown to be down-regulated in 3T3-L1 cells, a mouse adipocyte cell line, by insulin and isoproterenol administration [27, 28]. Smas et al. [27] went onto show that insulin activation of the PI3 K pathway leads to the down-regulation of ATGL with PI3 K inhibitors rescuing transcript levels. Rapid down-regulation of ATGL by both anabolic and catabolic hormones is intriguing and is as of yet unexplained. Hormones that increase lipolysis such as CL and isoproterenol paradoxically decrease ATGL gene and protein levels. This would suggest that catecholamine-induced lipolysis is partially independent of ATGL protein levels and most probably relies on regulation of ATGL activation. Zimmerman et al. [23] showed that ATGL is a phosphoprotein. Phosphorylation is a key signal for ubiquitination and 26S proteasomal catabolism of proteins [50]. However, ATGL was demonstrated *not* to be a substrate for PKA [23]; however, our data suggests ATGL is an indirect target of PKA signaling in brown adipocytes. In addition, our data show the proteasome inhibitor MG 132 does not rescue ATGL protein levels indicating β_3AR signaling causes ATGL protein level decreases due to non-proteasomal degradation. ERK 1/2 plays a role in MAPK signaling mediated lipolysis and can be activated by PKA. However, while blocking ERK 1/2 decreases lipolysis in primary brown adipocytes by $\sim$20%, it does not rescue ATGL protein levels. Similarly, the p38 signaling pathway does not mediate PKA-dependent ATGL degradation. Importantly, current studies show that CL activates Akt in primary mouse brown adipocytes and decreases ATGL protein levels via a PKA dependent, ERK 1/2, p38, and Akt-independent mechanism.

The current study showed that cold exposure at early time points elicits β_3AR and insulin-like signaling in BAT and primary brown adipocytes, including transient decreases in ATGL gene and protein levels. In this situation, fatty acids from the diet and mobilization of fatty acids from WAT can be a primary source for nonshivering thermogenesis in BAT rather than the break down of TAG stored in BAT. Also, appetite and glucose uptake in BAT increases during the early stage of cold exposure [42] providing metabolic substrates for nonshivering thermogenesis. Under conditions of long-term cold exposure with limited dietary glucose and circulating fatty acids, the TAG in BAT will most likely be hydrolyzed by ATGL to produce an energy substrate for nonshivering thermogenesis. H-FABP expression increases purportedly to shuttle fatty acids within the cell to the mitochondria as an oxidative substrate for nonshivering thermogenesis. Further investigation into the crosstalk between the PI3 K/Akt and the β_3-adrenergic pathway and how they affect lipid storage, fatty acid mobilization, transport, and utilization within BAT is warranted. A better understanding of the distinct differences between PI3 K and β_3AR crosstalk in WAT and BAT is important to endocrinology, adipose physiology, and metabolism. Finally, β_3AR agonists are exciting potential targets for pharmaceutical therapy of obesity; however, a better understanding of the mechanisms underlying this process is needed and will advance clinical management of obesity.

Abstract Statins decrease apoB-100-containing lipoproteins by increasing their fractional catabolic rates through LDL receptor-mediated uptake. Their influence on hepatic secretion of these lipoproteins is controversial. The objective of the study was to examine the influence of simvastatin on the secretion of apoB-100-containing lipoproteins in fasting non-obese subjects. Turnover of apoB-100-containing lipoproteins was investigated using stable isotope-labeled tracers. Multicompartmental modeling was used to derive kinetic parameters. Eight male subjects (BMI 25 ± 3 kg/m^2) with mild hypercholesterolemia (LDL cholesterol 135 ± 30 mg/dL) and normal triglycerides (111 ± 44 mg/dL) were examined under no treatment (A), under chronic treatment with simvastatin 40 mg/day (B) and after an acute-on-chronic dosage of 80 mg simvastatin under chronic simvastatin treatment (C). Lipoprotein concentrations changed as expected under 40 mg/day simvastatin. Fractional catabolic rates increased in IDL and LDL but not in VLDL fractions versus control [VLDL +35% in B (n.s.) and +21% in C (n.s.); IDL +169% in B ($P = 0.08$) and +187% in C ($P = 0.032$); LDL +87% in B ($P = 0.025$) and +133% in C ($P = 0.025$)]. Chronic (B) and acute-on-chronic simvastatin treatment (C) did not affect lipoprotein production rates [VLDL −8 and −13%, IDL +47 and +38%, and LDL +19 and +30% in B and C, respectively (all comparisons n.s.)]. The data indicate that simvastatin does not influence the secretion of apoB-100-containing lipoproteins in non-obese subjects with near-normal LDL cholesterol concentrations.

Keywords Apolipoprotein B-100 · Lipoprotein · Cholesterol · Statin · Simvastatin · Gas chromatography/mass spectrometry · Kinetics · Stable isotopes · Turnover · Multicompartmental modeling

Abbreviations

apoB-100	Apolipoprotein B-100
BMI	Body mass index
CHOD-PAP	Cholesterol oxidase phenol aminoantipyrine peroxidase
EDTA	Ethylene-diamine-tetra-acetic acid
FCR	Fractional catabolic rate
GPO-PAP	Glycerol-3-phosphate oxidase phenol aminoantipyrine peroxidase
HDL	High-density lipoproteins
HMG	4-Hydroxy-3-methylglutaryl
IDL	Intermediate-density lipoproteins
LDL	Low-density lipoproteins

PR Production rate
VLDL Very low-density lipoproteins

Introduction

3-Hydroxy-3 methylglutaryl (HMG) coenzyme A-reductase inhibitors (statins) have an established role in the treatment of hypercholesterolemia. Their efficacy in reducing cardiovascular morbidity and mortality in secondary [1, 2] and primary prevention [3] has been demonstrated in large randomized trials. HMG-CoA-reductase inhibitors inhibit competitively the rate-limiting enzyme of endogenous cholesterol biosynthesis. As a consequence, the intracellular pool of free cholesterol decreases and low-density lipoprotein (LDL) receptors are up-regulated, leading to an increased receptor-mediated clearance of LDL from plasma [4]. This mechanism is responsible for a large proportion of their cholesterol-lowering effect. However, a statin-induced decrease in lipoprotein production has also been proposed as a mechanism for their lipid-lowering effects [5]. The underlying mechanisms in vivo, however, that would mediate such an effect, are not fully understood. Except for their pronounced cholesterol-lowering properties, statins have also a modest effect (about 15–20%) in decreasing triglyceride concentrations [6]. In subjects with high intra-abdominal fat stores, an increased flux of free fatty acids to the liver produces an increased rate of hepatic triglyceride synthesis, which in turn leads to increased very low-density lipoprotein (VLDL) production, since the latter is partly determined by the intracellular availability of triglycerides [7–9]. This is also found in subjects with type 2 diabetes mellitus [10, 11] and there are a number of studies showing that, in this pathophysiological state, statins are able to decrease lipoprotein production [12, 13]. Interestingly, in obese individuals it has been shown that statins increase the catabolism of apoB-100-containing lipoproteins but do not alter their rates of production or secretion [14].

In the present study we focused on subjects with near normal body weight (mean body mass index 25 $\pm$ 3 kg/m^2) and normal serum triglyceride concentrations to investigate, in the fasting state, whether statins influence hepatic lipoprotein production. Since recent evidence suggests that the supply of cholesterol available for incorporation into nascent lipoprotein particles also exerts a regulatory influence on apoB secretion by the liver [15, 16], we investigated in addition the acute inhibitory effects of a high bolus dose of simvastatin in order to inhibit cholesterol synthesis and to stimulate LDL receptor expression to a maximum degree.

The main goal of the present study was to determine the influence of simvastatin on apoB-100 appearance rates and lipoprotein kinetics in fasting non-obese subjects with mild hypercholesterolemia. For this purpose, each subject was investigated with three turnover protocols: once without treatment, once during chronic simvastatin treatment at a standard dosage, and once during chronic simvastatin treatment after an additional acute-on-chronic high bolus dose of simvastatin.

Experimental Procedures

Study Design

This was an open label, three-way cross-over trial evaluating lipoprotein turnover under control (no treatment) conditions (phase A), under chronic simvastatin treatment (phase B) and under chronic simvastatin treatment after additional acute-on-chronic dosage (phase C). All subjects provided written informed consent. The study protocol was approved by the Ethics Committee of the Medical Faculty of the University of Bonn, and all procedures were performed in accordance with the Helsinki Declaration and its current revision. The trial was publicly registered (ClinicalTrials.gov Identifier: NCT00905541).

Study Population and Drug Treatment

Eight male healthy volunteers with mild hypercholesterolemia [LDL cholesterol (LDL-C) average 135 mg/dL] and normal triglycerides (average 111 mg/dL) were recruited on campus and in the community (to convert mg/dL into mmol/L multiply with 0.0259 for cholesterol and with 0.0114 for triglycerides). Main exclusion criteria were coronary events during the last year, unstable angina, active liver disease or persistent elevations of liver transaminases, renal insufficiency, diabetes mellitus or impaired glucose tolerance, thyroid dysfunction, alcohol abuse, any other metabolic disease or treatment with drugs affecting lipid metabolism. Subjects were unrelated at the first and second degree.

Each subject was studied three times. Five subjects were studied in the sequence A–B–C and three in the sequence B–C–A. Before phase A there was a wash-out period of at least 8 weeks for all drugs affecting lipid metabolism. Before phase B, subjects were treated with simvastatin 40 mg once daily in the evening for at least 6 weeks. The last dose before the infusion studies was taken at 07:00 PM on the preceding day. Before phase C, subjects took their normal evening dose at 07:00 PM; in addition, they received an oral dose of 80 mg simvastatin in the morning of the turnover protocol 1 h before isotope infusion.

Medication with 40 mg/day was continued through the whole sampling period of the turnover studies (phases B and C).

Experimental Protocol For In Vivo Stable Isotope Kinetics

The subjects were asked to adhere to their usual nutritional habits throughout the entire trial. For 4 days before turnover studies they kept a food diary to document nutrient intake. During the 4 days preceding the second and third turnover study, the subjects were asked to consume an identical diet based on their previously documented food diaries and again kept 4-day food diaries.

The subjects were admitted to the metabolic ward on the day of the infusion study at 07:30 AM. The last meal on the previous day was taken at 07:00 PM. This meal was a standardized meal provided by the investigators. After 07:00 PM neither food nor calorie-containing beverages were allowed until the end of the infusion study on the next day at 07:00 PM in order to prevent nutrient-induced lipoprotein production. Drinking of tap water or mineral water was permitted after 12:00 noon on the study day. Clinical status and vital signs were recorded during the infusion. Measurements of body weight and body composition (including body fat and body lean mass, intra- and extracellular water), performed between 08:00 and 09:00 AM on the study day, were determined by bioelectrical impedance analysis (Multi Frequency Analyzer B.I.A. 2000-M; Data Input, Frankfurt, Germany) in combination with the manufacturer's software Nutri4.

In the morning of the study day the subjects received an indwelling cannula for blood drawing in one forearm and another in the other forearm for isotope infusion. They remained in a recumbent position (45°) from 08:00 AM until the end of the infusion. At 08:00 AM they drank 400 mL of mineral water. At 09:00 AM, tracer administration was started with a bolus injection of [D_3]leucine (1.4 mg/kg body weight) immediately followed by a continuous infusion of [D_3]leucine (1.4 mg kg^{-1} h^{-1}) for a period of 10 h. Tri-deuterated leucine (L-[5,5,5-$^2H_3$]leucine) was obtained from MassTrace (Woburn, MA, USA), was dissolved in saline and was tested sterile and pyrogen-free.

During each turnover study, two baseline samples were drawn immediately before 09:00 AM and further blood samples were obtained for up to 240 h. Isotopic enrichment of free leucine in plasma was determined at 16 time points, in VLDL-apoB-100 at 20 time points, in intermediate-density lipoprotein (IDL)-apoB at 13 time points and in LDL-apoB at 12 time points.

Measurement of Lipoprotein and apoB Concentrations

Lipoprotein concentrations for pool size determinations were measured on the infusion days in eight separate samples. In each sample, cholesterol, triglycerides, and apoB-100 were determined in total blood and in the VLDL, IDL, and LDL fraction. Cholesterol and triglycerides were measured enzymatically according to the CHOD-PAP and the GPO-PAP method (Boehringer Mannheim, Germany), respectively. HDL cholesterol (HDL-C) was determined enzymatically after precipitation of apoB-100-containing lipoproteins [17]. The coefficient of variation for cholesterol measurements was 0.99% for total cholesterol, 2.64% for LDL-C, 2.22% for HDL-C and 1.14% for triglycerides. ApoB-100 concentration in plasma and in lipoprotein fractions was determined with a noncompetitive, enzyme-linked immunoabsorbent assay using immunopurified polyclonal antibodies on the Beckmann Array®-360 System (Beckmann Instruments, Munich, Germany).

Isolation of apoB-100 and Amino Acid Preparation

Lipoprotein Separation

Isolation of the lipoprotein fractions VLDL, IDL and LDL was performed using preparative sequential density ultracentrifugation. A 3.2-mL polycarbonate tube was filled with a 1.5-mL aliquot of plasma and 1.5 mL sodium chloride density solution (0.9%) and centrifuged at 16 °C in a TLA 100.4 rotor for 2.5 h at 100,000×*g* in an Optima TLX centrifuge (Beckmann Instruments, Munich, Germany). All used density solutions contained 1 g/L EDTA. After centrifugation, the supernatant containing VLDL (density $d < 1.006$ g/mL) was removed after tube-slicing with a CentriTube Slicer (Beckmann Instruments, Munich, Germany). To isolate the IDL fraction ($1.006 < d < 1.020$ g/mL), the remaining infranatant was transferred into a new tube adding a second, more dense sodium chloride solution (4.5%) and an analogous centrifugation step was started. After tube-slicing and transfer of the infranatant into a new tube the centrifugation procedure was repeated using an even more dense sodium chloride solution (15%) to separate the LDL lipoprotein fraction ($1.020 < d < 1.063$ g/mL).

ApoB-100 Separation, Isolation of Amino Acids and Amino Acid Derivatization

The apoB-100 of the lipoprotein fractions VLDL, IDL and LDL was isolated and purified using a previously described isopropanol precipitation method [18]. Sample preparation for gas chromatography–mass spectrometry was performed as previously described [19].

Determination of Isotopic Enrichment

Isotopic enrichment determination of leucine was performed on a Fisons GC8060/Trio 1000 quadrupole system (ThermoQuest, Egelsbach, Germany). The samples were injected into a 30 m × 0.32 mm, 0.25 μm DB-5MS capillary column (J & W Scientific, Rancho Cordova, CA, USA). Mass spectrometry was performed by negative-ion chemical ionization with methane as the reagent gas. Selected ion monitoring (SIM) of the leucine peak was performed for [$^2H_3$]-enrichment using the [M−HF] and [M−HF + 3] isotopomers ($m/z = 349$ and 352), respectively. Measurements were done in quadruplicates at baseline and in triplicates in subsequent samples. Because of the non-negligible mass associated with stable isotope tracers, raw enrichment data were transformed to tracer/tracee ratios using predescribed algorithms [20].

Kinetic Analysis

A multicompartmental model (Fig. 1) was used to describe VLDL-, IDL-, and LDL-apoB-100 isotopic enrichment data and to derive kinetic information. Each compartment or pool represents a group of kinetically homogenous particles. In the present study, the SAAM II program (SAAM Institute, Seattle, WA, USA) was used to fit the model to the observed tracer data. Metabolic parameters were subsequently derived from the model parameters giving the best fit. The model assumes that apoB-100 enters plasma through compartments 11, 21, or 31 (Fig. 1). Compartment 11 is used to describe the kinetics of apoB-100 in the VLDL subfraction. The VLDL particles in compartment 11 can be converted to IDL, or can be removed directly from plasma. The IDL section of the model is described by compartment 21. Particles in compartment 21 can be converted to LDL, or can be removed directly from the plasma. LDL-apoB-100 kinetics is described by compartment 31. IDL apoB can be derived from VLDL (compartment 11) or directly from the site of secretion. Similarly, LDL apoB can be derived from the delipidation cascade (IDL, compartment 21), or from the site of secretion.

Compartment apoB masses were included in the fitting procedure. After we fitted the model to the tracer/tracee data, apoB-100 fractional catabolic rates (FCR) and production rates (PR) were determined using the best fit. The FCR for all lipoprotein fractions were calculated by adding the individual rate constants, termed k values, leaving the compartments. For turnover calculation, we used a weighted, related to mass distribution, average of the turnover rates of individual pools. We were able to apply this model to all subjects studied under medication and under control conditions. All parameters were fitted as adjustables.

As indicated by the fractional distribution parameters d (Fig. 1), about 87% of the material was secreted as VLDL,

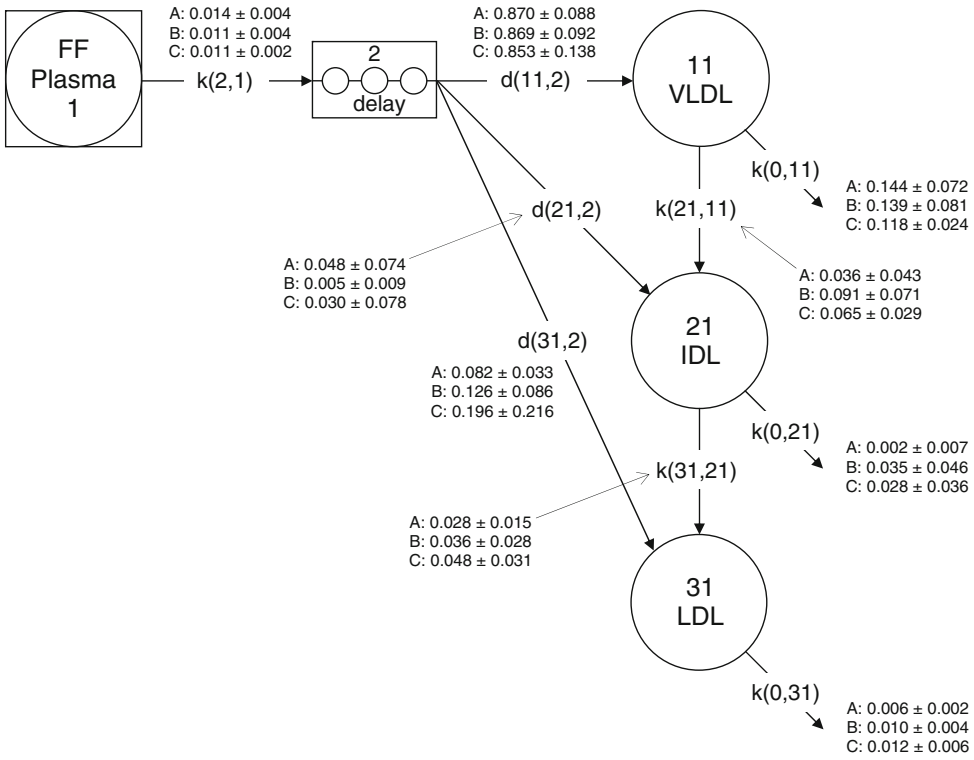

Fig. 1 Rate constants, pool sizes of apoB-100 and fractional distribution parameters out of the delay compartment in eight subjects under no-treatment conditions (phase A), during treatment with 40 mg/day simvastatin (phase B) and during chronic treatment with an additional oral bolus of 80 mg simvastatin (phase C). Unit for delay is given as hours ± SD, unit for rate constants is given as pools/d ± SD. *FF* forcing function

up to 4% as IDL and up to 8% as LDL. Under simvastatin treatment there was a trend towards a decrease in the proportion secreted as VLDL from 87 to 85%. However, these differences were not significant. There were significant differences between the main rate constants of the lipoprotein delipidation cascade between the three treatment phases. The conversion of VLDL to IDL was increased by simvastatin, as were the conversion from IDL to LDL and the final catabolism from the LDL compartment (see legend to Fig. 1).

Statistical Analysis

The primary study outcomes were the main kinetic parameters pool size, FCR, and PR determined by multicompartmental modeling. The null hypothesis was no change in kinetic parameters between treatment phases. Statistical analysis was performed using the non-parametric Friedman test to determine overall differences. Multiple comparisons between groups were performed using Wilcoxon signed rank tests. The trial was powered to achieve statistically significant results in the event of six out of eight cases showing unidirectional changes for one parameter. Statistical analysis was carried out using StatView Version 5.0 (SAS Institute, Inc., Cary, NC, USA). Compartment modeling was performed using SAAM II (Simulation, Analysis, and Modeling Software for Kinetic Analysis), Version 1.1.2 (SAAM Institute, University of Washington, WA, USA). Dietary protocols were evaluated using Prodi Version 4.5 Software (Wissenschaftliche Verlagsgesellschaft, Stuttgart, Germany).

Results

Characteristics of Subjects

Table 1 shows the baseline characteristics of the subjects. Mean age was 43 years and subjects were non-obese with a mean BMI of 25.3 kg/m^2. Lean body mass and fat mass were 76 and 24%, respectively, as measured by bioelectrical impedance analysis. Their apolipoprotein E (apoE) phenotype consisted of E2 and/or E3 alleles. None of the subjects smoked. All had normal fasting plasma glucose and insulin concentrations, and normal thyroid hormone levels. All other blood values were also in the normal range. Their mean ± SD baseline HDL cholesterol concentration was 35 ± 7 mg/dL. All subjects maintained their body weights throughout the study. Analysis of their dietary protocols did not show any differences between the three treatment phases (Table 2). Medication compliance was excellent as documented by pill count.

Table 1 Baseline characteristics of the subjects

Parameter	Mean ± SD	Range
Age (years)	43 ± 15	28–67
Height (cm)	180 ± 6	170–187
Weight (kg)	82 ± 7	74–95
Body mass index (kg/m^2)	25.3 ± 2.7	21.5–29.4
Lean body mass (%)	76 ± 4	69–80
Body fat mass (%)	24 ± 4	20–31
ApoE phenotype	E2/E3 (2 subjects) E3/E3 (6 subjects)	
HDL cholesterol (mg/dL)	35 ± 7	23–44
Plasma glucose (mg/dL)[a]	74 ± 7	67–89
Plasma insulin (mU/L)[a], normal range 3–17 mU/L	5.4 ± 2.1	1.7–9.0
Thyroid stimulating hormone (mU/L)[b]	1.2 ± 0.7	0.3–2.2

[a] All subjects were in the non-insulin resistant state, as analyzed by the homeostasis model assessment [(insulin × glucose)/405 < 1]

[b] All subjects were euthyroid

Lipoprotein Concentrations and Relative Composition

Lipoprotein Concentrations

Table 3 shows the lipoprotein concentrations at baseline (A) and during the two treatment phases (B and C). Between phases A and B total cholesterol, VLDL-C, IDL-C, and LDL-C decreased significantly by 27, 34, 44, and 29%, respectively. Decreases in phase C were significantly more pronounced when compared to phase B. Similarly, total plasma triglycerides, VLDL-, IDL-, and LDL-triglycerides decreased by 19, 13, 27, and 24% with significantly greater effects for plasma and VLDL-triglycerides during phase C. Plasma apoB-100, VLDL-, IDL-, and LDL-apoB-100 decreased significantly by 38, 25, 42, and 37%. There was no significant difference of phase B versus phase C.

Lipoprotein Composition

The ratio of cholesterol to apoB-100 indicates the density of lipoprotein particles, since each lipoprotein particle contains only one apoB-100 molecule. Under baseline conditions, the cholesterol content in relation to the apoB-100 content was highest in VLDL (ratio 2.6), followed by IDL (ratio 2.0) and LDL (ratio 1.7). Simvastatin treatment decreased the ratio in VLDL significantly by 14%, while it was unchanged in IDL and increased significantly in LDL by 13% (Table 3). In phase C, the decrease in VLDL was even more pronounced (−30%) and it reached also statistical significance in IDL (−18%), while the relative composition of LDL was not significantly

Table 2 Dietary protocols

Parameter	Phase A	Phase B	Phase C
Total energy (kcal/day)	2,363 ± 580	2,272 ± 564	2,321 ± 592
Energy per kg body weight (kcal/day)	29 ± 7	27 ± 5	28 ± 6
Proteins (%)	15 ± 2	15 ± 2	15 ± 3
Carbohydrates (%)	48 ± 7	46 ± 7	47 ± 8

changed. The ratio of triglycerides to apoB-100 showed a large variability. Under baseline conditions, VLDL had the largest triglyceride content (ratio 6.5) while it was lower in IDL (ratio 0.6) and LDL (ratio 0.2). Treatment did not significantly affect the relative composition, but an increase of the ratio of 20 to 50% indicated that treatment decreased apoB-100 to a greater extent than triglyceride content.

Kinetics of apoB-100

Detailed kinetic information obtained by multicompartmental model analysis is summarized in Table 4 and in Fig. 1. Mean VLDL, IDL, and LDL apoB-100 tracer/tracee ratios during phases A, B and C are shown in Fig. 2.

In short, IDL and LDL apo-B-100 pool sizes decreased significantly during phases B and C as compared to phase A [for IDL −42% ($P = 0.012$) and −49% ($P = 0.012$)]; for LDL [−36% ($P = 0.012$) and −42% ($P = 0.012$), for phases B and C respectively]. Pool size tended to decrease in VLDL [−25% in B ($P = 0.069$) and −20% in C ($P = 0.069$)]. There were no significant differences between phase B and C.

Fractional catabolic rates were significantly higher in IDL and LDL during phase B (+169 and +87%). The change in VLDL FCR did not reach statistical significance.

FCR fractional catabolic rate, *PR* production rate, *apoB-100* apolipoprotein B-100

† Wilcoxon signed-rank test

‡ Friedman test

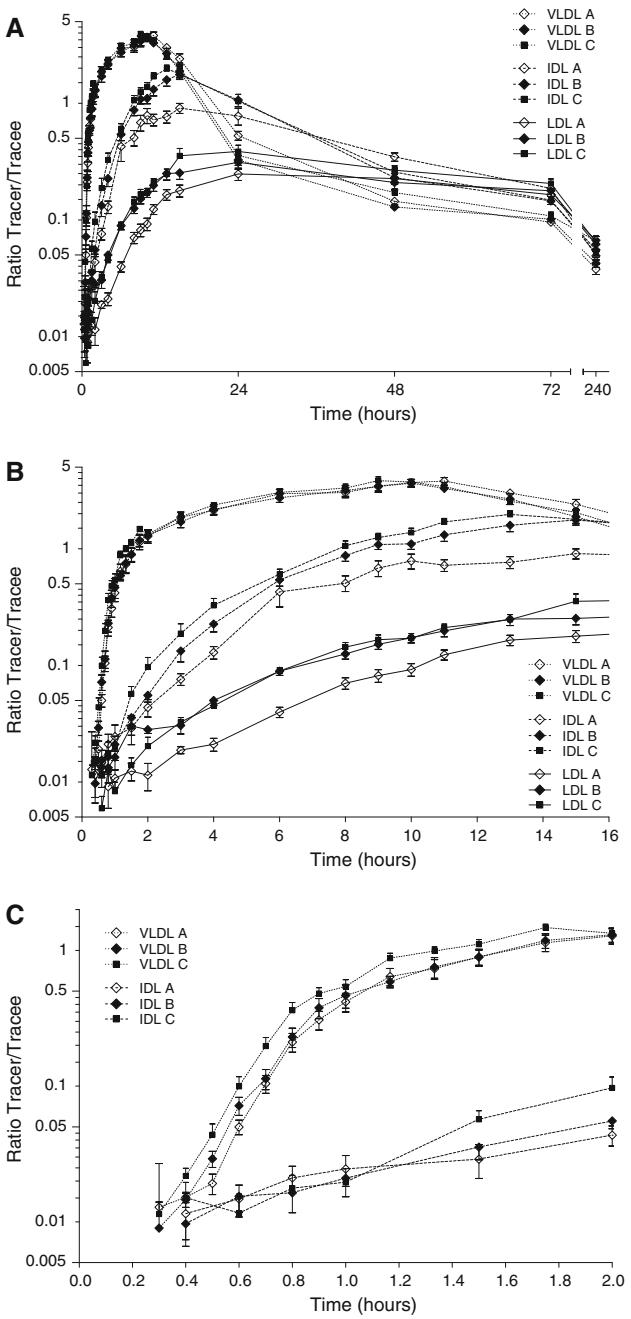

Fig. 2 Leucine tracer/tracee ratios for VLDL apoB-100 under no-treatment conditions (phase A), during treatment with 40 mg/day simvastatin (B), and after an additional bolus of 80 mg simvastatin during chronic treatment with 40 mg/day (C). Results are means ± SEM. To increase readability, *panel A* shows the whole time course of the study until 240 h, *panel B* until 16 h and *panel C* until 2 h (only VLDL and IDL)

During phase C, IDL and LDL FCRs tended to be further significantly increased (+187 and +133%) in comparison to phase B, while there was no difference between phases B and C in the VLDL FCR.

Regarding production rates, mean values were decreased in VLDL and increased in IDL and LDL, however these changes were not statistically significant.

Discussion

There is experimental [21, 22] and clinical [23–27] evidence suggesting that HMG-CoA-reductase inhibitors decrease the hepatic secretion of VLDL apoB-100, the precursor of the major apoB-100-containing lipoproteins. ApoB-100 is synthesized by the liver and secreted primarily with VLDL. Once in plasma, VLDL is subjected to hydrolysis by lipoprotein lipase that converts the triglyceride-rich particles into IDL and LDL. Therefore, the fall in LDL concentrations during statin treatment could also be due to a reduction in the conversion rate of VLDL to LDL, in addition to the enhanced receptor-mediated fractional removal of LDL from the circulation. This has been suggested by early investigations using radioisotope tracers [28]. In the present study we investigated apoB-100 lipoprotein turnover with a special focus on lipoprotein secretion or production.

The influence of simvastatin on apoB-100 kinetics was investigated in fasting non-obese subjects with near normal LDL cholesterol levels and normal triglycerides, to test the hypothesis that simvastatin decreases production of apoB-100-containing lipoproteins. Fasting state was chosen since it has been shown that the major predictor for VLDL apoB-100 production rate is feeding [29]. In our study, inhibition of HMG-CoA reductase (and thus cholesterol synthesis) using a standard dose of the most widely used statin resulted in the following major findings: Pools sizes of all three lipoprotein fractions decreased due to increased FCRs. FCRs were significantly increased in IDL and LDL. In VLDL, mean FCR also increased slightly but the change did not reach statistical significance due to a large variation of the response. Production rates tended to decrease in VLDL and to increase in IDL and LDL lipoprotein fractions, as derived from the multicompartment model.

It is generally assumed that statins lower cholesterol by enhancing lipoprotein catabolism through a statin-induced up-regulation of hepatic LDL receptors. However, additional mechanisms have been postulated, such as the production of an apoB-100-containing lipoprotein particle that is a better ligand for the LDL receptor or a reduced production of LDL apoB-100 due to either a decreased secretion of LDL directly into the plasma, or to a decreased conversion of VLDL to LDL (via IDL) [30]. Decreased conversion may be due to either reduced secretion of hepatic VLDL or increased removal of VLDL (and IDL) from the plasma by up-regulated LDL receptors. The

findings of our study confirm and expand these hypotheses. We found a clearly enhanced catabolic rate of LDL (FCRs increased by 87 and 133%, phases B and C, respectively). It should be pointed out that under our experimental conditions in phase C, acute-on-chronic statin administration, we achieved a situation in vivo where the expression of the LDL receptor can be expected to be maximal. Our data support the assumption that statins induce the production of a lipoprotein particle that is a better ligand for the LDL receptor, since the catabolic rate also of IDL but not of VLDL increased. We found that simvastatin treatment was associated with increased removal rate constants of IDL and LDL ($k(0,21)$ and $k(0,31)$). This finding could be explained by the simvastatin-induced changes in the composition of apoB-100-containing lipoproteins, thus increasing their affinity for the LDL receptor, as previously described [30]. The acute large dose of statin, however, was not reflected in changes to apoB-100 kinetic variables although cholesterol was reduced in lipoprotein fractions. These findings suggest that a further up-regulation of the processes responsible for the metabolism and clearance of apoB-100 from plasma is not possible due to the uncoupling of the statin effect on cholesterol concentrations (and synthesis?) and the impact on apoB-100 kinetics.

Our subjects had baseline VLDL PR and FCR very similar to those previously described in the literature for normolipidemic subjects [31]. Our data show that under simvastatin treatment the VLDL PR was not significantly decreased. Our results are in agreement to those of Lamon-Fava et al. [32] who showed that atorvastatin does not alter the VLDL PR of subjects with apo B-100 PR within the normal range of normolipidemic men and women. The VLDL-lowering effect (decrease in pool size of approximately 25%) is probably due to an increased catabolism of VLDL particles, although the VLDL FCR showed a large variability in the response to statin treatment from a decrease of −13% to an increase of +130%, whereas the variability in PR was not as great.

Regarding the observed increase in the LDL FCR, our results are in agreement to the results of Malmendier et al. [33] who, using radiolabeled isotopes, showed in normocholesterolemic subjects that simvastatin increases LDL FCR, and to those of Parhofer et al. [34] who found that in subjects with combined hyperlipidemia pravastatin had no effect on the kinetics of VLDL but was associated with an increased FCR of LDL. However, in a study in subjects with combined hyperlipidemia, Cuchel et al. [35] showed that lovastatin has no significant influence on the FCR of VLDL, IDL or LDL, but there was a significant decrease by 25 to 35% in the PRs in all three fractions. Differences in the characteristics of the subjects, study design, methodology and kinetic model may account for the differences in results among the studies. In particular, the relatively low baseline FCRs in our study may be explained by these differences.

In summary, it could be postulated that the reduction of LDL by statins through a decreased production of apoB can be assumed mainly in hyperlipidemic, but not in normolipidemic subjects [23–28, 35, 36]. Thus, higher baseline cholesterol and/or high triglyceride concentrations seem to be a prerequisite for this mechanism of action, which supports the hepatic lipid-availability hypothesis [7, 8].

The study has a number of limitations. Multicompartmental analyses usually require steady state conditions, which may not have been perfectly reached in phase C of our study, although mass changes were modeled in parallel. However, in lipoprotein turnover studies samples are usually taken over several days and a strict steady state cannot be assumed, unless subjects are completely fasted or continuously fed, both being unphysiological conditions. Another limitation may be the power of the statistical analyses. It has been shown though, that physiologically meaningful results in paired-design studies can be obtained with approx. eight subjects [37].

In conclusion, our data suggest that simvastatin affects mostly the metabolism of apoB-100-containing lipoproteins through an increase in their catabolic rate, which is further robustly increased after an acute-on-chronic statin administration. The lipid-lowering effect of simvastatin is not mediated through a decrease in apoB-100 lipoprotein production rates.

Acknowledgments The authors wish to thank Mrs. Anja Kerksiek for her excellent technical assistance.

Abstract In contrast to the consumption of long-chain triacylglycerols (LCT), consumption of medium- and long-chain triacylglycerols (MLCT) reduces the body fat and blood triacylglycerols (TAG) level in hypertriacylglycerolemic Chinese individuals. These responses may be affected by BMI because of obesity-induced insulin resistance. We aimed to compare the effects of consuming MLCT or LCT on reducing body fat and blood TAG level in hypertriacylglycerolemic Chinese subjects with different ranges of BMI. Employing a double-blind, randomized and controlled protocol, 101 hypertriacylglycerolemic subjects (including 67 men and 34 women) were randomly allocated to ingest 25–30 g/day MLCT or LCT oil as the only cooking oil for 8 consecutive weeks. Anthropometric measurements of body weight, BMI, body fat, WC, HC, blood biochemical variables, and subcutaneous fat area and visceral fat area in the abdomen were measured at week 0 and 8. As compared to subjects with BMI 24–28 kg/m^2 in the LCT group, corresponding subjects in the MLCT group showed significantly greater decrease in body weight, BMI, body fat, WC, ratio of WC to HC, total fat area and subcutaneous fat area in the abdomen, as well as blood TAG and LDL-C levels at week 8. Based upon our results, consumption of MLCT oil may reduce body weight, body fat, and blood TAG and LDL-C levels in overweight hypertriacylglycerolemic Chinese subjects but may not induce these changes in normal or obese hypertriacylglycerolemic subjects.

Keywords Medium-and long-chain triacylglycerols · Body fat · Blood triacylglycerols · Hypertriacylglycerolemia · Overweight · Chinese · Long-chain triacylglycerols

Abbreviations

ALT	Alanine aminotransferase
AST	Aspartate aminotransferase
BMI	Body mass index
HC	Hip circumference
HDL-C	High-density lipoprotein-cholesterol
LCT	Long-chain triacylglycerols
LDL-C	Low-density lipoprotein-cholesterol
MLCT	Medium- and long-chain triacylglycerols
SFA	Subcutaneous fat area
TAG	Triacylglycerols
TFA	Total fat area
VFA	Visceral fat area
WC	Waist circumference
WHR	Ratio of waist circumference to hip circumference

Introduction

The prevalence of being overweight or obese has increased by 40.7 and 97.2%, respectively, in mainland China since 1992 [1]. This trend will undoubtedly increase the incidence of chronic diseases such as hypertension, diabetes, stroke and coronary heart disease. The total medical cost

that can be attributed to being overweight and obese was estimated at 21.11 billion Chinese Renminbi (RMB) Yuan and accounted for 25.5% of the total medical costs for the four chronic diseases, or 3.7% of the total national medical costs, in 2003 [2]. The high economic burden of being overweight or obese suggests an urgent need to develop effective interventions for preventing and controlling overweightedness and obesity. Hypertriacylglycerolemia is an independent risk factor for cardiovascular disease [3, 4]. There is a suggestion that choosing the right type of dietary fat could be an effective strategy for preventing weight gain or fat deposition and reducing the blood levels of triacylglycerols (TAG) under an appropriate dietary regimen [3, 5].

Ordinary dietary fats are mainly long-chain triacylglycerols (LCT) composed of long-chain fatty acids with carbon numbers ranging from 14 to 18. In contrast, medium-chain triacylglycerols (MCT), composed of fatty acids with carbon numbers of 8–12, are found in palm oil and coconut oil, which are minor components of a normal diet. However, the carbon numbers of MCT used in our study were 8–10. Because MCT are hydrolyzed more rapidly and metabolized more completely than are LCT, rapid oxidation prevents deposition of fat [6]. For these reasons, MCT may be useful in dietary therapy. Animal studies have shown that consumption of MCT decreases body weight and the amount of fat deposited [7]. Dietary MCT also reduce body fat accumulation in healthy men and women [8]. Furthermore, ingestion of 18 g/day MCT has been shown to decrease body weight and waist circumference (WC) in moderately overweight humans with type 2 diabetes mellitus [9].

MCT are difficult to use as cooking oil because of a low smoke point and foam generation on being mixed with other vegetable oils or in frying. A new oil composed of medium- and long-chain triacylglycerols (MLCT) in the same glycerol molecule range produced by a transesterification technique has been developed recently as a cooking oil [10]. Our previous studies indicated that MLCT reduced body fat and blood TAG in Chinese hypertriacylglycerolemic subjects [11]. However, whether body mass index (BMI) affects the response in these hypertriacylglycerolemic Chinese individuals is unknown.

Elevated levels of free fatty acids (FFA) in the blood commonly seen in obese persons are associated with the expansion of adipose mass and insulin resistance. Blood cytokines such as leptin, plasminogen activator inhibitor-1 (PAI-1), tumor necrosis factor-α (TNF-α), and interleukin-6 (IL-6) levels were often increased in obese subjects. These are thought to promote insulin resistance [12]. Insulin resistance might hinder any increase in fat oxidation and induce difficulties in the reduction of body fat and TAG in obese subjects. These observations prompted us to investigate the response to MLCT consumption in subjects with different BMI categories.

The working group on obesity in China suggested that BMI values of 24–28 kg/m^2 and ≥28 kg/m^2 indicated overweight and obesity, respectively, in Chinese individuals [13]. We analyzed our previous data based on the BMI categories to elucidate whether overweight individuals responded differently to MLCT consumption than did obese individuals.

Materials and Methods

Study Design and Subjects

The study was carried out in accordance with the Helsinki Declaration and was approved by the Ethics Committee of the Chinese People's Liberation Army General Hospital. The study procedures were fully explained to all subjects, who gave their informed consent before the start of the study. The study was a double-blind, randomized clinical trial involving 76 men and 36 women with hypertriacylglycerolemia values of 1.7–4.5 mmol/L. All subjects had no history of diabetes, hypertension, renal and hepatic disease, or gastrointestinal disease and were not receiving any medication. The study population was randomly allocated to receive MLCT or LCT oil by random numbers assigned by the providers of the MLCT and LCT oil, who also encoded the oils with matching random numbers. Neither the subjects nor the researchers of this study knew which subject was receiving which oil during the study. Before starting the study, dietary energy intake for each individual was calculated using the Harris–Benedict equation. Food choice and amount for each subject were suggested by experienced dietitians and doctors by face-to-face communication. Recommended daily carbohydrates were about 55–60% of total daily calorie intake, and mainly came from complex carbohydrate of the starch food group, such as cereals and tubers. Ready-to-eat cereal products such as biscuits, crackers, instant noodles, etc. containing higher fat and/or higher refined sugar and alcoholic beverage were not allowed to be eaten during the study period. Recommended daily fats were about 25–30% of total energy intake, MLCT or LCT oil, as the only cooking oil, was to be consumed at a rate of 25–30 g/day, which was about 12–15% of the total daily energy intake, other types oil such as coconut were not allowed to be used during our study. Other fat mainly came from balanced foods such as egg, milk, lean red meat and white meat. These recommended foods provide balanced nutrients. The dietary regimen was maintained at relatively fixed energy and nutrients intake. In addition, both the time and the intensity of physical activity for

each subject were well controlled. A manual on the study was distributed to all subjects, in which all subjects were specifically advised how to maintain healthy bodily activity and to take moderately intensive exercise daily throughout the trial. The recommended activities were walking (4–5 km/h), housework, babysitting, and bicycle-riding (8–10 km/h), etc.

The subjects were instructed to record their physical activity intensity, duration and method for 3 days and the intake of the type and quantity of food for 3 days each week (including one weekend day) at baseline (week 0) and at weeks 2, 4, 6 and 8. The physical activities included walking (4–5 km/h), housework, childcare, and bicycle riding (8–10 km/h). The diaries were collected weekly to confirm that subjects were following the instructions, and if not, the subjects were advised to drop out of the study. Daily intake of energy, fat, protein, and carbohydrates was calculated from the food record on the basis of the China Food Composition Tables published in 2002.

Anthropometric and Biochemical Measurements

Anthropometric variables were measured by trained investigators. Body weight and height were measured to the nearest 0.1 kg and 0.1 cm. WC was measured at the umbilical level. Hip circumference (HC) was measured at the level of the greatest posterior protuberance. Both WC and HC were measured to the nearest 0.1 cm with the subject in a standing position, and the ratio of WC to HC (WHR) was calculated. All measurements were taken at baseline and at week 8.

Blood samples were taken in the morning after 12 h of overnight fasting at baseline and week 8. Levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), blood glucose, total cholesterol (TC), TAG, high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C) were measured using a 7600-automated system (Hitachi, Tokyo, Japan).

Measurement of Body Fat and Abdominal Fat Area by Computed Tomography (CT)

The measurements were carried out after 12 h overnight fasting at baseline and at week 8. Body fat was measured by use of a BCA-2A body composition analyzer (Tongfang, Qinghua, Beijing, China). Subjects underwent CT [Pro 16 CT (GE, USA)] scanning at the umbilical level at the Chinese People's Liberation Army General Hospital. Visceral fat area (VFA) and subcutaneous fat area (SFA) were obtained from the CT images as described in [14]. Blood sampling, anthropometric measurements and CT scanning were performed on the same day.

Test Oils

The test oils of MLCT and LCT were supplied by The Nisshin Oillio Group (Tokyo). The fatty acids and TAG compositions of MLCT and LCT are listed in Table 1 and the same as those in a previous report [10]. In MLCT, the concentration of medium-chain fatty acids (MCFA), C8:0 and C10:0, was 13% of total MLCT oil weight (Table 1).

Statistical Analysis

Data were expressed as means ±SD. The general linear model (GLM) was used to test almost all data except for a chi-square test for gender distribution. In our GLM analysis, fixed factors were BMI and oil, a random factor was gender, covariate was age. The full factorial model, which included main effects and factors interaction, was used in our study. If a significant difference was detected, comparisons of means were performed by Student's t test between the two groups and by a paired t test between the initial and final values in the same group. All analyses involved use of SPSS v10.0 for Windows (SPSS Inc.,

L long-chain fatty acids, *M* medium-chain fatty acids, *LCT* long-chain triacylglycerols, *MLCT* medium- and long-chain triacylglycerols, *ND* not detected

Chicago, IL, USA). The level of significant difference was set at $P < 0.05$.

Results

Subjects

Among the subjects, one had a traffic accident, one had a cerebral infarction, two were not willing to consume the specified oil and seven were unable to consume the oil for consecutive days (three were out of town on business and four were on vacation). Thus these eleven subjects were excluded from our study, and 101 subjects were enrolled finally in the study. There were 34 men and 16 women left in the LCT group, and 33 men and 18 women in the MLCT group at the end of the study. No gender distribution differences were noted between the two groups. The characteristics of the groups at the beginning of the study are shown in Table 2.

Intakes of Energy, Protein, Fat, Carbohydrate and Physical Activity Time and Gender Distribution

GLM analysis revealed that there was no significant difference in daily intake of total energy, protein, fat and carbohydrate or daily physical activity time among all the subgroups at baseline and week 8 ($P > 0.05$). In addition, chi-square analysis showed that there was no significant difference in gender distribution among all subgroups (Table 3).

Table 2 Characteristics of subjects consuming long-chain triacylglycerols (LCT) or medium- and long-chain triacylglycerols (MLCT) oil at baseline

Index	LCT ($n = 50$)	MLCT ($n = 51$)
Age (year)	53.2 ± 13.0	54.2 ± 12.5
Male (%)	34 (68.0%)	33 (64.7%)
Height (cm)	165.9 ± 8.8	166.5 ± 6.7
Body weight (kg)	71.5 ± 9.0	72.0 ± 11.4
BMI (kg/m^2)	25.9 ± 2.4	25.9 ± 3.3
Body fat weight (kg)	17.2 ± 4.4	17.4 ± 5.8

ALT alanine aminotransferase, *AST* aspartate aminotransferase, *BMI* body mass index, *TC* total cholesterol, *TAG* triacylglycerols

Anthropometric Measurements

GLM analysis showed that the oil had an effect, but the BMI no effect. As compared with their initial levels, body weight, BMI and WC decreased significantly in subjects with different BMI categories in the MLCT group. HC and WHR were lowered significantly in subjects with BMI 24–28 kg/m^2 in the MLCT group. WHR decreased significantly in subjects with BMI ≥28 kg/m^2 in the MLCT group ($P < 0.05$; Table 4). However, no similar changes in these indices were observed in the LCT group.

BMI × oil interaction was found using GLM analysis, further analysis revealed that there were greater decreases in the changes of body weight, BMI, WC and WHR in subjects with a BMI 24–28 kg/m^2 in the MLCT group as compared to their corresponding controls in the LCT group ($P < 0.05$; Table 4 and Fig. 1).

Body Fat Composition

GLM analysis showed that the oil has effects, but the BMI no effect. When compared with their baseline, body fat weight, TFA and SFA decreased significantly in subjects with BMI 24–28 kg/m^2 in MLCT group, but TFA and VFA increased in the same BMI category in the LCT group. Body fat weight and TFA was lowered significantly in subjects with a BMI <24 kg/m^2 in the MLCT group, however, VFA increased in the same BMI category in the LCT group ($P < 0.05$; Table 5).

BMI × oil interaction was found using GLM analysis, further analysis revealed the extent of decreases in changes and change rates of body fat weight, TFA and SFA in subjects with a BMI 24–28 kg/m^2 were greater in the MLCT group than those in corresponding subjects in the LCT group ($P < 0.05$; Table 5).

Blood Biochemical Variables

GLM analysis showed that the oil had effects, but the BMI no effect. When compared to their baseline, a significant decrease in blood TAG and an increase in HDL-C in subjects with a BMI 24–28 kg/m^2 in the MLCT group were observed; however, blood TAG, LDL-C and TC levels were significantly higher in the same BMI category subjects in the LCT group; LDL-C and TC increased significantly in subjects with a BMI <24 kg/m^2 in the LCT group. Blood TAG levels decreased significantly in subjects with a BMI ≥ 28 kg/m^2 in the MLCT group ($P < 0.05$; Table 6).

BMI × oil interaction was found by using GLM analysis, further analysis revealed that the extent of decreases in changes and change rates in blood TAG and LDL-C were greater in subjects with a BMI 24–28 kg/m^2 in the

Discussion

In this study, consumption of MLCT oil induced significant decreases in body weight, body fat, and SFA in hypertriacylglycerolemic and overweight subjects as compared with that of LCT oil. Our results agree with those of St-Onge et al. [15], who found that consumption of a diet rich in MLCT for 28 days resulted in greater loss of adipose tissue in overweight men than did a diet rich in LCT. Our results are similar to those of Tsuji et al. [8], Nosaka et al. [16] and Kasai et al. [17]. Tsuji et al. [8] who found that a 10-g/day MLCT consumption might reduce body weight and fat in individuals with a BMI ≥23 kg/m^2 as compared with LCT consumption. Nosaka [16] found similar effects on the body composition with one-half of the MCT intake than that in the previous study. Kasai et al. [17] reported that subjects consuming the test bread, which had been made with 14 g (about 6% of total energy) of

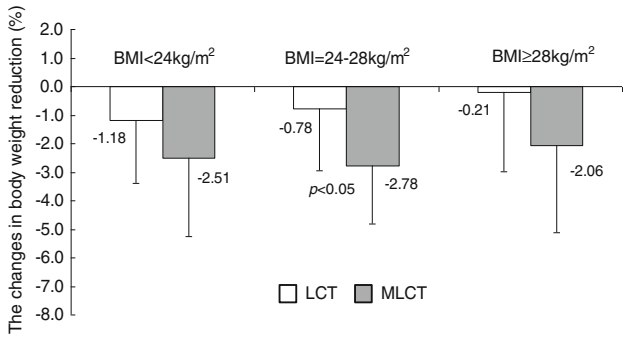

Fig. 1 The effects of LCT and MLCT on the changes in body weight reduction

MLCT containing 1.7 g MCFA had significant reduced body weight and body fat accumulation. From these results, we can suggest that an intake of 10–14 g MLCT can reduce body weight and body fat.

Yost and Eckel [18] conducted a study of the effect of an 800 kcal diet containing MCT. MCT intake did not result in greater weight loss in obese women than an isocaloric diet containing LCT. It is possible that small weight loss of MCT intake may be indistinguishable from the large weight loss effects of very low calorie diets. The study supports our finding that MLCT consumption may not be more effective at reducing fat mass in obese individuals than in overweight individuals.

Our results indicated that overweight subjects responded better to MLCT consumption than did lean or obese subjects. These different effects might be due to the metabolic difference in energy expenditure and fat oxidation in subjects with different body weights. A previous study showed that normal weight and morbidly obese subjects had similar increases in postprandial energy expenditure over resting metabolic rate value [19]; however, fat oxidation was found to be greater in normal weight subjects than in obese

subjects with MLCT consumption relative to LCT in another study [20]. Furthermore, in overweight people, those with relatively a lower body weight had the greatest increase in energy expenditure and fat oxidation [21]. Therefore, the intake of MLCT may be effective in reducing body weight and body fat with body weight not yet highly elevated.

Our results might be explained in part by a greater increase in diet-induced thermogenesis after ingesting MLCT than LCT [10, 22]. Ogawa et al. [10] conducted a study of 20 volunteers given a liquid meal containing 14 g of MLCT or LCT; intake of MLCT significantly increased diet-induced thermogenesis. With regard to the mechanism of thermogenesis, several studies have shown that MCT-fed rats had a higher oxygen consumption than LCT-fed rats after administration of norepinephrine or the sympathetic activation of brown adipose tissue [23–25]. Hence, intake of MLCT might not trigger greater diet-induced thermogenesis in obese subjects than in lean and overweight subjects.

Obesity is associated with insulin resistance [12]. Insulin resistance that is characterized by decreasing adipose tissue lipolysis and resisting increases in fat oxidation and increasing hepatic synthesis of triacylglycerols may explain in part that our results showed less response in obese subjects than in overweight subjects in body weight control after intake of MLCT. In other words, intake of MLCT did not induce greater lipolysis and fatty acid oxidation in obese subjects than in overweight subjects.

We also found that consumption of MLCT resulted in a reduced level of fasting blood TAG in hypertriacylglycerolemic and overweight subjects. The mechanism remains unclear. MCT promoting energy expenditure and fat oxidation in both liver and adipose tissue may have contributed to our results [26–29]. In addition to the effect of MCT consumption on fasting blood TAG reduction, MCT intake also induces lower postprandial TAG levels than with consumption of LCT or a soybean oil liquid diet [30, 31].

MLCT consumption did not affect blood cholesterol concentration as compared with LCT consumption; however, MLCT consumption decreased LDL-C concentration and increased HDL-C level. These results suggest that MLCT may have a protective role in the cardiovascular system. Why MLCT consumption does not affect serum cholesterol levels needs to be determined. One possible explanation is that the activity of 3-hydroxy-3-methylglutaryl-CoA, a key enzyme in cholesterol synthesis, is reduced after MLCT administration [32]. In addition, LDL receptor activity in mononuclear cells is higher with MLCT than trilaurin consumption [33].

In contrast to our results, Cater et al. [34] found that natural food supplemented with MLCT increased plasma TC, LDL and TAG levels as compared with a diet supplemented with long-chain fatty acids. The fat accounted for 53% of intake, the mean BMI was 27 ± 5 kg/m^2, and the total amount of fat intake and subject selection, as well as food composition, which may explain their conclusions. In the Temme et al. [35] study, exchanging of oleic acid with MCFA increased serum TC and LDL-C concentrations; however, the response did not differ significantly from the responses to oleic acid and myristic acid, so their conclusions need to be confirmed.

Conclusion

Intake of MLCT might help reduce body fat and levels of fasting blood TAG and LDL-C in hypertriacylglycerolemic and overweight Chinese subjects under an appropriate dietary regimen. MLCT might be useful for control of abnormal TAG metabolism and body fat accumulation in overweight subjects. However, a longer term and larger sample size clinical trial is needed to confirm the substantial effects of MLCT in overweight and hypertriacylglycerolemic individuals.

Abstract Genetic variations in the *APOA1/C3/A4/A5* gene cluster have been studied and proposed to be the leading key for susceptibility to cardiovascular diseases and age-associated disorders. We aimed to investigate the associations of rs12721026 (*APOA1*) and rs1729408 (*APOA5*) polymorphisms and their haplotypes with some age-related diseases, as well as with lipids and proteins serum levels in a cohort from a Brazilian Elderly Longitudinal Study (EPIDOSO). Genotyping was performed by polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP). Statistical analyses were carried out using logistic regression analysis, Student's *t*-test, and linkage disequilibrium (LD) analysis. Polymorphic allele frequencies were 0.095 and 0.449 for rs12721026 and rs1729408, respectively. The C-allele of rs1729408 was associated with higher high-density lipoprotein (HDL) ($P = 0.022$) and glycated hemoglobin levels ($P = 0.020$). We also showed that rs12721026 and rs1729408 were in LD. The GC haplotype, which is composed of the G-allele of rs12721026 and the C-allele of rs1729408, was significantly associated with obesity ($P = 0.028$), with higher glycated hemoglobin ($P = 0.006$), and fasting glucose ($P = 0.0003$) compared to the TT haplotype, which includes the wild-type alleles of both polymorphisms. Moreover, we found an association between the TC haplotype and higher HDL levels ($P = 0.0039$). This is the first time that haplotypes involving these polymorphisms were evaluated. Our results showed that these polymorphisms were involved in the development of obesity and in alterations of lipids and proteins serum levels in a Brazilian population. The present findings might also clarify the role of these polymorphisms and their haplotypes in lipids and proteins metabolism.

Introduction

Increased low-density lipoprotein (LDL) and triglyceride (TG) [1] and decreased high-density lipoprotein (HDL) plasma levels have been shown to be independent risk factors for cardiovascular diseases (CVDs) [2] and

important determinants of atherosclerosis susceptibility [3]. In Brazil, the main cause of adult death is CVD (32%), followed by neoplasia [4]. Genetic and environmental factors play a key role in lipoproteins and lipids serum levels [5]. In fact, several genetic variants have been evaluated and associated with lipid profiles [6]. In 2009, three genome-wide association studies described 20 new loci associated with lipid serum levels [1, 7, 8], including the apolipoprotein gene cluster *APOA1/C3/A4/A5*, on 11q23, which has been associated with CVD and alterations on HDL, LDL, and TG serum levels [9].

APOA1 comprises roughly 70% of the HDL protein mass and acts in the transport of cholesterol from the peripheral tissues to the liver [10]. Indeed, several studies have shown a relationship between *APOA1* and protection against atherosclerosis [11]. The rs12721026 polymorphism (also known as *Pst*I), located in the 3′ flanking region of *APOA1*, has been associated with the development of CVD [12, 13] and decreased HDL levels [13].

APOA5 has been involved in TG metabolism [14] and presents lower serum concentration in comparison to other apolipoproteins. *APOA5* knockout mice showed four-fold increased TG compared to wild-type alleles [15]. In the promoter region of *APOA5*, there is a well described polymorphism (rs662799) which has been widely associated with TG levels. Our previous report showed no association of rs662799 with age-related morbidities in the same elderly cohort studied in the present study [16]. rs1729408 (also known as SNP4—single nucleotide polymorphism 4), an *APOA4/A5* intergenic polymorphism, has been associated with systolic blood pressure and measures of obesity in European populations [17] and with higher HDL in the Chinese population [18]. However, rs1729408 was not associated with CVD and lipid plasma levels in the French population [19].

In the current study, we aimed to investigate the association of the rs12721026 and rs1729408 polymorphisms and their haplotypes with morbidities affecting a cohort from a Brazilian Elderly Longitudinal Study (EPIDOSO), as well as with TG, total cholesterol, HDL, very-low-density lipoprotein (VLDL), LDL, creatinine, urea, albumin, glycated hemoglobin (HbAc1), and fasting glucose serum levels.

Experimental Procedure

Studied Population

The studied population was a subsample of 341 subjects (238 females and 103 males) who participated in wave 4 (2000–2001) of the Elderly Longitudinal Study (EPIDOSO) [20]. This population was composed of individuals of European (89.2%), Japanese (3.3%), Middle Eastern (1.8%), mixed, and/or other (5.7%) origins. The mean age of this population was 79.75 ± 5.38 years (range 66–97). All participants were informed about the study protocol and provided information about previous medical conditions. The Institutional Research Ethics Committee approved this study and all subjects or their legal representatives signed an informed consent according to the Declaration of Helsinki.

Clinical inquiries were performed to obtain information about previous diseases, current medication use, lifestyle, anthropometric, and blood pressure measurements. Physicians performed the physical examination and blood samples were collected for laboratory procedures. Table 1 summarizes all of the characteristics of our sample. CVD was considered to be positive when individuals self-reported previous CVD and were taking specific medication prescribed by physicians. Subjects either currently using anti-hypertensive drugs or those with systolic blood pressure above 140 or diastolic blood pressure above 95 mmHg were considered to be positive for hypertension [21]. Those currently taking insulin or oral medication and those with fasting glucose equal to or above 126 mg/dl were considered to be positive for type II diabetes [22]. Subjects with body mass index (BMI) above 27 kg/m^2 were considered to be positive for obesity [23]. Cognitive function was evaluated using the Mini-Mental State Examination (MMSE) screening instrument, validated for

Table 1 Characterization of the sample

the Brazilian population. A cut-off score for low cognition level (roughly classified as dementia) was 24 (out of 30) and presents 80–90% sensitivity and 80% specificity [24, 25]. Depression was characterized by a score of above 5 using a validated Brazilian version of the Older Americans Resources and Services (OARS) questionnaire [26]. Although some studies have shown that self-reported past history and medical records are usually concordant for selected medical conditions in the elderly [27], past histories were only accepted when there was also evidence in physical examinations, electrocardiograms, computed tomography scans, or physician reports.

Laboratory Examinations

Laboratory examinations were performed as routine examinations using commercial kits. Lipids and lipid fraction measurements were performed using routine enzymatic tests. Urea, creatinine, and albumin serum levels and fasting glucose were investigated routinely by colorimetric, kinetic, and ultraviolet tests. HbAc1 was measured by high-performance liquid chromatography. The coefficients of variation for these measurements ranged from 2 to 3.5%.

DNA Extraction

Genomic DNA from whole blood was isolated using the QIAamp® DNA Blood Midi Kit (Qiagen, Hilden, Germany), according to the manufacturer's instructions.

Polymorphism Detection

For both polymorphisms, polymerase chain reaction (PCR) was carried out in 25 µl containing 100 ng genomic DNA, 0.1 mmol/l dNTPs (LGC, São Paulo, Brazil), 2.0 mmol/l $MgCl_2$, 1 U Taq DNA polymerase (LGC, São Paulo, Brazil), and 0.4 µmol/l of each primer (Biosynthesis Inc., Lewisville, TX) in 10% buffer. The primers used for genotyping were as previously described [28, 29]. For rs1729408, the mixture was denaturated for 5 min at 94°C, passed through 35 cycles of denaturing at 94°C for 30 s, annealing at 60°C for 30 s, and extension at 72°C for 30 s, with a final extension at 72°C for 7 min. Six microliters of PCR product (162 bp) were digested with 2 U of *Hae*III (NEB, Ipswich, MA) at 37°C for 16 h. For amplification of the 740 bp-fragment of rs12721026, the mixture underwent 5 min denaturation at 94°C, 35 cycles of 94°C for 40 s, 66°C for 40 s, and 72°C for 60 s, with a final extension at 72°C for 10 min. Four units of *Pst*I (NEB, Ipswich, MA) were added to 10 µl of PCR product and then incubated for 3 h at 37°C.

Statistical Analyses

Allele frequencies were calculated by allele counting as described by Emery [30]. The Hardy–Weinberg equilibrium was evaluated using the χ^2 test. To assess the association between allele and morbidity, we used logistic regression analysis, which considered morbidity as a dependent variable and allele, age, and sex as covariates in the model. Odds ratios (ORs) with 95% confidence intervals (CIs) were also calculated. The mean serum levels concerning lipids, lipid fractions, urea, albumin, creatinine, HbAc1, and fasting glucose were compared between the two allele groups by Student's *t*-test. The χ^2 test, logistic regression analyses, and Student's *t*-test were performed using SPSS® 16.0. Linkage disequilibrium (LD) and haplotype association analysis with morbidities were performed by a linkage disequilibrium analyzer (LDA) [31] and Haploview software [32]. The expectation–maximization algorithm was used to estimate haplotype frequencies and to verify the association between haplotypes and morbidities. The χ^2 test was used to compare the haplotypes frequencies of cases and controls concerning the morbidities studied. Haplotype association with serum levels was performed using a *F*-test computed from a linear model fitted to the estimated haplotypes by the SNPStats web tool [33]. Statistical significance was accepted at $P < 0.05$.

Results

Polymorphic allele frequencies were 0.095 and 0.449 for the rs12721026 and rs1729408 polymorphisms, respectively. These polymorphisms followed the Hardy–Weinberg equilibrium in the whole population ($\chi^2 = 2.5464$; df = 1; $P = 0.1105$ and $\chi^2 = 1.7059$; df = 1; $P = 0.1915$, respectively).

Our results showed that the C-allele of rs1729408 was associated with higher HDL ($P = 0.022$) and HbAc1 levels ($P = 0.020$; Table 2). Nevertheless, the rs12721026 polymorphism was neither associated with lipids and proteins serum levels nor with the detected morbidities. We found that the rs12721026 and rs1729408 polymorphisms were in LD ($D' = 0.5438$; $r^2 = 0.0366$; $P = 0.0016$). When haplotypes were analyzed, the GC haplotype, which is composed of the minor alleles of rs12721026 and rs1729408 respectively, was associated with obesity (Table 3; $P = 0.028$), higher levels of HbAc1 ($P = 0.006$), and fasting glucose ($P = 0.0003$) compared to the TT haplotype, which includes the wild-type alleles of both polymorphisms (Table 4). In addition, we also found an association of the TC haplotype, composed of the T-allele

Table 2 Student's *t*-test results concerning lipids and proteins serum levels and polymorphisms in the Brazilian elderly cohort

of rs12721026 and the C-allele of rs1729408, with higher HDL levels ($P = 0.0039$; Table 4).

Discussion

Our results showed that the rs1729408 C-allele frequency was 0.449 in our Brazilian elderly cohort, similar to other European populations (30–41%) [14, 17], such as French (0.39) [19] and British (0.34) [29]. Regarding the rs12721026 polymorphism, the G-allele frequency was 0.095 in our sample, similar to those observed in Australian (0.09) [34] and Mediterranean populations (0.11) [35].

We found a significant association between the rs1729408 C-allele and higher HDL levels ($P = 0.022$). Likewise, the CC genotype presented higher HDL plasma levels in Chinese patients with CVD [18], whereas no association was found with CVD in our sample, confirming previous data in the French population [19].

In addition, our results revealed an association of the rs1729408 C-allele with higher HbAc1 levels ($P = 0.020$). It has recently been shown that D-glucose regulates *APOA5* expression by dephosphorylation [36], suggesting an involvement of *APOA5* in glucose metabolism [17]. Another previous study including four regions of Europe also showed that this variant influenced insulin and glucose levels after an oral glucose tolerance test (OGTT) [17]. Furthermore, it has been reported that there are higher HbAc1 levels in hypertensive patients in relation to controls [37], as well as a correlation of the CC genotype with higher blood pressure [17]. In an European population, CC genotype carriers presented significant association with higher systolic blood pressure and higher waist-to-hip ratio, which is a measure of obesity [17], suggesting that HbAc1 levels may participate in hypertension development. Taken together, these data suggest that the *APOA4* and *APOA5* intergenic region might present binding sites for nuclear factors, which can be inhibited or altered in the presence of the rs1729408 C-allele, leading to alterations in lipid and glucose metabolisms.

Although we did not observe any association between rs12721026 and the studied morbidities, a tendency of association between the G-allele and obesity was shown in our sample ($P = 0.069$) (data not shown). In fact, rs12721026 has not been associated with CVD in Caucasians [34, 38], confirming our results. We have previously described an association of another polymorphism in the first intron of *APOA1*, rs5069, with obesity ($P = 0.04$) in the same cohort [39]. In addition, *APOA1* was correlated to adipokines in Asian Indian and Caucasian populations [40].

Table 4 SNPStats results associating rs12721026/rs1729408 haplotypes with glycated hemoglobin, fasting glucose, and HDL levels compared to the TT haplotype

Serum levels	*N*	Haplotype	Frequency	Difference (95% CI)	*P*-value
Glycated hemoglobin	304	GC	0.0756	0.81 (0.24–1.39)	0.006*
Fasting glucose	312	GC	0.0663	23.12 (10.69–35.55)	0.0003*
HDL	222	TC	0.3871	4.46 (1.46–7.46)	0.0039*

N number of individuals with measured lipid serum levels; 95% *CI* 95% of confidence intervals

* $P < 0.05$

Therefore, *APOA1* might be implicated in the development of obesity.

We did not detect any association between the rs12721026 polymorphism and lipids parameters levels, confirming other studies in European [41], Korean [42], and Swedish [43] populations. Conversely, TG genotype carriers presented higher TG levels than TT in the European population [44] and the G-allele has been associated with lower *APOA1* and HDL levels in several populations [13, 35, 45, 46]. These controversial results indicate that there might be another polymorphism in this cluster influencing the association results which deserves further investigation.

rs1729408 and rs12721026 polymorphisms were in LD ($P = 0.0016$) and their haplotypes were investigated. The GC haplotype was associated with obesity and presented a higher frequency in cases (0.098) than in controls (0.050), suggesting that the GC haplotype might be a risk factor for obesity. In the current study, we did find a tendency of association between the G-allele of the rs12721026 polymorphism and obesity; however, only in the presence of the rs1729408 C-allele did this association become significant. These findings suggest a synergistic effect of these polymorphisms on influencing obesity. Although rs12721026 and rs1729408 are located in a non-coding region, they might have a functional role in the metabolism. Other variants within *APOA5* have been described and associated with changes in BMI, supporting our findings [47].

We also observed higher HbAc1 and fasting glucose levels in GC compared to TT haplotype carriers. In the Indian population, rs12721026 was associated with increased risk for type II diabetes [48]. Our results showed an association of the rs1729408 C-allele and higher HbAc1 levels. Nevertheless, the association of the GC haplotype became stronger ($P = 0.006$), suggesting that the interaction between rs1729408 and rs12721026 polymorphisms might be involved in the development of hypertension.

Furthermore, our data showed that the TC haplotype was associated with higher HDL levels ($P = 0.0039$). *APOA1* and *APOA5* gene expression are modulated by peroxisome proliferator-activated receptor α (*PPARα*). Our group has previously reported an association of the C-allele of rs4253778 (*PPARα*) and higher HDL compared to the G-allele [49], suggesting that *APOA1* and *APOA5* are involved in the regulation of HDL levels, probably via *PPARα*.

In conclusion, rs1729408 was associated with higher HDL and HbAc1 levels. Moreover, the GC haplotype was associated with obesity and higher HbAc1 and fasting glucose levels and TC haplotype was associated with higher HDL levels. To our knowledge, this is the first time that haplotypes involving these polymorphisms have been evaluated. The present findings might clarify the influence of these polymorphisms in lipids and proteins metabolisms and their association with age-related diseases. Therefore, genetic variations in the *APOA1/C3/A4/A5* gene cluster may characterize important risk factors for metabolic homeostasis.

Identification and Characterization of Δ12, Δ6, and Δ5 Desaturases from the Green Microalga *Parietochloris incisa*

Umidjon Iskandarov · Inna Khozin-Goldberg · Zvi Cohen

Received: 3 February 2010 / Accepted: 15 April 2010 / Published online: 14 May 2010

Abstract The freshwater microalga *Parietochloris incisa* accumulates, under nitrogen starvation, large amounts of triacylglycerols containing approximately 60% of the ω6 very long-chain polyunsaturated fatty acid (VLC-PUFA), arachidonic acid. Based on sequence homology, we isolated three cDNA sequences from *P. incisa*, designated *PiDesD12*, *PiDesD6*, *PiDesD5*. The deduced amino acid sequences of the three genes contained three conserved histidine motifs; the front-end desaturases, PiDes6 and PiDes5, contained a fused N-terminal cytochrome *b5* domain. By functional characterization in the yeast *Saccharomyces cerevisiae*, we confirmed that *PiDesD6*, *PiDesD5* cDNA encode membrane bound desaturases with Δ6, and Δ5 activity, respectively. Both PiDes6 and PiDes5 can indiscriminately desaturate both ω6 and ω3 substrates. A phylogenetic analysis showed that the three genes were homologous to the corresponding desaturases from green microalgae and lower plants that were functionally characterized. Quantitative real-time PCR revealed the concerted expression pattern of all three genes in *P. incisa* cells subjected to nitrogen starvation, featuring maximum expression level on day 3 of starvation, corresponding to the sharpest increase in the share of arachidonic acid.

Keywords Arachidonic acid · Δ12-desaturase · Δ5-desaturase · Δ6-desaturase · Microalgae · Expression pattern · Nitrogen starvation · *Parietochloris incisa*

Abbreviations

ARA	Arachidonic acid
DGTS	Diacylglyceroltrimethylhomoserine
DHA	Docosahexaenoic acid

PtdCho	Phosphatidylcholine
PtdEtn	Phosphatidylethanolamine
RTQPCR	Real time quantitative polymerase chain reaction
TFA	Total fatty acids
VLC-PUFA	Very long-chain polyunsaturated fatty acids

Introduction

Very long-chain polyunsaturated fatty acids (VLC-PUFA) of 20 or 22 carbon atoms are indispensable components of human nutrition. They are necessary for normal life-long physiology and contribute to the well-being of the human body. Nutritionally important VLC-PUFA include the ω3-fatty acids, eicosapentaenoic acid (EPA, $20{:}5^{\Delta 5,8,11,14,17}$)

GenBank accession numbers for *PiDes12*, *PiDes6* and *PiDes5* and a partial sequence of actin gene of *P. incisa* are GU390531, GU390532, GU390533 and FJ548973.

and docosahexaenoic acid (DHA, 22:6$^{\Delta4,7,10,13,16,19}$) and the ω6-fatty acid, arachidonic acid (ARA, 20:4$^{\Delta5,8,11,14}$) which are the major components of membrane phospholipids of the retina, brain and testis. ARA, together with DHA, are the predominant fatty acids in the human brain and breast milk. ARA is necessary for normal fetal growth, and cognitive development in infants [1]. Many studies highly recommended supplementation of infant formula with DHA and ARA [2]. Besides the structural function in membranes, ARA is the primary substrate in eicosanoids biosynthesis which regulates many physiological processes such as homeostasis, reproduction, immune and inflammatory responses.

The green freshwater microalga *Parietochloris incisa* (Trebouxiophyceae) is known to accumulate extraordinarily large amounts of ARA-rich triacylglycerols (TAG) [3, 4]. When *P. incisa* is cultivated under nitrogen starvation, ARA constitutes about 60% of total fatty acids (TFA) and over 95% of cellular ARA is deposited in TAG in cytoplasmic lipid bodies [5].

The biosynthesis of VLC-PUFA in microalgae follows two major pathways, designated as ω6 and ω3. In these pathways, linoleic acid (LNA; 18:2$^{\Delta9,12}$) and α-linolenic acid (ALA; (18:3$^{\Delta9,12,15}$) go through sequential Δ6 desaturation, Δ6 elongation and Δ5 desaturation, yielding ARA and EPA, respectively [6–9]. For example, in the red microalga *Porphyridium cruentum* and the green microalga *P. incisa*, oleic acid (18:1$^{\Delta9}$) is first desaturated to 18:2$^{\Delta9,12}$ and γ-linolenic acid (GLA, 18:3$^{\Delta6,9,12}$) through Δ12 and Δ6 desaturations, followed by elongation to dihomo-γ-linolenic acid (DGLA, 20:3$^{\Delta8,11,14}$) and Δ5 desaturation to yield ARA via the ω6 pathway [9, 10]. In *P. incisa*, the extraplastidial lipids, phosphatidylcholine (PtdCho) and the betaine lipid, diacylglyceroltrimethylhomoserine (DGTS), are involved in the Δ12 and, subsequently, the Δ6 desaturations, whereas phosphatidylethanolamine (PtdEtn) along with PtdCho are the suggested major substrates for the Δ5 desaturation of 20:3$^{\Delta8,11,14}$ to 20:4$^{\Delta5,8,11,14}$ [10]. The same enzymes are involved in the biosynthesis of VLC-PUFA through the ω3 pathway in the green microalga *Ostreococcus tauri* [11]. VLC-PUFAs may also be generated by an alternative Δ8 desaturation pathway. For example, in the marine haptophyte *Isochrysis galbana* and in the fresh water euglenophyte *Euglena gracilis*, where LNA and ALA are first elongated by C18 Δ9-specific fatty acid elongase followed by sequential Δ8 and Δ5 desaturations to ARA or EPA [8, 12, 13]. The extraplastidial Δ12 desaturase is an integral ER-bound protein which is responsible for the desaturation of 18:1$^{\Delta9}$ and production of 18:2$^{\Delta9,12}$, mainly on PtdCho [14–16]. Δ5 and Δ6 desaturases contain a fused cytochrome *b*5 domain in their N-terminus, serving as an electron donor, and introduce a double bond at a site closer to the carboxyl group than any of the pre-existing double bonds in the substrate fatty acid, thereby called 'front-end' desaturases [17–20]. Desaturases with Δ6 or Δ5 activity have been isolated from various organisms [21–26]. In algae, particularly, genes coding for desaturases were cloned from two diatoms *Phaeodactylum tricornutum* [27] and *Thalassiosira pseudonana* [28], and few species of marine picoeukaryotes, belonging to the class Prasinophyceae of Chlorophyta, such as *Ostreococcus tauri* [29], *Mantoniella squamata* [30], and *Micromonas pusilla* [31]. Some of these desaturases have been introduced together with PUFA-specific elongases into constructs for transformation of yeast and oil seed plants to reconstitute VLC-PUFA biosynthesis in the heterologous organisms [13, 29, 31–35].

Coexpression of the Δ5 and Δ6 desaturases from the diatom *P. tricornutum* in yeast in the presence of either ω3 or ω6 C18 substrates yielded ARA and EPA, demonstrating that they can function in both the ω3 and ω6 pathways with similar efficiency [27]. In *Arabidopsis thaliana*, VLC-PUFA biosynthesis was achieved through reconstitution of an alternative pathway by introducing genes encoding Δ9 elongase from *I. galbana*, Δ8 desaturase from *E. gracilis* and Δ5 desaturase from *Mortierella alpina* [13]. Recently, it was shown that some algal front end desaturases can act also on fatty acids esterified to CoA [29–31] similarly to mammalian front-end desaturases. These desaturases attracted much attention since such acyl-CoA-dependent enzymes, originating from photosynthetic organisms and having the correct substrate specificities may eliminate the need for the rate-limiting exchange of substrates between lipid and acyl-CoA in oil seed plants genetically modified to produce VLC-PUFA [29–34].

In the present work, we report the identification of three cDNA putatively encoding for Δ12, Δ6, and Δ5 desaturases, respectively, in *P. incisa.* Functional activities with fatty acid preferences were conferred for Δ6 and Δ5 desaturases by heterologous expression in the yeast *Saccharomyces cerevisiae*. Transcripts for all three desaturases are concertedly up-regulated during nitrogen starvation, that triggers ARA accumulation, and the level of expression is correlated with the increase in the share of ARA.

Materials and Methods

Strains and Growth Conditions

Axenic cultures of *P. incisa* were cultivated on BG-11 nutrient medium [36] in 250-ml Erlenmeyer glass flasks in an incubator shaker at controlled temperature (25°C) and illumination (115 μmol quanta m^{-2} s^{-1}) under an air/CO_2 atmosphere (99:1, v/v) and a speed of 170 rpm [3]. For N-starvation experiments, cells of daily-diluted cultures were collected by centrifugation, washed three times in

sterile double distilled water and resuspended in N-free BG11 medium. To prepare an N-free BG-11 medium, sodium nitrate was omitted and ferric ammonium citrate was substituted with ferric citrate. Biomass was sampled at time 0, and in 1.5, 3, 7 and 14 days from the onset of N-starvation for determination of growth parameters, and was further used for fatty acid analysis and RNA isolation. Duplicate samples were collected from three separate flasks for each time point and measurement. Growth parameters, dry weight and chlorophyll contents were determined as previously described [37].

RNA Isolation

Aliquots of the cultures were filtered through a glass fiber filter (GF-52, Schleicher & Schuell, Germany); cells were collected by scraping and immediately flash-frozen in liquid nitrogen and stored at −80°C for further use. Total RNA was isolated by the procedure described by Bekesiova et al. [38]. Three independent RNA isolations were conducted for each time point. The total RNA samples were treated with RNase-free Baseline-ZERO™ DNase (Epicentre Technologies, Madison, WI, USA) before being used in cDNA synthesis for real-time PCR experiments.

Gene Cloning

Partial sequences of the Δ12, Δ6, Δ5 desaturase and actin genes were obtained by PCR (ReddyMix PCR Master Mix, Thermo Scientific, Surrey, UK) using the degenerated primers listed in the Table 1. To generate the full-length cDNA, 3′-and 5′-rapid amplification of the cDNA ends (RACE) was performed using a BD Smart™ RACE cDNA Amplification Kit (BD Biosciences Clontech, Foster City, CA, USA). Gene specific primers were designed (Table 1) and RACE PCR reactions were conducted using 5′ and 3′-RACE-Ready cDNA made from 1 μg total RNA of N-starved cells with 50× BD Advantage 2 polymerase mix

N, R, Y, H, K, W, S, D and I designate mixtures of nucleotides, A/G/T/C, A/G, T/C, A/T/C, G/T, A/T, G/C, A/G/T and inosine, respectively

[a] Underlined

(Clontech Laboratories Inc., Mountain View, CA, USA). The PCR products of the expected sizes were excised, purified from the gel (NucleoSpin Extract II purification kit, Machery-Nagel, Duren, Germany) and ligated into a pGEM T-Easy vector (Promega, Madison, WI, USA). The full-length cDNA were assembled based on the sequences of the 5′ and 3′ RACE fragments.

Expression and Functional Characterization in the Yeast *Saccharomyces cerevisiae*

The ORFs encoding for the Δ12, Δ6, and Δ5 desaturases were amplified using *PfuUltra* II fusion HS DNA polymerase (Stratagene, La Jolla, CA, USA) with the respective primer pairs (Table 1). The forward primers contained a restriction site (underlined) and a yeast translation consensus (boldfaced) followed by ATG. The reverse primers contained a restriction site (underlined) and a stop codon (boldfaced). Following restriction and ligation to the pYES2 vector (Invitrogen, Carlsbad, CA, USA), the constructs were used to transform *S. cerevisiae* strain W303 by the PEG/lithium acetate method [39]. The yeast cells harboring the empty pYES2 vector were used as control. Transformants were selected by uracil prototrophy on yeast synthetic medium (YSM) lacking uracil (Invitrogen, Carlsbad, CA, USA). For functional expression, a minimal selection medium containing 2% (w/v) raffinose was inoculated with the pY*PiDesΔ12*, pY*PiDesΔ6* or pY*PiDesΔ5* transformants and grown at 27°C for 24 h in a water bath shaker. Five ml of sterile YSM, containing 1% (w/v) Tergitol-40 and 250 μM of the appropriate fatty acid substrate, were inoculated with raffinose-grown cultures to obtain an OD of 0.2 at 600 nm. Expression was induced by adding galactose to a final concentration of 2% (w/v) and cultures were further grown at 27°C for 48 h. Cells were harvested by centrifugation, washed twice with 0.1% $NaHCO_3$, freeze-dried and used for fatty acid analysis.

Fatty Acid Analysis

Fatty acid methyl esters (FAME) were obtained by transmethylation of the freeze-dried *P. incisa* or yeast biomass, with dry methanol containing 2% H_2SO_4 (v/v) and heating at 80°C for 1.5 h while stirring under an argon atmosphere. Gas chromatographic analysis of FAME was performed on a Thermo Ultra Gas chromatograph (Thermo Scientific, Italy) equipped with PTV injector, FID detector and a fused silica capillary column (30 m × 0.32 mm; ZB WAXplus, Phenomenex). FAME were identified by co-chromatography with authentic standards (Sigma Chemical Co., St. Louis, MO, USA; Larodan Fine Chemicals, Malmö, Sweden) and FAME of fish oil (Larodan Fine Chemicals). Each sample was analyzed in duplicates of three independent experiments. The structures of fatty acids were confirmed by GC-MS of their pyrrolidine derivatives [40] on HP 5890 equipped with a mass selective detector (HP 5971A) utilizing a HP-5 capillary column and a linear temperature gradient from 120 to 300°C.

Lipid Analysis

The biomass of *S. cerevisiae* was heated with isopropanol at 80°C for 10 min and lipids were extracted by the method of Bligh and Dyer [41]. Total lipid extract was separated into neutral and polar lipids by silica Bond-Elute cartridges (Varian, CA, USA) using 1% of ethanol in chloroform (v/v) and methanol to elute neutral and polar lipids, respectively [42].

Polar lipids were separated into individual lipids by two dimensional TLC on Silica Gel 60 glass plates (10 × 10 cm, 0.25 mm thickness (Merck, Darmstadt, Germany) according to Khozin et al. [9]. Neutral lipids were resolved with petroleum ether:diethyl ether:acetic acid (70:30:1, v/v/v). Lipids on TLC plates were visualized by brief exposure to iodine vapors, scraped from the plates and were transmethylated for the fatty acid analysis as previously described.

Real-Time Quantitative PCR

Template cDNA for real-time quantitative PCR (RTQPCR) was synthesized using 1 μg of total RNA in a total volume of 20-μL, using oligo dT primer (Reverse-iT TM 1st Strand Synthesis Kit, ABgene, Surrey, UK). Each 20-μL cDNA reaction was then diluted threefold with PCR grade water.

Primer Design and Validation for Real-Time Quantitative PCR

Real-Time Quantitative PCR (RTQPCR) primer pairs were designed for the *PiDes12*, *PiDes6*, and *PiDes5* genes and the house keeping gene actin, *PiAct* using the PrimerQuest tool (http://test.idtdna.com/Scitools/Applications/Primerquest/). Primer pairs were validated as described by Iskandarov et al. [43]. The nucleotide sequences of primer pairs and the amplicon sizes are presented in Table 2.

Results

Isolation and Identification of cDNA for Δ12, Δ6, and Δ5 Desaturase Genes of *P. incisa*

The partial sequences of the Δ12, Δ6 and Δ5 desaturase gene homologues were isolated using degenerate oligonucleotides (Table 1) targeting conserved amino acid motifs identified in algae, lower plants and fungi [26, 27, 44, 45].

Table 2 Primers used in RTQPCR experiments

A partial sequence of the actin gene was amplified based on nucleotide similarity with the actin gene of *Chlamydomonas reinhardtii* [46] to be used as a house keeping gene in RTQPCR experiments.

Partial sequences of 503, 558 and 636 bp, corresponding to the Δ12, Δ6, and Δ5 desaturase genes, respectively, were used for designing gene specific primers that were used to amplify the 5′- and 3′- ends of the expected genes. Assembling the 5′ and 3′ RACE PCR product sequences resulted in the identification of three cDNA clones with sequence homologies to known Δ12, Δ6, and Δ5 desaturase genes. The full-length cDNA corresponding to Δ12, Δ6, and Δ5 desaturase genes were thus designated *PiDes12*, *PiDes6*, and *PiDes5*. The ORFs for *PiDes12*, *PiDes6* and *PiDes5* genes were 1.140, 1.443, and 1.446 bp in length, respectively, coding for the corresponding predicted proteins of 380, 481 and 482 amino acids. The predicted amino acid sequence of *PiDes12* is 64 and 62% identical to that of *Chlorella vulgaris* (BAB78716) and *C. reinhardtii* (XP_001691669), respectively, while it shares more than 50% identity with those of higher plants. It contains three conserved histidine motifs HxxxH, HxxHH and HxxHH. The deduced amino acid sequence of PiDes6 is 52 and 51% identical to those of the Δ6 desaturases from the liverwort *Marchantia polymorpha* (AAT85661) and the moss *Ceratodon purpureus*, respectively (CAB94993). It is also 45% identical to the *M. alpina* Δ6 desaturase (ABN69090). PiDes5 shares 55 and 51% identity with the Δ5 desaturase from the microalgae *M. squamata* (CAQ30478), and *O. tauri* (CAL57370), respectively, and 54% with that from *M. polymorpha* (AAT85663) but is only 36% identical to the *M. alpina* Δ5 desaturase (AAC72755). Both PiDes6 and PiDes5 contain N-terminal fused cytochrome *b5* domain including the HPGG motif and the three histidine boxes found to be conserved in front-end desaturases [19, 27]. The three characteristically conserved histidine-rich motifs with amino acid patterns of $HD_{(E)}$xxH, HxxHH, QxxHH in Δ6 desaturases, and HDxxH, QHxxxHH, QxxHH in Δ5 desaturases are also present in PiDes6 and PiDes5, respectively (Supplementary Fig. 1).

Phylogenetic Analysis

An unrooted phylogenetic tree (Fig. 1) of PiDes12, PiDes6, PiDes5 and several functionally characterized desaturases from all three groups was constructed to identify their functional and phylogenetic relationships by the neighbor-joining program in MEGA4 [47]. The deduced amino acid sequence of PiDes12 is closely related to Δ12 desaturases of green algae and very similar to those of higher plants. The sequences of PiDes6 and PiDes5 cluster with Δ6 and Δ5 desaturases, respectively, from algae, moss and fungi. PiDes6 is very similar to the *M. polymorpha* (MpDEs6) and *P. tricornutum* (PtD6p) Δ6 desaturases, while PiDes5 appears to be closely related to the Δ5 desaturase from the moss *M. polymorpha* and shares more sequence similarity with the Δ5 desaturase from the chlorophytes *M. squamata* and *O. tauri* than with those of fungal origin. However, both Δ6 or Δ5 desaturases from *M. squamata*, Δ6 desaturases of *O. tauri*, *O. lucimarinus,* and *M. pusilla* appear to be structurally more similar to each other than to any of the known desaturases from either group.

Functional Expression of PiDes12, PiDes6, and PiDes5 in *S. cerevisiae*

The functional activities of the proteins encoded by *PiDes12*, *PiDes6* and *PiDes5* were examined by heterologous expression in *S. cerevisiae*. To this aim, the pYES2 constructs pY*PiDes12,* pY*PiDes6* and pY*PiDes5* containing the ORFs for PiDes12, PiDes6, and PiDes5, respectively, were transformed into *S. cerevisiae*. The yeast cells, harboring the empty vector pYES2 (control), did not demonstrate desaturation activity on the exogenously provided fatty acid substrates (Fig. 2). GC analysis of the FAME of the yeast transformed with pY*PiDes12,* did not reveal a significant conversion of endogenous $18{:}1^{\Delta 9}$ since only a small peak corresponding to $18{:}2^{\Delta 9,12}$ appeared on chromatograms (0.3% of TFA; Supplementary Fig. 2). An attempt to increase the activity of the recombinant protein by the optimization of yeast translation consensus was not successful.

PiDes6 and PiDes5 expressions were induced in the presence of the main ω6 substrates for Δ6 or Δ5 fatty acid desaturases, $18{:}2^{\Delta 9,12}$ and $20{:}3^{\Delta 8,11,14}$, respectively. New peaks corresponding to $18{:}3^{\Delta 6,9,12}$ and $20{:}4^{\Delta 5,8,11,14}$, respectively, were detected, confirming the predicted function of PiDes6 and PiDes5. The expression of PiDes6 in the presence of $18{:}3^{\Delta 9,12,15}$ resulted in the appearance of the corresponding Δ6 desaturation product $18{:}4^{\Delta 6,9,12,15}$ (Fig. 2). PiDes6 desaturase was neither active on endogenous yeast fatty acids nor on exogenously-provided $18{:}1^{\Delta 9}$. PiDes6 was not active on $20{:}3^{\Delta 11,14,17}$ either, whereas PiDes5 desaturated it to the non-methylene-interrupted $20{:}4^{\Delta 5,11,14,17}$. PiDes5 converted $20{:}4^{\Delta 8,11,14,17}$ into the

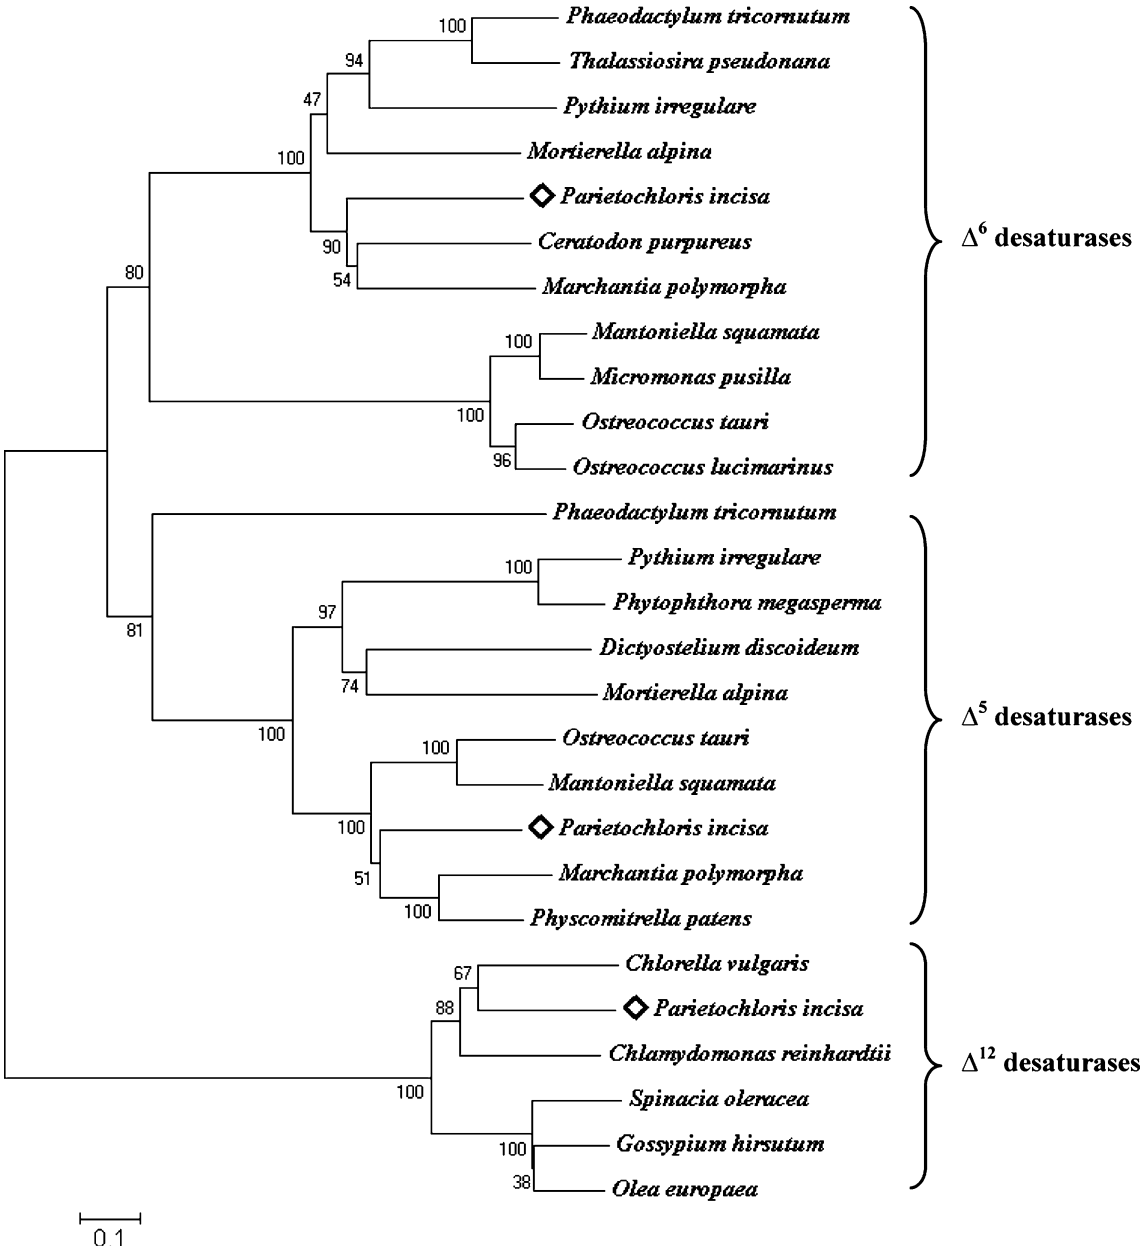

Fig. 1 An unrooted phylogram of PiDes12, PiDes6, PiDes5 and some functionally characterized Δ12, Δ6 and Δ5 desaturases (vertebrate and invertebrate desaturases are not included). The alignment was generated by the CLUSTAL W program and the unrooted phylogram was constructed in the neighbor-joining method using the MEGA4 software [47]. GenBank sources of the sequences are: BAB78716 (Δ12, *Chlorella vulgaris*), XP_001691669 (Δ12, *C. reinhardtii*), BAC22091 (Δ12, *Spinacia oleracea*), AAL37484 (Δ12, *Gossypium hirsutum*), AAW63040 (Δ12, *Olea europaea*), CAB94993 (Δ6, *Ceratodon purpureus*), AAT85661 (Δ6, *M. polymorpha*), BAA85588 (Δ6, *M. alpina*), AAL92563 (Δ6, *P. tricornutum*), AAX14505 (Δ6, *T. pseudonana*), (Δ6, *Pythium irregulare*), CAL57370 (Δ5, *O. tauri*), AAT85663 (Δ5, *M. polymorpha*), AAL13311 (Δ5, *P. irregulare*), CAD53323 (Δ5, *Phytophthora megasperma*), BAA37090 (Δ5, *Dictyostelium discoideum*), AAC72755 (Δ5, *M. alpina*), CAQ30478 (Δ5, *M. squamata*), CAQ30479 (Δ6, *M. squamata*), AAW70159 (Δ6, *O. tauri*), CS020055 (Δ5, *P. patens*)

respective Δ5 product, $20{:}5^{\Delta5,8,11,14,17}$ (EPA) as well as the added $18{:}1^{\Delta9}$ into the non-methylene-interrupted $18{:}2^{\Delta5,9}$ (Fig. 2). The Δ5 position on $18{:}2^{\Delta5,9}$ was determined by a characteristic peak of $m/z = 180$ on the GC-MS spectra of its pyrrolidine derivative (not shown). The presence of $18{:}2^{\Delta5,9}$ was also observed in the chromatograms of the PiDes5 transformant supplied with C20 fatty acids. In addition, a tiny peak, tentatively identified as $18{:}4^{\Delta5,9,12,15}$ was present on the chromatogram of the PiDes5 transformant fed with $18{:}3^{\Delta9,12,15}$ (Table 3).

We also conducted a kinetic analysis of ARA emergence in TFA of the PiDes5 transformant during 24 h following

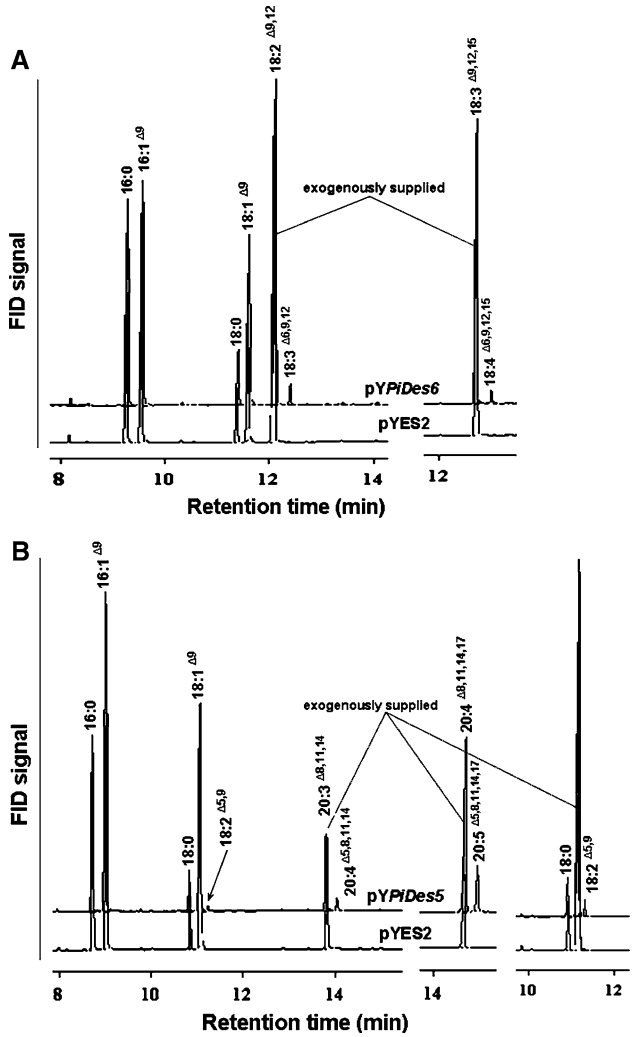

Fig. 2 GC of FAME of recombinant yeast harboring pYES2 (control), pY*PiDes6* (**a**) fed with $18{:}2^{\Delta 9,12}$ or $18{:}3^{\Delta 9,12,15}$, and pY*PiDes5* (**b**) fed with $20{:}3^{\Delta 8,11,14}$, $20{:}^{\Delta 8,11,14,17}$ or $18{:}^{\Delta 9}$

the addition of $20{:}3^{\Delta 8,11,14}$ (DGLA). Results showed that ARA peak was evident already after 3 h (corresponding to 10.9% substrate conversion) with a gradual but slow increase (up to 15.1% conversion) after 24 h. Fatty acid analysis of the major polar and neutral lipids of the yeast transformed with pY*PiDes5* was performed 24 h after feeding with $20{:}3^{\Delta 8,11,14}$ to study the pattern of ARA distribution within individual lipids. In the transformed yeast, ARA appeared in phospholipids with similar conversion rates (Table 4), but with the highest proportion detected in PtdCho. It was also present in the neutral lipids: TAG, free fatty acids (FFA), diacylglycerol (DAG) and sterol esters (SE). Given that TFA content in PtdCho, a major phospholipid of *S. cerevisiae* [48], amounted for about 16% of total lipids in pY*PiDes5* transformant fed with DGLA (Table 4), PtdCho allocated the main part of ARA attached to phospholipids.

Table 3 Conversion percent of the supplied fatty acids by PiDes6 and PiDes5 in *S. cerevisiae*

Fatty acid substrate	Desaturase product and conversion (%)	
	PiDesΔ6	PiDesΔ5
$18{:}1^{\Delta 9}$	–	$18{:}2^{\Delta 5,9}$ (4.2)
$18{:}2^{\Delta 9,12}$	$18{:}2^{\Delta 6,9,12}$ (5.1)	–
$18{:}3^{\Delta 9,12,15}$	$18{:}4^{\Delta 6,9,12,15}$ (4.5)	$18{:}4^{\Delta 5,9,12,15}$ (1.4)[a]
$18{:}3^{\Delta 6,9,12}$		–
$20{:}3^{\Delta 11,14,17}$	–	$20{:}4^{\Delta 5,11,14,17}$ (10.0)
$20{:}3^{\Delta 8,11,14}$	–	$20{:}4^{\Delta 5,8,11,14}$ (16.4)
$20{:}4^{\Delta 8,11,14,17}$		$20{:}5^{\Delta 5,8,11,14,17}$ (17.1)

Yeast strain W303 transformed with pYES2-*PiDES6* and pYES2-*PiDES5* was grown for 48 h at 26°C in the presence or absence of different fatty acid substrates (250 μM). FAME from the whole cells were prepared and analyzed by GC as described in "Materials and Methods". Desaturation (percentage of conversion) was calculated as (product × 100)/(substrate + product)

[a] Tentative identification

Expression Profiles of *PiDes12, PiDes6*, and *PiDes5* Under Nitrogen Starvation

To use actin as a house-keeping gene in quantitative real-time PCR experiments, we amplified a partial fragment (503 bp) of the *P. incisa* actin gene using the primers whose design was based on the *C. reinhardtii* actin cDNA (XM_001699016). Indeed, the expression level of the actin gene did not significantly change throughout the nitrogen starvation. *PiDes12, PiDes6,* and *PiDes5* were upregulated following the transfer to Nitrogen starvation, reaching the highest expression level on day 3 and decreasing thereafter to a level about 15–20 fold higher than that at time 0 (Fig. 3). Both the *PiDes12* and *PiDes5* genes were expressed at levels approximately 65- to 70-fold higher on day 3 than at time 0, while the *PiDes6* transcript was about 45-fold higher (Fig. 3). The expression patterns of *PiDes12, PiDes6,* and *PiDes5* correlated with the enhanced biosynthesis of ARA in *P. incisa* cells (Table 5).

Discussion

The capacity of *P. incisa* to accumulate large quantities of ARA-rich TAG under nitrogen starvation, suggested that it would be of great interest to study its genes and enzymes involved in the accumulation of VLC-PUFA. In the present work, we have thus cloned the *P. incisa* Δ12, Δ6, and Δ5 desaturases which in conjunction with a recently cloned Δ6 specific PUFA elongase [43], represent a set of *P. incisa* genes involved in the biosynthesis of ARA. The deduced amino acid sequences of PiDes12, PiDes6, and PiDes5 contain three histidine rich motifs (his-boxes) that are

characteristic of all membrane bound desaturases [22–29, 49–51]. Both PiDes6 and PiDes5 contain a fused cytochrome *b5* at their N-terminus, supporting their microsomal localization, similar to other functionally characterized front-end desaturases [52, 53].

Heterologous expression of PiDes6 and PiDes5 in yeast cells confirmed their Δ6 and Δ5 activity by conversion of supplemented fatty acids to the corresponding desaturation products. PiDes12, however, demonstrated very low desaturation activity, which we could not improve by the 5′ modification of the inserted sequence. A similar low activity in yeast was also demonstrated in some cases, such as for Δ5 and Δ12 desaturases of *O. tauri* and *Chlorella vulgaris* NJ-7, respectively [30, 54]. There are several possible explanations for the low activity of the recombinant protein in the heterologous expression including mistargeting, posttranslational modifications, etc., although we do not have experimental data to support this assumption.

Functional characterization of PiDes6 and PiDes5 confirmed the previously reported substrate specificities of the Δ5 and Δ6 desaturases which are generally restricted to C18 and C20 substrates, respectively [23, 24, 27]. PiDes6 and PiDes5 desaturated both ω3 and ω6 fatty acids with similar efficiency (Fig. 2; Table 3). Various results concerning ω3/ω6 substrate preference were reported for functionally characterized Δ6 and Δ5 desaturases from different organisms that were expressed in yeast. The ω6 and ω3 substrates were equally used by the Δ6, Δ5 and Δ4 desaturases of *Leishmania major* [55], the Δ6 desaturases of the diatom *P. tricornutum* [27] and the green alga *O. tauri* [29]. The Δ6 desaturase of *T. pseudonana* exhibited a slightly higher preference for the exogenous ω3 fatty acid, ALA [28], whereas the Δ5 desaturase of *T. pseudonana* did not show a preference for either ω6 or ω3 substrates. Recently cloned Δ6 desaturases from the microalgae *M. squamata, M. pussila* and *O. lucimarinus* displayed a strong preference for the ω3 substrate ALA [30, 31, 56]. A preference for ω3 substrates was also reported for the *Primula* Δ6-desaturase [57] and for all fish Δ6 desaturases studied to date [58].

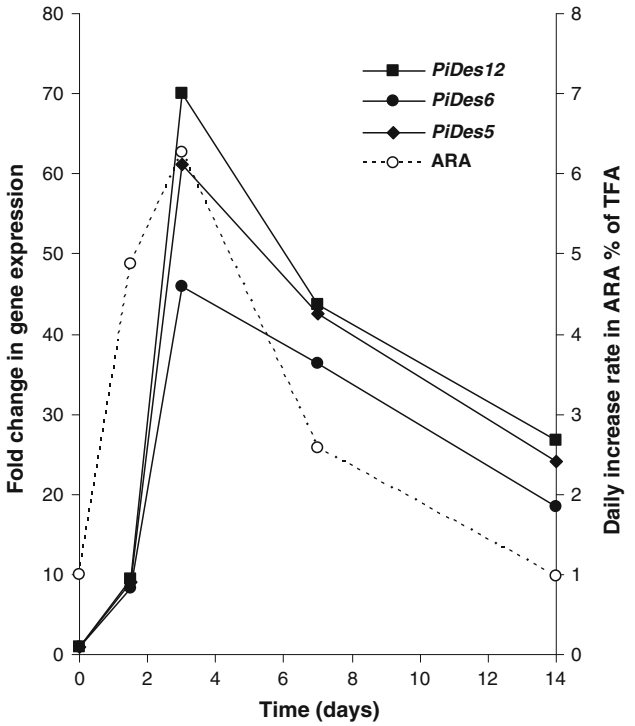

Fig. 3 Changes in expression of the *PiDes12*, *PiDes6*, and *PiDes5* genes under N-starvation and daily increase in ARA percent share in total fatty acids. The transcript abundance of the genes was normalized to that of the actin gene

A front-end PiDes5 desaturated its principal substrate $20:3^{\Delta 8,11,14}$ as well as $20:4^{\Delta 8,11,14,17}$; in addition, non-methylene interrupted fatty acids were also produced as a result of its activity on $20:3^{\Delta 11,14,17}$, and on both endogenous and exogenous $18:1^{\Delta 9}$, but with lower efficiency. The Δ5 desaturases of different origins have been previously shown to be promiscuous in heterologous systems [13, 23, 32, 50], as a result, non-methylene interrupted FA were detected in yeast [23, 27, 28] and in transgenic canola [50]. Exceptionally, the Δ5 desaturase of trypanosome *L. major* utilized $20:3^{\Delta 8,11,14}$ and $20:4^{\Delta 8,11,14,17}$ with a similar efficiency but not $20:3^{\Delta 11,14,17}$ or $20:2^{\Delta 11,14}$ [55]. An unusual

case is the *C. reinhardtii* cytochrome *b5* fusion protein (CrDES) which acts as an ω13 desaturase and inserts Δ5 double bond on both $18{:}1^{\Delta 9}$ and $18{:}2^{\Delta 9,12}$ producing the non-methylene interrupted $18{:}2^{\Delta 5,9}$ and $18{:}3^{\Delta 5,9,12}$, while adding a Δ7 double bond to $20{:}2^{\Delta 11,14}$ and $20{:}3^{\Delta 11,14,17}$ [59]. Apparently, in addition to the fatty acid chain length, the location and number of double bond, and the form of the substrate (lipid- or CoA-bound) are also crucial for Δ5 desaturation.

Differently from PiDes5, PiDes6 desaturated neither the yeast major monounsaturated fatty acids nor the exogenously supplied 18:1. Unlike some reported Δ6 desaturases [27, 28, 60–63], PiDes6 did not act on $20{:}3^{\Delta 11,14,17}$, indicating that it is specific for Δ9 C18 PUFA. It appears that not only the organism being transformed, but also the gene origin, may determine the substrate specificity of the recombinant Δ6 and Δ5 desaturases.

It was shown in the radiolabeling studies with *P. incisa*, that PtdCho and DGTS are used for lipid-linked C18 Δ6 desaturation whereas mostly PtdEtn is used for C20 Δ5 desaturation [3]. In recent years, a few examples of desaturases that act on CoA-activated rather than on lipid-linked fatty acids were reported [29–31, 56]. Sequence similarity analysis of algal and lower plant Δ6 or Δ5 desaturases, revealed that the Δ6 and Δ5 desaturases of *M. squamata* are highly similar to those of *O. tauri* and *O. lucimarinus,* respectively (Fig. 1). One can indeed assume that their structural similarity may indicate to the functionally confirmed acyl-CoA dependency. Unlike Δ5 desaturases of *M. squamata* and *O. tauri*, their Δ6 desaturases appear to be somewhat more similar to their mammalian Δ6 desaturases homologs, e.g., mouse (NR_062673) and human (NP_04256) [64] than to those of lower plants.

PiDes5 featured higher substrate conversion rate in comparison to PiDes6. A relatively fast emergence of substantial percentage of ARA (10.6% conversion after 3 h of feeding) pursued us to study ARA distribution in individual lipid classes of the transformed yeast (24 h of feeding). A uniform distribution of desaturation products in yeast lipids may serve as an indication for acyl-CoA dependency [30, 31]. Interestingly, the *M. polymorpha* Δ6 desaturase was suggested to use acyl substrates in both glycerolipids and the acyl-CoA pool [26]. The expression of the *M. squamata* Δ5 desaturase in the presence of DGLA resulted in the accumulation of nearly similar amounts of ARA in all phospholipid classes and in the neutral lipids [30]. At the same time, the expression acyl-lipid desaturases resulted in a preferential accumulation of the product in PtdCho. In the present work, ARA was detected in all analyzed phospho- and neutral lipid classes of *S. cerevisiae* expressing PiDes5 (Table 4). Similar conversion rates were determined in phospholipids, however, ARA partition showed preference for the major phospholipid PtdCho followed by PtdEtn. Thus, these data and sequence similarity with functionally characterized acyl-lipid desaturases (Fig. 1) confirmed that in *P. incisa*, phospholipids PtdCho and PtdEtn are the main site for lipid-linked Δ5 desaturation [10]. It is necessary to mention that *P. incisa* desaturases produced relatively low activity in heterologous yeast system in comparison with high endogenous activity in the algal cells.

The quantitative RT-PCR results revealed that the gene expression levels of *PiDes12*, *PiDes6*, and *PiDes5* during the course of nitrogen starvation followed a similar pattern. The major transcriptional activation of the all three desaturases occurred on day 3 coinciding with a sharp rise in the percentage of ARA, which almost doubled (Fig. 3, Table 5). The same expression pattern featured the *P. incisa* Δ6 PUFA elongase [43], however, at lower level. The concerted transcriptional activation of the *PiDes12*, *PiDes6*, *PiDes5,* and *PiELO1* genes was accompanied by an increase in the percent share of 18:1, a main chloroplast-derived fatty acid exported to ER and substrate of microsomal Δ12 desaturase. Thus, we assume that despite the lack of significant activity in the yeast expression system, we cloned the Δ12 desaturase of *P. incisa* responsible for 18:2 production in the ER. This gene is highly expressed in the alga under conditions requiring active production of 18:2. Possibly, further optimization of the codon usage could result in higher conversion rates. High expression of ARA biosynthetic genes in *P. incisa* was accompanied by enhanced Δ5 and Δ6 desaturations of precursor fatty acids in the ω6 pathway (Table 5), a major pathway of ARA biosynthesis in *P. incisa* [10, 65].

Understanding the mechanisms underlying gene transcription regulation in metabolic pathways and characteristics of enzymes involved in ARA-rich TAG biosynthesis in *P. incisa* is a prerequisite for manipulating algal species for sustainable production of algal oils of high pharmaceutical and nutraceutical values. There is a significant body of information on the reconstitution of VLC-PUFA biosynthetic pathway in yeast and higher plants using microalgae-derived Δ6 and Δ5 desaturases in different combinations with PUFA elongases [31–35], whereas, so far, there were no attempts in molecular engineering of algal VLC-PUFA biosynthesis. Acyl-CoA algal desaturases, when expressed in higher plants, are often characterized by higher substrate conversion rates than that of the lipid-linked desaturases and convert precursors to VLC-PUFA more efficiently [29, 31, 34]. A most recent example is a metabolic engineering of an EPA biosynthesis pathway in tobacco leaf, consisting of the three algal enzymes, the acyl-CoA dependent Δ6-desaturase of *M. pusilla* with ω3 preference, the Δ6-elongase of the marine microalga *Pyramimonas cordata* and the Δ5-desaturase of *Pavlova salina,* producing 26% EPA in TAG [31]. This was performed employing an elegant and fast leaf assay for the transient expression and identification of the effective gene combination to produce desired VLC-PUFA *in planta*. The metabolic engineering of microalgae for desired fatty acid composition will be facilitated by the further development of genetic transformation tools for the wide range of microalgal species.

Acknowledgments Authors would like to thank Mrs. Shoshana Didi-Cohen for the dedicated technical assistance.

Abstract The present study was performed to investigate the effect of dietary conjugated linoleic acid (CLA) on the growth performance, immune parameters and disease resistance to *Aeromonas hydrophila* of juvenile Jian carp. A total of 900 juvenile Jian carp (10.71 ± 0.02 g) were randomly allocated into six groups of each three replicates, feeding isonitrogenous (35% crude protein) and isolipidic (7.8% crude fat) diets containing graded amounts of CLA (0, 0.5, 0.8, 1.4, 1.7, and 2.0%) for 60 days. After a 60-day growth test, a challenge trial was conducted by intraperitoneal injection of *Aeromonas hydrophila* to determine the effect of CLA on disease resistance of juvenile Jian carp. The results showed that diets incorporated with a proportion of up to 2.0% CLA without effect on weight gain, feed intake, and feed conversion ratio, but improved immune parameters and disease resistance of juvenile Jian carp. The dietary CLA level of optimal disease resistance to *Aeromonas hydrophila* was estimated to be 1.7% in juvenile Jian carp using broken-line analysis.

Keywords Conjugated linoleic acid · Growth · Immunity · Disease resistance · Juvenile Jian carp

Abbreviations

CLA	Conjugated linoleic acid
LD_{50}	50% lethal dose
CFU	Clonal formation unit
SD	Standard deviation
FI	Feed intake
WG	Weight gain
FCR	Feed conversion ratio
RBC	Red blood cell count
WBC	White blood cell count
SRF	Survival rate during growth trail
SRV	Survival rate after challenge
LA	Lysozyme activity
TIBC	Total iron-binding capacity

Introduction

Conjugated linoleic acid (CLA) is a mixture of positional (9, 11; 10, 12; or 11, 13) and geometric (*cis* or *trans*) isomers of linoleic acid (18:2n-6). The two main naturally occurring isomers being *cis*-9, *trans*-11 and *trans*-10, *cis*-12, are known to possess biological activity [1]. Schwarz et al. [2] found the amounts of monounsaturated and polyunsaturated fatty acids are reduced, and the amounts of saturated fatty acids are increased in carp after being given a diet containing CLA. Choi et al. [3] carried out a study showing that carp fed with the CLA supplemented diets with the c9, t11- and tl0, c12-CLA isomers as the major components and the c9, c11-, cl0, cl2-, t9, t11-, and tl0, t12-CLA as the minor ones incorporated into the phospholipids and neutral lipid fractions. The CLA content in the muscle hepatopancreas, testes, and ovaries of carp fed with a CLA supplemented diet for 8 weeks was positively related to the CLA content of the diets [3]. The effects of dietary CLA supplements on growth performance have

been studied in a number of fish species. In common carp *Cyprinus carpio* [2], Atlantic salmon *Salmo salar* [4, 5], yellow perch *Perca flavescens* [6], tilapia *Oreochromis niloticus* [7], rainbow trout *Oncorhynchus mykiss* [8–10], channel catfish *Ictalurus punctatus* [11], a dietary CLA supplement did not affect their weight gain, feed intake, and feed conversion ratio. However, some studies found that weight gains and specific growth rates were improved in channel catfish [12] and common carp [13] fed with the diets containing CLA. Therefore, the effects of CLA on fish growth performance remain uncertain.

Recently it has been reported that CLA has immunomodulatory properties and enhances terrestrial animal immune function [14–16] when the animals have been fed with a CLA supplemented diet. To our knowledge, there is a lack of information about the relationship between CLA and the immune response in fish. Only recently, has one study showed that inclusion of CLA up to 1% increased sea bass juveniles *Dicentrarchus labrax* plasma lysozyme activity and was positively correlated with an alternative complement pathway [17].

The present study aim was to determine the effects of a dietary CLA supplement on growth performance, immune parameters, and disease resistance to *Aeromonas hydrophila* of juvenile Jian carp *Cyprinus carpio* var. Jian.

Materials and Methods

Diet Preparation

The formulation of the basal diet is shown in Table 1. Fish meal, soybean meal and rice gluten meal were used as protein sources. The CLA was added to the diets at the expense of the fish oil so that all the diets remained isolipidic. The CLA (containing 87.6% CLA methyl esters as a 50:50 mixture of c9, t11 and t10, c12 isomers) was obtained from the Xin Jiang Technical Institute of Physics and Chemistry, Chinese Academy of Sciences. Six experimental diets were formulated to supplement with 0, 0.5, 0.8, 1.4, 1.7 and 2.0% CLA. Table 2 shows the fatty acid profiles of the diets. Crude protein and lipid content values were the measured according to AOAC [18]. Available phosphorus, lysine, methionine and cystine content values were calculated according to feed ingredients composition values [19].

Fish Feeding and Challenge

A total of 900 juvenile Jian carp (10.71 ± 0.02 g) were randomly allocated into each of 18 glass aquaria (90 × 30 × 40 cm^3). Each aquarium was randomly assigned to one of three replicates of six groups. Fish were acclimatized to the experimental conditions with their respective diet for 1 week prior to starting the growth trial. Fish were fed daily with the respective diet 8 times per day at 0700, 0900, 1100, 1300, 1500, 1700, 1900, and 2100 hours, and were carefully observed to ensure satiation without overfeeding for 60 days. A closed system with continuous aeration and daily replacement of water in the

aquarium was used. The aquaria system, operation of the culture system, and water quality were as previously described in [20].The experimental units were under a natural light and dark cycle (approximately 13 h L:11 h D). The water temperature was maintained at 21 ± 1 °C.

After the growth trial, five fish with a similar body weight were removed from each aquarium and moved to a tank with the same conditions, allowed to adapt to the culture conditions for 5 days, and then kept for another 17 days in a challenge trial. Fish were challenged by intraperitoneal injection with *Aeromonas hydrophila* (10^{10} cfu mL^{-1}, LD_{50}) at a dose of 0.5 mL $fish^{-1}$ by the method reported in [21]. The experiment conditions were the same as in the growth trial.

Sample Collection and Analysis

Fish were weighed at the beginning and end of the growth trial. At the end of the growth trial, five fish were taken from each aquarium, the blood was collected from the caudal vein using a syringe with heparin to prevent coagulation. The red blood cells and the white blood cells were counted by the method in [21]. At the end of the challenge trial, five fish per aquarium were anesthetized with MS-222 (Sigma Chemical) 12 h after their last feeding. Blood was collected from the caudal vein, stored at 4 °C overnight, and centrifuged at 3,000*g* for 10 min, the supernatant was stored at −20 °C for analysis. The serum agglutination activity was determined using a hemagglutination assay [22]. The activity was expressed as the titer, i.e., the reciprocal of the highest dilution showing complete agglutination. The lysozyme activity of the serum was measured using a method based on the ability of lysozyme to lyse the bacterium *Micrococcus lysodeikticus* described in [21]. The total iron-binding capacity was determined according to [23].

Calculations and Statistical Analyses

All data are presented as means ± SD and subjected to one-way analysis of variance followed by Tukey's test to determine significant differences among treatments, and probability values $P < 0.05$ indicates a significant difference. The broken-line model was used to calculate the optimal dietary CLA supplement in juvenile Jian carp for the maximal survival rate after challenge [24].

Table 4 Effect of dietary CLA supplementation on red blood cell count (RBC, 10^8 cell mL^{-1}) and white blood cell count (WBC, 10^6 cell mL^{-1}) in juvenile Jian carp

CLA (%)	RBC	WBC
0	11.60 ± 0.18^{a}	1.80 ± 0.14^{a}
0.5	12.37 ± 0.17^{b}	2.67 ± 0.29^{b}

1.4	13.80 ± 0.13^{d}	3.60 ± 0.24^{cd}
1.7	13.78 ± 0.07^{d}	3.72 ± 0.20^{d}
2.0	13.78 ± 0.13^{d}	3.61 ± 0.28^{d}

Mean ± SD ($n = 3$).Values sharing the same superscripts are not significantly different ($P < 0.05$)

Results

Table 3 shows growth and feed utilization parameters of fish fed the basal diet or diets with varying levels of CLA. Growth of the Jian carp was unaffected by CLA, neither having any significant effect on final weight, weight gain, and feed intake, nor feed conversion ratio ($P > 0.05$). Red blood cell count and white blood cell count were significantly increased in response to the CLA increasing up to 1.4%, and remaining nearly constant thereafter ($P < 0.05$, Table 4). There was no difference in survival rate among all dietary treatments in growth trail ($P > 0.05$, Table 5). However, with the increasing of dietary CLA levels, survival rate after challenge with *Aeromonas hydrophila* was increased with CLA increasing gradually up to 1.4%, and then remaining nearly constant ($P < 0.05$, Table 5). Lysozyme activity, hemagglutination titer, total iron-binding capacity, and blood cell counts showed the same change, increased significantly with the CLA increasing up

Table 3 Effects of dietary CLA supplementation on final weight and feed intake (FI, g $fish^{-1}$), weight gain (WG), and feed conversion ratio (FCR) of juvenile Jian carp

CLA (%)	Initial weight	Final weight	WG	FI	FCR

1.7	16.36 ± 0.97[c]	8.00 ± 1.00[c]	10.40 ± 0.40[c]
2.0	15.58 ± 0.84[c]	7.67 ± 0.58[c]	10.40 ± 0.40[c]

Mean ± SD. ($n = 3$).Values sharing the same superscripts are not significantly different ($P < 0.05$)

to 1.4%, thereafter kept nearly constant ($P < 0.05$, Table 6). According to the broken-line analysis, the values of the parameters of dietary CLA level were: for SRV, 1.7 ± 0.1%, $Y = 57.7 - 14.7x$ (R-X_{LR}); for RBC, 1.4 ± 0.1%, $Y = 13.8 - 1.6x$ (R-X_{LR}); for WBC, 1.0 ± 0.1%, $Y = 3.6 - 1.9x$ (R-X_{LR}); for LA, 1.2 ± 0.1%, $Y = 15.9 - 5.3x$ (R-X_{LR}); for log_2HA, 1.6 ± 0.2%, $Y = 7.8 - 1.0x$ (R-X_{LR}); for TIBC, 1.1 ± 0.2%, $Y = 10.3 - 2.7x$ (R-X_{LR}). ($P < 0.05$, $R^2 = 0.99$). The nutrient response curve generated by the broken-line equation is given in Fig. 1.

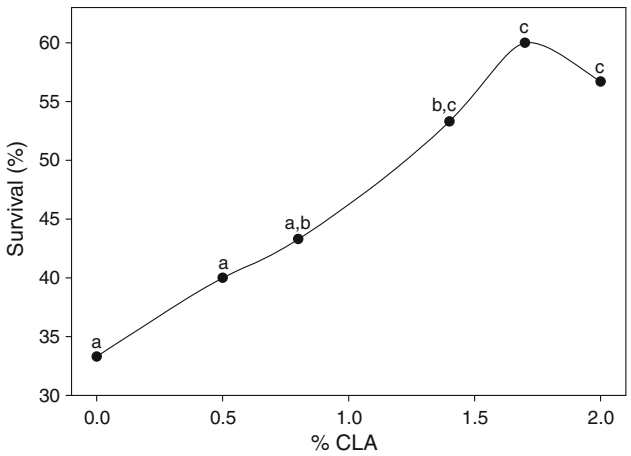

Fig. 1 Broken line analysis of the survival rate after *Aeromonas hydrophila* challenge in Jian carp fed the diets containing different CLA levels for 60 days (values sharing the same superscripts are not significantly different, $P < 0.05$)

Discussion

The results show that juvenile Jian carp weight gain, feed intake and feed conversion ratio were not influenced significantly by a 0.5–2.0% CLA supplement. Similar results have been reported for common carp weight gain, feed conversion ratio, and daily growth rate [3]. Some reports showed that 1.0% CLA in the diet improved the specific daily growth rate and feed conversion ratio in common carp, but 5.0 and 10.0% CLA decreased growth performance [13]. These different results may possibly be attributed to the total dietary lipid level different, 15% [13] and 10% [3].

The survival rate in the challenge trial is usually used to reflect fish disease resistance [25–28]. The present study firstly indicated dietary supplement CLA could improve the survival rate of juvenile Jian carp after being challenged with *Aeromonas hydrophila*. To our knowledge, there is no available information on CLA increasing fish disease resistance. The dietary CLA supplement in juvenile Jian carp to optimal disease resistance was 1.7% using broken-line regression with the survival rate after challenge with *Aeromonas hydrophila*.

The positive effect of CLA on disease resistance of juvenile Jian carp may be attributed to the improved immunity parameters. Fish possess non-specific defense mechanisms, such as the phagocytic mechanisms developed by macrophages and granular leukocytes, and are also the first animals to have developed both cellular and humoral immune responses mediated by lymphocytes [29]. The non-specific immune system is started up immediately and a series of immune responses are activated, including recognition, adhesive and opsonization, and bacterial growth inhibition and lysis [30]. As a variety of germ line-encoded pattern recognition receptors, lectins show binding specificity for different carbohydrates such as mannose, *N*-acetyl glucosamine or fucose, this leads to opsonization, phagocytosis and activation of the complement system [31]. The hemagglutination titer was improved by CLA in the present study. There is no information about the relationship between CLA and the serum hemagglutination titer of fish or animal. A recent study has shown that CLA was positively correlated with an alternative complement

pathway in sea bass juveniles [17]. Transferrins reduce infection by binding iron, thereby reducing iron availability to invading organisms, which restrict bacterial or fungal multiplication until the immune system can respond [29]. The total iron-binding capacity reflects serum transferrins' iron-binding properties [32]. The present result showed CLA could enhance total iron-binding capacity of juvenile Jian carp serum. There is no available information about CLA increasing fish total iron-binding capacity. Lysozyme, an important factor in the immune defense of both invertebrates and vertebrates, is found in the serum, mucus, and other tissues of fish [29]. Gram-positive bacteria can be directly damaged by lysozyme [29]. The present results indicated that CLA could improve serum lysozyme activity of juvenile Jian carp. A recent study has shown that CLA increased sea bass juveniles plasma lysozyme activity [17].

In conclusion, the present results showed that diets a supplement of up to 2.0% CLA did not alter weight gain, feed intake, and feed conversion ratio, but promoted immune parameters and disease resistance of juvenile Jian carp. The dietary CLA supplement was estimated to be 1.7% for optimal disease resistance to *Aeromonas hydrophila* in juvenile Jian carp.

ORIGINAL ARTICLE

Characteristics of the Fatty Acid Composition of a Deep-Sea Vent Gastropod, *Ifremeria nautilei*

Hiroaki Saito · Jun Hashimoto

Received: 16 November 2009 / Accepted: 23 April 2010 / Published online: 12 June 2010

Abstract Neutral and polar lipids in the soft parts of a gastropod species, *Ifremeria nautilei*, collected from deep-sea hydrothermal vents, were examined to assess the trophic relationships in hydrothermal vents. The vent gastropod obtains many of its lipids from symbiotic chemosynthetic microorganisms. The major polyunsaturated fatty acids (PUFA) both in the triacylglycerols and phospholipids of the gastropod consist of a limited number of n-3 and n-6 PUFA: arachidonic acid (20:4n-6), icosapentaenoic acid (20:5n-3), and docosapentaenoic acid (22:5n-3), without docosahexaenoic acid (DHA, 22:6n-3). Noticeable levels of various n-6 PUFA, such as 18:2n-6,9, 20:2n-6,9, 20:3n-6,9,12, and 20:3n-6,9,15 with significant levels of 16:1n-6 and 18:1n-6 indicate the biosynthetic characteristic of the endosymbionts. The lack of DHA in all specimens suggests a limitation of its lipid biosynthesis ability with its symbionts. This finding with regard to the lipids is unusual for a marine animal in the grazing or detrital food chain because many marine animal lipids evidently contain high levels of DHA with low levels of n-6 fatty acids. Such contradictory findings lead to some new insights into the absence of a biosynthetic pathway for DHA in *I. nautilei*, and provide evidence that DHA in this species is dispensable. Similar to herbivorous gastropods, the lack of DHA with significant levels of n-6 PUFA in this species also indicates its selective assimilation of specific microorganisms, such as chemosynthetic bacteria in hydrothermal vents, because significant levels of DHA were found in carnivorous mollusk lipids.

Keywords Chemoecology · Gastropod · Docosapentaenoic acid · Geothermal energy · Hydrothermal vents · Marine-grazing food chain · Polyunsaturated fatty acids · Symbiotic microorganisms

Abbreviations

ARA	Arachidonic acid
DMA	Dimethylacetals
DMOX	4,4-Dimethyloxazoline
DHA	Docosahexaenoic acid
DPA	Docosapentaenoic acid
EPA (IPA)	Icosapentaenoic acid
GC–MS	Gas chromatography–mass spectroscopy
MUFA	Monounsaturated fatty acids
NMID	Non-methylene interrupted dienes
NMR	Nuclear magnetic resonance
PtdCho	Phosphatidylcholine
PtdEtn	Phosphatidylethanolamine
PUFA	Polyunsaturated fatty acids
TAG	Triacylglycerols
TFA	Total fatty acids

Introduction

It is generally known that all marine animals, not only marine fishes but also invertebrates, characteristically accumulate various sorts of n-3 polyunsaturated fatty acids (PUFA) in their cell membranes; in particular, docosahexaenoic acid

(DHA, 22:6 n-3) and icosapentaenoic acid (EPA, 20:5 n-3) are the major PUFA in their tissues [1–3]. These n-3 PUFA are considered to originate from phytoplankton, which depend on solar energy, and from unique deep-sea barophilic bacteria [1, 4, 5]. It is also well-known that many marine animals in higher trophic levels through the food web, accumulate these long-chain PUFA [1, 6, 7]. As for the fatty acid determination of mollusk lipids, some bivalve species (Bivalvia), such as oysters and mussels, have been investigated in detail (for oysters, Ostreidae: [8–11]; for pearl oysters, Pteriidae: [12]; for scallops, Pectinidae: [13, 14]; for clams, Veneridae: [15]; and for mussels, Mytilidae: [16–18]). Nevertheless, there is relatively little information available on the biochemical components of other mollusk species; there are only a few reports on both lipids and the fatty acid compositions of Gastropoda (for limpets: [19], for abalones Haliotidae: [20]).

The deep-sea gastropod, *Ifremeria nautilei* (black snail), occurs in the hydrothermal vents of the Manus Basin in the Western Pacific Ocean [21]. Although adequate attention has been paid to the clarification of this species' ecological function [22–24], the chemical components in its glycerolipids have yet to be rigorously elucidated [25]; in particular, a detailed analysis of its PUFA. Although the isolation from their hosts and cultivation of symbiotic marine microorganisms is very difficult, in particular vent organisms, we are able to know their lipid physiology by investigation of the host lipids, which reflect those of the symbionts. Information on the symbionts' lipids may be obtained by comparative analysis of the lipid and fatty acids in its muscles and gills, in which they specifically have bacteriocytes. Moreover, the nutrition of the snail mainly depends on the products of the symbionts, because of the hosts' reduced stomach [23–25]. To assess the trophic relationships in hydrothermal vents, the lipid and fatty acid compositions of the lipids in its various organs were analyzed in the present study.

Materials and Methods

Materials

The samples of *I. nautilei* are listed in Table 1. They were collected in the Manus Basin of the Western Pacific Ocean at a depth of 1,668 m at 03°43′S and 151°41′E on 07 November 1999 (dive No. 1150 of the submersible "*Shinkai 2000*," which belongs to the Japan Marine Science and Technology Center). In total, ten *I. nautilei* samples were obtained (Table 1; Fig. 1). In the Manus Basin, research of the JAMSTEC has systematically been performed for more than 10 years, and much data has been collected on vent and seep animals. We also had a chance

Table 1 Biological data of the *Ifremeria nautilei*

Scientific name	Date	Locality	Depth (m)	Temperature (°C)	Replicate animals (n)	Height (mm)	Width (mm)	Weight (g)

Results are expressed as means ± standard error ($n = 10$). *I. nautilei* were collected by dive #1150 of *Shinkai 2000*

Fig. 1 Photograph of the vent gastropod *Ifremeria nautilei* Bouchet & Warén. Samples were collected by the submersible *Shinkai 2000*. The vent snail was caught at a depth of 1,668 m at 03°43′S and 151°41′E in the Manus Basin of the Southwestern Pacific Ocean on 07 November 1999 (dive No. 1150 of the submersible "*Shinkai 2000*," which belongs to the Japan Marine Science and Technology Center). *Scale* shown in "cm"

to get some specimens of black snails at the Basin. The snails were considered to be in the growing stage, because we could not find any signs of maturation.

Lipid Extraction and Analysis of Lipid Classes

After 4 months of storage at −40 °C in the laboratory, all samples of *I. nautilei* were dissected into three groups of organs (gill, foot and viscera) after taking measurements, the organs were individually immersed in a mixture of chloroform and methanol (2:1, vol/vol) at −25 °C for 2 days prior to lipid extraction (Table 1). Each sample was homogenized in the same solvent and a portion of the homogenized sample was extracted according to the Folch procedure [26]. The crude lipids of the organs of *I. nautilei* were separated into classes on silicic acid columns (Merck and Co. Ltd., Kieselgel 60, 70–230 mesh), and a quantitative analysis of the lipid constituents was performed using gravimetric analysis of fractions collected from column chromatography [27]. The first eluate (dichloromethane/*n*-hexane, 2:3, v/v) was collected as steryl esters, wax esters, and diacyl glyceryl ethers fractions. This was followed by eluting triacylglycerols (TAG) with dichloromethane and eluting the sterols with dichloromethane/ether (35:1, v/v); eluting the diacylglycerols with dichloromethane/ether (9:1, v/v); eluting the free fatty acids with dichloromethane/methanol (9:1, v/v); eluting the phosphatidylethanolamine (PtdEtn) with dichloromethane/methanol (1:5, v/v); eluting ceramide aminoethyl phosphonate and other minor phospholipids with dichloromethane/methanol (1:20,v/v); and eluting phosphatidylcholine (PtdCho) with dichloromethane/methanol (1:50, v/v). The lipid classes from each lipid fraction were identified by comparison of the retention factor (Rf) values of standards using plate thin-layer chromatography (Merck and Co. Ltd., Kieselgel 60, with a thickness of 0.25 mm for analysis), and by the characteristic peaks observed in nuclear magnetic resonance (NMR) [27]. All sample lipids were dried under argon at room temperature and stored at −40 °C (Table 2).

NMR Spectrometry and the Determination of Lipid Classes

Spectra were recorded on a GSX-270 NMR spectrometer (JEOL Co. Ltd., Tokyo, Japan) in a pulsed Fourier transform mode at 270 MHz in a deuterochloroform solution using tetramethylsilane as the internal standard [27].

Preparation of Methyl Esters and Gas–Liquid Chromatography Analysis

The compositions of the fatty acid methyl esters were determined by gas–liquid chromatography. Analysis was performed on a Shimadzu GC-8A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) and an HP-5890 (Hewlett Packard Co., Yokogawa Electric Corporation, Tokyo, Japan) and both gas chromatographs were equipped with an Omegawax-250 fused silica capillary column (30 m × 0.25 mm i.d.; 0.25 μm film, Supelco Japan Co. Ltd., Tokyo, Japan). The temperatures of the injector and the column were held at 230 and 215 °C, respectively, and the split ratio was 1:76 (FID detector at 240 °C). Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min. In the fatty acid compositions of PtdEtn, low levels of dimethylacetals (DMA), such as DMA 18:0 and DMA 20:1, were included (Table 3). The theoretical values of the fatty acid compositions were obtained by subtracting the DMA from the total fatty acids (TFA) of PtdEtn [12].

Quantitation of individual components was performed by means of a Shimadzu Model C-R3A (Shimadzu Seisakusho Co. Ltd.) and an HP ChemStation System (A. 06 revision, Yokogawa HP Co. Ltd.) electronic integrators.

Preparation of 4,4-Dimethyloxazoline Derivatives (DMOX) and Its Analysis by Gas Chromatography–Mass Spectrometry (GC–MS)

DMOX derivatives were prepared by adding an excess amount of 2-amino-2-methyl- propanol to a small amount of the fatty acid methyl esters (for example, 30 mg of the acid methyl esters with 1 mL of 2-amino-2-methylpropanol) in a test tube under an argon atmosphere. The mixture was heated at 180 °C for 18 h. The reaction mixture was cooled and poured into saturated brine and extracted with

n-hexane. Triplicate extractions with *n*-hexane were carried out, and the extract was washed with saturated brine, then dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure, and the samples were again dissolved in *n*-hexane for analysis by GC–MS [27].

Analysis of the DMOX derivatives and the methyl esters was performed on an HP G1800C GCD Series II GC–MS (Hewlett Packard Co., Yokogawa Electric Corporation) instrument equipped with the same capillary column for determining the fatty acids with an HP WS (HP Kayak XA, G1701BA version, PC workstations). The temperatures of the injector and the column were held at 230 and 215 °C, respectively. The split ratio was 1:75, and the ionization voltage was 70 eV. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min.

The fatty acid methyl esters and DMOX derivatives were identified by comparison of the mass spectral data obtained by GC–MS (Table 4; Figs. 2, 3, 4). For example, the representative chromatograms of the DMOX derivatives (visceral and foot TAG of specimen No. 8) are shown in Figs. 2 and 3 plus Table 4. The MS-spectra of its DMOX derivatives representing several major PUFA, such as two n-3 PUFA 20:5n-3 and 22:5n-3, are displayed in Figs. 3 and 4. As presented in Fig. 3 (a representative spectrum of 20:5n-3 at 15.526 min in one peak from 15.2 to 15.7 min in the chromatogram of visceral TAG DMOX in Fig. 2), the MS peaks of its DMOX derivative are M^+-355 and 126 (base peak), with four pairs of peaks (M-312/300, M-272/260, M-232/220, and M-192/180) reflected by four double bonds as Δ-17 (n-3), Δ-14 (n-6), Δ-11 (n-9), and Δ-8 (n-12), and two peaks (M-153/136) reflected by a Δ-5 (n-15) double bond. Similarly, for 22:5n-3 at 27.274 min in one peak from 27.0 to 27.6 min in the chromatogram in Fig. 2, the MS peaks of its DMOX derivative in Fig. 4 are M^+-383 and 126 (base peak), with five pairs of peaks (M-340/328, M-300/288, M-260/248, M-220/208, and M-180/168) reflected by five double bonds as Δ-19 (n-3), Δ-16 (n-6), Δ-13 (n-9), Δ-10 (n-12), and Δ-7 (n-15).

Statistical Analyses

Ten experimental replications were completed for each lipid class. For all samples of fatty acids analyzed by GLC, 11 to 22 replications were completed. Significant differences of the means were determined using Student's *t* test at a significance level of $P < 0.05$.

Results and Discussion

Data are mean ± SE (replications, $n = 11$–22). The major fatty acids were selected if at least one mean datum was detected at a level of 0.3% or more of the total fatty acids

[a] 16:1n-7 contained significant levels of 16:1n-6

content in the foot was 0.9% of the wet weight in all samples. The mean lipid content in the foot samples was low, while that of the others (2.2% of wet weight for the gills and 6.0% for the viscera) was high, suggesting that *I. nautilei* accumulates lipids mostly in the viscera. As shown in Table 2, triacylglycerols (TAG, 29.3–65.1%) was the major component in all organ lipids, with low levels of other neutral lipids, such as wax esters, steryl esters, diacylglyceryl ethers, diacylglycerols, and free fatty acids. The gastropod contained medium levels of sterols (3.8–17.5%) and phospholipids (PtdEtn at 9.5–24.9% of TFA and PtdCho at 5.4–10.4% of total lipids), with small levels of ceramide aminoethyl phosphonate (1.8–2.3% of total lipids). Comparatively high levels of lipid content and TAG in all organs suggests a high nutritional condition in the hydrothermal vents and high ability of the endosymbionts to produce autotrophically because the gastropod wholly depends on thiotrophic chemoautotrophic bacteria [23, 24]. All *I. nautilei* lipids mainly contained glycerol derivatives (TAG, diacylglycerols, free fatty acids, PtdEtn, and PtdCho) and the total proportion of these derivatives reached about 75.5–91.5%, with low levels of other lipids (wax esters and diacylglyceryl ethers). The lipid class of vent gastropod *I. nautilei*, which contained TAG as the major component in all organs (Table 1), differed from those of normal gastropod species (*Haliotis fulgens*: [20]), whose neutral lipid levels were very low. The foot of normal shallow-water snails generally contains phospholipids as the major components [28].

Fatty Acid Composition and Its Similarity to Depot TAG Lipids Among All Organs of *I. nautilei*

The fatty acids of TAG (more than 0.3% of TFA) in all organs (gill, viscera, and foot) are shown in Table 3. Although the fatty acid composition of TAG slightly varied among the three organs, the kinds of major fatty acids were almost the same in all organs. Five dominant fatty acids (more than about 3% of TFA) in gill TAG were found in the samples: 16:0 and 18:0 as saturated fatty acids, 16:1n-7(6), 18:1n-6, and 18:1n-7 as monounsaturated fatty acids (MUFA), with significant levels (more than about 1% of TFA) of four fatty acids: 14:0, 20:1n-7, 20:1n-13, and 22:2n-7,15. Similarly, eight dominant fatty acids in tissue (viscera and foot) TAG were also found in all samples: 16:0 and 18:0 as saturated fatty acids, 16:1n-7(6), 18:1n-6, 18:1n-7, 20:1n-7, and 20:1n-13 as MUFA, and 20:2n-7,15 as non-methylene interrupted dienoic acid (NMID), with significant levels of five other fatty acids: 18:1n-9, 18:2n-8,13, 20:2n-6,13, 20:5n-3 (icosapentaenoic acid; EPA), and 22:5n-3 (docosapentaenoic acid; DPA). In the neutral lipids, both in the gill and tissues (foot and viscera), unusually high levels of total n-7 MUFA were found and this suggests

All the retention times of DMOX derivatives in I. nautilei accord with Fig. 2

a "R. time" means "retention time."

bacterial contributions [22–24, 29] because high levels of n-7 MUFA, such as vaccenic acid, 18:1n-7, were found in sulfur-oxidizing bacteria [30, 31]. Vaccenic acid is considered to be derived from Δ9-desaturation before C_2 elongation of 16:0, and 20:1n-13 may also be derived from 18:0 by Δ5-desaturation and C_2 elongation, similar to the findings previously reported [32].

Despite similar fatty acids found both in gill (bacterial) and tissue TAG, some of the fatty acid levels in the tissue TAG differed from those in gill TAG. In the tissue TAG, two NMID (18:2n-8,13 and 20:2n-7,15) occurred and higher levels of relatively longer-chain and higher-unsaturated acids (18:2n-8,13, 20:1n-7, 20:1n-13, 20:2n-6,13, 20:2n-7,15, and 22:2n-7,15) with lower levels of the shorter-chain ones (14:0, 16:1n-7, 18:1n-6, and 18:1n-7) were found, compared with those in the gill TAG. In consideration of the first absorption of assimilated lipids in the gill, where the symbionts specifically inhabit, these findings suggest lipid conveyance from the gill to the tissues, and enzymatic biosynthesis in *I. nautilei* tissues. Such a phenomenon is probably caused by the active function of Δ-5 desaturase and C_2 elongase at the tissue levels [33]. Furthermore, significant levels of n-3 PUFA (2.2–2.6% for EPA and 0.8–1.0% for n-3 DPA) were characteristically found only in tissue TAG. The EPA and n-3 DPA in the tissue TAG suggest that these long-chain n-3 PUFA were concentrated or biosynthesized in the tissue TAG, similar to other normal shallow-water gastropod tissues (*Haliotis laevigata* and *Haliotis rubra*: [34]). At least, the mollusks have Δ-5 desaturase [18, 33] and are able to synthesis a double bond at the n-15 position in C_{20} fatty acids; for example, 20:3n-6,9,15, ARA, 20:4n-3,6,9,15, EPA, and 22:4n-3,6,9,15 were considered to be derived by Δ-5 desaturase [33].

In the present study, the detailed fatty acid composition of the gastropod was determined; in particular, all n-3 and n-6 PUFA were determined [25]. The thiotrophic symbionts, which mainly produced n-3 and n-6 PUFA, markedly differed from some vent-bivalve symbionts, which biosynthesize only n-4 non-methylene interrupted (NMI) PUFA [27].

Fatty Acid Composition in Tissue Phospholipids of *I. nautilei*

The major fatty acid compositions in the gill, viscera, and foot phospholipids of *I. nautilei* are also presented in Table 3. The fatty acid composition in the tissue PtdEtn included medium levels of DMA, such as DMA 18:0 and DMA 20:1 and this finding suggests that plasmalogens-type PtdEtn are biosynthesized in the gastropod tissue.

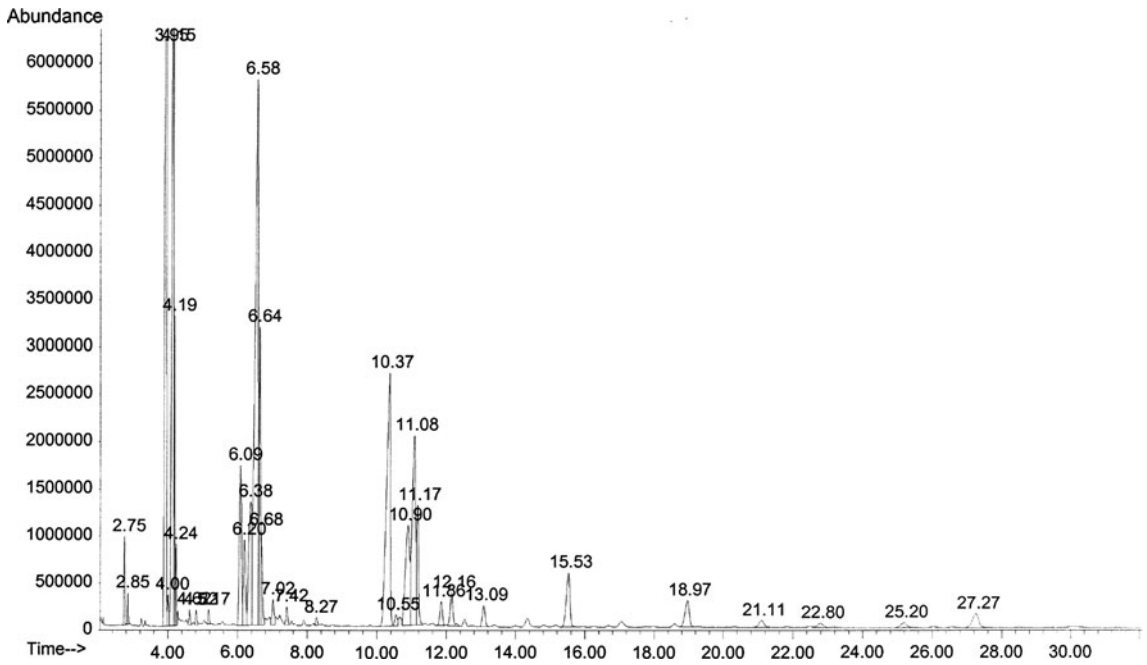

Fig. 2 The chromatogram of the DMOX derivatives of the fatty acids in *I. nautilei* visceral TAG (measured on 20 February 2001). Analysis of the DMOX derivatives was performed on a HP G1800C GCD Series II gas chromatograph mass spectrometer equipped with an Omegawax-250 fused silica capillary column with the HP WS (HP Kayak XA, G1701BA version, personal computer workstations). The temperatures of the injector and the column were held at 230 and 210 °C, respectively. The split ratio was 1:75, and the ionization voltage was 70 eV, respectively. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min. Each MS spectrum was obtained by every 0.009 min; for example, a spectrum at 15.526 min (Scan No. 1505 in Fig. 3) is one of the representative spectra of EPA, because the EPA was detected from 15.2 to 15.7 min as one peak in the chromatogram of DMOX derivative of the *I. nautilei* visceral TAG and more than 50 spectra of EPA were obtained by scanning of the peak. Simiarly, a spectrum at 27.274 min (Scan No. 2816 in Fig. 4) is one of the representative spectra of n-3 DPA, because the n-3 DPA was detected from 26.9 to 27.5 min as one peak in the chromatogram of DMOX derivative of the *I. nautilei* visceral TAG and more than 50 spectra of EPA were obtained by scanning of the peak

Although the fatty acid composition of phospholipids differed from that in TAG, the kinds of all fatty acids were the same in all organs. In addition, significant levels of 18:2n-6 (linoleic acid) and 20:2n-6 were observed only in the polar lipids, compared with low levels of those in TAG. Linoleic acid was probably derived from 18:1n-6 by using Δ-9 desaturase, and noticeable levels of 18:1n-6 were found only in TAG.

Ten major fatty acids were found in all organ PtdEtn: 16:0 and 18:0 as saturated fatty acids, 16:1n-7(6), 18:1n-7, 20:1n-7, and 20:1n-13 as MUFA, 20:2n-7,15 as NMID, 20:4n-6 (arachidonic acid; ARA) as n-6 PUFA, and EPA and n-3 DPA as n-3 PUFA, with significant levels of six n-6 fatty acids: 18:1n-6, 18:2n-6, 20:2n-6, 20:3n-6,9,12, 20:3n-6,9,15, and 22:2n-6,9,12,15. Nine similar fatty acids were the major components in PtdCho: 16:0 as saturated acid, 16:1n-7(6), 18:1n-7, and 20:1n-13 as MUFA, 20:2n-7,15 as NMID, 18:2n-6 and ARA as n-6 PUFA, and EPA and n-3 DPA as n-3 PUFA, with significant levels of 18:0, 18:1n-6, 20:1n-7, 20:2n-6, 20:3n-6,9,12, and 20:3n-6,9,15. Although the saturated fatty acid and MUFA levels in PtdEtn differed from those in PtdCho, the major kinds of PUFA in PtdEtn were the same as those in PtdCho. As for PUFA in the gastropod, three PUFA (ARA, EPA, and n-3 DPA) were the major PUFA both in PtdEtn and PtdCho, and this phenomenon differed from that in TAG, which contained low levels of these PUFA. In the present study, it has been confirmed that all *I. nautilei* polar lipids contained medium levels of total PUFA (21.9–28.3% for PtdEtn and 18.2–30.1% for PtdCho), which were probably concentrated of the tissue level. The significant PUFA levels in the *I. nautilei* lipids may be influenced by the high pressures in the deep sea, similar to those in barophilic bacteria [35, 36]. Compared with the fatty acid compositions of shallow-water carnivorous mollusks [19, 28], high levels of 18:1n-7 and 20:1n-13 and significant levels of long-chain n-6 PUFA, such as ARA and 22:4n-6, without shorter-chain n-3 PUFA (18:3n-3 and 18:4n-3) and DHA were only observed in the *I. nautilei* lipids. In particular, the polar lipids of *I. nautilei* gills contained high levels of n-6 PUFA, while high n-3 PUFA levels were found in those of its viscera and foot. The levels of long-chain PUFA in the *I. nautilei* lipids are similar to those of some herbivorous gastropod lipids [20, 34] because significant levels of long-chain PUFA, such as ARA, 22:4n-6, and n-3 DPA, without DHA, were found in both species.

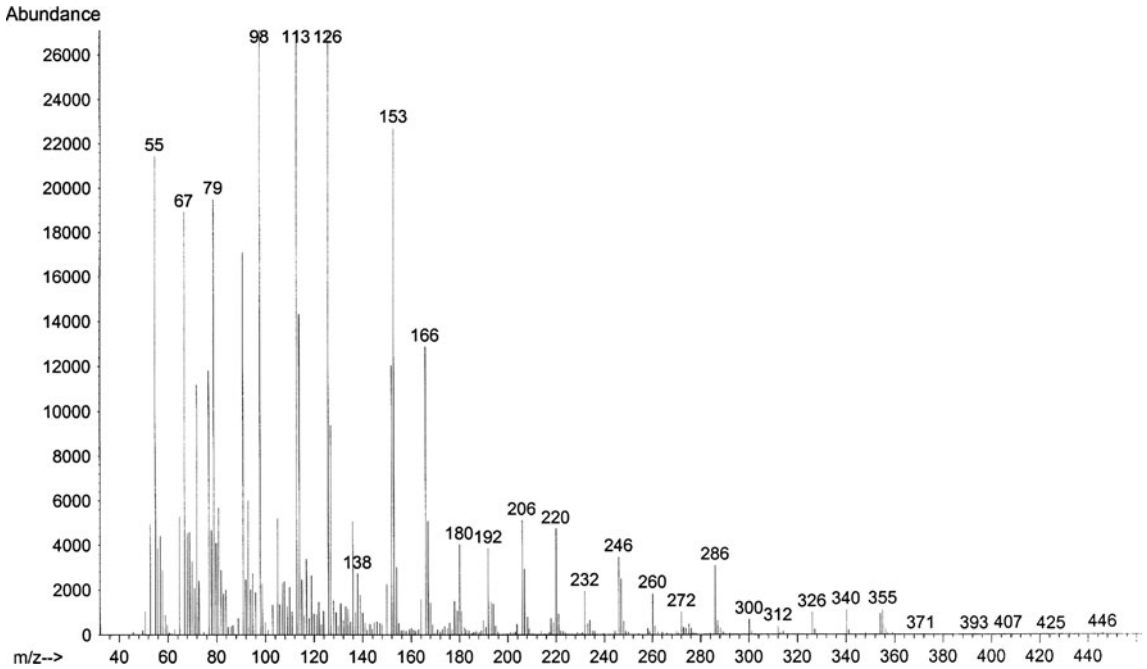

Fig. 3 The MS peaks of the DMOX derivative of EPA are M^+-355, 340, 326, 312, 300, 286, 272, 260, 246, 232, 220, 206, 192, 180, 166, 153, 136, 126, 113 (base peak), and four pairs of the peaks M-312 and M-300, M-272 and M-260, M-232 and M-220, and M-192 and M-180 is, respectively, reflected by Δ-17 (n-3), Δ-14 (n-6), Δ-11 (n-9), and Δ-8 (n-12) double bonds, and a pair of the M-153 and M-136 shows a Δ-5 (n-15) double bond

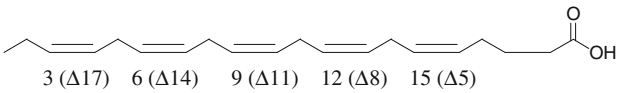

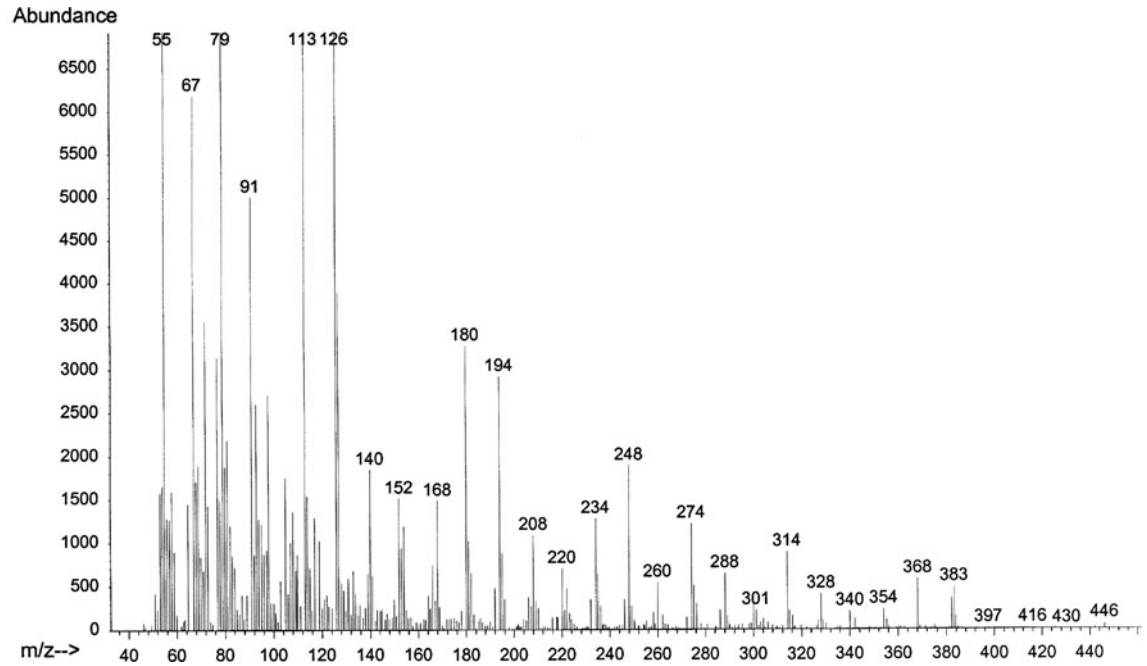

Fig. 4 The MS peaks of the DMOX derivative of n-3 DPA are M^+-383, 368, 354, 340, 328, 314, 300, 288, 274, 260, 248, 234, 220, 208, 194, 180, 166, 152, 140, 126, 113 (base peak), and four pairs of the peaks M-340 and M-328, M-300 and M-288, M-260 and M-248, M-220 and M-208, is, respectively, reflected by Δ-19 (n-3), Δ-16 (n-6), Δ-13 (n-9), and Δ-10 (n-12) double bonds and three peaks of M-166, M-168, and M-180 shows a Δ-7 (n-15) double bond

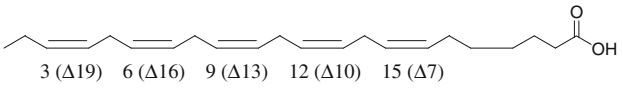

The profile of PUFA in all the polar lipids of *I. nautilei* differed from those in other marine carnivorous gastropods [19, 25, 28], which have high levels of n-3 PUFA (from 18 to 20 carbons) with low or trace levels of n-6 PUFA. For example, 18:2n-6 and its various derivatives (20:2n-6, 20:3n-6, 20:3n-6,9,15, ARA and 22:4n-6) were the characteristic fatty acids in all organ PtdEtn and PtdCho of *I. nautilei*, similar to those in herbivorous gastropod lipids [20, 34]. This implies a specific trophic relationship with the symbiotic bacteria because there are no macroalga species in the deep sea. In particular, the high levels of total n-6 PUFA in the gill phospholipids (17.1% for PtdEtn and 19.2% for PtdCho), which may be directly influenced by the bacterial lipids [22–25], were *I. nautilei*'s unusual characteristic. The levels of total n-6 PUFA in the gill phospholipids were significantly higher than those of total n-3 PUFA. On the contrary, in the gastropod tissues (foot and viscera), the levels of total n-3 PUFA (n-3 PUFA: 12.3–15.6% for PtdEtn and 9.2–15.6% for PtdCho) were higher than those of total n-6 PUFA (n-6 PUFA: 9.5–12.4% for PtdEtn and 8.7–14.2% for PtdCho), and this indicates the requirement of n-3 PUFA in *I. nautilei*, similar to normal gastropods and fishes. Based on the present facts, the existence of medium levels of n-3 PUFA in the phospholipids differed from those in TAG, demonstrating a high accumulation mechanism of all PUFA in the gastropod tissues [1, 12, 33]. Furthermore, in spite of the accumulation of n-3 PUFA in the tissue polar lipids, the lack of DHA in all tissues is unusual for marine animals, and such a phenomenon points to the regulation of lipids assimilated from the symbiotic bacteria, because it is thought that the products of the symbionts are a major component of *I. nautilei*'s diet [22–24]. The lack of DHA in all organs of *I. nautilei* tissues also indicates its specific nutritional source as being only the symbionts [23] and its incapability to biosynthesize DHA. This speculatory remark is well supported by some reports, in which extremely low levels of DHA are said to be exhibited in the tissue lipids of some herbivorous marine gastropods (DHA: 0.21% for periwinkle *Littorina littorea*, [28]; non-detectable and 0.4% for the limpets *Patella peroni* and *Cellana tramoserica*, and 0.2–0.9% for the chiton *Ponerplax costata*, [19]; 0.2–0.3% for wild green lip abalone *Haliotis laevigata* and black lip abalone *Haliotis rubra*, [34]; non-detectable for *Haliotis fulgens*, [20]), which also feed on specific macroalgae. These findings suggest the non-essentiality of DHA for these mollusks [32, 37]. These herbivorous marine mollusks also have limited kinds of n-6 PUFA (only 18:2n-6 and ARA) as the major acids (ARA levels: 10.6–38.8% for the limpets *Patella peroni* and *Cellana tramoserica*, and 12.6–30.9% for the chiton *Ponerplax costata*, [19]; 10.7–14.3% for wild green lip abalone *Haliotis laevigata* and black lip abalone *Haliotis rubra*, [34]; 10.0–14.2% for *Haliotis fulgens*, [20], which originate from their dietary algae, while the symbionts may biosynthesize significant levels of various n-6 PUFA, such as 18:2n-6, 20:2n-6, 20:3n-6, 20:3n-6,9,15, and ARA. Furthermore, the similarity of the fatty acid compositions of the same snail, which were collected from different areas, indicates its species' characteristic [25].

Non-essentiality of DHA in the Lipids of *I. nautilei*

Differing from the essentiality of n-3 PUFA for marine fishes and shallow-water bivalves [38], *I. nautilei* may accumulate n-6 PUFA as a possible substitute for n-3 PUFA in order to maintain cell membrane fluidity. It is noteworthy that all marine animals show a tendency to accumulate PUFA in their tissues, but differences in the degree of accumulation of n-6 and n-3 PUFA among mollusks species might be regulated by their food web [12]. In connection with the role of the food web, many pelagic fishes accumulate n-3 PUFA, such as DHA, through the marine-grazing food chain originating from phytoplankton having an elongation of shorter n-3 PUFA. In general, DHA is the dominant PUFA in both the PtdEtn and PtdCho of almost all higher trophic marine animals and they maintain consistently high DHA levels by continuous exploitation and its subsequent accumulation in vivo [7]. In addition, all marine fishes require DHA as the most important fatty acid, because it is an essential fatty acid that they are unable to biosynthesize in vivo, which differs from the ability of freshwater fishes [39, 40].

On the contrary, similar to the fluctuation of DHA levels in the polar tissue lipids of *P. fucata* (PtdEtn; 18.4–33.2% and PtdCho; 23.2–40.9%, [12]), the lack of DHA in the fatty acid composition of vent bivalves [18, 27] and the vent gastropod, *I. nautilei*, suggests that DHA is not indispensable as the most important essential fatty acid for mollusks, and they possibly contain these higher PUFA for the maintenance of the fluidity of their cell membranes. Thus, our findings encapsulate some typical features of the regulation of the lipid physiology of *I. nautilei*, and the lack of DHA content implies a limitation on the part of the symbiotic organisms and the absence of a biosynthetic pathway for DHA in this species. The lack of DHA with significant levels of other various PUFA in *I. nautilei* lipids suggests that it is unable to biosynthesize DHA, similar to the incapability of marine fishes. With respect to the level of PUFA, almost all marine animals mainly have n-3 PUFA as the major PUFA, while ARA is generally undetectable or negligible in their lipids [1, 6, 7]. On the contrary, phytoplankton are often rich in both n-3 PUFA and n-6 PUFA, therefore, significant levels of n-6 PUFA are found in the phospholipids of their primary consumers (e.g., sweet smelt *Plecoglossus altivelis*, [41]). This

characteristic indicates that its symbionts produce various n-6 PUFA and simultaneously have a limit for lipid biosynthesis of n-3 PUFA.

Biosynthesis of NMID in *I. nautilei*

The noticeable levels of 22:4n-6 and DPA in both tissue lipids suggest that this snail may have the enzymes for biosynthetic C_2 elongation in its tissues, similar to the synthetic pathway of other bivalves [15, 18, 33]. For example, 22:4n-6, which is considered to be derived from C_2 elongation of ARA, indicates the contribution of elongase. Furthermore, the levels of 20:2n-7,15, which is a long-chain NMID, in the phospholipids were markedly higher than those in TAG, with lower levels of 14:0, 16:1n-7, and 18:1n-7 in the phospholipids, compared with the high levels of shorter MUFA in TAG. These points imply that bacterial 16:1n-7 and 18:1n-7 are precursors for 20:2n-7,15, which is considered to be derived from Δ-5 desaturation and the second C_2 elongation of 18:1n-7 after the C_2 elongation of 16:1n-7 also suggests the contribution of desaturase, similar to other NMID derivatives [33]. *I. nautilei* may be able to biosynthetically transform shorter MUFA to longer NMID, localizing mainly close to the polar phospholipids [12], because specific high levels of NMID were observed only in the polar lipids. In light of the above discussion, it is inferred that the same physiological elongation and desaturation mechanisms exist as in other mollusks, such as *Pinctada fucata* [12]. Consequently, the high levels of NMID in the phospholipids suggest that this snail is able to biosynthesize only lowly unsaturated PUFA, such as NMID at the tissue level using Δ5- and Δ9-desaturases, similar to other mollusk species [18, 33].

Acknowledgments The authors thank Prof. Mutsumi Sugita, Shiga University, for kindly donating the authentic ceramide aminoethyl phosphonate which originated from the freshwater clam *Corbicula sandai* and for his valuable discussion of the bivalve lipids. The authors also thank Ms. Sumiko Terada, Ms. Mikiko Tanaka, and Mr. Akihito Takashima for their skilled technical assistance. This work was supported in part by a research project, "Development of New Technology for Treatment and Local Recycling of Biomass, D-2100" from the Ministry of Agriculture, Forestry, and Fisheries of Japan.

Sitosterol Thermo-oxidative Degradation Leads to the Formation of Dimers, Trimers and Oligomers: A Study Using Combined Size Exclusion Chromatography/Mass Spectrometry

Magdalena Rudzinska · Roman Przybylski · Yuan Yuan Zhao · Jonathan M. Curtis

Received: 30 October 2009 / Accepted: 21 April 2010 / Published online: 29 May 2010

Abstract Phytosterols are recognized as functional food components with cholesterol reducing properties in humans. The formation of phytosterol oligomers as a result of the thermo-oxidative degradation of sitosterol is shown to occur. The existence of oligomers is demonstrated by size exclusion chromatography (SEC) and confirmed by combined SEC-atmospheric pressure chemical ionization mass spectrometry (SEC/APCI-MS). A speculative structure for the sitosterol dimer with 3,7′ linkage is proposed consistent with data from tandem mass spectrometry and exact mass measurements. Higher molecular weight species arising from the formation of trimers or higher oligomers are seen in the mass spectra. Fragments of sitosterol formed by thermo-oxidative processes are also shown to oligomerize and their common structural characteristics are demonstrated by tandem mass spectrometry. The results presented provide evidence for the possible formation of oligomeric species involving sterols in addition to those known for acylglycerides in vegetable oils subjected to extreme oxidative stress such as in frying.

LC/MS	Liquid chromatography–mass spectrometry
SEC	Size exclusion chromatography

Introduction

Sterols comprise a major portion of the unsaponifiable matter of most vegetable oils and are mainly present as free, esterified with fatty and phenolic acids, and as glucosides. Phytosterols similar in chemical structure to cholesterol, are prone to oxidation particularly at elevated temperatures as used during frying [1, 2]. Oxidative degradation of phytosterols leads to the formation of oxidized sterol derivatives, volatile flavor components and oligomers [3–6]. Dutta et al. [7] studied the formation of phytosterol oxides during potato chips and French fries frying in different oils. Lampi et al. [8] and Soupas et al. [9] established that the sterol structure and oil matrix are the main factors affecting the formation of oxidative derivatives.

The mechanism of sterol oxidation is similar to free radical oxidation of fatty acids [10]. The initial step involves the formation of a C-7 carbon centered radical adjacent to the double bond at C-5 and C-6 in ring B of the

sterol. As a result, 7-hydroperoxide epimers are formed and due to their instability decompose to corresponding hydroxyl derivatives [11]. Interaction of hydroperoxy radicals with another sterol molecule leads to the formation of epoxy derivatives [11]. When sterols and their oxidized derivatives are subjected to elevated temperatures, a variety of low and high molecular weight components are formed indicating that oxidized derivatives are precursors and initiators [3, 11]. In sterol oligomers, monomers are connected by bridges formed by carbon–carbon, ether, and peroxy types of bonds [11, 12]. Dimers of steroids are formed during metabolism and are a physiologically important form of molecules involved in regulation and for these compounds a variety of bonding between monomers has been established [13]. Interest in oligomer formation in oils has been mainly aimed at triacylglycerol polymerization. Oligomers formed during frying in soybean oil have been shown to contain carbon–carbon and ether type bonds between triacylglyceride molecules [12, 14]. Triacylglyceride oligomers negatively affect digestion of lipids in experimental animals often leading to the initiation of negative changes during the development of large intestine cells [15].

Soupas et al. [16] demonstrated the formation of oxyphytosterols and oligomers of triacylglycerols during short time pan-frying using canola oil and margarine enriched in phytosterols and phytostanols. Even though only small amounts of these components were formed, the data indicates the formation of free radicals and the free radical mechanism of degradation which may initiate degradation of other lipids and the formation of detrimental compounds [16, 17]. Rudzinska et al. [3] showed that temperature and time are the main factors affecting the type and the amounts of degradation products formed. At frying temperatures, predominantly oligomers were formed with limited amounts of oxidized phytosterols; this indicates that the latter were the main precursors of all components formed during thermo-oxidative degradation of phytosterols [3].

Recently it has been established that phytosterols can be effective in impeding atherosclerosis and hypercholesterolemia mainly by lowering the cholesterol level in the blood [18–20]. Oxidative instability of phytosterols, similar to cholesterol, and formation of oxysterols may negatively affect health due to already proven negative effects of oxyphytosterols on some metabolic processes [21].

This study is a part of a larger program aimed at increasing our understanding of phytosterol oxidation chemistry. Here, we focus on the identification of oligomers formed during heating of sitosterol in the presence of sufficient amounts of oxygen. Although the literature contains many studies showing the formation of oligomers in oils, most rely on the use of size exclusion chromatography with non-specific detectors such as refractive index or evaporative light scattering detectors and hence give little information on the molecular structures of the oligomeric products. In contrast, recent studies have combined reversed phase chromatography to mass spectrometry using atmospheric pressure chemical ionization (APCI) or electrospray ionization (ESI) to study triacylglyceride oligomers [22, 23]. In this way, oligomers up to tetramers of triolein with and without additional oxygen atoms were observed. A similar technique was applied for the separation and identification of cholesterol and phytosterol oxides [24, 25]. In this paper we present for the first time to our knowledge, the mass spectra of phytosterol oligomers and proposing fragmentation of these molecules. The data presented underline the complexity of oligomeric products formed during degradation of sterols. Although the assignment of chemical structure remains somewhat speculative, the level of detail provided by LC/MS experiments still represents a significant advance.

Materials and Methods

Materials

β-Sitosterol was purchased from Calbiochem Brand (San Diego, CA, USA). The supplier declared 95% purity for the β-sitosterol, however when analyzed its composition was as follows: 71% β-sitosterol, 19% sitostanol, 8% campesterol and 2% campestanol. Solvent, tetrahydrofuran (THF) with HPLC purity was obtained from VWR (Mississauga, ON, Canada).

Sample Preparation

The sitosterol standard (500 mg) was put into glass tubes with a 200 mL capacity. To the tubes, 100 mL of pure oxygen was added to prevent oxygen starvation conditions, which usually change the mechanism of oxidation. Samples were heated at 180 °C for 24 h.

Separation of Oligomers

Oligomers were analyzed by size exclusion chromatography (SEC) according to ISO Method 16931-2009 [26]. Separation was performed on a Finnigan Surveyor HPLC (Thermo Electron Corporation, Waltham, MA, USA). Components were separated on three size exclusion columns coupled in series (Phenogel 500A, 100A and 50A; 5μ, 300 × 4.60 mm; Phenomenex, Torrance, CA, USA). THF was used as the mobile phase at a flow rate of 0.3 mL/min, and column temperature of 30 °C. Sample solution in THF of 10 µL was injected onto the columns and

components detected with an evaporative light scattering detector (ELSD, Sedex 75, Sedere, Alfortville, France) operated at 30 °C with an air pressure of 2.5 bar. Fractions of tetramers, trimers, dimers, monomer and fragmented sterol were collected, however oligomer and fragmented sterol fractions were contaminated because baseline separation was impossible to achieve (Fig 1a). Collected oligomer fractions were stored at −18 °C prior to LC/MS analysis.

Identification of Polymers

All LC/MS analyses were conducted on an Agilent 1200 HPLC (Agilent Technologies; Palo Alto, CA, USA) coupled to a QSTAR Elite mass spectrometer (Applied Biosystems/MDS Sciex; Concord, ON, Canada) using an atmospheric pressure chemical ionization (APCI) in positive ion mode. Analyst QS 2.0 software was employed for data acquisition and analysis. Two size exclusion columns (Phenogel 100Å, 5 μm, 4.6 mm × 250 mm, Phenomenex, Torrance, CA, USA) connected in series were used with THF as mobile phase in isocratic mode with a flow rate of 0.2 mL/min.

The mass spectra were acquired over the mass range of *m/z* 100–2,000. The APCI probe was kept at 370 °C. The other instrumental conditions were as follows (nitrogen gas flow rates are given in arbitrary units assigned by the Analyst QS2.0 software) curtain gas 30; auxiliary gas 6; nebulizing gas 75; discharge needle current 2 μA. The declustering potential (DP), focus potential (FP), and DP2 were 30 V, 120 V and 5 V, respectively. All mass spectra were recorded using the high resolution time-of-flight mass analyzer providing mass accuracies below 5 mDa over the range of *m/z* reported here. In the interests of clarity, all *m/z* values in the figures are reported as nominal values or rounded to one decimal place. All elemental compositions reported in the text and schemes are the most probable matches within the expected *m/z* range and wherever possible are confirmed by multiple experiments.

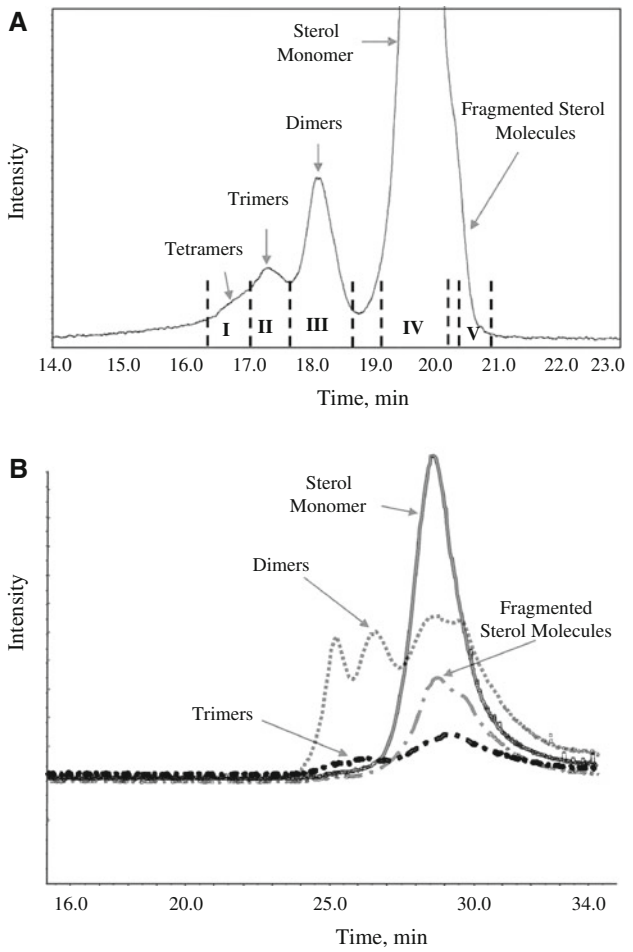

Fig. 1 **a** SEC-ELSD chromatogram of sitosterol thermo-oxidative degradation products formed during heating at 180 °C for 24 h showing times for collected fractions I to V; **b** SEC-APCI/MS total ion current (*TIC*) chromatograms of the five fractions collected in the SEC separation shown in **a**. For details see "Methods"

Results and Discussion

The sitosterol standard was heated at 180 °C for 24 h and Fig. 1a shows the SEC chromatogram of the products formed using ELSD (3). We were able to separate five groups of components differentiated by molecular size, where the monomer dominated. Dimers, trimers and tetramers were separated from monomer, however, these groups overlap. The amount of oligomers increased as time increased during heating at 180 °C (3). We reported earlier that oligomers were formed at 120 °C in a similar way to those formed at 180 °C but with lower abundance and largely without the formation of fragmented sterols (FSs). In contrast, at 60 °C there was little or no oligomer formation (3).

The five fractions identified in Fig. 1a were collected from SEC runs in a semi-preparative mode and components were identified by combined SEC/APCI-MS. In Fig. 1b the combined total ion chromatograms of these fractions are presented. It should be noted that the ELSD detects all non-volatile compounds that are nebulized to aerosol particles, whereas LC/MS requires molecules to be first converted to ions in the gas phase. For APCI, this results in considerable discrimination against molecules due to high molecular weight, volatility, thermal stability, polarity etc. Hence, for example, the distinct trimer peak seen in the SEC/ELSD trace (Fig. 1a) is not seen in the corresponding trimer fraction by SEC/APCI-MS (Fig. 1b) due to the low response to this high molecular weight compound. Nonetheless, qualitatively at least, it can be

seen that the dimer and trimer fractions do show earlier eluting peaks in the SEC traces (Fig. 1b) compared to the monomer.

Sterol Monomer Fraction

The monomer peak collected after heating at 180 °C for 24 h was analysed by combined SEC-APCI/MS as shown in Fig. 2. Surprisingly, the expected MH^+ at *m/z* 415 for the sitosterol was not observed in this fraction. As we have established already, under the conditions applied all sterols present in the standard mixture were oxidized and transformed into variety of the degradation products (3). An extracted total ion chromatogram (TIC) of low abundance ion at *m/z* 415 is shown in Fig. 2a but from the exact mass it was clear that this has elemental composition of $C_{28}H_{47}O_2$ rather than $C_{29}H_{51}O$ as expected for the MH^+ ion of sitosterol. This was consistent with the MSMS spectrum of *m/z* 415 which showed losses of two water molecules, confirming the presence of two oxygen atoms in the structure. Furthermore, the APCI spectrum of sitosterol gave a base peak at *m/z* 397 (i.e. $[M + H\text{-}H_{20}]^+$, $C_{29}H_{49}$) not observed in Fig. 2. Thus, the monomer fraction likely contains largely oxidized sterols. This can be seen in Fig. 2b where the major species at *m/z* 429 was found to have an elemental composition of $C_{29}H_{49}O_2$ and the presence of two oxygen atoms is also confirmed by losses of the two water molecules observed in the MSMS spectrum (not shown) giving fragment ions at *m/z* 411 and 393. In addition, in the MSMS spectrum of *m/z* 429 a fragment ion at *m/z* 175, confirmed as $C_{12}H_{15}O$ was observed, consistent with fragmentation across the C ring of the mono-oxygenated form of the basic sitosterol structure (Scheme 1). A further fragment in the MSMS spectrum at *m/z* 253 has an elemental composition of $C_{19}H_{25}$ which is due to loss of two water molecules and the side chain (Scheme 1). Thus, the major component of the monomer fraction is confirmed to be a mono-oxygenated sitosterol;

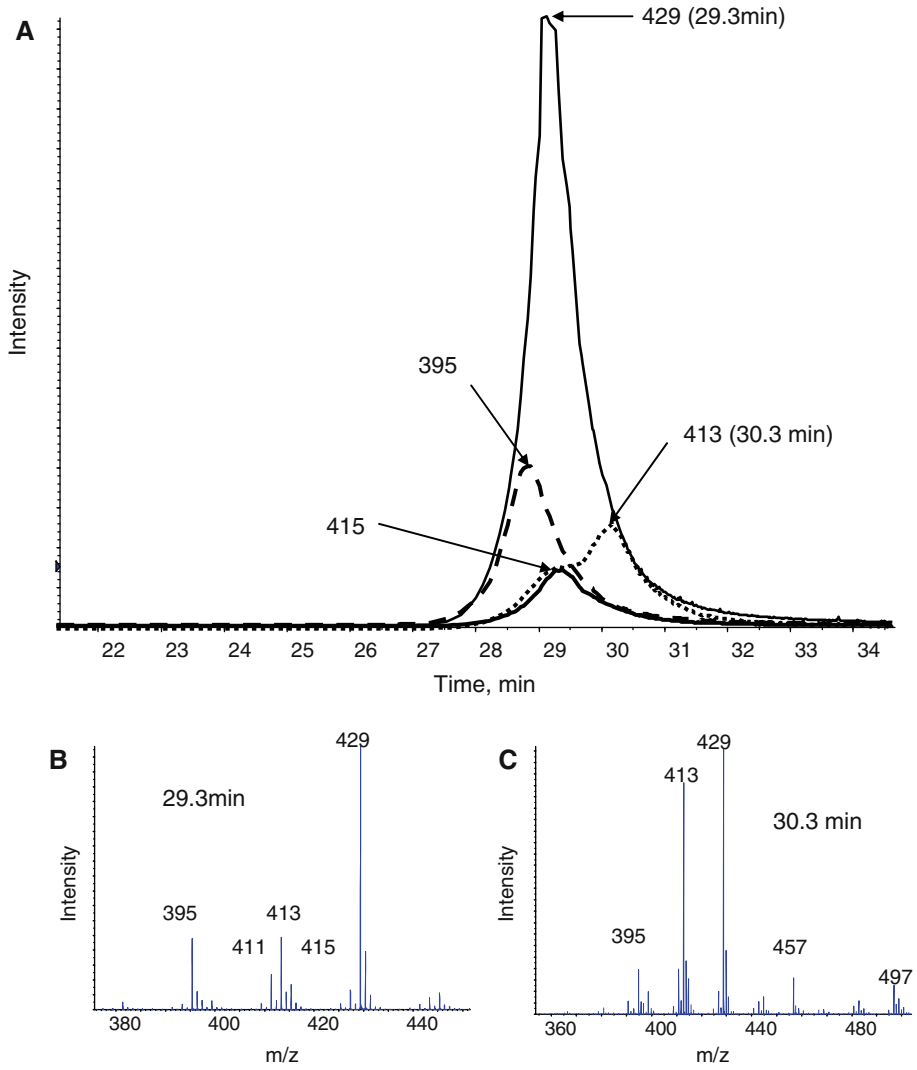

Fig. 2 SEC-APCI/MS extracted ion chromatograms **a** and mass spectra **b**, **c** of the monomer fraction. For details see text

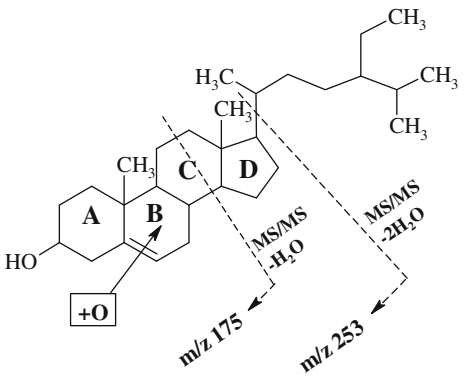

Scheme 1 The proposed MS/MS fragmentation for oxidized sterol molecule at *m/z* 429 ($C_{29}H_{49}O_2$)

whether this additional oxygen is added to the ring structure or side chain or exists as hydroperoxide cannot be determined from this experiment.

Figure 2c also indicates the presence of a compound at *m/z* 413 with elemental composition $C_{29}H_{49}O$ eluting at 30.3 min. This compound has a molecular formula consistent with an additional double bond compared to sitosterol. The MS/MS spectrum of this compound shows a fragment ion at *m/z* 255 with an elemental composition of $C_{19}H_{27}$ which is an unsaturated steroid ring system. Also seen in Fig. 2c is a lower intensity ion at *m/z* 411 whose MSMS spectrum shows a fragment ion at *m/z* 253 indicating further ring unsaturation.

Note that the sterol standard used in these experiments contained 71% *β*-sitosterol, 19% sitostanol, 8% campesterol and 2% campestanol which further complicates interpretation of the mass spectra of monomers. Overall, fragmentation of monomer ions indicates the presence of two oxygen molecules, indicative of sterol oxides. Kemmo et al. [24, 25] also established similar fragmentation and type of ions during the analysis of different types of sterol oxides.

Fragmented Sterol Fraction

It is clear that the component of the thermo-oxidative degradation that represents FSs cannot be fully resolved from the monomers (Fig. 1). Thus, as expected the fragmented monomer fraction obtained still contains a large amount of monomers as seen by the SEC-APCI/MS trace (Fig. 3). In Fig. 3, the two mass spectra presented are the background subtracted spectra averaged across the two marked retention time periods **1** and **2**. In period **1**, a large number of species are seen not only in the mass region of *m/z* 390–420 expected for altered and unaltered sterol monomers. In fact, compounds with *m/z* range extending to ~700 are evident as well as the expected lower molecular weight fragments. It is difficult to interpret all of these

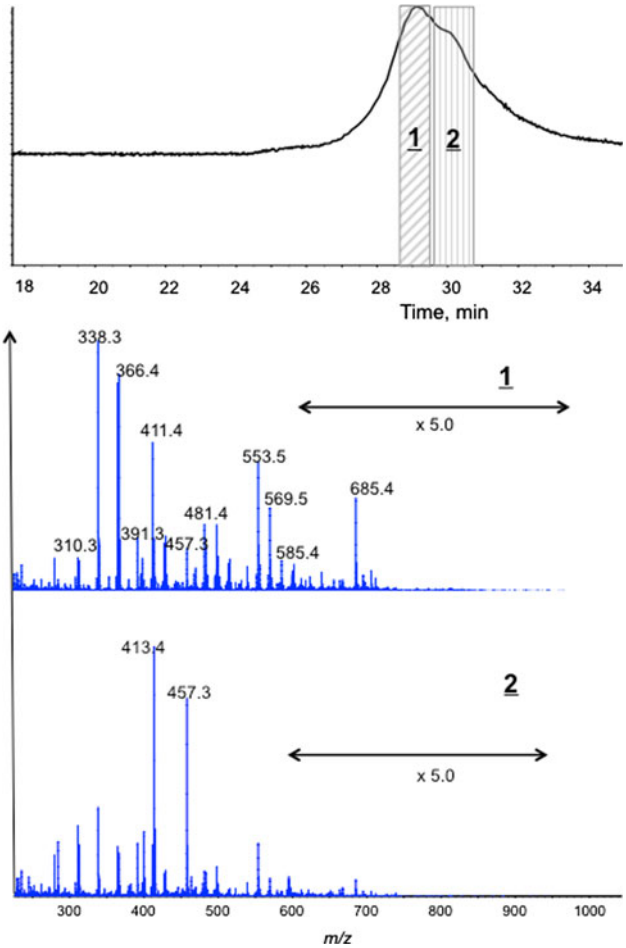

Fig. 3 SEC-APCI/MS total ion current chromatogram and background subtracted mass spectra of components present in portion 1 and 2 of the "fragmented" monomer fraction. For details see text

species, but an illustration of the chemistry occurring is found in period **2**, whose components actually overlap period **1** and beyond. Two major ions are seen in period **2**, namely *m/z* 413 and 457. The former ion has been described above as the dominant species in the monomer fraction. An extracted total ion chromatogram of ions with *m/z* 457 is seen in Fig. 4a. Surprisingly, this ion was found to have likely elemental composition of $C_{24}H_{41}O_8$ containing an apparently disproportionate number of oxygen atoms. The MSMS spectrum of these species is shown in Fig. 4c which suggests that *m/z* 457 might be the protonated dimer of *m/z* 228 since the latter ion has an elemental composition of $C_{12}H_{21}O_4$. Further investigation of the FS fraction for higher oligomers revealed the presence of these FS trimer and tetramer ions at *m/z* 685 and 913, respectively. It should be pointed out that these ions are not cluster ions formed in the ion source of the mass spectrometer since they are separated chromatographically as the distinct compounds in the mass chromatograms shown in Fig. 4a. The FS monomers (not shown) were present at

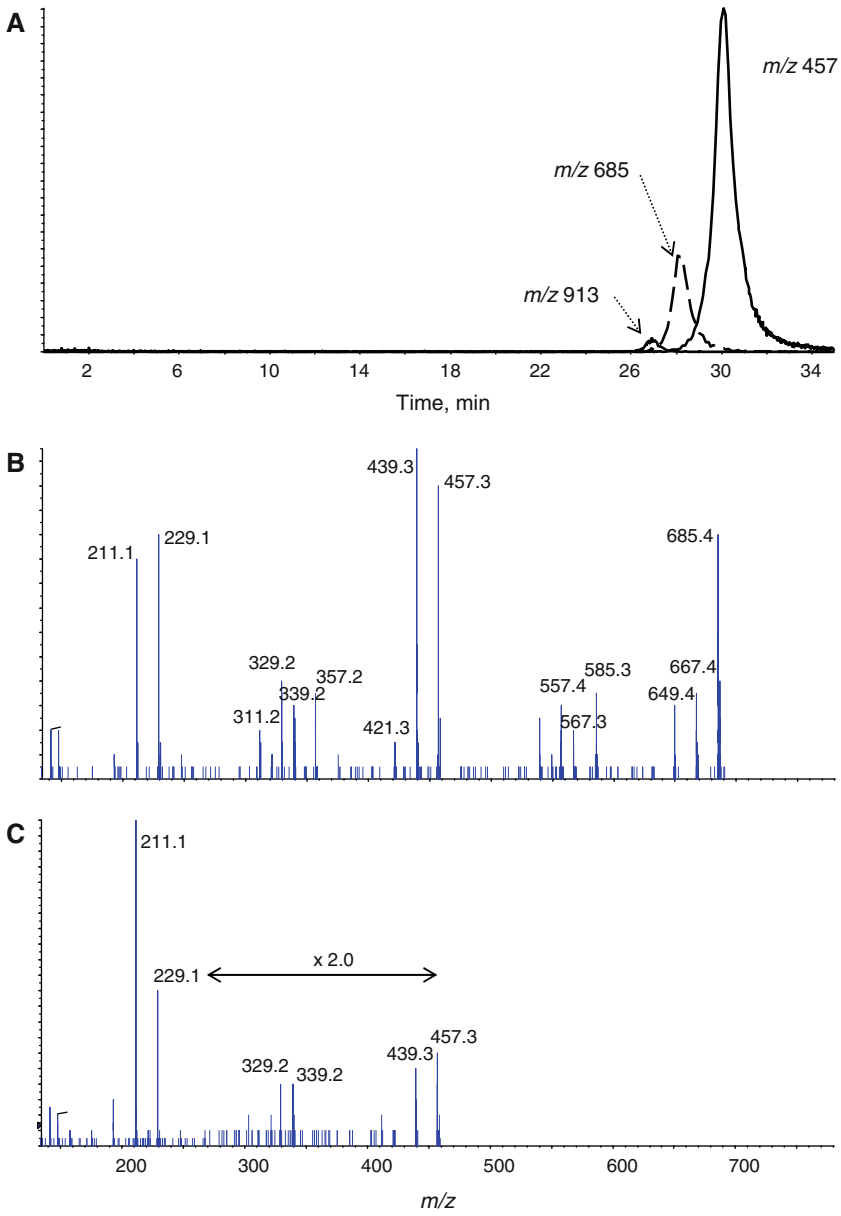

Fig. 4 **a** SEC-APCI/MS extracted ion chromatograms and **b**, **c** MS/MS spectra of the components present in the fragmented monomer fraction. For details see text

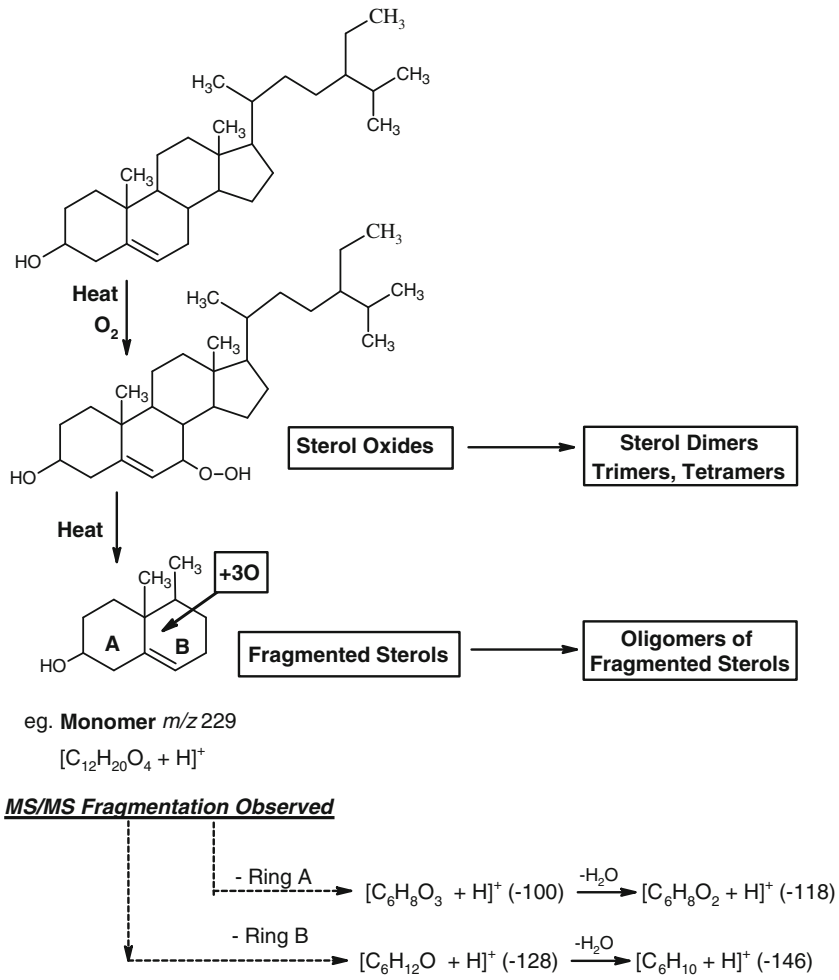
very low intensity which could be due to their reactivity, the fractionation procedure, or both.

The MSMS spectrum of the FS trimer with elemental composition of $C_{36}H_{61}O_{12}$ is given in Fig. 4b. The protonated FS monomer and FS dimer peaks can be seen at *m/z* 229 and 457, respectively and the similarities between the MSMS spectra of FS dimer and FS trimer are clearly seen (Fig. 4b and c). Scheme 2 gives a possible rationalization of the formation of these FS oligomeric compounds based on the sitosterol structure. The nature of the oxygenated FS monomer must at this point remain highly speculative. It is believed that sterol oxidation is initiated by abstraction of a hydrogen atom to generate a free radical, which in turn reacts with oxygen forming next generation of radicals and sterol 7-hydroperoxides [11, 24]. It seems likely that the A/B sterol rings are involved in forming the monomer and that reactive hydroperoxy radicals would be involved in further reactions to give oligomers and other products. The position(s) of oxygen atoms cannot be determined from the MSMS spectra and hence are not located in Scheme 2. However, common neutral losses of 100, 118, 128 and 146 fragments are seen from each FS oligomer and additionally the protonated forms of these neutrals (i.e *m/z* 101,119, 129 and 147) were seen in MSMS spectra (not shown in Fig. 4). The elemental compositions indicate that the fragment ions due to loss of 100 Da retain three of the four oxygen atoms present in the monomer and this is indicated by their location on ring B in Scheme 2 whilst the original sitosterol hydroxyl group is left unchanged. However, many other arrangements are possible.

Scheme 2 Formation of sterol oxides, oligomers, sterol fragments and oligomers of sterol fragments. A speculative structure of an observed fragmented sterol monomer and MS/MS data is included. The elemental compositions are based on measured exact masses but the location of the oxygen atoms cannot be determined



Sterol Dimer Fraction

It can be seen from Fig. 1a that the intact sterol dimer fraction is relatively small compared to the sterol monomer fraction. Furthermore, the dimer peak is not completely separated from either monomer or trimer peaks. Thus, it is not surprising that the SEC-APCI/MS total ion chromatogram of the sterol dimer fraction shows presence of other components. These peaks can be further resolved by considering extracted ion chromatograms based on the following *m/z* ranges 350–450, 450–900 and 950–1,500 corresponding to sterol monomers, dimers and trimers (Fig. 5). The extracted ion chromatogram for the monomer *m/z* range is comprised of two major peaks; the one at longer retention time (~29 min) corresponds to the major monomer component, as seen in Figs. 1 and 2, whilst the peak at shorter retention time (~27 min) is also seen in the sterol dimer *m/z* range trace below it in Fig. 5. The extracted ion chromatogram for the sterol trimer *m/z* range shows a single major component at the expected high molecular size end of the chromatogram (i.e shorter retention time on SEC). The corresponding peak seen in

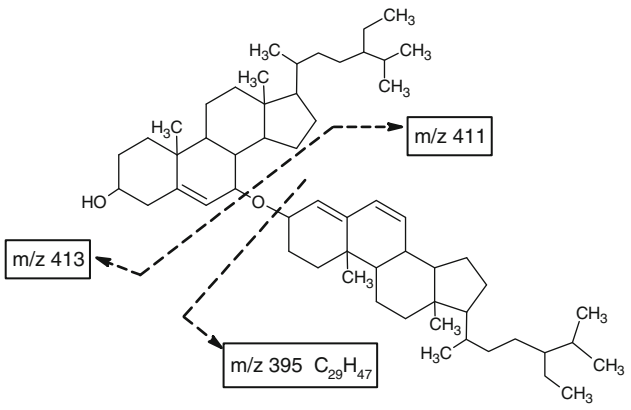
the sterol dimer *m/z* range trace above it in Fig. 5 is most likely due to ion source fragmentation of sterol trimer ions under APCI conditions, although the presence of molecular species in this *m/z* range cannot be ruled out.

In Fig. 6, mass spectra are presented which were obtained by averaging across each of the four partially resolved peaks (labelled **A** to **D**) in the total ion chromatogram of the sterol dimer fraction. The mass spectrum of peak **D** is dominated by *m/z* 457 which is formed as a result of thermo-oxidative fragmentation followed by dimerization as described above for the FS fraction; in peak **C** *m/z* 685 is the FS trimer. Peak **B** contains a wide range of species in the *m/z* 800–900 which correspond to oxidized sterol dimers. The dominant fragment ion at *m/z* 395 ($C_{29}H_{47}$) is characteristic of the dehydrated form of the sitosterol monomer and the most abundant dimer ion at *m/z* 825 ($C_{58}H_{97}O_2$) could be a dimer of two sterol molecules. Scheme 3 shows a putative structure where a 3-, 7′- ether bridge links an oxidized sitosterol monomer to a second sitosterol molecule in its dehydrated form. Clear evidence exists for preferential oxidation of sterols at the 7 position [8, 24, 25]. The MSMS spectrum of this sterol dimer shows the major loss of a water molecule (minor loss of two waters) and an abundant fragment ion at *m/z* 395, as also seen in the mass spectrum. Minor peaks at *m/z* 411 and 413, also significant fragment ions in the mass spectrum, may reflect fragmentation across the bridging ether group as suggested in Scheme 3.

In addition to the most abundant ion at *m/z* 825, many other dimeric species are present in peak **B** within *m/z* 800 and 960 (Fig. 6b) mainly containing either two or four oxygen atoms. Thus, although the present data is inadequate to deduce definitive structures, it nonetheless provides clear proof for the formation of sterol dimers under thermo-oxidative conditions, consistent with the prediction from the SEC chromatograms (Fig. 1a). Furthermore, the data confirms that oxidized derivatives are the main precursor in oligomer formation. The spectrum of peak **A** is dominated by an oligomer of *m/z* 955 of unknown structure and an ion at *m/z* 551 ($C_{35}H_{67}O_4$) (Fig. 6a). Ions of *m/z* intermediate between those expected for sterol dimers and trimers including the dominant ion of *m/z* 955 may be formed by reactions between oxidized fragments and sterol monomers and dimers. In fact, many dimers might be formed considering the many possibilities for connecting bridges, particularly among phytosterols where there are additional tertiary and quaternary carbons in the side chain structure. However, it is also possible that ions such as *m/z* 955 are actually fragment ions of sterol trimers formed in the mass spectrometer ion-source.



Scheme 3 The proposed structure and potential MS/MS fragmentation of the sterol dimer with *m/z* 825

Sterol Trimer Fraction

The SEC-APCI/MS extracted ion chromatograms for the trimer fraction is shown in Fig. 7 using the same *m/z* ranges as used in Fig. 5. Despite the fact that total ion trace shows little response at the retention times corresponding to trimers (earlier than about 26.5 min), compounds with *m/z* > 950 were detected, thus demonstrating the existence of trimers. The low signal-to-noise that is evident in the chromatogram makes it apparent that APCI is not ideal for the analysis of these compounds. However, the ions with *m/z* above those expected for dimers can be observed, as in Fig. 6 peak A, and can be tentatively interpreted as ions formed from the fragmentation of trimer ions. The oligomers with the highest molecular weight, tetramers, were

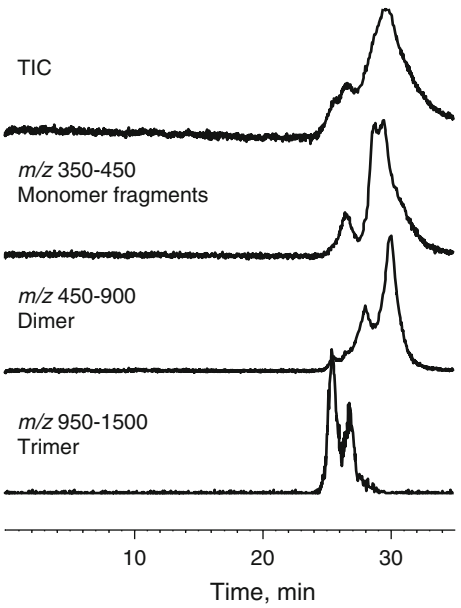


Fig. 7 SEC-APCI/MS TIC and extracted ion chromatograms of the sterol trimer fraction formed during heating sitosterol at 180 °C for 24 h. For details see text

detected using an ELSD (Fig. 1a) but intact tetramers could not be detected by APCI/MS. Future work will therefore look at alternative ionization methods more suitable for the study of labile high molecular weight species.

In conclusion, the above work demonstrates the ability of phytosterols to form oligomeric structures when heated in the presence of oxygen for prolonged time, as occurs during frying. Further work is required to understand the mechanism of oligomer formation and the effect of oil matrixes. The formation of oxidative derivatives of sterols and their subsequent interactions with sterols and triacylglycerides is clearly of importance in food processing. Assessment of any biological activity of phytosterol oligomers and oxidized derivatives needs to be considered especially due to the recent trend of enriching foods with phytosterols.

Near-Infrared Spectroscopy and Partial Least-Squares Regression for Determination of Arachidonic Acid in Powdered Oil

Meiyan Yang · Shaoping Nie · Jing Li · Mingyong Xie · Hua Xiong · Zeyuan Deng · Weiwan Zheng · Lin Li · Xiaoming Zhang

Received: 18 March 2010 / Accepted: 21 April 2010 / Published online: 14 May 2010

Abstract Near-infrared (NIR) spectroscopy was evaluated as a rapid method of predicting arachidonic acid content in powdered oil without the need for oil extraction. NIR spectra of powdered oil samples were obtained with an NIR spectrometer and correlated with arachidonic acid content determined by a modification of the AOCS Method. Partial Least-Squares regression was applied to calculate models for the prediction of arachidonic acid. The model developed with the raw spectra had the best performance in cross-validation ($n = 72$) and validation ($n = 21$) with a correlation coefficient of 0.965, and the root mean square error of cross-validation and prediction were both 0.50. The results show that NIR, a well-established and widely applied technique, can be applied to determine the arachidonic acid content in powdered oil.

Abbreviations

NIR	Near-infrared
ARA	Arachidonic acid
PUFA	Polyunsaturated fatty acids
FAMEs	Fatty acid methyl esters
FID	Flame ionization detector
SNV	Standard normal variate
MSC	Multiplicative scatter correction
WT	Wavelet transforms
OSC	Orthogonal signal correction
PLS	Partial Least-Squares
RMSEC	Root mean square error of calibration
RMSECV	Root mean square error of cross-validation
RMSEP	Root mean square error of prediction

Introduction

Arachidonic acid (ARA, C20:4, n-6), one of the members of the n-6 fatty acid family, is an important structural component of the central nervous system. The content of ARA present in brain and nerve tissue is 40–50% of the polyunsaturated fatty acids (PUFA), and it even reaches 70% in nerve endings. Many studies have shown the prenatal and postnatal importance of ARA in early human (brain) development [1–3]. Though ARA can be synthesized by linoleic acid in vivo through chain elongation and desaturation, the process is quite complicated, which not only needs sufficient substrate and positive equilibrium energy condition but also enough activity of fatty acid desaturases. Early studies have shown that the ARA status of bottle-feeding infants is lower than that of breast-feeding infants [4–6]. So the addition of ARA in the form of powdered oil to infant formula milk powder is widely accepted nowadays.

An adequate amount of ARA in newborn nutrition is important, as the investigation results indicated that the average content of ARA in human milk is 0.5–0.7% in different places across the world [7]. Determination of ARA is usually carried out according to the official method by gas chromatography with a flame ionization detector, which is time-consuming, expensive and labor-intensive when used to monitor industrial processes. Therefore, a rapid, simple and accurate method is in great demand to evaluate the ARA content in powdered oil.

Near-infrared (NIR) spectroscopy has proved to be a valid analytical tool for food products [8]. Several references of the use of NIR spectroscopy to construct models evaluating components content were found in the literature. For example, it has been employed to analyze fat content in milk powder [9], to estimate fatty acid content in intact seeds of oilseed [10], to evaluate carotenoids content in maize [11], and α-tocopherol in vegetable oils [12]. However, none of these was related to new technique products, such as powdered oil.

The main objective of this work was to construct a model based on FT-NIR spectroscopy, in combination with multivariate calibration methodologies to predict the ARA content in powdered oil.

Materials and Methods

Reagents

All reagents were of analytical grade and absolute *n*-hexane was of chromatographic grade. Standard methyl arachidonate was purchased from Sigma-Aldrich Co. (St. Louis, MO). Standard solutions of methyl arachidonate were prepared in absolute *n*-hexane and stored at 4 °C before analysis.

Samples Preparation

ARA oil was used to prepare unknown samples with different ARA concentrations as weight percentages. By a spray drying process, one hundred ($n = 100$) powdered oil samples were manufactured with ARA oil concentrations ranging from 10 to 34% to represent the diversity of commercially available powdered oils. All the samples were stored at room temperature (20 °C) in the dark.

Reference Methods

Total fat and fatty acid methyl esters content were measured using Rose-Gottlieb and AOCS Method with a modification [13]. The modification was a change in GC temperature programming (described later). Briefly, 1.0 g of sample was weighed into a Mojonnier tube, and 0.1 g Taka amylase and 10 mL distilled water at about 50 °C were added. The sample was treated with ammonia–alcohol in a water bath (65 °C) for 15 min, and subsequently extracted with diethyl and petroleum ethers. The diethyl and petroleum ethers were evaporated over a steam bath, and the extracts were the total fat. The method [14] for the preparation of fatty acid methyl esters (FAMEs) was as follows: 10 mg extracted oil (accurate to 0.1 mg) was accurately weighed into a stoppered-glass tube, 2 mL of hexane added, followed by adding 1 mL of 2 mol/L potassium hydroxide in methanol, and then, the tube was closed and shaken well for 2 min. After 30 min, the upper layer was transferred to a test tube, followed by adding a small amount of anhydrous sodium sulfate to remove excessive moisture, and then the dry hexane solution was transferred to a 1.5-mL glass vial for the following analysis.

FAMEs analysis was performed on an Agilent 6890N gas chromatograph equipped with a flame ionization detector (FID) and an Agilent autosampler 7683-B injector (Agilent Technologies, Little Fall, NY, USA). A fused-silica capillary column CP Sil-88 (100 m × 0.25 mm id., 0.20 μm film thickness, Varian Inc.) was used for the separation of fatty acid methyl esters. Hydrogen was the carrier gas with a flow rate of 1.8 mL/min. The temperature of the injector and detector was set at 250 °C with an injection volume of 1.0 μL by using the splitless mode. The analysis was carried out using a temperature programming consisting of an initial temperature 45 °C (held 4 min), ramp 13 °C/min to 175 °C (held 27 min), ramp 4 °C/min to 215 °C final temperature (held 25 min). A standard curve was calibrated by a series of methyl arachidonate samples with the concentrations of 0.5, 1.0, 1.5, 2.0, 2.5, 3.0 and 4.0 mg/mL, respectively. The ARA in the analyzed oil samples was identified by comparing the retention times with the standard. Quantification of ARA was performed using the external calibration curve.

FT-NIR Instrumentation and Spectral Collection

The NIR spectra were measured on a Nicolet 5700 spectrometer using a Baseline™ Diffuse Reflectance Accessory and an InGaAs detector (Madison, USA).

NIR absorbance spectra were registered in the range of 4,000–10,000 cm^{-1} with a 16 cm^{-1} resolution and 64 scans. Gain was selected automatically. Happ–Genzel apodization was applied, mode zero filling was disabled, and the interferometer mirror speed was set at 1.5798 cm/s. About 1 g of the sample in powder form was densely packed in a glass sample vial (2 cm in diameter and

1.2 mm in wall thickness). The background spectrum was recorded every 4 h while each sample underwent four replications and the spectra were averaged before they were subjected to multivariate analysis. All spectra were collected by OMNIC 7.0 software and recorded as log $(1/R)$, where R is the relative reflectance.

Data Processing and Development of the Calibration Model

The data acquired from the NIR spectrometer contain noises in addition to sample information. In order to obtain reliable, accurate and stable calibration models, it is necessary to pre-process spectral data before modeling. At present, there are many pre-processing methods, such as smoothing, derivative, standard normal variate (SNV), multiplicative scatter correction (MSC) and some new methods including wavelet transforms (WT) and orthogonal signal correction (OSC) [15, 16]. Smoothing that includes Savitzky–Golay smoothing is one of the methods often used to eliminate noises [17]; the first and second derivatives are used to remove background and increase spectral resolution. SNV removes the multiplicative interferences of scatter, particle size, and the change of light distance as well as MSC [18, 19]. It corrects both multiplicative and additive scatter effects. In this study, five data pre-processing methods were applied comparatively, which were SNV, MSC, first derivative, second derivative and Savitzky–Golay smoothing.

Calibration models between chemical data (data from gas chromatography) and NIR spectra were developed using Partial Least-Squares (PLS) regression with cross-validation in the TQ analyst 7.1.0 software package (Thermo-Nicolet). The data set was split randomly into a training ($n = 75$) and a validation set ($n = 25$). The optimum number of PLS factors in the calibration models was determined by cross-validation and defined by the PRESS function (predicted residual error sum of squares) in order to avoid overfitting of the models [20]. The relative performance of the established model was assessed by the required number of factors while the root mean square error of calibration (RMSEC), the root mean square error of cross-validation (RMSECV), and its predictive ability were evaluated from the root mean square error of prediction (RMSEP). The spectral regions used for PLS models were selected automatically.

In addition to these statistics, the importance of calibration outliers must be considered. The spectrum outlier diagnostic finds the spectra of the standards which are most unlike the others, and the Chauvenet test was used to decide whether the difference is significant. If the standard fails the test, it is considered an outlier.

Results and Discussion

Reference Method Measurement of ARA

Figure 1 shows the GC chromatograms of the standard and a sample, which were used to identify and quantify the contents of ARA in our samples. The standard curve is shown in Fig. 2 with the equation $Y = 6978.8X + 320.71$ ($R^2 = 0.9997$). The accuracy, precision and detection limit of the laboratory using the modified AOCS Method is 90.2–101.4%, 0.8% and 0.25 mg/L, respectively.

Range, mean value, and standard deviation for ARA content in the samples are given in Table 1 for the calibration and validation data sets.

Spectral Characteristics

Representative NIR spectra of powdered oil samples are shown in Fig. 3 as raw spectra (Fig. 3a) and spectra treated with first derivative processing (Fig. 3b). As shown in Fig. 3, the main absorption peaks of the samples were observed in the range of 4,000–6,000 cm^{-1} instead of the whole NIR region. The regions we chose to develop models were suggested by the software automatically, which are 4,250–4,358 cm^{-1} (A), 5,723–5,881 cm^{-1} (B), respectively. Region A is characteristic of the combination of C–H stretching vibration with bending vibration mode of $-CH_3$ and $-CH_2$. The spectrum of region B is characteristic of the first overtone of the C–H stretching vibration of $-CH_3$ and $-CH = CH-$ groups [21].

NIR Models

The outliers should be eliminated as an essential step in the optimization procedure of the models already developed. During the calibration development, seven spectral outliers were detected. Table 2 shows the statistics of the NIR spectral data for predicting ARA in powdered oil samples after the outlier samples elimination. The data confirm that the spectral allows the creation of a calibration set which represents the usual variability encountered by powdered oil.

PLS models were developed using five spectral pretreatments based on the selected 93 NIR spectra of the powdered oil samples. The prediction capability was evaluated by correlation coefficient (r), RMSEC and RMSECV. It is expected to have ideal models with the lower RMSEC and RMSECV as well as the higher correlation coefficient r. Different latent variables were applied to build the calibration models and the optimum number of factors was selected by the PRESS diagnostic shown in Fig. 4. The results of different spectral pretreatment models are shown in Table 3.

n number of samples, *SD* standard deviation

Figure 4 shows that the RMSECV decreases sharply with the first two factors and gradually decreases as the third variable is incorporated into the calibration model. As the number of factors increases further, RMSECV begins to increase at 4 PLS factors. An increase in the RMSECV indicates that the data have been overfitted by incorporating spectral information into the model that is not related to ARA. In this case, 3 PLS factors were chosen as the optimum.

The model developed with the raw spectra had the best performance in cross-validation ($n = 72$) and validation ($n = 21$) with RMSECV of 0.50, correlation coefficient of 0.965, RMSEP of 0.50 (Table 3 and Fig. 5). The models developed with various pretreatments such as derivative, smoothing, SNV, MSC and the combination of these pretreatments decrease the modeling effect, and it may be because of the useless information they introduced due to their own characteristics. Just as the first and second derivatives are used to remove background and increase spectral resolution, the drawback of derivative is that it would bring noises [22]. Or some useful information was smoothed out when use Savitzky–Golay smoothing to eliminate noises, which might cause distortion of spectral signals. Another possible explanation for this can be that pretreatments affect the information distribution, while the spectral regions used to build models with different pretreatments were the regions chose by original spectra, which lead to unsatisfactory treatment effects. Thus, it is necessary to choose appropriate data pretreatment to build

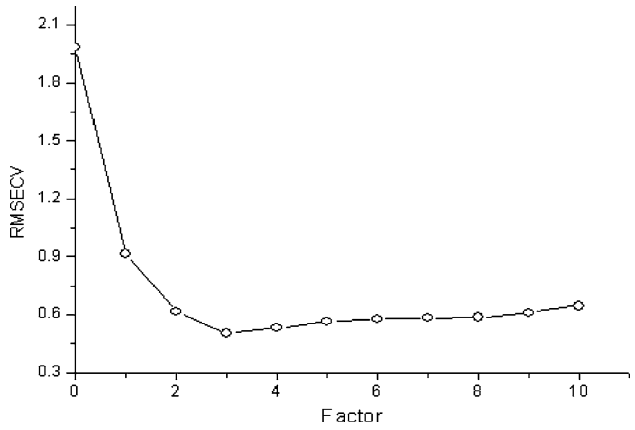

Fig. 4 The PRESS diagnostic results for PLS calibration model

the calibration model based on the detection objective and instrument function.

The satisfied calibration and prediction result of the PLS model show the feasibility for the measurement of ARA content in powdered oil using NIR spectra. Moreover, the algorithm used for developing calibration equations (PLS) allows one to optimize the number of factors to avoid overfitting.

The present study has provided a rapid determination method for ARA content in powdered oil. The results indicate that the determination of ARA content in powdered oil could be successfully performed through NIR spectroscopy combined with chemometrics methods of the PLS model. Five spectral pretreatments methods, SNV, MSC, first derivative, second derivative and Savitzky–Golay smoothing were used. The spectral regions used for ARA analysis in powdered oil were selected by software automatically. The model using raw spectra achieve higher accuracy compared to other pretreatments. This nondestructive method could greatly simplify the analysis of such compounds, because no extraction step with organic solvents is required and samples are readily analyzed in minutes. Further selection of valuable information of

Acyl-CoA Binding Protein Gene Ablation Induces Pre-implantation Embryonic Lethality in Mice

Abstract Unique among the intracellular lipid binding proteins, acyl-CoA binding protein (ACBP) exclusively binds long-chain fatty acyl-CoAs (LCFA-CoAs). To test if ACBP is an essential protein in mammals, the ACBP gene was ablated by homologous recombination in mice. While ACBP heterozygotes appeared phenotypically normal, intercrossing of the heterozygotes did not produce any live homozygous deficient (null) $ACBP^{(-/-)}$ pups. Heterozygous and wild type embryos were detected at all post-implantation stages, but no homozygous ACBP-null embryos were obtained—suggesting that an embryonic lethality occurred at a pre-implantation stage of development, or that embryos never formed. While ACBP-null embryos were not detected at any blastocyst stage, ACBP-null embryos were detected at the morula (8-cell), cleavage (2-cell), and zygote (1-cell) pre-implantation stages. Two other LCFA-CoA binding proteins, sterol carrier protein-2 (SCP-2) and sterol carrier protein-x (SCP-x) were significantly upregulated at these stages. These findings demonstrate for the first time that ACBP is an essential protein required for embryonic development and its loss of function may be initially compensated by concomitant upregulation of two other LCFA-CoA binding proteins, but only at the earliest pre-implantation stages. The fact that ACBP is the first known intracellular lipid binding protein whose deletion results in embryonic lethality suggests its vital importance in mammals.

Abbreviations

ACAC	Acetyl CoA carboxylase
ACBP	Acyl-CoA binding protein
CAPN2	m-calpain
CoA	Coenzyme A
DBI	Diazepam binding inhibitor protein
FASN	Fatty acid synthase
L-FABP	Liver fatty acid binding protein
LCFA-CoA	Long-chain fatty acyl-CoA
PCR	Polymerase chain reaction
PPARα	Peroxisome proliferator-activated receptor-α
PPARγ	Peroxisome proliferator-activated receptor-γ
SCP-2	Sterol carrier protein-2
SCP-x	Sterol carrier protein-x
SREBP	Sterol regulatory element binding protein

Introduction

Acyl-CoA binding protein (ACBP), also known as diazepam-binding inhibitor (DBI), is a soluble 10-kDa lipid-binding protein ubiquitously expressed in all tissues of eukaryotic species examined [1, 2]. ACBP expression differs significantly among cell types and is highly regulated by hormones (insulin, androgens). Via the ACBP

promoter, ACBP expression is also determined by several nuclear transcription factors important in lipid and glucose metabolism: peroxisome proliferator-activated receptors (PPARs) -α and -γ as well as sterol regulatory element binding protein (SREBP) [3–7]. Unique among the intracellular lipid protein families, ACBP exhibits very high affinity (<10 nM K_ds) and specificity exclusively for long-chain fatty acyl-CoAs (LCFA-CoAs) [8, 9]. LCFA-CoAs are potent regulators of a wide variety of enzymes, signaling receptors, and nuclear regulatory proteins involved in fatty acid and glucose metabolism [1, 10, 11]. In vivo, pancreatic insulin secretion is affected by LCFA-CoA and ACBP levels as well as by glucose [12–14]. Most important, the key enzymes in de novo fatty acid synthesis (ACAC, acetyl CoA carboxylase; FASN, fatty acid synthase) are inhibited by the LCFA-CoA end product ($K_i < 50$ nM) [10, 15]. By binding LCFA-CoA, ACBP removes this end-product inhibition to stimulate ACAC and FAS [10, 15]. Likewise, by binding and reducing the unbound levels of LCFA-CoAs, ACBP plays important roles not only in normal regulation of LCFA-CoA transport, metabolism, signaling, vesicular trafficking, and nuclear regulation, but also in opposing the deleterious effects of elevated intracellular LCFA-CoA levels associated with diabetes and obesity [10, 13]. The physiological relevance of ACBP is supported mainly by studies of ACBP overexpression in yeast, mice, rats, and plants (*Arabidopsis*) [16–18]. ACBP-overexpressing mice fed control chow exhibit altered hepatic lipid metabolism [9]. ACBP-overexpressing rats fed a medium-chain fatty acid-rich diet have improved glucose tolerance and lower serum insulin levels [18]. Finally, a single nucleotide polymorphism in the human ACBP gene promoter is associated with reduced risk of type 2 diabetes in two German study populations—probably due to increased transcriptional activity of ACBP [19].

While the above findings suggest that loss of ACBP could result in major disruptions of normal phenotype and possible lethality, the available evidence to date is unclear. Depletion of the ACBP protein in the wild-type DTY10A yeast strain results in a slower growing phenotype, which subsequently adapts to a faster growing phenotype (frequency > $1{:}10^5$), while other ACBP-null yeast strains rapidly adapt, such that growth rate is unaffected [20, 21]. A conditional ACBP knock-down in yeast alters lipids, membranes, and vesicle accumulation, but is not lethal [20]. Although disruption of the 10-kDa ACBP gene in the plant *Arabidopsis* is not lethal, *Arabidopsis* expresses at least five additional ACBP genes that also bind LCFA-CoAs—probably compensating for the loss of the 10-kDa ACBP [22, 23]. Multiple independent genes encode different functional paralogues of ACBP even within a single species [2, 24]. In mammals, these include: (1) 10-kDa ACBP [also called liver ACBP (L-ACBP)] and its two distinct homologues (testes, T-ACBP; brain, B-ACBP); (2) ACBP-like domains in several large, multifunctional proteins; and (3) multiple inactive pseudogenes [2, 24]. Several studies with transformed mouse and human cell lines suggest that knock-down of ACBP (ACBP antisense RNA or siRNA) is very deleterious—inhibiting differentiation or resulting in lethality [25, 26]. However, because transformed cells are often deficient in the other LCFA-CoA-binding proteins [1, 11, 27, 28], it is difficult on this basis alone to predict if ACBP is an essential protein in mammals. While recent studies with mice carrying the spontaneous nm1054 mutation suggest that deletion of ACBP is not an embryonic lethality, this conclusion is complicated by the nature of the nm1054 mutation, which arose in CBA/J mice as a result of a large genomic deletion (about 400 kb) that contains all or part of at least six genes, only one of which encodes ACBP [29–31]. On a homozygous C57BL/6J mouse background, the nm1054 mutation results in significant prenatal lethality, and the very few live-born homozygotes almost all die before weaning [31]. However, on a mixed background comprised of at least two different mouse strains, the nm1054 mutation is not embryonically lethal, but instead the mice live to adulthood and exhibit a phenotype characterized by sparse hair, skin lipid metabolic abnormalities, male infertility (uniformly infertile on all genetic backgrounds), failure to thrive, hydrocephaly, and anemia [29–31]. Consequently, the complexity of the nm1054 mutation makes it difficult to assign the individual contribution(s) of ACBP to the phenotype independent of the other five concomitantly deleted genes, and/or downstream effects of deleting the promoter and intronic regions of all six genes.

The purpose of the present investigation was to resolve whether ACBP is an essential protein in a mammalian system by ablating only the ACBP gene function by homologous recombination in mice. The data show that loss of ACBP resulted in early pre-implantation embryonic lethality by the 8-cell stage. The fact that ACBP is the first known intracellular lipid binding protein whose single gene deletion results in embryonic lethality suggests its vital importance in mammals.

Materials and Methods

Materials

Construct Preparation

A BAC clone containing the known expressed ACBP sequence was obtained from the BACPAC Resource Center (Oakland, CA). This clone was fully sequenced to

confirm the presence of the full-length expressed mouse ACBP gene rather than one of many inactive mouse pseudogenes (DNA Technologies Core Laboratory, Texas A&M University). Restriction enzymes were from Invitrogen (Carlsbad, CA) while DNA purification kits (Miniprep, Maxiprep, Agarose Gel Extraction kits, PCR purification kits) were from Qiagen (Valencia, CA). Prime-A-Gene labeling was from Promega (Madison, WI), and oligonucleotides from Integrated DNA Technologies (Coralville, IA)

Embryonic Stem Cells

The 129S6-derived embryonic stem (ES) cell line W4 was from Taconic Inc. (Hudson, NY) while primary mouse embryonic fibroblasts (PMEF) were from Specialty Media (Phillipsburg, NJ). Fetal bovine serum was from Summit Biotechnology (Fort Collins, CO) while cell culture media and components (non-essential amino acids, penicillin, streptomycin, L-glutamine, G418, sodium pyruvate) were from Invitrogen (Carlsbad, CA). Leukemia inhibitory factor (LIF, ESGRO®) was from Chemicon (Temecula, CA).

Embryo Isolations

M2 and M16 media, Pregnant Mare Serum Gonadotropin (PMSG), human chorionic gonadotropin (hCG), mineral oil and hyaluronidase were from Sigma-Aldrich (St. Louis, MO), Potasium Simplex Optimized Medium (KSOM) was from Millipore (Billerica, MA), and ES cell injection needles and blastocyst holding capillaries were from Eppendorf (Hamburg, Germany).

Animals

All animal protocols were approved by the Institutional Animal Care and Use Committee (IACUC) at Texas A&M University. Male and female inbred C57BL/6NCr mice were from the National Cancer Institute (Frederick Cancer Research and Developmental Center, Maryland). ACBP genetically-engineered mice were generated as described in the section below. All mice were maintained in microisolators, with a 12 h light/dark cycle in a temperature-controlled facility (25 °C), access to standard commercial rodent chow (Teklad®, Harlan, Indianapolis, IN, USA) and water ad libitum. Mice were monitored by the presence of sentinels quarterly and found negative for all known mouse pathogens.

Generation of ACBP Gene-Ablated Mice

The ACBP-null targeting construct was designed to replace the N-terminal promoter region (including the known SREBP and PPARγ response elements), exon 1, intron 1, exon 2, and part of intron 2 of the ACBP gene with a neomycin cassette. The following two overlapping genomic DNA fragments from mouse clone RP23-430P22 (BACPAC Resources Center, BPRC, Oakland, CA, USA) were used to form the backbone of the ACBP gene targeting construct: a 7 kbp *Xho*I clone containing the promoter region, exon 1, exon 2, and the surrounding intronic sequences of the ACBP gene, and a 7 kbp *Hin*dIII clone containing exons 1 through 3 and surrounding intronic sequences. ACBP genomic sequences were confirmed by extensive restriction mapping and DNA sequencing (DNA Technologies Core Laboratory, Texas A&M University). The 5′ arm of homology was generated by ligating a 4.2 kbp *Xho*I/*Sma*I fragment from the 7 kbp *Xho*I clone into pBlueScript-SK (pBS-SK; Stratagene, La Jolla, CA, USA). An intermediate targeting construct consisting of the neomycin resistance marker and a 3.9 kbp *Xho*I/*Hin*dIII fragment from the 7 kbp *Hin*dIII clone was generated by ligating the neo cassette from a pPGK-Neo vector to the 3.9 kbp *Xho*I/*Hin*dIII fragment. Ligating the 5′ homology arm with the intermediate targeting construct pre-digested with *Sma*I completed the targeting construct. Once complete, the targeting construct was linearized with *Not*I and electroporated into the W4 ES cell line maintained on a PMEF feeder layer. Disruption of the ACBP gene was generated through homologous recombination. After selection with G418, DNA was isolated from surviving clones, digested with *Hin*dIII, and screened by Southern blotting analysis following standard protocols. Using a 760-bp 3′ probe, targeted clones were identified by Southern blotting with the presence of a 4.5-kbp band while absence of the targeting construct was indicated by a 7-kbp band. Southern blotting used a 3′ probe constructed from sequence immediately after the disrupted locus (between *Bam*/*Sma* and *Hin*dIII). Four positive clones were expanded and injected into C57BL/6NCr blastocysts to create chimeric mice following standard procedures. Four male chimeras from two separate ES cell clones were identified by coat color and bred to C57BL/6NCr females to determine germ-line transmission of the targeted allele. Tail DNA from the chimera/wild-type backcross F1 offspring were initially screened with Southern blotting by standard procedures to verify germline transmission. Subsequent generations of heterozygote/heterozygote and wild-type crosses (for PCR controls) were genotyped by PCR, with the following primer sets: forward primer (ACBP-anchor, 5′-CAA CCT CTG CCA TCA CCT ATT C-3′); reverse primer wild type (ACBP-wt, 5′-TTC TCT GTA TAG CTC TGG CTG G-3′) and reverse primer gene ablation (ACBP-ko, 5′-GGT GGC TAC CCG TGA TAT TG-3′), for 35 cycles with an annealing temperature set at 58 °C. The ACBP-null mice described herein were

Isolation of Pre- and Post-Implantation Stage Embryos

ACBP heterozygous or wild-type (control) females were paired overnight with ACBP heterozygous or wild-type males, respectively and checked for the presence of a copulation plug the next morning. The day of the copulation plug was designated 0.5 post coitum (dpc). Females were humanely euthanized by cervical dislocation immediately prior to embryo isolation. Post-implantation embryos were obtained by dissecting the uterus at 9.5, 11.5, 14.5 and 17.5 dpc. These embryos were freed of any extra-embryonic tissue and then prepared for PCR analysis. Pre-implantation embryos were obtained by flushing the oviducts or uterus, depending upon the time point. One-cell and two-cell (cleavage) oocytes were isolated from the oviducts the same morning of the copulation plug (0.5 dpc) and the following morning (1.5 dpc), respectively. Eight-cell (morula) stage embryos were isolated from the oviduct on the third day (2.5 dpc) and blastocysts were obtained by flushing the uterus on the fourth day (3.5 dpc). Hepes-buffered M2 medium was used to flush and handle all embryos, and KSOM under mineral oil was used for up to 6 days for in vitro culture of all pre-implantation embryos at 37 °C, 5% CO_2. One-cell stage embryos were treated with 1 mg/ml of hyaluronidase and subsequently rinsed 5–10 times in sterile M2 medium to remove cumulus cells. The development and morphology of pre-implantation stages were monitored by visualizing the embryos with an inverted phase contrast microscope (Nikon Diaphoto 300, Nikon, Tokyo, Japan) at 12-h intervals after oocyte collection.

Genotyping of Pre- and Post-Implantation Embryos

Genotyping of individual pre-implantation embryos was performed using the REDExtract-N-Amp Tissue PCR kit (Sigma-Aldrich, St. Louis, MO) according to the manufacturer's protocol. Genomic DNA from post-implantation embryos was obtained by digesting a small section of tail in 500 μl of lysis buffer (10 mM Tris–HCl, 1 mM EDTA, 300 mM Na acetate, 1% SDS, 0.2 mg/ml proteinase K) for 6 h at 55 °C, followed by 20 min at 95 °C to inactivate the proteinase K. The lysate was used directly for PCR

genotyping. The same PCR primer sets to genotype embryos were used as with the live offspring. Initial embryo genotyping was performed on embryos isolated from the F2 intercross heterozygote generation. All embryos genotyped for real-time reverse transcriptase polymerase chain reaction (Q-rtPCR) were from the N6 heterozygote intercross generation or greater.

Quantitative (Real-Time) Reverse Transcriptase PCR

Q-rtPCR was performed on total RNA from 2.5-dpc embryos isolated and purified using RNeasy Micro kit (Qiagen,Valencia, CA, USA) according to manufacturer's protocol. Expression patterns were analyzed with an ABI PRISM 7000 Sequence Detection System (Applied Biosystems, Foster City, CA, USA) using TaqMan® One Step PCR Master Mix Reagent kit, gene specific TaqMan® PCR probes and primers, and the following thermal cycler protocol: 48 °C for 30 min for reverse transcription prior to amplification, 95 °C for 10 min before the first cycle, 95 °C for 15 s, and 60 °C for 1 min, repeated 60 times. For other specific probes and primers, TaqMan® Gene Expression Assay products for mouse peroxisome proliferator-activated receptor-α (Pparα, Mm00440939_m1); sterol carrier protein 2 (Scp-2, Mm01257982_m1); m-calpain (Capn2, Mm00486669_m1), and Custom-TaqMan®-Assay products sterol carrier protein-x (Scp-x, SEQ_SCPX-EX23); acyl-CoA binding protein (Acbp, SEQ_ACBP). Measurements were performed in duplicate and analyzed with ABI PRISM 7000 SDS software to determine the threshold cycle (C_T) from each well. Primer concentrations and cycle number were optimized to ensure that reactions were analyzed in the linear phase of amplification. To analyze the Q-rtPCR data, mRNA expression of Pparα, Scp-2, Scp-x, and Capn2 in homozygous null pre-implantation embryos were normalized to a housekeeping gene (18S rRNA); made relative to the control wild-type pre-implantation embryos, and calculated using the comparative $2^{-\Delta\Delta C_T}$ method [32], where $\Delta\Delta C_T = [C_T$ of target gene $- C_T$ of 18 s$]_{\text{ACBP-nullembryos}} - [C_T$ of target gene $- C_T$ of 18 s$]_{\text{wild typeembryos}}$ as described in User Bulletin 2, ABI PRISM 7000 SDS.

Results

Generation of ACBP Gene-Ablated Mice

The strategy for generation of a mouse ACBP-null targeting construct was dictated by the biological activity of ACBP proteolytic fragments as well as the unique nature of the ACBP gene itself. For example, the N-terminal region of ACBP is the precursor of two major biologically active peptides active in lipid metabolism, signaling, and insulin secretion [14, 33, 34]. In addition, alternative splicing in the mouse ACBP gene results in transcription of two mRNA transcripts encoding proteins of 86 and 135 amino acids, respectively [7]. Although western blotting of mouse liver homogenates with several different polyclonal anti-ACBP antisera detected the 10-kDa ACBP coded by the transcript for 86 amino acids, these antisera did not detect a 15.9-kDa ACBP coded by the alternate transcript for 135 amino acids (not shown). Nevertheless, the mouse ACBP-null targeting construct was designed to replace the N-terminal promoter region (including the known SREBP and PPARγ response elements), exon 1, intron 1, exon 2, and part of intron 2 of the ACBP gene with a neomycin cassette (Fig. 1a). Chimeric ACBP gene ablated mice were developed using this construct as described in Methods. The offspring from chimera/wild-type backcrosses were genotyped by Southern blotting using a 3′ probe constructed from sequence almost completely after the disrupted locus (horizontal solid bar after exon 3 and *Bam*/*Sma*). Southern blotting of *Hind*III-digested DNA revealed wild-type (7 kB) and targeted heterozygous (4.5 kB) DNA (Fig. 1b). A PCR screen from tail clips was then developed (Fig. 1c), using the two primer sets as described in Methods, for genotyping all other offspring.

ACBP Heterozygous Mice Are Phenotypically Normal

Wild-type and heterozygous mice were indistinguishable with respect to visual appearance, post-implantation embryonic weight (Fig. 2a), body weight at weaning (not shown), adult body weight (Fig. 2b), and fertility (not shown). Since only one of the two ACBP alleles was deleted in the heterozygous mice, rtPCR and Western blotting detected only the expected 10-kDa ACBP in livers of both wild-type and heterozygous mice (not shown).

The ACBP-Null Mutation is Embryonically Lethal

The F1 ACBP heterozygotes were intercrossed to produce ACBP-null offspring. Instead of the expected Mendelian 1:2:1 ratio of 25% wild-type, 50% heterozygous, and 25% null ACBP mice, examination of 171 total F2 offspring from 21 litters yielded no homozygous null ACBP pups (Fig. 3). The remaining greater than 2:1 ratio of heterozygous to wild-type mice was consistent with the absence of adverse effects of the mutant allele in the heterozygotes (Fig. 3), and average litter size was within the normal range of a hybrid B6:129 strain (D. Landrock, unpublished data). Pregnant females were carefully monitored until the day of parturition. No evidence for increased neonatal lethality or cannibalization was noted. Taken together, these data indicated a potential embryonic lethality.

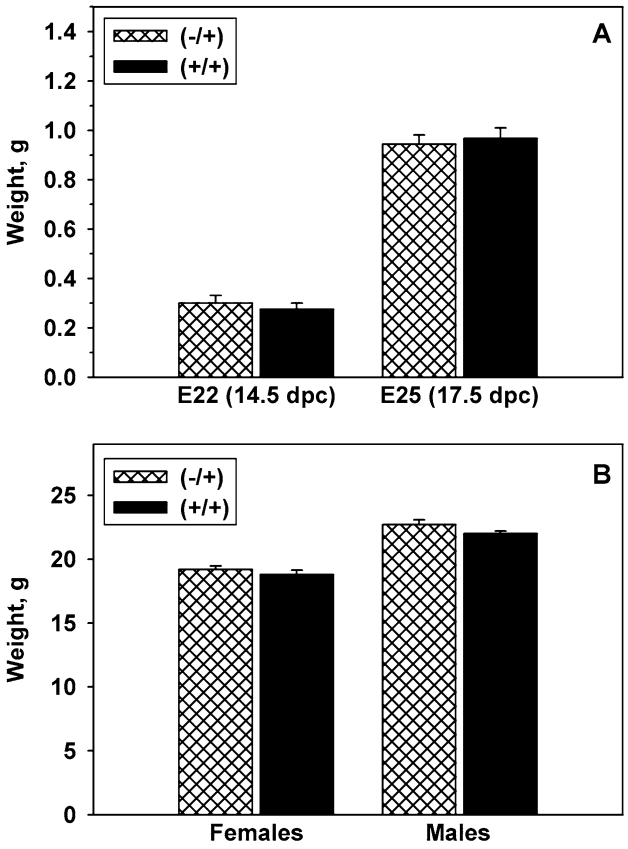

Fig. 2 Body weights of heterozygous (−/+) and wild-type (+/+) post-implantation embryo littermates and adult counterparts. Full body weights of wild-type (**a**, *solid bars*) and ACBP heterozygous (**a**, *cross-hatched bars*) post-implantation embryos are indicated at the E22 (14.5 dpc) and E25 (17.5 dpc) stages. Body weights of adult wild-type (**b**, *solid bars*) and ACBP heterozygous ACBP (**b**, *cross-hatched bars*) male and female counterparts. There were no significant differences in any of the groups

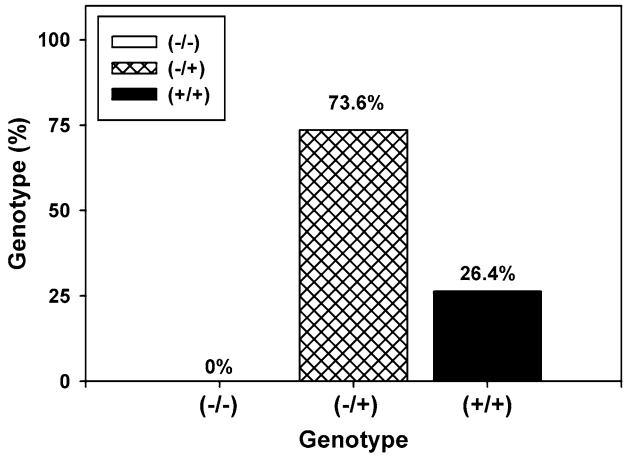

Fig. 3 Genotypes of live F2 offspring from ACBP heterozygote male and female F1 intercrosses. From 21 intercross litters of mice, no homozygous ACBP-null offspring were detected. ACBP heterozygotes constituted 73.6% (126) of offspring (*cross-hatched bar*). Wild-type mice represented 26.4% [45] of offspring (*solid bar*). (−/−) homozygous ACBP-null; (−/+) ACBP heterozygotes; (+/+) wild-type mice from the same litters

Genotypes of Post-implantation Embryos

To determine if ACBP gene ablation resulted from a post-implantation embryonic lethality, the genotypes of post-implantation F2 embryos from F1 ACBP heterozygote/heterozygote intercrosses were determined. Of the 35 post-implantation embryos isolated, no ACBP homozygous null embryos were recovered 9.5 dpc (E15, 9 total, Fig. 4a), 11.5 dpc (E19, 8 total, Fig. 4b), 14.5 dpc (E22, 9 total, Fig. 4c), and 17.5 dpc (E25, 9 total embryos, Fig. 4d). No evident indicators of resorbed embryos were found during dissection. Thus, ACBP-null embryos never formed, or died prior to or very shortly after implantation.

Genotypes of Pre-implantation Embryos

To determine if ACBP-null mice resulted in a pre-implantation embryonic lethality, the genotypes of 310 of 510 pre-implantation F2 embryos from F1 ACBP heterozygote intercrosses were determined at the 2-cell (oocyte), ~8-cell (morula), and ~32-cell (blastocyst) stages. At the oocyte stage, the amount of DNA recovered for PCR was minimal; thus it was not possible to identify the genotype of all oocytes at this stage. Of over 200 oocytes recovered, 36 were clearly identified as to genotype, of which 4 were the homozygous null ACBP genotype (Table 1). As shown by representative light microscopic images, the null ACBP oocytes (Fig. 5a) did not differ in appearance from wild-type oocytes (Fig. 5e). Of 146 morulae recovered, 17 were the ACBP homozygous null genotype (Table 1). Similarly, light microscopy showed that the ACBP-null morulae (Fig. 5b) did not differ significantly in appearance from wild-type (Fig. 5f). In contrast, while 128 blastocysts were recovered and genotyped, none were the ACBP-null genotype (Table 1). Furthermore, light microscopy showed that some blastocysts appeared to be undergoing degeneration (Fig. 5d), while the majority appeared normal (Fig. 5h). Due to DNA degradation, it was not possible to definitively genotype the degenerating blastocysts. These dead/dying blastocysts most probably represented ACBP homozygous null embryos. Thus, ACBP gene ablation resulted in early pre-implantation embryonic lethality beginning by the 2.5-dpc morula (8-cell) stage, and none were viable by the 3.5-dpc blastocyst (~32-cell) stage.

Q-rtPCR of ACBP in Pre-implantation Embryos

To determine if the lethality was associated with total absence of ACBP transcription, 2.5 and 3.0-dpc embryos

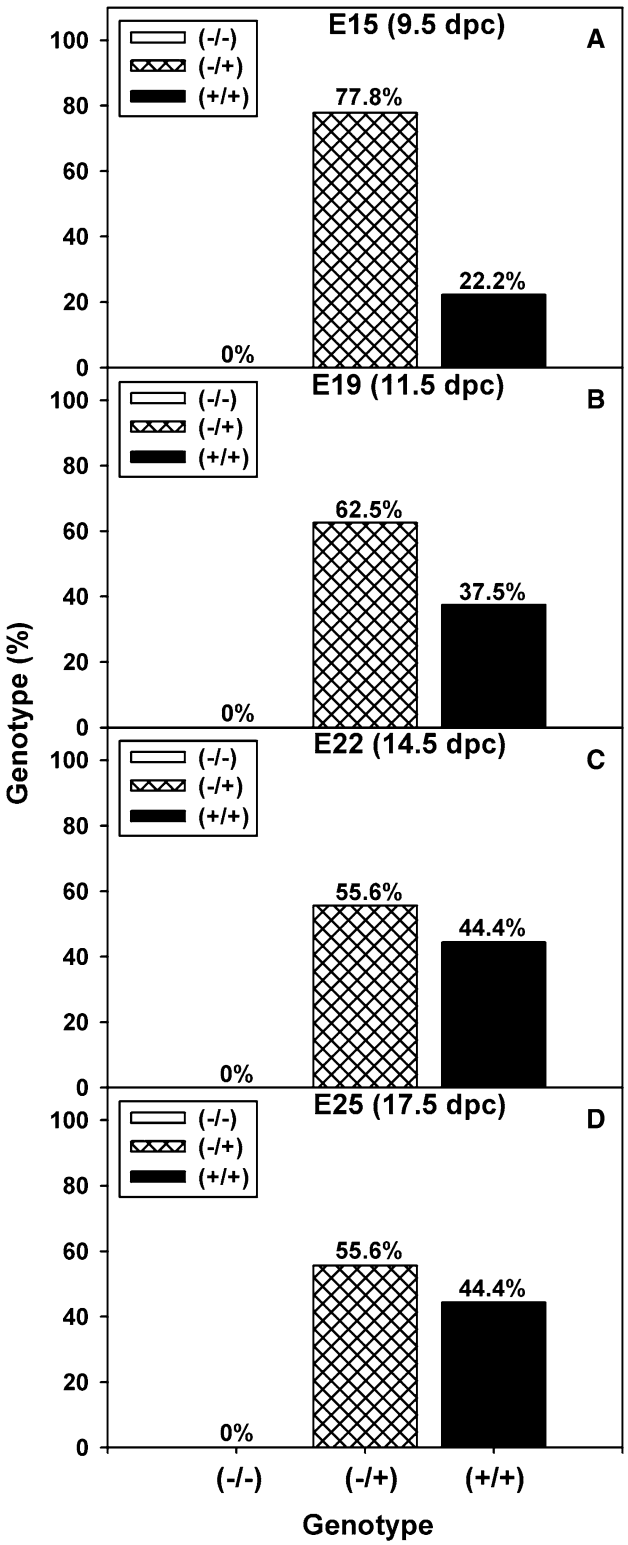

Fig. 4 Genotypes of post-implantation embryos from ACBP heterozygote intercrosses. Embryos were examined at four stages of development: **a** E15 (9.5 dpc, 9 total embryos); **b** E19 (11.5 dpc, 8 total embryos); **c** E22 (14.5 dpc, 9 total embryos); and **d** E25 (17.5 dpc, 9 total embryos). (−/−) homozygous ACBP null (*open bars*); (−/+) ACBP heterozygotes (*cross-hatched bar*); (+/+) wild-type mice from the same litters (*black bar*). Values represent percent of total embryos for each genotype obtained at the indicated developmental stages

Table 1 Genotype distribution among pre-implantation embryos from heterozygote F1 intercrosses

Embryo		Genotype					
Stage	Age (dpc)	(−/−)		(−/+)		(+/+)	
		Total	%	Total	%	Total	%
Blastocyst (∼32-cell)	3.5	0	0	81	63.3	47	36.7
Morula (∼8-cell)	2.5	17	11.6	99	67.8	30	20.6
Oocyte (2-cell)	1.5	4	11.1	22	61.1	10	27.8

Genotyping was performed by PCR (*dpc* days post coitum)

from ACBP heterozygote intercrosses were examined by Q-rtPCR. The ACBP transcript was detected in wild-type and heterozygous embryos at the 2.5-dpc morula (Fig. 6a, b) and 3.0-dpc stage (Fig. 6b) just prior to blastocyst formation. In contrast, no Acbp gene transcript or alternate spliced longer transcript was detected in the morula 2.5-dpc stage of ACBP-null embryos (Fig. 6a, b). The absence of Acbp transcript in the 2.5-dpc null embryos was consistent with correct insertion of the construct into the Acbp gene. Detection of Acbp transcript in 3-dpc ACBP-null embryos was not possible because no ACBP-null embryos were found by this late morula/early blastocyst stage (Fig. 6b, ∞). Thus, the Acbp transcript was absent in the ACBP homozygous null 2.5-dpc stage morula, preceding the embryonic lethality by the blastocyst 3–3.5-dpc stage (Figs. 5d, 6b). Western blotting to determine presence of the ACBP protein in the null morulae was not possible due to the limited amount of material present at this early stage of development.

Concomitant Upregulation Of Other Long-Chain Fatty Acyl-CoA Binding Proteins

Since ACBP gene ablation was not lethal at the morula 2.5-dpc stage, the possibility that loss of ACBP was temporarily compensated for at least in part by upregulation of another cytosolic LCFA-CoA binding protein was examined. Sterol carrier protein-2 (SCP-2) and sterol carrier protein-x (SCP-x) bind LCFA-CoAs with similar affinities as ACBP [8, 35]; their ablation is not lethal [36–38]; and they are expressed as early as the zygote 1-cell stage, slightly earlier than ACBP at the 2-cell stage (Supplemental Fig. S1A). Scp-2 expression in ACBP-null 2.5-dpc morulae was upregulated tenfold (Fig. 6a). Likewise, expression of Scp-x in ACBP-null morulas (2.5 dpc) was upregulated over 50-fold (Fig. 6a). These data suggest that significant upregulation of SCP-2 and SCP-x may indicate an attempt to compensate for the loss of ACBP to maintain viability.

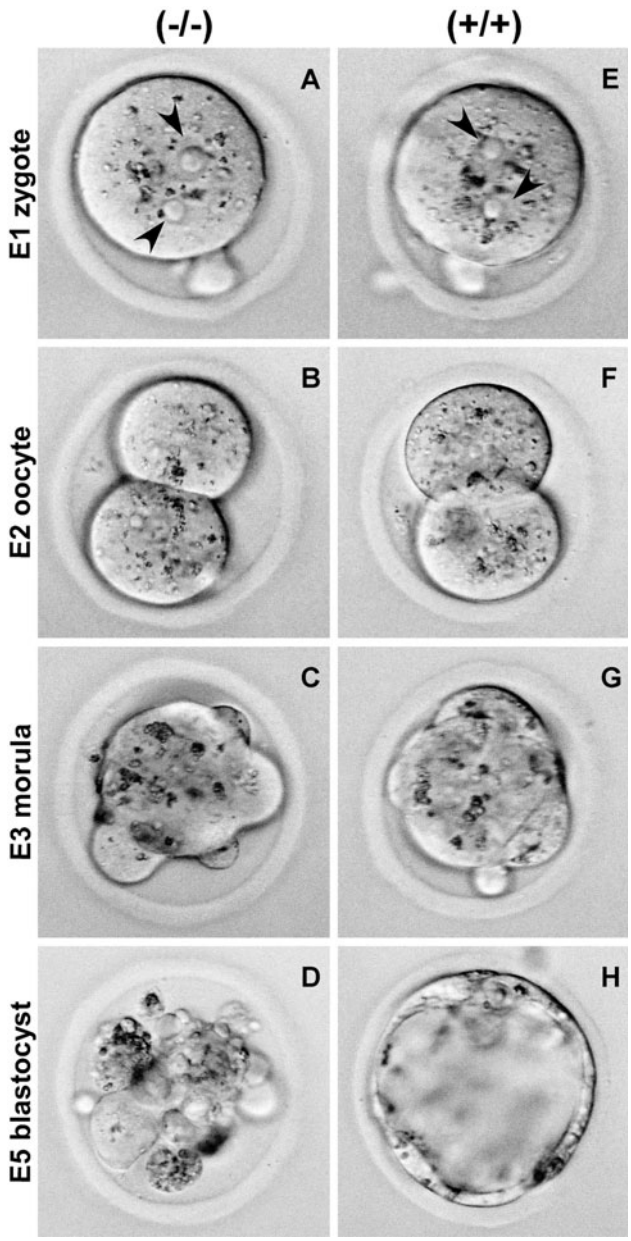

Fig. 5 Pre-implantation development of homozygous ACBP-null and wild-type embryos. E1 (0.5-dpc) oocytes from ACBP heterozygote intercrosses were isolated, cultured in KSOM medium, and photographed every 12 h to monitor their development. At the indicated times, each embryo was genotyped by PCR. **a**–**d** show representative homozygous null ACBP pre-implantation embryos, while **e**–**h** show representative wild-type embryos at the same stages. Pre-implantation embryos at the E1 early oocyte stage (0.5 dpc, **a**, **e**) have *arrows* pointing to the two pronuclei, indicating fertilization; **b**, **f** indicate the E2 oocyte cleavage stage (1.5 dpc); **c**, **g**, the E3 morula stage (2.5 dpc); and **d**, **h** the E5 blastocyst stage (3.5 dpc). Degeneration of several embryos at the blastocyst stage probably represent dead/dying ACBP homozygous null embryos (**d**); DNA isolation was attempted numerous times but was too degenerated for definitive genotyping. (−/−) homozygous ACBP null; (−/+) ACBP heterozygotes; (+/+) wild-type mice

Fig. 6 Expression of ACBP and other key long-chain fatty acyl-CoA binding proteins in pre-implantation embryos. Embryos were isolated from ACBP heterozygote intercross mice, and levels of ACBP, sterol carrier protein-2 (SCP-2), sterol carrier protein-x (SCP-x), peroxisome proliferator-activated receptor-α (PPARα), and m-calpain were determined by Q-rtPCR as described in "Methods". **a** Acbp, Scp-2, Scp-x, and Pparα expression was determined in homozygous ACBP-null embryos (*open bars*) and wild-type embryos (*solid bars*) at the 2.5-dpc morula stage (E3). Values represent means ± SEM; $*p < 0.05$ between ACBP-null and wild-type embryo; $***p < 0.0001$ between ACBP-null and wild-type embryo. **b** Acbp and m-calpain expression was determined in homozygous null ACBP, heterozygous ACBP, and wild-type ACBP embryos at the morula (E3, 2.5 dpc) and early blastocyst (E4, 3.0 dpc) stages. (∞) indicates no live embryos found. (−/−) homozygous ACBP null; (−/+) ACBP heterozygous; (+/+) wild-type embryos

The possibility that ACBP gene ablation may result in compensatory upregulation of the nuclear peroxisome proliferator-activated receptor-α (PPARα) was also investigated. PPARα exhibits high affinity for LCFA-CoAs [39, 40] and PPARα coactivator recruitment and transcriptional activity are regulated by both LCFA-CoAs and ACBP [39–42]. Furthermore, expression of the PPARα transcript occurred by the zygote (1-cell) stage, thereby preceding the appearance of ACBP, which normally occurs at the oocyte cleavage (2-cell) stage (Supplemental Fig. S1A). However, ACBP gene ablation did not significantly alter the expression of Pparα transcript at the morula (2.5-dpc) stage. Thus, viability of very early pre-implantation ACBP-null embryos was not associated with concomitant upregulation of PPARα.

Since ACBP is a potent activator of m-calpain, a protease involved in apoptosis [43], the possibility that

m-calpain transcript (Capn2) is expressed at an early pre-implantation embryonic stage was investigated. Capn2 was not expressed in the morula (2.5 dpc) embryonic stage of ACBP-null, heterozygote, or wild-type embryos (Fig. 6b). Since Capn2 was not detected until 3.0 dpc and no ACBP-null pre-implantation embryos were detected by that stage, embryonic lethality at >2.5 dpc was not associated with ACBP activation of m-calpain.

Effect on Unbound Free Long-Chain Fatty Acyl-CoA (LCFA-CoA) Concentration

LCFA-CoAs are potent regulators (K_is as low as 50 nM) of many enzymes, transporters, and receptors involved in lipid and glucose metabolism (Supplemental Table S1). Since determination of LCFA-CoA and ACBP protein concentrations would require more material than is present in these early stage embryos to be detectable, the effect of ACBP on the free unbound LCFA-CoA concentration was modeled over the known physiological range of LCFA-CoAs and ACBP concentrations in mammalian tissues (see Supplementary Materials, Methods). At the upper range of physiological ACBP concentration (50 μM), ACBP very effectively buffered the unbound LCFA-CoA concentrations over a relatively broad range (Supplemental Fig. S2A). The unbound LCFA-CoA concentration was <50 nM up to 40 μM total LCFA-CoA (Supplemental Fig. S2B). In contrast, estimated lower physiological ACBP concentration (6 μM) was relatively ineffective in buffering the unbound LCFA-CoA level (Supplemental Fig. S2A), which was >50 nM even at 10 μM total LCFA-CoA (Supplemental Fig. S2B). Taken together, these data suggest that the loss of ACBP would probably result in significantly increased free unbound LCFA-CoA levels within the null embryo cells, which in turn would adversely affect many proteins, enzymes, and receptors involved in both lipid and glucose metabolism.

Discussion

Although long-chain fatty acyl CoAs (LCFA-CoAs) are well known intermediates in fatty acid metabolism, they are also potent metabolic regulators of multiple enzymes/proteins involved in fatty acid and glucose metabolism [1, 10, 13]. While physiologic tissue total LCFA-CoA levels are in the 5–150 μM range [1, 10, 13], even surprisingly low levels (50–500 nM) of free unbound LCFA-CoAs inhibit a broad variety of enzymes, transporters, signaling receptors, and nuclear receptors involved in key cellular processes such as fatty acid and cholesterol synthesis, transcription of genes in lipid metabolism, mitochondrial fatty acid oxidation, and glucose metabolism (Supplemental Table S1). The respective K_is by LCFA-CoA for many of these proteins are as much as 3,000-fold lower than the range of total LCFA-CoA levels in tissues [1, 10, 13]. Since these proteins are known to be active in tissues, the actual unbound free LCFA-CoA levels are much lower (10–20 nM) due to buffering by intracellular LCFA-CoA binding proteins–especially by ACBP (rev. in [1, 10, 13]. The present investigation determining the effect of ACBP gene ablation on the phenotype of mice yielded the following insights.

First, the phenotype of ACBP gene-ablated mice on a C57BL/6NCr background was more severe than that of the more complex nm1054 spontaneous mouse mutation on a C57BL/6J or mixed strain background. Loss of only the ACBP gene function was embryonically lethal at the pre-implantation stage in ACBP-null mice on a C57BL/6NCr background. While spontaneous loss of ACBP together with at least five other genes (an earlier study indicated as many as 200 genes) also resulted in significant prenatal lethality in homozygous nm1054 null mice on a C57BL/6J background, almost all of the few live-born pups die before weaning and few have been weaned successfully [30, 31]. In contrast, loss of ACBP (along with 5 other genes) elicited a somewhat milder phenotype (sparse hair, skin lipid metabolic abnormalities, male infertility, failure to thrive, hydrocephaly, anemia) in homozygous nm1054 mice on a mixed (two different strains) mouse background [29–31]. It is yet to be determined why the nm1054 mutation resulting in loss of ACBP as well as five other genes is less 'lethal' than deletion of the ACBP gene alone. While it cannot be ruled out that loss of the promoter sequences in our construct may have also affected the expression of other genes and thereby contributed to pre-implantation embryonic lethality, it is unclear why the loss of even more promoter sequences due to deletion of six genes in the nm1054 mutation resulted in a less severe phenotype. One possibility is that the loss of one or more of the five additional genes (i.e. loss of exons as well as intronic sequences, and N-terminal promoter sequences) may have contributed in an as yet not understood manner to compensate for the loss of the ACBP. The different mouse strain backgrounds of the ACBP-null mice (C57BL/6NCr) and nm1054 mice (C57BL/6J or mixed CBA, 129) may also have played a role, since phenotype versus strain differences have also been noted in ACBP gene deletions in different yeast strains [20, 21] as well as deletions of other gene-ablated mouse models [44, 45]. The importance of genetic background is emphasized by a recent report comparing two yeast strains (Σ1278b and S288c) wherein about 5,100 genes were systematically deleted [46]. While 894 genes were essential in both strains, 44 genes were essential only in Σ1278b and 13 genes were essential only

in S288c. Examination of hybrid strain crosses of 18 mutants that were lethal in Σ1278b, but not in S288c, yielded viable progeny in all cases and their conditional phenotype was associated with numerous modifier genes that differ between the strains [46]. On the basis of this and previous work, it was concluded that "conditional essentiality is almost always a consequence of complex genetic interactions involving multiple modifiers associated with strain specific genetic variation rather than classical digenic synthetic lethality" [46]. As has been seen in many other cases, genetic background can profoundly affect the phenotypes manifest upon gene ablation. While such 'discrepancies' often cause controversy, they also identify potentially important areas of future research.

Second, deletion of the 10-kDa ACBP encoding gene in the mouse is the first known embryonically lethal mutation in any of the intracellular LCFA-CoA binding protein families. At least three families of soluble lipid binding proteins appear to buffer cytoplasmic LCFA-CoA levels by binding LCFA-CoAs with high affinity, in the order: acyl-CoA binding protein (ACBP) [1, 10, 13] >sterol carrier proteins (SCP-2, SCP-x) [47] >select fatty acid binding proteins [FABP1 (L-FABP) >>FABP7, FABP2, FABP3 (B-FABP, I-FABP, H-FABP)] [48–50]. Of these LCFA-CoA binding proteins, only ACBP, SCP-2/SCP-x, and FABP3 are expressed in pre-implantation embryos (Supplementary Figure S1). However, FABP3 (H-FABP) binds LCFA-CoA even more weakly than FABP1 (L-FABP)—a protein not expressed in pre-implantation embryos (Supplementary Figure S1) [48, 49]. Thus, redundancy in LCFA-CoA binding proteins is much more limited in pre-implantation embryos than in more mature tissues. These data would suggest that loss of one of the lower affinity LCFA-CoA binding proteins would not probably be lethal, and to date lethality has not been observed upon gene ablation of several members of the large FABP protein family, including: Fabp1 (liver L-FABP), Fabp2 (intestinal I-FABP), Fabp3 (heart H-FABP), Fabp4 (adipocyte A-FABP), Fabp5 (keratinocyte K-FABP), and Fapb7 (brain B-FABP) [44, 51, 52]. Likewise, ablation of SCP-2 and SCP-x is not lethal [37, 38, 53]. Even loss of both L-FABP and SCP-2/SCPx (intercross of L-FABP null mice and SCP-2/SCP-x null mice) does not result in lethality [54]. Thus, embryonic lethality in mice ablating the gene encoding the 10-kDa ACBP is unique among the multiple LCFA-CoA binding proteins known to exist in the cytoplasm of mammalian tissues.

Third, the ACBP gene ablation-induced embryonic lethality at very early pre-implantation stages where the embryo is not well differentiated was consistent with studies showing that ACBP-specific siRNA treatment of highly undifferentiated mouse and human tumor cells is lethal [26]. The observed lethality of ACBP-specific siRNA treatment was probably due to loss of LCFA-CoA buffering capacity concomitant with loss of ACBP in the context of the already markedly reduced levels of other LCFA-CoA binding proteins (e.g. FABPs, SCP-2/SCPx) in transformed cells (rev. in [1, 11, 27, 28]. The fact that some apparently normal ACBP-null embryos, albeit reduced in expected numbers, were still alive at the 1–8 cell pre-implantation stages, but not at later embryonic stages, was most probably due to the presence of residual maternal ACBP protein. Consistent with the fact that almost all maternal mRNA is degraded by the end of the 2-cell stage [55, 56], the ACBP mRNA was not longer detected in the 8-cell stage pre-implantation embryos. However, since the ACBP protein has a relatively long half life (i.e. $t_{1/2}$ of 25–53 h) [55–57], some maternal ACBP protein was probably present in the 4-cell, but not in the 8-cell pre-implantation stage. Concomitant upregulation of two less prevalent LCFA-CoA binding proteins (SCP-2 and SCP-x, primarily in peroxisomes) shown herein may have also facilitated survival at the morula (8 cell) stage, but was insufficient to assure survival by the blastocyst (~32 cell, 3.5-dpc) stage.

Fourth, the early pre-implantation embryonic lethality in ACBP-null mice was consistent with the importance of ACBP in preventing deleterious effects of LCFA-CoAs on sensitive enzymes involved in energy production and fatty acid biosynthesis. While fatty acids (primarily derived from endogenous triglycerides) are the major energy source in unfertilized oocytes, thereafter very little energy is derived from fatty acids and intracellular triglyceride is maintained relatively constant [58]. Since there is too little glycogen to sustain the pre-implantation embryo, especially that of the mouse, the pre-implantation embryo is heavily dependent on an exogenous energy supply for synthesizing fatty acids [58]. Pyruvate and lactic acid in oviductal fluid represent the major carbon sources of mouse pre-implantation embryos up to the 4-cell stage, while glucose serves this purpose thereafter [58–60]. Acetyl CoA derived from these nutrients is oxidized to produce energy or is used as a substrate for fatty acid synthesis required for formation of membranes and longer-term energy storage than can be accomplished by energy storage as glycogen. The two key enzymes in fatty acid synthesis [acetyl CoA carboxylase (ACAC, rate limiting); fatty acid synthase (FASN)] are both end-product inhibited by fatty acyl-CoA [10, 15]. Acetyl CoA carboxylase is especially sensitive (K_i 50 nM) to the presence of even very low levels of LCFA-CoA [10]. By binding LCFA-CoAs, ACBP very effectively removes the LCFA-CoA end-product inhibition of ACC and FASN [10, 15]. The importance of these fatty acid synthetic enzymes in early embryogenesis is underscored by the fact that ablation of ACC or FASN results in an early embryonic and

pre-implantation embryonic lethality [61, 62]. As shown herein, loss of ACBP (the major high-affinity LCFA-CoA binding protein) is expected to eliminate most of the LCFA-CoA buffering capacity. The other major LCFA-CoA binding protein (FABP1, i.e. L-FABP) is not induced until much later in development. While two other LCFA-CoA binding proteins (SCP-2, SCP-x) are present and concomitantly upregulated in ACBP-null pre-implantation embryos, these proteins are largely compartmentalized in peroxisomes and are present at much lower level (rev. in [47]. Since ACBP is thought to be the most effective of the LCFA-CoA binding proteins in buffering the unbound free LCFA-CoA concentration [1, 10, 63], complete loss of ACBP would thus be expected to greatly increase unbound free LCFA-CoAs over that normally present in cells and tissues—thereby inhibiting ACC and FASN enzymes essential for de novo fatty acid synthesis.

Fifth, ACBP exhibits a unique role in early pre-implantation embryonic development as compared to the other intracellular LCFA-CoA binding proteins. Several other cytoplasmic LCFA-CoA binding proteins (FABPs 5, 4, and 3; SCP-2, SCP-x) are expressed already by the zygote 1-cell to morula 8-cell stages (Supplemental Fig. S1), but gene ablation of many of these proteins is not lethal [37, 38, 44, 51–53]. ACBP is also known to enter the nucleus, bind nuclear receptors (PPARα, PPARγ) involved in lipid and glucose metabolism, and regulate transcriptional activity of these receptors [11, 64–66]. PPARα itself exhibits high affinity for and is regulated by LCFA-CoAs transported by ACBP [11, 39, 40]. While PPARs α and γ are both present at the zygote one-cell stage (Supplemental Fig. S1), ablation of PPARα is not lethal, and ablation of PPARγ is lethal but not until much later, i.e. the post-implantation E10 stage [67, 68]. Thus, it is unlikely that dysregulation of PPARs in response to ACBP deletion accounts for the observed very early pre-implantation lethality.

Finally, the 10-kDa ACBP does not appear to be an essential protein in other eukaryotes, since its deletion results in the appearance of revertants (yeast) and probably compensated by distinct other ACBP genes in the nematode (*C. elegans*), insect (*D. melanogaster*), and plants (*Arabidopsis*) [20, 22, 23, 69–71]. It is also important to note that in mammals the gene encoding the 10-kDa ACBP also expresses two additional transcripts (due to alternate transcription initiation) encoding distinct ACBP homologues (testes T-ACBP; brain B-ACBP) [2, 24]. In silico analyses of several databases (NCBI UniGene, http://www.ncbi.nlm.nih.gov/unigene; European Bioinformatics Institute, http://www.ebi.ac.uk) indicates the presence of expressed sequence tags (ESTs) for all three mRNAs derived from the human ACBP gene (only two have active promoters), for only the mRNA encoding the rat 10-kDa ACBP, and for two mRNAs encoding the mouse 10-kDa ACBP (87 amino acid) and a mouse 15.9 kDa (135 amino acid) ACBP-related protein [7]. While two additional mouse ESTs [one from brain (BE652768) and one from testis (AA4927130)] have been reported [7], a search of several databases attributed both of these ESTs to the known gene encoding the 10-kDa ACBP protein (Mouse Genome Informatics Database, Jackson Labs, Bar Harbor, ME; NCBI UniGene database, October 2009, http://www.ncbi.nlm.nih.gov/unigene). Mammals (mouse, rat, human) also process multiple inactive pseudogenes [NCBI UniGene database, October 2009, http://www.ncbi.nlm.nih.gov/unigene); [2, 24]]. While the physiological relevance of potentially two mRNA transcripts of the mouse ACBP gene in early pre-implantation embryonic development is not clear, the mRNA encoding ACBP was present in all wild-type mouse embryos examined but not in homozygous ACBP-null 8-cell stage pre-implantation embryos or thereafter.

In summary, the studies presented herein addressed for the first time the role of ACBP single gene ablation on development in mice. ACBP gene ablation resulted in pre-implantation embryonic lethality between the morula (8 cell) and blastocyst (32 cell) stages. In contrast to ACBP-null mouse, gene ablation of several other cytosolic LCFA-CoA binding proteins also expressed at these early pre-implantation embryonic stages is not lethal. Thus, ACBP represents the first discovered LCFA-CoA binding protein whose ablation results in lethality. While the exact role of ACBP in normal pre-implantation embryonic development remains to be identified, at least two general possibilities may be considered: (1) Since the high affinity of ACBP for LCFA-CoAs results in highly effective buffering of total LCFA-CoAs to maintain unbound free LCFA-CoAs at low levels, loss of ACBP probably results in a significant increase of unbound free LCFA-CoA levels. The elevated unbound free LCFA-CoA levels would consequently inhibit highly LCFA-CoA sensitive enzymes (e.g. acetyl CoA carboxylase, fatty acid synthase) required for normal glucose metabolism and fatty acid synthesis in these rapidly growing pre-implantation embryos; and (2) Since ACBP normally interacts with and regulates several nuclear receptors (e.g. PPARs) present in early pre-implantation embryos, loss of such interactions may result in abnormal transcriptional regulation of genes involved not only in lipid and glucose metabolism but also development. Both factors could contribute to the lethality observed in these early pre-implantation ACBP-null embryos. Future studies using an inducible construct or a conditional knockout approach (e.g. as applied to acetyl-CoA carboxylase and fatty acid synthase [72, 73]) should allow further discrimination of the physiological functions of ACBP.

Acknowledgments This work was supported in part by the USPHS, National Institutes of Health grants, DK41402 (FS and ABK), GM31651 (FS and ABK), and DK70965 (BPA). The helpful professional assistance of Dr. Danna Zimmer and technical assistance of Amy L. Boedeker is very much appreciated.

Received: 9 September 2009 / Accepted: 6 May 2010 / Published online: 28 May 2010

Abstract Vaccenic acid (*trans*-11-$C_{18:1}$) chemically resembles elaidic acid (*trans*-9-$C_{18:1}$) which is assumed to increase the risk of cardiovascular diseases, and thus could exert similar effects. Possible different oxidation rates of vaccenic versus elaidic acid were checked in muscles and liver, and through related gene expression in normal rat liver cells. In hepatic mitochondria, carnitine palmitoyltransferase (CPT) I exhibited comparable activity rates with both *trans*-isomers. CPT II activity was 30% greater ($P < 0.05$) with vaccenic than with elaidic acid as nonesterified fatty acids (NEFAs) or acyl-CoAs. Activity of the first β-oxidation step was similar between the isomers in all the tissue slices and liver extracts assayed. Respiration rates were comparable with both *trans*-isomers as NEFAs in various liver extracts, but were 30% greater ($P < 0.05$) with vaccenoyl-CoA than with elaidoyl-CoA in liver mitochondria. Vaccenic acid was oxidised 25% more ($P < 0.05$) by liver peroxisomes than elaidic acid. In hepatocytes cultured with *trans*- and corresponding *cis*-$C_{18:1}$ isomers, gene expression of CPT I, hydroxyacyl-CoA dehydrogenase and hydroxymethylglutaryl-CoA synthase was at least 100% increased ($P < 0.05$), but was unchanged with vaccenic acid, relative to controls. In conclusion, the position and geometry of the double bonds in acyl chains are suggested to confer on vaccenic and elaidic acid specific biochemical properties that might differently affect their fates in tissues.

Keywords Vaccenic and elaidic acid · β-Oxidation · Mitochondria · Carnitine palmitoyltransferase · Peroxisomes · Gene expression

Abbreviations

ACO	Acyl-CoA oxidase
ACS	Acyl-CoA synthetase
BSA	Bovine serum albumin
CPT	Carnitine palmitoyltransferase
FA	Fatty acid
HAD	Hydroxyacyl-CoA dehydrogenase
HMG	Hydroxymethylglutaryl (in HMG-CoA synthase)
NEFA	Nonesterified FA
PFAOS	Peroxisomal FA-oxidising system
PPAR	Peroxisome proliferator-activated receptor

Introduction

Coronary artery disease has been correlated with increased plasma LDL/HDL cholesterol ratios and apolipoprotein B levels [1, 2]. These atherosclerosis risk factors have allowed to assess the potential atherogenicity of dietary fats, particularly of partially hydrogenated vegetable oils (PHVO) processed for margarine production [3–5].

Increasing the intensity of the hydrogenation process gave rise to the formation of *trans*-FAs whose levels ranged from 1 to 60% of total FAs [6]. Elaidic acid (*trans*-9-$C_{18:1}$) may reach 30–40% and vaccenic acid (*trans*-11-$C_{18:1}$) 10% of total *trans*-FAs [7, 8]. Elaidic acid was suspected to exert atherogenic effects because the consumption of margarines rich in this isomer was associated with increased LDL cholesterol and apolipoprotein B in humans [9–11]. *Trans*-FAs are also synthesised in ruminants by biohydrogenation of ingested fats and are recovered in meat and milk fats, as well as dairy derivatives [12]. Of all the *trans*-$C_{18:1}$ isomers identified in dairy fats, vaccenic acid is the most abundant (>80%) [7, 13, 14]. Epidemiological surveys have shown that there is an increased risk of developing coronary heart disease with diets enriched in PHVO, compared to fats of ruminant milk, meat and derivatives [15–17]. However in hamsters fed triglycerides containing *trans*-FAs, plasma LDL/HDL cholesterol ratios increased more with vaccenic than with elaidic acid [18]. Yet with the same animal model, the hypercholesterolemic effect of PHVO was recently demonstrated not to directly depend on the presence of elaidic or vaccenic acid [19].

To date, studies aimed at examining atherogenic fats have failed to directly ascribe to *trans*-FAs negative effects on lipoprotein composition and/or vessel wall structure. Indeed, the fates and properties of elaidic or vaccenic acid may be greatly altered, for instance, by the beneficial presence of FAs contained in the associated fats of diets, as n-3 polyunsaturated FAs or conjugated linoleic acid derived from vaccenic acid [20, 21]. The fact that versatile experimental models, atherosclerosis markers and dietary fat blends provide inconsistent results, prompted us to use ex vivo experimental models exposed to pure *trans*-FAs. In these assays performed in rats with different cell extracts, our goal was to determine whether vaccenic acid exhibits the same biochemical fates and properties as elaidic acid. If these *trans*-FAs exert singular biological effects, a necessity was that they are weakly, and possibly differentially, *β*-oxidised by cells. The present study was then devoted to reactions promoting complete or partial degradation of $C_{18:1}$ isomers in whole cells, mitochondria and peroxisomes. The effects of both *trans*-FAs on the gene expression of FA-oxidation-related proteins were also investigated in cultured hepatocytes. Elaidic and vaccenic acids were compared in parallel with oleic acid (*cis*-9 isomer) and *cis*-11-$C_{18:1}$, respectively. The study was mainly focussed on cell activities of liver whose pivotal role in the re-distribution of ingested lipids to the other organs is achieved via lipoprotein secretion. Rats received a common standard diet, instead of diets enriched in the mentioned isomers, to prevent specific effects on enzyme activities through selective incorporation in membranes [22, 23].

Experimental Procedure

Chemicals

Oleic (*cis*-9-$C_{18:1}$), elaidic (*trans*-9-$C_{18:1}$), *cis*-11-octadecenoic (*cis*-11-$C_{18:1}$) and vaccenic (*trans*-11-$C_{18:1}$) acids were purchased from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C]oleic acid was obtained from Amersham Biosciences Europe (Saclay, France). The other [1-^{14}C]isomers were specifically prepared by CEA (Gif sur Yvette, France) from commercial unlabelled FAs and $^{14}CO_2$ using procedures described in [24]. Radiochemical purity (>98%) of [1-^{14}C]labelled compounds was determined by RP-HPLC (Zorbax SB C18; acetone/(methanol/water/acetic acid, 50:50:1, by vol), 60:40, by vol) and TLC (Silicagel Merck 60F254, pentane/diethylether/acetic acid, 80:20:0.1, by vol). They were all stored in chloroform/ethyl alcohol (50:50, by vol) at −30 °C. Evaporation of solvents under nitrogen was followed by the saponification of FA with NaOH or KOH for assays with whole cells or intracellular organelles, respectively, and their binding to essentially FA-free bovine serum albumin (BSA). These preparations were added to the other components of media immediately prior to incubation. L-[*methyl*-^{3}H]carnitine was from Amersham. BSA, collagenase (type I) and other biochemicals were from Sigma. Methylene chloride, 2,4,6-collidine, ethyl chloroformate and tetrahydrofuran, supplied by Aldrich Chemical Co. (Milwaukee, WI), were used for acyl-CoA synthesis [25]. Concentrations of synthesised acyl-CoAs were determined through their respective molar extinction coefficients at 260 nm and correction based on their 232/260 nm ratios, relative to those with pure products [26–28].

Animals

Official French regulations (N° 87848) for the use and care of laboratory animals were followed throughout and the experimental protocol was approved by the local ethic committee for animal experimentation (N° BL0612). Male Wistar rats were purchased from Janvier (Le Genest St Isle, France). They were kept at 23 °C in a light-controlled room (light period fixed between 08:00 am and 08:00 pm). They had free access to tap water and were fed a standard laboratory chow (ref AO4 from UAR, Epinay-sur-Orge, France) containing 58.7% carbohydrate, 17% protein, and 3% fat (palmitic, stearic, oleic and linoleic acids representing 8.7, 1.7, 26.7 and 48.3%, respectively, of the total FA mass). When rats were 7–8-week-old (250–300 g), they

were fasted for ~18 h, anaesthesised with isoflurane and killed by exsanguination at 08:00 am.

Activity Rate Measurements

All the biochemical activity measurements were previously carried out with increasing substrate concentrations, but the concentration adopted for each experimental procedure was selected among those giving rise to the increasing part of activity curves.

FA Oxidation by Tissue Slices

Gastrocnemius muscle, heart and liver tissues were cut with a scalpel blade on an ice-cooled glass plate in slices of ~0.5 mm in thickness, divided into strips of ~2 × 1 mm (1 to 1.5 mm^3 volume) in Krebs-Henseleit buffer consisting of 118 mM NaCl, 4.7 mM KCl, 1 mM KH_2PO_4, 1.2 mM $MgSO_4$, 0.5 mM $CaCl_2$, and 25 mM $NaHCO_3$, pH 7.4, rinsed five times in the same medium and blotted on absorbent paper. Tissue strips (0.2 g each) were placed on a circular glass filter (16 mm diameter) with 0.4–0.6 mm diameter pores, limited in periphery by a glass ring (2 mm in height). This assembly was supported by 10-mm high glass legs that allowed the incubation medium to be conveniently stirred with a magnetic bar. The device was inserted in a 30-mm high beaker containing 2.5 mL of Krebs-Henseleit buffer with 1 mM L-carnitine. The reaction was started by the injection of 1 mL of [1-^{14}C]FA (84 GBq/mol) with BSA (0.4 mM and 50 μM of final concentration, respectively) between the device and the beaker, which allowed the total medium to nearly cover the tissue strips. The whole system was placed into a 50-mL plastic bottle under 95% O_2, 5% CO_2 atmosphere. After 1 h of incubation at 37 °C, the reaction was stopped by addition of 1.5 mL of 25% (w/v) perchloric acid, which precipitated proteins, FAs still unesterified, acyl-CoAs and acylcarnitines. A small glass ladle (10 mm diameter) containing 0.4 mL of Hyamine (Packard, Meriden, CT) and fitted to a rubber cork was immediately introduced into the plastic bottle to trap the $^{14}CO_2$ released from the acidified medium. After 2 h, the media were filtered using Millipore filters (0.45 μm pore size) under very low pressure and 1 mL of each filtrate containing the acid-soluble products (ASP; short metabolites issued from FA oxidation) was added to 3.5 mL of Ultima Gold XR (Packard) for radioactivity measurements. The radioactivity of $^{14}CO_2$ trapped into Hyamine was counted in the same scintillation mixture. The radioactivity of ASP + CO_2 allowed to determine the number of FA molecules whose β-oxidation reactions affected at least the labelled carboxylic end of each $C_{18:1}$ isomer studied.

FA Oxidation by Liver Cells

Hepatocytes were isolated through a two-step collagenase perfusion as in [29]. Cell viability was assessed by trypan blue exclusion and suspensions with viability lower than 85% were discarded. FA oxidation was performed in 1 mL of Krebs-Henseleit buffer containing 1 mM L-carnitine, 0.4 mM [1-^{14}C]FA (16 GBq/mol) and 0.2 mM BSA. The reaction was initiated by the addition of 0.8 million cells (about 1.76 mg protein) per assay and was stopped after 30 min with 3 mL of 10% (w/v) perchloric acid. Radioactivity of CO_2 and ASP was measured as indicated for liver slices. Oxygen consumption with FAs was measured polarographically at 30 °C using a Clark-type oxygen-electrode (Yellow Springs Instruments, Yellow Springs, OH) in 1.6 mL Krebs-Henseleit buffer with 2 mM malate. After addition of 0.8 million cells, 1 mM L-carnitine was first injected to consume endogenous FAs. After 3 min, a volume of 50 μL of a mixture containing each $C_{18:1}$ isomer and BSA was added both at 0.2 mM of final concentration. Respiration rates were corrected from control values obtained in the absence of exogenous FA.

FA Oxidation by Liver Homogenates

Liver pieces were homogenised by manual rotation of a Teflon pestle in an ice-cooled Potter–Elvehjem apparatus [30] and diluted (1:40, w/v) in a chilled mixture of 0.25 M sucrose, 2 mM EGTA and 10 mM Tris/HCl, pH 7.4. Mitochondrial and peroxisomal β-oxidation of labelled FAs was performed in two specific media as indicated in [30, 31]. Liver homogenate (2.5 mg of wet tissue) was added to each vial containing 1 mL of either medium. The reaction was initiated by the addition of 50 μM [1-^{14}C]FA (55 GBq/mol) with 35 μM BSA. After 30 min, CO_2 and ASP were collected after addition of 3 mL of 10% (w/v) perchloric acid and their radioactivity was measured as described above for liver slices. For respiration measurements, a volume of freshly prepared homogenate corresponding to 2.5 mg of fresh liver was injected in 1.6 mL of medium containing 130 mM KCl, 25 mM HEPES, 0.1 mM EGTA, 3 mM $MgCl_2$, 10 mM KP_i, 1 mM ATP, 50 μM CoA, 0.5 mM DTT, 2 mM malate. L-carnitine and ADP (1 and 2 mM, respectively) were then added. Control oxygen consumption was recorded for 3 min, then a 50 μL-volume of a mixture containing each $C_{18:1}$ isomer with BSA (both at 0.2 mM of final concentration) was added. Final respiration rates were corrected from control values, as for hepatocytes.

FA Oxidation by Mitochondrial Fractions

The procedure of mitochondrial isolation is reported in [30] using a medium containing 1% FA-free BSA to bind free

FAs released during the cell disruption. The protein content of mitochondrial fractions cleared from BSA was performed using the bicinchoninic acid procedure [32]. The purity of these fractions was checked through activity of enzymes specific to mitochondria, peroxisomes and microsomes, as detailed in [33]. Oxidation of labelled FAs was determined in the presence of 0.3 mg of mitochondrial protein as in [34] with 50 μM [1-^{14}C]FA (66 GBq/mol) and 35 μM BSA. The reaction was stopped after 8 min by addition of 4 mL of 10% (w/v) perchloric acid and the radioactivity of CO_2 and ASP was measured as above. Oxygen consumption was recorded in the presence of 1.2 mg of mitochondrial protein with 10 μM $C_{18:1}$ isomers as NEFAs in the medium used for liver homogenates, or as acyl-CoAs in a similar medium devoid of $MgCl_2$, ATP and CoA. Respiration rates were corrected from control values obtained in the presence of carnitine before the injection of NEFAs or acyl-CoAs.

FA Oxidation-Related Enzyme Activities

Acyl-CoA synthetase (ACS) activity was measured in 0.5 mL of medium containing 0.35 M Tris (pH 7.4), 8 mM $MgCl_2$, 5 mM DTT, 10 mM ATP, 0.1 mM CoA, Triton WR 1339 (1 mg/mL), 10 μM [1-^{14}C]FA (1 TBq/mol) at 25 °C, in the presence of 40 μg mitochondrial or 8 μg microsomal (prepared as in [33]) protein. The reaction was stopped after 1 min with 1.5 mL of 10% perchloric acid (w/v). Unreactive NEFAs were removed by three extractions with 2 mL of diethylether. The aqueous medium was then neutralised with 25% Tris (w/v) to solubilise acyl-CoAs, and the associated radioactivity was measured in Ultima Gold XR. The transfer of isomers onto carnitine *via* carnitine palmitoyltransferase (CPT) I and II activities was studied using NEFAs (that require to be previously esterified to CoA through mitochondrial ACS activity) or directly using acyl-CoAs. CPT I activity was measured with 80 μM NEFAs or acyl-CoAs in the presence of 25 or 50 μM BSA, respectively, and CPT II with 50 μM NEFAs or acyl-CoAs, both in the absence of BSA. The common point of these assays carried out in 1 mL of medium in the presence of ~0.3 mg of mitochondrial protein was the preincubation time of 2 min before addition of 0.4 mM L-[methyl-^{3}H]carnitine (92.5 GBq/mol). The complete procedure with extraction of acylcarnitines has been detailed in [30].

Peroxisomal FA Oxidation-Related Activities

To complement the peroxisomal FA oxidation measurements obtained above with whole liver homogenates, the activity of the peroxisomal FA oxidising system (PFAOS), that is a key-sequence of the peroxisomal FA oxidation pathway, was achieved through the CN^--insensitive acyl-CoA-dependent NAD^+ reduction in the presence of 20 μM $C_{18:1}$-CoA isomers as in [35]. Peroxisome-enriched fractions used for greater accuracy were prepared from liver homogenised in a sucrose medium with 1% BSA, centrifuged between 12,000 and 18,000*g* for 10 min, and rinsed two times in the absence of BSA.

Gene Expression

Hepatocytes isolated as above were preincubated in William Medium E (PAN-Biotech GmbH, Aidenbach, Germany) containing 10% (v/v) fetal bovine serum and 1% (v/v) antibiotic antimycotic solution (Sigma Chemical, Co.) in water-saturated atmosphere (5% CO_2, 95% air) for ~3 h at 37 °C, in dishes of 60 mm in diameter (~3×10^6 cells per dish). The attached cell monolayer was gently washed with 3 mL of fresh William Medium E medium without fetal bovine serum to remove the unattached and non-viable cells. The incubation was started with the addition of 4 mL of William Medium E containing 100 μM $C_{18:1}$ isomer bound to 50 μM BSA and 1% antibiotic antimycotic solution, in a water-saturated atmosphere (5% CO_2, 95% air) at 37 °C. After 24 h of incubation, total mRNA of the hepatocyte monolayers from three distinct dishes were extracted using Tri-Reagent (Euromedex, Souffelweyersheim, France) as in [36] and were reverse-transcripted using an Iscript cDNA kit (Bio-Rad, Marnes-la-Coquette, France). Real-time PCR was performed as already described [37] in a 96-well plate using an iCycler iQ (Bio-Rad) from 2.5 ng cDNA for samples or 25, 2.5, 0.25 and 0.025 ng for standards). Primer pairs were designed using 'Primers!' software and were synthesised by MWG-Biotech AG (Ebersberg, Germany). Table 1 details the sequences of the forward and reverse primers, the melting temperatures of these primers and the length of PCR products. Data were analysed using the Bio-Rad and Microsoft Excel software. The relative gene expression was calculated from standard curves for each gene after normalisation with β-actin.

Statistics

Differences between groups were determined performing repeated measures of ANOVA followed by the Tukey–Kramer multiple comparison post-hoc test using GraphPad Instat 3.1 software. Differences were considered significant at $P < 0.05$.

Results

Entry of Isomer $C_{18:1}$ Chains into Mitochondria

This entry of FAs into mitochondria is mediated by CPT I whose activity depends on acyl-CoA formation by ACS.

Table 1 Primers for real-time PCR

ACO acyl-CoA oxidase, *CPT* (carnitine palmitoyltransferase) I and II, *HAD* hydroxyacyl-CoA dehydrogenase, *HMG* (hydroxymethylglutaryl)-CoA synthase, *PPARα* peroxisome proliferator-activated receptor α

Activity rates of ACS in microsomes and mitochondria towards oleic acid were found to be 23.0 ± 3.5 and 5.1 ± 1.2 nmol/min per mg protein, respectively, and these values did not exhibit, in either cellular fraction, statistical differences towards the other $C_{18:1}$ isomers assayed (unpublished data). Figure 1a shows that activity rates of the ACS-CPT I sequence with NEFAs were comparable with all $C_{18:1}$ isomers. Strict CPT I activity with vaccenoyl-CoA was 45% lower than with elaidoyl-CoA or oleoyl-CoA (Fig. 1b). CPT II activity measured with NEFAs (Fig. 1c) or acyl-CoAs (Fig. 1d) was ~28% greater with vaccenic acid than with elaidic acid. CPT II exhibited opposite effects between both *cis*-isomers when they were used as NEFAs (*cis*-9 > *cis*-11) or acyl-CoA (*cis*-11 > *cis*-9) (Fig. 1c vs. 1d).

Oxidation Related to the Carboxylic End of $C_{18:1}$ Isomers

Slices of skeletal muscle and heart, both energy-demanding organs, exhibited equivalent capacities to oxidise the four $C_{18:1}$ isomers, as assessed by the release onto CO_2 + acid-soluble products (ASP) of the radioactivity initially hold by

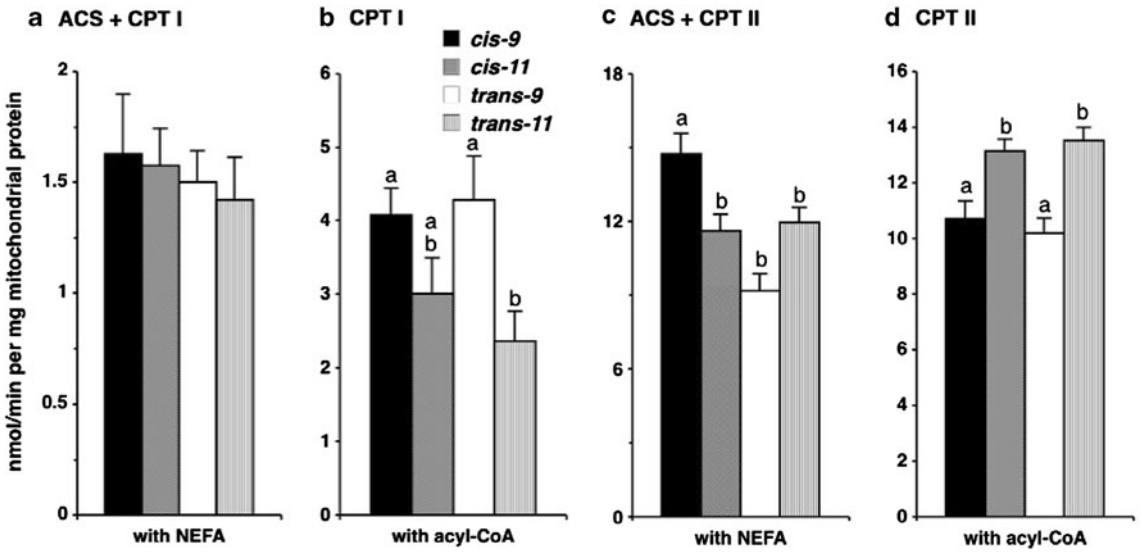

Fig. 1 Carnitine palmitoyltransferase (CPT) I and II activities in liver mitochondria with $C_{18:1}$ isomers used as nonesterified fatty acids (NEFA) requiring the previous action of acyl-CoA synthetase (ACS), or directly as acyl-CoAs. Concentrations of either substrate in the final media were 80 and 50 μM for CPT I and CPT II, respectively. All results are expressed as nmol of $C_{18:1}$ isomers in either form bound to carnitine/min per mg of mitochondrial protein. *T-bars* show SEM ($n = 4$). For each series of incubation, values with different *letters* on columns statistically differ at $P < 0.05$

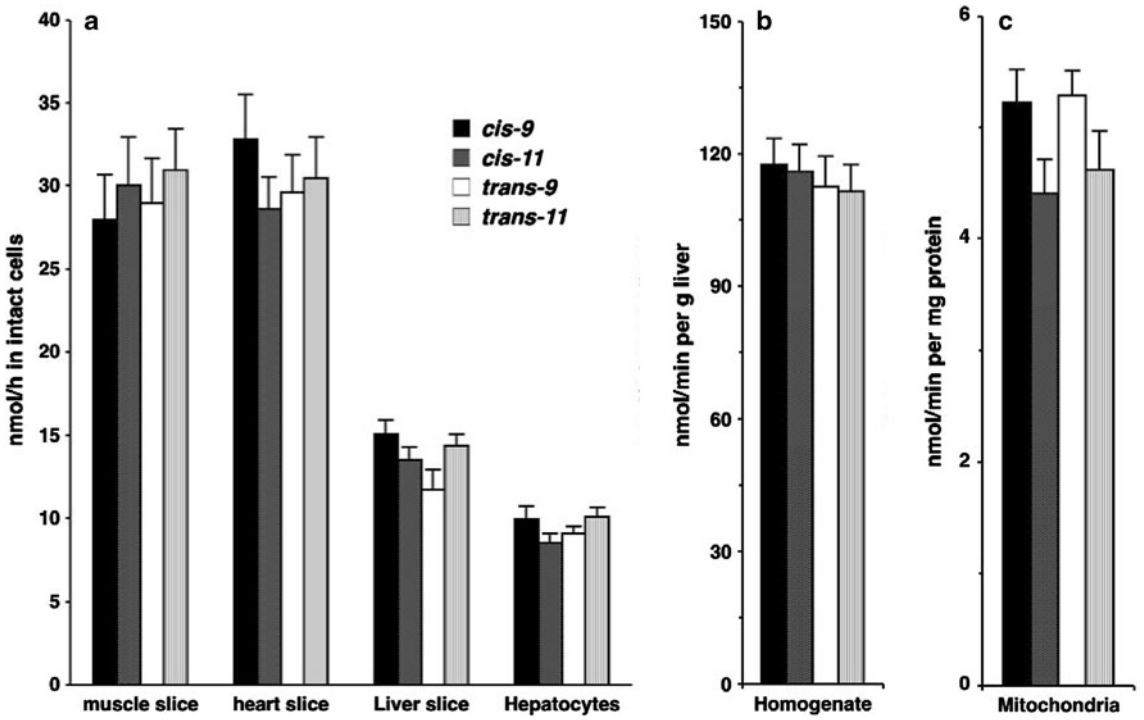

Fig. 2 Carboxylic end β-oxidation of $C_{18:1}$ isomers. The number of molecules involved was expressed per g of gastrocnemius muscle, heart and liver slices, or per mg of hepatocyte protein after 1 h of incubation in the presence of 0.4 mM [1-^{14}C]$C_{18:1}$ isomers. The results with liver homogenates and mitochondrial fractions were expressed per min per g liver and mg mitochondrial protein, respectively, after incubation in the presence of 50 μM [1-^{14}C]$C_{18:1}$ isomers. *T-bars* show SEM ($n = 4$). For each series of experiments performed with a same tissue or tissue extract, values found between the isomers tested did not differ ($P > 0.05$) as the statistic test used

the carboxylic end of FAs (Fig. 2a). This denotes that a same number of FA molecules entered into mitochondria have at least undergone the first β-oxidation cycle. This is qualitatively worth for liver slices and hepatocytes, but at 55 and 70% lower amplitudes, respectively, than for muscle slices (Fig. 2a). As regards the activity exerted by FA oxidation-related organelles in liver homogenates, i.e. after cell disruption, or in liver mitochondria, no statistical difference in FA oxidation rates was observed between the four isomers (Fig. 2b, c). Figure 3 shows that vaccenic acid was ~25% more oxidised by liver peroxisomes than the other $C_{18:1}$ isomers on the basis of the radioactivity released from labelled carboxylic end by liver homogenates (carnitine-independent FA oxidation). In partially purified peroxisomal fractions, PFAOS activity rates were 25% greater with vaccenic and elaidic acid than with their *cis*-isomers.

Oxidation Related to the Whole Isomer $C_{18:1}$ Molecules

Mitochondrial oxygen consumption was stimulated with FA substrates when the respiratory chain was activated through dehydrogenation of metabolites originating from β-oxidation reactions (as acetyl moieties) and concomitant ADP phosphorylation. As the number of acyl chains entering the β-oxidation process was the same in each tissue for all the isomers assayed (Fig. 2a) and slightly different in liver mitochondria (Fig. 2c), respiration rates on the isomers could provide further information about the amount of acetyl moieties successively released from each FA chain by β-oxidation. Figure 4 shows that oxygen consumption rates by hepatocytes, liver homogenates and isolated mitochondria were at least 50% lower with *trans*- than with *cis*-$C_{18:1}$ isomers used as NEFAs (panels a, b, c). With liver mitochondria and acyl-CoAs that are direct substrates for CPT I, respiration rates were comparable with vaccenoyl, oleoyl and *cis*-11-octadecenoyl chains, but 33% lower with elaidoyl chain (Fig. 4d).

Hepatocyte FA Oxidation-Related Gene Expression

Long- and very-long chain FAs are known to exert regulatory effects on FA metabolism-related pathways. Here we studied the effects of the four $C_{18:1}$ isomers on the expression levels of FA oxidation-related proteins in cultured hepatocytes (already depleted from carnitine during the isolation procedure). When hepatocytes were incubated in the absence of carnitine, gene expression of CPT I, HAD and hydroxymethylglutaryl-CoA (HMG-CoA) synthase was statistically increased with *cis*-9, *cis*-11 and *trans*-9-$C_{18:1}$

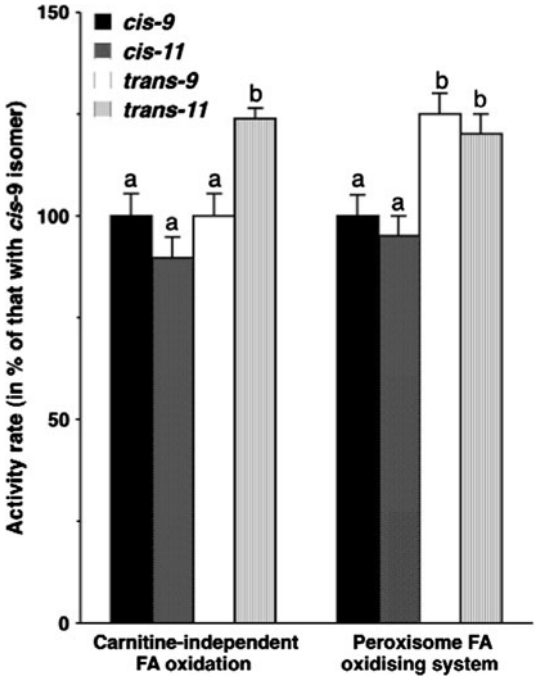

Fig. 3 Peroxisomal activities with $C_{18:1}$ isomers as substrates in rat liver. Results are expressed as percentages ± SEM ($n = 3$) by reference to values obtained with *cis*-9 isomer (oleic acid). The carnitine-independent FA oxidation rate was measured in liver homogenates with unesterified [1-^{14}C]$C_{18:1}$ isomers and was 38 ± 2 nmol/min per g wet liver with oleic acid. The NADH production by the peroxisomal FA oxidising system (PFAOS) was recorded in partially purified peroxisomal fractions with CoA-esterified $C_{18:1}$ isomers and was 0.20 ± 0.01 μmol/min per g wet liver with oleoyl-CoA. For each activity, values with different *letters* on columns statistically differ at $P < 0.05$

isomers, but not with vaccenic acid (Fig. 5a, c, d). In the presence of carnitine, increased expression levels were still observed for CPT I, particularly with oleic and elaidic acids (Fig. 5a), but were absent for HAD or of very low amplitude for HMG-CoA synthase with the effective isomers (Fig. 5c, d).

Discussion

Most of our observations related to β-oxidation and obtained with cell extracts in the presence of pure isomers reflect only part of the biochemical cell actuality. The studied reactions should be also considered in the context of other FA-related metabolic pathways. Under these ex vivo conditions, the slightly shifted location of the *trans*-double bond in vaccenic versus elaidic acid appeared to have unequal consequences for both mitochondrial and peroxisomal FA oxidation activities and FA oxidation-related gene expression.

Entry of FA Chains into Mitochondria

Activation of NEFAs by CoA is a prerequisite before the carnitine-dependent activities allow acyl chains to cross the mitochondrial inner membranes. Comparable acyl-CoA synthetase activities with the four isomers in the presence of responsible organelles fully support previous results obtained with *cis*- [38] and *trans*- [39] isomers under other experimental conditions. This suggests that CPT I was

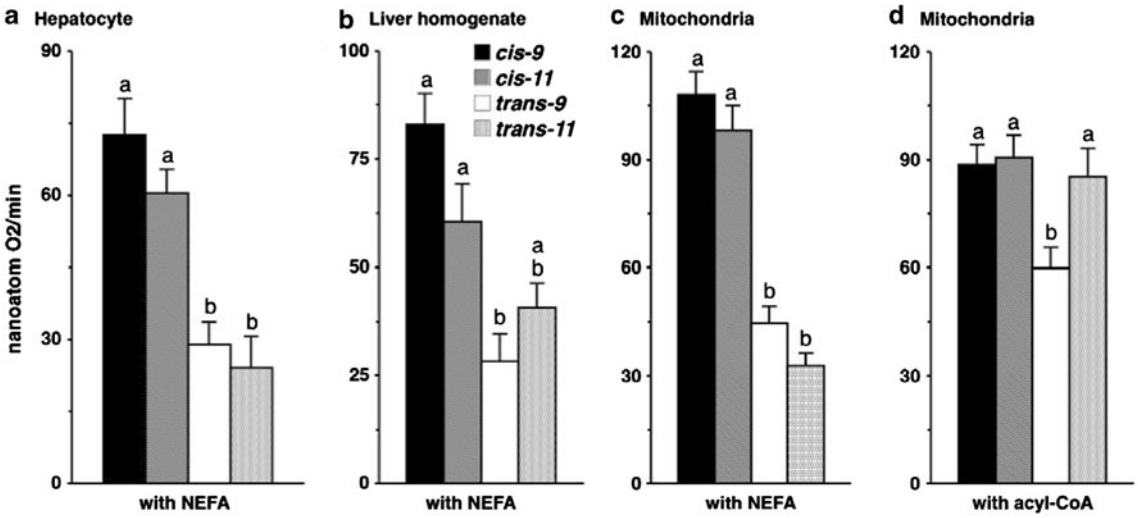

Fig. 4 Respiration on $C_{18:1}$ isomers in hepatocytes, liver homogenates and mitochondria. The isomers were used as nonesterified fatty acids (NEFA) at 0.2 mM, 20 and 10 μM concentrations with hepatocytes, liver homogenates and mitochondria, respectively, and as acyl-CoA at 10 μM concentration with mitochondria. The results are expressed as nanoatom O_2/min per mg hepatocyte protein, per g homogenised liver and per mg mitochondrial protein. *T-bars* show SEM ($n = 4$). For each series of incubation, values with different *letters* on columns statistically differ at $P < 0.05$

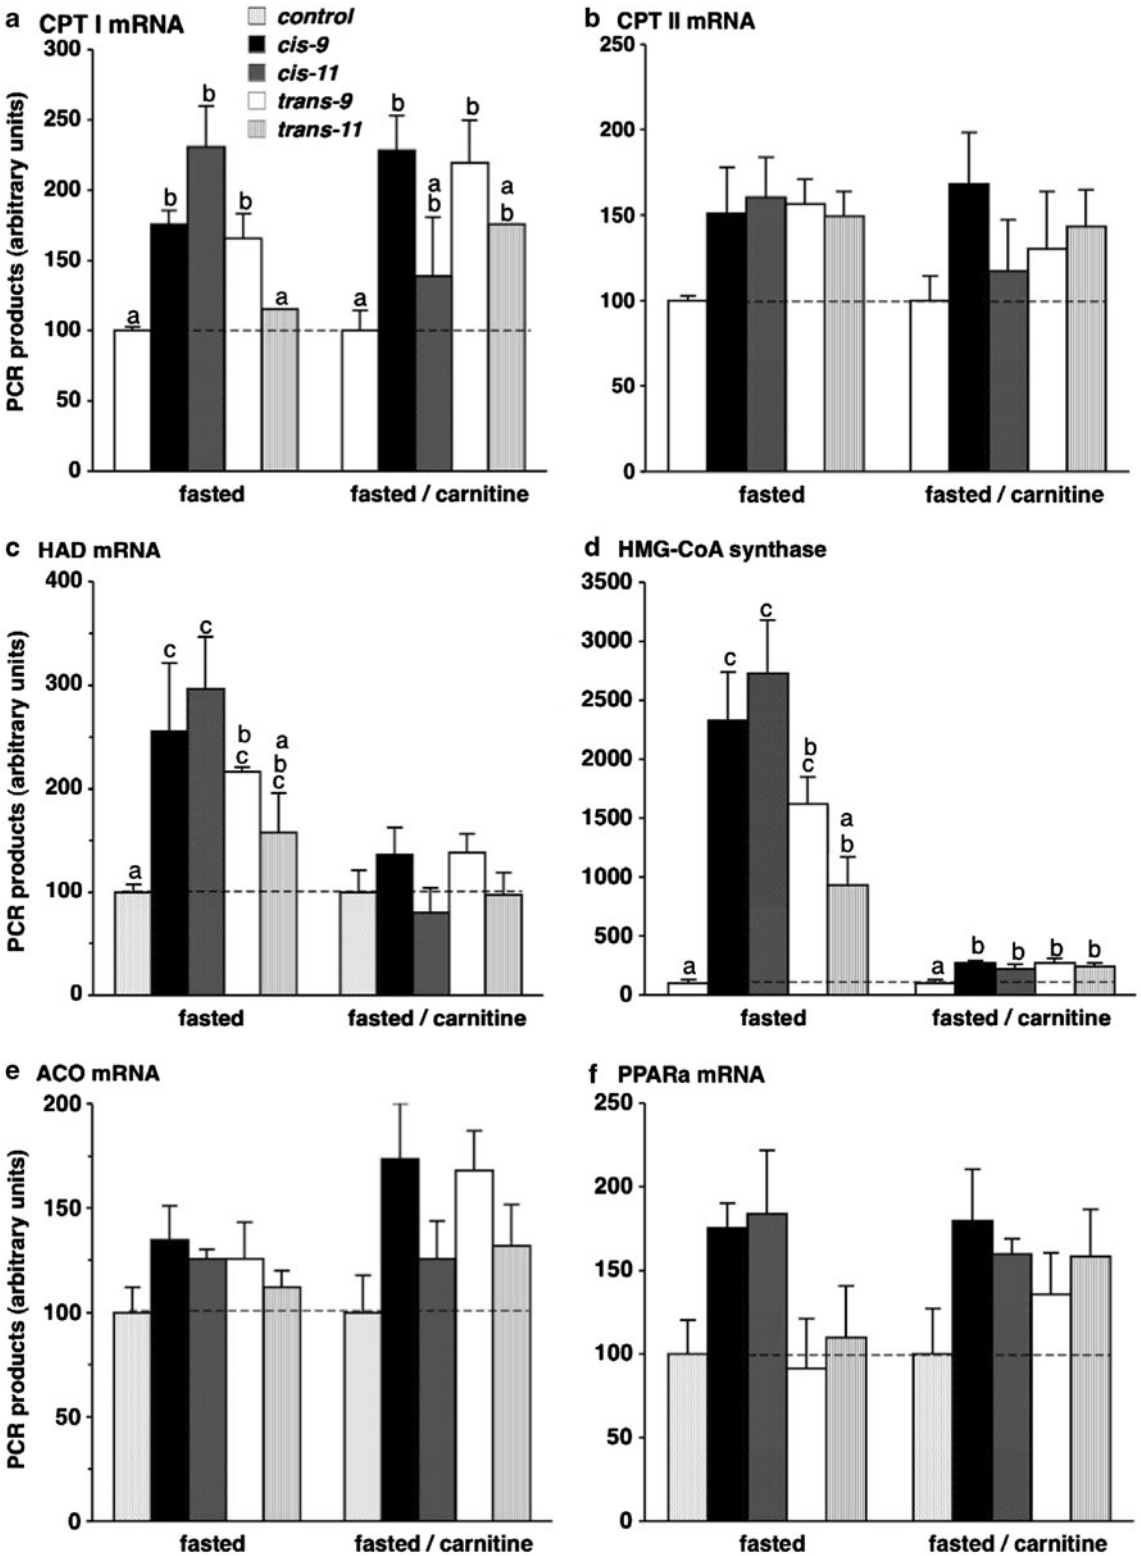

Fig. 5 mRNA levels of β-oxidation-related proteins after incubation of fasted rat hepatocytes with $C_{18:1}$ isomers in the absence or presence of carnitine. Arbitrary units $\pm$ SEM with $n = 3$ (different hepatocyte culture dishes) are percentages expressed by reference to control assays (*dotted lines*) performed in the absence of any $C_{18:1}$ isomer (=100 for each series of experiments). Different *letters* on columns denote statistically different results at $P < 0.05$

provided, through our experimental procedures, with equal amounts of $C_{18:1}$-CoA isomers. However in whole cells, NEFAs and acyl-CoAs are very largely bound to specific FA- and acyl-CoA binding proteins, respectively, while unbound forms remain in the nanomolar range concentrations [40, 41]. At lowest concentrations assayed, ACS/CPT I sequence, strict CPT I and CPT II were found to exhibit comparable activities with any of isomers (unpublished data). This would allow an identical number of acyl chains, bound to carnitine, to cross the mitochondrial inner membranes and to equally provide, bound to CoA, the actual β-oxidation reactions. Nevertheless, the requirement of other cell metabolic pathways for acyl-CoAs could limit the availability of these substrates for the CPT I reaction. Indeed, CPT I activity rates were comparable with elaidoyl- and oleoyl-CoA in isolated mitochondria (Fig. 1b), but the data obtained with permeabilised hepatocytes [42] showed that elaidic acid was transferred less to carnitine that oleic acid. This suggests that, in whole cells, other metabolic pathways could have differential affinities for elaidic and vaccenic isomers, with direct consequences on the respective in situ CPT I action. However the data obtained with isolated mitochondria show that elaidic and vaccenic acids exhibit clear different specificities for either CPT I or II activity (Fig. 1b, d).

β-Oxidation Reaction

In muscle, heart and liver cells, the same number of $C_{18:1}$ isomer molecules losing their first carbon pair by β-oxidation totally agrees with other data obtained only with [1-^{14}C] labelled oleic and elaidic acid in vivo [43–45] and in vitro [46]. In our study, the four isomers having crossed mitochondrial membranes, through comparable carnitine-dependent activity rates, were then equivalent substrates for long-chain acyl-CoA dehydrogenase (LCAD) both in whole cells and liver extracts. With equal numbers of $C_{18:1}$ chains entering the mitochondrial β-oxidation reactions, oxygen consumption rates due to dehydrogenations connected to the respiratory chain informed about the extent to which each fatty chain was β-oxidised. This technique shows that respiration in liver cells, homogenates and mitochondria was always lower with *trans*-isomers (elaidic acid > vaccenic acid) than with *cis*-isomers, all used as NEFAs. It was, however, unexpected that mitochondrial respiration rates with vaccenoyl-CoA and both *cis*-acyl-CoAs were to the same extent and ~30% lower with elaidoyl-CoA. Such a difference has been previously observed, but only between oleoyl- and elaidoyl-CoA, by Yu et al. [45]. These authors showed that the major β-oxidation intermediate of elaidic acid, 5-*trans*-tetradecanoyl-CoA, reduces the β-oxidation progress because of its low-affinity for LCAD. Under comparable experimental conditions, our results suggest that the formation of *trans*-intermediates occurring during the β-oxidation of vaccenoyl-CoA has no negative effect on the mitochondrial β-oxidation activity. On the whole, our data show that vaccenoyl-CoA is a worthy β-oxidation substrate in isolated mitochondria and peroxisomes. This conclusion does not exclude that, in intact cells, acyl-CoAs can be diverted towards other metabolic pathways.

Effect of $C_{18:1}$ Isomers on β-Oxidation-Related Gene Regulation

In hepatocytes cultured in the absence of carnitine, it is worth underlining the increased expression of CPT I and more particularly of HAD and HMG-CoA synthase, with the $C_{18:1}$ isomers in the order *cis*-11 ≥ *cis*-9 ≥ *trans*-9, relative to controls, but also the lack of effect with vaccenic acid. In the media devoid of carnitine, very few intermediates of mitochondrial β-oxidation were produced, which limits to acyl chains and derivatives outside mitochondria a role in the transcription mechanisms. Under these conditions, the respective capacity of isomers to bind transcription factors, such as CoA-derivatives [47], appears to differ according to the position and geometry of the double bond, with weak or null efficiency for the *trans* isomers whose the double bond was in 9 or 11 position, respectively. Because PPARα expression was unaffected by any of isomers, the up-regulation of CPT I, HAD and HMG-CoA synthase might be due to the ability of acyl-CoAs to bind PPARα at basal level in cells [47, 48]. However in the presence of NEFAs, CPT I was also demonstrated to be up-regulated through a PPARα-independent mechanism [49]. Such mechanisms could also apply to our culture assays, in which the isomers transferred into cells were still under free form and also partially esterified to CoA. In hepatocytes cultured in the presence of carnitine, isomers were further esterified as acylcarnitines [50], which allowed part of them to enter the β-oxidation pathway. The weak levels of HAD and HMG-CoA synthase expression with *cis*-9, *cis*-11 and *trans*-9 isomers could be then due to the loss of induction capacities of active isomers when their concentrations decreased under limit values. Under the artificial conditions of culture hepatocytes, vaccenic acid did not appear to exert the same induction effect on FA oxidation-related genes as elaidic acid.

On the whole, a number of FA oxidation related-parameters with vaccenic versus elaidic acid did not match each other both in whole cells and isolated organelles. The data suggest that vaccenic acid is a better oxidation substrate than elaidic acid with subcellular organelles related to FA β-oxidation, and it does not affect FA oxidation-related gene expression. Within cells, vaccenic and elaidic acid could also enter other metabolic pathways and could

be, for example, esterified into membranes or desaturated as conjugated *cis*-9, *trans*-11 linoleic acid [20, 21].

Abstract The use of the matrix 9-aminoacridine has been recently introduced in matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry analysis of both anionic and cationic phospholipids. In the present study, we take advantage of this technique to analyze the lipids of porcine olfactory mucosa and a membrane fraction enriched in cilia. Thin-layer chromatography (TLC) and ^{31}P-NMR analyses of the lipid extracts were also performed in parallel. MALDI-TOF-MS allowed the identification of lipid classes in the total lipid extract and individual lipids present in the main TLC bands. The comparison between the composition of the two lipid extracts showed that: (1) cardiolipin, present in small amount in the whole olfactory mucosa lipid extract, was absent in the extract of membranes enriched in olfactory cilia, (2) phosphatidylethanolamine species were less abundant in ciliary than in whole epithelial membranes, (3) sulfoglycosphingolipids were detected in the lipid extract of ciliary membranes, but not in that of epithelial membranes. Our results indicate that the lipid pattern of ciliary membranes is different from that of whole-tissue membranes and suggest that olfactory receptors require a specific lipid environment for their functioning.

Introduction

Inhalation of odors across the surface of the olfactory epithelium of the animal nose activates the olfactory signaling cascade, which involves the binding of ligands to receptors localized on primary sensory cells, the olfactory sensory neurons (OSN). The OSN are bipolar neurons of the pseudostratified olfactory epithelium, having a thin sensory axon extending to higher brain regions and a single dendrite that ends with a knob, from which long fine cilia protrude, directly projected into the mucous of the olfactory epithelium.

Olfactory cilia are the sites of the sensory transduction apparatus. The binding of odorants to G-protein-coupled seven-transmembrane olfactory receptors (OR) activates the $G\alpha_{olf}$ subunit of a specific heterotrimeric G-protein complex, which stimulates the enzyme adenylcyclase III (AC3) to synthesize the second messenger molecule cyclic-adenosine-monophosphate (cAMP). cAMP in turn activates the opening of cyclic-nucleotide-gated ion channels present on the plasma membrane, generating electrical signals in the primary sensory axons [1, 2].

Each OSN expresses only one type of OR out of a repertoire of about 1,000 [3]. Numerous OSN expressing the same OR are dispersed in the olfactory mucosa, while their axons converge to form glomeruli in the olfactory bulb, where a precise distribution or map of odors exists.

It is known that several proteins involved in the sensory signaling cascade are compartmentalized in specialized membrane subdomains, called lipid rafts, which are expected to be spread in the olfactory ciliary membranes [4, 5].

In the lipidomics era it is surprising to find out that only a few analyses of the lipids of olfactory mucosa have been reported in the literature. Old reports described the lipid composition of plasma membranes isolated from bovine [6] and rat [7] olfactory mucosa, while no data are available either on pig olfactory mucosa in toto, or on isolated olfactory cilia.

It would be helpful to have an overview of the specific set of lipids in the sensory cilia in order to investigate the possible functions of lipids in signal transduction, adaptation, xenobiotic metabolism and OSN maturation.

The present study provides the first general characterization of the membrane lipids of the neuroepithelial olfactory mucosa covering pig turbinates and information on lipids associated with the specialized membrane domain of pig olfactory cilia.

Materials

The nasal cornets of pig were kindly provided immediately after sacrifice by the slaughterhouse in Ruvo di Puglia (Bari, Italy). The Cyclic AMP [^{3}H] assay system was purchased from Amersham (Freiburg, Germany). Odorants (Sigma–Aldrich, St. Louis, MO) were usually prepared as stock solutions in ethanol or DMSO. All organic solvents used were commercially distilled and of the highest available purity (Sigma–Aldrich). Plates for TLC (Silica gel 60A, 10 × 20 cm, 0.25 mm thick layer), obtained from Merck (Darmstadt, Germany), were washed twice with chloroform/methanol (1:1, by vol) and activated at 120 °C before use. The following lipid standards were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL): 1,2-dimyristoyl-*sn*-glycero-3-phosphate (sodium salt) (14:0 PtdOH), 1,2-dimyristoyl-*sn*-glycero-3-phospho-L-serine (sodium salt) (14:0 PtdSer), 1,2-dipalmitoleoyl-*sn*-glycero-3-phosphoethanolamine (16:1 PtdEtn), 1,2-dioleoyl-*sn*-glycero-3-phospho-(1′-myo-inositol) (ammonium salt) (18:1 PtdIns), 1′,3′-bis [1,2-dimyristoyl-*sn*-glycero-3-phospho]-*sn*-glycerol (sodium salt) (14:0 Ptd_2Gro), 1,2-dimyristoleoyl-*sn*-glycero-3-phosphocholine (14:1 (Δ9-Cis) PtdCho), 1,2-distearoyl-*sn*-glycero-3-phosphocholine (18:0 PtdCho), 1,2-di-*O*-phytanyl-*sn*-glycero-3-phosphocholine (4ME 16:0 diether PtdCho), *N*-palmitoyl-D-*erythro*-sphingosylphosphorylcholine 16:0 CerPCho (d18:1/16:0). The matrix for MALDI-TOF–MS (9-aminoacridine hemihydrate) was purchased from Acros Organics (Morris Plains, MJ).

Methods

Isolation of Membranes Enriched in Olfactory Cilia

Ciliary membranes were detached and isolated from pig olfactory epithelia as previously described [8, 9]. The pig olfactory epithelia, situated on both left and right ethmoturbinates, were carefully stripped from the underlying bone and washed in ice-cold Ringer solution (120 mM NaCl, 5 mM KCl, 1.6 mM K_2HPO_4, 1.2 mM $MgS0_4$, 25 mM $NaHCO_3$, 7.5 mM glucose, pH 7.4) plus 1 mM PMSF within 10–20 min of slaughter. All operations were carried at 0–4 °C. The olfactory cilia were detached using a calcium shock procedure, raising the calcium concentration in the Ringer solution up to 10 mM. After gently shaking (20 min at 4 °C), the deciliated epithelia were removed by centrifugation (7,000*g* for 5 min). The supernatant was collected and the pellet incubated again with the solution containing 10 mM calcium ion for 20 min. After removing the deciliated epithelia by centrifugation, the supernatants containing the detached cilia were combined. Membranes enriched in olfactory cilia were collected by centrifuging at

27,000*g* for 15 min, and resuspended in Buffer A (3 mM $MgCl_2$, 2 mM EDTA, 10 mM Tris/HCl, 1 mM PMSF, pH 7.4) with 5% glycerol. Ciliary membranes were apportioned into small volumes and saved at −80 °C. The protein concentration was determined by the Bradford method [10], with bovine serum albumin as standard.

Whole-Tissue Membrane Isolation

Pig olfactory epithelia, carefully dissected as described in the previous paragraph, were suspended in 5–7 volumes of hypotonic Ringer solution (Ringer without NaCl) and homogenized on ice with a Potter homogenizer. Cartilage fragments and large epithelia pieces were removed by low speed centrifugation followed by filtration. The filtrate was then centrifuged twice at 1,500*g* for 10 min and the pigmented pellet removed. The final supernatant was centrifuged at 27,000*g* for 20 min to generate a light yellow pellet. This pellet was suspended in 5% glycerol-containing Buffer A and stored at −80 °C.

Adenylcyclase Assay

Adenylcyclase activity was assayed according to a modified version of the method described previously [11, 12]. All assays were carried out at 37 °C. Briefly 70 µl of cilia suspension (50–100 µg protein/ml) was mixed with 360 µl of stimulating buffer containing 200 mM NaCl, 10 mM EGTA, 50 mM MOPS, 2.5 mM $MgCl_2$, 1 mM DTT, 0.05% sodium cholate, 1 mM ATP, 20 µM GTP, 1 mM IBMX buffered at pH 7.4, with or without a stimulant (200 µM odorants or 5 µM forskolin). The incubation of cilia with the stimulating buffer (15 min at 37 °C) was stopped by adding 350 µl of ice cold 10% perchloric acid. Then samples were centrifuged at 2,500*g* for 5 min at 4 °C; 400 µl of the supernatant was added to 100 µl of 10 mM EDTA pH 7.0. The samples were then neutralized by adding 500 µl of a mixture containing 1,1,2-trichlorotrifluoroethane and tri-*n*-octylamine, mixed and then three phases were obtained by centrifugation; the upper phase contained the water soluble components and was used to estimate the amount of cAMP produced during the incubation of cilia with substrates. The cAMP was determined by radioimmunoassay using an Amersham kit.

Lipid Extraction

Total lipids were extracted from membranes using the Bligh and Dyer method [13] in the presence of 0.01% DTT as antioxidant. 6 ml of methanol/chloroform (2:1, by vol) was added to a 1.6 ml membrane suspension (about 6 mg proteins). The mixture was gently shaken for 15 min and then centrifuged to collect the supernatant. The residue pellet was re-extracted by adding 7.6 ml of methanol/chloroform/water (2:1:0.8, by vol). The mixture was again shaken for 15 min and centrifuged. Then 4 ml each of chloroform and 0.2 M KCl were added to the combined supernatant extracts to obtain a two-phase system, chloroform and methanol/water (1:0.9, by vol). After complete phase separation, the lipid-containing chloroform phase was brought to dryness under argon; dried lipids were weighed, suspended in a small chloroform volume and saved at −20 °C.

Thin-Layer Chromatography

Total lipid extracts were analyzed by TLC on silica gel plates and lipids were eluted with Solvent A, chloroform/methanol/acetic acid/water (85:15:10:3.5, by vol). For 2D-analysis, the plates were developed using Solvent B, chloroform/methanol/ammonium hydroxide (65:25:5, by vol), in the first dimension, and Solvent A in the second dimension. The solvent used for separation of neutral lipids on 1D-TLC was Solvent C, hexane/ethyl ether/acetic acid (70:30:1, by vol). Individual phospholipids were identified by reference to authentic lipid standards (Sigma–Aldrich). Lipids were detected by spraying plates with 5% sulfuric acid, followed by charring at 120 °C. Additional confirmation of the identity of lipids was obtained using (a) molybdenum blue reagent (Sigma–Aldrich), specific for phospholipids, (b) 0.5% α-naphthol in methanol/water (1:1, by vol), specific for glycolipids, (c) ninhydrine 0.25% in acetone/lutidine (9:1, by vol), for free amino groups [14]. To analyze in detail the various lipid components of the extracts, bands present on 1D-TLC, developed in Solvent A, were scraped and lipids extracted from silica, as previously described [14]; then lipid bands were analyzed by mass spectrometry.

MALDI-TOF Mass Spectrometry

Lipid analysis was performed as previously described [15]. Briefly total lipid extracts (10 mg/ml; dissolved in chloroform/methanol (1:1, by vol)) were diluted from 20 to 200 µl with isopropanol/acetonitrile (60:40, by vol). After mixing 10 µl of diluted sample with 10 µl of 9-aminoacridine (10 mg/ml; dissolved in isopropanol/acetonitrile (60:40, by vol)), 0.3 µl of the mixture was spotted on the instrument plate. The same procedure was followed to analyze the lipid standards (1 mg/ml). MS analysis was performed on a Bruker Microflex spectrometer (Bruker Daltonics, Bremen, Germany). Mass spectra were acquired in the positive and negative mode by averaging 600 consecutive laser shots (50 shots per subspectra). Synthetic lipid standards (Avanti Polar Lipids) were used as external standards for calibration.

NMR Spectroscopy

^{31}P-NMR analysis of phospholipids present in the total lipid extract was performed by following the previously described method [16, 17]. The method is based on the use of a methanol reagent containing D_2O and a dissolved EDTA salt, prepared as follows. The cesium salt of EDTA was prepared by titrating a 0.2 M suspension of EDTA free acid with CsOH to a pH of 6.0, at which point free EDTA was in solution; EDTA salt solutions were evaporated to dryness on a freeze-dry apparatus, dissolved in a minimum volume of D_2O to exchange labile ^{1}H for ^{2}D, dried a second time and dissolved in D_2O to a concentration of 0.2 M. The final methanol reagent was prepared by dissolving 1 ml of D_2O-EDTA solution in 4 ml of methanol. The use of D_2O is solely in order to provide a deuterium reference signal for magnetic resonance field-frequency stabilization; it is not essential for signal narrowing. Between 1 and 5 mg of phospholipid standards and 12 mg of total lipid extract were dissolved in 0.8 ml of deuterated chloroform. To this solution 0.4 ml of methanol reagent (containing Cs/EDTA) was added, and the mixture stirred gently. Two liquid phases were obtained, a larger chloroform phase and a smaller water phase. By using a Pasteur pipette, the sample was placed in an NMR test tube, where it separated within 1 min. The sample tube turbine was adjusted so that only the chloroform phase was detected by the NMR spectrometer's receiver coil. Magnetic field stabilization was obtained through the deuterium resonance of deuterated chloroform. Unless otherwise specified, samples were analyzed with proton broad-band decoupling to eliminate ^{1}H-^{31}P multiplets. Under these conditions each spectral resonance corresponded to single phosphorus. ^{31}P chemical shifts were relative to 85% H_3PO_4 as an external standard. Samples were analyzed using a Bruker DRX500 Avance instrument (Bruker Daltonics, Bremen, Germany).

Results

Whole-tissue membranes (WM) of neuroepithelial cells were isolated from pig olfactory epithelium and total lipids were extracted to be analyzed; in addition to the WM, a membrane fraction enriched in olfactory cilia (CM) was isolated by following the so-called calcium-shock method [8, 9], briefly described in Fig. 1.

Ciliary membrane enrichment was estimated by assay of odor-stimulated AC3 activity (i.e. an activity marker for olfactory cilia); Table 1 reports the specific AC3 activity both in membranes enriched in olfactory cilia and in the whole-tissue membranes, in the absence and in the presence of stimulants. Basal, forskolin-stimulated and odor-stimulated AC3 activity was observed in both the

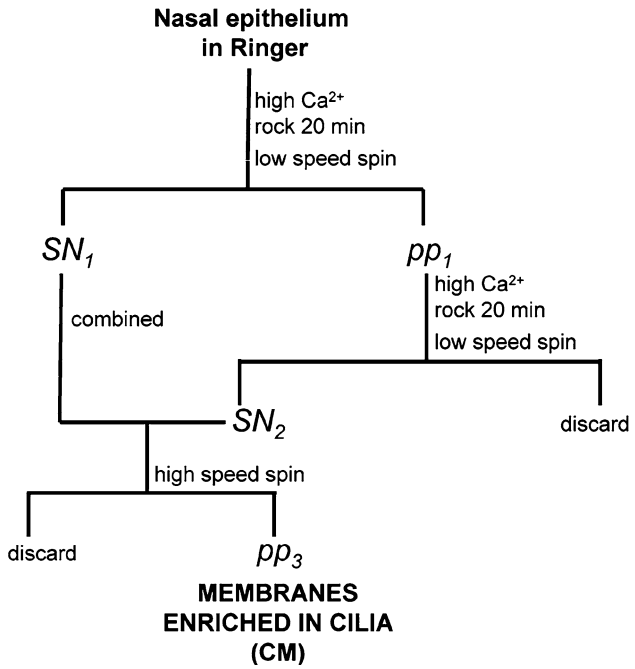

Fig. 1 Calcium-shock scheme for isolating membranes enriched in olfactory cilia. The pig olfactory epithelia were suspended in ice-cold Ringer solution containing 10 mM $CaCl_2$ (twice). To separate tissue fragments, fractions were centrifuged at low speed (7,000*g* for 5 min). To collect membranes enriched in olfactory cilia, the combined supernatants were centrifuged at high speed (27,000*g* for 15 min). The final membrane pellet was resuspended in Buffer A/5% glycerol and stored at −80 °C

membrane preparations, but it is evident that forskolin- and odor-stimulated activities were higher in the membrane fraction enriched in cilia.

Total lipids were extracted from the two different membrane preparations isolated from epithelial cells of pig nose; the lipid/protein ratio was about 1.2 in both membrane fractions. Figure 2 shows the two-dimensional TLC analyses of the total lipid extracts of CM (a) and WM (b). Lipid band identification was performed by comparison with authentic standards (St, in Fig. 2c). The two lipid profiles were similar; five main bands arose from the separation of polar lipid components during the chromatographic run, while neutral lipid bands could be seen close to the solvent front. Polar lipid bands corresponded to the following lipid classes (in R_f order): sphingomyelin (CerPCho) (as a doublet), phosphatidylinositol (PtdIns), phosphatidylcholine (PtdCho), phosphatidylserine (PtdSer), and phosphatidylethanolamine (PtdEtn); cardiolipin (Ptd_2Gro) was a minor lipid component present in the lipid extract of WM, while it was absent in the lipid extract of CM. Another difference between the two TLC plates in Fig. 2a, b was in the intensity of PtdEtn spot, which was more intense in whole than ciliary membranes. Glycosphingolipids (cerebrosides, gangliosides, sulfatides), relatively abundant components of nervous tissue cells, could

Table 1 Adenylcyclase activity in isolated membranes

	Basal activity ± SEM	Forskolin-stimulated activity ± SEM	Odor-stimulated activity ± SEM
Membranes enriched in cilia	197.7 ± 25.3	850.5 ± 39.4	480.1 ± 26.6
Whole-tissue membranes	60.9 ± 18.6	280.3 ± 13.2	150.5 ± 10.2

Cyclase assay was carried out with 5 μM forskolin or with an odor mixture containing 100 μM each of eugenol and citralva, as described in "Methods". The specific activity is reported as pmol cAMP/mg/min. The values are averages of three separate experiments. SEM refers to standard error of the mean

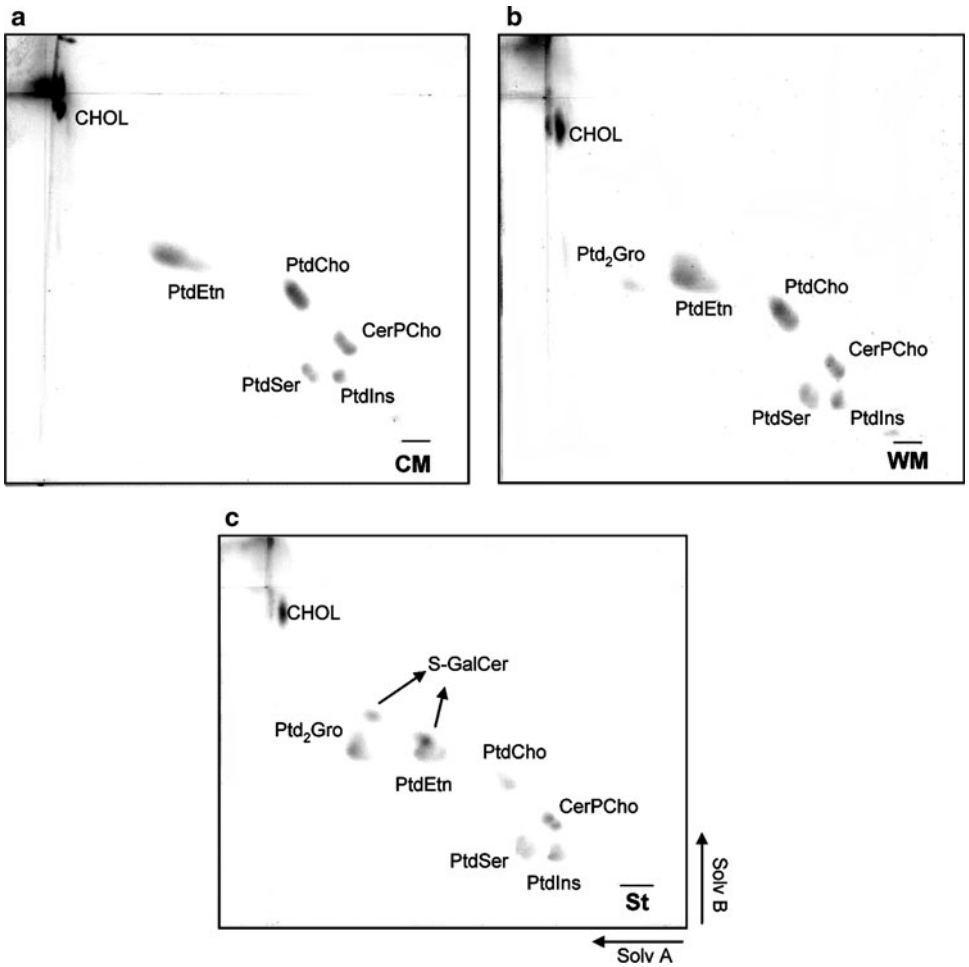

Fig. 2 2D-TLC of the lipid extracts of membranes isolated from pig olfactory epithelium. Total lipids were extracted from the membrane preparations isolated from epithelial cells of pig nose and from membranes enriched in olfactory cilia, as described in "Methods". Eighty micrograms of the lipid extract of whole-tissue (WM) and enriched in olfactory cilia (CM) membranes were loaded in the TLC plates (**a**) and (**b**), respectively. The following pair of solvents was used: Solvent B chloroform/methanol/ ammonium hydroxide (65:25:5, by vol), and then Solvent A chloroform/methanol/acetic acid/water (85:15:10:3.5, by vol). Total lipids were detected by spraying with 5% sulfuric acid and charring at 120 °C. On the TLC plate in (**c**) eight micrograms of each lipid standard were loaded. S-GalCer, galactocerebroside sulfate; Ptd_2Gro, cardiolipin; CHOL, cholesterol; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; CerPCho, sphingomyelin

be not detected by this technique either in whole or in ciliary membranes. Finally it was difficult to compare the cholesterol (CHOL) spots in WM and CM, because they were too close to the solvent front overlapping with other neutral lipid components, such as fatty acids and diacylglycerols. All together the TLC data in Fig. 2 document that our preparation of ciliary membranes was devoid of mitochondrial membranes and is characterized by a lower PtdEtn content than the whole membranes.

The difference in the PtdEtn content was also evident in the 1D-TLC lipid profiles (Fig. 3). To further investigate on the CHOL content of WM and CM, we analyzed their lipid extracts by 1D-TLC using a solvent for neutral lipids (as described in "Methods"). The results revealed that cholesterol percentage did not differ between the two lipid extracts and amounted to about 10% (Fig. 4).

To gain detailed information on the lipid classes present in pig olfactory mucosal cells, the total lipid extract of whole-tissue membranes was analyzed by MALDI-TOF-MS, using the novel matrix 9-aminoacridine allowing a fast reliable analysis of both zwitterionic and anionic lipid species [15]. Main lipid bands isolated from preparative 1D-TLC were also analyzed by MALDI-MS. Furthermore ESI-MS analysis of the lipid extract was performed to support the identification of lipid classes by MALDI-TOF-MS (not shown).

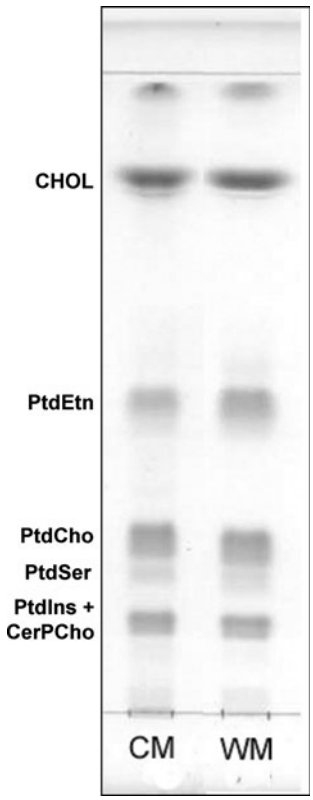

Fig. 3 1D-TLC lipid profiles of whole-tissue (WM) and enriched in olfactory cilia (CM) membranes. Total lipids (60 micrograms) were detected by charring. Solvent A was used

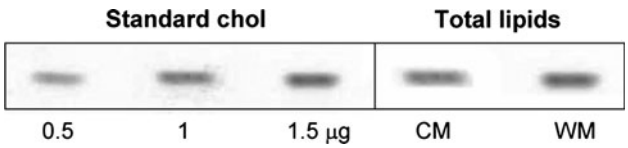

Fig. 4 Cholesterol content of whole-tissue (WM) and enriched in olfactory cilia (CM) membranes. Ten micrograms of each lipid extract was loaded on the TLC plate. The following solvent was used: Solvent C, hexane/ethyl ether/acetic acid (70:30:1, by vol). Only the CHOL bands are shown (note that with Solvent C polar lipids do not separate and are all together at the sample deposition line). The quantitative analysis of CHOL content was performed by video-densitometry (ImageJ software), using standard CHOL loaded on the same plate to construct the calibration curve

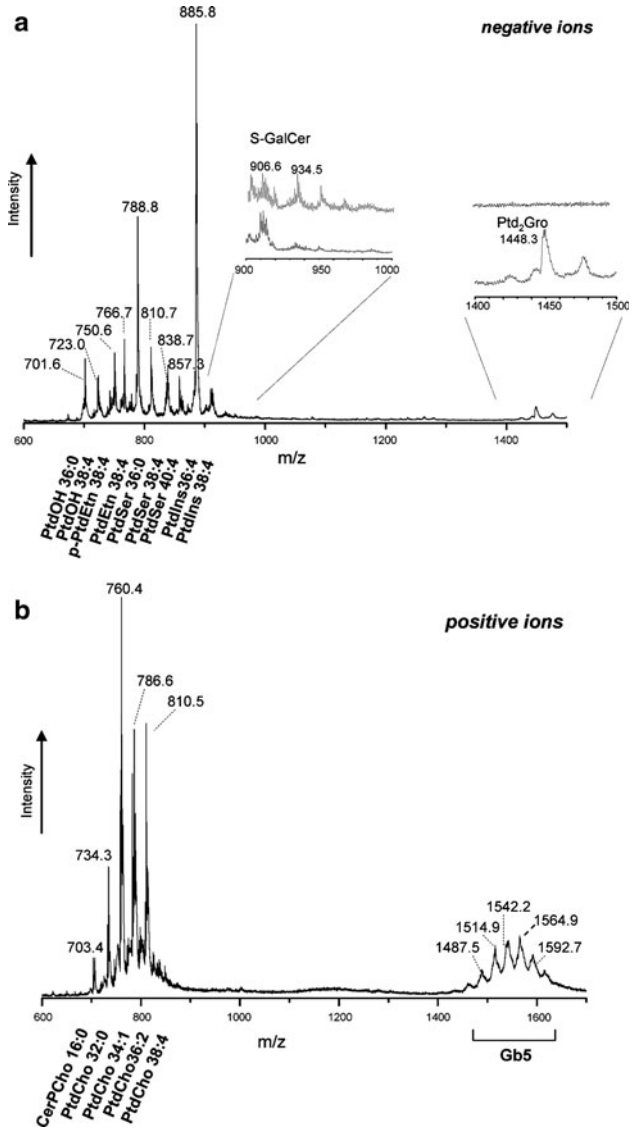

Fig. 5 MALDI-TOF mass spectrum profiles of the lipid extract of pig epithelial membranes in the negative (**a**) and positive (**b**) mode. The insets enlarge the two regions *m/z* 900–1,000 and 1,400–1,500 and show the comparison of the lipid profile of membranes isolated from the whole epithelium (*lower line*) with that of membranes enriched in olfactory cilia (*upper line*). PtdOh, phosphatidic acid; p-PtdEtn, plasmenyl-phosphatidylethanolamine; S-GalCer, galactosylceramide sulfated; Gb5, globopentaosylceramides

The mass spectrum acquired in the negative mode (Fig. 5a) showed two main peaks at *m/z* 885.8 and 788.8, corresponding to the molecular ions $[M - H]^-$of PtdIns 38:4 and PtdSer 36:2, respectively. The minor peaks at *m/z* 750.6, 766.7 and 810.7 corresponded to the molecular ions $[M - H]^-$ of plasmenyl-PtdEtn, PtdEtn and PtdSer (all 38:4 species), respectively. Furthermore the peaks at *m/z* 838.7 and 857.3 were attributed to a PtdSer 40:4 and PtdIns 36:4. Two small peaks were present in the high *m/z* range; the peak at *m/z* 1448.3 was attributed to the molecular ions $[M - H]^-$ of a cardiolipin, having four linoleic acid (18:2) chains, while the peak at *m/z* 1475.8 was not assigned. Of course the apparent amounts of the various lipids in the MALDI profiles depend on the lipid individual tendency to ionization together with its abundance in the extracts.

MALDI-TOF-MS analysis also allowed the direct identification of minor lipid components of olfactory neuroepithelial cells, such as sulfoglycosphingolipids (i.e. sulfatides). A detailed description of the advantages of MALDI-TOF in the analysis of sulfatides has been recently reported [18].

The peak at *m/z* 906.6 in the inset of the mass spectrum of Fig. 5a can be attributed to a sulfoglycosphingolipid, precisely to the sulfated galactosylceramide (S-GalCer), consisting of a C24:0 hydroxy-fatty acid plus the sphingoid 4-sphingenine (d18:1).

The mass spectrum acquired in the positive mode (Fig. 5b) was dominated by PtdCho species: the peaks at *m/z* 734.3, 760.4, 786.6 and 810.5 corresponded to the molecular ions $[M + H]^+$ of PtdCho 32:0, 34:1, 36:2 and 38:4, respectively; the minor peak at *m/z* 703.4 can be attributed to the molecular ion $[M + H]^+$ of the sphingolipid CerPCho 16:0.

Furthermore the peaks at higher *m/z* suggested the presence of other complex glycosphingolipids, such as gangliosides. The peaks between *m/z* 1,400 and 1,600 were attributed to globopentaosylceramides (Gb5), which give strong $[M + Na]^+$ ions, corresponding to glycosphingolipids all containing a C_{18}-sphingosine base and various fatty acids. The oligosaccharide chain of these glycosphingolipids consists of two *N*-acetylgalactosamine, two galactose and one glucose residue. In particular the major peaks at *m/z* 1,564.9 and 1,542.2 appear to correspond to the $[M + Na]^+$ and $[M + H]^+$ ions of species containing saturated fatty acids with 24 carbon atoms respectively, while that at *m/z* 1,514.9 to the $[M + H]^+$ ion of a specie having C22:0. The minor peaks at *m/z* 1,487.5 and 1,592.7 can be attributed to the $[M + H]^+$ ion of Gb5 with C20:0 and to the $[M + Na]^+$ ion of Gb5 with C26:0, respectively. Galactocerebrosides, giving signals in the range *m/z* 800–850, were not well distinct from the background.

The lipid extract obtained from the membrane fraction enriched in cilia was also analyzed by MALDI-TOF-MS; the mass spectra obtained (negative and positive mode) were similar to those of whole-tissue membranes. Some differences were found in the spectrum acquired in the negative mode, in the intervals of *m/z* values 900–1,000 and 1,200–1,600. These regions of the MALDI-TOF mass spectrum are reported in the insets of Fig. 5a, in order to allow direct comparison of MALDI-TOF-MS lipid profiles of the two different lipid extracts. It can be seen that in the mass spectrum of CM lipid extract: (a) cardiolipin was absent, in agreement with previous TLC data (see Fig. 2a); (b) additional peaks were present between *m/z* 930–960 suggesting that the ciliary membranes contained other sulfoglycosphingolipids, besides the S-GalCer at *m/z* 906 (see inset in Fig. 5a).

This last finding arises from the particularly high sensitivity of MALDI-MS in the detection of sulfoglycosphingolipids in the tissue lipid extracts; the cluster centered at *m/z* 934 indicates, on qualitative basis, the presence of an enrichment of long-chain sulfoglycosphingolipids (S-GalCer 26:0) in the specialized membrane of cilia.

Tables 2 and 3 report the main phospholipid and glycolipid classes, resulting from the MALDI-TOF-MS analysis of the total lipid extracts and individual TLC bands. Like lipids of nervous tissue, polar lipids of the olfactory mucosa contain mainly arachidonic (20:4) and stearic (18:0) fatty acids.

Finally, in order to check for quantitative differences in lipid composition between the whole-tissue and ciliary membranes, the total lipid extracts of both the membrane preparations were analyzed by ^{31}P-NMR spectroscopy. In order to assign NMR peaks to the lipid components in the extracts, authentic standard phospholipids were analyzed under the same experimental conditions and their chemical shifts are reported in Table 4.

Table 2 MALDI-TOF signals of phospholipids of pig olfactory epithelium

Class of phospholipid	Ion	Total fatty acid carbon n:n of double bonds													
		(32:0)	(32:1)	(34:1)	(34:2)	(36:0)	(36:2)	(36:4)	(38:4)	(40:4)	(16:0)	(18:0)	(22:0)	(24:0)	(36:4) (36:4)
Ptd_2Gro	$[M - H]^-$	–	–	–	–	–	–	–	–	–	–	–	–	–	1,448
PtdOH	$[M - H]^-$	–	–	–	–	701	–	–	723	–	–	–	–	–	–
PtdEtn	$[M - H]^-$	–	–	–	–	–	742	–	766	–	–	–	–	–	–
p-PtdEtn	$[M - H]^-$	–	–	–	–	–	–	–	750	–	–	–	–	–	–
PtdCho	$[M + H]^+$	734	–	760	–	–	786	–	810	–	–	–	–	–	–
PtdSer	$[M + H]^+$	–	734	–	–	–	–	–	–	–	–	–	–	–	–
PtdSer	$[M - H]^-$	–	–	–	760	788	–	–	810	838	–	–	–	–	–
PtdIns	$[M - H]^-$	–	–	–	–	–	–	857	885	–	–	–	–	–	–
CerPCho	$[M - H]^+$	–	–	–	–	–	–	–	–	–	703	731	787	815	–

Data reported are obtained from the analysis of total lipid extracts and bands isolated from preparative TLC. The *m/z* values are reported. The numbers (*x*:*y*) denote the total length and number of double bonds of both acyl chains, respectively, except for PtdEtn plasmalogen species (denoted with p-PtdEtn), in which the acyl chain at the *sn*-1 position is replaced with an alkenyl. For CerPCho species, the numbers in brackets correspond to the length and number of double bonds of the acyl chain, attached to the sphingosine base. For Ptd_2Gro species, the numbers refer to the two pairs of acyl chains

Table 3 MALDI-TOF signals of glycolipids of pig olfactory epithelium

Class of glycolipid	Ion	*m/z*	No. of sulfated residue	Chain length (carbon n:n of double bonds)		Oligosaccharides (no. of residues)		
				Sphingoid	Acyl	Glc	Gal	GalNAc
S-GalCer 24:0	$[M - H]^-$	906.6	1	18:1	24:0h	–	1	–
S-GalCer 26:0	$[M - H]^-$	934.5	1	18:1	26:0h	–	1	–
Gb5 26:0	$[M + Na]^+$	1,592.7	–	18:0	26:0	1	2	2
Gb5 24:0	$[M + Na]^+$	1,564.9	–	18:0	24:0	1	2	2
Gb5 24:0	$[M + H]^+$	1,542.2	–	18:0	24:0	1	2	2
Gb5 22:0	$[M + H]^+$	1,514.9	–	18:0	22:0	1	2	2
Gb5 20:0	$[M + H]^+$	1,487.5	–	18:0	20:0	1	2	2

S-GalCer, galactosylceramide sulfate; Gb5, globopentaosylceramide; Sphingoid, amino-alcohol chain; Acyl, fatty acid; h, hydroxylated fatty acid; Glc, glucose; Gal, galactose; GalNAc *N*-acetylglucosamine

Table 4 ^{31}P-chemical shifts of standard phospholipids

Lipid	ppm
PtdCho	0.115
PtdIns	0.621
CerPCho	0.911
PtdSer	0.894
PtdEtn	1.066
Ptd_2Gro	1.148

Chemical shifts are referenced to 85% H_3PO_4 as an external standard. The samples were prepared in the Cs/EDTA analytical reagent, as described in "Methods"

By comparing the two NMR spectra illustrated in Fig. 6 it can be seen that PtdCho, PtdIns, PtdSer, PtdEtn and CerPCho species were present in both the lipid extracts of WM (a) and CM (b); PtdSer and CerPCho peaks (at about 0.9 ppm) were very close to each other and not well resolved in the case of spectrum in panel a, because WM possibly contain more PtdSer and CerPCho species than CM.

The sums of the peak areas in the two spectra were 13.87 and 15.39 in CM and WM, respectively; this indicates that the total lipid phosphorus per mg of total lipid extract in CM was slightly lower than in WM and represents an indirect indication of the presence of an higher proportion of glycosphingolipids in cilia, compared to whole membranes. The last main peak at 1.05 ppm was assigned to a plasmenyl-PtdEtn lipid, in agreement with a previous literature report [19]; also the small, but clearly visible peak at 0.18 ppm can be attributed to plasmalogen PtdCho species, as well [19]. The Ptd_2Gro peak in the NMR profile of whole membranes was absent because its relative proportion in the lipid extract was below the sensitivity limit of NMR analysis.

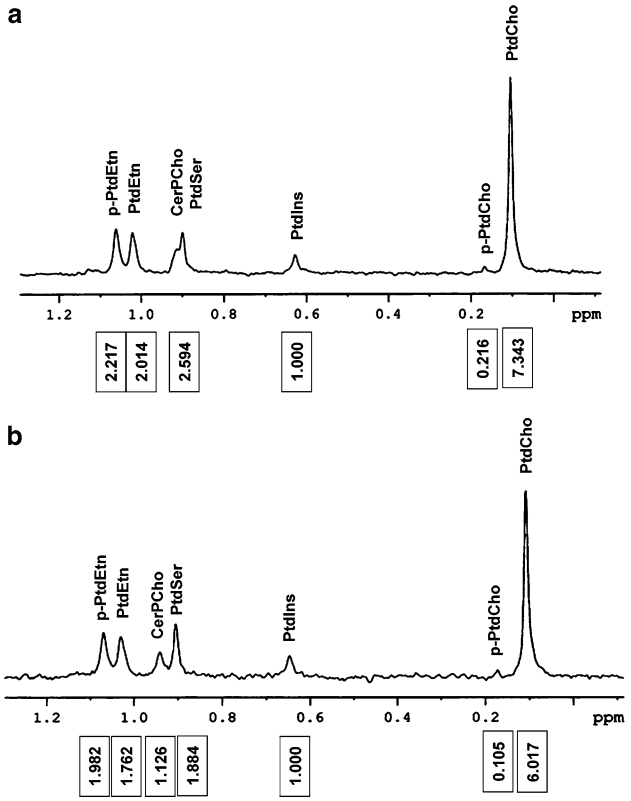

Fig. 6 ^{31}P-NMR spectra of the lipid extract of whole-tissue (**a**) and enriched in olfactory cilia (**b**) membranes. The areas of peaks are reported below the *x*-axis

The differences in the area peaks of the two NMR spectra indicate that the proportions of various lipid classes in the two lipid extracts were different. The area ratios PtdEtn species/(PtdSer + CerPCho) in CM and WM were 1.23 and 1.62 respectively, indicating that the proportion of PtdEtn species (as the sum of diacyl- and acyl-alkyl forms) was lower in CM extract in agreement with results from TLC analyses (Figs. 2, 3).

Discussion

Lipid research can offer important elements to complete our understanding of the genesis of sensory perception pathologies. For example anosmia, i.e. the inability to perceive odors, can arise from loss of olfactory cilia or impairment in the olfactory signaling cascade [20]. The complete comprehension of the mechanisms of ciliogenesis and assembly of membrane signaling molecules requires an integration of lipid and protein studies.

The present paper describes the results of a study on cellular lipids of porcine olfactory mucosa, previously selected to investigate the response of olfactory cilia to explosives, in the frame of an investigation to understand the molecular basis of the ability of an animal nose to detect buried landmines [21]. In the pig nose the olfactory mucosa is well distinct from the respiratory mucosa, while in other mammals technical difficulties are often involved in obtaining olfactory tissue from ethmoids without concomitant excision of non-olfactory tissue [7].

As the olfactory mucosa consists of three cell types (olfactory sensory neurons, supporting and basal cells), results of whole membrane lipid analyses refer to the average lipid composition of membranes arising from the different cell types in the epithelium.

A combination of a number of different analytical techniques was used to analyze in detail the lipids of olfactory neuroepithelium together with the novel MALDI-TOF-MS approach based on the use of the versatile matrix 9-aminoacridine [15].

The results shown here indicate that the lipid composition of olfactory mucosa in pig is similar to that of bovine and rat [6, 7]. Phospholipids account for about 85–90% (by weight) of the total lipid of mucosa, with zwitterionic lipids (PtdEtn, PtdCho and CerPCho) being more abundant (about 70%) than anionic species (PtdSer, PtdIns, Ptd_2Gro, PtdOH). Most phospholipids show a polyunsaturated fatty acid content with the arachidonic acid (20:4) residue predominating. The fatty acids in sphingomyelin, however, are totally saturated and include C16:0, C18:0, C22:0, and C24:0 chains.

Although separation of acyl-acyl from alkyl-acyl forms of phospholipids cannot be easily achieved by TLC, NMR analyses reveal that peak areas of alkyl-acyl PtdEtn almost equal the diacyl-PtdEtn species, as previously reported for mammalian brain tissue [22]. MALDI-TOF-MS analyses indicate that the main PtdEtn species contain C18 and C20 chains.

As regards glycosphingolipids, sulfoglycosphingolipids having C24:0 hydroxy-fatty acid and the sphingoid 4-sphingenine (d18:1), and pentaosylceramides containing a C_{18}-sphingosine base and various fatty acids, were only detected by MALDI-TOF analysis.

Here information on the lipid composition of a membrane fraction enriched in olfactory cilia is also reported. In the past biochemical exploration of the olfactory cilia was mostly based on a membrane preparation protocol established by Chen and Lancet [9]. Thus, the examination of the cilia preparations yields many of the molecular details, which support the current concept for olfactory signal transduction. In the present study we isolated a membrane fraction enriched in ciliary membranes of about the same quality as the analogous preparation obtained by other authors from rat tissue [23]. The lack of cardiolipin in the lipid extract of cilia represents a good internal index of the absence of mitochondrial and possibly other intracellular membranes in our preparation. However, we cannot exclude the presence of microvillar fragments of support cells in our ciliary membrane preparation.

In summary, the present analysis of the lipid extracts of whole-tissue membranes and enriched ciliary membranes shows that: (1) PtdEtn species are less abundant in ciliary membranes than in total epithelial membranes (TLC and NMR findings), and (2) long-chain sulfoglycosylsphingolipids (S-GalCer 26:0) are enriched in ciliary membranes compared to the crude olfactory membranes. The roles of sulfoglycosylsphingolipids in metabolism and functions of nervous tissue have been recently reviewed [24]. In principle, given the importance of lipids in signaling, any difference in the lipid bilayer composition might be considered a factor that can affect the membrane transduction properties. A decrease of membrane PtdEtn content was previously described in brain pathologies [22]. In olfactory cilia a decrease of PtdEtn level implies an increase in other membrane lipids, such as CerPCho, PtdSer and PtdIns, having a well known role in the assembly of lipid rafts (CerPCho, PtdSer) and signal transduction (PtdIns).

On the other hand, PtdEtn is preferentially located in the inner membrane leaflet, where it is associated with acidic phospholipids such as PtdIns [25]. Being cone-shaped phospholipid, PtdEtn can influence the determination of membrane curvature; it has been reported that intracellular tubular membranes of Golgi apparatus have a minor amount of PtdEtn compared to plasma membrane [25]. The possibility of a correlation between the low PtdEtn content and the high curvature in cross section of tubules of olfactory cilia remains to be investigated.

Although the presence of cholesterol-rich rafts in the olfactory cilia has been indirectly suggested by some biochemical studies [4, 5], here no cholesterol enrichment was found in the lipid extract of the ciliary membranes. However it should be considered that the analysis of the CM lipid extract gives information on the average lipid composition of the membrane lining the long (up to 100 μm) tubular structure of cilia, which presumably consist of different biochemical and functional domains.

In particular as it has been shown that cholesterol is absent at the necklace (or base) of the ciliary structure [26,

27], cholesterol in the CM lipid extract might represent the average of cholesterol in the proximal and distal tubular membranes. In conclusion, we cannot exclude the presence of cholesterol-rich domains (i.e., rafts) in ciliary membranes on the basis of the lack of cholesterol enrichment in the lipid extract of ciliary membranes.

Another element of complexity in the interpretation of lipid data arises from the recent finding that the chemosensory apparatus of cilia is also present at the level of the emergency cone of the sensory olfactory axon [28].

Here besides reporting the first lipidomic data on olfactory mucosa in toto, we show for the first time the presence of different lipid domains in the membranes of neuroepithelial olfactory cells. Our study complements recent proteomic studies, in which many ciliary proteins, that mediate chemo-electrical transduction, amplification and adaptation of the primary sensory signal, have been identified [29–32].

Acknowledgments We thank F. Naso of the University of Bari for the use of the MALDI-TOF instrument. This work was supported by the Italian Ministry of Defence (Contract n. 685/18.12.2003), by Regione Puglia (Grant code 15, Sens&MicroLab) and by Fondazione Cassa di Risparmio di Puglia, Bari, Italy.

ORIGINAL ARTICLE

Reversible Inhibitory Effects of Saturated and Unsaturated Alkyl Esters on the Carboxylesterases Activity in Rat Intestine

Ping Li · Chun-liu Zhu · Xin-xin Zhang · Li Gan · Hong-zhen Yu · Yong Gan

Received: 3 March 2010 / Accepted: 19 May 2010 / Published online: 8 June 2010

Abstract This study was conducted to investigate the relationship between the carbon chain length/double bonds of alkyl esters and their inhibitory potency/mechanism on carboxylesterases (CESs). CESs activity was evaluated by inhibition of adefovir dipivoxil (ADV) metabolism in rat intestinal homogenates. Furthermore, the inhibitory effect of BNPP and ethyl (*E*)-hex-2-enoate (C8:1) on drug absorption was evaluated in situ intestinal perfusion model. The results showed that the rank order of the inhibitory potency on CESs was C10:0 > C8:0 > C6:0 > C4:0 > C12:0, C8:1 > C8:0, C6:1 > C6:0, while the esters (C14:0, C13:1, C16:0, C18:0, C17:1, C20:0) were found to have no inhibitory effect at investigated concentrations. However, the unsaturated esters (C20:1, C20:2, C20:3) displayed the inhibitory effect on CESs. Moreover, the double reciprocal plots indicated that alky esters inhibited the CESs in competitive and mixed competitive ways which were reversible. In addition, the result of most effective CESs inhibitor C8:1 from in situ experiment showed that C8:1 can inhibit the CESs-mediated intestinal metabolism and improve the drug absorption. And the inhibition had no time-dependent effect, compared with that of BNPP groups. The study suggested that alkyl esters can be served as effective and reversible CESs inhibitors, besides that their inhibitory potency/mechanism can be affected by their carbon chain length/double bonds.

ADF	Adefovir
ADV	Adefovir dipivoxil
BNPP	Bis-*p*-nitrophenylphosphate
CESs	Carboxylesterases
EE	Ethyl (*E*)-hex-2-enoate
LDH	Lactate dehydrogenase
Mono-ADV	Mono-(POM) PMEA

Introduction

The mammalian carboxylesterases (CESs; EC.3.1.1.1) belong to the α/β hydrolase-fold family of enzymes which are highly expressed in liver, intestine and kidney [1–3]. These enzymes are responsible for activation of ester prodrugs such as antitumor drugs (CPT-11 and capecitabin), antiviral drugs (tenofovir disoproxil and bis(POC)-PMPA) and narcotics (cocaine, heroin, and meperidine) [4–7]. They also play an important role in detoxification of many insecticides [8] and pharmaceuticals [9]. Because CESs metabolize a range of pharmaceuticals, the use of its inhibitors could potentially be valuable in modulating the efficacy of these therapeutics. Thus, studies concerned about inhibitors of CESs have attracted increased interest recently.

A number of different structural motifs have been developed for the inhibition of CESs, for example, organophosphates, trifluoromethyl ketones and aromatic ethane-1, 2-diones [10–12]. However, none of these inhibitors has been used in laboratory animals as oral administration, due to the unclear biocompatibility. While

some of the fruit extracts like edible strawberry juice [5, 13] and grapefruit juice [14, 15] are reported as relative safe CESs inhibitors, which can also be also used orally. The fruit extracts can inhibit the CESs because they contain various flavoring esters which have the ability to inhibit the CESs. In previous studies, several kinds of alkyl esters were described as inhibitors, such as: ethyl butyrate, ethyl caproate and so on [6, 13]. However, the relationship between the carbon chain length/double bonds of alkyl esters and the potency of CESs inhibition has not been described. Therefore, in our paper, we compared with each other various alkyl esters' inhibitory potency on CESs. Then we determined the relationship between the carbon chain length/double bonds of the alkyl esters and their inhibitory potency on CESs. Furthermore, we characterized the type of inhibitory mechanism of the selected ethyl esters and evaluated the inhibitory effect on drug absorption by the in situ perfusion experiment of rat.

Experimental Procedure

Materials

ADV and ADF were bought from the Sunheat Chemical Co. (Purity >96%). (Shanghai, China). Mono-ADV (Purity >98%) was a gift from Taizhou Shanhyu Chemical Import and Export Co. (Hangzhou, China). Ethyl acetate (>99%), ethyl caproate (99%), ethyl oleate (98%) were all purchased from the Sinopharm Chemical Reagent Co. (Shanghai, China). Ethyl butyrate (99%), ethyl caprylate (98%), capric acid ethyl ester (98%), ethyl laurate (98%), and ethyl myristate (98%), ethyl palmitate (98%) were purchased from the Shenbao Flavors and Fragrances Co. (Shanghai, China). Ethyl stearate (99%) was from the QianWei Oil Science & Technology Co. (Shanghai, China). Ethyl linoleate (99%) was a gift from the JinBan Food Co. (Shanghai, China). Ethyl γ-linolenate (99%) was purchased from the Energy Chemical Co. (Shanghai, China). Ethyl (*E*)-hex-2-enoate (98%) was from the Apple Flavors and Fragrances Co. (Shanghai, China). Crotonic acid ethyl ester (98%) was purchased from TCI Co. (Shanghai, China). 11-Dodecenoic methyl (>99%) and palmitelaidic acid methyl ester (>99%) were purchased from the Shanghai Zhongyitai International Trading Co. (Shanghai, China). BNPP (Purity >98%) was purchased from Sigma (Shanghai, China). Hanks' balanced salt solution (HBSS) was composed of 0.40 g/l KCl, 0.06 g/l KH_2PO_4, 8.00 g/l NaCl, 0.05 g/l Na_2HPO_4 (anhydrous), 1.00 g/l D-glucose, 0.35 g/l $NaHCO_3$, and was adjusted to pH 7.4. Krebs–Ringer Buffer (K–R) composition: 7.80 g/l NaCl, 0.35 g/l KCl, 0.37 g/l $CaCl_2$, 1.37 g/l $NaHCO_3$, 0.02 g/l NaH_2PO_4, 0.02 g/l $MgCl_2$, 1.48 g/l D-glucose (pH 6.8). Double distilled water was used. All other chemicals were of reagent grade.

Animals

Male Sprague–Dawley (SD) rats (body weight 280 ± 20 g) were obtained from the Medical Animal Test Center of the Shanghai Institute of Materia Medica (Shanghai, China). All experiments were performed according to the Shanghai Institute of Materia Medica guidelines for experimental animal care. The rats were fasted for 12 h prior to the experiment and had free access to water.

Preparation of Homogenates from Rat Intestinal Mucosa

The intestinal homogenates were prepared following the method used by Van Gelder et al. [16]. Briefly, the rat jejunum excised within 30 min after anesthetizing the animals, subsequently, a 20 cm segment was cut along the longitudinal axis and washed with ice-cold HBSS (pH 7.4) to remove the intestinal contents. Mucosa was removed by scraping with a glass microscope slide. The scrapings were homogenized at 0 °C in 10 ml of cold HBSS for 5 min using Ultra Turrax (IKA, Type T 10B, Guangzhou, China) at 6,000 rpm. After centrifugation at 10,000 rpm for 10 min at 4 °C, the supernatants were harvested and kept at −20 °C. The protein content was prepared to 0.1 mg/ml as an enzymatic preparation according to the Bradford method [17] using BSA as the standard when being used.

IC_{50} Determination

To determine the IC_{50} (concentration of inhibitors that results in 50% inhibition of original esterase ability) value [18]: the enzymatic preparations (0.1 mg/ml) were preincubated for 5 min; then the ADV solutions (10 mM DMSO stock solution) together with various concentrations of the inhibitors were added and incubated for 15 min at 37 °C. The same system without inhibitors served as the control group. The final drug concentration was always 100 μM and the final DMSO concentration was 1% which had no effect on esterase activity. By taking 100 μl of the incubation solution into 200 μl of ice-cold methanol, the reactions were stopped. The concentration range of each inhibitor was as follows: C4:0 ethyl acetate (6.38–102.15 mM); C6:0 ethyl butyrate (3.12–49.93 mM); C8:0 ethyl caproate (2.57–41.14 mM); C10:0 ethyl caprylate (2.10–33.67 mM); C12:0 capric acid ethyl ester (11.11–177.72 mM); C6:1 crotonic acid ethyl ester (3.36–53.74 mM); C8:1 ethyl (*E*)-hex-2-enoate (2.78–44.54 mM); C14:0 ethyl laurate (37.79–151.16 mM); C16:0 ethyl myristate (33.54–134.15 mM); C18:0 ethyl palmitate (30.13–120.50 mM);

C20:0 ethyl stearate (33.82–135.28 mM); C13:1 11-Dodecenoic methyl ester (38.14–152.54 mM); C17:1 palmitelaidic acid methyl ester (32.60–130.39 mM); C20:1 ethyl oleate (1.17–18.68 mM); C20:2 ethyl linoleate (1.18–18.80 mM); C20:3 ethyl γ-linolenate (1.24–19.87 mM). All the alkyl esters were expressed according to the literatures [19, 20] and their structures are described in Fig. 1. By taking 100 μl of the incubation solution into 200 μl of ice-cold methanol, the reactions were stopped. The samples were vortexed for 20 s and centrifuged at 8,000 rpm for 5 min at 4 °C, then the supernatant was taken and analyzed by HPLC as described below.

Inhibitory Mechanism of Ethyl Caproate, Ethyl (*E*)-hex-2-enoate and Ethyl Oleate

Three esters (C8:0, C8:1 and C20:1) were chosen and represented the saturated short-chain esters, the unsaturated short-chain esters and the unsaturated long-chain esters respectively. To characterize the inhibitory models of the representative esters, the enzymatic preparations (0.1 mg/ml) were preincubated for 5 min; then the ADV solution (10 mM DMSO stock solution) was added and incubated in the presence of various concentrations of the inhibitors for 5 min at 37 °C. The final drug concentration ranges from 25 to 100 μM. The concentration range of each inhibitor was as follows: ethyl caproate (0–41.14 mM); ethyl (*E*)-hex-2-enoate (0–44.54 mM); ethyl oleate (0–18.68 mM). All samples were processed and analyzed as described in section "IC_{50} determination".

The enzyme kinetics equations were as follows:

$$V = \frac{V_{\max}[S]}{K_m\left(1+\frac{[I]}{K_i}\right)+[S]}$$
$$\frac{1}{[V]} = \frac{K_m}{V_{\max}}\left(1+\frac{[I]}{K_i}\right)\cdot\frac{1}{[S]}+\frac{1}{V_{\max}} \quad (1)$$

where $[S]$ is the concentration of the substrate (μM), $[I]$ is the concentration of the inhibitor (mM).

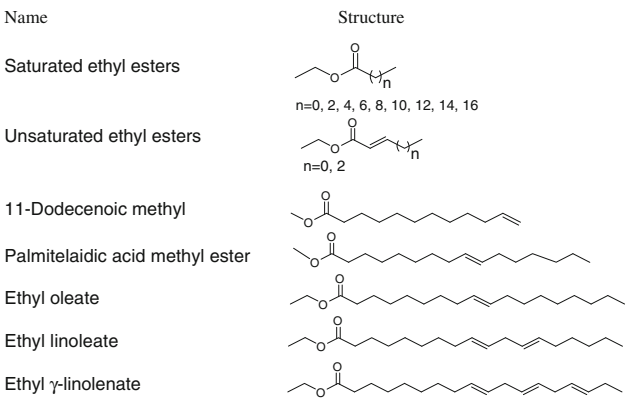

Fig. 1 The chemical structures of the alkyl esters

In Situ Perfusion Experiments with Superior Mesenteric Vein Blood Sampling

In situ perfusion experiments were performed primarily based on a previously described method [13, 21, 22] with modifications. Briefly, Male Sprague–Dawley (SD) rats were used. The terminal 10–20 cm of the ileum was cannulated. Blood from the superior mesenteric vein was collected in heparinized tubes at 27.5 min. In addition, 100 μl samples were taken from the perfusion medium after 2.5, 7.5, 12.5, 17.5, 22.5, and 27.5 min respectively. Then each of the sample was added to 400 μl of ice-cold methanol to stop the reaction and processed as in the section "IC_{50} determination" before being analyzed by HPLC. ADV absorption was evaluated in the absence (control group) of two CESs inhibitors ethyl (*E*)-hex-2-enoate (EE) and BNPP. In the control group, the investigated intestine was pre-exposed for 40 min to a K–R (pH 6.8) solution. Posteriorly, an isotonic solution of ADV (200 μM) was perfused. In additional experimental groups, we analyzed the effect of previous exposure (40 min) to the BNPP (400 μM)/EE (63.3 mM) upon ADV intestinal absorption and the absorption assay was performed as previously described. In BNPP/EE group I, after being pre-exposed identically as the control group, in the absorption experiment, a solution containing ADV (200 μM) plus BNPP (400 μM)/EE (63.3 mM) was perfused. In BNPP/EE group II, the investigated intestine was pre-exposed to an isotonic and buffered solution of BNPP (400 μM)/EE (63.3 mM) for 40 min, the absorption experiment was carried out as in BNPP/EE group I. Perfusate samples were tested for lactate dehydrogenase (LDH) release to measure cellular membrane damage using the LDH kit (Nan Jing Jian Cheng Shen Wu Yan Jiu Suo, 50T, Shanghai, China) [6].

HPLC Analysis for Drug Concentration In Vitro

ADV and its metabolite Mono-ADV were analyzed using a validated HPLC method with some modifications [23]. The HPLC system (Model SIL-20A, Shamadzu, Japan) was composed of an autosampler (SIL-20A), a pump (LC-20AT), a diode array detector (SPD-M20A) and a work station (Shimadzu liquid chromatography). The column used was Intersil $ODSC_{18}$ (4.6 mm×150 mm, 5 μm). The inject volume was 20 μl and the flow rate was 1 ml/min, mobile phase B consisted of 50 mM ammonium acetate buffer solution, 2 mM tetrabutylammonium hydrogen sulfate (pH 4.0); while A consisted of total methanol. Separation was carried out with 95% mobile phase B over 5 min, followed by a linear gradient from 95% to 30% mobile phase B over 5 min and with an isocratic stage of 5 min, then return to the initial condition (95% phase B) for 5 min. The retention time for ADV,

mono-ADV was 17.2, 14.6 min respectively. The intra-day and inter-day RSD were all below 5% for ADV concentration ranging from 0.625 to 40 μg/ml and mono-ADV concentration ranging from 0.625 to 40 μg/ml.

LC/MS/MS Analysis for Plasma Drug Concentration

The concentration of Mono-ADV and ADF in plasma was determined by a validated LC–MS/MS method [24], wherein, 9-(3-phosphonylmethoxypropyl) adenine was selected as the internal standard. The serum sample (0.2 ml) was pretreated by precipitating protein with methanol (0.4 ml) and the supernatant was injected for analysis. The analyte was separated on a Diamonsil C_{18} column (250×4.6 mm i.d., 5 μm; Beijing Dikma Co., Beijing, China) by isocratic elution with methanol: water: formic acid (20: 80: 1 v/v/v) at a flow rate of 0.5 ml/min and analyzed by an API 4000 triple-quadrupole mass spectrometric instrument (Applied Biosystems, Foster City, CA, USA) in multiple reaction monitoring mode. An electrospray ionization (ESI) source was applied and operated in the positive ion mode. Selected reaction monitoring (SRM) mode with the transitions of m/z 274 → m/z 162, m/z 388 → m/z 256/358 and m/z 288 → m/z 176 were used to quantify ADF, mono-ADV and the internal standard, respectively. The linear calibration curve was obtained in the concentration range of 0.02–4.0 μg/ml for ADF and 0.001–1.0 μg/ml for mono-ADV. The lower limit of quantitation of ADF/mono-ADV was 0.02/0.001 μg/ml.

Data Analysis

For the determination of the IC_{50}/K_i values, all analyses were performed using the mean values obtained from two independent experiments. The esterase activities in the presence of the inhibitors were expressed as percentages of the corresponding control values. The IC_{50} value was determined graphically. Moreover, the ClogP was calculated at http://www.organic-chemistry.org/prog/peol. The inhibition model was evaluated by graphical analysis with Lineweaver–Burk double reciprocal plots (1/[velocity] versus 1/[substrate]). Fits to competitive, noncompetitive, or mixed type inhibition models were evaluated according to the method described by Tseng SJ [25]. The K_i/K_i' values were calculated according to the following ways. Slopes of the inhibition lines were determined from linear regression analysis and converted to apparent K_m/V_m (K_m/V_m, app) values. Apparent K_m/V_m values were then plotted versus the concentration of inhibitors to generate K_i values (the x-intercepts of the linear regression line). Likewise, the y-intercepts were determined from linear regression analysis and converted to apparent $1/V_m$ ($1/V_m$, app) values. Apparent $1/V_m$ values were then plotted versus the concentration of inhibitors to generate K_i' values (the x-intercepts of the linear regression line).

For the perfusion experiments, on the one hand, due to slight variations in perfusate concentrations, the calculated steady-state perfusate concentration of ADV in each experiment was normalized to a target concentration of 200 μM, and the steady-state perfusate concentration of mono-ADV in each experiment was calculated as increased mono-ADV; on the other hand, results of the perfusion experiments with ADV absorption were expressed as ADV metabolites (ADF plus mono-ADV) appearing in the mesenteric plasma.

Statistical Analysis

All values were expressed as means ± standard deviation (SD). Statistically difference were determined by ANOVA followed by Tukey's test for multiple comparisons at a significance level of $P = 0.01$ or 0.05. All statistical analysis was performed using the GraphPad Instat for windows version 3.05 (GraphPad Software, Inc., CA, USA).

Results

IC_{50} Determination

Table 1 summarizes the comparative inhibitory effects of saturated alkyl esters and unsaturated alkyl esters on the metabolite formation in rat intestinal homogenates. The ADV was chosen as a probe and the CESs activity was evaluated by measuring metabolite formation in intestinal homogenates. The IC_{50} value was determined by plotting the log concentration versus relative remaining esterase activity of each test sample using software Origin 8.0, as shown in Figs. 2 and 3. The results showed that inhibitory potency of alkyl esters was based on their carbon chain length and the number of double bounds in the esters. The rank order of the inhibitory potency on CESs was C10:0 > C8:0 > C6:0 > C4:0, with a chain length of the esters less than or equal to 10. As the chain length of esters increases to 12, the inhibitory potency decreased acutely; and when the chain length of esters exceeded 12, both the saturated esters (C14:0, C16:0, etc.) and unsaturated esters (C13:1, C17:1) were found to have no inhibitory effect at investigated concentrations. However, the inhibitory effect emerged as the double bonds appear in the long-chain alkyl esters, like the C20:1, C20:2, etc. In addition, we compared the inhibitory potency between the saturated ethyl esters and unsaturated ethyl esters with the same carbon chain length. We found that unsaturated ethyl esters demonstrated even stronger inhibitory potency compared with

Table 1 IC_{50} values of alkyl esters on inhibiting the metabolism of ADV mediated by CESs

Alkyl esters	IC_{50} (mM)	ClogP	Alkyl esters/reference inhibitor	IC_{50} (mM)	ClogP
C4:0 ethyl acetate	124.1 ± 43.5	0.91	Reference inhibitor	$(3.3 \pm 1.2) \times 10^{-4}$	
C6:0 ethyl butyrate	70.2 ± 26.8	1.84	C6:1 crotonic acid ethyl ester	9.5 ± 3.6	1.48
C8:0 ethyl caproate	26.4 ± 4.3	2.77	C8:1 ethyl (*E*)-hex-2-enoate	5.6 ± 0.8	2.41
C10:0 ethyl caprylate	9.2 ± 1.0	3.7	C13:1 11-Dodecenoic methyl	NI	4.82
C12:0 capric acid ethyl ester	865.7 ± 515.6	4.63	C17:1 palmitelaidic acid methyl ester	NI	6.62
C14:0 ethyl laurate	NI	5.55	C20:1 ethyl oleate	7.5 ± 2.4	7.98
C16:0 ethyl myristate	NI	6.48	C20:2 ethyl linoleate	31.6 ± 1.0	7.62
C18:0 ethyl palmitate	NI	7.41	C20:3 ethyl γ-linolenic	21.0 ± 8.3	7.26
C20:0 ethyl stearate	NI	8.34			

NI Non-inhibited

Reference inhibitor BNPP was used as the specific inhibitor of CESs

the saturated ethyl esters, for instance: C8:1 > C8:0, C6:1 > C6:0.

Inhibitory Mechanism Determination

Type of inhibition of each inhibitor on CESs is shown in Fig. 5 and the K_i/K_i' values of them are also presented in Table 2. The Lineweaver–Burk plots below proved that all three investigated alkyl esters were reversible inhibitors, with different plots indicating different mechanisms. The inhibition lines of ethyl caproate intersect on the *y*-axis, illustrating that such inhibitors do not affect V_{max}, showing a competitive inhibitory mechanism. Similarly, the inhibition lines of ethyl (*E*)-hex-2-enoate intersect on the second quadrant, displaying a mixed competitive inhibitory mechanism. The results showed that ethyl oleate with long carbon chain also inhibit CESs in a mixed competitive way, with the inhibition lines intersect on the second quadrant.

In Situ Perfusion Experiments with Superior Mesenteric Vein Blood Sampling

Figure 6a shows the disappearance of ADV equivalents (ADV plus mono-ADV) and the appearance of a mono-ADV metabolite in the lumen during perfusion of the rat intestinal segment with ADV in the pre-exposed or co-perfused of BNPP (400 μM). A significant ($P < 0.05$)

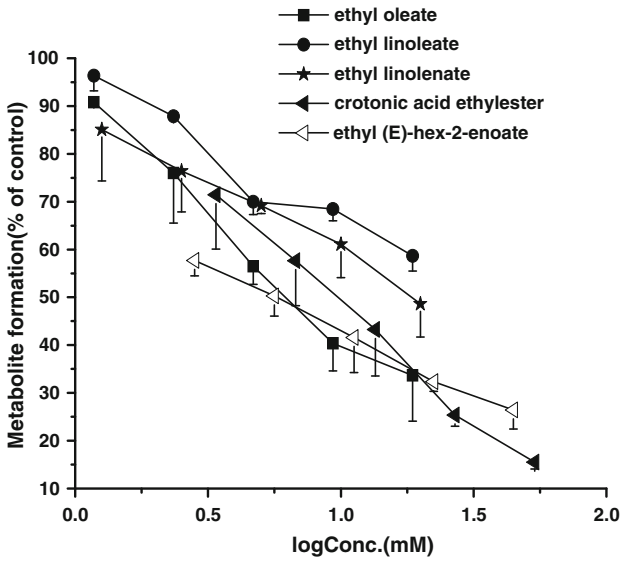

Fig. 3 The IC_{50} determination of unsaturated ethyl esters in intestinal homogenates of rat. Activities were expressed as a percentage of metabolite formation compared with the control group. Results were means ± SD error bar of duplicate determinations

Table 2 K_i/K_i' values and inhibitory models of alkyl esters on inhibiting the metabolism of ADV mediated by CESs

Alkyl esters	C8:0 ethyl caproate	C8:1 ethyl (*E*)-hex-2-enoate	C20:1 ethyl oleate
K_i/K_i' (mM)	18.3	11.8/9.3	5.6/21.7
Models	Competitive	Mixed competitive	Mixed competitive

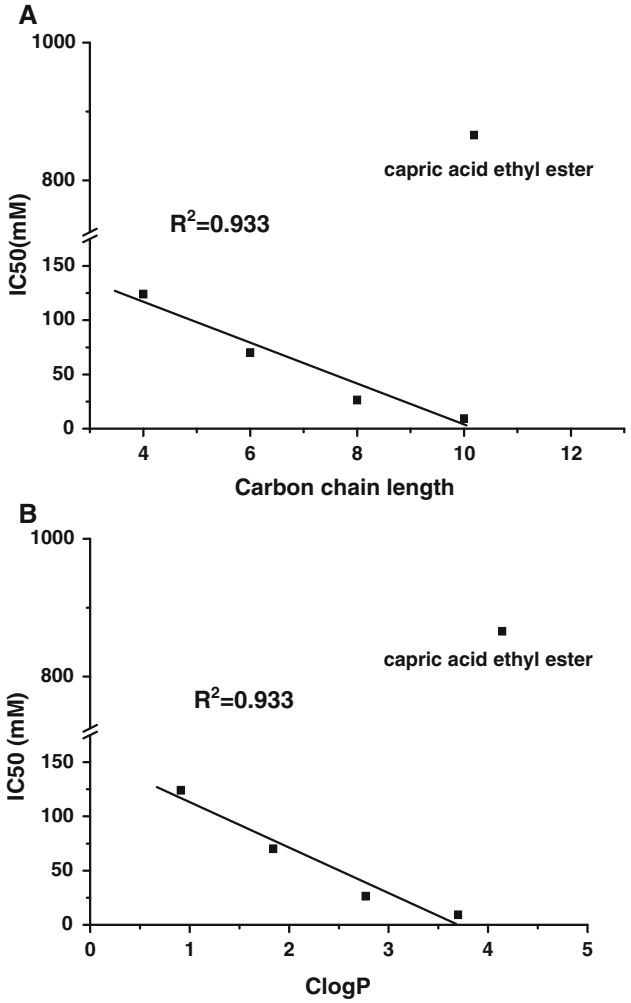

Fig. 4 The relationship between carbon chain length/ClogP of ethyl esters and inhibitory potency

decrease of ADV equivalents was observed in BNPP group I and II at 27.5 min, compared with that of control group; meanwhile, there was a very significant ($P < 0.01$) increase in mono-ADV metabolite in the lumen at 27.5 min in the control group, compared with that of both BNPP groups; simultaneously, a 4.4/2.2-fold increase in ADV metabolites appearing in the plasma was observed at 27.5 min in BNPP groups II/I respectively, as compared with the control group (Fig. 7). On the other hand, the effect of prior 40 min exposure of the rat intestine to BNPP in BNPP group II increased the drug disappearance at 27.5 min significantly with respect to the BNPP group I ($P < 0.05$) (Fig. 6a); in addition, a significant ($P < 0.05$) appearance of mono-ADV metabolite was observed at 27.5 min in BNPP group I, compared with that of BNPP group II; meanwhile, a 0.8-fold increase in ADV metabolites appearing in the plasma was observed in BNPP group II, compared with BNPP group I (Fig. 7).

Figure 6b shows the disappearance of ADV equivalents and the appearance of mono-ADV metabolite in the lumen during perfusion of the rat intestinal segment with ADV in the pre-exposed or co-perfused of EE (63.3 mM). A significant ($P < 0.01$) decrease of ADV equivalents was observed in both two EE groups at 27.5 min, compared with that of the control group; in addition, a significant ($P < 0.01$) appearance of mono-ADV metabolite was observed in control group, compared with that of two EE groups; simultaneously, a similar increase (1.0/1.2-fold) of ADV metabolites absorbing in the plasma was observed at 27.5 min in EE group II/I respectively, as compared with the control group (Fig. 7). On the other hand, the effect of prior 40 min exposure of the rat intestine to EE in EE group II did nöt increase the drug disappearance or decrease the metabolite formation with respect to the EE group I ($P = 0.1/0.8$) (Fig. 6b); meanwhile, no more ADV metabolites appearing in the plasma was observed in EE group II, compared with EE group I (Fig. 7).

Discussion

Previous studies have demonstrated that alkyl esters could be one kind of safe and effective CESs inhibitor, however, no other studies concerning the relationship between the alkyl esters' structure and inhibitory potency have been reported [6, 13]. It is necessary to provide structure-related insights into the interaction between CESs and alkyl esters. Thus, the development of alkyl esters for use in modulating CESs-mediated metabolism in vivo would be easier.

The present study investigated the influence of carbon chain length and level of unsaturation on the inhibitory potency of a homologous series of esters (Figs. 2, 3, 4). As we can see, there are four kinds of alkyl esters in this homologous series of esters. They are saturated short-chain esters (C4–C12), unsaturated short-chain esters (C4–C12), saturated long-chain esters (C14–C20), unsaturated long-chain esters (C14–C20). The result of saturated short-chain esters was inconsistent with previous studies, as shown in Fig. 4a, there is linear correlation between carbon chain length and IC_{50} values with $R^2 = 0.933$ [6]; besides, we found that IC_{50} values were also dependent on ClogP values of the saturated short-chain esters, which was in line with the CESs inhibitors isatins [12]. Meanwhile,

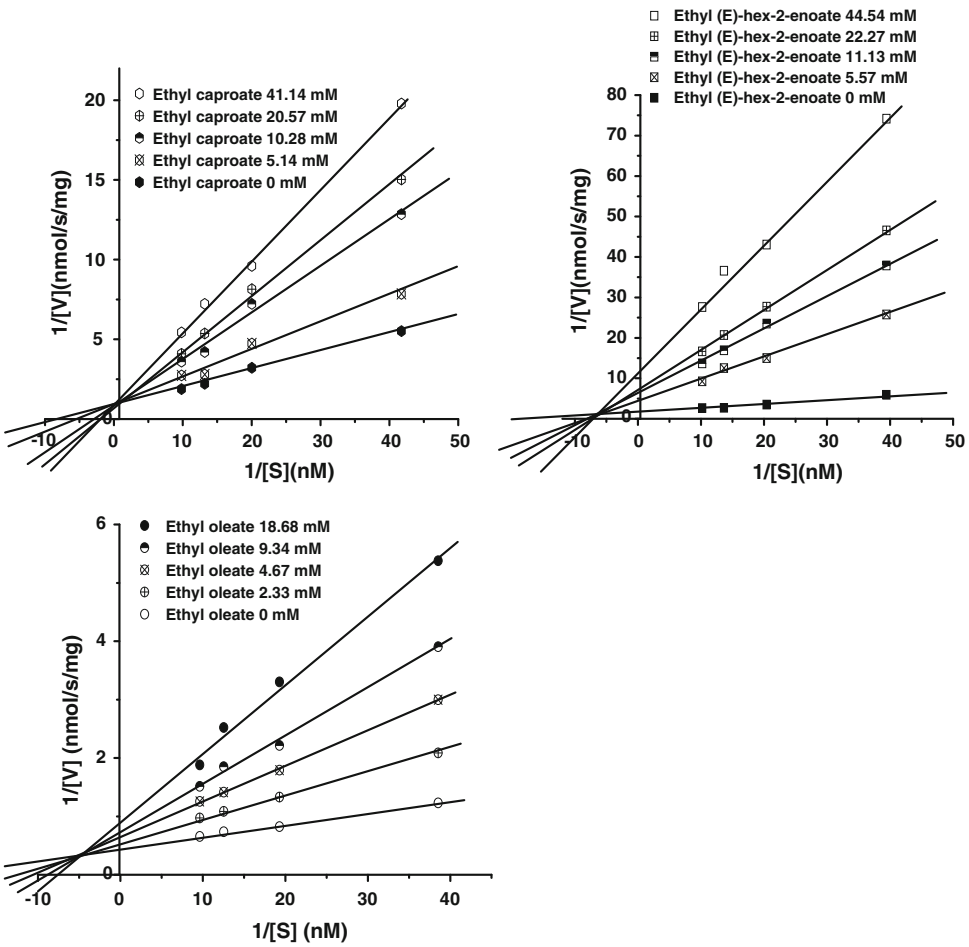

Fig. 5 Lineweaver–Burk plots of the effect of ethyl esters on formation of mono-ADV in rat intestinal homogenates. Each result represents the mean of duplicate determinations. *Lines* represented results of linear regression of transformed data

unsaturated short-chain esters demonstrated even stronger inhibitory potency compared with the saturated short-chain esters, which has not been reported before. Furthermore, both the saturated long-chain esters (C14:0, C16:0, C18:0, C20:0) and unsaturated long-chain esters (C13:1, C17:1) showed no inhibitory effect on CESs. But the unsaturated long-chain esters (C20:1, 2, 3) demonstrated a similar inhibitory potency as the saturated short-chain esters did, which has not been reported before. According to the literature [26], fatty acid esters like C20:1 may be hydrolyzed by CESs in vivo, which indicates that fatty acid esters can interact with the enzyme. It then explains why the (C20:1, 2, 3) demonstrated an inhibitory potency similar to that of the saturated short-chain esters. Moreover, the fatty acid esters are often employed as an excipient in lipid formulation as the oil phase or cosurfactant [27], which makes it possible to incorporate the fatty acid esters as CESs inhibitors into the formulations, thus improving the absorption of ester prodrugs. In addition, the above-mentioned different inhibitory potencies of these esters may be due to various affinities of esters for the active pocket of CESs [28, 29]. As reported [6], there are all kinds of physiochemical characteristics that can affect the inhibitor's affinity to the active site of the enzyme, including the size, steric hindrance and hydrogen bonding potential. In our study, we chose a homologous series of esters with different carbon chain length and level of unsaturation of carboxylic acids, which would lead to different steric hindrances and hydrogen bonding potentials respectively, thus finally influence the inhibitors' affinity to the active site of the enzyme, resulting in different inhibitory potency.

Our result also showed that the structure of the inhibitors can also affect the inhibitory mechanism. According to the Lineweaver–Burk plots (Fig. 5), all investigated ethyl esters demonstrated reversible inhibitory mechanism but with different specific ones. The ethyl caproate (C8:0) can inhibit the CESs in a competitive mechanism, which may be owing to its similar structure to the real substrate of the CESs [30]. Because ADV is the substrate of CESs [22], the C8:0 and ADV compete for access to the active pocket of CESs. However, the ethyl (*E*)-hex-2-enoate (C8:1) and ethyl oleate (C20:1) indicated the different inhibitory mechanisms of CESs. The exact reason for the observations was unknown, but one possible explanation is that the CESs utilizes a two-step serine hydrolase mechanism

involving the formation of a covalent acyl-intermediate on the active site serine residue, enabling larger and more varied substrate molecules access to the buried catalytic residues [31]. As reported, unsaturated fatty acids could bind to CYP enzymes to form a type I spectral change and inhibit the metabolism of some drugs, but saturated fatty acids, were not capable of producing the type I spectral change when binding to CYP enzymes [32]. Thus, we hypothesized that the unsaturated alkyl esters might bind to the CESs-substrate complexes, which would cause the enzymes' conformation change, reducing the enzyme activity and showing a mixed inhibitory mechanism [33].

Rat ileum perfusion was used to study the effect of CESs inhibitors on the intestinal absorption of the prodrug ADV, because of the similar degradation rate of its homologue prodrug tenofovir disoproxil in homogenates from rat ileum compared with homogenates from human ileum [17]. EE (C8:1) was chosen to be studied in the intestinal perfusion experiment, owing to its strongest inhibitory effect on CESs (Table 1). The result of the perfusion study showed that a significant decrease in mono-ADV metabolite formation during perfusion in the presence of BNPP/EE (Fig. 6), indicated that ADV was protected against CESs-mediated metabolism by BNPP/EE. In addition, there was increased absorption of ADV in BNPP/EE groups (Fig. 7), which was in accordance with the drug disappearance in perfusate. This is because BNPP/EE can prevent ADV from degrading into its metabolites and more prodrug ADV remained (Fig. 6). Since the prodrug ADV is more permeable than its metabolites [23], the absorption could be enhanced in the presence of BNPP/EE. Moreover, according to our results, 40 min of intestine pre-exposure to BNPP decreased the mono-ADV metabolite formation and increased ADV absorption versus the BNPP group I (Figs. 6a, 7), which suggested that BNPP inhibition has time-dependent effect. This can be attributed to BNPP's covalent binding to the CESs, which is irreversible. Consequently, a CES-inhibited condition might be obtained by 40 min preperfusion with BNPP at 400 μM [34–36]. However, 40 min of intestine pre-exposure to EE didn't show any difference with the EE group I which had no pre-exposure to EE (Figs. 6b, 7). The result demonstrated that the EE inhibition has no time-dependent effect. Because EE may bind to enzymes with non-covalent interactions

such as hydrogen bonds, hydrophobic interactions and ionic bonds, which are reversible and can be easily removed by dilution or dialysis. Therefore, EE could be a transitory and safe CESs inhibitor, compared with the irreversible inhibitor BNPP that was also proved to have a toxic effect (e.g. $LD_{50} = 410$ mg/kg i.p. in mice) [37].

The increase absorption of ADV by the CESs inhibitors was not due to any considerable mucosa damage. This was shown by measuring the effect of CESs inhibitors on the release of LDH in the perfusate as an indication of cell membrane disruption [38]. No significant increase in LDH activity was observed when it was in the presence of CESs inhibitors such as: BNPP and EE ($22.0 \pm 1.9/19.0 \pm 2.1$ U/l cm in BNPP group II/EE II, compared with 19.9 ± 1.4 U/l cm in control group). Therefore, it can be concluded that BNPP and EE at the investigated concentration, did not affect the intestinal cell membranes.

In conclusion, the present study indicates that alkyl esters showed variable inhibitory effects on CESs-mediated ADV metabolism and that the number of double bonds, as well as the carbon chain lengths in the esters, may therefore play an important role in the inhibition of CESs. Furthermore, the alkyl eaters, especially the aliphatic esters, are biocompatible and can be used as a functional excipient in formulations to increase the ester prodrug absorption.

Anti-scratching Behavioral Effects of *N*-Stearoyl-phytosphingosine and 4-Hydroxysphinganine in Mice

Kwon-Ryeol Ryu · Bomi Lee · In-Ah Lee · Sekwan Oh · Dong-Hyun Kim

Received: 2 February 2010 / Accepted: 3 June 2010 / Published online: 29 June 2010

Abstract *N*-Stearoyl-phytosphingosine (SPS) and 4-hydroxysphinganine (phytosphingosine, PS), which are sphingolipids frequently found in mammalian skin, plants, and yeast, have been used as ingredients in cosmetics. In mice, treatment with SPS and PS inhibited histamine-induced scratching behavior and vascular permeability. These agents inhibited the expression of the allergic cytokines, IL-4 and TNF-α, and the activation of the transcription factors, NF-κB and c-jun, in histamine-stimulated skin tissues. These agents also showed potent anti-histamine effects in the Magnus test using guinea pig ileum. Based on these results, SPS and PS may improve scratching behavioral reactions in skin by regulating the action of histamine and the activation of the transcription factors NF-κB and c-jun.

Introduction

Pruritus, an unpleasant cutaneous sensation that provokes the desire to scratch, can be local or widespread and is associated with atopic dermatitis, urticaria, cholestasis, and uremia. Many endogenous amines, proteases, growth factors, neuropeptides, opioids, eicosanoids and cytokines can act as pruritogens [1–3]. Pruritus can cause skin lesions and contribute to severe psychological disturbances [4]. Thus, inhibition of this response can improve the quality of life. To evaluate the effect of scratching-inhibitory agents, mouse models of histamine, substance P- or compound 48/80-induced scratching behavior have been used [2, 5]. However, there is no specific remedy available for this common symptom.

Ceramides play an important role as intracellular lipid second messengers and as components of the outer layer of the skin [6–8]. Indeed, the outer layer of mammalian skin is abnormally rich in long chain ceramides [9, 10]. These ceramides are located in the lipid phase between the corneocytes of the skin; this lipid phase is composed of ceramides, free fatty acids and cholesterol. The ceramides of the skin are composed of long chain fatty acids with lengths between C16 and C34 and are bound to a long chain di- or tri-hydroxy base through an amide linkage. The most common ceramides are sphingosine, 6-hydroxysphingosine and phytosphingosine. The lipid phase regulates skin water homeostasis and protects the body from bacterial, enzymatic or chemical assaults [10–12]. Therefore, the amounts and the ratios of different ceramide molecules in the skin are crucial for the barrier properties of the skin. The lack or reduction of a ceramide fraction in the skin directly impacts physiological function, leading to the appearance of a number of skin diseases and/or skin irritations [13, 14].

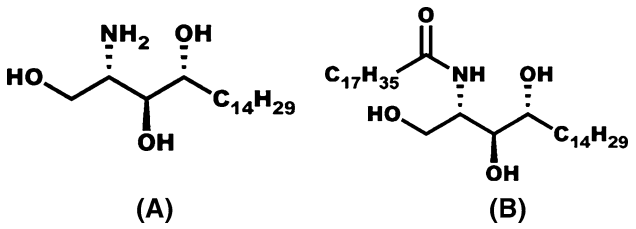

Fig. 1 Structures of phytosphingosine (**a**) and *N*-stearoyl-phytosphingosine (**b**)

Sphinganine (dihydrosphingosine) and 4-hydroxysphinganine (phytosphingosine) are the predominant free long-chain bases in lipid extracts of plant tissues, although they are typically minor components of complex plant sphingolipids [15, 16]. Sphinganine, 4-hydroxysphinganine and their C18 and C20 analogs are the major long-chain bases in yeast. These analogues have been used as cosmetic ingredients due to their pharmacological activities in dermal inflammatory disorders [17]. In particular, *N*-stearoyl-phytosphingosine (SPS) and 4-hydroxysphinganine (PS) (Fig. 1) are widely used as cosmetics ingredients. However, their anti-scratching effects have not been studied thoroughly. Therefore, in the present study, we investigated their anti-scratching behavioral effects in mice.

Experimental Procedure

Materials and Reagents

Histamine and Evans blue dye were purchased from Sigma Co. (St. Louis, MO, U.S.A.). Azelastine was donated by Dr. Nam-Jae Kim, an adjunct professor at Kyung Hee University. Antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Enzyme-linked immunosorbent assay (ELISA) kits were from Pierce Biotechnology (Rockford, IL, USA). Optimal Cutting Temperature (OCT) compound was purchased from Sakura Finetek (Torrance, CA, USA).

Animals

Male ICR mice (20–22 g, 5 weeks old) were obtained from the Charles River Orient Experimental Animal Breeding Center (Seoul, Korea). All animals were housed in wire cages at 20–22 °C, relative humidity of 50 ± 10%, air ventilation frequency of 15–20 times/h and 12-h illumination (07:00–19:00; intensity, 150–300 Lux), fed standard laboratory chow (Charles River Orient Experimental Animal Breeding Center, Seoul, Korea), and allowed water ad libitum. All procedures related to the animals and their care conformed to international guidelines, 'Principles of Laboratory Animal Care' (NIH publication no. 85-23, revised 1985 and Kyung Hee University 2008).

Assay of Scratching Behavior Frequency

The behavioral experiments were performed as previously described [18]. Before the experiments, male ICR mice were acclimated in acrylic cages (22 × 22 × 24 cm) for about 10 min and divided into groups of six. The rostral part of the skin on the back was clipped, and 300 μg/50 μL of histamine dissolved in saline was injected intradermally using a 29-gauge needle. The control mice received a saline injection instead of histamine. Immediately after the intradermal injection, the mice (one animal/cage) were put back into the same cages and their scratching behavior was recorded using an 8-mm video camera (SV-K80, Samsung, Seoul, Korea) under automated conditions. The number of times the mouse scratched the injection site using the hind paws was counted and compared with the scratching of other sites, such as the ears. Each mouse was used for only one experiment. The mice generally scratched several times during 1 s, thus each series of such behavior over 60 min was counted as one incident of scratching.

Measurement of Vascular Permeability

The increase in vascular permeability caused by scratching agents was assessed as reported by Choo et al. [18]. After the intradermal injection of 300 μg/50 μl of histamine into the rostral part of the back of each mouse, 0.2 ml of 1% saline solution of Evans blue dye was injected intravenously. Test samples were orally administered 1 h before the scratching agents. Mice were sacrificed 60 min later by cervical dislocation and the scratching agent-injection site was excised. The skin specimen was dissolved in 1 ml of 1 M KOH solution by overnight incubation, and 4 ml of 0.2 M phosphoric acid solution-acetone (5:13) mixture was added. After shaking, the precipitates were filtered off and the amount of dye was measured colorimetrically at 620 nm.

Histopathological Study

For histopathological analysis, 300 μg of histamine was injected intradermally into the back skin of mice and a skin specimen was excised 60 min later. The skin specimen was fixed in 4% paraformaldehyde, embedded in OCT compound, sectioned (5 μm), stained with hematoxylin and eosin, and examined at ×40–100 magnification.

Analysis of IL-4 and TNF-α by Enzyme-Linked Immunosorbent Assay (ELISA) and Immunoblot

Histamine-induced skin tissue specimens were homogenized in ice-cold lysis buffer (10 mM Tris, pH 7.5, 10 mM NaCl, 3 mM $MgCl_2$, 0.05% Nonidet P-40, 1 mM EGTA,

1:100 protease inhibitor cocktail, and 1:100 phosphatase inhibitor cocktail). Lysed specimens were centrifuged at 2700×*g* for 10 min at 4 °C. The supernatant containing the cytosol was further centrifuged at 20,800×*g* for 15 min at 4°C to obtain the cytosolic fraction. The nuclei in the pellet were washed 3 times by gentle resuspension in wash buffer (10 mM PIPES, pH 6.8, 300 mM sucrose, 3 mM $MgCl_2$, 1 mM EGTA, 25 mM NaCl, 1:100 protease inhibitor cocktail and 1:100 phosphatase inhibitor cocktail) and centrifugation at 2700×*g* for 5 min at 4 °C [19, 20]. The supernatants (50 µl) were transferred to 96-well ELISA plates, and the concentrations of IL-4 and TNF-α were then determined using commercial ELISA kits (Pierce Biotechnology, Inc., Rockford, IL, USA)

Immunoblot analyses of phospho-p65 and phospho-c-Jun in the nuclear fraction and p65 NF-κB and c-jun in the cytosolic fraction were performed as previously reported [20]. The protein fractions of the skin tissue specimens were subjected to electrophoresis on 10% sodium dodecyl sulfate–polyacrylamide gel and then transferred to a nitrocellulose membrane. Phospho-p65, phospho-c-Jun, p65 NF-κB and c-jun were assayed with the corresponding antibodies. Immunodetection was carried out using an enhanced chemiluminescence detection kit (Thermo Fisher Scientific Inc., Rockford, IL, USA).

Anti-histamine Action Assay

Male Hartley guinea pigs (300 ± 30 g) were sacrificed by exsanguination and the ilea were prepared in cold Tyrode solution. The prepared ileal strip was then suspended in a 10-ml Magnus tube (32°C, 95% O_2 + 5% CO_2) containing Tyrode solution. Each test agent was added to the preparation 30 s before treatment with histamine (1×10^{-6} M). The percentage contraction is shown as a percentage of the maximal response to histamine.

Statistics

All data are expressed as the means ± standard deviation, and statistical significance was analyzed by one-way ANOVA followed by a Student Newman–Keuls test.

Results

Inhibitory Effects of SPS and PS on Histamine-Induced Scratching Behavior in Mice

To evaluate the anti-scratching behavioral effects of SPS and PS, we first measured the inhibition of histamine-induced scratching behavior frequency in mice (Fig. 2a). SPS and PS inhibited the scratching behaviors induced by histamine. At 50 mg/kg, orally administered SPS and PS reduced the scratching behavior frequency by 67 and 59% in histamine-stimulated mouse skin. We also investigated their effects in histological exams (Fig. 2b). Compared to the normal group, the histamine-treated control group exhibited severe inflammation, manifested as remarkable epidermal hyperplasia and the infiltration of inflammatory cells, such as dendritic cells, into the dermis. SPS and PS inhibited these inflammatory symptoms.

Inhibitory Effects of SPS and PS on IL-4 and TNF-α Protein Expression Induced by Histamine in Mice

The inhibitory effects of SPS and PS against IL-4 and TNF-α protein expression in mouse skin stimulated with histamine were measured by ELISA (Fig. 3a, b). Histamine increased IL-4 and TNF-α protein expression by 2.5- and 2.3-fold, respectively. SPS and PS potently inhibited histamine-induced cytokine production. At 50 mg/kg, SPS and PS inhibited IL-4 expression by 75 and 37%, respectively, and TNF-α expression by 88 and 70%, respectively.

SPS and PS also inhibited the histamine-induced activation of the transcription factors, NF-κB and c-jun, which regulate TNF-α and IL-4 expression, respectively (Fig. 3c).

Inhibitory Effects of SPS and PS on Histamine-Increased Vascular Permeability and Ileal Contraction

We also measured the inhibitory effects of SPS and PS on the histamine-induced vascular permeability in mice (Fig. 4). Orally administered SPS and PS potently inhibited the histamine-induced vascular permeability. At 50 mg/kg, SPS and PS inhibited the vascular permeability by 51 and 50%, respectively.

We also investigated the inhibitory effect of SPS and PS on the histamine-induced small intestine muscle contraction involving the H1-receptor in guinea pig ilea (Fig. 5). At 10 µM, SPS and PS inhibited histamine-induced ileal contraction by 55 and 51%, respectively.

Discussion

Mast cells and basophils are critical components in various biological processes of allergic diseases [21, 22]. These cells express surface membrane receptors with high affinity and specificity for IgE. The interaction of antigen-bound IgE and surface membrane receptors releases histamine, prostaglandins, leukotrienes and cytokines. These endogenous amines and cytokines can act as pruritogens [22, 23]. The cytokines also activate chemotaxis and phagocytosis of neutrophils and

Each test agent (dissolved in 2% Triton X-100) was added to the preparation 30 s before treatment with histamine (1×10^{-6} M): *closed triangles*, SPS; *closed squares*, PS; *closed circles*, azelastine. Each experiment was performed in duplicate

macrophages. Finally, cytokine-induced reactions cause tissue inflammation. Exogenous pruritogens, such as compound 48/80, also increase the permeability of the lipid bilayer membrane by causing membrane instability. The increase of lipid bilayer membrane permeability may be essential for the release of mediators from mast cells [24]. Therefore, antiallergic agents, such as anti-histamines, steroids and immunosuppressants, have been used to treat allergic and pruritic diseases [25–27]. Even though antiallergic agents are widely used, many of these agents have limited effects in terms of improving these diseases.

In this study, SPS and PS inhibited the scratching behaviors and vascular permeability induced by histamine. The anti-scratching behavioral effects of SPS and PS were proportional to their inhibitory effects against vascular permeability. SPS and PS also inhibited the scratching behavior induced by compound 48/80, an exogenous pruritogen (data not shown). Moreover, SPS and PS showed antihistamine activity in the guinea pig ileum. These results suggest that SPS and PS may repress vascular permeability by inhibiting histamine action and thus inhibit scratching behavior. In a study of their inhibitory mechanism, SPS and PS inhibited TNF-α and IL-4 expression as well as activation of the transcription factors, NF-κB and c-jun, in skin tissues stimulated with histamine. NF-κB is an important signal in immune responses of allergic diseases [28]. Histamine activates NF-κB in skin tissues. In the present study, SPS and PS inhibited histamine-induced activation of NF-κB. Furthermore, SPS and PS inhibited c-jun activation. c-Jun regulates expression of IL-4, which is an IgE-switching cytokine [29]. These results suggest that SPS and PS may inhibit TNF-α and IL-4 expression by regulating the activation of their transcription factors, NF-κB and c-jun.

Ceramides are major lipid second messengers that inhibit cell proliferation and induce apoptosis via dephosphorylation and inactivation of several proliferative and anti-apoptotic molecules [30–32]. In addition, various studies have reported the beneficial role of ceramide molecules in the renewal of the skin's intrinsic protective layer, especially to increase the effective barrier function with respect to water loss, thus reducing skin irritation and inflammation [21, 22]. These results suggest that SPS and PS may regulate skin water homeostasis and protect the body against bacterial, enzymatic or chemical impacts.

Based on these findings, SPS and PS may improve pruritic reactions in skin by regulating the action of histamine, the activation of the transcription factors NF-κB and c-jun, and skin water homeostasis.

Received: 26 January 2010 / Accepted: 26 May 2010 / Published online: 24 June 2010

Abstract Dyslipidemias and physicochemical changes in low-density lipoprotein (LDL) are very important factors for the development of coronary artery disease (CAD). However, pathophysiological properties of electronegative low-density lipoprotein [LDL(−)] remain a controversial issue. Our objective was to investigate LDL(−) content in LDL and its subfractions (phenotypes A and B) of subjects with different cardiovascular risk. Seventy-three subjects were randomized into three groups: normolipidemic (N; $n = 30$) and hypercholesterolemic (HC; $n = 33$) subjects and patients with CAD ($n = 10$). After fasting, blood samples were collected and total, dense and light LDL were isolated. LDL(−) content in total LDL and its subfractions was determined by ELISA. LDL(−) content in total LDL was lower in the N group as compared to the HC ($P < 0.001$) and CAD ($P = 0.006$) groups. In the total sample and in those of the N, HC, and CAD groups, LDL(−) content in dense LDL was higher than in light LDL ($P = 0.001$, 0.001, 0.001, and 0.033, respectively) The impact of LDL(−) on cardiovascular risk was reinforced when LDL(−) content in LDL showed itself to have a positive association with total cholesterol ($\beta = 0.003$; $P < 0.001$), LDL-C ($\beta = 0.003$; $p < 0.001$), and non-HDL-C ($\beta = 0.003$; $P < 0.001$) and a negative association with HDL-C ($\beta = -0.32$; $P = 0.04$). Therefore, LDL(−) is an important biomarker that showed association with the lipid profile and the level of cardiovascular risk.

people) in the world, followed by cancer (7.6 million deaths) and chronic respiratory diseases (4.1 million deaths) [1].

The "traditional" risk factors for CHD, as identified in the Framingham study, include high levels of total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C), low levels of high-density lipoprotein cholesterol (HDL-C), as well as elevated blood pressure, tabagism, and age [2]. In addition, obesity, familial history of premature CHD, and physical inactivity contribute to other classical risk factors being now considered important associated factors [3].

Despite the environmental risk factors and LDL-C blood levels, evaluation of low-density lipoprotein (LDL) subfractions according to the phenotype is a more specific marker. LDL can be separated into two subclasses: Phenotype A (predominance of large and light LDL particles) and Phenotype B (small and dense LDL particles), which have been considered predictors of cardiovascular risk [4].

Beyond the phenotypic differences, growing evidence suggests that qualitative changes in LDL are related to the development of atherosclerosis [5–7]. Electronegative particles generated by oxidative modification appear to play a key role in the atherogenicity of LDL. However, non-enzymatic glycosylation, enrichment of non-esterified fatty acids, enzymatic modification by phospholipase A_2 or platelet-activating factor acetylhydrolase (PAF-AH), hemoglobin cross-linking, and possibly other mechanisms not yet identified could contribute to increasing the proportion of electronegative low-density lipoprotein [LDL(−)] in plasma [8].

LDL(−) is a minimally modified form of LDL that can both be identified as an initiating factor of atherosclerosis and contribute to the atherogenic potential of LDL, thus increasing cardiovascular risk [7, 9]. LDL(−) is enriched with lipid peroxides and is associated with small and dense LDL [10, 11]. Apo E, apo C-III [12], hemoglobin [13], and PAF-AH [14] have been reported to be associated with LDL(−). Presence of these proteins would increase LDL(−) density, which has been observed in normocholesterolemic subjects [8]. Moreover, Chappey et al. [12] showed a bimodal distribution of LDL(−) between the light and dense LDL subfractions. Nevertheless, the pathophysiological action of LDL(−) is yet unclear.

In this context, the aim of our study was to evaluate LDL(−) distribution between LDL subfractions (phenotypes A and B) in subjects with different levels of cardiovascular risk.

Materials and Methods

Study Population

Seventy-three outpatients of both sexes, aged 25–65 years, and with different levels of cardiovascular risk were recruited in the Heart Institute and the Clinical Hospital (School of Medicine, University of Sao Paulo), SP, Brazil. The subjects were randomly distributed into the normolipidemic (N; LDL-C <160.0 mg/dL, with no clinical cardiovascular events, $n = 30$), hypercholesterolemic (HC; LDL-C ≥160.0 mg/dL, with no clinical cardiovascular events, $n = 33$), and coronary artery disease (CAD; LDL-C ≥160.0 mg/dL, with clinical diagnosis of atherosclerosis, $n = 10$) groups. The atherosclerotic coronary disease was diagnosed by clinical evaluation, electrocardiogram with ischemia, and positive ergometric test and/or positive myocardial scintigraphy and/or coronarography with obstruction of at least 50% in one of the arteries. Subjects with diabetes, renal disease, obesity (BMI ≥35.0 kg/m^2), smokers and alcoholics were excluded from the trial. A 2-month period was observed for washout of hypocholesterolemic drugs, hormone therapy, and antioxidant supplements. The present study was approved by the Ethics Committee of both the Heart Institute (InCor) (#2585/05/005) and Clinical Hospital (#562/05) of the Medical School, University of Sao Paulo (Brazil).

Sample Characteristics

Information on the subject's race, risk factor for CAD [2], and daily metabolic energy consumption were obtained by direct interview. BMI was determined as weight (kg) divided by standing height (m) squared [15], and waist circumference (WC) was measured midway between the lowest rib margin and the iliac crest [16].

Blood Samples

After a fasting period of 12–15 h, aliquots of venous blood (20.0 mL) were collected into Vacutainer® tubes with ethylenediamine tetraacetic acid (EDTA; 1.0 mg/mL). Plasma was immediately separated and aliquoted into tubes containing butylhydroxytoluene (BHT; 100.0 μM), aprotinin (10.0 μg/mL), benzamidine (10.0 μM), and phenylmethylsulphonyl fluoride (PMSF; 5.0 μM) and stored at −70 °C until analysis. Very low-density lipoprotein (VLDL), LDL, and HDL were isolated from the plasma by preparative sequential ultracentrifugation (18 h, 105,000×g, 4 °C) using a Sorvall ultracentrifuge (Sorvall Ultra Pro80, Sorvall Products, Newtown, CT, USA) equipped with a fixed-angle rotor (T-1270) [17]. Subfractions were separated from LDL by ultracentrifugation (18 h, 105,000×g, 4 °C), using a density cut-off point of 1.043 g/mL to separate low- and high-density LDL particles. The denser LDL subfraction (phenotype B) contained particles with $1.043 \leq d < 1.063$ g/mL and the most buoyant LDL subfraction (phenotype A) contained particles with $1.019 < d < 1.043$ g/mL. These LDL subfractions were dialyzed

against 150.0 mM sodium chloride, 1.0 mM EDTA and 10.0 mM trizma base (pH 7.2, 4 °C, 12 h). All reagents were purchased from Sigma Chemical (St. Louis, MO, USA).

Lipid and Protein Analyses

Cholesterol and triglyceride concentrations were determined from plasma and lipoprotein fraction by using colorimetric enzymatic commercial kits (Labtest®, MG, Brazil). Non-HDL cholesterol levels and the TC/HDL-C and LDL-C/HDL-C ratios were calculated for all samples. Protein concentration in plasma and lipoproteins were determined by using the Lowry method [18].

LDL(−) Analyses

LDL, and the dense and light LDL subfractions were diluted (1:800, 1:10, and 1:10, respectively) in 0.01 M carbonate–bicarbonate buffer (pH 9.6) and were used to coat (overnight, 4 °C) the microtiter plates (Costar®, model 3690, Cambridge, MA, USA). Non-adsorbed material was washed and discarded; then the plates were blocked with 5% skimmed milk in phosphate-buffered saline (PBS) and incubated (2 h, 37 °C). The plates were washed with PBS-Tween (0.05%, 4 times) and, after addition of anti-LDL(−) monoclonal antibody (MAb; INPI #2637/2002; 9.2 μg/mL; 50 μL/well), they were again incubated (2 h, 37 °C). After a new wash with PBS-Tween, horseradish peroxidase-conjugated polyclonal goat anti-mouse IgG antibody (Rockland Immunochemicals for Research, Gilbertsville, PA, USA; 50 μL/well) diluted 1:5,000 (v/v) in skimmed milk (1% in PBS) was added to the wells and incubated (2 h, 37 °C). After the plates were washed, a solution containing the substrate 3,3′,5,5′-tetramethylbenzidine (TMB; 250.0 μL), phosphate–citrate buffer (12.0 mL; pH 4.2), and hydrogen peroxide (10.0 μL) was added (50.0 μL/well). All samples were analyzed in triplicate. After a 30-min delay for color development, the colored product concentration was evaluated by light absorption (Bio-Tek® Instruments, Winooski, VT, USA; $\lambda = 450$ nm); the concentrations were calculated as a function of optical density (OD) readings: $(OD_{sample} - OD_{background}) \times$ title.

Statistical Analyses

Differences between the values for the N, HC, and CAD groups were evaluated by one-way analysis of variance (ANOVA) and the Kruskal–Wallis test. Differences between the LDL subfractions were evaluated by the Student's *t* test for independent samples and the Mann–Whitney test. Univariate linear regression analysis was used to evaluate the association between LDL(−) levels (dependent variable) and the lipid profile (independent variable). Data were expressed as means ± standard deviation (SD). The SPSS Statistical Package (version 15.0) was used for all analyses. A cut-off level of $P < 0.05$ was adopted to infer statistical significance.

Results

The characteristics of the subjects included in this study are shown in Table 1. Groups N (40.0 ± 9.9 years), HC (45.0 ± 10.0 years), and CAD (54.0 ± 7.7 years) consisted of male ($n = 7$, 11, and 5, respectively) and female ($n = 23$, 22, and 5, respectively) subjects. The subjects in the CAD group were older than those in the N and HC groups ($P = 0.001$ and 0.03, respectively). No statistical differences were found between sexes and races in the groups. Therefore, all results were analyzed using age as a covariate. No significant differences were found between groups for BMI and WC. None of the subjects were smokers or consumed alcohol. The risk factors for hypertension and age were different in the CAD group as compared to the N ($P < 0.001$ and =0.01, respectively) and HC ($P < 0.001$ and =0.02, respectively) groups. The percentage of subjects with low HDL-C in the N group was lower than that in the CAD group ($P = 0.04$). The values for energy consumption were similar among the three groups. As expected, the subjects in the N group showed lower values for TC and LDL-C than those in the HC ($P < 0.001$ and 0.001, respectively) and CAD ($P < 0.001$ and 0.001, respectively) groups. The values for HDL-C in the CAD group were lower than those in the N group ($P = 0.02$). However, no significant differences in TAG concentration were found among the three groups. In addition, the values for non-HDL-C and the TC/HDL-C and LDL-C/HDL-C ratios in the N group were lower than in the HC ($P < 0.001$, 0.001, and 0.001, respectively) and the CAD ($P < 0.001$, 0.001, and 0.001, respectively) groups.

The levels (OD in Log) for LDL(−) in LDL in the HC (7.1 ± 0.4) and CAD (7.1 ± 0.2) groups were higher than in the N (6.7 ± 0.5) ($P < 0.001$ and =0.006, respectively) group (Fig. 1). The levels (OD in Log) for LDL(−) in dense LDL were higher than in light LDL in the total sample (2.7 ± 0.8 vs. 2.1 ± 0.5, $P = 0.001$) in the N (2.7 ± 0.8 vs. 2.1 ± 0.4, $P = 0.001$), HC (2.7 ± 0.8 vs. 2.0 ± 0.6, $P = 0.001$), and CAD (2.7 ± 0.8 vs. 2.2 ± 0.4, $P = 0.033$) groups (Fig. 2). Therefore, LDL(−) content in LDL varied according to the cardiovascular risk and, independently of this characteristic, LDL(−) content showed a higher association with dense LDL when LDL(−) was analyzed in subfractions of LDL from the N (55.6 vs. 44.4%), HC (57.1 vs. 42.9%), and CAD (55.7 vs. 44.3%) groups. The intra- and inter-assay coefficients for total

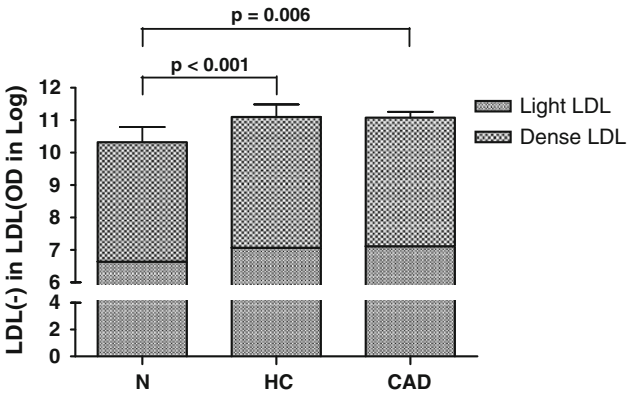

Fig. 1 LDL(−) concentration in LDL among the three groups. Normolipidemic (*N*; $n = 30$), hypercholesterolemic (*HC*; $n = 33$) and coronary artery disease (*CAD*; $n = 10$) groups

LDL (intra = 1.8 ± 1.9; inter = 3.8 ± 2.7), dense LDL (intra = 3.5 ± 4.1; inter = 2.6 ± 1.2), and light LDL (intra = 4.5 ± 4.6; inter = 2.9 ± 1.9) showed that ELISA, as used in the present study, was a valid method for assessing LDL(−) content.

In addition, when univariate linear regression analysis was used, the content of LDL(−) in total LDL showed a positive association with TC ($\beta = 0.003$; $P < 0.001$), LDL-C ($\beta = 0.003$; $P < 0.001$), and non-HDL-C ($\beta = 0.003$; $P < 0.001$). However, a negative association with HDL-C was obtained for LDL(−) content in total LDL ($\beta = -0.32$; $P = 0.04$) and dense LDL ($\beta = -0.66$; $P = 0.02$) when all samples ($n = 73$) were analyzed (Table 2).

Discussion

The purpose of this study was to evaluate LDL(−) content in subjects with different levels of cardiovascular risk and to determine the association between their cardiovascular risk and lipid profile. CHD are complex and multifactorial, and dyslipidemia is present in most subjects with clinical events. Other factors were recently investigated and LDL(−) was associated with increased cardiovascular risk [8, 19].

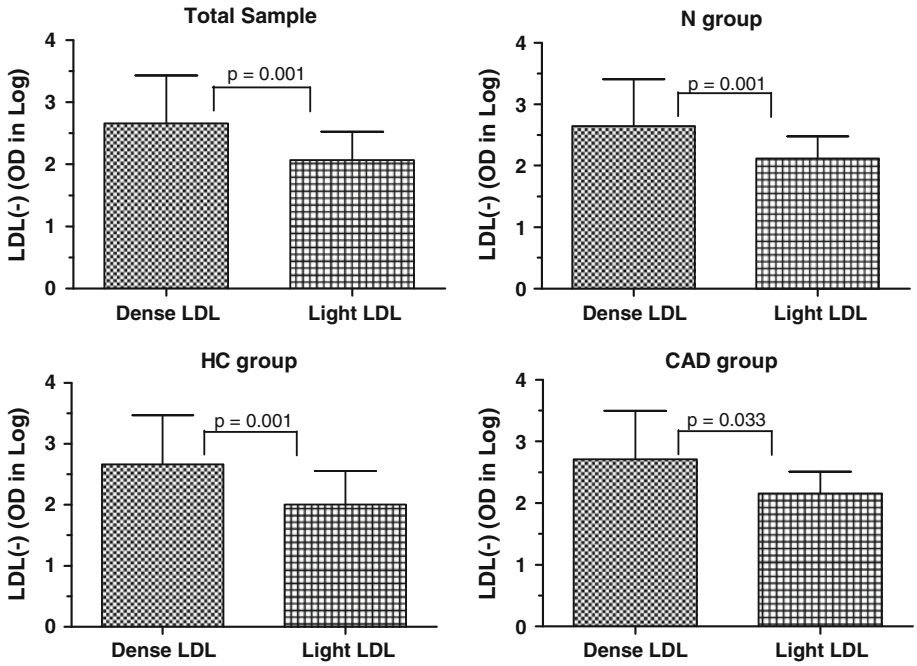

Fig. 2 LDL(−) concentration in dense and light LDL in total sample and groups isolated. Normolipidemic (*N*; $n = 30$), hypercholesterolemic (*HC*; $n = 33$) and coronary artery disease (*CAD*; $n = 10$) groups

Table 2 Linear regression analysis of LDL(−) content in LDL and dense LDL

	β	R^2 (%)	*P*
LDL(−) in LDL			
Total cholesterol	0.003	0.24	<0.001
LDL-C	0.003	0.30	<0.001
HDL-C	−0.321	0.06	0.043
Non-HDL-C	0.003	0.28	<0.001
LDL(−) in dense LDL			
HDL-C	−0.661	0.08	0.022

However, a number of technical limitations have made LDL(−) detection difficult [19]. Some studies evaluated LDL(−) by semi-quantitative methods [9, 11, 20]. Sensitive and specific anti-LDL(−) MAb-based ELISA evaluations were developed allowing the role of LDL(−) to be investigated [19, 21, 22].

Oliveira et al. [7], proposed that LDL(−) levels may be a biochemical marker for cardiovascular disease risk. Furthermore, Hulthe and Fagerberg [6] concluded that subjects with at least one plaque in the carotid or femoral arteries have oxLDL levels significantly higher than those found in subjects without plaques. These observations reinforce the notion that oxidized LDL and possibly LDL(−) have a potential role in atherosclerosis. LDL(−) was found to be elevated in animals and humans with hypercholesterolemia and atherosclerosis [19, 23, 24]. In the present study, as in the studies mentioned above, the values for LDL(−) content in subjects with dyslipidemia and atherosclerosis were shown to be higher than those in the N group. Such profiles could be observed only when LDL(−) content was analyzed in LDL.

In fact, LDL(−) content in LDL from subjects in the HC and CAD groups was shown to be higher than in the N group. Moreover, LDL(−) content in dense LDL was higher than in light LDL, irrespective of the clinical status of the subjects evaluated. Such a profile had previously been observed by Sevanian et al. [10, 11], who showed that LDL(−) has a higher association with small and dense LDL. However, Sánchez-Quesada et al. [25] observed that LDL(−) was equally distributed between light (1.022–1.027 g/L) and dense (1.047–1.056 g/L) LDL from hypertriglyceridemic subjects. LDL(−) was relatively frequent in dense LDL subfractions (1.039–1.056 g/L) from normolipidemic subjects. Finally, LDL(−) proportion was relatively high in all LDL subfractions, mainly in the two lightest (1.022–1.027 g/L) ones from patients with familial hyperlipidemia [25]. According to these authors, distribution of LDL(−) in these subjects depends on their lipid profile. We propose that LDL(−) content was influenced by the lipid profile being more frequent in dense LDL particles (phenotype B), although independently of the subjects' clinical status. In addition, the subjects included in this study did not show hypertriglyceridemia or familial hyperlipidemia, suggesting that LDL(−) has different physicochemical characteristics and origin as previously observed by Sánchez-Quesada et al. [25].

It should be emphasized that both different density cut off values and different (quantitative or qualitative) methods were used to determine LDL(−) content in the LDL

subfractions in those studies. To our knowledge, the present study is the first one in which LDL(−) content in LDL subfractions was determined by ELISA. Thus, our results should be confirmed with a larger sample.

Regarding the oxidative origin of LDL(−), our results confirm those reported in the study of Dejager et al. [26]. These authors observed that the lag phase in dense LDL was shorter than in light LDL after copper-induced oxidation. Thereafter, La Belle et al. [27] verified that dense LDL was more electronegative than light LDL. Therefore, among light and dense LDL particles, the dense ones showed themselves to have the highest oxidative susceptibility [10].

It is well established that the proportion of small and dense LDL particles in patients with CAD is higher than in healthy subjects [28, 29]. Although the size of LDL particles was not evaluated in the present study, detection of LDL(−) in dense LDL contributed to better understand the atherogenic role of the particles present in phenotype B. The impact of these results was reinforced by regression analysis, which revealed that LDL(−) content has a positive association with classical markers of cardiovascular risk (TC, LDL-C, and non-HDL-C), but a negative association with HDL-C.

In conclusion, we report herein that LDL(−) content in HC and atherosclerotic subjects was higher than in normolipidemic individuals. The atherogenic role of LDL(−) was evidenced by both association of this subfraction with the patients' lipid profile and a higher proportion of dense LDL in phenotype B. Regarding the clinical importance of our findings, we suggest that evaluation of LDL(−) content should be included in future epidemiological studies to better assess the risk of individuals with cardiovascular disease.

Acknowledgments The present study was financially supported by grants from FAPESP (#04/11792-6). The authors acknowledge Dr Paulo Boschcov, former professor at UNIFESP, for his revision of the final version of the manuscript.

Abstract Oxidative modification of low-density lipoprotein (LDL) has been reported in thalassemia, which is a consequence of oxidative stress. However, the levels of oxidized high-density lipoprotein (HDL) in thalassemia have not been evaluated and it is unclear whether HDL oxidation may be linked to LDL oxidation. In this study, the levels of total cholesterol, iron, protein, conjugated diene (CD), lipid hydroperoxide (LOOH), and thiobarbituric acid reactive substances (TBARs) were determined in HDL from healthy volunteers and patients with β-thalassemia intermedia with hemoglobin E (β-thal/Hb E). The protective activity of thalassemic HDL on LDL oxidation was also investigated. The iron content of HDL_2 and HDL_3 from β-thal/HbE patients was higher while the cholesterol content was lower than those in healthy volunteers. Thalassemic HDL_2 and HDL_3 had increased levels of lipid peroxidation markers i.e., conjugated diene, LOOH, and TBARs. Thalassemic HDL had lower peroxidase activity than control HDL and was unable to protect LDL from oxidation induced by $CuSO_4$. Our findings highlight the oxidative modification and poor protective activity of thalassemic HDL on LDL oxidation which may contribute to cardiovascular complications in thalassemia.

Keywords Thalassemia · HDL · LDL oxidation · Oxidative stress · Oxidized HDL

Abbreviations

CD	Conjugated diene
HDL	High-density lipoprotein
LDL	Low-density lipoprotein
LOOH	Lipid hydroperoxide
OD	Optical density
TBARs	Thiobarbituric acid reactive substances
β-thal/Hb E	β-Thalassemia with hemoglobin E

Introduction

β-Thalassemia/hemoglobin E (β-thal/Hb E) is a syndrome caused by mutation on β-globin gene (from β-26 glutamine to lysine) that is prevalent in the southeast Asia. The abnormal globin complex is unstable and leads to hemolytic anemia and hemosiderosis [1]. The iron-bound molecules such as hemichrome and hemin may undergo a chain of oxidative reactions with biomolecules and cause dysfunctions of platelets and vascular endothelial cells [2–5]. Dyslipoproteinemia in thalassemia [6–9] is a consequence of lipid peroxidation associated with iron overload [10, 11]. The low cholesterol levels were related to depletion of vitamin E and severity of thalassemia [2, 12].

Oxidative modification of thalassemic LDL had been reported [7–11, 13, 14] which was related to the increased protein and triglyceride content but decreased cholesterol and vitamin E content [9]. The presence of oxidized LDL in thalassemia was evidenced by high levels of CD and TBARs in LDL [10, 11], and the elevated levels of oxidized LDL antibody in plasma [13]. The high levels of circulating oxidized LDL in thalassemia were demonstrated to associate with the early atherosclerosis and endothelial dysfunction responsible for cardiovascular complications of the disease [14, 15].

HDL particles exert anti-atherogenic activities by three major mechanisms: reverse cholesterol transport, carrying oxidized lipids from tissues and LDL back to liver, and protection of LDL from oxidation [16–20]. The protective activity of HDL on LDL oxidation involves enzymatic and non-enzymatic mechanisms. Enzymes located in HDL such as paraoxonase-1, platelet-activating factor acetylhydrolase, and lecithin-cholesterol acyltransferase have been shown to hydrolyze oxidized lipids and thus inhibit LDL oxidation [17, 21, 22]. For example, HDL-associated paraoxonase-1 was shown to possess peroxidase activity because of its ability to hydrolyze LOOH and hydrogen peroxide [23]. This enzyme was believed to protect HDL and LDL from oxidation. By non-enzymatic mechanisms, HDL could inhibit LDL oxidation by chelation of metal ions by apolipoprotein A-I [24] and by action of antioxidants such as vitamin E and carotenoids [25]. These findings indicate that several antioxidant mechanisms exist in HDL.

Thalassemic HDL was shown to have low cholesterol content, high triglyceride content, abnormal apo A-I [7, 8], and impairment of paraoxonase activity [26, 27]. Although the increased levels of oxidized LDL in thalassemia have been reported, the levels of oxidized HDL and its association with LDL oxidation have not been defined. We hypothesize that thalassemic HDL is oxidatively modified and has impaired activity to protect LDL from oxidation.

Methods

Subjects

This study was approved by the Committee on Ethical Practice and the Ethical and Scientific Review Subcommittee of Mahidol University. Informed consent was obtained from 27 healthy volunteers at the blood bank, Ramathibodi hospital and 22 patients with thalassemia intermedia (β-thalassemia/Hb E) at the Hematology Unit, Faculty of Medicine Siriraj Hospital, Mahidol University. The healthy volunteers (11 males and 16 females) were 24–52 years of age (mean ± SD = 32 ± 10.3 years). The thalassemic patients (10 males and 12 females), aged 17–50 years (mean ± SD = 32 ± 11.6 years), were clinically in a steady state with no iron chelation therapy and blood transfusion for at least 1 month before the study. The serum ferritin levels of patients ranged from 322 to 5,602 ng/mL. The patients and healthy volunteers who had history of supplemental vitamin intake within a month or cigarette smoking were excluded from the study.

Blood Collection and Plasma Preparation

Blood was collected in glass tubes using EDTA (1.5 mg/mL) as anticoagulant after 8 h of fasting. Plasma was separated by centrifugation at 2500*g* for 10 min at 4 °C and kept at −70 °C within a week before use. For assay of the peroxidase activity of HDL, heparinized blood (1 unit/mL) was used.

Lipoprotein Separation

Lipoproteins were separated by sequential density gradient ultracentrifugation using a Beckman Optima LE-80K centrifuge and a Ti 90 rotor at 548,000*g* at 4 °C. The plasma was adjusted to desired density by addition of a mixture of Mork's salt solution and concentrated KBr solution. LDL was obtained at density between 1.019–1.063 g/mL, HDL_2 at density between 1.063 and 1.125 g/mL, and HDL_3 at density between 1.125 and 1.210 g/mL [28]. These lipoproteins were stored at −70 °C until analysis within 1 week.

HDL Composition

The composition of HDL_2 and HDL_3 was determined by the following methods: levels of protein content by modified Lowry's method [29], total cholesterol by an enzymatic test kit (Bio-medical Laboratory, Thailand) to yield quinoneimide dye with maximum absorption at 550 nm, and total iron content by measuring the ferrozine-ferrous ion complex at the optical density (OD) 562 nm [30].

Lipid Peroxidation

Measurement of conjugated diene (CD, an initial lipid peroxidation marker): 100 μg protein/mL of lipoprotein suspension was diluted with 2 mL of 10 mM PBS. The OD at 234 nm was measured immediately to avoid autoxidation in room air [31]. The amount of CD was calculated with the use of the molar extinction coefficient (ε_{234} = 29,500 M^{-1} cm^{-1}) [32].

Measurement of lipid hydroperoxide (LOOH, a marker of lipid peroxidation produced in the propagation phase): 100 μg protein/mL of lipoprotein suspension was added to 3 mL of 4.5 mM $FeSO_4$ dissolved in 0.2 M HCl with 3%

deaerated methanolic solution of KSCN. The mixture was incubated at room temperature for 30 min, then the OD at 500 nm was measured [33].

Measurement of thiobarbituric acid reactive substances (TBARs, a final lipid peroxidation marker): 500 μL of lipoprotein suspension (100 μg protein/mL) was used to determine the levels of TBARs with spectrofluorometer (Jasco FP 770, Japan Spectroscopic Co. Ltd. Tokyo, Japan) at 515 nm excitation and 553 nm emission wavelength [34].

Protective Activity of HDL on LDL Oxidation

LDL oxidation was determined as LOOH levels. LDL and HDL were dialyzed in 10 mM PBS (pH 7.4) for 24 h at 4 °C. LDL oxidation was conducted in the absence or presence of HDL. LDL/HDL mixture (ratio 1:1) containing 200 μg protein/mL in 2 mL of 10 mM PBS buffer (pH = 7.4) was incubated with 30 μM $CuSO_4$ at 37 °C for 90 min.

Peroxidase Activity of HDL

Hydrogen peroxide (H_2O_2, 2.5 μg/mL) was added to the HDL suspension (100 μg protein/mL). The levels of peroxide in HDL were determined by the KSCN-method [33] at the times 0, 15, 30, 60, and 90 min, comparing them with the levels of peroxide in PBS.

Statistical Analysis

All data are presented as means ± SD. Data processing and statistical analysis were done by Prism, version 4.0 (GraphPad Software Inc., San Diego, CA). Analysis of variance (ANOVA) with Tukey's multiple comparison test or Student's *t* test were used to compare with acceptable *P* value less than 0.05.

Results

Composition and Oxidation of Thalassemic HDL

The cholesterol content in HDL_2 and HDL_3 of β-thal/Hb E patients was significantly lower in β-thal/Hb E than those of control ($P < 0.01$) (Fig. 1a). Total iron content of thalassemic HDL_2 and HDL_3 (6.80 ± 3.38 and 6.94 ± 3.38 mM, respectively) was higher than the levels found in healthy volunteers (1.03 ± 0.40 and 0.57 ± 0.34 mM) ($P < 0.01$) (Fig. 1b), but no difference in protein content was noted between the two groups (Fig. 1c).

HDL_3 of β-thal/Hb E, however, showed increased levels of CD (Fig. 2a). The HDL_2 and HDL_3 of β-thal/Hb E had increased levels of LOOH (HDL_2, 1.14 ± 0.34 versus 0.48 ± 0.42 μM; HDL_3, 1.23 ± 0.38 vs 0.70 ± 0.39 μM) ($P < 0.05$) (Fig. 2b). Levels of the final lipid peroxidation product (TBARs) in thalassemic HDL_3 were higher than those of control HDL_3 (0.41 ± 0.08 versus 0.22 ± 0.08 μM) ($P < 0.05$) (Fig. 2c). Although the levels of CD and TBARs in HDL_2 were not different from control, the ratio of CD, LOOH, and TBARs to cholesterol in HDL_2 and HDL_3 appeared to be higher in thalassemia than in control (Fig. 2d–f).

Protective Effect of HDL on LDL Oxidation

The peroxidase activity of HDL from healthy volunteers and of β-thal/Hb E patients was monitored by measuring a

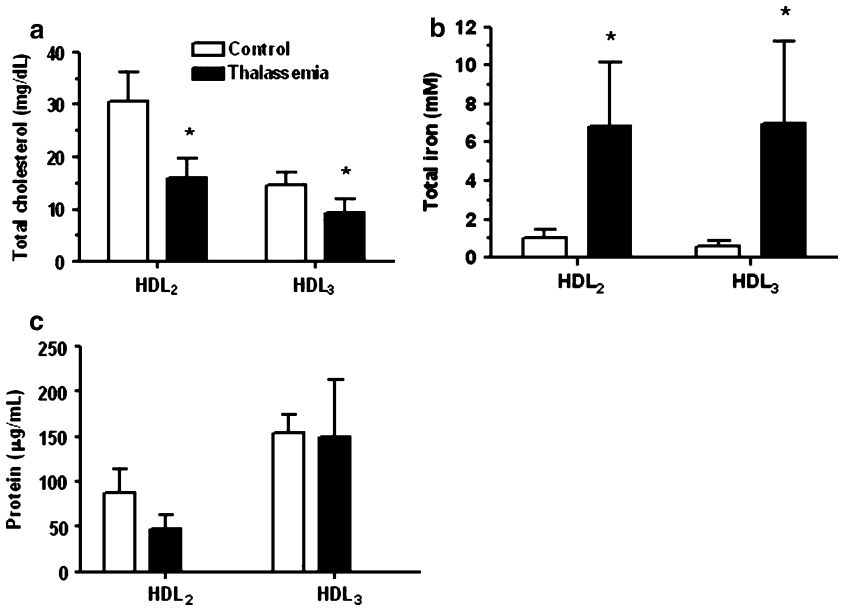

Fig. 1 Biochemical composition of HDL_2 and HDL_3 obtained from control healthy volunteers ($n = 12$) and thalassemia patients ($n = 10$). **a** Total cholesterol (mg/dL). **b** Total iron content (mM). **c** Protein content (μg/mL). Data are means ± SD. *$P < 0.05$ with the unpaired *t*-test compared with control

Data are means ± SD. $^*P < 0.05$ with the unpaired *t* test compared with control

decrease of peroxide levels after addition of 2.5 μg/mL H_2O_2 to the HDL mixture for 90 min (Fig. 3a). In PBS, without addition of HDL, there was no change in peroxide levels after 90 min. Control HDL from healthy volunteers decreased peroxide levels to 47% of the initial values after 90 min of incubation. Thalassemic HDL showed the slower rate of peroxide decrease and after 90 min of incubation the levels decreased to 72% of the initial levels.

To test whether thalassemic HDL has the ability to prevent LDL oxidation, oxidation of LDL (200 μg protein/mL) obtained from healthy volunteers was induced by 30 μM $CuSO_4$ in the presence and absence of HDL. The maximal LOOH levels (6.23 ± 1.43 μM) were obtained at 90 min following incubation of LDL and $CuSO_4$ at 37 °C and then the levels decreased gradually. Thus, the effect of HDL on LDL oxidation induced by $CuSO_4$ was examined by measuring LOOH levels at this time point. Control and thalassemic HDL was also oxidized by the same concentration of $CuSO_4$ and the LOOH levels at 90 min were 4.81 ± 0.97 and 4.75 ± 0.63 μM, respectively (Fig. 3b). When the control HDL from healthy volunteers was added into the LDL/$CuSO_4$ mixture, LDL oxidation was decreased significantly by 44% (LOOH content = 3.46 ± 0.57 μM, $P < 0.05$ compared with the mixture without HDL). However, the thalassemic HDL was unable to prevent LDL oxidation (23% decrease, LOOH content = 4.82 ± 0.83 μM).

Discussion

HDL is known to regulate lipoprotein metabolism and reverse cholesterol transport which contributes to the anti-atherogenic property. The anti-atherogenic activity of HDL is related to their cholesterol levels, especially when those levels are higher than 60 mg/dL [35]. In addition, HDL possesses the protective activities that prevent lipoprotein oxidation by carrying oxidized lipids from peripheral tissues and LDL to liver. HDL also contains enzymes including paraoxonase-1 [23, 36], lecithin/cholesterol acyltransferase [19, 22], and platelet-activating factor acetylhydrolase [17] that are believed to be responsible for the protective antioxidant activity on LDL oxidation.

Our study demonstrates that thalassemic HDL is oxidatively modified, probably because of oxidative stress, high iron content, and impaired peroxidase activity to protect HDL itself. The oxidative changes of thalassemic HDL are also related to the low cholesterol content in HDL. Thalassemic HDL contains high concentrations of lipid peroxidation products (CD, LOOH and TBARs), but low cholesterol content. HDL_3 had significantly higher levels of lipid peroxidation markers than HDL_2. HDL_2 had no difference in the levels of CD and TBARS compared to control, however, the ratio of these markers to cholesterol content was increased. These suggest that the oxidative modification of thalassemic HDL has association with the

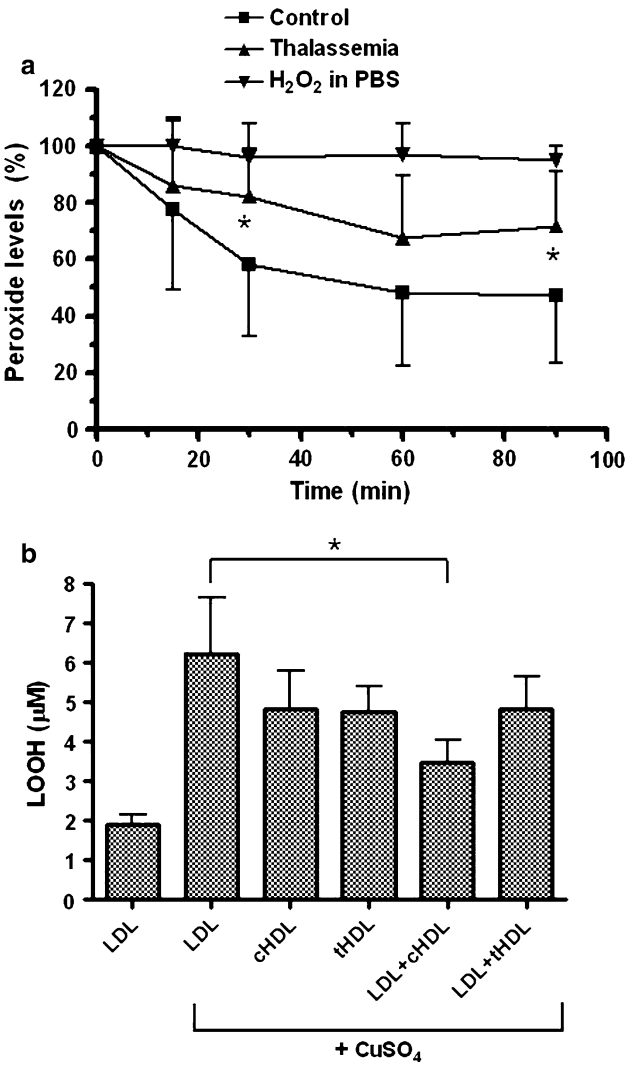

Fig. 3 Peroxidase activity and protective effect of HDL on LDL oxidation. **a** Peroxidase activity of HDL from healthy volunteers ($n = 10$) and β-thal/HbE patients ($n = 10$). Levels of peroxide were measured at different time after addition of 2.5 μg/mL H_2O_2 into HDL mixture (100 μg protein/mL) at 37 °C. *$P < 0.05$ compared between control and thalassemia. **b** Lipid hydroperoxide (LOOH) levels in LDL obtained from healthy volunteers ($n = 5$) were measured before and after incubation with 30 μM $CuSO_4$ for 90 min at 37 °C. LOOH levels were also determined in control HDL (cHDL) and thalassemic HDL (tHDL) ($n = 5$ each) in the presence of $CuSO_4$. All reaction mixtures contained final protein concentration of 200 μg/mL. The ratio of LDL:HDL was 1:1. Data are mean ± SD. * $P < 0.05$ as analyzed by one-way ANOVA with Tukey's multiple comparison test

increased oxidative stress in thalassemia [2, 4]. Our data that HDL_3 (an innate HDL which is important in reverse cholesterol transport) has higher lipid peroxidation markers than HDL_2 (a form of HDL after accepting cholesterol) corresponds to the functions of HDL_3 that serves to accept oxidized lipids from other lipoproteins and tissues [18, 37–39]. Thus, the antioxidant mechanisms within HDL_3 act to remove oxidized intermediates and lessen accumulation of LOOH and TBARs in HDL_2.

In addition to accepting oxidized lipids from tissues and lipoproteins and carrying them back to liver [18], HDL_3 contains paraoxonase-1 which possesses peroxidase activity [40]. This enzyme located on HDL_3 is believed to involve in the enzymatic protection against lipoprotein oxidation [23]. Decreased activity of plasma and HDL-associated paraoxonase-1 was reported in thalassemia [26, 27]. The impaired peroxidase (or paraoxonase-1) activity of thalassemic HDL could be secondary to an increase of circulating proinflammatory oxidized lipids that negatively regulate paraoxonase-1 functions [41]. In other words, the oxidative stress and iron overload in thalassemia could lead to inhibition of HDL-associated paraoxonase-1 that protects both HDL and LDL from oxidation. Consequently, both HDL and LDL are oxidatively modified in thalassemia, causing an accumulation of oxidized lipids as indicated by elevated levels of oxidative markers in thalassemic HDL. Apart from the low peroxidase activity of HDL, increased oxidative stress in thalassemia would result in elevated oxidized lipids in blood and tissues, which are transferred to HDL. Thus, the low peroxidase activity within HDL and increased transfer of oxidized lipids to HDL would cause accumulation of lipid peroxidation markers in thalassemic HDL.

LOOH is an important intermediate of lipid peroxidation. Lipid peroxidation is triggered by free radical species such as hydroxyl radical derived from iron-mediated reduction of hydrogen peroxide (H_2O_2) and by non-radical species including LOOH. The process is generally described as three phases: initiation, propagation, and termination. In initiation phase, for example, hydroxyl radical ($^{\cdot}OH$) can abstract hydrogen from polyunsaturated fatty acids at the Sn-2 position of phospholipids of LDL. The process proceeds via the formation of conjugated diene and peroxyl radical ($LOO^{\cdot}$) which either forms LOOH or degrades to release aldehydes [17]. In propagation phase, LOOH undergoes Fenton-like reaction in the presence of metal ions, producing lipid alkoxyl ($LO^{\cdot}$) and peroxyl radicals that cause chain of reactions. Finally, the bi-molecular reactions of alkyl ($L^{\cdot}$) or peroxyl radicals produce non-radical products in termination phase. The peroxidase activity of HDL is thus important in terminating the propagation of lipid peroxidation by removal of LOOH and H_2O_2. Poor peroxidase activity of thalassemic HDL-associated paraoxonase-1 would result in retention of LOOH in HDL and increased susceptibility of LDL to oxidation in the presence of high iron content.

In conclusion, our study demonstrates the existence of oxidized HDL in thalassemia, which has low peroxidase activity and poor ability to protect LDL from oxidation. The poor protective activity of thalassemic HDL is

consistent with the compositional changes and high levels of oxidative markers. This impaired function of HDL would promote generation of pathogenic oxidized LDL that could be responsible for cardiovascular complications in thalassemia.

Acknowledgments The authors would like to thank Prof. Dr. Suthat Fucharoen, Prof. Dr. Pensri Pootrakul from Thalassemia Research Center, Institute of Science and Technology for Research and Development, Mahidol University; Dr. Wanchai Wanachivanawin from Department of Medicine, Faculty of Medicine Siriraj Hospital, Mahidol University for screening and care of thalassemic patients. We also thank to all staffs and blood donors of Blood Bank Ramathibodi Hospital.

Biochemical Studies on Sphingolipid of *Artemia franciscana* (I) Isolation and Characterization of Sphingomyelin

Hisao Kojima · Takashi Inoue · Mutsumi Sugita · Saki Itonori · Masahiro Ito

Received: 19 November 2009 / Accepted: 27 January 2010 / Published online: 24 June 2010

Abstract Sphingomyelin was isolated from cysts of the brine shrimp *Artemia franciscana* using QAE-Sephadex A25, Florisil and Iatrobeads column chromatographies. The chemical structure was identified using thin-layer chromatography, gas–liquid chromatography, infrared spectroscopy and matrix-assisted laser desorption ionization time-of-flight mass spectrometry. The ceramide moiety of sphingomyelin consisted of stearic, arachidic, and behenic acids as fatty acids, and hexadeca-4- and heptadeca-4-sphingenines as sphingoids. By comparative analysis, the ceramide component of *Artemia* sphingomyelin appears unique in invertebrates and vertebrates. Biological functions of sphingomyelin have largely been investigated using mammalian-derived sphingomyelin. In mammals, a wide variety of molecular species of sphingomyelins have been reported, especially derived from nerve tissue, while the lower animal *Artemia* contains this unusual sphingomyelin perhaps because of having a much simpler nervous system. The purified unusual sphingomyelin derived from *Artemia franciscana* might be a very useful tool in elucidating the functions and mechanisms of action of this mediator.

Introduction

Sphingomyelin (SM), or ceramide phosphocholine, consists of ceramide and phosphorylcholine moieties. It is the sphingolipid analogue of phosphatidylcholine, which is important as a precursor of intracellular mediators [1, 2]. SM is a component of microdomains and lipid rafts, which play the foundational role in several immune responses and intercellular signaling [3, 4].

The study of SM began in the late nineteenth century, and SM was first isolated from brain tissue in the 1880s [5] and its structure characterized as *N*-acyl-sphingosine-1-phosphorylcholine in 1927 [6]. Later, SM was isolated and characterized from many vertebrate organisms such as humans, bovines, rats, mice, and frogs [7–10], but was not isolated from invertebrates until later. SM was reported as a major phosphosphingolipid in vertebrates and a minor phosphosphingolipid in invertebrates using thin-layer chromatography (TLC) [11]. In the last few decades, SMs have been isolated and characterized from several

invertebrate organisms, i.e. the octopus *Octopus vulgaris* [12], the crawfish *Cambarus claki* [13], the pearl oyster *Pinctada martensii* [14, 15], the squid *Loligo paelei* [16, 17], the parasitic nematode *Ascaris suum* [18], the crab *Erimacrus isenbeckii* [19], the honey bee *Apis melliferea* [20], the moth *Manduca sexta* [21], and the ascidians *Ciona intestinalis*, *Halocynthia roretzi*, *Halocynthia aurantium* and *Styela clava* [22]. An SM-recognizing toxin, lysenin, was extracted from the earthworm *Eisenia foetida* [23]. The phylogenetic distribution of SM on invertebrate and vertebrate spermatozoa was screened using lysenin binding as an SM-specific probe, and was shown to be different from the previously-accepted distribution. In other words, SM was widely distributed in invertebrates except for Echinodermata and Lophotrochozoa [24–26]. SM should be identified from such organisms to better understand its phylogenetic distribution and fundamental role.

In this paper, we report the isolation and characterization of SM from cysts of the brine shrimp *Artemia franciscana*, and compare the ceramide composition of SM in known invertebrate and vertebrate organisms.

Experimental Procedure

Isolation of Sphingomyelin

The cysts (diapausing eggs) of brine shrimp (2.5 kg) purchased from A & A Marine LLC (Salt Lake City, Utah, USA) were ground to powder in a mortar. Lipids were extracted once with 4.5 l of chloroform/methanol (2:1, by vol) for 3 h, once with 4.5 l of the same solvent mixture over night and once with 4 l of chloroform/methanol (1:1, by vol) over night at room temperature. The combined chloroform–methanol extracts were concentrated by a rotary evaporator at 40 °C, and subjected to mild alkaline hydrolysis in 700 ml of 0.5 M KOH in methanol to eliminate acyl- and alkenyl-glycerolipids. The hydrolyzate was acidified with several drops of conc. HCl (pH 1), kept for 1 h at room temperature, and dialyzed against tap-water for 2 days. The inner fluid was concentrated to near dryness in vacuo at 40 °C, and dissolved in 120 ml of chloroform/methanol (2:1, by vol). The solution was divided into 8 centrifugal tubes, precipitated with 150 ml of cold acetone per tube, centrifuged at 3,000 rpm at 4 °C for 15 min, and the resulting supernatant was removed by decantation. The remaining precipitate was re-suspended with cold acetone, and centrifuged. This step was repeated once more, and the resulting precipitate was dried (yield: 4.4 g). The alkaline-stable product was dissolved in 90 ml of chloroform/methanol (2:1, by vol), and to this was added 90 ml of methanol and 16 ml of water to obtain a volume ratio of chloroform/methanol/water of 30:60:8. This was mixed with 20 g of QAE-Sephadex A-25, OH^- form (GE Healthcare Co.). The resulting slurry was applied to a column (3.4 × 32 cm) packed with 40 g of QAE-Sephadex A-25 equilibrated with chloroform/methanol/water (30:60:8, by vol). The column was chromatographed successively with chloroform/methanol/water (30:60:8, by vol; 1.5 l), pure methanol (300 ml), and 0.45 M ammonium acetate in methanol (1.5 l). The separation of sphingolipids was monitored by TLC. The neutral and zwitterionic sphingolipid fraction obtained from the pass-through eluate was acetylated in 40 ml of pyridine/acetic anhydride (3:2, by vol) for 18 h, and evaporated to dryness. The acetylated fraction was then chromatographed on a column (2.0 × 90 cm) packed with 120 g of Florisil, 60–100 mesh (Nacalai Tesque, Inc.) using the slightly modified method of Saito and Hakomori [27]. The column was eluted successively with 840 ml of hexane/dichloroethane (1:4, by vol), 840 ml of pure dichloroethane, 840 ml of dichloroethane/acetone (1:1, by vol), 1.68 l of dichloroethane/methanol (9:1, by vol), 1.4 l of dichloroethane/methanol (3:1, by vol), 843 ml of dichloroethane/methanol/water (2:8:1, by vol), 1.1 l of chloroform/methanol/water (6:4:1, by vol), and 843 ml of chloroform/methanol/water (2:8:1, by vol). The eluate obtained using chloroform/methanol/water (6:4:1, by vol) was evaporated to dryness, deacetylated with 40 ml of 0.5 M KOH in methanol at 37 °C for 6 h, neutralized with conc. HCl, and dialyzed against tap-water for 2 days. The inner fluid was concentrated to near dryness in vacuo at 40 °C.

Thin-Layer Chromatography

The solvents used for TLC were as follows; *n*-butanol/acetic acid/water (12:3:5, by vol), chloroform/methanol (92:8, by vol), chloroform/methanol/water (6:4:1, by vol), and chloroform/methanol/acetic acid/water (6:4:1:1, by vol). The zwitterionic sphingolipid on thin layer plates of silica gel 60 (Merck KGaA) was visualized by spraying with Dittmer-Lester reagent [28]. The hydrophilic material obtained from the zwitterionic sphingolipid was developed on a cellulose plate, Avicel SF (Funakoshi Chemicals Co.) and visualized with Hanes-Isherwood reagent [29].

Fatty Acid Analysis

For determination of fatty acid composition, 0.1 mg of sample was methanolyzed with 0.2 ml of 1 M anhydrous methanolic HCl at 100 °C for 3 h. The fatty acid methyl esters produced were extracted with *n*-hexane and analyzed by GC and GC–MS.

Sphingoid Analysis

Sphingoid composition was determined by the method of Gaver and Sweeley [30]. In brief, about 0.2–0.3 mg of sample was methanolyzed in 0.2 ml of aqueous HCl-methanol reagent (methanolic reagent containing 8.6% conc. HCl and 9.4% water) at 70 °C in the oven for 18 h. The hydrolyzate was extracted with *n*-hexane to remove fatty acids, and the residual methanolic phase was dried under nitrogen gas and made alkaline with 0.6 ml of methanol/1 M sodium hydroxide (4:3, by vol). Sphingoids were extracted into a lower phase by adding 0.72 ml of chloroform, which was then washed twice with 0.4 ml of methanol/water (1:1, by vol), trimethylsilylated, and analyzed by GC and GC–MS.

Gas Chromatography and Gas Chromatography-Mass Spectrometry

Compositional analyses of fatty acids and sphingoids were carried out using a Shimadzu GC-18A gas chromatograph with a capillary column of Shimadzu HiCap-CBP 5 (0.22 mm × 25 m). The temperature increase was programmed at 4 °C/min from 170 to 230 °C for fatty acid analysis and 2 °C/min from 210 to 230 °C for sphingoid analysis. Electron impact ionization mass spectra were taken using a Shimadzu GCMS-QP5050 gas chromatograph-mass spectrometer with the same capillary column under the following conditions; interface temperature, 250 °C, injection port temperature, 240 °C, helium gas pressure, 100 kPa, and ionizing voltage, 70 eV. The oven temperatures for GC–MS analysis were 80 °C (2 min) → 170 °C (20 °C/min) → 240 °C (4 °C/min) for fatty acids, and 80 °C (2 min) → 210 °C (20 °C/min) → 230 °C (4 °C/min) for sphingoids, respectively.

Infrared Spectroscopy

Infrared spectroscopy (IR) was performed using a Shimadzu FTIR-8400S spectrophotometer with a MIRacle A single reflection horizontal ATR using a ZnSe prism (PIKE Technologies, Inc). *Artemia* SM was dissolved in chloroform/methanol (2:1, by vol) and 50 μg of SM was put on the sampling area of the ATR and air-dried, and was scanned by 45 times accumulation.

Hydrolysis with Butanolic HCl

About 5 mg of SM was hydrolyzed with 1 ml of *n*-butanol/6 M HCl (1:1, by vol) in boiled water for 60 min. The reaction mixture was partitioned by adding 1 ml of water. The butanolic phase was dried by a rotary evaporator and the residue was washed with acetone. The acetone insoluble material was dissolved in chloroform/methanol (9:1, by vol) and fractionated on a column (0.6 × 10 cm) packed with Iatrobeads (6RS-8060, Mitsubishi Kagaku Iatron Inc., Tokyo). The column was eluted successively stepwise with 10 ml of chloroform/methanol at ratios of 8:2, 7:3, 6:4, and 5:5 (by vol). The eluates obtained from this column using chloroform/methanol 6:4 were pooled and analyzed by TLC and IR for identification of sphingosylphosphocholine.

Hydrolysis with Hydrofluoric Acid

About 5 mg of SM dissolved in 0.5 ml of dimethylsulfoxide was hydrolyzed in 3.5 ml of hydrofluoric acid at room temperature for 20 h. The reaction mixture was dialyzed against tap-water for 2 days and the inner fluid concentrated to near dryness in vacuo at 40 °C. The product was dissolved in chloroform and fractionated on a column (1.4 × 6 cm) packed with Iatrobeads. The column was eluted successively with 10 ml of chloroform/methanol 98:2 (by vol), 95:5, 9:1 and 8:2. The eluates obtained from this column using chloroform/methanol 9:1 were pooled and analyzed by TLC and IR for identification of the ceramide moiety.

Hydrolysis with Phospholipase C

About 2 mg of SM was suspended in 0.2 ml of 50 mM Tris–HCl buffer (pH7.5), containing 0.1 ml of 20 mM calcium chloride and 0.2 ml of diethyl ether, and hydrolyzed with 500 μg of phospholipase C derived from *Clostridium perfringens* (Sigma–Aldrich Co.) at 37 °C for 24 h. The reacted mixture was heated in boiled water for a few seconds to evaporate diethyl ether. The residual fluid was partitioned by adding 2 ml of chloroform/methanol (2:1, by vol) and the upper phase was analyzed by TLC for identification of phosphocholine. The lower phase was applied to a column (1.4 × 6 cm) packed with Iatrobeads and eluted successively with 10 ml of chloroform/methanol 98:2 (by vol), 95:5, 9:1, and 8:2. The eluates obtained using chloroform/methanol 9:1 were pooled and analyzed by TLC and IR for ceramide identification.

MALDI-TOF MS

MALDI-TOF MS analysis was performed using an Applied Biosystems/Voyager-DE STR Biospectrometer with a nitrogen laser (337 nm) and an acceleration voltage of 20 kV, operating in the reflector positive-ion mode and the post-source decay (PSD) mode. The matrix used was α-cyano-4-hydroxycinnamic acid (α-CHCA; Proteomics Grade, Wako Chemical Co.). External mass calibration was provided by the $[M + Na]^+$ ions of angiotensin I (1296.69

mass units; Sigma–Aldrich Co.) in the reflector and PSD modes and Bradykinin Fragment I–V (573.31 mass units; Sigma–Aldrich Co.) in the reflector mode.

Results and Discussion

Isolation of Sphingomyelin

Crude sphingolipids (4.4 g) were obtained from 2.5 kg of cysts of the brine shrimp *Artemia franciscana* after alkaline and acid treatment of chloroform/methanol extracts (398 g). In TLC analysis of the crude sphingolipids, a single positive band was detected using Dittmer-Lester reagent (Fig. 1). This band was assumed to be sphingomyelin from its R_f value. There was no double positive band to either Dittmer-Lester or ninhydrin reagents, as would have been seen if ceramide aminoethylphosphonate (CAEPn) and ceramide phosphoethanolamine (CPEA) were present (data not shown). The crude sphingolipids were chromatographed on a QAE-Sephadex column and the lipid fraction obtained was purified by Florisil column chromatography after acetylation. SM was deacetylated and returned to its original state (634 mg).

Infrared Spectroscopy Analysis

Artemia SM was analyzed by infrared spectroscopy (Fig. 2). Absorption peaks corresponding to the amide bond, the hydroxyl group of phosphoric acid, and choline were observed at about 1,550, 1,650, 1,220, and 960 cm^{-1} from *Artemia* SM and standard SM of bovine brain, respectively.

Gas Chromatography Analysis

Gas chromatography was carried out to determine the fatty acid and sphingoid composition of the ceramide portion of *Artemia* SM (Table 1). In the analysis of fatty acids, behenic acid was a dominant component (85.4%), with stearic acid (11.6%) and arachidic acid (3.0%) also being present (Fig. 3a). In the sphingoid analysis, only two sphingenines, hexadeca-4-sphingenine (67.9%) and heptadeca-4-sphingenine (32.1%), were detected (Fig. 3b, c).

20:0	3.0	d17:1	32.1
22:0	85.4		

Confirmation of Sphingomyelin

To confirm the existence of the *N*-acylamide bond, SM from both *Artemia* and bovine brain was hydrolyzed with *n*-butanol and HCl. Following butanolysis, the product from both types of SM was positive to ninhydrin reagent and shifted to a lower R_f value (Fig. 4a). Another IR analysis was performed after this butanolysis. Compared with the spectra of intact SM, absorption by the reaction product showed loss of both the amide bond at about 1,550 and 1,650 cm^{-1} and the methylene group at about 2,800 and 2,900 cm^{-1} (Fig. 5b). This shows the loss of the fatty

acid portion by butanolysis and the existence of sphingosylphosphocholine in *Artemia* SM.

Furthermore, *Artemia* SM was hydrolyzed with hydrofluoric acid to dissociate the ester bond. After hydrolysis, the R_f value of hydrophobic material from *Artemia* SM corresponded on TLC to that of non-hydroxy ceramide of bovine brain (Fig. 4b). IR analysis was also performed on this hydrophobic material. Compared to the spectra of intact *Artemia* SM, absorption of the hydrolyzate disappeared both for the hydroxyl group of phosphoric acid at about 1,220 cm^{-1} and for choline at about 960 cm^{-1} (Fig. 5c). This shows the removal of phosphocholine by the hydrofluoric acid treatment and the existence of non-hydroxy ceramide in *Artemia* SM.

Artemia SM was also hydrolyzed with phospholipase C to dissociate the phosphoric diester bond. After hydrolysis, the R_f value of hydrophilic material derived from *Artemia* SM corresponded to that of authentic phosphocholine on cellulose TLC (Fig. 4c). On the other hand, the IR spectrum of the phospholipase C hydrolyzate's hydrophobic component showed the disappearance of both the hydroxyl group of phosphoric acid at about 1,220 cm^{-1} and choline at about 960 cm^{-1} (Fig. 5d). This indicates both the existence of phosphocholine in *Artemia* SM, and its removal by phospholipase C treatment. The analytic methods employed here (gas chromatography, and TLC and IR analysis before and after various hydrolytic treatments) have thus demonstrated that *Artemia* SM consists of fatty acid, sphingoid, sphingosylphosphocholine, ceramide and phosphocholine. Consequently, this SM is confirmed to be ceramide phosphorylcholine.

MALDI-TOF MS Analysis

The putative structures of *Artemia* SM were confirmed by positive-ion mode MALDI-TOF MS analysis as shown in Fig. 6a and summarized in Table 2. Mass spectra were observed corresponding to the combination of fatty acids and sphingoids detected in gas chromatographic analyses. Several different pseudomolecular ions were observed because of different ceramide species, which were in agreement with the mass values calculated from the proposed structures, e.g.: the $[M + H]^+$ ions at *m/z* 759.61 and

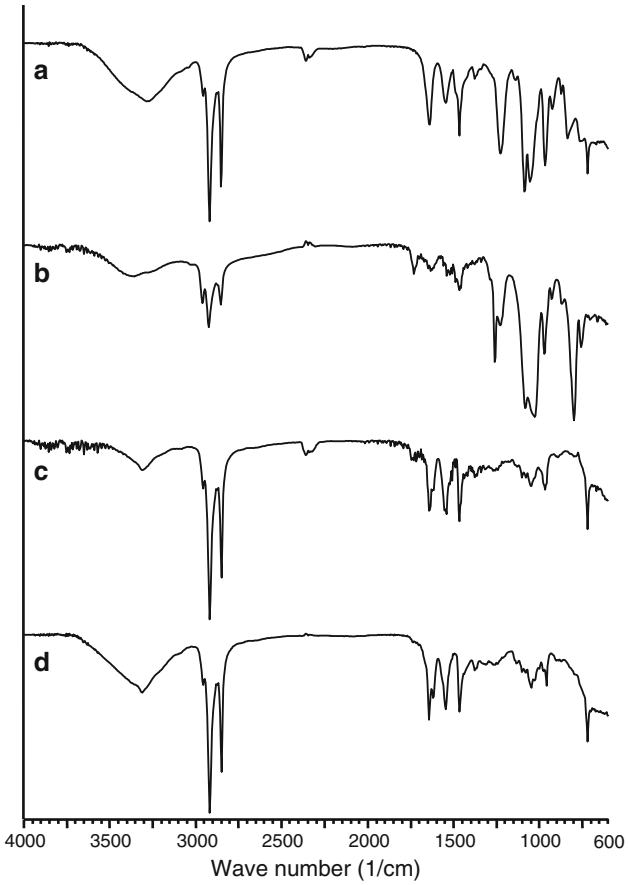

Fig. 5 Infrared spectra of *Artemia* sphingomyelin and its hydrolyzate. **a** Sphingomyelin, **b** sphingosylphosphocholine obtained by acid butanolysis, **c** ceramide obtained by hydrofluoric acid hydrolysis, and **d** ceramide obtained by phospholipase C hydrolysis

773.62 coincided with the mass value of 1 mol each of phosphocholine, fatty acid (22:0) and sphingoid (d16:1 and d17:1; see Table 2); and the $[M + Na]^+$ ion at *m/z* 781.60 and 795.62 coincided with the mass value of the same combination. The sodiated peaks were of stronger intensity than the protonated ones.

To confirm the assignment of SM species, MALDI-TOF MS analysis in the PSD mode was carried out (Fig. 6b). The three major fragments in this mass spectrum correspond to the sodiated product less the trimethylamine ($[M–N(CH3)3 + Na]^+$ ion at *m/z* 722.5) or less the phosphocholine head group ($[M–N(CH3)3C2H5O4P + Na]^+$ ion at *m/z* 598.3), as well as protonated phosphocholine ($[N(CH3)3C2H6O4P]^+$ ion at *m/z* 183.7). The theoretical mass of protonated phosphocholine is *m/z* 184.1. The difference between measured mass and theoretical mass was 0.4 Da, which is within measurement error of PSD mode on Voyager spectrometer. Consequently, we assigned the fragment *m/z* 183.7 as protonated phosphocholine. From spectrometric data and degradation analyses, we identified the chemical structure of *Artemia* SM (Fig. 6c).

Ceramide Components of Sphingomyelin in Vertebrate and Invertebrate

In vertebrates, SMs have been detected in mammals and frogs [9], but their structures have only been characterized in mammals [32–43]. Fatty acids of SM in several tissues from various mammals are predominantly composed of palmitic and lignoceric acids, and there has been no report showing arachidic acid as the major component. In studies of SM sphingoids in mammals, octadecasphingenine is dominant while hexadeca-, heptadeca- and cosadecasphingenine are reported as minor components. Structural analyses of SM in invertebrates have been reported from *Pinctada martensii* [15] and *Loligo paelei* [16, 17] (Mollusca), *Ascaris suum* (Nematoda) [18], *Cambarus clarki*, *Erimacrus isenbeckii*, *Apis melliferea* and *Manduca sexta* (Arthropoda) [13, 19–21], and the ascidians *Ciona intestinalis*, *Halocynthia roretzi*, *Halocynthia aurantium* and *Styela clava* (Urochordata) [22]. The major fatty acids are palmitic and stearic acid in Mollusca, lignoceric and hydroxylignoceric acid in *Ascaris suum*, unsaturated docosanoic and behenic acid in Arthropoda, and stearic, palmitic and behenic acid in Urochordata. Dihydroxy sphingoids with a polyunsaturated base are common in SMs from Mollusca. Tetradecasphingenine is common in SMs from Arthropoda. In Urochordata the main sphingoids are octadecasphingadienine and hexadecasphingenine.

This study presents the isolation and characterization of *Artemia* SM as the 8th report in protostomes. The major components of SM from the brine shrimp are, unusually, behenic acid-hexadecasphingenine and behenic acid-heptadecasphingenine, although these components are found as minor components in SM of bovine milk [34, 35, 43], rennet stomach [36] and *Halocynthia aurantium* and *Styela clava* [22]. All of these are deuterostomes. In all phosphosphingolipids except for SM, the ceramide components of *Artemia* SM are present in millipede CPEA, although only as minor components [31]. In other words, it is characteristic of the ceramide composition of SM from the brine shrimp that behenic acid-hexadecasphingenine and behenic acid-heptadecasphingenine are present in unusually high proportions, namely about 60 and 30%, respectively.

Sphingomyelin plays an important role in several immune responses and intercellular signaling. Ceramide and sphingosylphosphocholine have been reported to act as lipid mediators, ceramide in apoptosis [44] and cell cycle arrest [45], and sphingosylphosphocholine in Ca^{2+} influx inhibition [46], stimulation of inositol phosphate production [47] and induction of superoxide anion formation [48]. Most of these investigations utilized commercially supplied lipids composed of octadecasphingenine. Furthermore, there is an interesting report that relates function and acyl-group components [49]. That report indicates that SM

Table 2 Summary of MALDI-TOF MS analysis of *Artemia* sphingomyelin

	Fatty acid—Sphingoid	Found (*m/z*)	Calculated (*m/z*)	Ionization
(a)	C18:0—d16:1	703.55	703.58	$[M + H]^+$
(b)	C18:0—d16:1	725.54	725.56	$[M + Na]^+$
(c)	C18:0—d17:1	739.56	739.57	$[M + Na]^+$
(d)	C20:0—d16:1	753.57	753.59	$[M + Na]^+$
(e)	C22:0—d16:1	759.61	759.64	$[M + H]^+$
(f)	C22:0—d17:1	773.62	773.65	$[M + H]^+$
(g)	C22:0—d16:1	781.60	781.62	$[M + Na]^+$
(h)	C22:0—d17:1	795.62	795.64	$[M + Na]^+$

is specifically required for expression of glucuronyltransferase activity and that difference in enzyme activity is affected by the degree of saturation in the fatty acid portion. Thus, acyl-chain differences in the aliphatic component may affect function. Fortunately, *Artemia* SM could supply unusual ceramides and sphingosylphosphocholine for research purposes, after hydrolytic removal of its phosphoric acid group and after butanolysis, respectively. The unusual SM derived from *Artemia franciscana* might be very useful in elucidating functions and mechanisms of action of the mediators.

Acknowledgments The authors thank Dr. Fujita for his valuable comments. The authors also thank Dr. John T. Dulaney who kindly read this manuscript while it was in preparation and for providing helpful comments.

COMMUNICATION

Enhanced Bioavailability of Eicosapentaenoic Acid from Fish Oil After Encapsulation Within Plant Spore Exines as Microcapsules

Ammar Wakil · Grahame Mackenzie · Alberto Diego-Taboada · J. Gordon Bell · Stephen L. Atkin

Received: 12 March 2010 / Accepted: 30 April 2010 / Published online: 22 May 2010

Abstract Benefits of eicosapentaenoic acid (EPA) can be enhanced by raising their bioavailability through microencapsulation. Pollen can be emptied to form hollow shells, known as exines, and then used to encapsulate material, such as oils in a dry powder form. Six healthy volunteers ingested 4.6 g of fish oil containing 20% EPA in the form of ethyl ester first alone and then as 1:1 microencapsulated powder of exines and fish oil. Serum bioavailability of EPA was measured by area under curve ($AUC_{0–24}$). The mean $AUC_{0–24}$ of EPA from ethyl ester with exine ($M = 19.7$, $SD = 4.3$) was significantly higher than ethyl ester without exines ($M = 2$, $SD = 1.4$, $p < 0.01$).The bioavailability of EPA is enhanced by encapsulation by pollen exines.

Introduction

Eicosapentaenoic acid (EPA) and docosahexaenoic acid, the main long chain polyunsaturated fatty acids (LCPUFA), can only be obtained from a fish and shellfish rich diet. Recent trials have shown that EPA in the form of ethyl ester added to statins in hypercholesterolaemic Japanese resulted in 19% relative risk reduction in major cardiovascular events [1]. Instead of being taken to prevent nutritional deficiency they are now being taken to prevent diseases with an inflammatory pathology, including cardiovascular diseases [2]. One strategy to raise plasma concentration of LCPUFA is to optimise their absorption and bioavailability.

Microencapsulation has been used to mask unpleasant taste in food sciences as well as to protect against light and airborne oxidation [3, 4]. Pollen and plant spores, from mosses and ferns have an outer layer skeleton known as the exine that is composed of sporopollenin [5, 6]. Exine microencapsulation technology has been shown to provide excellent taste masking for fish oils [7], they have been investigated for use as a contrast agent [8] and attempts have been made to introduce them as a novel method of

oral delivery of substances into the blood stream as opposed to the parenteral route [9].

In this study we have investigated whether encapsulating the ethyl ester form of fish oil with exine microcapsules extracted from readily available and renewable *Lycopodium clavatum* spores, can enhance the bioavailability, measured by area under the curve, of EPA delivered as ethyl ester alone.

Experimental Procedure

This was an open-labelled study. Six healthy volunteers without concomitant illnesses or medications were recruited from an advertisement for healthy volunteers in Hull University and Hull Royal Infirmary. The study protocol was approved by the Hull and East Riding Research Ethics Committee. All subjects received dietary counselling by an academic dietician to avoid fish or omega-3 fatty acid intake in their diet 2 weeks before and during the course of the trial. Coffee, flax seed and alcohol were avoided a day prior, during and a day after each visit. A run in period of 1 week was followed by two visits with a 3-week between-visits wash-out period. Each subject ingested 4.6 g of fish oil containing 20% of EPA in the form of the ethyl ester at each visit. In the first visit the fish oil was given in the form of a liquid immediately after defrosting. In the second visit the fish oil was encapsulated into exines and the subsequent powder was ingested. Blood samples were taken at baseline (prior to ingesting the fish oil preparations) for fatty acids and lipid analysis and again at 2, 4, 6, 8 and 24 h from ingesting the fish oil for fatty acids analysis. Serum was instantly separated by centrifugation at 2,000*g*, and stored at −80 °C before batch analysis of total serum fatty acid compositions by the Nutrition Group, Institute of Aquaculture, University of Stirling, Stirling UK, as described before [10]. 0.5 mL serum was extracted by the Folch et al. method [11], using chloroform/methanol (C/M; 2:1 vol/vol). The extracted lipid was dissolved in 0.8 mL of C/M, 2:1 vol/vol and dried under nitrogen in a pre-weighed glass vial, and desiccated for 16 h. Final lipid extracts were re-suspended in C/M (2:1 vol/vol) + 0.01% (wt/vol) butylated hydroxytoluene (BHT), at a concentration of 10 mg/mL and stored at −70 °C.

Fatty acid methyl esters (FAME) were prepared by acid-catalysed transesterification of 0.5 mg of total lipid and 50 μg of 17:0 internal standard in 2 mL of 1% (vol/vol) H_2SO_4 in methanol at 50 °C overnight [12]. Samples were neutralised with 2% $KHCO_3$ and extracted twice with 5 mL isohexane/diethyl ether (1:1 vol/vol) + BHT and finally dissolved in 0.3 mL of isohexane prior to FAME analysis.

Measurement of Serum Fatty Acids

FAME were separated and quantified by GLC (Fisons 8160, Carlo Erba, Milan, Italy) using a 60 m × 0.32 mm × 0.25 μm film thickness capillary column (ZB Wax, Phenomenex, Macclesfield, England). Hydrogen was used as carrier gas (flow rate of 4.0 mL/min) and the temperature programme was from 50 to 150 °C at 40 °C/min then to 195 °C at 2 °C/min and finally to 215 °C at 0.5 °C/min. FAME were identified using well characterised in house standards and commercial FAME mixtures (Supelco™ 37 FAME mix, Sigma-Aldrich Ltd., Gillingham, England). Blood was withdrawn after 30 min and examined under a confocal microscope to investigate for the presence of exines, which are naturally fluorescent.

Fish oil supplements were provided by Croda Europe, Goole, UK. Each vial had 4.6 g of fish oil containing 20% EPA in the form of its ethyl ester. They were shipped in dark containers and kept in a −20 °C freezer until ready for defrosting at visit 1. At visit 2, the defrosted oil was encapsulated with 4.6 g of exines no more than 24 h prior to ingestion and the dark container was filled with nitrogen to prevent oxidation. Exines extracted from *Lycopodium clavatum* spores were supplied by Sporomex Ltd, UK, and were prepared as detailed previously [7]. Microencapsulation was performed by mixing exines with oil (1:1 weight for weight) by gently stirring to form a homogeneous paste that was then subjected to a vacuum (ca. 10 hPa) for 2 h to facilitate passive loading of oil into the particles through the nano-porous sporopollenin walls.

Area under the curve ($AUC_{0-24\ h}$) was used to determine the bioavailability of EPA from the different supplements. The mean $AUC_{0-24\ h}$ for EPA was calculated using the linear trapezoid method and baseline levels were normalised to zero. We also observed visually the time of the maximum concentration (T_{max}). Comparisons of mean AUCs and T_{max} with and without exines were made using paired sample *t* test via SPSS version 15.

Results

The two male and four females' demographics are summarised in Table 1. The mean baseline of EPA percentage to total fatty acids in the six subjects was comparable to that reported in another study with healthy volunteers; $M = 0.69$, SEM = 0.04% versus $M = 0.64$, SEM = 0.08%, respectively [13]. There was no significant difference between the baseline concentration of EPA (mg/100 mL) in the first visit ($M = 2.15$, SD = 0.6) and the second visit ($M = 2.0$, SD = 0.6, $p = 0.49$). The mean AUC of EPA from ethyl ester with exine ($M = 19.7$, SD = 4.3) was significantly higher than that obtained from ethyl ester

Table 1 Subjects' demographics

Demographics	Mean (SD)
Systolic blood pressure (mm Hg)	131 (7)
Diastolic blood pressure (mm Hg)	78 (4)
Total cholesterol (mmol/L)	4.7 (0.45)
Triglyceride (mmol/L)	1.06 (0.24)
High density lipoprotein (mmol/L)	1.25 (0.35)
Low density lipoprotein (mmol/L)	2.7 (0.84)
Total cholesterol/high density lipoprotein	4 (1.21)
Body mass index (Kg/m^2)	23.5 (2.2)

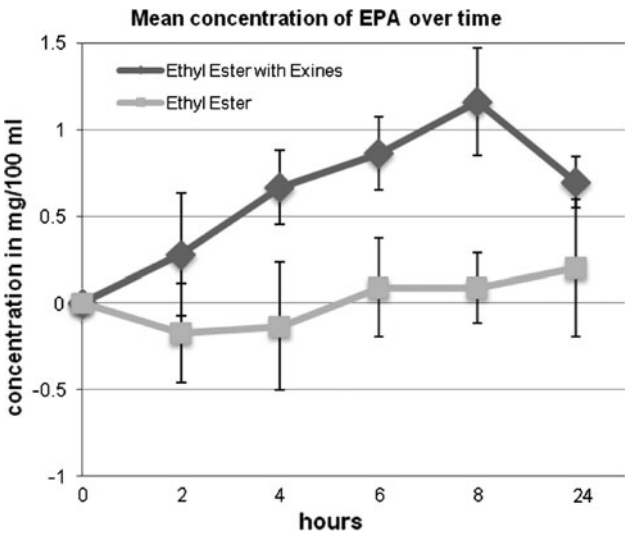

Fig. 1 The change in mean EPA serum level over time obtained from the ethyl ester of EPA with and without exines

without exines ($M = 2$, SD $= 1.4$, $p < 0.01$). When the mean concentration of EPA in serum over time was plotted, after subtracting the mean sera concentrations of the respective time from the mean baseline concentration, it was evident that microencapsulation in exines had significantly enhanced the EPA absorption as reflected by the serum concentration (Fig. 1). The mean time of maximum (T_{max}) concentration for EPA when fish oil was encapsulated with exines ($M = 7.6$ h) was not different from the maximum concentration without exines ($M = 6.8, p = 0.4$), results not shown. Confocal microscopy (Bio-Rad Radiance 2100 laser scanning microscope equipped with Ar (488 nm), Green HeNe (563 nm) and Red diode (637 nm) laser lines connected to a Nikon TE-2000E inverted microscope) showing an empty fluorescent exine before ingestion and an apparently intact exine in blood plasma after ingestion (Fig. 2). Micrographs of oil filled exines before ingestion and those recovered from blood, following ingestion, were also obtained using a Leica Cambridge Stereoscan 360 scanning electron microscope (SEM) operated by Tony Sinclair, Institute of Chemistry for Industry, University of Hull (Fig. 3).

Discussion

In this study, there was a significant rise in the bioavailability of EPA as measured by $AUC_{0–24\ h}$ when the ethyl ester form of fish oil was encapsulated into the novel exine microcapsules, which has not been reported before. Previous studies have focussed on the encapsulation of fish oil to preserve its qualities and prevent oxidation [4], rather than to enhance bioavailability. Although there are no previous studies on the effect of the bioavailability of EPA encapsulated into exines, encapsulation technology is commonly used in pharmaceutical preparations to improve bioavailability. For example, the use of a mixture of wax and fat has been used to achieve controlled drug release in the circulation [14] while the use of microspheres to produce mucoadhesive polymers can help maintain intimate contact with the mucosa of the gastrointestinal tract thereby achieving improved bioavailability [15]. Exines have been used as a natural substance to mask-taste but this is the first pilot study to investigate its potential use to improve bioavailability of orally ingested fish oil in the ethyl ester form

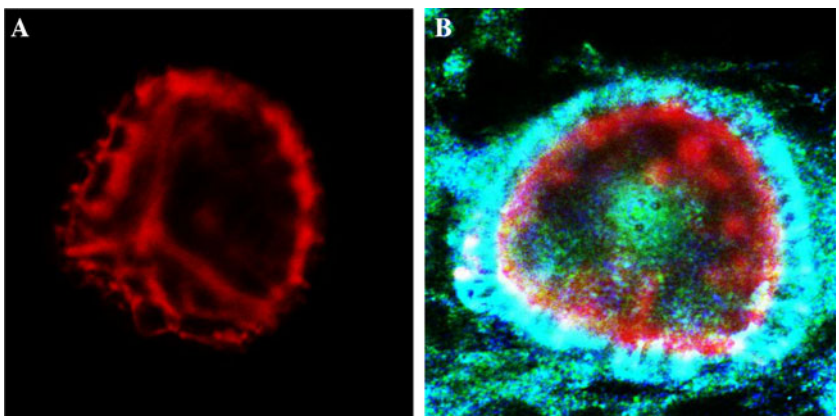

Fig. 2 **a** Confocal microscopy (×60) of an empty sporopollenin exine (*red*) showing its architecture and fluorescence. **b** An exine (*red*) previously filled with fish oil, found in the blood, 30 min after ingestion showing accumulation of material on the outside (*blue*)

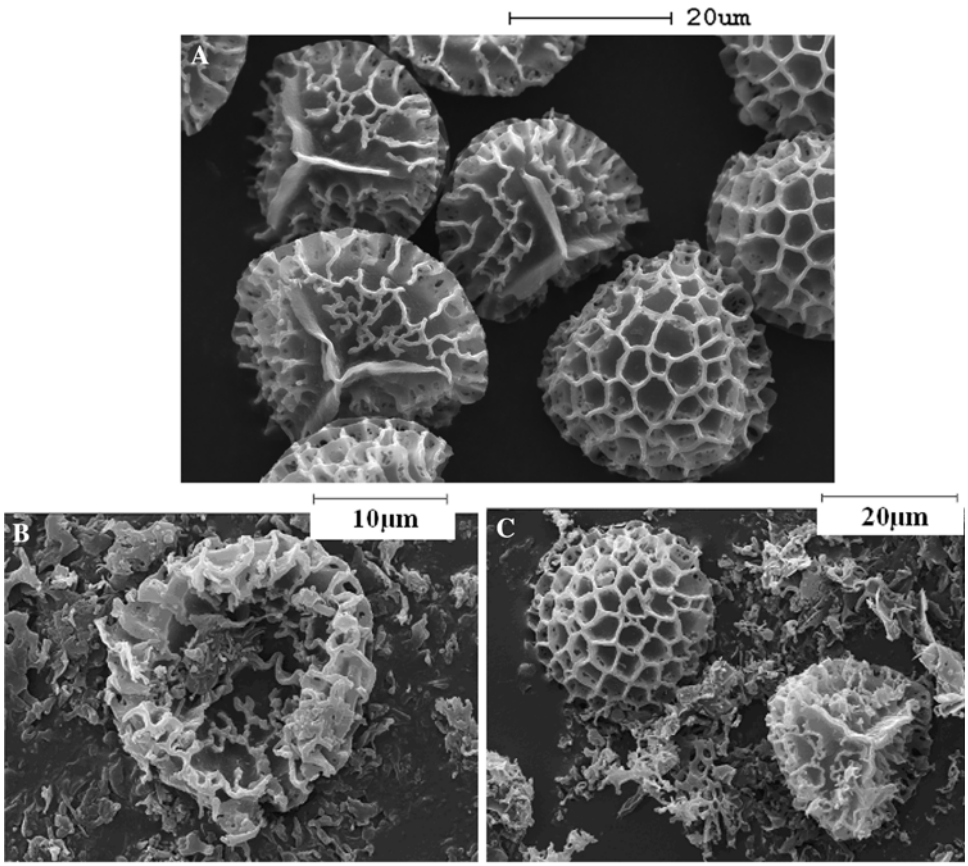

Fig. 3 SEM images of exines (25 µm) from *L. clavatum* spores prior to ingestion, filled with oil (**a**) and those recovered in vivo 30 min after ingestion (**b**, **c**)

[7]. The mechanism by which exine microencapsulation can enhance oil absorption is unclear, but might be due to the protective structure of fish oil-enriched exines whereby the whole unit could travel unhindered through the mucosal lining without releasing its inner core until it has entered into the circulation. This increase in bioavailability was independent of the T_{max} that is a measure of the time to achieve the maximum concentration, suggesting that exines may enhance the absorption at the early stages and continue to do so throughout the 24 h period, in contrast to a natural slower pace of absorption of EPA in the early period of supplementation.

Whilst it is difficult to cost this method, it is expected there would be no significant extra cost compared with other microencapsulation processes; however, no other technique has the advantage of anti-oxidant properties giving a long shelf-life, or has been shown to taste mask and also to have a relatively high loading level. The preparation of the exines is simple and inexpensive with the total cost of the microencapsulation within the exines being less with readily available pollens such as that for rye or maize.

The major limitation to this pilot study is the small number of participants. However, as a proof of the hypothesis, our results were highly significant and further in vitro and in vivo studies are warranted to explain this phenomenon.

In summary, this study showed that exines obtained from *Lycopodium clavatum* spores encapsulating fish oil in the ethyl ester are associated with an improvement in LCPUFA bioavailability as measured by the $AUC_{0-24\ h}$, that may be due to the oil being transported into the blood stream more efficiently by the intact exines.

Conflict of interest statement None.

METHODS

Methods of Emulsifying Linoleic Acid in Biohydrogenation Studies In Vitro May Bias the Resulting Fatty Acid Profiles

Ratchaneewan Khiaosa-ard · Florian Leiber · Carla R. Soliva

Received: 28 August 2009 / Accepted: 9 June 2010 / Published online: 27 June 2010

Abstract The effects of three emulsifying methods on ruminal fatty acid biohydrogenation (BH) in vitro were compared. Using a static in-vitro gas test system, four replicates of each treatment were incubated in buffered ruminal fluid. Hemicellulose (300 mg dry matter) was supplemented either with or without linoleic acid (9*c*12*c*-18:2, 5% in diet dry matter) and incubated for 4 and 24 h. Three methods of emulsifying 9*c*12*c*-18:2 were tested: (1) ethanol, (2) Tween® 80, and (3) sonication. The products were then compared to non-emulsified 9*c*12*c*-18:2. Out of the three emulsifying methods tested, ethanol and sonication resulted in stable 9*c*12*c*-18:2 emulsions, indicating good 9*c*12*c*-18:2 distribution, while the Tween® 80 emulsion was less stable. BH was strongly inhibited by treating 9*c*12*c*-18:2 with ethanol and sonication at different steps of the BH-pathway, resulting in changed concentrations of certain BH intermediates. The fatty acid profile generated from the major BH-pathways of 9*c*12*c*-18:2 with Tween® 80 was comparable to that without emulsification after 24 h of incubation. We conclude that it is not recommended to emulsify lipids before incubating them in vitro when investigating fatty acid BH. If emulsification of 9*c*12*c*-18:2 is necessary, Tween® 80 seems to be the method that interferes least with BH.

FAME	Fatty acid methyl esters
LNA	Linoleic acid
PUFA	Polyunsaturated fatty acids

Introduction

Investigations on the ruminal biohydrogenation (BH) of polyunsaturated fatty acids (PUFA) are commonly conducted using in-vitro techniques, as well as other methods, due to the lack of rumen-fistulated animals. Often, PUFA are emulsified before being administered to the various types of fermenters. The most common emulsifying methods applied in such studies so far are ethanol [1], Tween® 80 (commercial non-ionic surfactant) [2], and sonication [3]. The emulsification of fatty acids is used to promote fatty acid distribution in the incubation liquid; in addition, this technique allows for a more precise dosage of the lipids when using micropipettes. However, fatty acid emulsification methods might have additional side effects such as affecting the microbial metabolism. Therefore, they could alter the extent and kinetics of ruminal lipolysis and BH [4]. Such side effects are unwanted, as in-vitro studies aim to simulate in-vivo conditions as well as possible. Furthermore, in trials using ruminants, the emulsification of dietary fatty acids is only very rarely required.

There are indications of side effects on some ruminal microbes due to certain fatty acid emulsification methods but, to the authors' knowledge, no investigation has been carried out so far to investigate their actions on microbial BH-pathways or their implications for the interpretation of

the fatty acid results obtained. It has been shown that concentrations of linoleic acid (9*c*12*c*-18:2) up to 0.8 mg ml^{-1} were appropriate, i.e., they revealed no inhibitory effect on ruminal microbial BH, for in-vitro BH studies investigating either non-emulsified 9*c*12*c*-18:2 [5] or 9*c*12*c*-18:2 emulsified with Tween® 80 [6]. In addition, about the same dosage of non-emulsified 9*c*12*c*-18:2 showed no effects on microbial fermentation patterns [7]. In contrast, sonicated 9*c*12*c*-18:2 at a concentration of 50 μg ml^{-1} of incubation liquid revealed an inhibitory action on the growth of *Clostridium proteoclasticum*, a ruminal stearate producer [8]. The third emulsifying method, ethanol, was shown to affect the mixed ruminal microbes at a dosage of 34 ml l^{-1} by increasing total short-chain fatty acid and acetate formation, as well as methane production, in vitro [9]. These results emphasize the importance of not only choosing suitable emulsifying methods when investigating specific fatty acid–related aspects of BH in vitro, but also considering possible systematic artifacts induced by the emulsifying method chosen, as these might affect the ruminal microbes.

The aim of this in-vitro study was to investigate and compare the three emulsifying methods, each of which has been used individually for emulsification in previous fatty acid-related in-vitro studies. In this way, the study assessed their possible side effects on fatty acid BH profiles when they have been incubated with mixed ruminal microbes. The emulsification methods chosen for testing in the present study were sonication, Tween® 80, and the most frequently used emulsifier, ethanol. The present study should give enough information for determining the most suitable emulsification method when carrying out ruminal BH studies in vitro.

Experimental Procedure

In-Vitro System and Experimental Design

Two experimental runs were carried out using the static in-vitro gas test system (Hohenheim gas test, [10]). As a carbohydrate source for the ruminal microbes, hemicellulose (xylan from oat spelt containing ≥70% xylose, ≤10% arabinose, and ≤15% glucose after hydrolysis; Sigma-Aldrich, MO, USA) was incubated as a single feed source in the amount of 300 mg dry matter (DM) without or with 15 mg (50 g kg^{-1} of feed DM) of 9*c*12*c*-18:2 (non-esterified, ≥99% purity, Sigma-Aldrich GmbH, Buchs, Switzerland). The fatty acid 9*c*12*c*-18:2 was either directly added into the incubation liquid serving as control or pretreated with one of the three different emulsifying methods. The three emulsifying methods for distributing 9*c*12*c*-18:2 in incubation liquid were applied as follows: (1) Tween® 80 (polyoxyethylene sorbitan mono-oleate, containing 10% total fatty acids consisting of 71.8% 9*c*-18:1, 0.17% 9*c*12*c*-18:2 in the fatty acid composition; Sigma-Aldrich, Saint Louis, MO, USA) was used as an aqueous Tween® 80 solution (1% Tween® 80, v/v) and 9*c*12*c*-18:2 was added at an amount of 50 mg ml^{-1} Tween® 80 solution following [2]; (2) an ethanol-9*c*12*c*-18:2 emulsion was prepared by dissolving 50 mg of 9*c*12*c*-18:2 in 1 ml of 96% ethanol, as described in [1]; (3) finally, 50 mg of 9*c*12*c*-18:2 was dispersed with 10 ml of deionized water in an ultrasonic bath (TEC-25, Telsonic AG, Bronschhofen, Switzerland) for 3 min, applying a method slightly modified from Fellner et al. [11] and Wallace et al. [3]. Further treatments consisted of incubations where the emulsifying methods were applied without 9*c*12*c*-18:2 (the same amounts of Tween® 80, ethanol, and deionized water added to the incubation liquid already containing hemicellulose). Another treatment containing neither 9*c*12*c*-18:2 nor any emulsifying agent was also included. The four treatments containing no 9*c*12*c*-18:2 were subsequently used only as functional treatments for the calculation of result for the 9c12c-18:2-containing experimental treatments.

Incubations were carried out for 4 and 24 h, with each treatment being incubated in four replicates at an incubation temperature of 39 °C following the protocol outlined in Soliva and Hess [10]. Briefly, ruminal fluid was collected before morning feeding from a non-lactating Brown-Swiss cow receiving hay ad libitum and 1 kg of concentrate per day. The cow was handled according to the Swiss guidelines for animal welfare. Ruminal fluid was then filtered through four layers of medicinal gauze (1,000 μm pore size, Type 17; MedPro Novamed AG, Flawil, Switzerland) and mixed with pre-warmed buffer solution (1:2; v/v). Then, 30 ml of the ruminal fluid/buffer mixture (hence "incubation liquid") was dispensed anaerobically into the incubation units already containing the feed substrate hemicellulose. Once they were filled with incubation liquid, 15 mg of non-emulsified or emulsified 9*c*12*c*-18:2, or only the emulsifier itself, was introduced into the incubation units and the liquid volume was recorded. When the incubation was halted after 4 or 24 h, the incubation liquid was stored at −20 °C until being analyzed for its fatty acids profiles and recovery. Incubation liquid samples of the treatments with and without 9*c*12*c*-18:2 at 0 h (not incubated) were also collected for analysis.

Fatty Acid Analysis

The incubation liquid samples were thawed at refrigerator temperature overnight. Then, 0.3 ml of an internal standard, 19:0 (Sigma-Aldrich GmbH, Buchs, Switzerland, prepared as 1 mg ml^{-1} in dichloromethane), was added to 10 ml of the incubation liquid samples. The lipids were

extracted from the samples using a non-chlorinated extraction technique [12], i.e., by adding 8 parts of propan-2-ol and 10 parts of cyclohexane to 11 parts of incubation liquid (v/v/v). For the second extraction step, a propan-2-ol to cyclohexane mixture of 1.3:10 (v/v) was used. The organic phase was collected and the solvents were evaporated using a Rota-Vap (Heidolph VV2000, Heidolph Elektro & Co., KG, Kelheim, Germany). The lipids were dissolved with 2 ml of chloroform that was later evaporated under a nitrogen gas stream. Subsequently, the free fatty acids were methylated by adding 1 ml of a toluene: methanol mixture (1:2; v/v) and 0.1 ml of trimethylsilyl-diazomethane (2 M in hexane), as recommended for samples containing conjugated fatty acids [13]. The methylation process, which was carried out at 40 °C for 10 min, was terminated by adding a drop of glacial acetic acid. Spare solvent and trimethylsilyl-diazomethane were removed by flushing with nitrogen gas. Lipid residues, including the fatty acid methyl esters (FAME), were then resolved with 200 µl of hexane and subsequently cleaned using thin layer chromatography [14]. The identification of the individual FAME was accomplished by carrying out two separate runs on a gas chromatograph (model HP 6890, Agilent Technologies Inc., Wilmington, DE, USA) equipped with a flame ionization detector. For the first run, a 30 m × 0.32 mm Supelcowax-10^{TM} capillary column (Supelco Inc., Bellefonte, PA, USA) was applied. A mixed FAME standard (Supelco 37 Component, Bellefonte, PA, USA) was used for the identification of the individual fatty acids. For detailed *cis*- and *trans*-18:1 isomer identification, a second run using a 200 m × 0.25 mm CP7421 capillary column (Varian Inc., Lake Forest, CA, USA) was performed. The identification of 18:1 isomers was achieved using reference *cis*- and *trans*-18:1 fatty acids (Sigma-Aldrich GmbH, Buchs, Switzerland) and the guidance provided by Kramer et al. [15]. Details of the conditions of both gas chromatograph procedures are described in Khiaosa-Ard et al. [16].

Calculations and Statistical Analysis

The fatty acid content in the incubation liquid was calculated from the known amount of the internal standard. The fatty acid recovery was calculated from the amount of fatty acid recovered after 4 or 24 h of incubation, compared to 0 h using the values of the functional treatments without 9*c*12*c*-18:2 as covariance. For the calculation of the results of the fatty acid profile, and prior to the calculation of the extent of BH, the respective amounts of fatty acids found in the incubation liquid for the functional treatments containing no 9*c*12*c*-18:2 were subtracted from the respective experimental treatments containing 9*c*12*c*-18:2. Thus, in the results, only fatty acids derived from the BH-pathway of 9*c*12*c*-18:2 were considered. The proportion of 9*c*12*c*-18:2 that was apparently biohydrogenated (%; 9*c*12*c*-18:2-BH) was quantified using an equation adapted from Li and Meng [17]: 100× (proportionate 9*c*12*c*-18:2 in total C18 FAME at 0 h—proportionate 9*c*12*c*-18:2 in total C18 FAME after 4 or 24 h of incubation)/proportionate 9*c*12*c*-18:2 in total C18 FAME at 0 h. This was done under the assumption, substantiated by findings of Moate et al. [6], that the concentration of 9*c*12*c*-18:2 (0.5 mg ml^{-1}) used had no inhibitory influence on the BH of the fatty acids. Total C18 unsaturated fatty acids were used to calculate the overall apparent extent of BH extent (%) in the same manner as for 9*c*12*c*-18:2.

Means of all results obtained were subjected to analysis of variance applying the GLM procedure of SAS (version 9.1, SAS Institute Inc., Cary, NC, USA), with emulsifying treatment and incubation time considered fixed effects, and the experimental run considered a blocking factor. Multiple comparisons among means were performed for all statistical evaluations using Tukey's method.

Results

The Emulsifying Methods' Distribution Quality and Effects on Fatty Acid Profile and Recovery

By visual observation, it was found that distribution of 9*c*12*c*-18:2 in the emulsion was better when ethanol (clear solution) was used in comparison to sonication (milky suspension) or Tween® 80 (some droplets aggregated on the surface). All emulsifying methods tested showed a better visual distribution in the emulsion and in the incubation liquid compared to non-emulsified 9*c*12*c*-18:2, where all of the 9*c*12*c*-18:2 aggregated on the liquid's surface.

The C18 fatty acid fraction of the 9*c*12*c*-18:2-supplemented incubation liquid made up 95.6% of total FAME prior to incubation (0 h). Related to total FAME, the C18 fraction consisted mainly of 9*c*12*c*-18:2 (89.9%), while 2.3% were made up of 9*c*11*t*-18:2 and 18:0, and 1.1% consisted of various C18 fatty acid isomers.

Recovery of total, as well as C18, fatty acids after 4 h of incubation was generally low, but clearly higher ($P < 0.001$) with the sonication and ethanol treatments compared to Tween® 80 and non-emulsified 9*c*12*c*-18:2 (control; Table 1). The extent of apparent 9*c*12*c*-18:2-BH was higher ($P < 0.001$) with Tween® 80 and sonication compared to the control and ethanol. By contrast, the extent of apparent overall BH was smaller ($P < 0.001$) with the sonication and ethanol method compared to the Tween® 80 method and the control. The emulsifying methods generally influenced most of the individual C18

Table 1 C18 fatty acid isomer profile and recovery in incubation liquid (g/100 g C18 fatty acids) after 4 and 24 h of ruminal linoleic acid (LNA, 9*c*12*c*-18:2) biohydrogenation in vitro ($n = 4$)

LNA added to the incubation liquid accounted for 94% of LNA in the total C18 fatty acid profile of the incubation liquid at 0 h incubation time

Within each subclass (i.e. row for 4 and 24 h of incubation), mean values followed by different letters are significantly different at $P < 0.05$

[A] Statistically analyzed using the positive controls as covariance

[B] Percentage of LNA apparently hydrogenated during 4 and 24 h of incubation, respectively, compared to LNA at 0 h incubation

[C] Referring to apparent completeness of biohydrogenation

fatty acid isomers differently ($P < 0.05$), except for 11*t*-18:1. The ethanol and sonication treatments had higher concentrations of 9*c*11*t*-18:2 by 4.64 and 6.37 times ($P < 0.001$), as well as higher 11*t*-18:1 by 2.65 and 3.56 times ($P = 0.053$), compared to non-emulsified 9*c*12*c*-18:2, respectively. Regarding these isomers, as well as 18:0, Tween® 80 was found to be in the same range as non-emulsified 9*c*12*c*-18:2. Both fatty acids, 9*c*11*t*-18:2 and 11*t*-18:1, were the most prevalent BH intermediate isomers in the profile in all treatments except for Tween® 80, which showed a higher 10*t*-18:1 proportion ($P < 0.05$) after 4 h of incubation compared to the other three treatments.

Total fatty acid recovery of the control was markedly higher after 24 h than after 4 h of incubation, and numerical treatment differences were not significant ($P > 0.05$). In contrast, the C18 fatty acid recovery showed a clear treatment effect ($P < 0.01$) and was highest for the ethanol treatment and lowest for the Tween® 80 method, with the other treatments being intermediate. The extent of overall apparent BH after 24 h of incubation was generally higher ($P < 0.001$), but showed the same trend as after 4 h of

incubation, with the sonication and ethanol treatments having lower BH than the other two treatments ($P < 0.001$). There was a significant incubation time effect regarding apparent 9*c*12*c*-18:2-BH ($P < 0.001$) as, after 24 h of incubation, 9*c*12*c*-18:2 (90–99%) had been biohydrogenated to a greater extent. The proportions of most C18 isomers, including 11*t*-18:1, 9*c*11*t*-18:1, and 9*c*12*c*-18:2 and 18:0, increased after 24 h compared to 4 h of incubation. The proportion of 9*c*11*t*-18:2 after 24 h was less in all treatments except ethanol. Compared to the other treatments, the proportion of conjugated linoleic acids, other than 9*c*11*t*-18:2, was higher ($P < 0.05$), with the ethanol method exhibiting about 7.5 times the initial amount. The BH intermediate 11*t*-18:1 and the BH end product 18:0 were more abundant in the incubation liquid after 24 h compared to after 4 h of incubation. Regarding 11*t*-18:1, higher ($P < 0.05$) proportions were found with the sonication method compared to the other treatments. The highest proportions of 18:0 in total C18 fatty acid occurred with non-emulsified 9*c*12*c*-18:2 and the Tween® 80 method ($P < 0.001$). There was a clear incubation time effect on almost all fatty acid parameters, except for the fatty acid isomers 9*t*-18:1, 10*t*-18:1, 13*c*-18:1, 15*c*-18:1, and conjugated 18:2 (9*c*11*t*-18:2 excluded).

Discussion

In the present in-vitro study, three common emulsifying methods were investigated and compared with each other and with non-emulsification with the aim of identifying possible side effects of this processes on ruminal lipid BH. This is important research because such effects would appear as artifacts and therefore bias the results in fatty acid-related ruminal in-vitro studies. Therefore, when planning an in-vitro experiment where lipid administration is required that necessitates the help of emulsification, these aspects are of high relevance.

Effects of the Emulsification Methods on Fatty Acid Recovery and BH of Linoleic Acid

The recovery of fatty acids was generally low in the present study, even with the stable emulsion treatments ethanol and sonication, which had been expected to improve fatty acid recovery. However, any system, either in vitro or in vivo, results in a basic loss of fatty acids to some extent [11, 18, 19]. During in-vitro incubation, lipids may be lost in several ways. For example, some lipids may attach to the incubation devices and, as a result, will not be retrieved in the sampling procedure. In the context of the present study, this might be due to the rather large glass surface of the incubation vessels and small amounts of incubation liquid. As expected, there was a higher fatty acid loss in the non-emulsified 9*c*12*c*-18:2, as well as in the emulsion prepared with the Tween® 80 method; this was more particularly the case at the short incubation time (4 h). Thus, for short-term in-vitro studies, to improve the recovery of added fatty acids, only sonication or the use of ethanol can be recommended. However, the clear time effect on the fatty acid profile and the terminal BH product, 18:0, found in general, as well as the different responses with time when using different emulsification methods, showed that results obtained after short-time incubation are not reliable unless they are used for kinetic evaluations in the context of repeated measurements [6]. The increase of fatty acid recovery found in the non-emulsified 9*c*12*c*-18:2 group with a time restriction of 4 h cannot be explained; however, it occurred repeatedly in each of the two experimental runs ($n = 4$).

Adhesion properties are a function of the chemical and physical nature of the fats, and therefore the possibility that the various BH products adsorbed onto the incubation vessels to different degrees cannot be excluded. However, when comparing the BH profile of the non-emulsified 9*c*12*c*-18:2 with profiles obtained in previous in-vitro studies [4, 6], as well as in an in-vivo trial [20], the pattern is comparable, i.e. the transient production of 9*c*11*t*-18:2 followed by a large accumulation of 11*t*-18:1. This supports the assumption that although the fatty acid recovery was limited in the present study, the actual fat recovered was of the same composition as the fat not recovered, and therefore the validity of the fatty acid profile was ensured.

The emulsifier Tween® 80 apparently induced alternative BH-pathways, which differed from the main cascade [21]. Thus, Tween® 80 produced artifacts in the BH-pathway of 9*c*12*c*-18:2 that have to be considered when comparing the results with those found in other studies. However, the main fatty acids, indicative of the extent of ruminal BH, did not substantially differ between non-emulsified 9*c*12*c*-18:2 and the Tween® 80–treated 9*c*12*c*-18:2 in the present study. Thus, provided the proportions of 18:1 isomers are interpreted with caution, Tween® 80 appears to be a suitable emulsification method in cases where the ruminal BH is to be tested in vitro.

In contrast, sonication and the addition of ethanol resulted in severe biases in the BH-pathway, rendering them unsuitable for appropriately simulating ruminal BH processes in vivo. It has been shown that the presence of feed particles promotes lipid BH by providing a site for lipids to adsorb and allowing exposure to BH processes [22]. Interestingly, a study by Harfoot et al. [23] found that low lipolysis and BH of trilinolein (0.3 mg ml^{-1} rumen content) occurred when only small amounts of the lipids were adsorbed to the plant particles. In contrast, in a second experiment in the same study, when a high proportion of

trilinolein was associated with the feed particle fraction, lipolysis and BH were high; this resulted in large amounts of free 18:0 in the feed particle fraction. Related to the results of the present study, this would mean that the small 9*c*12*c*-18:2 droplets formed in the stable 9*c*12*c*-18:2 emulsions with ethanol and sonication tended to stay in the liquid phase rather than being attached to feed particles. The unstable 9*c*12*c*-18:2 emulsion with Tween® 80 and no emulsification, however, might have attached to the feed particles to a greater extent, which would explain their higher apparent BH.

Using different emulsification methods to enhance the distribution quality of 9*c*12*c*-18:2 in the incubation liquid might cause toxicity of the fatty acid due to different bacterial species responsible for BH. This could result in different BH fatty acid profiles. The fact that the final step of the BH-pathway appeared to be specifically and severely impaired by sonicated 9*c*12*c*-18:2, resulting in an accumulation of 11*t*-18:1 and correspondingly lower concentrations of 18:0, is consistent with Maia et al. [8]. They showed that sonicated 9*c*12*c*-18:2 particularly inhibited some rumen bacterial species, including stearate-producing bacteria such as *C. proteoclasticum*. A significant increase in the 9*c*11*t*-18:2 and 11*t*-18:1 proportion observed with ethanol treatment indicates that there are inhibitory effects being generated in the second-last and last step of 9*c*12*c*-18:2 BH, which signified the inhibition of the double-bond hydrogenating steps, including *cis*-9 double-bond BH. This is a step that many bacterial species are capable of performing [21]. In the incubation study of Caldwell and Murray [24], which used higher ethanol concentrations than were employed in the present study, a general toxicity to ruminal bacteria was found. This was not the case in the present experiment, where no changes in total bacterial count (data not shown) were observed with the ethanol treatment. However, this does not exclude the possibility that specific rumen bacterial species and their activity were affected by the ethanol treatment.

Conclusion

The present study demonstrated that using emulsification methods to improve lipid distribution in incubation liquid in investigations of ruminal BH in vitro may bias the resulting fatty acid profile. Thus, when carrying out such studies, pretreatment of the lipids with any of the emulsification methods tested cannot be recommended. For cases when the emulsification of lipids seems necessary, Tween® 80 was the emulsification method that exhibited the least interference with the treatment effects, but the results might still be biased by some minor 18:1 isomers in this method. Sonication and ethanol were shown to severely inhibit ruminal BH when used as the administration method for 9*c*12*c*-18:2.

Acknowledgments We owe our thanks to Prof. M. Kreuzer for his support in the planning of this experiment.

Repletion of n-3 Fatty Acid Deficient Dams with α-Linolenic Acid: Effects on Fetal Brain and Liver Fatty Acid Composition

Akiko Harauma · Norman Salem Jr. · Toru Moriguchi

Received: 10 November 2009 / Accepted: 9 June 2010 / Published online: 13 July 2010

Abstract Docosahexaenoic acid (DHA) supply to the fetal brain depends upon the dam's dietary intake of n-3 fats. In this study, we measured the incorporation of DHA into the fetal brain and liver in n-3 fatty acid deficient (0.1% alpha-linolenate) mice upon switching to an n-3 fatty acid adequate (2.1% alpha-linolenate) diet. Second generation mice raised and maintained on an n-3 deficient diet during mating were switched to an n-3 adequate diet on embryonic day 1 (ED 1) or ED 13. Fatty acid analysis was performed on fetal brains and livers and on maternal serum on ED 13, 15, 17, and 19. Although fetal brain and liver DHA began at a very low level (both exhibited an 85% decline), recovery was nearly complete by ED 15 in the group switched near conception but thereafter diverged. The maternal serum and fetal liver were very similar in their DHA and docosapentaenoic acid time courses. However, when repletion began on ED 13, brain DHA recovery was only about 44%. These results suggest that a nutritional intervention with alpha-linolenic acid can nearly but incompletely rescue the mouse fetal DHA deficiency if began at the time of conception but that the third trimester is too late, thus leaving a large DHA gap.

Keywords Docosahexaenoic acid · Docosapentaenoic acid · Fetal brain · Infant nutrition · n-3 fatty acid deficiency

Abbreviations

DHA	Docosahexaenoic acid, 22:6n-3
DPAn-6	Docosapentaenoic acid, 22:5n-6
DTA	Docosatetraenoic acid, 22:4n-6
ALA	Alpha-linolenic acid, 18:3n-3
ARA	Arachidonic acid, 20:4n-6

Introduction

During prenatal development, polyunsaturated fatty acids, and docosahexaenoic acid (DHA, 22:6n-3), in particular, must be supplied by the mother via the utero-placental circulation. DHA may be synthesized from the precursor alpha-linolenic acid (ALA) by the maternal, placental and fetal tissues and long chain polyunsaturated fatty acids (LC-PUFAs) such as DHA may become concentrated in the fetal tissues and fetal brain, a phenomenon termed "biomagnification" by Crawford et al. [1]. The LC-PUFAs are also concentrated on the fetal side of the placental circulation [2, 3]. There has recently been a renewed interest in fetal accumulation of essential fatty acids, particularly with regard to DHA in the nervous system, as studies have explored the benefit for neurodevelopment of maternal supplementation with DHA [4]. Such studies are

often done against a background of the low n-3 fatty acid intake that is common in the US and many Western countries [5].

In the past, several studies have begun to establish the normal developmental pattern for fetal accumulation of organ DHA and its relationship to the maternal circulation and diet. An early study by Cunnane and Chen described the time courses of the major fatty acid concentrations in phospholipids and triglycerides in the developing rat brain, liver and carcass including an embryonic day (ED) 21 [6]. Green et al. [7] studied the phospholipid distribution and LC-PUFA concentration including that of DHA in rat brain over the last 10 days of prenatal development. Tam and Innis [8] recently presented the phospholipid and cholesterol distributions and the major brain phospholipid fatty acyl compositions in rat cortex on ED 19 and in postnatal development.

There have also been several investigations of dietary modulation of fatty acids on fetal brain and other organ composition. Yonekubo et al. [9] studied the effects of a maternal fish oil diet on brain and liver phospholipid DHA and arachidonic acid (ARA, 20:4n-6) content on ED 17, 19 and 21. Schiefermeier and Yavin [10] presented a detailed investigation of rats fed a control and an n-3 deficient diet that included maternal liver, and fetal brain and liver phospholipid fatty acyl compositions between ED 15 and 20. Innis and coworkers studied the effects of diets with a high and very low ALA content on brain cortex phospholipid fatty acyl compositions on ED 19 [8, 11].

The present work extends these studies by establishing a second generation n-3 fatty acid deficient female such that repletion with the n-3 fatty acid, ALA could be studied from the day of conception. This was compared to repletion with ALA on ED 13, i.e., the beginning of the third trimester of mouse gestation. Two reference groups were also maintained throughout the study, those with high (2.1% of total fatty acids) and very low ALA. The maternal serum was monitored for the expected effects of the dietary interventions and the fetal liver and fetal brain DHA and docosapentaenoic acid (DPAn-6, 22:5n-6) served as principal endpoints.

Materials and Methods

Animals and Study Design

The experimental protocol was approved by the Animal Care and Use Committee of the Wakunaga Pharmaceutical Co. in Japan. Female CD-1 (ICR) mice (F1) were obtained at 3 weeks of age from Charles River Japan, Inc. (Yokohama, Japan) and fed an n-3 fatty acid deficient (n-3 Def) diet or an n-3 fatty acid adequate (n-3 Adq) diet (see below for descriptions). They were maintained within our animal facility under conventional conditions, with controlled temperature (23 ± 3 °C), humidity (55 ± 10%), and illumination (12 h, 0700–1900 hours). At 7 weeks of age, they were mated with 8-week-old males of the same strain. Their litters were culled to 10 pups and the pups were weaned onto the same diet as their mothers. When the n-3-Def offspring females (F2) were 7 weeks old, they were mated with 8-week-old males of the same strain. The 60 pregnant n-3 Def mice thus obtained were divided into three dietary groups such that each dam within a group was from a different litter, thus the *n* number was based on the use of independent litters. There were 20 n-3 Adq dams to serve as an additional reference point.

One group of 20 dams was switched to an n-3 Adq diet at the time of mating (vaginal plug verified) and this group was termed the "ED1 Switch" group (Fig. 1). A second group of 20 pregnant dams was switched to the n-3 Adq diet at ED 13 and this group was termed the "ED13 Switch" group. The third group was maintained on the n-3 Def diet throughout pregnancy and was termed the "n-3 Def" group. In addition, the fourth group was maintained on the n-3 Adq diet throughout the F1 and F2 generations and was termed the "n-3 Adq" group. At days 13, 15, 17 and 19 of pregnancy, the dams were killed by decapitation, and brain and truncal blood was collected from the dams and the latter spun in a plastic centrifuge tube at 2300×*g* for 15 min at 4 °C. An aliquot of the upper phase (serum) was transferred to another tube. The liver and brains from each fetus were dissected out and all of the samples were then frozen at −80 °C prior to lipid extraction. The males were identified by a PCR method with Zfy gene primer (Proligo-Japan Co., Kyoto, Japan) to identify the Y gene in a liver DNA extract and using this criteria [12], the samples from one male fetus from each dam was selected for lipid analysis.

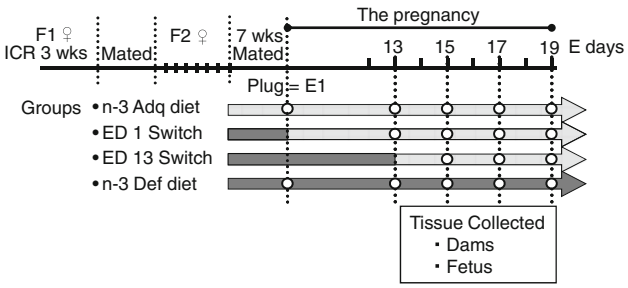

Fig. 1 Flow diagram illustrates study design. The n-3 Def diet was switched to the n-3 Adq diet at the time of mating (ED1 Switch) or on embryonic day 13, (ED13 Switch). The dams were killed by decapitation and tissues of dams and fetus collected at days 13, 15, 17 and 19 of pregnancy and analyzed for fatty acid composition by gas chromatography

Table 1 Composition of experimental diets

Ingredient	Amount (g/100 g diet)	
	n-3 Def.	n-3 Adq.
Casein, vitamin free	20	20
Carbohydrate:	60	60
Cornstarch	15	15
Sucrose	10	10
Dextrose	19.9	19.9
Maltose-dextrin	15	15
Cellulose	5	5
Mineral-salt mix	3.5	3.5
Vitamin mix	1	1
L-Cystine	0.3	0.3
Choline bitartrate	0.25	0.25
TBHQ	0.002	0.002
Fat	10	10
Hydrogenated coconut oil	8.1	7.75
Safflower oil	1.9	1.77
Flaxseed oil	None	0.48
Fatty acid composition[a]		
Saturates	83.8	80.2
Monounsaturates	2.9	4.0
18:2n-6	12.1	12.2
18:3n-3	0.10	2.1
20:4n-6	nd	nd
22:6n-3	nd	nd
n-6/n-3	101	5.7
18:2n-6/18:3n-3	121	5.7

The two experimental diets, an n-3 fatty acid adequate diet (n-3 Adq) and an n-3 fatty acid deficient diet (n-3 Def), were based on the AIN-93 [13] formulation with several modifications to obtain the extremely low basal level of n-3 fatty acid required in this study

[a] The 20:5n-3 and 22:5n-3 fatty acids were less than 0.01%, i.e., not detected (*nd*)

Experimental Diets

The diets used were modeled after the AIN-93G diet recommendations for rodents [13] (Table 1). However, the fat sources were altered to provide for the low n-3 fatty acid content required as a basal composition and balanced at 10 wt% fat content. The basal fat ingredients used were hydrogenated coconut and safflower oils for the n-3 Def diet and with flaxseed oil added to the n-3 Adq diet (Table 1). This diet was custom prepared and pelleted using low heat conditions (about 55 °C), then stored at 4 °C to prevent lipid oxidation (Oriental Yeast Co, Chiba, Japan) and the fatty acid distributions of the entire diets were quality assured within our own laboratory. The content of the key variable, alpha-linolenic acid (ALA) was 0.10 and 2.1% in the n-3-Def and n-3 Adq diets, respectively, while DHA was not detectable in either (Table 1). Diet and water were provided ad libitum.

Lipid Extraction, Transmethylation, and Gas Chromatography

Tissue samples were thawed, weighed, and homogenized in methanol-hexane and transmethylated in acetyl chloride according to the method of Lepage and Roy [14]. Varying amounts of the internal standards methyl docosatrienoate (22:3n-3) for brain and liver, and methyl tricosanoate (23:0) for serum, were added to each sample to compensate for differences in tissue weight and lipid concentration (70 μg/250 mg brain, 100 μg/250 mg liver, 20 μg/100 μl serum). As an aid in preventing lipid oxidation during the procedures, 50 μg/ml of butylated hydroxytoluene was added in methanol. The hexane extracts were concentrated in microvials for gas chromatographic (GC) injection.

GC Analyses

Fatty acid methyl esters were analyzed with an Agilent 6890N Network Gas Chromatograph (Agilent Technologies; Palo Alto, CA) equipped with a split injector, an 7683 automatic liquid sampler, an FID and a 208 V power supply to enable fast temperature ramping. The instrument was controlled and data was collected with GC Chemstation Rev.A.09.03 (Agilent Technologies). The column used was a DB-FFAP (15 m × 0.1 mm I.D. × 0.1 μM film thickness, J&W Scientific, Agilent Technologies). The detector and injector temperatures were set to 250 °C. The oven temperature program began at 150 °C with 0.25 min hold, ramp 35 °C/min to 200 °C, then 8 °C/min to 225 °C with 3.2 min hold and 80 °C/min to 245 °C with 2.75 min hold. Hydrogen was used as carrier gas at a linear velocity of 56 cm/s [15]. A custom-mixed, 28 component, quantitative methyl ester standard containing 10–24 carbons and 0–6 double bonds was used for assignment of retention times and to ensure accurate quantification (NuChek Prep 462, Elysian, MN). Fatty acid data were expressed as % of total peak area, which corresponded to weight% to within 5%, as demonstrated by quantitative standard mixtures. Internal standards were used to calculate tissue fatty acid concentrations.

Statistical Analysis

Data are expressed as the mean ± the standard error of the mean (SEM). All data were analyzed by two-way ANOVA using Statistica (Statsoft, Tulsa, OK, USA). These analyses of group, time and interaction for dam serum and fetal liver and brain all showed a highly significant result with $p < 0.0001$.

Results

Male offspring were compared to female offspring with respect to their liver and brain fatty acid composition, however, no changes were detected (data not shown). Therefore, only the male data are presented here.

In order to demonstrate the effects of the dietary fatty acid variation on the dam, an analysis of maternal brain (Table 3) and serum (Table 2; Fig. 2) was performed between 13 and 19 days gestation (ED 13 to ED 19). Analysis of the dam serum in the n-3 Def group indicated a much lower level of DHA (0.67 ± 0.04% of total fatty acids) relative to the n-3 Adq group (7.50 ± 0.54%, Fig. 2a). The ED1 Switch group, which had been switched to the n-3 Adq diet on the day of conception, displayed considerable recovery of DHA as it reached a level of 5.63 ± 0.28% on ED 13. By ED 15, the ED13 Switch group had increased to 2.56 ± 0.30% and thereafter gradually increased to 2.96 ± 0.21% by ED 19. It was of interest to note that in both the n-3 Adq and ED1 Switch groups, there was a decrease in serum DHA between days ED 15 and ED 19. This may possibly be due to the increased demand for DHA by the growing fetus. This decline was somewhat greater in the ED1 Switch group that the n-3 Adq group leading to a greater difference between these two groups in DHA content at ED 19 than was evident at ED 13.

Maternal serum DPAn-6 content (Table 2; Fig. 2b) was considerably greater in the n-3 Def group (3.82 ± 0.26%) relative to the n-3 Adq reference point (0.35 ± 0.03%) at ED 13. DPAn-6 appeared to increase in the n-3 Def and ED13 Switch group by ED 15 and decrease thereafter. Thus, it did not simply behave in an inverse manner to the DHA but was somewhat delayed in decreasing when DHA was increasing. The ED1 Switch group and the n-3 Adq group DPAn-6 levels remained fairly constant throughout the period of ED 13 thru ED 19. Although the ED1 Switch group had a content of DPAn-6 that had already declined by 73% (considering the starting point as n-3 Def at ED 1 and relative to the n-3 Adq level at ED 13), during the subsequent 6 days there was only a marginal further decline.

Of great importance with respect to maternal nutrition is the support of fetal brain DHA content. On ED 13, the brain DHA content in the n-3 Adq group was 4.95 ± 0.27% but only 0.72 ± 0.02% in the n-3 Def group (Fig. 3a) indicating an 85% decrease in the n-3 Def group. The ED1 Switch group had gained substantial DHA as it had 3.91 ± 0.26% DHA. The ED1 Switch group had nearly "caught up" to the n-3 Adq group by ED 15 as it attained a level of DHA that was about 98% of that the n-3 Adq animals. However, in subsequent time points it appeared not able to match the increases in brain DHA content found in the n-3 Adq group as they had very substantially grown to 12.62 ± 0.26% by ED 19 while the ED1 Switch group increased to 10.40 ± 0.10% at this time. The ED13 Switch group exhibited a slightly increased DHA content at ED 15 but a substantially greater amount relative to the n-3 Def on ED 17, rising to 4.38 ± 0.40%. By ED 19, this group had increased brain DHA content to 6.49 ± 0.49%, a level that was about half that of the n-3 Adq animals. The n-3 Def group increased brain DHA content only marginally between ED 13 (0.72 ± 0.02%) and 19 (1.66 ± 0.08%).

In the n-3 Def animals, the increase in brain LC-PUFAs that accompanied growth from ED 13 to ED 19 was largely composed of DPAn-6 (Fig. 3B) as it rose from 3.34 ± 0.16% to 9.12 ± 0.07% over this period. The ED13 Switch group exhibited a greater brain DPAn-6 at ED 15 (5.65 ± 0.17%) but remained constant at that level up until ED 19. This period of ED 15 to ED 19 corresponded to the rather rapid increase in DHA in this group. The ED1 Switch group had a brain DPAn-6 content (1.26 ± 0.11%) only marginally greater than the n-3 Adq group (0.84 ± 0.09%) at ED 13. The ED1 Switch group exhibited a gradually rising content of brain DPAn-6 ending up at 2.22 ± 0.10% by ED 19.

A more complete brain fatty acid profile is presented in Table 4 with the behavior of many other fatty acids during the ED 13 to ED 19 time period. There was a greater PUFA content at ED 19 relative to ED 13 in all groups. In the n-3 Def groups, there was generally greater n-6 PUFA content at ED 19 relative to ED 13, including 20:4n-6 and 22:4n-6, and principally DPAn-6. This was compensated for largely by a decreased content in monounsaturates, principally 18:1n-9. This pattern of increased brain n-6 PUFA and lower monounsaturate content associated with development was observed in all groups. There was a small increment in saturated fatty acid content in the ED 19 groups relative to the ED 13 groups.

The fetal liver DHA patterns for the four dietary groups were quite similar to the patterns described above for fetal brain. The n-3 Def group had very low liver DHA at ED 13 (0.90 ± 0.05%) while the n-3 Adq group contained 6.09 ± 0.32% (Fig. 4a) indicating an 85% decrease in the n-3 Def group. The ED1 Switch group contained 4.74 ± 0.13% DHA at ED 13 and this increased rapidly by ED 15 reaching 7.81 ± 0.17%, a value equal to that of the n-3 Adq group. However, it was of interest that the ED1 Switch group diverged from the n-3 Adq thereafter and ended the experiment at ED 19 at a value of 7.88 ± 0.48% DHA whereas the n-3 Adq group contained 9.46 ± 1.1% DHA. The ED13 Switch group increased in liver DHA continuously and gradually, reaching a final value of 4.25 ± 0.35% at ED 19. The n-3 Def group declined slightly in liver DHA over the course of the experiment, falling to 0.66 ± 0.11% on ED 19.

The fetal liver DPAn-6 profile for the four dietary groups bore a striking resemblance to the maternal serum. The n-3

Table 2 Maternal serum fatty acid composition

Fatty acid methyl esters from 12:0 to 24:1n-9 were analyzed. Each parameter is presented as the mean ± SEM, ($n = 5$). *DMA* indicates a dimethylacetal derivative of a plasmalogenic phospholipid

Statistically significant changes are represented as follow: $^{a}P < 0.01$, $^{b}P < 0.05$ compared with ED 13 or ED 19 in n-3 Def group, $^{c}P < 0.01$, $^{d}P < 0.05$ compared with ED 13 or ED 19 in n-3 Adq group, $^{e}P < 0.01$, $^{f}P < 0.05$ compared between ED 13 and ED 19 in each group, $^{w}P < 0.01$, $^{x}P < 0.05$ compared with non-pregnant n-3 Def mice, $^{y}P < 0.01$, $^{z}P < 0.05$ compared with non-pregnant n-3 Adq mice (one-way ANOVA followed by Tukey's HSD multiple range test)

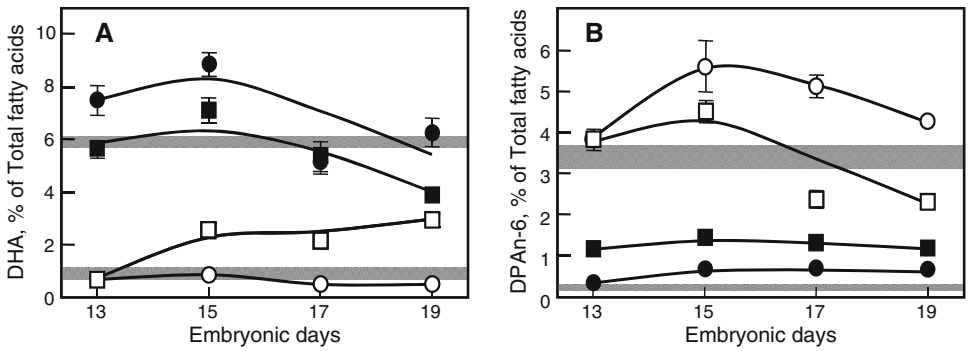

Fig. 2 Variation in docosahexaenoic acid (DHA) (**a**) and docosapentaenoic acid (DPAn-6) (**b**) in maternal serum during the period of the third trimester. The *hatched bars* indicate the level of the DHA or DPA in non-pregnant female mice bred by n-3 Def or n-3 Adq diet, respectively (DHA, n-3 Def, 0.91 ± 0.08; n-3 Adq, 5.90 ± 0.20; DPAn-6, n-3 Def, 3.41 ± 0.26; n-3 Adq, 0.22 ± 0.01%). The *closed circles* represent the n-3 Adq group, the *closed squares* are ED1 Switch group, the *open squares* are ED13 Switch group, and the *open circles* the n-3 Def group. Data at various time points are given as mean percent ± SEM ($n = 5$ mice per time point). The differences were statistically significant in a two-way ANOVA (DHA, $F(3, 63) = 293.0$, $P < 0.001$; n-3 Def, $P < 0.001$; ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Adq group and ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Def group, $P < 0.001$ between ED13 and ED1 switch groups by Tukey's HSD multiple range test, a group by embryonic day interaction $F(9, 63) = 9.187$; $P < 0.001$: DPAn-6, $F(3, 63) = 257.9$, $P < 0.001$; n-3 Def, $P < 0.001$; ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Adq group and ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Def group, $P < 0.001$ between ED13 and ED1 switch groups by Tukey's HSD multiple range test, a group by embryonic day interaction $F(9, 63) = 7.126$; $P < 0.001$)

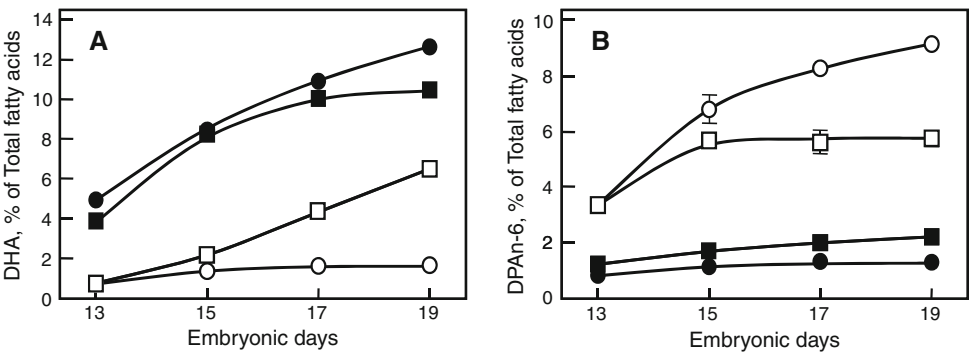

Fig. 3 Alteration of DHA (**a**) and DPAn-6 (**b**) in fetal brains during the period of the third trimester. *Symbols* same as in Fig. 2. The differences were statistically significant in a two-way ANOVA (DHA, $F(3, 63) = 427.8$, $P < 0.001$; n-3 Def, $P < 0.001$; ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Adq group and ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Def group, $P < 0.001$ between ED13 and ED1 switch groups by Tukey's HSD multiple range test, a group by embryonic day interaction $F(9, 63) = 15.04$; $P < 0.001$: DPAn-6, $F(3, 63) = 655.4$, $P < 0.001$; n-3 Def, $P < 0.001$; ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Adq group and ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Def group, $P < 0.001$ between ED13 and ED1 switch groups by Tukey's HSD multiple range test, a group by embryonic day interaction $F(9, 63) = 25.96$; $P < 0.001$)

Def group exhibited the properties of a high initial value for DPAn-6 (3.66 ± 0.10%) and a sizeable increase by ED 15 (to 5.56 ± 0.32%) and declining values thereafter, ending on ED 19 at 3.46 ± 0.45% (Fig. 4b). The ED13 Switch group responded to the increasing n-3 intake by decreasing DPAn-6 only after the ED 15 time point. The ED1 Switch group initially contained a rather low level of DPAn-6 (0.99 ± 0.07%) but gradually increased over the course of the experiment, ending at ED 19 at a value of 1.32 ± 0.09%. The n-3 Adq group remained constant over the course of the experiment at a liver DPAn-6 content of 0.50 ± 0.03%.

Discussion

This study established a very marked deficiency in brain DHA in the dams whose fetuses were studied; at the time of birth, the dams had a 62% lower brain DHA (n-3 Def, 4.92 ± 0.19%; n-3 Adq, 13.04 ± 0.20%) with compensation by a 30-fold greater content of DPAn-6 (n-3 Def, 9.89 ± 0.15%; n-3 Adq, 0.33 ± 0.01%). The effects of immediate repletion of the diet with ALA on the day of conception and also at the beginning of the third trimester were then evaluated with fetal brain and liver DHA and

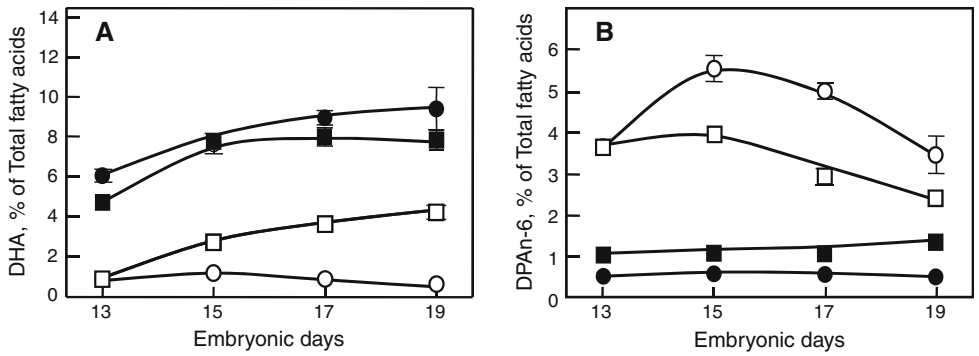

Fig. 4 Alteration of DHA (**a**) and DPAn-6 (**b**) in fetal livers during the period of the third trimester. *Symbols* are the same as in Fig. 2. The differences were statistically significant in a two-way ANOVA (DHA, $F(3, 63) = 311.2$, $P < 0.001$; n-3 Def, $P < 0.001$; ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Adq group and ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Def group, $P < 0.001$ between ED13 and ED1 switch groups by Tukey's HSD multiple range test, a group by embryonic day interaction $F(9, 63) = 4.841$; $P < 0.001$: DPAn-6, $F(3, 63) = 468.2$, $P < 0.001$; n-3 Def, $P < 0.001$; ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Adq group and ED13 switch, $P < 0.001$; ED1 switch, $P < 0.001$ compared with n-3 Def group, $P < 0.001$ between ED13 and ED1 switch groups by Tukey's HSD multiple range test, a group by embryonic day interaction $F(9, 63) = 12.50$; $P < 0.001$

DPAn-6 as key endpoints. Our key findings are that repletion of fetal brain DHA when ALA is repleted on ED 1 is nearly complete at ED 13 and 15 and DPAn-6 has declined to values near those of the n-3 Adq group. This recovery in the fetal brain tracks closely with DHA recovery in the maternal serum and the fetal liver; there is a striking similarity of the maternal serum DPAn-6 time course and that of the fetal liver. Repletion with dietary ALA on ED 13 leads to a slow and continuous replacement of fetal brain and liver DPAn-6 with DHA, a process that is about halfway completed by ED 19. Overall, the time courses of DHA content appeared to be very similar in fetal brain and fetal liver.

Only one other study exists in the literature, to our knowledge, where dietary n-3 fatty acid repletion was carried out during gestation and the fetal fatty acid composition studied, that of Schiefermeier and Yavin [10]. This detailed and pioneering study showed that there was an approximately 33% decline in DHA in the brain aminophospholipids, phosphatidylserine (PS) and phosphatidylethanolamine (PE), and in phosphatidylcholine (PC) when dams were fed an n-3 deficient diet (sunflower oil containing 0.26% ALA) relative to their control diet (soybean oil containing 6.7% ALA). Some of the dams were then subjected on ED 15 to a repletion diet containing over 21 wt% DHA and recovery of DHA was studied over the period of ED 15 to 20. These authors reported no significant changes in phospholipid distributions either as a result of the deficiency or of the repletion diet. However, a most notable result was that the high level infusion of dietary DHA beginning at ED 15 was capable of completely restoring fetal rat brain and liver DHA to the level of the soybean plus DHA diet by ED 18 in the brain and even more rapidly (ED 16.5) in the liver. It is also of significance that the levels of PE DHA were considerably higher in both the maternal and fetal tissues than the level found in the soybean diet, even though it contained a very high level of ALA (6.7 wt%). This study contrasts with ours in that the degree of DHA recovery was much faster and more complete. Of course, the rate and extent of tissue DHA recovery will be related to the fatty acid used (ALA vs. DHA) and the level of the fatty acid in the repletion diet. The 21 wt% level of DHA in the lipids of the Schiefermeier and Yavin study contrasts with 2.1% ALA used in our study for repletion. The 21% DHA dose may be considered as a therapeutic rescue whereas our approach would be considered the effects of a nutritional intervention. The degree of recovery must also be related to the degree of initial deficiency which in the present study was considerably greater as the deficiency was carried through two generations as opposed to starting at conception. Thus, these two papers together are complimentary in outlining the degree of maternal and fetal recovery of tissue DHA as it relates to several factors including the degree of initial deficiency, the particular n-3 fatty acid used for repletion and the level of that fatty acid as well as the length of time required for recovery. These studies show that a nutritional intervention with 2 wt% ALA in the third trimester or even on the day of conception is too late to normalize DHA and DPAn-6 content of fetal brain and liver in n-3 deficient rodents, but as demonstrated by Schiefermeier and Yavin, a large dose of preformed DHA is capable of restoring fetal DHA in the third trimester. It may be possible to normalize fetal brain DHA content with a somewhat lower dose of DHA so as to not antagonize the ARA levels.

In the Schiefermeier and Yavin study, it was demonstrated that the loss of DHA in the n-3 deficient diet group occurred within the aminophospholipids, PE and PS [10]. This was confirmed for rat brain PE and PS in ED 19

Table 3 Maternal brain fatty acid composition

Statistically significant changes are represented as follow: [a]$P < 0.01$, [b]$P < 0.05$ compared with ED 13 or ED 19 in n-3 Def group, [c]$P < 0.01$, [d]$P < 0.05$ compared with ED 13 or ED 19 in n-3 Adq group, [e]$P < 0.01$, [f]$P < 0.05$ compared between ED 13 and ED 19 in each group (one-way ANOVA followed by Tukey's HSD multiple range test)

embryos in a study of n-3 deficient (fed safflower oil) versus n-3 adequate (fed soybean oil) by Bertrand et al. [11] and for newborn brain cortex PE by Tam and Innis [8]. This is the expected result as it has long been appreciated that the main repository for brain DHA is within the aminophospholipids with PE being the largest component [16, 17] as has also been observed in rat liver [6, 9]. Therefore, it may be surmised that, although our study did not explicitly delineate the fatty acyl composition of various phospholipid pools, the loss and repletion of DHA as well as its replacement by DPAn-6 likely occurred in these aminophospholipids pools. Previous work has also shown that a low brain DHA status leads to a selective loss of brain PS [18] whereas an intra-amniotic administration of DHA leads to increased brain and liver PS [19].

Although the ED1 Switch group had "caught up" with respect to the brain and liver DHA level in the n-3 Adq reference group by ED 15, subsequent to that, the DHA level began to fall off with increasing divergence from ED 17 to ED 19. By ED 19, the DHA level in the ED1 Switch group was lower than that of the n-3 Adq group in the maternal serum and the fetal liver and brain. It is, however, of significance that the ARA level in the ED1 Switch group by ED19 had normalized relative to the n-3 Adq level.

It is noted that the maternal serum DHA level also declined in the n-3 Adq group, however, this group maintained a level similar to that of non-pregnant females (Table 2). This raises the question as to whether the rapid growth of the fetus at this end stage of development is placing too great a demand on the maternal ability to supply DHA due to her low body stores of DHA. The maternal serum DHA in the ED1 Switch group does in fact fall off after ED 15 and is only about 55% of what it was on ED 15 (see Fig. 2a). Analysis of the dam brain indicated that DHA in the n-3 Def group began at conception at $4.92 \pm 0.19\%$, rises to $6.68 \pm 0.28\%$ by ED 13 and to $8.99 \pm 0.13\%$ by ED 19 in the ED1 Switch group, while the n-3 Adq reference level is $13.36 \pm 0.31\%$ at ED 19. These data indicate that the dam brain is rapidly incorporating a large amount of DHA during gestation when she is switched to an n-3 Adq diet. We surmise that the origin of this DHA is from maternal liver and/or brain in vivo metabolism of the ALA being consumed in the diet.

At the same time, the total fatty acid of brain (μg/mg wet wt) is increasing from 13.95 ± 1.16 to 19.68 ± 0.09 between ED 13 and 19 in the ED1 Switch group. The total amount of DHA per brain in the ED1 Switch group over this 6 day time period rises in a rather spectacular fashion from 4.9 ± 1.3 to 126.4 ± 7.7 μg/brain (Table 4). This dramatic increase between ED 13 and 19 is associated with several factors including an increased total fatty acid concentration (41%), an over sixfold increase in brain weight and a selective increase in DHA content (rising over 25-fold). Similar observations were made in both the n-3 Def and the n-3 Adq groups during this period of development, with the latter group increasing DHA content the most. This rather extreme demand for fetal DHA coupled with the falling maternal serum percentage of DHA and the continuous uptake into maternal organs suggests that the ED1 Switch dams have a limited capacity to supply DHA. It is thus likely that the maternal dietary history with respect to n-3 fatty acid intake and tissue DHA accretion is an important factor for optimal maternal and infant nutrition. Low n-3 fatty acid intake clearly can lead to deficiencies in both fetal and maternal tissues and organs including the brain. An adequate source of preformed DHA is likely to prevent such deficiencies during fetal development.

Acknowledgment We would like to thank Ms. Yasuda of Wakunaga Pharmaceutical Co., for identification of fetus sex by PCR.

Effects of Seal Oil and Tuna-Fish Oil on Platelet Parameters and Plasma Lipid Levels in Healthy Subjects

Neil J. Mann · Stella L. O'Connell · Kylie M. Baldwin · Indu Singh · Barbara J. Meyer

Received: 3 May 2010 / Accepted: 29 June 2010 / Published online: 23 July 2010

Abstract Fish are a rich source of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), two long-chain polyunsaturated n-3 fatty acids (LC n-3 PUFA) with cardiovascular benefits. A related but less-investigated LC n-3 PUFA, docosapentaenoic acid (DPA), is more common in seal oil and pasture-fed red meats. This study compared indicators of platelet function and plasma lipids in healthy volunteers given supplements containing these different fatty acids (FA) for 14 days. Subjects, randomised into three groups of ten, consumed capsules of tuna oil (210 mg EPA, 30 mg DPA, 810 mg DHA), seal oil (340 mg EPA, 230 mg DPA, 450 mg DHA) or placebo (sunola) oil. Supplementary LC n-3 PUFA levels were approximately 1 g/day in both fish and seal oil groups. Baseline dietary FA and other nutrient intakes were similar in all groups. Both fish and seal oil elevated platelet DHA levels ($P < 0.01$). Seal oil also raised platelet DPA and EPA levels ($P < 0.01$), and decreased p-selectin ($P = 0.01$), a platelet activation marker negatively associated with DPA ($P = 0.03$) and EPA ($P < 0.01$) but not DHA. Plasma triacylglycerol decreased ($P = 0.03$) and HDL-cholesterol levels increased ($P = 0.01$) with seal oil only. Hence, seal oil may be more efficient than fish oil at promoting healthy plasma lipid profiles and lowering thrombotic risk, possibly due to its high DPA as well as EPA content.

Introduction

Cardiovascular diseases (CVD) are the leading causes of death in most westernised countries [1], the primary cause being atherosclerosis [2], a multi-factorial condition which becomes critical when it affects the supply of blood to the heart or brain [3]. One critical indicator of CVD risk appears to be the ratio between low-density lipoprotein (LDL)-cholesterol and high-density lipoprotein (HDL)-cholesterol [4], as atherosclerosis develops when distinct morphological forms of LDL invade the inner cellular lining of arteries and become oxidised [5, 6], promoting endothelial cell dysfunction. Subsequently, trapped monocytes and necrotic debris can rupture and trigger platelet activation and aggregation to induce an occlusive thrombus [6].

In general, if circulating platelets encounter endothelial damage, agonists such as collagen, adenosine triphosphate (ATP), adenosine diphosphate (ADP) and thrombin promote the activation of platelets and their adherence to exposed subendothelium, leading to thrombus formation [7]. Once activated, the platelets undergo shape change, exposing the cell adhesion molecule (CAM) p-selectin on their surface, initiating aggregation and releasing procoagulants. Mechanisms for controlling platelet activation are poorly understood, but there are indications that this may be linked to prostacyclin and nitrous oxide increasing intracellular levels of cyclic adenosine monophosphate (cAMP) [8, 9], as cAMP controls intracellular levels of calcium ions important for aggregation and adhesion; if levels of cAMP are increased, platelet activation and aggregation are reduced [9].

Epidemiological studies indicate that high intakes of long chain (>18 carbons) omega-3 polyunsaturated fatty acids (LC n-3 PUFA) are associated with decreased morbidity and mortality from CVD [10]. These LC n-3 PUFA at doses of around 3 g/day or more become incorporated in cell membrane phospholipids and then act to reduce inflammatory factors [10] and decrease hepatic triacylglycerols [11]. However, free LC n-3 PUFA in extracellular fluids appear to affect cardiac arrhythmias at doses of only 1 g/day [10]. In general intake of fish or use of fish oil supplement lowers CVD risk factors [12–14], apparently through the actions of eicosapentaenoic acid, C20:5n-3 (EPA), and docosahexaenoic acid, C22:6n-3 (DHA).

Both EPA and DHA have been shown to lower plasma triacylglycerol levels, an independent risk factor for CVD [15], as well as increase levels of HDL-cholesterol [16]. Supplementary EPA has successfully suppressed the expression of platelet activation markers and the release of platelet-derived microparticles capable of generating thrombin (a potent platelet aggregator), thereby retarding further platelet activation [17, 18]. There is evidence that EPA and DHA also reduce platelet aggregation [19].

Red meat contains relatively small amounts of EPA and DHA, but is rich in another LC n-3 PUFA: docosapentaenoic acid, C22:5n-3 (DPA), which is only present in small amounts in a few oily fish [20]. Reported intakes of DPA in countries such as France [21], Japan [22] and Denmark [23] are generally similar to Australian values [24]. Since Australians consume around six times as much meat as fish and seafood [25], this food contributes significantly (up to 43%) to the total LC n-3 PUFA intake of many Australians, and DPA may make up almost one-third of the LC n-3 PUFA in the average adult Australian diet [24]. As such, further investigation of its effects on cardiovascular and general health is required.

The similarity in molecular structure of DPA to EPA and DHA makes it feasible that DPA has similar beneficial effects to DHA and EPA on cardiovascular parameters. All three of these LC n-3 PUFA are significantly and inversely related to carotid intimal-medial thickness [22], and DPA, like EPA and DHA, has been shown to have an anti-aggregatory effect on platelets [26, 27]. A large prospective study in healthy males found that serum levels of EPA were not associated with reduced risk of acute coronary events, whereas subjects with the highest levels of combined DHA and DPA were at reduced risk compared to those with the lowest levels [28]. Supplementary seal oil, relatively rich (compared with fish oil) in DPA, has been found to induce an increase in the LC n-3 PUFA status of serum phospholipids in normal men, with the suggestion of a favourable shift in the balance of plasma pro-coagulant and anticoagulant activity [29]. LC n-3 PUFA have also shown anti-inflammatory effects in many experimental models as well as in clinical conditions of inflammation [10], and evidence for the specific benefits of seal oil in such cases has been mainly positive [30, 31], although not always significant [32].

Commercial quantities of pure food-grade DPA are not currently available for use in a clinical trial. Seal oil (which also contains EPA and some DHA) is the richest commercially-available source of DPA but, to our knowledge, no report of its effect on platelet activation has previously been published. This study examined the effects of seal oil on blood lipids and platelet factors compared to those of tuna-fish oil (which contains minimal DPA, 40% less EPA and double the DHA of seal oil) in healthy volunteers. A placebo oil containing no LC n-3 PUFA provided a control in this randomised double-blind parallel intervention study.

Experimental Procedures

Ethics Approval

The study protocol was approved by the RMIT University Human Research Ethics Committee and notification forwarded to the Australian Therapeutics Goods Administration.

Recruitment and Study Population

Thirty healthy volunteers (19 female and 11 male), aged from 20 to 50 years, were recruited for this pilot clinical trial after advertisement of the study and screening for suitability. Subjects had no known metabolic, endocrine or haematological diseases, were not smokers nor on any form of medication, and had moderate physical activity levels. Signed informed consent was obtained from all volunteers prior to randomisation. Study participants were required to complete a 7-day weighed food record before commencing the dietary fatty acid supplementation, to confirm that they were not consuming antioxidant or other nutrient supplements and to compare the general nutrient and fatty acid intakes in the different groups. The volunteers were requested not to modify their diet whilst participating in this study, and also asked to refrain from consuming aspirin-type products and fish oil supplements for 2 weeks prior to and during the study.

Experimental Design

The study was a randomised parallel double-blind placebo-controlled clinical trial conducted over 14 days (sufficient for complete platelet turnover). After an initial 14-day wash-out period (on a common diet very low in LC n-3 PUFA), subjects were randomly assigned to one of three groups: a placebo oil (Sunola—high oleic acid sunflower oil), tuna-fish oil or seal oil group. Each group consumed their combination of supplementary fatty acids in the form of 10 soft-gel capsules per day over the trial period. Subjects were instructed to consume their daily supplementary capsules with or after breakfast.

The placebo group received ten 500 mg capsules/day of sunola oil (85% 18:1n9, 5% 18:2n6, 5% 16:0) (Nu-Mega Ingredients Pty. Ltd., Australia), which is devoid of EPA, DPA, DHA and other LC PUFA, but provided approximately 4 g monounsaturated oil per day (Table 1). The fish oil subjects received four of the placebo capsules/day plus six 500 mg capsules/day of tuna-fish oil, which is rich in DHA and also contains EPA and a small amount of DPA (Nu-Mega Ingredients Pty. Ltd., Australia). The third group received ten 500 mg seal oil capsules/day (BGI Atlantic Marine Product Inc., Canada), containing EPA, DHA and significant amounts of DPA (over seven times that in the fish oil). The tuna-fish and the seal oil groups both received a total of just over 1 g/day of supplementary LC n-3 PUFA (Table 2).

Table 1 The principal fatty acid composition of supplementary oils used in this study (mg FA/500 mg oil)

Fatty acid	Placebo (sunola) oil	Fish oil	Seal oil
C18:1n-9	425	61	142
C20:5n-3 (EPA)	0	35	34
C22:5n-3 (DPA)	0	5	23
C22:6n-3 (DHA)	0	135	45
Total LC n-3 PUFA per 500 mg capsule	0	175	102

Subjects received 10 sunola oil capsules or six fish oil plus four sunola oil capsules or ten seal oil capsules, per day

Table 2 Total amount of supplementary oleic acid and principal long-chain n-3 PUFA (mg/day) supplied to subjects in each test group (through consumption of 10 soft-gel capsules per day)

Fatty acid	Placebo (Sunola) oil group	Fish oil group	Seal oil group
C18:1n-9	4,250	1,944	1,420
C20:5n-3 (EPA)	0	210	340
C22:5n-3 (DPA)	0	30	230
C22:6n-3 (DHA)	0	810	450
Total LC n-3 PUFA	0	1,050	1,020

Since only the seal oil contained squalene (12.5 mg/500 mg seal oil capsule), the fish oil and placebo group participants were given one 875 mg squalene capsule per week (equivalent to the seal group intake of 125 mg/day), to equalise squalene intakes within the groups.

It should be noted that seal oil also contains 0.3 mg/100 g vitamin A and 4.5 mg/100 g alpha-tocopherol [32], whereas tuna-fish oil contains less than 10 International Units of vitamin A and 0.21% of mixed natural tocopherols (NuMega Ingredients Ltd., Sydney).

All subjects initially completed a 7-day weighed food record to provide baseline nutrient values. Fasting blood was collected from each subject at day 0 and day 14 of the trial. Samples were analysed for whole blood platelet aggregation and adenosine triphosphate (ATP) release from platelet-dense granules. A full blood examination provided a platelet count and mean platelet volume (MPV). Platelet activation markers were measured using flow cytometry, and inflammation assessed via plasma C-reactive protein (CRP). A full blood lipid profile provided plasma total cholesterol, HDL-cholesterol, LDL-cholesterol and triacylglycerol levels, and platelet fatty acid content was assessed.

Dietary Analyses

The baseline nutrient intakes were determined using the software package FoodWorks (Xyris Software, Australia). Baseline fatty acid intakes were assessed using the RMIT University Fatty Acid Database available on FoodWorks.

Blood Collection

Subjects were requested to fast overnight (12–14 h), then blood was taken in the laboratory between 0700–0800 hours on days 0 and 14 of supplementation. To reduce platelet activation from venipuncture, subjects were carefully bled without a tourniquet. A 21-gauge needle was employed to collect blood into Greiner Bio-one Vacutainers (Interpath Services, Victoria, Australia) in the following sequence: one 2-mL tri-potassium ethylene-diamine-tetra acetic acid (EDTA) (1.8 mg/mL) tube, two 5-mL tri-sodium citrate (3.8%) tubes, and one 10-mL serum separator tube. Handling and agitation of specimens were kept to a minimum.

Platelet Function Tests

Mean platelet volume (MPV) and platelet count were measured by using whole blood collected in EDTA-containing tubes with the use of a Beckman Coulter $A^c.T^{TM}$ 5diff analyser (Coulter Corporation, Miami, FL, USA), within 20 min of venipuncture**.** The performance of the analyser was validated daily, prior to full blood examination (FBE), using Coulter Calibrator and Controls Plus.

Blood collected in citrate-containing tubes was used to determine the extent of platelet aggregation and to measure the release of ATP from platelets. Whole blood platelet aggregation was measured within 1 h of venipuncture with an impedance aggregometer (Chrono-Log Corp, Philadelphia) equipped with MacLab software (ADInstruments Pty, Ltd, Castle Hill, Australia) for data quantisation and analysis. This method has been previously described by Murphy et al. [33]. Calibrations for impedance and ATP release were performed daily before analysing blood samples. Briefly, citrated whole blood was diluted with saline (1:1), 100 μL Chrono-lume® reagent (Chrono-Log Corp, Philadelphia) was added, the sample was then incubated, and mixed with agonists, either 2 μg collagen/mL [Chrono-Log Corp] or 1 mmol arachidonic acid/L (which was used to stimulate platelets for repeating the aggregation as a check for anti-inflammatory intake). Aggregation was recorded for 6 min. ATP released from the platelets reacted with luciferin-luciferase in the Chrono-Lume reagent and luminescence was measured at 650 nm by a photomultiplier tube (PMT) within the aggregometer, simultaneously with platelet aggregation.

Additional aliquots of citrated whole blood were used for measuring platelet activation. Whole blood was diluted with modified Tyrode's buffer and incubated for 5 min in the presence of 2 μg collagen/mL. Subsequently, aliquots of activated blood were incubated in the dark with monoclonal antibodies: phycoerythrin-conjugated CD41 (Immunotech, Marseille; which was used to identify platelets because it has specificity for the glycoprotein IIb portion of the glycoprotein IIb-IIIa antigen present on resting and activated platelets); fluorescein isothiocyanate-conjugated CD62P (Immunotech, Marseille; an activation-dependent antibody directed against P-selectin, a component of the α-granule membrane of resting platelets that becomes expressed on the platelet surface membrane upon activation); or one of the isotype controls, immunoglobulin G_1 (IgG_1). Samples were fixed with paraformaldehyde and incubated to prevent further artifactual in vitro platelet activation. Modified Tyrode's buffer was added to terminate the fixation, and samples were analysed on an EPICS Elite flow cytometer (Coulter Electronics) equipped with a 15-mW argon laser, with excitation at 488 nm. The fluorescence of fluorescein isothiocyanate and phycoerythrin was detected using 525 and 575 nm band pass filters, respectively. Single platelets were identified by gating on both phycoerythrin positivity (CD41 binding) and characteristic light scatter. (Because single platelets are smaller and less complex than other blood cells, including aggregated platelets, their forward scatter and side scatter are lower in comparison with other cells.) Once identified, the expression of P-selectin was determined by analysing 20,000 free platelets, collected at a rate of between 1,300 and 1,600 events/s. Activated platelets were defined as CD41-positive events that expressed P-selectin. The data are reported as a proportion of maximum CD62P expression.

C-Reactive Protein and Lipid Profile

Serum was separated from blood collected in a serum separator tube and analysed at the St. Xavier Francis Cabrini Hospital (Malvern, Victoria, Australia) using an automated biochemical analyser (Olympus AU2700). Calibrators and controls (Biorad Liquichek™ human chemistry controls) were run routinely to validate the performance of this instrument.

Anti-CRP antibodies (goat) were employed to aggregate with CRP in serum. The immuno-turbidimetric method (polyethylene glycol with tris-aminomethane buffer) was utilized for analysing the absorbance of the aggregates that were proportional to the CRP concentration within the sample.

Total cholesterol was measured using an enzymatic assay system (Integrated Sciences Ltd., Sydney, Australia) which produced a chromophore (quinoneimine dye)

quantified at 520/600 nm. Triacyglycerols were measured using a multi-step enzymatic assay (Integrated Sciences Ltd, Sydney, Australia) that resulted in production and measurement of the same quinoneimine dye. Similarly, HDL-cholesterol was determined using an enzymatic colorimetry kit (Thermo Trace Ltd, Melbourne, Australia), with the product detected at 340 nm. LDL-cholesterol was calculated using the Freidewald calculation [34].

Platelet Fatty Acid Content

Platelet-rich plasma was obtained by centrifugation at 1,950 rpm for 5 min and then the supernatant spun again at 1,000 rpm for 20 min. The platelet fatty acids were determined at Flinders Medical Centre (Bedford Park, Adelaide, Australia), following trans-esterification, separation and quantification as fatty acid methyl esters using a Hewlett-Packard 6890 gas chromatograph equipped with a 50 m BPX-70 capillary column (0.32 mm ID, 0.25 μm film thickness) (SGE Pty Ltd Victoria, Australia) [35].

Statistics

Statistical analyses were performed using the statistical package SPSS, version 13.0 (SPSS Inc., USA). Student's paired t tests were used to test significance between baseline and post-trial samples within groups, and one-way analysis of variance (ANOVA) used to determine significance between groups. Regression analysis was performed using Microsoft Excel 2002 (Microsoft Corporation) to examine associations between selected parameters. A statistical significance of $P < 0.05$ was applied to all data.

Results

Subjects

Three of the original 30 subjects withdrew from the study due to time constraints or difficulty with phlebotomy, all coincidently members of the placebo group. Remaining subjects were reasonably well matched for age and weight (Table 3). Subjects' compliance was verified through capsule count. No side effects were recorded other than 'fishy burps' experienced by a few subjects from the fish and seal oil groups during supplementation. No subject reported ingestion of aspirin during the study and this was confirmed by normal platelet aggregation curves obtained using (AA) as an agonist.

Table 3 Descriptive characteristics of study participants in the three test groups at baseline ($n = 27$)

Demographic parameters	Placebo ($n = 7$)	Fish oil ($n = 10$)	Seal oil ($n = 10$)
Gender: female/male	5/2	5/5	8/2
Age (years)	29 ± 5 (23–36)	30 ± 8 (21–43)	31 ± 6 (23–41)
Weight (kg)	68 ± 17 (50–98)	72 ± 14 (48–88)	78 ± 14 (60–99)

Values are means ± SD (range). n is number of participants

Baseline Nutrient and Fatty Acid Intakes

Incomplete food intake data were obtained from three subjects (one placebo and two seal oil volunteers), so that these final values were provided by 6 subjects (5 female, 1 male) in the placebo group, 10 (5 male, 5 female) in the fish oil and 8 (7 female, 1 male) in the seal oil group.

The baseline dietary data for all three study groups were generally similar, with no significant differences except for alcohol consumption, which was high in the seal oil group due to the atypical intake of one subject (Table 4). Total fat consumption was of the order of 70–80 g/day for all groups.

Baseline fatty acid intakes, including background levels of intake of EPA, DPA and DHA, and of total LC n-3 PUFA (of the order of 0.10 g/day), were also similar in all treatment groups (Table 5).

Fatty Acid Incorporation into Platelet Phospholipids

Table 6 shows that while most mean platelet fatty acid concentrations did not change in the placebo group, there were unexpected increases of almost 10% in DHA and 7% in total LC n-3 PUFA ($P = 0.04$ for both) at day 14. Subjects in the fish oil group had decreased platelet levels of total saturated fatty acids (−5%, $P = 0.03$), and highly significant increases in DHA (+78%, $P \leq 0.001$) and total LC n-3 PUFA levels (+40%) ($P \leq 0.01$). An increase in platelet EPA (41%) approached significance ($P = 0.06$) in the fish oil group. Platelet arachidonic acid (AA) levels did not change in any group. In subjects who received the seal oil supplement, levels of several fatty acids changed significantly. A decrease in 16:0 (−4%) was observed ($P = 0.02$), as was a decrease in total monounsaturated fatty acids (−6%, $P = 0.01$). Total n-9 and total n-7 contents both decreased ($P = 0.04$ and $P = 0.01$, respectively). Platelet concentrations of EPA increased considerably with seal oil (+204%, $P = 0.000$), as did those of DPA (+49%, $P = 0.01$) and DHA (+51%, $P < 0.01$). Total LC n-3 PUFA increased by 63% ($P < 0.01$). Analysis by ANOVA showed that the change in total n-9 was unique to the seal

Table 4 Average baseline daily nutrient intakes of the study participants who then received supplementary placebo (sunola oil), tuna-fish oil or seal oil capsules

Nutrient (day^{-1})	Placebo ($n = 6$)[a]	Fish oil ($n = 10$)	Seal oil ($n = 8$)[a]

Values are means ± SD

[a] Subject numbers were reduced because of incomplete dietary data (see text). Values were obtained from the following gender mix of subjects in the placebo, fish oil and seal oil groups: 5 female/1 male, 5 female/5 male, 7 female/1 male, respectively

group ($P = 0.04$). The unexpected increases in platelet DHA and total LC n-3 PUFA measured for the placebo group were significantly less than those observed for the fish and seal oil groups ($P < 0.01$). The increases in platelet EPA, DPA, DHA and total LC n-3 PUFA concentrations measured for the seal oil group were not matched by any other group (ANOVA: $P < 0.01$), except for DHA in the fish oil group.

Platelet Parameters

At baseline, there were no significant differences between groups for any platelet parameters, including LC n-3 PUFA levels. After 14 days' supplementation with placebo oil, fish oil or seal oil, no significant changes were observed in platelet volume (Table 7). An unexplained increase in platelet count was noted in the placebo (sunola) group, but fish oil and seal oil groups were unchanged. Platelet activation, determined by P-selectin (CD62p %) expression, decreased significantly after seal oil supplementation ($P = 0.01$), with no significant change in either the fish oil or placebo groups. ANOVA analysis confirmed a highly significant difference ($P < 0.01$) in effect on platelet activation between the seal oil group and the other two groups. Platelet aggregation was not significantly changed by supplementation in any of the three groups. An unexplained increase in platelet ATP release was induced by fish oil supplementation ($P = 0.02$), where the day 0–day 14 difference was approximately twice that observed in placebo and seal groups.

Because of the large effect of seal oil on platelet activation, platelet DPA, EPA and DHA levels were correlated with P-selectin expression. When the data pairs for all treatment groups at Day 0 and Day 14 of supplementation were pooled, there was no significant correlation between P-selectin and DPA ($P = 0.12$) or DHA ($P = 0.16$), but EPA and P-selectin were significantly negatively correlated ($P = 0.02$). When these Day 0 and Day 14 data were analysed separately, the baseline levels of EPA, DHA and DPA were not significantly associated with p-selectin levels. However, at Day 14 of supplementary treatment, a significant negative correlation was found between platelet p-selectin and both DPA ($P = 0.03$) and EPA levels ($P < 0.01$), but not DHA levels ($P = 0.13$) (Fig. 1).

Blood Lipid Profile and C-Reactive Protein

Baseline blood lipid profile parameters (total cholesterol, HDL- and LDL-cholesterol, and triacylgylcerols) and C-reactive protein (CRP) levels did not differ significantly between groups (Table 7). At day 14 of supplementation, total cholesterol and LDL-cholesterol were unchanged compared to baseline in all treatment groups. HDL-cholesterol increased significantly ($P = 0.01$) after 14 days' of seal oil intake, and approached significance in the fish oil group ($P = 0.06$). This pattern was maintained in the triacylglycerol results, where a significant decrease was induced by seal oil supplementation ($P = 0.03$) but only a tendency to decrease was observed in the fish oil group ($P = 0.06$). CRP did not change significantly within any group.

Discussion

This study compared the effects of a 14-day supplementation with seal oil, tuna-fish oil or a monounsaturated vegetable (sunola) oil in healthy volunteers. The results indicated that relatively small supplements of approximately 5 g/day of seal oil and 3 g/day of tuna-fish oil (each containing approximately 1 g LC n-3 PUFA) were sufficient to induce significant increases in the total LC n-3 PUFA content of platelets. Both seal and fish oil induced highly significant increases in platelet DHA, even though the supplementary intake of this fatty acid was almost twice as great in the fish oil group. The pattern of increase in platelet EPA levels roughly followed the relative amounts of EPA supplied by the supplements: EPA increase with fish oil was almost significant ($P = 0.06$), whereas the seal oil supplement, which provided approximately 60% more EPA, induced a highly significant increase in platelet EPA ($P < 0.01$), possibly involving some retroconversion of DPA to EPA as observed by Kaur et al. [36] in a rat model. In addition, the higher levels of DPA present in the seal oil supplement were reflected in a significant rise in platelet DPA ($P < 0.01$), while the very small DPA content of the fish oil induced no change. An unexpected increase in platelet DHA and in total LC n-3

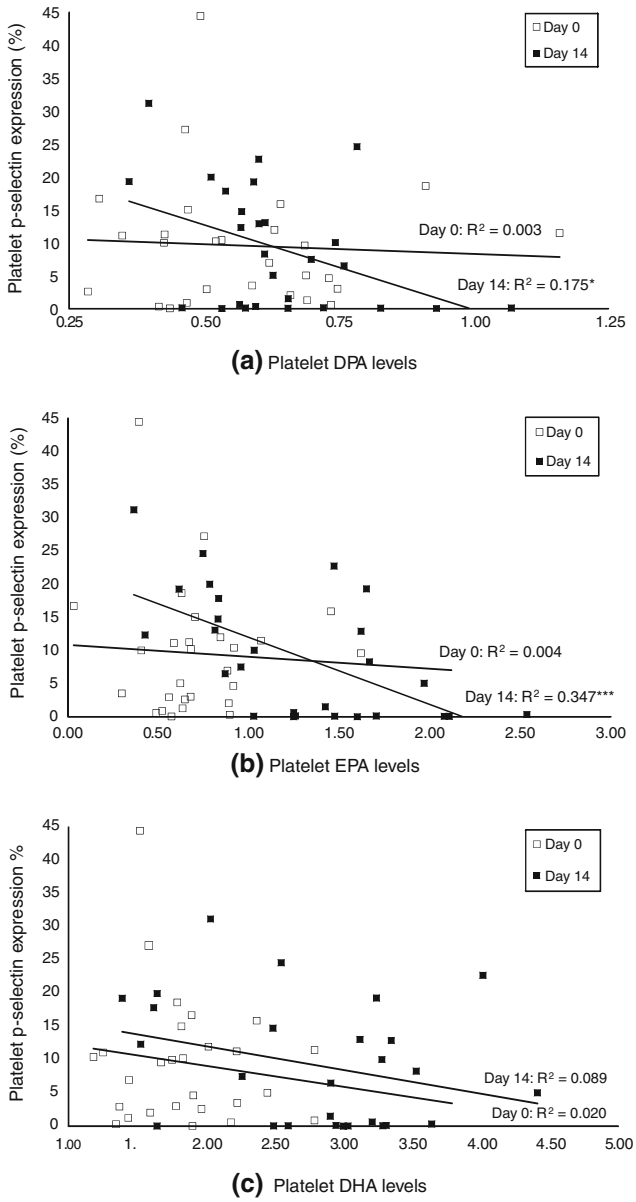

Fig. 1 Correlations between platelet levels of **a** DPA, **b** EPA, and **c** DHA (% of total FA) and platelet activation (P-selectin expression, %) for the pooled treatment groups (placebo/sunola oil, fish oil and seal oil) at day 0 and day 14 of supplementation. (*$P < 0.05$, ***$P < 0.005$ for Pearson's product moment)

PUFA was recorded for the placebo group, despite no DHA or alpha-linolenic (18:3n-3) acid being present in the placebo (sunola) oil. Similarly, there was a significant rise in platelet DHA levels in the seal oil group, despite the low concentration of DHA in the seal oil, most likely due to further desaturation of the DPA as seen in other studies [36].

Although both EPA and DHA have been shown to competitively displace AA from platelet phospholipids [11], AA levels did not change in this study with either seal or fish oil supplement, perhaps because of the relatively low dosages consumed. However, significant decreases in the cumulative content of platelet n-7 and n-9 fatty acids, as well as total MUFA, following seal oil intake were very likely due to displacement by the supplementary LC n-3 PUFA in the platelets. Interestingly, such changes were not seen with the tuna-fish oil, which contained the same total amount of LC n-3 PUFA but twice the DHA content and 60% of the EPA content of seal oil. Instead, fish oil induced a significant decrease in total saturated FA that was not observed with seal oil, suggestive of a preferential displacement of saturated FA in the platelets by DHA. As the overall total amount of n-6 fatty acids did not change significantly with fish or seal oil supplementation whilst total LC n-3 PUFA increased, both the fish oil and seal oil intakes induced a decrease in the n-6/n-3 ratio, also observed following 20 g/day seal oil treatment [29]. Such a reduction in platelet n-6/n-3 (LC PUFA) ratio is generally considered beneficial for the prevention of CVD [37], although a large study indicated that having a higher intake of n-3 PUFA is more critical for the prevention of coronary heart disease than the relative level of n-6 intake [38].

The most important finding in response to seal oil supplementation in this study was a significant reduction in platelet activation, as determined by platelet p-selectin expression. In contrast, fish oil supplementation did not affect this factor, although EPA has previously been shown to decrease platelet activation [17]. Rather, an unexpected increase in platelet ATP release, a promoter of platelet activation, was observed with fish oil consumption ($P = 0.02$). Although the dose of EPA in the fish oil (0.21 g/day) was less than that in the seal oil (0.34 g/day) the strength of the response to seal oil suggests that DPA along with EPA may be having a potent suppressive effect upon platelet activation, or the retroconversion of DPA to EPA is resulting in sufficient EPA to affect platelet surface activity. The finding of an inverse correlation between platelet activation and platelet DPA levels agrees well with the inhibitory effect on platelet reactivity previously observed with DPA treatment in vitro [26]. A lack of change in platelet activation with the fish oil treatment is consistent with its high DHA content (77%) and lesser EPA and DPA content compared to seal oil (Table 2), since DHA seems to have no association with p-selectin. At higher dosages of fish oil, the larger quantities of EPA might eventually result in depressed platelet activation, since we also found a negative correlation between platelet EPA levels and platelet P-selectin expression. Others have previously concluded that EPA but not DHA reduces platelet activation [39].

The lack of significant change in platelet aggregation with either seal oil or fish oil is not unexpected given the low doses used in this study; it echoes one result found with a 20-g dose of seal oil given to healthy males [29], but

not a later study which did find that 15 mL seal oil suppressed platelet aggregation in mixed gender subjects with mild hypercholesterolemia [40]. In the present study, as the DPA/EPA-rich seal oil supplementation was shown to decrease one aspect of platelet activation, we might have expected it to decrease platelet aggregation in turn, but this process may have required longer than 14 days or a higher dose of LC n-3 PUFA to reach significance. Others have reported that EPA and DHA appeared to have anti-platelet aggregation effects in vitro through differing actions on thromboxane production in platelets [11, 41]. However, thromboxane-induced aggregation was more potently blocked by DHA than EPA [41]. In vitro studies testing each of these LC n-3 PUFA individually demonstrated that DPA had a potent dose-dependant effect on collagen or AA-stimulated aggregation superior to that of DHA or EPA, which were very similar in effect [27]. The authors speculated that DPA has a potent effect which results in interference with the cyclooxygenase pathway and acceleration of the lipoxygenase pathway to inhibit aggregation [27]. Inhibition of collagen-induced aggregation and preservation of platelet morphology by DPA appears to be surface-mediated, as with DHA [26]. Evidence also exists for gender differences in in vitro platelet aggregation responses to LC n-3 PUFA [42], with EPA effectively decreasing platelet aggregation in blood from healthy males and females, while both DPA and DHA were significantly less effective in males compared with females.

In this study, the seal oil supplement also produced another outcome protective of CVD: a significant increase in HDL-cholesterol that was not observed with the fish oil. When Buckley et al. [43] compared the effects of 4.8 g/day EPA or DHA in normal adults, they found no effects on HDL-cholesterol. In contrast, supplementation with 2.4 g/day of EPA plus 1.6 g/day DHA (a combined total of 4 g/day, with exercise) induced increases in HDL-cholesterol [44] in a dose-dependent manner resembling the effects of fish consumption [16]. In our study, lack of significant change in HDL-cholesterol with the fish oil may reflect the considerably lower content of EPA (210 mg/day) plus DHA (810 mg/day) (i.e. 1.02 g/day combined) provided in this supplement. However, the combined dose of these FAs in the seal oil was even lower at 0.790 g/day (EPA 340 mg/day, DHA 450 mg/day), suggesting that it may be the 230 mg/day DPA that positively affected HDL-cholesterol in our participants, even at this low supplementary dose. In view of this result, it is difficult to explain why HDL-cholesterol did not change in two previous investigations with seal oil [29, 45], one involving a very large (20 g/day) oil supplement [29]. Confusingly, subjects given pure seal oil and those who received cod liver oil (rich in EPA and DHA) did not show a change in HDL-cholesterol, yet this factor increased significantly after supplementation with the same volume of a combination of seal oil and cod liver oil [45]. This almost suggests a synergistic effect of DPA and EPA, or else that the amount of EPA present in the combination oil dose reached a level which effected a detectable change.

Modest decreases in serum total cholesterol have been described after seal oil supplementation [12], but we observed no changes in either total cholesterol or LDL-cholesterol, in line with some other studies [29, 45]. Supplementary fish oil has previously been shown to decrease both total and LDL-cholesterol in patients at risk of CVD [13, 46], but this was not the case in our study of healthy volunteers taking relatively small dosages of tuna-fish oil. Larger doses or longer periods of supplementation may be necessary to see beneficial changes in lipid profile in healthy subjects. However, the ratio of HDL-cholesterol: LDL-cholesterol is generally considered more indicative of risk of CVD than total cholesterol levels, with a higher ratio reducing the risk of atherosclerotic heart disease [4]. As HDL-cholesterol increased significantly in our subjects receiving seal oil supplement, their corresponding HDL-cholesterol: LDL-cholesterol ratios must have shifted favourably.

Elevated triacylglycerols are a risk factor for CVD, and the seal oil supplementation induced a significant reduction in triacylglycerols. This agrees with some other findings in healthy subjects investigating seal oil [12, 47], but not all [29]. Intriguingly, combined seal oil/cod liver oil treatment reportedly decreased subject triacylglycerol levels where pure seal oil or cod liver oil did not [45], even at almost three times the dose of this study. The same modest seal oil dose as we have described, given over 6 weeks, also resulted in a significant decrease in plasma triacylglycerols as well as a significant improvement in blood pressure in hypertriglyceridaemic subjects, without a change in HDL-cholesterol [48]. In the present work, tuna-fish oil supplementation caused a non-significant ($P = 0.06$) decrease in triacylglycerols. The seal oil and fish oil both supplied approximately 1 g/day LC n-3 PUFA to the healthy volunteers, so the higher levels of DPA and/or of EPA in seal oil may be responsible for its greater effect on HDL-cholesterol and triacylglycerol levels. Buckley et al. [43] found a decrease in triacylglycerols in healthy subjects with DHA-rich but not EPA-rich oil supplementation. The DHA-rich oil they used contained six times the amount of DPA as the EPA-rich oil, which adds support to our speculation that DPA rather than EPA is the component in the (low-DHA) seal oil active in reducing triacylglycerol levels. Proposed mechanisms for decreases in triacylglycerol with LC n-3 PUFA involve chylomicron triacylglycerol clearance [49] and reduced absorption and synthesis of hepatic triacylglycerols and their increased catabolism [50]. Animal studies have specifically indicated that DPA may decrease triacylglycerols through a decrease in fatty acid synthesis [51].

Levels of inflammation, as indicated by CRP in this healthy volunteer population, were not significantly changed by any of the supplementary oils, an outcome shared by other studies [52]. However, recent work with high sensitivity-CRP showed a negative correlation between this surrogate marker of CVD risk and plasma total n-3 FA levels, as well as plasma EPA and DPA levels, in a larger subject population [53].

In conclusion, DPA in a low-dose seal oil supplement appeared to induce changes protective of cardiovascular health in healthy subjects. This relatively little-investigated LC n-3 PUFA appears to have acted (alone or with EPA) to depress platelet activation at the same time as it increased serum HDL-cholesterol and decreased triacylglycerol levels. The beneficial effects of the seal oil supplementation were greater than those of tuna-fish oil, which contained a similar amount of total LC n-3 PUFA but much more DHA, less EPA, and minimal DPA. Our results suggest that DPA, either directly or through retroconversion to EPA, may be more efficient at reducing some CVD risk factors than DHA. Larger and perhaps longer controlled studies, ideally using purified EPA, DPA and DHA in isolation, are needed to determine the mechanisms of DPA effects on platelet function particularly at different dosages in comparison with those of EPA and DHA. In the interim, this study suggests that seal oil may already be of use in modified foods, as a prophylactic for healthy individuals or as an aid to treatment for those with CVD or thrombosis. The current findings also have implications for consumers favouring meat over fish meals, as it appears that lean red meat, cooked appropriately using unsaturated fats, could provide beneficial amounts of DPA and EPA, without compromising cardiovascular health.

Acknowledgments We gratefully acknowledge the time and effort contributed by the study volunteers. This study was funded through a research grant from Meat & Livestock Australia (MLA).

Decreasing the Linoleic Acid to α-Linolenic Acid Diet Ratio Increases Eicosapentaenoic Acid in Erythrocytes in Adults

Received: 3 February 2010 / Accepted: 6 May 2010 / Published online: 22 May 2010

Abstract The n-6/n-3 fatty acid (FA) ratio has increased in the Western-style diet to ~10–15:1 during the last century, which may have contributed to the rise in cardiovascular disease (CVD). Prior studies have evaluated the effects on CVD risk factors of manipulating the levels of n-6 and n-3 FA using food and supplements or investigated the metabolic fate of linoleic acid (LNA) and α-linolenic acid (ALA) by varying the n-6/n-3 ratios. However, no previous studies have investigated the potential interaction between diet ratios and supplementation with eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). We used a factorial design approach with adults ($n = 24$) in a controlled feeding trial to compare the accretion of EPA and DHA into red blood cell membranes (RBC) by adding a direct source (algal oil supplement) of EPA and DHA in a diet with a 10:1 versus 2:1 ratio of n-6/n-3 FA. Subjects were randomized into 8-week crossover diet sequences and each subject consumed three of four diets [10:1, 10:1 plus supplement (10:1 + S), 2:1 and 2:1 + S]. LNA and ALA intakes were 9.4 and 7.7%, and 1.0 and 3.0% during the low and high ALA diets, respectively. Compared to the Western-style 10:1 diet, the 2:1 diet increased EPA by 60% ($P < 0.0001$) in RBC membranes without the direct EPA source and a 34% increase ($P = 0.027$) was observed with the 10:1 + S diet; however, DHA levels increased in both diet ratios only with a direct DHA source. Shifting towards a 2:1 diet is a valid alternative to taking EPA-containing supplements.

Introduction

The intake of n-3 fatty acids (FA) is associated with beneficial effects in the context of brain and visual development [1, 2], carcinogenesis [3], and modification of cardiovascular disease (CVD) risk [4–7]. More specifically, daily consumption of n-3 FA produces favorable effects on plasma lipids, eicosanoid metabolism, inflammatory markers, platelet aggregability, hemostasis, and, myocardial function [8].

The n-3 FA, eicosapentaenoic acid (EPA; 20:5n-3), docosahexaenoic acid (DHA; 22:6n-3) and α-linolenic acid (ALA; 18:3n-3) contribute only a small fraction of the total daily intake of FA in Western societies [9, 10]. Oily fish and fish-oil supplements are rich sources of EPA and DHA, the latter typically containing 30–50% n-3 FA by weight [11]. EPA and DHA are also naturally found in disproportionately low levels compared to saturated fat in animal tissue lipids (e.g. beef, pork, poultry, etc.), however they contribute to the overall intake because of the large amounts consumed by omnivores in Western societies [11]. Specific vegetable oils such as flax seed, canola and soybean oil and walnuts are rich sources of the essential n-3 FA ALA in contrast to n-6 rich oils such as corn, safflower and sunflower that contain only trace levels of ALA [12]. The typical Western-style diet has a n-6/n-3 ratio of approximately 10–15:1 as it features foods rich in corn, safflower and sunflower oil, and, contains scant sources of n-3 FA. Alternatively, the Mediterranean-style diet has a n-6/n-3 ratio of 2:1 as the main fats are monounsaturated n-9 FA coming from the ubiquitous olive oil [13].

Numerous studies have evaluated the effects of manipulating the absolute levels of n-6 and n-3 FA using fish, fish oil capsules, walnuts, algal oil capsules and flax seed oil [14–18]. Others have investigated the metabolic fate of LNA and ALA in the context of varying the n-6/n-3 ratios [19]. It is interesting that it is still unclear whether the addition of direct sources of EPA and DHA in the context of a diet with a high (10:1) versus low (2:1) ratio of n-6/n-3 FA yields increased levels of EPA and DHA in red blood cell (RBC) membranes. For example, if an individual consumes a 2:1 diet, does adding a supplement (fish or algal oil) containing EPA and DHA increase these FA in RBC membranes? Or, if an individual follows a Western style 10:1 diet, will they accrue EPA and DHA in RBC membranes while taking a supplement containing EPA and DHA? When evaluating the biological equivalency of ALA with that of EPA and DHA, it appears that the limiting factor may be the membrane saturation with these long chain n-3 FA. Increasing the absolute amount of ALA or decreasing the n-6/n-3 ratio to 4:1 appears to be inadequate for reaching desirable DHA levels that are achieved when a direct source of DHA is consumed. However, several practical issues remain unresolved and our present study revisits the two aforementioned questions using a novel approach. More specifically, would RBC membrane levels of EPA and DHA increase when the n-6/n-3 ratio is further reduced to 2:1, or does an individual still need to add a direct source of these FA to a Mediterranean-type diet? Additionally, would consuming a Western-style 10:1 diet ensure increased levels of EPA and DHA in RBC membranes as long as a direct source of these FA is included?

To address these two specific questions, we designed a trial using a factorial design approach in healthy adults to evaluate RBC membrane changes due to the consumption of a 10:1 versus 2:1 diet alone, and, changes resulting from consumption of a 10:1 versus 2:1 diet plus EPA/DHA supplement. This trial allows for the further evaluation of a potential interaction between the diet ratio and supplement.

Materials and Methods

Volunteers

Eligibility criteria included nonsmoking men and women, 20–70 years of age, body mass index (BMI) below 34.9 kg/m^2, and not known to have food allergies, hyperlipidemia, glucose intolerance, diabetes or any chronic disease likely to affect lipid metabolism, or to consume any fish, FA supplement or medications that would interfere with the study outcomes. A multi-stage participant screening process was employed that included a web-based screening questionnaire, informational group meeting, personal interview with two senior investigators and a preliminary blood test to rule out severe hyperlipidemia. Fasting blood lipid tests were performed spectrophotometrically by the Loma Linda University Medical Center clinical laboratory on a Roche Modular Analytics analyzer using a P800 module. Total cholesterol and triglyceride (TG) assays were evaluated using standard enzymatic methods. High density lipoprotein (HDL) cholesterol was evaluated using polyethylene (PEG) modified enzymes and dextran sulfate to provide selective catalytic activity toward the lipoprotein fractions. Low density lipoprotein (LDL) cholesterol was evaluated using a nonionic detergent combined with a sugar compound to selectively solubilize the lipid micelles to react with the enzymatic cholesterol reagents. Potential subjects were excluded if their plasma total cholesterol was >7.76 mmol/l and plasma TG was >3.33 mmol/l. Twenty-eight subjects were enrolled and 24 completed the study. The study was approved by the Loma Linda University Institutional Review Board. Informed written consent was obtained from all subjects.

Study Design

This was a controlled, factorial design, single blind, randomized, 4 × 3 incomplete cross-over study to evaluate the incorporation of EPA and DHA into RBC membranes from consumption of diets enriched with two different sources of n-3 FA in the background of two n-6/n-3 diet ratios. Subjects consumed a diet containing 30–35% energy from fat during a 1-week pre-study phase. Baseline data was collected at the end of this phase and subjects were then randomized to one of the multiple crossover diet sequences in which each subject consumed three of four study diets [10:1, 10:1 plus supplement (10:1 + S), 2:1 and 2:1 plus supplement (2:1 + S)] (Fig. 1). The 3 8-week study periods and 4 diets yielded 24 treatment sequences. All 24 subjects completed one sequence to achieve a balance for carry-over and period effect, which resulted in 18 subjects per group. There was a 4 to 6-week wash-out period between the dietary intervention periods.

The four study diets were defined by their EPA/DHA content and n-6/n-3 ratios (10:1 and 2:1; Table 1). The 10:1 "control" diet was low in both ALA and EPA/DHA and had a ratio approaching that of the American diet. The 2:1 diet was high in ALA-containing plant sources (~8 g ALA/2,400 kcal/day) and low in EPA/DHA. The 10:1 + S diet was high in EPA/DHA (0.20/0.72 g EPA/DHA per 2,400 kcal/day) and low in ALA-containing plant sources. Globally declining fish stocks and post-Kyoto awareness of the size of the human footprint have placed interest in finding alternative sources of n-3 FA that are readily available in large quantities and are renewable [20]. Thus, the high content of EPA/DHA was achieved by supplementing the diet with algal oil capsules (V-Pure®, Water 4 Investments, United Kingdom), which were administered proportional to a subject's isocaloric requirements (1 capsule per 300 kcal; 1 capsule contains 25 mg EPA and 90 mg DHA). The dose was selected based upon the American Heart Association's recommendation that persons consume between 650 and 1,000 mg of EPA + DHA daily [21]. The FA concentrations in the V-Pure® capsules were verified by ©Lipomics Technologies, Inc. using TrueMass® Total Lipid Analysis procedures that have been previously described [22]. The 2:1 + S diet was high in both ALA and EPA/DHA and was achieved by incorporating ALA-containing plant sources and the algal oil capsules.

Menus were designed for seven levels of energy intake, ranging from 1,500 to 3,300 kcal/day to accommodate the eucaloric requirements of the subjects. Daily energy intake was adjusted when necessary to maintain a stable body weight. The diets were in accordance with the "Acceptable Macronutrient Distribution Ranges" of the Dietary Reference Intakes for adults [23] and the recommendations of the 2005 Dietary Guidelines for Americans [24]. The target macronutrient distribution as percent energy was approximately 55–60% carbohydrate, 10–15% protein, 30–35% total fat, <10% saturated FA (SFA), 7–10% polyunsaturated FA (PUFA), 10–15% monounsaturated FA (MUFA), and, dietary cholesterol was less than 300 mg/day. Total trans FA content of the diet was <1% due to their known interference with the desaturation and elongation of both LNA and ALA.

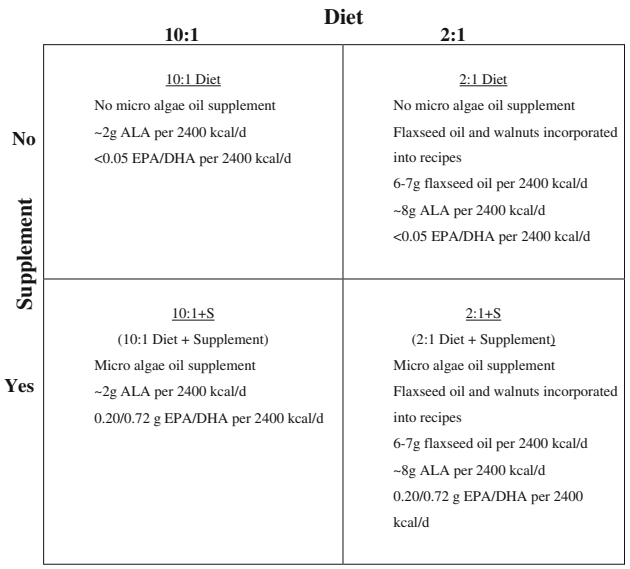

Fig. 1 Experimental dietary interventions for the 2 × 2 factorial design

Table 1 Planned nutrient analysis (Nutrition Data System for Research software version 2006, Nutrition Coordinating Center, University of Minnesota, Minneapolis, MN) and actual nutrient composition (Analyzed at Covance Laboratories, Madison, WI) of the 10:1 and 2:1 diets for the 2400 kcal (1 kilocalorie = 4.184 kJ) menu

Nutrient	10:1 diets		2:1 diets	
	Planned	Actual	Planned	Actual
Energy, kcal	2,372	2,556	2,384	2,568
Carbohydrate, % energy[a]	61	60	61	60

SFA, % energy	9	8	8	7
MUFA, % energy	10	8	10	9
PUFA, % energy	10	10	10	10
Trans FA, % energy	<1	<1	<1	<1
18:2n-6, g	22.9	26.6	17.2	21.9
18:3n-3, g	2.2	2.9	8.2	8.6
n-6/n-3 diet ratio	10.2	9.3	2.1	2.5

[a] Carbohydrate is calculated by subtracting the values for fat and protein intake from total energy intake

Participants were requested to maintain their usual lifestyle activities and to record in diaries provided to them any signs of illness, medications used, and any deviation from their current assigned diet.

Food Development and Preparation

Using commonly available food items, the research dietitian developed 11 meatless daily menus (including 2 weekends) using Nutrition Data System for Research software version 2006, developed by the Nutrition Coordinating Center, University of Minnesota, Minneapolis, MN. The 10:1 and 2:1 diets differed in the proportion and type of oils that were added to dinner entrees or that were constituents of salad dressings, baked goods, margarine and fried snacks (e.g. chips). More specifically, the 10:1 diets included a high proportion of corn oil and a lesser amount of soybean oil in contrast to the 2:1 diets that incorporated clear flax seed (Barlean's Organic Oils, Edmonds, WA), canola and soybean oil. Also, the 10:1 diets included peanut butter whereas the 2:1 diets featured walnuts.

Sunday through Friday, all foods were prepared in the University Metabolic Kitchen and individually weighed or apportioned for each subject, and, dinner was consumed in a private dining area. Breakfast, lunch and snacks for the following day were provided to the subjects after consumption of the dinner meal, which were consumed by the subjects on the following day. On Fridays, foods were provided for all Saturday meals and Sunday breakfast and lunch.

Quality Control and Dietary Compliance

Menu quality control was assessed by collecting duplicate food samples of the 11 menus on randomly selected days during each study period. The samples were homogenized and a 2% aliquot from each menu was kept frozen at −80 °C until chemically analyzed (Covance Laboratories, Madison, WI) for comparison with the computer analysis.

Subject deviations from the study protocol were not tolerated. Monitoring of dietary compliance was achieved by direct observation during the dinner meal by a senior investigator and by periodic examination of the subject's diaries.

Biological Data Collection and Assays

Venous blood was collected after an overnight 12-h fast at the start of each study period and on two non-consecutive days during week 8 for each study period. Plasma and serum were separated by centrifugation at 4 °C at 1,300×*g* for 10 min and made into aliquots and frozen at −80 °C until analyzed. FA composition of the RBC membrane was determined (Lipomics Inc., Sacramento, CA) at the end of each treatment using methods previously described [22]. Briefly, individual lipid classes were separated by preparative thin-layer chromatography and each lipid fraction was trans-esterified in 3 N methanolic HCL in a sealed vial under a nitrogen atmosphere at 100 °C for 45 min. The resulting FA methyl esters were extracted from the mixture with hexane containing 0.05% butylated hydroxytoluene and analyzed using a gas chromatograph (Hewlett-Packard model 6890, Wilmington, DE) equipped with a 30 m DB-225MS capillary column (J&W Scientific, Folsom, CA) and a flame-ionization detector as described previously [22]. All samples were analyzed in duplicate.

Statistical Analyses

A mixed model was used to compare effects of diet on the FA. The model included experimental diet (10:1, 10:1 + S, 2:1, 2:1 + S) and study period (1, 2, 3) as factors, and, controlled for baseline measurements, age and gender. Blocks of sequence, subjects nested within blocks, and study period × subject nested within blocks were also added into the model as random effects. The Kenward-Roger method was employed to estimate denominator degrees of freedom for tests of fixed effects. Tukey–Kramer Honestly Significantly Different (HSD) tests were performed to detect significant pair-wise differences among the four diets. A factorial design approach was also used to test the effect of the diet ratio, the supplement and for potential interaction between the diet ratio and supplement. All statistical analyses were performed using Statistical Analysis System software (version 9.1, SAS Institute Inc., Cary, NC). Significance was determined at $P < 0.05$.

Results

Characteristics of Study Subjects

Demographic and biological characteristics at baseline are shown in Table 2.

Dietary FA Intakes

During the three study periods, the mean fat intake from all food sources in both the 10:1 and 2:1 diets was 28% of total energy (Table 1). Mean carbohydrate and protein intake were equivalent, as well as SFA, MUFA, PUFA and trans FA. Flax seed oil and walnuts were substituted for high LNA oil in food preparation of the low LNA diets, which yielded a three to fourfold greater level of ALA and resulting n-6/n-3 ratio of 2.5:1 in contrast to a 9.3:1 ratio for the high LNA diets.

Table 2 Characteristics of study subjects at baseline

Characteristic	$n = 24$
Age (years)	42 ± 3
Gender	
Female	15 (62)
Male	9 (38)
Race	
Caucasian	16 (67)
Hispanic	4 (17)
African American	1 (4)
Asian	3 (12)
Weight (kg)	75.6 ± 14.5
BMI (kg/m^2)	25.4 ± 4.3
Plasma lipids, mg/dl[a]	
Total cholesterol	165 ± 48
LDL cholesterol	102 ± 41
HDL cholesterol	47 ± 14
TG	102 ± 56
Systolic blood pressure (mm Hg)	123 ± 16
Diastolic blood pressure (mm Hg)	74 ± 11

Data are means ± SD or *n* (%)

[a] To obtain mmol/l values for LDL cholesterol and HDL cholesterol, multiply values by 0.0259; and for TG, multiply values by 0.0113

Change in Participants' RBC Membrane FA Composition

The RBC membrane levels (mol%) of total SFA, MUFA, PUFA and specific n-6 and n-3 FA, and the ratios of arachidonic acid (20:4n-6) to dihomogamma linolenic acid (20:3n-6) (ARA:DGLA), ARA:EPA and DHA to docosapentaenoic acid DPA(n-3) after consuming the high and low n-6/n-3 diets with and without the algal oil supplement for 8 weeks were measured (Table 3). Neither the n-6/n-3 ratio of the diets nor the intake of the algal oil supplement affected the total levels of SFA, MUFA and PUFA after 8 weeks. The absolute levels of ALA, EPA, DHA and DPA(n-3) are shown in Fig. 2. LNA levels did not differ after the 8 week diet interventions, in contrast to the levels of ALA (Fig. 2a) that showed an expected increase in the 2:1 (0.52 ± 0.02) and 2:1 + S (0.44 ± 0.02) diets as compared to the 10:1 and 10:1 + S diets ($P < 0.0001$). All of the subjects showed an increase in ALA levels after consuming the 2:1 and 2:1 + S diets, hence reflecting the diet composition and serving as a biological marker of each subject's compliance. Compared to the 10:1 diet, the EPA (Fig. 2b) level after consumption of the 10:1 + S, 2:1 and 2:1 + S diets increased and were 0.60 ± 0.04 ($P = 0.02$), 0.71 ± 0.04 and 0.86 ± 0.04 ($P < 0.0001$), respectively. Notably, DHA (Fig. 2c) levels increased for the 10:1 + S ($P < 0.001$) and 2:1 + S ($P < 0.01$) diets while the DHA levels in the 10:1 and 2:1 diets were equivalently lower.

DPA(n-6) and ARA levels did not differ for the 4 dietary interventions. An increase in DPA(n-3; Fig. 2d) was found for the 2:1 diet (2.77 ± 0.12, $P = 0.019$) compared to the 10:1, 10:1 + S and 2:1 + S diets. In contrast to the 10:1 diet, DGLA levels decreased for the 10:1 + S and 2:1 + S diets, 1.43 ± 0.07 ($P = 0.04$) and 1.34 ± 0.07 ($P < 0.01$) respectively, however the ARA:DGLA ratio was equivalent for all 4 diets. The ARA:EPA ratio was lower in the 10:1 diet compared to the 10:1 + S, 2:1 and 2:1 + S diets, 22.00 ± 1.93 ($P = 0.002$), 18.25 ± 1.93 ($P < 0.0001$) and 15.59 ± 1.93 ($P < 0.0001$), respectively. Lastly, the EPA:ALA and the DHA:DPA(n-3) ratios were higher in the 10:1 + S diet, 3.52 ± 0.21 ($P < 0.001$) and 2.66 ± 0.16 ($P = 0.001$) respectively, in contrast to similar levels for the 10:1, 2:1 and 2:1 + S diets.

The factorial analysis for the diet effect (10:1 diet versus 2:1 diet) showed that the ARA level ($P = 0.037$) and the ratios for ARA:EPA ($P < 0.001$), EPA:ALA ($P < 0.001$) and DHA:DPA(n-3) ($P = 0.019$) were lower in contrast to the ALA ($P < 0.001$), EPA ($P < 0.001$), DPA(n-3) ($P = 0.003$) levels that were higher in the 2:1 diet (Table 4). The factorial analysis for the supplement effect (10:1 diet versus 10:1 + S diet) showed that the DGLA ($P < 0.001$), ALA ($P = 0.046$) and DPA(n-3) ($P = 0.007$) levels and the ARA:EPA ratio ($P = 0.001$) decreased in the 10:1 + S diet, and, the EPA and DHA levels and the ratios for EPA:ALA and DHA:DPA(n-3) increased (all $P < 0.001$). A negative interaction was found for the ARA:EPA ($P = 0.048$) and EPA:ALA ($P = 0.026$) ratios, which indicates that the combined effect was less than the sum of the separate diet effect and supplement effect.

Discussion

This controlled feeding study demonstrates that using flax seed oil and walnuts in the diets of healthy adult men and women to achieve a n-6/n-3 ratio of ~2:1 yields increased levels of EPA in RBC membranes without the use of a direct EPA source; however, DHA levels do not increase. Also, adding an algal oil capsule containing EPA and DHA to a n-6/n-3 ratio of 10:1 increases the levels of both EPA and DHA in RBC membranes. This study was also designed to test the interaction between an algal oil supplement in the context of an n-6/n-3 ratio of 10:1 that is found in Western societies versus a 2:1 ratio that approaches the traditional Mediterranean-style diet. To prepare the 2:1 and 2:1 + S diets, we incorporated flax seed oil and walnuts into the recipes and provided 3.0% in contrast to 1.0% dietary energy from ALA in the 10:1 and 10:1 + S diets. An intake of 3% energy from ALA is approximately

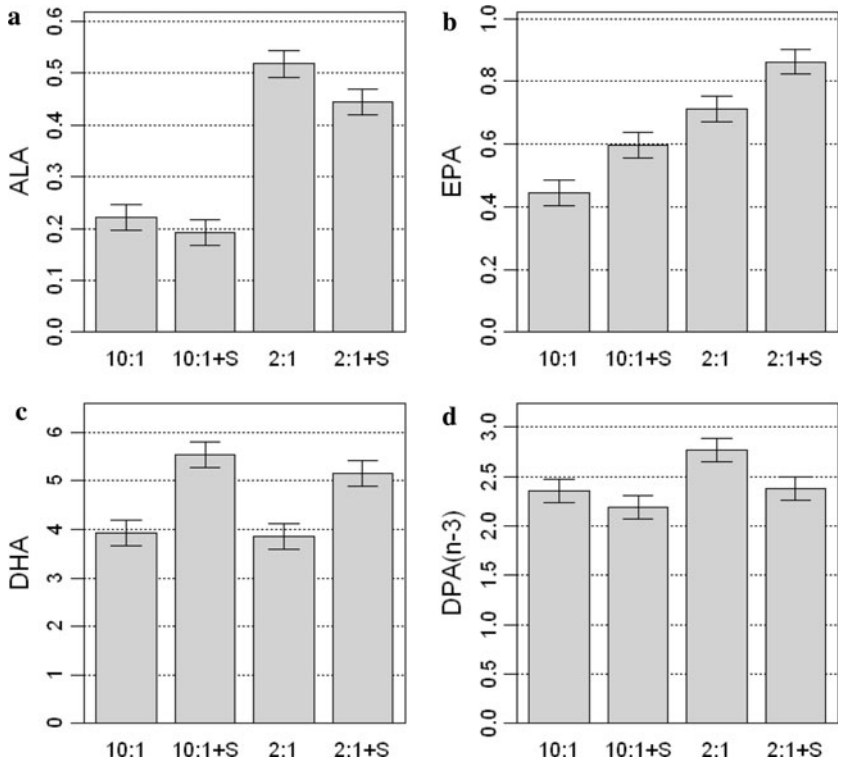

Fig. 2 Levels of fatty acids in red blood cell membranes

6 times the current mean ALA intake in the US diet [23]. In the context of the background diets, we provided LNA intakes of 9.4 and 7.7% total energy for the 10:1 and 2:1 diets, respectively, and did not induce higher levels of ARA. Liou et al. [19] have similarly reported that an intake of 10.5% energy from LNA with a n-6/n-3 ratio of 10:1 resulted in lower plasma phospholipids levels of EPA but did not induce higher levels of ARA when compared to an intake of 3.8% from LNA with a n-6/n-3 ratio of 4:1 in the context of an omnivorous diet. The 8 weeks of algal oil supplementation in this current study yielded a range of 575–1,265 mg/day of EPA plus DHA across the 1,500–3,300 kcal/day menus, yet the ARA levels in the RBC membranes were not changed. Alternatively, Arterburn et al. [25] compared the effects of supplementation with EPA and DHA on plasma FA and found a reduction in ARA levels. A possible explanation for our unexpected findings is that the V-Pure® supplement that we used contained 2.3 mol% of ARA, which may have masked a reduction in ARA levels.

Both n-6 and n-3 FA are known to compete for common enzymes in the synthesis of FA [26]. Ratios of substrates

and products are somewhat useful in evaluating potential major points of regulation in the stepwise conversion of LNA to both ARA and DPA(n-6), and, conversion of ALA to both EPA and DHA. LNA and ALA are both substrates for microsomal Δ6 desaturase (D6D); however there is an approximately two- to three-fold affinity of D6D for ALA [27]. Synthesis of DHA and 22:5n-6 from the 24 carbon FA (24:5n-3 and 24:4n-6) is also dependent on D6D, which provides a second opportunity for competition between substrates and the preferential entry of FA into cell membranes [28]. The resulting cell membrane composition from this competition has profound effects on eicosanoid metabolism, inflammatory markers, platelet aggregability, hemostasis, and, myocardial function [29–31].

The highest increase in EPA (94%) in RBC membranes was found after consumption of the 2:1 + S diet, which was expected as a result of providing both a direct source of EPA from the algal oil supplement and the metabolic conversion of ALA to EPA. Notably, the 60% increase in EPA levels after consumption of the 2:1 diet using flax seed oil and walnuts was not significantly different to the 34% increase found after consumption of the 10:1 + S diet, which implies that an adequate conversion from ALA to EPA occurs when a n-6/n-3 ratio of 2:1 exists. The ARA:DGLA ratio in the RBC membranes was not different between the 4 diets indicating that the step catalyzed by Δ5 desaturase (D5D) in the LNA pathway is not a limiting factor in the context of converting ALA to EPA providing that adequate ALA substrate is available.

Cell culture studies [28] support the hypothesis that high dietary consumption of LNA interferes with the desaturation of ALA due to competition for D6D between LNA and ALA, thus yielding increased levels of ARA and reduced levels of EPA and DHA. Our findings are consistent with this hypothesis as we demonstrated that the ARA:EPA ratio in the RBC membranes was lower for the 10:1 + S, 2:1 and 2:1 + S diets compared to the 10:1 diet in the context of similar ARA levels among the four dietary treatments. Consistent with the results of our study, Liou et al. [19] found that manipulating LNA-containing vegetable oils and keeping ALA constant to produce a 8.2:1 diet ratio decreased plasma phospholipid EPA levels, increased the ARA:EPA ratio, and, did not favor higher ARA levels after 4 weeks in healthy adult male omnivores as compared to a 2.1:1 diet ratio. When the conversion from ALA to EPA occurs, the conversion of DGLA to ARA is competitively inhibited and yields reduced amounts of ARA. Thus, the high ARA:EPA ratio observed in our 10:1 diet was due to the lack of a direct source of EPA and minimal availability of ALA for conversion to EPA.

Docosahexaenoic acid levels significantly increased by 41% in the RBC membranes after consumption of the 10:1 + S diet and 31% in the 2:1 + S diet as compared to the non supplemented 10:1 and 2:1 diets. Cell culture studies have shown that the accretion of DHA in cells supplemented with DHA is a result of incorporation of the direct DHA source as compared to the net effect of DHA synthesis via metabolic pathways and incorporation into cells supplemented with ALA [28]. The limited accretion of DHA derived from ALA in our study suggests that DHA synthesis from ALA is tightly regulated and relies upon the second D6D step, which is also used to convert ALA to 18:4n-3. Hence, there is the potential competition for D6D between ALA and 24:5n-3, and, ALA is the preferred substrate that saturates D6D leaving the conversion of 24:5n-3 to DHA compromised. It has also been shown that the elongase-2 (*Elo-2*) which converts 22:5n-3 to 24:5n-3 may be the limiting step in the synthesis of DHA from ALA [32]. The enzyme *Elo-2* is subject to genetic control [33] and exhibits tissue specific expression [34]. Thus, the

incorporation of DHA into the RBC membrane, although a good marker for dietary compliance, may not fully reflect the conversion of ALA to DHA in different tissues.

Consistent with our findings, Arterman et al. [16] demonstrated significant and equivalent increases in DHA in plasma phospholipids and erythrocytes from salmon intake or algal oil capsules in healthy adults. Also, Innis et al. [18] found a 50% increase in plasma DHA levels in healthy adults consuming an ARA (0.8 g/day) enriched fungal oil and a microalgal oil containing DHA (0.6 g/day) using a ARA:DHA diet ratio of 1.25:1 after 14 days. We found that when the n-6/n-3 ratio was altered to 2:1, or if we increased the absolute amount of ALA, this conversion was inefficient. In contrast, Goyens et al. [35] provided a 7:1 ratio omnivorous diet (7% energy from LNA and 1.1% energy from ALA) to 30 Dutch adults and found an increase in the absolute amount of DHA synthesized from ALA compared to a control diet [19:1 diet ratio; 7% energy from LNA and 0.4% energy from ALA] or low LNA diet [7:1 diet ratio; 3% energy from LNA and 0.4% energy from ALA]. However, there were no differences in percent DHA incorporated in the plasma phospholipids among the different diets in this study.

Investigating the ratio of DHA:DPA(n-3) may further an explanation of our study's DHA findings. There is no known physiological function for DPA(n-3), which is the intermediate FA produced by elongation of EPA prior to desaturation by the Δ4 desaturase (D4D) enzyme. The DHA:DPA(n-3) ratio was found to be similarly low after consumption of the 10:1 and 2:1 diets compared to the algal oil supplemented 10:1 + S and 2:1 + S diets. The lower ratios noted in the 10:1 and 2:1 diets are due to the high DPA(n-3) and low DHA levels in these diets. The significantly higher ratios found in the 10:1 + S and 2:1 + S diets suggests that providing a direct source of DHA is more influential than the n-6/n-3 ratio for successful accretion of DHA into RBC membranes.

Barcelo et al. [16] found that an intake of 2.4 g flax seed oil/day produced significant increases in ALA, EPA and DPA(n-3) compared to fish oil which produced only significant increases in EPA and DHA. Consistent to these findings, we demonstrated the highest increase in DPA (n-3) in the RBC membrane after consumption of the 2:1 diet indicating adequate conversion from EPA. The DPA(n-3) in the RBC membranes after consumption of the 10:1 + S diet and the 2:1 + S diet was similar to that of the 10:1 diet and significantly lower than the 2:1 diet. These findings suggest that DPA(n-3) levels may increase only as a means to produce DHA, and when a direct DHA source is provided DPA(n-3) may not be required. Also, Arterman et al. [15] found that levels of EPA and DPA(n-3) increased in plasma phospholipids and erythrocytes in a group of subjects consuming salmon (which contains EPA) versus a group of subjects consuming an algal oil supplement as the sole source of DHA. An additional explanation for these aforementioned findings may be that a retro-inhibition by DHA and/or EPA of desaturase activities occurs in the pathway leading to the synthesis of ARA from LNA, which has been consistently shown in cell culture studies using rats fed fish oil containing EPA and DHA [36, 37].

Our crossover feeding study had several strengths. The 8 week study periods and 4–6 week washout periods were of sufficient duration to assess changes in RBC membranes resulting from dietary manipulation of the n-6/n-3 ratio and/or absolute amount of EPA/DHA. By varying the type of oils, we achieved a greater extreme of ratios compared to prior investigations. Others have tested the effects of ratios further from these extremes or have kept only LNA or ALA constant. Our factorial design approach allowed us to test for interactions between the diet ratios and algal oil supplement. Additionally, the increase in ALA level observed in all of the subjects consuming the 2:1 and 2:1 + S diets served as a biomarker of excellent dietary compliance. Lastly, the background diet was meatless, which allowed us to evaluate the substrate and product ratios of solely plant-derived sources of ALA.

In conclusion, our study indicates that providing a diet with 3% energy from ALA and a n-6/n-3 diet ratio of 2:1 yields significantly higher EPA levels in RBC membranes and a 43% lower ARA:EPA ratio compared to a 10:1 diet. Use of a direct algal oil source of EPA/DHA yields significantly higher levels of EPA and DHA in persons consuming a Western-style 10:1 diet as well as a Mediterranean-style 2:1 diet. Many Western-style diets contain n-6/n-3 ratios in excess of 10:1, however a ratio of 4:1 or lower has been recommended for optimal health-promoting effects [38–40]. In practice, a 4:1 ratio is difficult to achieve as most people are reluctant to include several servings of oily fish in their diets weekly or take multiple fish oil capsules daily [12]. We showed that reducing LNA-rich oils and incorporating ALA-rich plant sources (flaxseed oil and walnuts) in recipes achieved an n-6/n-3 ratio potentially conducive to improved health outcomes and is sufficient to meet the EPA needs of individuals adhering to a vegetarian or meatless diet. The requirement for D6D by both ALA and 24:5n-3 and differences in tissue specific expression of *Elo-2* may influence the ability of RBC membranes to accumulate significant levels of DHA, which has implications for vegetarians, vegans, and persons unable or unwilling to include oily fish or fish oil capsules into their dietary regimens. Thus, inclusion of plant sources of ALA within a 2:1 diet negates the need to use a supplement containing EPA, but a DHA-rich source (i.e. algal oil supplement, DHA-enriched eggs) may be warranted for the aforementioned populations. At the population level, a

decreased intake of LNA with a concurrent increased intake of ALA-containing plant sources to achieve a ~2:1 diet ratio, plus a marine derived algal oil supplement containing EPA and DHA, is a sustainable alternative to ongoing public health recommendations supporting the intake of fish for the primary prevention of CVD.

Acknowledgments We would like to thank Water 4 Investment for supplying the V-Pure® Omega-3 EPA & DHA supplement, the California Walnut Commission for supplying the walnuts, and Barlean's Organic Oils for supplying the clear flax seed oil. We would like to express our gratitude to our Research Dietitian, Jennifer Fix, MPH, RD, and to the study participants without whom this investigation would not have been possible. M.W., S.R. and J.S. designed research; M.W. and J.S. conducted research; K.O. analyzed data; M.W., S.R. and J.S. wrote the paper. M.W. had primary responsibility for the final content. All authors have read and approved the final manuscript. This study was supported by the Center for Health and Nutrition Research at University of California, Davis.

ORIGINAL ARTICLE

trans-Fatty Acid Isomers in Adipose Tissue Have Divergent Associations with Adiposity in Humans

Liesbeth A. Smit · Walter C. Willett · Hannia Campos

Received: 20 January 2010 / Accepted: 14 June 2010 / Published online: 14 July 2010

Abstract The aim of this study was to evaluate the association between adipose tissue *trans*-fatty acid isomers and adiposity. This cross-sectional study included 1,785 subjects from Costa Rica. Fatty acid concentrations (as a percentage of the total fatty acids) in subcutaneous adipose tissue were assessed by gas–liquid chromatography. Dietary intakes were assessed with a food frequency questionnaire. Multivariate linear regression models were used to relate adipose tissue *trans*-fatty acid content to BMI, waist circumference, and skinfold thickness while adjusting for age, sex, and area of residence. To account for variations in lifestyle, we adjusted for smoking, physical activity, income, self-reported history of diabetes and hypertension, and for adipose tissue alpha-linolenic acid and energy intake in a third model. After adjustments, positive associations were found between 18:2*t*-fatty acids (primarily from partially hydrogenated oils) and BMI, waist circumference, and skinfold thickness (P for each association <0.01). Rumenic acid was positively associated with skinfold thickness ($P < 0.0001$), but not with BMI or waist circumference ($P > 0.05$). Inverse associations were found between 16:1n-7*t*-fatty acids and skinfold thickness and between 18:1*t*-fatty acids and BMI and waist circumference ($P < 0.0001$). This study suggests that individual *trans*-fatty acid isomers may have divergent effects on adiposity. 18:2*t*-fatty acids show consistent positive associations with measures of adiposity. These isomer-specific associations are an interesting new finding. Other prospective and intervention studies are necessary to examine these relationships further.

Introduction

trans-Fatty acids are unsaturated fatty acids characterized by the *trans* configuration of their double bonds. The two main industrially produced *trans*-isomers,18:1*t*-and 18:2*t*-fatty acids are created by partial hydrogenation of unsaturated fats and have well documented adverse effects on health [1, 2]. The health effects of 16:1n-7*t*-fatty acids and 18:2n-7*t* fatty acids collectively known as conjugated linoleic acid (CLA) are less well understood.

The 9c, 11*t* isomer of CLA, also known as rumenic acid, is found in ruminant food products. These natural *trans*-fats originate mainly from biohydrogenation of linoleic acid by fermentive bacteria in ruminants and by endogenous

synthesis from vaccenic acid by delta-9 desaturase [3]. Rumenic acid, represents ~80% of all CLA isomers in the diet [4], and is mainly found in dairy products in this population [5].

In humans and monkeys, high 18:1*t* and 18:2*t*-fatty acid intake appears to predispose to accumulation of body fat, particularly abdominal fat [6, 7]. Among more than 16,000 men who provided two measurements of abdominal circumference at an interval of 9 years, each 2% increase in total energy from *trans*-fatty acids (versus the same percent of energy from *cis*-polyunsaturated fat) was associated with a 2.7-cm increase in abdominal circumference ($P < 0.001$) after adjustment for measurement error and other risk factors [7]. Among more than 41,000 women who provided two measurements of body weight at an interval of 8 years, increases in *trans*-fatty acid intake were robustly associated with increases in body weight in both cross-sectional and longitudinal analyses, whereas intakes of other types of fat were not [8]. In a 6-year randomized controlled trial among 42 male African green monkeys feeding ~8% of energy 18:1*t*- and 18:2*t*-fatty acids resulted in a threefold greater weight gain compared with controls assigned to a diet containing *cis*-monounsaturated fatty acids ($P < 0.05$) [6]. However, evidence from human intervention studies has been inconclusive [9, 10].

The purpose of this study was to evaluate the associations between the most common *trans*-fatty acid isomers (18:1*t*, 18:2*t*, 16:1n-7*t* and rumenic acid) and adiposity in a population of Costa Rican adults. We used adipose tissue levels of *trans*-fatty acids as a marker for intake because the *trans*-fatty acid content of foods has changed considerably and subcutaneous adipose tissue is considered the best choice for the study of long-term fatty acid intake [11, 12].

Methods

Study Population

Subjects were randomly selected population controls from a case–control study on diet and heart disease conducted in Costa Rica as previously described [13]. Participation was 88%. We included a total of 1,334 men and 451 women. Subjects gave informed consent on documents approved by the Human Subjects Committee of the Harvard School of Public Health and the University of Costa Rica.

Data Collection

Data were collected by trained personnel visiting the subjects at their homes. Subjects provided information on socioeconomic, demographic, diet, and medical history during an interview. Anthropometric measures collected were height, weight, waist circumference and skinfold thickness for subscapular, suprailiac and triceps. All anthropometric measurements were taken from subjects wearing light clothing and no shoes, and collected in duplicate and averaged out for analyses. Field workers measured triceps (posterior upper arm, midway between the elbow and acromion), subscapular (1 cm below the lower tip of the scapula), and suprailiac (at the midline and above the iliac crest) using Holtain skinfold calipers. All measurements were taken on the right side of the body. Nonstretching fiberglass or metal tapes were used to measure the waist (smallest horizontal trunk circumference) and hip (largest horizontal circumference around the hip and buttocks) girths. A steel anthropometer and a Detecto bathroom scale or a Seca Alpha Model 770 digital scale accurate to 50 g were used to measure height and weight, respectively. The two scales were calibrated biweekly. Body mass index (BMI) was then calculated as weight (kg) divided by the square of the height (m^2). BMI categories were defined by general accepted cut-off points. Normal weight was determined as a BMI lower than 25 kg/m^2, overweight as a BMI between 25 and 30 kg/m^2 and obesity was defined as a BMI above 30 kg/m^2.

A subcutaneous adipose tissue biopsy was collected from the upper buttock with a 16-gauge needle and disposable syringe following procedures previously described [14]. Samples were stored in a cooler at 4 °C and transported to the fieldwork station where they were stored at −80 °C. Within 6 months, they were shipped on dry ice to the Harvard School of Public Health for long term storage in nitrogen tanks. Energy and nutrient intakes were assessed with a food frequency questionnaire developed and validated specifically for use among Costa Ricans [14, 15]. Dietary information obtained by the food frequency questionnaire was used for validation purposes and to assess confounding by dietary factors that do not have good biomarkers of intake. The fatty acid composition of all foods commonly used in Costa Rica was determined [16] and incorporated into the nutrient calculation.

Fatty Acid Analysis

Fatty acids were extracted from adipose tissue and analyzed by gas–liquid chromatography (GLC) [14]. The fatty acids in the adipose tissue biopsy were extracted using hexane/isopropanol (3:2) mixture and esterified with methanol and acetyl chloride. After esterification, the methanol and acetyl chloride were evaporated and the fatty acid methyl esters were dissolved in isooctane. The methyl esters were quantified by GLC using the following parameters: fused silica capillary *cis*/*trans*-column SP2560, 100 m × 250 mm internal diameters × 0.20 mm film

(Supelco, Belefonte, PA); splitless injection port at 240 °C; hydrogen carrier gas at 1.3 ml/min, constant flow; Hewlett-Packard Model (now Agilent) GC 6890 FID gas chromatograph with 7673 Autosampler injector (Palo Alto, CA); 1 ml of sample injected; temperature program of 90–170 °C at 10 °C/min, 170 °C for 5 min, 170–175 °C at 5 °C/min, 175–185 °C at 2 °C/min, 185–190 °C at 1 °C/min, 190–210 at 5 °C/min, 210 °C for 5 min, 210–250 °C at 5 °C/min, 250 °C for 10 min. Peak retention time and area percentages of total fatty acids were identified by injecting known standards (catalog numbers 47791, GLC-463, GLC-481b, N-16-M, N-21-M, N-23-M, N-24-M, U-45-M, U-46-M, U-59-M, U-71-M and UC-60-M, Nu-Chek_prep, Elysium, MN), and analyzed with the Agilent Technologies ChemStation A.08.03 software (Agilent Technologies, Inc., Palo Alto, CA). Twelve identical samples were analyzed throughout the study. The inter-assay coefficients of variation for 18:1*t*, 18:2*t*, and 18:2n-7*t* (9*c*,11*t*) fatty acids were 15.7, 6.4, and 5.2%, respectively. We previously showed that the *trans*-fatty acid concentration in adipose tissue is a good biomarker of *trans*-fatty acid intake in the Costa Rican population [14].

Statistical Analysis

Data are presented as means ± SD or *n* (%). The *trans*-fatty acids that we used in the analysis were defined as follows: 18:1*t* = 18:1*t* (n-7*t*) + 18:1*t* (n-9*t*) + 18:1*t* (n-11*t*); 18:2*t* = 18:2*t* (n-6*tt*) + 18:2*t* (n-6*ct*) + 18:2*t* (n-6*tc*). Data were analyzed with the SAS software v9.1 (SAS Institute, Cary, NC, USA) with the significance level set at $P < 0.05$. Partial Spearman correlation coefficients were calculated, adjusted for age, sex, and area of residence for the association between adipose tissue fatty acids and several subject characteristics and potential confounders.

Multivariate regression was used to estimate the β coefficients and *P* values of the association between adipose tissue *trans*-fatty acid isomer content and indicators of adiposity. These calculations were adjusted for the matching factors age, sex and area of residence. To account for variation in lifestyle and dietary habits, further models adjusted for smoking status, physical activity and income, and self-reported history of diabetes and hypertension. In a third model we also adjusted for adipose tissue alpha-linolenic acid, which is present in partially hydrogenated soybean oil used for cooking and was the major dietary source of 18:2*t*-fatty acids in this population [13].

Other potential confounders that were examined but not included in the final models were alcohol intake, fruit and vegetable intake, currently on weight loss diet, menopausal status, adipose tissue linoleic acid, arachidonic acid, long chain omega-3 fatty acids, and dietary patterns.

Results

The average BMI of all subjects was 26.4 kg/m^2 (Table 1). Subjects in the obese category were more likely to be female, have a higher income, a history of diabetes and hypertension and less likely to be physically active or smoke. Obese subjects had higher adipose levels of 18:2*t*-fatty acids and arachidonic acid, and lower levels of 18:1*t*-fatty acids, linoleic acid and alpha-linolenic acid.

The mean percentage plus standard deviation (SD) of *trans*-fatty acids in adipose tissue as percentage of total fatty acids was 2.7 ± 0.7 for total *trans*-fatty acids, 1.47 ± 0.53 for 18:1*t*, 1.15 ± 0.35 for 18:2*t,* 0.15 ± 0.06 for 16:1n-7*t* and 0.56 ± 0.18 for rumenic acid (Table 1).

Adipose tissue *trans*-fatty acid content corresponded with their intake from the diet. The average *trans*-fatty acid intake as a percentage of total calories was 0.77 ± 0.30% for 18:1*t*, 0.07 ± 0.07% for 18:2*t*, 0.06 ± 0.03% for 16:1n-7*t* and 0.10 ± 0.05% for rumenic acid.

Adipose tissue 18:1*t*, 18:2*t* and rumenic acid, but not 16:1n-7*t* were inversely associated with physical activity (Table 2). Within adipose tissue, the strongest correlation was between 18:1*t* and 18:2*t*-fatty acids (Spearman $r = 0.51$). Rumenic acid was weakly inversely associated with linoleic acid and alpha-linolenic acid (Spearman $r = -0.17$ and -0.08, respectively) and weakly positively with arachidonic acid (Spearman $r = 0.06$) (data not shown).

Results of the multivariate regression models for associations were reported as one SD unit increase in adipose tissue *trans*-fatty acids and measures of adiposity (Table 3). Increased adipose tissue 16:1n-7*t*- and 18:2*t*-fatty acids were associated with higher BMI and waist circumference, and 18:1*t*-fatty acids were associated with lower BMI and waist circumference. In contrast, 16:1n-7*t*-fatty acids were inversely associated with individual skinfold thicknesses, while rumenic acid was positively associated with each skinfold thickness. Adipose tissue 18:1*t*-fatty acids were not significantly associated with skinfold thickness. Rumenic acid was not significantly associated with BMI or waist circumference, but was positively related to skinfold thicknesses. In additional analyses, alpha-linolenic acid was inversely associated with BMI (model 3, beta −4.2, $p < 0.0001$) and waist circumference (model 3, beta −10.0, $p < 0.0001$).

Discussion

This cross-sectional study in the Costa Rican population evaluated the association between adipose tissue *trans*-fatty acid isomers and adiposity. We included both industrially produced (18:1*t* and 18:2*t*) and naturally occurring (16:1n-7*t* and 18:2n-7, 9*c*, 11*t*) *trans*-fatty acids. The most

associated with increased visceral and subcutaneous adiposity.

In addition to positive associations with adiposity, 18:2 *trans*-fatty acids have been found to be more adversely related to risk of cardiovascular disease (CVD) than are 18:1 *trans*-fatty acids [17–19]. A possible explanation for these adverse effects on CVD is that 18:2*t*-fatty acids are incorporated in the *sn*-2 position of phospholipids, where polyunsaturated fatty acids are usually found. This substitution might affect membrane properties and have effects on atherosclerotic pathways through increased macrophage adhesion [20].

16:1n-7*t*-fatty acids, from ruminant food sources, have not been widely investigated. In this study 16:1n-7*t*-fatty acids were positively associated with BMI and waist circumference, and inversely with skinfold thickness. This suggests that 16:1n-7*t*-may be associated with increased visceral, rather than subcutaneous fat storage. These findings are in contrast with rumenic acid, also from ruminant food sources, which is associated with increased subcutaneous adiposity. Although differences in fatty acid metabolism between visceral and subcutaneous fat depots have been found [21], we cannot explain the different associations of these natural *trans*-fatty acids with visceral and subcutaneous adiposity.

The finding of an inverse association between adipose tissue 18:1*t*-fatty acids and BMI is unexpected, given the positive associations found in other studies where 18:1*t*-fatty acids were the main *trans*-fatty acids in the diet [6, 8]. However, although the distribution of fat in monkeys fed a *trans*-fat diet favored an intra-abdominal distribution, the increases in body weight, weight circumference, subcutaneous and intra-abdominal fat were not significant, which is in line with our study [6]. We cannot exclude that this redistribution of fat also happened in our subjects. Also, Koh-Banerjee et al. [7] reported an increase in waist gain with higher *trans*-fat intake, but they did not validate the intake of *trans*-fatty acids in their food frequency questionnaire, which could introduce considerable bias since *trans*-fat content of foods has changed over time. In addition, short

term studies conducted in small animals fed 18:1*t*-fatty acids as their main source of *trans*-fatty acids support our findings. These randomized controlled trials with rabbits and mice showed decreases in body weight, and perirenal and epididymal weight when fed diets high in 18:1*t*-fatty acids [22, 23]. The discrepancy between the observations in this study and those in other studies on industrial *trans*-fatty acids and weight might also be explained by the relatively low consumption of 18:1*t*-fatty acids in Costa Rica.

Adipose tissue rumenic acid was not significantly associated with BMI or waist circumference but did relate positively to skinfold thickness. Studies in rodents show associations between CLA and decreases in body fat [24], but in humans the effects of CLA consumption on body weight are inconsistent [9, 10], which is in line with our findings.

Adiposity is primarily caused by an imbalance in energy consumption, leading to deposition of excess calories. However, Flint et al. [25] showed that *trans*-fatty acid consumption had no effect on either appetite or energy expenditure. Food sources of 18:1*t*-fatty acids are mostly processed baked goods, while the main source of 18:2*t*-fatty acids in our population is cooking oil. However, this does not logically explain why 18:1*t*-fatty acids are associated with decreased adiposity, and 18:2*t*-fatty acids with increased adiposity. A clear mechanism for the observed associations cannot be given. Also, biochemical mechanisms to explain these observations such as interference with essential fatty acid desaturation and elongation [26], insulin sensitivity [27] and fat cell size [28] does not explain the inverse associations we see with 18:1*t*-fatty acids and adiposity.

Together with the studies on *trans*-fatty acid isomers and CVD risk, the results from this study suggest that different associations exist between the individual *trans*-

fatty acid isomers and health outcomes. Currently there is a trend among the food industry to reduce *trans*-fatty acids in common foods, which then might be replaced with oils that are less hydrogenated and contain relatively more 18:2*t*-fatty acids. Although the primary goal is to improve public health, this might have more adverse effects because of the adverse associations of 18:2*t*-fatty acids with CVD and adiposity. While a causal effect cannot be determined in this study, extrapolation of our findings suggests that eliminating all industrial 18:2*t*-fatty acids would be associated with a 7.1-cm decrease in waist circumference.

The use of adipose tissue *trans*-fatty acids is both a strength and a limitation of the study. Adipose tissue levels are not dependent on imperfect measures of dietary intake or food composition tables to determine the amount of *trans*-fatty acids in foods, which can pose a problem in dietary analyses since the *trans*-fatty acid content of foods can vary considerably over time. However, the concentration of fatty acids in adipose tissue not only reflects intake, but also metabolism and substitutions between fatty acids.

Reverse causation may influence the associations found in this study; increases in body weight are readily noticed by participants, which can lead to changes in energy intake and the choice of foods or to increased physical activity. Also, residual confounding is possible because of imperfect measurements of physical activity, dietary factors, and health consciousness.

In summary, our study provides evidence that individual *trans*-fatty isomers have divergent effects on adiposity. The main finding is the consistent adverse association between industrial 18:2*t* and all measures of adiposity. Also, 16:1n-7*t* and rumenic acid, both *trans*-isomers mainly found in dairy foods, have divergent effects which has not been reported previously. These isomer-specific associations pose new questions on how *trans*-fatty acids influence metabolism and weight. Other prospective and intervention studies are necessary to examine this further. Regardless of an association with adiposity, elimination of partially hydrogenated oils from the diet is important in efforts to reduce the burden of cardiovascular disease.

Conflict of interest statement None.

Abstract The effect of an atherogenic diet on inflammatory response and elicited peritoneal macrophage (Mϕ) cholesterol accumulation in relation to aortic lesion formation was assessed in LDL receptor null (LDLr−/−) mice. Mice were fed an atherogenic or control diet for 32 weeks. The atherogenic relative to control diet resulted in significantly higher plasma monocyte chemoattractant protein-1 (MCP-1), tumor necrosis factor alpha (TNFα) and interleukin-6 (IL-6) concentrations, more aortic wall Mϕ deposition, higher serum non HDL-cholesterol concentrations and total cholesterol to HDL-cholesterol ratios, and greater accumulation of both aortic free and esterified cholesterol. Elicited peritoneal Mϕ selectively accumulated longer chain unsaturated fatty acids in their membrane, independent of the dietary fatty acid profile. Elicited peritoneal Mϕ isolated from mice fed the atherogenic relative to control diet had significantly less arachidonic acid levels, accumulated significantly higher esterified cholesterol, had significantly higher mRNA levels and secretion of MCP-1, and mRNA and protein levels of ATP-binding cassette A1. Diet treatment had no significant effect in elicited peritoneal Mϕ on TNFα and IL-6 mRNA levels and secretion. These data suggest that the atherogenic relative to control diet resulted in higher plasma inflammatory factor concentrations, less favorable lipoprotein profile, higher elicited peritoneal Mϕ cholesterol accumulation and inflammatory factor secretion, and more aortic wall Mϕ deposition, which in turn were associated with greater aortic cholesterol accumulation.

Keywords Atherogenic diet · Atherosclerosis · Cholesterol accumulation · Inflammatory response · Macrophage · LDLr−/− mouse

Abbreviations

Mϕ	Macrophage
LDLr−/−	LDL receptor null
MCP-1	Monocyte chemoattractant protein-1
TNFα	Tumor necrosis factor alpha
IL-6	Interleukin-6
MSR1	Membrane bound Mϕ scavenger receptor 1
CD36	Cluster of differentiation 36
ABCA1	ATP-binding cassette A1
SR-B1	Scavenger receptor B class 1
CCR2	CC chemokine receptor 2
PBS	Phosphate-buffered saline
TC	Total cholesterol
FC	Free cholesterol

Introduction

Historically, lipoprotein profiles and lipid accumulation in the blood vessel wall have been the major focus of research related to atherogenesis. More recently, a preponderance of evidence from clinical and experimental studies has suggested that inflammation is an important factor [1]. Macrophages (Mϕ) play a critical role in both intracellular cholesterol accumulation and deposition in the arterial wall. Aortic Mϕs express scavenger receptors that take up modified lipoproteins through membrane-bound Mϕ scavenger receptor 1 (MSR1) and CD36. Increased expression of MSR1 and CD36 facilitates the uptake of modified lipoproteins [2, 3]. Two Mϕ membrane proteins involved in cholesterol efflux are ATP-binding cassette A1 (ABCA1) and scavenger receptor B class 1 (SR-B1) [4]. When the Mϕ cholesterol influx is greater than the efflux, cholesterol homeostasis in Mϕ is disturbed, and cholesterol accumulation is favored. The resulting Mϕ-derived foam cells produce reactive oxygen species, which in turn modify lipoproteins, and secrete pro-inflammatory factors, which amplify the local inflammatory reaction [1].

Exposure of endothelial cells to inflammatory factors results in the expression of monocyte chemoattractant protein-1 (MCP-1) and its receptor, CC chemokine receptor 2 (CCR2), which direct the migration of monocytes into the intimal wall. Subsequent exposure of the monocytes to Mϕ colony-stimulating factor causes differentiation to Mϕ. Overexpression of MCP-1 is positively associated with monocyte accumulation in fatty streaks [5]. Major pro-inflammatory factors include interleukin-6 (IL-6) and tumor necrosis factor alpha (TNFα). They are synthesized by monocytes/Mϕ and several other types of cells, such as T cells, endothelial cells and adipocytes, and in turn stimulate the synthesis of other inflammatory factors [6, 7]. Dietary fatty acids and cholesterol have been shown to alter the concentrations of these biomarkers of inflammation and the atherogenic process [8–10].

We used the LDL receptor null (LDLr−/−) mouse fed diets high in saturated fat and cholesterol (atherogenic diet) or low in those components (control diet) as an animal model to assess the relationship between aortic lesion formation and the inflammatory response. Our hypothesis was that the atherogenic diet would accelerate aortic lipid accumulation due to induction of an atherogenic lipoprotein profile, elevate plasma inflammatory biomarker concentrations, increase cholesterol accumulation in and inflammatory factor secretion from elicited peritoneal Mϕ, and change expression and protein levels of genes associated with these processes.

Experimental Procedures

Animals and Diets

Twenty-two 8-week-old, male LDLr−/− mice (Jackson Laboratory, Bar Harbor, Maine) initially weighing 20.2 ± 2.8 g were placed in individual cages with stainless-steel wire bottoms in a windowless room maintained at 22–24°C, 45% relative humidity and a daily 10/14 light/dark cycle with the light period from 0600 to 1600 hours. After 1 week of acclimation, mice were weighed and randomly assigned to one of two groups. The mice were fed either a control diet low in butterfat (4% fat, w/w, 9% energy) and cholesterol (0.02%, w/w) or an atherogenic diet high in butterfat (20% fat, w/w, 38% energy) and cholesterol (0.2%, w/w) ad libitum. The atherogenic diet was modified from Harlan Teklad atherogenic diet TD.88137. The composition of the diets is provided in Supplementary Table 1, and the fatty acid profile of the diets is provided in Supplementary Table 2. Body weight and food intake were recorded weekly over a 32-week period. In order to ensure adequate quantities of Mϕ for the proposed work, 5 days prior to killing, mice were given an intraperitoneal injection of 1.0 ml Brewer thioglycollate broth (4.05 g/100 ml) to elicit peritoneal Mϕ accumulation [11]. Immediately after a 16–18 h fast, the mice were anesthetized with CO_2 and killed by exsanguination. Blood was collected by retro-orbital bleeding to harvest serum at weeks 0, 12 and 32 and by cardiac puncture to harvest plasma at week 32. Heart, aorta and elicited peritoneal Mϕ were collected and treated as described in the next section. Serum and plasma were obtained by blood centrifugation at

1,100×g at 4°C for 25 min. The animal protocol was approved by the Animal Care and Use Committee of the Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, and was in accordance with guidelines provided by the National Institutes of Health Guide for the Care and Use of Laboratory Animals. Data from the mice fed the atherogenic diet were used for comparison purposes to address an unrelated experimental question [12].

Atherosclerosis Lesion Quantitation

The mouse hearts were perfused in situ for 1 min with diethylpyrocarbonate treated-phosphate-buffered saline (PBS) containing 1.5 μmol/l aprotinin and 0.1 mmol/l phenylmethylsulfonyl fluoride through a cannula inserted into the left ventricle. Eight randomly chosen aortas were dissected from the aortic root to the iliac bifurcation using a stereoscopic zoom microscope. As a measure of atherosclerotic lesion, total cholesterol (TC) and free cholesterol (FC) were quantified (8 aortas/group) as previously described [13, 14]. Esterified cholesterol (EC) was calculated as the difference between the two measures. The residual delipidated aortic tissue was digested in 1N NaOH, and total protein was determined using a bicinchoninic acid (BCA) kit (Pierce Ins., Rockford, IL).

Immunohistochemistry

In each group of mice, three randomly chosen aortic arches, from the left aortic valve to the right subclavian artery branch, were embedded in OCT compound (Tissue-Tek 4583; Sakura Finetek), snap-frozen in liquid nitrogen and stored at −80°C until sectioning. The aortic arches were sectioned at a 5-μm thickness and stained in the pathology facility at New England Medical Center. Rat anti-mouse monocyte/Mϕ antibody (MCA519G; Serotec, Raleigh, NC) was used to identify monocyte/Mϕ deposition.

Serum Lipid Profile

Serum TC, HDL-cholesterol (HDL-C) and triglyceride concentrations were measured using an Olympus AU400 analyzer with enzymatic reagents (Olympus America, Melville, NY). Non-HDL-cholesterol (non HDL-C) was calculated as the difference between TC and HDL-C [15].

Plasma Concentrations of Inflammatory Factors

Plasma TNFα, IL-6 and MCP-1 concentrations were measured using Quantikine® ELISA kits (R&D Systems, Minneapolis, MN).

Elicited Peritoneal Mϕ Culture and Stimulation

Immediately after harvesting, elicited peritoneal Mϕ were cultured in RPMI1640 medium (ATCC, Manassas, VA) containing 2% heat-inactivated fetal bovine serum (Invitrogen, Carlsbad, CA) for 2 h (1×10^6 cells per ml). One million cells were stimulated with 1 μg/ml lipopolysaccharide (LPS) for 15 h, and inflammatory factors released into the culture medium were measured. The remaining cells were washed with PBS three times and used for the measurement of cholesterol content, fatty acid profile, mRNA and protein levels of genes involved in inflammation and cholesterol accumulation.

Cholesterol content and fatty acid profile: elicited peritoneal Mϕ TC, FC and protein concentrations were determined as described above for the aorta. Mϕ fatty acid profiles were determined by gas chromatography as previously described [16].

Secretion of inflammatory factors: TNFα, IL-6 and MCP-1 secretion from LPS-stimulated elicited peritoneal Mϕ were measured using DuoSet® ELISA kits (R&D Systems, Minneapolis, MN). Elicited peritoneal Mϕ attached to the culture plates were digested with 0.5N NaOH, and total protein was determined using BCA kits (Pierce Ins., Rockford, IL).

Western blot and real-time PCR: protein was extracted from elicited peritoneal Mϕ using RIPA kit (Santa Cruz, Santa Cruz, CA). Western blotting was performed as previously described [15] with the following primary antibodies: SR-B1 (Novus Biologicals, Littleton, CO), ABCA1 (Novus Biologicals, Littleton, CO), CD36 (Cascade Bioscience, Winchester, MA) and β-actin (Sigma, St. Louis, MO). Signals were visualized by chemiluminescence (Amersham Biosciences, Piscataway, NJ) and quantified using a GS-800 calibrated densitometer (Bio-Rad, Hercules, CA).

RNA was extracted from Mϕ using RNeasy mini kit (Qiagen, Valencia, CA). cDNA was synthesized from RNA using SuperScript™ II reverse transcriptase according to the manufacturer's instruction (Invitrogen, Carlsbad, CA). Primers for peroxisomal proliferator activated receptor (PPAR)β, PPARγ, MSR1, CD36, SR-B1, ABCA1, MCP-1, TNFα and β-actin (Table 1) were designed using Primer Express version 2.0 (Applied Biosystems, Foster City, CA). β-actin was used as an endogenous control. Primer amplification efficiency and specificity were verified for each set of primers. cDNA levels of the genes of interest were measured using power SYBR green master mix on real-time PCR 7300 (Applied Biosystems, Foster City, CA). cDNA levels of IL-6 and PPARα were measured using Taqman® gene expression assays and Taqman® PreAmp master mix kit (Applied Biosystems, Foster City, CA). The reaction condition was 95°C for 10 min, 40 cycles of 95°C for 15 s, 60°C for 1 min and one cycle of

dissociation stage. mRNA fold change was calculated using the 2[-Delta Delta C(T)] method [17].

Statistical Methods

Prior to statistical testing, data were checked for normality, and appropriate transformations were made when necessary (PROC UNIVARIATE; SAS version 9.1, SAS Institute Inc, Cary, NC). Unpaired Student's t test (PROC TTEST) was performed to compare group means. Differences were considered significant at $P < 0.05$. Untransformed data are presented in text, figures and tables as mean $\pm$ standard deviation (SD).

Results

Animal Body Weight and Food Intake

With one exception at the 10-week feeding point, there was no significant difference in the body weight between mice fed the two experimental diets during the 32-week feeding period (data not shown). Although the weight of food eaten was higher in the mice fed the control diet, on the basis of energy intake, the two groups were similar.

Aortic Lesion Composition

Shown in Fig. 1a is a representative aorta from each group of mice. Chemical composition of eight aortas per group indicated that mean TC was 5.5-fold ($P < 0.001$) higher in mice fed the atherogenic compared to control diet (Fig. 1b). This was contributed by higher amounts of both FC (4.9-fold, $P < 0.001$) and EC (6.4-fold, $P < 0.001$). There was stronger staining for Mϕ in the cross sections of aortic arch isolated from the atherogenic compared to control diet-fed mice (Fig. 1c).

Serum Lipid Profile

Although similar at baseline, serum non-HDL-C ($P < 0.001$) concentrations and ratios of TC to HDL-C

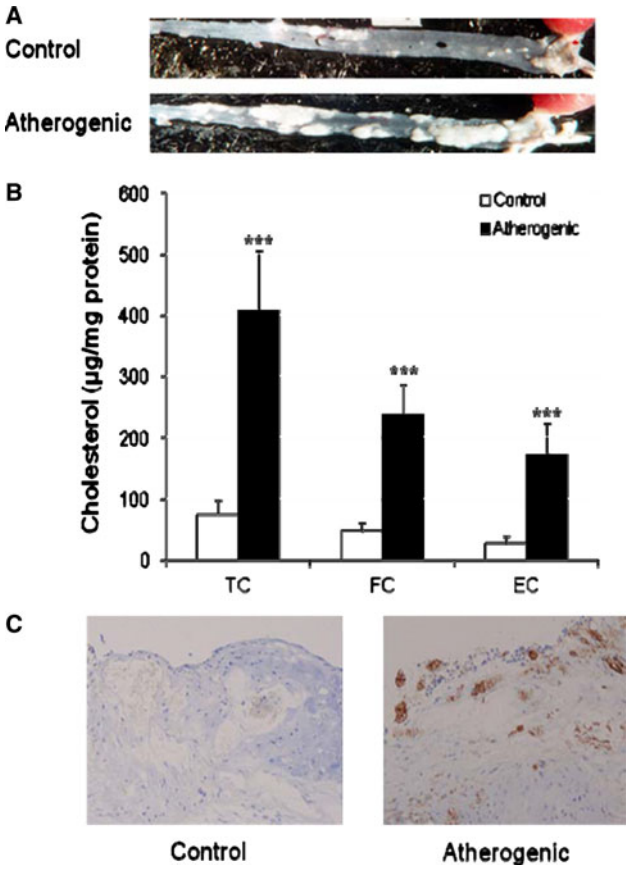

Fig. 1 Representative aortas from each diet group; white areas denote atherosclerotic lesion (**a**); aortic cholesterol content in whole aortas (**b**), and Mϕ immunostaining by an antibody to mouse Mϕ surface marker in the cross-sections of aortic arches (**c**) in LDLr−/− mice. Magnified (×200) images of aortic arch cross sections. The intensity of the *brown color* corresponds to the presence of Mϕ. $n = 11$ in each group. Values are mean $\pm$ SD. Unpaired Student's t test (PROC TTEST) was performed to compare two group values. The difference is expressed as $^{***}P < 0.001$

($P < 0.001$) were significantly higher in the atherogenic relative to control diet-fed mice at the 12-week feeding point, and these differences were maintained throughout the study period (Fig. 2). By the end of the 32-week feeding period, serum HDL-C concentrations declined

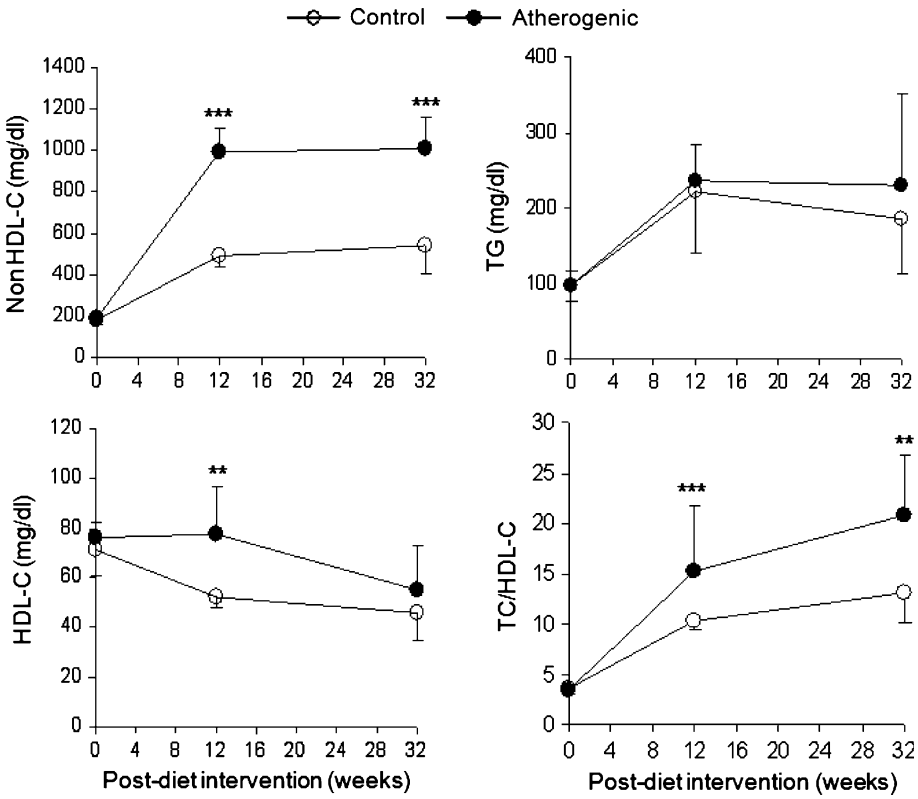

Fig. 2 Serum lipid profiles in LDLr−/− mice. Serum was obtained at 0-, 12- and 32-week post-diet interventions. $n = 11$ in each group. Values are mean ± SD of untransformed data. Prior to the statistical analysis the following transformations were made: TG at 0 week (*inverse*), HDL at 12 week (*square*), non-HDL-C at 12 week (*inverse*), TC/HDL-C at 32 week (*square*). Unpaired Student's *t* test (PROC TTEST) was performed to compare two group values. The difference is expressed as $^{**}P < 0.01$, $^{***}P < 0.001$

similarly between the two groups of mice, 35 and 28% in mice fed the control and atherogenic diets, respectively. During that same time period, triglyceride concentrations increased by 94 and 139% in the mice fed the control and atherogenic diets, respectively.

Plasma Concentrations of Inflammatory Factors

At the end of the 32-week feeding period, the mice fed the atherogenic relative to control diet had significantly higher plasma concentrations of all three of the inflammatory factors assessed: MCP-1 (144%, $P < 0.01$), TNFα (325%, $P < 0.01$) and IL-6 (188%, $P < 0.001$) (Fig. 3).

Elicited Peritoneal Mϕ Fatty Acid Profiles

The total SFA, monounsaturated fatty acid (MUFA) and polyunsaturated fatty acid (PUFA) profile of the elicited peritoneal Mϕ was similar between the two diet groups. With the exception of small differences, the percentage of omega (ω)-6 PUFA ($P < 0.01$) was significantly lower, whereas that of ω-3 PUFA ($P < 0.001$) was significantly higher in the elicited peritoneal Mϕ isolated from the atherogenic relative to control diet-fed mice (Table 2). Although alpha-linolenic acid (ALA, C18:3ω-3) levels were higher than eicosapentaenoic acid (EPA, C20:5ω-3) and docosahexaenoic acid (DHA, C22:6ω-3) in both diets,

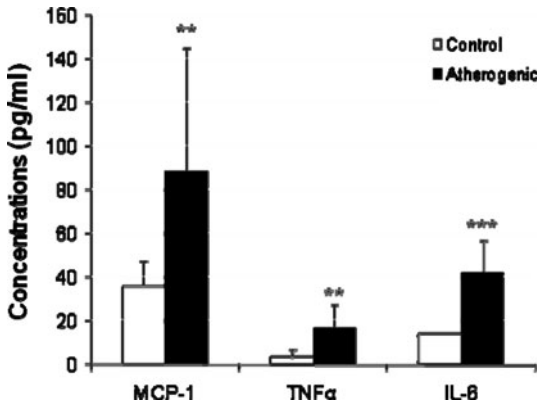

Fig. 3 Plasma concentrations of inflammatory factors in LDLr−/− mice. $n = 11$ in each group. Values are mean ± SD of untransformed data. Prior to the statistical analysis, the following transformations were made: MCP-1 (inverse) and IL-6 (inverse). Unpaired Student's *t* test (PROC TTEST) was performed to compare two group values. The difference is expressed as $^{**}P < 0.01$, $^{***}P < 0.001$

DHA plus EPA levels were 18-fold higher than ALA in elicited peritoneal Mϕ isolated from the two groups of mice. Although linoleic acid (LNA, C18:2ω-6) levels were more than 60-fold higher than arachidonic acid (ARA, C20:4ω-6) in both diets, ARA levels were 1.8-fold and 1.4-fold higher than LNA in elicited peritoneal Mϕ isolated from mice fed the control and atherogenic diet, respectively.

$n = 11$ in each group. Values are mean ± SD of untransformed data. Prior to the statistical analysis, the following transformations were made: C16:0 (square), C20:1 (inverse), C20:2 (inverse), C20:5ω-3 (square root), C22:2 (1/square root), C22:5ω-6 (square root), PUFA (inverse), ω-6 PUFA (inverse). Unpaired Student's t test (PROC TTEST) was performed to compare two group values. Within a row the difference is expressed as $^{**}P < 0.01$, $^{***}P < 0.001$

[a] Control: low saturated fatty acid and low cholesterol diet

[b] Atherogenic: high saturated fatty acid and high cholesterol diet

Elicited Peritoneal Mϕ Cholesterol Content

To examine the potential relationship between aortic and Mϕ cholesterol accumulation, we measured elicited peritoneal Mϕ cholesterol content. Elicited peritoneal Mϕ TC was 34% ($P < 0.01$) higher in the atherogenic relative to control diet-fed mice (Fig. 4). This was accounted for primarily by the EC fraction, which was 104% ($P < 0.01$) higher in the atherogenic diet-fed mice.

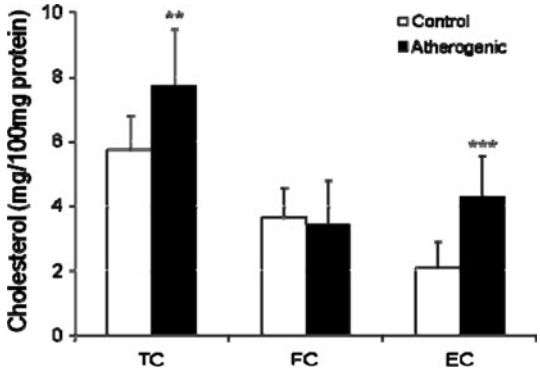

Fig. 4 Elicited peritoneal Mϕ cholesterol content in LDLr−/− mice. $n = 11$ in each group. Values are mean ± SD of untransformed data. Prior to the statistical analysis, FC (inverse) was transformed. Unpaired Student's t test (PROC TTEST) was performed to compare two group values. The difference is expressed as $^{**}P < 0.01$, $^{***}P < 0.001$

mRNA and Protein Levels of Genes Involved in Cholesterol Accumulation in Elicited Peritoneal Mϕ

To investigate the mechanism(s) underlying the higher EC content in the elicited peritoneal Mϕ harvested from the mice fed the atherogenic diet, we measured the protein and mRNA levels of genes involved in cholesterol accumulation. The atherogenic diet resulted in significantly higher ABCA1 mRNA ($P < 0.01$) and protein ($P < 0.01$) levels, albeit a modest difference, whereas SR-B1 and CD36 mRNA and protein levels were similar between two diet groups (Fig. 5a, c). There was no significant effect of diet treatment on mRNA levels of MSR1, PPARα, PPARβ/δ and PPARγ.

mRNA Levels and Secretion of Inflammatory Factors in/From Elicited Peritoneal Mϕ

To explore whether plasma concentrations of inflammatory factors were determined by Mϕ secretion, we measured MCP-1, TNFα and IL-6 mRNA levels and secretion in/from elicited peritoneal Mϕ. MCP-1 secretion was 51% higher ($P < 0.01$) in mice fed the atherogenic relative to control diet (Fig. 5b). This was accompanied by 1.5-fold higher MCP-1 mRNA levels ($P < 0.05$) (Fig. 5c). There was no significant effect of diet treatment on TNFα and IL-6 mRNA levels in and secretion from elicited peritoneal Mϕ—suggesting these cells were not a major determinant of plasma TNFα and IL-6 concentrations.

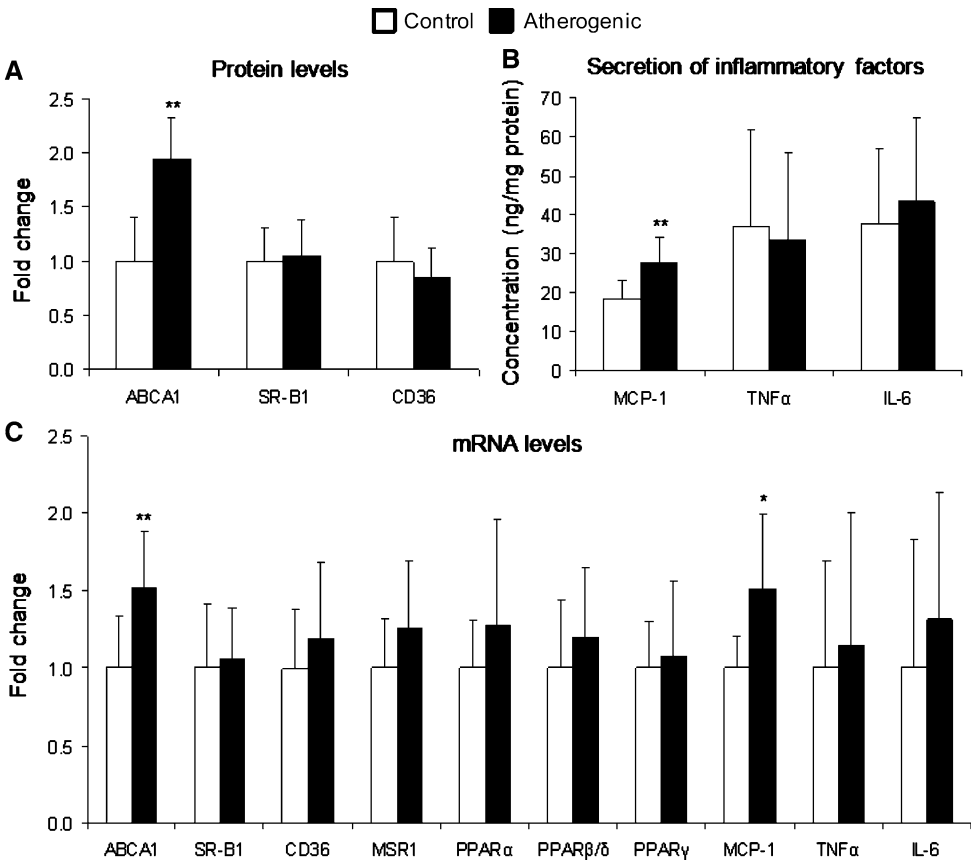

Fig. 5 Protein levels of ABCA1, SR-B1 and CD36 (**a**), secretion of MCP-1, TNFα and IL-6 (**b**), and mRNA levels of genes (**c**) in/from elicited peritoneal Mϕ isolated from LDLr−/− mice at the end of the 32-week feeding period. $n = 11$ in each group. Values are mean ± SD of untransformed data. Prior to the statistical analysis, mRNA levels of TNFα [1/log(TNFα)] were transformed. Unpaired Student's t test (PROC TTEST) was performed to compare two group values. The difference is expressed as $^{*}P < 0.05$, $^{**}P < 0.01$

Discussion

In humans, consumption of high SFA and cholesterol diets is positively associated with cardiovascular disease (CVD) risk [18, 19]. The inflammatory process is a major contributor to the development of atherosclerotic plaque [1, 20]. IL-6, MCP-1 and TNFα are important biomarkers of inflammation [6, 21, 22]. Epidemiological studies have shown a positive association between the Western-type diet and plasma MCP-1, IL-6 and TNFα concentrations [23–25]. The present study is the first to simultaneously assess the effect of an atherogenic diet in the LDLr−/− mouse on atherosclerotic lesion formation, aortic Mϕ accumulation, plasma inflammatory factor concentrations, cholesterol accumulation and inflammatory factor secretion in/from elicited peritoneal Mϕ isolated from these mice, and Mϕ gene expression and protein levels associated with these processes. We demonstrated that diet-induced atherosclerotic lesion formation in LDLr−/− mice was associated with higher inflammatory response. Changes in peritoneal Mϕ isolated from these mice may, in part, have exacerbated the aortic lesion formation.

LNA and ALA were the most abundant ω-6 fatty acids, and accounted for more than 84 and 79% of total ω-6 and ω-3 fatty acids in two diets, respectively. ARA only accounted for 0.2 and 1.4% of total ω-6 fatty acids in the control and atherogenic diet, respectively. However, ARA accounted for about 41.5 and 38.7% of total ω-6 fatty acids in elicited peritoneal Mϕ isolated from the control and atherogenic diet-fed mice, respectively. The percentage of LNA was about one third less than that of ARA in elicited peritoneal Mϕ isolated from two groups of mice. ALA represented about 3% of total ω-3 fatty acids in elicited peritoneal Mϕ. EPA and DHA were the most abundant ω-3 fatty acids and accounted for more than 56% of total ω-3 fatty acids in elicited peritoneal Mϕ. These data suggest that peritoneal Mϕ selectively accumulated longer chain unsaturated fatty acids in their membrane, independent of the fatty acid profile of the diet. Similar data have been reported by others [26]. Whereas the total SFA, MUFA and PUFA prolife of the elicited peritoneal Mϕ was similar between the two groups of mice, the ω-6 PUFAs were significantly higher, and ω-3 PUFAs were significantly lower in elicited peritoneal Mϕ isolated from the control relative to atherogenic diet-fed mice. ARA accounted for about 38.4 and 28.3% of total PUFA in elicited peritoneal Mϕ isolated from the control and atherogenic diet-fed mice, respectively. EPA plus DHA accounted for about 5.3 and 15.3% of total PUFA in elicited peritoneal Mϕ isolated from the control and atherogenic diet-fed mice,

respectively. ARA was significantly lower and EPA plus DHA significantly higher in elicited peritoneal Mϕ isolated from the atherogenic relative to control diet-fed mice. Further studies are required to detect whether these differences are a result of uptake of cholesterol-rich lipoproteins or specific fatty acid synthesis caused by diets or inflammation.

Overexpression of MCP-1 has been positively related to monocyte accumulation in the arterial vessel wall, a major event leading to the development of atherosclerosis [5, 27]. Studies in humans have shown that elevated serum MCP-1 concentrations are an inflammatory biomarker positively associated with CVD [27–29]. In MCP-1 and LDL receptor double null mice, lower monocyte deposition and vessel wall lipid accumulation have been observed compared to LDLr−/− mice [30, 31]. LDLr−/− mice fed a Western diet had elevated plasma MCP-1 concentrations, which were associated with more aortic lesion area compared to the mice fed chow diet [32]. In this study, in elicited peritoneal Mϕ, both MCP-1 mRNA levels and secretion were significantly higher in LDLr−/− mice fed the atherogenic diet compared to those fed the control diet. This is consistent with previous reports that a similar atherogenic diet resulted in higher MCP-1 mRNA levels in and protein secretion from adipocytes in mice [32–34]. Although the atherogenic diet resulted in elevated plasma IL-6 and TNFα concentrations, there was no significant difference in mRNA and secretion of TNFα and IL-6 from elicited peritoneal Mϕ isolated from two groups of mice. TNFα and IL-6 can be produced by liver, endothelial, adipocytes or T cells [35–37]. Preliminary work suggested that liver TNFα and IL-6 production was 1.5-fold ($P < 0.05$) and 2.0-fold higher ($P < 0.05$), respectively, in mice fed the atherogenic relative to control diet despite higher plasma concentrations of these cytokines (unpublished data). These data suggest that elevated plasma IL-6 and TNFα concentrations were mediated, as least in part, by liver cells.

Apolipoprotein E-deficient mice fed a high SFA and cholesterol diet had significantly higher MCP-1 mRNA levels in both liver and aorta compared to mice fed only a high SFA diet [38]. The atherogenic diet might increase the expression of MCP-1 through upregulated Toll-like receptor 4 (TLR4). Stimulation of TLR4 by LPS can induce activation of nuclear factor-kappa B (NF-kB) and expression of cytokines [39]. TLR4 is expressed in murine and human lipid-rich atherosclerotic lesions, and colocalized with Mϕ both in murine atherosclerotic lesion and human shoulder coronary artery plaque [40]. In vitro studies have shown that oxidized LDL (ox-LDL) can upregulate the expression of TLR4 in human monocyte-derived Mϕ [40]. We cannot rule out the possibility that high levels of ox-LDL in the atherogenic diet-fed mice stimulated the expression of TLR4, which increased the binding of LPS, and further upregulated the expression of MCP-1. Due to the limited number of elicited peritoneal Mϕ obtained from each mouse, we could not test the above hypotheses in this study.

In this study, ARA levels were significantly higher than EPA plus DHA in the elicited peritoneal Mϕ isolated from two groups of mice. In addition, the percentage of ARA was significantly higher, whereas that of EPA plus DHA were significantly lower, in the elicited peritoneal Mϕ isolated from the control relative to atherogenic diet-fed mice. Our previous study [41] has shown that ARA significantly lowered MCP-1 mRNA levels and secretion from Mϕ differentiated from THP-1 monocytes. ARA and EPA had a more pronounced effect than DHA. ARA can be metabolized to 15-deoxy-delta^{12,14}-PGJ$_2$ (15dPGJ$_2$), a natural ligand for PPARγ [42]. 15dPGJ$_2$ has been consistently shown to have anti-inflammatory properties by serving as a potent agonist to activate PPARγ [43, 44]. Some studies have shown that activated PPARγ could be a promoter-specific repressor of NF-kB target genes that regulate inflammation in Mϕ [45]. There was not a significant difference in the PPARγ expression in the elicited peritoneal Mϕ isolated from two groups of mice. ARA might lower MCP-1 expression through activating PPARγ instead of changing its expression.

The atherogenic diet resulted in more Mϕ deposition in the aortic wall. In situ, these cells play an important role not only in the inflammatory response, but also in uptake of modified LDL, and accumulation and deposition of cholesterol [46, 47]. Based on the results from previous studies [11, 48, 49], the expression and production of inflammatory factors is comparable between resident and elicited peritoneal Mϕ. In our study, elicited peritoneal Mϕ were used to ensure an adequate number of cells were harvested. Elicited peritoneal Mϕ TC and EC content change was similar to that seen in the aortas of the respective mice. To determine whether the difference in Mϕ cholesterol content resulting from the two different diets was due to an imbalance of influx or efflux, we assessed mRNA and protein levels of two genes involved in cholesterol efflux, SR-B1 and ABCA1, and two genes involved in cholesterol influx, MSR1 (only mRNA levels) and CD36. There was no significant difference in protein levels of CD36 and SR-B1 in elicited peritoneal macrophages isolated from the two groups of mice. An antibody to detect protein levels of MSR1 was not available. The atherogenic diet resulted in higher mRNA and protein levels of ABCA1 in this study, but not the other factors assessed. These data are consistent with other studies showing that Mϕ ABCA1 expression is upregulated in atherosclerotic lesions, as a compensatory mechanism in response to cholesterol enrichment [50, 51]. ABCA1 is a direct transcriptional target of liver-X-receptors (LXR) [52–54]. LXR is activated by cholesterol

metabolites. We speculate that higher circulating lipoprotein concentrations, especially apolipoprotein B-containing lipoproteins, would favor increased Mϕ cholesterol content, which in turn would alter cellular cholesterol homeostasis and trigger an upregulation of ABCA1 expression. The atherogenic diet may have activated LXR through increasing Mϕ production of LXR ligands, such as 22(R)-hydroxycholesterol and 27-hydroxycholesterol. Ligand activated-LXR can upregulate ABCA1 gene expression and enhance ABCA1-mediated cholesterol efflux from elicited peritoneal Mϕ isolated from the atherogenic diet-fed mice. In addition to the cholesterol enrichment-induced regulation, it has been reported that SFA increase and PUFA decrease ABCA1 expression at both transcription and post-translation levels [55, 56]. However, there was no significant difference in SFA and PUFA composition in elicited peritoneal Mϕ isolated from two groups of mice. The higher levels of TC and EC in the peritoneal Mϕ may have resulted from higher circulation oxLDL concentrations, upregluation of genes associated with cholesterol influx or/and downregulation of genes associated with cholesterol efflux, which were not determined due to limited numbers of Mϕ harvested from each mouse.

In summary, these data suggest that LDLr−/− mice fed a diet high in SFA and cholesterol, relative to the control diet, had higher plasma inflammatory factor concentrations, less favorable lipoprotein profiles, higher elicited peritoneal Mϕ cholesterol accumulation and inflammatory factor secretion, and more Mϕ deposition in the aortic wall, which in turn were associated with greater aortic cholesterol accumulation.

Abstract In the screening of DNA polymerase (pol) inhibitor, we isolated lutein, a carotenoid, from the crude (unrefined) pressed oil of canola (low erucic acid rapeseed, *Brassica napus* L.). Commercially prepared carotenoids such as lutein (**1**), zeaxanthin (**2**), β-cryptoxanthin (**3**), astaxanthin (**4**), canthaxanthin (**5**), β-carotene (**6**), lycopene (**7**), capsanthin (**8**), fucoxanthin (**9**) and fucoxanthinol (**10**), were investigated for the inhibitory activities of pols. Compounds **1**, **2** and **8** exhibited strong inhibition of the activities of mammalian pols β and λ, which are DNA repair- and/or recombination-related pols. On the other hand, all carotenoids tested had no influence on the activity of a mammalian pol α, which is a DNA replicative pol. Lutein (**1**) was the strongest pol inhibitor of mammalian pols β and λ in the prepared ten carotenoids tested, but did not influence of the activities of mammalian pols α, γ, δ and ε. The tendency for pols β and λ inhibition by these carotenoids showed a positive correlation with the suppression of TPA (12-*O*-tetradecanoylphorbol-13-acetate)-induced inflammation. These results suggest that cold pressed unrefined canola/rapeseed oil, or other oils with high levels of lutein and other carotenoids, may be useful for their anti-inflammatory properties.

Abbreviations

Pol	DNA polymerase (EC 2.7.7.7)
TPA	12-*O*-tetradecanoylphorbol-13-acetate
dsDNA	Double-stranded DNA
dTTP	2′-deoxythymidine 5′-triphosphate
DNase I	Deoxyribonuclease I
HIV-1	Human immunodeficiency virus type-1
DMSO	Dimethyl sulfoxide

Introduction

Our laboratory has long been interested in the integrity of the genome of eukaryotes and its relation to cell differentiation. DNA replication, recombination and repair in eukaryotes are key systems to maintain these processes [1], and DNA polymerases (pols) have important roles. Pol

catalyzes the addition of deoxyribonucleotides to the 3′-hydroxyl terminus of primed double-stranded DNA (dsDNA) molecules [2]. In this regard, we have concentrated our efforts on investigating eukaryotic pols associated with these processes [3].

The human genome encodes at least 14 pols to conduct cellular DNA synthesis [4, 5]. Eukaryotic cells contain three replicative pols (α, δ and ε), mitochondrial pol γ, and at least ten non-replicative pols (β, ζ, η, θ, ι, κ, λ, μ, ν and REV1) [4–6]. Pols have a highly conserved structure, which means that their overall catalytic subunits vary, on the whole, very little among species. Conserved structures usually indicate important, irreplaceable functions of the cell, the maintenance of which provides evolutionary advantages. Because not all functions of eukaryotic pols have been fully elucidated, selective inhibitors of pols are useful tools for distinguishing pols and clarifying their biological functions. Pols are not only essential for DNA replication, repair and recombination, but are also involved in cell division. Selective inhibitors of pol are considered a group of potentially useful anticancer and antiparasitic agents, because some inhibitors suppress human cancer cell proliferation and have cytotoxicity [7].

We have therefore been searching for natural compounds that selectively inhibit each of these eukaryotic pols [7, 8]. In this study, we screened pol inhibitors from Canola/rapeseed (*Brassica napus* L.) crude extract, which is the screw pressed component after canola oil production. We isolated lutein, a carotenoid, as a mammalian pol inhibitor, focused on the anti-inflammatory effect of the carotenoids (i.e., compounds **1** to **10**), and investigated the chemical constituents which inhibited the activities of pols and anti-inflammation.

Experimental Procedures

Materials

The crude (unrefined) oil of canola (low erucic acid rapeseed, *Brassica napus* L.) was pressed by J-Oil Mills Inc. (Yokohama, Japan). Lutein (**1**), zeaxanthin (**2**), β-cryptoxanthin (**3**), astaxanthin (**4**), canthaxanthin (**5**), β-carotene (**6**), lycopene (**7**), capsanthin (**8**) and fucoxanthin (**9**) were purchased from Sigma-Aldrich Japan K.K. (Tokyo, Japan), and the purity of these carotenoids was ~98%. Fucoxanthinol (**10**) was enzymatically converted from fucoxanthin (**9**), as described by Tsukui et al. [9]. The chemically synthesized DNA template and nucleotides, such as poly(dA) and [^{3}H]-deoxythymidine 5′-triphosphate (dTTP) (43 Ci/mmol), were purchased from GE Healthcare Bio-Sciences (Little Chalfont, UK). DNA primer, such as oligo(dT)$_{18}$, was customized by Sigma-Aldrich Japan K.K. (Hokkaido, Japan). All other reagents were of analytical grade and purchased from Nacalai Tesque Inc. (Kyoto, Japan).

Structure Determination

The NMR spectra (^{1}H and ^{13}C) were recorded on a Bruker 400 MHz spectrometer (Avance DRX-400). The IR spectrum was recorded on a Jasco FT/IR-410 spectrometer. The mass spectrum was obtained with an Applied Biosystems mass spectrometer (APIQSTAR pulsar i).

Enzymes

Pol α was purified from calf thymus by immuno-affinity column chromatography, as described by Tamai et al. [10]. Recombinant rat pol β was purified from *E. coli* JMpβ5, as described by Date et al. [11]. The human pol γ catalytic gene was cloned into pFastBac. Histidine-tagged enzyme was expressed using the BAC-TO-BAC HT Baculovirus Expression System according to the supplier's manual (Life Technologies, MD, USA) and purified using Pro-Boundresin (Invitrogen Japan, Tokyo, Japan) [12]. Human pols δ and ε were purified from the nuclear fraction of human peripheral blood cancer cells (Molt-4) using the second subunit of pols δ and ε-conjugated affinity column chromatography, respectively [13]. Recombinant human His-pol λ was overexpressed and purified according to a method described by Shimazaki et al. [14]. Fish pol δ was purified from the testis of cherry salmon (*Oncorhynchus masou*) [15]. Fruit fly pols α, δ and ε were purified from early embryos of *Drosophila melanogaster*, as described by Aoyagi et al. [16, 17]. Pol α from a higher plant, cauliflower inflorescence, was purified according to the methods outlined by Sakaguchi et al. [18]. The Klenow fragment of pol I from *E. coli* and human immunodeficiency virus type-1 (HIV-1) reverse transcriptase (recombinant) were purchased from Worthington Biochemical Corp. (Freehold, NJ, USA). T4 pol, *Taq* pol, T7 RNA polymerase and T4 polynucleotide kinase were purchased from Takara Bio (Tokyo, Japan). Bovine pancreas deoxyribonuclease I (DNase I) was obtained from Stratagene Cloning Systems (La Jolla, CA, USA).

DNA Polymerase Assays

The reaction mixtures for pol α, pol β, plant pol α and prokaryotic pols were described previously [19, 20], and those for pol γ, and pols δ and ε were as described by Umeda et al. [12] and Ogawa et al. [21], respectively. The reaction mixture for pol λ was the same as for pol β. For pols, poly(dA)/oligo(dT)$_{18}$ (A/T = 2/1) and dTTP were used as the DNA template-primer and nucleotide (i.e., dNTP) substrate,

respectively. For HIV-1 reverse transcriptase, poly(rA)/oligo(dT)$_{18}$ (A/T = 2/1) and dTTP were used as the template-primer and nucleotide substrate, respectively.

The compounds were dissolved in distilled dimethyl sulfoxide (DMSO) at various concentrations and sonicated for 30 s. Aliquots of 4 μl sonicated samples were mixed with 16 μl of each enzyme (final amount 0.05 units) in 50 mM Tris–HCl (pH7.5) containing 1 mM dithiothreitol, 50% glycerol and 0.1 mM EDTA, and kept at 0 °C for 10 min. These inhibitor-enzyme mixtures (8 μl) were added to 16 μl of each enzyme standard reaction mixture, and incubation was carried out at 37 °C for 60 min, except for *Taq* pol, which was incubated at 74 °C for 60 min. Activity without the inhibitor was considered 100%, and the remaining activity at each concentration of the inhibitor was determined relative to this value. One unit of pol activity was defined as the amount of enzyme that catalyzed the incorporation of 1 nmol dNTP (i.e., dTTP) into synthetic DNA template-primers in 60 min at 37 °C under the normal reaction conditions for each enzyme [19, 20].

Other DNA Metabolic Enzymes Assays

The activities of calf primase of pol α, T7 RNA polymerase, T4 polynucleotide kinase and bovine DNase I were measured in standard assays according to the manufacturer's specifications, as described by Tamiya-Koizumi et al. [22], Nakayama and Saneyoshi [23], Soltis and Uhlenbeck [24], and Lu and Sakaguchi [25], respectively.

Anti-Inflammatory Assay

The mouse inflammatory test was performed according to Gschwendt's method [26]. This experiment complied with the regulations concerning animal experimentation and the care of experimental animals of Kobe-Gakuin University. Briefly, a solution of the test compound in acetone (250 μg and 500 μg/20 μl) was applied to the inner part of the ear. Thirty minutes after the test compound was applied, a solution of 12-*O*-tetradecanoylphorbol-13-acetate (TPA) (0.5 μg/20 μl of acetone) was applied to the same part of the ear. To the other ear of the same mouse, methanol and a TPA solution were applied as a control. After 7 h, a disk (6 mm in diameter) was obtained from the ear and weighed. The inhibitory effect (IE) of inflammation is presented as the ratio of the increase in weight of the ear disks: IE: {[(TPA only)-(tested compound plus TPA)]/[(TPA only)-(vehicle)] × 100}.

Molecular Simulation

The molecular structure of lutein (**1**) was constructed based on Discovery Studio (DS) 2.1 (Accelrys, Inc., San Diego, CA) on a PC terminal (Express; NEC) linked with Regatta (96 nodes; IBM). Energy minimization was achieved using a solvation model and calculated by the GBSW parameter with Minimization and Dynamics protocols within DS. The calculation used a CHARMm (Chemistry at HARvard Macromolecular Mechanics) force-field.

Results

Isolation of the Mammalian Pol Inhibitor from the Pressed Extract of Canola/Rapeseed (*Brassica napus* L.)

Since the chloroform-soluble phase of the Canola/rapeseed crude pressed extract (1 g extract per 10 ml chloroform) had inhibitory activity against mammalian pols, the chloroform extract (50 g) was subjected to SiO_2 column chromatography and then eluted with $CHCl_3$:MeOH (v/v 50:1). The active fractions were purified by SiO_2 column chromatography using benzene:MeOH (v/v 15:1). The active fractions were subjected to SiO_2 column chromatography and then eluted with *n*-hexane : acetone (v/v 3:1). The active fractions were finally purified by Sephadex LH-20 column chromatography eluted with $CHCl_3$:MeOH (v/v 1:1). Finally, a yellow powder (compound **1**) was obtained (5.8 mg).

Structure Determination of Compound **1**

The molecular formula of compound **1** was determined to be $C_{40}H_{56}O_2$ by the high resolution mass spectrum. The presence of two secondary hydroxyl groups was revealed by two methine signals at δ 4.00 and 4.25 and IR absorption at 3416 cm^{-1}. The ^{1}H- and ^{13}C-NMR spectra showed that compound **1** has a polyene structure and ten methyl groups. From the above data, compound **1** was identified as a carotenoid, lutein. These spectroscopic data were consistent with those reported [27, 28]. The analyzed data of compound **1** are shown below.

Lutein (**1**): ^{1}H NMR (400 MHz, $CDCl_3$) : δ = 0.85 (3H, s), 1.00 (3H, s), 1.07 (6H, s), 1.37 (1H, dd, J = 13.2 Hz, 6.8 Hz), 1.48 (1H, t, J = 12.0 Hz), 1.63 (3H, s), 1.74 (3H, s), 1.77 (1H, m), 1.84 (1H, dd, J = 13.2 Hz, 6.0 Hz), 1.91 (3H, s), 1.97 (3H, s), 1.97 (3H, s), 1.97 (3H, s), 2.04 (1H, dd, J = 16.8 Hz, 9.6 Hz), 2.36-2.42 (2H, m), 4.00 (1H, m), 4.25 (1H, m), 5.43 (1H, dd, J = 15.6 Hz, 10 Hz), 5.55 (1H, s), 6.12 (2H, m), 6.14–6.17 (3H, m), 6.24 (1H, m), 6.26 (1H, m), 6.36 (1H, d, J = 14.8 Hz), 6.36 (1H, d, J = 14.8 Hz), 6.58–6.68 (4H, m). ^{13}C NMR (100 MHz, $CDCl_3$): δ = 12.75, 12.75, 12.81, 13.1, 21.6, 22.9, 24.3, 28.7, 29.5, 30.3, 34.0, 37.1, 42.5, 44.6, 48.4, 55.0, 65.1, 65.9, 124.5, 124.8, 124.9, 125.6, 126.2, 128.7, 130.0, 130.1, 130.8,

131.3, 132.6, 132.6, 135.1, 135.7, 136.4, 136.5, 137.6, 137.6, 137.72, 137.74, 138.0, 138.5. IR (NaCl): 3416, 3018, 2960, 2927, 2867, 1577, 1443, 1368, 1037, 970 cm^{-1}. HRMS (ESI): *m/z* calcd for $C_{40}H_{56}O_2Na$ ($[M + Na]^+$): 591.4172, found: 591.4180.

Effects of Lutein-Related Carotenoids (Compounds **1**–**10**) on Mammalian Pols α, β and λ

First, we investigated the pol inhibitory activity of the purified compound **1** compared with the commercially purchased reagent (specially purified grade of lutein), which showed the same strong inhibitory effect (data not shown); therefore, we used the commercially purified reagent in later parts of this study.

We obtained commercially-available carotenoids, lutein (**1**), zeaxanthin (**2**), β-cryptoxanthin (**3**), astaxanthin (**4**), canthaxanthin (**5**), β-carotene (**6**), lycopene (**7**), capsanthin (**8**) and fucoxanthin (**9**), and fucoxanthinol (**10**) was enzymatically synthesized from fucoxanthin (**9**), as described by Tsukui et al. [9]. The inhibitory activity of calf pol α, rat pol β and human pol λ against 10 and 100 μM of each compound was investigated (Fig. 1). In mammalian pols, pol α and pols β and λ were used as representative replicative pol and repair/recombination-related pols, respectively [5, 29]. All compounds tested had no influenced on pol α activity (Fig. 1a), but lutein (**1**), zeaxanthin (**2**) and capsanthin (**8**) inhibited the activities of pols β and λ (Fig. 1b, c). The inhibitory effect on pol β showed the same tendency as that on pol λ, lutein (**1**) had the strongest inhibitory effect on these pols of the tested compounds, and the effect of the three compounds ranked as follows: lutein (**1**) > zeaxanthin (**2**) > capsanthin (**8**). When activated DNA (i.e., DNA digested by bovine DNase I) was used as the DNA template-primer instead of poly (dA)/oligo$(dT)_{18}$ (A/T = 2/1), the mode of inhibition by these compounds did not change (data not shown).

Effects of Lutein (**1**) on Various Pols and Other DNA Metabolic Enzymes

Since lutein (**1**) was the strongest inhibitor of mammalian pols β and λ in the carotenoids (compounds **1**–**10**) investigated (Fig. 1), we focused on lutein (**1**) in this section. As shown in Table 1, this compound only inhibited pols β and λ activities in mammalian pols, and these pols were dose-dependently suppressed to the same extent, with IC_{50} values of 45.0 and 12.8 μM, respectively. On the other hand, lutein (**1**) had no significant influence on the activities of fish (cherry salmon) pol δ, insect (fruit fly) pols α, δ and ε, pol α from plants (cauliflower) and prokaryotes, such as the Klenow fragment of *E. coli* pol I, T4 pol and *Taq* pol. This compound did not inhibit the activities of the other DNA metabolic enzymes tested, including calf primase of pol α, HIV-1 reverse transcriptase, T7 RNA polymerase, T4 polynucleotide kinase and bovine DNase I.

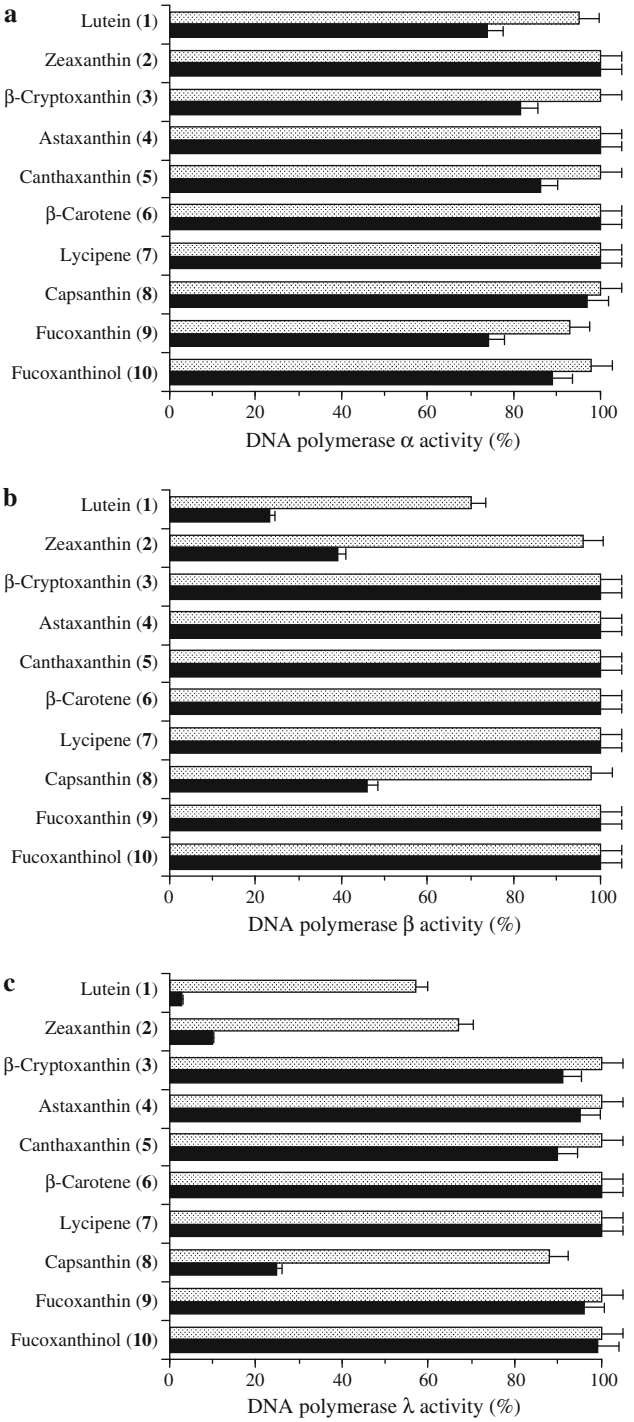

Fig. 1 Inhibitory effect of carotenoids (compounds **1**–**10**) on the activities of mammalian pols. Ten μM (*gray bar*) and 100 μM (*black bar*) of each compound was incubated with calf pol α (**a**), rat pol β (**b**) and human pol λ (**c**) (0.05 units each). Percent relative activity is shown. Pol activity in the absence of the compound was taken as 100%. Data are shown as the means ± SEM of three independent experiments

Table 1 IC_{50} values of lutein (**1**) on the activities of various DNA polymerases and other DNA metabolic enzymes

Enzyme	IC_{50} value (μM)
Mammalian DNA polymerases	
Calf DNA polymerase α	>200
Rat DNA polymerase β	45.0 ± 2.3
Human DNA polymerase γ	>200
Human DNA polymerase δ	>200
Human DNA polymerase ε	>200
Human DNA polymerase λ	12.8 ± 0.7
Fish DNA polymerases	
Cherry salmon DNA polymerase δ	>200
Insect DNA polymerases	
Fruit fly DNA polymerase α	>200
Fruit fly DNA polymerase δ	>200
Fruit fly DNA polymerase ε	>200
Plant DNA polymerases	
Cauliflower DNA polymerase α	>200
Prokaryotic DNA polymerases	
E. coli DNA polymerase I (Klenow fragment)	>200
T4 DNA polymerase	>200
Taq DNA polymerase	>200
Other DNA metabolic enzymes	
Calf primase of DNA polymerase α	>200
HIV-1 Reverse transcriptase	>200
T7 RNA polymerase	>200
T4 polynucleotide kinase	>200
Bovine deoxyribonuclease I	>200

This compound was incubated with each pol (0.05 units) and other DNA metabolic enzymes. One unit of pol activity was defined as the amount of enzyme that catalyzed the incorporation of 1 nmol of dNTP (i.e., dTTP) into the synthetic DNA template-primers (i.e., poly(dA)/oligo$(dT)_{18}$, A/T = 2/1) in 60 min at 37 °C under normal reaction conditions for each enzyme. Enzyme activity in the absence of the compound was taken as 100%. Data are shown as the means ± SEM of four independent experiments

To determine whether the inhibitor resulted in binding to DNA or the enzyme, the interaction of lutein (**1**) with dsDNA was investigated based on the thermal transition of dsDNA with or without the compound. The Tm of dsDNA with an excess amount of lutein (**1**) (100 μM) was measured using a spectrophotometer equipped with a thermoelectric cell holder. In the concentration range used, thermal transition of Tm was not observed, whereas ethidium bromide used as a positive control, a typical intercalating compound, produced a clear thermal transition. We then investigated whether an excessive amount of nucleic acid (i.e., poly(rC)) or protein (i.e., bovine serum albumin (BSA)) could prevent the inhibitory effect of lutein (**1**) to determine whether the effect resulted from their non-specific adhesion to mammalian pols β and λ, or selective binding to specific sites. Poly(rC) and BSA had little or no influence on the pol inhibitory effect of lutein (**1**), suggesting that binding to the pol molecule occurs selectively. These observations indicated that lutein (**1**) did not intercalate to DNA as a template-primer, and the compound could directly bind to the enzyme and inhibit its activity.

These results suggested that lutein (**1**) might be a potent and selective inhibitor of mammalian repair/recombination-related pols, such as pols β and λ.

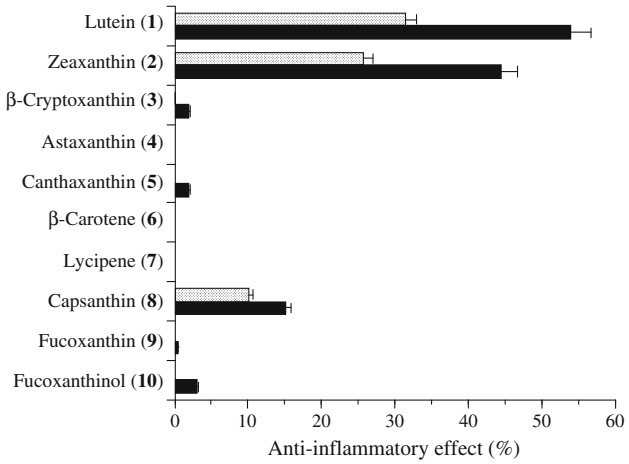

Fig. 2 Anti-inflammatory activity of carotenoids (compounds **1–10**) toward TPA-induced edema on mouse ear. 250 μg (*gray bar*) and 500 μg (*black bar*) of compounds **1–10** were applied individually to one ear of each mouse, and after 30 min TPA (0.5 μg) was applied to both ears. Edema was evaluated after 7 h. The inhibitory effect is expressed as the percentage of edema. Data are shown as the means ± SEM of six independent experiments

Anti-Inflammatory Effects of Lutein-Related Carotenoids (Compounds **1–10**)

We previously reported a relationship between mammalian pol λ inhibitors and anti-inflammatory activity [30–33]. Using the mouse inflammatory test, we examined the anti-inflammatory properties of the carotenoids. An application of TPA (0.5 μg) to the ear induced edema, the weight of an ear disk 7 h after the application having increased 241%. As shown in Fig. 2, lutein (**1**) achieved the strongest reduction in TPA-induced inflammation among the compounds tested, and the inhibitory effect was 31.4 and 54.0% for 250 and 500 μg/ear, respectively. The 2nd and 3rd compounds, zeaxanthin (**2**) and capsanthin (**8**), respectively, showed inhibitory effects, but other compounds had little or no effect on inflammation. The effect of ten carotenoids on anti-inflammation showed almost the same tendency as the inhibitory effect on pols β and λ (Fig. 1).

TPA is a compound that promotes tumorigenesis [34], and is generally used as an artificial inducer of

inflammation [35, 36]. TPA-induced inflammation can be distinguished from acute inflammation, and is accompanied by fibroblastic proliferation and granulation. These results suggested that the molecular basis of the so-called promotion of oncogenesis involves a biochemical process which requires pols, especially repair/recombination-related pol λ; therefore, some carotenoids, such as lutein (**1**), could have anti-inflammatory activity based on its inhibition of mammalian pol λ.

Structure and Bioactivity Relationship of Lutein-Related Carotenoids

Lutein (**1**), a xanthophyll family of carotenoid, consists of chains with 8 conjugated double bonds (polyene chain) containing closed rings at each end of the chain. Zeaxanthin (**2**) is a stereoisomer of lutein (**1**), differing only in the location of a double bond in one of the hydroxyl groups. Figure 3a shows the chemical structures between bioactive

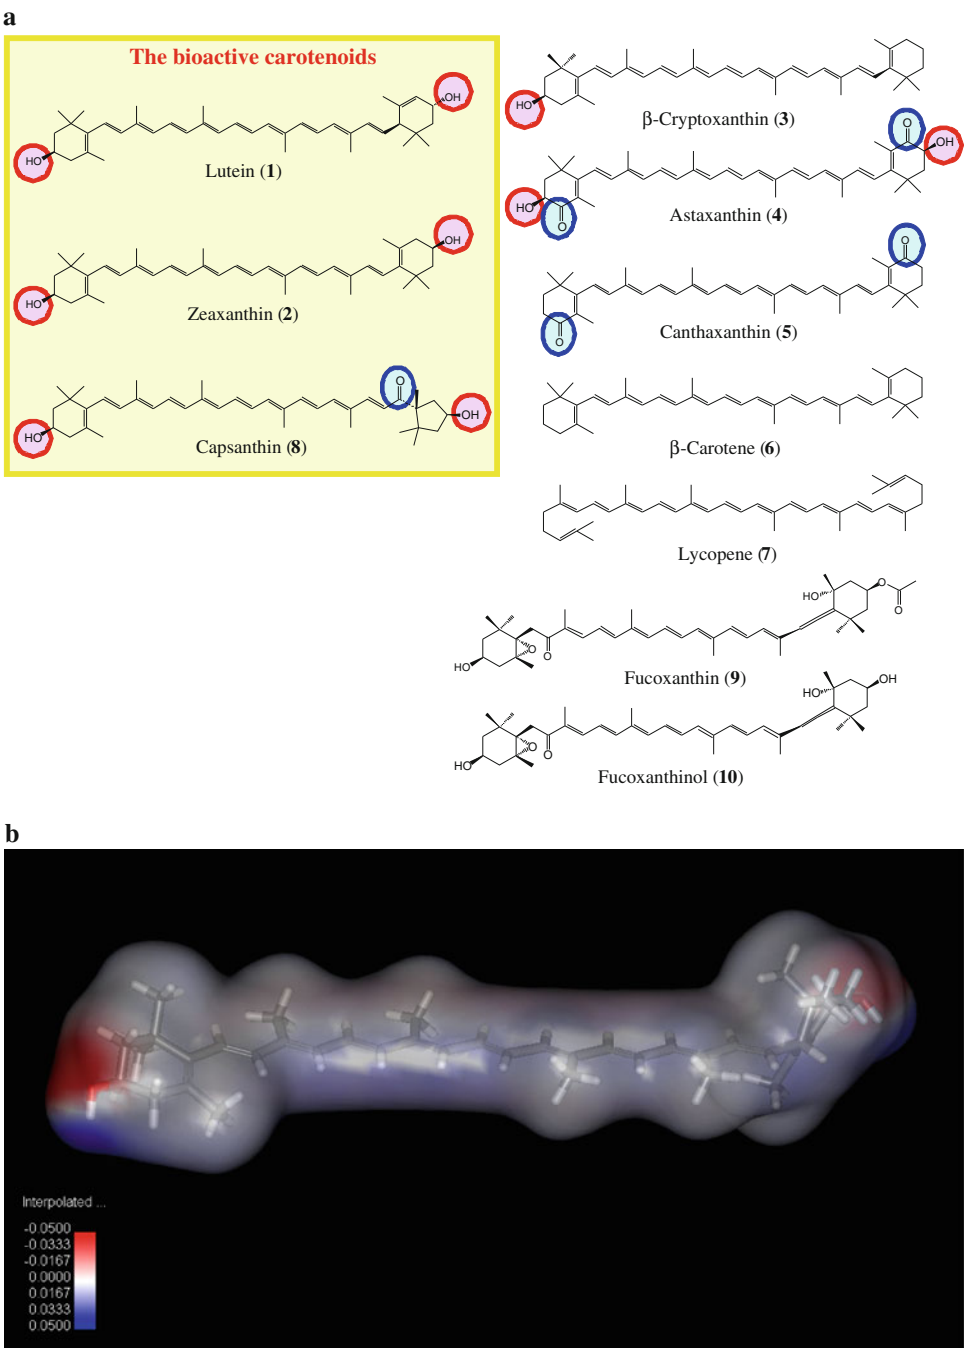

Fig. 3 Chemical structures of bioactive carotenoids. **a** Bioactive carotenoids, which have mammalian pols β and λ inhibitory activity and anti-inflammatory activity, are shown. Lutein (**1**), zeaxanthin (**2**), β-cryptoxanthin (**3**), astaxanthin (**4**), canthaxanthin (**5**), β-carotene (**6**), lycopene (**7**), capsanthin (**8**), fucoxanthin (**9**) and fucoxanthinol (**10**). Hydroxyl and ketone groups are highlighted by *red* and *blue circles*, respectively. **b** Stick model of energy-minimized three-dimensional structure of lutein (**1**) was built using the Discovery Studio (DS) 2.1 modeling software (Accelrys Inc., San Diego, CA, USA). Carbons, oxygens and hydrogens are indicated in *gray*, *red* and *white*, respectively. Electrostatic potential over commonly surfaces was also analyzed using DS. *Blue areas* are positively charged, *red areas* are negatively charged, and white areas are neutral

carotenoids [i.e., lutein (**1**), zeaxanthin (**2**) and capsanthin (**8**)] and other compounds. In the bioactive carotenoids, two hydroxyl groups (i.e., red circles in Fig. 3a) one on each side of the carotenoid molecule must be important for pols β and λ inhibition and anti-inflammation. Although astaxanthin (**4**) has two hydroxyl groups on both side rings, this compound did not show prominent inhibitory activities against these pols and the anti-inflammatory effect; therefore, two ketone groups (i.e., blue circles in Fig. 3a) on both sides of the carotenoid molecule markedly prevented these activities. Since fucoxanthin (**9**) and fucoxanthinol (**10**) had no inhibitory effects on pol activity and inflammation, these frames of the carotenoids must significantly prevent bioactivity.

Lutein (**1**) was the strongest inhibitor of mammalian pols β and λ and had the strongest anti-inflammation activity of the carotenoids tested. To obtain information about the molecular basis of the difference in inhibition between lutein (**1**) and its nine related carotenoids, computational analysis was performed using molecular simulation and surface analysis software. As shown in Fig. 3b, energy-minimized three-dimensional structure of lutein (**1**) is stick shaped, and both sides of the compound consist of a ball-like conformation. The length and width of this molecule were 30 and 5.0 Å, respectively, which might fit the pocket of the active site in mammalian pols β and λ. Lutein (**1**) consists of both hydrophilic ends and a hydrophobic center, and the distribution of positive- and negative-charged regions in the hydrophilic areas of the both sides must be important for bioactivity.

Discussion

Evaluation of the purified carotenoids (compounds **1**–**10**) revealed that the inhibitory activities of pols β and λ had a high correlation with the anti-inflammatory effect (Figs. 1, 2). On the other hand, no compounds affected the activity of replicative pol α. These results led to the speculation that TPA-induced inflammation may involve a process requiring repair/recombination-related pols.

Pols β and λ are in the pol X family [37]. Although the in vivo biochemical function of pol λ is unclear as yet, pol λ appears to work in a similar manner to pol β. Pol β, which is widely known to have roles in the short-patch base excision repair (BER) pathway [38–41], plays an essential role in neural development [42]. Recently, pol λ was found to contain 5′-deoxyribose-5-phosphate (dRP) lyase activity, but no apurinic/apyrimidinic (AP) lyase activity [43] and to be able to substitute pol β in in vitro BER, suggesting that pol λ also participates in BER. Northern blot analysis indicated that transcripts of pol β were abundantly expressed in the testis, thymus, and brain in rats [44], but pol λ was efficiently transcribed mostly in the testis [37]. Bertocci et al. [45] reported that in mutant mice in which pol λ was knocked out were not only viable and fertile, but also displayed a normal hyper-mutation pattern.

TPA not only causes inflammation, but also influences cell proliferation and has physiological effects on cells because it is a tumor promoter [36]; therefore, anti-inflammatory agents are expected to suppress both mammalian cell proliferation and DNA replication/repair in nuclei related to the action of TPA. Since pol λ is a repair-related pol [46], the result that the molecular target of carotenoids was pol λ is well-matched. If so, the pol λ inhibitor might be an inhibitor of chronic inflammation. A positive relationship between anti-inflammatory and pol λ-inhibitory activities was found, and this might be useful as a new and convenient in vitro assay to screen for novel anti-chronic inflammatory compounds.

Lutein (**1**) is one of over 600 known naturally occurring carotenoids. Found in green leafy vegetables such as spinach and kale, this compound is employed by organisms as an antioxidant and for blue light absorption. Lutein is sometimes present in plants as fatty-acid esters, with one or two fatty acids bound to the two hydroxyl groups. Saponification of lutein esters yields lutein in approximately a 1:2 M ratio. This compound is also found in egg yolks, animal fats and the corpus luteum. Lutein is a lipophilic molecule and is generally insoluble in water. The presence of the long chromophore of conjugated double bonds provides the distinctive light-absorbing properties. The polyene chain is susceptible to oxidative degradation by light or heat and is chemically unstable in acids. Lutein is widely known as the primary nutrient for protecting ocular function. No toxicities or adverse reactions have been reported in the scientific literature for lutein at doses of up to 40 mg daily for 2 months [47]. It has long been thought that carotenoid intake also reduces the risk of certain forms of cardiovascular disease [48–50], stroke [51, 52] and cancer [53, 54]. From this study, we could suggest that some carotenoids, such as lutein, have new bioactivity as anti-inflammation.

In conclusion, the inhibitory effects on repair/recombination-related pols had the same tendency as on TPA-induced inflammation, suggesting that the inhibitory activity of pol λ might be important for the anti-inflammatory effect. A biologically active carotenoid, lutein, was isolated from pressed unrefined canola (rapeseed) oil. It is likely that a significant portion of the lutein would be removed during the bleaching step of conventional refining, bleaching and deodorization [55]. A cold pressed unrefined canola oil may have valuable anti-inflammatory properties and inhibit mammalian pol λ. Carotenoids, especially lutein (**1**), may provide valuable structural information that can be used in a drug design strategy for new anti-inflammatory agents.

Abstract Increased oxidative stress is associated with type-2 diabetes and related cardiovascular diseases, but oxidative modification of LDL has been partially characterized. Our aim was to compare the lipid and fatty acid composition as well as the redox status of LDL from diabetic patients and healthy subjects. First, to ensure that isolation of LDL by sequential ultracentrifugation did not result in lipid modifications, lipid composition and peroxide content were determined in LDL isolated either by ultracentrifugation or fast-protein liquid chromatography. Both methods resulted in similar concentrations of lipids, fatty acids, hydroxy-octadecadienoic acid (HODE) and malondialdehyde (MDA). Then, LDLs were isolated by ultracentrifugation from eight type-2 diabetic patients and eight control subjects. Compared to control LDL, diabetic LDL contained decreased cholesteryl esters and increased triglyceride concentrations. Ethanolamine plasmalogens decreased by 49%. Proportions of linoleic acid decreased in all lipid classes, while proportions of arachidonic acid increased in cholesteryl esters. Total HODE concentrations increased by 56%, 12- and 15-hydroxy-eicosatetraenoic acid by 161 and 86%, respectively, and MDA levels increased by twofold. α-Tocopherol concentrations, expressed relative to triglycerides, were lower in LDL from patients compared to controls, while γ-tocopherol did not differ. Overall, LDL from type-2 diabetic patients displayed increased oxidative stress. Determination of hydroxylated fatty acids and ethanolamine plasmalogen depletion could be especially relevant in diabetes.

ELSD	Evaporative light-scattering detector
Etn-PL	Ethanolamine phospholipids
FPLC	Fast-protein liquid chromatography
GPE	Glycerophosphoethanolamine
HETE	Hydroxy-eicosatetraenoic acid
HODE	Hydroxy-octadecadienoic acid
MDA	Malondialdehyde

MUFA	Monounsaturated fatty acids
PC	Phosphatidylcholine
PL	Phospholipid
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
SM	Sphingomyelin
TBA	Thiobarbituric acid
TBARS	Thiobarbituric acid reactive species
TG	Triacylglycerols
UC	Ultracentrifugation

Introduction

Type-2 diabetes is associated with an increased risk for atherosclerosis. There is strong evidence that oxidative stress plays a key role in the onset of diabetes [1] and in the development of vascular complications of the disease [2]. Low-density lipoproteins (LDL) are important targets of oxidation, and oxidative modification of LDL is involved in the pathogenesis of atherosclerosis [3]. Oxidative stress has been mostly assessed in plasma from diabetic patients, which showed increased concentrations of thiobarbituric acid-reactive species (TBARS) [4] and isoprostanes [5], both end-products of lipid peroxidation. Evidence for increased oxidative stress in LDL from type-2 diabetic patients is indirect, mostly based on increased plasma levels of autoantibodies against oxidatively modified LDL [6]. More data on specific parameters of LDL oxidation are therefore needed and could be useful to define predictive biomarkers for cardiovascular risk.

The aim of this study was to assess oxidative stress specifically in LDL from type-2 diabetic patients compared to LDL from healthy subjects. First, we compared the lipid composition and redox status of LDL isolated by the conventional sequential flotation ultracentrifugation (UC) to that of LDL separated by fast-protein liquid chromatography (FPLC) in order to check if isolation of LDL by UC did not lead to artifactual oxidation of the particles, as previously suggested [7]. Then, we performed detailed analysis of lipid classes including fatty acids and different complementary markers of lipid peroxidation in diabetic and control LDL.

Materials and Methods

Blood Collection

Regarding the comparative study of LDL separated by UC or FPLC, venous blood from three healthy blood donors (33 ± 13 years) was collected on citrate phosphate dextrose (citrate 15.6 mM, sodium citrate 89.4 mM, monosodic phosphate 16.1 mM, dextrose 128.7 mM, pH 5.6, one volume for seven volumes of blood) as an anticoagulant. Plasma was immediately separated by centrifugation at 1,500*g* for 10 min and spiked with 1 mM EDTA and 10 μM butylhydroxytoluene (BHT).

Regarding the clinical study, type-2 diabetic patients (8 men, aged 59 ± 2 years) recruited in the Department of Endocrinology and Metabolic Diseases (HCL Lyon) were matched for sex and age to healthy subjects (8 men, aged 51 ± 4 years). Exclusion criteria were smoking, antioxidant/vitamin supplementation, anti-aggregatory drugs and insulin treatment. Hypolipidemic drug (statins and fibrates) treatment was suspended for 7 days before venipuncture. Control subjects were in good health as assessed by medical history, and exclusion criteria were any pathology including diabetes. Written informed consent was obtained from all participants, and the study was approved by the local ethics committee (CCP Sud Est IV). Plasma was separated by centrifugation at 1,500*g* for 10 min of blood collected on EDTA; 10 μM BHT was added to plasma, which was immediately frozen at −80°C under nitrogen for further characterizations.

LDL Isolation by Ultracentrifugation

LDLs (density 1.019–1.063) were separated from plasma by potassium bromide stepwise UC. UC was carried out in a TLA 100.3 fixed-angle rotor of a Beckman TL-100 table top UC (Beckman Coulter France, Roissy CDG, France). The LDL fraction was dialyzed extensively against phosphate buffered saline (NaCl 136.8 mM, KCl 2.6 mM, KH_2PO_4 1.71 mM, Na_2HPO_4, $12H_2O$ 8 mM, pH 7.2) containing 1 mM EDTA.

LDL Isolation by FPLC

LDLs were isolated from plasma by gel filtration chromatography at 4°C as previously described [8] and modified as follows [9]. Briefly, a BioRad System FPLC (Bio-Rad Laboratories, Marnes-la-Coquette, France) equipped with a Superose 6 HR 10/30 column (GE Healthcare Europe GmbH, Munich, Germany) was used with 10 mM Tris-HCl, 150 mM NaCl, pH 7.4 buffer containing 2 mM EDTA and 0.02% sodium azide as a running buffer. After loading filtered plasma, chromatography was carried out with a flow rate of 0.3 ml/min under a pressure of 150 psi. Fractions of 0.3 ml were collected, and the concentrations of triglycerides (TG) and total cholesterol in the eluted fractions were measured (BioMérieux, Marcy l'Etoile, France). LDL fractions were concentrated on a Millipore filter of 30,000 MW (10 min at 4,000*g*).

Protein, Total LDL Cholesterol and Triacylglycerol Determinations

Colorimetric determination of protein concentration was processed according to the modified Lowry method [10]. Enzymatic determination of total cholesterol and TG were processed using commercial kits (BioMérieux, Marcy l'Etoile, France).

LDL Cholesterol Determination

Lipid classes were separated by HPLC coupled to an Evaporative Light Scattering Detector (ELSD) according to the modified method of Seppanen-Laakso [11].

Fatty Acid Composition of LDL Lipid Classes

After the addition of appropriate internal standards (1,2-diheptadecanoyl-sn-glycero-3-phosphocholine, 1,2-diheptadecanoyl-sn-glycero-3-phosphoethanolamine, 1,2,3-triheptadecanoyl-sn-glycerol and heptadecanoyl cholesteryl ester), total LDL lipids were extracted twice by the addition of ethanol (3 vol) and chloroform (6 vol) in the presence of BHT (50 μM). Lipid classes were then separated by thin-layer chromatography. The first solvent mixture chloroform/methanol (80:8, v/v) allowed us to separate neutral lipids from phospholipids (PL). The second solvent mixture chloroform/methanol/water (63:27:4, by vol.) separated phosphatidylcholines (PC), ethanolamine phospholipids (Etn-PL) and sphingomyelins (SM). Neutral lipids were separated in TG and cholesteryl esters (CE) by a second thin-layer chromatography using hexane/diethylether/acetic acid (80:20:1, by vol.) as solvent. The different spots were scrapped off, treated with trifluoride boron/methanol (1:1, v/v) for 90 min at 100°C. The derivatized fatty acid methyl esters were then extracted twice with isooctane and separated by GLC, using an HP 6890 gas chromatograph equipped with a SP 2380 capillary column (0.25 μm, 30 m × 0.25 mm, Supelco, Bellefonte, PA).

Quantification of Total LDL Monohydroxylated Fatty Acids

Following the lipid extraction as described above, dried extracts were subjected to ethanolic hydrolysis with 10 M KOH for 20 min at 60°C [12]. No reduction of lipid hydroperoxides was carried out. Non-esterified hydroxylated fatty acids and fatty acids were first separated on an Oasis Sep-Pak cartridge column (Waters, Milford, MA). The column was activated with 6 ml of methanol and 6 ml of water before loading the sample. Then, it was washed with 8 ml of 2% NH_4OH water and 8 ml of methanol. Products were eluted with 8 ml of acetonitrile/2-propanol (60:40, v/v) containing 5% formic acid. Non-esterified hydroxylated fatty acids were secondly separated by thin-layer chromatography with hexane/diethylether/acetic acid (60:40:1, by vol.) as mobile phase and extracted from silica with methanol. Then, hydroxylated fatty acids were separated by reverse phase-HPLC on X Bridge C_{18} column (3.5 μm, 4.6 × 150 mm column, Waters, Milford, MA) using a gradient solvent of acetonitrile and water (pH 3) and detected at 235 nm.

Malondialdehyde Determination in LDL

Malondialdehyde (MDA) concentration was determined by RP-HPLC according to the method of Therasse and Lemonnier [13]. LDL samples, mixed with thiobarbituric acid (TBA) (10 mM), acetic acid and BHT (5 mM), were heated for 60 min at 95°C. The TBA-MDA adducts were then extracted with ethyl acetate and separated onto a Nucleosil C_{18} column (5 μm, 4.6 × 250 mm, Macherey–Nagel, Hoerdt, France) using methanol/water (20:80, v/v) as mobile phase. Detection was performed by fluorimetry (excitation 515 nm, emission 553 nm).

Vitamin E Determination in LDL and Plasma

Tocopherol concentrations were determined by RP-HPLC [14]. Tocopherols were first extracted from LDL and plasma (1 vol) twice with hexane (4 vol) after the addition of ethanol (1 vol). Then, they were separated onto a Nucleosil C_{18} column (5 μm, 4 × 150 mm, Macherey-Nagel, Hoerdt, France) using methanol/water (98:2, v/v) as mobile phase. Detection was performed by fluorimetry (excitation 295 nm, emission 340 nm) and quantification was allowed by the addition of tocol as an internal standard.

Statistical Analysis

Results are expressed as the mean ± SEM. Comparisons between groups were performed using a non-parameter Mann-Whitney test. Statistical significance was established at $p \leq 0.05$. Correlation coefficients were determined using linear regression analysis.

Results

Comparison of LDL Isolated by Ultracentrifugation and Fast-Protein Liquid Chromatography

In order to determine whether isolation of LDL by UC generated LDL with a lipid composition and lipid redox

status comparable to those issued from FPLC separation, fresh plasma samples from healthy volunteers were subjected in parallel to the two procedures. There were no differences between lipid composition in LDL either separated by UC or FPLC. As expected, CE was the major lipid class in LDL (51%) followed by cholesterol (29%) and few TG (3.4%). PCs were the major phospholipids present in LDL (11%) (data not shown).

The GLC analysis of fatty acid methylesters derived from Etn-PL allowed us to determine the fatty dimethylacetals (DMA) representative of alkeny,acyl-GPE (or PE plasmalogens), a subclass particularly sensitive to oxidative stress. No difference in total DMA concentrations was found between both methods of isolation (6.1 ± 1.7 nmol/mg protein in LDL isolated by UC vs. 4.6 ± 2.9 nmol/mg protein in LDL isolated by FPLC) representing 15.8 ± 4.6% vs. 12.5 ± 8% total fatty acids in Etn-PL, respectively.

The concentrations of linoleic acid (18:2n-6), the most abundant polyunsaturated fatty acid (PUFA) and substrate for lipid peroxidation, were similar in LDL either isolated by UC or FPLC (1,638 ± 44 vs. 1,543 ± 17 nmol/mg protein). As shown in Table 1, the stable primary products issued from the peroxidation of 18:2n-6, 9-hydroxy-octadecadienoic acid (HODE) and 13-HODE represented 0.05% of the parent molecule and were present in similar concentrations regardless of the LDL isolation method. The ratio of total HODEs to its parent fatty acid was also similar in LDL isolated by UC or FPLC. One of the aldehydes arising from the decomposition of fatty acid hydroperoxides, MDA, was found to be formed in similar amounts in LDL either separated by UC or FPLC. Concerning the main antioxidants, α- and γ-tocopherol were present in similar concentrations in LDL isolated by either method. Overall, the lipid composition and the redox status were similar whatever the LDL separation method.

Table 1 Redox status of LDL isolated by UC or FPLC

	UC	FPLC
9-HODE (pmol/mg cholesterol)	217 ± 140	196 ± 132
13-HODE (pmol/mg cholesterol)	242 ± 47	228 ± 25
HODE/18:2n-6 (μmol/mol)	519 ± 162	499 ± 151
MDA (pmol/mg cholesterol)	118 ± 9	131 ± 32
α-tocopherol (nmol/mg cholesterol)	3.68 ± 0.58	3.68 ± 0.72
γ-tocopherol (nmol/mg cholesterol)	0.39 ± 0.14	0.31 ± 0.06

Lipid Composition and Redox Status of LDL from Diabetic Patients Compared to LDL from Healthy Subjects

Clinical Characteristics

Type-2 diabetic patients ($n = 8$) had poorly controlled diabetes as shown by elevated values of glycated hemoglobin HbA_{1c} (10.6 ± 0.9%) and glycemia (9.2 ± 1.3 mM) compared to healthy volunteers (5.4 ± 0.1% and 5.6 ± 0.2 mM, respectively, $n = 8$). They presented a metabolic syndrome as assessed by their large waist circumference of 118.1 ± 8.4 cm, elevated TG of 2.5 ± 0.2 mM and low HDL-cholesterol of 0.9 ± 0.1 mM [15]. Sex- and age-matched healthy volunteers had values of waist circumference (91.3 ± 1.7 cm), TG (1.3 ± 0.1 mM) and HDL-cholesterol (1.4 ± 0.1 mM) in the expected normal range.

Lipid and Fatty Acid Compositions of Diabetic LDL Compared to Control LDL

The concentrations of main lipid classes were determined in LDL from type-2 diabetic patients and healthy subjects (Table 2). In diabetic LDL, the concentration of CE, the main LDL lipid class, decreased by 21%, whereas concentrations of TG increased by 75%. No changes in cholesterol, PC and Etn-PL concentrations were observed between the two groups.

The fatty acid composition of the main LDL lipid classes, namely CE and PC, showed several differences between diabetic patients and control subjects. As shown in Table 3, PUFA represented 62% of the total fatty acids in CE from control LDL, and their proportion significantly decreased in diabetic LDL. In particular, 18:2n-6, the main PUFA, decreased, whether expressed in mole percent (−11%) or in nmol/mg protein (−30%). Arachidonic acid

* $p \leq 0.05$ and ** $p \leq 0.01$ compared with LDL from healthy subjects

(20:4n-6) proportion significantly increased by 43% in diabetic LDL, unlike its concentration. An increase in saturated fatty acid (SFA) proportion was observed, while the monounsaturated fatty acid (MUFA) proportion was unchanged between the two groups (Table 3). Concerning PC, the main PL class, lower proportions and concentrations of the major fatty acid 18:2n-6 (−12 and −17%, respectively) were present in diabetic LDL compared to control LDL, while the proportion of 20:4n-6 tended to increase. No significant changes of SFA and MUFA were observed (Table 4). In Etn-PL including the PE plasmalogen subclass, DMA represented 22.9% of the total fatty chains present in Etn-PL from control LDL and only 11.8% of those in PE from diabetic LDL. The 49% decrease reflected a significant decrease of each DMA species, namely 16:0, 18:0 and 18:1n-9 DMA produced by transmethylation of the sn-1 position of plasmalogens (Fig. 1). The sum of DMA species negatively correlated with HbA_{1c} % ($r^2 = 0.61, p < 0.001$).

Lipid Peroxide and Antioxidant Content of Diabetic LDL Compared To Controls

The concentrations of total (both free and esterified) hydroxylated fatty acids, the stable primary products of non-enzymatic peroxidation of PUFA, were assessed in LDL from patients and control groups. As shown in Table 5, 9-HODE and 13-HODE, derived from 18:2n-6, were detected, and their concentrations significantly increased by 49 and 44%, respectively. In addition, the ratio of total HODE to its parent fatty acid increased by

HETE hydroxy-eicosatetraenoic acid, *HODE* hydroxy-octadecadienoic acid

5- and 9-HETE. The concentrations of 12-HETE and 15-HETE increased by 161 and 86%, respectively, whereas the ratio of HETE to 20:4n-6 did not increase significantly. Concentrations of MDA significantly increased by twofold in diabetic LDL compared to control LDL (102 ± 18 vs. 49 ± 5 pmol/mg cholesterol, respectively, $n = 7$ to 8). They positively correlated with HbA_{1c} % ($r^2 = 0.62$, $p < 0.001$).

α-Tocopherol concentrations in LDL did not differ between patients and controls when expressed per mg cholesterol (3.47 ± 0.43 vs. 2.79 ± 0.24 nmol/mg cholesterol). However, when expressed relative to TG, α-tocopherol levels significantly decreased by 32% in LDL from diabetic patients compared to control subjects (14.3 ± 1.1 vs. 21.2 ± 2.5 nmol/mg TG, $p < 0.05$). γ-Tocopherol did not significantly change in diabetic LDL compared to control LDL when expressed per mg cholesterol (0.46 ± 0.08 vs. 0.29 ± 0.06 nmol/mg cholesterol) or per mg TG (1.8 ± 0.3 vs. 2.3 ± 0.5 nmol/mg TG). In plasma, α-tocopherol concentrations did not differ between diabetic patients and control subjects (12.2 ± 1.2 vs. 11.9 ± 1.2 μmol/l). The concentrations of plasma α-tocopherol in patients (5.4 ± 0.5 mmol/mol TG) were significantly lower than concentrations in controls (9.8 ± 0.7 mmol/mol TG) when expressed relative to TG, but not when expressed relative to cholesterol (2.8 ± 0.5 vs. 2.0 ± 0.2 mmol/mol cholesterol). γ-Tocopherol concentrations were similar in plasma from diabetic patients and controls (1.7 ± 0.3 vs. 1.6 ± 0.4 μmol/l) and whether expressed relative to cholesterol (0.41 ± 0.10 vs. 0.25 ± 0.06 mmol/mol cholesterol) or TG (0.68 ± 0.09 vs. 1.22 ± 0.21 mmol/mol TG).

Discussion

In the present study, we first compared LDL isolated by UC to those isolated by FPLC in order to use a method expected to minimize the artifactual oxidative modification of the particles during processing. It has indeed been suggested that conventional UC may cause structural changes in lipoproteins, whereas FPLC does not affect lipoprotein structure [7]. Our results show that the isolation of lipoproteins by UC or FPLC results in similar concentrations of lipids, fatty acid proportions and lipid peroxide content in LDL. Proportions of lipid classes were equivalent in LDL isolated by either method and close to those reported in the literature [16, 17]. Concentrations of PE plasmalogens particularly prone to oxidation [18] were similar in LDL, whatever the method of isolation, suggesting that the procedure of UC and dialysis was not more damaging than FPLC.

Regarding the substrates for lipid peroxidation in LDL isolated by UC, total concentrations of PUFA were 2,074 nmol/mg protein, including 1,638 nmol/mg protein of 18:2n-6, in good agreement with published data [19, 20]. Similar concentrations were obtained after FPLC isolation of LDL (1,961 nmol/mg protein PUFA including 1,543 nmol/mg protein 18:2n-6), indicating that PUFAs were not more autooxidized in LDL separated by UC and further dialyzed. In accordance with the PUFA composition of LDL, very little peroxidation of PUFA occurred in LDL from healthy volunteers since hydroxylated derivatives of 18:2n-6 (9- and 13-HODE) represented 0.05% of the parent molecule, whatever the method of LDL isolation. Finally, concentrations of MDA, commonly used as an index of overall lipid peroxidation, and of tocopherol isomers, the main LDL antioxidants, were similar in LDL either isolated by UC and FPLC. This rules out a loss of

MDA and vitamin E during the dialysis process following UC, as previously reported [21, 22]. As separation of lipoproteins by UC led to LDL particles with lipid and lipid peroxide contents comparable to those issued from FPLC, UC was used to determine the profile of LDL from type-2 diabetic patients compared to that of LDL from healthy subjects.

Although there is evidence of increased oxidative stress in type-2 diabetes, it has been mainly based to date on the measurement of a single biomarker, not reflecting the overall oxidative damage. In addition, oxidative stress has been mostly assessed in plasma [23] and not in LDL. We provide evidence that LDL from type-2 diabetic patients displayed increased oxidative stress compared to LDL from healthy volunteers. First, diabetic LDL showed increased TG and decreased CE. Such a modified lipid composition may reflect a higher percentage of small dense LDLs, which are known to be more prevalent in type-2 diabetes [24, 25]. It has indeed been shown that small, dense, TG-rich LDL particles are subjected to exchange processes that remove CE from the core and replace it with TG [26, 27], and are more susceptible to oxidation [28]. To identify original markers of oxidative stress in LDL from diabetic patients, different complementary indices representative of different steps in the lipid peroxidation process were assessed. We show that PE plasmalogens decreased by 49% in diabetic LDL compared to control LDL. Plasmalogens were shown to contribute to the oxidation resistance of LDL and can serve as endogenous antioxidants in situ and in vitro [18, 29]. Loss of plasmalogens in LDL could represent a marker of oxidative stress in diabetic patients. In addition, plasmalogens have been involved in many diseases [30], but to our knowledge, this is the first evidence for decreased concentrations of plasmalogens in type 2 diabetes.

Since 18:2n-6 and 20:4n-6 are the main PUFA in LDL, their stable primary products of peroxidation, HODE and HETE, were determined as well as the ratio of oxidation product to parent fatty acids, described as a biomarker of oxidation status of LDL [31]. We show for the first time that both free and esterified HODE, representing 0.04% of the parent molecule in control LDL, increased by 49% in LDL from diabetic patients. This reflects free radical peroxidation of 18:2n-6 and is in line with the decrease of 18:2n-6 in the PUFA-rich, lipid classes, CE and PC. Consequently, the HODE to 18:2n-6 ratio was significantly higher (+58%) in diabetic LDL than in control LDL. Because of the lack of appropriate standards, we could not confirm the presence of trans,trans-HODE stereoisomers as shown in plasma [32, 33], but cannot exclude them. Total HETE represented 0.08% of the parent molecule in control LDL, indicating that 20:4n-6 is more susceptible to oxidation. 12- and 15-HETE increased by 161 and 86% in diabetic LDL, while 8- and 11-HETE tended to increase. However, there was no significant increase of the HETE to 20:4n-6 ratio due in part to the increased proportion of 20:4n-6 in CE. This paradoxical increase of 20:4n-6 cannot be explained from the present investigation, but might result from exacerbation of Δ6 and Δ5 desaturase activities in type-2 diabetes leading to increased production of 20:4n-6 from 18:2n-6. As insulin activates both enzymes [34], this situation may occur in type-2 diabetes, which is associated with chronic hyperinsulinemia periods. Finally, increased lipid peroxidation in LDL from diabetic patients compared to control LDL was confirmed by twofold increased concentrations of MDA. This is in agreement with previously reported increased levels of serum lipid peroxides, measured as thiobarbituric acid-reactive substances, in plasma from patients suffering from diabetes [4, 35]. Regarding the main lipid-soluble antioxidant in LDL, α-tocopherol, its concentration was significantly lower in LDL from diabetic patients compared to control LDL when expressed relative to TG, but not when expressed relative to cholesterol. Similar results were obtained in plasma. While most studies did not show any difference in α-tocopherol between diabetic patients and control subjects [4], a previous study also reported decreased α-tocopherol-to-TG ratios, but unchanged α-tocopherol-to-total cholesterol ratios in LDL [36]. Although these results need to be confirmed in a larger population, the decrease of plasma and LDL α-tocopherol relative to TG in patients could be simply due to increased triglycerides levels in diabetic patients.

Altogether, our results show higher levels of lipid peroxidation markers in LDL from poorly controlled type 2 diabetic patients compared to control LDL. Since significant negative and positive correlations between HbA_{1C}% and plasmalogens and MDA, respectively, were observed, it can be then hypothesized that the increased non-enzymatic glycation of LDL, as assessed by HbA_{1C}, could have contributed to the increased non-enzymatic lipid peroxidation of LDL in patients [37]. The role of these modified parameters in the biological properties of oxidatively modified LDL in atherosclerosis still needs to be elucidated.

In conclusion, we show that isolation of LDL by UC is no more damaging than FPLC separation, as far as oxidative modification of lipids is concerned. We give new information on the baseline values of different and complementary lipid peroxides present in LDL from healthy subjects, which may serve as references to unravel lipid abnormalities in LDL from diabetic patients. We also show that increased lipid peroxidation is present in LDL from type-2 diabetic patients and may be evidenced by the measurement of hydroxylated fatty acids and PE plasmalogens.

Acknowledgments We thank the subject participants for their contribution. We also thank the nursing staff at the Hospices Civils de Lyon for their help with blood sample collection and some analyses. METHODS

Isomerization of 9c11t/10t12c CLA in Triacylglycerols

Alfred A. Christy

Received: 20 May 2010 / Accepted: 16 July 2010 / Published online: 6 August 2010

Abstract Isomers of conjugated linoleic acid from 7t9c through 12t14t can be induced by thermal treatment of triacylglycerol samples of 9c11t or 10t12c fatty acids in glass tubes. The formation of conjugated linoleic acids (CLAs) has been observed during thermal induction of the above-mentioned triacylglycerols at 250, 280 and 320°C. The concentrations of isomers formed in the mixture varied depending on the temperature and duration of the heating experiments. The objective of this study was to find a suitable thermal induction temperature and time that can produce most of the isomers of CLAs from the above-mentioned triacylglycerols. Such a mixture would give researchers a reference standard that can be used in the identification of CLAs in GC analyses of relevant samples. Fifteen-microlitre portions of the triacylglycerol samples containing 9c11t/10t12c fatty acid were placed in micro-glass ampoules, sealed under nitrogen and then subjected to thermal treatment. The glass ampoules were removed at regular time intervals, cut open, and part of the samples was analysed by infrared spectroscopy using attenuated internal reflectance technique. The remainder of the samples was subjected to derivatisation into their methyl esters. The methyl esters of the isomerised fatty acids were then analysed by gas chromatography after appropriate dilution in heptane. The results show that the thermally induced glyceride samples of 9c11t/10t12c fatty acids gave CLA profiles containing isomers ranging from 7t9c to 12t14t. However, the concentrations of the isomers are different depending on the duration of the thermal induction. It appears that [1,5] sigmatropic rearrangements and positional isomerisations take place in the heated mixtures. The rearrangements and positional isomerisations are accelerated by increasing temperature. The glyceride samples heated to 325°C form isomers within 30 min and provide a mixture of CLA isomers that can be used as reference sample containing the methyl esters of CLAs.

Introduction

Research on conjugated linoleic acids (CLA) has become intense during the past few years because of their effects on carcinosis, atherosclerosis, the immune system, lipid metabolism and body composition. Furthermore, the focus on CLA is also due to their health benefits [1–9].

The conjugated isomers of linoleic acid in milk and fats are generally found in *trans*/*cis*, *cis*/*trans* and *trans*/*trans* forms. There are several conjugated linoleic acids present in milk and fat from the cud-chewing animals. Of these, 9c11t is dominant, with about 80–90% of all the conjugated linoleic acids. The isomer 7t 9c was found in most of the dairy products as the second dominant CLA fatty acid

e-mail: alfred.christy@uia.no

[10]. The isomer 9c11t is also thought to be the most biologically active [1, 2]. There are other isomers of CLAs in small concentrations [11]. These include *cis–cis*; *trans–trans*; *cis–trans* and *trans–cis* isomers of 7,9; 8,10; 9,11; 10,12 and 11,13 CLAs. There are 20 isomers from the above five CLA positional isomers. Several of these isomers have been identified in different food products. The 9c11t and 10c12t isomers are found in hydrogenated vegetable oils [11]. These are also found in equal proportion in the alkali isomerised methyl linoleate [13]. The concentrations of the other isomers are negligible [13].

The identification of different isomers of CLAs in samples of interest, in a chemical reaction aimed at synthesising CLA isomers or to prove or disprove the presence or absence of any CLA in a system of interest needs reference samples of CLAs. The two important CLAs namely 9c11t and 10t12c were prepared in large quantities by alkali isomerisation of 9c12c linoleic acid [14]. Eulitz et al. [14] synthesised eight CLA isomers, 8,10 through 11,13, by isomerising CLA mixtures by p-toluene sulfinic acid or iodine catalyst. Jain and Proctor [15] synthesised 9c11t, 9t11c, 10t12c and 10c12t CLA isomers in large quantities for the first time by UV photoirradiation of soya oil in the presence of iodine catalyst. The photoirradiation was carried out for 144 h to achieve this. Destaillats and Angers [16] were able to prepare 8t10c and 11c13t CLA isomers by heat teatment of 9c11t and 10t12c CLAs. Destaillats and Angers [11] demonstrated that the whole series of CLA isomers could be produced by starting from a mixture of methyl esters of 9c11t and 10t12c fatty acids. A two-step process was necessary in the preparation of these isomers: a heat-induced [1, 5] sigmatropic rearrangement in the first step and catalyst-induced positional isomerisation in the second. The formation of different isomers followed the mechanistic pathways outlined by Destaillats and Angers [11].

The chemistry and mechanistic pathways involved in the formation of CLAs as discussed in the research reports above spurred interest in looking at alternative ways of producing the isomers of CLAs. During preliminary investigations, it came to light that the [1, 5] sigmatropic transformations and positional isomerisations could be achieved by subjecting triacylglycerols of CLAs to a suitable high temperature. It was also clear that the duration of thermal treatment altered the concentrations of different isomers. The procedure adopted for the directed sequential synthesis of conjugated linoleic acids by Destaillats and Angers needed a total of 33 h (13 h for sigmatropic rearrangement reaction and 20 h for subsequent geometrical isomerisation) for the synthesis of CLA isomers ranging from $\Delta^{7,9}$ to $\Delta^{12,14}$. A straight-forward procedure that can reduce the isomerisation time and give a mixture that contains the same isomers should be preferred. The triacyl glycerols of 9c11t and 10t12c were selected because these can be easily prepared through alkali isomerisation, and then this mixture could be thermally induced to produce all the other isomers.

The aim of this paper is to demonstrate for the first time that the formation of CLA isomers ranging from 7,9 to 12,14 can be induced through the thermal induction of the triacylglycerol of 9c11t or 10t12c fatty acid. Furthermore, it is also the intention to look at the mechanistic aspects of the thermal induction for the formation of CLA isomers.

Experimental

Samples and Methods

The triacylglycerols of the 9c11t and 10t12c fatty acids were purchased from Larodan Chemicals, Sweden. The chemicals such as methanol, BF_3/methanol, NaOH, NaCl and $MgSO_4$ needed for derivatisation were purchased from Sigma-Aldrich. Methyl esters of 9c11t and 10t12c were prepared by esterification of the respective triacylglycerols.

The heating experiments were carried out in micro-glass ampoules as described in Ref. [17]. Three sets of glass ampoules containing the triacylglycerol samples were prepared. The first set of samples containing the triacylglycerols of the 9c11t or 10t12c fatty acids were placed in small glass vials and placed in a gas chromatographic oven (Agilent 5890) set at 250°C. Samples were then removed at 24-h intervals until the all the samples were exhausted. The experiment was repeated in the same manner with the second and third set of samples at 280 and 325°C except the samples treated at 325°C were removed at 30-min time intervals.

Infrared Spectroscopic Measurements

The samples from the thermal induction experiments were subjected to infrared measurements. A PerkinElmer Spectrum One FT-IR spectrometer equiped with a Harrick single reflectance ATR accessory and lead glycine sulphate detector was used in measuring the infrared spectra. Each sample was spread on the ATR crystal using a capillary glass tube. A total of 30 scans at a resolution of 4 cm^{-1} were then measured in the range of 4,000 to 600 cm^{-1} with previously scanned ATR crystal spectrum as the background. The ATR crystal was washed with acetone and dichloromethane after each measurement. A new capillary tube was used each time for the application of the sample to avoid cross contamination. All the infrared spectra were saved in absorbance format. Second derivative spectra of the absorption spectra were obtained using the derivative option in the scanning program of the instrument.

Gas Chromatographic Analysis

The glass ampoules containing the rest of the triacylglycerol samples were subjected to derivatisation as described in Ref. [17]. The methyl esters of the products of the thermal induction were extracted in heptane. The GC analysis was carried out by using a PerkinElmer auto XL system gas chromatograph. A 100-m capillary column with 0.25 mm internal diameter coated with 0.20-µm-thick 90%-bis-(cyanopropyl)-methyl polysiloxane stationary phase with a small amount of phenyl groups in the backbone of the polymer (HP 88) was used in the separation of the methyl esters of the fatty acid isomers. A temperature program with initial temperature 150°C with equilibration time of 1 min, then a temperature gradient of 0.5°C/min up to 170°C was used. The temperature was held at 170°C for 40 min. The peak identification was carried out by comparing the reported conjugated linoleic acid profiles in references [10, 11, 13, 14] and methyl esters prepared from the 9c11t and 10t12c triacylglycerols as described in the section "Samples and methods". The peaks in the chromatograms were then integrated, and their relative percentages were calculated using an excel spread sheet.

Results and Discussion

Infrared Spectroscopy

Infrared spectra of the CLA samples from the above experiments were recorded to confirm and complement the gas chromatographic analysis. CLAs with *cis–trans* and *trans–cis* configurations give rise to two specific absorptions at around around 946 and 986 cm^{-1} because of the =CH out-of-plane deformation vibration [18]. The CH out-of-plane deformation vibration of the *trans–trans* isomers absorb around 982–988 cm^{-1}, and *cis–cis* isomers do not absorb in this region. The =CH deformation vibrations of the methylene interupted *cis–trans, trans–cis* and *trans–trans* linoleic acid isomers absorb at approximately 967 at 4 cm^{-1} resolution at room temperature [19–22].

The second derivative profiles of the infrared spectra of the 9c11t/10t12c triaclylglycerol samples thermally induced at 250°C are shown in Fig. 1. The spectra show that the peak at 947 cm^{-1} decreases in intensity. The peak at 985 cm^{-1} also decreases, but because of the contribution of the absorption due to the *trans-trans* isomers of the CLA formed, the decrease is not parallel to the decrease in the intensity of the peak at 947 cm^{-1}. There is also a new peak appearing around 967 cm^{-1} indicating the formation of methylene interupted *cis–trans/trans–cis/trans–trans* isomers in the mixture.

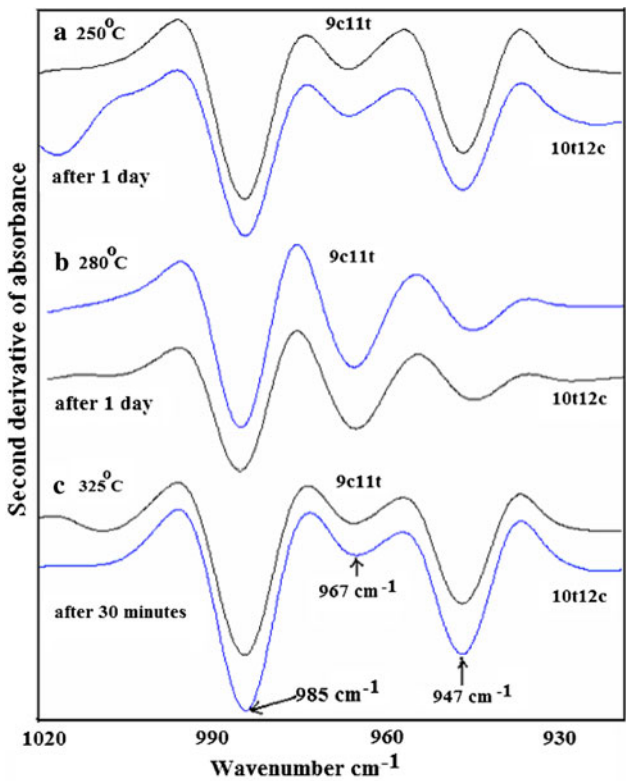

Fig. 2 Second derivative infrared profiles of thermally treated 9c11t and 10t12c triacylglycerol samples at 250, 280 and 325°C

The second derivative profiles of the infrared spectra of the 9c11t/10t12c triacylglycerol samples thermally induced at 250, 280 and 325°C are shown in Fig. 2. The spectra in

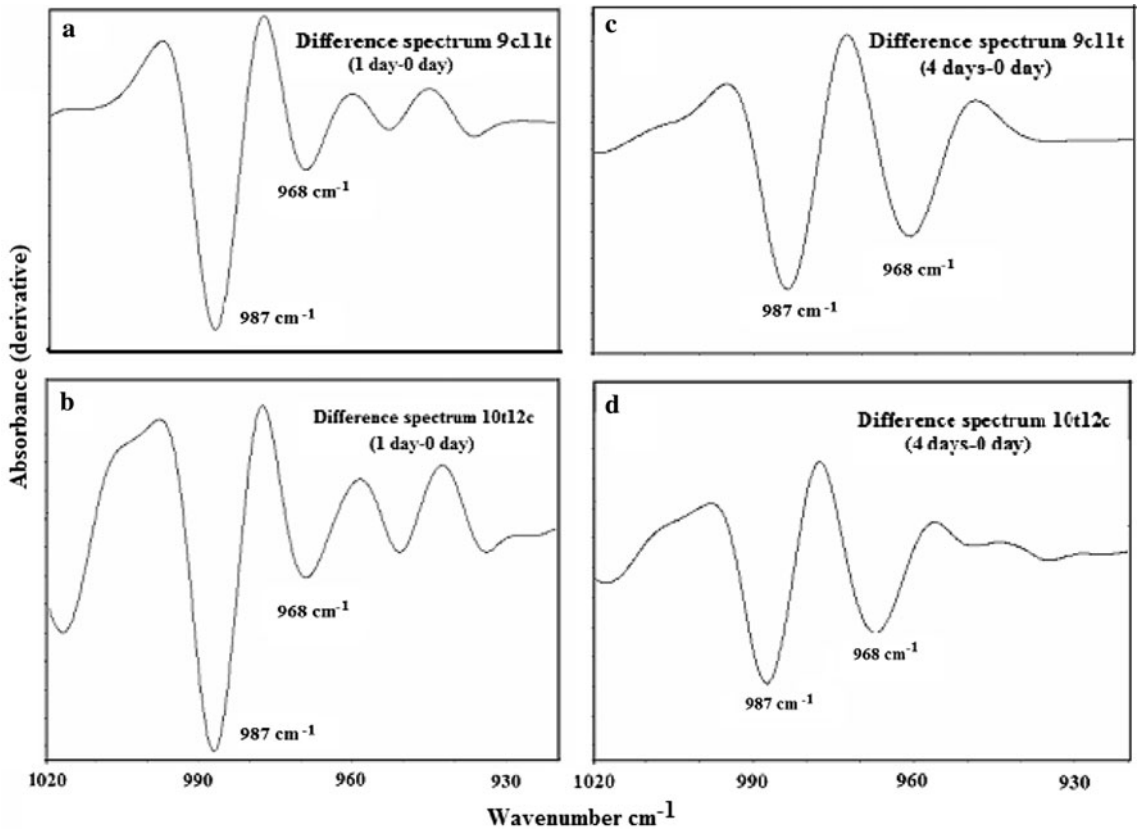

Fig. 3 Interactive substraction of the second derivative infrared spectrum of the starting material from the spectra of samples thermally induced at 250°C

the figure show that the intensity of the second derivative infrared peaks at 985 cm^{-1} of the samples thermally induced for 30 min at 325°C are higher than the peaks of the samples thermally induced for 24 h at 250 or 280°C. This is an indication of the formation of relatively higher concentrations of *trans–trans* CLAs in the thermally induced samples. This can be further confirmed by a proper interactive subtraction of the second derivative spectrum from the spectrum of starting material. The subtraction was carried out using the procedure found in the PerkinElmer instrument software. The results of the substraction are shown in Fig. 3.

Gas Chromatography

The gas chromatograms of the FAME of the thermally induced triacylglycerol samples containing 9c11t and 10t12c fatty acids are shown in Figs. 4 and 5, respectively, CLA profiles are identical to the FAME of most of the CLAs ranging from 7,9 through 12,14, except their relative concentrations. The effect of temperature is clear from the first two samples of the thermal induction. The samples heated at 280°C contain all the isomers of the CLAs, but their relative concentrations are small. The *trans–trans* isomers dominate in the sample. A comparison of the CLA profiles in the heated samples at 250, 280 and 325°C show that there are three pairs of CLA isomers standing out clearly from the rest of the profiles. They are 9c11t, 8t10c; 10c12t, 9t11c and 11c13t, 10t12c. The relationships between the area percentages of the components in the above pairs and thermal induction times are given in Fig. 6. For each starting material, the members in each pair have the similar relative concentrations in all the test samples. When the thermal induction experiments were carried out with 9c11t, the relative concentrations of 9t11c and 10c12t were higher than the concentrations of 10t12c and11c13t (Fig. 6). The thermal induction with triacylglycerol containing 10t12c shows again that the concentrations of 9t11c and 10c12t were higher than the concentrations of the pair 8t10c and 9c11t. It appears that the isomers 10c12t and 9t11c are at the intermediate position of the [1, 5] sigmatropic transformation sequence of the three pairs mentioned above.

Mechanism

A figure depicting the [1, 5] sigmatropic transformations and positional isomerisations in the CLAs from 7,9 through 12,14 is given in Fig. 7. The mechanisms related to the

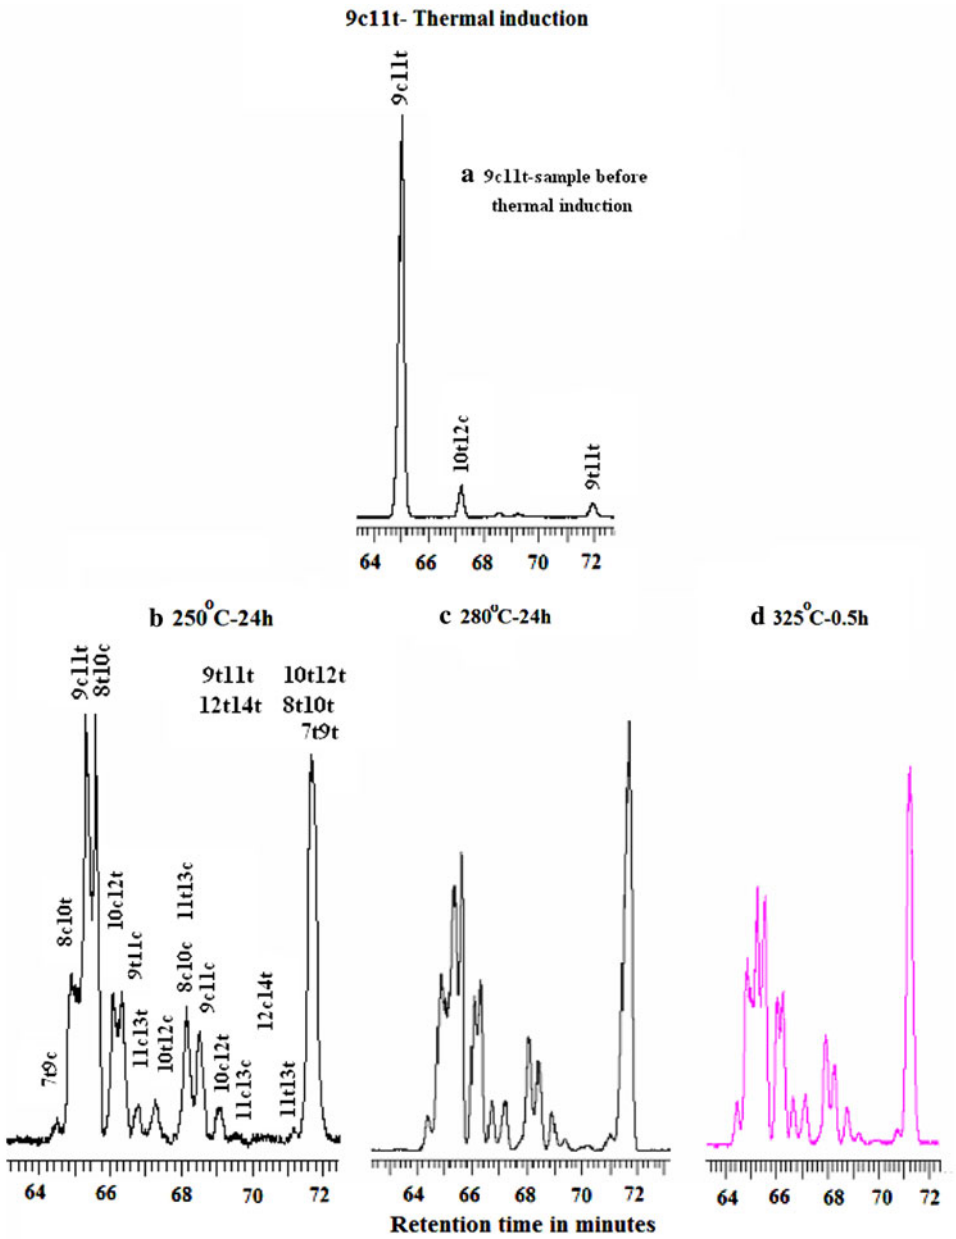

Fig. 4 Gas chromatograms of thermally induced 9c11t triacylglycerol samples

[1, 3] and [1, 5] sigmatropic transformations, and positional isomerizations can be found in Destaillats and Angers [11, 16] and Christy [23]. The figure is similar to the one formulated by Destaillats and Angers [11, 16] and Christy [23], but presented collectively in a manner to explain the appearance of the *cis–trans* and *trans–cis* isomers of CLAs that can be expected in a thermal induction experiment of another *cis–trans* CLA isomer. Thermal induction of 9c11t yields very little or no 11t13c and 12c14t isomers. The 9c11t isomer lies far away from this pair in the sequence. At the same time, the thermal induction of 10t12c, which lies closer to this pair in the sequence than 9c11t, shows the presence of 11t13c and 12c14t. Similarly, the weak appearance of the peaks representing 7t9c and 8c10t isomers during the thermal induction of 10t12c can be explained in the same manner. Furthermore, the 9c11t isomer lies closer to the 7t9c and 8c10t isomers in the sequence, and therefore thermal induction of 9c11t should show peaks representing these CLA isomers. It is interesting to note that the CLA fatty acids 9t11c and 10c12t are in the middle of the sequence of CLAs ranging from 7,9 to 12,14. It appears that a part of CLA isomers with relatively high concentrations compared to the rest of the CLA isomers can be prepared by selecting and thermally inducing a triaclyl glycerol containing a suitable *cis–trans* CLA fatty acid. Accordingly, thermal induction of either 9t11c or 10c12t should give CLA isomers with relatively higher concentrations of most of the isomers.

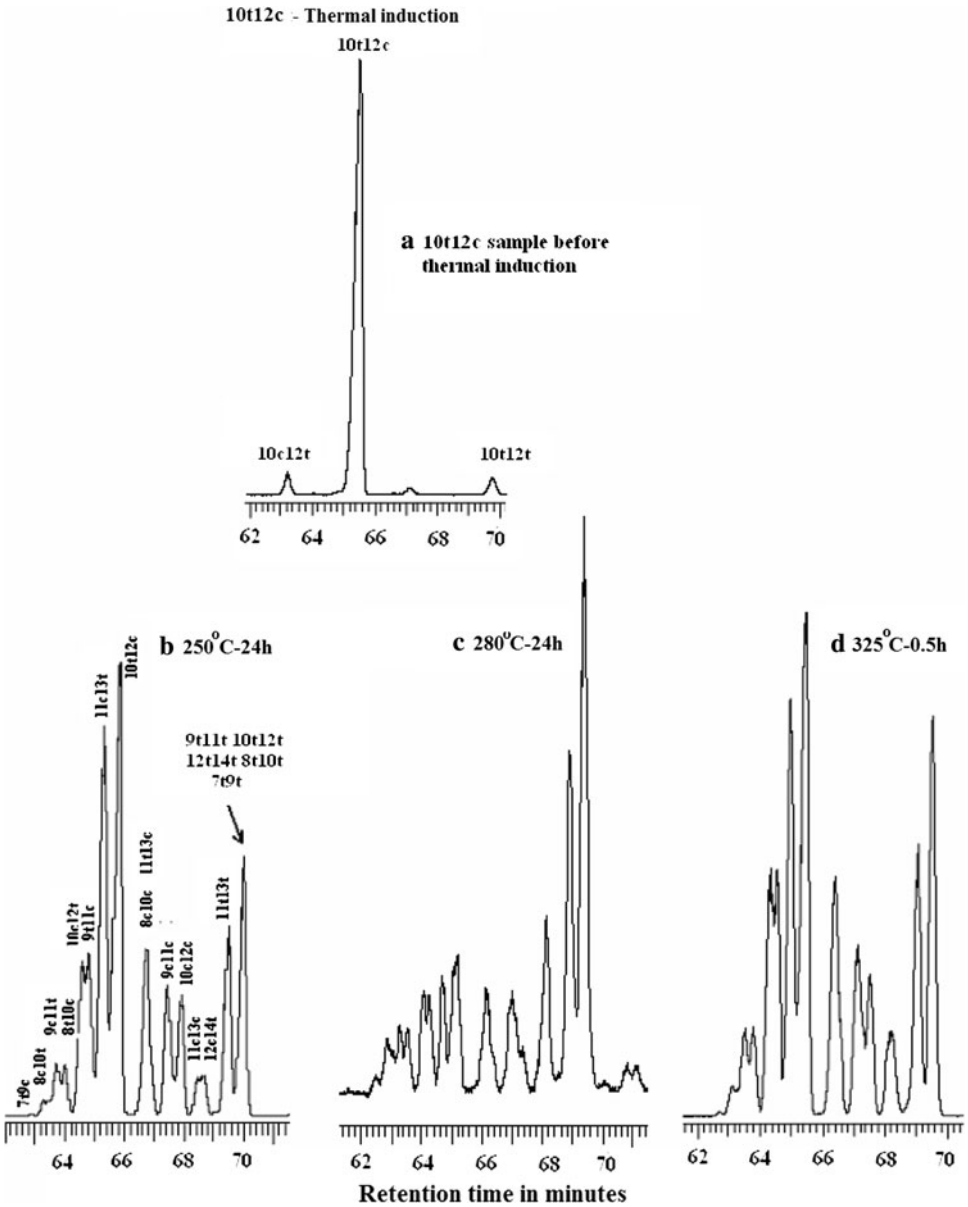

Fig. 5 Gas chromatograms of thermally induced 10t12c triacylglycerol samples

In addition to CLA isomers, the thermally induced mixtures also contain another peak accompanied by other very minor peaks in the chromatograms eluting 15 min earlier than the CLA isomers (Fig. 8). This peak is prominent in the samples thermally induced for 1 day at 250 and 280°C. At the same time, it is very small in the samples thermally induced for 30 min at 325°C. The identity of the relatively large peak in the group was confirmed as methylene interrupted 9t12t (18:2) fatty acid. In an earlier report [23], it was shown that the CLAs can also be formed by thermally inducing a triacylglycerol containing 9t12t fatty acid. Therefore, the formation of 9t12t (18:2) is possible during thermal induction of CLA fatty acids. The reaction takes place through an intramolecular [1, 3], sigmatropic rearrangement or a free radical chain reaction mechanism [16, 23]. The identification of 9t12t led to the inclusion of the [1, 3] sigmatropic transformation part in the mechanism presented in Fig. 7.

The peak in the infrared at 967 cm^{-1} also supports the identity. The absorption can be due to methylene interupted *cis–trans*, *trans–cis* and *trans–trans* isomers of fatty acids. The formation of 18:2 *trans–trans* fatty acid during the induction of either 9c11t or 10t12c fatty acids also stresses one point that the formation is specific of their standards. If the thermal induction of 9t12t can form 9c11t and 10t12c through an intermediate 9t11t, then the other CLA fatty acids can also be formed from *trans–trans* fatty acids such as 7t10t, 8t11t, 10t13t and 12t15t. However, it was not

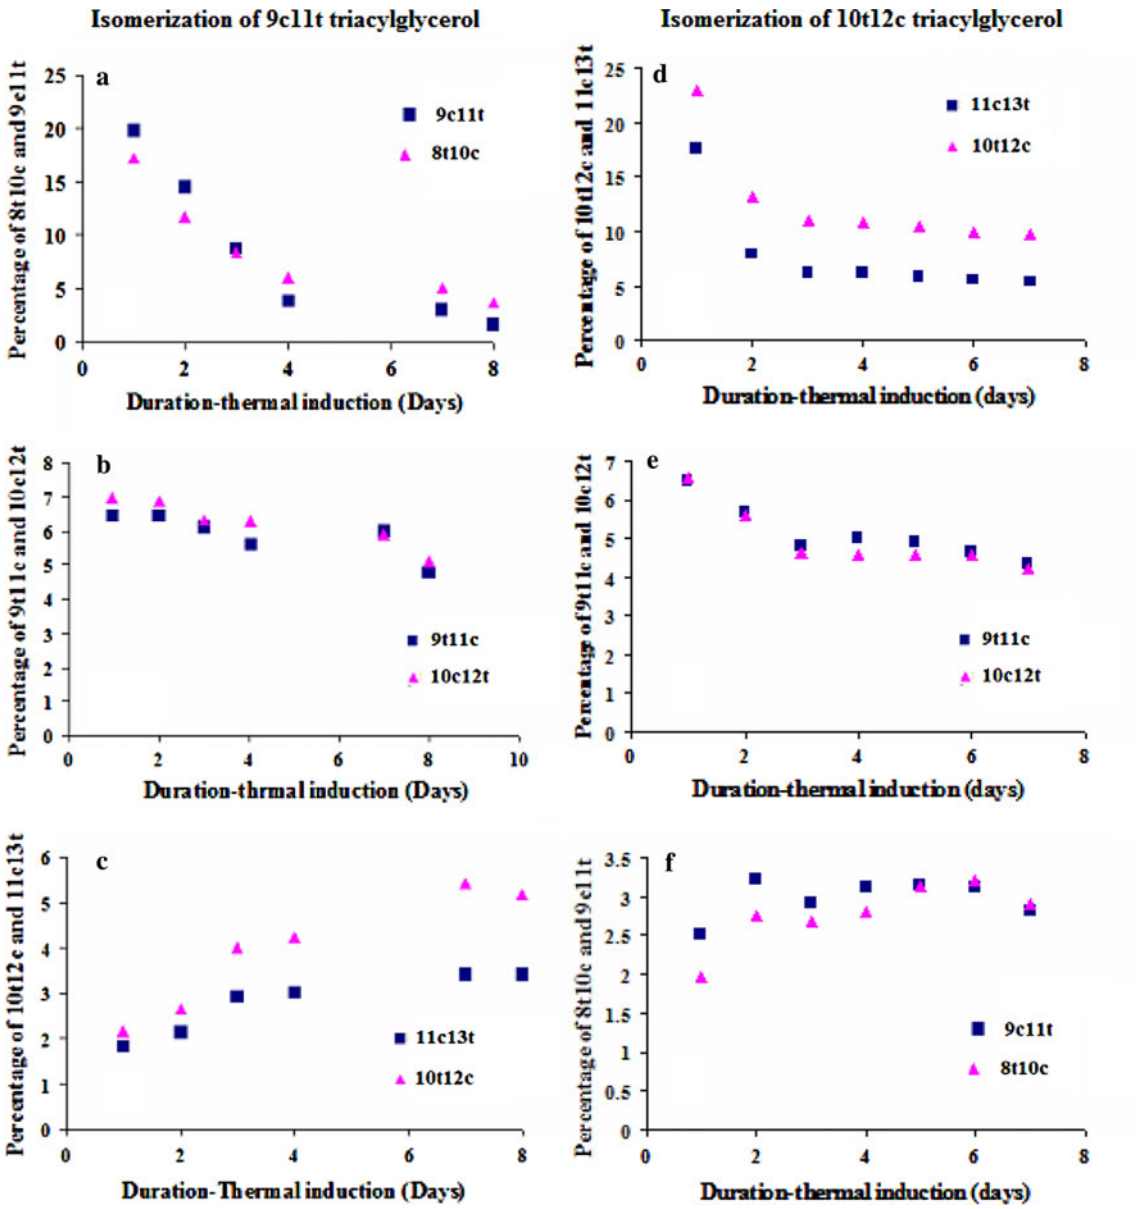

Fig. 6 Plots showing the relationships between relative percentages of the isomers formed in the mixtures during thermal induction of 9c11t and 1oc12t triacyl glycerol samples at 250°C

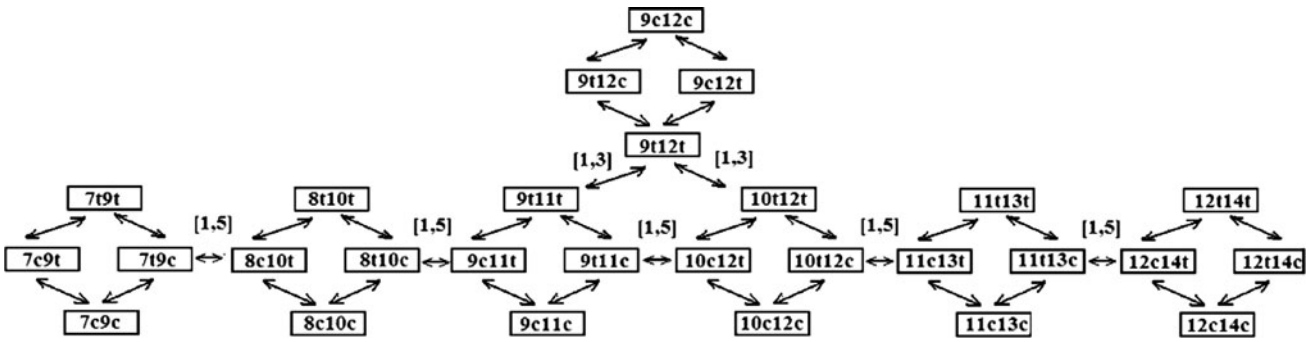

Fig. 7 Isomerisation sequence of conjugated linoleic acids

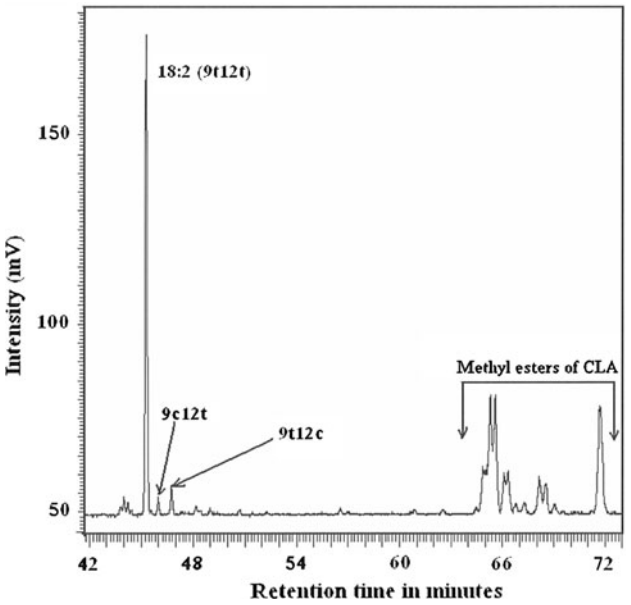

Fig. 8 Gas chromatogram of thermally induced 9c11t triacylglycerol sample

possible to confirm the presence of any of these *trans–trans* fatty acids because of the low concentrations and non-availability of the standards.

In this paper, it has been shown that the CLA isomers ranging from 7,9 through 12,14 can be prepared in one step by thermally inducing either 9c11t or 10t12c CLA. The formation of the isomers is relatively faster in the thermal induction of the samples at 325°C. The thermal induction of 10t12c CLA at 325°C for 30 min yields almost all the CLA isomers in detectable amounts that can be used as a reference sample. Furthermore, the preparation time of the isomers can be shortened from several hours to minutes, and several steps involving wet chemical reactions can be avoided. In addition, the isomerisation time used in the two-step synthesis forms high concentrations of *trans–trans* isomers of the CLAs, which elute together at the end as a very tall and broad peak (as shown in Ref. [11]) and dilute the other CLAs in the sample mixture. The isomerisation sequence presented in Fig. 7 and the experimental evidence provided in Fig. 6 clearly indicate the direction of isomerisation and the products one can expect in an experiment. Thermal induction of a CLA isomer is expected to give isomers that are close to the starting material. However, with the relative ease of obtaining either 9c11t or 10t12c CLA isomers, it is convenient to start with one of these isomers.

To illustrate the formation and the relative concentrations of the CLA isomers in the mixture, a thermal induction sequence diagram is presented utilising the pioneering work of Destaillats and Angers [12]. The figure gives an idea about which CLA isomer to select for the thermal induction to induce and form the CLA isomers one desires to prepare.

With the information presented in this paper, the mechanism involving the formation of CLA isomers has advanced one more step in the forward direction.

METHODS

RP-HPLC/MS-APCI Analysis of Branched Chain TAG Prepared by Precursor-Directed Biosynthesis with *Rhodococcus erythropolis*

Olga Schreiberová · Tereza Krulikovská · Karel Sigler · Alena Čejková · Tomáš Řezanka

Received: 26 May 2010 / Accepted: 29 June 2010 / Published online: 16 July 2010

Abstract Reversed phase liquid chromatography–atmospheric pressure chemical ionization mass spectrometry (RP-HPLC/MS-APCI) was used to analyze both synthetic triacylglycerols (TAG) having 1–3 branched fatty acids (FA) in the molecule, and natural TAG prepared by precursor directed biosynthesis from valine, leucine and isoleucine and the corresponding branched short-chain acids in cultivations of *Rhodococcus erythropolis*. The technique made it possible to identify and quantify TAG differing in a single branched-chain FA. Altogether 11 TAG were synthesized, out of which 8 were synthesized stereospecifically. Branched- and straight-chain-TAG were separated and identified while TAG differing only in *iso* or *anteiso* FA could not be separated. The APCI mass spectra of *iso*-, *anteiso*- and straight-chain TAG were completely identical. The natural material was found to contain 19 TAG having at least one branched FA. Cultivation on six different substrates showed, apart from the presumed and common incorporation of precursors to *iso*-even, *iso*-odd and *anteiso* FA, also some unusual features such as an increase in the content of odd-FA after the addition of Val (attributed to catabolism of Val to propionate) or the appearance of branched monounsaturated FA. The two-sample paired *t* test, when applied to the TAG, showed that only the pair Val and isobutyrate differ in incorporation into FA—see, e.g. proportions of M/M/O and brM/brM/O (1.2:1.2 and 1.9:1.2, respectively). Also, incorporation of Val (isobutyrate) yielded only TAG having two branched FA in the molecule, whereas Leu and Ile (isovalerate and 2-methylbutyrate) gave only TAG with a single branched FA in the molecule.

Introduction

Many prokaryotic microorganisms such as *Mycobacterium* sp., *Nocardia* sp., *Micromonospora* sp., *Dietzia* sp., *Gordonia* sp., *Streptomyces* sp. and *Rhodococcus* sp. accumulate large amounts of lipids in lipid bodies in the cells and mycelia [1, 2]. In the genus *Rhodococcus*, the information about the structure of lipids in the cytoplasmic lipid bodies, in particular triacylglycerols (TAG), is rather scarce [3, 4].

As a carbon source, the genus *Rhodococcus* can utilize very unusual compounds such as hexadecane [5] or phenyldecane that gives rise to triacylglycerol in which one fatty acid was replaced by a phenyldecanoic acid residue [6], or 1-chloro-, l-bromo- and 1-iodohexadecane that ultimately yield ω-halogen fatty acids (FA) [7]. Furthermore, alkanes can be directly oxidized and activated to the respective acyl-CoA thioesters and incorporated into TAG [3, 8]. The composition of the TAG is known to vary strongly when the cells are cultivated on propionic acid, which is activated to propionyl-CoA, resulting in a much higher fraction of odd-numbered FA (over 95% total FA) [8]. With valerate addition the proportions of odd-chain FA can reach nearly 85% total FA.

With other bacteria, the addition of branched amino acids, i.e. Val, Leu or Ile, or their metabolites such as isobutyric (i-Bu), isovaleric (i-Va) or 2-methylbutyric (2-MeBu) acids into the culture medium induces the production of increased amounts of branched FA enriched with the given branched-FA depending on the starter unit (addition of Val produces even-*iso*-FA, addition of Leu odd-*iso*-FA, addition of Ile odd-ai-FA). This fact has been noted many times in myxobacteria [9], in *Nonomuraea* sp. [10], *Propionibacterium freudenreichii* [11], *Staphylococcus xylosus* [12] or *S. carnosus* [13].

Current studies have shown that branched chain FA, predominantly i-15:0 (*iso*-pentadecanoic) and ai-15:0 (*anteiso*-pentadecanoic) inhibit the growth of various cancer cell lines both in vitro and in vivo [14, 15]. Other experiments have documented that their activity decreases with an increase or decrease in chain-length from i-16:0 (isopalmitic) [16]. This effect is explained as being due to cancer cells being more dependent on fatty acid biosynthesis than healthy cells.

As shown in our earlier study of *Rhodococcus* lipids [17], LC–MS analysis of odd-chain TAG is still largely unexplored, mostly due to the scarcity of sources with odd-chain TAG. The situation with branched-chain TAG from natural sources is even worse. To our knowledge only two sources of branched TAG have so far been identified, both of them of bacterial origin. Metz et al. [18] used GC–MS to separate and identify intact TAG from *Streptomyces avermitilis* containing odd- and even-chain FA including *iso*- and *anteiso*-FA. Another source of branched TAG is milk; branched FA contained in it are largely derived from bacteria leaving the rumen [14, 15]. With one exception [19], even here branched TAG have not been separated from straight-chain TAG. All other studies [20, 21] mention only odd-chain TAG, although branched-TAG also have to be present, as seen from the analysis of FA in butter [19, 21]. Figure 1 in the paper by Marai et al. [21] clearly shows the presence, between peaks 48:0 (PPP) and 49:0 (PPMa), of two unidentified peaks that could belong to TAG 49:0 having branched margaric acids (i.e. i-17:0 and/or ai-17:0). Only Myher et al. [19] have given the TCN (theoretical carbon number) for branched TAG 0.38 less than for straight-chain TAG; to our knowledge this is thus the only paper that has explored the LC–MS of branched TAG.

Based on our previous experience with the cultivation of *Rhodococcus* [22] and with LC–MS of lipids [23, 24] we used here precursor directed biosynthesis to prepare branched TAG, which were qualitatively and quantitatively analyzed by using synthetic standards.

Experimental

Microbial Material

Rhodococcus erythropolis CCM 2595 obtained from the Czech Collection of Microorganisms (Masaryk University, Brno, Czech Republic) was subjected to a 6-month

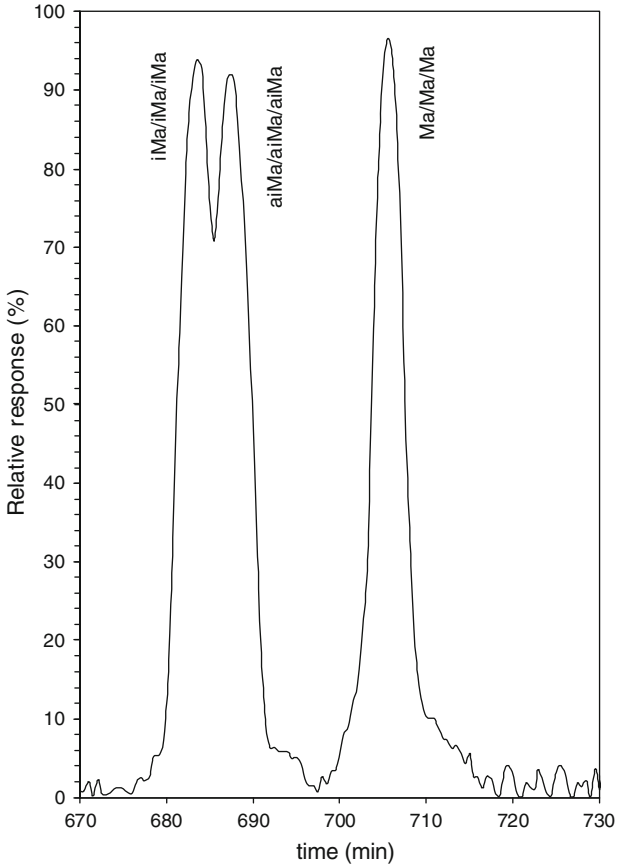

Fig. 1 RP-HPLC/APCI-MS chromatogram of three synthetic TAG (Ma/Ma/Ma, iMa/iMa/iMa, and aiMa/aiMa/aiMa)

physiological adaptation to phenol. The strain reached a high growth rate in the presence of succinate (10 g/L) used as the sole carbon source. Cells were grown in the basic mineral medium (g/L: KH_2PO_4 0.17; $MnCl_2{\cdot}4H_2O$ 0.001; K_2HPO_4 0.13; $CaCl_2{\cdot}2H_2O$ 0.00026; $(NH_4)_2SO_4$ 0.71; $FeSO_4{\cdot}7H_2O$ 0.0006; $MgCl_2{\cdot}6H_2O$ 0.34; $Na_2MoO_4{\cdot}2H_2O$ 0.002; pH was adjusted to 7.0) containing alternatively amino acids or short carboxylic acids (sodium salts) as the carbon source (valine, leucine, isoleucine, isovalerate, isobutyrate, 2-methyl butyrate—each 3 g/L) and 1 g/L of succinate as cosubstrate. The cultivations were performed on a rotary shaker at 100 rpm and 30 °C.

The cells were collected at the end of exponential phase (97 h) by centrifugation (10 min, 9,050*g*), washed twice with physiological solution and lyophilized (dry biomass yield depending on the C-sources: 353 mg/L—valine, 438 mg/L—leucine, 663 mg/L—isoleucine, 690 mg/L—isovalerate, 583 mg/L—isobutyrate, 645 mg/L—2-methyl butyrate, 890 mg/L—succinate).

Standards and Isolation

Acetonitrile, 2-propanol, hexane, dichloromethane, glycerol, 4-dimethylaminopyridine (DMAP), *N*,*N*′-dicyclohexyl-carbodiimide (DCC), and standards of glyceryl tripalmitate and glyceryl triheptadecanoate were purchased from Sigma-Aldrich (Prague, CR). The mono- and diacylglycerols were purchased from Larodan Fine Chemicals, Malmo, Sweden.

Preparation of Mixed FA Composition TAG

The esterification of glycerol with acids has been described previously [25]. Briefly, a rapidly stirred suspension of 1,3-diacylglycerol or 1,2-diacylglycerol (10 μmol), the acid (11 μmol), and a catalytic amount of 4-dimethylamino-pyridine (2 μmol) in anhydrous CH_2Cl_2 (5 mL) was treated with *N*,*N*′-dicyclohexyl-carbodiimide (12 μmol). The resulting mixture was stirred under N_2 for 24 h at room temperature, diluted with CH_2Cl_2, and filtered to remove precipitated 1,3-dicyclohexyl urea. The filtrate was washed with 0.5 N HCl, saturated aqueous $NaHCO_3$, H_2O, and brine and dried ($MgSO_4$). The solvent was removed in vacuo, and the remaining residue was purified by TLC (silica gel H, developed in hexane/diethyl ether/acetic acid (70:30:1, by vol.). The yields of appropriate TAG are in Table 1. The purity (see also Table 1) of individual synthesized TAG was determined by RP-HPLC, for the conditions see below.

Preparation of Single FA Composition TAG

The TAG were prepared as described above, only the ratios of FA and glycerol were different, i.e. for 10 μmol of FA, 3 μmol of glycerol, 4 μmol of 4-dimethylaminopyridine, and 36 μmol of *N*,*N*′-dicyclohexyl-carbodiimide was used. Further separation and purification was identical, see above. The yields are in Table 1.

The lyophilized cells were mixed with 10 mL of hexane and the mixture was stirred for 15 min. The cells were filtered off, hexane was evaporated and the oil samples

Table 1 Synthesis of TAG

Alcohol (1 μmol)	Acid/μmol	TAG	Yield (%)	Purity (%)
Glycerol	Ma/3.15	Ma/Ma/Ma	92	≥99
Glycerol	iMa/3.15	iMa/iMa/iMa	90	≥99
Glycerol	aiMa/3.15	aiMa/aiMa/aiMa	87	≥99
1-Monopalmitin	Ma/2.10	P/Ma/Ma	75	≥99
1-Monopalmitin	iMa/2.10	P/iMa/iMa	73	≥99
1-Monopalmitin	aiMa/2.10	P/aiMa/aiMa	76	≥99
1,2-Dipalmitin	Ma/1.05	P/P/Ma	69	>98
1,2-Dipalmitin	iMa/1.05	P/P/iMa	68	>98
1,2-Dipalmitin	aiMa/1.05	P/P/aiMa	70	>98
1,3-Dipalmitin	Ma/1.05	P/Ma/P	68	>98
1,3-Diheptadecanoin	P/1.05	Ma/P/Ma	64	>97

were dissolved in an acetonitrile-2-propanol-hexane mixture (1:1:1, v/v/v), which was injected on the column.

FAME Analysis

The TAG (10 mg) were saponified overnight in 10% KOH–MeOH at room temperature. A fatty acid fraction obtained from saponification was partitioned between alkali solution (pH 9) and Et_2O to remove basic and neutral components. The aqueous phase, containing FA, was acidified to pH 2 and extracted with hexane. The fatty acid fraction was methylated using CH_2N_2. GC–MS of fatty acid methyl ester (FAME) mixture was done on a Finnigan 1020 B in EI mode. Splitless injection was at 100 °C, and a fused silica capillary column (Supelcowax 10; 60 m × 0.25 mm i.d., 0.25 mm film thickness; Supelco, Prague) was used. The temperature program was as follows: 100 °C for 1 min, subsequently increasing at 20 °C/min to 180 °C and at 2 °C/min to 280 °C, which was maintained for 1 min. The carrier gas was helium at a linear velocity of 60 cm/s. All spectra were scanned within the range of *m/z* 50–500. The structures of FAME were confirmed by comparison of retention times and fragmentation patterns with those of the standard FAME (Supelco, Prague).

RP-HPLC/MS-APCI

The HPLC equipment consisted of a 1090 Win system, PV5 ternary pump and automatic injector (HP 1090 series, Agilent, USA) and two Hichrom columns HIRPB-250AM 250 × 2.1 mm ID, 5-μm particle size, in series. This setup provided us with a high-efficiency column—approximately 26,000 plates/250 mm. A quadrupole mass spectrometer system Navigator (Finnigan MAT, San Jose, CA, USA) was used for analysis. The instrument was fitted with an atmospheric pressure chemical ionization source [vaporizer temperature 390 °C, capillary heater temperature 260 °C, corona current 7 μA, sheath gas—high-purity nitrogen, pressure 0.45 MPa, and auxiliary gas (also nitrogen) flow rate 15 mL/min]. Positively charged ions with *m/z* 200–1,000 were scanned with a scan time of 0.5 s. The whole HPLC flow (0.35 mL/min) was introduced into the APCI source without any splitting. TAG were separated using a gradient solvent program with acetonitrile (ACN) and 2-propanol (iPrOH) as follows: initial ACN/iPrOH (99:1, v/v); linear from 5 to 120 min ACN/iPrOH 30:70, v/v); held until 30 min; the composition was returned to the initial conditions over 10 min. Isocratic separation by the mixture ACN/iPrOH 65:35, v/v) was used for resolution of the regioisomers. A peak threshold of 0.07% intensity was applied to the mass spectra.

The saturated synthesized TAG (Ma/Ma/Ma, iMa/iMa/iMa, and aiMa/aiMa/aiMa) were dissolved in ACN/iPrOH mixture (99:1, v/v) to concentrations of 1, 5, 10, 50, and 100 μg/mL. All calibration curves were measured using a 10 μL injection volume of solutions in three repeated analyses and the average peak areas were used for the construction of calibration curves. For reliable quantitation, concentrations of individual TAG in analyzed samples have to be in a given interval (after a suitable dilution). The limits of detection at S/N = 3 were determined with the injection volume 10 μL and averaged as 1 μg/mL for saturated TAG. RFs are expressed relative to Ma/Ma/Ma, which is set to 1.00. For MS-APCI *a* and *b* values are coefficients of the linear calibration dependence $y = ax + b$ and RFs are calculated as $RF = a_{Ma/Ma/Ma}/a_{TAG}$, because *b* values can be neglected. Here r^2 is the value of coefficient of determination, *y* corresponds to the peak areas and *x* is the concentration in μg/mL.

Data acquisition and analyses were performed using PC with MassLab 2.0 for Windows XP applications/operating software.

Results and Discussion

As seen in Table 2, FA from *Rhodococcus* comprise not only odd-chain FA [17], but also branched-chain FA that

Table 2 Fatty acid compositions (%) of seven cultivations of *R. erythropolis* at 30 °C with different carbon sources [succinate, Val, Leu, Ile, isobutyric (i-Bu), isovaleric (i-Va) and 2-methyl-butyric (2-MeBu) acid] as determined by GC–MS

[a] Minority fatty acids up to 0.1% of total fatty acids were omitted

were produced by precursor directed biosynthesis from branched chain precursors. In view of the scarcity of data on branched chain TAG (see above) we decided to synthesize a series of standards (see Table 1) that were used to verify the basic chromatographic and mass spectral characteristics. The standards were synthesized by conventional procedures, as simply as possible and with the highest yield. We followed the procedure described by Lie Ken Jie and Lam [26] who synthesized TAG of AAB, ABA, BBA and BAB types. Commercially available glycerol, monoacyl- and diacylglycerols (1-palmitin, 1,2-dipalmitin, 1,3-dipalmitin and 1,3-diheptadecanoin) yielded a total of 11 TAG by mild organic synthesis performed at 25 °C for 24 h under catalysis with dicyclohexylcarbodiimide (DCC) and 4-dimethylaminopyridine (DMAP) (see "Experimental").

Individual TAG were analyzed by RP-HPLC. Figure 1 shows the chromatographic analysis of three synthetic TAG, Ma/Ma/Ma, iMa/iMa/iMa, and aiMa/aiMa/aiMa. The separation of straight-chain TAG from both branched-chain TAG presented no problems while separation of iMa/iMa/iMa from aiMa/aiMa/aiMa was hours-long—a time span unacceptable in the analysis of a natural sample—and succeeded only under isocratic conditions using the mobile phase ACN-iPrOH (65:35, v/v).

Chromatographic separation of branched TAG having two branched FA in the molecule (two i-17:0 or two ai-17:0) from straight-chain counterparts presents no problems—gradient elution provided a base-line separation of P/Ma/Ma from P/aiMa/aiMa or P/Ma/Ma from P/iMa/iMa, as shown in Figs. 2 and 3. Separation of two branched TAG such as P/iMa/iMa and P/aiMa/aiMa could be accomplished only by isocratic elution and only with synthetic TAG. We ascribe this phenomenon to the much higher complexity of the natural mixture that results in a mutual influencing and overlapping of peaks.

In the case of TAG having a single branched FA we succeeded in separating only those TAG that differed in the site of branching. The separation was successful only in the pairs P/P/Ma and P/P/iMa, and P/P/Ma and P/P/aiMa, in both the synthetic and the natural mixture and with both isocratic and gradient elution. The separation P/P/iMa and P/P/aiMa was unsuccessful.

Positional isomers such as P/P/Ma and P/Ma/P or P/Ma/Ma and Ma/P/Ma were partially separated only with isocratic elution (see [27] for positional isomers, i.e. POP and PPO). These two pairs were much more poorly separated than positional isomers in which individual FA differ in two methylene groups, such as P/P/S and P/S/P [17].

The APCI mass spectra of an AAA type TAG are very simple. For instance, trianteisomargarin (aiMa/aiMa/aiMa), exhibits four clusters of ions, i.e. $[M+H]^+$ ($[TAG]^+$, i.e. $[aiMa/aiMa/aiMa]^+$) at *m/z* 849, $[M\text{-}RCOO]^+$ ion ($[DAG]^+$, i.e. $[aiMa/aiMa]^+$) at *m/z* 579 arising by the loss of margarate $[RCOO+58]^+$ called also ($[MAG]^+$, i.e. $[aiMa]^+$) at *m/z* 327, and $[RCO]^+$ ion (FA^+, i.e. $aiMa^+$) at *m/z* 253, see also Table 3 and Fig. 4.

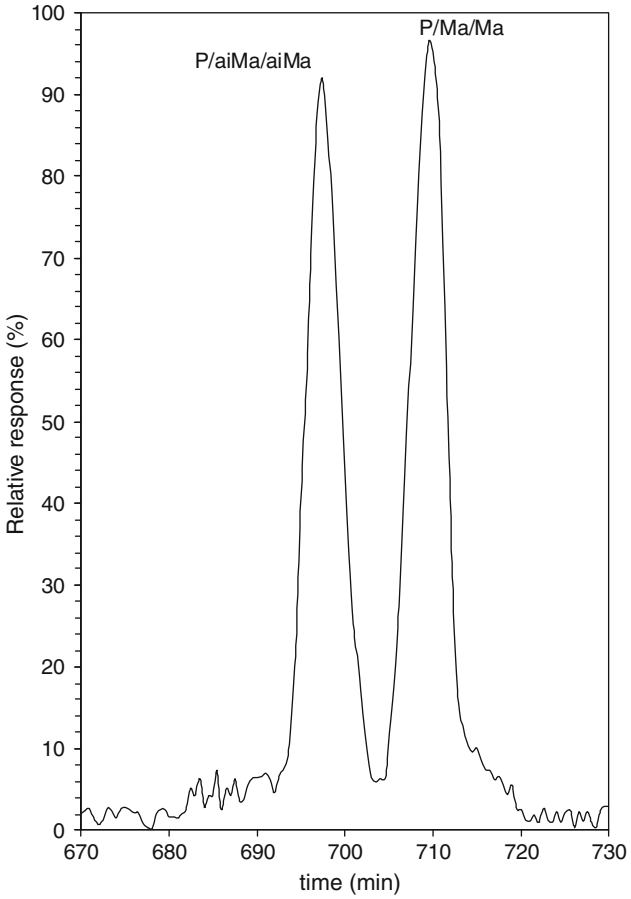

Fig. 2 RP-HPLC/APCI-MS chromatogram of two synthetic TAG (P/Ma/Ma and P/aiMa/aiMa)

APCI mass spectra of all synthetic TAG, i.e. Ma/Ma/Ma, iMa/iMa/iMa, and aiMa/aiMa/aiMa were completely identical. Minute differences in the intensity of ions at *m/z* 41, 43, 55, and 57 can be found only in electron impact mass spectra. These ions arise probably by splitting of the termini of aliphatic chains although Dinh-Nguyen [28] states, based on the comparison with deuterium-labeled compounds, that the situation is more complex. Unfortunately, the HPLC-electron impact connection is not feasible and the determination of all three chain types, i.e. *n-*, *iso-* and *anteiso-* would always require a comparison of natural TAG with a synthetic TAG standard.

The above data clearly show that any combination of branched- and straight-chain acyls in TAG cannot be resolved based on mass spectrum. Even so we performed another experiment with synthetic TAG (P/Ma/Ma and P/aiMa/aiMa, see Figs. 5, 6) that could facilitate the

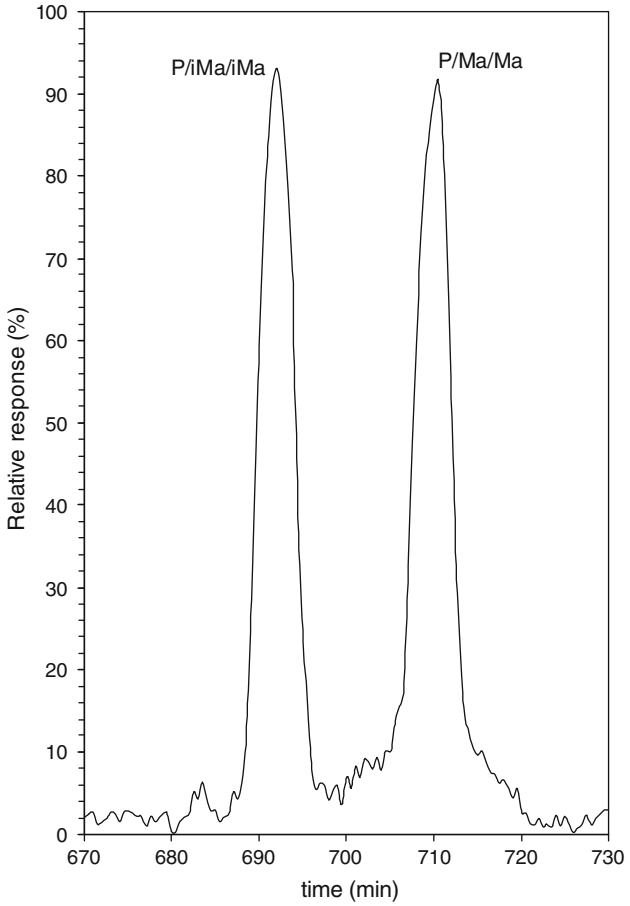

Fig. 3 RP-HPLC/APCI-MS chromatogram of two synthetic TAG (P/Ma/Ma and P/iMa/iMa)

resolution of individual acyls by using MS/MS. However, the MS/MS of the daughter ion at *m/z* 253 ($[RCO]^+$), i.e. ion with the same *m/z* value for all three acyls of all three acids (margaric, *iso*-margaric and *anteiso*-margaric acids) failed to reveal any perceptible change in the intensity of ions in the interval of 35–253 Da (spectrum not shown); this result finally excluded the possibility of distinguishing branched- and straight-chain TAG by MS-APCI.

The mass spectrum of ABB type TAG such as P/aiMa/aiMa (Fig. 6), which contains two FA, exhibits, in addition to $[M+H]^+$ at *m/z* 835, also two acylium ions, with *m/z* at 239 (P^+) and *m/z* 253 ($aiMa^+$), respectively. The spectrum naturally features also ions of the type $[MAG]^+$ at *m/z* 313 ($[P]^+$) and *m/z* 327 ($[aiMa]^+$), respectively. Like with aiMa/aiMa/aiMa, also $[DAG]^+$ ions caused by the loss of margarate at *m/z* 565 and palmitate at *m/z* 579 are present, resulting in ($[P/aiMa]^+$ (type $[AB]^+$) and $[aiMa/aiMa]^+$ (type $[BB]^+$) ions, respectively.

Similarly, the mass spectrum of an ABC type TAG, i.e. TAG containing three different FA, such as P/brMa/S, see Fig. 7, shows three triplets of ions—three $[M\text{-}RCOO]^+$ ions at *m/z* 565, 579, and 593, corresponding to loss of stearate to give $[brMa/P]^+$, loss of margarate to give $[P/S]^+$, and palmitate to give $[brMa/S]^+$, respectively. Another triplet, $[MAG]^+$ at *m/z* 341, 327, and 313 is formed by $[S]^+$, $[brMa]^+$, and $[P]^+$ ions. The last triplet belongs to ions S^+ (*m/z* 267), $brMa^+$ (*m/z* 253), and P^+ (*m/z* 239).

Some authors [17, 29–32] observed that the relative intensities of the $[M\text{-}RCOO]^+$ ions, i.e. $[DAG]^+$, could be used to obtain information on the positions of FA within

Table 3 TAG identified in *R. erythropolis*, their retention times (RT), acyl carbon number (ACN), the masses of protonated molecules, and characteristic fragment ions of TAG

the TAG. A rule was formulated about the energetically less favorable loss of FA from position *sn*-2 and formation of $[M\text{-}RCOO]^+$ i.e. 1,3-$[DAG]^+$ ions. The cleavage of these bifunctional TAG gives rise to an isomeric pair of the same $[DAG]^+$ ions, i.e. $[AA]^+$ and $[AB]^+$. The ratio of $[AA]^+$:$[AB]^+$ was found to be lower for the ABA isomer, since formation of the 1,2-isomer of the $[AB]^+$ ion is energetically more favorable than generating the analogous 1,3-$[AB]^+$ ion from the AAB isomer. If these two fragments were energetically equivalent, then the intensity of ions $[AA]^+$ and $[AB]^+$ should be in a 1:2 ratio irrespective of the position of the A or B acyl substitution on the glycerol backbone, which does not occur—see, e.g. Figs. 8 and 9. The positional isomers understandably differed in the intensity of ions types $[P/P]^+$ and $[P/iMa]^+$ since the least abundant $[M\text{-}RCOO]^+$ ion is known to correspond to loss of the FA from the *sn*-2 position.

The $[P/P]^+$:$[P/Ma]^+$ ratio observed for P/Ma/P (Fig. 8) is only 35:100, indicating that the formation of the 1,3-$[PP]^+$ ion is energetically unfavorable. On the other hand, in P/P/iMa (Fig. 9) the $[P/P]^+$:$[P/iMa]^+$ ratio is 80:100 and the rule can thus be used to determine the structure of this positional isomer. This is in agreement with the result of the organic synthesis. Apart from determining the structure of natural compounds the rule can be used for confirming the structure of synthesized standards, since the synthesis may involve racemization or the original diacylglycerols need not contain only pure *sn*-1,2 or *sn*-1,3 positional isomer. Consequently, the two regioisomers show two different spectra.

To show that even a complex biological material such as *R. erythropolis* biomass can yield mass spectra that make it possible to identify TAG, we present in Figs. 10 and 11 the spectra of brM/brM/O and also brX/P/O. Identification of

these and other TAG was performed as described above and given in Table 3.

As expected, and in agreement with literature data, addition of Val and isobutyrate [10, 32] induced the biosynthesis of branched FA. No i- or ai-FA, neither odd- nor even-chain ones, were detected in control cultivation whereas the addition of any of the two precursors caused an increase of i-14:0 from 0 to 8.1% and a rise of i-16:0 from 0 to 18.1% (precursor Val). Precursor directed biosynthesis based on i-Bu showed comparable results, see Table 2. The overall proportion of even-i-FA increased to one quarter of total FA as compared to control (cultivation on succinate as the only carbon and energy source).

Apart from the increase in even-i-FA, an increased content was also noted with odd-straight-chain FA, i.e. 15:0 and 17:0. This is probably due to the fact that one of the possible products of Val (and also isobutyrate) catabolism is propionate, which serves as a starter unit of odd-straight-chain FA. Analogous effect, i.e. increased proportion of odd-straight-chain FA, was found in cultivations of other bacteria [10, 33].

Precursor directed biosynthesis of FA with the use of Leu or i-Va as starter units leads to an increase in odd-i-FA (i-15:0 to 14.8% with Leu and 14.2% with i-Va, i-17:0 to as much as 19.5% with Leu and 20.2% with i-Va). The proportion of these FA rose to 35% of total FA. These results are in agreement with the effect of both starter units described in the literature [12, 34].

The presence of Ile and 2-MeBu in the medium caused an expected increase [11] in ai-FA (ai-15:0 to 19.1% with Ile and 20.4% with 2-MeBu; ai-17:0 to 21.3% with Ile and 19.7% with 2-MeBu). These C-sources had the greatest effect on the FA composition, the content of ai-FA increasing to 40% of total FA.

Following the addition of given precursors, corresponding branched-chain monoenoic FA were identified in amounts of about 0.5% total FA. In contrast to straight-chain monoenoic FA only C17 and C18 branched-chain monoenoic FA were identified. This phenomenon can be explained in two ways. The first possibility is that the appropriate desaturase has a higher affinity for longer chains; this corresponds with the fact that no straight-chain monoenoic C14 and C15 FA were found. The other possibility is that the high melting point of straight-chain FA lowers the membrane fluidity to an extent that forces the bacterium to biosynthesize branched-chain monoenoic FA with a lower melting point in order to enhance membrane fluidity. The melting point of myristic acid je 54 °C, margaric (n-17:0) 61 °C, while that of ai-margaric (ai-17:0) is a mere 37 °C. Hence a change of branching from straight-chain to ai (e.g. C17 fatty acid) the melting point drops by 24 °C, whereas chain shortening of straight-chain from C17 to C14 (i.e. myristic acid) only by 17 °C. Melting point of (*Z*)-15-methyl-hexadec-12-enoic acid (i-17:1) is 21–22 °C. We therefore assume that fluidity change is affected much more by branching than the shortening of FA.

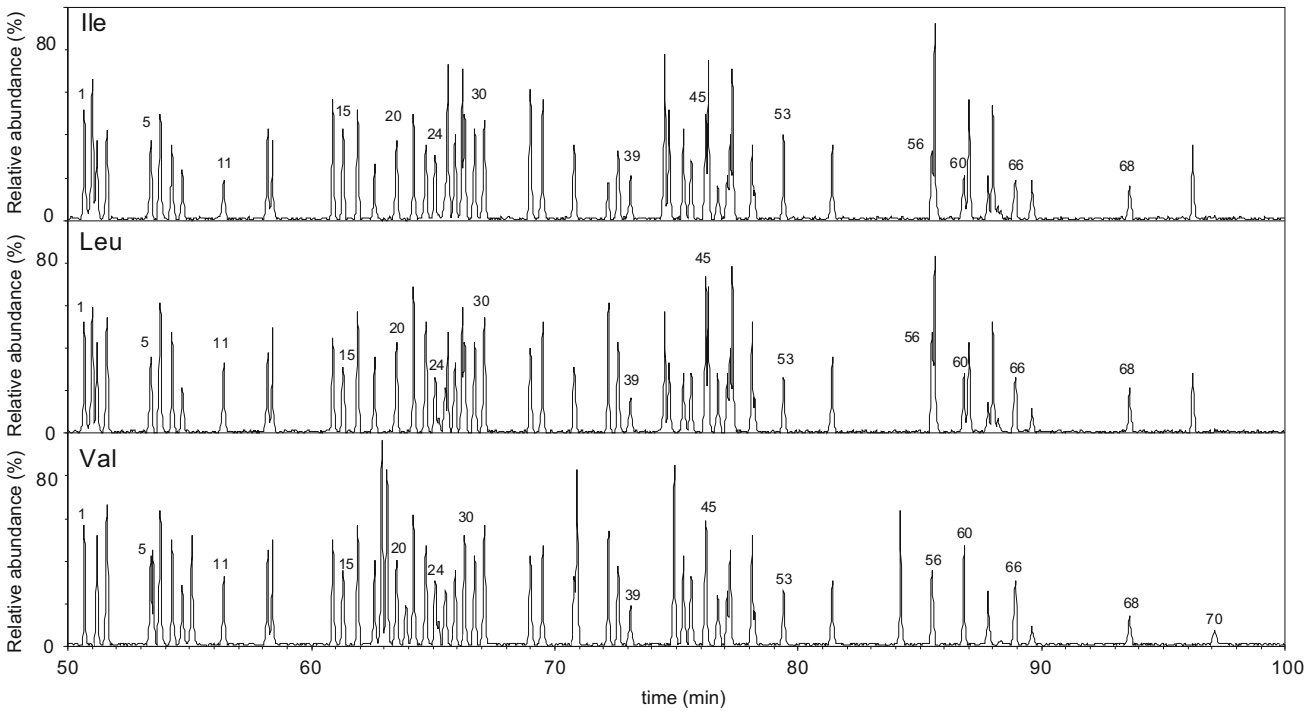

Fig. 12 RP-HPLC/APCI-MS chromatogram of the TAG from *R. erythropolis* cultivations at 30 °C with different carbon sources (Val, Leu, and Ile) as determined by RP-HPLC/MS-APCI

Cultivations in the presence of Leu and Ile and the corresponding short FA (i-Va and 2-MeBu) did not show any catabolism to acetate and propionate. Ile is known to be catabolized to acetate and propionate, Leu to acetoacetate and acetate [35]. In the former case we can assume that the starter units, i.e. acetate and propionate, have the same influence on the biosynthesis of even and odd FA and their contribution is thereby in fact eliminated (1 mol of Leu or i-Va gives rise to 1 mol of acetate and propionate and contributes thereby by the same molar amount to the biosynthesis of even and odd FA).

In the case of Ile (2-MeBu) only acetate and no propionate is formed. Because the proportion of even FA is major (more than 75% of total FA), an increase in the content of the precursor, i.e. acetate, has no further effect on the ratio of even and odd FA arising in the biosynthesis.

The results of the cultivation fully supported our assumption that *Rhodococcus* is eminently suitable for precursor directed biosynthesis of branched FA.

Chromatogram of TAG obtained after cultivation of *Rhodococcus* with three amino acids (Val, Leu and Ile) is shown in Fig. 12. Three pairs of mutually metabolically coupled precursors were used - Val and i-Bu, Leu and i-Va, Ile and 2-MeBu. The given amino acid gives rise to corresponding branched FA, which is then incorporated into the molecule of appropriate FA.

Table 4 gives mean (three independent sequential measurements) relative peak areas of 69 TAG from *Rhodococcus* determined in control cultivation on succinate and in individual cultivations using precursor directed biosynthesis with six starter units. It should be stressed that these values were calculated without using response factors, similarly as in our preceding paper in which we also analyzed unusual plant TAG [36]. None of the standards is commercially available and the 11 TAG that we synthesized represent a small fraction (<1/6) of the total possible TAG. Since the other standards are not available, the values are only semi-quantitative. This however does not prevent comparison of the outcomes of individual cultivations because these comparisons involve structurally similar TAG. An extrapolation of the response factors for TAG differing only in the branched chain (e.g. brMa/S/O and Ma/S/O) is unfortunately not feasible since we do not know the differences between straight- and branched chains. Despite this we attempted to quantify the results for Ma/Ma/Ma, iMa/iMa/iMa, and aiMa/aiMa/aiMa, see "Experimental". If a value of 1.00 is arbitrarily allotted to straight-chain TAG (Ma/Ma/Ma), the correction factor for *iso* TAG is 0.97 and for ai-TAG 0.99. In the case of a real sample, and also of several synthetic standards, we have failed to separate TAG differing only in branching (i.e. *iso* and *anteiso*).

Table 4 Relative quantities (%) of TAG identified in *R. erythropolis* cultivations at 30 °C with different carbon sources [succinate, Val, Leu, Ile, isobutyric (i-Bu), isovaleric (i-Va) and 2-methyl-butyric (2-MeBu) acid] as determined by RP-HPLC/MS-APCI

[a] Minority TAGs up to 0.1% of total TAGs were omitted

The two-sample paired *t* test revealed that a significant incorporation of precursors into the molecules of TAG appeared only in the pair Val and i-Bu (*P* value is 0.012). This value of the *t* test shows that at 5% significance level we reject the hypothesis of zero differences. The values for the other two pairs, i.e. Leu and i-Va and Ile and 2-MeBu, are different (*P* value is 0.154 and 0.453, respectively). This feature can be demonstrated in the ensuing pair of TAG, i.e. M/M/O and iM/iM/O. Precursors such as Val or i-Bu cannot give rise to ai-FA. Based on the *t* test we can thus infer that more Val was incorporated in branched TAG than i-Bu, because the ratio of Val:i-Bu incorporation in the former species was 1.2:1.2 while in branched TAG it was 1.9:1.2. Further confirmation of this fact is seen in Table 4. Another feature distinguishing the incorporation of Val (i-Bu) from that of the other two pairs (Leu/i-Va and Ile/2-MeBu) into the molecular species of TAG is the presence of only those molecular species that have two branched FA in the molecule, whereas with Leu and Ile (and the corresponding short-branched acids) the only identified molecular species of TAG were those having only one branched FA in the molecule. Based on the chromatographic behavior of the standards we synthesized we can confirm that the separation and identification of the molecular species of TAG potentially produced by *Rhodococcus* and differing in branched chain FA is feasible. The outcome of such analysis depends understandably on the detection limit, which was in our case 0.1% total TAG. We cannot exclude the possibility that under conditions different from those used in this study, e.g. in stress-inducing culture conditions or in biofilm, the proportions of individual TAG will change. The sum of branched TAG after precursor directed biosynthesis ranged from 21% for the compound with the lowest incorporation, i.e. i-Bu, to 33% for Ile. These data strongly imply that *Rhodococcus* is a good producer of branched chain FA and corresponding TAG and can be successfully used as a biotechnologically important microorganism producing these substances that have considerable pharmacological potential.

In conclusion, RP-HPLC/MS-APCI made it possible to identify and quantify TAG differing in a single branched-chain FA. Branched- and straight-chain-TAG were separated and identified while TAG differing only in *iso*- or *anteiso*-FA could not be separated since their APCI mass spectra were completely identical. Branched TAG having two branched FA in the molecule were successfully separated from straight-chain counterparts by gradient elution. TAG having a single branched FA were separated only if they differed in the site of branching. Positional isomers such as P/P/Ma and P/Ma/P or P/Ma/Ma and Ma/P/Ma were partially separated only with isocratic elution.

METHODS

Development of a Novel Sandwich ELISA for Measuring Cell Lysate ABCA1 Protein Levels

Abstract ATP-binding cassette transporter A-1 (ABCA1) mediates the transfer of cellular cholesterol to lipid-poor apolipoproteins. Liver X receptors (LXRs) are regulators of cholesterol homeostasis that increase transcription of ABCA1. Synthetic LXR agonists developed to date have been shown to induce ABCA1 mRNA expression and increase reverse cholesterol transport. Unfortunately, there have been few options for quantitatively measuring ABCA1 protein levels, including a previously described competitive ELISA standardized to an ABCA1 peptide with a sensitivity of 80 ng/ml. To address this unmet need, we developed a novel sandwich ELISA standardized to full-length human recombinant ABCA1 protein with sensitivity of approximately 0.5 ng/ml. To determine if the sandwich ELISA had adequate sensitivity to detect LXR-induced increases in ABCA1, we utilized it to measure ABCA1 levels in untreated and LXR agonist-treated human (THP-1) macrophage cells and human peripheral blood mononuclear cells (PBMC). Data obtained from the ELISA demonstrated an approximately eightfold increase in ABCA1 levels in both macrophages as well as PBMC in response to LXR agonist treatment, and results were highly correlated with those obtained by immunoprecipitation and western blotting. Together, these results suggest that the sandwich ELISA may be a sensitive and effective method for quantitating ABCA1 protein levels.

Abbreviations

ABCA1	ATP-binding cassette transporter A-1
ApoA1	Apolipoprotein A1
CPT	Cell preparation tube
DMSO	Dimethyl sulfoxide
ELISA	Enzyme-linked immunosorbent assay
HDL	High density lipoprotein
HDL-C	High density lipoprotein cholesterol
LXR	Liver X receptor
LDL	Low density lipoprotein
LDL-C	Low density lipoprotein cholesterol
PBMC	Peripheral blood mononuclear cells
PMA	Phorbol 12-myristate 13-acetate
PPAR	Peroxisome proliferator-activated receptor
RCT	Reverse cholesterol transport
TD	Tangier disease

Introduction

ABCA1-mediated active transport of cellular cholesterol and phospholipids to lipid poor apolipoprotein A1 (Apo-A1) produces high-density lipoproteins (HDL) and represents the initial and rate-limiting step in the reverse cholesterol transport (RCT) pathway [1–4]. Cellular cholesterol efflux and the RCT pathway ultimately lead to inhibition of atherosclerotic lesion formation [5]. Moreover, an inverse correlation exists between HDL levels and cardiovascular disease, and several efforts have identified HDL as being an

atheroprotective factor against coronary artery disease [6–9]. In light of these observations, many researchers have investigated ways to up-regulate RCT [10, 11]. As a result, ABCA1 has become a target for up-regulation.

ABCA1 is a 254 kDa integral membrane protein and is a member of a superfamily of ABC transporters that utilize ATP to transport substrates between cellular compartments and across cell membranes [3, 12]. The function of ABCA1 as a key regulator of HDL became apparent in 1999, when loss of ABCA1 gene function was determined to be the cause of Tangier disease (TD). Patients with TD exhibit extremely low levels of HDL, and have increased incidence of premature coronary artery disease [2, 13–15]. In recent years, several novel gene mutations and defects in the ABCA1 transporter have been characterized as resulting in TD [16–18].

ABCA1 expression is modulated by several metabolites including cAMP, sterols, and peroxisome proliferator-activated receptor agonists [4, 19]. Furthermore, the nuclear liver X receptors α and β (LXRs) are oxysterol activated cholesterol sensors that have been shown to play a key role in increasing serum HDL-C concentrations in mice [20–23]. Additionally, synthetic LXR agonists have been described as up-regulating ABCA1 mRNA and stimulating reverse cholesterol efflux [19, 24, 25].

Methods for measuring ABCA1 mRNA levels have thus been critical in understanding RCT [26]; however, the hydrophobic nature of ABCA1, a protein that contains 12 membrane spanning domains, has made it difficult to develop quantitative assays for ABCA1 protein levels. Recently Paul and colleagues described a competitive assay for measuring ABCA1 in cell lysates from human tissues and fibroblasts with a sensitivity of 80 ng/ml [27]. In order to better understand the effects of LXRs and related compounds on ABCA1 protein, an even more sensitive assay that can be used with different cellular matrices would be desirable. Recognizing the advantages that such an assay would provide, we set out to develop a sandwich ELISA to measure ABCA1 protein levels.

Experimental Procedures

Expression and Purification of Human ABCA1 Protein

Human ABCA1 (accession number: NM_005502) cDNA was purchased from Openbiosystem Co. (Cat# EHS1001-99865381, Clone ID: 9056784, accession number: BC146856). The cDNA contains one mutation based on accession number NM_005502 and the human genome sequence database. The mutation was corrected using PCR–based mutagenesis (Current Protocols in Molecular Biology). The corrected nucleotide sequences encoding full-length ABCA1 were inserted into pFastBac1 vector (Invitrogen) with a C-terminal Flag tag. P0 recombinant baculovirus was generated according to the Bac-to-Bac protocol (Invitrogen). P0 virus was amplified by infecting Sf9 cells (Invitrogen) with 0.1% volume of virus and harvesting 5 days post infection to generate P1 virus. For protein production, 500 ml of Sf9 cells per 2-L flask were infected at 1.5×10^6 cells/ml using 5 ml of P1 virus per flask. Infections were carried out at 27 °C and 135 rpm. Cells were spun down, rinsed with PBS and the pellets frozen at −80 °C. Flag-tagged ABCA1 was purified by anti-Flag M2 affinity chromatography from frozen cell pellets according to the manufacturer's instructions (Sigma).

Purified rABCA1-Flag protein was solubilized in buffer (50 mM Tris, pH 7.5, 150 mM NaCl, and 0.1% Triton X-100) and the final protein concentration was determined by Bradford using BSA as a standard. The identity of the purified protein was confirmed by western blotting, and the protein was stored at −80 °C in small aliquots prior to subsequent use. Purity of the recombinant ABCA1 protein was assessed by loading 250 ng of the protein onto a 4–20% tris–glycine polyacrylamide gel (Invitrogen). Molecular weight markers (SeeBlue, Invitrogen) were also loaded onto the gel for size comparison. One-dimensional electrophoresis was performed for 85 min at 175 V in a gel chamber containing tris–glycine SDS running buffer, and the gel was visualized following staining with Coomassie Blue.

ABCA1 Antibodies

Due to the hydrophobic nature of this 12-membrane spanning domain protein, a number of different approaches were taken to raise antibodies against the protein that could recognize both the recombinant and endogenous human ABCA1 protein in native phase. These approaches included attempting to raise rabbit polyclonal antibodies against six independent ABCA1 peptides. These rabbit polyclonal anti-peptide antibodies and a number of other antibodies including commercial antibodies were evaluated for their ability to recognize ABCA1 protein in native phase. To determine which antibodies might be suitable, more than a dozen different antibodies were evaluated for their ability to immunoprecipitate ABCA1 from control or TO901317-stimulated THP-1 cell lysates. Eventually, two antibodies were identified that were capable of immunoprecipitating ABCA1 and were compatible with each other in a sandwich ELISA format. The first was a monoclonal antibody that was raised against a C-terminal portion of the protein corresponding approximately to amino acids 1,800–2,250. The second was a polyclonal antibody raised against a mid-region of the protein corresponding approximately to amino acids 1100–1300. The exact epitopes of these

antibodies are not known at the present time, although the monoclonal antibody likely recognizes a linear epitope as it proved capable of detecting recombinant and endogenous ABCA1 protein via Western blotting as described below.

Macrophage Lysate Preparation

Human (THP-1) monocytes were differentiated with 20 nM PMA for 24 h, trypsinized, and seeded at 1.5×10^6 cells/well in RPMI 1640 (Hyclone) with 10% LPDS and 50 μM 2-mercapthoethanol (Sigma) in 96-well plates and incubated at 37 °C in 95% air:5% CO_2 for 6 h. Following attachment, cells were treated with 1 μM of Tularik LXR agonist TO901317 (purchased from Sigma) or 0.1% DMSO (vehicle) in the same media for 24 h. After treatment, media was removed, and the cells were washed once with PBS. Cells were then lysed with 25 μl/well of ice cold lysis buffer (50 mM HEPES, 150 mM NaCl, 5 mM EDTA, 5 mM EGTA, and 1.0% Triton X-100, pH 7.40 supplemented with Sigma phosphatase inhibitor cocktails I and II and Roche protease inhibitor cocktail). The plate was shaken at 900 rpm for 1 min, frozen at −20 °C, thawed, shaken again and the contents of the wells were collected and stored at −80 °C prior to subsequent analysis.

Peripheral Blood Mononuclear Cell Preparation

Whole blood was collected from four human donors directly into 8-ml sodium heparin cell preparation tubes (CPT). Immediately following collection, tubes were centrifuged for 25 min at 2,200 rpm in a large swinging bucket centrifuge (Jouan CR312). CPT plasma was transferred to fresh, siliconized borosilicate tubes in 5-ml aliquots for treatment. Aliquots from each donor were treated as follows: un-treated, 0.1% DMSO (vehicle), 1 μM LXR agonist TO901317, and 10 μM LXR agonist TO901317. The samples were incubated at 37 °C under an atmosphere of 95% air:5% CO_2 for 24 h. Following incubation, samples were spun 10 min at 1,500 rpm, and the supernatant (plasma) was drawn off. Peripheral blood mononuclear cells (PBMC) were washed three times with 500 μl of PBS. Cells were lysed with 500 μl of lysis buffer at 4 °C for 1 h, and PBMC lysates were transferred to polypropylene microfuge tubes and stored at −80 °C.

Immunoprecipitation of ABCA1

For THP-1 macrophages, immunoprecipitations (IP) were performed on 50 μl of lysate (4×10^6 cells/ml) added to 950 μl of lysis buffer. For PBMC, IP were performed on 400 μl of lysate (3×10^5 cells/ml) added to 1.6 ml of lysis buffer. ABCA1 protein was immunoprecipitated with 5 μg of anti-ABCA1 monoclonal antibody (raised against a C-terminal portion of the protein corresponding approximately to amino acids 1,800–2,250) covalently attached to 20 μl of Seize Primary covalent coupling beads (Pierce) by incubating antibody in phosphate buffer with aminolink resin and coupling beads according to the manufacturer's protocol. Following overnight incubation at 4 °C, beads were washed three times with lysis buffer, and 30 μl of 2X sample buffer (100 mM Tris, pH 6.80, 40 g/l SDS, 200 ml/l glycerol, 20 mg/l bromophenol blue, 0.05% 2-mercaptoethanol) were added to the beads. Samples were vortexed, boiled for 5 min, vortexed again and spun down. Each supernatant was then transferred to a fresh microfuge tube and stored at −20 °C prior to subsequent Western blotting.

Western Blotting

Samples, molecular weight markers (SeeBlue, Invitrogen), and controls were loaded onto a 4–20% tris–glycine polyacrylamide gel (Invitrogen) and electrophoresed for 85 min at 175 V in a gel chamber with tris–glycine SDS running buffer. Contents from the gel were then transferred to nitrocellulose (Amersham) by applying 100 V for 2 h at 4 °C. Blots were blocked with TBS-Casein blocking buffer for 1 h at room temperature. Following blocking, blots were washed three times with Tris buffered saline + Tween (TBST) and probed with monoclonal anti-ABCA1 antibody (1 μg/ml in blocking buffer) for 1 h at room temperature. Blots were washed three times with TBST and probed with an HRP-labeled goat anti-mouse IgG (diluted 1:2,500 in blocking buffer) for 1 h at room temperature. Blots were washed three times with TBST and once with TBS. Afterward, blots were developed with the chemiluminescent reagent Supersignal ECL substrate reagent (Thermo) for approximately 1 min, air-dried, and exposed to Kodak Bio-Max Light film for approximately 1–2 min.

ABCA1 ELISA

The 96-well polystyrene plates were coated overnight at 4 °C with 100 μl of 5 μg/ml polyclonal anti-ABCA1 antibody (diluted in Pierce carbonate-bicarbonate coating buffer, pH 9.0). The following day, wells were washed three times with TBST and blocked for 1 h with TBS-casein (Pierce). After washing again as above, 100 μl of recombinant ABCA1 standard curve aliquots (serial 1:2 dilutions ranging from 250 ng/ml to 0.25 ng/ml in lysis buffer + 1% BSA) and cell lysate samples were added to the appropriate wells. In the case of PBMC lysates, samples were run neat on the ELISA, while THP-1 lysates were run at a 1:10 dilution on the ELISA. The plate was allowed to incubate 2 h at room temperature. Following six washes with TBST, biotinylated monoclonal anti-ABCA1 antibody

(1 μg/ml, prepared using a Pierce EZ-link kit according to the manufacturer's protocol) was added to the plate at 100 μl/well, and allowed to incubate 1 h at room temperature. Following this incubation, the plate was again washed six times with TBST. Afterward, 100 μl of streptavidin-HRP (Jackson Labs) diluted 1:5,000 was added to each well. The plate was again incubated for 1 h, a final series of six washes was performed, and 100 μl of 3,3′, 5,5′-tetramethylbenzidene substrate (TMB, Pierce) was added to the wells and incubated at room temperature for 30 min. The development reaction was stopped with an equal volume addition of 2 N phosphoric acid, and plates were read on a Spectromax plate reader at 450 nm. ELISA dilution curves for the recombinant standards and samples were determined to be parallel, and the ELISA also demonstrated excellent dilutional linearity. The sensitivity of the assay (limit of the blank or mean plus 3 SD of the zero calibrator) was determined to be 0.5 ng/ml.

Data Analysis

SigmaPlot, version 8.0 was used for fitting of the calibration curves for the ABCA1 ELISA. Data were analyzed and plotted using the program FigP (Biosoft, St. Louis, MO). Statistical analysis was performed using the same program. A p value of less than 0.05 was considered to indicate statistical significance.

Results

The first step toward development of our novel sandwich ABCA1 ELISA consisted of production of recombinant full-length ABCA1 protein (rABCA1). The resulting recombinant protein was a C-terminal, flag-tagged, baculovirus-generated full-length rABCA1. Purity of the rABCA1 protein was assessed by one-dimensional gel electrophoresis followed by Coomassie blue staining (Fig. 1a), which indicated that the protein migrated as a predominate 250 kDa band. Based on the results shown in Fig. 1a, the recombinant protein was judged to be approximately 90% pure. The identity of the protein was subsequently confirmed by Western blotting (Fig. 1b).

Following expression and characterization of rABCA1, multiple antibodies were evaluated by immunoprecipitating ABCA1. To determine which antibodies might be suitable, more than a dozen different antibodies were evaluated for their ability to immunoprecipitate ABCA1 from control or TO901317-stimulated THP-1 cell lysates. As Fig. 2a demonstrates, many of these antibodies (including Abcam 7360 and Novus NB 400) failed to efficiently immunoprecipitate ABCA1 in native phase, and this was not unexpected considering the hydrophobic

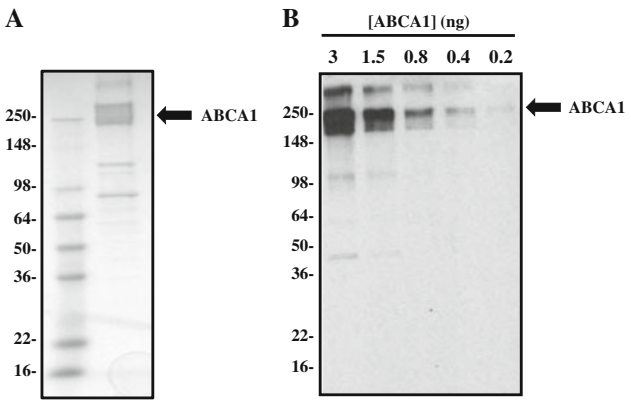

Fig. 1 Characterization of full length human recombinant ABCA1 protein. **a** Recombinant ABCA1 protein (250 ng) prepared as described in the Methods was analyzed by SDS-PAGE followed by Coomassie blue staining to assess purity of the protein. Recombinant ABCA1 protein migrated as a predominate band with a molecular weight of approximately 250 kDa, consistent with both the predicted molecular weight of the protein and the observed size of endogenous ABCA1 from THP-1 cells and PBMC. **b** In order to further confirm the identity of the recombinant ABCA1 protein, multiple dilutions of recombinant ABCA1 protein were analyzed by Western blotting with monoclonal anti-ABCA1 antibody. Western blotting analysis demonstrated an immunoreactive band at 250 kDa, consistent with the migration of the protein as described in **a**

nature of the 12 membrane-spanning domain protein. Two antibodies were eventually identified that were capable of binding the protein in native phase. The two antibodies were tested with each other in a sandwich ELISA format and were found to be compatible with each other with the optimal orientation determined to be polyclonal capture antibody (raised against a mid-region of the protein corresponding approximately to amino acids 1,100–1,300) and monoclonal conjugate antibody (raised against a C-terminal portion of the protein corresponding approximately to amino acids 1,800–2,250).

The resulting ELISA thus incorporated a polyclonal capture antibody that is paired with a biotinylated monoclonal detection antibody, which is subsequently detected with streptavidin-HRP. To prepare a suitable standard curve for the assay, recombinant protein was first diluted to a concentration of 250 ng/ml and then subsequently serially diluted 1:2 to establish a 12-point standard curve. Figure 2b shows a representative standard curve from the final version of the sandwich ELISA.

Once the ABCA1 sandwich ELISA was developed, we examined the effect of a well known LXR agonist (TO901317) on human THP-1 macrophage expression of ABCA1 protein. In order to do this, human-THP-1 macrophages were differentiated and treated with 1 μM LXR agonist TO901317 or 0.1% DMSO (vehicle control), and incubated for 24 or 48 h. Following cell lysis, the resulting lysates were analyzed using the ELISA as well as by

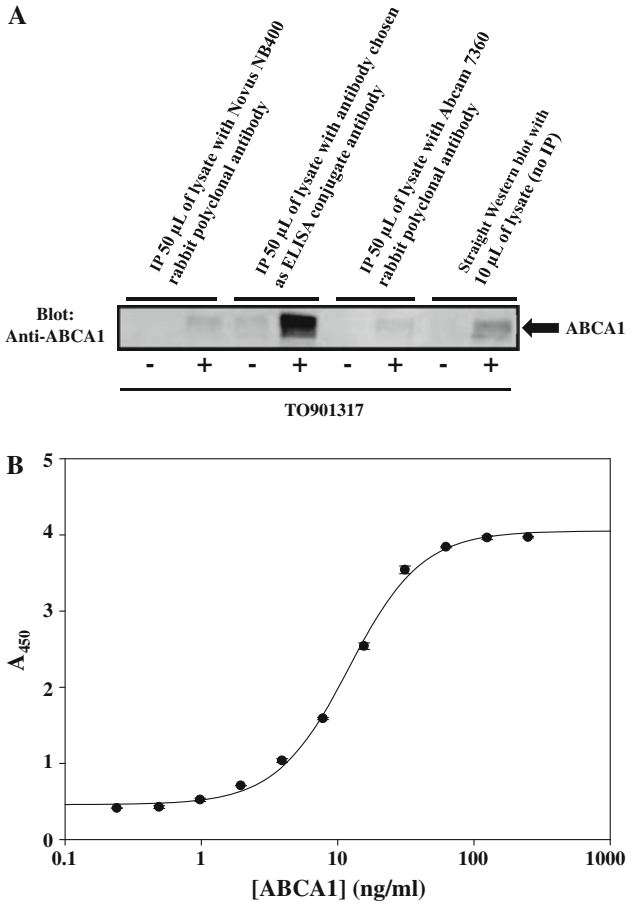

Fig. 2 Development of ABCA1 sandwich ELISA. **a** To determine suitable antibodies for a sandwich ELISA, more than a dozen different antibodies were evaluated for their ability to immunoprecipitate ABCA1 from control or TO901317-stimulated THP1 cell lysates. Most antibodies such as Novus NB400 or Abcam 7360 were not able to efficiently immunoprecipitate ABCA1. In contrast, the antibody eventually chosen as one of the antibodies for the sandwich ELISA very effectively immunoprecipitated ABCA1. Results are representative of those obtained from screening more than a dozen different anti-ABCA1 antibodies. **b** Following screening of antibodies as described in **a**, an ABCA1 sandwich ELISA was developed using a polyclonal capture antibody and monoclonal conjugate antibody. The optimal orientation of antibodies was determined to consist of a polyclonal capture antibody and conjugate, biotinylated monoclonal antibody. A recombinant ABCA1 standard curve was established by starting at a concentration of 250 ng/ml followed by serial 1:2 dilutions down to 0.25 ng/ml. The resulting ELISA standard curve provided a suitable dynamic range for quantitation of ABCA1 protein, with an approximate sensitivity of 0.5 ng/ml

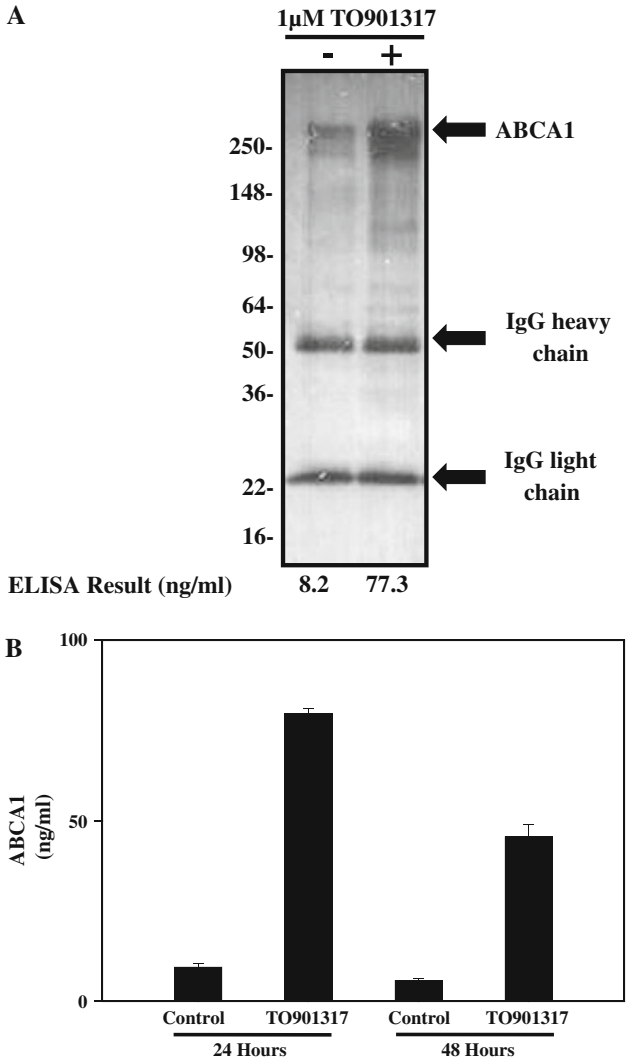

Fig. 3 Liver X receptor (LXR) agonist-induced increases in ABCA1 protein levels in THP-1 human macrophages. **a** Human THP-1 macrophage cells were treated with 1 µM of the LXR agonist TO901317 for 24 h. Following processing, cell lysates were analyzed by immunoprecipitation and Western blotting. Results are representative of two independent experiments. **b** LXR agonist-induced increases in THP-1 macrophage cell ABCA1 protein at 24 and 48 h were quantitated using the ABCA1 sandwich ELISA described in Fig. 2. Results are shown as the mean ± SEM for triplicate determinations

immunoprecipitation and Western blotting. Figure 3 shows the results from these experiments in which TO901317 caused a dramatic increase in ABCA1 protein expression in the THP-1 cells.

THP-1 lysates were analyzed using our novel sandwich ABCA1 ELISA, and the results were compared to those obtained using immunoprecipitation and Western blotting. Figure 3a shows the immunoprecipitation and Western blotting results. Figure 3b shows the ELISA results, which quantitated the LXR agonist up-regulation of ABCA1. As Fig. 3b demonstrates, TO901317 caused a significant increase in THP-1 ABCA1 protein expression at both 24 and 48 h compared to vehicle control. After 24 h, vehicle-treated THP-1 lysates contained 9.6 ± 0.7 ng/ml of ABCA1 protein while TO901317-treated lysates contained 79.7 ± 1.4 ng/ml of ABCA1 protein ($p < 0.001$ vs. control). After 48 h, vehicle-treated THP-1 lysates contained 5.8 ± 0.4 ng/ml of ABCA1 protein while TO901317-treated lysates contained

45.6 ± 3.4 ng/ml of ABCA1 protein ($p = 0.005$ vs. control).

To investigate the possibility that our novel sandwich ABCA1 ELISA might have relevance as a clinical biomarker for LXR agonists, PBMC were harvested from human donors and incubated with 1 or 10 μM TO901317 or 0.1% DMSO (vehicle control) for 24 h. Following cell lysis, the resulting PBMC lysates were analyzed by ELISA as well as by immunoprecipitation and Western blotting. Figure 4a shows the immunoprecipitation and Western blotting results from these experiments in which TO901317 caused a marked increase in ABCA1 protein expression in the human PBMC.

Similar to the THP-1 lysates, PBMC lysates were also analyzed using our novel sandwich ABCA1 ELISA, and the results were compared to those obtained in Fig. 4a using immunoprecipitation and Western blotting. Figure 4b shows the results of this series of experiments, in which the use of the sandwich ELISA quantitated LXR agonist up-regulation of ABCA1 in human PBMC. As Fig. 4b demonstrates, TO901317 caused a significant increase in THP-1 ABCA1 protein expression in human PBMC at 24 h compared to vehicle control. After 24 h, untreated and vehicle-treated human PBMC lysates contained less than 0.5 ng/ml of ABCA1 protein while 1 μM TO901317-treated human PBMC lysates contained 3.2 ± 0.3 ng/ml of ABCA1 protein ($p = 0.002$ vs. control) and 10 μM TO901317-treated human PBMC lysates contained 4.6 ± 0.6 ng/ml of ABCA1 protein ($p = 0.008$ vs. control).

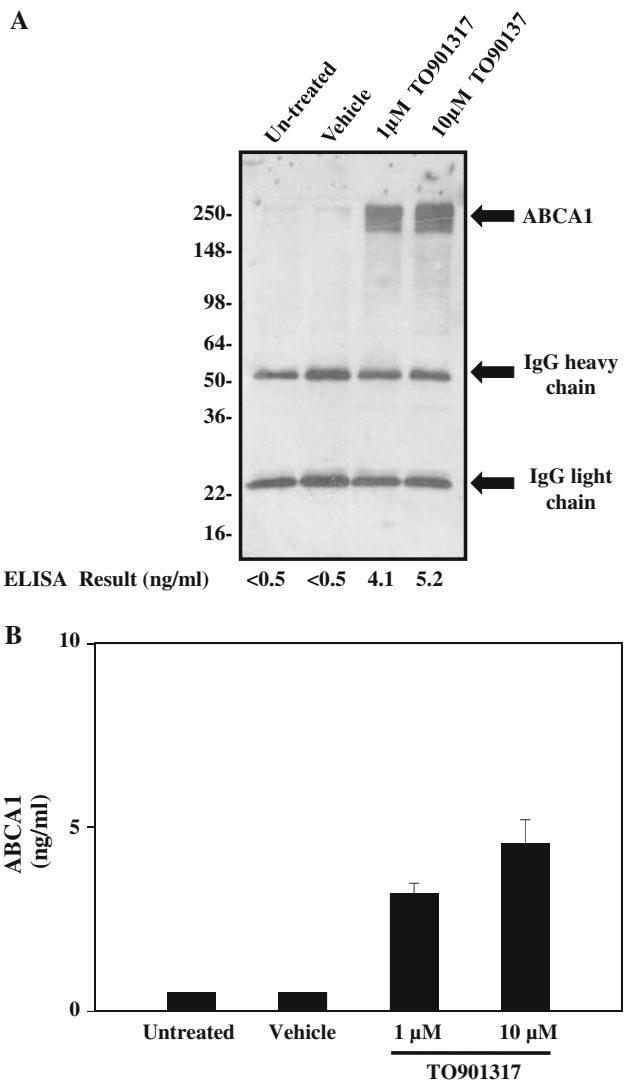

Fig. 4 A Liver X receptor (LXR) agonist increases ABCA1 protein levels in human PBMC. **a** Human PBMC were treated with 1 and 10 μM of the LXR agonist TO901317 for 24 h. Following processing, PBMC lysates were analyzed by immunoprecipitation and Western blotting. Results are representative of those observed from four different human blood donors. **b** LXR agonist-induced increases in human PBMC at 24 h were quantitated using the ABCA1 sandwich ELISA described in Fig. 2. Results are shown as the mean ± SEM for quadruplicate determinations

Discussion

The critical role of ABCA1 in cholesterol efflux and RCT makes it an attractive target for therapeutic development on several fronts. As a result, there has been a need for a sensitive method for quantifying ABCA1 at the protein level. This has been made difficult due to the fact that ABCA1 is a membrane protein containing 12 membrane-spanning domains. Paul and colleagues recently described a competitive ELISA that was standardized to an ABCA1 peptide and had a reported sensitivity of 80 ng/ml [27]. In the current study, we describe a sandwich ELISA standardized to full-length recombinant ABCA1 protein with a sensitivity of approximately 0.5 ng/ml.

This estimation of sensitivity of the ELISA, however, must be interpreted with some caution due to the fact that the recombinant protein used to standardize the assay was not 100% pure, but was only approximately 90% pure as judged by Coomassie blue staining. As a result, the true sensitivity of the assay may not be 0.5 ng/ml. In addition, it is possible that the assay may recognize authentic cellular ABCA1 protein differently than recombinant ABCA1 protein. This too could mean that the actual sensitivity of the assay for endogenous analyte may not be 0.5 ng/ml. It also cannot be ruled out that the assay may have cross-reactivity for other cellular protein components, which could also alter the estimate of true sensitivity of the assay. Nor can it be ruled out that there may be some cellular fraction of ABCA1 protein (perhaps up to 10%) that is not measured by the assay. Therefore, while the ELISA can be used to measure relative changes in ABCA1 protein expression levels such as those that occur in THP-1 cells and PBMC following LXR agonist stimulation, absolute

protein levels measured by the assay must be interpreted in the proper context.

Macrophage LXRs play a major role in the inhibition of atherosclerosis via direct regulation of ABCA1 gene expression [28, 29]. Therefore, THP-1 macrophage cells provide a relevant model for screening LXR agonists, and additional non-LXR compounds that may target up-regulation of RCT by increasing ABCA1. In this study, we used our novel ABCA1 sandwich ELISA to examine the effect of a well-known LXR agonist, TO901317, on THP-1 macrophage ABCA1 protein expression. Our ELISA demonstrated that TO901317 induced an approximate eightfold increase in ABCA1 protein levels. The dramatic increases observed help indicate that the sandwich ELISA may be a reliable method to measure the efficacy of LXR agonists.

We also isolated and treated human PBMC with TO901317 to determine if a similar LXR-induced increase in ABCA1 could be measured. Similar to what was observed for the THP-1 cells, the resulting data again demonstrated an approximate eightfold increase induced by the LXR agonist. Together, these data are consistent with the known up-regulation of ABCA1 mRNA and protein (as assessed by Western blotting) following LXR agonist treatment [24, 30, 31], indicating that our ELISA is capable of quantitating LXR agonist-induced increase in ABCA1 in human PBMC.

While statins are currently the most effective lipid lowering agents for at risk hyperlipidemic patients, there remains a significant portion of affected patients who are either not able to tolerate statins, or for whom statin treatment does not result in a desired reduction of LDL-C levels. Furthermore, there are data that suggest statins actually down-regulate ABCA1 gene expression in macrophages by inhibiting the synthesis of an oxysterol ligand for LXR [32, 33]. Such findings imply that treatments targeting the up-regulation of ABCA1 could be beneficial in enhanced lipid lowering for patients already being treated with statins. As cardiovascular disease remains the leading cause of morbidity and mortality in developed countries, several approaches are being taken to capitalize on the atheroprotective benefits of increasing RCT. Therefore, our novel sandwich ELISA described in this study, which provides a sensitive method to quantitatively measure ABCA1 protein levels, may have utility for the development of compounds designed to increase ABCA1 protein expression and reverse cholesterol transport.

Abstract Clinical studies have shown that fiber consumption facilitates weight loss and improves lipid profiles; however, the beneficial effects of high fermentable fiber low glycemic index (GI) diets under conditions of weight maintenance are unclear. In the Legume Inflammation Feeding Experiment, a randomized controlled cross-over feeding study, 64 middle-aged men who had undergone colonoscopies within the previous 2 years received both a healthy American (HA) diet (no legume consumption, fiber consumption = 9 g/1,000 kcal, and GI = 69) and a legume enriched (1.5 servings/1,000 kcal), high fiber (21 g/1,000 kcal), low GI (GI = 38) diet (LG) in random order. Diets were isocaloric and controlled for macronutrients including saturated fat; they were consumed each for 4 weeks with a 2–4 week break separating dietary treatments. Compared to the HA diet, the LG diet led to greater declines in both fasting serum total cholesterol (TC) and low density lipoprotein cholesterol (LDL-C) ($P < 0.001$ and $P < 0.01$, respectively). Insulin-resistant (IR) subjects had greater reductions in high density lipoprotein cholesterol (HDL-C; $P < 0.01$), and triglycerides (TAG)/HDL-C ($P = 0.02$) after the LG diet, compared to the HA diet. Insulin-sensitive (IS) subjects had greater reductions in TC ($P < 0.001$), LDL-C ($P < 0.01$), TC/HDL-C ($P < 0.01$), and LDL-C/HDL-C ($P = 0.02$) after the LG diet, compared to the HA diet. In conclusion, a high legume, high fiber, low GI diet improves serum lipid profiles in men, compared to a healthy American diet. However, IR individuals do not achieve the full benefits of the same diet on cardiovascular disease (CVD) lipid risk factors.

VLDL	Very low density lipoprotein

Introduction

Numerous studies have shown an inverse association between intake of dietary fiber and risk for chronic diseases such as cardiovascular disease (CVD) [1, 2] and type 2 diabetes mellitus [3]. The beneficial effects may be partially due to fiber's hypocholesterolemic [4–6] and hypoinsulinemic effects [3]. On the basis of a number of epidemiological studies on coronary heart disease (CHD) [7–9], the Institute of Medicine (IOM) currently recommends a daily consumption of 14 g of fiber per 1,000 kcal for Americans (DGA 2005).

Legumes, such as pinto, navy, kidney, lima, and black beans, are a rich source of dietary fiber but the effects of these types of beans on blood lipid levels are limited. A meta-analysis of 67 controlled trials was conducted to quantify the hypocholesterolemic effects of major dietary fibers [10]. The results demonstrated that daily intake of 2–10 g of soluble fiber was associated with significant decreases in total cholesterol (TC, −1.7 mg/L per gram) and low density lipoprotein cholesterol (LDL-C, −2.2 mg/L per gram). A 12-week randomized dietary intervention with 40 men and women with metabolic syndrome and 40 healthy subjects [11] reported that daily intake of a bean entrée (130 g of cooked dry pinto beans) lowered serum TC by 8% in the healthy population and by 4% in the metabolic syndrome group. A limitation of legume-related studies is that most recent interventions have been conducted with a single test meal [12–15] or fiber supplement [16, 17] and some of these studies were designed to test short-term effects in hours or days [12, 14, 15].

The Legume Inflammation Feeding Experiment (LIFE Study, [18]) was a randomized controlled cross-over feeding study designed to test the effects of a legume-rich, high fermentable fiber, low glycemic index (GI) diet on biomarkers of inflammation and insulin resistance in middle-aged men at high risk for colorectal cancer. An important secondary objective of the LIFE Study was to evaluate the effects of diet on serum lipids. We hypothesized that the high legume low GI diet would significantly improve serum lipid profiles. To our knowledge, this was the first randomized controlled, cross-over feeding study designed to assess the hypocholesterolemic effects of a mixture of the five types of beans under conditions of weight maintenance.

Subjects and Methods

Subjects and Recruitment

All aspects of this study were approved by the Institutional Review Boards of the Pennsylvania State University and the National Cancer Institute. Sixty six non-smoking male subjects age 35–75 who had undergone colonoscopies within the previous 2 years were recruited in Central Pennsylvania. The study was conducted from February 1st, 2006 to August 6th, 2008. History of colorectal adenomas (yes or no) was combined with insulin resistance (yes or no) for group classification. Insulin resistance was defined by a homeostasis model assessment (HOMA-IR) index level. The formula for calculation is as follows: fasting insulin (μU/mL) × fasting glucose (mmol/L)/22.5 [19]. Subjects with a HOMA-IR index level equal or higher than 2.6 were considered insulin resistant [20, 21].

Criteria and Restrictions

All participants were prescreened by telephone interview and a clinical screening test for study eligibility. In addition to the colonoscopy, subjects had to meet the following criteria: (1) weight maintenance or less than 10% body weight loss 6 months prior to the present study, (2) body mass index (BMI) within 20–37 kg/m^2, (3) no history of

colorectal cancer, bowel resection or inflammatory bowel disease, (4) no serious medical conditions, e.g., heart disease, stroke, diabetes, renal or kidney disease, liver disease or cirrhosis, or cancer within the last 10 years, (5) not taking vitamin/mineral, herbal, or other nutritional supplements, and (6) not taking any cholesterol-lowering, glucose-controlling, or non-steroidal anti-inflammatory (e.g. aspirin) medications.

The subjects who met the eligibility criteria were invited to undergo clinical screening tests including a fasting blood draw at the General Clinical Research Center (GCRC) at Penn State University in University Park, PA, USA. Eligible subjects were asked to return to the GCRC to have resting metabolic rate measured and completed three 24-h telephone diet calls (two on weekdays and one on weekend) to estimate daily energy requirements.

Diet and Study Design

A detailed explanation of diet and study design was published previously [18]. In brief, the randomized controlled cross-over feeding study consisted of a first 4-week diet period, a 2–4 week compliance break, and a second 4-week diet period. The time period allowed for the test diet intervention was sufficient to assure that lipids had stabilized [22]. Subjects were first randomly assigned to either a healthy American diet (HA) or an isocaloric legume diet (LG; approximately 250 g of cooked pinto, navy, kidney, lima, and black beans per day), and then were switched to the other diet for the second feeding period. All foods for this study were prepared and distributed by the metabolic diet center at the GCRC. On weekdays, the participants ate breakfast or dinner at the GCRC and on Fridays, all the packed foods for weekends were taken home. The dietitians recorded body weight and food consumption at each visit. Uneaten foods were very little; they were returned to the GCRC and were measured and recorded by study dietitians daily as a measure of compliance. Seven-day cycle menus were created for each test diet and evaluated for percentages of energy contributed by each of the macronutrients using Nutrition Data System for Research (NDS-R, 2006, Minneapolis, MN, USA); GI and GL were calculated using Food Processor (2005). Total energy intake was adjusted by study dietitians in 200 kcal increments to maintain participants' body weights during the diet periods (e.g. 2,000, 2,200, 2,400, 2,600 kcal, etc.). Subjects were allowed up to two alcoholic beverages per week while consuming the study diets. We used the same or similar foods to design our menus. For example, subjects had tuna pasta salad as lunch during the HA menu which was replaced by Italian bean and tuna salad during the LG menu. For dinner, the HA diet provided ginger chicken and rice, while the LG diet provided ginger chicken and beans. The ingredients of the two ginger chicken dishes were the same except that the substitution of beans for rice. The LG diet provided much of the protein from plant sources and the HA diet provided more protein from chicken (skinless) in order to meet the dietary recommendation for cholesterol. Daily compliance questionnaires indicated very good test diet adherence. Table 1 shows the composition of the participants' diets at entry (pre-study) and the two test diets.

Sample Collection and Measurements

Anthropometric measurements were completed using standardized methods by well-trained nurses at the GCRC on Penn State University Park campus. At the beginning and end of each test diet period, a 12-h overnight fasting blood sample was drawn and serum was collected for measurement of TC, LDL-C, HDL-C and TAG. All blood samples were centrifuged at $3{,}200 \times g$ for 15 min at 4°C, the supernatant was separated and aliquoted in cryovials, and stored at −80°C. Serum lipids were measured at Penn State Hershey Medical Center in the laboratory of Dr. Laurence Demers. All samples from each subject were grouped together for analysis in the same batch. Lipids were measured using enzymatic procedures on an automated chemistry analyzer (Roche); the intra- and inter-assay coefficients of variations (CV) for all biomarkers of interest were less than 5%. Fasting plasma insulin was measured using a human-specific insulin RIA (Linco-Millipore, MA, USA, HI-14 K; sensitivity, 2–200 μU/mL; inter-assay CV, 2.9–6.0%; intra-assay CV, 2.4–4.4%). Fasting plasma glucose was measured via an immobilized enzyme biosensor using the YSI 2300 STAT Plus Glucose and Lactate analyzer (Yellow Springs Instruments; inter- and intra-assay CV were less than 5%).

Statistical Analysis

The means for the pre-study diet were calculated by 3-day diet recalls and the means for the two test diets were based on the average of each 7-day menu for a 2,000 kcal diet (Table 1). The experimental diets and participants' pre-study diets were compared using one-way analysis of variance (ANOVA) with the Tukey test to adjust for the multiple comparisons. Baseline characteristics stratified by subjects' insulin resistance status were compared using one-way ANOVA. Log-transformation of HOMA-IR index, TAG, and TAG/HDL-C were performed for the analyses because of skewed distributions. General linear mixed models with repeated measurement (Proc mixed) were used to test for the effects of diet, period, and their interactions with change scores of all outcome variables. Subject was treated as a random and diet treatment as a

Table 1 Nutrient and food profile of the experimental diets (compared to pre-study diet)

Nutrient/food group	Pre-study diet	Healthy American (high GI) diet	Legume (low GI) diet	*P* value[a]
Glycemic index	60 ± 6	69 ± 3[b]	38 ± 2[b,c]	<0.001

Total fiber (g/1,000 kcal)[d]	9 ± 3	9 ± 1	21 ± 1[b,c]	<0.001
Soluble fiber (g/1,000 kcal)[d]	2 ± 1	2 ± 1	4 ± 1[b,c]	<0.001
Insoluble fiber (g/1,000 kcal)[d]	7 ± 2	7 ± 1	17 ± 1[b,c]	<0.001
Cholesterol (mg/1,000 kcal)[d]	125 ± 52	98 ± 9	70 ± 11[b]	0.001
Fruit (serving/1,000 kcal)[d]	0.7 ± 0.6	0.9 ± 0.4	1.3 ± 0.3[b]	0.02
Vegetable (serving/1,000 kcal)	1.4 ± 0.7	1.8 ± 0.5	2.2 ± 0.6[b]	0.01
Legume (serving/1,000 kcal)[d,e]	0.1 ± 0.2	0.0 ± 0.0	1.5 ± 0.0[b,c]	<0.001

Values are reported as means ± SD. The mean for 3-day diet recalls were used to assess participants' pre-study diets, the means of 7-day menus (on 2,000 kcal level) reflect the two test diets (HA and LG)

[a] *P* values reflect the overall difference across the three diets using one-way ANOVA with Tukey tests to adjust for the multiple comparisons

[b] Different from pre-study diet, $P < 0.1$

[c] Different from Healthy American diet, $P < 0.1$

[d] Data were log-transformed for analysis

[e] Legumes were excluded in the vegetables

fixed effect. Akaike Information Criteria (AIC) and Bayesian Information criteria (BIC) were evaluated to decide model correlation structure; we used unstructured based on these comparisons and because we believed the covariance between diet treatments might be different. Likelihood ratio tests were used to test for treatment effects. Analyses were also completed using paired *t* tests with similar results. Potential confounding by age, BMI, adenoma status (yes/no), insulin resistance status (yes/no) and initial biomarker status at study entry was assessed. We also evaluated potential diet period and diet order effects for their influence on end points of interest and no carry over effect was detected. The results indicated that initial insulin resistance status may be an important modifier for the interpretation of the changes of some biomarkers at study entry; therefore, we conducted analyses stratified by insulin resistance status. There was no evidence that adenoma status was an important effect modifier; therefore, stratified results were not presented. The change scores of outcomes were based on the differences between the beginning and the end of each dietary period for this variable. The percentage changes were calculated based on the change scores and respective biomarker value at study entry. In addition, we evaluated and visualized the association between insulin resistance at study entry and the changes in lipids during dietary intervention using Pearson correlation and linear regression. Analyses were performed using SAS version 9.1 (SAS Institute, Inc, Cary, NC, USA). Significance was set at $P < 0.05$.

Results

Sixty-four subjects finished all test diet periods. Two subjects dropped out in the first week of the first test diet period because of loss of interest (completion rate = 97%). Subjects who were insulin-resistant (IR) had higher BMIs, larger waist circumferences, and higher fasting serum glucose, insulin, and TAG levels than those who were insulin-sensitive (IS) (Table 2). Subjects with a previous history of adenomas were older than those who were adenoma-free; other descriptive variables did not vary significantly by adenoma status (data not shown).

Effects of Experimental Diets on Serum Lipids

Changes in lipids on the two test diets are presented in Table 3. Compared with the HA diet, the LG diet resulted in significantly greater reductions in TC (−11 ± 3 mg/dL, $P < 0.001$) and LDL-C (−9 ± 3 mg/dL, $P < 0.01$) levels.

Table 2 Baseline characteristics of study subjects by insulin resistance status

	Overall mean	Insulin sensitive (IS)	Insulin resistant (IR)	*P* value[a]

[d] Statistical significance of the difference in change between the two diets

[e] Data were log-transformed for the analysis

The LG diet reduced TC (10%, $P < 0.001$), LDL-C (10.9%, $P < 0.001$), and TAG (14.8%, $P < 0.01$) over the 4 week feeding period. The HA diet also reduced TC (4%, $P < 0.01$) and TAG (12.6%, $P < 0.01$) but had less effect on LDL-C (3.1%, $P = 0.09$). Both test diets slightly lowered HDL-C concentrations. We also analyzed three ratios (TC/HDL-C, LDL-C/HDL-C, and TAG/HDL-C) that are predictors of CVD risk. The changes between test diets did not differ. The LG diet was associated with significant reductions in TC/HDL-C (3%, $P = 0.02$) and LDL-C/HDL-C (3.5%, $P = 0.02$) over the 4 week feeding period. The HA diet was associated with a significant reduction in TAG/HDL-C (13.5%, $P = 0.03$).

Effects of Experimental Diets on Serum Lipids Stratified by Insulin Resistance Status

We observed effect modification of the diet on biomarkers of interest by IR status (HDL-C, P-interaction = 0.03; TAG, P-interaction = 0.03; TC/HDL-C, P-interaction < 0.001; TAG/HDL-C, P-interaction = 0.01); therefore, we present our results stratified by insulin resistance status (IR or IS, Table 4). Among IS subjects, the LG diet led to greater reductions in TC (−14 ± 4 mg/dL, $P < 0.001$), LDL-C (−10 ± 4 mg/dL, $P < 0.01$), TC/HDL-C (−0.30 ± 0.10, $P < 0.01$), and LDL-C/HDL-C (−0.20 ± 0.08, $P = 0.02$), compared with the HA diet. The 4-week LG diet favorably

[b] Data were log-transformed for the analysis

reduced almost all lipid profiles; however, the 4-week HA diet only improved TC concentrations. Both test diets reduced HDL-C concentrations (−2 ± 1 mg/dL, $P = 0.02$, respectively) without between-diet difference.

Among IR subjects, the HA diet tended to have more favorable effects on the TAG/HDL-C ratio ($P = 0.02$), compared with the LG diet. The LG diet significantly decreased fasting serum TC, HDL-C, and LDL-C concentrations ($P < 0.001$ for each) but not in TAG or the HDL-related ratios. The HA diet significantly decreased TC, TAG, and TAG/HDL-C ($P = 0.01$, $P < 0.001$, and $P < 0.01$, respectively).

Effects of Insulin Resistance Status at Study Entry on Lipid R esponses

We calculated the differences between the change scores during the LG diet and those during the HA diet (subtract the change scores over the HA diet from the change scores over the LG diet) and regressed on HOMA-IR values (at study entry). Figure 1 shows an inverse association; subjects with worse insulin resistance at study entry had smaller reductions in TC/HDL-C ratio ($\beta = 0.27, R^2 = 0.11$, $P = 0.03$).

Discussion

In the LIFE study under conditions of weight maintenance, the legume-rich, high fermentable fiber, low GI diet (LG) led to greater reductions in fasting serum TC and LDL-C concentrations. It is possible that the higher fiber and reduced cholesterol consumption acted to decrease fat absorption and lower hepatic synthesis of cholesterol contributing to lower circulating lipids. Another possibility is that the reduced GI and GL of the legume diet played a role in favorably altering lipid concentrations. Low GI and GL diets favor insulin sensitivity. Insulin inhibits the mobilization of free fatty acids from adipose tissue, thus lowering hepatic production of very low density lipoprotein (VLDL) and maintaining low levels of TC and LDL-C. Possibly, these changes accounted for greater reductions in TC and LDL-C concentrations on the LG diet.

Many but not all [23, 24] studies have shown hypocholesterolemic effects of dietary fiber [11, 13, 16, 17, 25–27]; however, studies specifically on legume consumption are still limited. Anderson et al. [4] reported that incorporating 100 g of dried beans into a Western diet for 28 days decreased TC (18.7%) and LDL-C (23.1%) in men ($n = 6$). In a feeding study of 24 hyperlipidemic men who

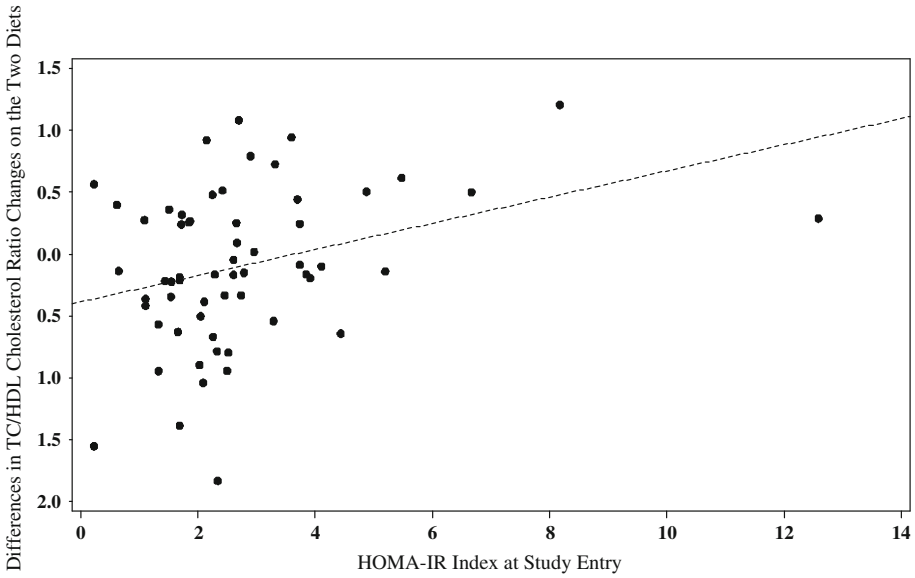

Fig. 1 Relationship between HOMA-IR index at study entry and differences in TC/HDL cholesterol ratio changes (Delta TC/HDL-C ratio) on the two diets. Delta TC/HDL cholesterol was calculated by subtracting the change scores over the HA diet from the change score over the LG diet, thus $\text{change}_{LG} - \text{change}_{HA}$ ($n = 64$; $\beta = 0.266$, $R^2 = 0.11$, $P = 0.025$)

consumed 120 or 162 g beans with tomato sauce for 21 days [28], both serum TC and LDL-C were significantly decreased (10.4 and 8.4%, respectively). Pittaway et al. [29] reported that an addition of 104 g of chickpeas into ad libitum diet for 12 weeks led to improvements in both TC (7.7 mg/dL) and LDL-C (7.3 mg/dL) among 13 pre- and 19 postmenopausal women and 13 men at high risk for CVD. Collectively, these studies demonstrate a hypocholesterolemic effect of legume consumption; yet, they were not designed as controlled feeding experiments. Among these clinical studies, weight changes either were not mentioned [14, 25, 30] or weight slightly decreased [26]. In our study, subject body weights were measured daily and their calorie intake adjusted for weight maintenance; therefore, changes in lipids were independent of weight loss.

The present study showed that both the LG diet and the HA diet significantly lowered fasting TAG concentrations. Our observations supported several [28, 31] but not all [13, 14] earlier feeding studies in terms of TAG-lowering influence. We observed that the HA diet lowered fasting TAG similarly to the LG diet. We compared the total and added sugars of the two experimental diets with that of the subjects' own diet; however, we did not find significant differences. It is possible that the TAG-lowering effects might not result from fiber consumption or GI. The LG diet provided increased plant protein in the diet. To match protein intake and maintain a lower cholesterol intake, we added more chicken, milk, and fish to the HA diet. Differences among both test diets compared to pre-study diets (e.g. protein consumption) may have contributed to the reductions in TAG observed with both diets [32].

Fruit and vegetables are good sources of many vitamins, minerals and bioactive compounds, which have been shown to possess cardioprotective effects. Antioxidants in fruit and vegetables such as vitamin C, carotenoids, vitamin E, and flavonoids may reduce CVD by reducing lipid oxidation and inflammation in the artery wall. The B-complex vitamins such as folate and B_6 may reduce CVD by lowering circulation homocysteine. A number of epidemiological studies demonstrate the inverse association between fruit and vegetable consumption and CVD risk [33–37]. In the National Heart, Lung, and Blood Institute Family Heart Study of 4,466 men and women aged 25 and older followed from 1993 to 1995 [38], persons in the higher range of fruit and vegetable consumption (mean of 5.4 servings/day for men and 5.5 servings/day for women) had lower fasting LDL-C concentrations (P for trend <0.0001 for each), compared to those in the lower range (mean of 1.4 servings for both). In the present study, we observed that both the LG and HA diets provided higher amounts of fruit and vegetables compared with subjects' usual diets, although the differences were only significant between the LG diet and subjects' usual diets.

Several cross-sectional studies have reported that high dietary GI was inversely associated with HDL-C [39–43] and positively associated with LDL-C [43] and TAG concentrations [40, 43]. High dietary GL was inversely associated with HDL-C [39, 40, 43, 44] and was positively associated with TAG concentrations [40, 43, 44]. Ma et al. [41] reported an inverse associations between GL, TC and LDL-C concentrations; however, Du et al. [42] reported non-significant associations between GL and lipid and lipoprotein concentrations. Randomized intervention trials

showed that low GL diets [45, 46] favorably improved HDL-C and/or TAG concentrations. In the present study, we observed that a high legume low GI/GL diet significantly reduced fasting serum TC and LDL-C concentrations; the results are consistent with the previous investigations. We also observed that fasting HDL-C concentrations decreased after the 4-week low GI/GL dietary intervention, which is not consistent with the aforementioned studies. The difference may be due to different study designs and target populations. In addition, unlike these studies, the present study controlled subjects' body weight and overall food intake.

The LIFE study was designed to evaluate the effects of fiber consumption on lipid profiles; however, other components such as phytosterols may also consider a mechanism for lipid reduction. Stanols and sterols, are primarily present in nuts, vegetable oils, seeds, cereals, and legumes [47]. Plant stanols and sterols have similar chemical structures to cholesterol; they may reduce cholesterol absorption by enterocytes [48] and the esterification rate of cholesterol in the enterocytes [49]. Decreased cholesterol absorption stimulates cholesterol synthesis [50] as well as the expression of LDL receptor mRNA [51] increasing LDL clearance and lowering LDL production resulting in lower circulating total cholesterol levels.

Metabolic syndrome causes dyslipidemia partially as the result of insulin resistance [52]. Our results demonstrate that insulin resistance may blunt response to a legume-enriched, high fiber diet. Among IS subjects, the LG diet led to significant reductions of all lipid profiles as well as the three ratios; however, among IR subjects, the same diet only had strong effects on the reductions of TC, LDL-C, and HDL-C. The HA diet led to significant reductions in TC and HDL-C among IS subjects; the same diet also had strong effects on TC, TAG, and TAG/HDL-C among IR subjects. Lefevre et al. [53] reported that subjects who had higher BMIs and waist circumferences, greater percentages of body fat and higher fasting insulin concentrations had smaller reductions in TC, LDL-C, TC/HDL-C after a Step II (low fat, low saturated fat) diet. Our results are consistent with this study. We observed that subjects who had higher HOMA-IR values at study entry had smaller reductions in TAG, TC/HDL-C, LDL-C/HDL-C, and TAG/HDL-C after the LG diet, though the reduction was only statistically significant for TC/HDL-C. Different from Lefevre's report, we found that subjects' BMIs at study entry did not predict changes in any lipid profiles or HDL-C related ratios.

Many human clinical studies have shown that a reduced intake of saturated fat may lower the risk for cardiovascular disease by decreasing TC and LDL-C concentrations [22, 32, 53, 54]. The effects of these types of diets on lowering TAG levels have been variable [22, 32, 54]. In the present study, we observed that moderate total (34%) and saturated fat (12%) with high fermentable fiber consumption also lowered TC and LDL-C concentrations, whereas the HA diet only lowered TC. The differences observed between test diets was significant for TC and LDL-C demonstrating an effect of total and soluble fiber, and possibly GL. Changes of this magnitude suggest that high fermentable fiber consumption may be another approach to lower risk for CVD [55].

There are several strengths of our study. First, we implemented a randomized, cross-over controlled feeding study design. In addition, we matched the two test diets so that they were isocaloric and provided similar percentages of energy from total fat, saturated fat, carbohydrate, and protein under conditions of weight maintenance. Second, though fiber consumption was higher than daily recommendations, the LG diet was well-tolerated.

There are some limitations in the present study. The present study defined insulin resistance by the HOMA-IR index, which has been widely used for clinical evaluation of insulin resistance. The cutoff value used in our study and others is somewhat subjective; however, the decision was based on two recent human clinical trials [20, 21]. Additionally, studies show that the classification of insulin resistance according to the HOMA-IR index is highly correlated to the ones based on the euglycemic insulin clamp technique, the gold standard for evaluation of insulin sensitivity/resistance [56, 57]. The LG diet included less dietary cholesterol than the HA diet; therefore, we are not able to rule out the possibility that dietary cholesterol consumption contributed to the observed effects on serum cholesterol levels. However, our analysis showed that the difference in dietary cholesterol between the LG and HA diet was not statistically significant. In addition, a 20 mg/day increment in dietary cholesterol intake only results in a very small change of serum cholesterol according to a meta-analysis of 27 studies [58]. Next, we only measured the changes in selected lipid/lipoprotein biomarkers. Recent studies indicate that small dense LDL-C particle (sd-LDL) level is a better predictor for CHD [59] than LDL-C. Apolipoprotein B (apoB) is the primary apolipoprotein in LDL-C; measurement of apo B may provide additional information on changes in LDL particle size. Similarly, apo A-I is the primary apolipoprotein in HDL-C; measuring the change in apo A-I may help to track the change in HDL particle size.

In conclusion, this study adds to the growing evidence that incorporating legumes in the moderate-fat diet improves lipid profiles, thus potentially lowering CVD risk. However, a cautionary note must be added since insulin resistance is highly prevalent and increasing, and individuals in this study with insulin resistance responded less favorably to the legume enriched, high fermentable fiber,

low glycemic index diet than those without insulin resistance.

Acknowledgments The present study was supported by the National Cancer Institute (subcontract 25XS101) with partial support provided by the General Clinical Research Center at Penn State University (NIH M01 RR 10732). We would like to thank Amy Ciccarella, Sami Heim, and Mary Lou Kiel for their help with menu and food preparation, Diane Mitchell and Linda Phelps for their assistance with the analysis of 24-h dietary recalls, and Dr. Lawrence Demers at Hershey Medical Center for the measurement of lipid profiles. All of the authors have read and approved the final submitted manuscript and there was no conflict of interest with the present paper. The authors' contributions were as follows: ZZ conducted research with participants, data analysis, and write up of manuscript; EL designed the research, contributed to data interpretation and manuscript preparation; PMKE and NHC contributed to data interpretation and manuscript preparation; DB conducted research with participants and and was involved with the write up of the manuscript; MJR contributed to data analysis and the write up of the manuscript; JSU, GB, and RSC contributed to data interpretation and the write up of the manuscript; and TJH designed research, contributed to data interpretation and manuscript preparation, and study oversight.

Abstract Certain fatty acids in canola oil (CAN) have been associated with a reduced risk of breast cancer. This study assessed the effects of CAN on proliferation and death of human breast cancer cells in vitro and in vivo in chemically induced mammary carcinogenesis. We hypothesize that CAN reduces breast cancer cell growth by inducing cell death. In a series of in vitro experiments, human breast cancer T47D and MCF-7 cells were cultured and treated with CAN and two chemotherapeutic drugs, tamoxifen and cerulenin. Cell proliferation and caspase-3 and p53 activities were measured. Reduced cancer cell growth and increased expression of caspase-3 and p53 were seen in T47D and MCF-7 cells treated with CAN. Moreover, CAN showed synergistic cancer cell growth inhibition effects with tamoxifen and cerulenin. In a subsequent live animal experiment, 42 female Sprague–Dawley rats were randomly assigned to corn oil (CORN) or CAN diets, and mammary tumors were chemically induced by *N*-nitroso-*N*-methylurea. CAN-dieted rats had reduced tumor volumes and showed an increased survival rate as compared to CORN-dieted rats. We demonstrated that CAN has suppressive effects on cancer growth, and reduces tumor volumes. The results suggest that CAN may have inhibitory effects on breast cancer cell growth, and warrants further investigation of the synergistic effects of CAN with anti-cancer drugs.

Keywords Canola oil · Breast cancer · Tamoxifen · Cerulenin · Caspase-3 · p53 · Sprague–Dawley rat · *N*-nitroso-*N*-methylurea

Abbreviations

ALA	Alpha-linolenic acid
CAN	Canola oil
CORN	Corn oil
ER	Estrogen receptor
FITC	Fluorescein isothiocyanate
MTS	Dimethylthiazol carboxymethoxyphenyl sulfophenyl tetrazolium
NMU	*N*-nitroso-*N*-methylurea
OA	Oleic acid
PI	Propidium iodide

Introduction

Breast cancer is the most common malignancy among women in western countries, where one out of every eight will develop it during her lifetime [1, 2]. More than 180,000 new breast cancer diagnoses are made in the United States each year, and over 40,000 women will die from the disease [3]. This high incidence of breast cancer in the US is associated with diets rich in total and saturated fats, which are typical of western lifestyles [1, 4]. However, many epidemiological studies provide evidence for a close relationship between certain fatty acids, such as omega-3, and reduced cancer risk [5, 6].

Dietary fats have profound effects on cell membrane, metabolism and gene expression. Essential fatty acids, like omega-3 and omega-6, cannot be synthesized by the human

body and must be obtained in the diet [7]. Canola oil (CAN) contains both of these fats, along with low levels of saturated fat, and high levels of monounsaturated (oleic acid, OA) and polyunsaturated (alpha-linolenic acid, ALA) fatty acids [8, 9]. The majority of studies to date have linked ALA and OA with a reduced risk of breast cancer, but omega-6 and saturated fats with an increased risk [6, 10].

A lower ratio between omega-6 and omega-3 fatty acids seems to be helpful in reducing the risk of breast cancer, and CAN has a very favorable 2:1 ratio between omega-6 and omega-3 fatty acids [8]. When this ratio is imbalanced, a variety of health issues may appear, including breast cancer [11, 12]. It has been established that certain fatty acids have inhibitory effects on cancer cells, but the role of omega-6 and omega-3 fatty acids remains controversial [13]. Even so, ensuring that the consumption of omega-6 and omega-3 fatty acids is in the correct ratio could protect against breast cancer [9, 10].

The health benefits of CAN are widely accepted in the field of nutrition, particularly in relation to cardiovascular disease. However, information is limited on its effects on breast cancer. We hypothesize that CAN reduces breast cancer cell growth by inducing cell death. The objectives of this study were to determine if CAN affects the proliferation and death of human breast cancer cells in vitro with chemotherapeutic drugs, and to see if it reduces the susceptibility of cancer cells to chemically induced mammary carcinogenesis in vivo.

Experimental Procedure

Cell Culture

The estrogen receptor (ER) positive human breast cancer T47D (ductal carcinoma) and MCF-7 (adenocarcinoma) cell lines were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA). They were grown in Roswell Park Memorial Institute 1640 medium (RPMI 1640, Gibco-Invitrogen, Carlsbad, CA, USA) and Dulbecco's modified Eagle's minimum essential medium (DMEM, Gibco-Invitrogen), respectively. Both were supplemented with 10% v/v heat-inactivated fetal bovine serum (Gibco-Invitrogen) and 1% v/v antibiotic–antimycotic solution (Gibco-Invitrogen) and grown at 37 °C in a 5% CO_2-humidified atmosphere.

Materials

CAN was filtered and added aseptically from stock solutions to 100% ethanol and brought to a final ethanol concentration of 0.5% v/v [14]. CAN stock solutions were pre-warmed and vigorously stirred before addition to cell medium. The appropriate or optimal doses of CAN and chemotherapeutic drugs, tamoxifen (10 μM, Sigma-Aldrich, St Louis, MO, USA) and cerulenin (5 mg/l, Sigma-Aldrich), were determined from dose response studies. Controls always included ethanol at the appropriate concentration.

Cell Proliferation Assay

The colorimetric MTS (3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium) assay (CellTiter 96 Aqueous One Solution Reagent, Promega, Madison, WI, USA) was used to measure cell proliferation. Briefly, cells were seeded in 96-well flat-bottomed tissue culture plates (5×10^3 cells/well in 100 μl), and exposed to CAN. After 24–96 h of incubation, they were incubated for 1–4 h with 10% MTS solution. The degree of cell proliferation was evaluated numerically by measuring the absorbance at 490 nm with a SpectraMax Microplate Reader (Molecular Devices, Sunnyvale, CA, USA). The cell proliferation was calculated and expressed based on the following formula: ([treated cell absorbance − initial (seeding) cell absorbance]/initial (seeding) cell absorbance) × 100.

Caspase-3 Assay

The protease activity of caspase-3 was measured using a colorimetric assay with the CaspACE assay system (Promega). Briefly, cells were cultured in 24-well flat-bottomed tissue culture plates (5×10^4 cells/ml) and treated with CAN. Cultured cells were washed twice with phosphate-buffered saline (PBS) and re-suspended in a cell lysis buffer (Promega). Cell lysates were incubated with a colorimetric substrate, *N*-acetyl-Asp-Glu-Val-Asp-amino-*p*-nitroanilide (Ac-DEVD-*p*NA). After an overnight incubation, the release of *p*-nitroaniline from Ac-DEVD-*p*NA was measured at 405 nm.

p53 Assay

The p53 activity was determined by using an enzyme immunometric assay kit (TiterZyme EIA Kit, Assay Designs, Ann Arbor, MI, USA). Cultured cells (5×10^4 cells/ml) were washed twice with PBS and re-suspended in cell lysis buffer (Sigma-Aldrich). The cell lysates were centrifuged. The supernatants were incubated on a plate pre-immobilized with p53 polyclonal antibody and they reacted with the labeled antibody. The absorbance was measured at 450 nm.

Flow Cytometric Analysis

Cell death was determined by double-staining with fluorescein isothiocyanate (FITC)-conjugated annexin V and propidium iodide (PI) (Sigma-Aldrich) as described previously [15]. Cells were harvested and washed with PBS containing 0.5% bovine serum albumin (Sigma-Aldrich) and 0.1% sodium azide (Sigma-Aldrich). They were then incubated with FITC-conjugated annexin V and PI. Cells were washed and then analyzed using an Accuri C6 cytometer and Cflow software (Accuri Cytometers, Ann Arbor, MI, USA).

Chemotherapeutic Drug Treatments

T47D and MCF-7 cells were seeded in 96-well flat-bottomed tissue culture plates (5×10^4 cells/ml). They were cultured simultaneously for 24–96 h with media containing various combinations of CAN and the chemotherapeutic drugs tamoxifen and cerulenin. Afterwards, cell proliferation was measured.

Animals and Diets

Forty-two female Sprague–Dawley rats (3 weeks of age) were purchased from Harlan (Indianapolis, IN, USA) and acclimated to the experimental environment for 1 week with ad libitum access to water and a standard control AIN-76 diet. After acclimation, all rats were randomly assigned to receive modified AIN-76 CORN or CAN diets (Table 1) [16]. All animal procedures and techniques were approved by the Institutional Animal Care and Use Committee of North Dakota State University. The experimental diets were formulated to be both isocaloric and isonitrogenous.

Table 1 Composition of the experimental diets

Ingredients	Diets (per 100 g)	
	Corn oil	Canola oil
Sucrose	50.0	37.8
Casein	20.0	20.0
Corn starch	15.0	15.0
Cellulose	5.0	12.2
Mineral mix	3.5	3.5
Vitamin mix	1.0	1.0
DL-Methionine	0.3	0.3
Ethoxyquin (antioxidant, mg)	10.0	21.0
Corn oil	5.0	–
Canola oil	–	10.0

Tumor Induction and Measurement

All rats were injected subcutaneously with a single dose of *N*-nitroso-*N*-methylurea (NMU, Sigma-Aldrich, 50 mg/kg body weight) dissolved in PBS acidified with acetic acid. The rats were palpated twice weekly to detect the presence of mammary tumors. The time of appearance of the first tumor (latency period) and location of mammary tumors were recorded and tumor sizes were measured. The tumor volume was calculated using the following formula: (length $\times$ width)/2 [17].

Statistical Analysis

Cell culture experiments were conducted at least three times in triplicate or quadruplicate. Results are expressed as means $\pm$ SEM of independent determinations. Statistical analysis was performed using Student's t test and one-way ANOVA followed by Tukey's test (Minitab Release 14.1, Minitab Inc., State College, PA, USA). Differences were considered significant at $P < 0.05$. Animal experiment data were analyzed using the General Linear Models (SAS 9.1, Statistical Analysis System Institute, Cary, NC, USA) with a two sample t test. For comparison of the least square means, values on tumor volumes were log scaled ($\log_{10}$ tumor volume).

Results

T47D and MCF-7 Cancer Cell Growth Response

The cell proliferation of T47D and MCF-7 cells was examined in the presence of 0.001–1 mM of CAN for time- and dose-dependent studies. At 0.001 and 0.01 mM concentrations, CAN did not have any significant inhibitory effect on T47D and MCF-7 cells. However, cell growth was decreased at 0.1 mM (data not shown). As shown in Fig. 1, CAN treatment resulted in a significant growth inhibition of T47D and MCF-7 cells in a time-dependent manner. In T47D cells, a 1 mM dose of CAN caused 31.4% growth inhibition (Fig. 1a) after 96 h of CAN treatment. Similar inhibition was also evident in MCF-7 cells, at 21.8% cell growth inhibition (Fig. 1b) after 96 h of CAN treatment. CAN showed a time- and dose-dependent effect which was detectable during early and late phases of cell growth in T47D and MCF-7 cells.

Caspase-3 and p53 Activities, and Cancer Cell Death

In order to determine if the cell growth inhibition effect of CAN was caused by the induction of apoptosis, caspase-3 and p53 expressions were analyzed by enzyme assays. In

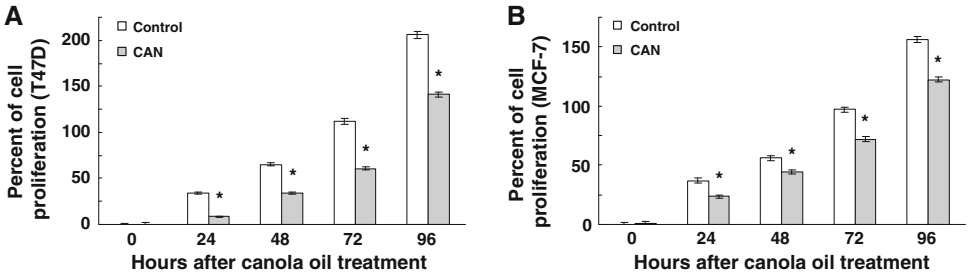

Fig. 1 Effects of CAN on time-dependent cancer cell growth. **a** T47D and **b** MCF-7 cells were treated with 1 mM of CAN. Data in **a** and **b** are means ± SEM ($n = 12$) and expressed as percentages of cell proliferation ([treated cell absorbance − initial (seeding) cell absorbance]/initial (seeding) cell absorbance) × 100. *Different from control, $P < 0.05$

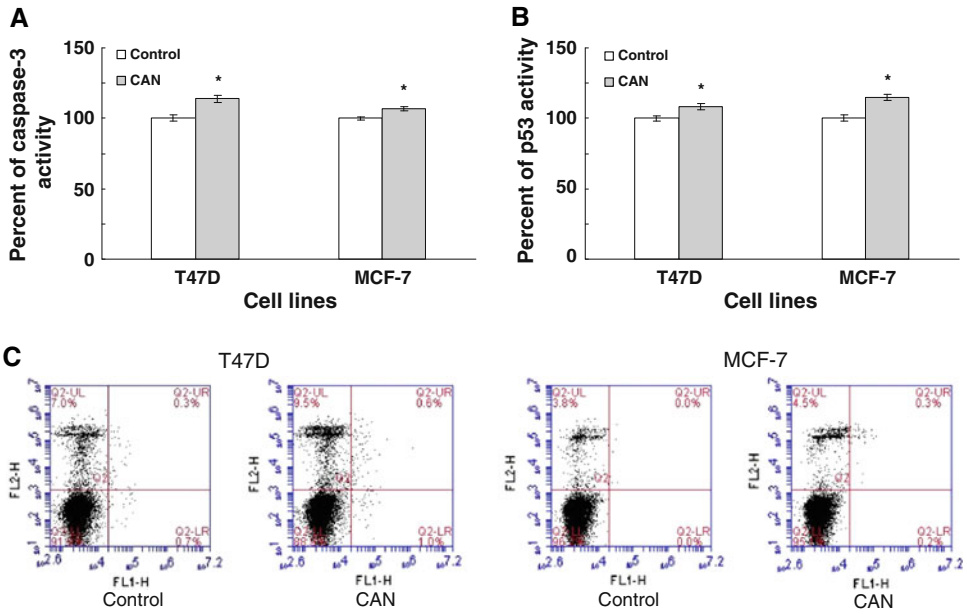

Fig. 2 Caspase-3 and p53 activities of 1 mM CAN-treated T47D and MCF-7 cells. **a** Caspase-3 activity of CAN treatment (1 mM) for 96 h. **b** p53 activity of CAN treatment (1 mM) for 96 h. **c** Cell death and apoptosis of 1 mM CAN-treated T47D and MCF-7 cells for 72 h. Cells were stained with Annexin V-FITC (FL1, *X* axis) and PI (FL2, *Y* axis). Data in **a** and **b** are means ± SEM ($n = 9$) and expressed as percentages of control cell caspase-3 or p53 activities (treated cell absorbance/control cell absorbance) × 100. *Different from control, $P < 0.05$

T47D and MCF-7 cells, 1 mM of CAN significantly increased caspase-3 and p53 activities. At 96 h after CAN treatment, the change in caspase-3 of T47D and MCF-7 cells was 16.2 and 8.2% (Fig. 2a), and the change in p53 was 8.4 and 14.8% (Fig. 2b), respectively. These results suggest significant up-regulation of caspase-3 and p53 activities in both cell lines. Consistent results were also obtained with flow cytometric data on cancer cell death. CAN showed increased cell death in both T47D (7.0 vs. 9.5%) and MCF-7 (3.8 vs. 4.5%) cells (Fig. 2c).

Possible Synergistic Effects of CAN with Chemotherapeutic Drugs on Cancer Cell Growth Inhibition

Based on the data showing cell growth inhibition and apoptosis in T47D and MCF-7, in order to evaluate a possible synergistic or additive effect of CAN, the anti-cancer drugs tamoxifen and cerulenin were assessed in combination with CAN. CAN showed significant synergistic effects with tamoxifen and cerulenin. As shown in Fig. 3, a combination of 1 mM CAN and 10 μM tamoxifen resulted in 49.0 and 5.7% growth inhibition (Fig. 3a, compared to tamoxifen alone) in T47D and MCF-7 cells at 96 h after treatment. Similar to tamoxifen, a combination of 1 mM CAN and 5 mg/l cerulenin resulted in 40.5% and 6.5% growth inhibition (Fig. 3b) at 96 h after treatment, compared to cerulenin alone.

Tumor Volumes and Survival Rate In Vivo

We determined the in vivo effect of CAN using Sprague–Dawley rats. Breast tumors were induced in rats by subcutaneous injection of the alkylating carcinogen NMU. There were no significant differences in initial (85.9–86.5 g) and final (231.3–234.1 g) average body weights between CORN and CAN groups. The latency period was determined to be the days between NMU administration and the first day of tumor detection. The tumor incidence was based on the percentage of rats that developed at least one tumor at

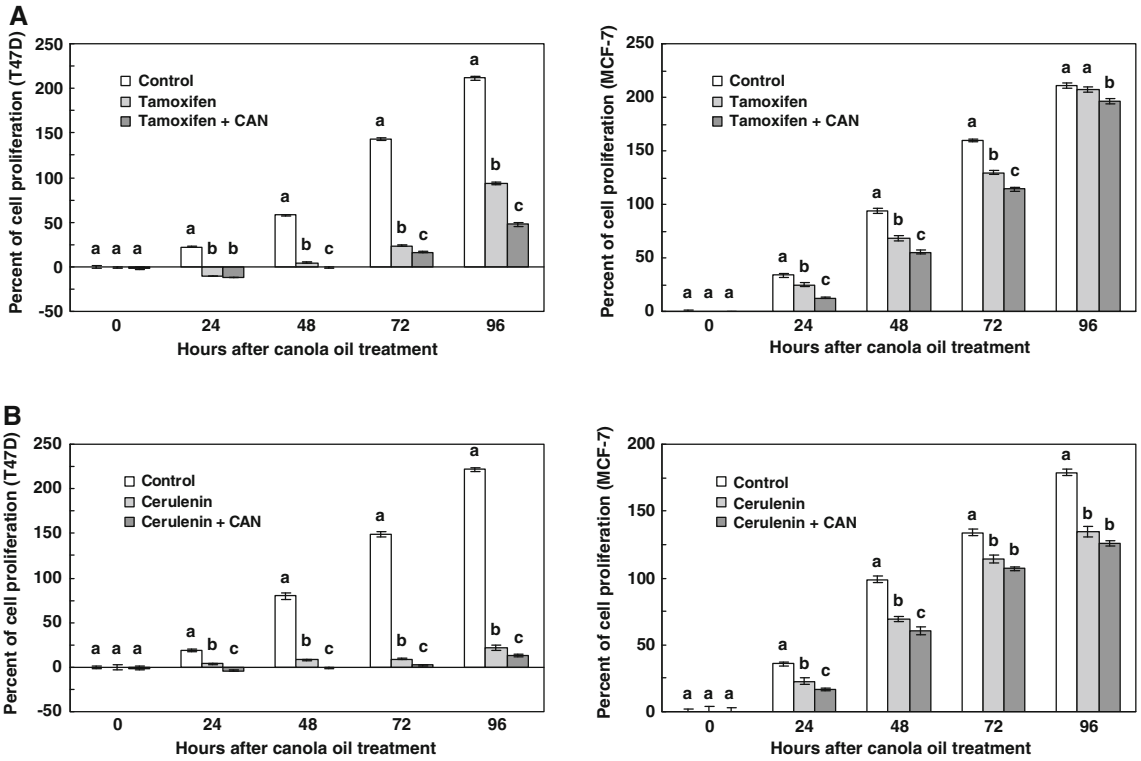

Fig. 3 Effects of CAN with tamoxifen and cerulenin on T47D and MCF-7 cell proliferation. **a** Effect of 1 mM CAN and 10 μM tamoxifen. **b** Effect of 1 mM CAN and 5 mg/l cerulenin. *Bars* represent means ± SEM ($n = 12$) and are expressed as percentages of cell proliferation ([treated cell absorbance − initial (seeding) cell absorbance]/initial (seeding) cell absorbance) × 100. *Bars* within time with *different superscripts* are different ($P < 0.05$)

25 weeks after NMU administration. As shown in Table 2, the latency period was not affected by the CAN diet compared to the CORN diet. However, the CAN diet reduced the tumor incidence (Table 2) and increased the survival rate (Fig. 4a). Moreover, mammary tumor volumes were significantly reduced in the CAN group, compared to the CORN diet (Fig. 4b, Table 2).

Table 2 Comparison of the tumor incidence, latency period, number of tumors, and tumor volumes between CORN and CAN groups

	Corn oil	Canola oil	*P* value
Tumor incidence[a] (%)	71	57	
Latency period[b] (days)	93.00 ± 6.90	103.40 ± 7.70	0.34
Number of tumors[c] (tumors/rat)	1.93 ± 0.30	1.50 ± 0.33	0.33
Tumor volume[d] (mm^3/rat)	2.32 ± 0.06	1.61 ± 0.06	0.01

Values are means ± SEM

[a] Percentage of rats that developed at least one or more tumors at 25 weeks after NMU injection

[b] Determined as the days between NMU injection and the first day of tumor detection

[c] Values were determined at 25 weeks after NMU injection

[d] Values were averaged over the 15-week period of tumor existence and then log scaled, $\log_{10}$ (tumor volume)

Discussion

Dietary fats are important not only as energy sources, but also for their role in metabolism and gene expression [7]. Regulation of genes associated with cell growth and death may reflect an adaptive response to changes in the type of fatty acids ingested and demonstrate that the type of lipid is more closely associated with breast cancer risk than the quantity of lipid [18]. The two major fatty acids in CAN, ALA and OA, have been shown to play important roles in the modulation of cancer cell growth and death [6, 10]. This study investigated the effects of CAN in the well established ER+ breast cancer cells and NMU-induced mammary tumor animal models, particularly those concerning cancer cell growth and synergism of CAN with chemotherapeutic drugs.

CAN was shown to be effective in reducing cancer cell growth and inducing cell death (Figs. 1, 2). Moreover, as shown in Fig. 3, the growth of T47D was completely inhibited by the chemotherapeutic agents, tamoxifen and cerulenin with CAN (1 mM) at 24 h of treatments. However, MCF-7 showed continued growth with tamoxifen and cerulenin, and this may imply that T47D and MCF-7 cells have distinct growth patterns. Although there were similar increases in caspase-3 and p53 activities between T47D

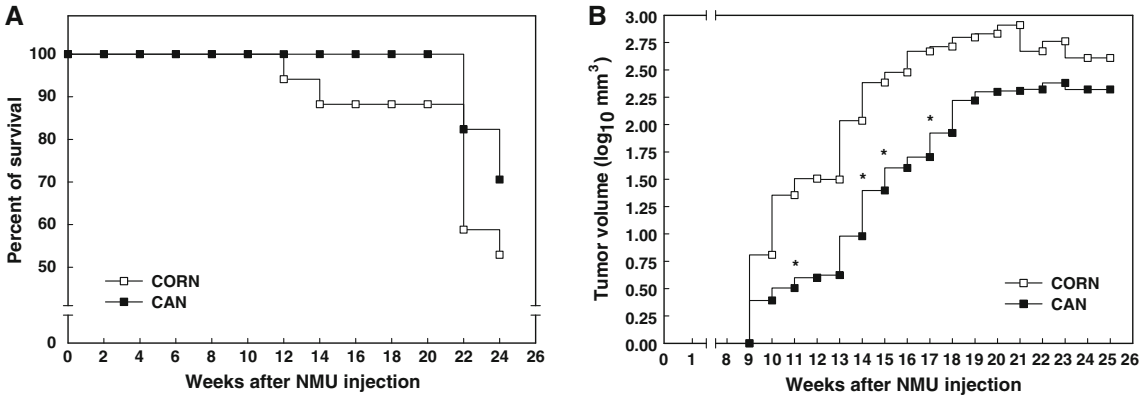

Fig. 4 In vivo effects of CAN in Sprague–Dawley rats. Data represent the average survival rates (**a**) and tumor volumes (**b**) of rats fed CORN and CAN in response to a single dose of NMU carcinogen injection. Data are expressed as percentages of survival and logarithmic average tumor volumes ($n = 21$). *Different from control, $P < 0.05$

and MCF-7 cells in response to CAN, the growth inhibition of T47D was greater than that of MCF-7, suggesting that other mechanisms may also participate in the reduction of cell growth. We have also shown that dietary CAN may reduce tumor volumes in NMU-induced carcinogenesis. Mammary tumor growth was significantly reduced in the CAN fed group (Fig. 4b, $P = 0.01$) and the survival rate of the CAN group increased compared to the CORN group (Fig. 4a). The CAN group also showed a lower number of tumors and longer latency period than the CORN group (Table 2, no statistically significant differences).

The effect of CAN on cell growth and caspase-3 activity was also investigated in the non-cancerous human mammary epithelial MCF-10A (fibrocystic disease) cell line. In contrast to T47D and MCF-7 cancer cell lines, which showed significant reduced cell growth, CAN did not affect the proliferation of non-cancerous mammary cells (MCF-10A) in vitro at concentrations as high as 1 mM (Fig. 5a). The explanation for the differential effect of CAN on cancerous and non-cancerous mammary cells is not known. However, it is interesting to note that caspase-3 activity is similar in CORN and CAN treated MCF-10A cells, suggesting that caspase-3 may play a role in T47D and MCF-7 cancer cell death (Fig. 5b, $P = 0.87$).

ERs play important roles in mammary growth and differentiation [19]. The specific receptors ER alpha and ER beta have distinct roles in mammary development [19]. Some studies indicate that ERs mediate the breast cancer-promoting (ER alpha) or -inhibiting (ER beta) effects of estrogens [20]. However, the exact role of ERs in breast cancer is still not clear. In a study by Hardman [21], 8% of CAN significantly reduced ER negative MDA-MB 231 tumor cell growth and modified cell membrane composition in nude mice. It is not clear how CAN affects both kinds of breast tumors, but CAN seems to reduce cell growth in both ER positive and ER negative breast cancer cells.

Dietary fat intake and breast cancer risk has been a considerable topic of interest in cancer research. Many of the established risk factors are linked with nutrition, suggesting that dietary intervention may be a significant factor in breast cancer prevention and therapy [22]. A recently published population-based, multi-ethnic, case–control study suggests that women cooking with hydrogenated fats or CORN have a higher risk of breast cancer than women cooking with CAN [23]. Flaxseed, a rich source of ALA (with approximately a 1:2 ratio between omega-6 and omega-3 fatty acids), has been shown to decrease breast cancer risk; 10% of dietary flaxseed reduced 50% of MCF-7 cancer cell growth with tamoxifen in nude mice [24].

Several in vivo and in vitro studies have also shown that omega-3 fatty acids have inhibitory effects on the initiation, promotion, and progression stages of breast cancer [6, 25]. Epidemiological studies showed that groups of people who consume diets high in omega-3 and OA could have lower breast cancer incidence rates [6, 11]. Omega-3 and OA have also been found to inhibit mammary tumor cell proliferation and to enhance immune cell function against breast cancer [18, 26].

The anti-estrogen agent, tamoxifen, and fatty acid synthase inhibitor, cerulenin, were used to measure the synergistic effects of CAN in this study. Tamoxifen is used for the treatment and prevention of ER+ breast cancer in high-risk women. The drug competes with estrogen for ER binding and therefore inhibits ER-mediated cancer growth [27]. Cerulenin, a noncompetitive inhibitor of fatty acid synthase, inhibits fatty acid synthesis and thereby induces cell death of breast cancer cells [28]. Increasing the susceptibility of cancer cells to chemotherapeutic agents may have significant implications in cancer therapy, and

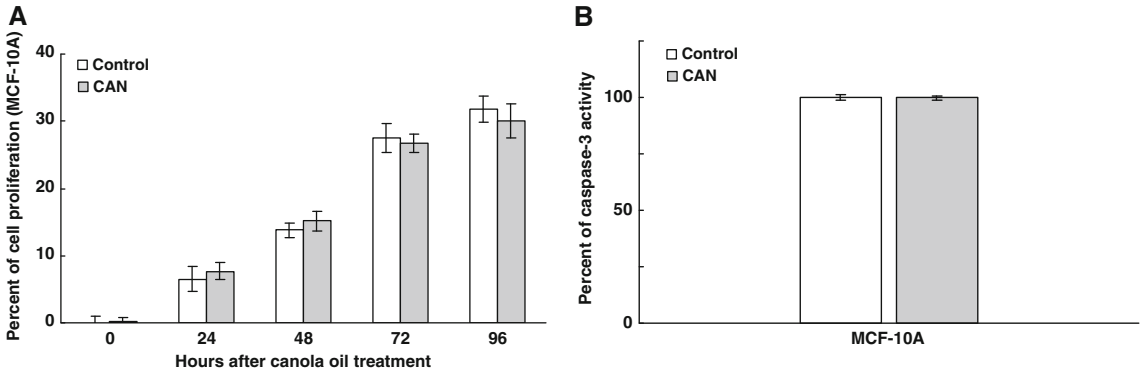

Fig. 5 Cell growth and caspase-3 activities of 1 mM CAN treated MCF-10A cells. Data in **a** are means ± SEM ($n = 12$) and are expressed as percentages of cell proliferation ([treated cell absorbance − initial (seeding) cell absorbance]/initial (seeding) cell absorbance) × 100. Data in **b** are means ± SEM ($n = 9$) and are expressed as percentages of control cell caspase-3 activities (treated cell absorbance/control cell absorbance) × 100. *Different from control, $P < 0.05$

inducing cell death in cancer cells may be an effective strategy to inhibit cancer growth [29].

Our findings suggest that a 2:1 omega-6 to omega-3 fatty acid ratio may be optimal for cancer growth inhibition, while a higher ratio may increase tumor growth. In addition, our work also suggests that OA may reduce tumor growth. The inhibitory effect of CAN may be due to its low omega-6 to omega-3 fatty acid ratio (2:1) and high OA (61%) as compared to the high omega-6 to omega-3 fatty acid ratio (57:1) and low OA content (29%) in CORN [8]. T47D and MCF-7 cells showed significant cell growth inhibition with CAN supplementation to both drug treatments. However, the inhibition of T47D cells was greater than that of MCF-7 cells (Fig. 3a, b). This discrepancy may have been the result of other mechanisms at work in T47D cell proliferation. These mechanisms may have inhibited the growth of T47D cells more than that of MCF-7 cells. Since the mechanisms responsible are not known, further studies need to be conducted, especially in the expression of several key genes involved in tumor growth. This may show differences in expression of tumor growth-related genes in T47D and MCF-7.

In conclusion, our results show that CAN has anti-proliferative and synergistic effects on breast cancer cell growth in vitro with chemotherapeutic drugs, and reduces in vivo mammary tumor cell growth in rats. The synergistic effects of CAN with tamoxifen and cerulenin may be useful in reducing the doses of chemotherapeutic drugs and increasing the chance of long-term survival. In order to validate these findings, a more in-depth investigation into the relationship between CAN and chemotherapeutic drugs is needed. For example, since ER beta induces breast cancer cell death, further studies could determine whether CAN increases ER beta expression, inhibiting breast cancer cell growth and increasing susceptibility of breast cancer cells to chemotherapeutic drug actions. Moreover, how CAN shows synergistic effects with therapeutic drugs may be examined in relation to ER expression, membrane composition and gene expression changes. These results may provide useful data for the development of improved nutritional strategies for reducing breast cancer risk.

Abstract n-3 Polyunsaturated fatty acids (PUFA) have a chemopreventive effect while n-6 PUFA promote carcinogenesis. The effect of these essential fatty acids may be related to oxidative stress. Therefore, the study was designed to evaluate the effect of different ratios of fish oil (FO) and corn oil (CO) in the prevention of colon cancer. Male Wistar rats were divided into control, dimethylhydrazine dihydrochloride (DMH) treated, FO + CO (1:1) and FO + CO (2.5:1). All the groups, except the control received a weekly injection of DMH for 4 weeks. The animals were sacrificed either 48 h later (initiation phase) or kept for 16 weeks (post initiation phase). DMH treatment in the initiation phase animals showed mild to moderate inflammation, decreased ROS and TrxR activity, increased antioxidants, apoptosis and ACF multiplicity. The post initiation study showed severe inflammation with hyperplasia, increased ACF multiplicity and ROS levels, a decrease in antioxidants and apoptosis. The FO + CO (1:1) treated animals showed severe inflammation, a decrease in ROS, an increase in antioxidants and apoptosis in the initiation phase. FO + CO (1:1) in the post initiation phase and FO + CO (2.5:1) in the initiation showed mild inflammation, increased ROS, apoptosis and decreased antioxidants. There was a decrease in ACF multiplicity and ROS levels, increased antioxidants and apoptosis in the post initiation phase study. The present study suggests that FO has a dose- and time-dependent chemopreventive effect in colon cancer mediated through oxidative stress and apoptosis.

industrialized countries and its incidence is increasing in the developing countries [1]. Cancer is a disease associated with very high mortality. Diagnosis of cancer at the early stages can be made with the estimation of the biomarkers. Aberrant crypt foci (ACF) have been regarded as precancerous lesions and are widely used as a biomarker of colon cancer in a number of studies [2]. ACF are the only endpoints which provides a quantitative approach to assess the disease process and the underlying cellular and molecular events as affected by cancer preventive or promoting agents [3].

Cancer is strongly influenced by various environmental factors, with diet being one of the major modifying agents [4]. Dietary factors have been documented as playing a significant role in the development and progression of the colon cancer [5]. Diets high in fat have been linked with an increased risk of various types of cancers particularly of the breast, colon and prostate gland [6]. Increasing evidence from animal and human studies indicate that not only the amount but in particular the types of dietary fat differing in fatty acid composition are important factors in colon tumor development [7, 8]. It has been reported that, a higher intake of total saturated fat leads to an increased risk of cancer [9]. Out of the essential PUFA, the beneficial effect of marine-derived n-3 polyunsaturated fatty acids on coronary artery disease, hypertension, diabetes, arthritis and other inflammatory and autoimmune disorders and cancer has been convincingly demonstrated by epidemiological and experimental studies [8, 10–12]. On the other hand, n-6 PUFA have been shown to have proinflammatory and procarcinogenic effect [8, 13]. Both of these classes of fatty acids are important components of cell membranes and are substrates for the same enzymes and thus compete with each other [14]. n-3 PUFA have greater affinities for the enzyme, which means that increasing the dietary intake of n-3 PUFA reduces the desaturation of linoleic acid (LA) and consequently increase the production of eicosanoids that are anti-inflammatory and anticarcinogenic in nature [15]. Therefore, it has been suggested that a balanced n-3/n-6 PUFA ratio in diet rather than the absolute intake of either is essential for normal growth and development and may be responsible for a decrease in the incidence of various disorders including cardiovascular diseases and cancer [10, 12, 13]. Moreover, it is believed that therapeutic ratio of n-3 and n-6 is different for different diseases and for colon cancer this ratio has still not been worked out. Hence two different ratios of n-3 and n-6 have been used in the present study to assess the chemopreventive potential in experimental colon carcinogenesis.

There has been a lot of interest in characterizing the mechanism by which these fatty acids exert their effects in carcinogenesis. The possible mechanism includes one or more of the following: oxidative stress, apoptosis, disrupted cell cycle and cell proliferation [14] Oxidative stress is a condition associated with an increased generation of reactive oxygen species (ROS) or impaired cellular antioxidant capacity leading to an imbalance between radical generating and scavenging potential. The unsaturation in the lipids is prone to oxidation and the metabolites of the lipid peroxidation (LPO) generate the promutagenic exocyclic DNA adducts [16, 17]. It was reported that low-levels of PUFA induced oxidative stress which was cytostatic, while higher levels of oxidative stress resulted in apoptosis and still higher levels caused cellular necrosis [18]. Oxidative stress can initiate and/or mediate a number of signalling cascades, including apoptosis due to alterations in the cellular redox balance. Oxidative stress caused by increased free radical generation and/or decreased antioxidant levels in the target cells and tissues has been suggested to play an important role in carcinogenesis [19, 20]. It has been observed that the tumoricidal action of n-3 PUFA is a free radical dependent process [21] and their consumption leads to an increase in lipid peroxidation by reactive oxygen species due to a multiplicity of double bonds [22]. An increase in lipid peroxidation may lead to oxidative stress which is counteracted by various antioxidants including glutathione (GSH), thioredoxin (Trx), catalase (CAT), superoxide dismutase (SOD), glutathione peroxidase (GPx) [23, 24]. Takashi et al. [25] reported that genes for antioxidant enzymes were upregulated in mice fed with fish oil supplemented diets.

It has been reported that higher oxidative stress leads to apoptosis. Programmed cell death plays an essential role in the elimination of mutated cells/transformed cells [26].Thus, in order to survive, cancer cells must develop highly efficient and usually multiple mechanisms which help in averting apoptosis. In fact, evading apoptosis is regarded as one of the hallmarks of cancer cells [27]. A number of workers have shown that the effect of n-3 PUFA on the colon cancer might be mediated through an increase in apoptosis [28–30].

To date the effect of alteration of dietary ratio of n-3 and n-6 PUFA on oxidative stress and apoptosis has not been evaluated. Therefore this study is designed to evaluate the effect of different dietary ratios of fish oil and corn oil on dimethyl hydrazine induced colon cancer and mediation of oxidative stress in this process.

Materials and Methods

Chemicals

N,*N*′-Dimethylhydrazine dihydrochloride (DMH) and a thioredoxin reductase assay kit were obtained from Sigma

Chemical Company, St. Louis, USA. M-30 cytoDEATH monoclonal antibody was purchased from Boehringer Mannheim, Germany. Fluorescein isothiocyanate (FITC)-conjugated goat anti-mouse IgG_1 was purchased from Bangalore Genei, Bangalore, India. Fish oil under the brand name Seven Seas Sea cod was a generous gift from Universal Medicare Pvt. Ltd., Mumbai, India. The fish oil contains 20% of EPA and DHA, 24% of other n-3 Fatty acids, 0.16% of Vitamin A and 0.001% of Vitamin D. Corn oil under the brand name Arawana from Wilmar International Ltd. was obtained from Shanghai, China. It contains 50% of n-6, 1.3% of n-3 and 26.4% of n-9 PUFA. The mineral mixture (Agrimin) was obtained from Virbac Animal health India Pvt. Ltd., Mumbai, India. All other chemicals used in the study were of analytical grade.

Experimental Animals

Male Wistar rats weighing 100–150 g were obtained from and housed in the Central Animal House, Panjab University, Chandigarh. The experimental protocols were approved by the Institutional Ethics Committee and conducted according to Indian National Science Academy Guidelines for the use and care of experimental animals. Rats were housed in polypropylene cages in the animal house and were acclimatized for 7–10 days before being used in the experimental study. Water was given ad libitum.

Diets

To assess food consumption, 20 randomly selected rats were monitored for 10 consecutive days. Food consumption per cage was calculated by subtracting the leftover food from that of the previous day. Spillage was also monitored and was negligible. Finally, the diets were prepared fresh and modified according to the groups as shown in the Table 1. The diets were prepared on the basis of the American Institute of Nutrition standard reference diet AIN-76A [31]. The purified diet was supplemented with 5% soya oil instead of corn oil to meet the essential fatty acid requirement in the diet. The soya oil contained 54.3% of n-6, 6.3% of n-3 and 22.2% of n-9 PUFA [32]. The composition of diet was adjusted so that the animals in all the dietary groups would consume the same amount of calories. The lipid composition in normal diet for the rodents should be up to 30% [33] and for the humans the dietary recommendations of lipids is 20% for adult females and 15% for the adult male [34]. Therefore, to explore the therapeutic potential, it was decided to vary the ratios of n-3 PUFA rich fish oil and n-6 PUFA rich corn oil at 20% which is well within the normal optimal range. In the modified diets PUFA were supplemented with varying ratios of n-6 and n-3 along with 5% soya oil. The lower ratio had 7.5% corn oil and 7.5% fish oil in (1:1) while the higher ratio (2.5:1) had fish oil (10.3%) and corn oil (4.7%). However, the dietary regimens fall in the optimal range of the fat to be given to rodents to meet the better growth. In order to prevent the formation of oxidized lipids, diets were prepared fresh every day. Feeders were removed and washed daily.

Experimental Design

The experimental protocol is clearly represented in Fig. 1. The animals ($n = 112$) were divided into the following experimental groups:

Control group Rats received a purified diet and a weekly sham injection of the 1 mM ethylenediamine tetra-acetic acid (EDTA), pH 6.5, for a period of 4 weeks.

DMH treated Rats received a purified diet and were administered a weekly intraperitoneal injection of DMH (20 mg/kg body weight) for a period of 4 weeks. DMH was dissolved in 1 mM EDTA (pH-6.5). DMH is metabolized in the liver to azoxymethane (a known colon carcinogen), ultimately leading to the generation of methyldiazonium ions and carbonium ions, which are active carcinogenic electrophiles that manifest their action in the colon [35].

FO + CO (1:1) The animals received a modified diet supplemented with an equal ratio of fish oil and corn oil

Table 1 Composition of the experimental diets

Diet content (%)	Control	DMH treated	FO + CO (1:1)	FO + CO (2.5:1)
Casein	20	20	23.5	23.5
Fat	5 (soya oil)	5 (soya oil)	5 (soya oil) + 7.5 corn oil + 7.5 fish oil	5 (soya oil) + 4.3 corn oil + 10.7 fish oil
Sucrose	65	65	44.72	44.72
Fiber (wheat bran)	5	5	5.9	5.9
Mineral mix	3.8	3.8	4.46	4.46
Vitamin mix	1.0	1.0	1.18	1.18
Choline chloride	0.2	0.2	0.24	0.24

Diet was formulated according to the American Institute of Nutrition standard reference diet, with the modification of varying sources of carbohydrate and protein

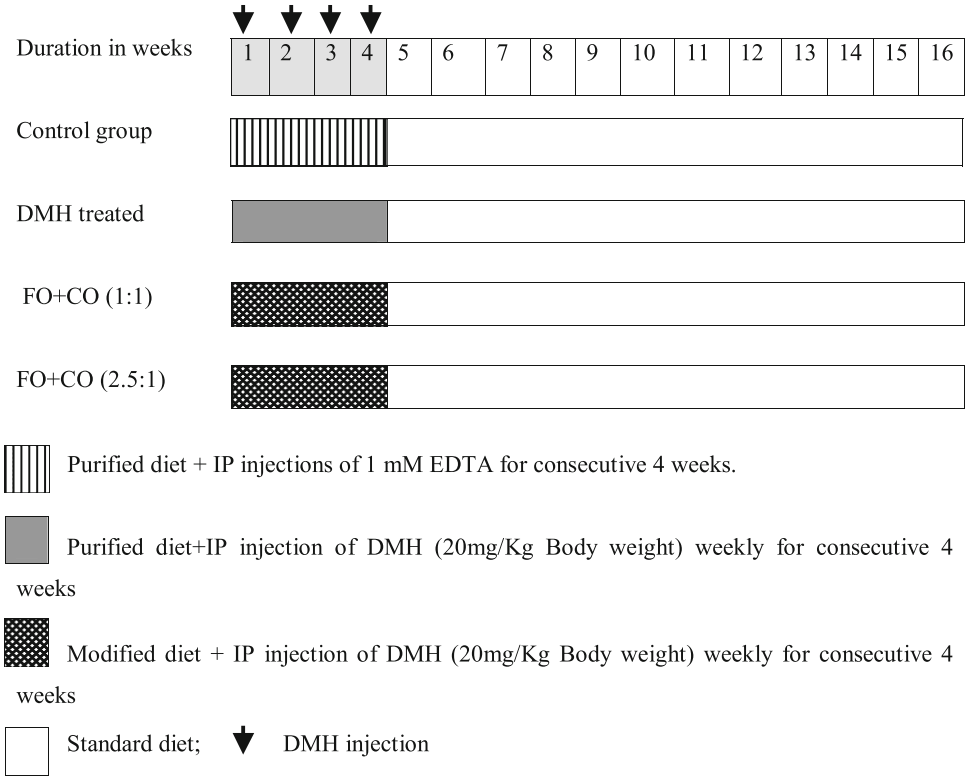

Fig. 1 Experimental design of the study

and were given a weekly intraperitoneal injection of 20 mg/kg body weight DMH for 4 weeks.

FO + CO (2.5:1) The animals were given a modified diet with a varying ratio of fish oil and corn oil and administered a weekly dose of intraperitoneal injection of DMH (20 mg/kg body weight) for 4 weeks.

The initiation phase study comprised of animals sacrificed 48 h after EDTA/DMH injections [36] and the animals kept for 12 weeks after the treatment regimen constituted the post initiation phase study. All the animals were sacrificed by cervical dislocation.

Measurement of ACF Count

The entire colon was processed for the determination of ACF in the following manner [2]. The entire colon (from caecum to anus) was removed and washed thoroughly with PBS, cut longitudinally, laid flat on a wet filter paper, and fixed with 10% buffered formaldehyde solution overnight. The colon was then stained with 0.2% methylene blue prepared in saline for 3–5 min. The ACF formed by one or more aberrant crypts, can be easily visualized on a background of normal crypts since aberrant crypts have larger, often elongated openings and a thicker lining of epithelial cells compared with normal crypts. For topographic assessment of the colon, mucosal ACF was counted using a light microscope (40×). The ACF were classified as small (1–3); medium (4–6); or large (6 and more) by the number of crypts per foci. The total number of ACF/rat was calculated as the sum of the small, medium and large ACF.

Histopathological Examination

The colon was removed and flushed with warm Ca^{2+} and Mg^{2+} free phosphate buffered saline (PBS). For each rat, the 10 cm of the distal colon was taken for histopathology and fixed in the 10% formalin. Sections were prepared and stained with hematoxylin and eosin. The slides were photographed and evaluated by a histopathologist without any prior knowledge of the experimental design.

Isolation of Colonocytes

The colonocytes were isolated by the method of Sanders et al. [37]. The rats were killed by cervical dislocation and the entire colon from the caecum to rectal ampulla was removed and flushed with Ca^{2+} and Mg^{2+} free-PBS. The colon was cut longitudinally to expose the lumen and placed in warm Ca^{2+} and Mg^{2+} free-Hank's buffered salt solution (HBSS), 30 mM EDTA, 5 mM dithiothreitol (DTT), 0.1% bovine serum albumin (BSA). After a 15-min incubation, the mucosal side was gently scraped, to remove intact crypts and surface cells from lamina propria. The isolated cells was then centrifuged at 600×*g* and washed

twice in warm HBSS with Ca^{2+} and Mg^{2+} and 0.1% BSA. The final volume was made up to 2 mL. The cells were counted using a hemocytometer and were adjusted to contain 1×10^5 cells/mL. The cell viability was measured according to the trypan blue exclusion method of Freshney [38] and found to be in the range of 60–90%.

Assay for the Generation of Reactive Oxygen Species

The net intracellular generation of ROS was measured by the method of Rosenkranz et al. [39], using oxidation sensitive fluorescent dye, 2′,7′-dichlorofluorescein diacetate (DCFH-DA). The 2′,7′-dichlorofluorescein is non-permeable and gets trapped in the cells. It gets oxidized to the highly fluorescent compound 2′,7′-dichlorofluorescein by intracellular ROS. Briefly, the isolated colonocytes were incubated with 10 μM DCFH-DA at 37 °C for 30 min, washed with HBSS and finally suspended in 300 μl of HBSS. The intensity of DCF fluorescence was measured in the cells with Fluorescence-activated cell sorter (FACS) Calibur flow cytometer (Becton–Dickinson) equipped with an excitation and emission laser line at 488 and 530 nm, respectively. A total of 10,000 events were counted and the histograms were analyzed using Cell Quest software and compared with histograms of control untreated cells.

Measurement of Antioxidant Enzymes

The cell lysates was prepared by homogenization of cells in 50 mM potassium phosphate buffer containing 250 mM sucrose, 1 mM EDTA, 1 mM DTT, 0.1% Triton X-100 (v/v) followed by centrifugation for 3 min at 10,000×*g*. The supernatant was used for further assays.

SOD (EC 1.15.1.1) activity was assayed by the method of Kono [40] in the cell lysates. One unit of enzyme was defined as the enzyme concentration required for inhibiting the reduction of NBT dye by 50% in 1 min under the assay conditions and expressed as units per milligram protein.

CAT (EC 1.11.1.6) activity was assayed by the method of Luck [41] in the cell lysates. CAT activity was assayed spectrophotometrically following a decrease in absorbance of H_2O_2 at 240 nm. One unit of enzyme activity is defined as amount of enzyme required to degrade 1 micromole of H_2O_2 in 1 min and is expressed as units per milligram protein.

GSH content was estimated in the cell lysates according to the method of Ellman [42]. GSH on reaction with 5,5′-dithiobis-(2-nitro-benzoic acid) [DTNB] gives a yellow colored product with absorption maxima at 412 nm. The standard curve was prepared for GSH with a concentration range of 0.2–1 mM. The results were expressed in micromoles per milligram protein.

Glutathione peroxidase (EC 1.11.1.9) was measured in the cell lysates by the method of Lawrence and Burk [43]. The reaction measured the rate of GSH oxidation by H_2O_2, catalyzed by GPx. GSH was maintained at constant concentration by the addition of exogenous GR and NADPH, which converted the GSSG to GSH. The rate of GSSG formation was then measured by change in the absorbance of NADPH at 340 nm for 3 min at 30 s intervals. One unit of GPx is defined as enzyme concentration required for the formation of 1 μmol of $NADP^+$ per min and results are expressed as Unit/mg protein

Glutathione reductase (EC 1.8.1.7) activity was assayed using the method of Carlberg and Mannervik [44] by measuring GSH formed by NADPH. The values are expressed as micromoles of NADPH oxidised per minute milligram protein.

Glutathione-*S*-transferase (GST) (EC 2.5.1.18) was assayed in cell lysates according to the method of Habig et al. [45]. This assay was based on the rate of increase in conjugate formation between GSH and 1-chloro-2,4-dinitrobenzene (CDNB). The enzyme activity was determined by monitoring the changes in absorbance at 340 nm for 3 min at 30 s interval. The enzymatic activity was expressed as micromoles of CDNB-GSH conjugates formed per minute per milligram protein.

Thioredoxin reductase (TrxR) (EC 1.8.1.9) was estimated by the method of Arner and co-workers [46] using a thioredoxin reductase assay kit obtained from Sigma Chemical Company, St. Louis, USA. The assay is based on the reduction of DTNB with NADPH to 5-thio-2-nitrobenzoic acid (TNB) that produces a strong yellow color that is measured at 412 nm. In crude biological samples, other enzymatic activities, such as GR and GPx also reduce DTNB. Therefore, determination of activity of thioredoxin reductase was done by subtracting the activity of sample with the activity in the presence of thioredoxin reductase inhibitor.

The protein in the cell lysates sample was done by the method of Lowry et al. [47] and the results were expressed in milligram per milliliter.

Apoptosis Measurement Using the M-30 cytoDEATH Antibody

Apoptosis was measured by using M-30 cytoDEATH (Boehringer Mannheim, Germany). M-30 cytoDEATH is the monoclonal antibody that recognizes a specific caspase cleavage site with cytokeratin 18 that is not detectable in native CK 18 of the normal cells as well as in the necrotic cells. It is a unique and specific tool for the easy and reliable determination of early apoptotic events in the cell and is the valid and acceptable method in comparison to the TUNEL [48, 49]. Cells were fixed and permeabilized in methanol by adding the alcohol drop wise with constant shaking to avoid the aggregate formation and kept at

−20 °C overnight. The cells were centrifuged at 5,000 rpm and alcohol was removed. The pellet was again washed twice with PBS/BSA. The final pellet was suspended in the PBS/BSA and incubated with M30 CytoDEATH monoclonal antibody for 30 min, at room temperature. The cells were washed with PBS and counterstained with FITC conjugated anti mouse IgG1 (Bangalore Genei, India) for 1 h at room temperature in the dark. The cells were washed with PBS and finally suspended in PBS. The mean fluorescence intensity, as a measure of apoptosis, was determined with fluorescence-activated cell sorter (FACS) Canto flow cytometer (Becton–Dickinson) equipped with an excitation and emission laser line at 495 and 520 nm, respectively. A total of 10,000 events were counted and the histograms were analyzed using Cell Quest software and compared with the histogram of control untreated cells.

DNA Fragmentation

Genomic DNA was extracted with the help of DNA extraction kit (Chromous Biotech, India). The purified samples were electrophoresed on 1% agarose gel. After electrophoresis, the DNA was visualized for fragmentation by ethidium bromide staining.

Statistical Analysis

The results are expressed as mean ± standard error of mean (SEM). The statistical significance of data was evaluated by one way analysis of variance (ANOVA), using statistical package for social sciences (SPSS) software version 9.0 for windows. The data was analyzed by post-hoc analysis with Least Square Difference to compare means. A value of $P < 0.05$ was considered to indicate a significant difference between groups. Data was analyzed using general factorial analysis of variance after testing for normality and homogeneity of variance.

Results

Effect of Fish Oil and Corn Oil on Oxidative Stress Parameters

Initiation phase study

The results of ROS generation are shown in Table 2. A decrease in ROS levels was observed on treatment with DMH as compared to control animals ($P < 0.001$).The ROS levels were elevated in animals fed a high fat diet with the effect being more pronounced at a higher ratio of fish oil which was not significantly different from the control animals. The results of antioxidants' are tabulated in Table 3. There was a significant elevation in the activities of SOD and CAT in DMH treated animals with respect to control animals ($P < 0.05$).The marked elevation was also observed in the activities of both the enzymes, SOD and CAT in the animals fed with FO + CO (1:1) with respect to controls ($P < 0.001$) and DMH treated animals ($P < 0.01$ and $P < 0.001$), respectively. However, a significant decrease was observed in the activity of both the enzymes in the animals fed on FO + CO (2.5:1).

The glutathione levels in the carcinogen treated animals and in animals fed with FO + CO (1:1) were increased significantly as compared to the normal controls ($P < 0.05$) while a significant decrease in GSH was observed in animals fed with FO + CO (2.5:1) with respect to the carcinogen treated ($P < 0.001$) and animals on the lower ratio of the oils.

DMH treatment did not alter GPx activity, though in rats fed with FO + CO (1:1), GPx activity significantly increased ($P < 0.01$) with respect to control and DMH treated group ($P < 0.05$).

GR activity was increased in all the treated groups as compared to the controls. The activity was elevated most in the DMH treated group ($P < 0.001$).However, FO + CO treatment led to a decrease in the activity of the GR as compared to the DMH treated animals ($P < 0.05$) with the effect being more pronounced at higher ratio.

GST activity was drastically increased in carcinogen treated rats as compared to the controls ($P < 0.001$). On feeding the high fat diets, the activity was still significantly higher as compared to the normal controls ($P < 0.001$).

There was no significant decrease in the activity of TrxR in DMH treated and FO + CO (2.5:1) in comparison to controls but the activity was significantly decreased in animals fed FO + CO (1:1).

Post Initiation Phase Study

The results of ROS generation are shown in Table 2. The ROS levels were found to be significantly higher in the carcinogen treated group ($P < 0.001$) as well as in the group fed FO + CO (1:1) as compared to the control ($P < 0.001$) in the post initiation phase study. However, the animals on FO + CO (2.5:1) showed no significant difference from control animals.

The antioxidants' level in the post initiation study is shown in Table 4. There was a marked decrease in the activities in the CAT and SOD in all the groups ($P < 0.001$) as compared to the control. The activity was elevated in the group treated with FO + CO (2.5:1) as compared to the DMH treated group.

A significant decrease in the GSH levels were observed in all the groups in the post initiation phase as compared to the control animals ($P < 0.01$) with the effect being more pronounced in FO + CO (2.5:1) fed animals ($P < 0.001$).

Table 2 ROS levels in the initiation phase and post initiation phase studies in the colon carcinogenesis

Groups	Initiation phase	Post initiation phase
ROS generation (MFI)		
Control	104.08 ± 5.10	44.30 ± 2.41
DMH treated	32.85 ± 5.55[a]	69.78 ± 3.43[a]
FO + CO (1:1)	53.99 ± 5.27[a,c]	81.33 ± 4.21[a,b]
FO + CO (2.5:1)	107.63 ± 22.4[d,e]	44.98 ± 1.10[d,e]

The results are expressed as mean ± SEM for $n = 8$

[a] $P < 0.001$ with respect to control

[b] $P < 0.01$ with respect to DMH treated

[c] $P < 0.05$ with respect to DMH treated

[d] $P < 0.001$ with respect to DMH treated

[e] $P < 0.001$ with respect to FO + CO (1:1)

There was a significant decrease in the activities of GPx, GR and GST in the DMH treated group and the group fed FO + CO (1:1) in comparison to the control animals ($P < 0.05$, $P < 0.001$ and $P < 0.001$, respectively). However in animals fed FO + CO (2.5:1), there was an elevation in the activities of these enzymes in comparison to the DMH treated group ($P < 0.001$, $P < 0.05$ and $P < 0.05$) respectively.

The Effect of Fish Oil and Corn Oil on M-30 cytoDEATH Levels

The levels of M-30 cytoDEATH on administration of fish oil and corn oil in different ratios are presented in Table 5. A significant increase in apoptosis in DMH treated animals was observed in the initiation phase ($P < 0.001$). The treatment with fish oil and corn oil in both the ratios showed significant decrease in the apoptotic levels as compared to DMH treated group ($P < 0.05$). In the post initiation phase study, there was a significant decrease in apoptosis in DMH treated group ($P < 0.05$). On treatment with the oils, the apoptosis were significantly increased with FO + CO (1:1) ($P < 0.05$) and FO + CO (2.5:1) ($P < 0.001$) respectively. The increase in apoptosis with higher ratio was also significant in comparison to the lower ratio of fish oil and corn oil ($P < 0.001$).

The Effect of Fish Oil and Corn Oil on DNA Fragmentation

The results of the DNA fragmentation are presented in Fig. 2 (initiation phase and post initiation phase). In the initiation phase study, there was an increased DNA fragmentation in the carcinogen treated group as compared to FO + CO treated groups. In the post initiation phase groups, there was maximum fragmentation in the animals treated with FO + CO at a ratio of 2.5:1, followed by FO + CO (1:1) and DMH treated group.

The Effect of Fish Oil and Corn Oil on the ACF Count

The results for the ACF count are documented in Table 6 and were identified as the discrete aggregation of aberrant/abnormal crypts.

In the initiation phase study, ACF multiplicity was significantly increased in DMH treated group as compared to the controls ($P < 0.001$). A major decrease in the ACF

Table 3 Activity of antioxidants in the isolated colonocytes in the initiation phase study

Groups	Control	DMH treated	FO + CO (1:1)	FO + CO (2.5:1)
SOD (U/mg protein)	412.23 ± 41.97	645.19 ± 96.18[c]	974.57 ± 41.67[a,d]	411.45 ± 48.33[e,f]

Table 5 Effect of fish oil and corn oil on apoptosis

Groups	Initiation phase	Post initiation phase
Apoptotic levels in colonocytes (MFI)		
Control	39.57 ± 4.73	61.57 ± 9.81
DMH treated	68.57 ± 6.94[b]	42.60 ± 4.06[a]
FO + CO (1:1)	43.67 ± 5.55[c]	62.75 ± 2.74[c]
FO + CO (2.5:1)	53.87 ± 3.27[c]	96.25 ± 4.89[b,d,e]

Values are mean ± SEM of eight observations in each group

[a] $P < 0.05$ with respect to control

[b] $P < 0.001$ with respect to control

[c] $P < 0.05$ with respect to DMH treated

[d] $P < 0.001$ with respect to DMH treated

[e] $P < 0.001$ with respect to group FO + CO (1:1)

count was observed in the animals treated with FO + CO (2.5:1) in comparison to the DMH treated rats ($P < 0.01$) and FO + CO (1:1) ($P < 0.01$).

A similar trend was observed in ACF count in the post initiation phase study.

The Effect of Fish Oil and Corn Oil on Histopathology of the Colon

The normal histological features of the colon are shown in Fig. 3a. In the initiation phase study, the animals in the DMH treated group showed mild to moderate inflammation (Fig. 3b). The inflammation consisted predominantly of lymphocytes and some plasma cells and was chiefly centered in the submucosa. Animals with moderate inflammation showed prominent lymphoid follicles surrounded by lymphocytes and plasma cells. However, in the group supplemented with FO + CO (1:1) (Fig. 3c), the inflammation was dense and infiltrated the mucosa. In addition, Low grade lymphoma of MALT type was found in two animals. The FO + CO (2.5:1) animals showed a normal mucosa or mild inflammation (Fig. 3d) demonstrating the inhibitory effect of the higher ratio of fish oil and corn oil in the experimental colon carcinogenesis.

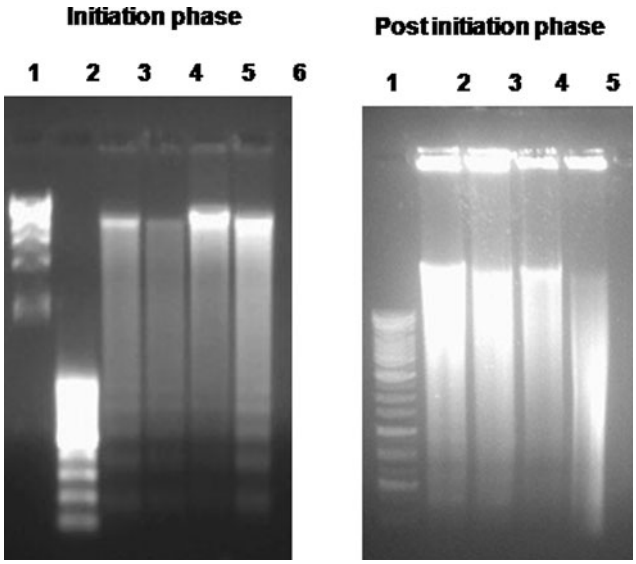

Fig. 2 A representative gel photograph of the DNA fragmentation pattern observed in the animals of various groups in the initiation phase and post initiation phase study. Initiation phase: *lane 1* markers (23–10 kbps), *lane 2* markers (1–0.1 kbps), *lane 3* controls, *lane 4* carcinogen treated, *lane 5* FO + CO (1:1) and *lane 6* FO + CO (2.5:1). Post initiation phase: *lane 1* markers (2–0.1 kbps), *lane 2* control, *lane 3* carcinogen treated, *lane 4* FO + CO (1:1) and *lane 5* FO + CO (2.5:1)

Table 6 Effect of FO + CO on the number of ACF present in the colonic mucosa

Groups	Small	Medium	Large	Total no. of ACF
Initiation phase study (ACF/colon)				
Control	0.25 ± 0.25	1.75 ± 0.85	1.50 ± 0.29	3.50 ± 0.87
DMH treated	4.66 ± 2.67	3.00 ± 0.58	9.30 ± 0.33[a]	17.00 ± 2.52[a]
FO + CO (1:1)	3.5 ± 1.19	2.00 ± 0.58	6.25 ± 0.48[a,d]	11.75 ± 2.06[b]
FO + CO (2.5:1)	3.0 ± 1.00	2.00 ± 0.58	4.00 ± 0.41[a,d]	8.00 ± 1.96[e,g]
Post initiation phase study (ACF/colon)				
Control	1.60 ± 1.03	3.00 ± 0.63	4.80 ± 0.86	9.40 ± 1.54
DMH treated	7.00 ± 1.87[b]	2.60 ± 1.16	20.80 ± 2.42[a]	30.60 ± 420[a]
FO + CO (1:1)	6.00 ± 1.29[b]	4.50 ± 2.50	13.25 ± 3.09[c,f]	23.75 ± 5.94[c]
FO + CO (2.5:1)	2.00 ± 0.91[d]	3.50 ± 0.29	8.50 ± 1.26[d]	13.75 ± 2.10[e]

The results are expressed as mean ± SEM for $n = 6$

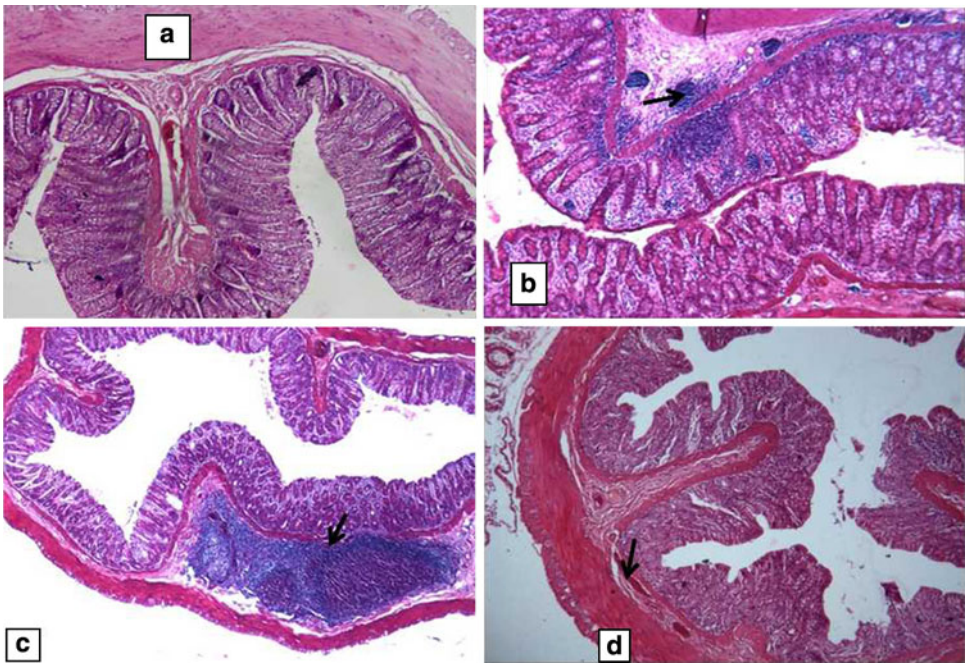

Fig. 3 **a** Light micrograph of the rat colon in the control showing normal mucosa, submucosa and crypt (H&E, ×40). **b** Light micrograph of the rat colon in the DMH treated animals showing mild inflammation (H&E, ×40). **c** Light micrograph of the rat colon in the FO + CO (1:1) showing severe inflammation (H&E, ×40) and low grade lymphoma of mucosa associated lymphoid tissue (MALT) formation (H&E, ×40). **d** Light micrograph of animals in FO + CO (2.5:1) showing normal mucosa

Figure 4a represents the histopathological features of colon in the post initiation phase study. There is severe inflammation with large lymphoid tissue formation and hyperplasia. There was distorted morphology of cells in carcinogenic animals (Fig. 4b). However, in FO + CO treated group in the equal ratio, there is varied gland size with increased intraglandular space and colitis with marked regenerative changes (Fig. 4c). The animals in the group supplemented with FO + CO (2.5:1) showed normal features with increased intra glandular space and regenerative changes (Fig. 4d).

Discussion

The results clearly indicate that administration of the procarcinogen DMH in the presence of fish oil and corn oil brings about profound alterations in the ROS and

antioxidant status. ROS have multiple functions and are implicated in tumor initiation and progression [20, 50]. While the higher levels of ROS can cause DNA damage and ultimately apoptosis, low levels of ROS in cancer cells has been suggested to promote cell proliferation mediated by redox signalling [51].

In the present investigation, treatment with DMH led to a decrease in the ROS generation with a concomitant increase in SOD and CAT in initiation phase. The level of GSH and GSH dependent enzymes were raised along with the increase in the apoptosis. Increase in the activities of SOD and CAT in the carcinogen treated animals have also been reported by other workers [52, 53]. An increased expression of GSH, GPx and GST in the neoplastic cell confers a selective growth advantage against onslaught of oxidative stress and allows these cells to propagate and proliferate [54]. The TrxR activity was reduced on treatment with DMH. It has been observed that TrxR and GPx expression are regulated in the contrasting manner in colon cancer cell line [55], which indeed was the observation in the present study. The upregulation of the antioxidants with a decrease in ROS levels may be an early cellular adaptive response. Therefore the cells may be able to maintain the ROS levels below the toxic threshold that benefit their proliferation as required in the process of carcinogenesis which is also suggested by other workers [56–58]. The increase in the apoptosis in the initiation phase indicates the enhanced rate of cell death with the carcinogen treatment. Most studies have shown that the proportion of epithelial cells undergoing apoptotic cell death increases in the course of the adenoma–carcinoma sequence [59, 60].

However, in the post initiation phase study, there was an increase in the levels of ROS generation and decreased activities of antioxidants and apoptosis. An increase in ROS generation in the progression phase of carcinogenesis has also been documented earlier [61, 62]. Increased ROS generation may serve as an endogenous source of DNA damaging agents that promote genetic instability and favor the process of carcinogenesis. There was decrease in the apoptosis as indicated by M-30 cytoDEATH levels and DNA fragmentation. Hence, the decreased apoptosis and increased DNA damage will favor the survival of the cancerous cell and promote the process of carcinogenesis as documented by the other studies also [62–64]. The increased damage in the colon was also supported by the increased ACF count and the hyperplastic changes observed in the histopathology in the present study.

On supplementing the fish oil and corn oil at the lower ratio (1:1), there was a decrease in ROS generation, TrxR and apoptosis with a concomitant rise in the antioxidants' activity in the initiation phase study. These results of initiation phase of lower ratio of fish oil and corn oil are in agreement with the study of Wang et al. [65], who reported decreased generation of ROS with increased activities of SOD, CAT and GPx in fish oil fed group in the atherosclerotic rats. A higher SOD activity will lead to an increased generation of H_2O_2 in the animals. H_2O_2 are detoxified by CAT and GPx. Hence, higher antioxidant levels in the treated cells are able to neutralize the free radical generation. TrxR activity is targeted by a number of anti-cancer drugs and potent inhibitors that alter cancer related properties of malignant cells [66]. Thus, its decrease

may be an important defense in the cancer progression which indeed is the result on treatment with the lower ratios of fish oil and corn oil. In addition, n-3 PUFA were able to activate the immune response and cause increased inflammation which indeed was the observation in the present study. In the post initiation phase study, fish oil in the lower ratios could enhance ROS levels and decrease the antioxidants' levels. n-3 PUFA are known to activate the chemoprevention by increasing the ROS levels. It is also known that n-3 PUFA improves the efficacy of chemotherapeutic regimens by increasing the ROS levels and that leads to tumoricidal effect [50].The histopathological observations and the decreased ACF count of the present study also support the preventive effect of fish oil with regenerative changes.

Administration of higher ratio of fish oil and corn oil (2.5:1) in the initiation phase showed a significant increase in the ROS levels as compared to the carcinogen treated animals with increased antioxidant levels. The cancer chemopreventive strategies have been reported to induce ROS levels which lead to DNA damage and ultimately apoptosis [51, 67]. Our findings of supplementation with the higher ratio of fish oil and corn oil are in agreement with the report showing a decrease in the activities of the CAT and GPx in the cancer cells lines on treatment with the DHA [68]. Increased LPO with decreased GPx and GST activities in tumorigenic rats are suggestive of the oxidative stress [69–71].

However, in the post initiation phase there was a decrease in the ROS levels on supplementing the fish oil and corn oil in the (2.5:1) ratio in the present study. CAT, SOD, GSH levels were decreased while there was an increase in the GR and GPx activity and DNA fragmentation. The normal levels of ROS with decrease in SOD and CAT attributes to the fact that GSH/GSSG redox signalling may play a major role. GSH/GSSG ratio is maintained by GR which uses the reducing power of NADPH to convert to GSSG to GSH [72]. Our study has also shown an increase in the GR activity along with the decrease in the GSH levels that may affect the redox potential. Therefore, the redox potential is modulated in the fish oil and corn oil treated animals which in turn have been implicated to modulate cell survival and death signals such as NF-$\kappa\beta$, PKC and caspases leading to apoptosis [72, 73]. Our study had also shown an associated increase in the apoptotic levels. In addition, regenerative changes were also seen in the groups administered with the fish oil and corn oil thereby supporting our hypothesis.

The ambiguity in the levels of ROS in the present study on supplementing different ratio of fish oil and corn oil can be explained by the fact that DHA is known to have a dose- and time-dependent effect on lipid peroxidation [74].It has been reported that low doses of DHA led to a decrease in the lipid peroxidation while an increase in dosage led to an increase in the lipid peroxidation. Lipid peroxidation in turn, is modulated by the cellular antioxidant defense system [74].

Morphological changes along with the ACF with the increased multiplicity serve as the markers of the chemopreventive response in both human and experimental colon cancer [75]. Treatment with the DMH in the rats led to an increase in the incidence and multiplicity of the ACF and inflammation in the colon. Various studies involving DMH induced colon carcinogenesis in rat model indicate that morphological surface alterations such as the proliferative activity and dysplasia in colonic mucosal epithelium start developing during the process of carcinogenesis [76–78]. However, there was a decrease in the ACF incidence and multiplicity with decreased inflammation of colon on treatment with the fish oil and corn oil in different ratios. A reduction in the ACF multiplicity has been reported in connection to the cancer chemoprevention [79, 80]. The protective action of the higher ratio in reducing the multiplicity of ACF are supported by the studies showing dose dependent effect of DHA administration on ACF incidence and multiplicity in colon cancer [81, 82]. The increase in the ACF incidence and multiplicity in the post initiation study may be attributed to the age related changes which has been reported by the previous studies [81, 82]. In the present study, the decreased ACF count with histopathological examination showing a normal mucosa and crypt accompanied by regenerative changes suggest the efficacy of the higher doses of fish oil and corn oil.

To conclude, the present study suggests that administration of fish oil and corn oil has a dose- and time-dependent chemopreventive effect in experimental colon cancer with a better efficacy of FO + CO (2.5:1). The chemoprevention effect may be mediated by modulation of oxidative stress and apoptosis.

Acknowledgments The study would have been incomplete without the invaluable help of Dr. Sharma and Mr. S. Singh, Department of Statistics, Panjab University, Chandigarh who provided the necessary expertise in the statistical analysis. The authors would like to acknowledge funding from the Indian Council of Medical Research as Ms. Pooja Sarotra is SRF-ICMR [Grant No. 3/1/3/JRF/75/MPD/2005 (11143)].

ORIGINAL ARTICLE

Lower Efficacy in the Utilization of Dietary ALA as Compared to Preformed EPA + DHA on Long Chain n-3 PUFA Levels in Rats

Ramaprasad R. Talahalli · Baskaran Vallikannan · Kari Sambaiah · Belur R. Lokesh

Received: 17 March 2010 / Accepted: 8 August 2010 / Published online: 24 August 2010

Abstract We made a comparative analysis of the uptake, tissue deposition and conversion of dietary α-linolenic acid (ALA) to its long chain metabolites eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) with preformed EPA + DHA. Diets containing linseed oil [with ALA at ~2.5 (4 g/kg diet), 5 (8 g/kg diet), 10 (16 g/kg diet), 25% (40 g/kg diet)] or fish oil [with EPA + DHA at ~1 (1.65 g/kg diet), 2.5 (4.12 g/kg diet), 5% (8.25 g/kg diet)] or groundnut oil without n-3 polyunsaturated fatty acids (n-3 PUFA) were fed to rats for 60 days. ALA and EPA + DHA in serum, liver, heart and brain increased with increments in the dietary ALA level. When preformed EPA + DHA were fed, the tissue EPA + DHA increased significantly compared to those given ALA. Normalized values from dietary n-3 PUFA to tissue EPA + DHA indicated that 100 mg of dietary ALA lead to accumulation of EPA + DHA at 2.04, 0.70, 1.91 and 1.64% of total fatty acids respectively in liver, heart, brain and serum. Similarly 100 mg of preformed dietary EPA + DHA resulted in 25.4, 23.8, 15.9 and 14.9% of total fatty acids in liver, heart, brain and serum respectively. To maintain a given level of EPA + DHA, the dietary ALA required is 12.5, 33.5, 8.3 and 9.1 times higher than the dietary EPA + DHA for liver, heart, brain and serum respectively. Hence the efficacy of precursor ALA is lower compared to preformed EPA + DHA in elevating serum and tissue long chain n-3 PUFA levels.

Keywords α-Linolenic acid · Eicosapentaenoic acid · Docosahexaenoic acid · Serum lipids · Tissue lipids

Abbreviations

ALA	α-Linolenic acid (18:3 n-3)
ANOVA	Analysis of variance
ARA	Arachidonic acid (20:4 n-6)
DHA	Docosahexaenoic acid (22:6 n-3)
DPA	Docosapentaenoic acid (22:5 n-3)
EPA	Eicosapentaenoic acid (20:5 n-3)
FO	Fish oil
GNO	Groundnut oil (peanut oil)
HDL	High density lipoprotein
LDL	Low density lipoprotein
LNA	Linoleic acid (18:2 n-6)
LSO	Linseed oil
ND	Not detected
PUFA	Polyunsaturated fatty acid (s)
SD	Standard deviation
SFA	Saturated fatty acid

Introduction

The principal n-3 polyunsaturated fatty acids (n-3 PUFA) consumed by vegetarian populations are α- linolenic acid (ALA, 18:3n-3) and the dietary intake of eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3) in these subjects is negligible. The intake of EPA and DHA is restricted to people who consume fish. However the vegetarians refrain from consuming fish and have to depend on the dietary ALA for EPA and DHA. ALA is elongated and

desaturated to 24:6 (n-3) by the following steps, 18:3 → 18:4 → 20:4 → 20:5 → 22:5 → 24:5 → 24:6 after which 24:6 (n-3) is shortened to DHA by one step of β-oxidation in peroxisomes [1]. Therefore ALA has to play a major role in vegetarians for the maintenance of EPA and DHA supply to the body.

The bioavailability of an individual fatty acid is influenced by the presence of other fatty acids and, for many years, studies have focused on apparent differences in the deposition of linoleic acid (LNA, 18:2n-6) and ALA in tissue lipids [2]. The ALA did not appear to accumulate to the same extent as that of LNA even under circumstances where equal amounts of LNA and ALA are fed [3]. Bazinet et al. [4] evaluated the utilization of ALA in growing rats consuming a diet deficient in n-6 PUFA. After 90 days, whole-body ALA accumulation was 55% lower, total n-3 PUFA accumulation was 21% lower, and ALA disappearance was 14% higher in n-6 PUFA deficient rats. Part of the reduction of whole-body ALA in n-6 PUFA-deficient rats was due to the 25% increase in net conversion of ALA to long-chain n-3 PUFA. Despite adequate ALA intake, n-6 PUFA deficiency decreased the accumulation of ALA and total n-3 PUFA. Thus n-6 PUFA affected the homeostasis of ALA. Humans show differences in LNA and ALA accumulation. While linear relationships were found between dietary ALA and EPA levels in plasma, LNA in the plasma increases linearly with dietary LNA [5]. The factors controlling the conversion of ALA to EPA and DHA may be an important determinant for maintaining adequate amounts of ALA, EPA and DHA in cells for optimal tissue function. Many researchers have extensively reviewed the essentiality of n-3 PUFA and emphasized on dose response effects of these fatty acids on its incorporation in tissues [6]. The levels of the long chain n-3 PUFA in serum and tissue are dependent on intake of either their precursors or preformed product. If an increased level of ALA is to be promoted for maintaining a given level of long chain n-3 PUFA, it is necessary to consider to what extent dietary ALA is absorbed, stored and converted into long chain metabolites.

In the present investigation, the effect of different levels of ALA or preformed EPA + DHA on the incorporation of long chain n-3 PUFA into serum and tissue lipids were studied. The implications of this uptake of n-3 PUFA on the risk factors that have a bearing on cardiovascular functions were also studied.

Experimental Procedures

Materials

Cholesterol, Dipalmitoyl phosphatidyl choline, triolein, and α-cellulose were purchased from Sigma Chemical Co, (St. Louis, MO, USA). Heparin and MnCl2 were obtained from Sisco Research Laboratory (Mumbai. India). Refined groundnut oil (Peanut oil) was purchased from a local supermarket. Fish oil (FO) (Sea Cod; brand name for cod liver oil by Seven Seas Ltd, Hull UK which is marketed in India by Universal Medicare Pvt. Ltd. Gujarat, India) was purchased from a Government pharmacy. Linseed oil (LSO) was obtained by cold pressing linseed which was double filtered and stored at 4°C after flushing the container with nitrogen gas. All the chemicals and solvents used were of analytical grade and solvents were distilled prior to use.

Animals and Diets

Male Wistar rats (OUTB-Wistar. IND-cft (2c) weighing 50 ± 4 g were grouped by random distribution ($N = 6$ animals per group). They were placed in individual cages with a 12-h light: dark cycle, in an approved animal house facility at the Central Food Technological Research Institute in Mysore, India. Rats were given the diet fresh each day and leftovers from the diets were weighed and discarded. Growth of the rats was monitored by weighing at regular intervals. The rats had free access to food and water throughout the study. The ingredients used in the basal diet were (g/100 g): casein 20; cellulose 5; sucrose 54; AIN-76 mineral mix 3.5; AIN-76 vitamin mix 1; methionine 0.3; choline chloride 0.2; and fat 16 [7]. Diet containing only groundnut oil (GNO) as sole source of fat served as control. Incremental amounts of LSO or FO were added and made isocaloric with GNO. After 60 days of feeding, rats were fasted overnight and sacrificed under ether anesthesia. Blood was drawn by cardiac puncture and serum was separated by centrifugation at 1,100*g* for 30 min. Liver, heart, brain and adipose were removed, rinsed with ice-cold saline, blotted, weighed and stored at −20°C until analyzed. The experimental protocol for these studies was approved by Animal Ethics Committee Nominated by Government of India.

Analysis of Lipids

Lipids were extracted from serum and tissues by the method of Folch et al. [8]. Serum and liver cholesterol levels were quantitated by the method of Searcy and Bergquist [9]. HDL cholesterol was estimated after precipitating LDL with heparin-MnCl2 reagent [10]. Phospholipids were measured by the method of Stewart [11] using dipalmitoylphosphatidyl choline as reference standard. Triacylglycerol were estimated by the method of Fletcher [12]. Fatty acids were analyzed as methyl esters [13] by gas chromatography (Shimadzu 14B fitted with FlD) using fused silica capillary column 25 m × 0.25 mm (Parma bond FFAP-DF-0.25: Machery-Nagel Gm BH Co.

II Duren, Germany). The operating conditions were: initial column temperature 160°C, injector temperature 210°C and detector temperature 250°C; column temperature was programmed to ramp 6°C per min to reach final temperature of 240°C. Nitrogen gas was used as the carrier. Individual fatty acids were identified by comparing retention times of standards (NU-Check prep. Inc., Elysian Minnesota, USA) and were quantitated by online chromatopack CR-6A integrator.

Statistics

The results were analyzed statistically by ANOVA [14]. A p value of <0.001 is considered to be significantly different.

Results

Fatty Acid Composition of Diet

Fatty acid composition of control and experimental diets are given in Table 1. LSO was added to increase the ALA content of the diet to provide ~2.5, 5.0, 10.0 and 25.0% ALA. The LNA/ALA ratios in the LSO containing diets were found to be 9.15, 4.52, 1.96 and 0.69. Similarly addition of FO increased the EPA and DHA level of the diet. The diet with FO provided approximately 1.0, 2.5 and 5.0% EPA + DHA. The LNA/EPA + DHA ratios in the diet were found to be 16.46, 7.62 and 4.18. The LNA content was maintained between 18 and 24% in all the experimental diets. The amounts of diet consumed in different groups were comparable. There was no significant change in the food efficiency ratio and body weight gained by rats fed diet containing different amounts of LSO or FO compared to control groups (Data not shown).

Serum Lipid Profile of Rats Fed Diets Containing Different Levels of LSO or FO

The rats fed ALA containing diets were found to contain 1.0, 1.9, 3.3 and 5.9% of ALA in serum lipids when the diet contained 2.5, 5.0, 10.0 and 25.0% ALA respectively (Table 2). The sum of EPA and DHA content in these animals were found to be 1.0, 1.7, 2.9 and 5.1% respectively. The corresponding ratios of EPA + DHA/ALA in serum lipids were 1.0. 0.89, 0.88 and 0.86 respectively indicating a moderate conversion of ALA to long chain n-3 PUFA. However, the total amount of ALA accumulated in the serum of rats fed LSO containing diets did not exceed 5.9% of total fatty acids even when the diet contained ALA to an extent of 40 g/kg diet. The EPA + DHA levels in the serum of rats fed diet containing 1.0, 2.5 and 5.0% EPA + DHA were found to be 3.4, 6.1, and 9.7% indicating that preformed long chain n-3 PUFA on weight basis compared to ALA was efficiently incorporated in lipoproteins and as shown in following sections was also incorporated in tissue lipids. Thus feeding diets containing LSO or FO at increasing concentrations resulted in accumulation of n-3 PUFA in the serum. The n-3 PUFA was not detected in control rats fed GNO. A dose dependent decrease in the serum total cholesterol level in both LSO and FO fed rats was observed (Table 3). At 2.5, 5.0, 10.0 and 25.0% ALA level in the diet the total cholesterol in serum was decreased by 7, 14, 17 and 26% respectively compared to rats given control diets. Whereas, at 1.0, 2.5 and 5.0%

Table 1 Fatty acid composition (mg%) of diets

Table 3 Serum lipid profile (mg/dL) of rats fed n-3 fatty acids from LSO or FO at incremental levels

Parameters	GNO	ALA 2.5%	ALA 5.0%	ALA 10.0%	ALA 25.0%	EPA + DHA 1.0%	EPA + DHA 2.5%	EPA + DHA 5.0%
Total cholesterol	93.4 ± 3.8^{b}	86.9 ± 2.6^{c}	80.0 ± 3.1^{de}	77.2 ± 3.2^{efg}	69.2 ± 3.8^{f}	83.7 ± 2.9^{ce}	76.0 ± 4.5^{e}	70.4 ± 4.7^{fg}
HDL cholesterol	48.0 ± 3.0^{b}	44.4 ± 1.9^{b}	38.5 ± 1.5^{cd}	36.0 ± 2.6^{cd}	34.6 ± 2.5^{d}	41.5 ± 2.2^{c}	36.6 ± 0.9^{d}	35.4 ± 1.9^{d}
LDL + VLDL cholesterol	45.4 ± 1.9^{b}	42.4 ± 1.2^{b}	41.0 ± 2.7^{bc}	40.0 ± 3.5^{bc}	34.6 ± 5.5^{c}	42.2 ± 3.8^{b}	39.4 ± 4.0^{b}	37.0 ± 4.1^{bc}
Phospholipids	114.4 ± 10.2^{b}	106.7 ± 8.5^{b}	104.6 ± 8.4^{b}	108.9 ± 5.6^{b}	107.9 ± 7.5^{b}	114.2 ± 7.9^{b}	120.6 ± 7.1^{b}	110.4 ± 5.5^{b}
Triacylglycerol	147.5 ± 6.7^{b}	138.9 ± 3.8^{b}	130.8 ± 6.3^{c}	119.6 ± 8.8^{d}	106.7 ± 10.4^{c}	129.6 ± 4.9^{c}	117.3 ± 8.4^{d}	107.7 ± 9.7^{d}

Values are means ± SD ($n = 6$ rats). Values not sharing a common superscript within a row are statistically significant (0.001). For abbreviations see Table 1

levels of EPA + DHA in the diet, the total cholesterol was decreased by 10, 19 and 25% respectively. Similarly, serum triacylglycerol in rats fed diets with 2.5. 5.0, 10.0 and 25.0% ALA levels decreased by 6, 11, 19 and 28% respectively compared to control animals. In rats fed diets with EPA + DHA at 1.0, 2.5 and 5.0% levels decreased triacylglycerol by 12, 20 and 27% respectively. These studies indicated that both ALA as well as long chain n-3 PUFA in the diet can effectively decrease serum cholesterol and triacylglycerol levels in rats, but higher levels of ALA were required to get comparable effects of EPA + DHA containing diets.

Liver Lipid Profile of Rats Fed Diets Containing Different Levels of LSO or FO

The fatty acid profile in liver lipids of rats fed diet with different amounts of ALA or EPA + DHA are given in Table 4. The ALA levels of liver lipids in rats fed diets containing 2.5. 5.0, 10.0 and 25.0% ALA were found to be 0.8, 1.9, 3.2 and 4.4% respectively. The EPA and DHA level in these rats were found to increase in a dose dependent manner with an increase in the ALA level in the diet. The EPA levels in the liver of rats fed diets with ALA content of 2.5, 5.0, 10.0 and 25.0% were found to be 0.7, 1.2, 3.5 and 3.9% of total fatty acids respectively and the DHA levels in the liver were found to be 0.4, 0.9, 1.6 and 2.7% of total fatty acids respectively. Control rats fed GNO contained neither ALA nor EPA + DHA. These studies indicated that ALA from the diet was taken up and further metabolized to long chain n-3 PUFA to a certain extent. Similarly, the EPA + DHA in the diets significantly increased the EPA and DHA level in the liver lipids. The EPA levels in the liver of rats fed diets containing 1.0, 2.5 and 5.0% EPA + DHA were found to be 2.4, 6.2 and 9.5% respectively and DHA levels were found be 2.6, 5.7 and 8.7% of total fatty acids respectively. These studies indicated that ALA or EPA + DHA from the diet is taken up and incorporated in liver lipids. However, higher levels of preformed long chain n-3 PUFA accumulated in liver even

Table 4 Liver tissue fatty acid profile (%) of rats fed n-3 fatty acids from LSO or FO at incremental levels

Values are means ± SD ($n = 6$ rats). Values not sharing a common superscript within a row are statistically significant (0.001). For abbreviations see Table 1

Table 5 Liver lipid profile (mg/g tissue) of rats fed n-3 fatty acids from LSO or FO at incremental levels

Parameter	GNO	ALA 2.5%	ALA 5.0%	ALA 10.0%	ALA 25.0%	EPA + DHA 1.0%	EPA + DHA 2.5%	EPA + DHA 5.0%
Total cholesterol	10.9 ± 0.4^{b}	9.9 ± 0.2^{c}	9.45 ± 0.1^{dg}	8.61 ± 0.1^{e}	8.00 ± 0.2^{f}	10.09 ± 0.1^{c}	9.72 ± 0.1^{cg}	9.2 ± 0.1^{df}
Triacylglycerol	16.9 ± 0.9^{b}	15.5 ± 0.5^{bc}	14.4 ± 0.6^{cd}	13.53 ± 0.6^{de}	12.12 ± 0.5^{e}	15.29 ± 0.5^{c}	13.98 ± 0.5^{de}	12.77 ± 0.9^{e}
Phospholipids	25.2 ± 1.4^{b}	26.0 ± 2.9^{b}	28.2 ± 2.3^{b}	28.2 ± 3.0^{b}	28.77 ± 2.0^{b}	25.14 ± 2.3^{b}	25.14 ± 1.3^{b}	25.36 ± 1.3^{b}

Values are means ± SD ($n = 6$ rats). Values not sharing a common superscript within a row are statistically significant (0.001). For abbreviations see Table 1

though it was provided at a dosage, which is significantly lower than that of ALA. The total cholesterol and triacylglycerol level decreased in a dose dependent manner when rats were fed a diet containing incremental amounts of ALA or EPA + DHA (Table 5). In rats fed diets containing LSO to provide ALA at 2.5, 5.0, 10.0 and 25.0% levels, the total cholesterol levels decreased by 9, 13, 21, and 27% respectively and triacylglycerol levels were lowered by 8, 15, 20 and 28% respectively compared to the control group. In rats fed diets containing FO with EPA + DHA levels of 1.0, 2.5 and 5.0% lowered the total cholesterol level by 7, 11 and 16% respectively and triacylglycerol levels by 10. 17 and 24% respectively compared to the control group.

Heart, Brain and Adipose Tissue Fatty Acid Profile of Rats Fed Diet with Different Levels of LSO or FO

The fatty acid profile of the heart (Table 6), brain (Table 7) and adipose (Table 8) tissues were significantly altered when different levels of ALA or EPA + DHA were fed to rats. EPA was not detected in the heart of control rats as well as in rats fed 2.5% ALA in the diet, but very small amounts of EPA was detected when ALA was fed at levels greater than 5.0% in the diet. The initial level of DHA in the heart tissue of control rats was found to be 3.8% of total fatty acids and was raised to 4.2, 4.8 and 6.0% respectively when ALA levels were maintained at 5.0, 10.0 and 25.0% in the diets. However, feeding FO at incremental levels significantly increased the DHA level in the heart. From the initial 3.8% of total fatty acids, the DHA level was raised to 8.2, 11.2 and 15.1% of total fatty acids in rats fed diet with 1.0, 2.5 and 5.0% EPA + DHA.

Feeding incremental level of ALA to rats resulted in an increase in the levels of DHA by 13–49% in brain tissue. The initial level of DHA in brain tissue of control rats was found to be 8.3% and was raised to 9.4, 10.4, 11.2 and 12.4% respectively when ALA levels were maintained at 2.5, 5.0, 10.0 and 25.0% in the diet. ALA was detected in the brain tissue of rats fed diets containing ALA at 10.0 and 25.0%. Feeding diets containing FO resulted in a 37–104% increase in the DHA level from 8.3 in the control to 11.4, 13.1 and 16.9% of total FAs in rats when EPA + DHA levels in the diet were maintained at 1.0, 2.5 and 5.0% levels respectively.

The level of ALA in the adipose tissue increased when incremental amounts of ALA were given in the diet. The ALA in adipose tissue was found to be 1.9, 3.9, 6.9 and

Table 6 Heart tissue fatty acid profile (%) of rats fed n-3 fatty acids from LSO or FO at incremental levels

12.1% of total fatty acids respectively when the ALA content in the diets was kept at 2.5, 5.0, 10.0 and 25.0%. EPA and DHA were not detected in the adipose tissue of rats fed diet with different levels of ALA; however, feeding FO resulted in a significant incorporation of EPA and DHA in adipose tissue. The EPA levels were found to be 0.8, 2.6 and 4.9% of total fatty acids respectively when diets containing 1.0, 2.5 and 5.0% were fed to the rats. The corresponding DHA levels observed in the adipose tissue of these rats were 0.9, 2.8 and 5.2% respectively.

Discussion

The primary objective of this investigation was to evaluate the uptake of ALA from a vegetable oil source and its subsequent conversion to long chain n-3 PUFA in different tissues. This is compared with the uptake of preformed long chain n-3 PUFA obtained from FO. These uptakes were monitored at comparable levels of LNA in the diet. The study indicated that with the increase in the dietary ALA levels, there was a corresponding increase in the levels of ALA with a small but significant increase in the accumulation of EPA + DHA in the serum and liver. Though ALA levels in the diet were increased from 4 to 40 g/kg diet, the ALA levels in serum lipids increased from only 1.0–5.9% of total fatty acids. Long chain metabolites of ALA, namely, EPA + DHA also increased from 1 to 5% of total fatty acids in serum lipids. This indicated that though higher amounts of ALA are fed to rats, only a small proportion of ALA and its long chain metabolites are accumulating in serum lipids. Earlier studies have shown that dietary ALA increased the

tissue long chain n-3 PUFA level in rats [15, 16] and in suckling piglets [17]. However, preformed EPA + DHA were taken up by the serum and liver much more efficiently than that derived from ALA. Thus at 2.5 and 5.0% ALA in the diet, EPA + DHA was observed to an extent of 1.0 and 1.7% in serum and 1.1 and 2.1% of total fatty acids in liver lipids. Whereas, with similar levels of preformed EPA + DHA in the diet, these long chain n-3 PUFA were found to accumulate to an extent of 6.0 and 9.7% in serum, and 11.9 and 18.2% of total fatty acids in liver lipids respectively. This indicated a more efficient uptake and retention of preformed long chain n-3 PUFA in serum and liver [18].

The lower levels of long chain n-3 PUFA in subjects given ALA rich diets compared to those given preformed EPA + DHA is the subject matter of many recent studies. Most of the investigators are of the opinion that this is due to extensive oxidation of ALA once it is ingested [19–21]. The competition of LNA for delta-6 desaturase may reduce conversion of ALA to long chain n-3 PUFA. The background diet is another factor which can modulate the conversion process. MacDonald and Garg [22] noticed that conversion of ALA to EPA was highest in rats receiving saturated fats but lowest in the PUFA fed rats. In addition, the ability of ALA conversion to long chain n-3 PUFA particularly DHA varied depending on the animal models used. Fu and Sinclair [23] noted that increased ALA intake increases tissue ALA but had very little effect on tissue DHA in guinea pigs. Humans also showed limited capacity to convert ALA to DHA [24]. However, in rats, dietary ALA increased DHA to a small but significant level [22, 25]. The ALA can also undergo metabolism in a recycling pathway [26]. Unlike ALA, long chain fatty acids like DHA seem to undergo less β-oxidation and carbon recycling.

These studies indicate that ALA is subjected to metabolism in different routes and hence the actual amount that is available for its conversion to long chain n-3 PUFA may be limited under most circumstances. On the other hand, preformed long chain n-3 PUFA are more resistant to metabolic changes such as β-oxidation and carbon recycling [26] which may indicate its ready availability for uptake by tissues. This may contribute to an increased uptake of preformed long chain n-3 PUFA in comparison with those derived from ALA.

The ratio of n-6 to n-3 fatty acids is often considered to be crucial for the conversion of ALA to long chain n-3 PUFA as n-6 fatty acid (LNA) can compete with delta-6 desaturase which acts on both n-6 and n-3 fatty acids [27, 28]. It is also shown that in the presence of LNA, the ALA is oxidized to greater extent and hence may not be available as substrate for synthesis of its long chain metabolites [29]. In our studies the ratio of n-6 to n-3 fatty acids were varied from 9.11 to 0.69. In spite of such large range of ratios used for LNA to ALA in the diet, ALA was converted to EPA and DHA in serum and tissues at all the ratios of n-6 to n-3 fatty acids used in the diet. This indicated that LNA did not influence delta-6 desaturase responsible for converting ALA to long chain n-3 PUFA. Further, LNA accumulation and its conversion to arachidonic acid (ARA) were also found to be dependent on the levels LNA available in the diet. ALA even though varied from 2.5 to 25.0% in the diet, did not significantly influence accumulation of LNA and the conversion to ARA again indicating that neither LNA nor the ALA interfered with each other metabolism to long chain PUFA. However, when preformed EPA + DHA were given in the diet, there was a progressive accumulation of these fatty acids in serum and the liver, which took place at the expense of LNA and ARA. This may indicate that n-6 fatty acids are displaced by long chain n-3 PUFA in serum and the liver.

The changes in the n-3 PUFA levels in different tissues in response to dietary lipids were not uniform. The DHA content in heart did not change appreciably up to 10.0% ALA in the diet. Even at a 25.0%, the ALA level in the diet there had only a 54% increase in DHA content above that found in the control group. However, DHA levels increased by 110, 187 and 287% when EPA + DHA was included in the diet at 1.0, 2.5 and 5.0% respectively. The EPA levels were also increased in FO fed animals as compared to those given higher levels of ALA in the diet. The extent of dietary EPA uptake compared to dietary DHA was significantly lower. Studies have shown that the DHA incorporation exceeds that of EPA even if DHA is fed at lower levels [30]. Our results, supports the general view that heart tissue readily takes the n-3 fatty acids, particularly DHA.

The brain is another organ, which is highly enriched in DHA. The high levels of DHA in the brain of a number of mammalian species irrespective of their size led to early speculations that this fatty acid plays a crucial role in the nervous system [31]. Many studies using ALA deficient diets have shown reductions in the level of DHA in brain and loss of many cognitive functions [32, 33]. Feeding incremental amounts of ALA in the diets progressively increased DHA levels by 13-49% when ALA levels were increased from 2.5 to 25% in the diet. Similarly in rats fed 1.0–5.0% EPA + DHA in the diet increased DHA levels in brain by 37–104% over that found in the control animals. A small increase in the EPA and docosapentaenoic acid (DPA) (22:5 n-3) level was also observed in rats fed diets containing ALA or EPA + DHA. Even limited production/accumulation of EPA and DPA from dietary ALA may be physiologically relevant as they may provide a circulating reservoir for DHA synthesis in tissues.

Adipose tissue normally does not contain long chain n-6 or n-3 fatty acids. However, ALA accumulation in the adipose tissue increased linearly in response to an increasing ALA content in the diet. Feeding incremental amounts of ALA from 2.5 to 25.0% in the diet resulted in the accumulation of ALA from 1.9 to 12.1% in the adipose tissue. This is of particular interest, since adipose tissue represents one of the important storage tissues for ALA [34] that can be made available to the body when needed. We, however, did not detect any long chain n-3 PUFA in adipose tissue. Our findings are in agreement with the results of Lin and Connors [34] and also Kajwara et al. [35], which showed that when rats were given perilla oil which contained ALA to an extent of 60% resulted in an accumulation of ALA to an extent of 12% but less than 1% EPA and DHA was detected in adipose tissue. These studies indicated that adipose tissue might not be of major importance in DHA deposition following ALA intake, whereas they represent the main storage compartment for ALA [15].

These studies indicated that significant differences do exist in handling ALA and long chain n-3 PUFA which prompted Abedin et al. [36] to suggest that effect of LNA, ALA, ARA and DHA on tissue fatty acid composition may be an indicator for differential handling of essential fatty acids by the body. They further state that the incorporation of long chain n-3 PUFA in neural tissue which has been most extensively studied are not the same as those observed in other tissues like liver and heart and therefore it is necessary to explore the potential differences in handling of long chain PUFA which may have distinguishable effects on physiological factors [36]. This again underscores the need for caution while recommending dietary ALA as an alternative to long chain n-3 PUFA. The low conversion of ALA to DHA even when used in low and high concentrations in the diet in rat and pig models is shown in Table 9. Based on our results, the amount of dietary n-3 PUFA required to increase EPA + DHA levels in different tissues was calculated. Consumption of 100 mg

of ALA will result in the accumulation of EPA + DHA at 2.04, 0.70, 1.91 and 1.64% of total fatty acids respectively in the liver, heart, brain and serum. Similarly consumption of 100 mg of preformed EPA + DHA in the diet resulted in 25.4, 23.8, 15.9 and 14.9% of total fatty acids in liver, heart, brain and serum respectively. This indicated that to maintain a given level of long chain n-3 PUFA the dietary ALA required is 9.1, 12.5, 33.5 and 8.3 times higher than that could be achieved with preformed EPA + DHA in the diet for serum, liver, heart and brain respectively. Earlier studies on weanling rats showed that 0.16% of radio-labeled DHA given orally is recovered in the brain compared with 0.008% recovered when radio-abeled ALA was given which is a difference of 20 fold between ALA and DHA for its incorporation in brain lipids [37]. In guinea pigs, 10 times more dietary ALA compared to DHA was required to maintain a given level of DHA in brain [36]. In baboons preformed dietary DHA was 7 times more effective as a substrate for neural DHA than that derived from dietary ALA [38]. These studies indicated high efficiency of preformed DHA to raise the levels of tissue DHA as compared to that obtained from ALA in the diet. All these observations have prompted Sinclair to suggest that there is a clear need to define a physiological end point while fixing the requirements for ALA rather than the conventional criteria adopted for fixing recommended dietary allowance for essential fatty acids [39]. Our studies do support such a need for fixing the criteria for ALA intake.

In conclusion, the present study indicates that ALA could be an alternative source for long chain n-3 PUFA if taken at higher levels in the diet. This could be elongated and desaturated to long chain n-3 PUFA to a limited extent and it also has beneficial effects in lowering serum lipid levels. However, significantly higher levels of ALA in the diet are required for mimicking the effects of preformed EPA + DHA in the diet. These results, which were observed in rats, however need to be validated in humans using natural sources of n-3 PUFA before recommending ALA as an alternative to EPA + DHA in the diet.

Abstract The high ingestion of oleic (OLA) and linoleic (LNA) acids by Western populations, the presence of inflammatory diseases in these populations, and the importance of neutrophils in the inflammatory process led us to investigate the effects of oral ingestion of unesterified OLA and LNA on rat neutrophil function. Pure OLA and LNA were administered by gavage over 10 days. The doses used (0.11, 0.22 and 0.44 g/kg of body weight) were based on the Western consumption of OLA and LNA. Neither fatty acid affected food, calorie or water intake. The fatty acids were not toxic to neutrophils as evaluated by cytometry using propidium iodide (membrane integrity and DNA fragmentation). Neutrophil migration in response to intraperitoneal injection of glycogen and in the air pouch assay, was elevated after administration of either OLA or LNA. This effect was associated with enhancement of rolling and increased release of the chemokine CINC-2$\alpha\beta$. Both fatty acids elevated L-selectin expression, whereas no effect on β_2-integrin expression was observed, as evaluated by flow cytometry. LNA increased the production of proinflammatory cytokines (IL-1β and CINC-2$\alpha\beta$) by neutrophils after 4 h in culture and both fatty acids decreased the release of the same cytokines after 18 h. In conclusion, OLA and LNA modulate several functions of neutrophils and can influence the inflammatory process.

Keywords Neutrophil migration · Inflammation · Adhesion molecules · Cytokines · Oleic acid and linoleic acid

Introduction

The interest in studying the effects of fatty acids on aspects of the immune response began in 1970, when Pipette and Saugier [1] demonstrated the effects of an intravenous infusion of lipid emulsion on leukocytes isolated from rabbits. Although the effects of ω-3 [2] and ω-6 [3–6] polyunsaturated fatty acids have been frequently addressed in previous studies, little information is available about the action of oleic acid (OLA), the major ω-9 fatty acid in the human diet, on immune function. Previous in vitro studies have shown that OLA inhibits protein kinase C activity in lymphocytes [7], the release of myeloperoxidase [8] and the chemotaxis of human neutrophils [9], but that it can promote necrosis and apoptosis of human lymphocytes [10]. Increased ingestion of olive oil (a major source of oleic acid) has been associated with a reduction in cardiovascular disease, rheumatoid arthritis and a variety of cancers (reviewed by Waterman et al. [11]). These effects are attributed to OLA and/or the phenols present in this oil. Since oxidative stress and inflammation are important factors involved in the etiology of these diseases and neutrophils are important cells involved in the inflammatory response, it is relevant to study the effects of OLA and other fatty acids on neutrophil functions.

Neutrophils are the first cells that migrate into tissues in response to invading bacteria or other microorganisms, and they act to destroy invading pathogens through an array of microbiocidal mechanisms [12] such as phagocytosis, and production of reactive oxygen species, cytokines and proteolytic enzymes.

Here we investigate the effects of oral administration of unesterified OLA and LNA on neutrophil responses: migration, expression of adhesion molecules, interaction with endothelium and production of proinflammatory cytokines. Changes in neutrophil responses due to fatty acids could delay or accelerate inflammation onset and/or resolution.

Experimental Procedure

Reagents

OLA, LNA, fetal bovine serum (FBS), HEPES, penicillin, streptomycin, sodium bicarbonate, lipopolysaccharide (LPS) (*Escherichia coli* strain 0111:B4), *N*-formyl-methionyl-leucyl-phenylalanine (fMLP), oyster glycogen and RPMI-1640 culture medium supplemented with L-glutamine were from Sigma Chemical Co. (St. Louis, MO, USA). Fluorescein isothiocyanate labeled anti rat-L-Selectin (anti-rat CD62L) and anti rat-b2-integrin (anti-rat CD18) were purchased BD PharMingen Technical (San Diego, CA, USA).

Animals

Male Wistar rats weighing 180 ± 20 g (from the Department of Physiology and Biophysics, Institute of Biomedical Sciences, São Paulo University, Brazil) were maintained at 23°C under a light: dark cycle of 12:12 h. Animals received chow (Nuvital, Curitiba, Brazil—containing 22% protein, 4.5% fat, 40.8% carbohydrate, 8% fiber, reaching 3.0 kcal/g total metabolizable energy) and water ad libitum. The fatty acid composition of the chow is presented in Table 1. Food and water consumption were evaluated after each 48 h.

The Animal Care Committee of the Institute of Biomedical Sciences approved the experimental procedure of this study (Protocol number: 86).

Administration of Oleic and Linoleic Acids

According to the Department of Agriculture of USA [13] the average daily consumption of monounsaturated and polyunsaturated fat by adult men in the USA is 38 and 23 g,

Table 1 Fatty acid composition of the chow

Fatty acids	(%)
Caproic acid (6:0)	–
Caprylic acid (8:0)	0.37
Capric acid (10:0)	0.21
Lauric acid (12:0)	15.35
Myristic acid (14:0)	0.05
Palmitic acid (16:0)	17.06
Margaric acid (17:0)	0.10
Estearic acid (18:0)	2.23
Eicosapentaenoic acid (20:5 ω-3)	1.81
α-Linolenic acid (18:3 ω-3)	3.04
Docosahexaenoic acid (22:6 ω-3)	–
Arachidonic acid (20:4 ω-6)	–
Palmitoleic acid (16:1)	–
Linoleic acid (18:2 ω-6)	42.59
Oleic acid (18:1 ω-9)	17.15
Total	100
Saturated fatty acids	35.39
Unsaturated fatty acids	64.60

respectively. This is mainly in the form of OLA and LNA, respectively [13]. Considering this information, we calculated the equivalent doses to use in rats. The diets were supplemented by the oral route (by gavage) with pure OLA or LNA at doses of 0.11, 0.22 and 0.44 g/kg body weight, daily for 10 days. Control animals received 0.22 g/kg body weight of water by gavage. Other studies have demonstrated that ingestion of fatty acids for short periods is able to change low density lipoprotein fatty acid composition [14], modify plasma concentrations of inflammatory markers [15] and reduce the severity of diabetes mellitus in rats [16].

Nutritional Parameters

Based on food intake and fatty acid supplementation, total caloric intake (kcal/day) was calculated as ((mean food intake × 3.0 kcal) + kcal from fatty acid supplementation)/days of supplementation.

Biochemical Determinations

Blood samples were allowed to clot, and the sera were isolated by centrifugation at 1,000×*g* for 10 min and kept at −20°C before determination. Serum alanine transaminase (ALT), aspartate transaminase (AST), lactate dehydrogenase (LDH) and free fatty acids were determined by routine laboratory methods using BioClin kits (Belo Horizonte, Brazil) and Wako chemicals (Neuss, Germany).

Histological Analysis

Histological evaluation of the small intestine was done by a pathologist who was blinded to the experimental groups, and it was based on the following parameters: villus:crypt ratio, epithelium, reactivity of the crypt, calciform cells number, number of intraepithelium lymphocytes, Peyer plates reactivity, muscle layer, nerve plexuses.

Neutrophil Preparation

Rat neutrophils were obtained by intraperitoneal (i.p.) lavage with 40 mL calcium and magnesium free PBS (pH 7.4), 3 h after i.p. injection of 10 mL 1% (w/v) sterile glycogen solution (Sigma type II, from oyster) in PBS. The cell suspension was centrifuged at 4°C (500*g* for 10 min). The number of viable cells (>95% neutrophils) was determined in a Neubauer chamber under an optical microscope by trypan blue exclusion.

Determination of Neutrophil Fatty Acid Composition

Extraction of total lipids from neutrophils (1×10^6 cells) was performed following the method of Folch et al. [17]. Fatty acid composition of neutrophils was determined by reverse phase high performance liquid chromatography (HPLC). In brief, the samples were saponified and methylated by heating for 2 h with 2 mL of 0.5 mol/L sodium methylate. The fatty acid methyl esters formed were recovered with hexane and analyzed in a Shimadzu HPLC equipped with a fluorescence detector, using a Supelco fused silica column (25 cm × 4.6 mm).

Culture Conditions

Neutrophils obtained as described above were maintained in RPMI-1640 culture medium containing 10% FBS, glutamine (2 mmol/L), Hepes (20 mmol/L), streptomycin (100 μg/mL), penicillin (100 international units/mL) and sodium bicarbonate (24 mmol/L). Cells (2.5×10^6 cells/mL) were incubated in 24-well polystyrene culture plates at 37°C and 5% CO_2 with or without 5 μg/mL LPS for 4 and 18 h. This concentration of LPS is used to stimulate rat neutrophils [18]. At the end of the incubation period, cell supernatant was collected and stored at −80°C until to the measurement of CINC-2$\alpha\beta$ and IL-1β concentrations.

Cell Membrane Integrity Assay

Cells (1×10^6) were centrifuged at 1,000 rpm for 5 min at 4°C and the pellet obtained was resuspended in 500 μL PBS. Thereafter, 50 μL propidium iodide (50 mg/mL in PBS) were added and the cells then were analyzed by flow cytometry (FACSCalibur, Becton–Dickinson, USA). Propidium iodide is a highly water-soluble fluorescent compound that cannot pass through intact membranes and is generally excluded from viable cells. Fluorescence was measured using the FL2 channel (orange-red fluorescence-585/42 nm). Ten thousand events were analyzed per experiment. Cells with propidium iodide fluorescence were then evaluated by using Cell Quest software (Becton–Dickinson).

DNA Fragmentation Assay

Cells were centrifuged as described above. The pellet obtained was resuspended in 300 μL hypotonic solution containing 50 μg/mL propidium iodide, 0.1% sodium citrate, and 0.1% Triton-X-100. This detergent permeabilizes the cells, allowing the dye to be promptly incorporated into DNA. Cells were then incubated for 30 min at room temperature. DNA fragmentation was analyzed by flow cytometry after DNA staining with propidium iodide according to the method described above. Fluorescence was measured and analyzed also as described.

Expression of Adhesion Molecules (L-Selectin and β_2-Integrin) Evaluated by Flow Cytometry

In order to estimate L-selectin or β_2-integrin expression, leukocytes were isolated from abdominal aorta blood and collected with EDTA solution (100 mg/mL). Erythrocytes were lysed using an ammonium chloride solution (0.13 M) and leukocytes were recovered after washing with PBS. Cells (1.0×10^6) were stimulated with *N*-formyl-methionyl-leucyl-phenylalanine (fMLP; 10 nM) for 10 min for L-selectin and 30 min for β_2-integrin measurement. After washing, leukocytes were further incubated for 30 min at 4°C in the dark with 10 µL fluorescently conjugated monoclonal antibody against rat L-selectin or rat β_2-integrin. Immediately after incubation, cells were analyzed in a FACScalibur flow cytometer. Data from 10,000 cells were obtained and only morphologically viable neutrophils were considered for analysis. Leukocytes were separated by size and granularity through flow cytometry. As circulating leukocytes in rats are represented by lymphocytes (about 80–85%), neutrophils (about 10–15%), monocytes (about 4–5%) and eosinophils (about 1%), gates were selected as mononuclear (lymphocytes and monocytes) and polymorphonuclear (neutrophils and eosinophils) leukocytes [19, 20].

Intravital Microscopic Assay

Rats were anesthetized and the mesentery was exteriorized. After surgery, the animals were kept on a special board thermostatically controlled at 37°C that included a transparent platform on which the tissue to be transilluminated was placed. The preparation was kept moist and warmed by irrigating the tissue with a warmed Ringer-Locke solution (pH: 7.2–7.4; NaCl 154 mM; KCl 5.6 mM; $CaCl_2 \cdot 2H_2O$ 2 mM; $NaHCO_3$ 6 mM and glucose 5 mM) containing 1% gelatin. The rate of the solution outflow onto the exposed tissue was controlled to keep the preparation in continuous contact with a film of liquid. Transilluminated images were obtained by optical microscopy (Axioplan II, equipped with ×5.0/0.30 plan-neofluar or ×10.0/0.25 Achroplan longitudinal distance objectives/numeric aperture and ×1.0, 1.25 or 1.60 optovar, Carl Zeiss). The images were captured using a video camera (ZVS, 3C75DE, Carl Zeiss) and were transmitted simultaneously to a TV monitor and a computer. Images obtained in the TV monitor were recorded on video-tape. Digitized images were subsequently analyzed by using an image-analyzing software (KS 300, Kontron).

Leukocyte–Endothelial Interaction

The interaction between leukocytes and vessel walls was evaluated by determining the number of rolling and adherent leukocytes on the post capillary venule wall (20–30 µm diameter, 200 µm length) of the mesentery at 10-min intervals. Three fields were evaluated in each animal. Leukocytes moving in the peripheral of the axial stream, in contact with the endothelium, were considered to be rollers [19]. These leukocytes moved sufficiently slowly to be individually visible and were counted as they rolled past a selected point on one side of the vessel during 10 min. The number of leukocytes adherent to the endothelium (stopped at the vessel wall) was determined in the same vascular segment during 10 min. A positive control (fMLP) was used in this assay. After analysis of rolling and adhered cells, 10 µL fMLP (10^{-8} M) was applied on the mesentery and after 10 min rolling and adherent cells were counted.

Air Pouch Assay and Exudate Preparation

Induction of rat skin air pouches was performed according to the method described by Edwards et al. [21]. Briefly, 20 mL of sterile air (using 0.22 µm Fluoropore filters) was insufflated into the subcutaneous tissue of the back trunk of rats under anaesthesia. Seven days later, an additional 10 mL of sterile air was insufflated. Negative controls received 1 mL of sterile PBS, and positive controls received 1 mL of sterile PBS plus fMLP (10 nM) through the same route. Four hours after the injection of the stimulus, the animals were killed by decapitation and the inflammatory exudate was collected after washing the cavity with 2 mL of sterile PBS. The suspension was centrifuged at 500*g* for 10 min at 4°C. Cells were counted in a Neubauer chamber. The supernatant was assayed for CINC-2$\alpha\beta$ by ELISA (DuoSet; R&D Systems, Minneapolis, MN, USA), according to the supplier's instructions.

Ex Vivo Cytokine Production

Neutrophils (2.5×10^6 cells) were incubated in the presence or absence of LPS (5 µg/mL) in an environment containing 5% CO_2 at 37°C in a humid atmosphere for 4 or 18 h. The concentrations of CINC-2$\alpha\beta$ and IL-1β in the supernatant were determined by using a commercially available enzyme-linked immunosorbent assay kit (R&D Systems, Minneapolis, MN, USA).

Statistical Analysis

Comparisons were performed using one-way ANOVA and Dunnett's multiple comparison post test. The significance was set at $p < 0.05$. Results were expressed as means ± SEM. Pearson's correlation test was used to identify the association between the production of cytokines and the doses of the fatty acids.

Results

Food, calorie and water intake were not modified by administration of OLA or LNA (Table 2). Animals receiving OLA or LNA did not show any clinical sign of toxicity, such as diarrhea or hair loss. The concentrations of free fatty acids in plasma were not changed by administration of either OLA or LNA (data not shown). The highest dose (0.44 g/kg body weight) of OLA or LNA did not induce an alteration in the activity of AST, ALT or LDH (Fig. 1a, b, c).

Furthermore, morphological analysis of the small intestine was performed to investigate if the route of administration, as a single bolus, and the amount of fatty acids given caused changes. There was no change in the following parameters measured: villus:crypt ratio, epithelium, reactivity of the crypt, calciform cells number, Peyer plates reactivity, muscle layer and nerve plexuses (Supplemental Fig. S1).

No alteration in membrane integrity of DNA fragmentation of neutrophils was observed in cells isolated from rats treated with OLA or LNA for 10 days compared to neutrophils isolated from control rats (water) (Fig. 2), indicating that any functional effects observed in this study do not result from increased cell death due to fatty acid administration.

Neutrophils from the OLA and LNA groups (dose 0.22 g/kg body weight) had higher contents of oleic and linoleic acids (increase of fourfold and 14%, respectively) (Fig. 3). No alteration was observed in the content of arachidonic acid between the groups (Fig. 3). The contents of saturated, unsaturated, and ω-3 fatty acids were not affected by OLA or LNA administration (data not shown).

Neutrophil recruitment in response to injection of glycogen solution was increased in the animals that received OLA (0.22 and 0.44 g/kg body weight) or LNA (all doses) (Fig. 4). Considering this result, we evaluated the expression of adhesion molecules on the surface of neutrophils. We chose the dose of 0.22 g/kg body weight because this dose of either OLA or LNA markedly increased the recruitment of neutrophils. Both fatty acids increased L-selectin expression on the membrane surface (Fig. 5a) in

Table 2 Food intake (g/day), caloric intake (kcal/day) and water ingestion (mL/day) by rats supplemented with different doses of oleic or linoleic acid during 10 days

Doses	0	0.11	0.22	0.44
Oleic acid (g/kg body weight)				
Food intake (g/day)	23.00 ± 0.92	20.65 ± 0.38	22.19 ± 0.85	22.59 ± 0.91
Caloric intake (kcal/day)	69.02 ± 2.76	62.19 ± 1.15	67.04 ± 2.56	68.68 ± 1.25
Water ingestion (mL/day)	37.5 ± 1.70	35.5 ± 0.84	41.75 ± 2.72	40.00 ± 1.58
Linoleic acid (g/kg body weight)				
Food intake (g/day)	23.00 ± 0.92	20.53 ± 0.27	20.65 ± 1.69	21.0 ± 0.63
Caloric intake (kcal/day)	69.02 ± 2.76	61.81 ± 0.81	62.40 ± 5.08	63.9 ± 1.91
Water ingestion (mL/day)	37.5 ± 1.70	36.25 ± 0.39	37.40 ± 2.68	35.25 ± 2.03

The values are presented as means ± SEM of ten animals per group

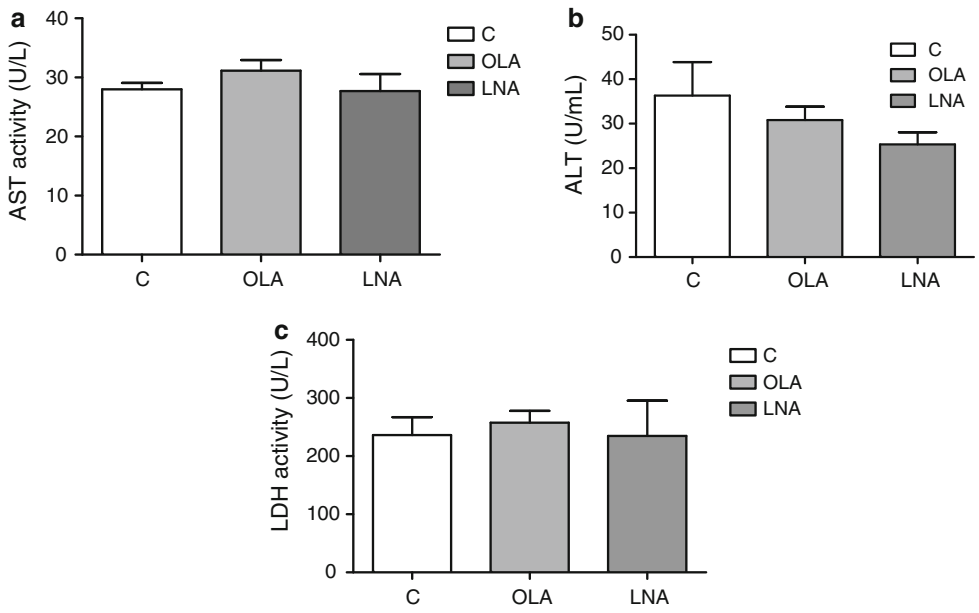

Fig. 1 Activities of aspartate transaminase (AST), alanine transaminase (ALT) and lactate dehydrogenase (LDH) in the serum of rats supplemented with oleic or linoleic acids (dose 0.44 g/kg body weight). The values are presented as means ± SEM of five animals per group

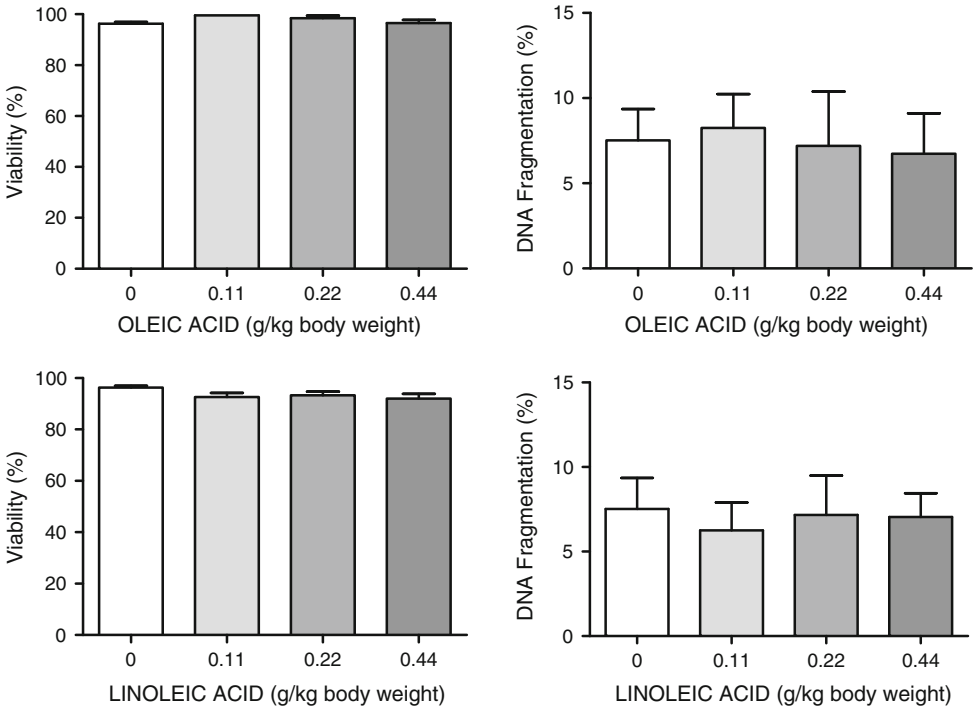

Fig. 2 Cellular viability and DNA fragmentation of neutrophils isolated from rats supplemented with different doses of oleic or linoleic acid. The values are presented as means ± SEM of seven animals per group

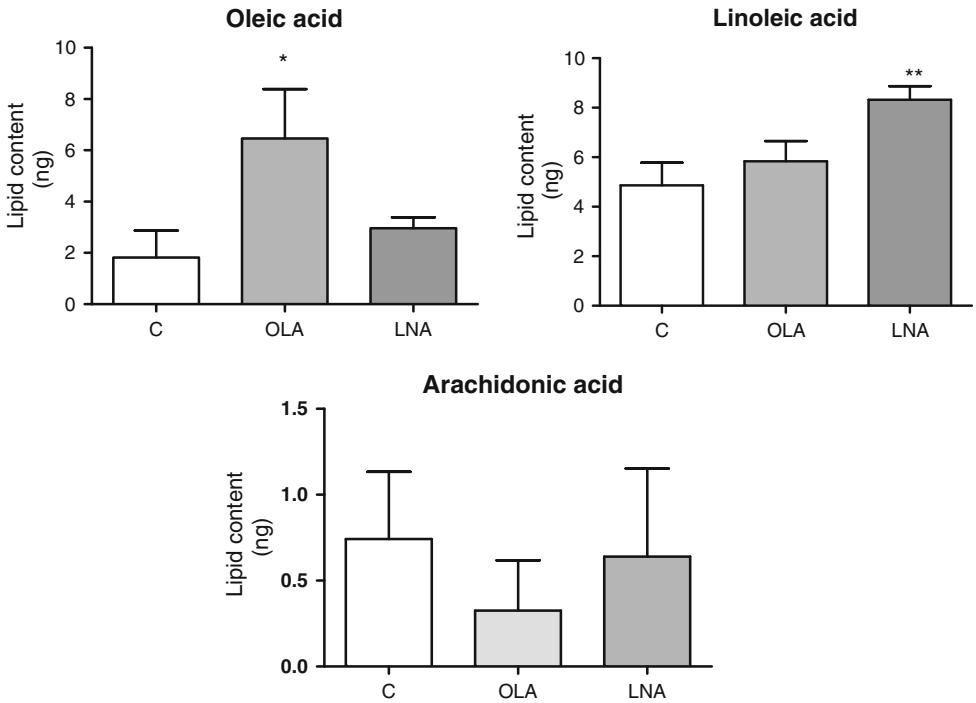

Fig. 3 Content of oleic, linoleic and arachidonic acids in neutrophils isolated from rats supplemented with oleic or linoleic acids (dose 0.22 g/kg body weight). Content is presented as ng in 1×10^6 cells. The values are presented as means ± SEM of seven animals per group. $^*p < 0.05$ and $^{**}p < 0.01$ indicates significant difference in relation to C, as indicated by ANOVA and Dunnett post hoc test

non-stimulated neutrophils, but no alteration was found for β_2-integrin expression (Fig. 5b). Neutrophil stimulation with fMLP increased the expression of both adhesion molecules. However, no effect of OLA or LNA was observed on the expression of adhesion molecules in fMLP stimulated neutrophils (Fig. 5a, b).

In vivo analysis, by intravital microscopy, of neutrophil interaction with the endothelium, showed that both fatty acids increase the rolling of leukocytes, but only LNA augmented the number of adherent leukocytes under basal conditions (Fig. 6a, b). After application of fMLP there was a significant increase in the number of rolling and

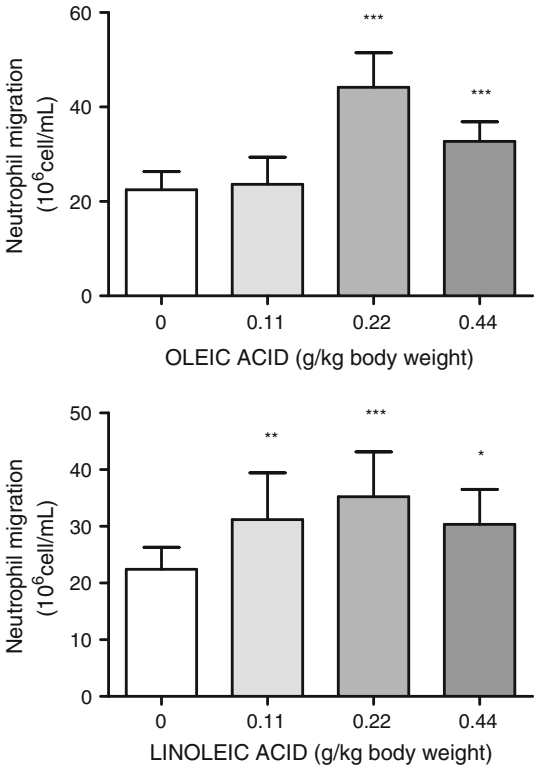

Fig. 4 Neutrophil influx into the peritoneal cavity induced by injection of glycogen solution in rats supplemented with different doses of oleic or linoleic acids. The values are presented as means ± SEM of ten animals per group. $*p < 0.05$, $**p < 0.01$ and $***p < 0.001$ indicates significant difference in relation to C as indicated by ANOVA and Dunnett post hoc test

adherent cells. LNA increased the number of rolling and adherent leukocytes after fMLP stimulus (Fig. 6a, b).

To further investigate the effect of fatty acids on neutrophil migration, the air pouch assay was used. The migratory response of neutrophils in vivo was elevated by both fatty acids in comparison to control (without fMLP). This response was accompanied by a significant increase in the concentration of CINC-2$\alpha\beta$, which plays an important role in neutrophil recruitment in rats (Fig. 7a, b). In a stimulated condition (fMLP), however, no significant alteration was observed with the fatty acid treatments (Fig. 7a, b).

The influence of the ingestion of OLA or LNA on the ex vivo production of proinflammatory cytokines by neutrophils was also evaluated. The concentration of CINC-2$\alpha\beta$ and IL-1β in the supernatants of neutrophils incubated for 4 and 18 h was determined. Despite a positive correlation between the treatment with OLA (doses 0.11, 0.22 and 0.44 g/kg body weight) and the production of CINC-2$\alpha\beta$ ($r^2 = 0.92$ Pearson correlation test; $p = 0.02$) and IL-1β ($r^2 = 0.92$ Pearson correlation test; $p = 0.001$) by neutrophils incubated for 4 h in the absence of LPS, no significant difference was observed compared to the control group (Fig. 8a, c). LNA increased the production of CINC-2$\alpha\beta$ and IL-1β by unstimulated neutrophils in a dose-dependent manner ($r^2 = 0.93$ and 0.98, respectively; $p = 0.01$ and 0.003, respectively). This effect was statistically significant at the dose of 0.44 g/kg body weight (Fig. 8a, d). After LPS-stimulation, OLA had no effects in the production of these cytokines, whereas, LNA (0.44 g/kg body weight) reduced the production of CINC-2$\alpha\beta$ (Fig. 8a, b).

After 18 h of incubation, both fatty acids significantly diminished CINC-2$\alpha\beta$ and IL-1β production by neutrophils in basal condition (PBS). In LPS-stimulated neutrophils, OLA (all doses) reduced the production of IL-1β but did not alter production of CINC-2$\alpha\beta$ (Fig. 9a, c).

Discussion

OLA is a major fatty acid component of meat, animal fat, milk, eggs, and some vegetable oils and is also a major fatty acid component of vegetable oils used in food manufacture [22]. LNA is a major fatty acid component of many vegetable oils, including some used in food manufacture and in animal feeds [22]. Thus, OLA and LNA are the predominant unsaturated fatty acids in the Western diet

[13]. Variation in intake of these two fatty acids may influence chronic disease risk, particularly diseases with an inflammatory component.

The serum activity of AST, ALT and LDH is used as a clinical marker of liver injury [23, 24]. Damaged hepatocytes release these enzymes into the extracellular space from where they enter into the circulation, so augmenting their circulating activity. The finding that the highest dose of OLA or LNA (0.44 g/kg body weight) did not elevate the serum activity of these enzymes, indicates a lack of toxicity when these fatty acids are administered in the free form by gavage as was done here.

The augmentation in neutrophil migration seen is possibly due to an increase in L-selectin expression and in the production of chemoattractant CINC-2$\alpha\beta$. LNA promoted the release of proinflammatory cytokines after a short incubation period (4 h) and both fatty acids inhibited this release after a prolonged incubation (18 h). In the presence of LPS, only LNA reduced CINC-2$\alpha\beta$ production by neutrophils after 4 h. However, OLA inhibited the production of IL-1β but did not affect CINC-2$\alpha\beta$ release by stimulated neutrophils incubated for 18 h. These observations reinforce the idea that OLA modifies neutrophil responses and should not be used as a control in further studies.

Fatty acids can accumulate into droplets in the cytoplasm or be incorporated into the phospholipids in cell membranes. The incorporation of fatty acids in neutrophils (either in the membrane or in droplets) is one, but not the only, possible mechanism involved in the effects seen here [25]. Since the cells continually degrade and replace their lipids [26], the difference in the incorporation of OLA and LNA into neutrophils could be due to the metabolism of LNA, keeping in mind that an inflammatory process was induced in the peritoneum and the cells were collected 3 h after. Another possible explanation is that each of these fatty acids exerts its effect by a different mechanism, which may not necessarily involve incorporation of the fatty acid into the cell membrane. More studies are necessary to clarify which mechanisms are involved in the effects of OLA and LNA seen in the present study.

Neutrophil recruitment requires adhesion and transmigration through blood-vessel walls, a process that involves at least four steps: rolling, activation, adhesion and transmigration. This is a highly regulated process that requires

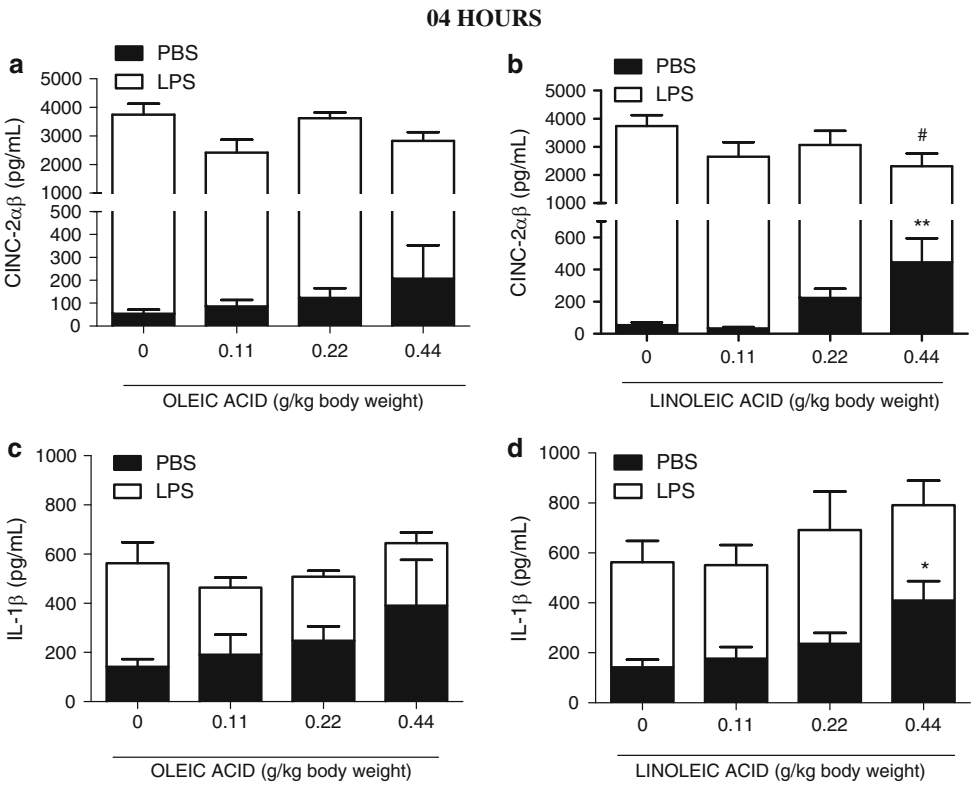

Fig. 8 Concentrations of CINC-2$\alpha\beta$ (**a, b**) and IL-1β (**c**, **d**) in the supernatant of neutrophils isolated from rats supplemented with different doses of oleic and linoleic acids and cultured during 4 h. coordinated participation of cytokines (including chemokines), and endothelial and leukocyte adhesion molecules (immunoglobulins and selectins) [12]. Selectin–ligand interactions are characterized by rapid bond formation and dissociation, an interaction that mediates the first step of leukocyte adhesion, the rolling [12]. Firm attachment of

leukocytes to the endothelium requires the interaction of integrin ligands on the leukocyte surface through immunoglobulin superfamily members, i.e., ICAM-1, ICAM-2 and VCAM-1, expressed on the endothelium [27]. Effects of OLA and LNA on endothelial cell expression of integrin ligands are conflicting: some authors demonstrated increases [15, 28] and others found decreases in the expression of adhesion molecules [29–31]. These contrasting results possibly occurred due to differences in the experimental conditions such as the cell type, time of incubation and fatty acid concentrations used.

In the present study the administration of either OLA or LNA augmented the rolling of neutrophils and the migration response without affecting the expression of β_2-integrin. Considering that the slowing of neutrophils allows these cells to recognize chemotactic molecules and to elicit a chemoattractant-receptor-mediated event [12], these results can be associated to the increase in L-selectin expression and chemokine production by neutrophils in a β_2-integrin independent-response. Studies with ω-6 fatty acids have shown an increase in the migratory response of neutrophils through the increase in the production of prostaglandin D_2 [32]. According to Tsuzuki et al. [33], olive oil increases the expression of α_4-integrin and L-selectin on lymphocytes and thereby enhances the adherence of these cells. We observed an elevation in the number of adherent neutrophils after administration of LNA, but OLA had no effect. In our study, the use of pure fatty acids ensured that the effects observed are not due to minor constituents present in the parent oils or to the combination of different fatty acids as found in oils.

Another important function of neutrophils is the production of proinflammatory cytokines such as CINC-2$\alpha\beta$ and IL-1β. CINC-2$\alpha\beta$ (also referred as IL-8) is a potent chemoattractant for neutrophils. Blockade of IL-8 receptors inhibits neutrophil influx to inflamed areas [34]. Augmentation in the production of CINC-2$\alpha\beta$ hastens the inflammatory response through an increase of neutrophil influx and activation. IL-1β is produced by leukocytes after infection or injury. This cytokine stimulates cell metabolism and increases the expression of several genes coding for enzymes than increase the production of biologically active molecules such as arachidonic acid metabolites [35].

Previous studies investigated the effect of OLA and LNA ingestion on the production of inflammatory mediators. Baer et al. [36] did not observe significant differences in the concentration of C-reactive protein and IL-6 after ingestion of an OLA-rich diet by humans. Mice supplemented with olive oil exhibited reduced neutrophil production of PGE_2, LTB_4, MCP-1, and TNF-α in endotoxic shock [37]. Ingestion of a diet rich in OLA resulted in a reduction of IL-1β, TNF-α and IL-6 release by murine macrophages cultured for 18 h [38]. On the other hand, consumption of LNA by mice was correlated with an increase in plasma concentration of IL-1β after LPS injection [39].

The production of cytokines is transient and time-dependent [40]. These characteristics are important to avoid the overproduction and, consequently, the deleterious effects of cytokines. In the present study, we observed that LNA increased the production of IL-1β and CINC-2$\alpha\beta$ after 4 h of incubation, but at 18 h, the concentration of these cytokines was lower than in the control group. This effect shows that LNA can accelerate the mechanisms responsible for the production/release of cytokines early in the inflammatory response, perhaps by promoting the transcription of pre-formed RNA [41]. The later decrease in production/release of cytokines could be due to the synthesis of a transcriptional repressor and/or a decrease in mRNA half-life [41]. OLA, at the same doses, did not alter the production of IL-1β and CINC-2$\alpha\beta$ after a short period of incubation (i.e., 4 h). However, OLA also reduced the production of these cytokines after 18 h of incubation in the presence (IL-1β) or absence of LPS (IL-1β and CINC-2$\alpha\beta$). The difference in the concentrations of CINC-2$\alpha\beta$ between 4 and 18 h is small in the OLA group. This suggests that the action of OLA is more pronounced upon the inhibition of the later process. Our results reinforce the point that LNA is more pro-inflammatory than OLA, although both alter cytokine production by neutrophils. The different responses observed between the incubation times can involve a diverse range of mechanisms [42, 43], but further studies are necessary to clarify this point.

In conclusion, we demonstrated that unesterified OLA or LNA given by gavage modify several neutrophil functions, in vivo and ex vivo, and indicate that these fatty acids may affect the course of inflammation.

Abstract Dysregulation of lipid metabolism is frequently associated with inflammatory conditions. The mechanism of this association is still not clearly defined. Recently, we identified a nuclear oxysterol, 25-hydroxycholesterol-3-sulfate (25HC3S), as an important regulatory molecule involved in lipid metabolism in hepatocytes. The present study shows that 25HC3S and its precursor, 25-hydroxycholesterol (25HC), diametrically regulate lipid metabolism and inflammatory response via LXR/SREBP-1 and IκBα/NFκB signaling in hepatocytes. Addition of 25HC3S to primary rat hepatocytes decreased nuclear LXR and SREBP-1 protein levels, down-regulated their target genes, acetyl CoA carboxylase 1 (ACC1), fatty acid synthase (FAS), and SREBP-2 target gene HMG reductase, key enzymes involved in fatty acid and cholesterol biosynthesis. 25HC3S reduced TNFα-induced inflammatory response by increasing cytoplasmic IκBα levels, decreasing NFκB nuclear translocation, and consequently repressing expression of NFκB-dependent genes, IL-1β, TNFα, and TRAF1. NFκB-dependent promoter reporter gene assay showed that 25HC3S suppressed luciferase activity in the hepatocytes. In contrast, 25HC elicited opposite effects by increasing nuclear LXR and SREBP-1 protein levels, and by increasing ACC1 and FAS mRNA levels. 25HC also decreased cytoplasmic IκBα levels and further increased TNFα-induced NFκB activation. The current findings suggest that 25HC and 25HC3S serve as potent regulators in cross-talk of lipid metabolism and inflammatory response in the hepatocytes.

Keywords Oxysterol sulfation · Oxysterol metabolism · Lipid metabolism · Inflammatory response · Nuclear orphan receptor · LXR · NFκB · IκBα

Abbreviations

25HC	25-Hydroxycholesterol
25HC3S	25-Hydroxycholesterol-3-sulfate
ABCA1	ATP-binding cassette, sub-family A, member 1
ABCG5	ATP-binding cassette, sub-family G, member 5
ACC1	Acetyl-CoA carboxylase 1
CYP27A1	Mitochondrial cholesterol 27-hydroxylase
FAS	Fatty acid synthase
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
HepG2	Human hepatocellular carcinoma cell line
HMGR	3-Hydroxy-3-methylglutaryl-coenzyme A reductase
IκBα	Nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibitor, alpha
IL-1β	Interleukin-1, beta
LDLR	Low density lipoprotein receptor
LXR	Liver X receptor
LXRE	LXR responsive elements
NAFLD	Nonalcoholic fatty liver disease
NFκB	Nuclear factor of kappa light polypeptide gene enhancer in B-cells

SULT2B1b	Sulfotransferase family, cytosolic, 2B, member 1b
TNFα	Tumor necrosis factor, alpha
TRAF1	TNF receptor associated factor 1

Introduction

Lipid metabolic disorders and inflammation are closely associated and contribute to the pathogenesis of many serious diseases including atherosclerosis, diabetes, and nonalcoholic fatty liver disease (NAFLD), which are major causes of morbidity and mortality in the United States. The American Liver Foundation estimated that currently up to 5% of American children over age 5 have NAFLD. A "two-hit" model has been proposed for the development of NAFLD [1]. The "first hit" is the initial excess lipid accumulation in the form of free cholesterol, free fatty acid, and triglycerides, induced by insulin resistance in hepatocytes. In the "second hit," excess lipids in hepatocytes lead to cell injury, setting off a cascade of necro-inflammatory changes that include the accumulation of mixed inflammatory cells and hepatocyte ballooning with Mallory body. A sub-set of NAFLD patients goes on to develop progressive fibrosis. Therefore, decreasing hepatic lipid levels and repressing the inflammatory response are the keys to NAFLD therapy. Understanding the cross-talk between lipid accumulation and inflammation is fundamental for the prevention of NAFLD. However, the cellular mechanisms controlling lipid metabolism and inflammatory response are presently unknown.

Oxysterols can act at multiple points in cholesterol homeostasis and lipid metabolism [2–5]. Recently, we identified a novel oxysterol, 25-hydroxycholesterol-3-sulfate (25HC3S), that accumulates in hepatocyte nuclei following overexpression of the mitochondrial cholesterol delivery protein, StarD1 [6–8]. This oxysterol is synthesized from sulfation of 25-hydroxycholesterol (25HC) by sterol sulfotransferase 2B1 (SULT2B1b) [9]. Sulfation of oxysterol is expected to make an even more polar sterol that should efflux more rapidly from cells. The oxysterol sulfation is believed to be an inactivation process since expression of SULT2B1b attenuated oxysterol-stimulated LXR signaling both in vivo and in vitro cultured mouse cells [10]. However, our recent reports have suggested that 25HC3S has different direct effects on lipid metabolism in HepG2 cells and macrophages compared to its precursor 25HC. 25HC increased SREBP-1c mRNA and protein levels and induced its targeting genes, but 25HC3S had the opposite effects [11, 12]. Because the expression of SREBP-1c is a target gene of LXR [13], the results indicate that 25HC and 25HC3S may diametrically opposite-regulate LXR activation. Several chemically synthesized oxysterol sulfates also display antagonistic activity against LXR [14].

Several reports show that the nuclear oxysterol receptor, LXR, actively participates in the inflammatory response [15–18]. The mechanism is not fully understood. For example, while synthetic LXR agonists could blunt the LPS-induced up-regulation of adhesion molecules (ICAM-1, VCAM-1, E-Selectin), 22-hydroxycholesterol and 24, 25-epoxycholesterol enhanced the response. Microarray profiling further showed that the endothelial gene expression profiles of 22-hydroxycholesterol and the artificial LXR ligand T0901317 largely differed, and unexpectedly shared only a restricted number of genes [19]. Other LXR-activating oxysterols such as 24,25-epoxycholesterol, 25-hydroxycholesterol, and 27-hydroxycholesterol, stimulated the endothelial expression of inflammatory markers [19].

In this study, we further demonstrate that 25HC3S and its precursor 25HC are potent regulators of hepatic lipid metabolism as well as inflammatory response in hepatocytes. We provide the evidence that their effects are mediated via activation/inactivation of the nuclear receptors, SREBP and NFκB signaling pathways, in both HepG2 cells and primary rat hepatocytes.

Materials and Methods

Cell culture reagents and supplies were purchased from GIBCO BRL (Grand Island, NY). Hepatoma cell line (HepG2) cells were obtained from American Type Culture Collection (Rockville, MD). The reagents for real-time RT-PCR were obtained from AB Applied Biosystems (Warrington WA1 4 SR, UK). Antibodies against LXRα/β (sc-13068), SREBP-1 (sc-8984), FAS (sc-55580), ACC1 (sc-30212), IκBα (sc-371), NFκB (sc-372), Lamin B1 (sc-56145), and Lamin AC (sc-20681) were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Antibodies against ABCA1 (ab18180) were from Abcam (Cambrige, MA). LXR agonist T0901317 was from New Cayman Chemical (Ann Arbor, MI). Assay kits for cholesterol E assay, free cholesterol assay, and Wako NEFA-HR [2] assay kits for free fatty acid were obtained from Wako Bioproducts (Richmond, VA). Infinity triglyceride assay kit was from Thermo Electron (Arlington, TX). FuGENE HD transfection reagent was obtained from Roche Applied Science (Indianapolis, IN). The Dual-Glo Luciferase Assay System and pGL3-NFκB-luc were purchased from Promega (Wisconsin, WI). The chemicals used in this research were obtained from Sigma Chemical (St. Louis, MO) or Bio-Red Laboratories (Hercules, CA). All solvents were obtained from Fisher (Fair Lawn, NJ) unless otherwise indicated.

Cell Culture

HepG2 cells were grown in MEM media containing non-essential amino acids, 30 mM $NaHCO_3$, 10% fetal bovine serum (FBS), 1 mM L-glutamine, 1 mM sodium pyruvate, and 1% Pen/Strep, and incubated at 37°C in 5% CO_2. When cells reached ~80% confluence, the oxysterols in DMSO or in ethanol (the final concentration in media was <0.1%) were added, and the cells were harvested as indicated. Nuclear and cytoplasmic fractions were isolated using NE-PER®, Nuclear and Cytoplasmic Extraction Reagents (Pierce, Rockford, IL).

Primary rat hepatocytes (PRH) were provided by the core facility in Virginia Commonwealth University (Richmond, VA) as described previously [20]. Cells were seeded on 60-mm tissue culture dishes in Williams' E medium containing 10% FBS, thyroxine (0.1 μM), and dexamethasone (0.1 μM). Three hours after plating, culture medium was removed, and fresh medium and the oxysterols in DMSO or in ethanol were added as indicated. Experiments were performed in PRH to corroborate findings in experiments conducted in HepG2 cells.

Cell Proliferation and Cytotoxicity Assay

HepG2 cells were plated in 96-well plates. After treatment with 25HC or 25HC3S for 48 h, 10 μl/well of CellTiter 96Aqueous One Solution Reagent [3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazolium bromide (MTT) reagent] was added. After incubation at 37°C for 1 h in a humidified 5% CO_2 atmosphere, the absorbance at 490 nm was recorded with an ELISA plate reader. Control refers to incubations in the presence of vehicle only (0.1% of DMSO or ethanol) and was considered as 100% viable cells [20].

Western Blot Analysis of Nuclear LXR, NFκB, SREBP-1, and Intracellular FAS, ACC1, ABCA1, and IκBα Levels

Cytoplasmic protein extracts or nuclear protein extracts, 50 μg, otherwise as indicated, were separated on 7.5 or 10% SDS-PAGE gels and transferred onto a polyvinylidene difluoride (PVDF) membrane using a Bio-Rad Mini-Blot transfer apparatus as described previously [21]. Membranes were blocked in Tris-buffered saline (TBS) containing 5% nonfat dried milk for 1 h. The specific proteins were determined by incubation with specific antibodies against LXR, SREBP-1, NFκB, FAS, ACC1, ABCA1, or IκBα overnight at 4°C with shaking. After washing, the membrane was incubated in a 1:3,000 dilution of a secondary antibody (goat anti-rabbit or anti-mouse IgG-HRP conjugate; Bio-Rad, Hercules, CA) at room temperature for 1 h in the washing buffer (TBS containing 0.5% Tween 20). The protein bands were visualized using SuperSignal West Pico Chemiluminescent Substrate Kit (Pierce, Rockford, IL). Cytoplasmic proteins were normalized to β-actin; nuclear proteins were normalized to Lamin AC.

LXR Transcription Factor Assay

LXR transcription factor activity was measured using an enzyme-linked immunosorbent assay (LXR Transcription Factor Assay kit; Cayman Chemical, Ann Arbor, MI). HepG2 cells were treated with 25HC3S or 25HC for 2 h. The cells were then rinsed, and the nuclear proteins were extracted according to the manufacturer's instructions. Twenty micrograms of the nuclear proteins was added to a 96-well plate that had been immobilized by specific dsDNA sequences containing the LXR responsive elements (LXRE). After incubating for 1 h, the wells were washed and incubated with primary LXR antibody, which recognizes the accessible epitope on LXR protein upon LXRE DNA binding. The HRP conjugated secondary antibody, which provides a sensitive colorimetric readout, was added and incubated for 1 h. The reaction was stopped, and absorbance was read at 450 nm in a spectrophotometer.

Determination of mRNA Levels by Real-Time RT-PCR

Total RNA was isolated from oxysterol- or vehicle-treated HepG2 or PRH using SV Total RNA Isolation Kit (Promega, Wisconsin, WI), which included DNase treatment. Total RNA, 2 μg, was used for the first-strand cDNA synthesis as recommended by the manufacturer (Invitrogen, Carlsbad, CA). Real-time RT-PCR was performed using SYBR Green as indicator on ABI 7500 Fast Real-Time PCR System (Applied Biosystems, Foster City, CA). The final reaction mixture contained 10 ng of cDNA, 100 nM of each primer, 10 μl of 2× SYBR® Green PCR Master Mix (Applied Biosystems, Foster City, CA), and RNase-free water to complete the reaction mixture volume to 20 μl. All reactions were performed in triplicate. PCR was carried out for 40 cycles of 95°C for 15 s and 60°C for 1 min. The intensity of fluorescence was read during the reaction, allowing a continuous monitoring of the amount of PCR product. Each CT value of target gene was normalized to the CT value of internal control GAPDH. The sequences of primers are summarized (Table 1, Supplemental Materials) as previously described at http://www.pga.mgh.harvard.edu/primerbank/.

Oil Red O Staining of Total Intracellular Neutral Lipids

HepG2 or PRH cells were seeded on 22 × 22-mm glass coverslips in six-well plates. After the medium was replaced, cells were cultured in fresh medium with 20%

FBS and treated with different concentrations of 25HC3S or vehicle control for 48 h as indicated. Cells were fixed with 3.7% formaldehyde in phosphate-buffered saline (PBS) for 30 min followed by washing three times with PBS. The cells were stained with 0.2% Oil Red O in 60% isopropanol for 10 min and washed three times with PBS. The images were taken with the use of a microscope (Olympus, Tokyo, Japan) equipped with 40× lenses.

Quantitative Measurements of Total Cholesterol, Free Cholesterol, Free Fatty Acids, and Triglycerides

HepG2 cells were seeded on 60-mm tissue culture dishes and treated with control vehicle and different concentrations of 25HC3S or 25HC for 48 h as indicated. The cells were collected with 0.5 ml of PBS and sonicated. Total lipids were extracted by addition of 10 ml of chloroform–methanol (2:1, vol/vol) mixture. The extract, 0.5 ml, was evaporated to dryness and dissolved in 100 μl of isopropanol containing 10% of triton X-100 for cholesterol assays, isopropanol only for triglyceride assay, or the NEFA solution (0.5 g of EDTA-Na_2, 2 g of Triton X-100, 0.76 ml of 1 N NaOH, and 0.5 g of sodium azide/l, pH 6.5) for free fatty acid assay. The total and free cholesterol, triglyceride, and free fatty acid assays were performed according to the manufacturer's instructions. Each lipid concentration was normalized to protein concentration.

Transfection and Promoter Reporter Gene-Luciferase Assays

HepG2 cells were seeded in 96-well plates. When cell density reached 90–95%, the cells were transfected with an expression plasmid as indicated using a lipid-based FuGENE HD transfection reagent according to the manufacturer (Roche, Indianapolis, IN). A synthetic *renilla* luciferase reporter, phRG-TK (Promega, Wisconsin, WI), was used as a luciferase internal standard. For NFκB reporter gene assay, 50 ng of pGL3-NFκB-luciferase reporter and 50 ng of phRG-TK vector (internal standard) were co-transfected following the manufacturer's instructions. After 24 h following the transfection, HepG2 cells were treated with different concentrations of 25HC3S or 25HC for another 24 h or further stimulated with TNFα for 6 h. Luciferase activities were determined using the Dual-Glo Luciferase Assay System according to the manufacturer's protocol (Promega, Wisconsin, WI). The amount of luciferase activity was measured using a TopCount NXT Microplate Scintillation and Luminescence Counter (Packard, Meriden, CT) and normalized to the amount of phRG-TK luciferase activity. Transfection was carried out in triplicate for each sample, and each experiment was repeated three times.

Examination of Intracellular NFκB Translocation by Confocal Microscopy

HepG2 cells were cultured on coverslips in six-well plates. When cell density reached 20–30%, the cells were treated with 25HC or 25HC3S at different concentrations as indicated for 3 h alone or for 8 h before adding 100 ng/ml of TNFα for 15 min. The cells on coverslips were washed with PBS, fixed with 3.7% formaldehyde for 10 min at 4°C, and then rinsed with PBS three times at room temperature. They were permeabilized with PBS containing 0.1% of Triton X-100 for 3 min and washed with PBS before blocking by incubation with 5% normal goat serum in PBS overnight at 4°C. For interaction with primary antibodies, cells were incubated with 2.5% normal goat serum in PBS containing antibody against NFκB for 1 h at room temperature. Cells were washed in PBS containing 0.05% of Tween 20 for three times, each time for 10 min. The bound primary antibodies were visualized with Alexa Fluor 488 goat anti-mouse IgG. The minor groove of double-stranded DNA as a nuclear marker was stained with DAPI. After washing, coverslips were mounted on slides and viewed with a Zeiss LSM 510 Meta confocal microscope, scale bar = 20 μm.

Statistics

Data are reported as mean ± standard deviation (SD). Where indicated, data were subjected to *t*-test or ANOVA analysis and determined to be significantly different at $P < 0.05$.

Results

Effects of 25HC3S and 25HC on Nuclear LXR Levels

To examine the effect of 25HC3S and its precursor 25HC on LXR activation, total nuclear proteins were extracted, and nuclear LXR protein levels were determined by Western blot analysis. As shown in Fig. 1, addition of 25HC3S to primary rat hepatocytes led to time- (Fig. 1a, upper panels) and concentration- (Fig. 1b, upper panels) dependent decreases in LXR protein levels in the nuclei. When the cells were incubated in the presence of oxysterols for 2 h, 25HC3S decreased while 25HC increased the nuclear LXR levels to the maxima. The changes are concentration dependent at the indicated time. Similar results were observed in HepG2 cells as shown in Fig. 1A in Supplemental Online Materials. To confirm that the increasing band with molecular weight 48 kDa in the nuclei was LXR protein, an artificial LXR ligand, T0901317, was used as positive control. As shown in

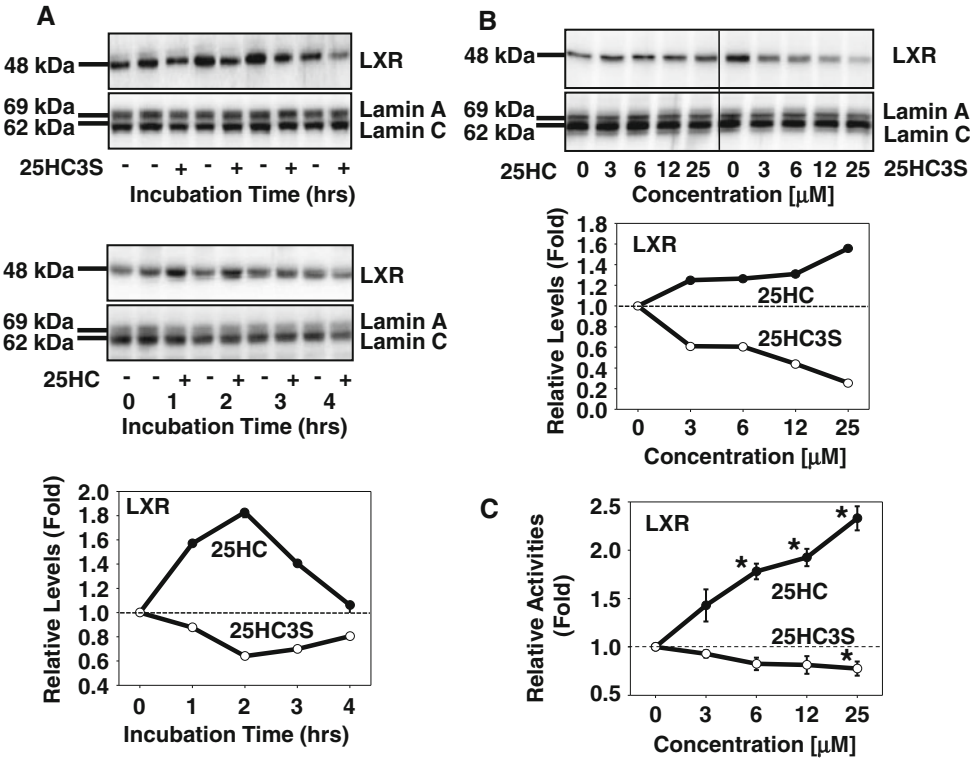

Fig. 1 Effects of 25HC3S and 25HC on nuclear LXR protein levels. The nuclear LXR protein levels in the treated PRH with 25HC or 25HC3S at the different times (**a**) and at different concentration points (**b**). Each positive band was quantified by the Image Data Analyzer and normalized to Lamin AC. The data represent one typical blot of three separate experiments. The LXR transcription factor-binding activities in the treated HepG2 with 25HC3S or 25HC were determined by the ELISA (**c**). Each value represents the mean of triplicate determination ±SD. *Asterisk* represents statistical significance ($P < 0.05$)

Fig. 1B in Supplemental Online Materials, T0091317 showed a time- and concentration-dependent increase in the nuclear LXR levels with the same molecular weight. The results suggest that 25HC3S suppresses LXR activation while 25HC increases activation. To confirm the nuclear LXR levels, LXR responsive element (LXRE)-immobilized ELISA was carried out as shown in Fig. 1c. As expected, the ELISA assay showed that nuclear extracts treated with 25HC3S decreased their LXRE-binding activities, while nuclear extracts treated with 25HC increased their LXRE-binding activities, both in a concentration-dependent manner ($P < 0.01$) (Fig. 1c).

Effects of 25HC3S and 25HC on LXR and SREBP Target Gene Expression

To determine the effects of 25HC3S and 25HC on LXR activities, total RNA was isolated from primary rat hepatocytes treated for 6 h. Real-time RT-PCR was used to determine the mRNA levels of LXR responsive genes, SREBP-1, ABCA1, and ABCG5; SREBP-1 responsive genes, FAS and ACC1; and SREBP-2 responsive genes, HMGR and LDLR. As shown in Fig. 2, there were significant decreases in SREBP-1, ACC1, FAS, SREBP-2, HMGR, and LDLR mRNA levels following 25HC3S treatment and increases in ABCA1, ABCG5, FAS, and ACC1 mRNA levels following 25HC addition to the cells in culture. Interestingly, both 25HC3S and 25HC decreased the levels of SREBP-2 mRNA and its responsive genes, HMGR and LDLR. Western blot densitometry analysis showed that 25HC increased nuclear SREBP-1, cytoplasmic FAS, and ACC1, while 25HC3S decreased nuclear SREBP-1, cytoplasmic FAS, and ACC1 protein levels, as shown in Fig. 3. Similar results were observed in HepG2 cells (data not shown). These results are consistent with the mRNA data in Fig. 2.

Effects of 25HC3S and 25HC on Intracellular and Total Cellular Lipid Levels in Primary Rat Hepatocytes and HepG2 Cells

To examine the intracellular lipid levels, total neutral lipids were examined by Oil Red-O staining. As shown in Fig. 2(A) in Supplemental Online Materials, 25HC3S significantly decreased the intracellular neutral lipid levels in HepG2 and primary rat hepatocytes. Biochemical quantitative analysis showed that addition of 6 μM 25HC3S decreased cellular total cholesterol (48 μg/mg protein) by 40%, free cholesterol (30 μg/mg protein) by 50%, triglyceride (150 μg/mg protein) by 25%, and free fatty acids (4.8 μg/mg protein) by 40%, compared to control cells as shown in Fig. 4. In contrast, 25HC increased free fatty acid levels, slightly decreased total cholesterol and triglycerides, and did not affect free cholesterol levels. These results are consistent with those from mRNA and protein analysis. 25HC3S decreases nuclear LXR and

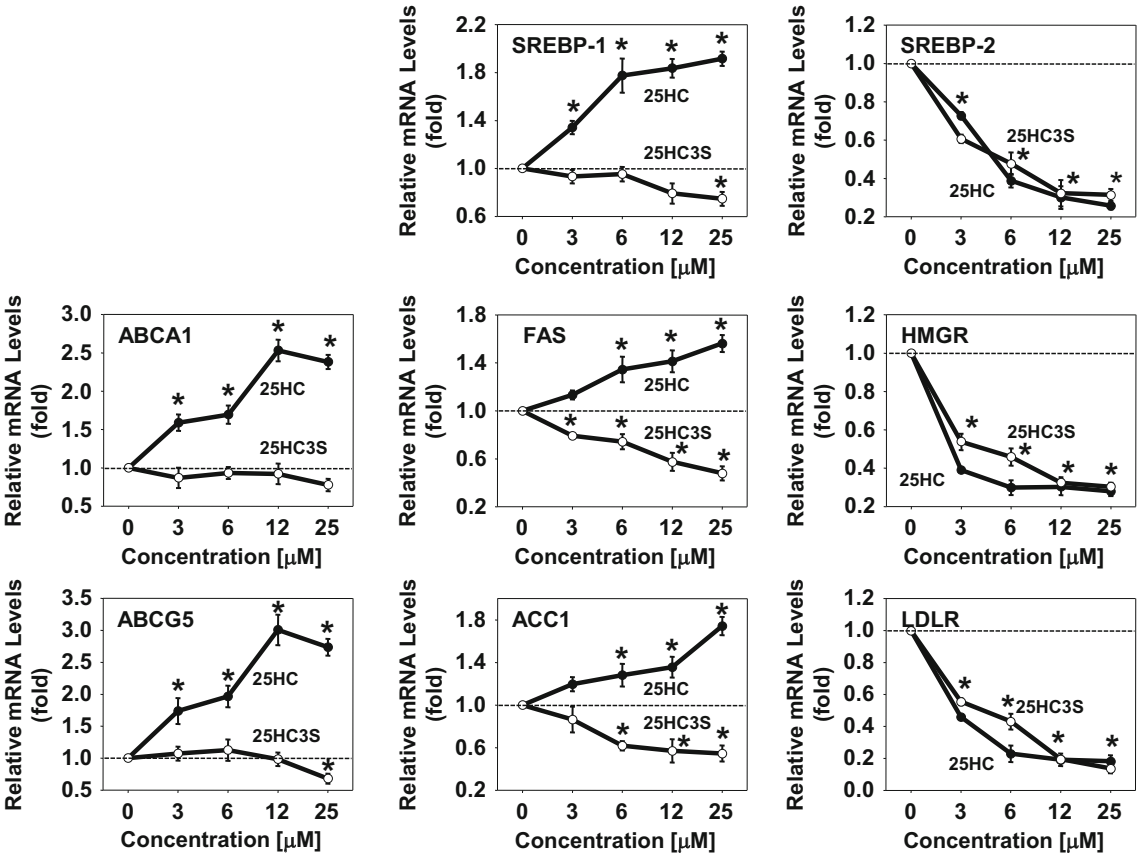

Fig. 2 Effects of 25HC3S and 25HC on the expression of LXR and SREBP target genes at mRNA levels. Following the treatment of PRH cells with 25HC3S or 25HC at the indicated concentrations for 6 h, effects of 25HC3S and 25HC on the expression of LXR target genes (*left*); SREBP-1 target genes (*middle*); SREBP-2 target genes (*right*) were determined by real-time RT-PCR analysis. Each value represents the mean of triplicate determinations ±SD. Symbol *asterisk* represents statistically significance ($P < 0.05$)

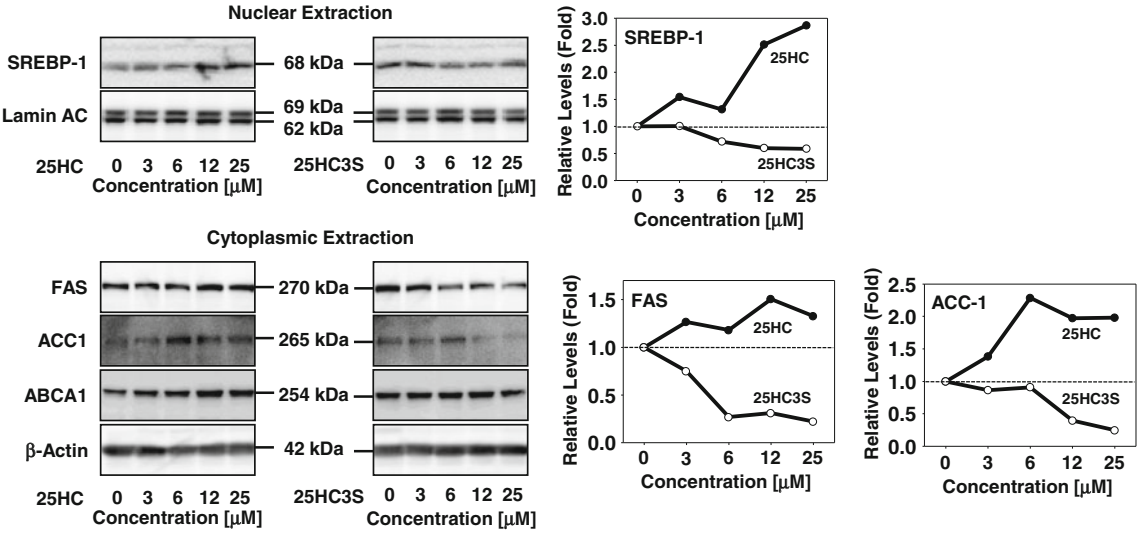

Fig. 3 Effects of 25HC3S and 25HC on the expression of SREBP-1, ABCA1, FAS and ACC1 at protein levels. Following the treatment of PRH cells with 25HC3S or 25HC at the indicated concentrations, nuclear SREBP-1 protein levels after 6 h treatment and cytoplasmic ABCA1, FAS and ACC1 protein levels after 24 h treatment, were determined by Western blot. Each positive band was quantified by the Image Data Analyzer and normalized to Lamin AC or β-actin. *Solid circles* represent 25HC treatments; *open circles* represent 25HC3S treatments

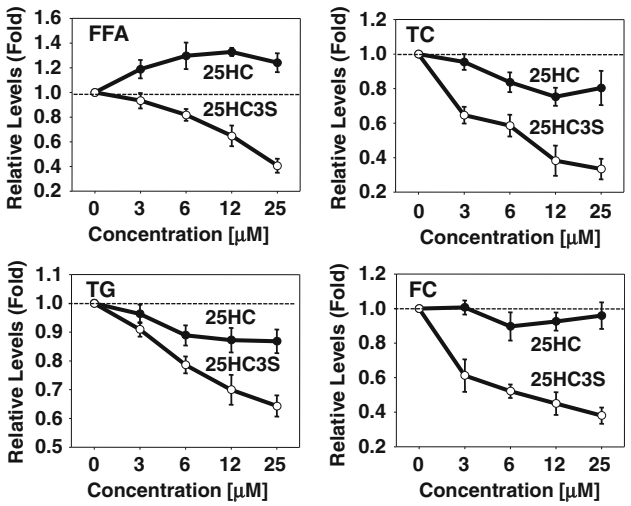

Fig. 4 Effects of 25HC3S and 25HC on total cellular lipid levels in HepG2 cells. HepG2 were treated with 25HC3S or 25HC at the indicated concentrations in the presence of 20% FBS for 48 h, total cellular lipids were extracted, and each individual lipid was chemically analyzed and normalized by protein amount as described in "Materials and Methods." Each value represents the mean of triplicate determination ±SD

subsequently inhibits expression of SREBP-1 and its target genes, while both 25HC3S and 25HC decrease SREBP-2 mRNA levels and its target gene expression (Figs. 2, 3).

Effects of 25HC3S and 25HC on Cell Proliferation in HepG2 Cells

MTT reagent assay was used to study the effect of 25HC and 25HC3S on the cell viability. As shown in Fig. 2(B) in Supplemental Online Materials, the percentages of relative cell number after treatment for 48 h were not affected by 25HC3S and slightly decreased by 25HC. The difference in cell viability between 25HC3S and control vehicle was not significant, as previously reported [11]. These results indicate that 25HC3S does not induce cell death and cytotoxicity.

Effects of 25HC3S and 25HC on Cytoplasmic IκBα and Nuclear NFκB Levels in Primary Rat Hepatocytes and HepG2 Cells

Both IκBα and NFκB play an important role in the inflammatory response pathway [22, 23]. To study the effects of

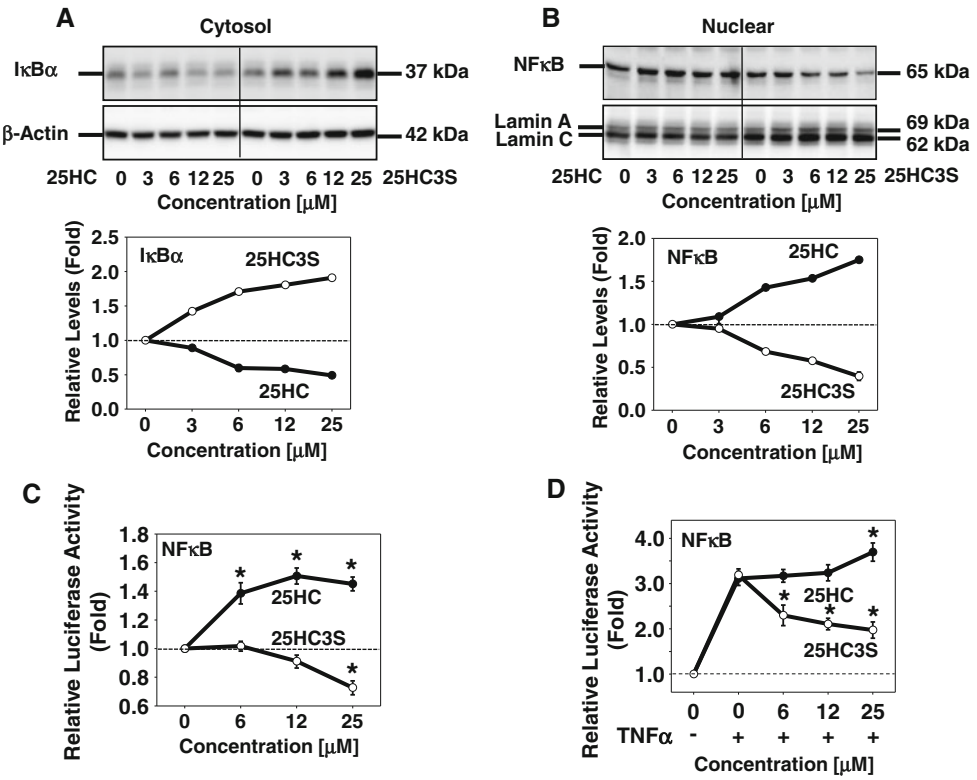

Fig. 5 Effects of 25HC3S and 25HC on expression of IκBα protein levels in cytoplasmic extracts and NFκB protein levels in nuclear extracts in HepG2 cells. Effects of 25HC3S and 25HC on IκBα protein levels (**a**) in cytoplasm and NFκB protein in nuclei (**b**) were analyzed by Western blot. Effects of 25HC3S and 25HC on NFκB promoter reporter gene activities were determined by luciferase activity assay and normalized by the amount of phRG-TK luciferase activity. HepG2 cells were cotransfected with pGL3-NFκB-dependent reporter gene-Luc and phRG-TK vector for 24 h, and treated with the indicated concentrations of 25HC3S or 25HC for another 24 h (**c**), or further stimulated with the 100 ng/ml of human TNFα for 6 h (**d**). The data represent the mean of triplicate determinations ±SD. Symbol *asterisk* represents statistically significance ($P < 0.05$) compared with TNFα treatment

25HC3S and 25HC on the inflammatory response, the cytoplasmic and nuclear proteins were extracted from the treated HepG2 cells (Fig. 5) and primary rat hepatocytes (Fig. 3 in Supplemental Online Material). The protein levels of IκBα in the cytoplasmic fractions and NFκB in the nuclear fractions were determined by Western blot analysis. Addition of 25HC decreased cytoplasmic IκBα and increased nuclear NFκB levels, while 25HC3S increased cytoplasmic IκBα and decreased nuclear NFκB levels in a concentration-dependent manner (Fig. 5a, b).

NFκB-dependent reporter gene assay showed that treatment with 25HC increased luciferase activity while 25HC3S decreased its activity in HepG2 cells (Fig. 5c). As a positive control, treatment with TNFα increased luciferase activity by threefold. Interestingly, pretreatment with 25HC3S inhibited TNFα-induced increase in NFκB reporter activity, while 25HC slightly increased the reporter activity (Fig. 5d). The results indicate 25HC3S not only blocks the NFκB nuclear translocation, but also decreases NFκB promoter-binding activity.

Addition of 25HC3S Represses Inflammatory Response

Addition of TNFα significantly decreased IκBα protein levels in the cytoplasm of HepG2 cells during 15–30-min incubation. The lκBα levels had rebounded by 60 min as shown in Fig. 6a. These results suggest that TNFα rapidly increases IκBα degradation, and the lower levels of IκBα feed back to stimulate its synthesis. The results are consistent with the previously published mechanism [24, 25]. Thus, the 15-min incubation with TNFα was chosen for the study of effects of 25HC3S and 25HC on the inflammatory response. Pretreatment with 25HC3S significantly blocked TNFα induced-decreases in IκBα levels in a concentration-dependent manner in cytoplasmic fractions, while 25HC further lowered IκBα levels as shown in Fig. 6b. Moreover, pretreatment with 25HC further increased TNFα-induced increases in nuclear NFκB levels. In contrast, 25HC3S decreased TNFα-induced nuclear NFκB levels in a concentration-dependent manner as shown in Fig. 6c.

Immunohistochemical study using DAPI nuclear staining together with the NFκB antibody showed that NFκB proteins were widely distributed in the cytoplasm and nuclei of HepG2 cells (Fig. 7). Compared with control cells treated with ethanol, treatment with 25HC increased the nuclear NFκB fluorescence intensity and decreased the intensity in the cytoplasm, which are similar with those treated with TNFα. However, treatment with 25HC3S decreased the nuclear intensity and blunted TNFα stimulation. The results indicate that 25HC3S decreases NFκB

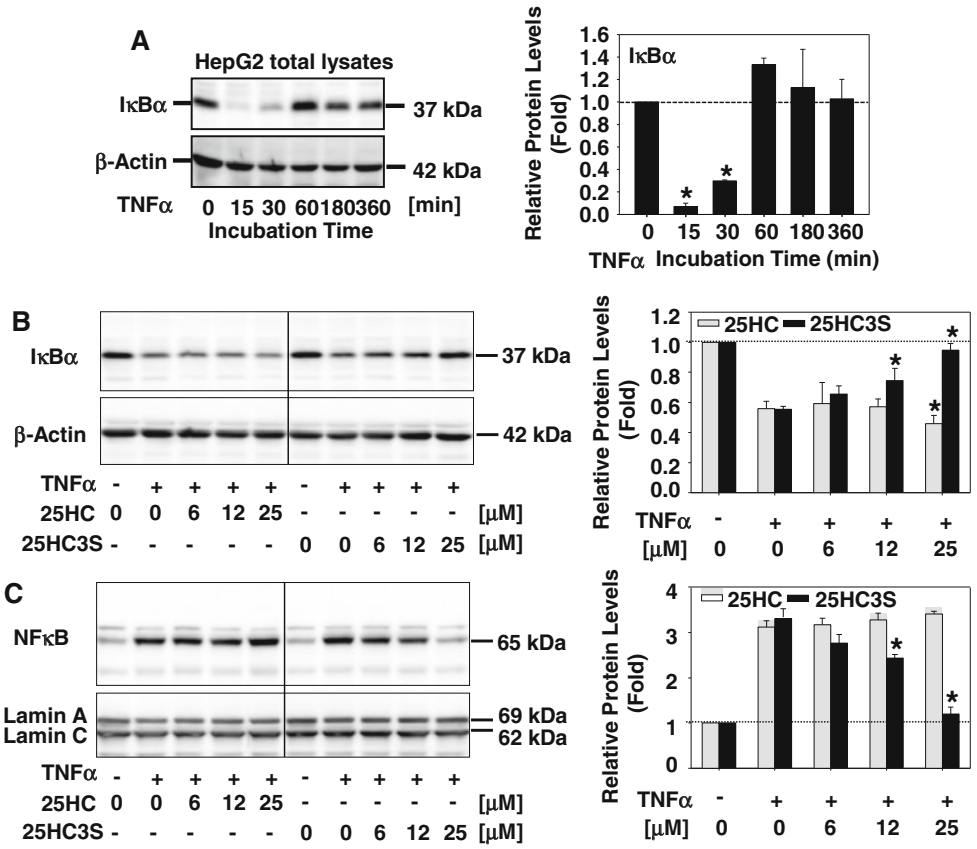

Fig. 6 Effects of 25HC3S and 25HC on IκBα protein levels and translocation of NFκB protein induced by TNFα in HepG2 cells. Cytoplasmic IκBα protein and nuclear NFκB were determined by Western blot after HepG2 cells were treated with 100 ng/ml of human TNFα for different times (**a**) or stimulated with TNFα for 15 min in the pre-treated cells with 25HC3S or 25HC at the indicated concentration for 8 h (**b**, **c**). The data represent the mean ± SD of three repeat experiments. Symbol *asterisk* represents statistical significance ($P < 0.05$)

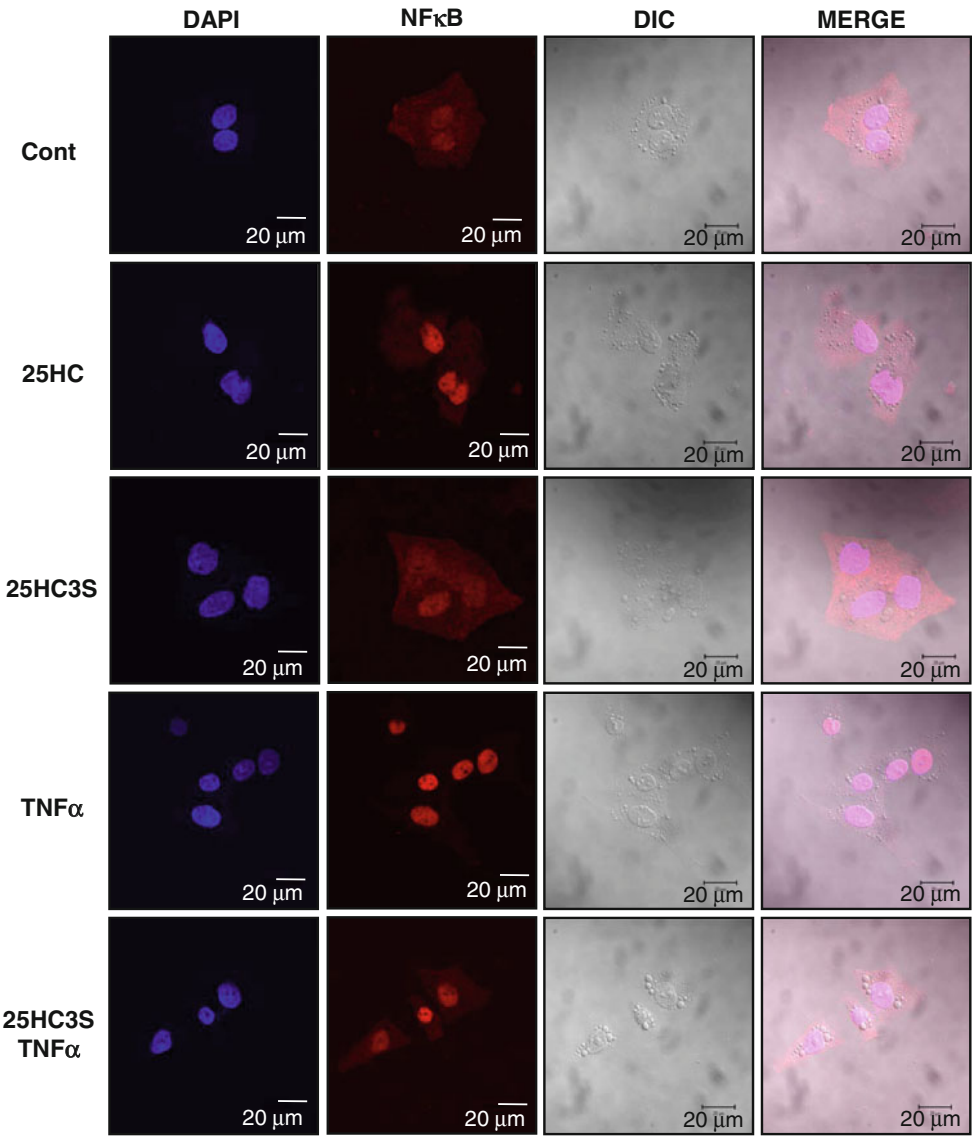

Fig. 7 Effects of 25HC3S and 25HC on NFκB translocation and 25HC3S on the TNFα-stimulated NFκB translocation into the nuclei in HepG2. Intracellular distribution of NFκB protein in HepG2 cells was analyzed by confocal microscopy. The left panel shows nuclear staining (*blue*); the middle left panel shows the localization of NFκB with the monoclonal antibody (*red*); the middle right panel shows a differential interference contrast (DIC) image; the right panel shows the merged image obtained by superimposing the three images mentioned above. The data represent randomly selected pictures as described in "Materials and Methods"

levels in the nuclei by increasing cytoplasmic IκBα levels and decreasing NFκB nuclear translocation.

TNFα increased expression of pro-cytokines including TNFα by 200 fold, IL-8 by 100 fold, NFκB by 4 fold, TRAF1 by 10 fold, IL-1b by 10 fold, and IκBα 9 fold, which are similar with those previously reported [22, 23]. Consistently, pretreatment of 25HC3S repressed the TNF-induced expression of NFκB, IL-8, TRAF1, and TNFα in HepG2 cells as shown in Fig. 8.

Discussion

We previously reported that 25HC and 25HC3S appear to function as agonist and antagonist of nuclear receptor LXR in macrophages [12]. 25HC sulfation links the regulation of cholesterol metabolism with fatty acid biosynthesis via LXR signaling pathway. LXRs present in two forms, LXRα and LXRβ. LXRα is restricted to the liver, adipose tissue, and macrophage, whereas LXRβ is ubiquitously expressed. Hepatic lipogenic activity of LXRs is predominantly under control of LXRα, although the oxysterols can activate both forms of LXRs [26–28]. Based on our results, we are assuming that most of the response LXR protein was LXRα since 25HC3S significantly decreased SREBP-1 and FAS. However, the results from Cayman Chemical LXRβ assay (Fig. 1c) indicate that 25HC3S decreases nuclear LXRβ protein levels, too. We concluded that 25HC3S represses both LXRα and LXRβ activities. When intracellular cholesterol levels increase, cholesterol can be delivered to mitochondria and metabolized to oxysterols, including 25-hydroxycholesterol (25HC) and 27-hydroxycholesterol (27HC) by CYP27A1 [9]. The oxysterols can in turn activate LXRs and subsequently regulate expression of

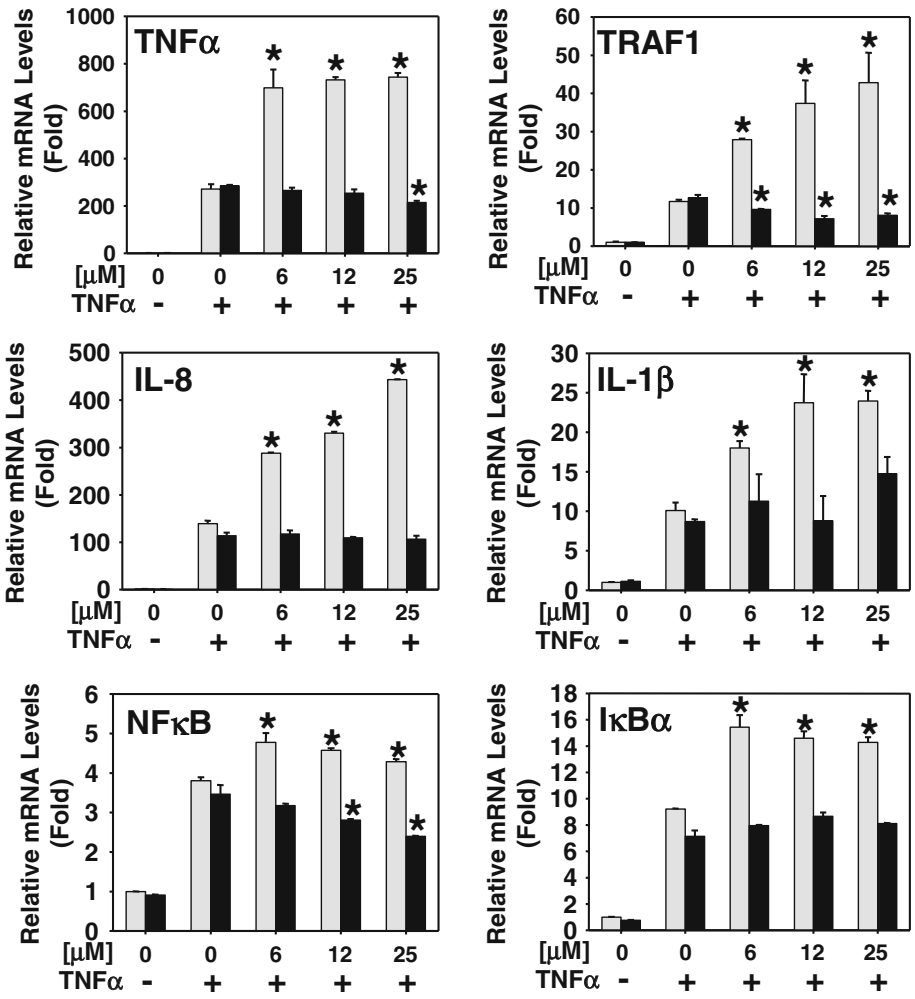

Fig. 8 Effects of 25HC3S and 25HC on NFκB target gene expression stimulated by human TNFα in HepG2. Following the stimulation of HepG2 cells with 100 ng/ml of human TNFα for 6 h in the pre-treatment with 25HC3S (*solid bar*) or 25HC (*open bar*) at the indicated concentration for 8 h, total mRNA was extracted, and NFκB target genes were determined by real-time RT-PCR analysis and were normalized to GAPDH. The graphs represent one of three experiments. Each value represents the mean of triplicate determination ±SD. *Asterisk* represents statistical significance ($P < 0.05$) compared with TNFα treatment

their targeting genes, which are involved in cholesterol metabolism, cholesterol efflux, and cholesterol uptake [2, 4, 29, 30]. On the other hand, we have shown that oxysterols such as 25HC also increase the gene expression involved in fatty acid biosynthesis, which may decrease cholesterol biosynthesis via using acetyl CoA as a common metabolic precursor. When the level of 25HC increases, 25HC can be further sulfated by SULT2B1b to 25HC3S [9]. The present results show that 25HC3S inhibits LXR activation, decreases SREBP-1 expression and activation, and subsequently downregulates lipid biosynthetic pathways. Thus, the present results provide the evidence that 25HC3S and 25HC are potent regulators that link cholesterol metabolism to fatty acid biosynthesis. 27-Hydroxycholesterol 3-sulfate (27HC3S) has never been detected in cells. Thus, whether 27-hydroxycholesterol can be sulfated is unknown.

The role of oxysterols in inflammatory response is controversial: some reports describe that oxysterols suppress the inflammatory response via the LXR signaling pathway [15–18]. Oxysterols can activate LXRs and subsequently repress a set of proinflammatory gene expressions after stimulation with LPS and cytokines [19, 31]. However, many other studies found that oxysterols induce inflammatory response and oxidation [19, 32, 33]. For example, 25HC substantially increased LPS-induced IL-1β mRNA expression and secretion in human monocyte-derived macrophages. 25HC is also a potent inducer of MCP-1, MIP-1β and IL-8 secretion in vitro [31, 34]. 25HC treatment gives rise to a significant increase in NFκB transcriptional activity, not only by affecting the IκB degradation and the translocation of p65/NFκB to the nucleus, but also by regulating the p65/NFκB transactivation [35]. 25HC also induces inflammation and oxidation through inducing slight mitochondrial dysfunctions and increasing reactive oxygen species (ROS) [35]. The present study shows that 25HC decreases cytoplasmic IκBα and increases nuclear NFκB levels following TNFα stimulation in hepatocytes. In contrast, 25HC3S increases the IκBα and decreases the nuclear NFκB levels. The results indicate that 25HC and 25HC3S diametrically regulate the inflammatory response.

Accumulation of fatty acids, free cholesterol, or oxysterols is able to induce inflammatory responses. It is possible that all of these compounds play their roles in pro-inflammatory responses respectively. We cannot rule out specific response by each of the elements at the presence. The important finding in the present study is that 25HC3S is able to suppress TNFα-induced inflammatory response, which is different from free cholesterol, fatty acids, or oxysterols. Oxysterols are reported to play an important role in both the lipid metabolism and inflammatory response [18, 36–38]. However, the mechanism of the cross-talk between lipid metabolism and inflammatory response has not been fully understood. The present results that 25HC (substrate) and 25HC3S (product) diametrically regulate activities of key enzymes, receptors, and transporters by interacting with two or more nuclear receptors implies the physiological role of 25-hydroxycholesterol sulfation. These results suggest that the oxysterol sulfation could be another novel systematic regulatory pathway involved in regulating lipid metabolism and inflammation.

It is noted that the concentrations we used for 25HC3S are relatively high. The levels of endogenous 25HC3S are very low. We barely detected the compound in human liver tissues, 0.1 μg/g of liver tissues, by the LC/MS/MS system [8]. This level can be substantially increased by overexpression of mitochondrial cholesterol delivery protein (StAR), indicating a physiological significance. We have tried to monitor 25HC3S levels following the addition of 25HC3S at the indicated concentrations in the macrophages but failed, indicating only a few of the molecules are able to enter the cells because of its hydrophilic properties. The effective concentration would be much lower than what we added in the experiments. 25HC3S was discovered in hepatocyte nuclei following increasing mitochondrial cholesterol delivery, indicating this compound is initially synthesized in mitochondria and translocated to nuclei. We believe that 25HC3S functions as an intracellular regulatory molecule via nuclear receptor(s) rather than through plasma membrane receptor(s).

γ-Tocotrienol Reduces Squalene Hydroperoxide-Induced Inflammatory Responses in HaCaT Keratinocytes

Received: 25 February 2010 / Accepted: 27 July 2010 / Published online: 17 August 2010

Abstract Squalene hydroperoxide (SQ-OOH), the primary peroxidation product of squalene (SQ), accumulates at the surface of sunlight-exposed human skin. There are however only a few studies on the pathogenic actions (i.e., inflammatory stimuli) of SQ-OOH. Here, we evaluated whether SQ-OOH induced inflammatory responses in immortalized human keratinocytes (HaCaT). We found that SQ-OOH caused an increase in the expression of inflammatory genes such as the interleukins as well as cyclooxygenase-2 (COX-2). In concordance with the upregulation of COX-2 mRNA, SQ-OOH enhanced reactive oxygen species generation, nuclear factor kappa B activation, COX-2 protein expression, and prostaglandin E2 production. Therefore, the pro-inflammatory effects of SQ-OOH may be mediated in part via COX-2. On the other hand, γ-tocotrienol (γ-T3, an unsaturated form of vitamin E) was found to ameliorate the SQ-OOH actions. These results suggest that SQ-OOH induces inflammatory responses in HaCaT, implying that SQ-OOH plays an important role in inflammatory skin disorders. As a preventive strategy, inflammation could be reduced via the use of γ-T3.

Introduction

By virtue of covering the entirety of the body, human skin is the largest of the human organs. The skin surface contains secretions from the sebaceous gland, which consist mainly of squalene (SQ; Fig. 1), triacylglycerol, wax esters, and sterols [1]. When skin is exposed to sunlight including ultraviolet (UV) light [2, 3], peroxidation of the skin surface lipids can occur.

Previously, we have established methods for the sensitive and selective determination of lipid hydroperoxides [4–8], and have discovered that SQ hydroperoxide (SQ-OOH;

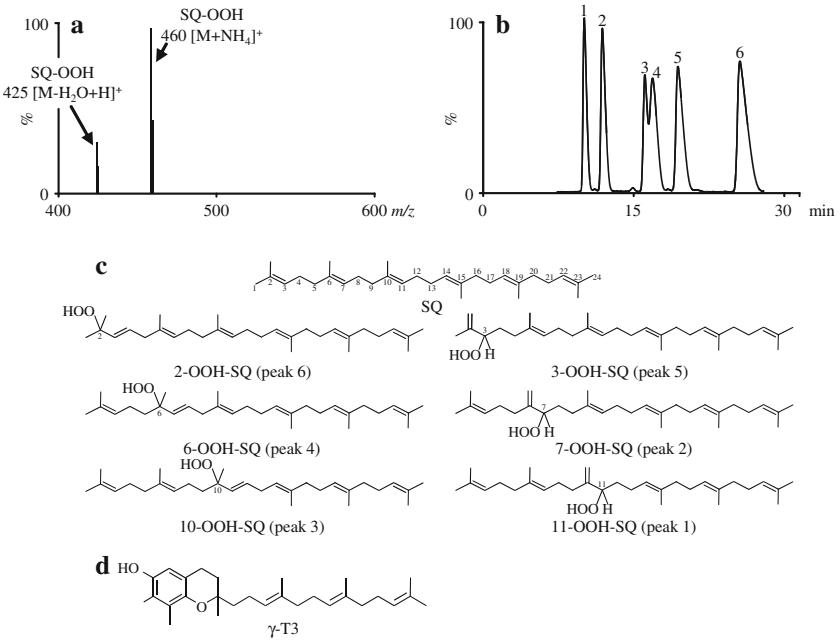

Fig. 1 SQ-OOH and γ-T3. For preparation of SQ-OOH, SQ (100 mg) was dissolved in 50 mL of ethanol (containing 0.01 mg/mL Rose Bengal as a sensitizer), and was photooxidized with a 100 W tungsten lamp at 4 °C for 6 h. From the photooxidation products, SQ-OOH was chromatographically purified. To evaluate purity, the isolated SQ-OOH was subjected to high-performance liquid chromatography coupled to UV, mass spectrometry, or tandem mass spectrometry, and NMR. Analytical conditions were the same as those described in our previous study [14]. From the data [e.g., MS spectrum (**a**) and UV chromatogram (**b**)], the SQ-OOH was considered to be a pure mixture of six isomers (2-OOH-SQ, 3-OOH-SQ, 6-OOH-SQ, 7-OOH-SQ, 10-OOH-SQ, and 11-OOH-SQ) (**c**). Percentages of the SQ-OOH isomers were 19 mol% 2-OOH-SQ, 17 mol% 3-OOH-SQ, 24 mol% 6-OOH-SQ, 10 mol% 7-OOH-SQ, 13 mol% 10-OOH-SQ, and 17 mol% 11-OOH-SQ. The chemical structure of γ-T3 is shown in (**d**)

Fig. 1) is produced in human skin [9, 10], which suggests that skin SQ may be the principal lipid photooxidation target. In support of this supposition, there have been an increasing number of studies concerning skin SQ-OOH production due to sunlight or UV exposure [11–13]. For instance, we recently reported that the concentration of SQ-OOH in normal forehead skin was about 1,000 μg/g skin lipids, which increased to 2,800 μg/g skin lipids after 3 h of sunlight exposure [14].

As increasing evidence of skin SQ-OOH has emerged, it has become implicated in the pathogenesis of skin alterations (e.g., sunburn and acne) [15–20]. A recent cell culture study using keratinocytes [21] suggested possible mechanisms for the pathogenic actions of SQ-OOH, which include the activation of nuclear factor kappa B (NF-κB) and the production of inflammatory interleukin (IL)-6. The study [21] provided some understanding of the role of SQ-OOH in the development of inflammatory skin diseases, although it had some weaknesses due to the lack of data concerning other inflammatory mediators [e.g., cxyclooxygenase-2 (COX-2)] as well as the uncertainty of the crude SQ-OOH used as the test compound. Other possible oxidation products in the crude SQ-OOH could have been responsible for intervention effects during the physiological evaluation of SQ-OOH. Therefore, the inflammatory action of SQ-OOH needs to be further clarified by the use of authentic, pure SQ-OOH.

On the other hand, as a preventive strategy against skin inflammation, compounds that can ameliorate the actions of SQ-OOH might be of therapeutic utility [22]. In the present study, we hypothesized that tocotrienol (T3, unsaturated vitamin E) could be a candidate to inhibit these inflammatory actions because T3 accumulates in the skin of animals fed a diet containing T3 [23, 24], and, besides its physiological activities [25], T3 has been suggested to provide skin protection against UV-induced inflammatory damage in a rat study [26].

In this study, we prepared pure SQ-OOH and evaluated the effect of SQ-OOH, either alone or with γ-T3 (a representative T3 isomer found in natural sources such as rice bran [27]; Fig. 1d), on various inflammatory mediators in a cell culture of human keratinocytes (HaCaT) [28].

Materials and Methods

Materials

SQ-OOH was prepared from SQ by our previously described method [14]. The SQ-OOH had high purity

(>98% by high-performance liquid chromatography to mass spectrometry), but was a mixture of six isomers differing in the position of the hydroperoxide group (Fig. 1). γ-T3 (purity > 92%) was purchased from Chromadex (Santa Ana, CA, USA). WST-1 reagent was obtained from Dojindo Laboratories (Kumamoto, Japan). All other reagents were of the highest grade commercially available.

Cells and Cultures

HaCaT were supplied by Prof. Norimichi Nakahata (Graduate School of Pharmaceutical Sciences, Tohoku University, Japan). The cells were cultured in Dulbecco's modified Eagle medium (DMEM) (Sigma, St. Louis, MO, USA), supplemented with 10% fetal bovine serum (FBS) (Dainippon Pharmaceutical, Osaka, Japan), 100 U/mL penicillin, and 100 μg/mL of streptomycin (GIBCO, Milan, Italy) at 37 °C in a humidified atmosphere of 95% air and 5% CO_2.

Preparation of the Experimental Media

SQ-OOH (or γ-T3) was dissolved in ethanol at a concentration of 50 μM. The solution was diluted with DMEM to prepare the experimental medium. The experimental medium contained 0.1% FBS and 0.5–5.0 μM SQ-OOH, either alone or together with 0.1–1.0 μM γ-T3. The concentration of ethanol in the experimental medium was up to 0.1%, which did not affect cell viability. Similarly, media containing only vehicle (0.1% ethanol) or SQ (0.5–5.0 μM) were prepared.

RNA Extraction

HaCaT (1×10^6 cells/60-mm dish) were preincubated in 0.1% FBS/DMEM for 24 h, and then the medium was changed to the experimental medium. After incubation for 3 h, total RNA was isolated with an RNeasy plus Mini kit (Qiagen, Valencia, CA, USA) for the real-time quantitative reverse transcriptase-PCR (RT-PCR) assay. The amount of total RNA was spectrophotometrically determined at 260 and 280 nm. RNA integrity was confirmed by visualizing intact 28S and 18S ribosomal RNA on formaldehyde denaturing agarose gel.

Real-Time RT-PCR Assay

For the real-time RT-PCR assay using a DNA Engine Opticon 2 System (MJ Research, Waltham, MA, USA), cDNA was synthesized from the total RNA using a Ready-To-Go T-Primed First-Strand Kit (Amersham Pharmacia Biotech, NJ, USA). The cDNA was subjected to PCR amplification using a SYBR Premix Ex Taq (Takara Bio, Shiga, Japan) and gene specific primers for IL-1β, IL-6, IL-8, tumor necrosis factor-α (TNF-α), COX-2, and β-actin. Sequences of the PCR primers for each gene are outlined in Table 1. Melt curve analysis was performed following each PCR reaction to confirm the presence of a single reaction product. In addition, representative PCR products were subjected to electrophoresis on a 2.0% agarose gel to verify that a single band was present. The ratio between the mRNA content of β-actin and each gene was defined as the normalization factor.

Cell Viability

Cell viability was evaluated by WST-1 assay [29]. WST-1 is a tetrazolium salt that is converted into a soluble formazan salt by succinate-tetrazolium reductase in the respiratory chain of active mitochondria in proliferating, viable cells. The amount of formazan produced is directly proportional to the number of viable cells. HaCaT (1×10^4 cells/well) were preincubated in 0.1% FBS/DMEM in 96-well plates for 24 h, and then the medium was changed to

Table 1 Primer sequences for cDNA amplification of selected genes

Gene	GenBank accession number	Sequence
IL-1β	NM_000576	Forward 5′-CCAGGGACAGGATATGGAGCA-3′
		Reverse 5′-TTCAACACGCAGGACAGGTACAG-3′

the experimental medium. After incubation for 3 and 24 h, 10 μL of WST-1 solution was added to each well and was incubated at 37 °C for 3 h. Cell viability was estimated by measuring the absorbance (450/655 nm) of the medium using a microplate reader (Model 550, Bio-Rad, Tokyo, Japan).

Evaluation of Reactive Oxygen Species

The generation of intracellular reactive oxygen species (ROS) was evaluated using the fluorescent dye 2, 7-dichlorodihydrofluorescein (DCDHF) diacetate (Cayman Chemicals, Ann Arbor, MI, USA) [30]. ROS in cells cause oxidation of DCDHF diacetate, yielding the fluorescent product 2,7-dichlorofluorescein. HaCaT (1×10^4 cells) were preincubated in 0.1% FBS/DMEM in 96-well plates for 24 h, and then the medium was changed to the experimental medium. After incubation for 3 h, the medium was changed to fresh DMEM containing 10 μM DCDHF diacetate, followed by incubation for 30 min. The cells were washed with HBSS, and fluorescence intensity was determined using a GENios Plus Multi-Detection Microplate Reader with enhanced fluorescence (Tecan Inc., Research Triangle Park, NC, Switzerland) at an excitation wavelength of 485 nm and an emission wavelength of 535 nm.

Electrophoretic Mobility Shift Assays

HaCaT (1×10^6 cells/60 mm dish) were preincubated in 0.1% FBS/DMEM for 24 h, and then the medium was replaced with the experimental medium. After 2 h incubation, the nuclear fraction of HaCaT cells was extracted and then applied to an electrophoretic mobility shift assay as described previously [31]. Briefly, the nuclear fraction was incubated with ^{32}P-end-labeled NF-κB oligonucleotides. The DNA-protein complex was separated from the unbound DNA probe in native 6% polyacrylamide gel at 150 V in 0.5% Tris–Boric acid EDTA (TBE) buffer. After electrophoresis, the gels were dried and visualized by autoradiography.

Western Blot Analysis

HaCaT (2×10^6 cells) were preincubated in 0.1% FBS/DMEM for 24 h, and then the medium was changed to the experimental medium. After incubation for 24 h, cellular proteins were prepared from the cells as previously described [32]. The cellular proteins (60 μg/well) were separated by sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE, 4–20% e-PAGEL, Atto, Tokyo, Japan). The protein bands were then transferred to polyvinylidine fluoride membranes (Amersham Pharmacia Biotech). After blocking nonspecific sites, the membrane was probed with primary antibodies, followed by a horseradish peroxidase-conjugated secondary antibody (Cell signaling Technology, Beverly, MA, USA). The detection of antibody reactions was performed with ECL Plus Western blotting reagents (Amersham Pharmacia Biotech). The antibodies used were anti-COX-2 (IBL, Takasaki, Japan), anti-inducible nitric oxide synthase (iNOS, BD Transduction Laboratories, San Diego, CA, USA), and anti-β-actin (Cell signaling Technology). Band intensities were evaluated by densitometry.

Enzyme-Linked Immunosorbent Assay

HaCaT (1×10^4 cells) were preincubated in 0.1% FBS/DMEM for 24 h, and then the medium was changed to the experimental medium. After incubation for 24 h, the conditioned medium was used to measure the levels of prostaglandin E2 (PGE2) using a commercial enzyme-linked immunosorbent assay (ELISA) kit (R&D Systems, Minneapolis, MN, USA), according to the manufacturer's instructions. The results were normalized to the number of cells per well.

Statistical Analysis

The data are expressed as means ± standard deviation (SD). We performed statistical analysis using ANOVA, followed by the Bonferroni/Dunn test for multiple comparisons among several groups. Differences were considered significant at $P < 0.05$.

Results

SQ-OOH Induces Expression of Inflammatory Mediator Genes in HaCaT Keratinocytes

Using the synthetic, purified SQ-OOH (Fig. 1), we observed upregulation of inflammatory mediator genes (IL-1β, IL-6, IL-8, TNF-α, and COX-2) in HaCaT treated with 5.0 μM SQ-OOH as compared to the gene levels of vehicle control or SQ treatment (Fig. 2). In the dose range employed (0.5–5.0 μM SQ-OOH; a range expected to encompass the physiological concentration encountered in human skin [14]), SQ-OOH did not affect cell viability (Fig. 3). Thus, it is conceivable that SQ-OOH at certain concentrations can lead to changes in the expression of HaCaT inflammatory genes (especially, IL-8 and COX-2) without affecting cell viability. Since the upregulation of COX-2 by SQ-OOH had not been previously reported, this was further evaluated in the following study.

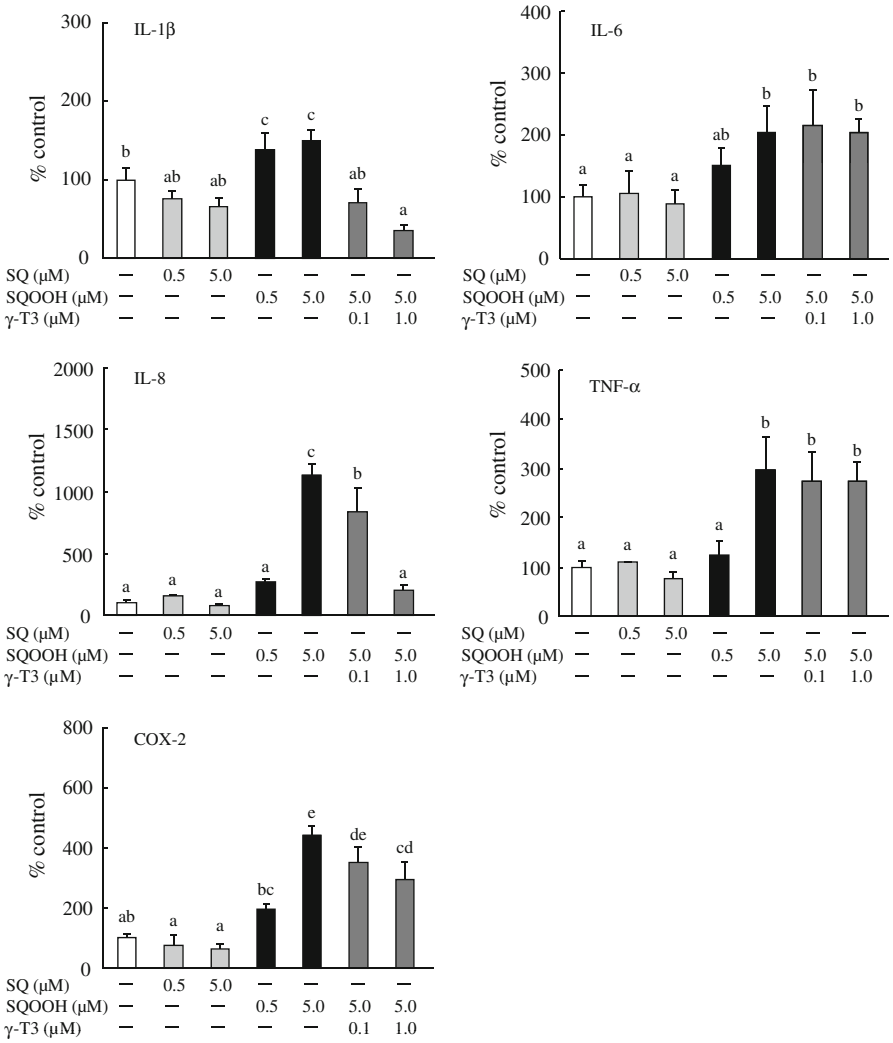

Fig. 2 Effect of SQ-OOH, either alone or with γ-T3, on IL-1β, IL-6, IL-8, TNF-α, and COX-2 mRNA expression in HaCaT cells. Experimental procedures are described in "Materials and methods". Data are expressed as percentages of vehicle (0.1% ethanol) control. Values are means ± SD ($n = 5$–6). Values with different superscripts are significantly different ($P < 0.05$)

COX-2 is Involved in the Inflammatory Effect of SQ-OOH in HaCaT Keratinocytes

In accordance with the upregulation of COX-2 mRNA (Fig. 2), 5.0 μM SQ-OOH enhanced ROS generation, NF-κB activation, COX-2 protein expression, and PGE2 production (Fig. 4). In addition to COX-2, an NF-κB-regulated protein (iNOS) was evaluated, but SQ-OOH had no effect on iNOS (Fig. 4). These results suggest that the pro-inflammatory effect of SQ-OOH is due in part to COX-2 expression through ROS generation and NF-κB activation.

γ-T3 Attenuates Inflammatory Effects of SQ-OOH in HaCaT Keratinocytes

γ-T3 (1.0 μM) attenuated SQ-OOH (5.0 μM) induced ROS generation, NF-κB activation, COX-2 mRNA expression,

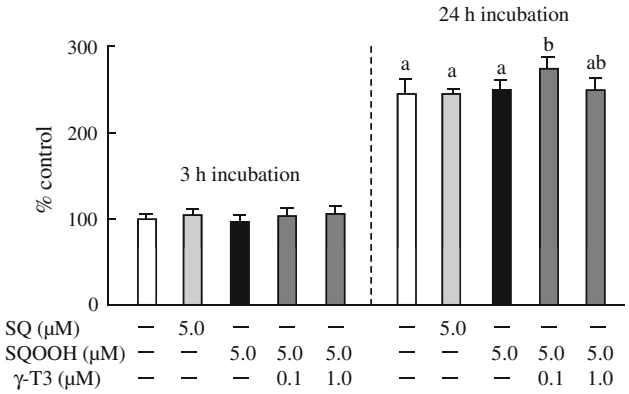

Fig. 3 Effect of SQ-OOH, either alone or with γ-T3, on HaCaT viability. Experimental procedures are described in "Materials and methods". Data are expressed as the percentage of vehicle (0.1% ethanol) control (3 h; 100%). Values are means ± SD ($n = 6$). Values with different superscripts are significantly different ($P < 0.05$)

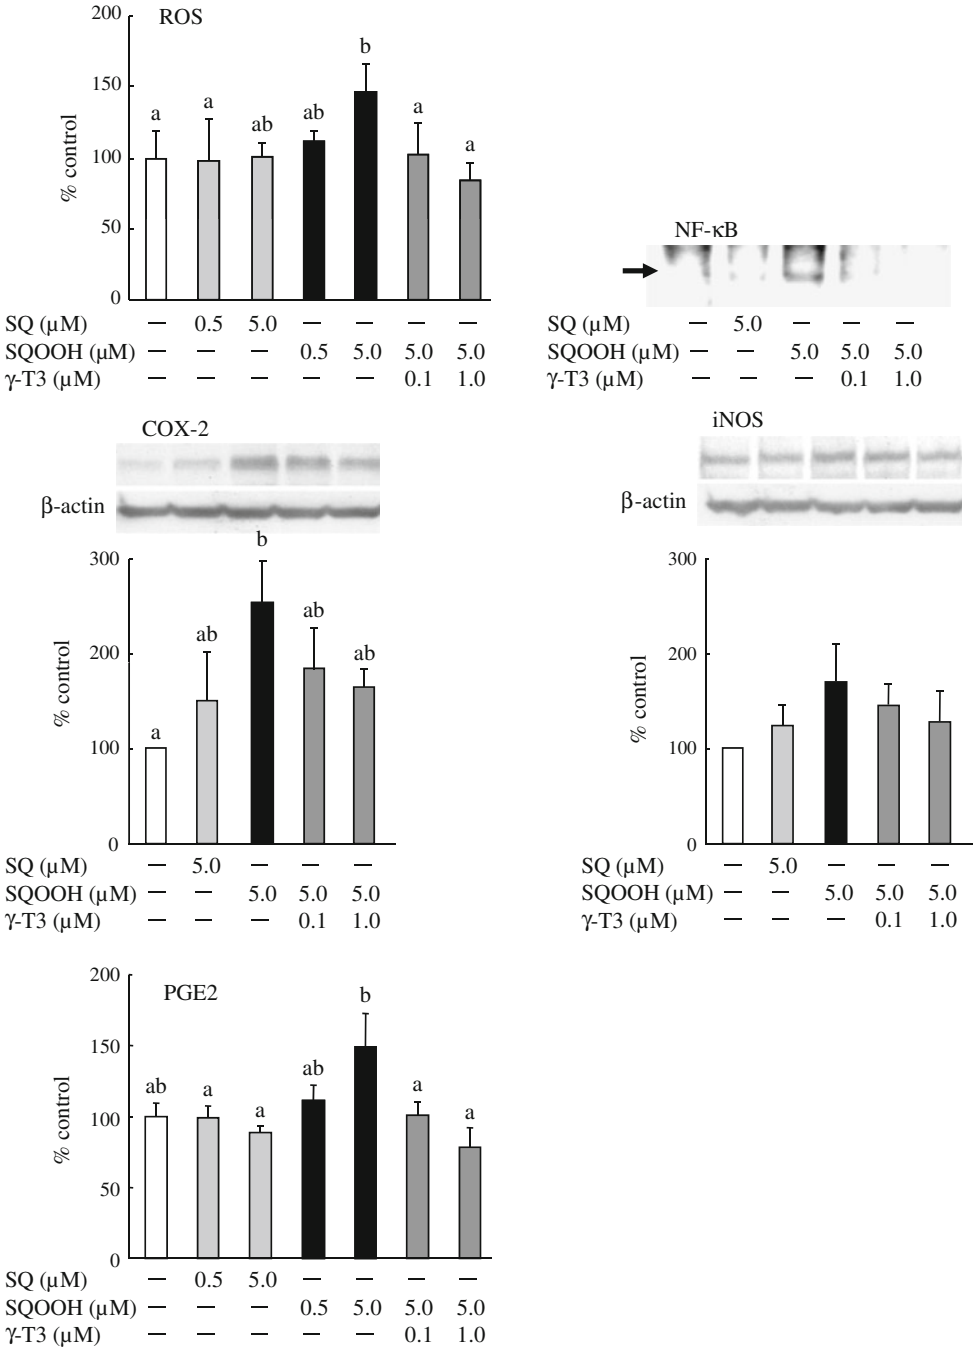

Fig. 4 Effect of SQ-OOH, either alone or with γ-T3, on ROS generation, NF-κB activation, COX-2 and iNOS protein expressions, and PGE2 production in HaCaT cells. Experimental procedures are described in "Materials and methods". Data are expressed as percentage of vehicle (0.1% ethanol) control. Values are means ± SD ($n = 5$–6 for ROS generation, $n = 3$ for NF-κB activation, $n = 3$ for COX-2 and iNOS protein expressions, and $n = 3$–4 for PGE2 secretion). Values with different superscripts are significantly different ($P < 0.05$). Representative examples of data from three replicate experiments are shown for the mobility shift assay and western blot analysis

and PGE2 production nearly to basal levels (Figs. 2, 4). Also, SQ-OOH induced COX-2 protein expression was moderately decreased ($P = 0.09$) by γ-T3 (1.0 μM) treatment. No meaningful differences in cell viability were found between cells treated with SQ-OOH alone or in combination with γ-T3 (Fig. 3). These results suggest a possible anti-inflammatory effect for γ-T3 by its ability to reduce SQ-OOH-induced ROS and inflammatory mediators (i.e., COX-2).

Discussion

Squalene, a component of human sebum normally absent in other primates [33], comprises 11–13% of the total skin surface lipids in human adults, and its highest concentrations are found in the chest and forehead [34, 35]. Because of the high distribution of SQ in skin and its tendency to undergo photooxidation [9–14], there has been interest in possible pathogenic actions of skin SQ-OOH.

In previous studies (mainly in vitro) evaluating potential pathogenic roles for SQ-OOH, researchers prepared SQ-OOH by subjecting SQ to UV exposure or photooxidation [17–21]. Such SQ-OOH preparations often cause excessive SQ peroxidation, yielding unwanted dihydroperoxide, trihydroperoxide, epoxide, ketone, and/or aldehyde products [18]. In many of these cases, the crude (or partly purified) SQ-OOH was subsequently used as a test mixture to evaluate pathogenic actions (e.g., inflammatory effect [21]). Thus, it would be difficult to definitively attribute any observed effects to specifically SQ-OOH. In the present study, SQ was subjected to photooxidation, and the SQ-OOH was chromatographically purified (Fig. 1). The purified SQ-OOH was a mixture of six isomers and did not contain other oxidation products. Since the purified SQ-OOH free from other oxidation products could induce inflammatory responses in HaCaT, SQ-OOH, and not other oxidation products, was deemed to play a principal role in inflammatory skin diseases.

Ottaviani et al. [21] were the first to report IL-6 production in HaCaT treated with SQ-OOH. However, an effect of SQ-OOH on other inflammatory mediators such as COX-2 remained unclear. We therefore aimed to evaluate the effect of SQ-OOH on various inflammatory mediators (IL-1β, IL-6, IL-8, TNF-α, and COX-2). We found that SQ-OOH caused significantly changes in the expression of these inflammatory genes in HaCaT (Fig. 2). Because SQ-OOH appeared to significantly impact the expression of IL-8 and COX-2 (Fig. 2), these two genes may play an important role in keratinocyte inflammation. On the other hand, some studies have shown a toxic effect of SQ-OOH [20, 22], while one study reported a proliferative effect [21]. In this study, no inverse effect of SQ-OOH was observed on cell viability (Fig. 3), which might be a reflection of the relatively low dose of SQ-OOH used (0.5–5.0 μM).

To our knowledge, this is the first report that shows an upregulation of COX-2 mRNA by SQ-OOH. COX-2 is one of the most critical enzymes related to inflammation and is required for the biosynthesis of PGE2 from arachidonic acid [36]. PGE2 induces cutaneous inflammation and modulates cellular immunity, which causes skin diseases such as atopic dermatitis [37]. ROS induce COX-2 expression via activation of the NF-κB signaling pathway [38, 39]. For these reasons, we investigated ROS, NF-κB, COX-2, and PGE2, and found that SQ-OOH induces ROS generation, NF-κB activation, COX-2 protein expression, and PGE2 production (Fig. 4). It is therefore likely that SQ-OOH generates ROS or affects the gene expression concerning ROS production. ROS cause activation of NF-κB, and activated NF-κB induces COX-2 expression, which result in the initiation of inflammatory responses (e.g., PGE2 production) in HaCaT. In summary, the pro-inflammatory effects of SQ-OOH may be due in part to COX-2 expression through ROS generation and NF-κB activation. On the other hand, unlike SQ-OOH, its reduced compound (SQ-OH) as well as other hydroperoxides (e.g., phospholipid hydroperoxides and hydrogen peroxide) (each 5 μM) had little or no effect on COX-2 mRNA expression (data not shown). This data implies that SQ-OOH plays an important role in inflammatory skin conditions.

Our findings (Figs. 2, 4) also suggest SQ-OOH is a potential therapeutic target for inflammatory skin diseases. Because T3 is capable of accumulating in skin and combating oxidative stress from UV or ozone in skin [23, 24, 40], we picked T3 from the array of available anti-oxidant compounds and investigated its possible ameliorative effect on SQ-OOH. T3 has recently received considerable attention for its biological properties [41–44], and we have previously found that T3 suppresses pathological angiogenesis [32, 45], an important stage in the progression of some disorders (i.e., diabetic retinopathy, rheumatoid arthritis, and cancers). In this study, we found that γ-T3 could attenuate SQ-OOH induced ROS generation, NF-κB activation, COX-2 mRNA and protein expressions, and PGE2 production (Figs. 2, 4). These results suggest a possible anti-inflammatory effect for γ-T3 that functions by reducing SQ-OOH-induced ROS and inflammatory mediators (i.e., COX-2). In support of this supposition, a previous study reported the ability of T3 to reduce COX-2 expression [46].

In conclusion, we have shown that SQ-OOH can induce inflammatory responses in HaCaT, which would in part be mediated via COX-2. On the other hand, other studies have mentioned that UV irradiation at the cutaneous surface can be trapped by SQ in the form of peroxidation products [15], and the cutis is not directly damaged by UV irradiation, which suggest that peroxidation of SQ has a functional, protective role against UV irradiation on the cutaneous surface. However, in this study, SQ-OOH acted as an inflammatory stimulus, implying that excessive SQ peroxidation causes inflammatory effects. SQ-OOH could therefore be considered a potential therapeutic target for skin inflammatory disorders. From this perspective, γ-T3 has potential use as a protective agent against skin diseases.

Acknowledgments We thank Prof. Norimichi Nakahata (Graduate School of Pharmaceutical Sciences, Tohoku University, Japan) for the donation of HaCaT, and Dr. Tadashi Uchino (National Institute of Health Sciences, Tokyo, Japan) for excellent technical advice. A part of this study was supported by KAKENHI (20228002 and 22780110) of JSPS, Japan. Financial support was also provided by the Foundation of Oil and Fat Industry Kaikan, Japan.

Abstract People with inflammatory bowel disease (IBD) are at risk for developing colorectal cancer, and this risk increases at a rate of 1% per year after 8–10 years of having the disease. Saturated and ω-6 polyunsaturated fatty acids (PUFAs) have been implicated in its causation. Conversely, ω-3 PUFAs may have the potential to confer therapeutic benefit. Since proton magnetic resonance spectroscopy (^{1}H MRS) combined with pattern recognition methods could be a valuable adjunct to histology, the objective of this study was to analyze the potential of ^{1}H MRS in assessing the effect of dietary fatty acids on colonic inflammation. Forty male Sprague-Dawley rats were administered one of the following dietary regimens for 2 weeks: low-fat corn oil (ω-6), high-fat corn oil (ω-6), high-fat flaxseed oil (ω-3) or high-fat beef tallow (saturated fatty acids). Half of the animals were fed 2% carrageenan to induce colonic inflammation similar to IBD. ^{1}H MRS and histology were performed on ex vivo colonic samples, and the ^{1}H MR spectra were analyzed using a statistical classification strategy (SCS). The histological and/or MRS studies revealed that different dietary fatty acids modulate colonic inflammation differently, with high-fat corn oil being the most inflammatory and high-fat flaxseed oil the least inflammatory. ^{1}H MRS is capable of identifying the biochemical changes in the colonic tissue as a result of inflammation, and when combined with SCS, this technique accurately differentiated the inflamed colonic mucosa based on the severity of the inflammation. This indicates that MRS could serve as a valuable adjunct to histology in accurately assessing colonic inflammation. Our data also suggest that both the type and the amount of fatty acids in the diet are critical in modulating IBD.

Introduction

Inflammatory bowel disease (IBD) is a very common condition in industrialized countries, including North America. It is estimated that about 1.4 million people in the US and 2.2 million people in Europe suffer from IBD [1]. The exact cause and pathogenesis of IBD are not known; however, the interplay of genetic, environmental and immune factors is considered to be involved in its causation. Many epidemiological and experimental studies have pointed out that there is a strong connection between diet and IBD. A diet that is particularly rich in ω-6 fatty acids and saturated fats is one of the major environmental factors implicated in the etiology of IBD [2]. Conversely, ω-3 polyunsaturated fatty acids (PUFAs) have been considered to be partially agonistic compared to ω-6 PUFAs and may confer therapeutic benefit in IBD [3, 4]. IBD is not a point event; it is a continuum of a disease process with remitting and relapsing course. People with long-standing IBD have a significant risk of developing colorectal cancer, and this risk increases at the rate of 1% per year after 8–10 years of the disease [5]. As such, early diagnosis and intervention can help prevent the progression of IBD to colon cancer. Currently, the data from experimental or randomized trials on the benefits of pharmacologic or dietary intervention on this window between IBD and colon cancer are very limited.

Presently, colonoscopy with biopsy of grossly inflamed and random parts of the colon is the gold standard for diagnosing IBD. However, it is known that in the diseased state, biochemical and physiological changes precede the histological manifestations of the disease, and as such, the technique exploiting metabolic abnormalities may be suitable to aid in early diagnosis. One such technique that can provide extensive biochemical information from tissue samples is proton magnetic resonance spectroscopy (^{1}H MRS) [6, 7]. MRS makes use of magnetic properties of atomic nuclei and provides information about the molecular structures of biochemicals/biomolecules. It is non-destructive, quantitative and highly reproducible. It has been utilized in lipid analysis of intact tissues and their aqueous/organic extracts as well as dietary fats due to its unique advantage in differentiating various lipid classes without the need for any chemical modification [8–11]. It has been used as an alternative to conventional techniques such as gas chromatography (GC) and/or high-performance liquid chromatography (HPLC) for the analysis of lipids from various biological specimens and dietary fats [8, 11]. It has been shown that the accuracy of MRS-based lipid analysis is comparable to that of GC and/or HPLC [9]. Although recent developments in MRS technology, such as high-resolution magic angle spinning (HR MAS), have greatly simplified the spectral data obtained from tissues/biopsied samples, the spectra are still very complex and require specialized methods for thorough data analysis [12]. The pattern recognition methods have proven to be valuable in the classification of biomedical data. These methods are being used in discriminating data obtained from humans and laboratory animals in pathologic and healthy states and have shown diagnostic value [13, 14]. In this study, we are using a statistical classification strategy (SCS)—a pattern recognition methodology developed in-house—for the data analysis. SCS methodology has been used for the classification of MRS data in biomedical applications [15, 16]. The study is based on the hypothesis that various dietary fatty acids modulate colonic inflammation differently and that ^{1}H MRS combined with SCS methodology has the potential to detect changes in the colonic metabolite profile induced by these dietary fatty acids.

Materials and Methods

Forty 3–4-week-old male Sprague-Dawley rats (Charles River, Canada) were used for this study. The rats were kept on a basic laboratory chow for 2 weeks before starting the study. For the 2-week duration of the study, the animals were divided into two major groups with 20 animals in each group. The animals in both groups were further divided into four subgroups (five animals in each subgroup) depending upon the composition of fatty acids in their diet. Low-fat corn oil (LFC) subgroup animals received an AIN 76A diet containing 5% corn oil; the high-fat corn oil (HFC) subgroup received 23% corn oil; the high-fat flaxseed oil (HFF) subgroup animals received 14% corn oil with 9% flaxseed oil; the high-fat beef tallow (HFB) subgroup received 5% corn oil with 18% beef tallow. The detailed composition of the diet mixture for each subgroup is provided in Table 1. The amount of cellulose (as Cellufil), vitamin mix, mineral mix and casein in the diet was adjusted to ensure that animals were fed isocaloric diets. In addition, all the animals in group 1 were fed with 2%

Table 1 Detailed composition of the diets fed to animals in each group (g/kg of the diet)

carrageenan in their diet for the entire 2-week period of the study. Carrageenan is an extract of red seaweed and has been shown to cause colon-specific inflammation. The animals in group 2, however, were not fed with carrageenan. The grouping of animals is schematically depicted in Fig. 1. Table 2 lists the detailed percent fatty acid composition of the different diet groups.

All the animal housing, specialized feeding and sample collection procedures were undertaken at the animal facility in the Department of Biology, University of Waterloo. At the end of 2 weeks, the animals were euthanized using the CO_2 asphyxiation method. This project was approved by the animal care committee at the Institute for Biodiagnostics, National Research Council of Canada and the University of Waterloo. The colon of each animal was excised after euthanizing the animal. The mucosal layer of the colon was scraped off using a glass slide by the method previously described by Briere et al. [17]. The mucosal samples were coded and stored in cryovials containing phosphate-buffered saline in deuterium oxide (PBS/D_2O) medium at −70°C. These coded cryovials were shipped on dry ice to the National Research Council of Canada, Winnipeg, for MRS and histological assessment.

^{1}H MRS Analysis

One-Dimensional Experiments

For ^{1}H MRS experiments, the samples were thawed and cut into 5–7-mm-long pieces along the longitudinal axis of the colon. This yielded 18–20 samples from each animal. ^{1}H MRS was conducted on alternate samples from each animal. Thus, a total of 119 spectra from group 1 and 127 spectra from group 2 were generated for our study. Each piece from the colon was counted as an independent observation for both MR analysis and histology. This was done as it is known that IBD can be very focal and does not involve all the parts of the colon in a consistent manner. This holds true in the clinical setting too as not all of the biopsies taken during a single colonoscopy at a single point of time show IBD-related changes. As we were comparing MR spectra from each piece with the histology of that piece, we found it more appropriate to compare the pieces as separate samples rather than group them together per animal.

The sample preparation technique used for conducting ^{1}H MRS was similar to the technique described by Kuesel et al. [18]. Briefly, the colon sample was placed in a glass

capillary tube filled with PBS/D_2O with one end plugged. This capillary was inserted into the NMR tube containing 300 µl of PBS/D_2O solution along with 5 µl of chemical shift reference, 3-trimethylsilylpropionic acid-d_4 sodium salt (TSP). ^{1}H MRS was conducted on these samples using a Bruker Avance 360 MHz spectrometer at 25°C with presaturation of the water signal. The acquisition parameters included: 90° pulse at 9.30 µs, number of scans = 256, spectral width = 4,990.02 Hz, relaxation delay = 3 s and time domain data points = 8 k. The samples were fixed in 10% neutral buffered formalin immediately after ^{1}H MRS experiments for histological assessment. Since the experimental time was only ~16 min, and the spectra were recorded without sample spinning, any mechanical damage to the tissue should be precluded.

Two-Dimensional MRS Experiments

^{1}H-^{1}H correlated spectroscopy (COSY) experiments using gradient pulses were performed on representative colon mucosal samples to unambiguously identify the metabolites whose signals were overlapping in one-dimensional (1D) spectra or were present at very low concentration. The acquisition parameters used were: spectral width = 4,990.02 Hz in both dimensions; time domain data points = 2,048; number of free induction decays (FIDs) with t_1 increments = 256; relaxation delay = 1 s and number of transients = 128. The resulting data were zero filled to 1,024 points in the t_1 dimension and Fourier transformed along both dimensions after multiplying the data by sine-bell window function shifted by $\pi/_2$.

Gas Chromatography

Fatty acid composition of dietary fats used in this study was analyzed by GC following the method described in AOCS-Official methods and protocols [19]. In brief, samples of all dietary groups underwent fat extraction/evaporation cycles using a mixture (1:1, v/v) of HPLC grade chloroform and methanol (Fisher Scientific Limited, Nepean, ON, Canada). Total amount of fat extracted from each dietary lipid was weighed before GC analysis. To 50 µl of extracted fat, 1 µl isooctane containing an exact amount of internal standard (C17: 1) and 12 ml 2% H_2SO_4 in methanol were added. The resulting mixture was heated with vortex for 2 h at 65–70°C to obtain a monophase system. After cooling to room temperature, 6 ml isooctane and 6 ml distilled water were added, stirred and allowed to stand. One milliliter of the upper clear layer of the esterified sample was subjected to automated GC analysis. In addition to the internal standard, we also ran a mixture of standard fatty acid methyl esters (Sigma Chemicals Co., St. Louis, MO) to ensure that the fatty acids are identified appropriately. The contribution of individual fatty acids to the dietary fat was calculated with reference to the internal standard.

Histology

Histology was performed on representative animals from both groups 1 and 2, using the same tissue used for the MRS experiment. Each sample was coded to avoid analysis bias, fixed in 10% neutral buffered formalin and finally embedded into paraffin blocks. The paraffin blocks were cut into 5-µm-thin sections and collected on coated glass slides. The sections were stained with hematoxylin and eosin (H&E) stain and examined at 60× magnification under a light microscope. Cellularity, crypt architecture and fibrosis were the broad criteria used for grading inflammation in the samples. Predominantly, the density of lymphocytes (represented by an arrow in Fig. 3) within the surface epithelium, lamina propria and invasion within the crypt epithelium were considered when assessing increased

cellularity. Destruction of crypt architecture (represented by a star in Fig. 3) by inflammatory cells and formation of crypt abscess were assessed under architecture. Fibrosis (represented by an arrowhead in Fig. 3) denoting chronicity of the inflammatory process was also assessed. When assessing each sample, these criteria were independently assigned mild, moderate or severe grade, and then a compiled composite score was given to the sample. The degree of inflammation was graded based on the proportion of the total sample inflamed. If 30% or less of the total section was inflamed, it was graded as mild. Sections having 30–60% inflammation were graded as moderate, and those with over 60% inflamed area were graded as having severe inflammation.

Statistical Classification Strategy

The statistical classification strategy (SCS) [16] is comprised of several stages, and depending on the data, some or all of the stages may be invoked. We employed the following stages:

Preprocessing

All spectra were subjected to normalization (scaling to unit area), smoothing and peak alignment (with respect to the external reference, TSP). This step also involves transformations (e.g., forming derivatives or ranking the spectral intensities). Only the subregion 0.5–4.5 ppm (1,184 data points) was used for SCS analysis. This region was selected to avoid artifacts due to the residual water signal at 4.7 ppm and also the external reference (TSP) peak at 0 ppm. Finally, the resultant 1,184-point spectra were rank-ordered to eliminate baseline differences between the spectra (The actual intensity values were replaced by their ranks to eliminate or reduce the influence of excessively large resonance intensities.)

Feature Selection/Extraction

The feature selection/extraction is a genetic-algorithm-based optimal region selection algorithm (GA_ORS) that involves the reduction of feature space dimension but retains the spectral identity [16]. A small number of discriminatory subregions are selected from the spectra in which adjacent spectral intensities are averaged. In an extension of the feature selection method, the data are split randomly into a number (N, e.g., $N = 50$) of training-test set pairs; one half of the split is for the training set, the other half the test set. For each split, a set of features is determined using a simple classifier, in this case linear discriminant analysis (LDA). This process produces N feature sets (generally different), and a histogram is constructed of feature selection frequency. The features most frequently selected are the eventual inputs for the final classifier. This stage is essential for reliable classifier development. Subregions identified in this study have been listed in Tables 3 and 4 for groups 1 and 2 (with and without carrageenan treatment).

Classifier Generation

In this step, the subregions determined by histogramming form the feature set that is submitted to the ultimate classifier, also an LDA classifier. The classifier's coefficients are obtained by our bootstrap-inspired approach. This involves splitting the data randomly 5–10,000 times into training and test sets, determining the individual coefficients for LDA and using these to test the corresponding test sets. A weighted average of the above coefficients is taken, and weights are determined by the classifier's performances on the test sets.

Results

Figure 2 shows the two-dimensional (2D) ^{1}H-^{1}H COSY spectrum of a typical colonic mucosa showing assignments for various metabolites. ^{1}H MR spectrum of the same sample is shown above the 2D plot. These assignments were also compared with those from recent reports [12, 20]. Owing to an extensive broadening of the lipid signals, the chemical shift region 2.70–2.90 ppm representing diallylic methylene protons [–CH=CH–(C**H**$_2$–CH=CH)$_n$–] was not well resolved. This obviates the identification of individual PUFAs present in the colonic mucosa. Similar observations were made in recent studies despite the use of advanced NMR techniques such as HR MAS [12, 20]. In addition to the lipid components, we have also detected choline-containing phospholipids such as phosphatidylcholine and other small molecules such as creatine, leucine, valine, lysine, alanine, threonine, aspartate, glutamine, glutamate, ethanolamine, uracil, tyrosine and phenylalanine.

SCS methodology was applied to the spectra obtained from colonic mucosa in three stages of the study. In the first stage, all the specialized dietary subgroups were compared with the LFC fed subgroup. The results of the first stage of SCS analysis from group 1 (treated with 2% carrageenan) and group 2 (not treated with carrageenan) are shown in Table 3. In group 1, the classifier assigned the spectra to their respective groups with high accuracy ranging from about 91–100%. The lowest accuracy of 91% was seen for the comparison between the LFC- and the HFB-fed subgroups. In this comparison, 4 out of 32 spectra from the LFC subgroup were misclassified, and 2 out of 34

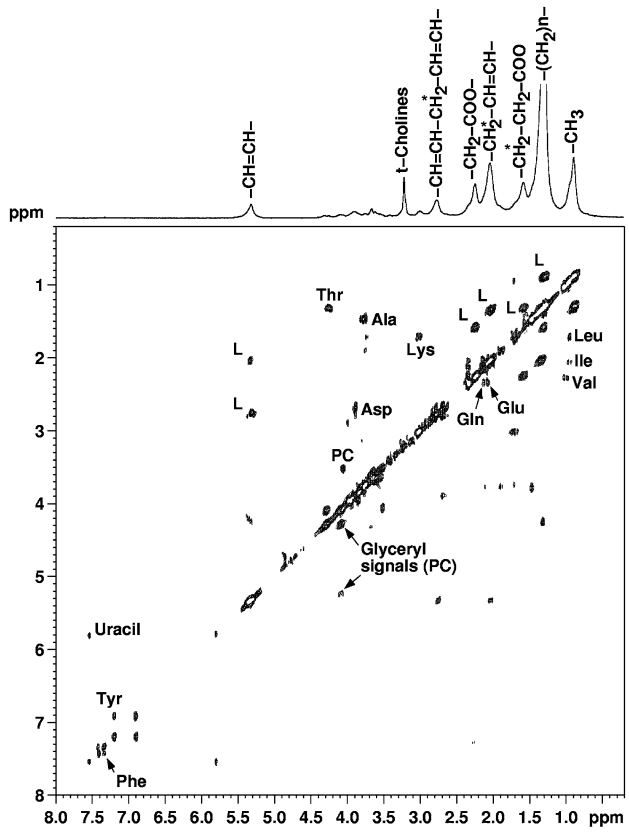

Fig. 2 Two-dimensional ^{1}H-^{1}H COSY spectrum (360 MHz, 25°C) of a typical colonic mucosa with labeling of various fatty acid signals along with other predominant biochemicals. Corresponding 1D ^{1}H spectrum is shown on the top of the 2D spectrum with assignments of lipid signals. Abbreviations: *L* lipid, *Leu* leucine, *Ile* isoleucine, *Val* valine, *Lys* lysine, *Glu* glutamate, *Gln* glutamine, *Ala* alanine, *Asp* aspartate, *Thr* threonine, *Tyr* tyrosine, *Phe* phenylalanine, *PC* phosphatidylcholine

spectra from the HFB subgroup were misclassified. The spectral subregions identified by SCS as being discriminatory are listed in Table 3. These regions could be attributed to the resonances due to the protons of the fatty acyl chain, creatine, leucine/isoleucine, valine and glyceryl protons of phospholipids. Similar observations were made for group 2 (see Table 3). The classification accuracy was very high, ranging from 96 to 100%. A major difference observed between the two groups was that creatine signals were found to be discriminatory in the classification of LFC and HFB in group 2, whereas glyceryl signals of phospholipids were found to be discriminatory in group 1 (for detailed assignments, see Table 3). The first stage of SCS analysis from group 1 and group 2 shows that dietary fat causes enough differences in the metabolite profile of rat colon that it can be discerned by SCS methodology. The results hold true when there is no extrinsic inflammatory agent and even when there is carrageenan-induced colonic inflammation. These differences could be due to difference in the amount of fatty acids, type of fatty acid or extent of inflammation within these groups. Therefore, the first stage of SCS analysis was followed by a second stage to assess if ^{1}H MRS could identify the differences between the effects of various dietary fats containing different fatty acids when keeping the total fat content in each dietary group constant.

In the second stage, the three specialized diet groups were compared against each other. All the animals in these three groups received 23% fat by weight in their diets; however, the type of fatty acid differed. The results of the second stage of SCS analysis of samples from groups 1 and 2 are shown in Table 4. ^{1}H MRS combined with SCS analysis depicted an accuracy of 98–100% in classifying

* In group 1, all animals were treated with 2% carrageenan to induce IBD; abbreviations are the same as in Table 1

the spectra to their respective groups. In addition to the regions identified during comparison of each group to the LFC group, resonances due to glutamic acid, total cholines and glycerophosphoethanolamine were also ascribed to be discriminatory in this analysis. In the second stage of group 2 analysis, ^{1}H MRS with SCS attained an accuracy of 97% in differentiating HFC from HFF, 98.4% between HFC and HFB, and 100% between HFB and HFF subgroups.

These results indicate that ^{1}H MRS can detect subtle differences in the metabolite profile of colon when the animals receive the same amount but different types of fats. The stage 1 analyses showed that MRS combined with SCS can detect differences between the LFC subgroup and HFC, HFF and/or HFB subgroups. The combination of these two results shows that ^{1}H MRS can detect differences in the colon caused not only by different amounts but also different types of fatty acids. The metabolites found to be discriminatory in the SCS analysis included creatine, glyceryl signals of glycerophospholipids, glycerophosphoethanolamine, glutamic acid, total cholines and signals from fatty acyl chains, particularly, the allylic/diallylic methylene protons (–**H**$_2$C–CH=CH–/–CH=HC–C**H**$_2$–CH=CH–) including (–C**H**$_2$–) chain, terminal –C**H**$_3$, and –C**H**$_2$–CH$_2$–COO– groups. It is worthwhile to note that the diallylic methylene protons (–CH=CH–C**H**$_2$-CH=CH–) are the predominant entities responsible for the classification of different dietary PUFAs in both groups 1 and 2. Metabolites resonating in the region 1.10–1.22 ppm could be assigned to the amino acids leucine/isoleucine and valine.

Having established that both the amount and type of dietary fat caused enough differences in the fatty acid profile of the rat colon and that ^{1}H MRS can accurately detect these changes, we proceeded to the third stage of analysis. The goal of this stage of analysis was to assess the accuracy of ^{1}H MRS in detecting changes in the metabolite profiles of the rat colons predominantly due to inflammation. For this, each subgroup in group 1 was compared to the corresponding subgroup in group 2 of our study. As shown in Table 5, the SCS analysis was highly accurate in classifying the spectra from each subgroup in group 1 versus the corresponding subgroup in group 2. SCS identified resonances due to total cholines, creatine, valine, leucine, phosphatidylcholine, and methyl and diallylic methylene protons of the fatty acid chain as discriminatory.

Table 5 Results of comparative SCS analysis between group 1 and group 2

Class	Accuracy (%)	Regions (ppm)	Metabolites
LFC	100	4.18–4.23	Phosphatidylcholine (–O–C**H**$_2$–)
		3.64–3.67	Phosphatidylcholine (–N–C**H**$_2$–)
		0.89–0.93	–C**H**$_3$
HFC	97.0	2.85–2.93	=HC–C**H**$_2$–CH=
		2.63–2.67	=HC–C**H**$_2$–CH=
		1.21–1.25	–Leucine/isoleucine/valine
HFF	100	3.20–3.24	Total cholines
		0.87–0.93	–C**H**$_3$
HFB	100	3.22–3.24	Total cholines
		2.95–3.04	Creatine
		0.85–0.92	–C**H**$_3$

Abbreviations are the same as in Table 1

The representative sections of H&E-stained samples from each group are shown in Fig. 3. Details of the criteria used to grade inflammation have been described in the Methods section. In group 1, sections from 21 out of 23 samples analyzed from the HFF subgroup were either not inflamed or had very mild inflammation. Similarly, out of 21 samples from the LFC subgroup, only 1 sample had

severe inflammation. On the other hand, all of the samples from HFB ($n = 20$) and HFC ($n = 23$) subgroups showed moderate to severe inflammation. Figure 4 shows the corresponding ^{1}H MR spectra of the colon tissue specimens whose histological sections are shown in Fig. 3. Due to extensive broadening of the ^{1}H MRS signals, it was difficult to monitor the modulation in the levels of various dietary fatty acids. However, it is obvious from Fig. 4 that creatine and total-cholines are decreased with the severity of the inflammation. Such metabolic information supplements histological data, which in turn can help in the accurate diagnosis of inflammation. In group 2 animals, very mild or no inflammation was observed in all the sections examined (data not shown).

Discussion

The main objective of this work was to study the effect of various dietary lipids on the modulation of the colonic inflammation in an IBD model. We utilized ^{1}H MRS combined with pattern recognition methods such as SCS to study the above effect. Inflammatory reactions cause biochemical changes, and MRS has the potential to detect these changes before histological manifestations [21]. In our earlier studies, we have confirmed that ^{1}H MRS in combination with pattern recognition methods could be a valuable adjunct to histology for the assessment of tissue whose status is intermediate between normal and malignant [22, 23]. Hence, ^{1}H MRS could be used for indirectly assessing the inflammatory processes.

The data were analyzed in three stages to answer three specific objectives of our study, sequentially. The first step was to identify whether ^{1}H MRS was able to identify differences between a low-fat diet and different types of high-fat diet in inflamed (group 1) and non-inflamed (group 2) colons. Those results showed that MRS was able to categorize the samples in their respective group with high sensitivity. Then the questions arose whether the differences seen were purely because of a difference in the amount of total fat in the diet or whether MRS was sensitive enough to categorize the samples accurately even when the same concentration, but different type of fatty acids was introduced in the diets. This led to stage 2 of the analyses where we compared the MR spectra from different high-fat diet groups against each other in both inflamed (group 1) and non-inflamed (group 2) colons. The results showed that ^{1}H MRS with SCS methodology was able to accurately classify the samples to their respective groups again. At this stage, we had confirmed the basic hypothesis of our overall project that different amounts and types of dietary fats affect the colon differently and that ^{1}H MRS is a sensitive technique to identify these differences. Therefore, we were at a stage where we could proceed to assess whether ^{1}H MRS could still categorize the samples with confidence when comparing the difference in inflammation between 'normal' and 'IBD-like' states of the colon. This was the reasoning for doing stage 3 of the analyses where

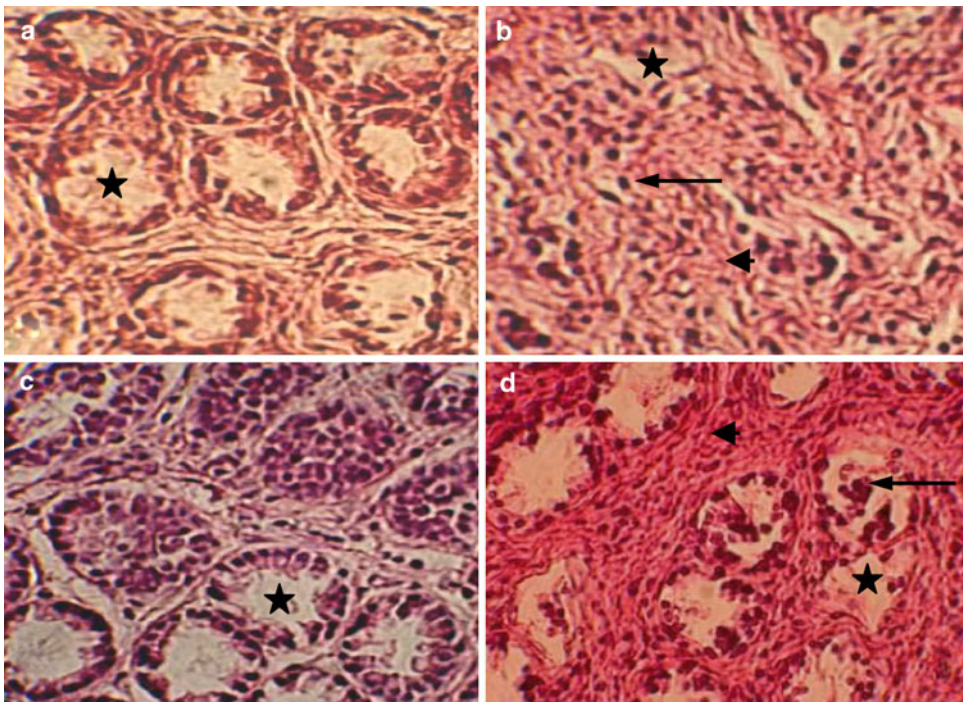

Fig. 3 Representative H&E-stained sections from each dietary group: the low-fat corn oil (LFC) group (**a**) showing normal architecture with uniform, well-spaced crypts (*star*) and no interstitial fibrosis or inflammation, while the section from the high-fat corn oil (HFC) group (**b**) shows moderate inflammation with distorted crypts (*star*), lymphocytic infiltrate (*arrow*) and interstitial fibrosis (*arrow head*). The section from high-fat flaxseed oil (HFF) (**c**) shows unremarkable architecture with uniform crypts (*star*) and no evidence of inflammation; the section from high-fat beef tallow (HFB) group (**d**) shows moderate inflammation with distortion of crypt architecture (*star*), lymphocytic infiltrate (*arrow*) and interstitial fibrosis (*arrowhead*)

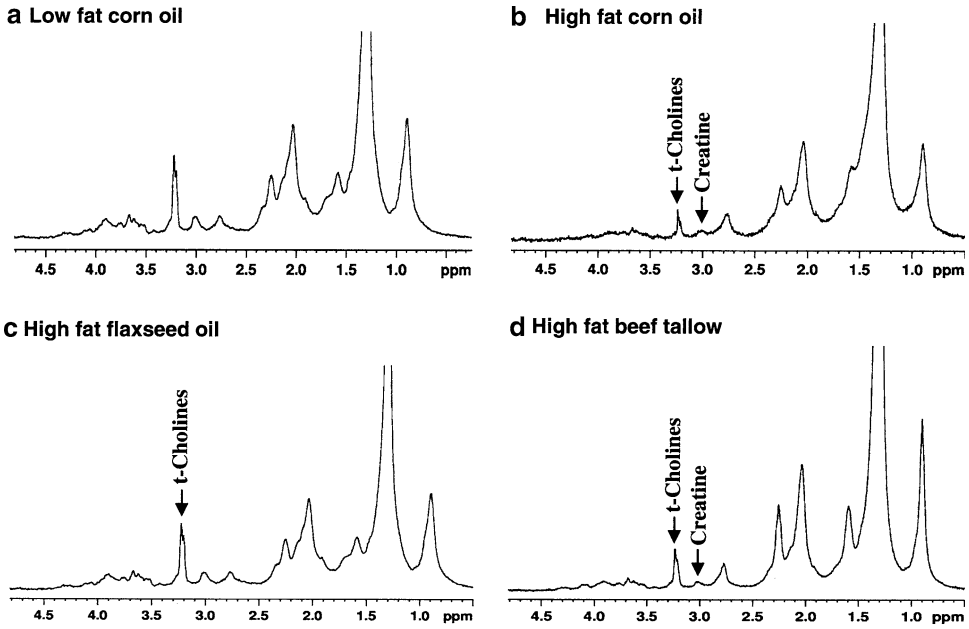

Fig. 4 ^{1}H MR spectra (360 MHz, 25°C) of the corresponding colonic tissue specimens whose histology is shown in Fig. 3 from each dietary group: **a** low-fat corn oil group (LFC), **b** high-fat corn oil (HFC) group, **c** high-fat flaxseed oil (HFF) group and **d** high-fat beef tallow (HFB) group. Some of the *peaks/metabolites* that showed change in their relative levels have been marked in the spectra

we compared each dietary subgroup from the 'carrageenan-treated' (group 1) with the corresponding subgroup from the 'non-carrageenan-treated' (group 2) separately. Since the dietary composition was the same, any differences seen in the MR spectra could be attributed to the difference in inflammation between the two subgroups. As we aim to eventually apply this methodology to assess the effect of different dietary fatty acids on modulation of inflammation in IBD, this was a critical step to confirm that ^{1}H MRS has the capability to categorize samples based on differences in the degree of inflammation.

The ^{1}H MRS signals found to be discriminatory in the SCS analysis included those from creatine, glyceryl signals of glycerophospholipids, glycerophosphoethanolamine, glutamine/glutamic acid, total cholines and parts of the fatty acyl chain, particularly the allylic/diallylic methylene protons. The implications of these metabolites are discussed herewith. Creatine is a metabolite that is found in normal tissues and serves as an energy reservoir. It is converted into phosphocreatine by adding a high energy phosphate bond in the presence of the enzyme creatine kinase. This is a reversible reaction, and whenever energy is needed, phosphocreatine is broken down to creatine while releasing the energy as ATP. Significant concentrations of creatine have previously been detected in human colonic mucosa [24]. The creatine kinase isoenzyme BB has been isolated from normal [25] and infracted colonic mucosa [26]. In an earlier study, the presence of significant amounts of creatine in normal colon tissue was attributed to a more developed muscular morphology of the colon [12]. In this study, we observed relatively high levels of creatine (2.88–3.10 ppm) in the LFC subgroup, whereas creatine was detected in negligible amounts in animals fed with HFC and HFB. However, the creatine levels were intact in the animals fed with HFF (Fig. 4). These observations indicate that muscular morphology was not disturbed in the animals fed with HFF, whereas it was upset in animals fed with HFC/HFB. As colonic inflammation causes cellular damage, demand for the energy would be high, which may result in the depletion of creatine stocks in these cells.

The region around 2.7–2.8 ppm denotes diallylic methylene protons from PUFAs [9]. PUFAs are critical for maintaining the membrane structure and function of various cells in the body [27]. Linoleic acid is an abundant PUFA in the cell membrane and a precursor of arachidonic acid. Arachidonic acid is the precursor in the synthesis of many inflammatory mediators such as the products of lipoxygenase pathway LT B4 and LT C4. These inflammatory markers are increased in many disorders in the human body including IBD [28]. Nishida et al. [29] observed an increase in arachidonic acid concentration in the colonic mucosa of patients with ulcerative colitis. Nieto et al. [30] also observed an increase in linoleic acid concentration in the colonic mucosa of rats 2 weeks after inducing experimental colitis. The linoleic acid incorporated into colonic cells may be used to synthesize arachidonic acid and inflammatory mediators. The GI tract is well known to be affected by dietary lipids. Colonocytes have fatty acid synthase including in colorectal cancer [31]. A high-fat diet does affect eicosanoid production in colonic mucosa. However, we recognize that inflammation is mediated via a complex network of different cell types in the colon, and almost every cell type is affected in the body by dietary lipids [32, 33]. These changes in colonic

mucosal lipid profile are similar in human ulcerative colitis as well as experimental colitis induced in animals. Using a gas chromatography technique, Hawthrone et al. [34] observed that the levels of unsaturated fatty acids, EPA and DHA increased in rectal mucosa after ω-3 PUFA supplementation. A similar effect on the colonic fatty acid profile was seen by Bartoli et al. [35] in Sprague-Dawley rats after ω-3 supplementation for 12 weeks. As mentioned earlier, due to extensive broadening of the ^{1}H MRS signals, we could not determine which specific PUFA contributed to the peak due to protons in the unsaturated region based solely on these spectra. We deduced that the predominant PUFA in a particular dietary group must have been responsible for the selection of the allylic/diallylic methylene protons peak as discriminatory (Tables 3 and 4).

Glutamine is the major fuel for intestinal cells. Significant levels of glutamine were observed both in human colon [36] and rat colonic mucosa [37]. Glutamate acts as an excitatory neurotransmitter in the intestinal neuronal cells. Intense glutamate staining was observed in the neural plexuses of human colon. It is being postulated that glutamate regulates acetylcholine release and motility in the colon [38]. Glutamic acid is converted to γ-aminobutyric acid by glutamic acid decarboxylase enzyme. Recently, it was shown that glutamic acid decarboxylase and γ-aminobutyric acid are present in the lamina propria of colonic mucosa of rats and may be involved in maturation and differentiation of colonic epithelial cells [39]. In the present study, although we detected small amounts of glutamine/glutamate in colonic mucosa using 2D COSY experiments, they were overlapping with those of lipid signals. As a result, we were not able to quantify these metabolites.

The comparison between group 1 and group 2 spectra shows that ^{1}H MRS combined with SCS can differentiate between inflamed and non-inflamed samples from the animals fed the same amount and type of fatty acids. In this comparison, total cholines were found to be discriminatory in addition to the metabolites mentioned above. In this study, total cholines were decreased in HFC/HFB fed animals. Martin et al. [12] observed significant levels of phosphatidylcholine, creatine, glycerol and triglycerides in the normal colon. Phosphatidylcholine is the predominant phospholipid present in the lipid bilayer of cell membranes [40] and in the colonic mucosal lining [41]. It is synthesized via the CDP-choline pathway, and the final step of this de novo synthesis is catalyzed by cholinephosphotransferase [42, 43]. Cholinephosphotransferase has also been implicated in the synthesis of platelet-activating factor (PAF), which is an inflammatory mediator and necessary signal for steps in the inflammatory cascade such as platelet activation and increase in vascular permeability. The active species of PAF have been shown to increase significantly in mucosal biopsies from ulcerative colitis patients [44]. Levels of PAF in stool are even considered to be diagnostic and indicative of severity in patients with ulcerative colitis [45]. The decreased levels of phosphatidylcholine in animals with severe inflammation seen in our study could be due to increased levels of PAF in colonic inflammation. We speculate that the cholinephosphotransferase could be more active towards the synthesis of PAF under inflammatory conditions. As there is increased apoptosis and cell turnover in IBD, there is increased demand for phosphatidylcholine to repair and regenerate the cells in colonic mucosa. This may have also contributed to the decreased levels of phosphatidylcholine/total cholines seen in our spectra, in line with earlier reports [14, 46, 47].

The histological assessment of group 1 (Fig. 3) samples showed that both LFC and HFF may be protective against inflammation. It points to the fact that both the amount and type of fatty acids supplemented may be important in modulating colonic inflammation. HFC and HFB subgroups showed significant inflammation in our study. The HFC diet supplied a high concentration of ω-6 fatty acids, which are pro-inflammatory and may have caused severe inflammation in that subgroup. The same trend holds true for the HFB diet, which supplies high amounts of saturated fats. On the contrary, the LFC diet, although it provides mainly ω-6 PUFAs, did not have a high enough concentration of these PUFAs to manifest severe pro-inflammatory effects. In a randomized control trial on patients with IBD, Bamba et al. [48] observed that a low-fat diet induced remission in 80% patients as compared to only 25% in the high-fat diet group. Interestingly, the fat they supplemented in the diet was soybean oil, which has a significant amount of ω-3 PUFAs. Similar effects were observed by Reddy et al. in a study on colon cancer [49]. They showed that rats fed with 20% corn oil had a significantly higher incidence of colon cancer than rats fed with 5% corn oil for the same duration [49]. More recently, Rao et al. [50] reported that in rats fed with high-fat fish oil (ω-3) and LFC (ω-6), this exerted a similar protective effect on colon tumor development as compared to a high saturated fat diet. Our results are in agreement with all these reports. In addition, the duration for which these PUFAs are administered is also important in regulating the outcome of the therapy. The effects of ω-3 and ω-6 fatty acids on IBD need to be studied in long-term studies. It is necessary to assess whether the effects of these fatty acids on IBD are reversible and the relapse and remission rates for patients who become non-compliant to the dietary modifications. Very mild or no inflammation seen in animals from group 2 could be due to variation in the normal mucosa, as usually some inflammatory cells are always present in the colon.

The results of this study show that ^{1}H MRS combined with SCS methodology can detect differences in the prevalence of inflammation in the colon of animals fed with both low-fat and high-fat diets. It can also differentiate between the subtle changes caused by the different fatty acids on the colon of animals fed with specialized diet. The fact that both LFC and HFF subgroups showed very mild or no inflammation implies that both the amount and the type of fatty acid in the diet are crucial in modulating inflammation. Our approach has the potential to complement histological examination of colon biopsies. The role of ^{1}H MRS as an adjunct to histology for diagnosing and differentiating between Crohn's disease and ulcerative colitis has already gained some footing [6]. The results of the current study will facilitate future endeavors to determine the utility of ^{1}H MRS in assessing inflammation, disease progression and response to dietary modification augmenting the mainstream methods such as histology. In this study, we kept the level of fat the same, but the fatty acid composition was altered in different high-fat diets. One of our future research goals is to conduct a study using different timelines for each dietary group of animals to show the temporal separation between biochemical and histological changes in IBD. Moreover, we will focus our study on the effect of individual fatty acids on colonic inflammation to understand their respective roles. We intend to use a combination of serum markers, ^{1}H MRS and histology at various time points.

Acknowledgements We would like to thank Saro Bascaramurty, who was the key resource for tissue sectioning and staining for histological assessment. We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for the strategic project grant to R.P. Bird, M. Eskin and T. Bezabeh.

ORIGINAL ARTICLE

Phytosterol Ester Constituents Affect Micellar Cholesterol Solubility in Model Bile

Andrew W. Brown · Jiliang Hang · Patrick H. Dussault · Timothy P. Carr

Received: 14 June 2010 / Accepted: 27 July 2010 / Published online: 13 August 2010

Abstract Plant sterols and stanols (phytosterols) and their esters are nutraceuticals that lower LDL cholesterol, but the mechanisms of action are not fully understood. We hypothesized that intact esters and simulated hydrolysis products of esters (phytosterols and fatty acids in equal ratios) would differentially affect the solubility of cholesterol in model bile mixed micelles in vitro. Sodium salts of glycine- and taurine-conjugated bile acids were sonicated with phosphatidylcholine and either sterol esters or combinations of sterols and fatty acids to determine the amount of cholesterol solubilized into micelles. Intact sterol esters did not solubilize into micelles, nor did they alter cholesterol solubility. However, free sterols and fatty acids altered cholesterol solubility independently (no interaction effect). Equal contents of cholesterol and either campesterol, stigmasterol, sitosterol, or stigmastanol (sitostanol) decreased cholesterol solubility in micelles by approximately 50% compared to no phytosterol present, with stigmasterol performing slightly better than sitosterol. Phytosterols competed with cholesterol in a dose-dependent manner, demonstrating a 1:1 M substitution of phytosterol for cholesterol in micelle preparations. Unsaturated fatty acids increased the micelle solubility of sterols as compared with saturated or no fatty acids. No differences were detected in the size of the model micelles. Together, these data indicate that stigmasterol combined with saturated fatty acids may be more effective at lowering cholesterol micelle solubility in vivo.

Introduction

Supplementation of human diets with plant sterols and stanols (collectively referred to here as phytosterols) and their esters can decrease serum LDL cholesterol concentrations [1], which is regarded as a modifiable risk factor for atherosclerosis. One way phytosterols lower serum LDL cholesterol is by disrupting intestinal cholesterol solubilization into micelles [2–5], which is a necessary step in the efficient absorption of cholesterol from the intestine [6]. However, the exact mechanisms for the actions of phytosterols have not been adequately defined.

Several studies have investigated the effects of individual sterols in simple systems of single bile acids with [2] or without [3–5] oleate or monoolein. However, the most quantitatively important source of cholesterol in the intestinal lumen is secreted from the gall bladder in a

complex mixture of bile salts and phospholipids. In spite of the relevance to intestinal uptake of sterols, few studies have compared phytosterol solubilities and their effects on cholesterol solubility in a mixed micelle system similar to bile [7]. In addition, some phytosterol esters, namely sterol stearates [8], are superior to other phytosterols in their ability to lower serum cholesterol, yet the mechanisms by which these esters impart their unique effects is unknown. Thus, the objectives of this study were to examine the effects of (1) sterol esters, (2) simulated hydrolysis products of sterol esters (fatty acids and sterols in equal ratios), and (3) phytosterol concentration on micellar cholesterol solubility in a model bile, mixed-micelle system.

Materials and Methods

Cholesteryl oleate (98%), oleic acid (99%), stearic acid (99%), sodium taurodeoxycholate (>97%), and sodium glycodeoxycholate (>97%) were purchased from Sigma-Aldrich (St. Louis, MO). Sodium glycocholate (98%) and granular phosphatidylcholine were purchased from ACROS Organics (Geel, Belgium). Sodium taurocholate (>97%) was purchased from Alfa Aesar (Ward Hill, MA). 5α-Cholestane was obtained from Steraloids (Newport, RI). Cholesterol (95%) was obtained from Mallinckrodt OR (Paris, KY). Palmitic acid (99+%) was obtained from MP Biomedicals (Irvine, CA). Sodium chloride, sodium azide, chloroform, and hexanes were purchased from Fisher Scientific (Fair Lawn, NJ). Methanol was purchased from VWR (West Chester, PA). Linoleic and α-linolenic acids (99+%) were purchased from Nu-Chek Prep (Elysian, MN). The total cholesterol kit, Chol, was purchased from Roche Diagnostics (Indianapolis, IN). Phospholipids C and Free Cholesterol E colorimetric assay kits, and campesterol (98.7%) were obtained from Wako Chemicals USA, Inc. (Richmond, VA). 24-Ethyl sterols were purchased or synthesized as previously described [9]. Briefly, stigmasterol (95%) was purchased from TCI America (Portland, OR) and partially or completely hydrogenated to make sitosterol or stigmastanol (a.k.a. sitostanol), respectively [10, 11].

Procedures

Model Bile Mixed Micelles

Simplified bile salt solutions modeling biliary bile salt compositions were limited to the glyco- and tauro-conjugates of cholate and deoxycholate in ratios similar to published values [7, 12, 13] for a final concentration of 52.5 mM total sodium salts of bile acids: glycocholate, 29.1 mM; taurocholate, 11.4 mM; glycodeoxycholate, 8.8 mM; and taurodeoxycholate, 3.4 mM. Concentrated stock solutions of phosphatidylcholine, free fatty acids, free sterols, and sterol esters were made in chloroform. Model bile mixed micelles were created by combining stock solutions and evaporating chloroform under a stream of N_2 at 50°C, followed by addition of the 52.5 mM bile salt stock solution to create a 1 ml solution. All solutions had a final concentration of 52.5 mM bile salts and 15 mM phosphatidylcholine, with the concentrations of free sterols, free fatty acids, and sterol esters varying depending on the experiment. Lipids and bile acids were sonicated in an ice bath using a Branson 450 Sonifier (Branson, Danbury, CT) with a probe tip at 30% of maximum output (400 W) for 15 min [7]. Immediately after sonication, micelles were separated by injecting 200 µl of the solution onto a 10/300 Superose 6 column using a Waters 600 Multisolvent Delivery System and eluted at 0.5 ml/min using a 6 mM bile salt eluent. Eluent was made by addition of 3:1 taurocholate/taurodeoxycholate (w/w) dissolved in 0.9% sodium chloride (w/v) with 0.01% sodium azide (w/v), followed by vacuum filtration using Millipore (Bedford, MA) 47 mm, 0.2-µm pore size, and nylon filters. Fractions were collected every minute (0.5 ml) in 12 × 75 mm polystyrene tubes (VWR) using an ISCO Retriever 500 (Lincoln, NE). Individual fractions were analyzed for phosphatidylcholine using Wako's Phospholipids C Kit. Phosphatidylcholine-containing fractions indicated the presence of micelles [7, 14] and were pooled for subsequent analysis of free sterols by GC.

Micelle Sterol Analysis

Free sterols were analyzed by extracting an aliquot of the pooled micelle-containing fractions with 5α-cholestane as an internal standard. The sample was dried under a stream of N_2 at 60°C and was extracted using a modified Folch procedure [15]. Briefly, 2 ml of chloroform/methanol (2:1, v/v) was added to each sample, and samples were vigorously vortexed for 1 min followed by addition of deionized water for a final water content of 20% of the total volume. Samples were centrifuged at 1,000×*g* for 5 min to separate phases; the organic phase was transferred to a new tube, dried under a stream of N_2, and resuspended in hexanes. Sterols were analyzed by GC using an HP (Wilmington, DE) 5890 Series II Plus Gas Chromatograph equipped with an HP 6890 Autosampler, a 30-m DB-5 column (Agilent Technologies, Santa Clara, CA), and a flame-ionizing detector. Peaks were identified by comparing retention times with that of known standards. For the experiments examining the effects of intact sterol esters on micellar cholesterol, total and free sterols were quantified enzymatically.

Statistics

Data were analyzed using the Mixed procedure of SAS software (version 9.2; SAS Institute, Cary, NC). Sterol and fatty acid effects on micelles were analyzed as a split-block design, with stock solutions of sterols or fatty acids as main effects, correcting for cholesterol stock solutions as blocking effects. Pairwise comparisons were made with the 'pdiff' option and corrected for multiple comparisons using the 'simulate' adjustment to account for unequal sample sizes. Significance was set at $P < 0.05$. Functions in the dose dependence study were calculated using Proc Model.

Results

Micellar Incorporation of Free Sterols

Initial tests demonstrated similar elution patterns and volumes to previous work [7]. The elution profile of a model bile mixed micelle containing 3 mM cholesterol, 52.5 mM bile salt, and 15 mM phosphatidylcholine is shown in Fig. 1a.

Sterol Esters and Model Bile Mixed Micelles

Elution profiles of free cholesterol, total sterols (free plus esterified sterols), and phospholipids did not differ when cholesteryl oleate was included in a mixed micelle containing free cholesterol, bile salt, and phosphatidylcholine as compared with a model micelle devoid of sterol ester (Fig. 1a, b). When only cholesteryl oleate was added, with no free cholesterol, neither free nor esterified sterol was detected in the micelle fraction, and the elution pattern of phospholipids was altered (Fig. 1c). The lack of incorporation of sterol esters in micelles was further shown by preparing model micelles with or without stearate esters of stigmasterol, sitosterol, stigmastanol, or cholesterol. Total sterol content (free plus esterified sterols) did not differ from free sterol content (2.22 ± 0.02 vs. 2.19 ± 0.04 mM, respectively, pooled across preparations, $n = 4$), indicating no measurable incorporation of sterol esters in the micelles. Additionally, the presence or absence of sterol esters in the preparation did not affect the free cholesterol content of the micelles.

Micelle Solubility of Individual Sterols

The solubilities of free sterols within micelles prepared from solutions containing 3 mM cholesterol, campesterol, stigmasterol, sitosterol, or stigmastanol were quantified (Fig. 2). Stigmasterol was incorporated into micelles quantitatively and significantly less as compared to cholesterol, sitosterol, and stigmastanol, while cholesterol, campesterol, sitosterol, and stigmastanol were equally incorporated.

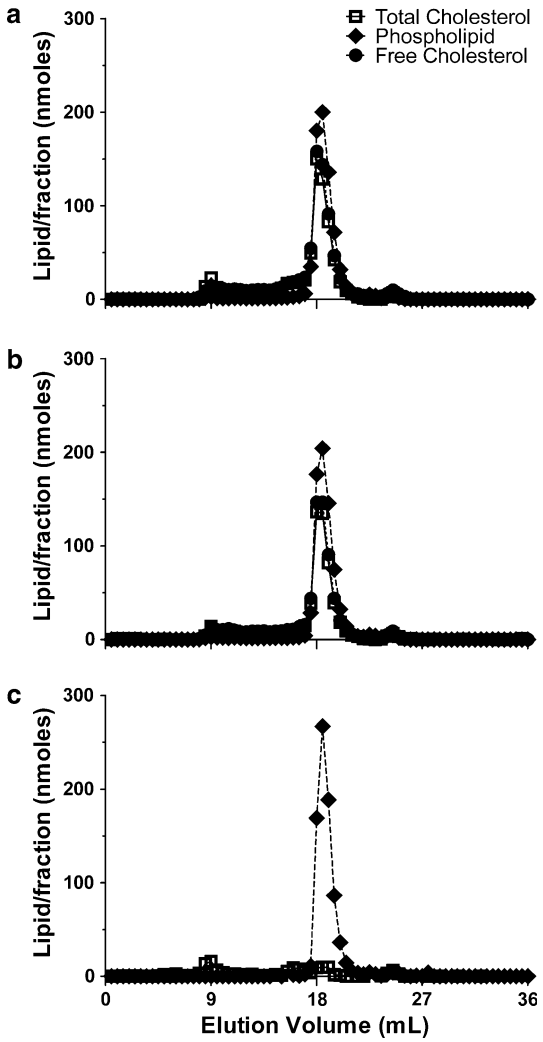

Fig. 1 Elution profiles of micelles separated by size-exclusion chromatography. Model mixed micelles were made by sonicating 3 mM cholesterol (**a**), 3 mM cholesterol and cholesteryl oleate (**b**), or 3 mM cholesteryl oleate (**c**) in the presence of 52.5 mM mixed bile salts and 15 mM phosphatidylcholine, followed by separation on a Superose 6 column at a flow rate of 0.5 ml/min. Fractions (1 min, 0.5 ml) were collected and analyzed for cholesterol, phosphatidylcholine, and total sterol. Each panel represents one preparation

Dose-Dependent Competition Between Sterols for Micellar Incorporation

Competition between stigmasterol and cholesterol for micelle incorporation was determined by adding 0, 1.5, 3, or 6 mM stigmasterol to model bile preparations containing 3 mM cholesterol (Fig. 3). As stigmasterol content increased, cholesterol content in the micelle decreased. Micellar cholesterol and stigmasterol contents were

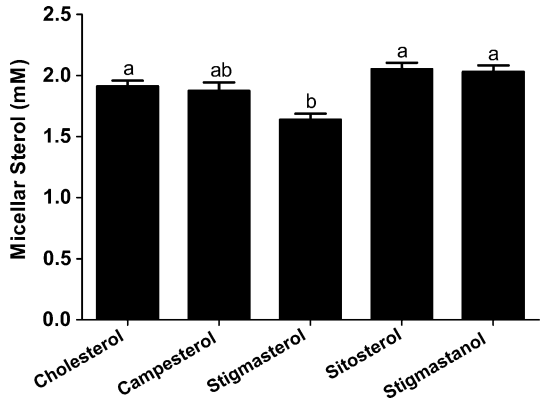

Fig. 2 Sterol solubility in mixed micelles. Mixed micelles were prepared by sonicating 3 mM of each sterol in the presence of 52.5 mM mixed bile salts and 15 mM phosphatidylcholine. Micelles were isolated by size-exclusion chromatography, and sterols were quantified by GC. Data are represented as means ± pooled SEM, $n = 3$; bars with differing letters indicate significantly different means, $P < 0.05$

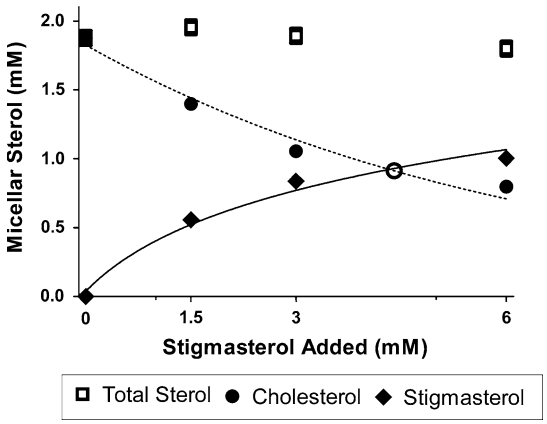

Fig. 3 Competition of stigmasterol and cholesterol for micelle incorporation. Stigmasterol (0, 1.5, 3, or 6 mM) was sonicated in the presence of 3 mM cholesterol, 15 mM phosphatidylcholine, and 52.5 mM mixed bile salts. Micelles were isolated by size-exclusion chromatography, and cholesterol and stigmasterol were quantified by gas chromatography. Micellar cholesterol solubility, modeled as a function of added stigmasterol, is represented by the *dashed line* (Eq. 1). Micellar stigmasterol solubility, modeled as a function of added stigmasterol, is represented by the *solid line* (Eq. 2). The *open circle* indicates the concentration of added stigmasterol at which micellar cholesterol would be expected to be decreased by half, which closely coincides with the intersection of the curves. Data represent means ± pooled SEM, $n = 3$; *error bars* may be eclipsed by the data markers

modeled as logarithmic and exponential functions, respectively. Cholesterol content was modeled as:

$$C = 1.83\exp(-0.158X) \quad (1)$$

and stigmasterol content was modeled as:

$$S = 0.53\ln(1.073(X + 1)) \quad (2)$$

where C is the final micellar cholesterol content in mM, S is the final micellar stigmasterol content in mM, and X is the stigmasterol added to the preparation in mM.

The amount of stigmasterol that would need to be added to decrease the cholesterol content by 50% according to Eq. 1 was 4.40 mM. This value corresponded closely to the solution of the two functions of $X = 4.33$ mM, where the amount of micellar stigmasterol and cholesterol are equal. Together, these values indicate approximately a 1:1 M substitution of micellar cholesterol for stigmasterol. The observation that more stigmasterol needs to be added than cholesterol for a 1:1 competition further demonstrates a lower micellar solubility of stigmasterol. Because stigmasterol had a lower solubility than other sterols (Fig. 2), other phytosterols may compete for micelle incorporation differently.

Free Sterol and Fatty Acid Effects on Micellar Sterol Content

Mixed micelles containing 3 mM free cholesterol were made with or without 3 mM palmitic, stearic, oleic, linoleic, or α-linolenic acids, and with or without 3 mM free campesterol, stigmasterol, sitosterol, stigmastanol, or additional cholesterol. Micellar cholesterol and phytosterol concentrations were measured by GC. No statistical interactions were detected between fatty acids and sterols, so pairwise comparisons were conducted among preparations pooled across fatty acids ('sterol effects,' Table 1, pooled $n = 17$–28) or among preparations pooled across sterols ('fatty acid effects,' Table 2, pooled $n = 15$–19). The fatty acid effects were calculated only on micelles that contained both phytosterols and cholesterol because the preparations that contained only cholesterol skewed the average cholesterol content upward and phytosterol content downward.

Adding an additional 3 mM cholesterol to the micellar mixture (for a total of 6 mM cholesterol) resulted in a significant increase, although not a doubling, in the concentration of cholesterol in the micelles, indicating that the micelles are saturated with cholesterol at a concentration somewhere between 3 and 6 mM.

The presence of phytosterols significantly decreased micellar cholesterol, with the phytosterol-containing preparations solubilizing approximately 50% of the micellar cholesterol of the saturated micelles. Modest differences were observed among the phytosterols tested: a 9% difference in the amount of micellar cholesterol was observed for the most (stigmasterol) and least (sitosterol) effective phytosterols, although neither stigmasterol nor sitosterol differed from stigmastanol and campesterol. However, stigmasterol itself was less well incorporated compared

with sitosterol, although again neither stigmasterol nor sitosterol differed from stigmastanol or campesterol. Together, these differences in individual sterol solubilities resulted in stigmasterol-containing preparations having significantly less total sterol than the other preparations except for the preparations that contained only 3 mM instead of 6 mM total sterol. Stigmasterol also differed from the other phytosterol-containing preparations by containing a greater proportion of micellar total sterol that was cholesterol, despite having a lower magnitude of cholesterol incorporated.

The presence or absence of saturated fatty acids (palmitic and stearic) had no effect on the incorporation of cholesterol or phytosterols in micelles. However, the presence of unsaturated fatty acids (oleic, linoleic, and α-linolenic), as compared with the saturated and no fatty acids preparations, increased micellar cholesterol (1.23 vs. 1.08 mM, respectively) and phytosterol (1.03 vs. 1.15 mM, respectively) contents. Total sterol content was similarly affected, but the proportion of micellar total sterol that was cholesterol was unaffected, indicating that incorporation of unsaturated fatty acids increased the sterol capacity of micelle preparations. However, no differences were detected in phospholipid content, indicating an additive rather than substitutive change.

Micelle Size

Elution volume was used as a surrogate marker of micelle size [16]. No differences were seen in elution volumes, indicating no detectable differences in micelle sizes across all sterol and fatty acid combinations (data not shown).

Discussion

Phytosterols and their esters are potent nutraceuticals. Understanding the mechanisms by which phytosterols lower serum LDL cholesterol may be important in optimizing a more potent phytosterol treatment. Variations in the fatty acid [8] and sterol [17] components of phytosterol esters can result in different efficacies with regard to cholesterol lowering. One mechanism by which this difference could occur is through differences in rates of hydrolysis of the esters. However, we previously demonstrated no differences in the hydrolysis of sitosterol and stigmastanol

esters or stearate and palmitate esters by pancreatic cholesterol esterase (EC 3.1.1.13) in vitro, and thus efficiency of hydrolysis likely does not directly determine the unique properties of some phytosterol esters [9]. Another mechanism for decreasing serum cholesterol concentrations could be diminishing cholesterol absorption by decreasing intestinal micellar cholesterol in the presence of mixtures of free fatty acids, free phytosterols, and/or intact phytosterol esters. We therefore examined the effects of sterol esters and their simulated hydrolysis products in a model bile, mixed-micelle system to approximate the effects of dietary sterols on biliary cholesterol, which is quantitatively more important than dietary cholesterol with regards to cholesterol absorption [18].

The model bile, mixed micelle system we used was created by using a combination of bile acids [7, 12, 13], while the ratio of cholesterol to phytosterol approximated the relative amounts of the sterols in the intestinal lumen during phytosterol supplementation. On average, 1,000 mg of cholesterol are secreted into the small intestine from the gall bladder daily [18], and the United States Cholesterol Education Program recommends up to 2,000 mg/day of phytosterols to lower serum cholesterol [19]. We therefore chose equal concentrations of sterols in the model micelle preparations to examine equal competition for micelle solubilization, as well as concentrations up to the 2:1 ratio of phytosterol to cholesterol that is expected in the intestinal lumen when consuming the recommended dose of phytosterols in order to examine dose-dependent effects. By examining equal ratios of phytosterol:cholesterol:free fatty acid, we also modeled the effects of complete hydrolysis of phytosterol esters on biliary cholesterol.

In this study, we demonstrated that intact phytosterol esters do not alter cholesterol micelle solubility, nor do they incorporate at a detectable level into mixed bile-salt/phosphatidylcholine micelles. In vivo models, however, demonstrate that both free and esterified sterols impart cholesterol-lowering effects [1]. This apparent discrepancy reinforces the concept that sterol esters must be first hydrolyzed to impart their cholesterol-lowering properties. The direct influence of phytosterol esters on enterocytes or intestinal phase compositions, however, cannot be precluded. Indeed, Nissinen and colleagues detected esters and free sterols in both the oily and aqueous fractions of jejunal aspirates [20]. The presence of esters in what was labeled the 'micellar phase' in the jejunal contents, combined with the absence of esters in micelles in our model, may indicate that esters are suspended in small lipid droplets [21] or solubilized in an aqueous particle other than mixed bile salt micelles in vivo.

The effects of fatty acids on the micellar solubility of sterols have been little studied. Previous results implicating improved cholesterol-lowering effects of stearic acid-containing phytosterol esters [8] led us to investigate the simulated hydrolysis products of various phytosterol esters, with the hypothesis that the stearic acid-containing micelles would solubilize less cholesterol when compared to micelles prepared with other fatty acids. While our data did indicate a lower cholesterol content in stearic acid-enriched micelles, the effect was not unique to stearic acid, but was also seen in palmitic acid-enriched micelles as well as micelles prepared without fatty acids. In addition, the difference between cholesterol content in micelles that incorporated unsaturated and saturated fatty acids was small (1.23 vs. 1.08 mM, respectively) compared to the 70% decrease in non-HDL cholesterol and the 85% decrease in cholesterol absorption observed in hamsters fed stearic acid esters of phytosterols [8]. Thus, the dietary effects of stearic acid-enriched phytosterol esters are likely not completely explained by decreasing the micellar solubility of cholesterol.

In a study of phytosterol esters derived from three oils used as supplements in humans (olive, sunflower, fish), no differences were observed among the treatment groups with regard to serum cholesterol concentrations [22], consistent with the similar cholesterol solubilization observed in the present study among micelles containing different unsaturated fatty acids. Conversely, another study showed that esterifying phytosterols with long chain omega-3 fatty acids synergistically lowered cholesterol, and the authors surmised that the effect was the result of decreasing micelle solubility [23]. Our data indicate the opposite: unsaturated fatty acids increased micellar cholesterol. Although the only omega-3 fatty acid we investigated was α-linolenic acid, whereas they used eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, our data suggest that if there is a unique effect of EPA and DHA on micellar cholesterol solubility, it is likely not the result of the degree of unsaturation or the omega-3 positioning of a double bond.

A number of studies have examined the thermodynamics of sterol solubilities in micelles and have demonstrated competition between cholesterol and other sterols for incorporation into micelles [4, 5, 7, 24, 25]. Although we also observed this competition, our results contrast markedly with those from several other studies. For instance, we found that four different phytosterols decreased cholesterol solubility to a very similar extent. Stigmasterol was, by a small margin, the most potent of the four, decreasing the concentration of micellar cholesterol and total solubilized sterols. This result is in contrast to a previous study on the solubility of cholesterol in sodium taurodeoxycholate micelles [4] that found stigmasterol to have the smallest effect among the sterols tested. The same study reported poor relative solubility of individual phytosterols in their system compared to cholesterol, whereas we observed almost equal solubility. The results of that study were

consistent with ours in terms of total sterol solubility: in their binary (two sterol) systems, total sterol content was relatively equal. On the other hand, a third study that used micelles of sodium taurocholate and oleate demonstrated an approximately 50% decrease in total solubilized sterol as the amount of sitosterol was increased [2]. In contrast, our dose-dependence experiment demonstrated no decrease in total solubilized sterol, but instead showed a 1:1 substitution of stigmasterol for cholesterol. The competition model we demonstrated does, however, reinforce the observations of Armstrong and Carey that micelles have a limited number of binding sites [5].

The disparities in results in sterol solubility studies probably reflect the differences in the micellar systems employed. The work reported here is based upon a model bile system, whereas other systems often use a single bile salt with or without another lipid component such as oleate. While these simpler systems do provide insight into the inherent solubility of various sterols in bile salt micelles, they may be less effective as models of intestinal micellar solubilization. Indeed, the lack of difference between individual phytosterols in our studies coincides with observations in clinical and animal trials. For example, similar decreases in serum cholesterol reduction were observed in humans upon administration of different combinations of phytosterols [26]. Analogous outcomes have been observed in rats [27] and hamsters (Ash and Carr, unpublished data) fed phytosterol esters varying only in the sterol component. It is likely that the differences in solubilities arise from the micelle composition, as the bile salt type and concentration both affect the solubility of sterols [5], as well as the presence of lyso- or phospholipids [28], oxidation of fatty acids [29], and amount of fatty acid [2]. The complexity of bile, then, is likely better able to accommodate different sterols than simpler systems. However, the decreased cholesterol solubilities when stigmasterol and saturated fatty acids are present may indicate that the combination of these components is more effective at decreasing cholesterol solubility in micelles than other combinations, though in vivo experiments must be conducted to validate these results on serum cholesterol and cholesterol absorption.

Abstract *N*-Acylethanolamines (NAE) are fatty acid derivatives, some of which function as endocannabinoids in mammals. NAE metabolism involves common (phosphatidylethanolamines, PEs) and uncommon (*N*-acylphosphatidylethanolamines, NAPEs) membrane phospholipids. Here we have identified and quantified more than a hundred metabolites in the NAE/endocannabinoid pathway in mouse brain and heart tissues, including many previously unreported molecular species of NAPE. We found that brain tissue of mice lacking fatty acid amide hydrolase ($FAAH^{-/-}$) had elevated PE and NAPE molecular species in addition to elevated NAEs, suggesting that FAAH activity participates in the overall regulation of this pathway. This perturbation of the NAE pathway in brain was not observed in heart tissue of $FAAH^{-/-}$ mice, indicating that metabolic regulation of the NAE pathway differs in these two organs and the metabolic enzymes that catabolize NAEs are most likely differentially distributed and/or regulated. Targeted lipidomics analysis, like that presented here, will continue to provide important insights into cellular lipid signaling networks.

Introduction

Endocannabinoids are endogenous lipid mediators that bind to and activate cannabinoid receptors in mammals to regulate a wide range of physiological and behavioral processes [1, 2]. The first endocannabinoid discovered was anandamide [3], or *N*-arachidonylethanolamine (a type of *N*-acylethanolamine, 20:4 NAE). It was promptly revealed that anandamide and other members of its class are generated as part of a metabolic pathway involving the common membrane lipid phosphatidylethanolamine (PE) and an unusual *N*-acylated derivative of PE, *N*-acylphosphatidylethanolamine (NAPE; reviewed in [4]). Although earlier research had established the metabolic relationship between these lipid classes in mammals and characterized the enzyme activities involved [5], molecular identification of fatty acid amide hydrolase (FAAH) was a critical step, leading to the ability to perturb the NAE metabolic pathway in order to further elucidate the pathway's physiological functions [6–8].

The overall pathway, termed the *N*-acylation-phosphodiesterase pathway, has more recently been designated the "endocannabinoid signaling pathway" to reflect its physiological function [9, 10]. However, this designation does not indicate the role of the pathway during response to ischemia; in fact, most of the early metabolic studies of this pathway were related to observations that both NAE and NAPE contents were elevated markedly in ischemic brain and heart tissues [11–14]. The overall endocannabinoid pathway, the structures of representative principal metabolite classes, and key enzymatic steps are summarized in Fig. 1.

Although the function of the endocannabinoid pathway relies mostly on the production and turnover of bioactive NAEs, the precursor pools of NAPEs can determine the prevailing mix of endogenous NAEs [4]. Indeed, a concept called the "entourage effect" has been proposed to explain how abundant NAE molecular species that do not activate cannabinoid receptors can influence the activity of minor components, such as 20:4 NAE, that do activate receptors. To date, the many ethanolamine lipid components of the NAE-metabolic pathway have rarely been profiled comprehensively and concomitantly [15–17]. Here, we employ a targeted lipidomics approach to exhaustively identify and quantify the major and minor PE, NAPE, and NAE species in mouse heart and brain tissues and examine the impact of the loss of FAAH in $FAAH^{-/-}$ mice [18] on the metabolites of the endocannabinoid pathway.

In the current work, *O*-diacyl and *O*-alk(en)yl,*O*-acyl PE and NAPE molecular species were identified directly in lipid extracts by electrospray ionization mass spectrometry (ESI-MS) using neutral loss scans and quantifying in relation to internal standards. NAEs were identified by GC-MS after chromatographic clean-up and quantified by isotope dilution MS, using procedures similar to those developed elsewhere [19]. Our results detail the metabolites of this important lipid signaling pathway. Moreover,

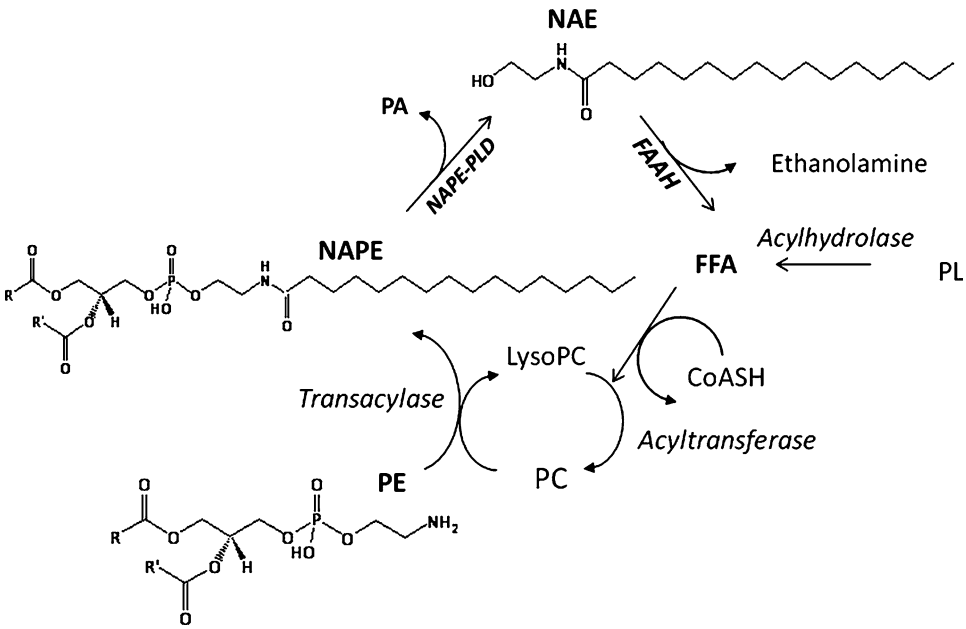

Fig. 1 *N*-acylethanolamine (NAE) metabolism in mammals. NAEs are derived from the hydrolysis of a minor membrane lipid, *N*-acylphosphatidylethanolamine (NAPE), by a phospholipase D (PLD) and are hydrolyzed by a fatty acid amide hydrolase (FAAH) into ethanolamine and free fatty acid (FFA). NAPEs are synthesized from free fatty acid (FFA) via a coordinated acyltransferase-transacylase reaction in which the *sn*-1-*O*-acyl moiety of phosphatidylcholine (PC) generated is transferred to the *N*-atom of phosphatidylethanolamine (PE)

the results suggest that ablation of FAAH in brain tissue results in dysregulation throughout the pathway, not just in anandamide content, as previously reported, while similar effects were not apparent in heart tissue [18, 20]. Comprehensive profiling approaches like those utilized here enable understanding of the metabolic regulation of important signaling pathways.

Experimental Procedures

Animals and Tissue Extracts

FAAH$^{-/-}$ mice were kindly provided by Dr. Benjamin F. Cravatt, The Scripps Research Institute, La Jolla, CA, and were genotyped as described previously [18]. Wild-type littermate control mice were used for comparisons. Animals were kept in a temperature-controlled room with 12-h light/dark cycles and free access to food and water. Animal use and care were reviewed and approved by the Institutional Animal Care and Use Committee. For each treatment, after euthanasia, brains and heart tissue from five animals were removed and flash frozen in liquid nitrogen.

Lipid Extractions

For glycerolipid analyses, tissues were homogenized with hot 2-propanol (70°C) with glass beads by beating for five 30-s bursts and combined with chloroform (0.45 g FW:2 ml 2-propanol:1 ml chloroform), and incubated on ice for 30 min before extracting overnight at 4°C. Monophasic lipid extracts were partitioned with chloroform and 1 M KCl (1:2 v/v). The lower organic phase was collected and washed three additional times with 2 volumes of 1 M KCl. Extracts were stored under nitrogen at −80°C until further analysis.

Phospholipid Analysis and Quantification

An automated electrospray ionization (ESI)-tandem mass spectrometry approach was used, and data acquisition was carried out as described previously [22] with modifications. Dried mouse brain and heart lipid extracts were dissolved in 1 ml chloroform/methanol (9:1). An aliquot of 2–30 µl of extract, equivalent to 0.5–2 mg tissue FW, was used. Precise amounts of internal standards, obtained and quantified as previously described [24], were added in the following quantities (with some small variation in amounts in different batches of internal standards): 0.66 nmoles of di14:0 PC, di24:1 PC, 13:0 lysoPC, and19:0 lysoPC, 0.36 nmoles of di14:0 PE, di24:1 PE, 14:0 lysoPE, 18:0 lysoPE, di14:0 PA, and di20:0 (phytanoyl) PA, 0.24 nmol di14:0 PS and di20:0 (phytanoyl) PS, 0.20 nmoles of 16:0–18:0 PI, and 0.16 nmoles of di18:0 PI. Solvent was added to the sample/standard mixture so that the final ratio of chloroform/methanol/300 mM ammonium acetate in water was approximately 300:665:35, and the final volume was 1.3 ml.

Mass spectra were acquired on a triple quadrupole MS/MS system (API 4000, Applied Biosystems, Foster City, CA). Unfractionated samples were introduced by continuous infusion into the Turbo V ESI source at 30 µl/min using an autosampler (LC Mini PAL, CTC Analytics AG, Zwingen, Switzerland) fitted with the required injection loop for the acquisition time. Sequential precursor and neutral loss scans of the extracts produced a series of spectra, with each spectrum revealing a set of lipid species containing a common head group fragment. Lipid species were detected in positive mode with the following scans: PC and lysoPC, $[M + H]^+$ ions with precursors of 184.1 (Pre 184.1); PE and lysoPE, $[M + H]^+$ ions with neutral loss of 141.0 (NL 141.0); PI, $[M + NH_4]^+$ ions with NL 277.0; PS, $[M + H]^+$ ions with NL 185.0; and PA, $[M + NH_4]^+$ ions with NL 115.0. The ion spray voltage was set at +5.5 kV, the source temperature at 100°C, the curtain gas at 20 (arbitrary units), and the ion source gases at 45 (arbitrary units); the interface heater was on. Declustering potentials were +100 V. Entrance potentials were +15 V for PE and +14 V for PC, PI, PA, and PS. Exit potentials were +11 V for PE and +14 V for PC, PI, PA, and PS. The collision gas, nitrogen, was set at 2 (arbitrary units). The collision energies were +28 V for PE, +40 V for PC, and +25 V for PI, PS and PA. The mass analyzers were adjusted to a resolution of 0.7 u full width at half height. For each spectrum, 8–80 continuum scans were collected in multiple channel analyzer (MCA) mode at a scan speed of 50 or 100 u per s.

The data were smoothed, the background of each spectrum was subtracted, and the peaks were centroided and integrated using custom script and Applied Biosystems Analyst software. Peaks corresponding to the target lipids in these spectra were identified, the data were corrected for isotopic overlap, and molar amounts were calculated in comparison to the internal standards in the same lipid class. A sample containing internal standard mixture only was also run through the same series of scans to correct for chemical or instrumental noise. The molar amounts of each lipid metabolite detected in the "internal standards-only" spectra were subtracted from the molar amounts of each metabolite calculated from the experimental mouse sample spectra. The "internal standards-only" spectra were used to correct the data from the following nine samples run on the instrument. Finally, the data were adjusted to account for the fraction of sample analyzed and normalized to the sample fresh weight. Data were reported as nmol or µmol of each detected lipid metabolite/g tissue FW. Measured

metabolite species include both diacyl and alk(en)yl,acyl glycerophospholipids. Although these two groups may exhibit some differences in mass spectral response, values for the alk(en)yl,acyl (as well as diacyl) species were quantified in relation to the diacyl/monoacyl phospholipid internal standards, and no response correction factors were employed for the alk(en)yl,acyl species.

NAPE Standard Acquisition and Synthesis

C17:0 fatty acid chloride was purchased from Nu-Check Prep (Elysian, MN); 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (di16:0 PE) and 1,2-dioleoyl-*sn*-glycero-3-phospho(*N*-arachidonoyl)ethanolamine (*N*-20:4 di18:1 PE) were from Avanti Polar Lipids (Alabaster, AL); 1-2-dipalmitoyl-*sn*-glycero-3-phospho(*N*-palmitoyl)ethanolamine (*N*-16:0 di16:0 PE) was from Sigma-Aldrich (St. Louis, MO); TLC plates (10 × 20 cm, scored, HPTLC-GHL silica gel, 150 μm) were from Analtech (Newark, DE). Other organic solvents and reagents were of the highest purity commercially available.

The NAPE molecular species *N*-17:0 di16:0 PE was prepared as described previously [23], with modifications. Briefly, C17:0 fatty acid chloride was reacted with a two-fold molar excess of di16:0 PE. The reaction was conducted in dichloromethane at 25°C for 2 h, using triethylamine as a catalyst. The products were washed with water and fractionated by silica gel TLC (chloroform/methanol/ammonia, 65:35:4) to separate the desired product NAPE species from unreacted PE and fatty acid chloride. The calculated retention factors for NAPE and PE were 0.60 and 0.40, respectively. Both the purchased and synthesized NAPE species were quantified by phosphate assay [25].

NAPE Analysis and Quantification

As noted above in the phospholipid analysis section, dried mouse brain and heart lipid extracts were dissolved in chloroform/methanol (9:1). The same sample solutions were used for both phospholipid and NAPE analysis. The synthesized *N*-17:0 di16:0 PE was employed as an internal standard to quantify the NAPE species in the sample extracts. *N*-17:0 di16:0 PE (1.1 nmole) was added to an aliquot of extract equivalent to 6–25 mg tissue FW. Solvent was added to the sample/standard mixture so that the final ratio of chloroform/methanol/300 mM ammonium acetate in water was 300:665:35, and the final volume was 1.3 ml.

Mass spectra were acquired on a triple quadrupole MS/MS system (API 4000 QTrap, Applied Biosystems, Foster City, CA). Unfractionated samples were introduced by continuous infusion into the Turbo V ESI source at 30 μl/min using an autosampler (LC Mini PAL, CTC Analytics AG, Zwingen, Switzerland) fitted with the required injection loop for the acquisition time. Sequential neutral loss scans produced a series of spectra, with each spectrum revealing a set of lipid species containing a common ammoniated *N*-fatty amide head group fragment corresponding to each common fatty acid. Lipids were detected in positive ion mode as $[M + NH_4]^+$ ions with the following scans: *N*-16:0 species with NL 396.3, *N*-18:2 species with NL 420.3, *N*-18:1 species with NL 422.3, *N*-18:0 species with NL 424.3, *N*-20:4 species with NL 444.3, *N*-22:6 species with NL 468.3, and *N*-22:5 species with NL 470.3. A scan for *N*-17:0 species (NL 410.3) was included in order to detect the internal standard. The declustering potential was set at +60 V, the entrance potential at +8 V, and the exit potential at +15 V. The ion spray voltage was set at +5.5 kV. The collision gas, nitrogen, was set at 2 (arbitrary units), and the collision energy was +45 V. The source temperature, curtain gas, ion source gases, interface heater, and mass analyzers were adjusted as for phospholipid analysis. For each spectrum, 100 cumulative scans were collected in multiple channel analyzer (MCA) mode at a scan speed of 50 u per s.

The data were smoothed, the background of each spectrum was subtracted, and the peaks were centroided and integrated using custom script and Applied Biosystems Analyst software. Peaks corresponding to the target lipids in each *N*-acyl class (each spectrum) were identified, the data were corrected for isotopic overlap due to the diacylglycerol portion of NAPE, and molar amounts were quantified relative to the *N*-17:0 di16:0 PE internal standard. A sample containing only the *N*-17:0 di16:0 PE standard was subjected to the same series of scans. The molar amounts of each lipid metabolite detected in the "standard-only" spectra were subtracted from the molar amounts of each metabolite calculated from the experimental mouse sample spectra to correct for chemical or instrumental noise. The "standard-only" spectra were used to correct the data from the following nine samples run on the instrument. Finally, the data were corrected for isotopic overlap between head groups (NL fragments), adjusted to account for the fraction of sample analyzed, and normalized to the sample fresh weight. Due to the presence in the NL 444.3 scan of peaks with *m/z* inconsistent with NAPEs in the *m/z* range of *N*-20:4-e40:7, *N*-20:4-e40:6, *N*-20:4-40:8, and *N*-20:4-40:7 NAPEs, these compounds were not measured in brain tissues. The interfering compounds were not present in the spectra of mouse heart tissue. Data were reported as mass spectral signal normalized to *N*-17:0 di16:0 PE/g tissue FW; the amount of signal produced by 1 pmol of *N*-17:0 di16:0 PE is 1. Data were evaluated for possible outliers using the *Q*-test [26] on NAPE lipid class totals; one *FAAH* ($^{-/-}$) mouse brain replicate (out of 5) was determined to be an outlier and was removed from

calculations. Measured species include both *N*-acylated diacyl and *N*-acylated alk(en)yl,acyl glycerophospholipids. As described for the phospholipid species, no response correction factors were employed for the alk(en)yl,acyl species.

Validation of NAPE Quantitation Method

Three experiments were performed to validate the above sequential NL scanning method for NAPE quantitation. To assess the linearity of the response, varied amounts (10–1,000 pmol) of the purchased *N*-16:0 di16:0 PE and *N*-20:4 di18:1 PE were analyzed in the presence of 200 pmol of the synthesized *N*-17:0 di16:0 PE internal standard. An abbreviated mass spectral analysis with scans for *N*-16:0, *N*-20:4, and *N*-17:0 NAPEs was performed on the API 4000 mass spectrometer. Responses of the *N*-16:0 di16:0 PE and *N*-20:4 di18:1 PE signals relative to the *N*-17:0 standard were measured.

The ability of ESI-MS/MS NAPE profiling to detect small changes in NAPE molecular species levels was also evaluated. Purchased *N*-16:0 di16:0 PE and *N*-20:4 di18:1 PE were utilized. Stepwise-increasing known amounts of these two species (4, 8, 20, and 60 pmol for the *N*-16:0 compound; 5, 10, 25, and 75 pmol for the *N*-20:4 compound) were spiked into samples containing roughly a 10 mg FW equivalent of a mixture of WT and $FAAH^{-/-}$ mouse brain extract. Each sample also contained 100 pmol of the synthesized *N*-17:0 di16:0 PE internal standard. An abbreviated mass spectral analysis with scans for *N*-16:0, *N*-20:4, and *N*-17:0 NAPE was performed on the API 4000 QTrap mass spectrometer. Responses of the targeted *N*-16:0 and *N*-20:4 compounds relative to the *N*-17:0 standard were calculated.

The variation in mass spectral response due to variation in the amount of biological sample analyzed was also examined. Samples were prepared with varying amounts of a mixture of WT and $FAAH^{-/-}$ mouse brain extract, approximately equivalent to 3.5, 7, 14, and 28 mg FW, and 200 pmol of the synthesized *N*-17:0 di16:0 PE internal standard. The full mass spectral analysis, with scans for *N*-16:0, *N*-18:2, *N*-18:1, *N*-18:0, *N*-20:4, *N*-22:6, *N*-22:5, and *N*-17:0, was performed on the API 4000 QTrap mass spectrometer. Data were processed as described above and reported as mass spectral signal of each targeted NAPE species relative to the *N*-17:0 di16:0 PE internal standard.

NAE Analyses

NAE extraction and purification were conducted as described by Muccioli and Stella [29]. Brain and heart tissues (mean fresh weights of 425 mg and 170 mg, respectively) from $FAAH^{-/-}$ and WT animals were removed from −80°C storage and homogenized in ice cold chloroform (1 ml per 100 mg of fresh tissue) using a glass tissue grinder. The homogenate was placed in an ultrasonic bath (60 W) for 2 min to disrupt cells. The extract was combined with 10 ml of ice cold chloroform containing deuterated NAE standards (D4-NAE 16:0 and D4-NAE 20:4, Cayman Chemical Co., Ann Arbor, MI; 50 ng each). Lipids were extracted by extraction (4:2:1 chloroform:methanol:water) by the addition of 5 ml cold methanol and 2.5 ml cold PBS buffer and returned to an ice cold ultrasonic (60 W) water bath for 10 min, followed by centrifugation. The organic phase was collected for further purification by solid phase extraction.

Silica SPE cartridges (100 mg, 1.5 ml; Grace Davison Discovery Sciences, Deerfield, IL) were conditioned with 2 ml methanol followed by 4 ml chloroform and, subsequent to loading the samples, the column was washed with 2 ml chloroform, and NAEs were eluted with 2 ml of 1:1 (v/v) ethyl acetate:acetone. The eluate was collected, evaporated under nitrogen, and derivatized with 50 µl BSTFA (Fisher Scientific, Houston, TX) and 25 µl dichloromethane for 30 min at 55°C. After derivatization, the samples were again evaporated under nitrogen and reconstituted in 50 ul hexane.

NAEs were identified via selective ion monitoring and quantified against the internal deuterated standards (saturated species against deuterated NAE 16:0 and unsaturated species against deuterated NAE 20:4) as TMS-ether derivatives by gas chromatography/mass spectrometry (model 6890 GC coupled with a 5973 mass selective detector; Agilent, Wilmington DE), as described previously [21]. NAE concentration was calculated based on fresh weight.

Results

In previous work, methods for analysis of NAEs by GC-MS [21] and phospholipids by direct infusion electrospray ionization mass spectrometry [27] were developed. Here, in order to comprehensively analyze lipids in the NAE biosynthetic pathway, we developed a method for direct infusion electrospray ionization mass spectrometry analysis of NAPE species. In solvent containing ammonium acetate, NAPE species form positively charged ammonium adducts $[M + NH_4]^+$ by electrospray ionization. By collision-induced dissociation, the ammonium adducts of NAPEs can be fragmented into a neutral head group fragment and a charged diradylglycerol (i.e., diacylglycerol or alk(en)yl, acylglycerol) fragment (Fig. 2). Scanning for neutral loss of an ammoniated *N*-fatty amide head group in a triple quadrupole mass spectrometer produces a spectrum revealing the NAPE molecular species that contain the

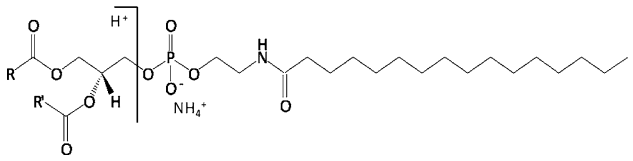

Fig. 2 Collision induced fragmentation of the ammonium adduct of *N*-16:0 PE

fragment, in other words, a spectrum of the NAPE class (Fig. 3). Sequential scanning for neutral loss of ammoniated *N*-fatty amide head groups corresponding to each common fatty acid provides a method to detect the molecular species of NAPE in all *N*-acyl classes (Fig. 3).

To determine whether neutral loss scanning provides an appropriate method for quantification, the linearity of the mass spectral response of the neutral loss scans was investigated (Fig. 4). The signals for two pure NAPEs were determined in relation to the signal from a known quantity of an internal standard, *N*-17:0 di16:0 PE. The response was determined to be linear, but both *N*-16:0 di16:0 PE and *N*-20:4 di18:1PE produced somewhat less signal per mole than *N*-17:0 di16:0 PE. This suggests that different NAPE molecular species vary somewhat in their ability to ionize and/or to undergo fragmentation under particular fixed mass spectral conditions. On the other hand, a spike-in experiment in which pure NAPE species were added to a biological mixture of lipids showed that their mass spectral signals, normalized to the *N*-17:0 di16:0 PE internal standard, were approximately proportional to the amount of each NAPE species added (Fig. 5). Finally, varying amounts of the biological sample while holding the level of internal standard constant resulted in normalized mass spectral responses proportional to the amount of sample added (Fig. 6). Taken together, the data in Fig. 3 through 6 show that, although response factors for individual NAPE molecular species vary (Fig. 3), the NAPE analysis provides a reliable means to compare levels of NAPE species among samples.

Endocannabinoid metabolism is influenced by both phospholipase D (PLD)-mediated hydrolysis of NAPE and FAAH-mediated breakdown of NAEs (Fig. 1). We examined the effect of FAAH disruption on the content and composition of NAE and various phospholipids, including NAPE and PE, in brain and heart tissue of wild-type and $FAAH^{-/-}$ mice. Total levels are summed from the individual molecular species. The data show that lipid content was generally higher in brain than in the heart tissue (Fig. 7). Compared to brain, heart phospholipids had little PS or PA. Both total NAE and PE content were significantly elevated in brain tissue of $FAAH^{-/-}$ mice compared to the wild-type controls. On the other hand, in heart tissue there was a significant increase only in PE, PI, and lysoPC content, while NAE content was the same between $FAAH^{-/-}$ and control mice.

To examine the relationship between NAE composition and the NAPE precursor pool, NAPEs were quantified according to *N*-acyl head group and these NAPE classes

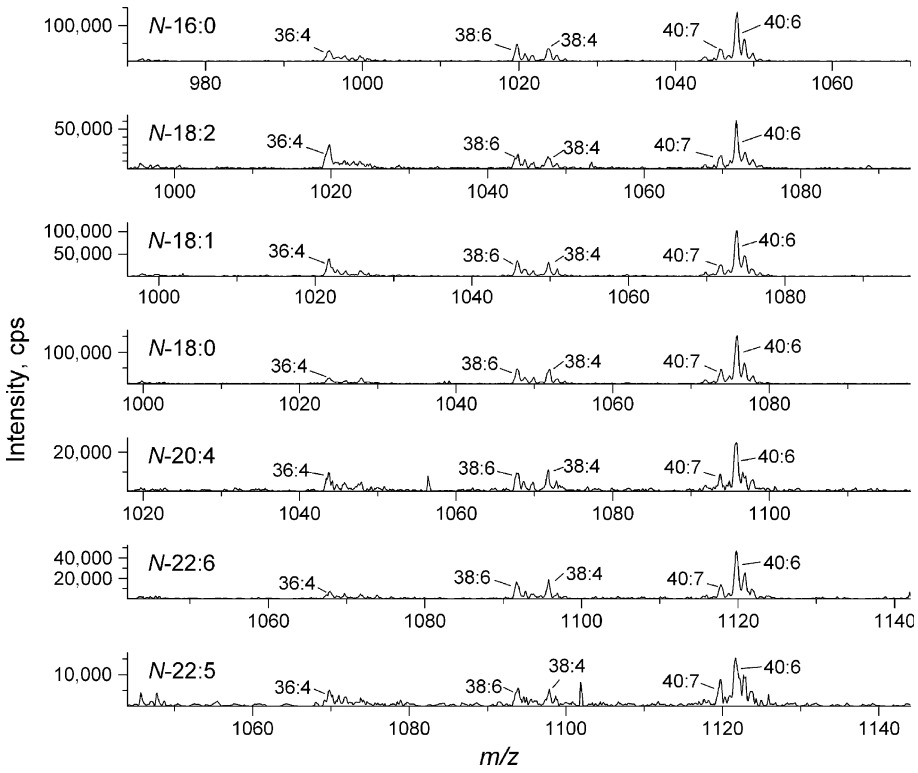

Fig. 3 Neutral loss scans targeting analysis of NAPE species with varying *N*-acyl groups. From top to bottom panels, the scans target *N*-16:0 PE (NL 396.3), *N*-18:2 PE (NL 420.3), *N*-18:1 PE (NL 422.3), *N*-18:0 PE (NL 424.3), *N*-20:4 PE (NL 444.3), *N*-22:6 PE (NL 468.3), and *N*-22:5 PE (NL 470.3) in mouse heart extract corresponding to 6–25 mg FW. The labels indicate the diacyl component (total acyl carbons: total carbon–carbon double bonds) of each detected NAPE

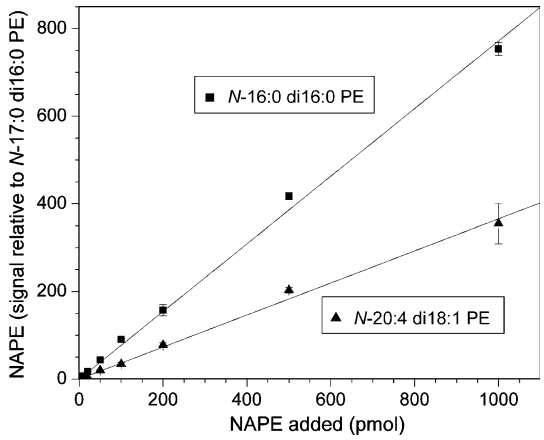

Fig. 4 Linearity of the mass spectral response. Varying amounts of *N*-16:0 di16:0 PE and *N*-20:4 di18:1 PE were combined with 200 pmol of internal standard *N*-17:0 di16:0 PE. Neutral loss signals for each NAPE molecular species are presented in relation to the signal from the internal standard; the amount of signal produced by 1 pmol of *N*-17:0 di16:0 PE is 1. $N = 5 \pm$ SD

were compared to the principal NAE types. Absolute quantities of NAPE and NAE and their composition were quite different between brain and heart tissue of mice (Figs. 8 and 9, respectively). The significantly higher level of NAE in the brain tissue of $FAAH^{-/-}$ mice, as compared to wild-type mice, was attributable mostly to 16:0 NAE (Fig. 8); the level of *N*-16:0 PE was also significantly higher in the brain tissue of $FAAH^{-/-}$ mice, as compared to wild-type mice. The concentration of 18:0 NAE species was higher in brain tissue of $FAAH^{-/-}$ mice as well. In contrast to predominant 16:0 NAEs and *N*-16:0 PEs in brain, heart tissue did not reveal a prevalent NAPE class or NAE type. Murine hearts showed no differences between $FAAH^{-/-}$ and wild-type animals in NAE types or NAPE classes. This suggests that FAAH disruption has a considerably greater effect on steady-state levels of endocannabinoid pathway metabolites in brain tissue than in heart tissue. Major differences in steady-state anandamide levels in brain extracts between $FAAH^{-/-}$ mice and wildtype littermates were not evident in our studies, which was inconsistent with previous reports quantifying 15-fold higher anandamide levels in brain tissues of $FAAH^{-/-}$ mice compared to FAAH+/+ mice [20, 28]. Differences may be due to organ preparation (euthanasia rather than decapitation) and/or tissue extraction procedures since anandamide levels seem to be particularly sensitive to preparation methods [29]. Nonetheless, the principal saturated NAE types (NAE18:0 and NAE16:0) quantified in our samples showed a significant elevation in brain tissues of knockout mice as expected (Fig. 8).

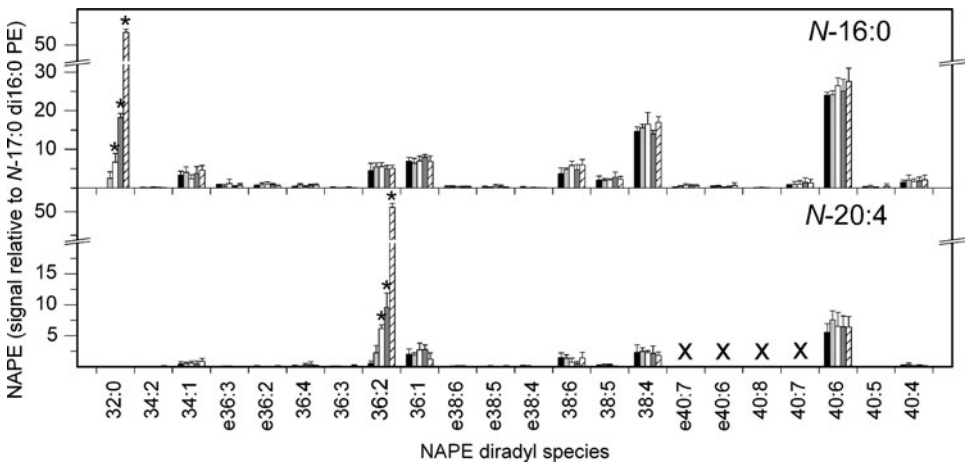

Fig. 5 The ability of ESI-MS/MS lipid profiling to detect small changes in NAPE molecular species. The lipid species in roughly 10 mg FW of mouse brain were analyzed and, to demonstrate the ability of the lipid profiling methodology to detect changes, small, known amounts of specific lipid species were added to the extract. One hundred pmol of internal standard *N*-17:0 di16:0 PE was added to each sample to provide quantitation. Neutral loss scans were performed as described in Experimental Procedures. Signals for each NAPE molecular species are presented in relation to the signal of internal standard *N*-17:0 di16:0 PE; the amount of signal produced by 1 pmol of *N*-17:0 di16:0 PE is 1. The additions of the lipid species indicated by the *asterisks* varied over a 15-fold range (with *bars* for each species representing no addition, 1× addition, 2× addition, 5× addition, and 15× addition). Specifically, the *black bars* (first series) represent the composition of the extract. The light *gray bars* (second series) represent extract with 4 pmol *N*-16:0 di16:0(32:0) PE and 5 pmol *N*-20:4 di18:1(36:2) PE added. The *white bars* (third series) represent extract with 8 pmol *N*-16:0 di16:0(32:0) PE and 10 pmol *N*-20:4 di18:1(36:2) PE added. The *dark gray bars* (fourth series) represent extract with 20 pmol *N*-16:0 di16:0(32:0) PE and 25 pmol *N*-20:4 di18:1(36:2) PE added. The *hatched bars* (fifth series) represent extract with 60 pmol *N*-16:0 di16:0(32:0) PE and 75 pmol *N*-20:4 di18:1(36:2) PE added. Designations for diradyl molecular species are: numbers only represent diacyl species as total acyl carbons: total carbon–carbon double bonds; e before a number indicates an ether-linked (alk(en)yl,acyl) species as total alk(en)yl + acyl carbons: total carbon–carbon double bonds, including any vinyl ether bonds present. "X" indicates molecular species that were not determined (see "Experimental Procedures"). $N = 5 \pm$ SD

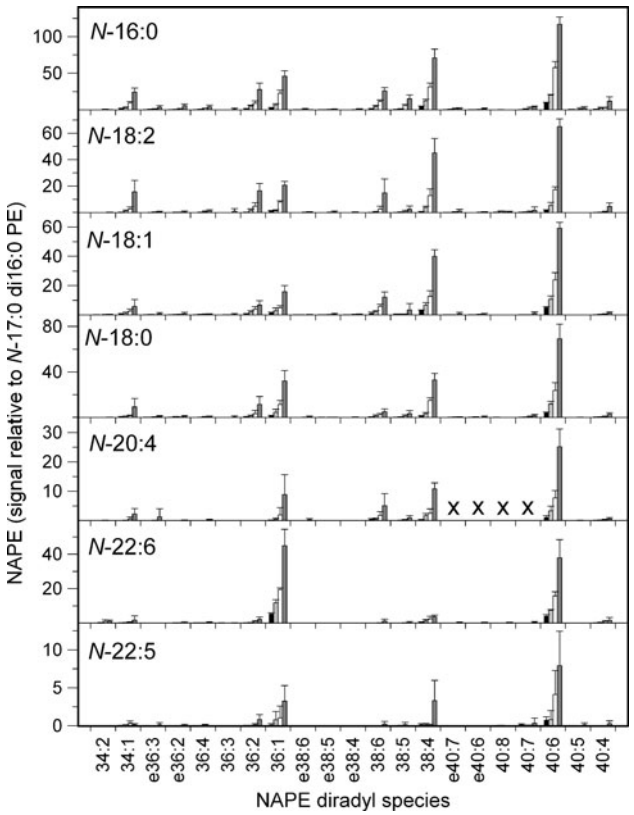

Fig. 6 Variation in mass spectral response with variation in amount of biological sample. Varying amounts of mouse brain extract were combined with 200 pmol of internal standard N-17:0 di16:0 PE. The amounts of mouse brain extract corresponded to approximately 3.5 mg FW (*black bars*, first series), 7 mg FW (*light gray bars*, second series), 14 mg FW (*white bars*, third series), and 28 mg FW (*dark gray bars*, fourth series). Neutral loss signals for each NAPE molecular species are presented in relation to the signal from the internal standard; the amount of signal produced by 1 pmol of *N*-17:0 di16:0 PE is 1. Designations for diradyl molecular species are: numbers only represent diacyl species as total acyl carbons: total carbon–carbon double bonds; e before a number indicates an ether-linked (alk(en)yl,acyl) species as total alk(en)yl + acyl carbons: total carbon–carbon double bonds, including any vinyl ether bonds present. "X" indicates molecular species that were not determined (see "Experimental Procedures"). $N = 5 \pm$ SD

Although useful for visualizing potential NAE precursors, grouping of NAPE species by common *N*-acyl chains (Figs. 8, 9) does not reveal the remarkable complexity of NAPEs. Therefore, a detailed molecular species profile of NAPE was generated for brain and heart tissue of wild-type and $FAAH^{-/-}$ mice (Figs. 10, 11). In brain tissue of mice, the most abundant molecular species with 16:0 at the *N*-position contained PE 36:2, 36:1, 38:6, 38:4, and 40:6, where the species are indicated by total acyl carbons:total carbon–carbon double bonds in the combined acyl chains in the 1 and 2 positions on the glycerol (Fig. 10). Many *N*-16:0-containing species were significantly elevated in knockout mice compared to wild type, suggesting that the elevation of the *N*-16:0 PE molecular species in $FAAH^{-/-}$ mice affected those molecular species already prevalent in wild-type mice. *N*-18:2-containing NAPE molecular species were much less abundant overall; only five molecular species were quantified at more than 0.1 nmol/g FW, and none of these were elevated in $FAAH^{-/-}$ brain tissue (Fig. 10). *N*-18:1 and *N*-18:0 molecular species were somewhat more abundant and distributed among diradyl species in a manner similar to *N*-16:0 PEs; several molecular species were significantly higher in the $FAAH^{-/-}$ knockout tissues (Fig. 10). The anandamide-containing (*N*-20:4) NAPE pool was relatively minor in terms of overall abundance, and this subgroup showed no differences between wild-type and $FAAH^{-/-}$ in terms of quantity or composition. Similarly, the *N*-22:6 PE molecular species were not very abundant, and the *N*-22:5 PE class was very minor in brain tissue, with only a few molecular species identified in this subgroup. There were no significant differences in *N*-22:6 and *N*-22:5 PE species between wild-type and $FAAH^{-/-}$ mice.

Similar to brain tissue, murine heart tissue showed complexity in the molecular species composition of NAPE (Fig. 11). Some differences were immediately evident between heart and brain NAPE molecular species. First, the content of all NAPE molecular species in heart tissue was two- to four-fold less than in the brain tissue (compare NAPE class data in Figs. 8 and 9), and there was no difference in molecular species content of any NAPE type in heart tissue of $FAAH^{-/-}$ mice compared to wild type (Fig. 11).

Comparisons of PC and PE compositions of brain and heart (Figs. 12, 13) show that the diradyl compositions of these two major phospholipid classes are quite different from each other. In brain, 40:6 PE was the most abundant diradyl species for *N*-acylation, with 36:1, 38:6, and 38:4 species also being prominent (Fig. 10). In heart, 40:6 and 38:6 were most prominent with 38:4 and 36:4 also abundant (Fig. 11). These NAPE compositions resemble the PE compositions (Figs. 12, 13), supporting the notion that NAPE is derived from PE (Fig. 1).

Discussion

Considerable prior evidence has established the metabolic relationship of PE, its *N*-acylation to form NAPE, and the hydrolysis of NAPE to form the bioactive NAEs (Fig. 1). Several NAE types have been identified as endogenous ligands for the cannabinoid receptors, while other types act on other cellular targets [30–32]. The hydrolysis of the NAEs (endocannabinoids and others) by FAAH terminates their lipid mediator functions [8, 33]. Given the broad range of activities of the NAEs, the enzymes of this pathway represent important therapeutic targets [34, 35].

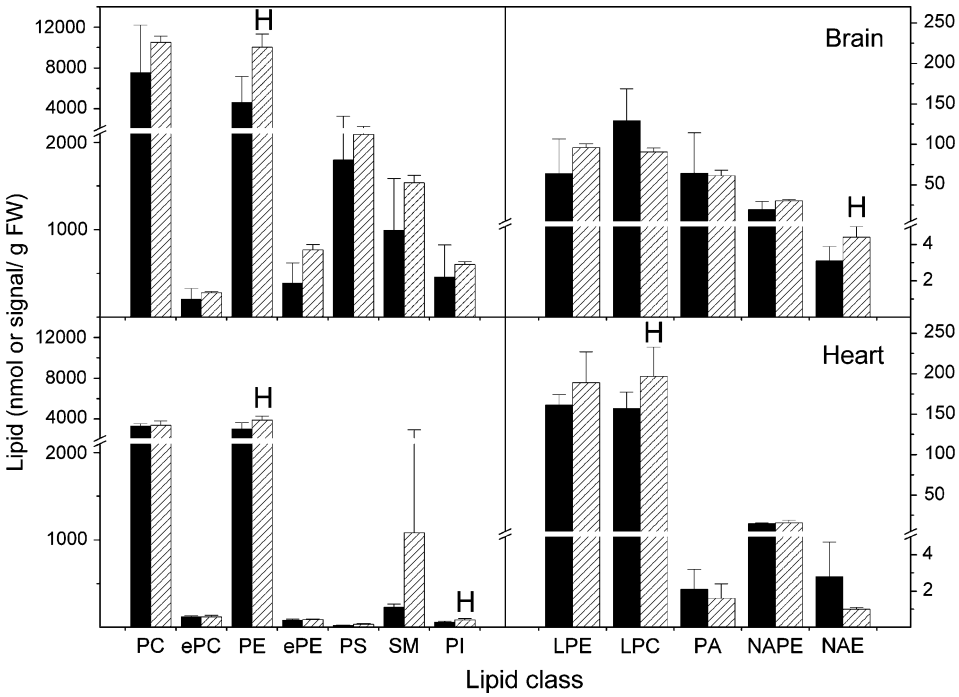

Fig. 7 Endogenous phospholipids and ethanolamine-containing NAE metabolites. Total lipid extracts of brain and heart tissue of wild-type (WT, *black bars*) and $FAAH^{-/-}$ (KO, *hatched bars*) mice were analyzed for phospholipid, including PE and NAPE and NAE content as described in "Experimental Procedures." *Right panels* use right-hand scale and *left panels* use left-hand scale. NAPEs are expressed as normalized signal/g FW; all others are expressed as nmol/g FW. $N = 4$ or 5 ± SD. Significance ($P < 0.05$) was determined by unpaired Student's t test for KO vs. WT. "H" indicates that the KO level is significantly higher than the wild-type value

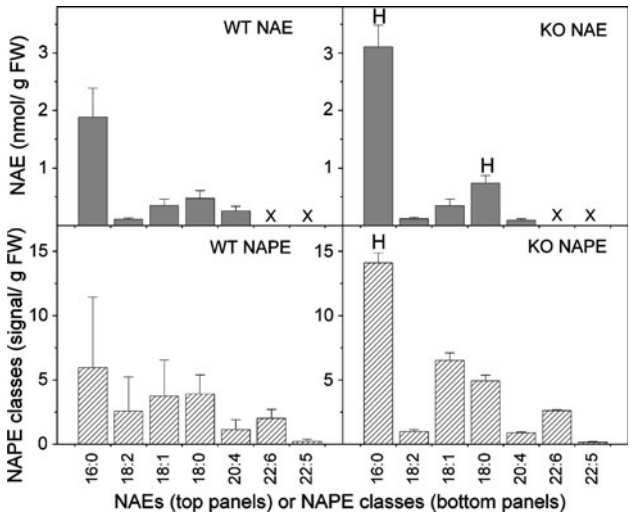

Fig. 8 Brain NAE species (*dark gray bars*) and NAPE classes (*hatched bars*) in wild-type (WT) and $FAAH^{-/-}$ (KO) mice. $N = 4$ or 5 ± SD. "X" indicates species that were not determined. Significance ($P < 0.05$) was determined by unpaired Student's t test for KO vs. WT. "H" indicates that the KO level is significantly higher than the wild-type value

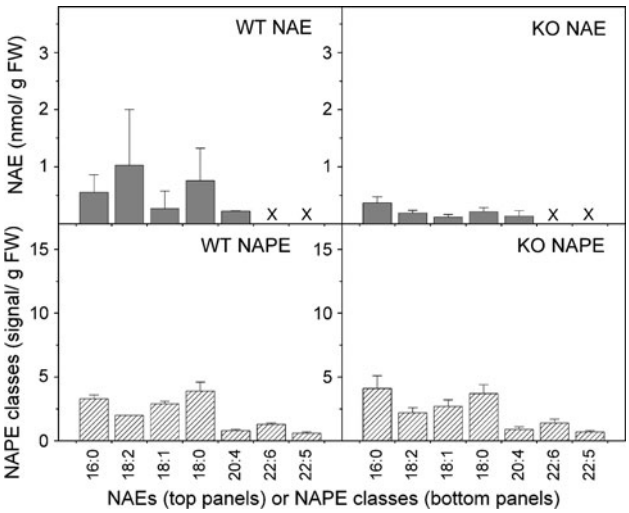

Fig. 9 Heart NAE species (*dark gray bars*) and NAPE classes (*hatched bars*) in wild-type (WT) and $FAAH^{-/-}$ (KO) mice. $N = 4$ or 5 ± SD. "X" indicates species that were not determined. Significance ($P < 0.05$) was determined by unpaired Student's t test for KO vs. WT

Often less appreciated are the large numbers of metabolites that are generated in this overall *N*-acylation-phosphodiesterase-FAAH pathway, many of which are cellular lipids with other functions and only some of which are identified and quantified for their lipid mediator functions.

Targeted lipidomics approaches permit comprehensive analysis of metabolites involved in a specific lipid metabolic pathway. Recently, sensitive and high-throughput analytical tools have been established to unravel the biological significance of individual molecules of the endocannabinoid system in the context of the interconnected network of their precursors and derivatives [36–38]. However, these studies were limited mostly to endocannabinoids that occur in minor quantities relative to the other non-cannabimimetic members of the large *N*-acylethanolamide family. Since we do not fully understand the nature of selective biosynthesis or degradation of a specific NAE type

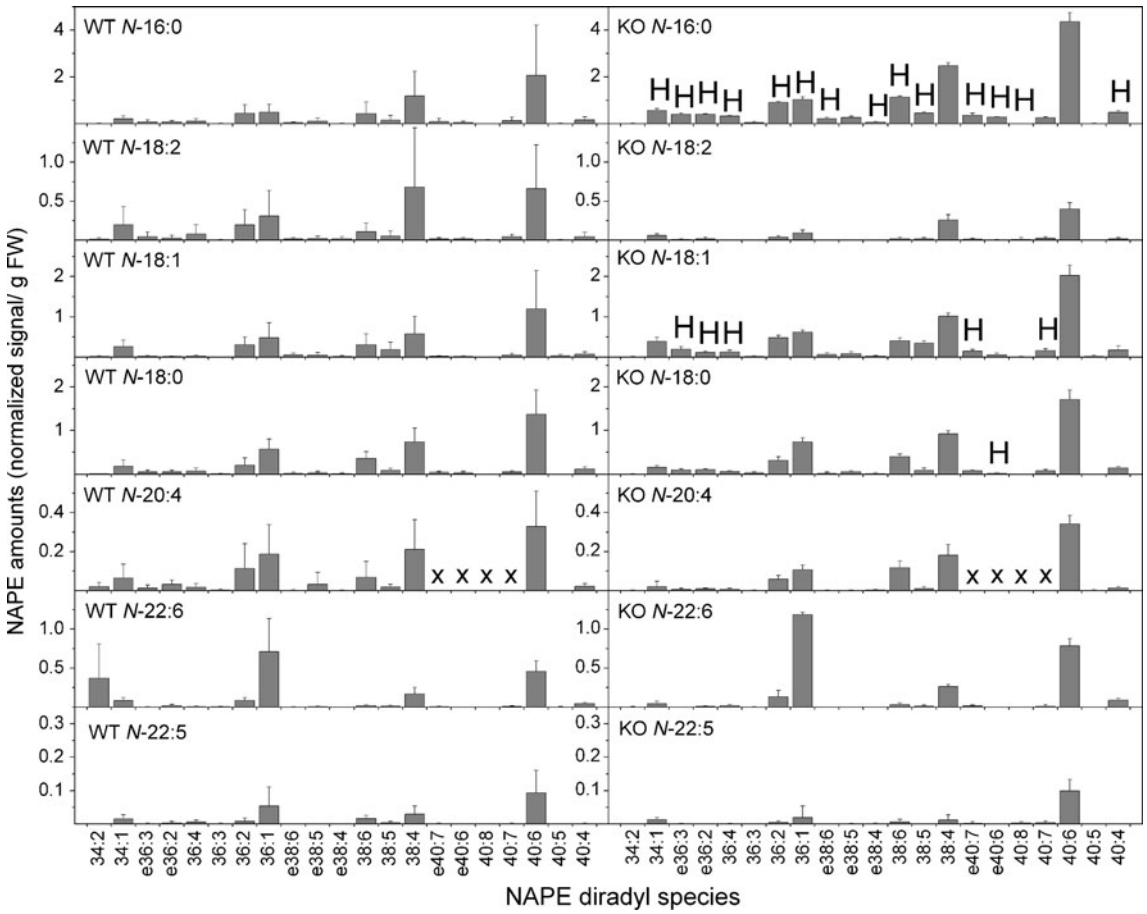

Fig. 10 Detailed profile of NAPE molecular species from brain tissue of wild-type (WT) and $FAAH^{-/-}$ (KO) mice. Designations for diradyl molecular species are: numbers only represent diacyl species as total acyl carbons: total carbon–carbon double bonds; e before a number indicates an ether-linked (alk(en)yl,acyl) species as total alk(en)yl + acyl carbons: total carbon–carbon double bonds, including any vinyl ether bonds present. "X" indicates molecular species that were not determined (see "Experimental Procedures"). $N = 4$ or $5 \pm$ SD. Significance ($P < 0.05$) was determined by unpaired Student's t test for KO vs. WT. "H" indicates that the KO level is significantly higher than the wild-type value

or its precursors (Fig. 1), especially under the influence of genetic perturbations of this regulatory pathway, we used a targeted lipidomics approach to elucidate changes in the profiles of PE, NAPE, and NAE in brain and heart tissue of wild-type and $FAAH^{-/-}$ mice.

Comparison of NAE metabolites and major and minor phospholipids between brain and heart tissue of mice revealed some similarities, but also several tissue-specific differences. The most abundant metabolite of the NAE regulatory pathway in brain and heart tissue was PE (Figs. 1, 7). It appears that the relative abundance of specific PE molecular species in the PE pool determines the molecular composition of NAPE rather than a preferential substrate selectivity of *N*-acyltransferase (Figs. 10 vs. 12 and 11 vs. 13). Furthermore, brain tissue of $FAAH^{-/-}$ mice showed accumulation of already abundant PE and NAPE molecular species rather than synthesis and accumulation of new or less abundant molecular species or remodeling of the amide-linked fatty acids of NAPE. These data suggest that lack of FAAH in brain tissue results in accumulation of NAE species, which may in turn affect the content but not the composition of the NAE precursor pool. Although total PE was significantly higher in the heart tissue of $FAAH^{-/-}$ mice when compared with wild type (Fig. 7), fewer PE molecular species contributed significantly to the overall increase in PE content in heart than in brain (Figs. 12, 13). The lesser FAAH-specific effect on NAE and its metabolites in heart tissue (Figs. 7–13) was not surprising because FAAH activity was reported to be negligible in heart tissue of mice [39].

Although the total NAE content was similar between the two tissue types, it is interesting to note that total PE and NAPE levels are lower in heart tissue (Fig. 7). Furthermore, *N*-16:0 PE and 16:0 NAE were the most predominant species in brain tissue, while heart tissue did not show preference for any specific type (Figs. 8, 9). It is possible that

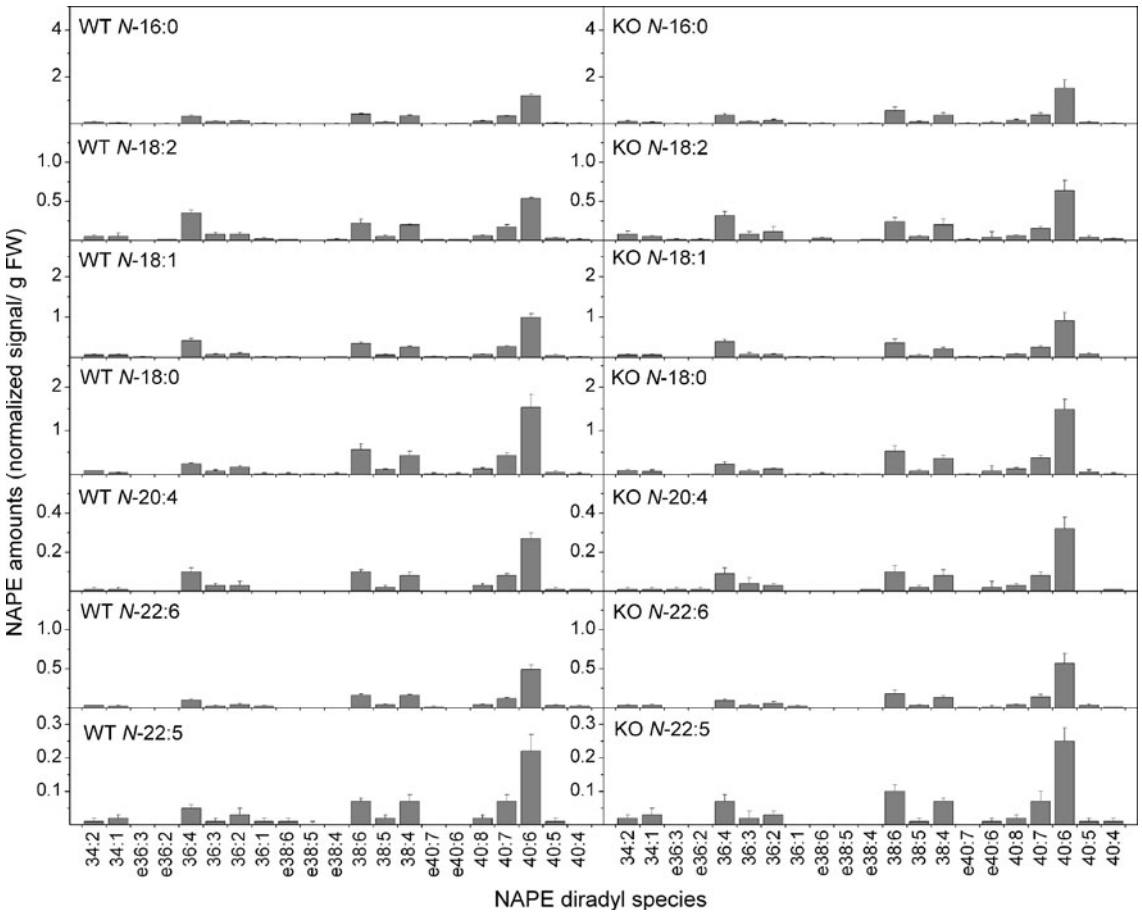

Fig. 11 Detailed profile of NAPE molecular species from heart tissue of wild-type (WT) and $FAAH^{-/-}$ (KO) mice. Designations for diradyl molecular species are: numbers only represent diacyl species as total acyl carbons: total carbon–carbon double bonds; e before a number indicates an ether-linked (alk(en)yl,acyl) species as total alk(en)yl + acyl carbons: total carbon–carbon double bonds, including any vinyl ether bonds present. $N = 4$ or $5 \pm$ SD. Significance ($P < 0.05$) was determined by unpaired Student's t test for KO vs. WT

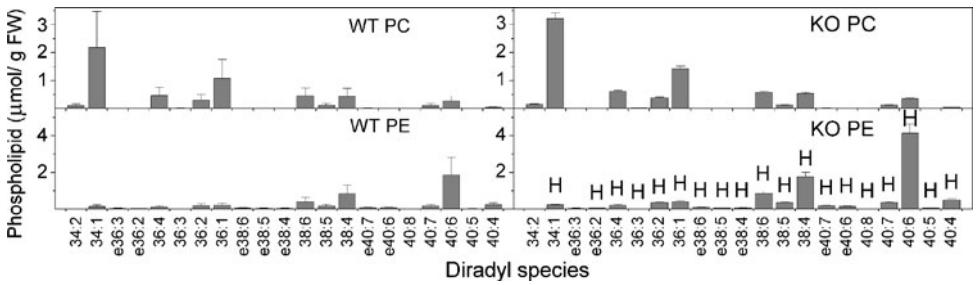

Fig. 12 PC and PE species from brain tissue of wild-type (WT) and $FAAH^{-/-}$ (KO) mice. Designations for diradyl molecular species are: numbers only represent diacyl species as total acyl carbons: total carbon–carbon double bonds; e before a number indicates an ether-linked (alk(en)yl,acyl) species as total alk(en)yl + acyl carbons: total carbon–carbon double bonds, including any vinyl ether bonds present. $N = 4$ or $5 \pm$ SD. Significance ($P < 0.05$) was determined by unpaired Student's t test for KO vs. WT. "H" indicates that the KO level is significantly higher than the wild-type value

N-acylethanolamine-hydrolyzing acid amidase, a second NAE-degrading amidase expressed in the heart and brain [40], may exhibit differential expression and activity in these tissues, potentially leading to some of the tissue-specific differences seen in levels of NAE species in $FAAH^{-/-}$ mice. The higher levels and distinctive composition of NAPE may suggest additional brain NAPE roles, such as maintenance of physical properties of membrane domains [41] and influence on signaling processes in the brain [42], in addition to serving as the precursor for NAE synthesis.

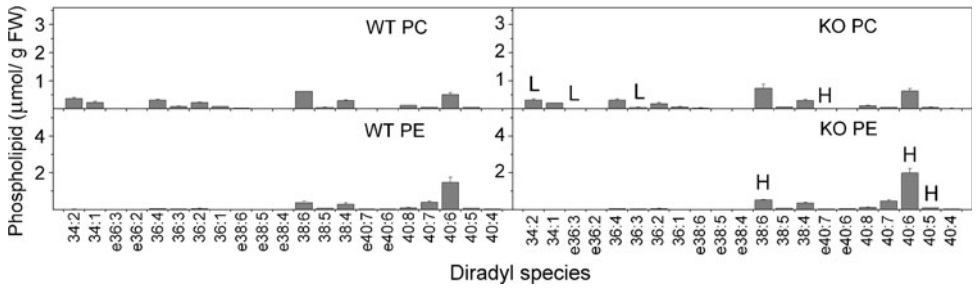

Fig. 13 PC and PE species from heart tissue of wild-type (WT) and $FAAH^{-/-}$ (KO) mice. Designations for diradyl molecular species are: numbers only represent diacyl species as total acyl carbons: total carbon–carbon double bonds; e before a number indicates an ether-linked (alk(en)yl,acyl) species as total alk(en)yl + acyl carbons: total carbon–carbon double bonds, including any vinyl ether bonds present. $N = 4$ or $5 \pm$ SD. Significance ($P < 0.05$) was determined by unpaired Student's t test for KO vs. WT. "H" indicates that the KO level is significantly higher and "L" indicates that the KO level is significantly lower than the wild-type value

Comparative analysis of major and minor phospholipids revealed higher levels of most phospholipids in brain tissue compared to heart, as expected, perhaps due to overall higher lipid content in the brain (Fig. 7). However, in $FAAH^{-/-}$ mice, brain tissue showed accumulation only in the PE and NAE contents, as discussed earlier. On the other hand, $FAAH^{-/-}$ heart tissue showed an increase not only in PE, but also in phosphatidylinositol (PI) and lysoPC. In fact lysoPC content was higher in wild-type heart tissue than in brain (Fig. 7). LysoPC is a byproduct of the *trans*-acylase reaction and might serve, together with other 1-lyso-phospholipids, as a precursor for the formation of 2-arachidonoylglycerol (2-AG) [43]. Additionally, hydrolysis of PI by a PI-specific phospholipase A_1 can also generate 2-AG [44]. Even though elimination of FAAH activity did not directly affect the NAE metabolites in heart tissue of mice, it may have influenced alternate endocannabinoid metabolic pathways by affecting the phospholipid composition.

Collectively, our targeted lipidomics results imply a metabolic *N*-acylation-phosphodiesterase pathway for acylethanolamides that is dominated by major cellular lipid constituents, but in which minor metabolites also play roles. Perturbation of FAAH may influence metabolite pools in this entire pathway, beyond simply the direct substrates for this enzyme; however, this influence by FAAH on NAPE and PE molecular species content is tissue-specific. Metabolic profiling tools like these developed here, applied to different physiological or pathological situations that have been attributed to endocannabinoid function, may help to reveal important new tissue-specific metabolic targets for therapeutic intervention at points of control not yet discovered.

Received: 22 December 2009 / Accepted: 16 July 2010 / Published online: 28 August 2010

Abstract In intensively reared dairy cows, milk fat secretion is reduced in response to high-concentrate diets and it is often referred to as the "milk fat depression" (MFD) syndrome. Some *trans* fatty acid (FA) isomers produced in the rumen of the cows, including *t*10,*c*12-18:2, are known for their inhibitory effect on mammary lipogenesis. To study whether this effect depends on the basal diet, duodenal infusions of *t*10,*c*12-18:2 were performed on cows fed four different diets (a factorial arrangement of forage:concentrate ratio and linseed oil supplementation). The overall response obtained with *t*10,*c*12-18:2 infusion was consistent with previous studies: a decrease in milk fat content and yield without significant variations in milk yield. Mean transfer efficiency of infused *t*10,*c*12-18:2 was 19.6%. However, the decrease in milk fat and FA yields (both de novo synthesis and preformed long-chain FA) was less pronounced in cows fed high-concentrate diets (−27% of the initial level), compared with cows fed low-concentrate diets (−42% of initial level). This difference was independent of dietary oil supplementation and milk FA yield before infusion. Results pertaining to effects of dietary forage:concentrate ratio were confirmed by statistical meta-analysis of data from previously published *t*10,*c*12-18:2 infusion experiments. This study shows that in cows fed MFD diets the mammary gland becomes more resistant to or experiences a lower response potential to further inhibition of lipogenesis and/or delta-9 desaturation of FA.

DMI	Dry matter intake
FA	Fatty acid
MFD	Milk fat depression
NDF	Neutral detergent fibre
NEFA	Nonesterified fatty acids
VFA	Volatile fatty acid

Introduction

Milk fat contributes to the value of milk for the dairy producer and is easily modified in quantity and quality by the cow's diet [1]. In intensively reared dairy cows, milk fat secretion is reduced in response to high-concentrate diets and it is often referred to as the "milk fat depression" (MFD) syndrome. For several decades, the physiological determinants of this phenomenon have been studied and has led to the current mainstream concept referred to as "biohydrogenation theory", supposedly explaining most, if not all, cases of MFD [2–4]. According to this theory, MFD is caused by some fatty acid (FA) isomers produced by

rumen microorganisms during the biohydrogenation of dietary polyunsaturated FA. To date, three isomers of conjugated linoleic acid (CLA) have been identified for their inhibitory role on mammary lipogenesis: *t*10,*c*12-18:2, *t*9,*c*11-18:2 and *c*10,*t*12-18:2 [5–7]. Exogenous infusions of these CLA decrease the yield of both preformed FA [mainly 16- and 18-carbon (C16 and C18) FA taken up by the mammary gland from the plasma] and short- and medium-chain FA (C4-C16) from mammary de novo synthesis, with generally greater depression in the de novo synthesized FA than the preformed FA.

Many studies with duodenal infusions of *t*10,*c*12-18:2 (the only commercially available inhibitory isomer) have demonstrated its inhibitory role on mammary lipogenesis, and the response of milk fat to increasing amounts of this isomer have been published [8]. However, duodenal flows of *t*10,*c*12-18:2 (and other inhibitory isomers) measured in vivo are far too low to explain the extent of diet-induced MFD. Most authors hypothesize that this discrepancy may be due to other inhibiting *trans* 18:1 or 18:2 isomers (still unidentified) [4, 9]. The isomer *t*10-18:1 is correlated with MFD [4, 10], but short-term abomasal infusions of this isomer suggest an inhibition of milk fat secretion only when infused at high doses (>50 g/day) [11, 12].

The biohydrogenation theory is accepted by most authors as the main mechanism explaining MFD. However, milk fat depressing diets (high concentrate, high starch, polyunsaturated fats, pasture sometimes) also alter ruminal environment (decrease in pH with high concentrate) and fermentation products (increased propionate production). MFD diets, thus, lead to a simultaneous increase of numerous FA isomers and other energetic nutrients, complicating the elucidation of related mechanisms. It is possible that components other than 18:2 isomers may contribute to MFD. To test this hypothesis, we compared the effect of *t*10,*c*12-18:2 duodenal infusions (mimicking one player of the "biohydrogenation theory" component of MFD) in cows fed diets with contrasting forage:concentrate ratio and supplemental oil content. The effect of *t*10,*c*12-18:2 on milk fat synthesis has indeed never been compared in different nutritional conditions in the same study, and this comparison could provide new insights on the regulation of milk fat yield.

Experimental Procedure

Animals, Diets and Treatments

Four lactating multiparous Holstein cows (55–87 DIM) with cannulas in the rumen and proximal duodenum were used in a 4 × 4 Latin square design with factorial arrangement of treatments (four diets differing in their forage:concentrate ratio and level of oil supplementation) during four 5-week periods to evaluate responses to duodenal *t*10,*c*12-18:2 infusions. The cows were fed a high-concentrate diet (HC, forage:concentrate ratio 35:65) or low-concentrate diet (LC, forage:concentrate 65:35) without added linseed oil (diets HC and LC) or with linseed oil supplemented at 3% of DM (diets HCO and LCO). This infusion study was part of a previously published experiment [10, 13, 14], during which a pre-infusion period (the first 4 weeks of each 5-week period) was used to study the cows' response to the diets. Experimental procedures are described in [10, 13, 14]. The sole forage was long-cut grass hay and the concentrate mixture was based primarily on ground wheat, rapeseed, sunflower meal, and wheat bran. Details of ingredient, chemical composition, and FA profiles of the diet have been presented previously [13]. The experimental protocol was approved by the Animal Care and Use Committee of INRA. All experimental procedures were conducted in accordance with the Use of Vertebrates for Scientific Purposes Act 1985. Cows were housed in a tie-stall barn during the experiment. The concentrate mixtures with or without linseed oil were prepared daily and, along with the forage, were offered in equal amounts at 0900, 1330, and 1700 hours for ad libitum consumption. Cows were milked at 0600 and 1630 hours. During the fifth week of each experimental period, the cows received *t*10,*c*12-18:2 from a duodenum infusion of 5 g/day of a commercial CLA source (t10c12-CLA 95%-FFA; Natural Lipids, Hovdebygda, Norway). The CLA mixture was composed of 0.20% *c*9-18:1, 0.95% *c*9,*t*11-18:2, 94.55% *t*10,*c*12-18:2 and 2.25% *t*9,*t*11 + *t*10,*t*12-18:2.

The CLA mixture was emulsified in skim milk to ensure a uniform supply during the infusion. Emulsions were prepared in the morning of each day prior to infusion by combining 5 g of CLA with 2 g glycerol (Sigma, G6279, Saint-Quentin Fallavier, France) and 1.1 g lecithin powder (Sigma, P5394, Saint-Quentin Fallavier, France) in 991.9 g skim milk at room temperature. The mixture was homogenized at 10,000 rpm for 2 min with a Polytron homogenizer (PT-HR 3000, Fisher Scientific Bioblock, France), and checked for the presence of clumps before stirring at medium-to-high speed for 30 min at room temperature. Emulsions were dispensed into 5-L plastic bags and stored at 4 °C until infusion. Duodenal infusion of CLA began at 1400 hours on day 0 and continued for 4 days. After 24 h, the empty bag was replaced with another bag containing 1 L of emulsion. Duodenal infusates were delivered via polyvinyl chloride tube (0.5 cm i.d.), that passed through the duodenum fistula. Peristaltic pumps (STA-131900; Desaga, Heidelberg, Germany) delivered the infusate continuously over 24 h. Infusion equipment was checked daily during treatment periods to ensure correct placement in the duodenum cannula.

Sampling, Measurements and Analyses

Milk production and dry matter intake (DMI) were recorded daily throughout the infusion period. Milk was sampled at each milking and pooled each day. Fatty acids in lyophilized milk were directly methylated with 1 mL of 2 N methanolic $NaOCH_3$ at room temperature for 20 min, followed by 1 mL of 14% boron trifluoride in methanol at room temperature for 20 min [15]. Fatty acids in plasma lipids were methylated with 2 mL of 0.5 N $NaOCH_3$ at 50 °C for 30 min, followed by 2 mL of 14% boron trifluoride in methanol at 50 °C for 30 min [16, 17]. In all cases, FA methyl esters were recovered in 1 mL of hexane. Tricosanoate (Sigma, Saint-Quentin Fallavier, France) was used as the internal standard. Samples were injected by autosampler into a Trace-GC 2000 Series gas chromatograph equipped with a flame ionization detector (Thermo Finnigan, Les Ulis, France). Methyl esters from all samples were separated on a 100 m × 0.25 mm i.d. fused silica capillary column (CP-Sil 88, Chrompack, Middelburg, The Netherlands). Identification of fatty acids and detailed analytical procedure have been previously described in [10].

Calculations and Statistical Analyses

Desaturation ratios were computed for 14:0, 16:0, 18:0, *t*11-18:1 and *t*13-18:1, using their respective monounsaturated counterparts (e.g. for 18:0 the ratio is *c*9-18:1/(18:0 + *c*9-18:1) × 100). For all data, individual cow responses to CLA infusion were computed for each period (data for d4, after 4 days of infusion, minus data for d0). The statistical analyses were conducted on these responses, analysed as a Latin square with factorial arrangement of treatments using the MIXED procedure of SAS (SAS Inst., Inc., Cary, NC, USA). The statistical model included: cow, period, concentrate level, oil level, concentrate × oil interaction, and residual error. Cow was the random effect. The overall response to CLA infusion (across all diets) was also tested against zero. The responses to CLA infusion for each diet were compared to zero, and multiple comparisons of means (between diets) were performed using Tukey tests. The initial values (before infusion) are reported in the tables for comparison only, because they differed between diets, but were not subject to statistical analyses (only responses to CLA infusion were).

To determine whether the differences in responses were due to the diet or to the initial values of milk fat, we used two approaches: (1) the response to CLA infusion was expressed as a percentage of the initial value and (2) we performed a meta-analysis of the CLA infusion experiments already published. For this meta-analysis, we reviewed the published experiments of *t*10,*c*12-18:2 infusions [5–8, 11, 12, 18–25]. We excluded the experiment of Bell and Kennelly [21], in which the infusion of 45 g/day of *t*10,*c*12-18:2 probably elicited different mechanisms than studies with lower doses [26]. From these data, we calculated the response to CLA infusions and then performed nonlinear regression analyses on these responses, including the effect of CLA dose, and other putative variables (chemical composition of the diet, initial values of milk fat yield and content, milk yield, etc.). The models used were exponential decrease models: $Y = a \times (1-e^{(-b \times \text{CLA dose})})$, parameters a and b being the maximal decrease and the slope of decrease respectively. The different models were compared using AICc criteria (Akaike Information Criteria, corrected for small samples, the model with the lowest AICc value is selected).

Results

DMI and Milk Production and Composition

Average DMI did not differ between basal diets, and was not affected by *t*10,*c*12-18:2 infusion (Table 1), except for the HCO diet, due to a drop in DMI for one cow (without affecting milk production). Milk production, initially lower for the LC diet, was not affected by *t*10,*c*12-18:2 infusion. Overall, after 4 days of infusion, the milk fat percentage and yield were markedly decreased by *t*10,*c*12-18:2 infusion, and the decrease was greater ($P < 0.05$) for low-concentrate diets, irrespective of the dietary oil content (Table 1). The other production variables were not affected by *t*10,*c*12-18:2 infusion (Table 1).

Plasma Composition

Among the metabolites measured in jugular and mammary veins, mammary concentrations of acetate and glucose were significantly increased and jugular–mammary differences of acetate were significantly decreased by *t*10,*c*12-18:2 infusion (Table 1). The other plasma components (beta-hydroxybutyrate, NEFA, free cholesterol, total cholesterol, free glycerol, lactate, phospholipids, triglycerides, urea, insulin) were not significantly altered by *t*10,*c*12-18:2 infusion (some data not shown). When the J–M difference was expressed as an apparent extraction rate (as a percent of the jugular level, data not shown), *t*10,*c*12-18:2 significantly decreased ($P < 0.05$) the apparent extraction rates of acetate (48.5% after infusion vs. 68.9% before), glucose (17.8 vs. 22.3%) and BHBA (31.5 vs. 45.6%), irrespective of the basal diet.

The concentrations and the percentages of FAs in the jugular plasma were not affected by *t*10,*c*12-18:2 infusion

[B] *P* values of the overall response to CLA infusion (across all diets) and the main effects of dietary concentrate level, oil, and their interaction on the response to CLA infusion. Only *P* values <0.05 are mentioned

(results not shown), except *t*10,*c*12-18:2 (Table 1), which reached a mean of 0.10 g/100 g FA, irrespective of the basal diet.

Milk FA Composition

Milk content of *t*10,*c*12-18:2 was not detectable at day 0 and progressively increased until day 3–4 (Fig. 1). Most of the short- and medium-chain FA percentages were significantly decreased by *t*10,*c*12-18:2 infusion (Table 2). Some FA were not significantly affected: 4:0, the odd- and branched-chain FA. The C14 and C16 FA were only slightly affected ($0.05 < P < 0.10$). The sum of C4–C16 was significantly decreased, whereas the sum of C18 FA was increased. Most individual C18 FA percentages were numerically increased (Table 3 for 18:0 and monounsaturated C18, Table 4 for polyunsaturated C18), but only some were significantly affected (18:0, *t*13-18:1, *c*14 + *t*16-18:1, *t*10,*c*12-18:2). *T*10,*c*12-18:2 reached the highest value with the LC diet (0.27 g/100 g FA) compared with all other diets (0.17–0.19 g/100 g FA). However, *t*10,*c*12-18:2 infusion did not modify the content of most C18 FA when expressed as a percentage of total C18 (data not shown).

Among the desaturation ratios, only those of C18 FA were significantly decreased by CLA infusion: 18:0 (from 66.1 to 62.8%), *t*11-18:1 (from 33.4 to 27.6%) and *t*13-18:1 (from 24.5 to 20.2%). These desaturation ratios decreased more with diets devoid of oil. Those of 14:0 and 16:0 were not significantly affected (Table 5).

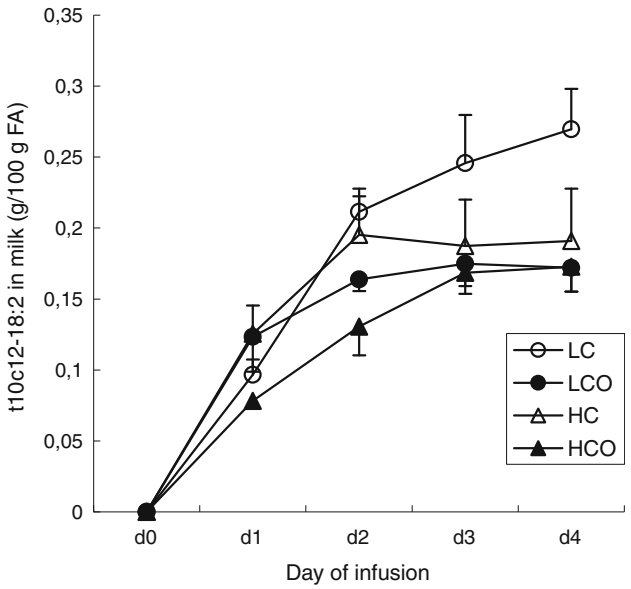

Fig. 1 Milk *t*10,*c*12-18:2 content (in g/100 g total FA) in cows fed a low- (*LC*) or high-concentrate (*HC*) diet, without (*LC, HC*) or with supplemental linseed oil (*LCO, HCO*) at 3% of DM, before the infusion (*d0*) and during 4 days of *t*10,*c*12-18:2 infusion into the duodenum

Milk Fat and FA Yields

The milk fat content and yield were decreased by *t*10,*c*12-18:2 infusion. The mean decrease over the four diets was −35.4%. The decrease was lower with high-concentrate diets than low-concentrate diets, independently of the initial yield and of oil supplementation (Table 6; Fig. 2).

The FA were grouped by chain length to discriminate between the effect of *t*10,*c*12-18:2 infusion on milk de novo synthesis and on preformed FA (C18) yield (Table 6). All the C4–C16 FA yields decreased to a greater extent than C18 yield across all diets. For all FA groups, the decrease in yield was lower with high-concentrate diets than low-concentrate diets (Table 6) independently of the initial yield (see Table 1) and of oil supplementation (except for C4–C8). The mean decrease of fat yield with high-concentrate diets was 27.5% of the initial yield, compared with 41.5% with the low-concentrate diets.

After 4 days of infusion, milk yield of *t*10,*c*12-18:2 varied between 0.85 g/day (HCO diet) and 1.13 g/day (LC diet), corresponding to a transfer efficiency of 17–23% of the amount infused daily at duodenum (mean 19.6%, no significant difference between diets).

Meta-Analysis of Published *t*10,*c*12-18:2 Infusion Studies

The database of the published data of *t*10,*c*12-18:2 infusion studies (including the present experiment) included 23 comparisons between a control and an infused groups. Several exponential decrease models were run and compared on these data. Models were adjusted on actual or percentage decrease data, and using diet composition data as additional factors on the *a* (maximal decrease) and *b* (slope of the decrease) parameters of the exponential models. The best model, based on the lowest AICc value, was the exponential model of percentage decrease with an effect of a proxy of the dietary forage/concentrate ratio (dietary neutral detergent fiber [NDF] content) on the *b* parameter:

$$\text{Milk fat content decrease (\% of initial)} = -43.9(\pm 3.6) \times \left(1 - e^{-0.00755 \times \text{NDF} \times \text{CLAdose}}\right)$$
(NDFin %DM and CLA dose in g/day, $n = 23$, $R^2 = 0.97$)

$$\text{Milk fat yield decrease (\% of initial)} = -47.2(\pm 4.4) \times \left(1 - e^{-0.00632 \times \text{NDF} \times \text{CLAdose}}\right)$$
(NDFin %DM and CLA dose in g/day, $n = 23$, $R^2 = 0.97$)

When the effect of the dose of *t*10,*c*12-18:2 was accounted for, the slope of the response was more pronounced with diets high in NDF: there is a linear effect of dietary NDF content on the slope of the response to *t*10,*c*12-18:2. The resulting model for milk fat content, computed for two NDF levels (25 and 45% of the diet, corresponding to the extreme values reported in published studies used are indicated as two lines on Fig. 3. None of the other variable tested (initial milk yield, milk yield response, initial fat yield) was significant when introduced in this model.

Discussion

The overall responses observed in the present experiment with *t*10,*c*12-18:2 infusions are consistent with the results of previous infusion experiments (reviews in [3, 26, 27]): a decrease in milk fat content and yield (−27 to −42% of the initial level), without significant variations in milk yield; the decrease was more pronounced for short- and medium chain FA, leading to milk richer in long-chain FA following infusions. The transfer efficiencies of *t*10,*c*12-18:2 (17–23%) were very close to the mean of 22% observed in previous infusion studies [8], and were not influenced by the basal diet. Transfer efficiencies of duodenal *t*10,*c*12-18:2 estimated from dietary studies with measurements of duodenal FA flows are highly variable, and were estimated to be between 50 and 100% (average 75%) in three studies [10, 28, 29], ca. 15% in one study [30], and higher than

Table 2 Percentages of selected FA (expressed as g/100 g total FA) in milk of cows fed a low- (LC) or high-concentrate (HC) diet, without (LC, HC) or with supplemental linseed oil (LCO, HCO) at 3% of DM

100% in two additional studies probably due to analytical inaccuracies [31, 32]. Thus, the transfer efficiency observed in infusion studies is three to four times lower than that estimated in dietary studies. This may be attributed to analytical biases in the analysis of *t*10,*c*12-18:2 duodenal flows and/or content in milk, or, more likely, to a low efficiency of infusions (lower absorption of infused lipid, due to supra-physiological dose or mode of infusion). Milk FA desaturation was only slightly affected by *t*10,*c*12-18:2 infusion, with only the desaturation ratios of C18 FA (the preferred substrates of delta-9 desaturase) being significantly affected. Indeed, alterations in milk fat desaturation ratios are not always observed when low amounts of *t*10,*c*12-18:2 are infused [3, 8, 18], suggesting that desaturation inhibition is not a major mechanism of action of *t*10,*c*12-18:2 at low doses.

The comparison of the responses to infusion between diets showed that, with the same dose of *t*10,*c*12-18:2, the decrease in milk FA yield relative to initial levels was less pronounced with high-concentrate than low-concentrate diets. This was not due to differences in initial levels of FA yield because relative decreases were not significantly related to initial levels. This was probably neither due to the duodenal flow of non-infused 18:2-inhibitory isomers if we compare the duodenal flows of FA corresponding to the four diets without infusion that have already been published [13]. Indeed, the sum of *t*10,*c*12 + *c*10,*t*12 + *t*9,*c*11 (the three inhibitory isomers identified to date) was higher with LC and HCO diets (0.52 and 0.41 g/day, respectively) and lower with LCO and HC diets (0.29 g/day), amounts that were very low compared to those infused (5 g/day). Thus, the observed differences between diets in decreases in milk FA yields were likely not linked to duodenal flows of inhibitory CLA isomers. Moreover, the amounts of *t*10,*c*12-18:2 secreted in milk following infusions were similar between diets (0.85–1.13 g/day), ruling out a

difference between diets due to different amounts of this isomer taken up by the mammary gland. The lower response to *t*10,*c*12-18:2 with high-concentrate diets was observed in the present study irrespective of whether the decrease was expressed in actual amounts (Table 1) or as percentage of initial value (Table 6). It was observed for all FA chain lengths (Table 6) and was also found in a meta-analysis of the published infusions of *t*10,*c*12-18:2 (Fig. 3). The coefficients found in the meta-analysis are very close to those reported in earlier studies from a smaller dataset [8] (for a NDF content of 40% DM, our slope for milk fat yield is calculated at −0.25, compared to a mean slope of −0.28 in [8]). Within the published studies involving CLA doses between 3 and 4.5 g/day, the studies using basal diets low in NDF (NDF < 36% DM in [6, 11, 18]) report decreases in milk fat content comprised between −20 and −27%, whereas the studies using basal diets higher in NDF (around 45% DM in [8, 33]) report decreases in milk fat between −35 and −39%, with similar initial milk fat.

We cannot totally exclude some saturation of the milk fat decrease, because a 50%-decrease seems to be the maximal response reported for *trans*10,*cis*12-18:2 infusions, as discussed previously in [34]. Our high-concentrate diets were already somewhat depressed compared to a standard diet, and the differences observed in the decrease could be interpreted as consequences of the initial situation. However, we argue for a specific effect of the basal diet on the response to CLA infusion, independent of the initial milk fat before infusion (see Fig. 2). The various modes of expression in this study (actual decrease, percentage decrease), together with the significant effect of dietary NDF content in the published responses from the database, advocate for an effect of the dietary forage:concentrate ratio, which modulates the main response driven by *trans*10,*cis*12-18:2 infusions. Thus, a less pronounced decrease in milk fat yield in cows fed high-concentrate diets is observed from the *t*10,*c*12-18:2 infusions published to date (the relationship is very similar for both milk fat yield and milk fat content, because milk yield is almost unaffected by *t*10,*c*12-18:2 infusions). However, it is difficult to develop hypotheses to explain this phenomenon, because data on intermediary metabolism (e. g. plasma composition) related to *t*10,*c*12-18:2 infusion are very scarce. Molecular mechanisms of MFD induced by

*t*10,*c*12-18:2 infusions at the mammary level have been described [3, 4], but this information is of limited help to explain the effect of dietary concentrate.

In the present experiment, low-concentrate diets resulted in higher ruminal acetate and lower propionate, with similar ruminal digestibilities of dietary components across

Table 6 Variation in milk yield, fat and FA, induced by *t*10,*c*12-18:2 infusion into the duodenum, in Holstein cows fed a low- (LC) or high-concentrate (HC) diet, without (LC, HC) or with supplemental linseed oil (LCO, HCO) at 3% of DM

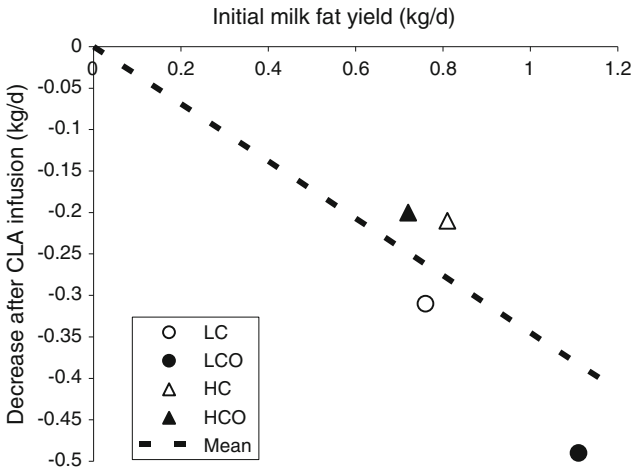

Fig. 2 Actual decrease in milk fat yield induced by t10,c12-18:2 infusion into the duodenum in Holstein cows fed a low- (*LC*) or high-concentrate (*HC*) diet, without (*LC, HC*) or with supplemental linseed oil (*LCO, HCO*) at 3% of DM. The *dotted line* indicates the mean response across all diets

diets [14]. High-concentrate diets probably induce higher ruminal propionate production and availability in cows [35]. From the present experiment, the only plasma characteristic with an interaction between *t*10,*c*12-18:2 infusion and basal diet was the jugular–mammary difference of acetate. Jugular acetate was higher with the low-concentrate diets irrespective of oil supplementation. Following *t*10,*c*12-18:2 infusion, mammary acetate increased, leading to a global decrease in jugular–mammary differences of acetate, which is consistent with the inhibition of mammary de novo synthesis by *t*10,*c*12-18:2. Moreover, this decrease was more pronounced for low-concentrate diets (Table 1) consistent with a more pronounced decrease in milk fat yield, including de novo synthesis (Table 6). No such phenomenon was observed with plasma triglyceride jugular–mammary difference (data not shown), the main source of preformed FA for the mammary gland, which did not change according to either diet or *t*10,*c*12-18:2 infusion.

A decrease in acetate mammary uptake could be the cause or the consequence of a decrease in mammary FA synthesis. Early theories of MFD encompassed variations in VFA, namely the acetate deficiency theory (acetate deficiency would be a limiting factor of mammary lipogenesis) and the 'glucogenic-insulin theory', according to which propionate and/or glucose from high-concentrate diets would increase circulating insulin and result in a shortage of lipogenic precursors for the mammary gland [36]. Indeed, VFA infusions in dairy cows induce variations in milk fat content and yield (increase following acetate infusions and decrease following propionate infusions) [37]. However, these theories have been dismissed because there is no reduction in ruminal acetate production with high-concentrate diets (but rather an increase in propionate production) [35], and the changes in FA composition following insulin-induced MFD are opposite to those observed following diet-induced MFD [36].

With the above discussion in mind, we hypothesize that cows fed high-concentrate diets are in a metabolic state that is already "detrimental" to lipogenesis: higher propionate, lower circulating acetate, and possibly higher *trans* 18:1 and 18:2 isomers. In particular, before infusions in the present experiment, the duodenal flow of *t*10-18:1 was higher with the HC and HCO (20–51 g/day) than LC and LCO diets (1–7 g/day) [13], which could have contributed to an inhibition of mammary lipogenesis [27] even before

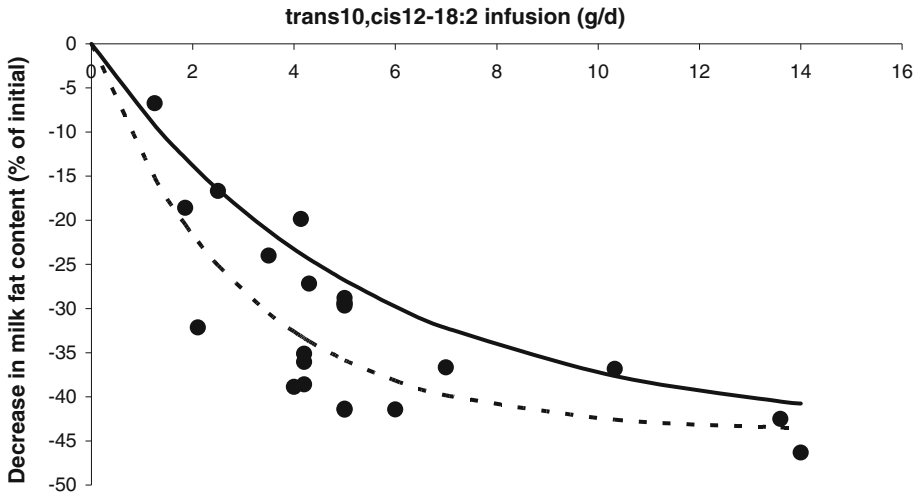

Fig. 3 Decrease in milk fat content following *t*10,*c*12-18:2 duodenal infusions in 23 groups of cows from 13 published experiments [5–8, 11, 12, 18–20, 22–25] and the present study. The *lines* show the exponential decrease model adjusted on these data, and computed for a basal diet containing 25% NDF (*solid line*) or 45% NDF (*dotted line*)

*t*10,*c*12-18:2 infusion. In this metabolic context, the mammary gland might have been more resistant to or might have experienced a lower response potential to further inhibition of lipogenesis and/or FA delta-9 desaturation. Taken together, all these events could explain the blunted response of cows fed a high-concentrate diet to *t*10,*c*12-18:2 infusion.

This experiment is the first published study comparing the impact of *t*10,*c*12-18:2 infusions on cows fed diets differing in concentrate and supplemental oil contents. Results reveal that the inhibition of mammary lipogenesis (both de novo synthesis and incorporation of long-chain FA) was less pronounced in cows fed high-concentrate diets. This response is independent of oil supplementation and milk FA yield before infusion. The impact of dietary concentrate on the milk fat yield response to *t*10,*c*12-18:2 infusion in our study has been confirmed by a meta-analysis of the previously published *t*10,*c*12-18:2 infusion experiments.

Acknowledgments We acknowledge the assistance of J.P. Pezant and the team of Les Cèdres Experimental Unit for feeding, milking, blood sampling, and caring for the cows, as well as P. Capitan, M. Tourret, and C. Delavaud for help in laboratory analyses.

This research received no specific grant and the authors declare no conflict of interest.

NIH, Science, and Baseball: Time for Reform?

Eric J. Murphy

Published online: 22 September 2010

Last fall I was reflecting on the state of science and the funding rate at the National Institutes of Health. Baseball was winding down for most teams, while again the World Series featured two teams from the east coast, while teams in the middle of America were again amazingly absent. There are all kinds of reasons why these teams are not as competitive, but in the end it comes down to money and components like market share. Yet unlike other professional sports in America, where salary caps have been used to level the playing field and to make small market teams more competitive, no such cap exists in baseball. While major league baseball has tried revenue-leveling plans (a luxury tax), in the end the wealthier teams get the better (higher-priced) players and the less-wealthy teams get to develop the players who end up going to the wealthier teams. The end result is diminished revenue for one set of teams as fans just stop showing up to the ballpark. Quite the opposite occurs for the wealthier teams as the fans come in droves to watch their stars come out at night. So what in the world does this have to do with science?

Well, many see baseball as a pure game. There are dimensions for the diamond, but every field is unique beyond the actual diamond. There is no time limit for the game, something unique in nearly all professional sports. There is a one-on-one component as there is the constant battle between the hitter and the pitcher. Yet despite this very individual aspect of the game, baseball is a team sport in which team work is essential for success. To me, academic science is a pure pursuit, but like baseball it contains a number of polar opposites, somewhat like what Hegel described in his version of the dialectic theory.

Science is a pursuit that requires a tremendous amount of personal drive and utilization of one's intellect. Meanwhile, despite this individual effort, we work in a "team" environment, sharing our thoughts and work with others through publications and interactions at scientific congresses as well as other outlets that provide for exchange of ideas. We collaborate on projects with colleagues, maximizing the potential for success by bringing many different talents to bear on the project. Similar to baseball being a game where singles and doubles win games, science is a pursuit where all of our collective progress on a particular topic is additive and that is what often shifts our understanding of the underlying biology of a particular problem. Just like a home run is exciting and gets the fans cheering for more, big significant discoveries in science are also exciting. But in the end, like in baseball, it is the summation of incremental successes that move a field forward. As an industry colleague has routinely noted, academic scientists often work on their own time scale, yet we all work within the time frame of our grants. So many of the attributes of baseball are seen in science, but again, so are many of the disparities.

So how does NIH fit into this paradigm? Simply put, certain institutions and laboratories continue to get rich, while others seek the equivalent of science life support. Institutions on the right and left coasts have more faculty, more "stars", and ultimately more infrastructure to support an enhanced research enterprise. As in baseball, this deepens the divide between the haves and the have-nots. Those of us at institutions in the middle of America who succeed, can transition to the coasts, like a rising star in baseball. Hence, the ultimate impact is a reduction in the small market institutions' capacity to compete as they lose

their intellectual infrastructure. This reduces the institutional ability to compete for grants, while enhancing the ability of the large market institutions.

In the end, NIH must reform how it allocates funds. While baseball has avoided the dreaded salary cap, is it time for NIH to institute an institutional and investigator grant dollar cap? If so, would this cap help to redistribute funds, permitting small market institutions to be in a better position to compete for grants and ultimately build infrastructure and retain "star" faculty? This would force institutions to triage grants internally, rather than the submission-in-mass process that currently exists, thereby reducing the load of already overworked study sections. If a cap is not the answer, what are other options?

In an abbreviated letter published in *The Scientist* (23(4):18, 2009), I briefly laid out a radical new funding method for the NIH. My proposed model rewards successful scientists across the country and across disciplines with a single, lifetime grant. The grant is a single award on the order of $15 million and the investigator's institution would be required to invest the principal of the grant in various investments to provide a safe, constant source of income from the investment. In doing so, the investigator can only use the investment income from the grant, which in most years would be between $500,000 and $750,000. Because our institutions use and rely on a federal subsidy called indirect costs (F&A), an additional $5 million is given to the institution to invest, with the investment income used as the indirect costs payment. Again, neither party can use the principal, which means upon retirement of the scientist, the money then becomes available for another investigator at another institution, in short a sustainable means of funding biomedical science efforts in the US. The catch is that any investigator receiving one of these awards is not permitted to apply for any other federal funding, but rather must use the investment income provided to fund their laboratory. Because nearly all institutions in America have endowments that are invested and managed locally, the overall infrastructure exists within academia and within research institutes to implement this model.

What are the advantages? Because NIH study sections appear to fund safe science and repeatedly demonstrate risk aversion, reducing the likelihood that riskier projects are funded, one clear advantage to this radical funding vehicle is a shift in the aversion to risk. We all know that risk is equal to a potential for high yield, which in science speak translates into discoveries. By eliminating the need of a scientist to secure grant funding for every idea, my proposal promotes an environment in which risk aversion is low, a polar opposite to what we currently have in place. An additional advantage is an elimination of the money raising aspects of academic science. Academic scientists spend upwards to 30–40% of their time chasing money in one form or another. Eliminating this activity will enhance the overall quality of science as investigators put more time into their creative efforts, thereby increasing the likelihood of progress and novel discoveries. Another advantage is promoting a stable work environment for students, postdoctoral fellows, and technical staff. This more-stable environment includes more time devoted by the investigator to interacting with each individual in the laboratory, enhancing the overall training of the next generation of scientists. Lastly, by taking more seasoned and experienced scientists out of the normal R01 and R21 funding mechanisms, the success rate for junior faculty will increase, ensuring a vibrant research community across disciplines and providing a sustainable scientific base for the US.

Of course there are disadvantages to this program as well. Scientist could become rather lazy and reduce their efforts in the field. While this could occur with some individuals, I doubt it would be too common of an occurrence. A 5-year review process, in which investigators would be required to provide an update on their progress, primarily by demonstrating the number and quality of publications, would mitigate these concerns. For individuals with 5–7 R01 grants in their laboratories, the amount of money provided is insufficient to run one of these so-called mega-labs, which often resemble a small biotech company in its management structure rather than an academic laboratory. Hence, there is a clear disadvantage for scientists who manage one of these mega-labs as they would have to potentially reduce staff commensurate with a reduction in financial resources. However, more importantly, market fluctuations could cause a temporary reduction in investment income and portfolio value. To minimize this risk, investigators will have to save in good years to buffer against the down years in the market, however we all know that rapid loses in the market are also followed by rapid gains. Again, while there are undoubtedly other disadvantages, I will limit my discussion to these.

Hence, if NIH would be willing to fund 500–1,000 of these grants per year for the next 5–10 years, there would be a tremendous reduction in the individuals competing in the traditional grant cycles. Risk aversion would be significantly reduced, enhancing the ability of scientists to study problems that frankly have limited chance of being funded in today's environment. By freeing up investigators' time, we are enhancing their ability to focus on projects and to formulate new, exciting ideas to test. Overall, this new model eliminates many of the problems associated with our current system and for those who qualify, it would produce a more stable and rewarding career. I believe that this model offers a sustainable system that will reward success while promoting risk, yet ensuring that funds would be available now and in the future to enhance the likelihood of success for our younger generation of scientists and provide the US with the capacity to continue our leadership in biomedical research.

LETTER TO THE EDITOR

Saturated Fat and Health: Recent Advances in Research

Richard D. Feinman

Received: 26 April 2010 / Accepted: 25 May 2010 / Published online: 9 September 2010

Saturated fat of plant or animal origin has been an important ingredient in Western and non-Western diets for centuries. For the past 30 or 40 years, dietary saturated fats have attained a poor reputation especially in relation to cardiovascular health; recommendations to reduce consumption persist even in the face of equivocal or contradictory evidence. This special theme issue of Lipids on saturated fat and health presents contributions from a "hot topic" session at the 100th AOCS annual meeting in Orlando Florida, in May 2009.

Two recent publications highlight the importance of this issue. A meta-analysis by Siri-Tarino et al. [1] showed that there was no significant evidence for concluding that dietary saturated fat is associated with an increased risk of cardiovascular disease (CVD). In addition, whereas some dairy products contribute to the intake of dietary saturated fat, a meta-analysis in this theme issue of the available prospective studies showed that dairy consumption is associated with decreases in CVD risk. The latest prospective cohort study confirms this conclusion for full fat dairy [2].

Although some long chain saturated fatty acids raise low-density (LDL) cholesterol in specific dietary interventions, these fatty acids may have a positive effect on the complex of other markers referred to as atherogenic dyslipidemia: increased concentrations of small, dense LDL particles, decreased high-density lipoprotein (HDL) particles and increased triglycerides, which may be a more important risk factor for myocardial infarction and CVD. Several authors in this theme issue have pointed out that even replacement of saturated fat with polyunsaturates may have a limited effect and low omega-3 fatty acid intake may carry a much larger CVD burden. Replacement with carbohydrates is likely to be detrimental.

Entries in this publication make the point that all mammalian newborns rely on milk, which typically contains 50% of its total fat as saturated fat. Newborns and adults have the machinery to manufacture saturated fatty acids when not present in the diet. In particular, the entry by Bruce German, points out that the brain makes a large amount of saturated fatty acid during myelination. Other work presented in this issue shows that a diet high in saturated fat has very different effects in the presence of carbohydrates than in their absence. A low carbohydrate diet that is high in saturated may actually lead to a reduction in plasma saturated fat compared to one that is also high in carbohydrate, a consequence of reduction of triglycerides in the low carbohydrate diet and persistent de novo fatty acid synthesis in the high carbohydrate diet.

From a metabolic standpoint, the existence of desaturases indicates the need to have direct experimental evidence on the role of dietary lipid intake on the circulating species and biological endpoints. Finally, it is clear that regarding saturated fatty acids as one group is an oversimplification. Individual saturated fatty acids have specific functions depending on chain length. The relation between dietary intake of fats and health is complicated and the current publications point to the need to reduce oversimplification. Is it possible that evolution found benefits to saturated fatty acids that current recommendations do not consider? Whereas diets inordinately high in any component, including saturated fat, are likely to be deleterious, finite quantities of a variety of saturated fatty acids may provide distinct benefits to various metabolic processes and overall health.

REVIEW

Saturated Fat and Cardiometabolic Risk Factors, Coronary Heart Disease, Stroke, and Diabetes: a Fresh Look at the Evidence

Renata Micha · Dariush Mozaffarian

Received: 3 December 2009 / Accepted: 27 January 2010 / Published online: 31 March 2010

Abstract Dietary and policy recommendations frequently focus on reducing saturated fatty acid consumption for improving cardiometabolic health, based largely on ecologic and animal studies. Recent advances in nutritional science now allow assessment of critical questions about health effects of saturated fatty acids (SFA). We reviewed the evidence from randomized controlled trials (RCTs) of lipid and non-lipid risk factors, prospective cohort studies of disease endpoints, and RCTs of disease endpoints for cardiometabolic effects of SFA consumption in humans, including whether effects vary depending on specific SFA chain-length; on the replacement nutrient; or on disease outcomes evaluated. Compared with carbohydrate, the TC:HDL-C ratio is nonsignificantly affected by consumption of myristic or palmitic acid, is nonsignificantly decreased by stearic acid, and is significantly decreased by lauric acid. However, insufficient evidence exists for different chain-length-specific effects on other risk pathways or, more importantly, disease endpoints. Based on consistent evidence from human studies, replacing SFA with polyunsaturated fat modestly lowers coronary heart disease risk, with ~10% risk reduction for a 5% energy substitution; whereas replacing SFA with carbohydrate has no benefit and replacing SFA with monounsaturated fat has uncertain effects. Evidence for the effects of SFA consumption on vascular function, insulin resistance, diabetes, and stroke is mixed, with many studies showing no clear effects, highlighting a need for further investigation of these endpoints. Public health emphasis on reducing SFA consumption without considering the replacement nutrient or, more importantly, the many other food-based risk factors for cardiometabolic disease is unlikely to produce substantial intended benefits.

Introduction

Reducing the consumption of saturated fatty acids (SFA) is a pillar of international dietary recommendations to reduce the risk of cardiovascular disease (CVD) [1–3]. The World Health Organization and the US Dietary Guidelines recommend consuming less than 10%E (percentage of total energy intake) from SFA [4], and the American Heart Association less than 7%E [3]. The strong focus on SFA as a risk factor for CVD originated in the 1960s and 1970s from lines of evidence including ecologic studies across nations, short-term metabolic trials in generally healthy adults assessing total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C), and animal experiments that together appeared to provide consistent support that SFA intake increased the risk of coronary heart disease (CHD).

However, several critical questions have remained about the relationship between SFA consumption and CVD risk. First, do health effects of reducing SFA consumption vary depending on whether the replacement nutrient is carbohydrate (CHO), monounsaturated fat (MUFA), or polyunsaturated fat (PUFA)? A historical emphasis on low fat diets has produced drops in SFA consumption in the US and many other nations, but with concomitant increases in CHO, rather than MUFA or PUFA, as the replacement nutrient [1]. Is there strong evidence to support this dietary strategy? Second, do health effects of SFA vary depending on the chain-length, i.e. comparing 12-, 14-, 16-, and 18-carbon SFA? Current dietary recommendations generally focus on overall SFA consumption, without strong attention on specific SFA. Third, what is the relationship between SFA consumption and risk of stroke and type 2 diabetes mellitus? Historically, research on SFA has focused largely on CHD.

Advances in nutritional science in the last two decades now provide a substantial body of evidence to answer these questions (Fig. 1). These include well-conducted randomized controlled trials (RCTs) of SFA nutrient substitutions and multiple risk pathways as endpoints, including multiple lipid and also non-lipid risk factors (rather than only TC and LDL-C); and large prospective cohort studies and meta-analyses of RCTs of SFA consumption and clinical disease endpoints, that provide more direct evidence for

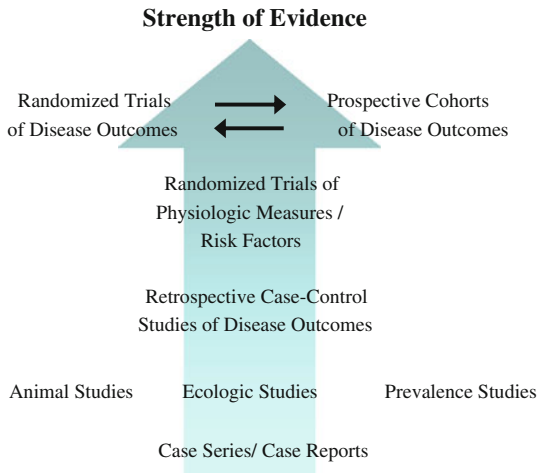

Fig. 1 Advances in nutritional science research paradigms. For causal inference about how dietary habits affect chronic disease, the best evidence is derived from randomized controlled trials (RCTs) of multiple risk pathways, observed differences in disease endpoints in prospective cohort studies, and effects on disease endpoints in RCTs. Conclusions can be considered most robust when these complementary lines of evidence provide concordant results. Adapted with permission from Harris, Mozaffarian, et al. 2009 [90]

effects on disease compared with changes in risk factors alone. Given the complementary strengths and limitations of these newer research paradigms, conclusions can be considered most robust when studies from each paradigm provide concordant evidence for health effects of SFA consumption. Together these research advances provide much stronger evidence for causal inference than data from prior available ecologic studies, limited metabolic studies, and animal experiments.

To elucidate the effects of SFA consumption on CVD risk based on the most current evidence, we reviewed the data from RCTs of multiple risk factors, large prospective cohort studies of disease endpoints, and RCTs of disease endpoints. When sufficient evidence was available, we particularly focused on the potentially different health effects of varying the replacement nutrient; of different chain-length SFA; and of specific effects on CHD, stroke, and diabetes.

Methods

Two investigators independently reviewed the literature for English-language articles published through Sep 2009 by performing searches of Medline, hand-searching of citation lists, and direct contact with experts. Inclusion criteria were any RCT or observational study in adults evaluating SFA consumption and the risk of CHD, stroke, or type 2 diabetes and related risk pathways, including lipids and lipoproteins, systemic inflammation, vascular function, and

insulin resistance (1,254 identified articles). Search terms included "saturated fat(s)", "lipoproteins", "inflammation", "blood pressure", "vascular function", "insulin resistance", "cardiovascular diseases", and "diabetes mellitus". We focused on identifying RCTs of major risk factors, large prospective cohort studies of disease endpoints, and RCTs of disease endpoints, given strengths of these designs and their complementary limitations. We excluded a priori animal experiments, ecological studies, commentaries, general reviews, and case reports. Studies were independently considered by the two investigators for inclusion; rare differences were resolved by consensus.

Effects on Cardiovascular Risk Factors

Lipids and Lipoproteins

RCTs have established clear multiple effects of SFA consumption on circulating lipids and lipoproteins [5, 6]. Each of these effects varies depending on the comparison nutrient, i.e., the nutrient isocalorically replaced for SFA (Fig. 2). Compared with CHO, SFA intake raises TC and LDL-C, but also lowers triglycerides and raises high-density lipoprotein cholesterol (HDL-C). Given these conflicting directions of effects, effects on apolipoproteins or, even better, a more global risk marker such as the TC:HDL-C ratio may provide the best overall indication of potential effects on CHD risk. Compared with CHO, SFA intake has no significant effects on the TC:HDL-C ratio or ApoB levels, and raises ApoA1 levels. In contrast, consumption of PUFA or MUFA in place of SFA leads to lowering of TC, LDL-C, and ApoB; slight lowering (for PUFA) of HDL-C and ApoA1; little effect on triglycerides; and lowering of the TC:HDL-C ratio. Compared with trans fatty acids (TFA), SFA intake has minimal effects on LDL-C but raises HDL-C and lowers triglycerides and lipoprotein(a), with improvement in the TC:HDL-C ratio [7]. Thus, consideration of which nutrient is being replaced is essential when considering lipid effects or designing dietary guidelines or policy measures related to SFA consumption. Overall, the changes in lipid and apolipoprotein levels predict minimal effects on CHD risk when CHO replaces SFA, benefits when PUFA or MUFA replace SFA, and harms when TFA replace SFA.

Effects of SFA consumption on serum lipids and lipoproteins further vary according to which specific SFA is consumed (Fig. 3) [5]. With CHO consumption as the reference, lauric (12:0), myristic (14:0), and palmitic (16:0) acid raise TC and LDL-C, whereas stearic acid (18:0) does

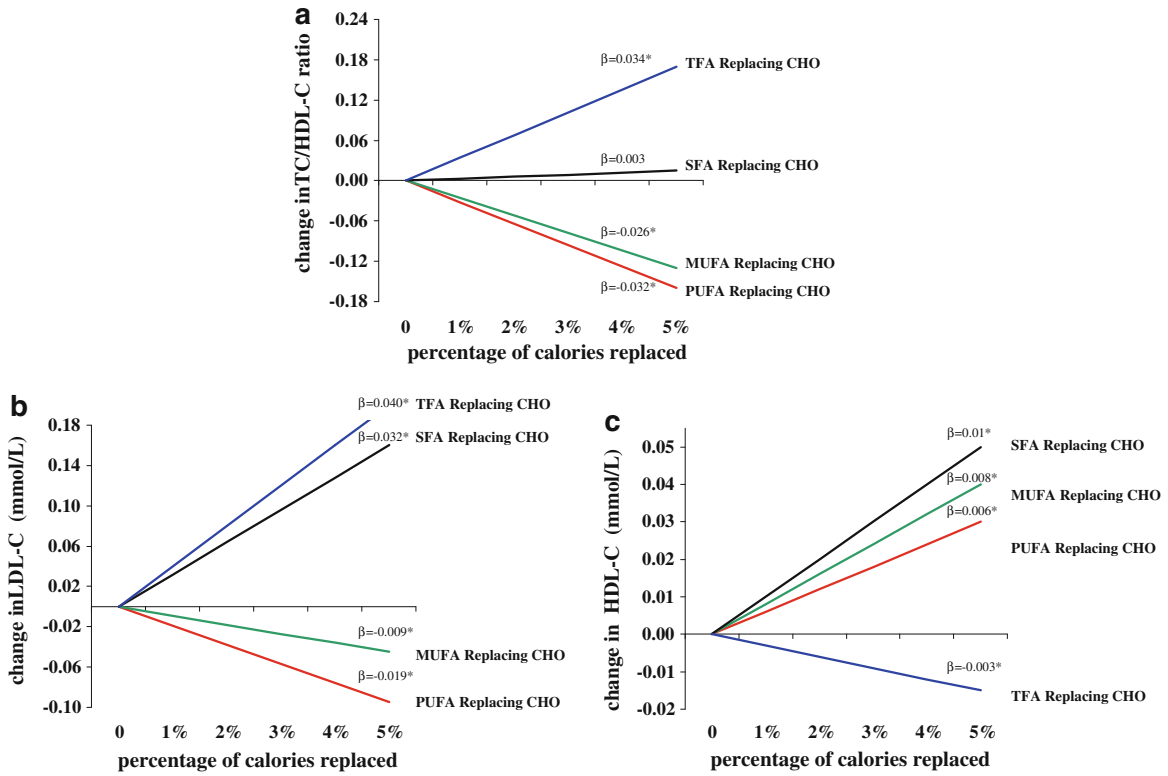

Fig. 2 Changes in blood lipid levels for consumption of saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA), or trans fatty acids (TFA) as an isocaloric replacement for carbohydrate (CHO) as a reference, based on two meta-analyses of randomized controlled feeding trials [5, 6]. β reflects the change for each 1% energy isocaloric replacement; $^*P < 0.05$

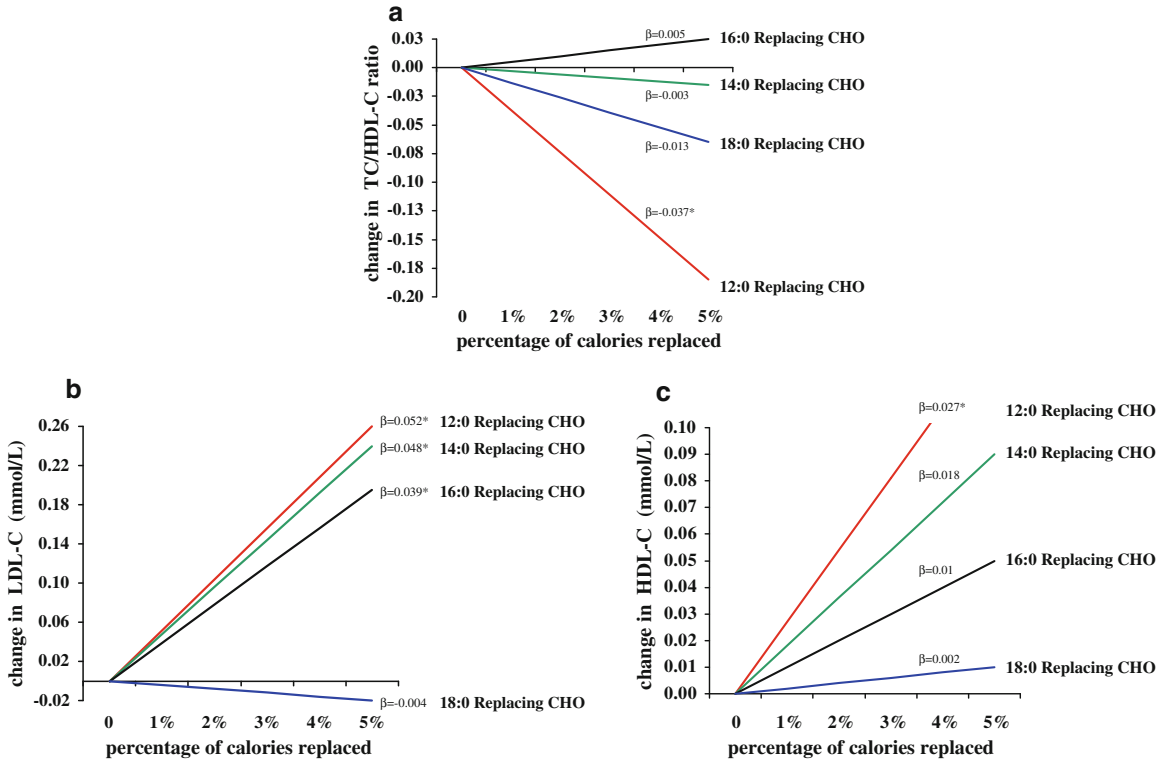

Fig. 3 Changes in blood lipid levels for consumption of different chain-length saturated fatty acids (SFA) as an isocaloric replacement for carbohydrate (CHO), based on meta-analysis of randomized controlled feeding trials [5]. β reflects the change for each 1% energy isocaloric replacement; $^*P < 0.05$

not. All SFA raise HDL-C, but HDL-raising effects are greater as chain-length decreases. Overall, the TC:HDL-C ratio is not significantly affected by myristic or palmitic acid consumption, is nonsignificantly decreased by stearic acid consumption, and is significantly decreased by lauric acid consumption (Fig. 3). These effects suggest little CHD benefit of replacing myristic, palmitic, or stearic acid with CHO, and potential harm of replacing lauric acid with CHO.

Systemic Inflammation

Inflammation independently increases risk of CVD and diabetes [8–11]. Compared with lipid effects, the influence of SFA consumption on inflammation is less well investigated, with mixed results. In a randomized cross-over trial, 20 healthy men consumed a high SFA (22%E SFA), a high MUFA (24%E MUFA), and a high CHO high PUFA (55%E CHO, 8%E PUFA) diet for 4 weeks [12]. At the end of each intervention period, participants were given a fat-rich breakfast (60%E fat) with similar fat composition to that of each diet. Consumption of a butter-rich breakfast (35%E SFA) had no effect on postprandial plasma levels of tumor necrosis factor (TNF)-α, interleukin (IL)-6 or monocyte chemoattractant protein (MCP)-1, compared with an olive oil-rich breakfast (36%E MUFA) or a walnut-rich breakfast (16%E PUFA) [12]. In another cross-over trial of 50 healthy men, consumption of low-chain SFA (12:0–16:0) for 5 weeks (8%E) had no effect on fibrinogen, C-reactive protein (CRP), or IL-6 levels; similar consumption of stearic acid (18:0) increased plasma levels of fibrinogen, but not of CRP or IL-6, compared with CHO [13]. Among hypercholesterolemic subjects ($n = 18$), a one-month diet with 16.7%E from SFA (butter), compared with 12.5%E from PUFA (soybean oil), resulted in a trend toward higher macrophage production of TNF-α, without effects on IL-6 [14].

Observational studies investigating associations between SFA intake and markers of inflammation are limited [15, 16]. Among 4,900 US adults, dietary SFA intake was not cross-sectionally associated with CRP levels, after adjusting for other risk factors and lifestyle behaviors [15]. Other cross-sectional studies have been very small and/or not multivariable-adjusted [16]. Observational studies of circulating (e.g., plasma) or tissue (e.g., adipose) SFA levels [17, 18] are helpful for investigating effects of metabolism but not of SFA consumption, as circulating and tissue SFA are poorly reflective of dietary SFA due to endogenous synthesis and regulation by lipolysis, lipogenesis, and beta-oxidation [19–22]. Overall, the limited and mixed evidence

Table 1 Effects of saturated fatty acids on blood pressure, endothelial function, and arterial stiffness in human feeding trials

Study	Outcome	*N*	Duration	Design	Comparison	SFA replaced by

precludes strong conclusions about potential pro-inflammatory effects of SFA consumption.

Blood Pressure, Endothelial Function, and Arterial Stiffness

Effects of dietary SFA on markers of vascular function including blood pressure, endothelial function, and arterial stiffness are similarly not well characterized [23]. A few observational studies have evaluated SFA intake and incidence of hypertension, with mixed results [24, 25]. Among 30,681 US men followed for 4 years, no significant associations were seen between SFA intake and incident hypertension, after adjusting for age, body mass index, and alcohol consumption [24]. In contrast, among 11,342 US men in the MRFIT study, SFA intake was cross-sectionally positively associated with systolic and diastolic blood pressure, after adjusting for risk factors and lifestyle behaviors, although no adjustments were made for other dietary fats, CHO, or protein [25].

Randomized controlled feeding trials ranging in duration from 3 weeks to 6 months have demonstrated mixed results of SFA intake compared with MUFA, PUFA, TFA, or CHO on measures of blood pressure, endothelial dysfunction, and/or arterial stiffness [23] (Table 1). Among nine trials assessing blood pressure, seven observed no differences between the different diets [26–34]. These trials evaluated a range of SFA consumption levels and replacement nutrients (Table 1). Improvements in BP were seen in two of five RCTs including a comparison to

MUFA, one of five RCTs including a comparison to PUFA, and zero of four RCTs including a comparison to CHO. Among four trials assessing indices of endothelial function, three observed differences in brachial artery flow-mediated dilatation (FMD) between the different diets [31, 35–37]. Improvements in endothelial function were seen in two of three RCTs including a comparison to MUFA, one RCT including a comparison to PUFA, and one of three RCTs including a comparison to CHO; endothelial function was worsened in one RCT replacing SFA with TFA. In two trials evaluating arterial stiffness as assessed by pulse wave velocity (PWV) [31, 37], no effects of reducing SFA consumption were seen, including two RCTs including a comparison to MUFA, one RCT including a comparison to PUFA, and two RCTs including a comparison to CHO. Thus, evidence for effects of SFA consumption on vascular function is mixed, with no clear pattern based on underlying population characteristics, SFA consumption levels, or the comparison nutrient, and with most studies suggesting no effects.

Insulin Resistance and Diabetes

SFA has been considered a risk factor for insulin resistance and diabetes mellitus [38], but review of the current evidence indicates surprisingly equivocal findings. SFA consumption inconsistently affects insulin resistance in controlled trials (Table 2) and has not been associated with incident diabetes in prospective cohort studies (Fig. 4) [39–52]. Among generally healthy individuals, most RCTs show no differences in markers of glucose-insulin homeostasis comparing different intakes of SFA versus MUFA, PUFA, or CHO. Findings are more mixed among individuals having or predisposed to insulin resistance. In these individuals, improvements in markers of glucose-insulin homeostasis were seen in three of five RCTs including a comparison to MUFA, one of three RCTs including a comparison to PUFA, and one RCT including a comparison to CHO. Among all these trials, the great majority were short-term (up to several weeks) and surprisingly small (<20 subjects). The two largest trials ($n = 162$, $n = 59$) found SFA to worsen several indices of glucose-insulin homeostasis in comparison to MUFA (two trials) or CHO (one trial).

Significant additional insight into effects of dietary fats on glucose-insulin homeostasis can be gained from long-term studies evaluating actual onset of diabetes. Among four large prospective cohort studies, none found independent associations between consumption of either SFA (Fig. 4) or MUFA and onset of diabetes [53–56]. In contrast, three of four cohorts [54] observed lower incidence of diabetes with greater consumption of PUFA and/or vegetable fat [53, 55, 56]. In the large Women's Health Initiative trial ($n = 45{,}887$), SFA intake was reduced in the intervention group from 12.7 to 9.5%E over 8 years as part of overall total fat reduction, largely replaced with CHO [57]. In this large RCT, this significant reduction in SFA consumption had no effect on fasting glucose, fasting insulin, homeostasis model assessment (HOMA) insulin resistance, or incident diabetes (RR = 0.95, 95% CI = 0.90–1.03).

Thus, some evidence from short-term RCTs suggests that SFA consumption in place of MUFA may worsen glucose-insulin homeostasis, especially among individuals predisposed to insulin resistance. However, several long-term observational studies and one large RCT suggest no effect of SFA consumption on onset of diabetes. Further confirmatory results of either harm or no effect in additional appropriately powered studies are needed given the present inconsistency of effects across all studies.

Weight Gain and Adiposity

The role of total dietary fat in obesity has been widely studied due to its high energy content (9 kcal/g) and subsequent potential for weight gain [58–60]. Based on RCTs of weight loss with balanced-intensity interventions (i.e., all individuals receiving similar guidance and follow-up, with only the specific dietary advice varying) and prospective observational studies of weight gain, the %E from total fat does not have strong effects on adiposity compared with overall quality and quantity of foods consumed. Evidence for independent effects of specific dietary fats such as SFA on weight gain or adiposity are much more limited. In two large prospective cohort studies, increases in SFA consumption were associated with very small increases in abdominal circumference [61] or body weight during 8–9 years follow-up [62] compared with CHO, after adjusting for other risk factors and lifestyle and dietary behaviors.

Relationships with Cardiovascular Events

Coronary Heart Disease—Prospective Cohort Studies

Most individual prospective cohort studies have not observed an independent relationship between SFA consumption and incident CHD [63–67]. The relatively small number of published studies, among the many available international cohorts, also raises concern for potential publication bias (i.e., additional unreported null studies). Two recent systematic reviews and meta-analyses, the first including 9 cohorts (11 estimates) evaluating 160,673 individuals [64], and the second including 16 cohorts among 214,182 individuals [68], found no significant

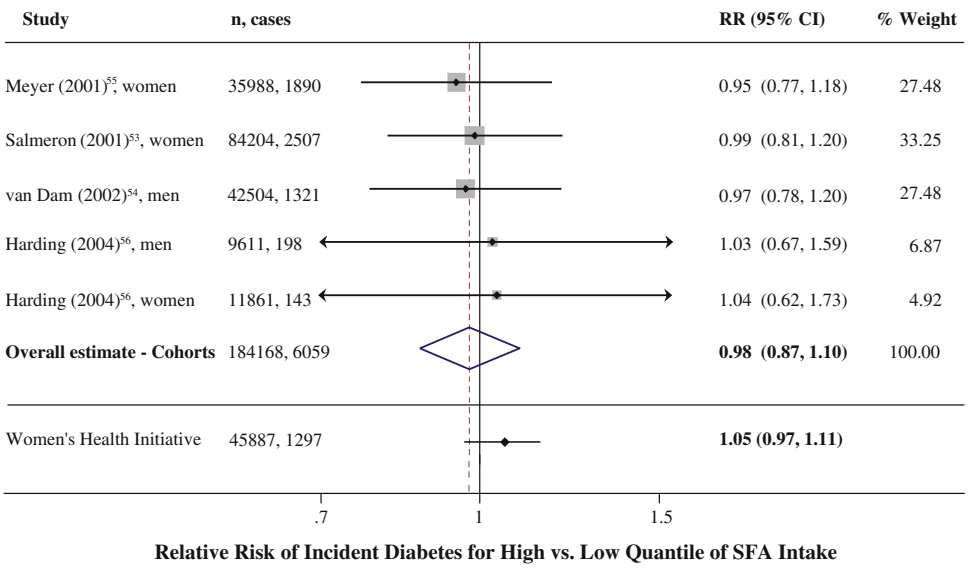

Fig. 4 Relative risk of incident diabetes associated with consumption of saturated fat (SFA). Multivariable-adjusted results from prospective cohort studies and the overall pooled result using fixed-effects meta-analysis are shown. Results from the Women's Health Initiative randomized controlled trial are also shown comparing controls (higher SFA intake) to the intervention group in which SFA was reduced by ~3.2%E over 8 years [79]. CI's for Harding et al.[56] were estimated based on the numbers of cases

association between SFA intake and CHD risk. Comparing the highest to the lowest category of consumption, the pooled RRs in these two meta-analyses were 1.06 (95% CI = 0.96–1.15) and 1.07 (95% CI = 0.96–1.19), respectively. These meta-analyses suggest no overall effect of SFA consumption on CHD events. However, these studies were unable to separately evaluate whether consuming SFA might have different effects on CHD events depending on the nutrient replaced, as would be suggested by differing effects of SFA, depending on the comparison nutrient, on blood lipids and apolipoproteins (Fig. 2).

The best observational evidence to-date of this question is a recent pooled analysis of individual-level data from 11 prospective cohort studies across three continents, including 344,696 individuals with 5,249 CHD events over 4–10 years of follow-up [69]. In fully multivariable-adjusted analyses, SFA consumption was associated with higher CHD risk only in comparison to PUFA. In other words, only consumption of PUFA in place of SFA was associated with lower CHD risk, whereas in fact consumption of CHO or MUFA in place of SFA was associated with higher CHD risk or trends toward higher CHD risk (Fig. 5). These associations were similar when analyses were restricted to CHD deaths only, and were not different in subgroups stratified by either sex or age.

Coronary Heart Disease—Randomized Controlled Trials

Eight RCTs have investigated the effects of consuming PUFA (either total or linoleic acid, LA) in place of SFA on CHD events [70–77]. Most of these trials individually found no significant effects. A recent meta-analysis of these RCTs, including a total of 13,614 participants with 1,042 CHD events, found that CHD risk was lowered by 10% for each 5%E greater PUFA intake replacing SFA [78] (Fig. 5). Many of these trials have important limitations, including for example not being double-blind; incompletely assessing compliance; randomizing sites rather than individuals and having open enrollment and drop-out; and/or including vegetable oils that contained omega-3 PUFA of plant origin that may provide cardiovascular benefits unrelated to decreased SFA intake. Nonetheless, the overall findings from these RCTs of CHD endpoints are consistent with the results from prospective cohorts (Fig. 5).

One large RCT has tested the effect of reducing SFA consumption, replaced largely with CHO, on CHD events. As described, the Women's Health Initiative trial randomized 46,558 women to lower total fat consumption, that included lowering of SFA consumption by ~3%E over 8 years, and largely replaced with CHO. Even though this was an unbalanced intervention (i.e., the intervention group received extensive dietary counseling, whereas the control group received usual care) that would generally bias toward risk-reduction in the intervention group, there were no significant effects on either incident CHD (RR = 0.93, 95%CI = 0.83–1.05) or total CVD (RR = 0.96, 95%CI = 0.89–1.03) [79]. This absence of benefit for substituting SFA with CHO is consistent with expected effects based on lipid changes (TC:HDL ratio) or observed relationships in prospective cohort studies (Fig. 5).

Stroke: Prospective Cohorts and Randomized Controlled Trials

Among five prospective cohort studies evaluating SFA consumption and incidence of stroke, one of three found

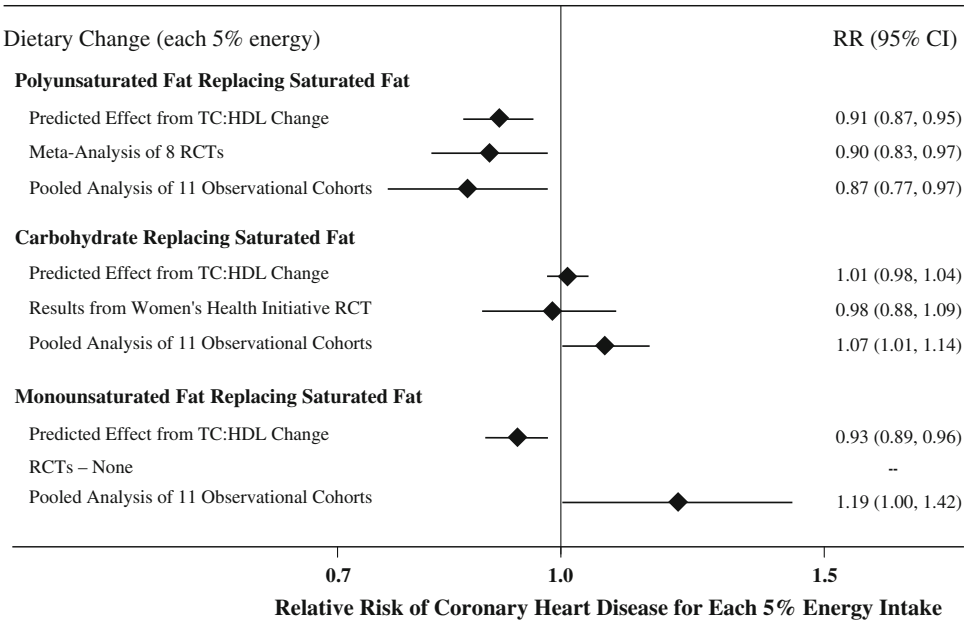

Fig. 5 Effects on coronary heart disease (CHD) risk of consuming polyunsaturated fat (PUFA), carbohydrate (CHO), or monounsaturated fat (MUFA) in place of saturated fat (SFA). Predicted effects are based on changes in the TC:HDL-C ratio in short-term trials [5], coupled with observed associations between the TC:HDL-C ratio and CHD disease events in middle-aged adults [91]. Evidence for effects of dietary macronutrients on actual CHD events comes from a meta-analysis of eight randomized controlled trials (RCTs) for PUFA replacing SFA, including 13,614 participants with 1,042 CHD events [78]; and from the Women's Health Initiative (WHI) RCT for CHO replacing SFA, including 46,558 individuals with 1,185 CHD events and ~3.2%E reduction in SFA over 8 years [79]. Evidence for observed relationships of usual dietary habits with CHD events comes from a pooled analysis of 11 prospective cohort studies, including 344,696 individuals with 5,249 CHD events [69]. Reproduced with permission from Mozaffarian et al., in press [78]

SFA to be associated with lower risk of ischemic stroke [80–82], and one of three found SFA to be associated with lower risk of hemorrhagic stroke [80, 83, 84]. Four prospective cohorts have also observed protective associations between animal protein intake, that is often consumed together with SFA, and risk of hemorrhagic stroke [85]. A recent systematic review and meta-analysis of eight prospective cohorts also found that SFA consumption was associated with trends toward lower risk of stroke: comparing the highest to the lowest category of SFA intake, the RR was 0.81 (95% CI = 0.62–1.05) [68]. In the Women's Health Initiative trial, reduction in SFA consumption did not have a significant effect on incident stroke over 8 years (RR = 1.02, 95% CI = 0.90–1.17) [79]. Thus, overall, SFA consumption does not appear to increase the risk of stroke, and in fact some studies suggest a protective effect. Further investigation of these effects, including independence from potential benefits of animal protein intake, is warranted.

Future Research Directions

The multiple well-designed studies reviewed herein provide substantial evidence for health effects of SFA consumption. However, important questions remain. Although replacement of SFA with CHO appears to provide no overall CVD benefit, indirect lines of evidence suggest that effects could vary depending on overall CHO quality [86–88]. For example, replacing SFA with less processed, higher fiber, lower glycemic index CHO could provide benefit, whereas replacing SFA with more processed, lower fiber, higher glycemic index CHO might have no effects or even be harmful. Effects of replacing SFA with CHO could also vary with an individual's susceptibility to insulin resistance/metabolic syndrome, in whom adverse metabolic effects of highly refined CHO may be more pronounced. Evidence for effects of replacing SFA with MUFA is mixed. Such effects could vary depending on other constituents in MUFA-containing foods (e.g., animal fats vs. vegetable oils), for example due to potentially beneficial phytochemicals and flavanols contained in the latter but not the former. Each of these issues requires direct investigation. Additionally, whereas the substantial differences in blood lipid effects of different chain-length SFA are clear, blood lipids represent only one set of intermediate risk markers. Investigation of the effects of different chain-length SFA on other risk pathways and, more importantly, on disease endpoints is urgently needed to determine the extent to which dietary and policy

recommendations should focus on specific SFA rather than overall SFA consumption. Additional investigation of effects of SFA consumption on blood pressure, endothelial function, insulin resistance, diabetes, and stroke (plus stroke subtypes) is also needed, including consideration of potential variation depending on both the replacement nutrients and specific chain-length SFA under consideration. Future research should also evaluate the health effects of specific foods consumed, i.e., SFA intake from different meats versus dairy versus tropical fats, as well as how individual factors, such as age, sex, lifestyle factors, predisposition to insulin resistance, or genetic variation, may alter such responses.

Conclusions

Current public health dietary recommendations often prioritize the reduction of SFA consumption to prevent CVD. A review of the current evidence, particularly findings from well-performed RCTs of risk pathways, large prospective cohorts of disease endpoints, and RCTs of disease endpoints, suggests that this focus may not produce the intended benefits. First of all, substantial evidence indicates that health effects of reducing SFA vary depending on the replacement nutrient. Based on the best evidence from human studies, replacing SFA with PUFA (e.g., vegetables, vegetable oils) lowers CHD risk, whereas replacing SFA with CHO has no benefits. Replacing SFA with MUFA has uncertain effects, based on mixed evidence within and across different research paradigms. Of note, the effects of replacing SFA with PUFA or CHO, but not MUFA, on clinical CHD endpoints could be relatively predicted from the effects of these nutrient substitutions on the TC:HDL-C ratio. Thus, policies that prioritize the reduction of SFA consumption without specifically considering the replacement nutrient may have little or no effects on disease risk, especially as the most common replacement in populations is often CHO.

Second, even under optimal replacement scenarios of SFA for PUFA, the magnitude of likely benefit warrants attention. RCTs of the blood TC:HDL-C ratio, prospective cohorts of disease endpoints, and RCTs of disease endpoints each converge on $\sim$10% reduction in CHD events for 5%E substitution of SFA with PUFA. This approaches the maximal plausible risk reduction in most populations; in the US, for example, such benefit would require overall population decrease from the current 11.5 to 6.5%E SFA consumption. Thus, although recommendations to replace SFA with PUFA appear appropriate, the much larger CVD burdens caused by other dietary factors (e.g., low omega-3, low fruits and vegetables, high trans fat, and high salt) [89] appear to warrant much more attention. Finally, although investigation of individual nutrients provides important information on potential underlying mechanisms of health effects, people make decisions about eating whole foods that contain multiple macro- and micronutrients in various amounts. Thus, food-based scientific research and policy recommendations may be most relevant in the modern era to understand and reduce the pandemics of chronic disease occurring in nearly all nations.

Atherogenic Dyslipidemia: Cardiovascular Risk and Dietary Intervention

Kiran Musunuru

Received: 31 December 2009 / Accepted: 22 March 2010 / Published online: 4 June 2010

Abstract Atherogenic dyslipidemia comprises a triad of increased blood concentrations of small, dense low-density lipoprotein (LDL) particles, decreased high-density lipoprotein (HDL) particles, and increased triglycerides. A typical feature of obesity, the metabolic syndrome, insulin resistance, and type 2 diabetes mellitus, atherogenic dyslipidemia has emerged as an important risk factor for myocardial infarction and cardiovascular disease. A number of genes have now been linked to this pattern of lipoprotein changes. Low-carbohydrate diets appear to have beneficial lipoprotein effects in individuals with atherogenic dyslipidemia, compared to high-carbohydrate diets, whereas the content of total fat or saturated fat in the diet appears to have little effect. Achieving a better understanding of the genetic and dietary influences underlying atherogenic dyslipidemia may provide clues to improved interventions to reduce the risk of cardiovascular disease in high-risk individuals.

Keywords Lipids · Lipoproteins · Cardiovascular diseases · Genetics

Definition of Atherogenic Dyslipidemia

Prospective epidemiologic studies have shown that blood levels of low-density lipoprotein cholesterol (LDL-C) significantly predict incident atherosclerotic cardiovascular disease (CVD), and LDL-C-lowering therapy has been repeatedly demonstrated in many populations to reduce CVD risk. This has led to the formulation of risk prediction algorithms for identification of high-risk individuals and specific LDL-C goals to be achieved with lifestyle and pharmacological interventions [1]. Many individuals with normal LDL-C levels nevertheless develop CVD [2], particularly in older age groups.

There is considerable heterogeneity among low-density lipoproteins (LDL), ranging from small, dense, lipid-depleted particles to large, buoyant cholesterol-enriched particles [3]. These particles have typically been grouped into four categories ranging from LDL1 (largest) to LDL4 (smallest) and subdivided even further into as many as eight subfractions. A number of studies have suggested that small LDL particles carry disproportionate atherogenic risk [4–7]. This suggests that treatment based on LDL-C levels alone potentially provides a suboptimal treatment for a significant proportion of at-risk individuals.

High-density lipoprotein cholesterol (HDL) also has a strong epidemiological relationship with CVD, with increased HDL-C levels protective against disease, and is divided into two to three subfractions. As with LDL-C, some studies suggest that specific HDL subfractions are more predictive of CVD than HDL-C [8], whereas others suggest no distinction [9–13].

Austin et al. first described a risk-conferring lipid/lipoprotein profile, termed "atherogenic dyslipidemia" or the "atherogenic lipoprotein phenotype," that comprises a higher proportion of small LDL particles, reduced HDL-C, and increased triglycerides [14]. Atherogenic dyslipidemia is characteristically seen in patients with obesity, the metabolic syndrome, insulin resistance, and type 2 diabetes mellitus [15, 16] and has emerged as an important marker for the increased CVD risk observed in these populations. Herein we review the present understanding of the

contribution of atherogenic dyslipidemia to CVD, as well as the genetic and dietary influences underlying atherogenic dyslipidemia.

Small LDL Particles, Total LDL Particles, and CVD Risk

Besides the traditional blood lipid measurements of LDL-C, HDL-C, and triglycerides, there now exist a number of alternative measures that assess lipoprotein subfractions in some way. The best established is the measurement of the blood concentration of apolipoprotein B (apoB). Each non-HDL particle—including LDL particles, intermediate-density lipoprotein (IDL) particles, very-low-density lipoprotein (VLDL) particles, chylomicrons, and their remnants—typically harbors one apoB molecule. Thus, the apoB measure represents a count of non-HDL particles circulating in the bloodstream. More sophisticated techniques can quantify the numbers of particle within each lipoprotein class, as well as within subfractions of each lipoprotein class; in addition, peak particle size within a class (e.g., LDL peak particle diameter) can be calculated. These techniques include analytical ultracentrifugation, gradient gel electrophoresis, nuclear magnetic resonance (NMR), and a relatively new gas-phase differential electrophoretic macromolecular mobility-based method (termed as the ion mobility method).

A number of studies have now used one of the lipoprotein subfraction measurement techniques to assess whether any of the subfractions have prognostic power for CVD or intermediate endpoints for CVD such as coronary calcium score or carotid intima-media thickness. Notably, many of these studies find that the small LDL particle concentration predicts cardiovascular endpoints comparably to if not better than LDL-C [7, 17–21].

There is biological plausibility for a causal role of small LDL particles in atherosclerotic disease, with evidence that small, dense, lipid-poor LDL particles may be inherently more atherogenic than large LDL particles [6]. They have greater susceptibility to oxidation than larger particles and thus may be more likely to instigate the inflammatory processes in vascular endothelium that underlie atherosclerotic disease. They bind more tightly to arterial proteoglycans and may penetrate into the arterial wall more easily. Finally, small LDL particles have relatively lower affinity for the LDL receptor compared to mid-size particles, resulting in decreased cellular uptake and increased time spent circulating in the bloodstream, where the particles would have prolonged influence on the atherosclerotic process.

However, each of the studies that have demonstrated that small LDL particle concentrations are predictive of cardiovascular endpoints also showed that the total LDL particle number (LDL-P) is similarly predictive [7, 17–21]. This is because the small LDL particle number is highly correlated with LDL-P. Intuitively, this can be explained by the reasoning that among individuals with equal LDL-C levels, the same of amount of cholesterol distributed among a larger number of particles implies that the particles must be of smaller size on average. It is possible, then, that all LDL particles are similarly atherogenic and the association of increased small LDL particle concentrations with disease is simply the result of the increased number of LDL particles, rather than small LDL particles being uniquely atherogenic. Epidemiological studies to date have not been able to unequivocally distinguish between these two possibilities.

Regardless of whether the small LDL particle number or LDL-P is used, either offers prognostic information distinct from the standard LDL-C measure obtained with a fasting lipid profile. Reinforcing this point was the finding in the Framingham Offspring Study that when participants were divided into four groups—low LDL-C + low LDL-P, low LDL-C + high LDL-P, high LDL-C + low LDL-P, high LDL-C + high LDL-P—stratification by LDL-P markedly discriminated by CVD event-free survival, whereas there was no difference seen with stratification by LDL-C [22].

Given the data suggesting a particular role for small LDL particles in CVD, and the epidemiological observation of the "atherogenic lipoprotein phenotype" of increased small LDL particle numbers, decreased HDL-C, and increased triglycerides, some lipoprotein assays have defined cutoffs for LDL peak particle size, with high particle sizes designated as "pattern A" (normal; defined as >25.5 nm when measured by gradient gel electrophoresis [3]) and low particle sizes designated as "pattern B" (having an increased proportion of small LDL particles and, thus, more likely to have atherogenic dyslipidemia; defined as ≤ 25.5 nm when measured by gradient gel electrophoresis) to aid clinicians in categorizing patients at risk for CVD.

Principal Component Analysis of Lipoprotein Subfractions

Although numerous studies have demonstrated that some lipoprotein subfractions are predictive of CVD, none of these studies systematically analyzed the interrelationships among all of the various lipoprotein subfractions to determine whether there are distinct combinations of subfractions that independently confer cardiovascular risk. To address this question, we have applied the technique of principal component analysis to identify interrelated combinations of subfractions and determine their relationship

with CVD in a large prospective cohort study, the Malmö Diet and Cancer-Cardiovascular Cohort (MDC-CC) [23]. Principal component analysis is a statistical method that analyzes the interrelationships between numerous variables and yields a fewer number of components that explain most of the correlation information of the original variables. Each of the resulting components is an independent linear combination of the original variables; furthermore, the components are fully independent of one another, i.e., they have zero correlation.

When we applied principal component analysis to eleven lipoprotein subfractions measured by ion mobility analysis of samples from more than 4,500 individuals in MDC-CC, we identified three major independent components, all of which were associated with incident CVD in the cohort [23, 24]. Notably, one of the three components represented a pattern of increased small and medium LDL particle concentrations, decreased large HDL particle concentrations, and increased triglycerides—corresponding to atherogenic dyslipidemia. This component was much more highly associated with incident CVD events (hazard ratio of 1.22 per 1 standard deviation) than LDL-C (hazard ratio of 1.10 per 1 standard deviation), indicating it to be a superior predictor of disease [23]. The other two principal components represented LDL-associated CVD risk (hazard ratio of 1.10 per 1 standard deviation) and HDL-associated CVD protection (hazard ratio of 0.81 per 1 standard deviation). Thus, our analysis established that atherogenic dyslipidemia is an epidemiologically distinct risk factor for CVD than the traditional risk factors of LDL-C and HDL-C and represents an independent mechanistic pathway contributing to the pathogenesis of CVD. Accordingly, there is a strong rationale to explore genetic and dietary modifiers of this pathway in order to better craft targeted interventions to reduce CVD risk.

Genetics and Atherogenic Dyslipidemia

Family-based segregation analyses suggest that the atherogenic lipoprotein phenotype has a strong genetic basis that likely reflects contributions from numerous genes [14, 25, 26]. Candidate genes include those that influence LDL peak particle size; family-based and twin studies indicate a large heritable component of LDL size, ranging from 40 to 60% of the trait. Genes with variants that have been reported to be associated with LDL size include: *CETP*, encoding cholesteryl ester transfer protein, which exchanges cholesteryl esters and triglycerides from HDL lipoprotein particles to LDL particles; *LDLR*, encoding the LDL receptor, which is responsible for cellular uptake of LDL particles from the bloodstream; *LPL*, encoding lipoprotein lipase, which hydrolyzes triglycerides in chylomicrons and VLDL particles, converting the latter to LDL particles, as well facilitating cellular lipoprotein uptake; *MTP*, encoding microsomal triglyceride transfer protein, which transfers triglycerides to nascent VLDL particles in hepatocytes; and the apolipoprotein genes *APOA5*, *APOB*, *APOC3*, and *APOE*, which are important constituents of varied lipoprotein particles [25–35]. All of these genes play credible roles in determining the size and lipid content of LDL particles as well as other lipoprotein particles and so might directly contribute to atherogenic dyslipidemia.

By applying principal component analysis in the MDC-CC, we were able to define a component representing atherogenic dyslipidemia. This enabled us to perform genetic analyses on this specific component and thereby identify gene variants directly linked to the dyslipidemia profile, rather than a property of an individual lipoprotein (such as LDL size). We took advantage of data from a recent genome-wide association study on lipid traits, which identified 30 genetic loci strongly linked to one or more of the blood LDL-C, HDL-C, and triglyceride levels [36]. We assessed the strength of association between SNPs in each of these genetic loci and the atherogenic dyslipidemia component. We found that variants in six loci, harboring the *CETP*, *LPL*, *APOA5*, *LIPC*, *GALNT2*, and *MLXIPL* genes, were highly associated with this component. In confirmation, each of the SNPs at these genes was also associated with small/medium LDL particle concentrations and—in the opposite direction—large HDL particle concentrations as well as HDL-C and/or triglycerides [23]. Interestingly, the variants at all but two of the six genes (*CETP* and *APOA5*) were not associated with LDL-C.

Thus, the MDC-CC study validated several of the genes previously linked to LDL size as also having variants associated with atherogenic dyslipidemia, as well as identifying a few novel candidate genes. The implicated genes may interact in biological pathways that regulate the different components of the dyslipidemia profile; conceivably, interventions targeting one or more of these specific genes may modulate an individual's lipid/lipoprotein profile in a clinically favorable way and reduce the risk of CVD, even if they do not affect blood LDL-C levels.

Effects of Diet on Atherogenic Dyslipidemia

An important question is whether alterations in diet—whether in regard to carbohydrate, fat, or saturated fat content—have predictable effects on lipoprotein profiles and, specifically, atherogenic dyslipidemia. This has implications for nutritional counseling for patients at risk for CVD: which diets are likely to induce or worsen atherogenic dyslipidemia and thereby increase CVD risk, and

thus should be avoided, and which diets may reverse the dyslipidemia and should be recommended. A related question is whether particular diets are of greater or less benefit in individuals with atherogenic dyslipidemia compared to those without it.

In one study, 105 healthy middle-age men were placed on high-fat (46% of calories from fat), low-carbohydrate and low-fat (24% of calories from fat), high-carbohydrate diets in a crossover design in which they experienced 6 weeks on each diet [37]. To simplify the interpretation of the study results, the proportions of types of fat (unsaturated vs. saturated, 1:1 ratio) and types of carbohydrates (simple vs. complex, 1:1) remained fixed in these diets. Across all subjects, there were significantly higher levels of triglycerides and the LDL3/LDL4 subfractions (small and very small LDL particle concentrations), as well as lower HDL-C levels, while on the low-fat diet compared to the high-fat diet. Thirty-six subjects who were pattern A or intermediate (as judged by LDL peak particle diameter) when on the high-fat diet converted to pattern B on the low-fat diet; all of the individuals who were pattern B on the high-fat diet remained pattern B on the low-fat diet. In a follow-up study, the individuals who had been pattern A on both the high-fat and low-fat diets were subjected to a very-low-fat diet (10% of calories from fat, with replacement by carbohydrates) [38]. One-third of the subjects converted to pattern B on this diet. Thus, reduction of fat along with increased carbohydrate intake altered lipoprotein profiles towards atherogenic dyslipidemia.

Of interest, individuals who were pattern B on a high-fat diet, when compared to those who were pattern A on a high-fat diet, experienced a much larger reduction in LDL-C when on a low-fat diet [37]. This was confirmed in both men and in pre-menopausal women, with a two- to threefold greater reduction in LDL-C observed [39, 40]. This phenomenon appeared to be the consequence of differential effects on lipoprotein profiles. Pattern A individuals experienced a larger decrease in LDL1 (large LDL particle concentrations) and an increase in LDL3 (small LDL particle concentrations) with little change in LDL2 (medium-large particle concentrations), whereas pattern B individuals displayed a decrease in LDL2 with a smaller decrease in LDL1 and no change in LDL3. Besides explaining the discrepancy in LDL-C alteration, these observations also explain why many pattern A individuals converted to pattern B (35%) but not vice versa (6%).

Extrapolating across all of these studies, the prevalence of pattern B increases with the amount of dietary carbohydrate and decreases with the amount of dietary fat. However, in these studies the changes in the proportions of calories derived from fat were largely balanced by reciprocal changes in calories from carbohydrates, making it difficult to determine whether dietary fat or carbohydrates are the major influence on atherogenic dyslipidemia. A study in 178 overweight men shed some light on this question. When compared on a higher-carbohydrate diet (54% of calories from carbohydrates, 1:1 simple:complex) versus a lower-carbohydrate diet (39% of calories from carbohydrates, 1:1 simple:complex), between which the difference was made up of protein calories (15 vs. 29%) rather than fat (minimal change), the subjects had a higher prevalence of pattern B when on the higher-carbohydrate diet [41]. This observation suggests that dietary carbohydrates are the principal driver of atherogenic dyslipidemia.

A more complete analysis with the 178 overweight men was highly informative as to the effects of varying carbohydrates and saturated fat, as well as weight loss, on lipoprotein profiles [42]. Four diets were compared: (1) 54% of calories from carbohydrates (1:1 simple:complex) with low saturated fat, (2) 39% of calories from carbohydrates (1:1 simple:complex) with low saturated fat, (3) 26% of calories from carbohydrates (1:1 simple:complex) with low saturated fat, and (4) 26% of calories from carbohydrates (1:1 simple:complex) with high saturated fat. Diets (1) and (2) had equal fat content, diets (3) and (4) had equal fat content that was higher than that of diets (1) and (2). The subjects underwent a weight-maintenance phase of 3 weeks on the assigned diets, followed by a weight-loss phase of 5 weeks (with a subsequent four-week weight stabilization period) on the same diets.

During the weight-maintenance phase, the subjects on the low-carbohydrate diets [(3) and (4)] experienced significant decreases in their triglyceride levels as well as their LDL3 and LDL4 levels (small and very small LDL particle concentrations); the individuals on the higher-carbohydrate diets displayed only modest changes. In contrast, during the weight-loss phase, the individuals on higher-carbohydrate diets experienced larger decreases in triglycerides and small LDL particle concentrations than did those on low-carbohydrate diets. Thus, by the end of the study, the higher-carbohydrate subjects had "caught up" with the low-carbohydrate subjects. The lower the dietary carbohydrate content, the lower the prevalence of pattern B, both after the weight-maintenance phase and after the weight-loss phase, although the differences in the prevalence of pattern B were smaller after weight loss, again pointing to a "catch-up" phenomenon.

Comparing the low-saturated-fat and high-saturated-fat low-carbohydrate diets [(3) vs. (4)], there were essentially no differences in changes in triglycerides, small LDL particle concentrations, or prevalence of pattern B, either in the weight-maintenance or weight-loss phases [42]. This finding indicates that dietary saturated fat content has little influence on the components of the atherogenic lipoprotein phenotype. This agrees with the results of a study that compared the effects of four-week treatments with a

high-saturated-fat diet (38% of calories from fat, with 20% of calories from saturated fat), a monounsaturated fatty acid (MUFA) olive oil-rich diet (38% of calories from fat, with 22% of calories from MUFA), and a high-carbohydrate diet (30% of calories from fat, with <10% of calories from saturated fat, and 55% of calories from carbohydrates) in 84 individuals [43]. (In all diets, ~40% of the carbohydrate calories came from simple carbohydrates, the remainder from complex carbohydrates.) There were no differences in triglycerides, LDL size, or prevalence of pattern B between the high-saturated-fat and high-MUFA diets; in contrast, both high-fat diets yielded higher LDL sizes than the high-carbohydrate diet, with one-third of the subjects converting from pattern A to pattern B with the high-carbohydrate diet. The lack of difference in LDL size seen between the two high-fat diets is consistent with two earlier studies, one of which noted a minimal increase in LDL size with a high-MUFA diet compared to a high-saturated-fat diet [44], the other of which reported no difference [45].

Finally, analysis of a prospective cohort study (the Framingham Heart Study) confirmed that fat content in the diet, after multivariable adjustment for carbohydrate intake and a variety of other potential confounders, did not significantly affect LDL size or triglyceride levels in either men or women [46]. This was true regardless of the quality of fat studied—total fat, saturated fat, MUFA, or polyunsaturated fatty acid (PUFA) content. Thus, it appears that both the quantity and quality of fat consumed (assuming no change in the number of calories obtained from carbohydrates) have minimal effects on the atherogenic lipoprotein phenotype.

Although it is possible that different types of carbohydrates may have different effects on lipoproteins, none of the discussed studies were able to shed light on this question, since in all cases the ratio of simple to complex carbohydrates was kept constant among the experimental diets. Given that carbohydrate intake appears to be the primary driver of atherogenic dyslipidemia, it would be desirable for future studies to directly compare diets in which the proportions of different types of carbohydrates are varied, with the overall number of calories coming from carbohydrates being held constant.

In conclusion, either lowering the dietary carbohydrate content or losing weight appears to attenuate atherogenic dyslipidemia (although there does not appear to be an additive effect of the two), whereas altering the total fat or saturated fat content has little influence. However, being placed on a lower-fat, higher-carbohydrate diet appears to result in lower LDL-C levels than a higher-fat, lower-carbohydrate diet, particularly for individuals starting with pattern B. Thus, it remains unclear whether having high or low dietary carbohydrate content is more beneficial for cardiovascular health. It should be noted that the intervention studies described above were all short-term (weeks) and so were not able to compare long-term CVD outcomes resulting from the various diets. Thus, we await long-term studies before these data can be used to help shape nutritional recommendations for patients at CVD risk.

Interactions of Genetics and Dietary Interventions

Given that both genetics and diet contribute to the atherogenic lipoprotein phenotype, it is natural to expect that there may be interactions between the two factors. For example, individuals with specific variants in a gene may experience changes in lipoprotein concentrations when placed on a particular diet, whereas individuals with other variants in the gene may be resistant to the effects of that diet. Another possibility is that individuals with one set of genetic variants may experience different types of lipoprotein changes than individuals with a different set of genetic variants, when all are placed on the same diet. This might manifest, for instance, as some individuals being more prone than others to developing atherogenic dyslipidemia on a high-carbohydrate diet. Although data is sparse in regard to whether such interactions exist, some limited work suggests that interactions may play an important role in determining lipoprotein profiles and may thus be informative for CVD risk prediction. For example, knowledge of a patient's genetic information may allow medical providers and nutritional counselors to predict what lipoprotein changes are likely to occur if the patient starts a particular dietary intervention and, thus, better advise the patient regarding lifestyle changes.

In one study, 50 individuals with pattern A lipoprotein profiles, offspring of 29 sets of parents, were tested for induction of pattern B with a very-high-carbohydrate diet [47]. Notably, all six of the subjects who converted to pattern B were descended from two pattern B parents. Quantitatively, LDL peak particle size decreased to a greater degree in offspring of two pattern B parents than in offspring of two pattern A parents. These findings suggest that there is a heritable basis for the induction of atherogenic dyslipidemia by a carbohydrate-rich diet.

A more detailed study was performed to examine the interaction of varied dietary fat content and variation in the *APOA5* gene, one of the genes previously linked to atherogenic dyslipidemia [39, 48]. An uncommon DNA sequence variant in *APOA5* (~6% frequency in individuals of European descent) that alters the 19th amino acid of the apoA-V protein from serine to tryptophan, termed *APOA5*3*, was compared to the usual variant at the DNA base, termed *APOA5*1*. Individuals who had a genotype of

*1/*3 (one of each variant), when compared to individuals with *1/*1 (two copies of the usual variant) had higher small LDL particle concentrations and triglycerides, as well as higher prevalence of pattern B, regardless of whether they were on a low-fat or high-fat diet. Also, there were higher small LDL particle concentrations and triglycerides and higher prevalence of pattern B when comparing all individuals on a low-fat diet compared to those on a high-fat diet. However, there were no differences in the relative changes of small LDL particle concentrations and triglycerides—or relative rates of pattern B—between *1/*3 and *1/*1 individuals on low-fat versus high-fat diets.

Thus, while both the *3 allele and, separately, a low-fat diet influenced the lipoprotein profile towards atherogenic dyslipidemia, there was no evidence for an interaction between genotype and diet. Interestingly, the only significant difference seen in the relative changes of lipoproteins between the two genotype groups on fat-varied diets was with the LDL2 subfraction (corresponding to medium-large LDL particle concentrations), where *1/*3 subjects experienced a threefold greater decrease in LDL2 than *1/*1 subjects when on a low-fat diet versus a high-fat diet [39]. Thus, *APOA5* did not appear to affect dietary induction of atherogenic dyslipidemia, though it did modulate dietary effects on some lipoproteins.

A somewhat different analysis in the Framingham Heart Study examined both the *APOA5*3* variant as well as a different variant that alters a DNA base in the *APOA5* promoter (–1131T > C, termed *APOA5*2*) with respect to potential interactions with dietary fat intake in modulating lipoproteins [46]. Individuals with the *APOA5*2* variant displayed increased triglycerides and smaller LDL size when the dietary PUFA content was >6% (by calories); individuals without the variant showed no differences with varied PUFA intake. There were no interactions of the *APOA5*2* variant with total fat, saturated fat, or MUFA intake, nor were there any interactions of the *APOA5*3* variant with any type of fat.

Thus, while both of the *APOA5* studies discussed here suggest that *APOA5* does influence the dietary effects of fat intake on lipoproteins, they disagree on the effects of specific gene variants. This highlights a critical problem in the study of gene-diet interactions, the lack of consistency between studies. In this example, the two studies differed in study design (one was a short-term interventional study, the other an observational prospective cohort study), the types of diets examined (one focused only on total fat intake, the other on total fat as well as specific types of fat), the variants examined (one focused only on *APOA5*3*, the other on both *APOA5*2* and *APOA5*3*), the measurement of lipoproteins (one assessed each of the LDL subfractions, the other only LDL size), and the populations studied (one focused on overweight men, the other on a population-based sample).

As such, it is difficult to draw any firm conclusions from any one gene-diet study in the absence of replication by another study that examined the same question using similar methodologies. For example, one study demonstrated that a Mediterranean-style, MUFA-rich diet compared to a high-carbohydrate diet increased LDL size in individuals with certain *APOE* gene variants but decreased LDL size in those with other *APOE* variants; [43] this is potentially a clinically important observation, but no confirmatory study has yet emerged, calling this observation into doubt. As pointed out by others, the field would greatly benefit from increased collaboration and coordination of studies among international nutrition researchers [49].

Conclusion

Atherogenic dyslipidemia appears to be an important independent risk factor for CVD, confirmed by principal component analysis of lipoprotein subfractions in a large prospective cohort study. As the genetic basis of lipoprotein metabolism becomes better understood, gene variants contributing to atherogenic dyslipidemia are being identified; these genes may serve as therapeutic targets to modulate the adverse effects of the dyslipidemia. It is clear that either reduction of dietary carbohydrate content or weight loss will improve an atherogenic dyslipidemic profile, whereas specifically altering fat or saturated fat content may have little influence. We await long-term clinical trials to assess whether genetic and/or dietary interventions with the intent of modifying the dyslipidemia will ultimately translate into reduction of CVD risk.

REVIEW

Saturated Fats: A Perspective from Lactation and Milk Composition

J. Bruce German · Cora J. Dillard

Received: 18 March 2010 / Accepted: 24 June 2010 / Published online: 23 July 2010

Abstract For recommendations of specific targets for the absolute amount of saturated fat intake, we need to know what dietary intake is most appropriate? Changing agricultural production and processing to lower the relative quantities of macronutrients requires years to accomplish. Changes can have unintended consequences on diets and the health of subsets of the population. Hence, what are the appropriate absolute amounts of saturated fat in our diets? Is the scientific evidence consistent with an optimal intake of zero? If not, is it also possible that a finite intake of saturated fats is beneficial to overall health, at least to a subset of the population? Conclusive evidence from prospective human trials is not available, hence other sources of information must be considered. One approach is to examine the evolution of lactation, and the composition of milks that developed through millennia of natural selective pressure and natural selection processes. Mammalian milks, including human milk, contain 50% of their total fatty acids as saturated fatty acids. The biochemical formation of a single double bond converting a saturated to a monounsaturated fatty acid is a pathway that exists in all eukaryotic organisms and is active within the mammary gland. In the face of selective pressure, mammary lipid synthesis in all mammals continues to release a significant content of saturated fatty acids into milk. Is it possible that evolution of the mammary gland reveals benefits to saturated fatty acids that current recommendations do not consider?

Keywords Saturated fat · Milk fat · Dietary intake · Lipoproteins

Abbreviations

LDL	Low-density lipoprotein
HDL	High-density lipoprotein
PPAR	Peroxisome proliferator activated receptor
PGC-1	PPAR gene transcription coactivator
LPS	Lipopolysaccharide

Introduction

Diet, Fatty Acids, and Lipoproteins

Lipids and their simplest structural elements, the fatty acids, provide myriad functions at all levels of cellular life. Nutritional scientists are still wrestling to develop a rudimentary understanding of the roles that dietary lipids exert. Lipids as simple fats are the most concentrated energy source in the diet. Until recently, this fact alone made lipids a valuable food component; however, a global epidemic of caloric imbalance and obesity has undermined this one aspect of lipid nutrition. Nonetheless, dietary lipids are well recognized as providing the essential fatty acids and to dissolve and aid in the absorption of fat-soluble vitamins. Fats also produce a broad range of effects to whole body metabolism when consumed in foods. These effects, although not yet fully understood, are a complex consequence of the absolute and relative fat content, the fatty acid composition, the structure of other components in the foods, the timing of consumption and individual variations among those consuming them. Once ingested, lipids

provide a diverse range of molecular functions and actions within cells and tissues beyond providing simple energy. Fatty acids are required for membrane synthesis, modifications of proteins and carbohydrates, construction of various structural elements in cells and tissues, production of signaling compounds and for oxidative fuel. The ability of lipids to associate spontaneously into multi-molecular structures of non-polar substituents provides a unique domain structure to biology (vesicles, globules, lipoproteins). These structures solubilize a variety of non-polar and poorly soluble cellular and extracellular constituents and transport such molecules within and between cells and tissues.

Given these various roles, why would saturated fats be so poorly thought of nutritionally? In one sense, saturated fats in the diet are unnecessary. All organisms, including humans, are fully capable of synthesizing saturated fatty acids. In the absence of sufficient dietary fat, the body is apparently capable of synthesizing all of the saturated fatty acids that it needs from the ubiquitous precursor building block acetate. This does not mean to infer that all saturated fatty acids are biologically indistinguishable. In fact, cells produce a remarkable diversity of saturated fatty acids under particular conditions, and although not all of their functions are known, they are clearly not simply interchangeable. Compositional analyses reveal remarkable specificities for particular saturated fatty acids in different lipid classes, cellular compartments and tissues [1]. Stubbs and Smith [2] reviewed studies aimed at understanding the requirement of membranes for specific fatty acid compositions. Interestingly, although composition is sensitive to polyunsaturated fatty acids, the content of saturated fatty acids in rat tissue membrane phospholipids is relatively constant at $\sim$40% regardless of dietary fat source, indicating a control mechanism at some level. The de novo synthesis of saturated fatty acids is inhibited by feeding a high-fat diet [3], and membrane fragility resulting from feeding a low dietary saturated fatty acid diet is overcome by feeding a diet rich in fat [4].

The complexity of structure and the diversity of functions of fatty acids, both unsaturated and saturated, remain poorly understood, and in only a few biological situations have distinct actions of fatty acids been described. The majority of research on fatty acids consumed in the diet has focused principally on their role in lipoprotein metabolism. Authors of a recent meta-analysis of prospective studies on dairy food consumption and incident vascular disease and Type 2 diabetes concluded that it is not possible to estimate quantitative relationships with disease incidence with any confidence. The authors also point out that apart from the effects of dairy foods on plasma lipids and on blood pressure, very little is known about the biological mechanisms underlying such relationships [5]. Even for lipoprotein metabolism, for which literally billions of dollars have been invested in research, little is actually known. For example, only in 2005 was the basic mechanistic link between saturated fatty acids and cholesterol metabolism revealed [6]. This relationship between saturated fat in the diet and cholesterol metabolism was one of the most baffling scientific challenges of the twentieth century. How could such a ubiquitous, non-essential component of diets and tissues—saturated fat—cause an increase in the accumulation of cholesterol-rich LDL in blood? As scientific research on cholesterol metabolism proceeded through the twentieth century, the question became even more perplexing. Brown and Goldstein [7] won the Nobel prize for identifying the LDL receptor on the liver as being what controlled the concentration of serum cholesterol. What then regulates the expression of the LDL receptor on the surface of liver cells? Cellular cholesterol levels within the liver cell simultaneously control cholesterol synthesis and uptake by regulating the expression of the genes for the proteins that make cholesterol in the cell and for the proteins that take up cholesterol from blood as LDL. Not surprisingly, when cholesterol levels in the cell are adequate, the genes are not turned on. However, when cholesterol levels are low, all of these genes are turned on using the identical transcription factor protein—sterol response factor binding protein [8]. Although these studies made sense of cellular cholesterol regulation—if the cell needs more cholesterol, it simultaneously turns on the genes to make more via cholesterol biosynthetic enzymes and takes more from blood via the LDL receptor—they failed to explain the role of diet in these processes.

If the same transcription factor turns on both cholesterol biosynthesis and the LDL receptor, how can saturated fat uncouple these two processes, simultaneously making more cholesterol and yet shutting down the receptor? Puigserver and Spiegelman [9] found that the liver contains an additional gene control system, the peroxisome proliferator activating receptor (PPAR), and it is in turn controlled by a higher order protein complex termed (logically) the PPAR gene transcription coactivator (PGC-1). This transcription factor coactivator family recruits entire complexes of proteins into transcriptional regulatory units controlling such multi-faceted properties as mitochondrial biogenesis [10]. In a striking result, Lin et al. [6] discovered that, when exposed to high levels of saturated fatty acids, liver cells both in vivo and in vitro actively turned on PGC-1b, and even more astonishingly, this coactivator simultaneously turned on cholesterol biosynthesis and turned off the LDL receptor. Thus, in one bold study, the basic target linking dietary saturated fat and serum cholesterol was revealed. This mechanism would account for the tendency of diets very high in saturated fat to raise total cholesterol in blood.

For some individuals, such a response could raise one of the risk factors for heart disease if they consumed diets high in saturated fat. An obvious question is what are the benefits to this biochemical response that would have caused it to be selected through evolution? Scientists are only now beginning to address the basic biological value of this regulatory control system. Nonetheless, diets very high in saturated fat would not seem prudent, as would any diet high in any food component.

Recommendations that the population decrease their intake of saturated fats was based not on a mechanistic understanding, but on years of observational evidence that dietary saturated fats generally increase blood cholesterol concentrations in animals and humans [11]. This alteration of risk factors does not necessarily lead to increases in heart disease and is certainly not universally true in all populations studied. Some studies of human populations evaluating the effects of saturated fat diets do not show the predicted elevation in heart disease; in fact, some studies see the reverse effect [12]. Recent studies are beginning to assign genetic or physiological explanations to these varying outcomes; for example, low birth weight appears to have an effect on subsequent responses to dietary fat [13]. Beare-Rogers [14] suggested that the saturated fatty acid requirements are also related to the stage of development. For example, saturated fatty acids appear to be essential for the newborn, the young and during rapid growth as they are required for the synthesis of membranes and lipoprotein.

Are Recommendations to Lower Total Fat Intakes Justified for Everyone?

Is the justification for broad recommendations to lower total fat intakes in all individuals supported by scientific evidence? In 1977, the US population was first recommended to reduce the intake of fat, with some recommendations being to reduce total fat to below 30% of calories [15]. The American Heart Association recommended that the percentage of calories be 28.6 and 25.3% total fat, respectively, and 9 and 6.1% saturated fat, respectively, in Step 1 and Step 2 diets for treatment of high blood cholesterol. This recommendation had unanticipated effects. Framingham Heart Study data showed that people with high triacylglycerol concentrations (>1.7 mmol/l) and low HDL cholesterol concentrations (<1.03 mmol/l) run a significantly higher risk of coronary artery disease [16]. The long-term health benefits of consuming a low-fat diet—particularly taking into account the variation in human responses—have not been proven and, to the contrary, some individuals move their risk profile, even for heart disease, in an adverse direction [17, 18]. In one study, healthy, non-diabetic volunteers consumed diets that contained, as a percentage of total calories, either 60% carbohydrate, 25% fat and 15% protein, or 40% carbohydrate, 45% fat and 15% protein [19]. Those consuming the 60% carbohydrate diet had higher fasting plasma triacylglycerol, remnant lipoprotein and remnant lipoprotein triacylglycerol, and lower HDL cholesterol without changing LDL cholesterol concentration. The low-fat diet lowered HDL cholesterol and caused a persistent elevation in remnant lipoproteins [19], both factors that are increasingly recognized to be important independent risk factors for heart disease and other metabolic diseases. These findings led the investigators to publish the question whether it is wise to recommend that all Americans replace dietary saturated fat with carbohydrate. It is important to point out that dietary carbohydrates have been associated with dyslipidemia [20], and lipoprotein risk factors are similar whether diets are high in fat and saturated fat or low in fat and high in sugar. Elevated triglyceride concentrations are related to increased hepatic secretion and impaired clearance of VLDL lipoprotein [21, 22]. Triglyceride response to dietary sugar may vary with the amount of sugar and the presence of other nutrients. Stanhope and Havel [23] reported that a high-fructose diet led to visceral adiposity, dyslipidemia and insulin resistance, and insulin resistance upregulates VLDL production. Perhaps the study most devastating to the basic principle that a lower fat diet improves the health of the entire population was a prospective study (The Women's Health Initiative Randomized Controlled Dietary Modification Trial) that selected approximately 49,000 women to compare a group of women consuming low-fat diets and increased fruit and vegetable consumption with a group receiving only diet-related education materials. After 8.1 years, there were no statistical differences in heart disease outcomes [24]. Two possible interpretations could be drawn from this study: first, that lower fat intakes have no effect on any women, and second, that individuals vary in their response to fat and some women are benefitted and some are adversely affected and the net numbers of each are relatively close, leading to a conclusion in this trial of no effect of a low-fat diet.

Individual Response to Dietary Fat Intakes

Ordovas [25] reviewed key factors in lipid metabolism and obesity that indicate an interplay among genes, gender, and environmental factors that modulate disease susceptibility. Studies of response to dietary fats have found variation among individuals [26] and differences between men and women [27] in their response to dietary fat changes. Studies of individual sensitivity to changes in dietary saturated fats showed groups of consistent hyper-responders and minimal responders within a population of

hypercholesterolaemic individuals [26]. Measurements of serum cholesterol in response to a decrease in dietary saturated fat showed that total cholesterol decreased to a greater extent in men than in women [27]. There are also differential responses in individuals that consume low-fat diets [28]. A series of studies showed that very-low-fat (10%), high-carbohydrate diets enriched in simple sugars increased the synthesis of fatty acids, especially palmitate, and that the individual differences in increased blood triglyceride concentrations varied considerably [29]. These fluctuations observed time after time have given impetus to the field of Nutrigenomics, and scientists are now pursuing more detailed analyses of individuals, their responses to diet and the mechanistic basis for variations in diet and health risk [30].

Controversy still remains high as to the roles that dietary fat and cholesterol play in the risk of heart disease, and the wealth of confounding factors demonstrate that saturated fat is not an overwhelming input variable for any population studied to date. Dietary saturated fats are not the only variables associated with heart disease—the causes are multi-factorial. The results of studies on the etiology of heart disease are inclusive and sometimes contradictory. It is time to take a broader view to the multiple actions and functions of each of the different saturated fats and a more individual view to assessment of diet and risk.

Biological Activities of Saturated Fatty Acids

The overwhelming emphasis on the role of saturated fats in the diet and risk of coronary heart disease has distracted investigators from studying other effects that individual saturated fatty acids may have in the body. This omission is perhaps important considering the abundance in mammalian milks of a wide range of saturated fatty acids with different chain lengths. In the context of evolution and the obvious natural selective pressure on the development of milk and all of its constituents, how do saturated fatty acids affect growth, development and survival of mammalian offspring?

Fatty acids are present in all body tissues, where they are a major part of the phospholipid component of the cell membrane. They contribute to the structural diversity within the membrane, which is now recognized to be a key aspect of membrane functions [31]. Fatty acids anchor proteins to particular regions of cell membranes, participate in signaling activities, transport cellular components and provide fuel. Saturated fatty acids have been suggested as being the preferred fuel for the heart [32]. In the absence of sufficient fat from the diet, the body synthesizes fatty acids, typically from carbohydrates. An interesting observation has been made that in adult rat liver, erucic acid (22:1)—a fatty acid that has been associated with heart disease and that is present in rapeseed oil—is rapidly converted to 18:0, demonstrating the conservation of carbons by chain-shortening of a monounsaturated fatty acid to an unsaturated fatty acid [33]. Even though all fatty acids present in the diet can be broken down and resynthesized into saturated fats, they have discrete effects. Different structures of fatty acids appear to have differing effects on a variety of metabolic and physiological processes when they are ingested.

Short-chain fatty acids are hydrolyzed preferentially from triacylglycerols and absorbed from the intestine into the portal circulation without resynthesis of triacylglycerols. These fatty acids serve as a ready source of energy. Butyric acid (4:0) is the shortest saturated fatty acid and is present in ruminant milk fat at 2–5% by weight [34], which on a molar basis is about one-third the amount of palmitic acid (16:0). Human milk contains a lower percentage (ca. 0.4%) of butyric acid. No other common food fat contains this fatty acid directly; however, the consumption of a wide range of fermentable carbohydrates can lead to the synthesis of butyric acid by endogenous microflora in the lower intestine. Butyrate is a well-known modulator of genetic regulation, and its ability to promote differentiation has led various investigators to pursue this mechanism as a means to alter the risk and development of cancer [35, 36]. This fatty acid also lowers processes of inflammation in the intestine, acting through short-chain fatty acid-binding receptors [37].

In bovine and human milk, caproic acid (6:0) is present at ca. 1 and 0.1%, respectively, and caprylic acid (8:0) and capric acid (10:0) are present at ca. 0.3 and 1.2%, respectively, of the milk fat. Not surprisingly from its nomenclature, goat milk contains the highest percentage of caprylic acid, at 2.7% of milk fat. Studies to date have documented that these three fatty acids have similar biological activities when tested as antimicrobial agents. Caprylic acid lowers salmonella infection in chickens [38]. Caprylic and capric acid have antiviral activity. The monoglyceride form, monocaprin, has been shown in vivo in animals to possess antiviral activity against retrovirus infection [39].

Lauric acid (12:0) is present in human and bovine milk at ca. 5.8 and 2.2%, respectively, of the milk fat. Studies have shown antiviral and antibacterial activities of lauric acid [40, 41]. Release of lauric acid in the stomach may have direct antimicrobial activities towards *Helicobacter pylori*, either as the fatty acid or monoacylglycerols produced by lingual lipase(s) acting on the triacylglycerols present milk fat [42, 43]. These antibacterial actions of lauric acid have been proposed to provide anticaries and antiplaque activities [44]. The overall antimicrobial effects of the medium-chain saturated fatty acids and their monoacylglycerol derivatives on various microorganisms,

including bacteria, yeast, fungi and enveloped viruses, were originally suggested to be acting through the lipid membranes of the organisms [45]. Support for this deactivation process has been shown using human and bovine milk [46]. Monolaurin released from milk lipids by lipases may account for milk's anti-protozoal activities [47]. The biological activity of laurate has been interesting in other aspects not related to the diet. For example, a remarkable experiment showed that monolaurate provided considerable protection from HIV infection when used topically on reproductive tissues in primates [48].

Bovine milk fat contains 8–14% myristic acid (14:0) and in human milk, it averages 8.6% of the milk fat. Human epidemiological studies have shown that myristic acid and lauric acid were the saturated fatty acids most strongly related to the average serum cholesterol concentrations in humans [49]. Nonetheless, several studies have shown that myristic acid increases HDL cholesterol at least as much as LDL cholesterol, and further studies have demonstrated that the unique positional distribution of myristic acid in the *sn*-2 position of triglycerides in milk fat is responsible for its tendency to raise HDL [50].

Palmitic acid is present in human and bovine milk at 22.6 and 26.3%, yet almost exclusively esterified at the *sn*-2 position of the triglyceride. This unusual stereospecific distribution appears to have important nutritional and biological implications. Human infants consuming a formula containing triacylglycerides similar to those in human milk (16% palmitic acid esterified predominantly to the *sn*-2 position) have improved intestinal absorption not just of the palmitic acid but calcium as well [51, 52]. Recently, Speigelman's group showed that palmitic acid stimulated the expression and activities of the transcription coactivator PGC-1b and by so doing promoted the transcriptional regulation of biosynthesis of lipoproteins from the liver [6]. This finding places a mechanistic understanding of the cellular actions of saturated fatty acids, particularly palmitic acid. In the context of milk, this mechanism implies that palmitic acid may have an important role in promoting successful lipoprotein metabolism in infants. This same transcription coactivator PGC-1b was also found to promote myocardial development [53]. Finally, PGC-1b was shown to increase biogenesis of mitochondria in neurons [54], further implying that this mechanism could well be involved in diverse aspects of metabolic regulation and its saturated fatty acid-appropriate development throughout the body in infants. It is not known if the presence of palmitic acid in human milk is important in the coordinate regulation and activity of PGC-1b in any of these activities.

Stearic acid (18:0) is an abundant fatty acid in milk, present in human and bovine milk fat at 7.7 and 13.2% of fat, respectively. Stearic acid is synthesized from palmitate via the elongase enzyme, either in the mammary gland by the same enzyme that is active in liver, coded by gene ELOV5 [55, 56], or by ELOV1, whose expression is induced in the mammary gland during lactation [57, 58]. Both of these genes are regulated by diet, hence the net production of stearic acid is under various aspects of metabolic control. Surprisingly, little research has pursued the specific actions of stearic acid when consumed in milk by infants, in spite of its abundance and obvious regulation within the mammary gland during fat synthesis. In adults, stearic acid does not appear to raise serum cholesterol, hence it is considered neutral to heart disease risk. This fatty acid may exert other effects also consistent with protection from heart disease via separate mechanisms. Healthy males who consumed dietary stearic acid (19 g/d) for 4 weeks exhibited beneficial effects on thrombogenic and atherogenic risk factors as compared with the effects of dietary palmitic acid [59].

Delivery of Fat-Soluble Nutrients

Fat-soluble nutrients include the essential nutrients vitamins A, D, E and K, carotenoids as vitamin A precursors, essential polyunsaturated fatty acids, and non-essential nutrients such as various tocopherols, phenolics, carotenoids (e.g., lycopene, lutein and zeaxanthin) and conjugated linoleic acid isomers that cannot be made by humans. Fat-soluble nutrients are increasingly recognized as pleotrophic nutrients with several discrete actions in addition to the direct functions for which their essentiality has been established. As a result, consumption of these components is considered to have biological activities beyond the simple prevention of deficiency and is consistent with many aspects of health [60–62]. In epidemiological studies, the abundance of fat-soluble nutrients in tissues is frequently reported to be inversely correlated with a variety of chronic and degenerative diseases, including cancers [63, 64], cardiovascular diseases [65, 66], diabetes [67] and specific tissue degeneration such as macular degeneration [68] [58, 59]. With the recognition that there are potential health values associated with the presence of fat-soluble nutrients in tissues, their absorption from the diet has become a key issue. In general, non-polar molecules are poorly absorbed, and it is not certain that the presence of a component in a food means that it will be absorbed and delivered to particular tissues in which it might be active [69]. The lipid-soluble components of milk appear to be well absorbed into and accumulated in tissues, although the basic mechanisms by which such a net delivery is accomplished are not known [70, 71].

Milkfat and HDL

Breast feeding stimulates the production of serum lipids and lipoproteins [72, 73]. Interestingly, this increase in

serum lipids in infancy is reversed in adulthood [74]. Nonetheless, throughout life, when compared with either carbohydrates or polyunsaturated fatty acids, the consumption of bovine milk fat results in the elevation of circulating HDL cholesterol. Decades of research have documented that blood HDL cholesterol concentrations are a very strong and independent predictor of heart disease [75]. This relationship has not been as successfully exploited therapeutically as lowering LDL, however, because HDL concentrations are not as responsive to diet and drugs as those of LDL. A major pharmacologic effort has pursued an increase in HDL cholesterol concentrations in humans as a means to reduce cardiovascular risk. This research is based on the extensive evidence of the associations of high HDL with protection from heart disease, even in the face of elevated LDL. There is also evidence of an opposite relationship, that low HDL is associated with increased risk, with or without elevated triglycerides. However, it has not been possible to assign independent variables to HDL differences, and studies have largely been based on HDL concentrations that are presumably high or low based on genetic rather than dietary determinants [76, 77].

HDL exert beneficial effects on overall health by myriad mechanisms, including binding and eliminating toxins, delivering bioactive compounds, protecting various cells and lipoproteins from damage and participating in their repair [78–80]. HDL is particularly important in the successful response to infection by binding and clearing bacterial endotoxin or lipopolysaccharide (LPS). LPS is the major glycolipid component of gram-negative bacterial outer membranes and is responsible for pathophysiological symptoms characteristic of infection. A wide variety of studies have documented that LPS is associated with plasma lipoproteins, suggesting that sequestering of LPS by lipid particles may form an integral part of a humoral detoxification mechanism [81, 82]. The binding of LPS to lipoproteins is highly specific under simulated physiological conditions, and HDL has the highest binding capacity for LPS [83, 84]. This basic protection mechanism may be particularly important for children [85] and for intestinally derived endotoxin. Thus, lipoprotein-binding protein–lipoprotein complexes may be part of a local defense mechanism of the intestine against translocated bacterial toxin. Because milk fats enhance HDL concentrations, they are of potential importance in protection against bacterial LPS toxicity.

Conclusions

The genes and biochemical processes of lactation that produce milk fat evolved under the constant selective pressure of nourishing mammalian infants. Lipids in milk are a source of energy for the neonate of each species. The composition and structures of lipids in milk provide bioactive components that, although not identified as "essential" nutrients by standard definitions, none-the-less serve important functions as structural building blocks, fuels, transport systems, anti-inflammatory, anti-bacterial and antiviral agents in the intestine. These lipids include triacylglycerols—which are metabolized to monoacyl- and diacylcerides and fatty acids—and phospholipids such as sphingomyelin. The lipids in milk are also carriers of important fat-soluble vitamins such as vitamin E, vitamin A and vitamin D.

The absolute quantities and proportionate balance of the various macronutrients in human diets remains the subject of both scientific research and public health speculation. Although unquestionably evolved to nourish infants, detailed examinations of milk and lactation in humans and other mammals are revealing new insights into structures and functions of different components in the diet, including fat. The gene set responsible for the production of lipids is a conspicuously retained subset of the genome throughout mammalian lactation, implying that milk is, in many respects, a lipid delivery system [86]. Saturated fatty acids are a significant component of all mammalian milks examined, including human milk. Thus, whereas diets inordinately high in any component are likely to be net deleterious, finite quantities of saturated fatty acids may provide distinct mechanistic benefits to various metabolic processes. Recognizing that different humans with different lifestyles respond differently to fat intakes and compositions implies that in the future, diets will be designed for individuals not populations. In such a future, finite intakes of specific saturated fats may actually be recommended.

ORIGINAL ARTICLE

The Consumption of Milk and Dairy Foods and the Incidence of Vascular Disease and Diabetes: An Overview of the Evidence

Peter C. Elwood · Janet E. Pickering · D. Ian Givens · John E. Gallacher

Received: 17 February 2010 / Accepted: 22 March 2010 / Published online: 16 April 2010

Abstract The health effects of milk and dairy food consumption would best be determined in randomised controlled trials. No adequately powered trial has been reported and none is likely because of the numbers required. The best evidence comes, therefore, from prospective cohort studies with disease events and death as outcomes. Medline was searched for prospective studies of dairy food consumption and incident vascular disease and Type 2 diabetes, based on representative population samples. Reports in which evaluation was in incident disease or death were selected. Meta-analyses of the adjusted estimates of relative risk for disease outcomes in these reports were conducted. Relevant case–control retrospective studies were also identified and the results are summarised in this article. Meta-analyses suggest a reduction in risk in the subjects with the highest dairy consumption relative to those with the lowest intake: 0.87 (0.77, 0.98) for all-cause deaths, 0.92 (0.80, 0.99) for ischaemic heart disease, 0.79 (0.68, 0.91) for stroke and 0.85 (0.75, 0.96) for incident diabetes. The number of cohort studies which give evidence on individual dairy food items is very small, but, again, there is no convincing evidence of harm from consumption of the separate food items. In conclusion, there appears to be an enormous mis-match between the evidence from long-term prospective studies and perceptions of harm from the consumption of dairy food items.

Introduction

Milk and dairy foods contain saturated fats, and their consumption often leads to a rise in plasma cholesterol level. This, together with the belief that milk is 'fattening', appears to have led to the widespread conviction that milk and dairy foods are a factor in obesity and in heart disease, and that their consumption should be limited.

At least ten hypotheses have been defined in attempts to explain the supposed harm from milk and dairy consumption [1]. The mechanism most frequently quoted is, undoubtedly, a rise in plasma cholesterol concentration following the ingestion of milk or a dairy food item. The drawing of conclusions about milk from its effect upon a single 'intermediate' variate, such as cholesterol level, is, however, quite unreasonable, as it ignores the fact that milk, being a complex food with a host of nutrients, is likely to affect many mechanisms relevant to the development of vascular and other diseases. The only valid basis for conclusions about a food item and health or survival comes from long-term studies of the consumption of that food and the incidence of disease or death.

Archie Cochrane was one of the first to urge that conclusions in clinical practice and in medical research are evidence-based, and that the evidence considered comes from all of the available, bias-free relevant studies [2]. The urgings of Cochrane and others have led to 'evidence-based

medicine' within the whole field of clinical and public health practice. Alvarez-León et al. [3] have, however, pointed out that statements about the benefits and risks of dairy product consumption appear to be based on selected physio-pathological data, such as relationships with cholesterol level, and not on valid epidemiological evidence, indeed, as Alvarez-León et al. commented: "Public health nutrition should not be unaware of the need for evidence-based conclusions."

The most convincing evidence on a food item and health would come from randomised controlled trials, but no adequately powered trials of milk or dairy consumption have been reported, nor are any likely to be conducted because of the numbers of participants required and the compliance that would be necessary from each participant. By default, the best evidence on dairy food consumption, health and survival comes, therefore, from long-term cohort studies with disease events and death as the outcomes.

We report the results of a literature search and meta-analyses of prospective cohort studies of milk and dairy food consumption as predictors, and death, vascular disease and diabetes as outcomes. We also summarise evidence from relevant retrospective case–control studies.

Experimental Procedure

As far as possible, the procedures in the review and meta-analyses which we conducted are those outlined by Egger et al. [4] and Moher et al. [5] using the statistical programmes available at http://www.systematicreviews.com.

Search Strategy

A number of searches were conducted using Medline, PubMed and ISI Web of Science, and four researchers were involved. Using the search terms for predictors: milk, dairy, dairy products, cheese, butter, cream and yoghurt, together with the terms for outcomes: death, heart disease and stroke, 138 papers were identified and limiting these to 'adult' gave 47 papers. The predictors together with the outcome terms diabetes and diabetes mellitus Type 2 gave 330 papers. From these, five papers were selected. Papers which used a composite of foods including dairy items as a predictor were not selected. A further three papers with relevant results, which had not been detected in the electronic searches but which had been identified by the lead author during extensive reading over the past ten and more years, were included.

In the end, a total of 38 reports of cohort studies were selected and used in the analyses presented. Five case–control retrospective studies which gave relevant data are described in what follows, but are not examined by meta-analyses. In an attempt to clarify uncertainties, and/or to obtain further data, letters were sent to 14 authors, but responses were obtained from only a very few.

Meta-Analyses

The results of a test of homogeneity between studies is given for each dairy food, together with estimates of the overall relative risk. Difficulties arose from the fact that the results of individual studies were reported in terms of relative risk, odds ratio or hazard ratio. These three measures of risk are not entirely equivalent. However, in almost all of the studies, the event rate is well below 10% and, in this situation, the odds ratio can be considered as a good approximation for the relative risk [4]. The hazard ratio is a comparison of time-to-event and, so, is not an approximation for the relative risk. However, repeating the summary calculations with and without the studies which reported a hazard ratio produced only a trivial difference in the results.

The summary statistic was calculated using the 'meta' command in the Stata statistical software package [4]. This uses an inverse-variance weighting to calculate fixed and random effects summary statistics. The 'meta' command was convenient as it calculates the variance using the confidence intervals of the risk estimate. Homogeneity was assessed using the Q statistic, which tests the null hypothesis that the variation between trials is compatible with chance. It follows a Chi-squared distribution with $n - 1$ degrees of freedom, where n is the number of studies being investigated. In many of our groupings, there was significant heterogeneity. The heterogeneity led to the choice of random effects models for the summary statistics. The adjusted relative risks (RR) given in each individual report were noted, and pooled estimates were obtained from these by weighting the natural logs of each reported RR by the inverse of the variance, as described by Gao et al. [6].

In addition to all of the above, data from relevant retrospective case–control studies are described in the text.

Results

Dairy Foods

Eight long-term cohort studies have reported on all-cause deaths in relation to dairy food consumption (Table 1). Unfortunately, two of the studies [7, 8] do not include sufficient data for inclusion in a meta-analysis. There is no significant heterogeneity between the results for the six studies ($P = 0.427$) and a meta-analysis suggests a small but significant reduction in total mortality in the subjects with the highest dairy consumption, relative to the risk in

Table 1 Dairy foods and all-cause mortality. Details of cohort studies in which the consumption of 'dairy foods' (see text) was related to the risk of death, with an estimate of homogeneity between the studies and the results of a meta-analysis

Study	Number in cohort (length of follow-up)	Number of deaths	Factors adjusted for	Adjusted estimate of risk (95% CI)	Predictive factor and subgroups compared
Kahn et al. [7] An Adventists cohort	22,033 subjects (21 years)	6,075	Age, sex, smoking, history of vascular disease, hypertension, diabetes	0.98 (NS)	3+ glasses/week vs <1 glass of whole milk
van der Vijver et al. [8] Dutch Civil Servants cohort	2,605 subjects (28 years)	Numbers not stated	Age, smoking, BMI, systolic BP, cholesterol, energy, alcohol	1.0 (0.7–1.4) men 0.8 (0.5–1.3) women	Top third of total calcium intake vs lowest third
Kelemen et al. [45] Iowa Women's cohort	29,017 subjects (15 years)	3,978	Age, BMI, smoking, energy, education, hypertension, post-menopausal, vitamins, fat intake, fruit, vegetables, fibre	1.10 (0.97–1.24)	A simulation study substituting a composite of milk, cream, ice cream yoghurt and cheese protein
Mann et al. [46] Oxford Vegetarian cohort	10,802 subjects (13.3 years)	383	Age, sex, smoking, social class	0.87 (0.68–1.13)	More than 1/2 pint milk/day vs less than 1/2
Ness et al. [30] Scottish Men cohort	5,765 men (25 years)	2,350	Age, social class, health behaviour and health status	0.81 (0.61–1.09)	1 pint+ milk/day vs no milk
Elwood et al. [31] Caerphilly cohort	2,512 men (20–24 years)	811	Age, smoking, social class, IHD, BMI, energy, alcohol, fasting cholesterol HDL cholesterol and triglycerides	1.20 (0.80–1.80)	1 pint+ /milk/day vs little or no milk
Trichopoulou et al. [47] A Greek cohort	1,013 diabetic subjects (4.5 years)	80	Age, gender, smoking, education weight and height, hip circum., insulin, hypertension, hyperchol., food groups	0.92 (0.71–1.19)	Increase in dairy foods by 1 SD/day
van der Pols et al. [48] Carnegie cohort	4,374 subjects (66–68 years)	1,468	Age, sex, area, energy, fruit, vegetables, eggs, protein, fat, energy	0.77 (0.61–0.98)[a] 0.77 (0.61–0.97)[a]	Top vs bottom quartile dairy Top vs bottom quartile milk

Data from Kahn et al. [7] omitted because of the absence of detailed data; van der Vijver et al. [8] omitted because it was based on the total dietary calcium; Kelemen et al. [45] omitted because it is a test of dietary substitution

0.64M person years; 5,092 deaths: heterogeneity between studies $P = 0.427$

Meta-analysis (random effects) RR (95% CI) for highest intake groups 0.87 (0.77–0.98)

vs = compared with, or relative to; 1 pint = 0.568 l

[a] In van der Pols et al. [48], the estimate for dairy intake was included in the above meta-analysis. This is reported as a hazard ratio and if it is omitted from the meta-analysis, the heterogeneity is $P = 0.470$ and the overall RR = 0.91 (0.78–1.05)

the subjects with the lowest consumption (RR) 0.87; 95% confidence limits (0.77, 0.98).

Milk

Table 2 summarises data from 11 cohort studies of milk consumption and ischaemic heart disease (IHD). Again, two do not include adequate data for inclusion in a meta-analysis. The results of the other nine cohorts show no significant heterogeneity ($P = 0.570$) and the overall risk of incident heart disease in the subjects with the highest milk intake, relative to those within each cohort with the lowest milk intakes, is 0.92 (0.80, 0.99).

As indicated in a footnote to Table 2, the result reported by Hu et al. [9] for whole milk (1.67; 1.14, 1.90) shows marked heterogeneity with all the other estimates of risk for milk. We have, therefore, used the estimate of Hu et al. [9] for skimmed milk in our meta-analysis. If, however, it is assumed that 20% of women in that cohort had been drinking whole milk and 80% skimmed milk, then an overall estimate of IHD risk in the cohort studied by Hu et al. [9] is 0.96 (0.74, 1.15), and putting this estimate into

Table 2 Milk and dairy consumption and incident ischaemic heart disease (IHD). Details of cohort studies in which the consumption milk and dairy foods was related to incident heart disease, with the results of a meta-analysis

Study	Number of subjects (length of follow-up)	Number of heart disease events	Factors adjusted for	Adjusted estimate of risk (95% CI)	Predictive factor
Snowdon et al. [33] An Adventists cohort	8,725 males 15,048 females (20 years)	758 841 IHD deaths	Age, smoking and other food items, weight, marital status	0.94 1.11	Two glasses of milk/day vs none
van der Vijver et al. [8] Dutch Civil Servants cohort	1,340 males 1,265 females	366 178 CHD deaths	Age, smoking, BMI, systolic BP, cholesterol, energy, alcohol	0.77 (0.53–1.11) 0.91 (0.55–1.50)	Top and bottom tertile of dietary calcium intake
Fraser [49] An Adventists cohort	26,473 subjects (duration not stated)	Total CHD no. not stated	None	1.33 ($P < 0.07$)	One glass or more whole milk vs none
Kelemen et al. [45] Iowa Women's cohort	29,017 subjects (15 years)	739 CHD deaths	Age, BMI, smoking, energy, education, hypertension, post-menopausal, vitamins, fat intake, fruit, vegetables, fibre	1.41 (1.07–1.87)	A simulation study substituting a composite of milk, cream, ice cream yoghurt and cheese for protein
Nettleton et al. [50] ARIC cohort	14,153 subjects (13 years)	1,140 incident heart failure	Age, sex, race, smoking, alcohol, prevalent disease, education, activity	1.08 (1.01–1.16)[a]	High-fat dairy: whole milk, cheese and ice cream
Shaper et al. [37] UK RHS cohort	7,735 subjects (9.5 years)	608 IHD events	Age, social class, smoking, cholesterol, blood pressure and diabetes	0.88 (0.55–1.40)	Milk drunk and taken on cereals vs 'none'
Mann et al. [46] Oxford Vegetarian cohort	10,802 subjects (13.3 years)	63 IHD deaths	Age, sex, smoking, social class	1.50 (0.81–2.78)	More than 1/2 pint milk per day vs less than 1/2 pint
Bostick et al. [51] Iowa women cohort	34,486 women (8 years)	387 IHD deaths	Age, energy, BMI, waist–hip ratio, diabetes, smoking, vit. E, saturated fat, oestrogen, alcohol, education, activity	0.94 (0.66–1.35)	Top and bottom quartile of milk products
Hu et al. [9] Health Prof. cohort	80,082 women (14 years)	939 total CHD	Age, BMI, menopause, HRT, smoking, alcohol, family history, hypertension, aspirin, exercise, vit. E	1.67 (1.14–1.90)[a] 0.78 (0.63–0.96)[a] 1.04 (0.96–1.12)[a] 0.93 (0.85–1.02)[a]	More than two glasses milk/day vs less than one/week: whole milk, skimmed milk, one serving per day high-fat dairy, one serving per day low-fat dairy
Ness et al. [30] Scottish Men cohort	5,765 men (25 years)	892 CHD deaths	Age, social class, health behaviour and health status	0.68 (0.40–1.13)	More than one pint milk/day vs less than one-third/day
Elwood et al. [31] Caerphilly cohort	2,512 men (20–24 years)	493 total IHD	Age, smoking, social class, IHD, BMI, energy, alcohol, fasting cholesterol, HDL cholesterol and triglycerides	0.71 (0.40–1.26)	One or more pint/day vs little or no milk/day
Al Delaimy et al. [52] Health Prof. cohort	39,800 subjects (12 years)	1,458 total IHD	Age, BMI, time period, smoking, alcohol, energy and vit E intake, activity, diabetes, hyperchol, family history, aspirin	1.03 (0.86–1.26) 1.01 (0.83–1.23)	Top and bottom quintile of dairy calcium intake Total dairy product intake
Larmarche [53] Quebec Cardiovasc. Cohort	2,000 men (13 years)	217 total CHD	Age, smoking, BMI, diabetes	0.73 (0.56–0.93)	Above and below average intake of dairy products

Table 2 continued

Study	Number of subjects (length of follow-up)	Number of heart disease events	Factors adjusted for	Adjusted estimate of risk (95% CI)	Predictive factor
Trichopoulou et al. [47] A Greek cohort	1,013 subjects (4.5 years)	46 CVD deaths	Age, gender, smoking, education, weight and height, hip circum., insulin, hypertension, hyperchol., food groups	0.95 (0.68–1.31)	150 g (one SD) increase in dairy products
Umesawa et al. [54] JACC cohort	21,068 men 32,319 women (10 years)	135 99 Total CHD	Age, sex, BMI, smoking, alcohol, sodium, potassium, fatty acids, area, menopause, hyperchol., diabetes	0.80 (0.45–1.44) 1.06 (0.50–2.25)	Top and bottom quintile of dairy calcium intake
Umesawa et al. [32] JPHC cohort	41,526 (13 years)	322 total CHD	Age, sex, BMI, smoking, alcohol, sodium, potassium, fatty acids, area, menopause, hyperchol., diabetes	1.09 (0.74–1.61)	Top and bottom quintile of dairy calcium intake
van der Pols et al. [48] Carnegie cohort[c]	4,374 subjects (66–68 years)	378 CHD deaths	Age, sex, area, energy, fruit, vegetables, eggs, protein, fat, energy	0.74 (0.45–.22)[a, b] 1.06 (0.49 1.31)[a, b]	Top and bottom quintile of dairy products Top and bottom quintile of milk

Data from Snowdon et al. [33] and Fraser [49] omitted because of the absence of detailed data; van der Vijver et al. [8] omitted because it was based on the total dietary calcium; Kelemen et al. [45] omitted because it is a test of dietary substitution; Nettleton et al. [50] omitted because the outcome is heart failure

4.3M person years; 16,212 IHD events: heterogeneity between studies $P = 0.570$

Meta-analysis: risk of a heart disease event in the subjects with the highest milk/dairy intake, relative to that in the subjects with the lowest intake: 0.92 (0.80–0.99)

[a] If Nettleton et al. [50] is included, the heterogeneity between studies $P = 0.033$; RR = 0.92 (0.82–1.03)

[b] An estimate for Hu et al. [9] based on the data for milk, assuming 20% of women had been on whole milk, 80% on skimmed, the heterogeneity is $P = 0.454$; overall RR = 0.88 (0.80, 0.97) and when van der Pols et al. is omitted (because an HR is stated), the heterogeneity is $P = 0.408$; RR = 0.88 (0.80–0.98). When the estimates of Hu et al. [9] for dairy is used, $P = 0.570$; RR = 0.92 (0.86–0.99)

[c] In van der Pols et al. [48], risk estimates which had been adjusted for calcium are not used because the inclusion of calcium may have led to over-adjustment

the meta-analysis gives an overall estimate for milk and heart disease of 0.91 (0.77–1.07). A similar problem arose with estimates derived from the same cohort of the US Nurses Health Study by Sun et al. [10]. They used plasma pentadecanoic acid as a surrogate for dairy fat consumption, though it can also be obtained from beef, lamb and venison. The estimate of risk for heart disease that they obtained is statistically inconsistent with estimates derived from other populations in which the same surrogate approach had been used [11]. It could possibly be that the women within the Nurses' Cohort who drank whole milk had become so highly selected with reference to a range of health-related behaviours that they may have become unrepresentative of any meaningful population group.

In a report based on 27,529 Adventists, Snowdon [12] states that milk was not related to all-cause mortality, but he gives no data. Likewise, Jacobsen and Stensvold [13] refer to "a large prospective study with more than 17,000 men and women followed for 11.5 years (which) showed an inverse relationship between milk drinking (predominantly full-fat milk) and the risk of cardiovascular death." One of the authors (BKJ) was contacted and details requested, but these are not now available.

A number of cross-sectional studies have been reported in which the past milk consumption of patients admitted to hospital with a myocardial infarct was compared with the past consumption by control subjects without evidence of vascular disease. This research strategy has uncertainties because only a proportion of patients survive an infarct and are questioned, and because the estimation of milk intake prior to the infarct is dependent upon memory. Four such studies have been reviewed elsewhere [14] and a meta-analysis yielded an overall relative risk of milk consumption and incident heart disease of 0.83 (0.66, 0.99). A further, unusual case–control study of 144 diabetic patients with peripheral vascular disease matched with 288 control diabetic patients reported an odds ratio of 0.71 (0.42, 1.19) for peripheral vascular disease in those who consumed milk more than seven times a week relative to those who took milk twice or less per week [15].

The estimates of risk for milk consumption and stroke incidence in the 11 cohorts summarised in Table 3 show

Table 3 Milk and dairy consumption and incident stroke. Details of cohort studies in which the consumption of milk and dairy foods was related to incident stroke events, with the results of a meta-analysis

Study	Number of subjects (length of follow-up)	Number and type of stroke	Factors adjusted for	Predictive factor	Adjusted estimate of risk (95% CI)
Iso et al. [19] Nurses Health cohort	85,764 women (14 years)	347 ischaemic	Age, smoking, time interval, BMI, alcohol, menopause, hormone use, exercise, multivitamins, fatty acid intake, history of hypertension, diabetes and cholesterol	Top and bottom quintile of dairy calcium	0.70 (0.51–0.97)
Kinjo et al. [55] A Japanese cohort	223,170 subjects (16 years)	3,084 thromboembolic	Age, sex, area, smoking, alcohol, occupation	Milk four or more times/week vs less than once/week	0.85 (0.77–0.92)
Ness et al. [30] Scottish Men cohort	5,765 men (25 years)	196 stroke deaths	Age, social class, health behaviour and health status	More than one pint/day vs less than one-third/day	0.84 (0.31–2.30)
Sauvaget et al. [56] Life span cohort	40,349 subjects (16 years)	1,462 stroke deaths	Sex, age, area, BMI, smoking, alcohol, education, diabetes, hypertension, radiation history	Milk almost daily vs none dairy products almost daily vs none	0.94 (0.79–1.12)[a] 0.73 (0.57–0.94)
He et al. [57] Health Prof. cohort	43,732 men (14 years)	451 ischaemic	Smoking, alcohol, BMI, activity, hyperchol., hypertension, aspirin, potassium, multivitamins, vit E, fruit and veg, energy	High-fat dairy once a day+ vs less than once a week	1.23 (0.74–2.03)
Elwood et al. [31] Caerphilly cohort	2,512 men (22–25 years)	185 ischaemic	Age, smoking, social class, IHD, BMI, energy, alcohol, fasting cholesterol, HDL cholesterol and triglycerides	One or more pint/day vs little or no milk	0.66 (0.24–1.81)
Abbott et al. [58] Honolulu heart cohort	3,150 men (22 years)	229 thromboembolic	Age, dietary K and Na, alcohol, smoking, activity, BP, glucose, cholesterol, glucose, uric acid, Hct	16 oz/day milk drunk vs non-drinkers	0.67 (0.45–1.00)
Larsson et al. [23] ATBC cohort	26,556 men (13.6.years)	2,702 cerebral infarcts	Age, smoking, alcohol, BMI, education, total cholesterol, diabetes, IHD, energy intake and activity, intake of various foods and original randomisation	Top quintile of a composite of low-fat, whole and sour milk vs lowest quintile	1.03 (0.96–1.10)
Umesawa et al. [54] JACC cohort	110,792 subjects (12.9 years)	284 stroke deaths	Age, sex, BMI, smoking, alcohol, sodium, potassium, fatty acids, area, menopause, hyperchol., diabetes	Top and bottom quintile of dairy calcium intake	0.53 (0.34–0.81)
Umesawa et al. [32] JPHC cohort	41,526 subjects (12.9 years)	664 ischaemic	Age, sex, BMI, smoking, alcohol, sodium, potassium, fatty acids, area, menopause, hyperchol., diabetes	Top and bottom quintile of dairy calcium intake	0.70 (0.52–0.94)
van der Pols et al. [48] Carnegie cohort	4,374 subjects (66–68 years)	121 stroke deaths	Age, sex, area, energy, fruit, vegetables, eggs, protein, fat, energy	Top and lowest quartiles of dairy Top and bottom quartile of milk	0.61 (0.27–1.38)[a] 0.60 (0.28, 1.33)

8.4M person years; 9,725 strokes: heterogeneity between studies $P < 0.000$

Meta-analysis: risk of a stroke in the subjects with the highest milk/dairy intake, relative to that in the subjects with the lowest intake: 0.79 (0.68–0.91)

[a] For both Sauvaget et al. [56] and van der Pols et al. [48], the results for 'dairy' are used in the meta-analysis

Table 4 Dairy foods, haemorrhagic stroke and sub-arachnoid bleeds. Details of cohort studies in which the consumption of dairy food was related to the risk of haemorrhagic stroke, or a sub-arachnoid bleed, with estimates of homogeneity between the studies and the results of meta-analyses

Study	Number of subjects (length of follow-up)	Number and type of disease event	Factors adjusted for	Adjusted RR (95% CI)	Predictive factor and subgroups compared
Kinjo et al. [55] A Japanese cohort	223,170 subjects (16 years)	4,773 haemorrhagic stroke deaths	Sex, age, area, smoking, alcohol, occupation	0.74 (0.68–0.80)	Milk four or more times/week vs once/week
He et al. [57] Health Prof. cohort	43,732 men (14 years)	124 haemorrhagic strokes	Smoking, alcohol, BMI, activity, hyperchol., hypertension, aspirin, potassium, multivitamins, vit E, fruit and veg., energy	1.22 (0.47–3.16)	High-fat dairy once a day or more vs less than once a week
Umesawa et al. [54] JACC cohort	21,068 men 32,319 women (10 years)	113 haemorrhagic strokes 128 haemorrhagic strokes	Age, sex, BMI, smoking, alcohol, sodium, potassium, fatty acids, area, menopause, hyperchol., diabetes	0.46 (0.23–0.91) 0.51 (0.28–0.94)	Top and bottom quintile of dairy calcium intake
Umesawa et al. [32] JPHC cohort	41,526 subjects (12.9 years)	425 haemorrhagic strokes	Age, sex, BMI, smoking, alcohol, sodium, potassium, fatty acids, area, menopause, hyperchol., diabetes	0.65 (0.43–0.97)	Top quintile of dairy calcium vs lowest quintile
Larsson et al. [23] ATBC cohort	26,556 men (13.6 years)	383 haemorrhagic strokes	Age, smoking, alcohol, BMI, education, total cholesterol, diabetes, IHD, energy intake and activity, intake of various foods and original randomisation	1.01 (0.82–1.20)[a] 1.32 (0.89–1.94)[a]	Top quintile of a composite of low-fat, whole and sour milk vs lowest quintile Top and lowest quintile of dairy products vs lowest quintile
0.36M person years: 5,946 haemorrhagic strokes: heterogeneity between studies $P = 0.014$					
Meta-analysis (random effects) RR (95% CI) for highest intake groups 0.75 (0.60–0.94)					
Umesawa et al. [54] JACC cohort	21,068 men 32,319 women (10 years)	37 sub-arachnoid bleeds 34 sub-arachnoid bleeds	Age, sex, BMI, smoking, alcohol, sodium, potassium, fatty acids, area, menopause, hyperchol., diabetes	0.19 (0.04–0.87) 0.41 (0.17–0.97)	Top and bottom quintile of dairy calcium intake
Umesawa et al. [32] JPHC cohort	41,526 subjects 12.9 years	217 sub-arachnoid bleeds	Age, sex, BMI, smoking, alcohol, sodium, potassium, fatty acids, area, menopause, hyperchol., diabetes	0.74 (0.46–1.61)	Top quintile of dairy calcium vs lowest quintile
Larsson et al. [23] ATBC cohort	26,556 men 13.6 years	196 sub-arachnoid bleeds	Age, smoking, alcohol, BMI, education, total cholesterol, diabetes, IHD, energy intake and activity, intake of various foods and original randomisation	1.26 (1.00–1.52)	Top and bottom quintile: dairy products, all milks (whole + low-fat + sour)
0.96M person years: 484 sub-arachnoid bleeds: heterogeneity between studies $P = 0.004$					
Meta-analysis (random effects) RR (95% CI) for highest intake groups 0.65 (0.32–1.31)					

vs = compared with, or relative to

[a] The results for haemorrhagic stroke are based on Larsson et al. [23] for milk. Using Larsson et al. [23] for dairy gives $P = 0.022$, RR = 0.76 (0.58–1.00)

significant heterogeneity, and although the overall estimate of risk is significant (0.78; 0.68, 0.91), this cannot be interpreted with confidence. However, the data on stroke in Table 3 relate, as far as is possible, to ischaemic stroke and in Table 4, reports on haemorrhagic strokes and sub-arachnoid bleeds are summarised. Five studies give evidence on haemorrhagic stroke, and, again, there is significant heterogeneity, but the overall risk in relation to dairy intake is 0.75; (0.60, 0.94). Only three studies give evidence on sub-arachnoid bleeds and, ignoring significant heterogeneity, the overall risk in those with the highest dairy intake is 0.65 (0.32, 1.31).

Butter and Cheese

Table 5 summarises the data from studies in which butter and cheese consumption were examined as possible predictors of vascular disease. For butter, the literature search identified only five cohort studies with incident vascular disease as the outcome. Only three of these give sufficient data to enable inclusion in a meta-analysis. The results are homogeneous, but the overall relationship between butter consumption and vascular events (0.93; 0.84, 1.02) is not statistically significant. In another early cohort study [16], 832 men were followed for 21 years. There were 267 incident CHD events and the authors commented: 'butter intake did not predict CHD incidence,' but no original data are given.

Several case–control studies of butter and vascular disease have been reported. In one, the previous diets of 106 patients with a myocardial infarct were compared with the diets of 105 controls, and an adjusted odds ratio of an infarct was reported as 2.80 (1.14, 6.85) for 'butter and margarine' [17]. In another, the use of butter by 287 women with an acute myocardial infarct was compared with that of 649 control women and an odds ratio in the upper third, adjusted for age alone, of 2.3 was reported [18]. In a study of diabetic patients, 144 with peripheral arterial disease were compared with 288 matched control patients and an odds ratio of 2.06 (1.15. 3.68) reported for the consumption of butter [15].

Evidence on cheese and vascular disease is also limited. Results have been reported from six cohort studies (Table 5), but sufficient data for a meta-analysis are given in only two. A difficulty arises here because, while random effects meta-analysis seems to be appropriate throughout the work in this paper, in the case of the two studies with cheese, there is a massive difference in the numbers of events and, hence, in the power of the two studies, with conclusions in one being based on only 64 vascular events and on 2,702 disease events in the other. It seems reasonable, therefore, for this one dairy item, to use a fixed effects model, thus, weighting the studies appropriately. This gives an overall estimate of risk from cheese of 0.90 (0.79, 1.03).

Other studies on cheese include a follow-up of 27,529 seventh-day Adventists over 20 years, in which it is stated that "…cheese… consumption (was) unrelated to stroke mortality" but no data are given [12]. In a report based on the 85,764 women in the US Nurses Health Study, the authors comment that the inverse association observed for stroke with dairy calcium was not restricted to milk, but was also observed for hard cheese [19], but, again, no data are given. Finally, in a wide-ranging review of studies of cheese consumption, Tholstrup [20] found "no convincing evidence of harm," and wrote of the 'neutral' effect of cheese on coronary heart disease.

A number of studies based on retrospective case–control comparisons examined cheese consumption and vascular disease. A comparison of the past diets of 106 patients with myocardial infarction and 105 control subjects [17] gave an adjusted odds ratio for cheese and yoghurt of 0.42 (0.18–1.03). In another case–control study of 111 myocardial infarction patients and 107 controls [21], an estimated odds ratio in the highest quartile of cheese intake of 0.34 (0.13, 0.91) was reported. In yet other case–control studies, estimates of 0.77 (0.54–1.11) [22] and 1.0 (no CIs stated) [18] were made for cheese consumption. Finally, Ciccarone et al. [15] reported an odds ratio for cheese consumption in 144 diabetic patients with peripheral vascular disease compared with 288 matched control diabetic patients of 0.61 (0.26–1.45).

Other Dairy Foods

Evidence on other individual dairy food items is very sparse indeed. The large ATBS cohort of Finnish male smokers originally enlisted for a randomised trial of antioxidant prophylaxis [23] yielded adjusted odds ratios for the quintile of subjects with the largest intake of cream (0.81; 0.72–0.92 for cerebral infarction and 0.72; 0.52–1.00 for intra-cerebral haemorrhage), yoghurt (1.08; 0.95–1.24 and 1.08; 0.58–1.28) and ice cream (0.92; 0.81–1.03 and 1.21; 0.89–1.63), none of which are significant. In the report on the US Nurses Health Study, Iso et al. [19] commented that the inverse association observed for stroke with dairy calcium was not restricted to milk, but was also shown for yoghurt and for ice cream.

Evidence from cross-sectional retrospective studies of these items comes from Tavani et al. [22], who reported an odds ratio for yoghurt in a case–control study based on 507 patients with an acute myocardial infarction of 0.55 (0.32–0.95). Biong et al. [21] based a study on 111 myocardial infarction patients and 107 controls and estimated an odds ratio in the highest quartile of ice cream of 0.99 ($P = 0.21$, no CIs stated). Finally, a case–control study of cream consumption in 432 diabetic patients yielded an odds ratio of 2.79 (0.93–8.35) for peripheral vascular disease [15].

Dairy Foods and Diabetes

Elsewhere [24], we have reported a meta-analysis of cross-sectional studies of milk and/or dairy consumption and the metabolic syndrome (RR in the highest consumers of milk and dairy: 0.74; 0.64–0.84). Five studies have now reported on dairy consumption and incident Type 2 diabetes (Table 6). The results of these studies (Table 6) are homogeneous, and the estimated overall relative risk for diabetes is 0.85 (0.75–0.96).

Table 5 Butter, cheese, and vascular disease and death. Details of cohort studies in which the consumption of cheese and of butter was related to a disease outcome or death, with estimates of homogeneity between the studies and the results of a meta-analyses

Study	Number of subjects (length of follow-up)	Number and type of disease event	Factors adjusted for	Adjusted estimate of risk (95% CI)	Predictive factor and subgroups compared
Kahn et al. [7] An Adventists cohort	22,033 subjects (21 years)	5,627 deaths	Age, sex, smoking, history of vascular disease, hypertension, diabetes	1.03 NS (1)	Butter daily cf less than once/week
Gartside et al. [59] NHANES I	5,811 (16 years)	CHD events Number not stated	Age, sex, race, poverty, region, BMI, smoking, education, activity, cholesterol	Increase in CHD events as butter intake rose $P = 0.026$	Use of butter
Shaper et al. [37] UK RHS cohort	7,735 subjects (9.5 years)	608 IHD events	Age, social class, smoking, cholesterol, blood pressure and diabetes	0.87 (0.79–1.06)	Use of butter cf margarine
Elwood et al. reported in Shaper et al. Caerphilly cohort	2,187 men (20–24 years)	605 vascular events	Age, smoking, social class, IHD, BMI, alcohol, total fat intake, systolic BP, diabetes	0.87 (0.69–1.11)	Use of butter cf margarine use
Larsson et al. [23] ATBC cohort	26,556 men (13.6 years)	2,702 cerebral infarcts 383 haemorrhagic 196 sub-arachnoid	Age, smoking, alcohol, BMI, education, total cholesterol, diabetes, IHD, energy intake and activity, intake of various foods and original randomisation	1.00 (0.87–1.14)[a] 1.44 (1.01–2.07) 0.98 (0.59–1.64)	Top quintile of butter cf lowest quintile
Data from Kahn et al. [7] and Gartside et al. [59] omitted because of absence of detailed data					
0.36M person years: 3,310 vascular disease events: heterogeneity between studies $P = 0.333$					
Meta-analysis (random effects) RR (95% CI) for highest intake groups 0.93 (0.84–1.02)					
Kahn et al. [7] An Adventists cohort	22,033 subjects (21 years)	6,075 deaths	Age, sex, smoking, history of vascular disease, hypertension, diabetes	0.96 NS[b]	Cheese on 5–7 days/week cf less than one
Snowdon et al. [33] An Adventists cohort	25,153 subjects (20 years)	758 male IHD deaths 841 female IHD deaths	Age, smoking and other food items, weight, marital status	0.95 ($P > 0.05$)[b] 0.91 ($P > 0.05$)[b]	Cheese daily cf none
Fraser [49] An Adventists cohort	26,473 (duration not stated)	Coronary events Number not stated	Not stated	0.97 NS	Three or more times/week cf less than once
Gartside et al. [59] NHANES I	5,811 (16 years)	CHD events	Age, sex, race, poverty, region, BMI, smoking, education, activity, cholesterol	0.88 ($P < 0.002$)	Once or more/day cf none
Mann et al. [46] A vegetarian cohort	10,802 subjects (13.3 years)	64 IHD deaths	Age, sex, smoking, social class	2.47 (0.97–6.26)	Cheese 5 or more times/week cf less than once
Larsson et al. [23] ATBC cohort	26,556 men (13.6 years)	2,702 cerebr. infarcts 383 haemorrhagic 196 sub-arachnoid	Age, smoking, alcohol, BMI, education, total cholesterol, diabetes, IHD, energy intake and activity, intake of various foods and original randomisation	0.88 (0.77–1.01)[a] 1.01 (0.72–1.41) 1.07 (0.66–1.72)	Top quintile of cheese cf lowest quintile
Data from Kahn et al. [7], Snowdon et al. [33], Fraser [49] and Gartside et al. [59] omitted because ofabsence of detailed data					
0.4M person years: 2,766 vascular disease events: heterogeneity between studies $P = 0.032$					
Meta-analysis (random effects) RR (95% CI) for highest intake groups 1.32 (0.49–3.56)

cf = compared, or, relative to

[a] Elwood et al. here represents data from the Caerphilly Cohort Study reported in Shaper et al. [15], re-analysed by us and updated

[b] The studies of cheese intake by Snowdon et al. [58], by Kahn et al. [7] and by Fraser [23] may be on the same cohort. None of these, nor Gartside et al. [20], could be included in the meta-analysis, as no estimates of error are given

[c] For Larsson et al. [10], only the results for cerebral infarction were included in the meta-analysis

Table 6 Milk and dairy consumption and diabetes. Details of cohort studies in which the consumption of milk and dairy foods was related to new cases of diabetes, with the results of a meta-analysis

Study	Number of subjects (length of follow-up)	Number of new diabetes	Factors adjusted for	Adjusted estimate of risk (95% CI)	Predictive factor
Choi et al. [60] Health Prof. Cohort	41,254 males (12 years)	1,243	Age, smoking, alcohol, energy, family history, hyperchol., hypertension, energy intake and activity	0.91 (0.85–0.97)	Increase of one serving of dairy foods/day
Liu et al. [61] Women's Health cohort	37,183 females (10 years)	1,603	Age, smoking, alcohol, BMI, hypertension, hyperchol, HRT, family history, energy and activity, dietary intakes randomisation	0.79 (0.67–0.94)[a] 1.04 (0.84–1.30) 0.92 (0.78–1.09)	Top and bottom quintile of all dairy foods Whole milk twice+/week vs <1/month Skim milk twice+/week vs <1/month
van Dam et al. [62] Caerphilly cohort	41,186 females (8 years)	1,964	Age, BMI, smoking, alcohol, education, family history, activity, energy, coffee, sugar, meat, whole grain consumption	0.93 (0.75–1.15)	Highest vs lowest quintile of total dairy intake
Elwood et al. [24] Caerphilly cohort	640 males (22–25 years)	41	Age, smoking, social class, IHD, BMI, alcohol, total fat intake, systolic BP	0.57 (0.20–1.63)	Highest and lowest quartile of milk intake
Villegas et al. [63] Shanghai women cohort	64,191 women (6.9 years)	2,270	Age, BMI, smoking, alcohol, waist–hip ratio, activity, income, education, occupation, hypertension, energy	0.60 (0.41–0.88)	>200 g milk/day vs none

1.7M person years: 7,121 new diabetic patients: heterogeneity between studies $P = 0.122$

Meta-analysis (fixed effects) RR (95% CI) for highest intake groups: 0.85 (0.75–0.96)

[a] The result from Liu et al. [61] for dairy is used in the meta-analysis

Discussion

Much has been written on the associations between the consumption of milk and dairy products and individual vascular risk factors, and, in particular, effects on plasma cholesterol level. An evaluation based upon a single risk factor for a disease can, however, be misleading. At the same time as affecting lipid markers of heart disease, the consumption of milk and dairy produce is associated with an increase in the level of high-density lipoprotein cholesterol [25, 26] and with a reduction in blood pressure [27, 28], and, furthermore, milk and dairy food items are likely to have effects upon many other biological mechanisms and disease processes. Even studies which have examined relationships with a cluster of risk factors for disease, such as the metabolic syndrome [24], cannot possibly give a valid estimate of the overall effect of a complex food such as milk on disease incidence.

Most concern appears to focus on milk consumption and heart disease, and the evidence we present on this is substantial. The studies are homogeneous and the meta-analysis of all of the available evidence suggests that there is a small but worthwhile reduction in risk of coronary heart disease (0.92; 0.80, 0.99) in the subjects who drink the most milk. The evidence which we present on milk and the risk of stroke is also substantial and suggests a reduction in both all stroke (0.79; 0.68–0.91) and in haemorrhagic lesions in those with the highest consumption of milk. A reduction in sub-arachnoid haemorrhage was unexpected, as the aetiology of this condition is totally different to that of thrombo-embolic or haemorrhagic stroke, but benefit from a reduction in blood pressure would be common to all of these events.

All-cause mortality also shows a reduction associated with dairy food consumption (0.87; 0.77–0.98). The evidence of a reduction in diabetes is also substantial, the results of the separate studies are homogeneous ($P = 0.122$) and the risk reduction in the highest consumers of dairy foods is statistically significant (0.85; 0.75–0.96).

The literature on milk and dairy consumption and cancer is extensive. A detailed examination of the evidence is beyond the scope of this review, but it has been reviewed by the World Cancer Research Fund and the American

Institute for Cancer Research [29]. The consumption of milk or dairy foods is associated with a significant reduction in colon cancer (the pooled RR from ten cohort studies is 0.78; 0.69–0.88 and for bladder cancer in four cohorts, the RR is 0.82; 0.67–0.99). There may, however, be an increased risk of prostate cancer, the relative risk estimated from eight cohorts being 1.05; 0.98–1.14. No relationship of importance with milk or dairy consumption was reported for any other cancer.

Apart, perhaps, from milk, no firm conclusions can, however, be drawn on the individual dairy food items. In fact, there is an extreme paucity of studies relating to individual dairy food items. We find this quite remarkable, given the strength of the beliefs about the undesirable effects of butter in particular. The disparity between the results on butter from cohort and from retrospective case–control studies is of concern. Thus, the overview of three cohort studies suggests a possible reduction in vascular disease risk (0.93; 0.84–1.02), while two cross-sectional studies suggested an increase and one an increase in peripheral arterial disease from the consumption of butter. This kind of inconsistency between evidence collected prospectively and evidence dependent upon the memory of patients is, however, not unknown in epidemiological research, and, perhaps, the main message of these data relates to the inadequacy of the evidence on butter and the other dairy items, rather than whether or not there is evidence of harm.

Unfortunately, it is not possible to estimate quantitative relationships with disease incidence for the consumption of a dairy item with any confidence. For example, within the studies reporting milk consumption, the quantity defined as 'high' varied in the different studies. Most studies used quartiles or quintiles of the distribution of intakes, while others defined milk intake in terms of the number of occasions on which milk or dairy foods were consumed. Nevertheless, several studies defined a 'high' intake as the consumption of one pint (568 ml) or more per day [30–32], in others two or more 'glasses' per day [19, 33], while in a study based on weighed dietary intakes [34], the mean daily consumption of milk in the subjects who showed a reduction in vascular disease and diabetes was a pint (568 ml) or more.

A number of systematic reviews of dairy foods have already been published and are consistent with what we present. Gibson et al. [35] identified 12 cohort studies and, from them, drew the conclusion that their review showed "no consistent findings to support the concept that dairy food consumption is associated with a higher risk of coronary heart disease." Mente et al. [36] looked at a number of foods, including milk. Their conclusion, based on five cohort studies, was that milk has "no significant association with coronary heart disease" (0.91; 0.73–1.00). Two earlier overview studies by us [14, 31] examined associations with milk, and, although based on smaller numbers of cohorts, the results of both are in close agreement with those which we now report.

There are, of course, serious limitations in the evidence we present. The cohort strategy is powerful, but it still has uncertainties and possible biases. In particular, estimates of risk for one item can be confounded by the effects of dietary and other factors apart from milk and dairy consumption. Then, there are differences in social class, smoking and other factors between subjects who drink milk and those who drink little or none, and some of the studies comment upon these [31, 37]. While all of the estimates upon which we have based our overall meta-analyses have each been adjusted for a number of confounding factors, as listed in the tables (age, social class, smoking, alcohol, activity etc.), residual confounding by unknown factors is still possible. While it is possible that this could possibly explain the observed reductions in vascular disease, diabetes and all-cause mortality, it seems highly unlikely that a true harmful effect of milk/dairy consumption on the diseases considered could have been missed simply because of some important, but as yet unknown, confounding factor(s). It is also possible, but again extremely unlikely, that publication bias has led to studies which showed harm from dairy consumption have been preferentially withheld from publication.

The issue of fat-reduced, skimmed milk and other fat-reduced dairy products remains. Despite the widespread beliefs that whole milk increases the risk of vascular disease, and is 'fattening', the appropriate question to ask is: do fat-reduced milks provide any advantage further to the benefits conferred by the consumption of whole dairy foods or milk, or does the removal of fat reduce the benefit of the whole items? Low-fat milks were not widely used in the US until about 1989 and about 2000 in the UK, and a large part of the follow-up periods of most of the cohort studies which we have included in the meta-analyses relate, therefore, to times when the milk and dairy items consumed were the full-fat items. Epidemiological studies are of necessity long term and, therefore, the data which we have summarised and the conclusion we have drawn relate overwhelmingly to whole milk and full-fat dairy items.

Given the promotion of fat-reduced milks by many authorities and the large increase in the consumption of fat-reduced milks and dairy items throughout the Western world, this is an area requiring critical study. A number of reports do give evidence on the incidence of disease events in subjects within the same cohort who drank whole milk and others who drank fat-reduced milk, and we have summarised some of these data elsewhere [14]. However, it is most important to accept that persons who

Table 7 Summary of the relative risk for milk and/or dairy food consumption and various diseases, together with the total numbers of deaths in England and Wales in 2008 from those causes

Cause of death[a]	Number of cohort studies (no. in analyses)	Estimate of the risk ratio for milk or dairy food consumption[b] (significance of heterogeneity between studies)	Number of deaths in England and Wales in 2008
All-cause deaths	8 (5)	0.87; 0.77–0.98 ($P = 0.427$)	509,090
Ischaemic heart disease (I20–I25)[a]	17 (13)	0.92; 0.80–0.99 ($P = 0.570$)	76,985
Stroke (I60–I69)[a]			
Thrombo-embolic	11 (11)	0.79; 0.68–0.91 ($P < 0.000$)	46,446
Haemorrhagic	5 (3)	0.75; 0.60–0.94 ($P = 0.014$)	7,497
Sub-arachnoid	3 (3)	0.65; 0.32–1.31 ($P = 0.004$)	8,000[c]
Type 2 diabetes (E10-15)[a]	5 (5)	0.85; 0.75–0.96 ($P = 0.122$)	5,541

[a] Causes of death as defined in the short list used in the classification of causes of death by the Office of National Statistics UK (Office for National Statistics: mortality statistics: cause (series DH2 No.32). London: The Stationery Office, 2008)

[b] Estimate of the risk of each disease in subjects with the highest consumption of milk/dairy, relative to the risk in the subjects with the lowest risk (usually the top and the bottom fifths in subjects ranked by consumption)

[c] This is an estimate of the total incidence and not the number of deaths

choose to drink fat-reduced milks will almost certainly have adopted other 'healthy' behaviours, and these will confound any differences in disease outcome within groups of persons defined by the type of milk consumed. It has to be accepted that these other confounding factors cannot all be known, but they will be responsible for biases which cannot possibly be estimated or allowed for. In the absence of evidence from large long-term randomised trials, the statement of German and Dillard [38] is, therefore, most apposite: "Such hypotheses (about fat-reduced milks) are the basis of sound scientific debate; however they are not the basis of sound public health policy."

On a priori grounds, milk would be expected to be beneficial to health. Calcium has many biological actions, including a reduction in fat absorption through the forming of soaps in the intestine and the binding of cholesterol and bile acids in the gut [39]. Of greater importance is a reduction of blood pressure by dietary calcium, and in a 6-year study of 2,245 older subjects in the Rotterdam Cohort Study, a 20% reduction in incident hypertension was attributed to dairy food consumption [40]. While calcium, magnesium and potassium are all required to prevent hypertension, dairy products are unique in providing a balanced supply of these elements [3, 41]. This may be why milk appears to have a greater effect on blood pressure than dietary calcium supplements [27]. Furthermore, in addition to the minerals provided by milk, certain peptides released on the digestion of milk proteins may have a beneficial effect on blood pressure by inhibiting the angiotension-1-converting enzyme, thus, modulating endothelial function [42].

Renaud et al. [43] described further effects of dietary calcium on thrombo-embolic mechanisms. They fed butter to rabbits and to half, they also gave high levels of calcium. The calcium led to a reduction in platelet aggregation, and a reduction in the severity of atherosclerosis. However, an examination of extensive platelet-related tests in 1,433 older men in the Caerphilly Cohort Study [44] gave no confirmatory evidence in terms of an association between milk consumption and platelet aggregation to adenosine phosphate ($P = 0.41$), or stressed template bleeding times ($P = 0.91$) (unpublished data).

The results of the literature search and meta-analyses presented here are summarised in Table 7 and in Fig. 1. The similarity of the estimates of risk is remarkable and, although conclusions have to be tentative, it seems not unreasonable to conclude that there is no evidence that dairy foods as a total group are associated with harm to health either in terms of death, heart disease, stroke or diabetes, but are probably beneficial in relation to these disease outcomes.

Apart from their effects on plasma lipids and on blood pressure, very little is known about the biological mechanisms likely to be involved in the relationships of milk and dairy foods with human diseases or, indeed, whether milk can be modified to provide increased health advantages. Clearly, more work should be done.

Due to a focus on the small rise in blood cholesterol with milk drinking, the debate on milk has never achieved a reasonable balance in the evaluation of risks and benefits. We believe that the debate about the health risks and benefits of milk and dairy consumption in Western communities should focus on evidence of direct relevance to

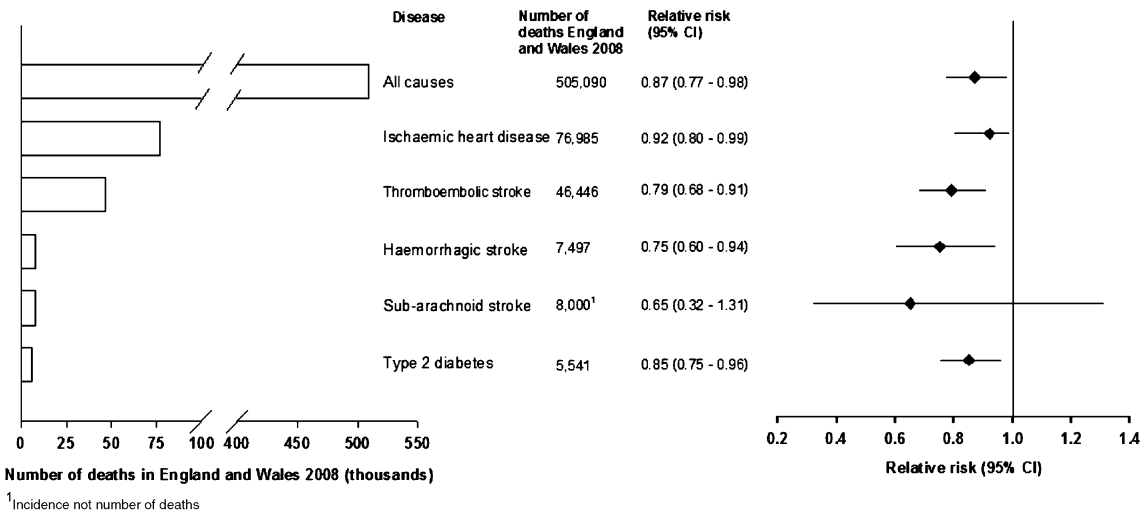

Fig. 1 The numbers of deaths in England and Wales in 2008 from various causes, and the risks for these causes in the subjects with the highest milk/dairy consumption, relative to the risk in the subjects with the lowest milk/dairy consumption

health and survival, such as we have presented in this review, and this would benefit greatly if it were supported by a concerted and targeted research effort to understand the underlying mechanisms.

The Complex and Important Cellular and Metabolic Functions of Saturated Fatty Acids

Philippe Legrand · Vincent Rioux

Received: 16 February 2010 / Accepted: 21 June 2010 / Published online: 13 July 2010

Abstract This review summarizes recent findings on the metabolism and biological functions of saturated fatty acids (SFA). Some of these findings show that SFA may have important and specific roles in the cells. Elucidated biochemical mechanisms like protein acylation (N-myristoylation, S-palmitoylation) and regulation of gene transcription are presented. In terms of physiology, SFA are involved for instance in lipogenesis, fat deposition, polyunsaturated fatty acids bioavailability and apoptosis. The variety of their functions demonstrates that SFA should no longer be considered as a single group.

Keywords Dietary saturated fatty acids · Myristic acid · Metabolism · N-myristoylation

Abbreviations

FA	Fatty acids
NMT	Myristoyl–CoA: protein N-myristoyltransferase
PL	Phospholipids
PUFA	Polyunsaturated fatty acids
SCD	Stearoyl–CoA desaturase
SFA	Saturated fatty acids
TAG	Triglycerides

Introduction

Observational studies have shown that high intake of saturated fatty acids (SFA) is positively associated with increased levels of blood cholesterol and high coronary heart disease mortality rates [1, 2]. However, more recent studies have shown inverse association [3, 4], and the meta-analysis by Siri-Tarino et al. [5] reopened the debate when writing that "there is no significant evidence for concluding that dietary saturated fat is associated with an increased risk of CHD or CVD". Without entering this interesting epidemiological debate on the deleterious effects of some of saturated fatty acids, it seems that they can be no longer considered as a single group in terms of structure, metabolism [6, 7] and cellular function. In this context, this review will focus only on recent findings suggesting that individual SFA possess specific properties associated with important biological functions.

New Aspects on the Metabolism of Saturated Fatty Acids

Cellular Origin of Saturated Fatty Acids

SFA usually account for 30–40% of total FA in animal tissues, distributed in palmitic acid (15–25%), stearic acid (10–20%), myristic acid (0.5–1%) and lauric acid (less than 0.5%). Palmitic and stearic acids are universally found in natural fats. Lauric acid is specifically abundant in copra (39–54%) and palmist oils (44–51%). Myristic acid and short-chain fatty acids (including butyric acid) represent each about 10% of FA in milk fat. Apart from the dietary sources, it is well known that the body is capable of synthesizing SFA. Because of their multiple potential origins, it has been difficult to quantify the real importance of dietary SFA when compared with endogenous SFA, especially for palmitic acid. Adipose tissue concentrations of C15:0, C17:0 but also C14:0 have been used as quantitative

markers of dairy consumption [8]. With regard to myristic acid, the amount of its endogenous biosynthesis [9] is indeed far smaller than the amounts consumed from dietary sources (4 g/day in a Swedish population) [10].

Desaturation of Saturated Fatty Acids

Recent findings on SFA concern their respective capacities to be desaturated. Every SFA from C12:0 to C18:0 is converted to its respective monounsaturated product through the action of Δ9-desaturase (Stearoyl–CoA desaturase, SCD) but with varying efficiency. In the rat [11], a clear increase in hepatic Δ9-desaturase activity is related to the carbon chain length, from C12:0 to C18:0. Evidence was also recently presented that palmitic acid, already known as a substrate of Δ9-desaturase, can also be desaturated by the mammalian Δ6-desaturase (Fatty acid desaturase 2: FADS2) [12]. Palmitic acid Δ6-desaturation produces sapienic acid (C16:1n-10) in the preputial gland of SCD1−/− mice [13] and in human sebaceous glands in which the expression of SCD is low [14]. The importance of this human physiological specificity remains to be determined.

Specific Biochemical Functions of Individual SFA

Regulation of Protein Activation by N-terminal Myristoylation

Myristic and palmitic acids are directly involved in the two classes of protein fatty acid acylation, N-terminal myristoylation and side-chain palmitoylation [15]. Protein N-myristoylation (Fig. 1) refers to the highly specific covalent attachment of myristic acid, by an amide linkage, to the NH_2-terminal glycine residue of increasing number of eukaryotic and viral proteins [16]. Myristoyl–CoA: protein N-myristoyltransferase (NMT, EC 2.3.1.97), the enzyme catalyzing this stable acylation, has been identified in many organisms. Genetic advances have revealed that mammals possess two distinct NMT genes, named type 1 and 2 [17–19]. The contribution of each gene transcript to NMT expression and activity in vivo, and the specific role of each NMT isoform in cellular replication, proliferation, and other cellular processes, is still under investigation [20–22]. They both seem to have a similar high substrate selectivity for myristic acid [17, 19]. The myristoyl moiety has been shown to mediate protein subcellular localization, protein–protein interaction or protein–membrane interactions (Fig. 1) required for the biological activities of the myristoylated proteins [16]. In the myristoylation pathway, myristic acid therefore exhibits a specific and important role for protein activation.

The proteins that are substrates of NMT include key components in intracellular signaling pathways, oncogenes, structural viral proteins, and common constitutive eukaryotic proteins. Computational prediction recently suggested that about 0.5% of all proteins in the human genome could be myristoylated [23]. New protein substrates identified recently in mammals are the tumor suppressor Fus1 [24], TRIF [25], the sphingolipid Δ4-desaturases type 1 and 2 [26], and truncated protein forms that become substrates after post-translational cleavage by caspases that reveals an internal myristoylation motif: BID [27], actin [28], gelsolin [29], and p21-activated protein kinase 2 [30].

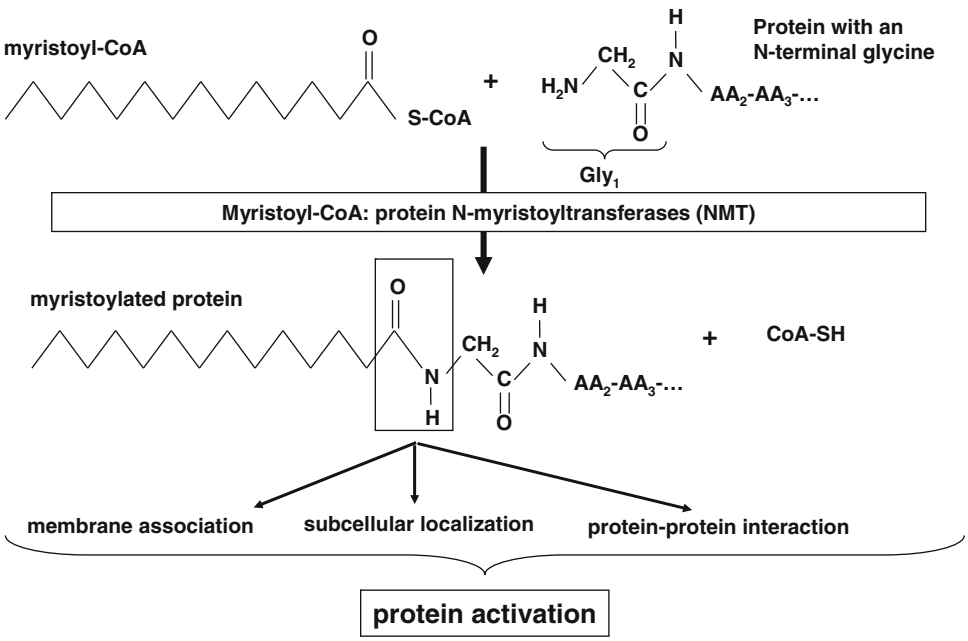

Fig. 1 N-terminal myristoylation of proteins with myristic acid by myristoyl–CoA: protein N-myristoyltransferases (*NMT*) and biological consequences for the myristoylated proteins

Can Myristic Acid be the Rate-Limiting Molecule in the Myristoylation Pathway?

Since endogenous biosynthesis of C14:0 [9] is very low as compared with dietary sources [10], one can ask if the amount of free myristic acid could be insufficient to provide myristoyl–CoA: protein N-NMT with enough co-substrate. In yeast, studies analyzing the activity of NMT have suggested that the enzyme was able to use both exogenous and endogenous myristic acid as the substrate [31–33]. During the process of the maturation of one protein, the pool of endogenous free myristoyl–CoA would probably be sufficient [34]. However, when considering the pool of myristoylable proteins or the specific process for the maturation of viral proteins like Gag or Nef during the course of a viral, retroviral or lentiviral infection, the amount of myristoyl–CoA co-substrate needed is considerable [35]. The requirement for myristic acid suggests that in certain cases, it could be the rate-limiting molecule in this mechanism or that competition could occur. In addition, the mechanism by which myristic acid initially esterified in the TAG or PL is used for myristoylation is unknown, too. The available evidence indicates that the intracellular concentration of free myristic acid in endothelial cells is crucial for the activation of thrombospondin-1 and could be modulated by its uptake from the medium through CD36 [36].

Regulation of Protein–Membrane Interactions by Palmitoylation

Protein palmitoylation refers to the post-translational formation of a thioester linkage between the side-chain of cysteine and palmitic acid, mainly [37], or other saturated fatty acids, like myristic and lauric acids [38]. A long time ago, the ester linkage between saturated fatty acids and serine or threonine residues was also reported [39], but since then, this type of linkage has not been described again.

Palmitoylation is involved in regulatory mechanisms because the association of the protein with the palmitoyl moiety is reversible and facilitates protein–membrane interactions and subcellular trafficking of proteins. Several signal transductions depend therefore on palmitic acid, including proteins that have been shown to undergo successive myristoylation and palmitoylation, like the α subunit of many heterotrimeric G proteins [40]. Mammalian protein palmitoyltransferases (also named Protein S-AcylTransferases PAT) are still under investigation [37]. The recent biochemical evidence of the PAT activity of a family of proteins that share a DHHC motif in yeast [41–43] has opened a new field of investigation.

Regulation of Gene Transcription by Saturated Fatty Acids

While dietary PUFA are known to regulate gene expression through their influence on transcription factors (PPAR, SREBP), the effect of SFA on gene transcription has been less explored. Lin et al. [44] have shown that SFA (C10:0–C18:0) strongly elevate the PGC-1β mRNA level, that co-activates the action of SREBP family of transcription factors, and consequently increase the transcription of lipogenic target genes (*FAS*, *SCD-1*). Co-activation of the nuclear receptor LXR/RXR also promotes VLDL secretion. SFA (but also monounsaturated FA) are known to bind hepatocyte nuclear factor 4 (HNF4). In liver cells, palmitate and oleate both enhanced the transcription of glucose-6-phosphatase gene. Palmitate also induced the recruitment of several transcription factors like NF-κB, HNF4, CEBPα, and PPARα [45]. SFA, when linked to the lipid A moiety of lipopolysaccharides, or free, also indirectly induce NF-κB nuclear translocation, activation and expression of COX-2, and other pro-inflammatory cytokines, through the recently described toll-like receptor 4-derived signaling pathways [46, 47]. Finally, because it is an inhibitor of the histone deacetylase activity, butyric acid regulates the expression of several genes, like *IL5*, by altering the histone acetylating status of their promoter regions, with consequences for the structure of chromatin [48, 49].

New Demonstrated or Putative Physiological Roles of SFA

Stearic Acid is Neutral for Cholesterol but Could be Pro-Lipogenic

As for the other long-chain saturated fatty acids, the health impact of stearic acid has been studied, showing no deleterious effect on cardiovascular disease risk [50, 51]. The high rate of C18:0 conversion to C18:1n-9 by Δ9-desaturation was suggested to explain this neutral effect on cholesterol metabolism, compared to the other SFA [52]. On the other hand, the desaturation of dietary stearate to endogenous oleate has been described as a stimulating factor for VLDL–TAG secretion in hepatocytes [53], and an essential step mediating the induction of lipogenesis [54] and the promotion of obesity [55], showing the very important role of SCD. The evidence concerning the putative effect of stearic acid on thrombotic tendency appears inconsistent [56, 57].

Myristic Acid Could Regulate PUFA Bioavailability

It has recently been suggested that myristic acid may be an activator of the conversion of α-linolenic acid to

docosahexaenoic acid (DHA). In cultured rat hepatocytes, myristic acid had a specific and dose-dependent effect on Δ6-desaturase activity [58]. In vivo, when myristic acid was supplied for 2 months in the diet of rats (from 0.2 to 1.2% of dietary energy), with similar level of dietary α-linolenic acid (1.6% of FA, 0.3% of energy), a dose–response accumulation of eicosapentaenoic acid (EPA) was shown in the liver and plasma [59].

In addition, in humans, compared with a diet containing 0.6% of myristic acid mainly in the *sn*-2 position in the TAG, a diet containing 1.2% of myristic acid during a 5-week consumption period significantly enhanced EPA and DHA levels in the plasma PL and DHA level in the plasma cholesteryl esters [60]. When the intake of myristic acid increased from 1.2 to 1.8% energy in the same population, EPA, DPA and DHA decreased significantly in plasma PL and EPA also decreased in cholesteryl esters [61]. This result suggest that, in humans, the effect of myristic acid on circulating (n-3) PUFA follows a U-shaped curve with a favorable turning point at around 1.2% of total daily energy.

So far as potential mechanism(s) of action are concerned, the increase in the activity of Δ6-desaturase by myristic acid was first postulated to be mediated by N-myristoylation (see below) because this enzyme exhibits an N-terminal glycine residue. However, we recently demonstrated that Δ6-desaturase is not myristoylated in vivo [26]. The hypothesis has been proposed that myristoylation of another protein of the whole complex of Δ6-desaturation, NADH cytochrome *b*5 reductase [62], could account for this increased activity.

Lauric Acid Could be a Precursor for ω3 Fatty Acid Biosynthesis

The low level of C12:0 conversion to C12:1n-3 in the liver of rats has led to the hypothesis that this monounsaturated fatty acid of the (n-3) series might be, under extreme physiological circumstances [for example animals deprived of (n-3) PUFA in the diet during a long period], an unusual precursor for the biosynthesis of α-linolenic acid, by successive Δ6-desaturation, elongation, Δ5-desaturation and two final elongations [11].

SFA May Play Multiple Roles in Early Events of Apoptosis

Specific histone deacetylase inhibitors, like butyric acid, selectively induce cellular differentiation, growth arrest and apoptosis in a variety of cancer cells [63]. Although contradictory effects have been reported [64], it seems that delivery of an adequate amount of butyrate to the appropriate site could protect against early tumorigenic events [65].

Several SFA may induce apoptosis via different ways. First, as already suggested above, butyrate and short-chain SFA may also have an effect on apoptosis [66]. Second, the pro-apoptotic effect of non-esterified palmitate and stearate was shown to require acyl–CoA formation and NF-κB activation [67]. Third, SFA may also influence apoptosis via the ceramide pathway by inducing ceramide de novo synthesis at several steps [68–70]. The first step catalyzed by the serine palmitoyltransferase involves serine condensation with palmitoyl–CoA [71]. The last step is catalyzed by dihydroceramide Δ4-desaturase (DES). We recently showed that both DES1 and DES2 isoforms are myristoylated and that this N-terminal modification significantly increased the activity of recombinant DES1 in COS-7 cells [26]. Compared with a recombinant unmyristoylable mutant form of DES1 (N-terminal glycine replaced by an alanine), the desaturase activity of the myristoylable wild-type DES1 was two times higher, in the presence of myristic acid incubated with the cells [26]. The description of this regulatory mechanism highlighted a new potential relationship between myristic acid, the saturated fatty acid capable of binding and activating the enzyme involved in the final de novo ceramide biosynthesis step, and lipoapoptosis induced through the ceramide pathway. Therefore, we subsequently hypothesized and showed that the myristoylation of recombinant DES 1 can target part of the enzyme to the mitochondria, leading to an increase in ceramide levels (specifically in the mitochondria) which in turn leads to apoptosis in the COS-7 cell model [72].

Medium-Chain Fatty Acids and Fat Deposition

A point of interest is the specific role played by medium-chain SFA. It has been reported that overfeeding with a medium-chain TAG diet in rats results in a diminished deposition of fat, when compared with rats overfed with isocaloric long-chain TAG [73]. This suggests an obligatory oxidation of medium-chain SFA in the liver, after transport via the portal vein, leaving no medium-chain TAG for accumulation in adipose tissue [73]. Another hypothesis for medium-chain TAG effect is their inhibitory effect on apoB synthesis, reducing the VLDL secretion by hepatocytes. This has been observed with octanoate in chicken hepatocytes [74].

Conclusion

We have reported here new knowledge on cellular and physiological functions of the different SFA. For this reason, SFA should no longer be considered as a single group in terms of structure, metabolism, and function.

Abstract We recently showed that a hypocaloric carbohydrate restricted diet (CRD) had two striking effects: (1) a reduction in plasma saturated fatty acids (SFA) despite higher intake than a low fat diet, and (2) a decrease in inflammation despite a significant increase in arachidonic acid (ARA). Here we extend these findings in 8 weight stable men who were fed two 6-week CRD (12%en carbohydrate) varying in quality of fat. One CRD emphasized SFA (CRD-SFA, 86 g/d SFA) and the other, unsaturated fat (CRD-UFA, 47 g SFA/d). All foods were provided to subjects. Both CRD decreased serum triacylglycerol (TAG) and insulin, and increased LDL-C particle size. The CRD-UFA significantly decreased plasma TAG SFA (27.48 ± 2.89 mol%) compared to baseline (31.06 ± 4.26 mol%). Plasma TAG SFA, however, remained unchanged in the CRD-SFA (33.14 ± 3.49 mol%) despite a doubling in SFA intake. Both CRD significantly reduced plasma palmitoleic acid (16:1n-7) indicating decreased de novo lipogenesis. CRD-SFA significantly increased plasma phospholipid ARA content, while CRD-UFA significantly increased EPA and DHA. Urine 8-iso $PGF_{2\alpha}$, a free radical-catalyzed product of ARA, was significantly lower than baseline following CRD-UFA (−32%). There was a significant inverse correlation between changes in urine 8-iso $PGF_{2\alpha}$ and PL ARA on both CRD ($r = -0.82$ CRD-SFA; $r = -0.62$ CRD-UFA). These findings are consistent with the concept that dietary saturated fat is efficiently metabolized in the presence of low carbohydrate, and that a CRD results in better preservation of plasma ARA.

RDA	Recommended daily allowance
SFA	Saturated fatty acids
TNF-α	Tumor necrosis factor-α

Introduction

The rationale for using carbohydrate-restricted diets (CRD) in an experimental setting is that dietary carbohydrate is the major stimulus of the glucose-insulin axis which, in turn has profound effects on several metabolic processes. The shift away from an anabolic state leads to an increase in fat oxidation thereby altering lipoprotein metabolism and cardio-metabolic profile [1]. Low carbohydrate diets consistently decrease fasting and postprandial plasma triacylglycerol (TAG), increase HDL-cholesterol (HDL-C), lower plasma insulin, and improve insulin sensitivity [2]. While LDL-cholesterol (LDL-C) responses are more variable, there is a consistent shift from small to larger particles [3]. These responses to carbohydrate restriction have been shown to occur in isocaloric experiments [4–6] indicating that the effects are not solely due to weight loss.

In our previous study of overweight men and women consuming a hypocaloric CRD, one of the most striking responses was a significantly greater reduction in plasma SFA levels in response to a CRD compared to a low fat diet, despite a threefold greater presence of *dietary* SFA in the carbohydrate-reduced diet [7]. Control of lipid metabolism, particularly SFA availability, is of current interest because of a recent meta-analysis showing that dietary SFA is not a risk factor for cardiovascular disease [8] and the indication that replacement by carbohydrate, in particular, may increase risk [9]. The extent to which plasma SFA reflects dietary saturated fat consumption is not clear-cut and is significantly affected by the presence of carbohydrate [3, 7]. Cassady et al. [10], for example, found that plasma palmitic and stearic acids did not depend on the saturated fat content of two different CRD. Two other studies reported lower plasma levels of SFA in response to diets that contained two to threefold greater intake of SFA but were lower in carbohydrate than standard intakes [11, 12].

The other remarkable finding in our previous investigation was a significant decrease in inflammatory markers despite a marked increase in plasma arachidonic acid (ARA) [7]. The metabolic intermediates in the production of ARA were decreased suggesting that synthesis was not increased. We proposed rather that the increase was due to better preservation of ARA. This idea was supported indirectly by the observation of significant reductions in several inflammatory cytokines that were also inversely correlated with changes in ARA. The ratio of n-6 to n-3 highly unsaturated fatty acids in phospholipids (PL) has received significant attention due to their conversion to eicosanoids of different biologic effects. The n-6 ARA (20:4n-6) more readily promotes inflammation when converted enzymatically or non-enzymatically to pro-inflammatory eicosanoids and F_2-isoprostanes [13, 14], whereas an increase in membrane eicosapentaenoic acid (EPA; 20:5n-3), an n-3 PUFA has anti-inflammatory effects and decreases risk of cardiovascular disease [15, 16]. Increasing ARA in membranes, however, does not inevitably lead to greater inflammation and may in fact have the opposite effect [15, 17]. The proinflammatory effects of ARA are due to metabolites produced subsequent to its release from membranes rather than the proportion of the intact fatty acid. Enzymatic metabolism of free ARA results in production of eicosanoids, and free radical-induced peroxidation of ARA results in the formation of isoprostanes. Measurement of isoprostanes is considered an accurate marker of oxidative stress, but it also represents a unique non-enzymatic degradation product of ARA [18].

Here, we extend the findings of our previous study by assessing plasma fatty acid composition responses in men who participated in two 6-week weight maintenance CRD feeding periods varying only in fatty acid composition. One CRD was designed to be high in SFA (emphasizing dairy fat and eggs), and the other was designed to be lower in saturated fat and consequently higher in unsaturated fat from both polyunsaturated (PUFA) and monounsaturated (MUFA) fatty acids (emphasizing fish, nuts, omega-3 enriched eggs, and olive oil). The objectives were to: (1) establish whether the disconnect between dietary and plasma SFA levels persists under isocaloric conditions, (2) determine if a weight stable CRD increases plasma ARA and the association with inflammatory markers and isoprostanes, and (3) determine whether an increase in dietary EPA and docosahexaenoic acid (DHA; 22:6n-3) on a CRD mitigates the increase in plasma ARA and its association with inflammatory markers and isoprostanes.

Experimental Procedures

Study Participants

Eight men, aged 38–58 years old, with BMI of 25–35 kg/m^2 participated in this controlled dietary intervention. Medical history, family history, and dietary intake from a 3 day diet record were collected at baseline. Exclusion criteria were abnormal glucose levels, hypercholesterolemia, a diagnosis of Type I or II diabetes, liver or other metabolic or endocrine dysfunction, hypertension, or use of cholesterol or diabetic medications. Subjects were also excluded if they were taking any supplements known to affect serum lipoprotein levels (i.e. fish oil, niacin, psyllium fiber) or inflammation (i.e. aspirin). Subjects were not excluded if they were already following a CRD, but were excluded if they were trying to lose weight or had a body mass that changed ±3 kg in the last 3 months. Subjects were asked to maintain their same activity level during the experimental period (verified by activity records) and sedentary individuals were not allowed to start a new exercise program in order to account for possible confounding effects on the dependant variables.

Study Design and Dietary Intervention

In a randomized, cross-over, controlled design, an isocaloric carbohydrate restricted high saturated fat diet (CRD-SFA) was compared to a CRD higher in unsaturated fat (CRD-UFA). Each dietary feeding period was 6 weeks in duration, based on previous research showing that the fatty acid composition of plasma PL stabilizes within 4–6 weeks of dietary change [19] and blood lipids stabilize within 6 weeks of a CRD [20]. Three weeks prior to starting each of the 6 week dietary feeding periods, all subjects were counseled to consume a run-in free-living weight-maintaining CRD (~10%en from carbohydrate, 65%en from fat, and 25%en from protein), using standardized procedures from our research laboratory. The purpose of this run-in period was to: aide in determining an appropriate energy level to maintain body weight; standardize subject's physiologic state before each diet; and initiate metabolic adaptations to carbohydrate restriction. Urinary ketones were monitored throughout the entire CRD run-in period and intervention using reagent strips (Bayer Corporation, Elkart, IN) to ensure compliance and to assure the presence of nutritional ketosis. After the run-in period, subjects were randomized to one of two dietary arms as described above. Following the 6 week feeding period, subjects returned to their individual baseline diet for 4 weeks. Once washed out, they returned to the same run-in CRD for another 3 weeks, and then crossed over to the next 6 week controlled CRD feeding arm.

Dietary energy for each subject was prescribed to maintain body weight, estimated using the Harris-Benedict equation and multiplied by an activity factor from 1.2 to 1.55 depending on individual activity level. This was averaged with their caloric intake during their baseline dietary intake and run-in CRD period. Composition of the experimental diets was developed using nutrient analysis software consisting of normal foods that differed only in the relative amount of saturated and unsaturated fatty acids, but were matched for food type, energy, total fat, dietary fiber, *trans* fat, and cholesterol (Food Processor 7.71, ESHA Research, Salem, OR). Validation of the daily nutrient composition was confirmed by chemical analysis (Covance Inc, Princeton, NJ). Table 1 shows the average nutrient intake for 3 days of the 7-day rotational menu via chemical analysis. A daily multi-vitamin and mineral

Values are mean percentages of total energy ± SD. *NA* data not available from habitual diet records. Habitual diets calculated from baseline 3-day food records of each participant. Habitual diets analyzed by Food Processor, ESHA Research, Salem, OR. Experimental diets analyzed by Covance Laboratories, Inc, Princeton, NJ

supplement at levels ≥100% of the RDA was also given to subjects and consumed throughout the entire intervention to ensure adequate micronutrient status.

In each 6-week feeding period, all food and beverages were provided for subjects in a 7-day rotational menu, and no other foods or beverages were allowed, unless they were calorie-free or very-low-calorie (i.e., tea, water, diet soda). Predominant foods in the CRD-SFA were high-fat dairy (cream, butter, cheese, and low-carbohydrate milk), eggs, meat, poultry, and white fish, and a few low omega-3 nuts and seeds (such as almonds). In the CRD-UFA, predominant foods were liquid omega-3 PUFA eggs (Egg Creations, Burnbrae Farms Ltd, ON, Canada. Containing EPA, DPA and DHA), hard shell omega-3 eggs (high in ALA and DHA), salmon, sardines, meat, poultry, olive oil, canola oil, low-fat low-carbohydrate dairy, walnuts, and seeds. Subjects picked up prepared, packaged food every Monday, Wednesday and Friday. All take-out food containers were returned unwashed and inspected to ensure that all food and fat had been consumed.

Anthropometrics

Body weight was measured weekly in the morning before food consumption and maintained within ±2 kg during the dietary intervention. Adjustments in caloric intake were made to maintain body weight within these parameters. Body composition was measured by dual-energy X-ray absorptiometry (Prodigy, Lunar Corporation, Madison, WI) at baseline, and at the start and end of each diet feeding intervention. Analyses were performed by the same blinded technician.

Blood Collection and Analysis

Blood samples were obtained at baseline, pre-dietary intervention and post-dietary intervention for both feeding periods. The sample was obtained from an arm vein after subjects rested quietly for 10 min in the supine position. Whole blood was collected into tubes with no preservative or EDTA and centrifuged at 1,500×*g* for 15 min and 4 °C, and promptly aliquoted into separate storage tubes which were stored at −75 °C until analyzed. A portion of serum (~3 ml) was immediately sent to a certified medical laboratory (Quest Diagnostics, Wallingford, CT) for determination of total cholesterol (TC), HDL-C, TAG, and calculated LDL-C concentrations using automated enzymatic procedures (Olympus America Inc., Melville, NY).

Glucose and insulin concentrations were analyzed in serum in duplicate (YSI 2300 STAT, Yellow Springs, OH, CV 0.5%) and radioimmunoassay (Diagnostic Systems Laboratory, Webster, TX, CV 4.3%), respectively, and used to calculate an index of insulin resistance [HOMA-IR; calculated as Glucose (mmol/l) Insulin (μIU/ml/22.5)]. The 75th percentile cut-off value for insulin resistance in non-diabetic individuals has been determined to correspond to a value of 2.29 [17]. Lipoprotein particle size of LDL-C was determined in serum using non-gradient polyacrylamide gel electrophoresis (Lipoprint LDL System, Quantimetrix Co., Redondo Beach, CA) as previously described [21]. Serum total ketone bodies were determined by a cyclic enzymatic method that measures both acetoacetate (AcAc) and 3-hydroxybutyrate (3-HB) (Wako Chemicals USA Inc, Richmond, VA). Absorbance was read at a wavelength of 404 nm on a microplate reader (Versa Max Molecular Devices Corp. Sunnyvale, CA, USA) and analyzed with associated SoftMax Pro software (CV 4.2%). Serum IL-6, IL-8, MCP-1, TNF-α, and leptin were measured using xMAP® technology on a Luminex® IS 200 system with antibodies to these analytes from LINCO Research (St. Charles, MO). Assays were completed in duplicate according to manufacturer's instructions (IL-6 CV 12.7%, IL-8 CV 10.4%, MCP-1 CV 7.3%, TNF-α CV 9.7%, Leptin CV 10.2%). High Sensitivity C-reactive protein (hs-CRP) was determined in serum on an IMMULITE Automated Analyzer using the commercially available immulite chemiluminescent enzyme immunometric assay (Immulite®, Diagnostic Products Corp., Los Angeles, CA, USA).

A 24-h urine collection was performed at baseline and post-dietary intervention. A 10-ml aliquot of urine was stored at −75 °C for subsequent analysis of F_2-Isoprostane (8-iso $PGF_{2\alpha}$) concentrations. All samples were analyzed in triplicate using column extraction followed by an ACE™ Competitive Enzyme Immunoassay with 8-Isoprostane enzyme-linked immunosorbent assay (EIA) kit (Cayman Chemicals, Ann Arbor, MI). Briefly, 2 ml frozen thawed urine was purified through an 8-Isoprostane Affinity Column (Caymen Chemicals), washed with column buffer and ultra pure water, and eluted with ethanol:water (95:5). Elution was dried with nitrogen; the volume of the dried sample was brought to 2 ml with enzyme immunoassay buffer in a 1:10 dilution. Absorbance was read at 420 nm and data was analyzed with a log-logit curve fit (CV 5.7%). The results were expressed relative to creatinine concentrations determined using Jaffe's colorimetric method (Cayman Chemicals) read at an absorbance of 490 nm (CV 3.2%).

Fatty Acid Composition

Plasma was shipped on dry ice to Lipid Technologies LLC (Austin, MN) and analyzed for plasma fatty acid composition in circulating PL, TAG and CE using capillary gas chromatography as previously described [7]. Lipids were extracted according to the method of Bligh/Dyer whereby

mixtures of plasma, methanol, chloroform and water were prepared such that lipid is recovered in a chloroform layer. The resulting lipid extracts were maintained under an atmosphere of nitrogen following extraction and kept frozen prior to additional processing. Immediately prior to lipid class separation, lipid samples were dried under a gentle stream of nitrogen, rediluted in 50 μl of chloroform and prepared for lipid class separation. Lipid classes were separated on commercial silica gel G plates (AnalTech, Newark, DE). The chromatographic plates were developed in a solvent system consisting of distilled petroleum ether (b.p.30–60 °C): diethyl ether: acetic acid (80:20:1, by vol). Following development, the silica gel plates were sprayed with a methanolic solution containing 0.5% 2,7-dichlorofluorescein which was then used to visualize lipid classes under ultraviolet light. Desired corresponding lipid bands were then scraped into Teflon-lined screw cap tubes. The samples were then transesterified with boron trifluoride (10%) in excess methanol (Supelco, Bellefonte, PA) in an 80 °C water bath for 90 min. Resulting fatty acid methyl esters were extracted with water and petroleum ether and stored frozen until gas chromatographic analysis was performed.

Lipid class fatty acid methyl ester composition was determined by capillary gas chromatography. Methyl ester samples were blown to dryness under nitrogen and resuspended in hexane. Resulting fatty acid methyl esters were separated and quantified with a Shimadzu capillary gas chromatograph (GC17) utilizing a 30 m Restek free fatty acid phase (FFAP) coating and EZChrom software. The instrument temperature was programmed from 190 to 240° at 7 °C/min with a final hold of 10 min, separating and measuring fatty acid methyl esters ranging from 12:0 to 24:1. The detector temperature was 250 °C. Helium carrier gas was used at a flow rate of 1.4 ml/min. and a split ratio of 1:25. Chromatographic data was collected and processed with EZChrom software (Scientific Products, CA). Fatty acids were identified by comparison to authentic fatty acid standards and quantitated with peak area and internal standard. Individual peaks, representing as little as 0.05% of the fatty acid methyl esters, were distinguished. Fatty acid data are expressed in relative (mol%) and absolute (nmol/ml) terms.

Statistics

ANOVA with repeated measures was used to evaluate changes from baseline across diets. Data that was not normally distributed was log transformed. Significant main effects were further analyzed using a Tukey post hoc test. Differences between values following CRD-SFA and CRD-UFA were evaluated using paired student's *t* test. The alpha level for significance was <0.05.

Results

Dietary Intake

Nutrient intake estimated at baseline from dietary records showed a lower than expected energy, 2,072 kcal/d compared to 2,513 kcal/d for the feeding periods. This was likely due to under-reporting at baseline (Table 1) [22] although it has been argued that the demands of gluconeogenesis and other processes require more energy for weight maintenance [23]. Habitual carbohydrate intake was also lower than the average American diet at 32%en reflecting two subjects who were habitually consuming a lower-carbohydrate diet. Both CRD were well tolerated and compliance was excellent as assessed by verbal feedback and inspection of returned food containers throughout the intervention. There was no consistent preference for one diet treatment over the other by subjects. Briefly, the main difference between the two low carbohydrate diets was in the relative amount of SFA, MUFA, PUFA (CRD-SFA = 31, 21, and 5%; CRD-UFA = 17, 25, and 15%). Although the CRD-UFA contained higher amounts of both n-6 and n-3 PUFA, the ratio of n-6/n-3 PUFA was lower in the CRD-UFA. Other nutrients, including cholesterol, were matched with the exception of (naturally occurring) *trans* fatty acids which were inherently higher on the CRD-SFA diet due to the higher intake of high-fat dairy. Compared to baseline, the CRD-SFA diet provided more than twice as much dietary SFA (86 vs. 40 g) while in the CRD-UFA, intake of SFA was 47 grams. Compared to baseline, the CRD-UFA provided more total PUFA (41 vs. 16 g), n-3 PUFA (3%en vs. 0.7%en), and n-6 PUFA (11%en vs. 7%en). Cholesterol intake in both diets was about twofold higher than baseline intake.

Body Weight and Composition

Body fat percentage and body mass of subjects after the two experimental diets were not significantly different from baseline. A small, but significant ($P < 0.05$) decrease in body mass (difference: 0.94 ± 0.13 kg) occurred following the CRD-UFA diet compared to the CRD-SFA diet (Table 2).

Blood Markers

Blood lipid, metabolic, and inflammatory markers are presented in Table 2. Serum ketones were moderately elevated as a result of carbohydrate restriction. Fasting plasma TC and LDL-C were variable but were higher on average following CRD-SFA compared to CRD-UFA. The increase in HDL-C following CRD-SFA (14%) and CRD-UFA (8%) from baseline resulted in no significant change in the TC/HDL or LDL/HDL ratios.

Table 2 Body composition and blood marker responses of subjects at baseline and following the two low carbohydrate diets

Characteristic	Baseline	CRD-SFA	CRD-UFA	ANOVA

8-iso $PGF_{2\alpha}$ (pg/mg creatinine)	629 ± 262	524 ± 146	425 ± 61	0.053

Values are means ± SD

HOMA-IR homeostasis model assessment insulin resistance index

* $P < 0.05$ from baseline based on repeated measures ANOVA and Tukey post hoc

† $P < 0.05$ from CRD-SFA diet (dependent *t* test)

$^{£}$ $P < 0.08$ from baseline

Consistent with numerous studies on CRD even in the absence of weight loss, a dramatic decrease in plasma TAG was seen. TAG fell from baseline by 39% after the CRD-SFA and by 34% on the CRD-UFA. There was also a decrease in TAG/HDL ratio for both the CRD-SFA (−39%) and CRD-UFA (−43%). LDL mean and peak particle size following the two diets were both significantly higher than baseline.

Blood glucose, insulin, and HOMA-IR were not significantly different from baseline or between diets. Using 2.29 as the cut-off point to define insulin resistance [21], two subjects were insulin resistant (HOMA-IR = 3.06 and 5.53) at baseline. HOMA-IR values were <2.29 for both subjects after the CRD-UFA and for one of the insulin resistant subjects after the CRD-SFA.

There were no significant differences in any of the serum inflammatory markers (hs-CRP, IL-6, IL-8, TNF-α, MCP-1, leptin) between the two interventions. Compared to baseline levels of urinary 8-iso $PGF_{2\alpha}$ (629 ± 262 pg/Creatinine mg), concentrations were reduced by 17% after the CRD-SFA (524 ± 146 pg/Creatinine mg; $P = 0.253$) and by 32% after the CRD-UFA (425 ± 61 pg/Creatinine mg; $P = 0.018$). After the CRD-UFA, all 8 subjects had lower urine 8-iso $PGF_{2\alpha}$ than baseline and 7 out of 8 had lower concentrations compared to the CRD-SFA.

Plasma Saturated and Monounsaturated Fatty Acids

The major changes in plasma SFA and MUFA were in the plasma TAG fraction. The mol% of total SFA in TAG was significantly lower following CRD-UFA compared to CRD-SFA (Table 3). At the same time, the effect was less than might be expected given the nearly two-fold difference in dietary saturated fat suggesting that the reduction in carbohydrate was the major determinant; there was, in fact, no difference in total SFA in TAG between baseline and CRD-SFA. The lower total SFA after the CRD-UFA was mainly attributed to a decrease in 16:0, the predominant SFA in plasma TAG although, again, the magnitude of the effect was small. Compared to baseline, 16:1n-7 mol% in plasma TAG was significantly lower following both CRD, but not different between CRD. A comprehensive list of fatty acids from TAG, PL and CE fractions is provided in Table 3.

Plasma Polyunsaturated Fatty Acids

The major changes in plasma PUFA were in the PL fraction. There were distinct differences between the CRD in plasma PL long chain n-6 and n-3 PUFA (Table 3). Compared to baseline, all subjects had an increase in 20:4n-6 after the CRD-SFA, and those values were higher than 20:4n-6 after the CRD-UFA in all but one subject. Interestingly, despite an increase in 20:4n-6 in response to the CRD-SFA the immediate precursor 20:3n-6 was not increased and was in fact lower than baseline. Total n-3 PUFA was significantly higher following the CRD-UFA than baseline and CRD-SFA values primarily due to greater increases in 20:5n-3 (EPA) and 22:6n-3 (DHA). The PL n-6/n-3 ratio (calculated as the sum of all n-6 PUFA divided by the sum of all n-3 PUFA), was significantly lower following CRD-UFA than CRD-SFA and baseline. Compared to baseline, the ARA/EPA ratio was significantly increased after the CRD-SFA whereas it was decreased after the CRD-UFA. Compared to baseline the ARA/EPA ratio was decreased after the CRD-UFA in all subjects, and it was higher during the CRD-SFA than the CRD-UFA in all subjects.

Intuitively, one might presume an increase in PL ARA would result in a corresponding increase in 8-iso $PGF_{2\alpha}$, yet we observed the opposite. There was a significant inverse correlation between changes in urine 8-iso $PGF_{2\alpha}$ and PL ARA on both low carbohydrate diets ($r = -0.82$ CRD-SFA, $P = 0.007$; $r = -0.62$ CRD-UFA, $P = 0.05$) indicating that those subjects who showed greater increases in plasma ARA had greater reductions in 8-iso $PGF_{2\alpha}$.

Discussion

Dietary saturated fat has been the focus of nutritional recommendations since the 1970 study of Ancel Keys [24]. Current recommendations are as low as 7% [25] although the subject has always generated some controversy. The biologic effect of dietary SFA is presumed to rest with its effect on plasma SFA and other lipid fractions but a number of reports in the literature suggest that this needs to be experimentally established [7, 11, 12]. In the current study, we used a controlled-feeding design to examine responses in plasma fatty acids, lipoproteins, isoprostanes and inflammatory markers in men who switched from their habitual diet to a CRD either high in SFA (CRD-SFA) or unsaturated fat (CRD-UFA) including eggs with long chain n-3 PUFA. The primary findings were that: (1) there is limited effect of dietary SFA on plasma SFA in the context of a weight maintenance low carbohydrate diet, (2) a weight maintenance CRD high in SFA (representing the typical nutrient composition of CRD we have studied in our many previous investigations) resulted in a significant increase in plasma ARA without an accompanying increase in inflammation or oxidative stress, (3) a weight maintenance CRD higher in unsaturated fat (CRD-UFA) including EPA and DHA (CRD-UFA) prevented the increase in plasma ARA while increasing plasma EPA and DHA content and significantly decreasing urine 8-iso $PGF_{2\alpha}$, a degradation breakdown product of ARA, and, (4) the changes in plasma ARA and urine 8-iso $PGF_{2\alpha}$ were inversely correlated on both CRD independent of fat composition supporting and strengthening our hypothesis of less catabolism of ARA (i.e., better preservation of ARA) on a CRD.

Saturated Fat

The most striking finding was the lack of association between dietary SFA intake and plasma SFA concentrations. Compared to baseline, a doubling of saturated fat intake on the CRD-SFA did not increase plasma SFA in any of the lipid fractions, and when saturated fat was only moderately increased on the CRD-UFA, the proportion of SFA in plasma TAG was reduced from 31.06% to 27.48 mol%. Since plasma TAG was also reduced, the total SFA concentration in plasma TAG was decreased by 47% after the CRD-UFA, similar to the 57% decrease we observed in overweight men and women after 12 week of a hypocaloric CRD [7]. These results can best be explained by the metabolic adaptations induced by carbohydrate restriction [1], notably less stimulation of insulin. Lower insulin levels result in increased lipolysis and fatty acid oxidation while simultaneously decreasing activity of key enzymes in de novo lipogenesis. From a mechanistic standpoint, restriction in dietary carbohydrate is the dominant dietary manipulation that accelerates fat mobilization and oxidation [26]. The lipid fraction most responsive to carbohydrate restriction was TAG. Higher incorporation of SFA into VLDL TAG is correlated with insulin resistance and adiposity [27], probably reflecting accelerated hepatic *de novo* lipogenesis. Plasma TAG transports the greatest amount of fatty acids that are actively involved in energy exchange. Therefore a decrease in plasma SFA, from reduced hepatic fatty acid synthesis or increased beta-oxidation, may attenuate atherogenic cell-signaling even in the presence of higher dietary SFA. The limited change in SFA in PL may be due to lower turnover in this fraction (the sn-1 position almost always carries a SFA), or to the short duration of this study. Previous studies have shown that increased plasma PL and CE SFA levels predict development of cardiovascular disease (CVD) [28, 29].

The presence of palmitoleic acid (16:1n-7) is an indicator of *de novo* fatty acid synthesis [30] since the compound is limited in the diet. Both isocaloric CRD feeding

periods in this study significantly decreased TAG 16:1n-7, suggesting that similar reductions in our previous experiments using a hypocaloric CRD [3, 7], were a consequence of carbohydrate restriction rather than calorie reduction or weight loss. Lower 16:1n-7 also provides an explanation for the lack of association between dietary and plasma SFA since the 16:0 species is the primary product of fatty acid synthesis. Parallel reduction in 16:0 and 16:1n-7 suggests that stearoyl-CoA desaturase-1 (SCD-1), the enzyme responsible for desaturating 16:0, was not down-regulated independent of lipogenesis, since, in that case, the proportion of 16:0 would be expected to rise. Increased plasma levels of SFA and 16:1n-7 have been reported in obese adolescents [31] and adults with MetSyn [32] and higher 16:1n-7 is associated with increased abdominal obesity, lipogenesis, and hypertriglyceridemia [33, 34].

Highly Unsaturated Fatty Acids

The increase in PL ARA in weight stable men after the CRD-SFA (order of 2 units expressed as mol%) is similar to the previously reported effect in overweight men on a hypocaloric diet [7] indicating that the latter was not due to weight loss. Replacing SFA with unsaturated fat including n-3 PUFA prevented the increase in plasma ARA, and also resulted in a marked increase in plasma EPA and DHA, likely a result of higher dietary intake on the CRD-UFA (1.5 g vs. 0.4 g/day). Previous studies have shown close association between dietary EPA and DHA and plasma EPA and DHA [35]. Increased plasma ARA following CRD-SFA may have resulted from less competition from n-3 PUFA for preferential acyl incorporation into the sn-2 position of phospholipids [36]. Dietary intakes of ARA were high in both CRD-UFA and CRD-SFA. Competition among n-3 and n-6 PUFA at the level of desaturation and chain elongation steps of fatty acid biosynthesis may also be important.

An increase in phospholipid ARA mol% and PL ARA/EPA ratio is commonly viewed as contributing to a pro-inflammatory and pro-oxidative state. These effects following CRD-SFA, however, were not accompanied by elevation of any of the inflammatory markers or 8-iso $PGF_{2\alpha}$. Along these lines, a meta-analysis of 14 case–control and prospective cohort studies found that increased ARA in plasma PL or triglycerides was not associated with coronary events [37], while a recent case-controlled study of acute coronary syndrome (ACS) found a U-shaped relationship between odds ratio for ACS and erythrocyte ARA content [38]. Ferrucci L et al. [15] demonstrated and inverse relation between plasma ARA and pro-inflammatory markers, in agreement with the current study. A CRD that resulted in an increased ARA/EPA ratio also decreased C-reactive protein (CRP) [17]. A number of other studies have failed to link increased ARA in plasma lipids with deleterious outcomes [39–43]. The lack of association between plasma PL ARA and plasma PL ARA/EPA ratio and inflammation following CRD-SFA supports the idea that ARA in plasma membranes is not pro-inflammatory, especially in the context of low dietary carbohydrate. In fact, there was a trend ($P < 0.08$) for an anti-inflammatory effect on the adipocytokine leptin. Although leptin is not a classic cytokine, several immune cells (including polymorphonuclear leukocytes, monocytes, macrophages and lymphocytes) have leptin receptors and their activity can be modulated by leptin. Leptin has also been shown to stimulate production of ROS by activated monocytes in vitro [44].

Previous CRD investigations indicate significant reductions in response to a low carbohydrate diet even when normalizing for changes in body or fat mass [3].

The isoprostane 8-iso $PGF_{2\alpha}$ is a free radical-catalyzed product of ARA measured as a general indicator of oxidative stress [18]. We found no change in 8-iso $PGF_{2\alpha}$ after the CRD-SFA despite a significant increase in plasma ARA. Similarly, a significant decrease in 8-iso $PGF_{2\alpha}$ was observed after the CRD-UFA where there was no change in plasma ARA. The inverse correlation between changes in plasma PL ARA and 8-iso $PGF_{2\alpha}$ indicates better preservation of ARA in response to a CRD. The fat sources in this diet, olive oil and lipid from fish and liquid omega-3 eggs, may have contributed to lower urinary 8-iso $PGF_{2\alpha}$ following CRD-UFA. Urinary excretion has been shown to be reduced by extra virgin olive oil [45], moderate fish oil supplementation (3.6 g/d n-3 PUFA), [46] and one daily fish meal (providing 3 g n-3 PUFA) reduced urinary F_2-isoprostane levels in dyslipidemic non-insulin-dependent diabetic patients [47].

Insulin Resistance Syndrome

Saturated fatty acids are often implicated in the worsening of insulin resistance [48], but the effect is contingent upon the presence of ample carbohydrate. Carbohydrate restriction in the presence of high saturated fat leads to improvement in insulin sensitivity despite increased lipolytic rates and release of fatty acids into the circulation [49]. In the current study, the two subjects who had insulin resistance at baseline improved after restricting carbohydrate. The TAG/HDL-C ratio is strongly correlated with insulin resistance and levels >3.5 are indicative of increased CVD risk [50]. All subjects showed TAG/HDL-C values less than this value after the CRD consistent with the HOMA-IR results. Carbohydrate restrictions thus improved insulin sensitivity independent of dietary fatty acid composition. Many factors can influence serum cholesterol responses to saturated fat [51] including genetic variations [52] and the current study showed high variability in LDL-C. Independent of LDL-C concentration, however, individuals with a predominance of small LDL particles (pattern B) have >threefold risk of CVD [53]. In the current study, the variable LDL response was accompanied by uniform increase in LDL particle size.

Dietary Recommendations

The current findings further challenge the broad recommendation to restrict saturated fat especially since those calories are likely to be replaced with carbohydrate. The many factors that contribute to the relation of fat intake and fatty acid composition have been reviewed [54], and our results emphasize the substantial impact of a low carbohydrate intake in regulating the connection between dietary and plasma SFA. A higher saturated fat intake can be efficiently metabolized in the presence of low carbohydrate and lead to consistent improvements in markers of CVD risk. Whereas studies of benefits of carbohydrate restriction are rarely cited in the literature, responses of even a single meal high in saturated fat are taken as convincing evidence even if done in the presence of high carbohydrate. Ultimately, however, long term studies show that replacement of saturated fat with carbohydrate is at best neutral [55, 56]. Persistence of recommendations in the face of continued failure of large trials to show an effect of saturated fat remains one of the strange anomalies in current medical science.

Substitution of a portion of the SFA within a CRD with UFA including a combination of both MUFA and n-6 and n-3 PUFA had a profound effect on plasma fatty acid composition, reduced oxidative stress, but did not alter the positive effects on features of metabolic syndrome (e.g., insulin, TAG, LDL particle size). As low carbohydrate diets become more widely prescribed and used, it will be important to determine the range of dietary fatty acids most conducive to improving long-term health. Our results point to a suitable diet that had an emphasis on low carbohydrate foods with fat sources emphasizing MUFA and n-3 PUFA (e.g., omega-3 eggs, avocado, salmon, sardines, meat, poultry, olive oil, canola oil, nuts and seeds) although there was little if any detriment in a higher saturated fat approach.

Abstract In this paper, we report the full-length coding sequence of bovine ATGL cDNA and analyze its expression in bovine tissues. Similar to human, mouse, and pig ATGL sequences, bovine ATGL has a highly conserved patatin domain that is necessary for lipolytic function in mice and humans. This suggests that ATGL is functionally intact as a triglyceride lipase in cattle. Tissue distribution of ATGL gene expression was highest in fat and muscle (skeletal and cardiac) tissue, while protein expression was solely detectible in the adipose tissue. The effect of 109 days of flaxseed supplementation on ATGL and adipocyte fatty acid-binding protein (FABP4 or A-FABP, E-FABP or FABP5) expression was examined in Angus steers. Supplemented steers had greater triacylglycerol (TAG) content in the muscle compared with unsupplemented ones. Additionally, supplementation increased A-FABP expression and decreased stearoyl-CoA desaturase 1 (SCD-1) expression in muscle, while total ATGL expression was unaffected. In summary, supplementation of cattle rations with flaxseed increased muscle TAG concentrations attributed in part to increased expression of key enzymes involved in lipid trafficking (A-FABP) and metabolism (SCD-1).

Introduction

Altering the fatty acid composition of beef products for human consumption adds value, creating a functional food which may enhance the overall health of meat-consuming individuals. In the Western diet, the consumption of n-3 fatty acids via dietary intake is low because of relatively low rates of fish consumption and the industrial production of animal feeds rich in grains containing n-6 fatty acids, leading to production of meat rich in n-6 and low in n-3 fatty acids [1]. In addition, it is important to mention that beef fat has a high degree of saturation due to the biohydrogenation of unsaturated dietary fatty acids by rumen microorganisms, though there is a variation in the n-6/n-3 ratio between breeds and production systems. It has been demonstrated that feeding diets high in flaxseed increases n-3 fatty acid content in beef and poultry [2–4]. We have previously shown that n-3 levels in Angus beef increased from 27 to 45 mg per 100 g [2]. The acceptable macronutrient distribution range set by the National Academy of Sciences, Institute of Medicine, Food and Nutrition Board in 2005 for total n-3 fatty acids is 0.6–1.2% of energy, 1.3–2.6 g for a person consuming 2,000 kilocalories per day. Studies indicate that in humans, a high intake of n-6 fatty acids shifts the physiologic state to one that is prothrombotic and proaggregatory, characterized by increases in blood viscosity and vasoconstriction, and reduced bleeding time, while high intake of n-3 fatty acids have anti-inflammatory, anti-thrombotic, anti-hypertensive, and anti-arrhythmic properties, while also improving arterial compliance, vasodilation, and serum lipid profiles [5–8]. The average Western diet has an n-6 to n-3 fatty acid ratio of approximately 20–30:1 [5], hence large scale production of n-3 enriched meats would provide alternative sources of n-3 fatty acids for consumers.

Supplementation with flaxseed changes not only the fatty acid composition of skeletal muscle of Angus steers [2], but may also affect lipid metabolism within the muscle altering total fat concentration. Because dietary n-3 fatty acids increase the expression of PPARγ in flax-supplemented cattle [2], the impact of this dietary regimen on the expression of adipose triglyceride lipase (ATGL) and on adipocyte fatty acid-binding protein (A-FABP, FABP-4) was examined in this study. ATGL is a newly discovered lipase which hydrolyzes the first ester bond of stored triacylglycerols, releasing nonesterified free fatty acids [9]. It is associated with lipid droplets and is found at high concentrations in adipose tissue, though it is present in tissues with lipid stores [10]. ATGL activity is required for PKA-stimulated fatty acid and glycerol release in murine embryonic fibroblast adipocytes [11] and is the rate-limiting step in hormone-induced lipolysis [9, 12]. The product, diacylglycerol, is then hydrolyzed by activated hormone sensitive lipase (HSL), which has a higher substrate affinity for diacylglycerol than triacylglycerol (TAG) [12]. A direct interaction between A-FABP and HSL promotes the hydrolysis of lipid droplet stored TAG, thus it is thought that A-FABP may be involved in fatty acid trafficking from the lipid droplet to the adipocyte membrane where the fatty acid leaves the cell [13, 14]. Thus, ATGL, HSL, and A-FABP work in concert to mobilize esterified fatty acids stores from lipid storing tissues, although the impact of n-3 fatty acid supplementation on expression of these key proteins in cattle is not fully characterized.

To address this question, we examined the expression of these proteins in longissimus muscle of Angus steers finished on a diet containing flaxseed rations. In addition, while the sequences of ATGL for mouse, swine, human, and avian species are known [9, 15, 16], the sequence of bovine ATGL and its response to dietary manipulation is not known. Herein, we report for the first time the sequence for bovine ATGL and characterize ATGL gene expression in cattle. We also demonstrate that ATGL gene expression was not influenced by dietary n-3 fatty acids in cattle, although the expression of A-FABP was increased, consistent with our previous work demonstrating an increase in PPARγ expression in these cattle [2].

Materials and Methods

Feeding Regimen for Angus Cattle

The experimental methods for the feeding of Angus steers were described in our previous report [2]. Briefly, 20 Angus steers that were 16 months old with a mean body weight of 414 kg (SD = 39 kg) at the start of the study were divided into two groups: flaxseed supplement (907 g/day) and control groups (10 steers per group). The basal diet of the grazing steers was forage during the first 2.5 months of the trial, then a combination of forage and concentrate for the next month and primarily concentrate for the final month [2]. Intake of feedstuffs for the basal diet of grazing steers was ad libitum and the percentage of their diet from flaxseed (907 g/day for final 107 days of supplementation) was therefore not determined. At the end of the flaxseed supplementation period, the steers were slaughtered and cross-sectional pieces of longissimus dorsi muscles (ribeye steaks) between the 12th and 13th ribs were collected from each carcass. Muscle tissues were stored at −80°C for later use.

Four Angus cattle with about 460 kg of body weight (~550 day old) were euthanized by captive bolt stunning and exsanguination at the Ohio State University's Meat Science Laboratory located in the Department of Animal Sciences, Columbus, OH, USA. Adipose tissue, heart, muscle, lung, liver, and kidney were collected immediately

after euthanization, snap-frozen in liquid nitrogen and stored at −80°C before total RNA and protein isolations to examine tissue distribution of ATGL expression. Animal care and procedures were approved by the OSU Institutional Animal Care and Use Committee.

RNA Isolation

RNA was isolated from bovine tissue samples using Trizol™ (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions. RNA quality was assessed by agarose gel electrophoresis. Approximately 1 μg of total RNA was reverse transcribed according to the manufacturer's instructions (Invitrogen Life Technologies—M-MLV reverse transcriptase).

Cloning of Bovine ATGL

Subcutaneous dorsal back adipose (100 mg) was sampled within 3 min of euthanization, snap-frozen in liquid nitrogen, and stored at −80°C before total RNA isolation. Complementary DNA from subcutaneous adipose tissue of Angus cattle was used as a template for PCR. Primers were designed according to several partial bovine DNA sequences that contain conserved sequence homology among human (Genbank accession numbers: AY894804, NM_020376) and mouse (AJ278476, AK031609) sequences. A MJ Research PTC-200 thermal cycler (MJ Research Inc., South San Francisco, CA, USA) and DNA Taq polymerase (Invitrogen) were used for all PCR. The PCR products were separated by electrophoresis on a 1% agarose gel and the appropriate band(s) excised and gel extracted using the Qiagen Gel Extraction kit (Qiagen, Alameda City, CA, USA). The product was then ligated to the pCR 2.1-TOPO vector using the TOPO TA Cloning Kit (Invitrogen). Positive clones were sequenced by The Ohio State University sequencing core facility using an Applied Biosystems 3730 DNA Analyzer (Foster City, CA, USA). The resulting sequences confirmed bovine ATGL by homology to the mouse, human, and pig and by identification of characteristic enzyme domains. Real-time primers were then designed to measure ATGL gene expression ("F2" 5′-GTGGACGGTGGCATCTCAGA-3′, "R2" 5′-TACAGGGATGGCCTCCGCTT-3′). Primers were designed to span genomic introns, thus allowing for detection of genomic DNA contamination. PCR using F2/R2 primers were optimized for use in real-time PCR.

Quantitative Real-Time PCR Detection of Total Gene Expression

Real-time PCR was performed using SYBR green I nucleic acid dye (Molecular Probes Invitrogen detection technologies) on an ABI 7300 (Applied Biosystems). AmpliTaq Gold™ (Applied Biosystems) was used in all real-time reactions as was the following thermal profile: 95°C 10 m, 40 cycles of 94°C 30 s, 58°C 60 s, 82°C 30 s. The C_T values for the internal control (cyclophilin) and target genes, as determined by the ABI software, were used to calculate gene expression using the $2^{-\Delta\Delta Ct}$ method. All target genes were normalized to cyclophilin and changes were calculated as relative fold-change to cyclophilin. Randomly selected samples from all real-time runs were resolved by agarose gel electrophoresis to ensure the amplification of one product. In addition, dissociation/melting curves yielded single peaks, indicating a single product with lack of primer dimers or genomic DNA contamination. "No template" negative controls were included in all PCR to detect contamination. Primer sequences used for the quantitative real-time PCR are shown in Table 1.

Protein Isolation and Immunoblotting

Approximately 80 mg of tissue was homogenized in 800 μl of lysis buffer (1% Triton X-100, 150 mM NaCl, 20 mM HEPES pH 7.5, 10% glycerol, 1 mM EDTA, 100 mM NaF, 100 μM sodium orthovanadate, 1 mM PMSF, and 10 μL/mL protease inhibitor cocktail (Sigma–Aldrich, P8340). The protein content of cell lysate was determined using the bicinchoninic acid (BCA) Protein Assay Kit (Pierce Chemical Co., Rockfold, IL, USA). Samples were separated by SDS-PAGE using the mini-Protean system (Bio-RadHer). The protein was wet-transferred to a PVDF membrane (Amersham Biosciences Hybond-P™), blocked in 5% non-fat dry milk in 1x-TBST (0.1% Tween 20) and incubated overnight at 4°C with primary antibody (1:3,000) specific to ATGL (Cell Signaling Technology, Inc., Danvers. MA, USA) in 5% non-fat dry milk. After washing in 1x-TBST, blots were incubated with the appropriated HRP-conjugated secondary antibody for 1 h at room temperature. Blots were washed before addition of ECL plus™ (Amersham Biosciences) and bands were detected with Hyperfilm™ (Amersham Biosciences).

Analysis of Triacylglycerol Mass

Samples were taken from visibly lean portions of frozen ribeye steak and immersed in liquid nitrogen. These samples were then pulverized at liquid nitrogen temperatures to a fine homogeneous powder. Pulverized muscle tissue from flaxseed-supplemented and non-supplemented Angus steers was weighed, homogenized in hexane: 2-propanol (3:2 by vol) using a Polytron tissue homogenizer, and the lipids were extracted [17]. The samples were subjected to centrifugation (2,750*g*, 4°C, 10 min) and the lipid containing solvent removed from the pellet. The samples were

reduced in volume using nitrogen evaporation and the lipid redissolved in a known volume of hexane:2-propanol (3:2 by vol). To analyze TAG mass, the samples were quantitatively applied to a thin layer chromatography plate (silica gel G, Analtech, Newark, DE, USA) and the neutral lipids separated using petroleum ether:diethyl ether:acetic acid (75:25:1.3 by vol). This method separates TAG from cholesteryl esters as well as from other neutral lipids, such as cholesterol and unesterified fatty acids [8]. The TAG was removed from the plate by scrapping and the sample placed into an acid-washed test tube to which concentrated sulfuric acid was added [18]. The tube was heated at 200°C for 15 min in a heating block and the sample subjected to centrifugation (2,500 *g* for 10 min) to pellet the silica. The absorbance at 375 nm was measured in a quartz cuvette using a Beckman DU-640 spectrophotometer (Fullerton, CA, USA). Absorbance was converted to mass using triolein glycerol (MW 882, Nuchek Prep, Elysian, MN, USA) and the values are expressed as μg/g wet weight (ww).

Bioinformatics, Sequence Analysis, and Statistical Analysis

Bioinformatics and sequence analysis were performed as previously described [11]. The sequence Scanner (v 1.0) was used to generate the chromatogram of cloned bovine ATGL cDNA by using Applied Biosystems genetic analyzer instruments. ATGL nucleotide and putative protein sequences of pig [15] and avian [16] were already reported and used for sequence analysis and comparison. Mouse and human ATGL nucleotide and putative protein sequences were obtained from NCBI. The alignment and comparison of nucleotide or protein sequences were done using ClustalX and GeneDoc™ software. The phylogenic tree was constructed by CLUSTAL W (Version 1.83) and MEGA 4 software (neighbor joining method) [19] using the putative ATGL protein sequences of various species. The neighbor joining method is a simplified version of the minimum evolution (ME) method using distance measures to correct for multiple hits at the same sites, and chooses a topology showing the smallest value of the sum of all branches as an estimate of the correct tree [19].

With the exception of the phylogenic branch lengths, all results are presented as mean ± SEM. Comparison of two means was accomplished by a Student's *t* test at $P \leq 0.05$ and 0.01. Comparisons among gene expression data were performed using one-way analysis of variance (ANOVA) followed by the Tukey's test at $P \leq 0.05$. Statistical analysis was performed using Minitab software (version 15.0).

Results

We identified several partial bovine DNA sequences in The Institute for Genomic Research (TIGR) database that were homologous to the human ATGL sequence. Primers were designed based on these sequences to clone a full length sequence of bovine ATGL. Soon after we cloned this sequence, another group submitted a bovine ATGL

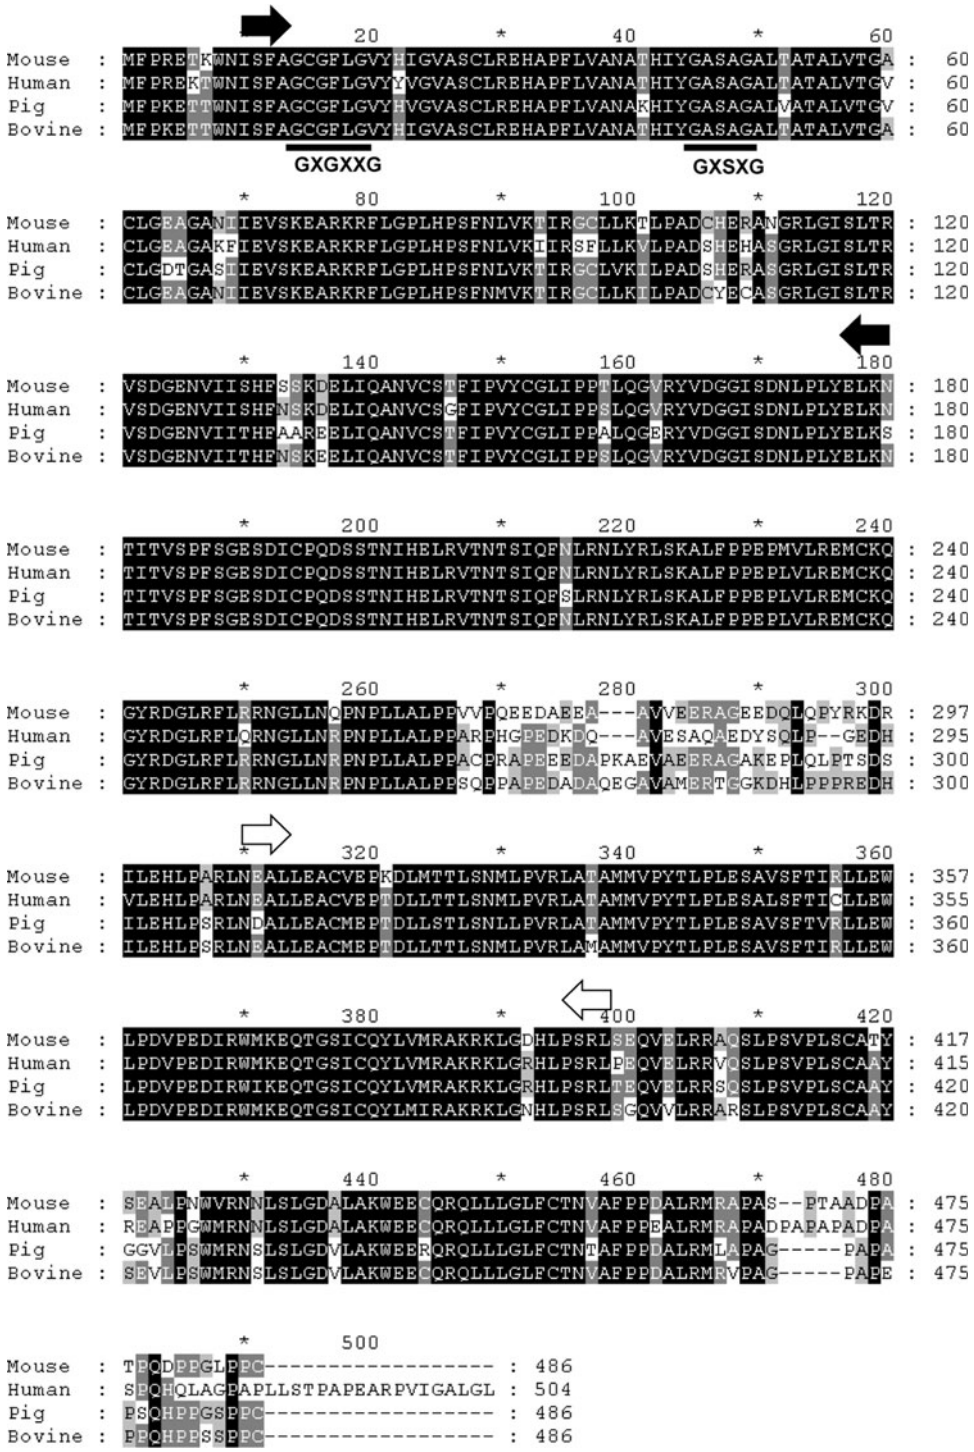

Fig. 1 Amino acid sequence alignment of cow, human, and mouse ATGL. *Black shading* indicates identical aa and *gray shading* indicates aa in the same R groups. The 10–180 aa at the N-terminal indicated as the *filled arrows* were identified as a patatin domain in the Pfam protein family data base. The conserved glycine-rich motif (G*X*G*XX*G) and the serine hydrolase motif (G*X*S*X*G) are shown at the N-terminus. The aa (310–400) indicated as *unfilled arrows* are hydrophobic domain

sequence to Genbank (XM_864571). Our sequence (Genbank FJ897536) and XM_864571 are identical except for a 1 bp mismatch which does not result in an altered amino acid sequence and may represent a polymorphism within the gene. Bovine and porcine ATGL share a great deal of homology. Like porcine ATGL, computer-generated translation analysis of the bovine ATGL cDNA yielded open reading frames of 486 aa (Fig. 1). In addition, there were additions of 3 aa (278–280) and deletions of 5 aa (467–471) in both cattle and pigs compared to human ATGL. Phylogenic analysis revealed that bovine and porcine ATGL proteins share greater homology to human than to mouse, quail, chicken, or turkey (Fig. 2). Bovine ATGL coding sequence has a 90% sequence homology to the human sequence (AY894804). The first 180 aa of the ATGL protein represent the patatin domain which is

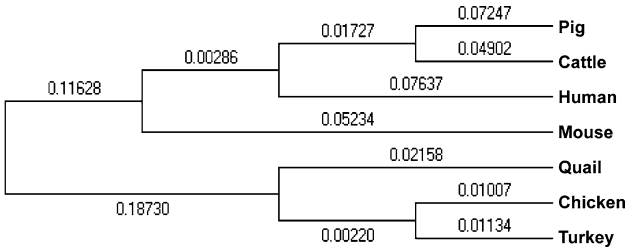

Fig. 2 A phylogenetic analysis of ATGL protein. A phylogenetic tree was constructed to determine the evolutionary relationship of ATGL proteins among various species. Mammalian ATGL proteins form a hierarchical structure distinct from the avian cluster demonstrating relatedness of the species by ATGL sequence. The values, representing branch lengths, are determined by the neighbor joining algorithm (see "Materials and Methods")

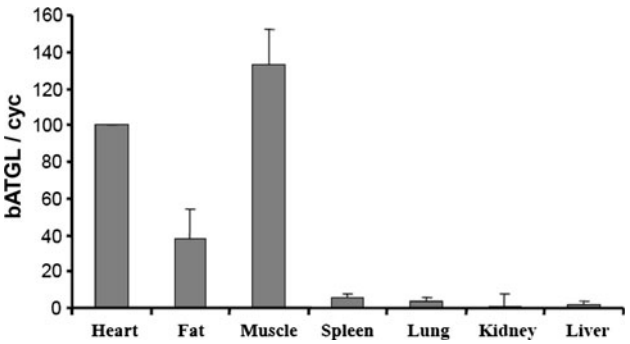

Fig. 3 Tissue distribution of bovine ATGL gene expression. Total RNA was isolated from various bovine tissues. The mRNA expression of bovine ATGL gene was determined by quantitative real-time RT-PCR and expressed as a ratio to cyclophilin expression. Data reported as means ± SEM ($n = 4$)

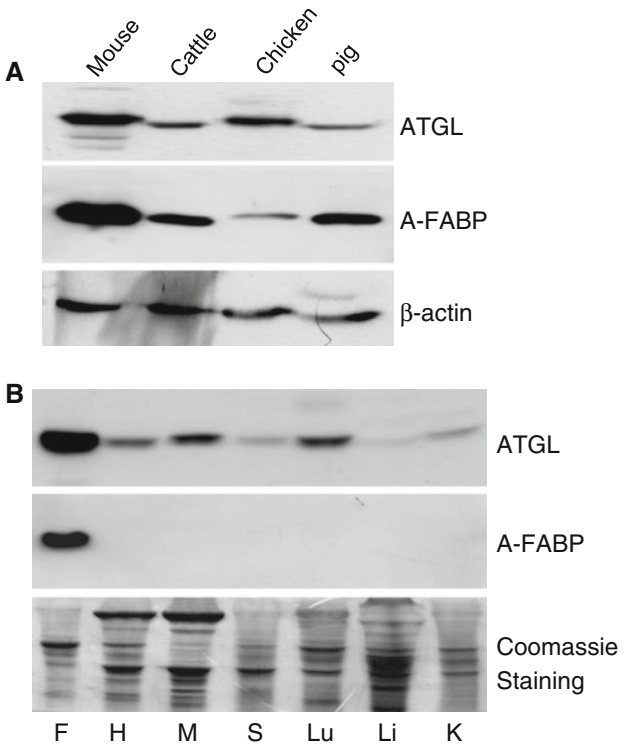

Fig. 4 The predominant expressions of adipose triglyceride lipase (ATGL) protein in bovine tissues. **a** Protein lysates from adipose tissues of mouse, cattle, chicken, and pig were separated by SDS-PAGE and immunoprobed with the ATGL antibodies as described in "Materials and Methods". The same protein lysates were subjected to Western blot analysis for A-FABP protein. β-actin was used as an internal control. **b** Equal amount of protein extracted from the subcutaneous adipose tissue (*F*), heart (*H*), muscle (*M*), spleen (*S*), lung (*Lu*), liver (*Li*), and kidney (*K*) were separated by SDS-PAGE and bovine ATGL protein was determined by Western blot analysis. The same protein lysates were also subjected to Western blot analysis for A-FABP protein. Commassie staining was assessed to verify similar levels of protein loading between samples

responsible for the lipolytic activity of ATGL (Fig. 1). The hydrophobic domain indicated in open arrows (310–398 aa) is conserved across human, cattle, pig, and mouse sequences with significant interspecies variations only occurring up and downstream of the domain.

ATGL gene expression in analyzed tissues revealed that the cardiac and skeletal muscle exhibited higher expression than the subcutaneous adipose tissue (Fig. 3). This may be unique to cattle, as expression of this gene in mouse and pig is highest in subcutaneous adipose tissue [15]. Expression in the spleen, lung, kidney, and liver were many fold lower than heart, muscle or adipose (Fig. 3).

To compare relative amounts of ATGL protein in different tissues, Western blot analysis for ATGL protein was performed using antibodies that recognize a conserved sequence around Pro186 of human ATGL. The molecular weight of ATGL protein as calculated by the Protein Molecular Weight program in Sequence Manipulation Suite [20] showed that mouse ATGL (486 aa) is 53.66 kDa, cattle (486 aa) is 53.35 kDa, chicken ATGL (483 aa) is 53.59 kDa, and pig ATGL (486 aa) is 53.19 kDa. Western blot analysis showed a single band (53 kDa) of ATGL proteins for the mouse, cattle, chicken, and pig (Fig. 4a), which is consistent with predicted molecular weights of ATGL. Therefore, we concluded that the antibodies were usable for the study of bovine ATGL protein expression. Western blot analysis for tissue distribution of ATGL protein showed that a strong single band of the expected size of the bovine ATGL protein was detected in adipose tissues, but other tissues expressed very low amounts of ATGL protein in cattle (Fig. 4b). When the membrane was probed with adipocyte-fatty acid-binding protein (A-FABP) antibody, A-FABP was detected only in adipose tissue at a short exposure time. Due to variation in amount of beta-actin among different tissues, Coomassie staining was assessed to verify similar amounts of protein loading among samples.

In order to determine if flaxseed supplementation (FS) altered muscle TAG mass, we analyzed the TAG content in the skeletal muscle. We found that the FS group exhibited a

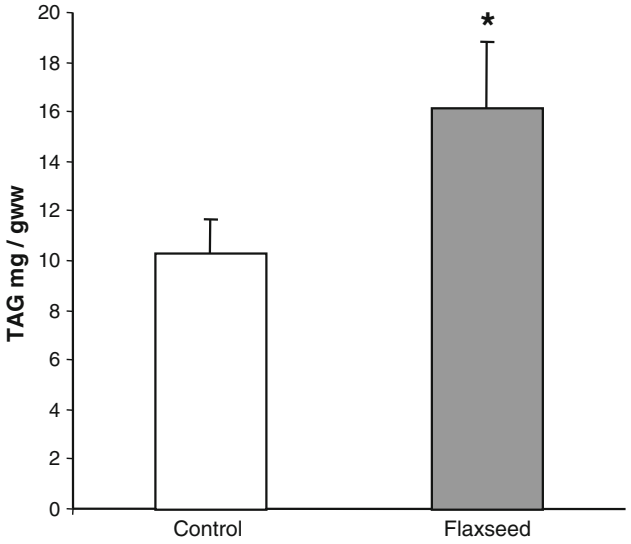

Fig. 5 Triacylglycerols (TAG) contents in the longissimus muscle of Angus steers with or without supplemental flaxseed. TAG content is reported as mg of TAG per g of wet weight ($n = 7$)

significant ($P < 0.05$) 1.5-fold increase in TAG per g of tissue over the control group (Fig. 5). This increase in TAG content was not the result of a net gain in lipid synthesis as the total phospholipid mass was not significantly different between groups (4.1 ± 0.4 nmol/g ww in control vs. 4.7 ± 0.6 nmol/g ww in FS group). Thus, the increased TAG content was due to not only synthesis, but also to accretion of dietary fatty acids.

To better understand how flaxseed supplementation specifically modulates TAG content, we focused on the expression of pertinent genes involved with fatty acid metabolism within the skeletal muscle. We found that flaxseed supplementation did not affect ATGL gene expression and protein content in skeletal muscle of the steers compared to control animals (Fig. 6a, b) when normalized to housekeeping genes/loading controls. Gene expression of HSL and lipoprotein lipase in the muscle were also unaffected by flaxseed supplementation. However, we examined the expression of adipose specific fatty acid binding proteins (A-FABP and E-FABP) as possible molecular indicators for increased muscle TAG accumulation. Both A-FABP and E-FABP were examined as these proteins are found in the adipocyte; In the A-FABP gene-ablated mouse, E-FABP expression demonstrates a compensatory increase in its expression [21]. A-FABP significantly ($P < 0.05$) increased with flaxseed supplementation (Fig. 6d), while E-FABP expression was unaltered (Fig. 6e). Stearoyl-CoA desaturase-1 (SCD-1) expression, the rate limiting enzyme catalyzing the desaturation of saturated fatty acids, was significantly ($P < 0.05$) decreased in muscle tissue by flaxseed supplementation ($P \leq 0.05$) (Fig. 6g).

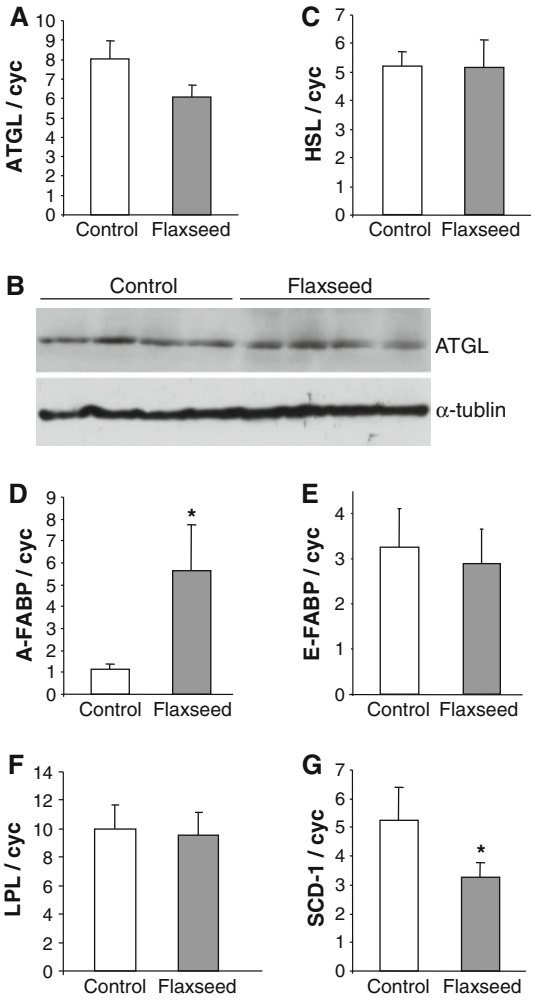

Fig. 6 Expression of genes involved in lipid metabolism in the longissimus muscle of Angus steers with or without supplemental flaxseed. Expression of ATGL (**a**), HSL (**c**), A-FABP (**d**), E-FABP (**e**), LPL (**f**), and SCD-1 (**g**) genes were measured by quantitative real-time PCR ($n = 9$–10). * Mean differences ($P < 0.05$). **b** The protein lysates were subjected to Western blot analysis for ATGL protein. α-tubulin was used as an internal control

Discussion

In this study, we cloned the cDNA encoding for bovine ATGL and compared its amino acid sequence with other species to determine interspecies variations and to examine interspecies conservation of lipase enzyme motifs. Comparison analysis of amino acid sequences of putative cattle ATGL protein with mouse, human, and pig revealed that two major domains; a patatin domain (1–180) and a hydrophobic domain (309–396) are conserved in these mammals. In the patatin domains, the active serine hydrolase motif (*GXSXG*) was GASAG and the glycine-rich motif (*GXGXXG*) was GCGFLG in all four species compared. These motives are conserved from yeast to mammals [22], suggesting functional importance for

ATGL activity across species. The hydrophobic domain of ATGL is responsible for the localization of ATGL protein on the surface of lipid droplets called the adiposome [23]. Point mutations and deletion of the hydrophobic domain in the human population cause neutral lipid storage disorder with cardiomyopathy due to inability of mutant ATGL to access the TAG substrate stored in the adiposomes [23]. However, mutations of the ATGL protein at the hydrophobic domain maintained lipase activities [23]. Conservation of two important domains in bovine ATGL suggests the evolutionary importance in maintaining the lipase activities as well as association with the surface of the adiposome.

ATGL is associated with the lipid droplet [10]. Therefore, it is logical to assume that tissues with a greater abundance of accumulated TAG, and thus a larger lipid droplet, will have increased expression of ATGL as seen in tissue distribution (Fig. 3). High relative expression of ATGL in adipose tissue is consistent with expression in mice; however, ATGL gene expression in cattle skeletal muscle seems to be high relative to most tissues tested, a pattern that was also observed in pig [15, 24]. Although ATGL gene expression in muscle was high, ATGL protein was not. The reasons for this observation are unclear; however, it might be explained by differences in translation efficiencies or degradation rates among the tissues. Again, this pattern is also observed in pig [15]. Cattle muscle ATGL expression is probably due to the presence of lipid droplets (adiposomes) in the myocytes within the muscle fibers themselves, as well as the presence of intramuscular adipocytes. Recent studies have shown that the disruption of the ATGL gene in mice and mutations of ATGL gene in the human resulted in excessive lipid accumulation in the muscle and heart, causing myocardial dysfunction [23, 25]. Recent studies showing the negative association of intramuscular fat with ATGL expression strongly suggest the involvement of ATGL in lipid metabolism in muscle [26, 27].

Others have shown that flaxseed supplementation during the finishing stage of beef cattle improved carcass quality with increased marbling scores (amount of intramuscular fat) and percentage of carcasses grading USDA Choice or greater [4, 28]. Increased TAG contents in the muscle of Angus beef cattle in the current study agree with these previous studies. The amount of TAG in the muscle can be largely attributed to intramuscular adipocytes with a minor contribution from lipid droplets within myofibers [29]. Therefore, increased TAG content in the muscle by flaxseed supplementation may be due to hypertrophy and/or hyperplasia of intramuscular adipocytes. A-FABP, an adipogenic marker, is expressed during adipocyte differentiation and maturation [30]. In fact, increased A-FABP expression is associated with increased marbling in cattle and increased TAG content [31], similar to what we have reported herein. In addition, elevated A-FABP expression is associated with increased intramuscular fat content in ducks [32], chickens [33, 34], and hogs [35, 36], suggesting that it is a broad biomarker for increased intramuscular fat deposition. Increased A-FABP expression in the muscle by flaxseed supplementation further supports the supposition that increased TAG is associated with increased adipogenic activities in the muscle.

PPARγ is a major transcription factor, promoting adipogenesis [30]. Our previous study showed that flaxseed supplementation in Angus steers increased PPARγ mRNA expression by 2.7-fold in the muscle compared with the control [2]. Comparative analysis of mammalian A-FABP promoters revealed that two PPAR binding sites are conserved in A-FABP promoters in mammals, including human, mouse, dog, pig, and cattle, and that PPAR agonists are strong transcription activators of A-FABP genes in mammals [37, 38]. Therefore, because A-FABP is a putative PPARγ-regulated gene, the effects of n-3 PUFA, alpha-linolenic acid on A-FABP expression may be attributable to PPAR agonism. This conclusion is supported by the findings that the n-3 long chain fatty acids alpha-linolenic acid and docosahexaenoic acids [39] as well as synthetic PPAR agonists (thiazolidinedione/glitazone class of compounds) acting as PPARγ ligands modulate PPAR binding activity, regulating expression of responsive genes. There is also evidence that A-FABP plays a role in regulating PPARγ activity by binding PPARγ directly and by channeling fatty acid ligands directly to PPARγ [40]. These findings support a role for regulation of a FABP-PPAR axis by dietary fatty acid ligands. Also, it should be noted that PPARγ activation in muscle cells of mouse, pigs, cattle, and humans results in transdifferentiation to adipocytes [41–46]. It is important to note that PPARγ expression is significantly elevated in these same cattle [2], consistent with the elevated expression of A-FABP. Thus, it is possible that enhancement of PPARγ activation/expression in the muscle by flaxseed supplementation may increase adipogenic activities as evidenced by increased TAG concentration and A-FABP expression.

Higher gene expression of ATGL was found in the adipocyte fraction in mice, pigs, and chickens compared to the stromal-vascular fraction which is partially composed of preadipocytes [15, 16, 47]. Localization of ATGL protein on the surface of lipid droplets and induction of ATGL expression during adipocyte differentiation further indicate association of ATGL expression with TAG content [10, 47]. In the current study, TAG content and A-FABP gene expression increased in the muscle with flaxseed supplementation, although ATGL expression was not different between groups. If ATGL expression were normalized to

TAG content, then ATGL expression would be lower in the FS group than the control. Though A-FABP is known to bind to HSL [13, 14, 48], we did not observe a difference in HSL gene expression between groups. A-FABP has an important role in modulating HSL activity by acting as a chaperone protein and directing HSL to the lipid droplet [14] where it may have a role in fatty acid efflux from the lipid droplet and out of the adipocyte. However, it is important to note that elevated A-FABP expression did not result in a change in muscle tissue E-FABP expression (Fig. 6d, e), though in A-FABP gene-ablated mice there was a compensatory increase in E-FABP expression [21]. In addition, muscle tissue H-FABP expression was not enhanced by dietary flaxseed supplementation [2], indicating that the elevation of A-FABP expression following flaxseed supplementation is specific to A-FABP and does not result in the overall increased expression of FABP found in muscle tissue. Hence, A-FABP is an important regulator of adipocyte lipid metabolism and is a consistent marker across species for intramuscular fat deposition, which is consistent with our results.

SCD-1 is a lipogenic enzyme that catalyzes desaturation resulting in the synthesis of monounsaturated fatty acids. SCD-1 gene expression is largely controlled by the transcription factors PPARα and SREBP-1c [49, 50]. Dietary PUFA decreases the expression of SCD-1 in the liver and adipose of diabetic mice [51, 52], which is consistent with our observations. More applicably, supplementation of beef cattle with n-3 PUFA in the form of fish oil also decreases SCD-1 mRNA expression in the muscle [53]. Archibeque et al. [54] reported that flaxseed supplementation at 10% of daily dry matter intake, which amounted to 1,096 g/day compared to 907 g/day for the present study, did not affect SCD-1 enzyme activities in the muscle of Angus steers; however, they did not report fatty acid composition or content of muscle. Herein, we demonstrate reduction of SCD-1 mRNA expression in skeletal muscle by flaxseed supplementation. This reduction is further supported by a 40% reduction in oleic acid content, the end product of SCD-1 enzyme aczivity, in the muscle of Angus beef with flaxseed supplementation [2], thereby mechanistically accounting for our previous observations in these cattle. Therefore, our data indicate that flaxseed supplementation decreases oleic acid content in the muscle via a reduction in SCD-1 expression.

In summary, bovine ATGL cDNA was cloned and sequenced for the first time. We showed that expression of bovine ATGL protein is adipose tissue specific among various tissues. Comparative analysis revealed that bovine ATGL protein also contained two conserved domains that are important for ATGL functioning. Flaxseed supplementation for approximately 3.5 months before slaughter increased muscle TAG concentration in Angus steers compared to unsupplemented animals. We attribute the increased muscle TAG content in part to the effects of flaxseed supplementation-derived alpha-linolenic acid on A-FABP expression via PPARγ agonism and our previously reported finding of elevated PPARγ expression. Although flaxseed supplementation did not alter expression of HSL or ATGL, it did decrease the expression of SCD-1, consistent with a reduction in oleic acid content in these cattle [2]. Flaxseed supplementation may have beneficial effects on marbling characteristics due to the altered expression of key genes associated with marbling in cattle and TAG content.

Short Chain Saturated Fatty Acids Decrease Circulating Cholesterol and Increase Tissue PUFA Content in the Rat

Philippe Legrand · Erwan Beauchamp · Daniel Catheline · Frédérique Pédrono · Vincent Rioux

Received: 19 January 2010 / Accepted: 20 September 2010 / Published online: 6 October 2010

Abstract This study investigates the effect of various dietary saturated fatty acid (SFA) profiles on plasma lipid parameters and tissue fatty acid composition in rats. The experiment was designed to monitor polyunsaturated fatty acids (PUFA) levels, while examining different amounts and types of SFA. Four isocaloric diets were prepared, containing 10–11 mol% of fatty acids (FA) as linoleic acid (LNA) and 2.5 mol% as α-linolenic acid (ALA), leading to an identical and well-balanced LNA/ALA ratio. The initial rapeseed oil/corn oil mixture providing ALA and LNA was enriched with olive oil to prepare the olive oil diet. The butterfat diet was supplemented with butterfat, containing short-chain SFA (C4:0–C10:0, 17 mol% of FA), lauric acid (C12:0, 3.2 mol%), myristic acid (C14:0, 10.5 mol%) and palmitic acid (C16:0, 14.5 mol%). The saturates diet was supplemented with trilaurin, trimyristin and tripalmitin to obtain the same level of lauric, myristic and palmitic acids as the butterfat diet, without the short-chain SFA. The trimyristin diet was enriched with trimyristin only. The results showed that the butterfat diet contributed to specific effects, compared to the olive oil diet and the saturates and trimyristin diets: a decrease in plasma total, LDL- and HDL-cholesterol, higher tissue storage of ALA and LNA, and a higher level of (n-3) highly unsaturated fatty acids in some tissues. This study supports the hypothesis that in diets with identical well-balanced LNA/ALA ratios, short chain SFA may decrease circulating cholesterol and increase tissue polyunsaturated fatty acid content in the rat.

Keywords Dietary saturated fatty acids · Plasma cholesterol · (n-3) Polyunsaturated fatty acids · Rat

Abbreviations

ALA	α-Linolenic acid
ARA	Arachidonic acid
DHA	Docosahexaenoic acid
DPA	Docosapentaenoic acid
EPA	Eicosapentaenoic acid
FA	Fatty acid(s)
HUFA	Highly unsaturated fatty acids
LNA	Linoleic acid
PL	Phospholipids
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
TAG	Triacylglycerol(s)

Introduction

Observational studies have shown that a high intake (more than 15% of daily energy intake) of saturated fatty acids (SFA) is positively associated with increased levels of blood cholesterol and high coronary heart disease mortality rates [1, 2]. Dietary SFA are therefore usually associated with negative consequences for human health. However, a recent meta-analysis of prospective epidemiologic studies suggested that there is no significant evidence for concluding that dietary saturated fat is

associated with increased risk of coronary heart disease or cardiovascular disease [3]. In addition, several other recent works have contributed to the emerging evidence that all dietary SFA are not necessarily associated with a negative impact on atherosclerosis biomarkers and that their specific identity, individual intake level and dietary origin must be considered [4–7]. For instance, short and medium chain SFA have been shown to have no increasing effect on plasma cholesterol in humans [8]. Myristic acid has deleterious effects on blood cholesterol level in animals and humans when provided at high level exceeding 4% of dietary energy [9, 10], but these negative effects disappear when its dietary level is moderate (1.0–2.5% of dietary energy) [11–14]. Stearic acid has also been demonstrated to be neutral on plasma cholesterol concentrations [15] and to have no negative effect on thrombotic markers in humans [16]. Furthermore, an increasing number of studies have shown that some SFA have important and specific biological roles in the cells [4]. Among SFA, specific biochemical functions can be assigned to myristic acid (C14:0) and palmitic acid (C16:0) that are directly involved in the two classes of protein fatty acid acylation, N-myristoylation and side-chain palmitoylation [17]. Butyric acid is also known to regulate the expression of several genes because it is an inhibitor of histone deacetylase activity [18].

In this context, the present study was aimed at investigating the impact of the saturated fat part of four isocaloric diets on plasma lipid parameters and tissue fatty acid composition in the rat. The experiment was designed to monitor PUFA levels, while examining different amounts and types of saturated fatty acids. The four diets contained equal amounts of α-linolenic acid (ALA, 2.5 mol% of FA, i.e. 0.55% of dietary energy) and linoleic acid (LNA, 10–11 mol% of FA, i.e. 2.6% of dietary energy), provided by a mixture of rapeseed and corn oils, and were supplemented respectively (i) with olive oil (olive oil diet), containing therefore low saturated fat; (ii) with butterfat (butterfat diet), containing short-chain SFA (C4:0–C10:0, 17 mol% of FA), lauric acid (C12:0, 3.2 mol%), myristic acid (C14:0, 10.5 mol%) and palmitic acid (C16:0, 14.5 mol%); (iii) with a mixture of trilaurin, trimyristin and tripalmitin (saturates diet) to obtain the same level of lauric, myristic and palmitic acids as the butterfat diet and (iv) with trimyristin only (trimyristin diet). Plasma lipid parameters and tissue fatty acid composition were measured in rats after a 8-week diet period, showing that the butterfat diet contributed to specific effects, compared with the olive oil diet and the two synthetic saturated fat diets: a decrease in plasma total, LDL- and HDL-cholesterol, a higher tissue storage of both ALA and LNA and a higher level of (n-3) highly unsaturated fatty acids (HUFA) in some tissues.

Materials and Methods

Chemicals

Solvents and chemicals were obtained from Fisher (Elancourt, France) or Sigma (St-Quentin Fallavier, France). Kits for measuring plasma cholesterol and triacylglycerols (TAG) were purchased from Bio-Mérieux (Lyon, France). Fractionated butterfat was given by Lactalis (Retiers, France). Tripalmitin and trilaurin were from Sigma. Trimyristin was extracted from powdered nutmeg by refluxing with diethyl ether (250 mL/100 g of nutmeg) for 5 h [19]. After filtration and concentration, the solution was cooled down to 0 °C. TAG were collected by filtration, washed twice with cold ethanol and re-crystallized from acetone. The purified nutmeg TAG extract contained 92.9% of myristic acid, 1.3% of lauric acid, 5.7% of palmitic acid, and traces of oleic acid and linoleic acid.

Diets

Diets were prepared at the Unité de Production d'Aliments Expérimentaux (UPAE, INRA, Jouy-en-Josas, France). They were isocaloric and varied only in the type of fat used. The composition was as follows (g/100 g): 42.6 corn starch, 19.8 casein, 21.3 sucrose, 0.9 cellulose, 3.6 mineral mix, 0.9 vitamin mix, 0.9 agar–agar and 10.0 lipid. Fat provided 22% of total energy. Lipid fractions of the diets were made by mixing natural and synthetic fats. Dietary fatty acids were carefully controlled with respect to LNA and ALA levels (Table 1), while examining different amounts and types of SFA. The olive oil diet was prepared by mixing rapeseed oil (19%), corn oil (5%) and olive oil (76%). The butterfat diet was obtained by mixing rapeseed oil (18%), corn oil (12%), fractionated butterfat (66.5%) and a small portion of trimyristin (3.5%). The saturates diet was a mix of rapeseed oil (21%), corn oil (8%) and olive oil (47%) supplemented with trilaurin (10%), trimyristin (11%) and tripalmitin (3%) to obtain the same exact level of lauric acid, myristic acid and palmitic acid as the butterfat diet (Table 1).

The trimyristin diet was prepared by mixing rapeseed oil (20%), corn oil (6%) and olive oil (63%) supplemented with trimyristin only to obtain the required level of C14:0 (12 mol% of FA). Finally, cholesterol in the butterfat diet amounted to 0.09 g/100 g and was not detected in the other three diets.

Animals

The experimental procedure was in compliance with recommendations of the 2003/65/CEE European directive for animal experimentation. Sprague–Dawley male rats

(60 g body weight, 6 weeks old at the beginning of the experiment) were obtained from the breeding center R. Janvier (Le Genest-St-Isle, France) and maintained on rat chow (nutriment A04, Scientific Animal Food and Engineering, Augy, France) with free access to water for one week before the study. Then, the rats were randomly assigned to four groups ($n = 6$ per group) and fed ad libitum with the four diets described above (olive oil, butterfat, saturates and trimyristin diets) for 8 weeks. At the end of this period, the rats were fasted overnight. On the following morning, they were anaesthetized with an intraperitoneal injection of pentobarbital (7.5 mg/100 g body weight) [13]. Blood samples were drawn into heparinized tubes by cardiac puncture. The tissues (liver, brain, epididymal fat, heart, testis, eyes) were removed, weighed, snap-frozen in liquid nitrogen and stored at −80 °C. The plasma was separated from the blood cells by centrifugation (2,500 g, 10 min, 4 °C). Plasma cholesterol and TAG were assayed with commercial enzymatic kits, according to the manufacturer's instructions.

Lipid Extraction and FA Analysis

Lipids from all the tissues except plasma and red blood cells were extracted using a mixture of dimethoxymethane/methanol (4:1 v/v) [20]. Lipids from the plasma and red blood cells were extracted from 1 mL-samples with a mixture of hexane/isopropanol (3:2 v/v), after acidification with 1 mL HCl 3 mol/L [21]. Lipid species (from liver and heart) were separated by thin-layer chromatography using silicagel H plates and a mixture of hexane:diethyl-ether:acetic acid (85:15:1 v/v/v). Phospholipids (PL) and TAG were scraped off the plate and extracted with 2 mL of diethyl ether for TAG, or 2 mL of methanol for PL, as described previously [13]. Total lipid extracts or lipid species were saponified for 30 min at 70 °C with 1 mL of

0.5 mol/L NaOH in methanol and methylated with 1 mL BF_3 (14% in methanol) for 15 min at 70 °C. FA methyl esters were extracted twice with pentane and analyzed by gas chromatography using an Agilent Technologies 6890N (Bios Analytic, Toulouse, France) with a split injector (40:1) at 250 °C and a bonded silica capillary column (30 m × 0.25 mm; BPX 70; SGE, Villeneuve-St-Georges, France) with a polar stationary phase of 70% cyanopropylpolysilphenylene-siloxane (0.25 µm film thickness). Helium was used as the carrier gas (average velocity 24 cm/s). The column temperature program started at 150 °C, was ramped at 2 °C/min to 220 °C, and held at 220 °C for 10 min. The flame ionization detector temperature was 250 °C.

Results Expression and Statistical Analysis

The results are expressed as means ± SD ($n = 6$). Data were analyzed by analysis of variance with the R statistical software followed by Tukey's multiple comparison tests. A value of $P < 0.05$ was considered to be statistically significant.

Results

Physiological Status and Plasma Lipid Parameters

Rats ($n = 6$ in each group) were fed the olive oil, butterfat, saturates and trimyristin diets (Table 1) for 8 weeks. The diets were designed to contain different amounts and types of SFA. The dietary consumption was identical in the four groups. At the end of this period, body weights, plasma lipid concentrations (Table 2), and total FA content of the tissues (Tables 3–7 and Supplemental Tables) were analyzed. The body weight of the animals was similar in the four groups. Significant differences between groups were found in the plasma lipid parameters of the rats (Table 2). Total cholesterol was significantly lower in the butterfat group than in the olive oil, saturates and trimyristin groups. Total cholesterol was also significantly lower in animals of the saturates group than in animals of the olive oil group. The low total cholesterol level of the butterfat group resulted both from significantly lower LDL-cholesterol than the olive oil and trimyristin groups and significantly lower HDL-cholesterol than the olive oil and saturates groups (Table 2). Consequently, the total cholesterol/HDL-cholesterol ratio was also significantly lower in the butterfat and saturates groups than in the olive oil and trimyristin groups. Plasma TAG (Table 2) and plasma total FA (Table 5) were significantly lower in the trimyristin group than in the saturates group. Finally, the total FA content in adipose tissue (Table 3), liver (Table 4), red blood cells (Table 6) and heart (Table 7), expressed as mol FA/g tissue, was similar.

Saturated FA Profiles of the Tissues

The composition of SFA in lipids of adipose tissue, liver, plasma, red blood cells, heart (Tables 3–7) and brain, testis, retina (Supplemental Tables 1–3) was first analyzed. The composition of SFA in lipid species (TAG and PL) was analyzed only in the liver and heart (Supplemental Tables 4–7). Although short-chain SFA (C4:0-C10:0) were present in the butterfat diet, they were not detected after feeding animals for 8 weeks with this diet, whatever the tissue analyzed. Lauric acid, which was present (3.2–4.1 mol% of FA) in the butterfat and saturates diets, was detected only in adipose tissue (1.3 mol% of FA) and liver (0.08 mol% of FA) of these two groups (Tables 3, 4). An expected increase in C14:0 level (Tables 3–7), with preferential incorporation into TAG rather than into PL as shown in the liver and heart (Supplemental Tables 4–7), was detected in all the tissues of the rats fed the butterfat, saturates and trimyristin diets (containing 10–12 mol% myristic acid) compared with olive oil diet (deprived of

ND not detected

myristic acid). Interestingly, the rats fed the butterfat diet had a significantly higher C14:0 amount in adipose tissue than the saturates and trimyristin animals (Table 3), although these three diets contained exactly the same amount of myristic acid (Table 1). Concerning C16:0, the butterfat and saturates diets contained 2 times more palmitic acid (14–16 mol%) than the olive oil and trimyristin diets (7–8 mol%) and its level in adipose tissue, liver and plasma (Tables 3–5) was related to its dietary level. Differences in C18:0 levels shown in adipose tissue, plasma and red blood cells, were also related to its higher dietary level in the butterfat diet (Table 1).

Monounsaturated FA Profiles of the Tissues

Oleic acid content was significantly higher in all the tissues of the olive oil group (70 mol% of oleic acid in the diet) compared to the butterfat group (34 mol% of oleic acid in the diet), except in the brain (Supplemental Table 1), with intermediate levels in the tissues of the trimyristin and saturates groups (Tables 3–7). Conversely, *trans* monounsaturated FA (C18:1 n-9 and n-7 *trans*) from the butterfat diet were detected in adipose tissue, liver and heart of the butterfat animals (Tables 3, 4, 7).

(n-3) PUFA Profiles of the Tissues

The 4 diets were designed to contain strictly equal amounts of ALA (2.5 mol% of FA) (Table 1). However, significantly higher amounts of ALA were found in the adipose tissue of the butterfat group compared to the olive oil, saturates and trimyristin groups (Table 3), in the liver of the butterfat group compared to the olive oil and saturates groups (Table 4) and plasma of the butterfat group compared to the olive oil and trimyristin groups (Table 5). Similar results were shown in the TAG fraction of liver (Supplemental Table 5). Among detected (n-3) HUFA, EPA (C20:5 n-3) was significantly higher in adipose tissue (Table 3) and red blood cells (Table 6) of butterfat animals compared to olive oil, saturates and trimyristin animals, and significantly higher in the heart of the butterfat group than in the saturates and trimyristin groups (Table 7). DPA (C22:5 n-3) was also significantly higher in the liver of the butterfat animals compared with the olive oil animals (Table 4), and in the heart (Table 7) and retina (Supplemental Table 3) of the butterfat animals compared with the olive oil, saturates and trimyristin animals. Similar results on DPA levels were shown in the PL fractions of liver and heart (Supplemental Tables 4 and 6). DHA was not

ND not detected

significantly different between the 4 groups, whatever the tissue analyzed. Concerning longer HUFA (C24:5 n-3 and C24:6 n-3), they were detected only in the retina (Supplemental Table 3), they were higher in the butterfat group. All these increases in individual HUFA resulted in a significantly higher level of total (n-3) HUFA and total (n-3) PUFA (ALA + n-3 HUFA) in adipose tissue of the butterfat group compared to the olive oil, saturates and trimyristin groups (Table 3), in the heart in the butterfat group compared to the olive oil and trimyristin groups (Table 7) and in the retina in the butterfat group compared to the olive oil group (Supplemental Table 3).

(n-6) PUFA Profiles of the Tissues

The 4 diets were designed to contain equal amounts of LNA (10-11 mol% of FA) (Table 1). However, significantly higher amounts of LNA were found in adipose tissue, plasma, heart and brain of the butterfat group compared to the 3 other groups (Tables 3, 5, 7 and Supplemental Table 1), in the liver of the butterfat group compared to the olive oil and saturates groups (Table 4) and in red blood cells of the butterfat group compared to the saturates and trimyristin groups (Table 6). Similar higher levels of LNA in the butterfat group were shown in the TAG and PL fractions of liver and heart (Supplemental Tables 4–7). Among detected (n-6) HUFA, C20:3 n-6 was significantly higher in red blood cells and heart of butterfat animals compared to saturates and trimyristin animals (Tables 6–7) and in the liver TAG and heart PL of the butterfat group compared to the olive oil group (Supplemental Tables 5–6). Higher levels of C20:4 n-6 appeared in the liver TAG of the butterfat group compared to the olive oil group (Supplemental Table 5). Conversely, C22:5 n-6 was significantly lower in red blood cells of butterfat animals compared to olive oil, saturates and trimyristin animals (Table 6) and significantly lower in the heart of the butterfat group compared with the trimyristin animals

(Table 7). These opposite differences in individual (n-6) HUFA did not result in any significant difference of total (n-6) HUFA in the tissues. However, the total (n-6) PUFA (LNA + n-6 HUFA) was significantly higher, due to the increase in LNA, in adipose tissue and heart of the butterfat group compared to the olive oil, saturates and trimyristin groups (Tables 3 and 7).

Discussion

This study was aimed at investigating the impact of the specific SFA composition of 4 diets with identical well-balanced LNA/ALA ratio on plasma lipid parameters and tissue fatty acid composition in rats. The rats were fed with these four diets for 8 weeks, as already done in two previous studies investigating more specifically the physiological effects of dietary myristic acid [13, 19].

First, the results on plasma lipid concentrations (Table 2) show that rats fed with the butterfat diet (LNA and ALA diet enriched with butterfat) have a lower level of plasma total cholesterol than the 3 other groups. Total cholesterol was also significantly lower in animals of the saturates group than in animals of the olive oil group. Therefore, the diet containing the highest level of SFA (about 52 mol% of FA; Table 1), coming from butterfat, led to the lowest level of plasma cholesterol. However, an extrapolation of this interesting result to humans is not easy since rats exhibit a low cholesterol ester transfer protein (CETP) activity and high HDL-cholesterol/total cholesterol ratio [22]. Moreover, the present study design uses test diets which can be considered as low fat in terms of dietary energy (22% of total energy from fat) when compared with typical human diet (30–35% of total energy from fat). However, usual fat for rat maintenance is about 8% of total energy from fat and the present study using 22% of energy from fat can therefore be considered as high fat in rodent models. In terms of saturated fat supply, the diets can be considered as moderate, varying from 12 to 52 mol% of total FA (i.e. 2.4–9.7% of total energy from saturated fat). Finally, a low amount of cholesterol (0.09 g/100 g diet) was present in the butterfat diet and no cholesterol was

detected in the three other diets, but it is now generally accepted that dietary cholesterol is not a significant factor in determining blood cholesterol levels in the general human population [23].

We found in the present study that plasma total cholesterol level was inversely correlated with dietary SFA level. The total cholesterol/HDL-cholesterol ratio, which is considered to be a better predictor of coronary heart disease risk (in humans) than LDL- and HDL-cholesterol themselves [24], was also significantly lower in the butterfat group than in the olive oil and trimyristin animals. In the literature, such a significant inverse correlation was found in postmenopausal women with relatively low total fat intake, showing that a greater saturated fat intake was associated with less progression of coronary atherosclerosis [25]. Another inverse correlation was also found between the dietary content of SFA from milk fat and serum concentration of cholesterol in 15-year-old Swedish adolescents [26]. A possible explanation was that milk fat may reduce the risk of cardiac diseases through reduced formation of small dense LDL particles [27]. As recently described in healthy men and women [24], our results suggest not only that a moderate consumption of dairy products does not increase the risk of cardiovascular diseases [12, 28], but also that it can be better in term of prevention than a diet deprived of SFA, like the olive oil diet in the present study.

Second, the other major interesting result of this study is the differential influence of the diets on tissue (n-3) and (n-6) PUFA concentrations (Tables 3–7). In order to compare their effects on PUFA composition, the diets were designed to contain strictly equal amounts of ALA (2.5 mol% of FA, i.e. 0.55% of dietary energy) and LNA (10–11 mol% of FA, i.e. 2.6% of dietary energy) in a ratio of 4.6 that meets human essential FA requirements [29]. The results showed an increased accumulation of both ALA and LNA in several tissues of butterfat animals compared to olive oil, saturates and trimyristin animals. Concerning the essential (n-6) and (n-3) HUFA, an effect of the butterfat diet was shown on the level of EPA and DPA (n-3). Although there were traces of DPA (n-3) in the butterfat diet, it seems that the increase shown in tissue EPA and DPA (n-3) is not

linked to the presence of these traces but more likely to other mechanisms (increased conversion from ALA, increased incorporation in specific tissues, lower β-oxidation) since no effect of ARA traces in the butterfat diet is shown on the level of tissue ARA. Therefore, the butterfat diet increased the level of tissue (n-3) HUFA, especially in the heart (Table 7) where these derivatives have been suggested to have cardio-protective effects [30] and in the retina (Supplemental Table 3) where they have been described to be important for neural development [31]. Altogether, these results show beneficial effects in the measured physiological parameters (circulating cholesterol and level of tissue (n-3) PUFA) of the butterfat diet (LNA and ALA diet enriched with butterfat) compared with the olive oil diet (LNA and ALA diet enriched with olive oil), with intermediate levels of the saturates diet (LNA and LA diet enriched with synthetic saturated TAG).

These results led us to wonder what can explain these differential effects, when considering the FA composition of the four diets (Table 1). The comparison of the dietary FA composition suggests firstly that some effects can be attributed to the presence of short and medium chain SFA (C4:0–C10:0) in the butterfat diet. Indeed, this diet is characterized by its high level in SFA from butterfat (about 52 mol% of total FA), including specifically short and medium chain SFA (C4:0–C10:0; 17 mol% of total FA) (Table 1). In the literature, dietary short and medium-chain SFA have been shown to have no increasing effect on plasma cholesterol in humans [8]. Moreover, C8:0 and C10:0 were hypocholesterolemic in the rat [32], in the dog [33], and C8:0 has an inhibitory effect on the synthesis of apoprotein B in the liver which is necessary for VLDL secretion [34]. An hypothesis for the beneficial effect of dietary short and medium-chain SFA is that they are directly absorbed through the portal vein leading to their preferential β-oxidation in the liver [35] whereas long-chain fatty acids are secreted as chylomicrons in the lymph and plasma, leading likely to an increased storage in adipose and other tissues. This metabolic specificity may explain not only the total absence of short and medium

chain fatty acids in every tissue but also their increased substrate competition with ALA and LNA for the β-oxidation pathway, leading to the sparing and increased storage of these two PUFA.

A 2nd difference between the olive oil and butterfat diets is the presence of myristic acid (Table 1), which is a characteristic of dairy fat. The saturates and trimyristin diets were therefore designed to answer the question of the relative effects of myristic acid versus short and medium chain saturated fatty acids. The results showed that the saturates diet lowered the plasma cholesterol level (Table 2) compared with the olive oil diet, but to a lesser extent than the butterfat diet. For instance, total cholesterol was significantly higher in the saturates group than in the butterfat group. Myristic acid has long been considered as having played a major role in the increase in blood cholesterol level in animals and humans, when provided at high level, exceeding 4% of dietary energy [9, 10]. However, when its dietary level is moderate (1.0–2.5% of dietary energy) no evidence of deleterious effects of this specific fatty acid has been reported [11–14, 25]. In humans, a moderate supply of myristic acid (1.8% of daily energy) was shown to improve lecithin cholesterol acyltransferase (LCAT) activity, which is considered beneficial in terms of HDL cholesterol concentration and reverse cholesterol transport [36]. Concerning now LNA, ALA and (n-3) HUFA concentrations, the effects shown after the butterfat diet (compared with olive oil diet) were less significant or disappeared in saturates animals (Tables 3–7). In addition, the trimyristin diet did not cause any differences in tissue n-6 and n-3 PUFA profiles (Tables 3–7), nor in plasma lipid parameters (except in HDL-cholesterol) in comparison to the olive oil diet (Table 2), which suggests that myristic acid alone, when provided as trimyristin at least, does not appear as responsible for the effects seen with the butterfat diet. However, we have also to take into account that myristic acid is mainly in the *sn*-2 position in dairy TAG of the butterfat diet, whereas it is equally distributed in the 3 positions in the synthetic saturated TAG of the two other saturated fat diets (saturates and trimyristin diets) [37]. It has been suggested that fatty acids in the *sn*-2 position are better absorbed in enterocytes [38], but there are still controversies about the real physiological impact of fatty acids when located in the *sn*-2 position [39, 40]. In our study, when analyzing the effect of the 3 diets containing 10-12 mol% myristic acid (butterfat, saturates and trimyristin), myristic acid was found significantly higher in adipose tissue of the rats fed the butterfat diet (Table 3), suggesting that myristic acid in *sn*-2 position is indeed better absorbed or better stored. Concerning the plasma lipid parameters, it remains difficult to relate the *sn*-2 position of myristic acid in dairy fat to the beneficial effect of the butterfat diet. Concerning the effect on (n-3) HUFA derivatives, we can suppose that myristic acid in *sn*-2 position and its subsequent increased bioavailability could increase Δ6-desaturase activity and long chain (n-3) HUFA tissue concentration, as already shown in cultured rat hepatocytes incubated with myristic acid [41].

A third specific characteristic of the butterfat diet, compared to the three other diets, is the presence of *trans* FA and conjugated linoleic acids (CLA) with possible biological effects. It has been shown that feeding rumenic acid (*cis* 9, *trans* 11 CLA) may beneficially affect lipoprotein profile in hamster [42]. However, CLA did not modify LNA and ALA metabolism in healthy human subjects consuming a diet with adequate intake of essential fatty acids [43].

Finally, one could consider that the high level of oleic acid in the olive oil diet (70 mol% of dietary FA) could be involved in the effects shown in this study, when compared to the butterfat and saturates diets. However, oleic acid is considered to be neutral in plasma lipid metabolism, when provided in the range 15–21% of total dietary energy [44, 45], which is the case in the present study (15.6% of total dietary energy). Olive oil is also known to contain high level of squalene (300–700 mg/100 g) and this phytosterol precursor has been shown to be at least partly absorbed and then quantitatively converted to cholesterol. The squalene content of olive oil could therefore contribute to an increase in plasma cholesterol concentration [46]. Concerning the effects on n-3 and n-6 PUFA, oleic acid is known to be a substrate of the Δ6-desaturase, and high level of tissue C18:1 n-9 could compete with LNA and ALA for the biosynthesis of HUFA of the n-9 series rather than HUFA of the n-6 and n-3 series. This hypothesis could explain some of the difference between the olive oil and butterfat diets regarding n-3 HUFA levels.

As a conclusion, the results show that in diets with identical well-balanced LNA/ALA ratio, the specific SFA composition has an impact on plasma cholesterol parameters and tissue PUFA content.

Abstract The pyruvate dehydrogenase complex (PDC) plays a critical role in lipid synthesis and glucose homeostasis in the fed and fasting states. The central role of the liver in the maintenance of glucose homeostasis has been established by studying changes in key enzymes (including PDC) and the carbon-flux via several pathways under different metabolic states. In the present study we have developed a murine model of liver-specific PDC deficiency using Cre-loxP technology to investigate its consequences on lipid and carbohydrate metabolism. There was no incorporation of glucose-carbon into fatty acids by liver in vitro from liver-specific *Pdha1* knockout (L-PDHKO) male mice due to absence of hepatic PDC activity. Interestingly, there was a compensatory increase in lipogenic capacity in epididymal adipose tissue from L-PDHKO mice. Both fat and lean body mass were significantly reduced in L-PDHKO mice, which might be explained by an increase in total energy expenditure compared with wild-type littermate mice. Furthermore, both liver and peripheral insulin sensitivities measured during a hyperinsulinemic-euglycemic clamp were improved in L-PDHKO mice. The findings presented here demonstrate (i) the indispensable role of PDC for lipogenesis from glucose in liver and (ii) specific adaptations in lipid and glucose metabolism in the liver and adipose tissue to compensate for loss of PDC activity in liver only.

Keywords PDC deficiency · *Pdha1* deletion · Lipogenesis · Glucose homeostasis · Liver glycogen · Liver · Adipose tissue · Hyperinsulinemic clamp

Abbreviations

PDC	Pyruvate dehydrogenase complex
L-PDHKO	Liver-specific pyruvate dehydrogenase knockout
PDH	Pyruvate dehydrogenase
FFA	Free fatty acid
TCA	Tricarboxylic acid

Introduction

The liver plays the central role in the maintenance of glucose homeostasis in mammals. Liver has the full complement of enzymes for the synthesis of glycogen, lipids (secreted as part of very low density lipoproteins) and other molecules from dietary carbohydrates in the fed state and for the synthesis of glucose from gluconeogenic precursors during the fasting state [1, 2]. Glucose from the dietary carbohydrates is initially converted into liver glycogen via both the direct and indirect pathways, the latter involving the following sequence: glucose to three carbon intermediates to glycogen [1, 3]. Lactate appears to be the major three-carbon precursor because it is readily produced from glucose by extrahepatic tissues [4]. The availability of substrate supply for the indirect pathway is supported by demonstration of a delayed activation by dephosphorylation

of the pyruvate dehydrogenase complex (PDC) in several mammalian tissues (including liver) in the immediate postprandial period [5, 6].

PDC is located at the cross-roads of glucose and fatty acid metabolism and hence the flux through mammalian PDC is tightly regulated by a phosphorylation (inactivation)/dephosphorylation (activation) mechanism catalyzed by a dedicated group of kinases and phosphatases [5, 7, 8]. In the fasting state PDC, in most tissues except the brain, is readily phosphorylated and inactivated inhibiting glucose oxidation. In the fed state PDC is reactivated by its dephosphorylation resulting in increased oxidative utilization of glucose in most tissues and lipid biosynthesis in the liver and adipose tissue [5, 7, 8]. Only after PDC reactivation (after an initial delay) in the liver and other tissues, can the oxidative metabolism of glucose support energy production and the biosynthesis of lipids from acetyl-CoA generated from glucose-derived pyruvate via the action of PDC [6, 9]. Thus, the timing and degree of reactivation of PDC in the liver plays a pivotal role in directing carbon flow from dietary carbohydrates to the synthesis of hepatic glycogen and lipids.

PDC deficiency is one of the major genetic disorders of oxidative metabolism resulting in congenital lactic acidosis and neurological dysfunctions [10, 11]. Although the majority of the genetic defects in human PDC is identified in the pyruvate dehydrogenase (PDH) α subunit gene (*PDHA1*) localized on chromosome X [12], the defects in the other component genes of the complex are also reported to cause similar clinical complications [11, 13]. To gain insight into the pathophysiology of PDC deficiency, we have developed a line of mice carrying an inducible null mutation in the *Pdha1* gene localized on chromosome X using the Cre-loxP system [14]. The *Pdha1* gene in mice encodes the α subunit of the pyruvate dehydrogenase (PDH) component of PDC in somatic cells [15]. Generation of a generalized null mutation in mice has proven to be lethal at an early embryonic stage in male mice in this model [14]. However, tissue-specific or cell-specific deletion of the *Pdha1* gene encoding the α subunit of PDH can allow fetal development and postnatal survival of males to enable investigation of its impact on glucose and lipid metabolism [16, 17].

In the present study, we generated liver-specific deletion of the *Pdha1* gene by breeding females ($Pdha1^{flox8/flox8}$ genotype) with liver-specific albumin/Cre expressing transgenic males [18] to create liver-specific PDC deficiency. The consequences of loss of liver PDC activity on whole body and tissue-specific carbohydrate and lipid metabolism in affected male mice were investigated using complementary in vitro and in vivo approaches. The results presented here show that whole body insulin sensitivity was increased and there are specific alterations in glucose and lipid metabolism in both the liver and adipose tissue in male mice with near complete PDC deficiency in the liver only.

Materials and Methods

Animals

All experiments were conducted in accordance with the *Guide for the Use and Care of Laboratory Animals* and approved by the Institutional Animal Care and Use Committee of University at Buffalo. Mice were housed under controlled temperature (22 ± 2°C) and lighting (12-h light; 0700–1900 h, 12-h dark; 1900–0700 h) with free access to water and a standard rodent laboratory diet (Harlan Teklad, Madison, WI). Generation of male and female mice harboring the $Pdha1^{flox8}$ allele(s) were done as described previously [14]. Briefly, two loxP sites were introduced into intronic sequences flanking exon 8 to generate the $Pdha1^{flox8}$ allele. Progeny carrying the $Pdha1^{flox8}$ allele was intrabred to produce a line of animals that carried only the $Pdha1^{flox8}$ allele. To initiate deletion of exon 8 in vivo in liver, homozygous $Pdha1^{flox8/flox8}$ females were bred with males from C57BL/6-TgN9AlbCre)21Mgn transgenic line obtained from the Jackson Laboratory which carried an autosomally integrated C*re* gene with liver-specific (hepatocyte-specific) albumin promoter [18]. For in vivo studies including body composition, energy balance and hyperinsulinemic euglycemic clamp study, male mice were maintained and studied in accordance with the Institutional Animal Care and Use Committee of Yale University School of Medicine. All of the experiments in this study were performed with 3–4 month-old male mice, and unless otherwise indicated all studies were performed in fed mice.

Genotype Analysis

Tail DNA from progeny were isolated as per manufacturer's protocol (Omniprep^{TM}I, Genotechnolgy, Inc.) and amplified using a *Pdha1* sense primer 5′ AGCAGCCAGCACGGA CTACT 3′ and antisense primer 5′ GCAGCCAAACAGA TTACACC 3′ and *Cre* primers sense 5′ GCATTTCTGG GGATTGCTTA 3′ and an antisense 5′ CCCGGCAAAAC AGGTAGTTA 3′ [14]. Animals in the fed state were deeply anesthetized, killed by decapitation, the livers were quickly removed, frozen in liquid nitrogen and stored at −70°C. A portion of the liver was processed for isolation of genomic DNA and polymerase chain reaction was carried out as described [14]. Thermal cycle consisted of initial denaturation at 95°C for 10 min, followed by 35 cycles of 1 min denaturation at 95°C, 1 min annealing at 68°C, 1.5 min extension at 72°C after a final extension at 72°C for 10 min,

25 µl of the final reaction was mixed with 15 µl of gel loading buffer and electrophoresed on 1% agarose gel stained with ethidium bromide.

Enzyme Activities and Protein Detection

For the assay of 'total' PDC activity, tissues from fed male mice were homogenized in KCl-MOPS buffer containing protease inhibitors. After three freeze–thaw cycles and centrifugation, samples were dephosphorylated with recombinant rat phospho-PDH phosphatase [19, 20], and stored at −80°C. Total PDC activity was determined by the production of $^{14}CO_2$ from [1-^{14}C]pyruvate [19]. PDC activity is expressed as munits/mg protein. For measurement of glycogen synthase activities, tissues were homogenized in ice-cold 50 mM Tris–HCl, pH 7.8 containing 100 mM NaF, 10 mM EDTA and a cocktail of the protease inhibitors and centrifuged at 1500×*g* for 5 min. Glycogen synthase activities (active and total forms) were measured in the supernatants using UDP-[U-^{14}C]glucose [21] and are expressed as nmol of UDP-glucose incorporated/min/mg soluble protein. Activity ratio is ratio of the 'active' to 'total' form of glycogen synthase activity. Tissue glycogen content was measured according to Lo et al. [22]. Proteins were measured using BioRad kit (Bio-Rad, Hercules, CA). To detect pyruvate dehydrogenase (PDH) proteins (α and β subunits) in solubilized tissue extracts, aliquots (20 µg of protein) were size fractionated on SDS-PAGE, transferred to nitrocellulose membrane, probed with a polyclonal anti-PDH rabbit primary antibody [19] and goat anti-rabbit IgG (H + L)-horse radish peroxidase conjugate secondary antibody. A purified mammalian PDH preparation was used as an internal molecular weight marker. Proteins bands were visualized by chemiluminescence method.

Body Composition and Whole Body Energy Balance

Fat and lean body masses were assessed by ^{1}H magnetic resonance spectroscopy (Bruker BioSpin, Billerica, MA). Metabolic measurements of unrestrained activity, energy expenditure, and food consumption were determined using a Comprehensive Animal Metabolic Monitoring System (CLAMS: Columbus instruments, Columbus, OH). Energy expenditure and food consumption data were normalized with respect to body weight. Energy expenditure was calculated from the gas exchange data using the following formula: Energy expenditure = (3.815 + 1.232 * RQ) * VO_2. Respiratory quotient (RQ) is the ratio of VCO_2 to VO_2, which changes depending on the energy source the animal is using. Locomotor activity was measured on *x* and *z*-axis using infrared beams to count the amount of beam breaks during the specified measurement period. Feeding was calculated from the change in the weight of chow in the Center-Feeder with respect to time.

In Vitro Synthesis of Fatty Acids

For study of lipogenesis in vitro, 3–4 month-old male mice were first fasted for 24 h and then refed for 24 h. Liver slices and pieces of adipose tissue (about 100 mg) were incubated in a sealed flask containing 3 ml of Krebs–Ringer bicarbonate buffer, pH 7.4, containing 0.5 mM $CaCl_2$, 0.3 U insulin and 50 mM glucose (3 µCi D-[U-^{14}C]glucose) or 10 mM [U-^{14}C]acetate plus 50 mM glucose at 37°C for 3 h. $^{14}CO_2$ was trapped and radioactivity was determined using a Beckman LS 6500 counter [23, 24]. Lipids from liver slices and pieces of adipose tissue were extracted with chloroform–methanol (2:1, v/v), saponified with alcoholic KOH, fatty acids fraction extracted with petroleum ether, and radioactivity was determined [23].

Hyperinsulinemic-Euglycemic Clamp

Seven days prior to the hyperinsulinemic-euglycemic clamp studies, indwelling catheters were placed into the right internal jugular vein extending to the right atrium. After an overnight fast, [3-^{3}H]glucose (high pressure liquid chromatography purified; Perkin Elmer, Boston, MA) was infused at a rate of 0.05 µCi/min for 2 h to assess the basal glucose turnover. Following the basal period, hyperinsulinemic-euglycemic clamp was conducted for 120 min with a primed/continuous infusion of human insulin (126 pmol/kg prime, 18 pmol/kg/min infusion) [25]. To estimate insulin-stimulated whole body glucose fluxes, [3-^{3}H]glucose was infused at a rate of 0.1 µCi/min throughout the clamps [25]. Rates of basal and insulin-stimulated whole-body glucose turnover and hepatic glucose production were determined as described [26]. Whole body glycolysis was calculated from the rate of increase in plasma ^3H_2O concentration divided by the specific radioactivity of plasma D-[3-^{3}H]glucose [26]. Whole body glycogen synthesis was estimated by subtracting whole body glycolysis from whole body glucose uptake, assuming that glycolysis and glycogen synthesis account for the majority of insulin-stimulated glucose uptake [27]. Additional blood samples were obtained for the measurement of plasma insulin and free fatty acid (FFA) concentrations at the end of basal and clamp periods.

Data Analysis and Presentation of Results

All results are expressed as means ± SEM of 'n' observations. Statistical differences between the means were accessed by Student's *t*-test.

Results

Characterization of Liver-Specific Pdha1 Knockout Mice

Breeding of targeted homozygous females ($Pdha1^{flox8}/^{flox8}$) with liver-specific wild-type alb-Cre^{+} ($Pdha1^{wt}/Y$; Cre^{liver+}) transgenic males resulted in male mice in the progeny with two different genotypes: $Pdha1^{flox8}$/Y, Cre^{liver-} (wild-type control mice) and $Pdha1^{\Delta ex8}/Y$, Cre^{liver+} [liver-specific PDH knockout (L-PDHKO) mice]. Only male progeny was used in this study because females carrying the *Cre* transgene would have variable expression of the normal allele due to Lyonization (random inactivation of the one of the two chromosome X). Initially the presence or absence of the *Cre* transgene in these mice was determined by PCR method using the tail DNA, and later it was confirmed by the same method using liver DNA. Polymerase chain reaction analysis of liver DNA from L-PDHKO mice ($Pdha1^{\Delta ex8}/Y$, Cre^{liver+}) showed near complete deletion (>95%) of the *Pdha1* gene compared to that from the wild-type control mice (Fig. 1a). Deletion of the loxP-flanked exon 8 by Cre recombinase resulted in the amplification of a 400 base pair product in the L-PDHKO mice whereas a 800 base pair amplification product was generated from the targeted $Pdha1^{flox8}$ allele of the wild-type control mice (Fig. 1a). As expected, there was no deletion in the $Pdha1^{flox8}$ allele in the skeletal muscle, heart and epididymal adipose tissue from the L-PDHKO mice (Fig. 1b).

There was no noticeable embryonic lethality (as evident from normal litter size) and the L-PDHKO mice were obtained with the expected frequency among male progeny. Newborn male L-PDHKO mice were indistinguishable from other littermates.

As predicted based on the results of polymerase chain reaction analysis, there was near complete loss of 'total' PDC activity in livers from L-PDHKO male mice compared to wild-type control male mice (Table 1). To further investigate the effect of deletion of the liver *Pdha1* allele in the knockout mice on the α and β subunits of the PDH component of the PDC, liver extracts were subjected to Western blot analysis using anti-PDH antibodies. Levels of both the α and β subunits of the PDH component were reduced to undetectable level in the liver extracts from the L-PDHKO male mice compared with wild-type control mice (Fig. 2). This finding is consistent with our previous observations that patients with genetic defects in the *PDHA1* gene only showed the loss of both the α and β subunit proteins of PDH due to instability of the β subunit in the absence of the α subunit in the mitochondrial preparations [13]. As expected, the levels of these two proteins in skeletal muscle, heart and epididymal adipose tissue

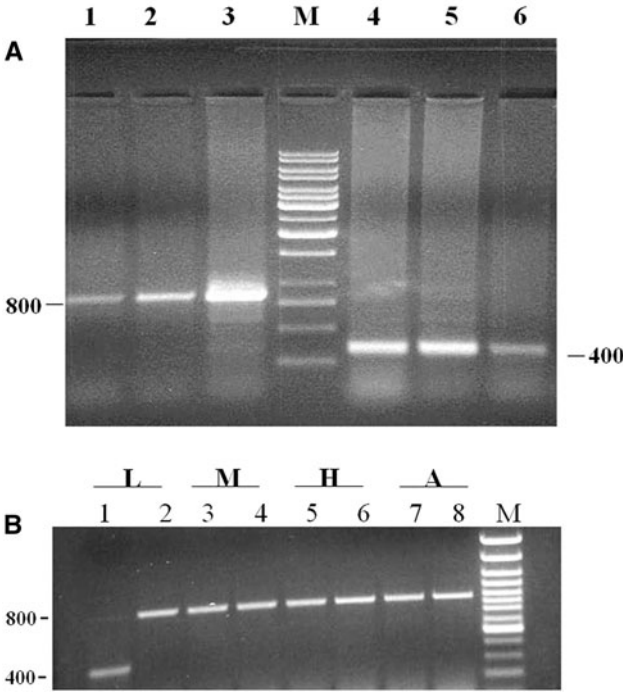

Fig. 1 Polymerase chain reaction amplification of chromosomal DNA of wild-type control ($Pdha1^{flox8}/Y$, Cre^{liver-}) and L-PDHKO ($Pdha1^{\Delta ex8}/Y$, Cre^{liver+}) male mice in the fed state. **a** In case of liver DNA from the controls, the *Pdha1* primers produced a 800 bp product (*lanes 1–3* for three different control littermate male mice) whereas the same primers produced a 400 bp product (*lanes 4–6*) with liver DNA from three L-PDHKO male mice indicating deletion of exon 8 in the *Pdha1* gene. **b** Polymerase chain reaction amplification of DNA from different tissues. Lanes with odd numbers are for a L-PDHKO mouse and even numbers are for a wild-type control mouse. Liver (*L lanes 1 and 2*), skeletal muscle (*M lanes 3 and 4*), heart (*H lanes 5 and 6*), and adipose tissue (*A lanes 7 and 8*). *M* indicates DNA ladder lane in both the gels

extracts from the two groups of mice were very similar (results not shown), indicating no effect of liver-specific deletion of the *Pdha1* on the levels of PDH proteins in other tissues.

Liver-Specific PDC Deficiency on Fat Mass, Energy Expenditure and Glycogen Stores

Adult L-PDHKO mice had lower whole body weight (by 12%) compared with wild-type control mice. Nuclear magnetic resonance analysis of body composition suggested that this was a consequence of a reduction in fat and lean mass by 33 and 9%, respectively (Table 1), compared with age-matched wild-type control mice. In order to further evaluate the reduction in body weight and fat mass [despite increased food intake], energy balance of the mice was assessed in an animal metabolic monitoring system for 4 days (2 days of acclimation followed by 2 days of measurements). L-PDHKO mice showed increased energy expenditure by 10% ($p < 0.05$) while locomotor activity

Table 1 Body weights and basal energy metabolic parameters from littermate wild-type control and L-PDHKO mice

Parameter	Wild-type	L-PDHKO
Body weight (g)	36.3 ± 1.4 (11)	31.8 ± 1.1 (10)*
Fat mass (g)	5.04 ± 0.66 (11)	3.36 ± 0.29 (10)*
Lean body mass (g)	26.14 ± 0.77 (11)	23.67 ± 0.84 (10)*
Energy expenditure (kcal/kg/h)	14.5 ± 0.4 (6)	16.0 ± 0.5 (6)*
Food intake (g/kg/h)	5.2 ± 0.4 (6)	5.8 ± 0.5 (6)*
Locomotor activity (counts)	73.1 ± 16.2 (6)	46.8 ± 4.9 (6)
Liver PDC (total) activity (mU/mg protein)	5.8 ± 0.2 (8)	0.08 ± 0.02 (8)***
Liver glycogen (mg/g)	55.2 ± 3.9 (9)	74.9 ± 4.4 (11)**
Muscle glycogen (mg/g)	7.9 ± 1.3 (4)	9.5 ± 1.0 (4)
Liver glycogen synthase active (mU/mg protein)	191 ± 2 (5)	175 ± 16 (5)
Liver glycogen synthase activity ratio (active/total)	0.60	0.66

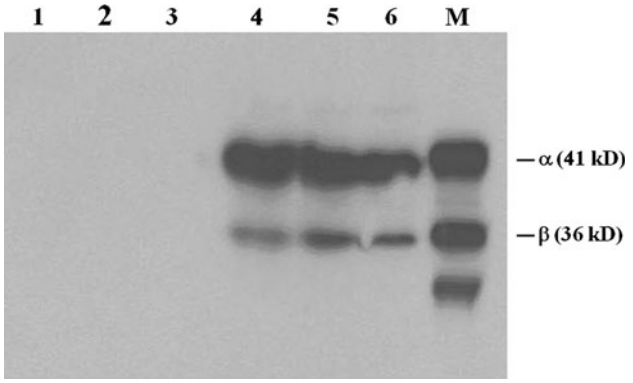

Fig. 2 Western blot analysis of PDH proteins in solubilized liver homogenates from wild-type control and L-PDHKO male mice in the fed state. Immunoblot analysis of liver homogenates indicating lack of PDH proteins (α and β subunits) in livers from three L-PDHKO male mice. (*Pdha1*$^{\Delta ex8}$*/Y Cre*$^{liver+}$; *lanes 1–3*) in comparison to three wild-type male mice (*Pdha1*^{flox8}*/Y Cre*$^{liver-}$; *lanes 4–6*). *M* purified PDH proteins [α (41 kDa) and β (36 kDa) subunits with a degraded lower molecular weight immunoreactive product]

did not differ in both groups ($p = 0.1$) (Table 1). However, when recalculated with respect to lean body mass, there was no difference in energy expenditure and food intake between groups (energy expenditure: 19.0 ± 1.1 vs. 20.0 ± 1.7 (WT vs. KO, $p = 0.624$) and food intake: 6.68 ± 0.29 vs. 7.69 ± 0.68 (WT vs. KO, $p = 0.1997$).

Interestingly, the glycogen content in the liver was significantly higher in L-PDHKO mice compared with wild-type control mice (Table 1) despite no change in the activity level of active glycogen synthase as well as percent active form of the enzyme in livers of L-PDHKO mice (Table 1). In contrast to the liver, the levels of glycogen in skeletal muscle from both the groups did not differ significantly (Table 1).

In Vitro Analysis of Lipogenesis

To investigate the consequence of L-PDHKO (and hence PDC function) on in vitro fatty acid biosynthesis, the incorporation of radioactive two-carbon fragments derived from D-[U-^{14}C]glucose or [U-^{14}C]acetate by liver slices was measured. The oxidation of either of these two labeled substrates to $^{14}CO_2$ by liver slices was not significantly different between the two groups of mice (Table 2). As predicted based on nearly complete absence of PDC activity, the incorporation of labeled two-carbon fragments generated from D-[U-^{14}C]glucose via the action of PDC into fatty acids was completely absent in liver slices from L-PDHKO mice compared with wild-type control mice (Table 2). As expected, the oxidation of [U-^{14}C]acetate to $^{14}CO_2$ and its incorporation into fatty acids by liver slices were similar between the two groups of mice, indicating that the pathway involving the biosynthesis of fatty acids from acetyl-CoA was not affected in the livers from L-PDHKO mice.

Since liver and adipose tissue are two major organs responsible for fatty acid synthesis, we speculated if there would be a compensatory increase in fatty acid synthesis in adipose tissue of L-PDHKO mice. Indeed, there was a marked increase in the incorporation of two-carbon fragments from both D-[U-^{14}C]glucose (about 2.5-fold) and [U-^{14}C]acetate (about fourfold) into fatty acids by epididymal adipose tissue from L-PDHKO male mice compared with wild-type control mice. There was also a significant increase in the oxidation of [U-^{14}C]acetate only to $^{14}CO_2$ by adipose tissue from L-PDHKO mice compared with wild-type control mice (Table 2), and could account for increased energy needs for increased lipid biosynthesis which cannot be obtained from glucose oxidation.

Hyperinsulinemic-Euglycemic Clamp in Liver-PDHKO Mice

In the fed and fasting conditions, the plasma levels of glucose and insulin in the L-PDHKO mice were not different from that of the littermate control male mice (Table 3). To further evaluate the role of hepatic PDC

deficiency on insulin action of glucose metabolism in vivo, we performed a 2-h hyperinsulinemic-euglycemic clamp in awake mice. During the clamp, plasma insulin was raised to ~360 pM (Table 3) and plasma glucose was clamped at ~6.5 mM in both groups (Fig. 3a). Plasma free fatty acid (FFA) concentrations were suppressed similarly in both groups by the insulin infusion (Fig. 3e, Table 3). L-PDHKO mice had increased whole body insulin sensitivity, as reflected by 60% higher glucose infusion rates required to maintain plasma glucose during the steady state of clamp as compared with the wild-type control group (Fig. 3b). This was accounted for by a 70% increase in insulin-induced suppression of hepatic glucose production (Fig. 3c) and a 23% increase in insulin-stimulated whole body glucose uptake (Fig. 3d). The increased whole body glucose uptake in the L-PDHKO group was accompanied by 45% increased glycogen synthesis rate, as compared with the wild-type control group (Fig. 3d).

Discussion

Our current understanding of the PDC regulatory mechanisms has been derived from both purified PDC preparations as well as by a variety of in vitro and in vivo experimental techniques employed for investigations of the carbon-flux via PDC in the liver under different dietary and/or hormonal conditions. In the present study, the generation of L-PDHKO mice has allowed us to reassess the known role of PDC in the disposal of glucose-carbons for energy production and lipid biosynthesis in the liver during the absorptive state and to uncover an unexpected compensatory effect on lipid synthesis in adipose tissue. Furthermore, L-PDHKO male mice showed improved insulin sensitivity in both the liver and peripheral tissues.

Since PDC is the only known reaction to generate acetyl-CoA from pyruvate, there was, as expected, no incorporation of ^{14}C from D-[U-^{14}C]glucose into long-chain fatty acids by liver slices from the L-PDHKO mice. Unexpectedly, there was a compensatory increase in lipogenesis from glucose in epididymal adipose tissue from the L-PDHKO mice. The mechanism by which this adaptive increase in lipogenic capacity is increased in adipose tissue in the L-PDHKO mice remains to be investigated. Under in vitro conditions, the oxidation of D-[U-^{14}C]glucose to $^{14}CO_2$ was not reduced in liver slices from the L-PDHKO mice compared to the controls largely due to (i) the use of D-[U-^{14}C]glucose (1-^{14}C of glucose can be converted to $^{14}CO_2$ via the pentose phosphate pathway) and (ii) possibly an increased flux of [U-^{14}C]pyruvate (derived from

D-[U-^{14}C]glucose) for carboxylation via pyruvate carboxylase and subsequent cycling in the tricarboxylic acid (TCA) cycle.

Hepatic glycogen can be formed either by a direct pathway or by an indirect pathway from gluconeogenic precursors [1, 3, 4]. In the fed state, glucose produced via gluconeogenesis is shunted into glycogen synthesis rather than being released by glucose-6-phosphatase and can also contribute to the measured "indirect pathway" [4]. Evidence indicates that a delayed reactivation of PDC in several extrahepatic tissues as well as in the liver is important for the provision of carbon-precursors for hepatic gluconeogenesis (primarily for glycogen deposition) and also for restricting hepatic lipogenesis from dietary carbohydrates during the immediate absorptive period after a glucose load to 48-h starved rats [5, 6, 9]. A gradual reactivation of PDC in the liver as well as in other tissues after feeding allows the utilization of diet-derived glucose for the biosynthesis of lipids and/or energy production. Even a low rate of decarboxylation of pyruvate via PDC (due to a delayed reactivation) during the first 2 h after refeeding of fasted normal rats can reduce the availability of pyruvate for gluconeogenesis plus glycogenesis in the liver. This diversion of pyruvate via PDC, however, could not occur in the L-PDHKO mice in this study and hence may explain an increased hepatic glycogen level observed in the L-PDHKO mice in fed condition.

Liver-specific *Pdha1* deletion resulted in significant changes in metabolic fuel regulation in the liver and adipose tissue. As anticipated, the blood glucose levels in L-PDHKO mice were not different from that of control mice in the fed condition because glucose utilization by the liver represents only a small fraction of the total glucose metabolism in vivo. To maintain TCA cycle flux and to compensate for this loss of PDC-derived acetyl-CoA in the liver of L-PDHKO mice, it is suggested that a comparable increase in acetyl-CoA production from fatty acids and possibly some amino acids must occur to support energy need for other biosynthetic processes in the liver. At the whole body level, the increased rates of fatty acid synthesis in the adipose tissue of L-PDHKO mice may be a compensatory mechanism to adjust to the need to increase the

hepatic flux of fatty acids into the TCA cycle. The similar levels of plasma FFA levels, as well as decreased whole-body fat mass, suggests that the increased adipose FFA synthesis rates are balanced possibly by the increased rates of hepatic FFA utilization.

The complete loss of hepatic PDC activity resulted in elimination of de novo hepatic FFA synthesis from glucose-carbon (Table 2), and possibly combined with an increased flux of FFA into acetyl-CoA as an alternate source may explain the increased insulin sensitivity of the liver in the L-PDHKO mice, as reflected in the greater suppression of hepatic glucose production. Recently, it has been shown that fatty acid-induced hepatic insulin resistance is associated with increased diacylglycerol concentrations and activation of *PKCε* by diacylglycerol [28, 29]. The increased demand by the L-PDHKO mice for circulating FFA to maintain normal rates of hepatic mitochondrial oxidative phosphorylation could lead to a decrease in FFA metabolites that are thought to activate PKCε and lead to changes in hepatic insulin sensitivity. At the whole-body level, we also observed an increase in insulin-stimulated peripheral glucose metabolism in the L-PDHKO mice. Under these clamp conditions, increases in oxidative and non-oxidative glucose disposal are chiefly by muscle and adipose tissue. The 23% increase in glucose uptake may be accounted for by the ~twofold increase in lipogenesis from glucose in adipose tissue and the 45% increase in whole body glycogen synthesis. In summary, it is suggested that the increased utilization of FFA by the liver to maintain normal rates of oxidative phosphorylation led to increased insulin sensitivity in peripheral tissues as well as liver.

Inhibition of Insulin and T_3-Induced Fatty Acid Synthase by Hexanoate

Murielle M. Akpa · Floriane Point · Sabine Sawadogo · Anne Radenne · Catherine Mounier

Received: 8 April 2010 / Accepted: 6 August 2010 / Published online: 1 September 2010

Abstract Fatty acid synthase (FAS) is responsible for the de novo synthesis of palmitate and stearate. This enzyme is activated by insulin and T_3, and inhibited by fatty acids. In this study, we show that insulin and T_3 have an inducing effect on FAS enzymatic activity, which is synergetic when both hormones are present. Octanoate and hexanoate specifically inhibit this hormonal effect. A similar inhibitory effect is observed at the level of protein expression. Transient transfections in HepG2 cells revealed that hexanoate inhibits, at least in part, FAS at a transcriptional level targeting the T_3 response element (TRE) on the FAS promoter. The effect of C6 on FAS expression cannot be attributed to a modification of insulin receptor activation or to a decrease in T_3 entry in the cells. Using bromo-hexanoate, we determined that hexanoate needs to undergo a transformation in order to have an effect. When incubating cells with triglyceride–hexanoate or carnitine–hexanoate, no effect on the enzymatic activity induced by insulin and T_3 is observed. A similar result was obtained when cells were incubated with betulinic acid, an inhibitor of the diacylglycerol acyltransferase. However, the incubation of cells with Triacsin C, a general inhibitor of acyl-CoA synthetases, completely reversed the inhibitory effect of hexanoate. Our results suggest that in hepatic cells, hexanoate needs to be activated into a CoA derivative in order to inhibit the insulin and T_3-induced FAS expression. This effect is partially transcriptional, targeting the TRE on the FAS promoter.

Introduction

Most fatty acids found in the diet have 14 or more carbons while medium chain fatty acids (MCFA) have a 6–10 carbon-chain. Large amounts of MCFA are found in coconut and palm kernel oil, representing more than 50% of the fatty acids [1]. They are also present in bovine milk, representing 4–12% of the total lipid content. However, their presence in milk depends on the genetic background, the stage of lactation and the diet of the animal [2]. Metabolism of MCFA in the liver is quite different from longer chain fatty acids. MCFA rapidly cross the mitochondrial barrier and do not required the carnitine palmitoyl transferase I (CPTI) for this transport. Subsequently, MCFA are activated by medium-chain acyl CoA synthase, forming CoA derivatives [3]. Their esterification is limited [4]. They are mainly oxidized, behaving more like glucose than fat [5]. However, in humans, they not only served as a source of energy, but can also be reesterified and deposited in the adipose tissue [6]. In addition, a study performed in rat showed that animals fed with medium chain triglycerides show a large number of triglycerides and phospholipids containing MCFA in adipose tissue [7].

Medium chain fatty acids have been used for more than 50 years in clinical nutrition to treat pancreatic insufficiency and fat malabsorption [8]. They have also been added to infant formulas, improving the energy intake that can be metabolized [6]. MCFA may have several implications in human health, including a decrease in fasting [9] and postprandial plasma lipid concentration [10], and in body weight [11], as well as an increase in insulin sensitivity [12]. In rats, the effect of MCFA on body weight appears to be mediated, by down regulation of adipogenic genes and PPARγ, as well as by inhibition of lipogenesis in adipocytes [7]. The effect on hepatic de novo lipid synthesis remains, however, to be demonstrated.

In contrast to rodents, lipogenesis in humans as in birds takes place mainly in the liver [13]. There are two central lipogenic enzymes that are tightly regulated by hormones and nutrients. Acetyl-CoA carboxylase (ACC) synthesizes malonyl-CoA from acetyl-CoA, which is in turn converted by fatty acid synthase (FAS) (EC.2.3.1.85) into long chain saturated fatty acids. FAS is expressed mainly in the liver and the brain. In vertebrates, FAS is a homodimer made of two peptide chains of about 260 kDa each [14, 15]. It is located in the cytoplasm of the cell [16]. In the presence of nicotinamide adenine dinucleotide phosphate (NADPH), this multifunctional enzymatic complex is responsible for the production of palmitate, a long chain saturated fatty acid, using acetyl-CoA and malonyl-CoA as building blocks. A single gene that gives rise to one mRNA in mouse and two in chicken and rat, due to alternative splicing, encodes FAS [17, 18].

In the liver, the activity of FAS, like most lipogenic enzymes [19], is regulated through nutrients and hormones. Starvation causes decreased activity of the enzyme, and refeeding restores it [20, 21]. A similar effect of refeeding is also observed on the mRNA expression level and stability, as well as on transcription [17, 21–24]. Insulin [25], triiodothyronine (T_3) [19, 26] and glucose stimulate FAS activity, whereas glucagon [25], medium chain fatty acids (MCFA) [27] and polyunsaturated fatty acids (PUFA) decrease it [28–31]. Insulin increases FAS activity by enhancing transcription through the modification of transcription factors' binding on the insulin response element (IRE) located on the promoter [25]. We recently demonstrated that insulin is also able to modulate FAS transcription through a specific T_3 response element (TRE) [32]. In the same study, we not only demonstrated that T_3 regulates FAS through a direct genomic action on the TRE, but also via a non-genomic action involving the activation of the PI3-kinase-ERK1/2 MAPK signaling pathway. MCFA specifically inhibit insulin and T_3-induced FAS activity by a still unknown mechanism [27]. The inhibition of FAS through MCFA is selective and specific, since they do not inhibit β-actin transcription and longer or shorter fatty acids have no effect whatsoever [27]. It was suggested that the active inhibitor is a derivative of the MCFA [27].

In the present study, we have shown that hexanoate and octanoate specifically inhibit insulin and T_3-induced FAS enzymatic activity in hepatocytes. We also showed that hexanoate works by modulating the level of FAS protein expression. This effect is partially due to transcriptional targeting of the TRE on the FAS promoter. The hexanoate is rapidly taken up by the cells and mainly metabolized into triglycerides and cholesterol esters. Hexanoate does not modify the activation of the insulin receptor, nor the entrance of T_3 in the cells. Using specific inhibitors of MCFA metabolism, it appears that acyl-CoA hexanoate, which is rapidly formed after the cellular uptake, needs to be generated in order to inhibit the insulin and T_3-induced FAS activity and expression.

Methods

Materials

Eggs from white Leghorn chickens were purchased from Couvoir Simentin (Mirabel, QC). Waymouth medium, 3,5,3-L-triiodothyronine, insulin, hexanoate, octanoate, etomoxir, betulinic acid, acetyl-CoA, malonyl-CoA, NADPH, and [^{14}C]-hexanoate were obtained from Sigma Aldrich (Saint Louis, MO). Fugene HD transfecting agent was obtained from Roche Diagnostic (Laval, QC). Triacsin C was obtained from Biomol Research Laboratories

(Cedarlane Laboratories limited, Hornby, ON). Collagenase H was obtained from Roche Diagnostic (Laval, QC). Anti-FAS, anti-GAPDH and anti-PY (PY99) antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). The FITC-labelled goat anti rabbit IgG was purchased from Invitrogen. The anti-IR (α-960) was a generous gift of Dr. B. I. Posner (McGill University, QC). Unless otherwise specified in the text, all other chemicals including the anti-T_3 antibody were purchased from Sigma.

Cell Culture and Transfection Procedure

Chick embryo hepatocytes (CEH) were isolated from livers of 19-day-old chick embryos [13] (protocol # 590 approved by the University animal care committee). Briefly, 12 chick livers were removed rapidly and placed in iced Krebs–Ringer bicarbonate buffer, pH 7.4. Chopped livers were then digested by Collagenase H and the resulting suspension was filtered through two layers of nylon mesh. The cells were collected by centrifugation and washed twice in Krebs–Ringer bicarbonate buffer. 2.5×10^6 cells were plated in 35 mm tissue dishes and cultured at 40°C under 5% CO_2 in Waymouth medium supplemented with streptomycin and penicillin. After 24 h, the medium was removed by aspiration and replaced by medium supplemented with 1.6 μM of T_3 and/or 100 nM of insulin, and incubated for an additional 24 h. The respective concentrations used in the experiments for T_3 and insulin were determined using a dose-response curve and from previously published studies [32]. The incubation was also performed in presence of 1 μM MCFA (hexanoate or octanoate resuspended in 1× PBS as a vehicle), triglycerides, carnitine–hexanoate or carnitine–octanoate. The triglycerides were coupled to bovine serum albumin (BSA) at a 1:4 ratio in order to facilitate their entry into the cell [33]. The experiments using radio-labeled compounds were performed with [^{14}C]-hexanoate that was added to the medium after a 24 h pre-incubation period with the various hormones, for either 1 or 24 h. For the experiments using inhibitors, the CEH were pre-incubated for 30 min with either DMSO 0.5%, 1 μM Etomoxir, 1 μM Betulinic acid or 5 μM Triascin C, followed by the hormonal treatment for 24 h.

The human hepatocarcinoma cells (HepG2) were cultured in modified Eagle medium (MEM) supplemented with streptomycin (100 μg/mL), penicillin (60 μg/mL), FBS (10%) and glutamine (4 mM final). The day before, cells were plated at 80% confluence (about 1×10^6 cells per well) in 12 well plates. They were then incubated for 24 h with 3.5 μL of Fugene HD, 0.75 μg of the DNA construct and 0.25 μg of pRSV-β-galactosidase, without serum nor antibiotics. The medium was then replaced with one containing hormones and fatty acid at the concentrations indicated on the figure legend. After 24 h of culture, the cells were harvested and the different cellular extracts were prepared.

Analysis of Cell Extracts

HepG2 cells were lysed at room temperature in CAT Elisa lysis buffer (Roche Diagnostics, Laval, PQ), and protein concentration [34], luciferase [35] and β-galactosidase [36] activities were measured. The results were expressed as luciferase activity per milligram of soluble protein and then normalized for transfection efficiency using the β-galactosidase activity. Transcriptional rates were expressed as a percentage of the standardized activity measured in the untreated cells.

FAS Activity

Fatty acid synthase activity was measured by tracking the decrease of absorbance at 340 nm as a result of NADPH disappearance due to the conversion of malonyl-CoA and acetyl-CoA into long chain fatty acids [37]. Following hormonal stimulation, 2–3 plates of treated cells (about 10×10^6 cells prepared from a pool of 12 chicks' livers) were harvested in 1× PBS. After a short centrifugation, the cells were re-suspended in ice-cold homogenization buffer. The cytosolic extracts were prepared through homogenization of the cells with a Dounce homogenizer. The lysates were subsequently centrifuged at 3,000 rpm for 15 min at 4°C. FAS activities were evaluated by mixing, in a Quartz cuvette, 50 μL of cell lysate, 0.5 M Kpi, pH 7; 25 μM acetyl-CoA; 100 μM NADPH; 3 mM EDTA and 1 mM DTT [38, 39]. The reaction was initialized by adding malonyl-CoA (0.1 mM final). The optical density (OD) at 340 nm was then monitored for 15 min at 40°C in a Cary-100 spectrophotometer (Varian, QC).

Western Blot Analysis

After treatment with various test agents at the times and concentrations indicated in the figure legends, HepG2 cells were rinsed twice with ice-cold 1× PBS (pH 7.4) and solubilized with lysis buffer (50 mM Hepes, pH 7.5, 150 mM NaCl, 10 mM sodium pyrophosphate, 100 mM sodium fluoride, 1.5 mM $MgCl_2$, 1 mM EGTA, 200 μM sodium orthovanadate, 1 mM phenylmethylsulfonyl fluoride, 10 μg/mL leupeptin, 10 μg/mL aprotinin, 10% glycerol, and 1% Triton X-100). Cell lysates were clarified by centrifugation at 10,000×g for 20 min at 4°C, and protein concentration in the resulting supernatants was determined using the BioRad protein assay (BioRad, Mississauga, ON). 20–100 μg of protein were mixed with 4 μL of 3× Laemmli sample buffer (2% SDS, 2% β-mercaptoethanol,

10% v/v glycerol and 50 mg/L bromophenol blue in 0.1 M Tris–HCl buffer, pH 6.8), heated at 100°C for 5 min, subjected to SDS-PAGE and then transferred to Immobilon-P membranes for immunoblotting. Membranes were incubated for 1 h in blocking buffer (1× TBS, 0,1% Tween-20: TBST) containing 5% milk and then overnight in 1× TBST containing 5% BSA and with the various antibodies: FAS (1:1,000), GADPH (1:1,000), Phosphotyrosine (1/1,000) and IR-α960 (1/1,000). After three successive washes in 1× TBST, membranes were incubated for 1 h at room temperature in 1× TBST in the presence of an anti-Rabbit IgG or an anti-Mouse IgG bound to the horseradish peroxidase (1/10,000). Signals were revealed using the ECL plus Western blotting detection reagent according to the manufacturer instructions (Roche Diagnostics, Laval, QC). The appropriate bands were quantified using the phospho-imager system (Molecular imager FX, Biorad, Mississauga, ON).

Flow Cytometric Analysis of T_3 Content

After 24 h starvation, HepG2 cells were treated for 1 h with T_3 or insulin and T_3 with or without hexanoate. Cells were rinsed with 1× PBS and fixed for 1 h in 0.25% of paraformaldehyde. Thereafter, the cells were permeabilized with 0.05% Tween 20 in 1× PBS containing 1% FBS. The hormone content was detected using a T_3 antibody (1/1,000) as a primary antibody and FITC-labelled goat anti rabbit IgG (1/1,000) as a secondary antibody. To control for the specificity of the signal, cell fluorescence was measured in the absence of both antibodies or only in the presence of the secondary antibody. The measurement was done in a FACS flow cytometer (Becton Dickinson) using 1×10^6 cells for each measurement. For the analysis of the result, a cellquest program was used.

Fatty Acid Uptake

Chick embryo hepatocytes were incubated in serum free Waymouth medium supplemented with hormones, inhibitors and [^{14}C]-hexanoate for 24 h as indicated on the figure legends. The uptake was then stopped, after removal of the culture medium, with a pre-heated solution (37°C) containing 0.5% BSA prepared in 1× PBS and 0.9% NaCl. The naked cells were then stripped and lysed in 0.1 M NaOH overnight at 4°C. Cell lysates were subsequently quantified by β-scintillation with the Liquid scintillation analyzer Tri-carb 2800 TR (Perkin Elmer, Quebec).

Lipid Profile

Chick embryo hepatocytes were incubated in serum free Waymouth medium supplemented with hormones, inhibitors and [^{14}C]-hexanoate for 24 h as indicated on the figure legends. The uptake was stopped with 0.2% BSA in 1× PBS. Lipids were extracted from the cells for 1 h in a hexane:isopropanol mix (3:2, v/v). The lysates were subsequently evaporated under nitrogen and re-suspended in 50 μL of chloroform. The samples and standards (cholesterol and cholesteryl oleate) were then migrated on a TLC silicate plate in a solution containing petroleum ether, anhydrous ether and glacial acetic acid (90:10:1), and revealed in an iodide saturated chamber. The strips were then cut, scraped and read by scintillation using the Liquid scintillation analyzer Tri-carb 2800 TR (Perkin Elmer, Quebec).

Results

Role of insulin, T_3 and Medium Chain Fatty Acids on FAS Enzymatic Activity

In the present study, we used CEH to measure FAS activity. Incubation of CEH with 100 nM insulin or 1.6 μM T_3 increases FAS enzymatic activity about threefold (Fig. 1a) and in the presence of both hormones, an important synergistic effect is observed, increasing the activity 14-fold. Similar hormonal effects were observed on the promoter activity demonstrating that this hormonal regulation is transcriptional [32]. We subsequently tested the effect of medium chain fatty acids (MCFA) on FAS enzymatic activity. Addition of 1 μM hexanoate or octanoate does not modify basal, insulin or T_3-induced FAS enzymatic activity. On the other hand, when MCFA were used in concordance with insulin and T_3, they had an inhibitory effect on FAS enzymatic activity of about half (Fig. 1b, c). The inhibition was even more effective when hexanoate was used (50%) compared to the effect of octanoate (40%).

Effect of Hormonal Treatment on Hexanoate Uptake

Our previous data demonstrated that hexanoate only inhibits FAS activity in the presence of both insulin and T_3. However, we could not exclude that in the absence of both hormones, the MCFA may not efficiently penetrate into the cell. In order to evaluate this hypothesis, we measured the uptake of [^{14}C]-hexanoate at each hormonal condition. In the absence of any hormonal treatment, hexanoate efficiently enters the cell. However, this uptake is significantly increased by the presence of either insulin, T_3 or both hormones (Fig. 2a). We have to note that regardless of the hormonal treatment used, the radio-labeled hexanoate was able to enter the cell unhindered and this in a very short time lapse. The results show that only after 1 h, the levels

In each condition, 1 μCi of [^{14}C]-hexanoate was also added. The C6 uptake was evaluated as indicated in "Methods". Results are expressed in cpm per milligram of protein and are the mean of three independent experiments. The *bars* indicate the SD. $^{*}P < 0.05$ for insulin and/or T_3 treated versus untreated cells. **b** FAS activity was measured as described in "Methods", using cell lysate from untreated (*white bars*) or treated with 100 nM insulin and 1.6 μM T_3-treated cells for 24 h (*black bars*) with addition of 1 μM hexanoate in the media (*crossed bar*) or in the enzymatic reaction buffer (*hatched bar*)

of [^{14}C]-hexanoate found in the cells are comparable to those found in cells exposed for 24 h.

Post-Translational Effect of Hexanoate on FAS Activity

In order to evaluate whether the inhibition by hexanoate was due to an allosteric competition, we added the MCFA

in the reaction buffer just before measuring the enzymatic activity. As depicted in Fig. 2b, the hexanoate needs to be present in the cell in order to efficiently inhibit the insulin and T_3-induced FAS activity (Fig. 2b), while the presence of hexanoate in the reaction buffer has no effect. In agreement with previous data, our results suggest that the MCFA regulates the level of FAS activity probably by modulating the level of FAS expression and not by acting at a post-translational level.

Effects of T_3, insulin, and hexanoate on FAS expression

In order to evaluate the effect of hexanoate on FAS expression, we measured the level of FAS protein in cells treated with various combinations of T_3, insulin and hexanoate by Western blot. As shown in Fig. 3a, hexanoate inhibits insulin and T_3-induced FAS protein expression by about 50%. This level correlates to the one observed on FAS activity, suggesting that hexanoate inhibits FAS activity by modulating its level of expression.

We next evaluated the effect of hexanoate on FAS transcription. We had previously demonstrated that T_3 and insulin target a specific TRE on the FAS promoter [20]. We cloned this TRE upstream of the minimal promoter of thymidine kinase and the luciferase reporter gene and transiently transfected the DNA construct into HepG2 cells. Luciferase activity was then measured in presence of T_3, insulin and hexanoate. As expected, in presence of T_3 or insulin, the luciferase activity was increased about 1.3-fold through the TRE whereas in presence of both hormones, the transcription increases more than 2-fold (Fig. 3b). When the cells are incubated with hormones and hexanoate, the transcriptional activity is inhibited by more than 25%. These results suggest that hexanoate regulates at least in part, FAS transcription via the TRE located on the FAS promoter.

Effect of C6 on Insulin Receptor Phosphorylation and T_3 Uptake

In order to evaluate the effect of C6 directly on the hormonal response, we measured the level of phosphorylation of the insulin receptor in HepG2 cells as well as the T_3 uptake. As expected, the tyrosine phosphorylation of the insulin receptor is only detected in the presence of insulin (Fig. 4a). The addition of C6 does not modify the phosphorylation state of the receptor with or without T_3.

Using flow cytometry, we evaluated the uptake of T_3 under various conditions. Incubation of cells only with the secondary antibody revealed a lower fluorescence than the one observed in the presence of both antibodies ($*P < 0.05$ comparing lane 1 to untreated and T_3-treated cells). Incubation of the cells with T_3 increases the detected fluorescence compared to untreated cells ($**P = 0.001$ comparing untreated to T_3-treated cells). This demonstrates the specificity of the fluorescence detection in our

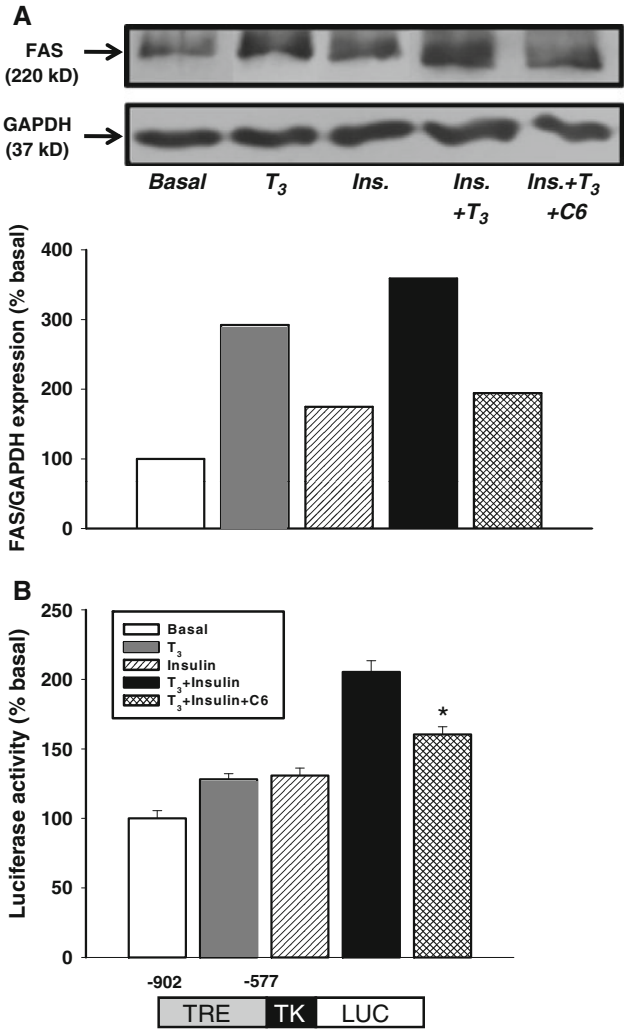

Fig. 3 Effect of hexanoate on FAS expression. **a** HepG2 cells were incubated for 24 h with T_3 (1.6 μM), insulin (100 nM) and/or C6 (1 μM). The cells were lysed; extracted proteins were resolved on 10% SDS-PAGE and then immunoblotted with either an anti-FAS antibody (*top panel*) or an anti-GAPDH antibody (*bottom panel*). The Western blot signals were quantified by densitometry and normalized to GAPDH. The results presented in the graph are expressed as a percentage of the signal intensity observed in untreated (*basal*) cells. **b** HepG2 cells were transiently transfected with the TRE-TK-LUC DNA construct (0.75 μg/well) and pRSV-βgal (0.25 μg/well) as described in "Methods". After removing the transfection medium, the hepatocytes were incubated for 24 h in MEM or in the same medium containing 1.6 μM of T_3, 100 nM of insulin or both hormones without or with 1 μM of C6. Results are expressed as luciferase activities normalized by β-galactosidase activity per milligram of soluble protein. They are represented as a percentage of the activity measured in the untreated sample and are the mean of at least three independent experiments. The *bars* indicate the standard deviation (SD). $*P = 0.02$ compared to insulin and T_3 treated cells. Schematic representation of the DNA construct is depicted in the bottom of the graph

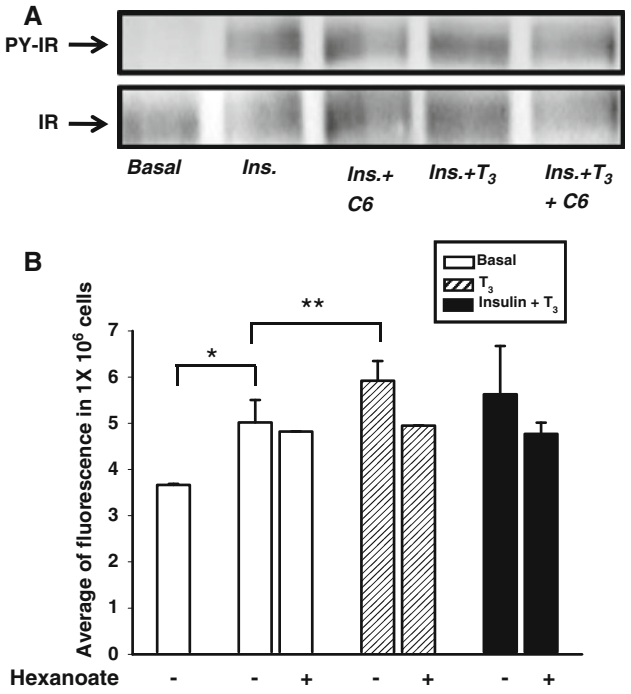

Fig. 4 **a** Effect of hexanoate on insulin receptor phosphorylation and T_3 uptake. HepG2 cells were incubated for 24 h with T_3 (1.6 μM), insulin (100 nM) and/or C6 (1 μM). The cells were lysed; 100 μg of extracted proteins were resolved on 10% SDS-PAGE and then immunoblotted with either an anti-phosphotyrosine antibody (*top panel*) or an anti-insulin receptor antibody (*bottom panel*). **b** HepG2 cells were incubated for 1 h with T_3 (1.6 μM), insulin (100 nM) and/or C6 (1 μM). Cells were fixed and permeabilized as described in "Methods". The T_3 content was measured by labeling the cells with an anti-T_3 antibody (1/1,000) and anti FITC goat anti-rabbit (1/1,000) except for the first condition (*first bar*) where a primary antibody was omitted. Fluorescence was then measured by flow cytometry. The results represent the average of three independent experiments and are expressed as the average of fluorescence detected in 1×10^6 cells. $^*P < 0.05$, $^{**}P = 0.001$

experiment. Addition of C6 does not modify the uptake of T_3, despite a tendency to decrease. However, these values did not reach the level of significance (Fig 4b). Taken together, our results show that C6 inhibits FAS activity and expression, but not by influencing the linkage between insulin and its receptor or the entrance of T_3 in the cells.

Effect of MCFA Metabolites on FAS Enzymatic Activity

As MCFA taken up by the cells are rapidly metabolized [40], we analyzed the cellular lipid profile after incubating the cells for 24 h with [^{14}C]-hexanoate. As depicted in Table 1, we showed that about 60% of the ^{14}C is now found in the triacylglycerol fraction. The presence of both insulin and T_3 even increases it to almost 66%. The rest of the ^{14}C end up in the cholesterol ester (around 25%) and phospholipids fractions (around 10%). However, the presence of both hormones appears to decrease this conversion, orienting the MCFA towards the esterification pathway.

Table 1 Hormonal effect on CEH lipid profile

	Basal	Insulin	T_3	Insulin + T_3
Phospholipids	11.6 ± 7.2	10.4 ± 5.0	12.2 ± 8.6	7.5 ± 3.2
Free cholesterol	1.0 ± 0.9	0.9 ± 0.8	0.9 ± 0.5	0.5 ± 0.3
Diacylglycerol	7.1 ± 3.2	4.5 ± 2.1	8.7 ± 5.6	5.0 ± 2.3
Triacylglycerol	55.7 ± 8.8	58.0 ± 7.4	50.8 ± 14.8	65.6 ± 3.0*
Cholesterol ester	24.6 ± 4.0	26.2 ± 5.1	27.4 ± 5.6	21.4 ± 4.3§

Cells were incubated for 24 h with hexanoate in presence or not of 100 nM insulin and/or 1.6 μM T_3. The lipid profile was revealed as indicated in "Methods". Results are expressed as percentage of the total radioactive content. Data are the mean of three independent experiments, ±SD

* $P = 0.001$ versus basal

§ $P = 0.01$ versus basal

Even if the hexanoate entering the cell appears to be mostly metabolized into triacylglycerol, we devised a strategy that should enable us to determine if hexanoate needs to be modified in order to inhibit FAS enzymatic activity (Fig. 5a). If it acts unchanged, we should see the same effect when bromo-hexanoate, a form of hexanoate that cannot be metabolized, is used. On the other hand, if bromo-hexanoate fails to inhibit FAS enzymatic activity, it strongly suggests that a metabolite is involved in the inhibitory process, be it through esterification or *β*-oxidation. In Fig. 5b, we observed that bromo-hexanoate has no inhibitory effect on insulin and T_3-induced FAS enzymatic activity, thus suggesting the implication of a metabolite. Incubation of cells with either glycerol–hexanoate (Fig. 5c) or carnitine–hexanoate (Fig. 5d) does not reveal any inhibition of FAS enzymatic activity. Taken together, our results suggest that after 24 h, the MCFA is metabolized, probably *β*-oxidized, but glycerol–hexanoate and carnitine–hexanoate are not directly responsible for the modulation of the FAS enzymatic activity.

Role of Fatty Acids Metabolism Inhibitors on the Effect of Hexanoate on FAS Enzymatic Activity

In order to validate our previous data showing that neither glycerol–hexanoate (Fig. 5c) nor carnitine–hexanoate (Fig. 5d) directly inhibit insulin and T_3-induced FAS enzymatic activity, we used specific pharmaceutical inhibitors to evaluate the role of each lipid metabolic pathway. In Fig. 6a, we can see that the inhibitory effect of hexanoate on insulin and T_3-induced FAS enzymatic

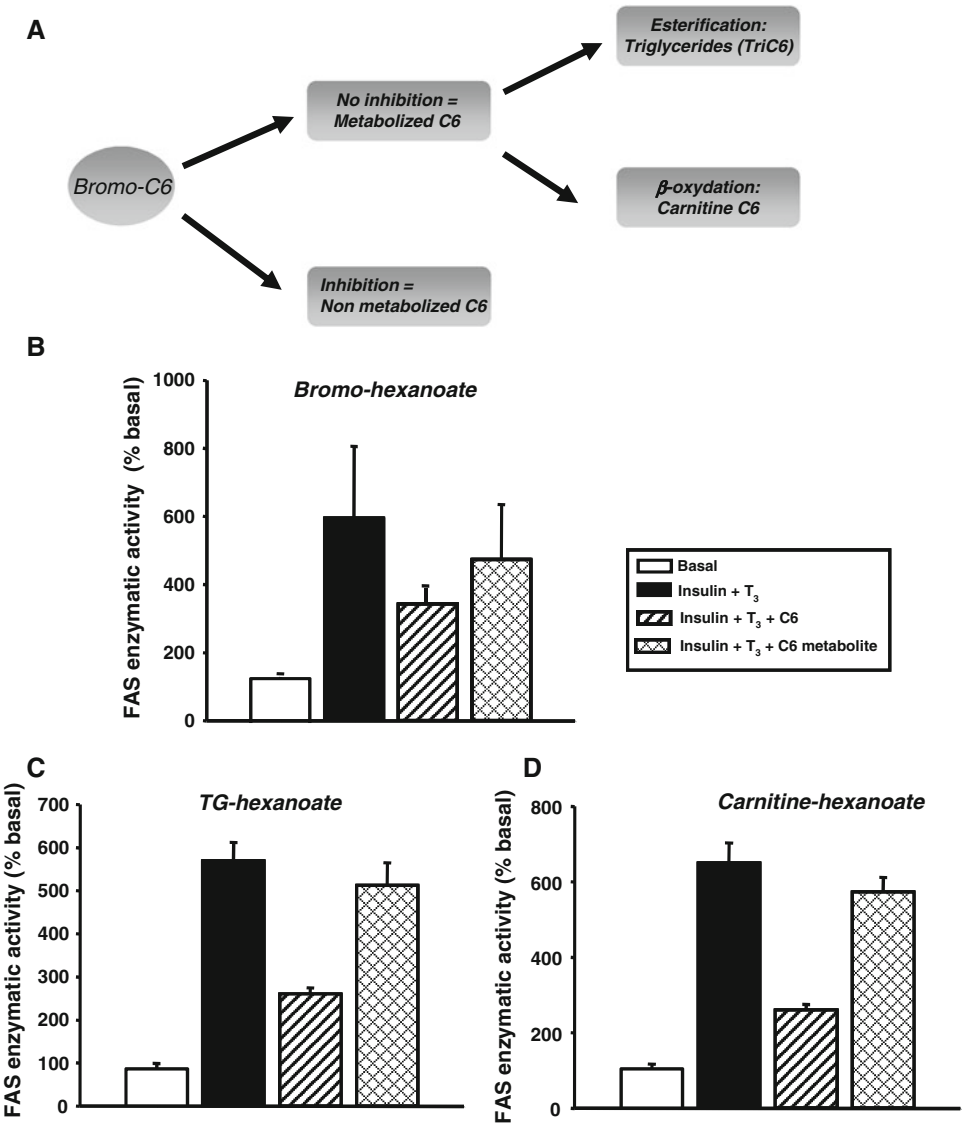

Fig. 5 Effects of the hexanoate metabolites on FAS enzymatic activity. **a** Schematic representation of C6 metabolism in CEH cells. CEH were incubated for 24 h in Waymouth media (*white bars*) or with addition of 100 nM insulin and 1.6 μM T_3 (*black bars*) supplemented with 1 μM of hexanoate (*hatched bars*). The effect of 1 μM bromo-hexanoate (**b**), 1 μM TG-hexanoate (**c**) or 1 μM carnitine–hexanoate (**d**) (*crossed bars*) was also evaluated. FAS activity was evaluated as indicated in "Methods". Results are the mean of at least three independent experiments and are expressed as a function of the value obtained in untreated samples. The bars indicate the SD

activity remained when the cells were treated with Etomoxir, an inhibitor of the CPT1. The same is true as shown in Fig. 6b, depicting the cells that were treated with Betulinic acid, a specific inhibitor of the diacylglycerol transferase (DGAT). We have to note that the presence of these inhibitors does not affect the uptake of hexanoate (Fig. 6d, crossed bars). These results confirm our previous observations suggesting that hexanoate is neither esterified nor *β*-oxidized in order to inhibit FAS enzymatic activity in the presence of insulin and T_3. However, the use of bromo-hexanoate demonstrated that hexanoate needs to be metabolized. It had previously been demonstrated that as soon as the MCFA enters the cell, it is rapidly transformed into an acyl-CoA derivative, reaction catalyzed by the octanoyl-CoA synthetase [1]. In order to test this hypothesis, we evaluated the effect of Triacsin C, a general inhibitor of acyl-CoA synthetases [41], on the inhibitory effect of hexanoate. Under those conditions, we saw a total abolition of the inhibitory effect induced by hexanoate, and recovered the synergic effect seen when the cells are stimulated with insulin and T_3 (Fig. 6c). The MCFA effect on FAS appears to be specific to hexanoyl-CoA, as the presence of Triascin C in the culture media in absence of C6 does not modify the insulin and T_3-induced FAS activity (Fig. 6c, grey bar). As observed for Etomoxir and Betulinic Acid, the Triacsin C has no effect on the uptake of hexanoate (Fig. 6d, crossed bars). Finally, we showed that hexanoyl-CoA is behaving like hexanoate on FAS activity as incubation of cells with this compound efficiently inhibits the insulin and T_3-induced FAS activity (Fig. 6e). As previously observed for C6 (Fig. 2b), the presence of hexanoyl-CoA in the reaction buffer does not modify the insulin and T_3-induced FAS activity (Fig 6e).

Taken together, our results suggest that in hepatocytes, hexanoate needs to be converted to an acyl-CoA derivative in order to inhibit the insulin and T_3-induced FAS

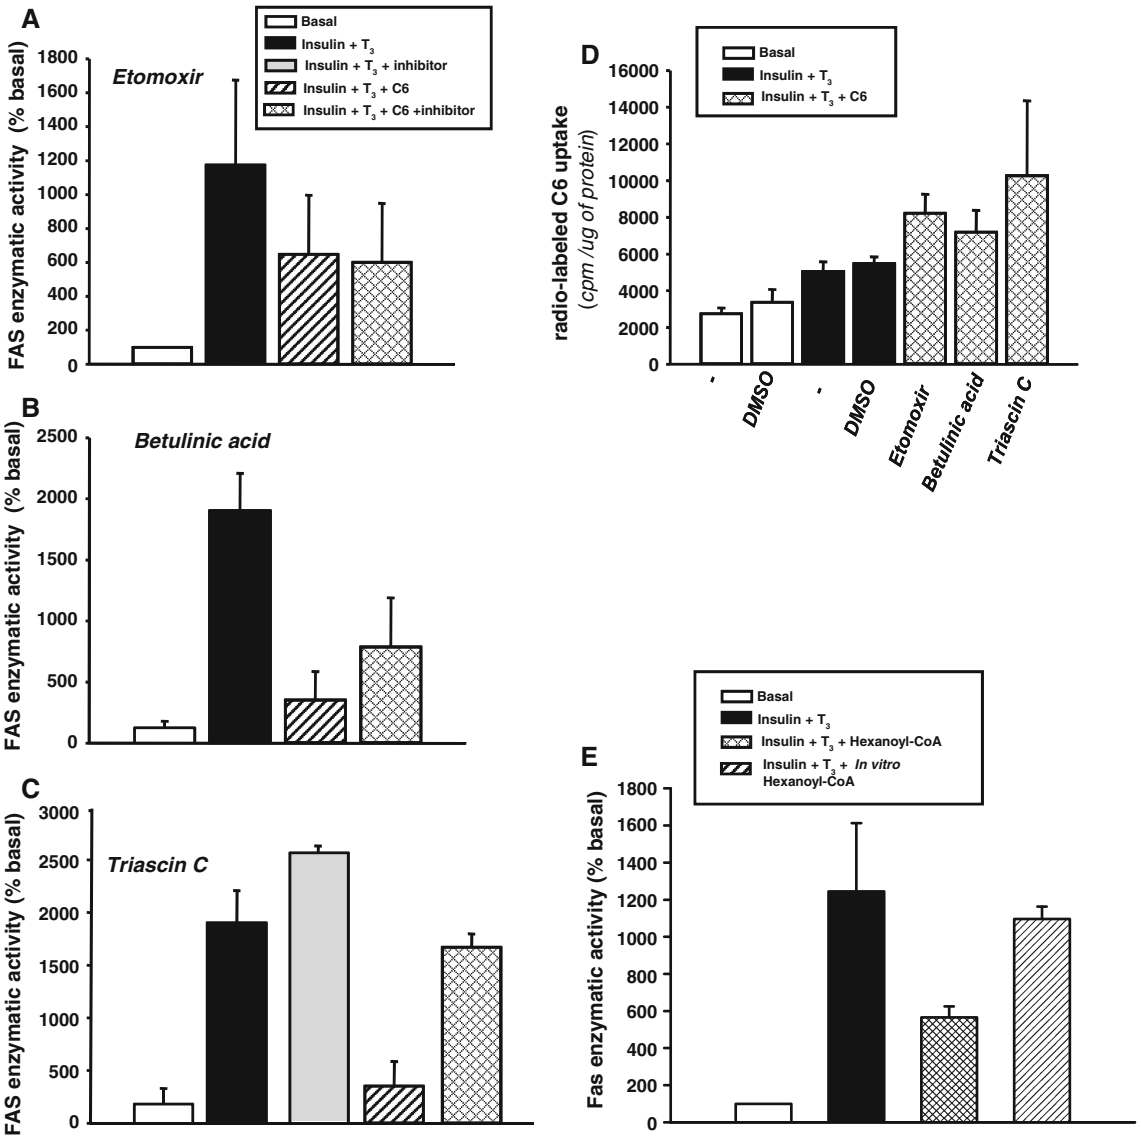

Fig. 6 Effects of lipid metabolic pathways inhibitors on FAS activity and C6 uptake. The CEH were incubated for 24 h in Waymouth media (*white bars*) or with addition of 100 nM insulin and 1.6 μM T_3 (*black bars*) in the presence or absence of hexanoate (*hatched bars*). The effects of (**a**) 1 μM Etomoxir, (**b**) 1 μM Betulinic acid and (**c**) 5 μM Triascin C (*crossed bars*) on insulin and T_3-induced FAS activity and C6 inhibition were also tested. For (**b**) and (**c**), 5% of DMSO was added to each treatment. FAS activity was evaluated as indicated in "Methods". Results are the mean of at least three independent experiments and are expressed as a function of the value obtained in untreated samples. The *bars* indicate SD. $^*P = 0.0065$ compared to Insulin/T_3/C6 treated cells. **d** CEH were incubated for 24 h with 1 μCi of [^{14}C]-hexanoate (*white bars*) and in presence of 100 nM insulin and 1.6 μM T_3 (*black bars*). DMSO was added as indicated in the figure. In addition, 1 μM Etomoxir, 1 μM Betulinic acid or 5 μM Triascin C were added (*crossed bars*) and the C6 uptake was evaluated as indicated in "Methods". Results are expressed in absolute values and are the mean of three independent experiments. The *bars* indicate SD. **e** FAS activity was measured as described in "Methods", using cell lysate from untreated (*white bars*) or treated with 100 nM insulin and 1.6 μM T_3-treated cells for 24 h (*black bars*) with addition of 1 μM hexanoyl-CoA in the media (*crossed bar*) or in the enzymatic reaction buffer (*hatched bar*)

enzymatic activity. Hexanoate acts at the transcriptional level, targeting a TRE on the FAS promoter and modulating its transcriptional activation in response to insulin and T_3. This inhibitory effect cannot be attributed to a modification of insulin receptor activation nor to a decrease in T_3 entry in the cells.

Discussion

Our findings show that hexanoate only inhibits FAS when the enzyme is stimulated by insulin and T_3. These two hormones are strongly secreted during the postprandial state, increasing de novo lipid synthesis. This allows

glucose and, to a lower extent, fatty and amino acids to be transformed into triglycerides and subsequently stored in adipose tissues. Decreasing insulin and T_3-induced FAS activity by hexanoate will probably decrease the amount of TG formed and subsequently the amount of VLDL secreted. This is in agreement with a study showing that incubation of hepatocytes with MCFA decreases VLDL secretion [42]. In addition, several studies have shown that diets containing MCFA can induce weight loss [8]. They attributed the weight loss to increased energy expenditure but also, as shown in our study, by decreased hepatic lipogenesis. The effects of MCFA are of great interest when looking at the inhibition of the postprandial state of de novo lipogenesis, which is associated with an increased secretion of insulin and T_3.

Previous studies have been shown that FAS is regulated at the transcriptional level [17, 43, 44], and that medium chain fatty acids, such as hexanoate and octanoate have an inhibitory effect [27]. This effect was only observed when FAS was stimulated with insulin and T_3. Recently, the need for hormone involvement in the MCFA action has also been observed on the inhibition of adipogenesis in 3T3-LI adipocytes [45]. In the same study, the authors also showed that in the absence of hormones, MCFA increase adipogenesis. As depicted in Fig. 1b, c, MCFA treatment in absence of any hormones leads to an increase in FAS activity. However, the difference does not reach statistical significance and needs to be further confirmed.

We and others have observed that hexanoate and octanoate, but not decanoate nor butanoate (data not shown, [27]), can inhibit FAS enzymatic activity. This inhibition is very specific to these two fatty acids, and more pronounced with hexanoate (about 50%) than with octanoate (about 40%) (Fig. 1b, c). In addition, the inhibitory effect of hexanoate appears to be targeted to lipogenic genes in as so far as FAS, malic enzyme and acetyl CoA carboxylase are concerned [46], because DNA content and transcription of the glyceraldehyde-3-phosphate dehydrogenase and beta-actin genes were not inhibited [27].

It has been previously demonstrated that hexanoate inhibits some lipogenic genes at the transcriptional level [27]. This was confirmed by our experiment showing that MCFA inhibition was not due to allosteric competition. In addition, we showed that hexanoate inhibits FAS through the inhibition of protein expression and transcriptional activity of the TRE. Roncero and collaborators [27] demonstrated that hexanoate and octanoate inhibit lipogenic enzymes activities at a transcriptional step, and did so within 30 min. This is in agreement with our observations showing that hexanoate was able to enter the cell unhindered in just 1 h.

We had previously demonstrated that the FAS TRE is targeted by insulin and T_3 [32]. As previously demonstrated for the malic enzyme promoter [47], we showed that hexanoate targets the TRE on the FAS promoter (Fig. 3b), inhibiting its transcriptional activity in the presence of insulin and T_3. The level of inhibition on the transcriptional activity of the FAS TRE is, however, lower than that observed at the FAS protein and activity levels (25 vs. 50%). It has been previously published that MCFA are able to modulate transcription by inhibiting the accumulation of mature SREBP-1c caused by T_3 and insulin [48]. We know that SREBP-1c regulates FAS transcription by binding an element located outside of the TRE used in our present study [49]. Therefore, the difference observed between the inhibition by C6 of FAS activity and the inhibition at the transcriptional level may be attributed to an effect of C6 on SREBP. This is currently under investigation.

The precise molecular mechanism of MCFA action on the TRE is still unknown. On the malic enzyme promoter, hexanoate does not modify the binding of T_3 to its nuclear receptor TR, neither does it modify the TR binding on the TRE [47]. Previous studies performed in mice have suggested that MCFA decrease PPARγ and SREBP-1c expression. A role of SREBP-1c cannot explain the effect of MCFA on the FAS promoter as in our experiment, the MCFA effect is observed when we use the sequence only including the TRE. The SREBP-1c binding site is not included in the tested DNA promoter fragment.

A previous study in chick embryo hepatocytes demonstrated that MCFA also act on the estrogen receptor (ER) [47]. On promoters, ER dimerizes with itself and not with one of its heterodimerization partners: RXR and PPAR. As the mechanism of MCFA on estrogen and T_3-induced transcription is probably the same, RXR and PPAR are probably not the target of MCFA on the FAS promoter.

In the present study, we showed that hexanoate does not modify the linkage between insulin and its receptor nor the entrance of T_3 in the cells (Fig. 4). However, we cannot exclude that C6 may affect downstream events on the insulin and T_3-activated signaling pathways. In neurons, MCFA are able to modulate intracellular MAPK pathways [50, 51]. We have recently demonstrated that insulin and T_3 mediate their effect on the TRE of the FAS promoter through the activation of a ERK1/2 MAPK pathway [32]. MCFA may modulate the activation of ERK1/2 leading to inhibition of FAS transcription. Finally, MCFA may act on GPCR, activating downstream signaling cascades [52], leading to the phosphorylation of transcription factors bound to the TRE, and modulation of FAS transcription [53]. The exact molecular mechanism of MCFA action on the FAS TRE is currently under investigation.

Our data show that the MCFA enters the cell rapidly. It is well established that MCFA uptake occurs by simple

diffusion without the implication of specific transporters [54, 55]. It is rapidly transformed into an acyl-CoA derivative through the action of a specific acyl-CoA synthetase [1]. This acylation occurs in the mitochondria as the MCFA easily crosses the double mitochondrial membrane and, unlike long-chain fatty acids, they do not require the presence of carnitine palmityl transferases [56]. This is in agreement with the fact that neither carnitine–hexanoate nor Etomoxir (inhibitor of CTPI) affect insulin and T_3-induced FAS enzymatic activity.

The CoA-derivative of MCFA can be transformed into ketone bodies through the β-oxidation pathway. However, this does not appear to be the case in CEH as most of the [^{14}C]-hexanoate taken up by the cells is now found in the triglyceride fraction (more than 60%; Table 1). Therefore, most of the Acyl-CoA hexanoate must be transformed into acetyl-CoA, becoming a carbon source for de novo lipid synthesis ending with the formation of new triglycerides and cholesterol derivatives [56]. This is supported by the fact that in the presence of insulin and T_3, the amount of [^{14}C]-TG is increased compared to the level measured in the absence of any hormonal stimulation (Table 1). Indeed, it is well known that insulin stimulates hepatic triacylglycerol secretion through the general activation of de novo lipid synthesis [57]. It is also well established that T_3 stimulates de novo lipid synthesis in the liver, increasing synthesis of TG [58, 59]. However, the use of betulinic acid, an inhibitor of DGAT, a rate limiting step in the esterification pathway (Fig. 6b) or the incubation of cells with TG-hexanoate (Fig. 5c) did not reveal any abolition of the inhibitory effect of hexanoate on insulin and T_3-induced FAS activity. The incubation of cells with Triacsin C, a general inhibitor of acyl-CoA synthetases [41], completely reversed the inhibitory effect of hexanoate on insulin and T_3-induced FAS activity. Therefore, our data strongly suggest that only the Acyl-CoA hexanoate, which is very rapidly formed after the uptake of the fatty acid by the cell [56], is able to modulate the FAS enzymatic activity. This is also in agreement with the fact that hexanoate is able to inhibit FAS transcription after only 30 min of incubation [27] and that direct incubation of cells with hexanoyl-CoA also abolished insulin and T_3-induced FAS activity (Fig. 6e).

In conclusion, in the present study we have shown that hexanoate is rapidly taken up by the chick embryo hepatocytes. It is subsequently metabolized into an acyl-CoA derivative that is able to specifically inhibit insulin and T_3-induced FAS activity. This inhibition results in decreased FAS protein expression levels. Hexanoate targeting the TRE on the FAS promoter is responsible for part of the inhibition observed at the protein level. We also showed that the C6 effect on FAS expression cannot be attributed to a modification of insulin receptor activation or to a decrease in T_3 entry in the cells.

Abstract Soybean lecithin (SBL), used as a phospholipid source in larval fish diets, may compromise growth and survival in marine species, and affect gene expression, due to differences in fatty acid composition relative to marine lecithins (ML). The potential of SBL as a phospholipid source in gilthead seabream microdiets as compared to ML was evaluated. Two stocking densities were tested in order to exacerbate possible dietary effects: 5 and 20 larvae L^{-1}. Larvae reflected dietary fatty acid profiles: linoleic acid was higher, whereas eicosapentaenoic and arachidonic acids were lower in SBL fed groups than in ML fed larvae. Highest stocking density decreased survival, and led to elevated saturates and lower docosahexaenoic acid levels in polar lipid. Muscle histology observations showed hindered growth potential in SBL fed larvae. Despite similar cortisol levels between treatments, higher glucocorticoid receptor (GR), as well as hormone-sensitive lipase (HSL) mRNA levels in SBL fed groups revealed a role for fatty acids in gene regulation. Further analysed genes suggested these effects were independent from the hypothalamus-pituitary-interrenal axis control and the endocannabinoid system. Cyclooxygenase-2 and gluconeogenesis seemed unaffected. For the first time in fish, a link between dietary lecithin nature and HSL gene transcription, perhaps regulated through GR fatty acid-induced activation, is suggested. Enhanced lipolytic activity could partly explain lower growth in marine fish larvae when dietary ML is not provided.

Keywords Dietary lipid · Stocking density · Gilthead seabream · Larvae · Fatty acids · Stress · Gene expression

Abbreviations

SBL	Soybean lecithin
ML	Marine lecithin
SAFA	Saturated fatty acids
MUFA	Monounsaturated fatty acids
PUFA	Polyunsaturated fatty acids
HUFA	Highly unsaturated fatty acids
TFA	Total fatty acids
PLA2	Phospholipase A2
COX-2	Cyclooxygenase-2
ACTH	Adrenocorticotropic hormone
POMC	Pro-opiomelanocortin
GR	Glucocorticoid receptors
FBPase	Fructose-1, 6-bisphosphatase
PKC	Protein kinase C
HSL	Hormone-sensitive lipase
GH	Growth hormone
CB1 receptor	Cannabinoid 1 receptor
ARA	Arachidonic acid

NF-κB	Nuclear factor-kappa B
PPAR	Peroxisome proliferator-activated receptor
HPI	Hypothalamus–pituitary–interrenal
2-AG	2-Arachidonoylglycerol
HPA	Hypothalamus–pituitary–adrenal
PEPCK	Phosphoenolpyruvate carboxykinase

Introduction

A dietary phospholipid source, particularly of marine origin, is generally recognised to promote growth and survival, as well as skeletal development, and perhaps stress resistance in fish larvae [1, 2]. Phospholipids are key cell membrane constituents, and have a relevant role in lipid transportation from the intestine which seems to be of utmost importance in larvae; they are also thought to influence dietary palatability [1]. Commercially available lecithins are mixtures of phospholipids obtained from oils of either vegetable or animal nature. Due to its market availability and relatively stable composition, soybean lecithin (SBL) is generally included as a phospholipid providing ingredient in larval diets, although its fatty acid composition differs greatly from that of marine lecithin (ML). Typically, SBL presents elevated linoleic acid levels and does not contain highly unsaturated fatty acids (HUFA) which characterize ML. Despite the abundance of HUFA under the triacylglyceride form in larval diets provided mostly through fish oil ingredients, some supply under the phospholipid form seems necessary to sustain growth in marine fish larvae [3, 4]. The reasons underlying this requirement are still poorly understood and further research is needed for the optimisation of larval diets. It would be plausible to hypothesise that deleterious effects of dietary SBL as compared with ML on growth and development in fish larvae could be due, at least partly, to changes in cell content of certain fatty acids and their metabolites which can play key roles in many cellular events, such as gene expression regulation [5–7].

Stress coping ability, which requires energy expenditure, has been increasingly recognised as a valuable parameter for the evaluation of physiological condition in fish. Eicosanoid production, their type and relative amounts, is supposedly influenced by the dietary supply of certain fatty acids and believed to play a major role on the success of the stress response in larvae, although seldom explored in fish stress studies [8, 9]. Eicosanoids are generated by the activity of phospholipase A2 (PLA2) and other enzymes, such as cyclooxygenase-2 (COX-2), over fatty acids derived from cell membrane phospholipids [10]. Other enzymes (lipoxygenase, epoxygenase) also contribute to eicosanoid production which may stimulate adrenocorticotropic hormone (ACTH) and modify induced cortisol release [8, 11]. The ability to recover homeostatic balance in response to stress is determined by a response system in which a variety of transcription factors and nuclear receptors are implied, possibly under direct or indirect influence of fatty acids or their metabolites [12]. Besides, the issue of cell membrane composition is also relevant for genomic steroid actions since the ability of a substance to partition into the membrane is critical for its bioavailability to intracellular receptors [13, 14].

This study was designed to test two diets differing in the phospholipid source, in seabream larvae. A relatively high stocking density was used as a chronic stressor with the aim of possibly intensifying effects of the diets on growth, survival, and stress associated parameters. Exploring effects of dietary lecithin source on aspects related to stress physiology was expected to provide clues for its metabolic regulation by dietary fatty acids. As such, the gene expressions of pro-opiomelanocortin (POMC, a precursor for ACTH), glucocorticoid receptors (GR, cortisol signaling mediators), COX-2, and fructose-1,6-bisphosphatase (FBPase, involved in stress-induced gluconeogenesis) were analysed. Furthermore, the expression of protein kinase C (PKC) gene was studied as a potential intermediary in steroidogenesis, and responsive to cellular ARA abundance [15, 16]. Other genes targeted were those for the rate-limiting enzyme hormone-sensitive lipase (HSL), growth hormone (GH), and cannabinoid 1 receptor (CB1 receptor). CB1 receptors are distributed within the central nervous system [17, 18] and their expression could reflect changes in dietary fatty acid supply, especially arachidonic acid (ARA). Also, histological analyses of the muscle were conducted in order to identify short-term effects of the experimental conditions on the growth potential of the larvae, which is believed to be related with the number of small sized muscle fibres in fish [19–21].

Experimental Procedure

Experimental Conditions

A bifactorial experiment was conducted during 7 days on gilthead seabream larvae. Eggs were obtained from the "Planta de Cultivos Marinos" of the University of Cádiz (Puerto Real, Spain) and placed in 200-L incubator tanks in

a flow-through system, with constant aeration. After hatching, the larvae were transferred into 300-L tanks and fed on *Nannochloropsis gaditana* (Fitoplancton marino, EasyAlgae) enriched rotifers (*Brachionus rotundiformis* and *B. plicatilis*; 5–15 per ml of tank water) from 5 to 25 days after hatching (DAH), according to the feeding protocols established by Polo et al. [22]. After 14 DAH, *N. gaditana* and *Isochrysis galvana* (T-Iso) enriched *Artemia nauplii* were also provided at 1–2 nauplii per ml. From 32 DAH onwards, fish were fed exclusively on microencapsulated diets (200–400 μm size), prepared according to the method described by Yúfera et al. [23], and containing commercial phospholipid mixtures (lecithins) of either marine (ML) or soybean (SBL) origin (Table 1). Both diets were formulated to present phosphatidylcholine and phosphatidylinositol, thought to be main growth-promoting fractions in lecithin for fish larvae, in a total content of approximately 1% of the diet as suggested by Coutteau et al. [24]. The ratio phosphatidylcholine/(phosphatidylinositol + phosphatidylserine) was maintained at 2.5 in both diets.

During the one-week inert feeding period, larvae were kept in a flow-through system consisting of eight cylindro-conical baskets (43 L) with a plankton net bottom immersed in one tank. Four of the baskets held seabream groups at a low density ("L" groups) of 5 larvae L^{-1} and other four held groups kept at the higher stocking density ("H" groups) of 20 larvae L^{-1}. The experimental diets were assigned so that each treatment was tested in duplicate (ML-L, ML-H, SBL-L, SBL-H). Feed was supplied in excess, manually during the day and with automatic feeders at night. Constant aeration was provided so as to maintain dissolved oxygen levels around 6 mg L^{-1}, water temperature was kept at 20 ± 0.5 °C and a light:dark photoperiod of 14:10 h was used. Water salinity was 33 g L^{-1}. Tank maintenance, removal of dead fish and uneaten feed were performed daily.

Sampling procedures

Initial fish samples were taken for determination of individual dry weight and total length at 32 DAH ($n = 10$). At the end of the experiment (39 DAH), fish samples were collected from all treatments for dry weight and total length determination ($n = 10$), muscle histology ($n = 6$), gene expression analyses through mRNA quantification ($n = 12$), whole-body cortisol ($n = 14$), and lipid quantification (minimum 100 mg body mass per tank). All larvae sampled were anaesthetised with an overdose of ethyl-4-amino-benzoate and washed with distilled water before storage or measurements, with the exception of animals used for gene expression analysis. These were immediately stored in an RNA stabilizing solution, RNA*Later*™

[o] Carbohydrates = 100 − (protein + lipid + ash)

(Ambion, Austin, TX, USA), at 4 °C overnight, then at −20 °C until analytical work was conducted. Whole larvae samples for histological analyses were fixated in a 0.1 M phosphate buffer containing 3% glutaraldehyde 25% EM and stored at 4 °C. Both cortisol determination and fatty acid analysis samples were stored in a −80 °C freezer to avoid material degradation and peroxidation until further analyses.

Analytical Methods

Experimental diets were analysed for proximate composition according to the following procedures: dry matter determined gravimetrically by drying in an oven at 105 °C for 24 h; crude ash by incineration in a muffle furnace at 500 °C for 5 h; crude protein (% N × 6.25) determined using an elemental analyzer (Thermoquest Flash 1112, Rodano, Italy) with sulphanilamide as a standard; total lipid extracted in chloroform:methanol (2:1, v/v) according to Folch et al. [25] and quantified gravimetrically after evaporation of the solvent under a stream of nitrogen followed by overnight vacuum desiccation. Total lipid was stored in chloroform:methanol (2:1, 20 mg ml^{-1}) with 0.01% butylated hydroxytoluene (BHT) at −20 °C until final analysis. Fatty acid composition of total lipid and polar lipid fraction of the diets was also determined following an acid catalyzed transmethylation [26]. Fatty acid methyl esters were extracted twice using isohexane:diethyl ether (1:1, v/v), purified on TLC plates and analysed by gas–liquid chromatography on a Thermo TraceGC (Thermo Fisher Scientific, Waltham, MA, USA) instrument fitted with a BPX70 capillary column (30 m–0.25 mm id, SGE), using a two-stage thermal gradient from 50 °C (injection temperature) to 150 °C after ramping at 40 °C min^{-1} and holding at 250 °C after ramping at 2 °C min^{-1}, using helium (1.2 ml min^{-1} constant flow rate) as the carrier gas, on-column injection, and flame ionisation detection. Peaks were identified by comparison with known standards (Supelco, Madrid, Spain) and a well characterised fish oil, and quantified by means of the response factor to the internal standard, 21:0 fatty acid, added prior to transmethylation, using a Chrompack program (Thermo Finnigan, San Jose, CA, USA). To carry out fatty acid composition analysis of the polar lipid fraction, total lipid extract was evaporated to dryness, diluted in chloroform (about 30 mg of lipids in 500 µl of solvent) and injected on a Sep-Pack silica cartridge (Waters S.A., Milford, MA, USA; [27]). After adsorption of the sample, 20 ml of chloroform were pushed through the cartridge with a syringe avoiding the formation of air bubbles and the non-polar fraction discarded. The fraction containing the polar lipids was eluted through the cartridge with 30 ml of methanol, collected and subjected to acid catalysed transmethylation as indicated above. Lipid class composition of the lecithins and diets was determined by high-performance thin-layer chromatography (HPTLC). Approximately 10 µg of lipid was applied as a 2 mm streak and the plate developed to two-thirds distance with methyl acetate/isopropanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, v/v), to separate polar lipid classes, and then fully developed with isohexane:diethyl ether:acetic acid (85:15:1, v/v). Lipid classes were visualised by charring at 160 °C for 15 min after spraying with 3% (w/v) aqueous cupric acetate containing 8% (v/v) phosphoric acid, and quantified by densitometry using a Bio-Rad GS-800 densitometer (Bio-Rad Laboratories, Spain) and the software QuantityOne (Bio-Rad Laboratories, Spain). The identities of individual lipid classes were confirmed by comparison with authentic standards.

The total length of the larvae was measured with a micrometer eye piece and whole body dry weight was determined by drying samples at 70 °C for several days until constant weight was attained. At the end of the trial, relative growth rate (RGR; [28]) was calculated for all treatment groups, as well as survival. Theoretical biomass was calculated as the product of survival by the mean weight of the larvae.

For muscle histology analyses complete transverse sections were cut from each fish at the level of the anal vent, washed in the fixation buffer, post-fixed in 1% osmium tetroxide, dehydrated, and embedded in TAAB resin according to Stickland et al. [29]. Transverse sections of 1 µm thickness were obtained using a Reichert ultramicrotome and stained with 1% toluidine blue. Slides were examined using a Zeiss image analysis system (KS 300, Kontron, Munich, Germany). White-muscle cross-sectional areas, small (less than 25 μm^2), and large (more than 25 μm^2) fibre numbers from a quadrant of each transverse section were quantified (as in 29).

Total lipid from larval tissues was extracted [25]. Separation of the polar lipid fraction and determination of its fatty acid profile in larvae samples were carried out as previously described.

A commercial cortisol enzyme-linked immunosorbent assay kit (ELISA; Neogen Corporation, Lexington, KY, USA) was used to assess whole-body cortisol levels in pooled larvae samples of about 20 mg (7 fish per sample). This was preceded by sample homogenisation in a phosphate buffered saline solution (PBS) and extraction with diethyl ether. The latter was performed following recommendations by Sink et al. [30] involving the addition of 100 µL of a food-grade vegetable oil per gram of sample body weight. Olive oil was used and previously assayed for cortisol to ensure no cross contamination would occur from animal fats. After extraction and solvent evaporation under a stream of nitrogen, lipid extracts containing cortisol were

reconstituted in the kit's extraction buffer, diluted to an appropriate factor and analysed according to the kit manufacturer's instructions. All samples and standards were run in duplicate. Intra- and inter-assay variation values were checked and a % CV of $\leq$20.0 was set as acceptable. Parallelism and linearity (passing limit $r^2 > 0.90$) were tested using serial dilutions of sample extracts.

For molecular analyses six larvae sampled from each tank were pooled, homogenised in Tri Reagent (Sigma, Poole, Dorset, UK) with an ultra-turrax (IKA, Werke GmbH & Co. KG, Staufen, Germany), and RNA extracted with chloroform followed by ethanol precipitation. Qiagen RNeasy columns (Qiagen, Crawley, UK) were used for DNase treatment and sample purification. Samples were eluted with Sigma Pure water (Sigma) and RNA concentration measured spectrophotometrically using a Nanodrop N-1000 system (Nanodrop Technologies, Wilmington, DE, USA). Formaldehyde gel electrophoresis was performed to determine the integrity of total RNA by analysing bands under UV light. Reverse transcription of sample RNA was performed with Quantitect Reverse Transcription Kit (Qiagen, Valencia, CA, USA) according to the manufacturer's instructions, using half a microgram of total RNA. The primers used were designed with the support of the Primer-3 Web-Software (Whitehead Institute for Biomedical Research, Cambridge, MA, USA) and synthesised by Eurofins MWG Operon (Ebersberg, Germany). Primer sequences and Accession numbers for the mRNAs analysed are described in Table 2. Genes analysed were GH, POMC, CB1 receptor, GR, HSL, FBPase, COX-2, and PKC. Real-time PCR, based on Quantitect Sybr Green detection (Qiagen), was performed on 2 µl cDNA samples, using a Chromo-4 Thermal Cycler (MJ Research Inc., Waltham, MA, USA). The relative concentrations of the target amplicons were calculated by the cycler's software (Bio-Rad, Hercules, CA, USA) from a standard curve created with serial dilutions of standard DNA. The relative concentrations of target sequences in each run were expressed as numbers of copies and normalised to 0.5 µg of total RNA. All PCR products were checked for specificity and purity from a melting curve produced by the thermal cycler software at the end of each run.

Statistical Analysis

Data were analysed by a two-way ANOVA with SPSS 16.0 software package using diet and stocking density as fixed factors. For data not presenting a normal distribution and/or variance homogeneity, log-transformation was applied. Differences were considered significant at an alpha level of 0.10 due to both small sample sizes caused by feasibility constraints, and the exploratory character of this experiment, as recommended by Rubin [31].

Results

Proximate composition of the experimental diets (dry matter basis) showed high protein content (69–70%) and lipid levels around 17–18% (Table 1). Saturated fatty acids and n-3 series polyunsaturates, particularly docosahexaenoic acid (DHA, 22:6n-3), were higher in the ML diet, whereas the SBL diet contained higher levels of linoleic (18:2n-6) and linolenic (18:3n-3) acids, as shown in Table 3. Concerning dietary polar lipid fractions, the levels of palmitic (16:0), eicosenoic (20:1n-9), and eicosapentaenoic (EPA, 20:5n-3) acids, as well as DHA, were more elevated in the ML diet than in the SBL treatment, whereas the latter presented a considerably higher content in linoleic acid than the ML diet.

At 32 DAH, larvae weighed 0.3 ± 0.0 mg and were about 7.9 ± 0.2 mm long. Although classic growth performance analysis was not a main objective of this study due to its short duration, data relative to larval dry weight, total length and relative growth rate (RGR) at the end of the experiment are presented (Table 4), along with survival and theoretical biomass results. No significant interaction effects between diet and stocking density were detected for these parameters. Statistical analyses revealed dietary effects on dry weight, total length and RGR, such that values obtained for ML fed larvae were higher than those presented by SBL fed groups. Groups offered the SBL treatment showed actual weight loss during the one-week period whereas animals fed on the ML diet grew at about 3.6–3.8% per day. Nonetheless, high variation was observed between replicate tanks with the ML-L treatment. Although the SBL diet seemed to compromise growth,

survival was not affected. Mortality occurred in all treatments, especially until around day 5 in "H" groups which resulted in lower stocking densities at the end of the experiment than initially established (Fig. 1). Overall, survival was lower in groups kept at the higher stocking density (54.2–59.5%) than in "L" groups (77.5–80.8%). Theoretical biomass decreased with both larval density ($P = 0.072$) and the SBL regime ($P = 0.092$).

Results from muscle histology analysis are shown in Table 5 and revealed no significant interaction effects between diet and stocking density for any of the measured parameters. Measurements of the cross-sectional area of a quadrant of fish muscle (Fig. 2) did not reveal statistical differences between treatments. Nonetheless, average values were between 37.4 and 42.1 mm^2 for fish stocked at low density, whereas those at high density showed average areas of 30.8–33.6 mm^2. Histological analysis of white muscle showed dietary effects on the total number and density of small fibres but not of large fibres. As such, fish fed the SBL diet showed about 28% less small fibre number and density compared to those fed the ML diet. Overall, histological analysis pointed to a higher growth potential in seabream supplied with ML as compared to SBL groups.

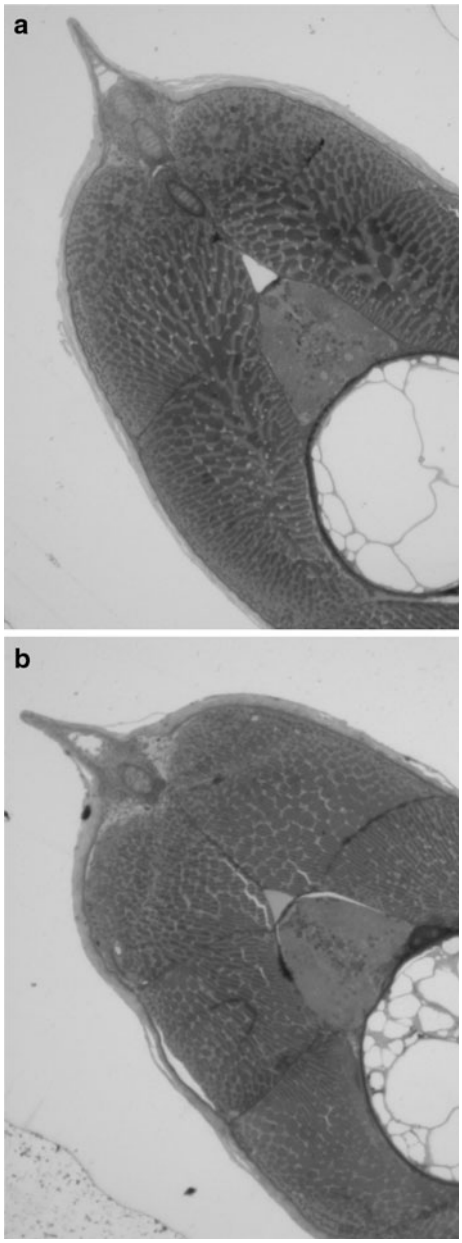

Fig. 2 Transverse sections through gilthead seabream larvae from ML-L (**a**) and SBL-L (**b**) experimental groups stained with 1% toluidine blue (20×)

Lipid content and total fatty acid composition of the larvae are described in Table 6. Total lipid content revealed a significant interaction effect between diet and stocking conditions such that slightly higher levels were found in SBL-H than SBL-L fish, whereas values were very similar between ML diet groups. Deposition of 18:2n-6 was higher in fish fed SBL than in ML fed groups. Also, slightly higher levels of 18:1n-9, 18:1n-7 and 18:3n-3 were detected in SBL fed animals, whereas ML fed fish showed larger accumulation of arachidonic acid (ARA, 20:4n-6) and EPA than SBL groups. Analyses of the polar lipid showed statistically significant interaction effects between diet and stocking density for 18:0, 20:1n-9, and 18:3n-3. Higher stocking density conditions resulted in increased total saturated fatty acid (SAFA) levels, particularly 18:0 in SBL fed groups (Table 7), and a reduction of total PUFA, especially DHA. Differences were also found due to dietary treatments. Linoleic and linolenic acids were higher in the polar lipid of SBL than ML fed animals, whereas ARA remained highest in ML fed fish. Contrary to findings in the total lipid fatty acid profile, EPA was kept at similar levels in all treatment groups. Besides, unlike the trend observed in dietary composition, DHA deposition in the larvae was apparently unaffected by its dietary content.

Whole-body cortisol analysis did not show a significant interaction effect between diet and stocking density or statistical differences between treatments. Results are presented in Fig. 3. Average values were about 8.0 ng g^{-1} (larval wet weight) in fish stocked at high density. In ML-L and SBL-L groups, average cortisol levels were 12.4 and 9.0 ng g^{-1}, respectively. Displacement curves for cortisol standards and sample serial dilutions are presented (Fig. 4a). Validation tests for the ELISA involving a vegetable oil volume-boosting method showed values of 5.07% for intra-assay coefficient of variation (% CV) and 18.7% for inter-assay CV. Linearity r^2 value was 0.9997 and parallelism was confirmed (Fig. 4b).

Results of the molecular analyses of gene expression are presented in Fig. 5. No significant interaction effects between diet and stocking density were identified for any

Values are means ± SD. Significant effects determined by two-way analysis of variance indicated by $*P < 0.10$ or *NS* not significant. Values referred for larvae initial fatty acid composition were based on typical values reported by Robin and Vincent [60] for 3 dph gilthead seabream

of the genes analysed. Quantification of mRNA for GH, POMC, CB1 receptor, FBPase, COX-2, and PKC showed no significant differences under the experimental conditions tested. Nonetheless, the expression of HSL and GR genes was up-regulated in SBL groups compared to ML fed larvae, whereas no statistical differences were found due to stocking density.

Discussion

Early life stages in gilthead seabream are characterised by hyperplastic growth of white myofibres [32, 33]. Small muscle fibres are evidence of ongoing fibre hyperplasia in fish muscle. This appears to have been less in fish fed the SBL diet than in those supplied with ML, which indicates hindered growth potential in the former although essential fatty acid requirements were met for the species, according to recommendations by Sargent et al. [34] and Castell et al. [35]. These authors point at n-3 HUFA requirements of about 1.5% of the diet when the ratio DHA/EPA is about 2, and ARA levels between 0.5 and 1.0% of total dietary fatty acids, respectively. On the other hand, survival was not affected by dietary lecithin source. Instead, high stocking density increased mortality, which was also related to higher levels of saturated fatty acids, particularly stearic acid (18:0), and lower DHA in the polar lipid fraction than found in "L" groups. Thus, we hypothesise that membrane fluidity might have been affected in "H" groups which could have disturbed the activity of membrane-bound enzymes, ion channels, or receptors and led to higher mortality. The reasons why high density stocking would cause the observed changes in polar lipid fatty acids are unclear but results suggested that seabream larvae might have a higher requirement for DHA under such rearing conditions.

In gilthead seabream larvae, 5% dietary SBL inclusion as provided in the present study was reported to increase microdiet consumption rates perhaps due to an attractant effect [36]. In another study, elevation of dietary polar lipid levels improved microdiet ingestion in seabream, regardless of its soybean or marine origin [37]. Although feed consumption was not determined in this experiment, similar survival between dietary treatments and the fact that whole-body fatty acid composition mirrored differences between diets indicated the acceptance of the experimental

diets. Therefore, the detrimental effects observed on growth performance could be attributed to dietary lecithin origin. Surprisingly, despite numerous publications reporting the importance of dietary phospholipids for fish larvae, no studies have been published on the viability of SBL use as compared to ML containing diets in marine species. The efficiency of HUFA supplied through diet under the phospholipid form in sustaining growth, as exemplified in this study, is generally recognised [2]. However, the reasons for this are yet unclear. Perhaps due to improved digestibility, marine phospholipids tend to be more efficient in supplying essential fatty acids than neutral lipids, although in freshwater fish SBL seems to satisfy larval phospholipid requirements [1].

As expected, dietary fatty acid composition was reflected in fish tissues. In SBL diet fed groups a significant increase in linoleic acid was noted in both total and polar lipids, concurrent with a decrease in ARA, relative to ML fed larvae. Besides potential effects on cell membrane lipid composition and function, dietary fat has profound effects on gene expression. Polyunsaturated fatty acids and their metabolites can act in conjunction with nuclear receptors and transcription factors to affect the transcription of a variety of genes [7] leading to changes in metabolism, growth and cell differentiation [6]. Thus, diet induced changes in gene expression could provide indications as to mechanisms by which dietary fatty acids could have regulated metabolism in larvae fed distinct lecithins.

Each point is the mean of duplicate determinations

Despite the absence of differences between treatments for whole-body cortisol concentrations, which were in accordance with values reported by Szisch et al. [1] for seabream, GR mRNA levels were higher in SBL diet fed fish. A similar trend was noted for HSL which has been identified as a glucocorticoid-sensitive gene in mammals [38], containing glucocorticoid responsive elements (GREs) in its promoter [39, 40]. This is also likely in fish as enhanced lipolytic activity and increased free fatty acid levels in the plasma are generally associated to the stress response (reviewed by Mommsen et al. [12]). HSL catalyses the rate-limiting step in fatty acid mobilization from stored triglycerides, determining the supply of energy substrates in the body [41]. A relative up-regulation of this enzyme in SBL fed fish could hinder or even impair growth as observed due to energy deviation away from anabolic metabolism. The observed effects on larval growth were not determined by differences in the gene expression of GH, the main regulator of postnatal somatic growth stimulating cell division, skeletal growth, and protein synthesis. GH can also enhance lipolysis in starved fish, as seen in seabream adipocytes [42]; however, feeding conditions did not differ among experimental groups and HSL results did not appear to be influenced by GH as its mRNA levels indicated.

Although GR mRNA and protein expression are not always correlated, as seen in rainbow trout [43] no such information is currently available for gilthead seabream. Present results suggested an effect of dietary fatty acid supply on the regulation of GR gene expression regardless of values detected by whole-body total cortisol analyses. Indeed, cortisol plasma concentrations may not always be correlated to cytosolic GRs [44], and increased intracellular concentrations of glucocorticoids can result from overexpression of 11-β hydroxysteroid dehydrogenase type 1 (11βHSD1; [45]) which converts cortisone to cortisol. Thus, both protein levels of this enzyme and GRs can determine the physiological activity of glucocorticoids. Several possible pathways for the modulation of GR gene expression by fatty acids may exist. Nuclear factor-kappa B (NF-κB), a GR transcription factor [46], can be activated in the presence of linoleic and oleic acids, as seen in rats [47], and may have contributed for the enhancement of GR expression in larvae fed the SBL diet. Peroxisome proliferator-activated receptors (PPARs), probably the best known factors in fatty acid regulation of gene transcription, also interact with NF-κB and AP-1 [48], both transcription factors for GRs (reviewed by Yudt and Cidlowski [49]). Indeed, linoleic acid was reported to be a potent PPAR activator relative to other fatty acids [50]. Another hypothesis for GRs fatty acid modulation is that ARA could bind these receptors at sites different from those bound by steroids, hence inhibiting their activity [51]. Dose-dependent suppression of GR binding has been reported for various unsaturated fatty acids likely as part of a negative feedback mechanism [52]. Nonetheless, in this study, seabream larvae showing lower GR and HSL transcripts presented only slightly higher ARA levels in body lipid.

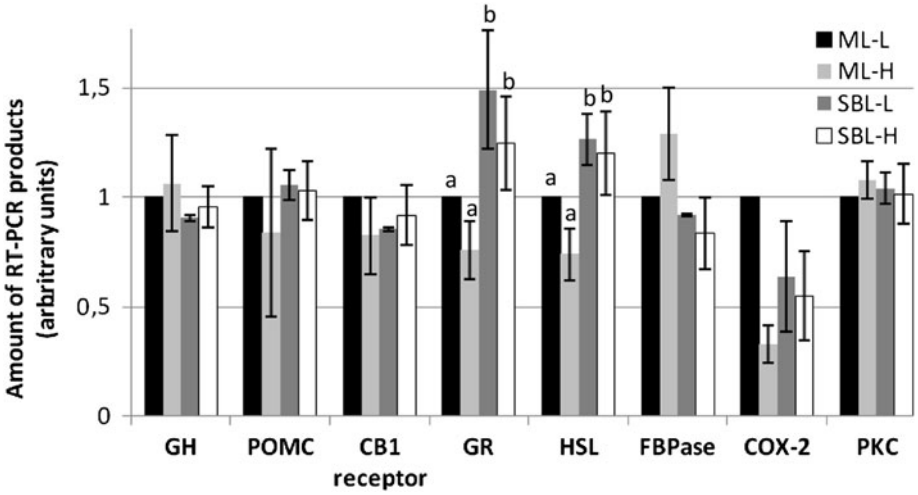

Fig. 5 Expression of genes using real-time PCR and SyBR green detection in gilthead seabream larvae submitted to the experimental conditions. The mRNA levels relative to ML-L treatment were arbitrarily defined as 1 unit. Data are expressed as means ± SE. Different letters mean significant differences ($P < 0.10$). *GH* growth hormone, *POMC* pro-opiomelanocortin, *CB1 receptor* cannabinoid CB1 receptor, *GR* glucocorticoid receptor, *HSL* hormone-sensitive lipase, *FBPase* fructose-1,6-bisphosphatase, *COX-2* cyclooxygenase-2, *PKC* protein kinase C

The gene expression of POMC which encodes for ACTH in gnathostomes was analysed due to the central role of ACTH on cortisol production. POMC gene expression results corroborated those obtained from cortisol measurements, further suggesting that the differential expression of the GR gene was not determined by fatty acids at the hypothalamus–pituitary–interrenal (HPI) axis level.

PKC has important roles in various biological processes (e.g., signal transduction, cell proliferation) including the tonic inhibitor control of steroidogenesis as reported in mammal cells stimulated by intracellular ARA [15, 16, 53]. In this study, results do not indicate that PKC was involved in maintaining similar cortisol levels between groups. In fact, PKC gene expression was so identical among samples and experimental conditions that it could potentially be used as a control gene in future studies with seabream, as suggested in humans [54].

An acute stress challenge could be required for the release of ARA in the cells and further evidencing effects of dietary fatty acid supply on the expression of stress response related genes. This could be underlying the lack of differences regarding PKC as well as COX-2 gene expression between treatments which did not appear to relate to the observed results regarding both GR and HSL genes. In fish, the endocannabinoid system is thought to be involved in the modulation of adaptive responses to environmental conditions [55]. For example, under non-stressful conditions, production of 2-AG (2-arachidonoylglycerol) is higher than in stressed animals, leading to CB1 receptor up-regulation, which depresses hypothalamus–pituitary–adrenal (HPA) axis activity in mammals [56]. Several lines of evidence indicate that, through CB1 receptor activation, endocannabinoids can also regulate NF-κB and AP-1 activities [57, 58], thus potentially interfering with GR activity and the stress response. The lack of differences between experimental groups was in accordance with results obtained for other analysed genes, like COX-2 and PKC further suggesting that the influence of dietary lecithin on GR and HSL genes was exerted, in non-acutely stressed larvae, at the level of GR activation through factors independent from the classic HPI axis regulation.

Gluconeogenesis, in which FBPase is a key enzyme, is responsible for glucose production in response to cortisol [12]. It is assumed that glucocorticoids stimulate gluconeogenesis by increasing PEPCK (phosphoenolpyruvate carboxykinase) gene transcription which contains a GRE, or by stimulating the supply of hepatic precursors (reviewed by Mommsen et al. [12]). Thus, both higher GR expression and lipolytic activity could have contributed to enhance gluconeogenesis; instead, statistically similar FBPase mRNA levels found between groups suggested a more dramatic increase in GR activity could be required to affect gluconeogenesis enzyme activities, as this is usually associated with a rise in plasma cortisol levels.

In summary, changes induced in body fatty acid phenotype through dietary SBL supply exerted a lipolytic effect, compared to ML fed fish, possibly mediated by GR activity, which could have contributed importantly for the detrimental effects observed on growth with the SBL diet. Furthermore, the proposed regulation of GR activity by fatty acids seems to have been independent from the action of the HPI axis, the endocannabinoid system, COX-2

activity, and did not appear to affect gluconeogenesis. On the other hand, no effects of rearing density were found in terms of the expression of genes analysed in this study, although rearing conditions are generally known to interfere with neuroendocrine homeostasis in fish.

The importance of dietary fatty acids on stress coping ability has been repeatedly demonstrated in fish larvae although with limited understanding of the physiological mechanisms involved. Studies regarding fatty acid control over fish GRs are scarce [59] despite their major role in linking and integrating signaling pathways and regulatory processes in cells, tissues, and whole organisms [49]. This aspect is not only relevant in marine fish larval nutrition but should be considered in dietary fish oil replacement research, a recognised priority for the sustainable production of farmed fish.

Acknowledgments The authors wish to thank Ms. Rosa Vázquez (Marine cultures service, University of Cádiz, Spain) for supplying the seabream eggs, Dr. Luísa Valente (Centro Interdisciplinar de Investigação Marinha e Ambiental, Portugal) and Mr. Manuel Arjonilla Medina (Analysis service of Instituto de Ciencias Marinas de Andalucía, CSIC, Spain) for kindly assisting in dietary composition analysis, and Dr. Gonzalo Martínez-Rodríguez (Instituto de Ciencias Marinas de Andalucía, CSIC, Spain) for the help provided during the experimental system set-up. Also, the authors acknowledge Noelia Gras and Marta Sastre (Centro de Acuicultura, IRTA, Spain) for the help provided in lipid extraction, lipid class and fatty acid analysis of the samples. Dulce Alves Martins was funded by Fundação para a Ciência e a Tecnologia, Portugal (SFRH/BPD/32469/2006). This study was funded by Consejería Innovación, Ciencia y Empresa, Junta de Andalucía (Spain) which is co-financed by FEDER (project P06-AGR-01697 to M. Yúfera). Publication benefits from participation in LARVANET COST action FA0801.

with enlargement (hypertrophy) of adipocytes, macrophage accumulation and subsequent changes in the production of bioactive proteins or adipokines to favor a more pro-inflammatory profile [3–5]. These changes are associated with obesity-related health problems, the development of metabolic syndrome and an increased risk of cardiovascular disease [6–8]. Some of the pro-inflammatory adipokines involved in pathogenesis of these diseases include angiotensinogen, tumor necrosis factor (TNF)-α and interleukin (IL)-6.

All components of the renin–angiotensin system (RAS), including angiotensin II (AngII) and its precursor angiotensinogen, are present in adipose tissue and this local RAS has been implicated in the regulation of adipose growth as well as the regulation of blood pressure [9, 10]. In support of this argument, mice that selectively over-express angiotensinogen in adipose tissue exhibit an increase in circulating angiotensinogen and are hypertensive [9]. Upon binding to its receptor, AngII also stimulates pro-inflammatory cytokines through the activation of nuclear factor-κB (NF-κB) [11], which further contributes to the pathogenesis of cardiovascular complications [12].

Due to the large increases in obesity-related cardiovascular complications, the need for preventative strategies is at an all time high. The use of dietary compounds to prevent or treat obesity-related cardiovascular risk factors may be an attractive idea for some. Conjugated linoleic acid (CLA) is a fatty acid derived from ruminant animals that is being examined for its potential health benefits [13]. Our laboratory has shown that feeding a mixture of CLA isomers to obese *fa/fa* Zucker rats favorably alters levels of adipokines in serum and epididymal adipose tissue, and at the same time reduces adipocyte size [14]. A recent study by Martins et al. [15] also showed increased serum adiponectin levels in obese Zucker rats given a mixture of CLA isomers and the potential for other cardiovascular benefits such as lowered plasminogen activated inhibitor-1 levels. At this time, however, it remains unclear which CLA isomer is responsible for reducing adipocyte size in an obese model and if other adipose-derived proteins may be affected. Research from other groups suggest that the t10,c12-CLA isomer may be responsible for the cardiovascular benefits, such as improving blood pressure by reducing adipose angiotensinogen mRNA [16]. At this point, however, it remains unclear whether these changes in angiotensinogen mRNA will affect angiotensinogen protein levels or if CLA would have an effect on AngII receptors. Additionally, previous studies examining CLA and NF-κB have primarily been carried out in culture models [17, 18], leaving the effects of CLA isomers in vivo on NF-κB activation in tissues still to be determined. This study was therefore designed to investigate the effects of individual CLA isomers on epididymal adipocyte size and to examine the relationship with the local adipose RAS in obesity. The study focused on epididymal adipose tissue as a visceral adipose depot because visceral adiposity is associated with metabolic complications of obesity and cardiovascular disease and is strong predictor of obesity-related risk factors and mortality [19, 20].

Materials and Methods

Animals and Diet

During an 8-week experimental period, 6-week old male *fa/fa* Zucker rats ($n = 6$/group; Harlan, Indianapolis, IN, USA) received diets based on the AIN-93 formula differing in the amounts of CLA isomers as previously published [21]. There were three groups (a) control diet (b) 0.4% (w/w) *cis*(c)9,*trans*(t)11-CLA diet, and (c) 0.4% (w/w) t10,c12-CLA diet. At the end of the feeding period, rats were euthanized by CO_2 asphyxiation and epididymal adipose tissue was dissected, frozen in liquid nitrogen or Cryogel embedding medium and subsequently stored at −80 °C until analyzed. The University of Manitoba Protocol Management and Review Committee approved the animal protocol which was in agreement with the Canadian Council on Animal Care Guidelines [22].

Morphometry

Tissues sections (10 μm thick) were cut on a cryotome and mounted on SuperFrost Plus glass slides. Sections were fixed in formaldehyde and assessed under a light microscope (BH2-RFCA; Olympus) equipped with a camera (Q-Imaging). Using Image J software as previously described [14], a continuous block of 25 cells was measured in every field to determine average cell size (μm^2) and mean adipocyte size per group was calculated. Based on Sturges' rule [23], 10 different classes of adipocyte area were determined and the cell size distribution for each treatment group was expressed as a percentage. The number of adipocyte was assessed by counting a 160 μm^2 area in the centre of each field/section and the mean number per group was calculated.

RT-PCR Analysis

Total RNA was isolated from epididymal adipose tissue using TRIzol reagent. The concentration of RNA and the purity of the samples were assessed spectrophotometrically. RNA was digested with DNase, reverse transcribed into cDNA and amplified with an Access RT-PCR system kit (Promega). Primer sequences for detection of angiotensinogen, AngII receptor1a, AngII receptor1b, TNF-α, IL-6,

F Forward primer, *R* reverse primer

IL-10 and ribosomal protein L32 (rpL32) mRNA can be found in Table 1. In view of the fact that high levels of pro-inflammatory mediators have been linked to obesity and CLA is considered effective against obesity [24], we also examined the anti-inflammatory mediator IL-10. cDNA products were run on an agarose gel, visualized with Vista Green Nucleic Acid Stain and relative intensity of the bands was quantified by densitometry. Results are expressed as arbitrary units after normalization to rpL32 expression.

Protein Extraction and Western Blotting

The bicinchoninic acid assay (Pierce) was used to determine total protein in samples isolated from adipose tissue using a mortar and pestle and 3× sodium dodecyl sulfate sample buffer. Adipose samples (15 μg protein) were analyzed by Western blotting as described previously [25] with antibodies (diluted 1:1,000) for angiotensinogen (Fitzgerald), AngII receptor 2 (Santa Cruz), TNF-α (Cell Signaling), IL-6 (Biosource), IL-10 (Biosource), NF-κB (Cell Signaling), F4/80 (Abcam) and total mitogen-activated protein kinase (MAPK) (Cell Signaling). The latter was used to account for possible variability in sample loading. Autoradiography and scanning densitometry with Quantity One image analysis software (BioRad) were used to capture and quantify band intensities.

NF-κB Activation

Nuclear extracts from epididymal adipose tissue samples were prepared using a Nuclear Extract Kit according to manufacturer's instructions (Active Motif). NF-κB binding activity was determined using a TransAM NF-κB Transcription Factor ELISA Kit according to manufacturer's instructions (Active Motif).

Statistical Analysis

Data were analyzed with Statistical Analysis Software (SAS 6.04; SAS Institute, Cary, NC, USA) to examine the effect of diet on cell size, mRNA and protein levels by a one-way analysis of variance (ANOVA) followed by Duncan's multiple range test. Differences were considered significant at $P < 0.05$ and all results are expressed as means ± standard error (SEM).

Results

Growth Performance and Feed Intake

There were no significant differences in body weight gained (control 433 ± 10 g; c9,t11-CLA 452 ± 9 g; t10,c12-CLA 453 ± 8 g) or epididymal adipose mass (data not shown) among groups. Likewise, daily food intake was similar among groups (control 27.2 ± 0.5 g/day; c9,t11-CLA 28.8 ± 0.6 g/day; t10,c12-CLA 28.9 ± 0.4 g/day).

Adipocyte Size

Previously we reported that a mixture of CLA isomers reduced adipocyte size [14], however, the contribution of the individual CLA isomers was not investigated. Therefore, the current study was designed to examine the effect of individual CLA isomers on adipocyte size. The group receiving the t10,c12-CLA isomer had 60% smaller adipocytes compared to the control and c9,t11-CLA groups (Fig. 1a, b). The distribution pattern of cell size shows that 80% of adipocytes in the t10,c12-CLA isomer group were <2,000 μm^2, with less than 2% of cells >5,000 μm^2, whereas the control group and the c9,t11-CLA group had a

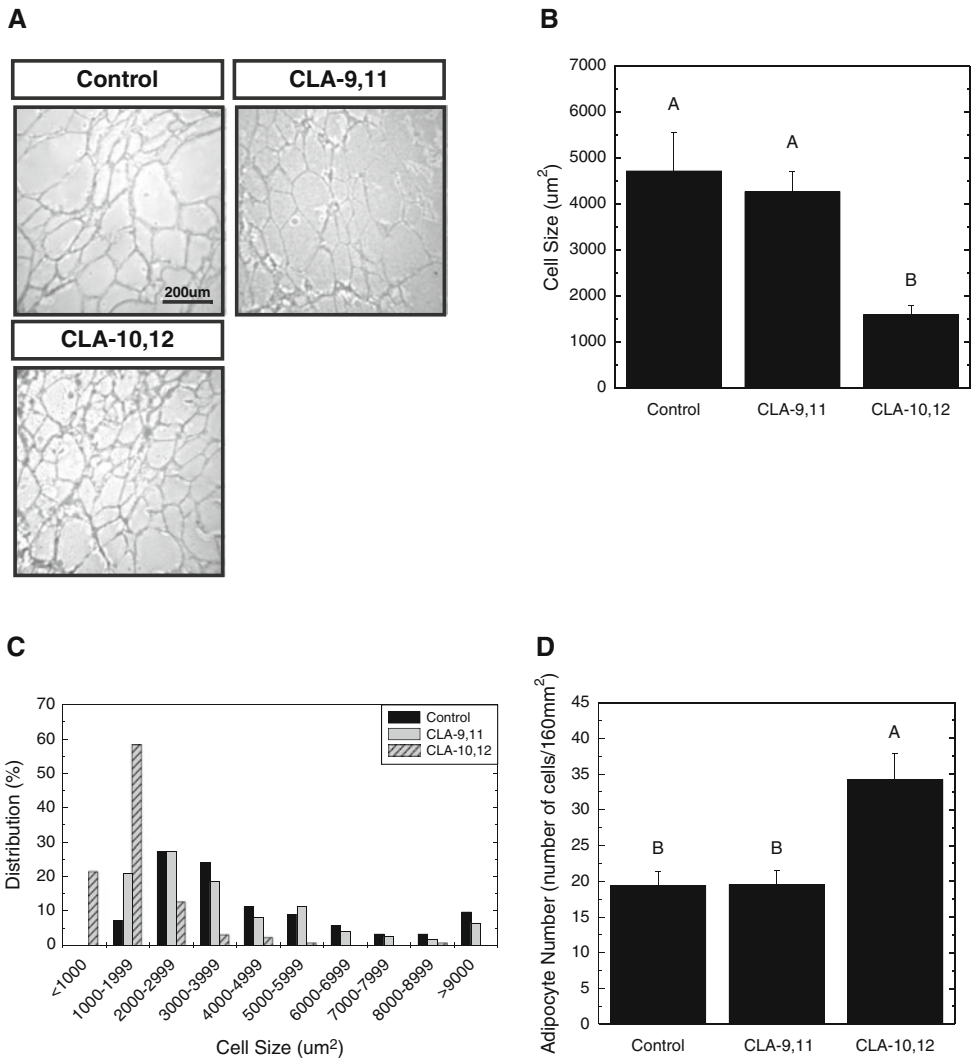

Fig. 1 Morphometry of epididymal adipose tissue from *fa/fa* Zucker rats fed CLA isomers for 8 weeks (n = 5/group). Adipocyte size (**a**) was quantified for each treatment group and cell size (**b**) is reported in μm^2 for the overall mean ± SEM. The distribution of adipocyte size (**c**) in each treatment group is also shown. Number of adipocytes (**d**) for each treatment group is reported as overall mean number of cells ± SEM per 160 mm^2. Means with different letters are significantly different ($P \leq 0.05$) as determined by Duncan's multiple range test. Control, *fa/fa* Zucker rats fed 0% CLA; CLA-9,11, *fa/fa* Zucker rats fed 0.4% c9,t11-CLA; CLA-10,12, *fa/fa* Zucker rats fed 0.4% t10,c12-CLA

53–63% of cells in the 2,000–5,000 μm^2 range and more than 25% of the cells were in excess of 5,000 μm^2 (Fig. 3c). The group receiving the t10,c12-CLA isomer also had 43% more adipocytes compared to the control and c9,t11-CLA groups (Fig. 1d).

Adipokines in Adipose Tissue

It is suggested that adipocyte size alters the production of adipokines [3–5] and because the t10,c12-CLA isomer reduced adipocyte size we decided to explore the adipokine status in the adipose tissue. Unexpectedly, the AngII precursor angiotensinogen was not changed at the gene (Fig. 2a) or protein level (Fig. 3a) in the adipose tissue of the rats fed CLA isomers. There was also no change in AngII receptors (Figs. 2e, f, 3b). Similarly, TNF-α, IL-6 and IL-10 mRNA were unchanged with CLA isomers (Fig. 2b–d). Likewise, protein levels of TNF-α, IL-6 and IL-10 were similar among all groups (Fig. 3c–e). Because macrophage infiltration occurs in obesity and contributes to the pro-inflammatory state of adipose tissue [5], the macrophage marker F4/80 was examined. None of the diets influenced the levels of macrophages within the adipose tissue (Fig. 4a).

NF-κB Activation

Given that NF-κB regulates many genes involved in inflammation [11], we next examined the levels of phosphorylated NF-κB and its promoter binding activity in epididymal adipose tissue. Neither CLA isomer affected either NF-κB phosphorylation (Fig. 4b) or DNA binding (Fig. 4c).

Discussion

The current study has demonstrated that feeding t10,c12-CLA to obese *fa/fa* Zucker rats reduces epididymal adipocyte size and increases cell number. The effect of CLA

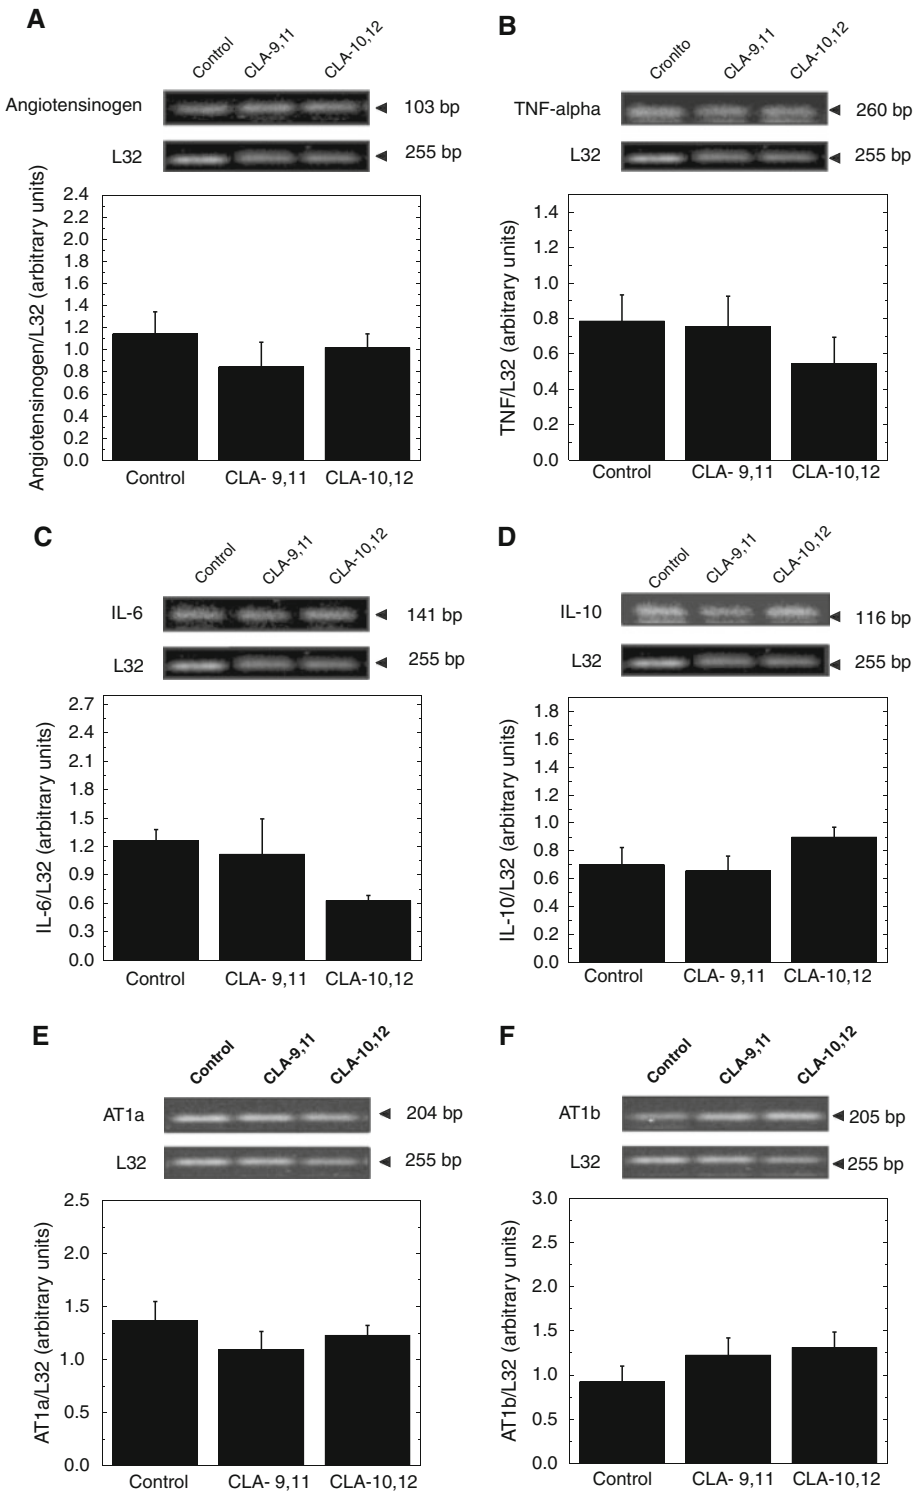

Fig. 2 Epididymal adipose tissue mRNA levels of angiotensinogen (**a**), TNF-α (**b**), IL-6 (**c**), IL-10 (**d**), AT1a (**e**) and AT1b (**f**) in *fa/fa* Zucker rats ($n = 6$/group). mRNA was analyzed using RT-PCR. The relative intensity of the bands was quantified by densitometry and normalized to that of ribosomal protein L32. Representative gels are shown for each plot. Data are presented as means ± SEM. No significant differences ($P > 0.05$) were detected by ANOVA. Control, *fa/fa* Zucker rats fed 0% CLA; CLA-9,11, *fa/fa* Zucker rats fed 0.4% c9,t11-CLA; CLA-10,12, *fa/fa* Zucker rats fed 0.4% t10,c12-CLA; AT1a, AngII receptor type 1a; AT1b, AngII receptor type 1b; L32, ribosomal protein L32; bp, base pair

on adipocyte size in rats has previously been examined with either a mixture of CLA isomers [14, 26] or single isomers in a non-obese model [27]. Earlier work examining the effects of CLA mixtures on adipocyte size revealed that other types of fat in the diet may influence the effects of CLA [14, 26, 27]. For example, rats consuming diets based on a soybean oil background and supplemented with a mixture of CLA isomers have reduced cell size [14, 26], whereas the effects of CLA are lost when the background consists of saturated palm oil [27]. In the same study that used palm oil, isomer specific effects were also examined and the c9,t11-CLA isomer increased adipocyte size and

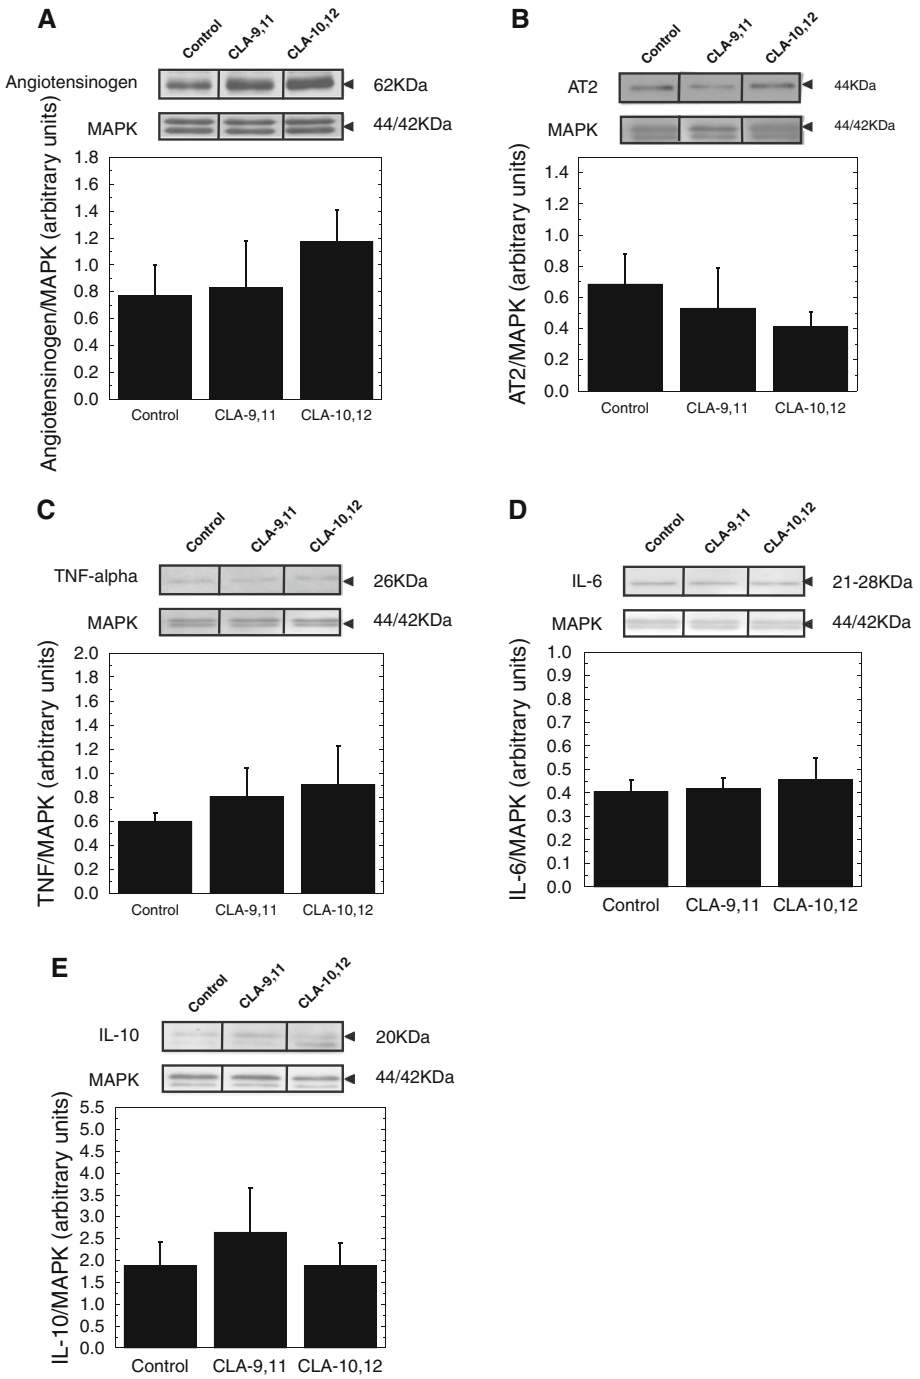

Fig. 3 Epididymal adipose tissue protein levels of angiotensinogen (**a**), AngII receptor type 2 (**b**), TNF-α (**c**), IL-6 (**d**) and IL-10 (**e**) in *fa/fa* Zucker rats ($n = 4$–6/group). Protein levels were measured using Western blot analysis. The relative intensity of the protein bands was quantified by densitometry and normalized to that of MAPK. Representative Western blots are shown for each plot. Data are presented as means ± SEM. No significant differences ($P > 0.05$) were detected by ANOVA. Control, *fa/fa* Zucker rats fed 0% CLA; CLA-9,11, *fa/fa* Zucker rats fed 0.4% c9,t11-CLA; CLA-10,12, *fa/fa* Zucker rats fed 0.4% t10,c12-CLA; AT2, AngII receptor type 2

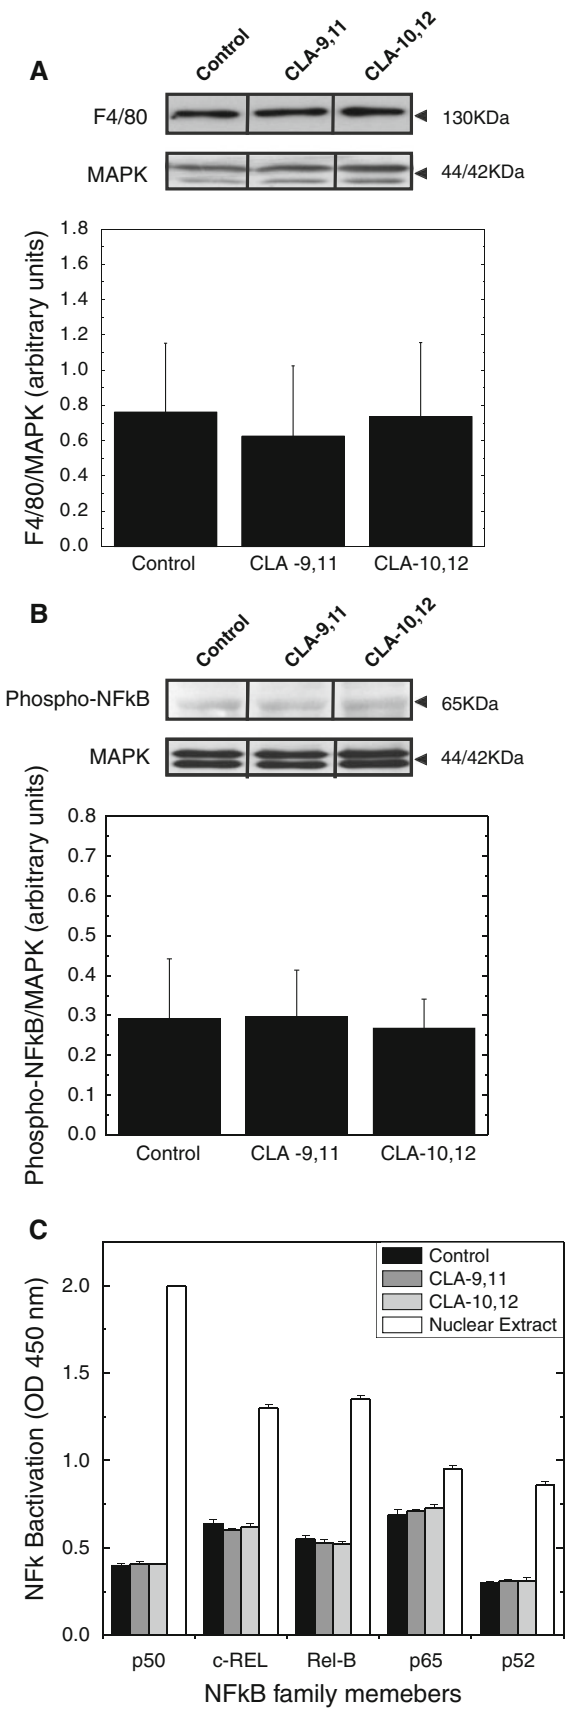
consequently decreased the number of adipocytes per unit of area in the inguinal and retroperitoneal depots of Wistar rats [27]. The increase observed with the c9,t11-CLA isomer was abolished when a mixture of CLA isomers was provided [27], suggesting t10,c12-CLA may have beneficial effects for reducing cell size. Lopes et al [27] also showed rats receiving the t10c12-CLA isomer had significantly more adipocytes per unit area compared to the group receiving the c9,t11-CLA isomer. In agreement with this hypothesis, our study demonstrated that the t10,c12-CLA isomer is responsible for reducing cell size and increasing adipocyte number. Additionally, because earlier work in *fa/fa* Zucker rats fed a mixture of CLA isomers demonstrated that reduced adipocyte size was associated with altered adipokines, we wanted to test if the beneficial changes in adipocytes size observed with the t10,c12-CLA isomer also produce changes in local adipose RAS and cellular adipokine status.

Evidence suggests that obesity-related complications may be due in part to the activation of a local RAS in



◀ **Fig. 4** Epididymal adipose tissue F4/80 (**a**), phosphorylated NF-κB levels (**b**) and NF-κB binding activity (**c**) in *fa/fa* Zucker rats ($n = 6$/group). Protein levels were measured using Western blot analysis. Relative intensity of the protein bands was quantified by densitometry and normalized to that of MAPK. A representative Western blot is shown. Activation of NF-κB was measured with TransAM ELISA kits (Active Motif). Data are presented as means ± SEM. No significant differences ($P > 0.05$) were detected by ANOVA. Control, *fa/fa* Zucker rats fed 0% CLA; CLA-9,11, *fa/fa* Zucker rats fed 0.4% c9,t11-CLA; CLA-10,12, *fa/fa* Zucker rats fed 0.4% t10,c12-CLA; nuclear extract, positive control

adipose tissue [9, 28, 29], however, in the current study, no significant differences were detected in adipose angiotensinogen levels or AngII receptors of CLA fed rats. To our knowledge this is the first report describing the effect of CLA isomers on AngII receptors. In contrast, previous work showed OLETF rats fed the t10,c12-CLA isomer had suppressed angiotensinogen gene expression in peri-renal adipose tissue [16]. Furthermore, Hainault et al. [30] showed angiotensinogen levels were greater in inguinal adipocytes isolated from obese compared to lean Zucker rats. Perhaps assessment of angiotensinogen mRNA or protein levels in different adipose depots or different models may be responsible for the varying results. Epididymal adipose tissue was investigated in this study because alterations in adipokine levels in epididymal adipose tissue have been noted in this animal model [14]. We measured angiotensinogen protein levels in epididymal adipose tissue as well as peri-renal adipose tissue (data not shown), however, we were unable to detect any dietary effects on angiotensinogen levels in either depot. Additionally, it may be that a reduction in fat mass is required in rats to achieve changes in angiotensinogen mRNA [31, 32].

Despite observing changes in adipocyte size, we did not note any changes in adipokine status or macrophage inflammation in the epididymal adipose tissue. However, it is still possible that the inflammatory mediators produced in liver, spleen, or other tissues could affect changes observed with CLA supplementation. Gollisch et al. [33] examined exercise as a means to reduce cell size and inflammatory cytokines in Sprague Dawley rats, however, results showed that maintenance of a small adipocyte size by exercise did not alter IL-6 or TNF-α mRNA compared to sedentary rats with increased adipocyte size. Thus, lifestyle interventions aimed at altering adipocyte size to improve inflammatory adipokine status of rats require more investigation before conclusions can be drawn. In contrast, studies in mice and isolated human adipocytes have clearly demonstrated that the t10,c12-CLA isomer increases mRNA levels of IL-6 and TNF-α in adipose tissue [17, 34]. Unlike the rat model used in the current study, mice

(irrespective of their metabolic state) also display increased macrophage infiltration when given t10,c12-CLA or a mixture of CLA isomers [17, 35–37]. This study thus adds to the literature that has demonstrated differences in the inflammatory response between mice and rats when given the t10,c12-CLA isomer.

Previous work using cell culture models suggests that CLA isomers may be able to modulate NF-κB activity [18, 38, 39], thus to our knowledge this is the first study to examine phosphorylation and binding activity of NF-κB in adipose tissue after dietary intervention. Our results in obese rats show no effect of either CLA isomer on NF-κB phosphorylation or binding activity, however, these results were not unexpected given that levels of the inflammatory adipokines examined were unchanged by the treatments. In contrast to the current study, isolated human adipocytes treated directly with t10,c12-CLA isomer have increased TNF-α and IL-6 mRNA and this was associated with an increase in IκBα phosphorylation and NF-κB binding activity [18]. Likewise, increased NF-κB binding activity was demonstrated in human umbilical vein endothelial cells treated with either the c9,t11-CLA or t10,c12-CLA isomer [38]. In a mouse macrophage cell line (RAW264.7), however, a mixture of CLA isomers reduced phosphorylated IκBα and NF-κB binding activity [39]. Additionally, a significant increase in NF-κB activity is observed in murine myotubes treated with t10,c12-CLA isomer but not murine myoblasts [40]. Thus, it appears that differing results occur not only between obese rat and mouse models but also different cell types, emphasizing the need for more research in this area. Future work is necessary to determine cell and species-specific effects of CLA isomers, as well as determine if therapeutic strategies that reduce adipocyte size can directly alter adipokine production and secretion.

In conclusion, this study demonstrates that t10,c12-CLA is the isomer responsible for the reduction in adipocyte size that was observed in an earlier study using a mixture of CLA isomers in *fa/fa* Zucker rats [14]. The reduction in adipocyte size, however, did not alter components the local adipose RAS such as angiotensinogen and AngII receptors, or associated adipokines such as TNF-α, IL-6 and IL-10. Furthermore, CLA isomers have no influence on macrophage infiltration or NF-κB activity in the adipose tissue of obese Zucker rats. Therefore, further work is needed to determine if there are any functional changes in the adipocyte as a result of reduced cell size via t10,c12-CLA isomer treatment.

Acknowledgments We would like to thank Danielle Stringer and Lisa Rigaux for help with the animal care and the contribution of the St. Boniface Hospital and Research Foundation towards infrastructure support. Financial support for this study was provided by grants from Dairy Farmers of Canada (C.T. and P.Z.) and Canada-Manitoba Agri-Food Research and Development Initiative (C.T. and P.Z.), and a Natural Sciences and Engineering Research Council of Canada as postgraduate scholarship (V.D.).

morphologic alterations, including impaired body-weight gain, changes in body composition, hepatic steatosis and lipid changes, both in animals and humans [1]. In order to reverse the negative consequences of protein depletion, it is important to supply an adequate equilibrium of nutrients. In this regard, Kern et al. [2] have recently reported that it is not recommended to provide a high protein diet, and that the type and amount of dietary fat might play an important role in the nutritional intervention to overcome the protein deficit stage.

Conjugated linoleic acid is a group of positionally and geometrically conjugated dienoic isomers of linoleic acid produced by the biological and/or industrial hydrogenation/isomerization of fatty acids (FA) [3]. In natural fats, *c*9,*t*11-CLA is the main CLA isomer, while synthetic products commercially available for human consumption are composed of an equimolecular mixture of *c*9,*t*11-CLA and *t*10,*c*12-CLA as main sources of FA isomers. *c*9,*t*11-CLA has called the attention of many researchers for its anti-carcinogenic properties [4] and today there is evidence of the beneficial and detrimental effects of both isomers on humans and experimental animals [5–7]. Although it is well known that the effects of the individual isomers are different, most clinical studies were carried out with different commercial mixtures containing predominantly *c*9,*t*11-CLA and *t*10,*c*12-CLA [8]. Considering that the FDA has recently approved CLA as a 'Generally Recognized as Safe' (GRAS) category [9] (http://www.fda.gov/Food/FoodIngredientsPackaging/GenerallyRecognizedasSafeGRAS/GRASListings/ucm153908.htm), a measure that will foster the commercial production of food and beverages with CLA supplementation, we believe that the study of its functional properties is relevant. In terms of functional impact, these FA have displayed several bioactive properties such as decrease of body fat, increase of lean body mass and protection against muscle catabolism induced by endotoxins [10], mainly in animal models. In well-nourished animals, CLA can be incorporated into tissues [11] and metabolized [12]. By means of different biochemical mechanisms, CLA modulates the concentration of triacylglycerol (TAG) in liver, adipose tissue and plasma [13], regulates the oxidative status [14], affects some enzyme activities [15] and changes the hormonal and mediators milieu [16] in different species.

Many of the effects attributed to CLA, such as increase in lean body mass and regulation of lipid metabolism, suggest that CLA could play an important role in the recovery of the catabolic status, as reported in animals injected with lipopolysaccharide [17]. We have reported elsewhere [18] the potential beneficial effect of CLA on the recovery of protein malnutrition. Another factor benefitting recovery after protein depletion could be the intake of high-energy-density diets [1] by increasing the amount of dietary fat. In this sense, previous work from our laboratory [18] demonstrated that the intake of a commercially available CLA oil showed preventive effects on liver and adipose tissue lipid accumulation when administered in protein repletion diets with high (20%, w/w) fat content, although no effects were observed on nitrogen retention. Given these findings, the first aim of the present study was to investigate the effect of CLA oil at two different amounts of dietary fat on parameters related to TAG regulation in rats during protein repletion, specifically hepatic TAG secretion and circulating TAG removal. As these changes could be related to alterations in the FA profile of plasma and different tissues, the second objective of this study was to assess the incorporation of CLA and the potential alterations on FA composition in plasma, liver and epididymal white adipose tissue (EWAT) of protein repleted rats. On the other hand, it has been suggested that protein depletion could lead to an increase in oxidative damage by diminishing antioxidant defenses [19]. Free radicals have been implicated in the development of several nutritional and metabolic diseases such as dyslipidemia and obesity [20], and hepatic steatosis has also been related to the onset of liver lipid peroxidation [21]. Since polyunsaturated FA and CLA intake has been previously reported to influence the oxidative status [14, 20], the modifications of lipid profile and/or FA metabolism could impact on liver lipid peroxidation. Therefore, our third aim was to investigate the effect of CLA on the liver oxidative status in rats fed CLA at two different amounts of dietary fat in protein repletion.

Materials and Methods

Materials

Most nutrient compounds, including vitamins and minerals for diet preparations were chemical grade or better, with the exception of corn oil (Mazola, Argentina), sucrose, cellulose, and corn starch which were obtained from local sources. CLA rich oil was kindly provided by Lipid Nutrition B.V. (Wormerveer, The Netherlands). Standards, biochemical reagents and enzymes were obtained from Sigma Chemical Co. (St. Louis, MO, USA). ^{3}H-Triolein was acquired from Perkin Elmer (Boston, USA). The plasma TAG kit was purchased from Wiener Co. (Rosario, Argentina). All solvents and reagents used for the FA quantification were of chromatography grade and all the other chemicals used were at least ACS purity.

Preparation of Diets

The composition of diets is shown in Table 1 and was based on the American Institute of Nutrition Ad Hoc

Table 1 Composition of the experimental diets (g/kg diet)

Ingredient	LP	C	C + CLA	HF	HF + CLA

Committee recommendation (AIN-93G) [22]. The control (C) diet (1656.9 KJ/100 g) contained 20% of casein as protein source and 7% of corn oil (20% of energy) as dietary fat source. The LP diet contained 5% of casein, isocalorically balancing the protein with carbohydrates. High energy diets were achieved by increasing 2.86-fold the total dietary fat content. Therefore, in the HF diet, 13% of oil replaced an identical amount of carbohydrates, obtaining a hypercaloric diet (1928.8 KJ/100 g and 38.5% of energy as fat). CLA was included in an "oil mixture", which contained 85% of corn oil and 15% of CLA rich oil. Thus, CLA represented 1% (w/w) in the C + CLA diet and 2.86% (w/w) in the HF + CLA diet, securing a constant ratio between CLA and the linoleic acid (18:2n-6) provided by corn oil, given the fact that the competition between CLA and this FA could affect the action of the former [11]. Corn oil was replaced by this "oil mixture" in both the C + CLA and HF + CLA diets. The CLA rich oil chosen for the present study is commercially available for human consumption, composed of an equimolecular mixture of *c*9,*t*11-CLA and *t*10,*c*12-CLA as main sources of isomeric FA. All diets exceeded the essential FA recommendations. The FA composition of corn oil and the "oil mixture" as methyl esters was determined by gas chromatography (GC) using the same procedure indicated below, as shown in Table 2. Each diet was freshly prepared every 3 days throughout the experimental period.

Animals and General Protocol

All the studies were conducted in agreement with the regulations of the School of Biochemistry, Guide to the Care and Use of Experimental Animals of Laboratory [23]. Experiments were carried out on male Wistar rats provided by the "Comisión Nacional de Energía Atómica" (Buenos Aires, Argentina) which were housed in the animal quarters. During the experimental period, they were kept under controlled conditions (23 ± 2°C and a 12-h light–dark cycle). For 2 weeks, the animals had free access to water and to the control (C) diet with recommended levels of nutrients [22], until they reached 100–110 g of body weight. A basal (B) group was formed with six of these animals. In order to obtain the basal values of some metabolic parameters, they were then weighed and sacrificed (9.00–11.00 a.m.) under anaesthesia (1 + 100 mg of azepromazine and ketamine/ kg b.w., respectively), to collect blood and dissected tissues according to the assay proposed or to perform the in vivo hepatic TAG secretion test. Blood samples were centrifuged at 4°C and plasma was immediately used or frozen and stored at −80 °C until analyzed. Liver, gastrocnemius muscle and EWAT were frozen, weighed and stored at −80°C until processed.

The rest of the animals were fed ad libitum an isocaloric low protein (LP) diet for 14 days. After this partial protein depletion period, six rats were weighed and killed following the procedure mentioned above, and the remaining animals were divided into four groups ($n = 6$) and fed ad libitum during a 30-day period with normal (20%, w/w) levels of casein, and 7% (w/w) or 20% (w/w) (high fat, HF) of dietary fat, supplemented or not with CLA; thus, the protein repletion dietary groups were identified C + CLA, C, HF + CLA and HF, respectively. At the end of the

protein repletion with the four recovery diets, all the animals were weighed and killed as previously mentioned.

Determination of Muscle Triacylglycerol Concentration

Portions of frozen muscle were powdered, homogenized in saline (10% w/v) and their TAG concentration was quantified by a spectrophotometric method [24].

Analysis of Lipoprotein Lipase Activities

Since skeletal muscle and adipose tissue are the main tissues involved in the removal of plasma TAG-rich lipoproteins by the lipoprotein lipase (LPL) enzyme, gastrocnemius muscle and EWAT were chosen to measure the LPL activities using ^{3}H-Triolein as a substrate, according to the technique described by Nilsson-Ehle and Schotz [25]. In the case of EWAT, the results were expressed as miliUnits (mU) per gram of EWAT (mU/g EWAT) and mU per whole pad of EWAT (mU/EWAT) (1 mU = 1 n-mol/min). In the gastrocnemius muscle, enzyme activity was expressed as mU/g gastrocnemius.

Estimation of In Vivo Hepatic Triacylglycerol Secretion

Another set of animals ($n = 36$) submitted to the same dietary treatments was fasted overnight and anaesthetized, as indicated above. 600 mg/kg of body weight of Triton WR 1339 in saline solution, an agent known to inhibit peripheral removal of TAG-rich lipoproteins, was injected i.v. [26]. Blood samples were taken immediately before and 120 min after the injection of Triton solution for the estimation of TAG accumulation in plasma. Since the weight of the animals was different between the experimental groups (especially between LP and C), the hepatic TAG secretion was calculated taking into account the TAG accumulation in plasma using the following formula:

$$\text{Hepatic TAG secretion}(\text{nmol}/\text{ml}/\text{min}) = [\text{TAG}_{120} - \text{TAG}_{0}]/120,$$

where TAG_0 and TAG_{120} were the plasma TAG concentration (nmol/ml) at 0 and 120 min after Triton WR 1339 administration and 120 was the experimental time in minutes.

Lipid Extraction and Fatty Acid Analysis

Total lipids were extracted from liver, EWAT and plasma samples collected at 0 and 120 min of the in vivo hepatic TAG secretion estimation test using the Bligh and Dyer [27] method. Extracted FA were methylated using sodium methoxide, and FA methyl esters (FAME) were analyzed by GC using a Shimadzu 2014 chromatograph equipped with a flame ionization detector. FAME were identified by comparison of their retention times relative to those of commercial standards (AccuStandard, New Haven, USA and Sigma, St. Louis, MO, USA). Another set of standards was provided by CYTED network 208RT0343. Chromatographic data processing was performed with GC Solutions software. All individual FA results were expressed as mol/100 mol of total FAME. FA with concentrations lower than 0.5 wt% were considered minor, and were not shown unless they were CLA isomers. FA composition of the lipids secreted by the liver was estimated considering plasma FA composition and lipid content at 0 and 120 min of the in vivo hepatic TAG secretion test.

Analysis of Liver Oxidative Stress Parameters

To quantify the liver lipid peroxidation (LPO), malondialdehyde was measured using the thiobarbituric acid method reported by Ohkawa et al. [28]. LPO was expressed as nmol malondialdehyde equivalents/g of liver.

Total liver glutathione (GSH) concentration, as the main non-protein sulfhydryl compound, was measured according to the method reported by Ellman et al. [29]. GSH concentration was expressed as μmol GSH/g of liver.

Catalase and glutathione peroxidase (GSH-Px) activities were assessed in liver by the method reported by Aebi [30] and Paglia and Valentine [31], respectively. CAT and GSH-Px activities were expressed as U (μmol/min)/mg protein. Protein concentrations in each fraction were determined by the method proposed by Lowry et al. [32].

Statistics

Values were expressed as the means ± standard errors of six animals per group. Statistical differences between the LP and B group mean, and between the C and LP group mean were established by unpaired Student's t test. The data to compare the effect of different diets during protein repletion was statistically analyzed by two-way ANOVA (2×2) using CLA supplementation and amount of dietary fat as independent variables. All post hoc multiple comparisons were made using Scheffe's critical range test. Significant differences were considered at $P < 0.05$.

Results

We found a significantly decreased hepatic TAG secretion in circulation (−26%) and a higher EWAT LPL activity (Table 3), which could be two of the biochemical mechanisms involved in the decrease of plasma TAG and the increase of hepatic TAG concentration previously observed

Table 3 Parameters related to TAG regulation

Values are means ± standard errors of the mean ($n = 6$)

B Basal, *LP* low protein, *C* control, *C + CLA* C supplemented with CLA, *HF* high fat, *HF + CLA* HF supplemented with CLA, *TAG* triacylglycerol, *LPL* lipoprotein lipase, *mU/g EWAT* miliUnits per gram of epididymal white adipose tissue, *mU/EWAT* miliUnits per whole pad of epididymal white adipose tissue, *NS* not significant

*$P < 0.05$ versus B. $^{\#}P < 0.05$ versus LP. Different superscript letters indicate significant differences at $P < 0.05$ by Scheffe's test after ANOVA (2 × 2) between protein repletion groups

during protein depletion [18]. In addition, gastrocnemius LPL activity was decreased, matching with the significantly reduced TAG concentration (μmol/g; LP 3.33 ± 0.33 vs B 5.35 ± 0.51, $P < 0.05$).

Protein repletion with 7% (w/w) of dietary fat (C group) restored hepatic TAG secretion. EWAT LPL activity (mU/g EWAT) was decreased in this dietary group, but as the weight of this tissue was increased, its contribution to the circulating TAG removal (mU/EWAT) was not changed. In addition, LPL activity, as well as the TAG concentration in gastrocnemius muscle remained unchanged when compared to the LP diet (μmol/g; C 3.95 ± 0.69 vs LP 3.33 ± 0.33, not significant).

Conjugated linoleic acid at 7% (w/w) of dietary fat increased the hepatic TAG secretion 15% without affecting LPL activity in both EWAT and muscle. In addition, muscle TAG concentration remained unchanged by CLA (μmol/g; C + CLA 3.22 ± 0.33 vs C 3.95 ± 0.69, NS). However, protein repletion with HF diets strikingly decreased TAG secretion by the liver (−23% vs C group) (Table 3). This fact was related to the low plasma TAG concentration and to the lack of normalization of hepatic TAG concentration. In contrast, the HF diet did not induce changes in LPL activity in EWAT or in muscle. The HF diet in the presence and in the absence of CLA showed higher muscular TAG concentration (μmol/g; HF 5.23 ± 0.52 and HF + CLA 4.44 ± 0.47 vs C 3.95 ± 0.69 and C + CLA 3.22 ± 0.33, $P < 0.05$, respectively), related to a slight but not significant increase in muscular LPL activity (Table 3).

All these alterations in the lipid metabolism were accompanied by modifications in FA composition in plasma, liver and EWAT. In plasma (Table 4), protein depletion mainly raised the levels of 16:0, 16:1n-9, 18:1n-9, 22:4n-6 and 22:5n-6, while it decreased the level of 18:0 FA. Protein repletion with 7% (w/w) of dietary fat tended to normalize these changes, even though not completely. On the other hand, protein repletion with HF diets decreased the levels of 16:0 and more markedly that of 16:1n-9, as well as it increased the levels of 18:0 and 18:2n-6. Dietary CLA was significantly incorporated into plasma lipids in C + CLA and HF + CLA groups, not linked to the amount ingested. The levels of *t*10,*c*12-CLA were much smaller than those of *c*9,*t*11-CLA, although both isomers were equimolecularly present in both CLA containing diets. CLA incorporation was associated to decreased 16:0 levels.

The FA composition of the lipids secreted by the liver during the TAG secretion test was shown in Table 5. Protein depletion increased the levels of 16:0 and 18:1n-9 and reduced 18:0 and 20:4n-6. In protein repletion, most of the FA alterations induced by the LP diet were normalized. As observed in basal plasma, dietary CLA was incorporated into the TAG secreted by the liver, not linked to the amount ingested. It can be assumed that the lipids secreted by the liver were more affected by CLA than by the amount of dietary fat. Mainly, CLA supplementation reduced MUFA and increased the 18:0 of the lipids secreted by the liver. With respect to 18:2n-6, besides the increase exerted by HF, CLA intake decreased its level, and this led to its normalization in the HF + CLA group.

Liver FA composition (Table 6) showed that protein depletion reduced the levels of 20:4n-6, 22:5n-3 and 22:6n-3 PUFA. Protein repletion with 7% (w/w) of dietary fat did not reverse these alterations. On the other hand, protein repletion with HF diets markedly increased the 18:2n-6 level, and it also decreased the level of C16 FA. In the liver of CLA fed rats, both CLA isomers were incorporated; however, the level of *t*10,*c*12-CLA was lower than that of *c*9,*t*11-CLA. In addition, mainly *t*10,*c*12-CLA level was higher in liver than in plasma, increasing the *t*10,*c*12-CLA/*c*9,*t*11-CLA ratio. The SCD-1 indexes were calculated in

liver by determining the amount of conversion of SFA (16:0 and 18:0) to MUFA (16:1 and 18:1). The 16:1/16:0 and 18:1/18:0 ratios served as a surrogate markers for SCD-1 activity as 16:0 and 18:0 were the predominant substrates for the SCD-1 enzyme. The changes on MUFA/SFA ratios exerted by the HF diets reduced both SCD-1 indexes. Although CLA incorporation was not associated with statistically significant changes in MUFA and SFA, the 16:1/16:0 ratio was decreased in 70% in HF + CLA versus HF group, while the 18:1/18:0 ratio was reduced 50% in C + CLA versus C group.

In EWAT, protein depletion decreased the level of 18:2n-6 and its derivatives, as well as it increased 18:0, 18:3n-3 and 22:5n-3 FA (Table 7). Protein repletion with 7% (w/w) of dietary fat normalized most of the changes in the FA profile induced by the LP diet. Recovery with the HF diets increased the level of 18:2n-6 and decreased that of 16:1n-9, reaching statistical significance in the presence of CLA. In EWAT, the incorporation of both isomers was higher than in liver and plasma, being 40% higher in HF + CLA than in C + CLA. In addition, the incorporation of *c*9,*t*11-CLA was around 70% higher than that of *t*10,*c*12-CLA.

The changes in hepatic TAG accumulation previously reported in this animal model and the alterations in the FA profile currently observed were accompanied by mild alterations in the oxidative stress related parameters, as can be seen in Table 8. Protein depletion increased LPO levels,

and this was related to a reduction in CAT activity despite a higher hepatic GSH concentration. Protein repletion normalized LPO levels and CAT activity. The presence of CLA, as well as HF diet intake, did not generate further modifications in the liver oxidative stress parameters.

Discussion

To the best of our knowledge, this is the first study to investigate the potential effect of CLA at two different amounts of dietary fat on the contribution of both hepatic

TAG secretion and capability of TAG removal by gastrocnemius muscle and EWAT, and its possible associations with changes in the FA composition in plasma, liver and epididymal white adipose tissue and the hepatic oxidative status in protein repleted rats. However, it is widely known that *c*9,*t*11-CLA and *t*10,*c*12-CLA have different effects on tissue FA metabolism and composition [11, 33, 34]. Therefore, an equimolecular mixture of both isomers was chosen in this study. Although the animal model seemed to be limited, it provided information about the effects of the CLA oil commercially available for human consumption.

The partial depletion of dietary proteins (5% casein) in the animal model under study was characterized by hypotriglyceridemia, hepatomegaly and steatosis [18, 35, 36]. The decreased hepatic TAG secretion and high EWAT LPL activity observed could explain, at least in part, the low plasma TAG concentrations previously found in this animal model [18]. In addition to changes in VLDL composition, assembly and secretion, associated with the decrease of VLDL apolipoprotein, phospholipids and TAG contents reported by other authors [35], our results of the low hepatic TAG secretion also correlated with the hepatic steatosis. Furthermore, in agreement with other studies [37], we also found that partial protein depletion decreased the muscle LPL activity and this was consistent with the decreased TAG concentrations observed in the gastrocnemius muscle. The alterations observed in the lipid metabolism were accompanied by modifications in FA composition in plasma, liver and EWAT. In plasma, protein depletion increased MUFA and 16:0 and decreased 18:0 levels. In liver, these changes were less pronounced without reaching statistical differences. The decrease observed in liver 20:4n-6 and n-3 FA was in agreement with that reported by other authors [36, 38]. As PUFA are more prone to oxidation than MUFA and SFA, the reduction in total PUFA and the increase in SFA might also explain the hepatic steatosis observed in the LP group. The TAG secreted by the liver presented FA compositional changes, similar to those observed in liver. On the other hand, EWAT showed an increase in n-3 FA, perhaps as a compensatory mechanism, storing these FA that were deficient in liver.

The hepatic steatosis observed in protein depleted animals could be an important factor in the induction of oxidative stress, reflected by the high LPO values. This action could be mediated, at least in part, by a decrease in the activity of a key antioxidant enzyme, such as CAT, and not completely counteracted by the increase in liver GSH concentration.

Normalization of hepatic TAG secretion in protein repletion with 7% (w/w) of dietary fat could be the main mechanism involved in the reversion of hepatic steatosis and decreased circulating TAG reported elsewhere [18]. This effect normalized most of the changes observed in the FA profile of plasma, EWAT, liver and TAG exported from liver. This mechanism could have more influence than certain enzymes involved in FA metabolism such as liver SCD-1, since 16:1/16:0 and 18:1/18:0 ratios remained unchanged in protein depletion and repletion.

Dietary CLA prevented hepatic lipid accumulation in partial protein repletion with a high amount of dietary fat [18]. The present study shows that hepatic TAG secretion was the most important mechanism involved in protein repletion when HF diets were used. Thus, while HF diets without CLA showed a low liver TAG secretion contributing to maintain the hepatic TAG accumulation, the presence of CLA prevented hepatic steatosis from increasing hepatic TAG secretion, and it also altered the FA profile of the lipids secreted by the liver. In addition, CLA was incorporated to the TAG secreted by the liver, concurrent with a decrease in MUFA and higher levels of n-6 PUFA. This evidence does not preclude the fact that changes in the composition and size of lipoproteins secreted by the liver could be modified by CLA, as shown in an in vitro study [39].

The presence of CLA did not affect muscular and EWAT LPL activity and this could also contribute to the lack of changes in plasma and muscle TAG concentration. Several authors [40, 41] reported contrasting results in hamsters and diabetic rats fed CLA without previous protein depletion. Clearly, the sensitivity and condition of the animals could be determining as well as the type of isomer used. The effects of CLA on LPL activity in EWAT and culture adipocytes are controversial [6], and the differences with our results might be related to experimental conditions. Furthermore, the increased muscle TAG concentration in protein repletion with HF diet was associated with a slight and not significant raise of muscle LPL activity. This fact could also be related to the high FA and energy availability provided by the diet.

Both CLA isomers were incorporated into liver, EWAT, plasma and lipids secreted by the liver. In all the samples, the level of *t*10,*c*12-CLA was much smaller than that of *c*9,*t*11-CLA, in agreement with the results from Kelley et al. [11] in different tissues of mice. This effect could be most likely due to a higher β-oxidation of *t*10,*c*12-CLA [42]. The CLA level was higher in EWAT, followed by liver, and then by plasma. In EWAT, both isomers were more abundantly incorporated in the HF + CLA diet than in the C + CLA diet, reflecting the higher level of CLA in the former. On the other hand, dietary CLA were similarly incorporated in plasma lipids in C + CLA and HF + CLA groups, reflecting that in both diets the total amount of CLA represented equal proportions of the dietary fat (15% of the total fat).

The tissue ratios between the level of SFA and MUFA of C16 and C18 FA can be used as SCD-1 indexes reflecting the enzyme activity [43]. Different levels of SCD-1 activity, index and/or expression have been associated with liver steatosis. For instance, Gutierrez-Juárez et al. [44] reported liver steatosis in a model of reduced SCD-1 expression. In our case, lower C16 and C18 FA SCD-1 indexes were associated with high fat intake, as expected, given the fact that the Scd1 mRNA expression was reported to be lower in animals fed 20% corn oil [45]. On the other hand, the effect of CLA on liver SCD-1 expression and activity has been studied in vitro [46, 47], but few studies of these parameters in animal models have been published in the literature [48]. These reports mainly concur in the fact that *t*10,*c*12-CLA decreases both enzyme expression and activity, in agreement with our results. Even though decreasing the SCD index, CLA was not related to higher hepatic TAG concentration. On the contrary, CLA intake with 20% (w/w) of dietary fat prevented hepatic lipid accumulation. In agreement with our results, Purushotham et al. [43] reported that CLA intake could reduce hepatic steatosis when it was produced by the previous intake of a HF diet instead of protein depletion. The apparent liver protective effect of CLA observed in previously malnourished rats was clearly opposite to that observed in well-nourished mice fed HF diets [49], where CLA drastically increased liver TAG concentration.

Protein repletion restored the liver oxidative status independently of the amount of dietary fat or the presence of CLA. The present results differed from those previously reported by our group [49], showing that HF diet intake induced LPO, and the presence of CLA in the diet could prevent this effect by increasing hepatic GSH concentration in a mouse model with no previous protein depletion.

In sum, this work provided further insight into the plausible role of commercially available CLA on the recovery from protein depletion with 7% (w/w) and high (20%, w/w) dietary fat content. Protein repletion only in the presence of CLA normalized plasma and liver TAG concentration independently of the amount of dietary fat through an increase of hepatic TAG secretion. In addition, CLA in protein repletion was incorporated into the plasma and tissues, its levels in EWAT being > liver > plasma, and that of *c*9,*t*11-CLA being >*t*10,*c*12-CLA. This was accompanied by alterations in FA composition. The determination of the mechanisms by which CLA and/or the content of dietary fat could regulate metabolic disorders associated with lipid metabolism might greatly contribute to understanding the development and intervention of diet-induced chronic disorders.

Acknowledgments We wish to thank Walter DaRú for his technical assistance with the animals. This work was financed by ANPCyT (Agencia Nacional Científica y Tecnológica, PICT # 25750, PICTO # 36181) and Universidad Nacional del Litoral-Cursos de Acción para la Investigación y Desarrollo (CAI+D 2006 No. 12/B616). We are also grateful to CYTED (Programa de Ciencia y Tecnología para el Desarrollo-Ministerio Español de Ciencia y Tecnología—BFI2002-00218) for the financial support of the Network 208RT0343, where this research was integrated

volunteers who had previously consumed pure unlabeled isomers during 24 weeks [3].

Methods

Materials

Unlabeled CLA isomers were provided by Natural Lipids Ltd. (Hovdebygda, Norway). [1-^{13}C]-9*c*,11*t* and [1-^{13}C]-10*t*,12*c* were synthesized as already described [4]. [1-^{13}C]-9*c*-18:1 was purchased (Isotec Inc. OH, USA). The chemical purity was ≥98% with isotopic purity 98.2% 9*c*-18:1, 99% 9*c*,11*t* and 98% 10*t*,12*c* by GC–MS. The triacylglycerol (TAG) form, containing two molecules of labeled fatty acid (positions 1(3) and 2) and one molecule of unlabeled 9*c*-18:1 (position 3(1)) was synthesized as published elsewhere [5] and packaged into individual doses of approximately 1 g of pure TAG in 30 g high oleic sunflower oil (Lesieur, Coudekerque, France). To maintain blinding, individual doses were labeled with the same code as during the 24 week clinical trial. Only Danone (Danone Research Center, Palaiseau, France) could unblind the study.

Study Protocol

This study was part of a placebo-controlled, double-blind, randomized intervention trial to compare the effects of 9*c*-18:1 (control), 9*c*,11*t*- and 10*t*,12*c*-CLA on body composition in healthy overweight men and women. Details of this study have been described elsewhere [3]. The isotope study followed 24 weeks of CLA/9*c*-18:1 treatment. The ^{13}C-labeled substrates were given as TAG to ensure high bioavailability [1, 6]. Twenty-four subjects among the group receiving 3 g/day of 9*c*-18:1 or 9*c*,11*t*- or 10*t*, 12c-CLA were randomly chosen and blinding preserved. Volunteer numbers per group ($n = 8$) were calculated based on our previous experience [7]. However, 2 volunteers from Maastricht withdrew and 22 subjects successfully completed the study: 8 from the 9*c*-18:1 (control) group (4 females, 4 males) and the 9*c*,11*t*-CLA group (3 females, 5 males), and 6 subjects from the 10*t*,12*c*-CLA group (2 females, 4 males). The study protocol was approved by the Ethical Committees in France and the Netherlands. Informed written consent of all the subjects was obtained prior to entering the study.

The study design (Fig. 1) was standardized between Clermont-Ferrand and Maastricht. Briefly, after an overnight (12 h) fast, O_2 consumption (vO_2) and CO_2 production (vCO_2) were measured for 30 min using a ventilated-hood indirect calorimeter (Deltatrac, Datex, Helsinki, Finland). The respiratory quotient (RQ, the ratio of vCO_2:vO_2) and energy expenditure (EE) were calculated at baseline and 2, 3, 5, and 8 h after ingestion of the tracers. Energy expenditure (EE) was calculated using Weir's equation [8] whereas, non-protein respiratory quotient (NPRQ) and substrate oxidation rates were calculated using equations from Ferranini [9].

Breath samples were collected into tubes (Vacutainer, Becton–Dickinson, Grenoble, France) at baseline to determine the basal ^{13}C abundance of breath CO_2, hourly for a period of 8, 24 and 48 h post-dose. Rate of expiration of $^{13}CO_2$ in breath was calculated by multiplying the vCO_2 by the enrichment of the breath CO_2 pool.

Subjects stayed fasted at the laboratory during these 8 h and were requested to remain in a resting, but not sleeping, state and to refrain from talking. Before leaving, they ate a meal without ^{13}C rich foods (e.g. maize and sugar cane). They also received advice to avoid these foods for the next 48 h.

Analytical Procedures

Breath $^{13}CO_2$ enrichments were analyzed by isotope ratio mass spectrometry (IRMS) (mGas system, Fisons Instruments, Middlewich, England). The CO_2 was introduced into the IRMS to measure the ^{13}C to ^{12}C isotopic ratio of the sample and calculate the isotopic abundance relative to the Vienna-PDB international standard (δ^{13}C in % vs. PDB) [10]. The rate of $^{13}CO_2$ production was calculated by multiplying $^{13}CO_2$ enrichment by CO_2 production (measured using indirect calorimetry) as previously published [10]. Cumulative $^{13}CO_2$ production, i.e. the area under the curve (AUC), was calculated using the trapezium rule [10].

Statistical Analysis

Results are given as means ± SD. Treatment effects were examined using ANOVA following by a non-parametric test

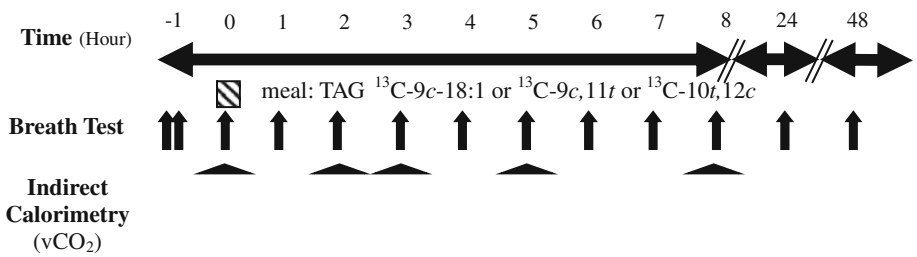

Fig. 1 Experimental design. Twenty-two subjects ingested labeled 1 g of TAG (9*c*-18:1 (control) or 9*c*,11*t* or 10*t*,12*c* isomer) mixed with 30 g of a high oleic sunflower oil

Carbohydrate oxidation (g/kg LBM/8 h)	1.96 ± 0.61	1.81 ± 0.34	1.83 ± 0.24	0.993

Values are means ± SD

(Fisher PLSD test) to compare the treatments pairwise, when a significant treatment effect was observed. Moreover, repeated-measures ANOVA were used to look for possible interactions between treatment and time. A two-way ANOVA analysis was performed to look for possible gender effects and a possible interaction between treatment and gender interaction. Statistics were performed by using Statview 5.0 (SAS Institute Inc., Cary, NC, USA).

Results

Mean values for age, height, BMI, waist/hip ratio, fat free mass, percentage body fat, and respiratory quotient (RQ) at the start of this study did not differ significantly between groups (Table 1). None of the parameters related to energy expenditure varied between groups (Table 1).

Excretion of $^{13}CO_2$ in the breath measured over 48 h followed a similar pattern in the three groups. Labeled fatty acid oxidation peaked between 5 and 6 h post-dose for all tracers and decreased thereafter to reach the basal ^{13}C-level at 24 and 48 h (Fig. 2). However, cumulative fatty acid oxidation determined from AUC results, was significantly higher for ^{13}C-9*c*,11*t*-CLA than for ^{13}C-9*c*-18:1 ($P < 0.01$) or ^{13}C-10*t*,12*c*-CLA ($P = 0.01$). There was no difference between 10*t*,12*c*-CLA and 9*c*-18:1 ($P = 0.66$).

The oxidation of CLAs was not affected by gender ($P = 0.73$) (data not shown). Oxidation rate of 9*c*,11*t*-CLA amounted for 31.0 ± 3.6% of the oral dose for 8 h. It was significantly higher than for 9*c*-18:1 (22.2 ± 8.0%) ($P = 0.02$) and 10*t*,12*c*-CLA (21.6 ± 8.7%) ($P = 0.02$).

Discussion

In the present study, we have assessed the oxidation of CLA isomers using a similar method to one previously published with n-3 fatty acids [7]. Our results show that

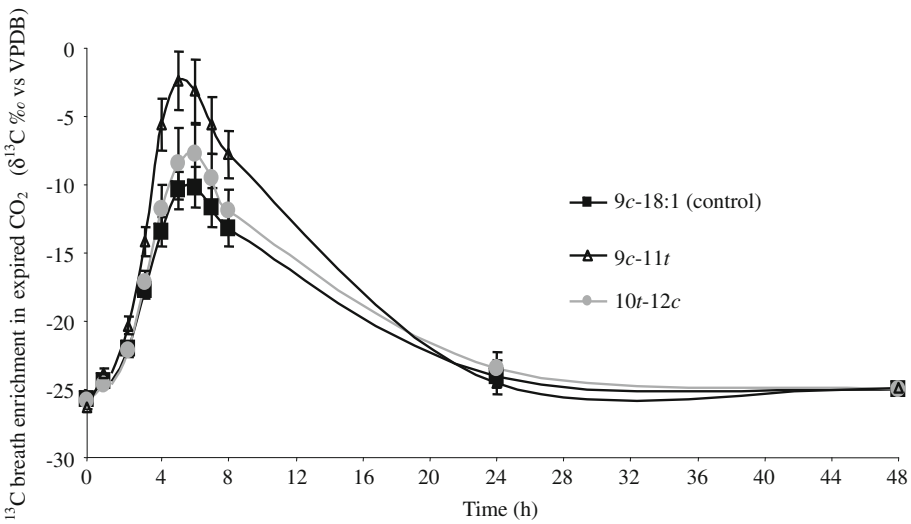

Fig. 2 Time course of the ^{13}C enrichment in breath $^{13}CO_2$ (vs. VPDB) after an oral dose of 1 g of TAG containing each [1-^{13}C]-9*c*-18:1 (control), [1-^{13}C]-9*c*,11*t* and [1-^{13}C]-10*t*,12*c* isomers given to 8, 8, and 6 volunteers in 9*c*-18:1, 9*c*,11*t* and 10*t*,12*c* groups, respectively. Values are means ± SEM

postprandial β-oxidation of 9*c*,11*t*-CLA is higher than that of 9*c*-18:1 and 10*t*,12*c*-CLA, contrary to our expectation. Results obtained in rodents and in vitro suggested that the 10*t*,12*c* isomer is more oxidized than the 9*c*,11*t* [1]. In addition, the reduced percentage of body fat observed in animals and the enhanced energy metabolism after administration of a CLA mixture has been attributed to the 10*t*,12*c* isomer [11, 12]. However, in mitochondria from liver homogenates, 10*t*,12*c*-CLA was less oxidized than 9*c*,11*t*-CLA, possibly because of its higher esterification rate which possibly prevented its entrance into β-oxidation [13]. Our present finding combined with the latter data suggest that the lower metabolic effect of 9*c*,11*t*-CLA may be attributed to its higher mitochondrial oxidation, but we did not investigate further the potential mechanisms related to our observation. A recent study by Goedecke et al. [14] demonstrated a greater incorporation of 10*t*,12*c*-CLA into adipose and muscle tissues compared with 9*c*,11*t*-CLA in healthy non-obese volunteers, perhaps for similar reasons.

Despite differences in postprandial oxidation between the two CLA isomers, we found that energy expenditure, RQ, NPRQ and fat oxidation were similar between the three groups (Table 1). These results are in accordance with two other studies. In the first one [15], resting RQ, fat oxidation, and energy expenditure were unchanged after a daily supplement containing 3 g of a mixture of CLA-isomers (11*c*,13*t*: ~23% (w/w), 10*t*,12*c*: ~23% (w/w) and 9*c*,11*t*: 18%) for 64 days in healthy normal-weight women. Body composition measured with DEXA-method, indicated that CLA had no effect on body fat mass. Moreover, Watras et al. [16] demonstrated that a 6 month CLA supplementation was associated with fat mass loss compared to placebo (-1.0 ± 2.2 and 0.7 ± 3 kg, respectively, $P = 0.02$), but without any effect on resting metabolic rate. These and our results are however in marked contrast with two other intervention studies. Consumption of a CLA supplement (50:50 9*c*,11*t* and 10*t*,12*c*) as TAG (3.76 g) for 98 days significantly increased basal energy expenditure in overweight men and women [17]. Similarly, with 3.2 g/day of CLA mixture (39.2% 9*c*,11*t* and 38.5% 10*t*,12*c*), energy expenditure and fat oxidation were enhanced during sleep in overweight men and women [18]. In addition, RQ during the 24 h period tended to decrease. This was, however, not associated with changes in the oxidation of dietary fat as monitored by labeled oleate and palmitate administered during a breakfast meal [18]. These discrepancies require additional exploration on the effect of CLA isomers on whole body energy metabolism.

Our study is the first that has examined the in-vivo metabolic behavior of pure CLA-isomers in humans. It has, however, some limitations. First, the sample size with six to eight volunteers per group is small, even if statistical significance between the groups was reached. Secondly, oxidation was measured at rest, while physical exercise may modify fatty acids utilization [15]. Thirdly, we only studied oxidation within a time frame of 48 h and do not know what happened with the remaining label. Despite these limitations, we can conclude that 9*c*,11*t* is more rapidly oxidized compared than 10*t*,12*c* CLA.

Acknowledgments We are grateful to Asgeir Saebo (Natural ASA, Norway) for providing the CLA isomers. For their invaluable help, we are most grateful to the participants. C. Giraudet (Clermont) and P. Rousset (Clermont) are acknowledged for the analyses of the $^{13}CO_2$ isotopic enrichments. Supported by The European Commission: conjugated linoleic acid (CLA) in functional food: a potential benefit for overweight middle-aged Europeans, Fifth (EC) framework program QLK1-1999-00076.

remove lipids from the cells, followed by quantification by weighing or chromatography [4–13]. Solvent extractions from microalgae are typically based on the methods using chloroform and methanol published in the 1950s by Folch et al. [14] and Bligh and Dyer [15]. It is well recognised that solvent extraction often extracts lipids incompletely, particularly free fatty acids, and can extract significant quantities of non-nutritive, non-saponifiable material such as pigments [16–18]. Small modifications in the protocol can have a large effect on extraction efficiency [19]. Smedes and Askland [20] tested various ratios of chloroform and methanol, described by the Bligh and Dyer method, and suggested that the yield of lipid could be increased by using a higher methanol content. This implied that the original Bligh and Dyer method resulted in incomplete extraction. Iverson et al. [19] compared the Bligh and Dyer and the Folch methods for a range of marine tissues, and concluded that the Bligh and Dyer method significantly underestimated the lipid content of samples containing more than 2% lipids. The effect was aggravated by increasing lipid content, resulting in an underestimation of 50% compared to the Folch method in the samples with the highest lipid content.

Gas chromatography (GC) can be used to quantify individual fatty acids as well as the total fatty acid present in a lipid extract. GC of lipids requires derivatisation to volatilise the samples [21]. This is normally achieved by converting saponifiable lipids [in biological samples, mainly triacylglycerols (TAG) and phospholipids] to FAME by addition of an excess of methanol and a catalyst, in a reaction known as transesterification [21, 22]. This eliminates the problem of extraction of non-fatty acid substances, such as pigments, as these are not detected by GC, but the accuracy of quantification is still dependent on the completeness of the extraction.

Instead of improving extraction methods, some investigators have eliminated extraction completely by transesterifying lipids in situ. Direct transesterification (DT) was first successfully performed in 1963 by Abel and co-workers [23]. Since then, it has been verified by numerous researchers in a variety of tissues, as a simple and rapid method of quantifying fatty acids by combining extraction and transesterification into one step. Diverse methods have been used for DT, but most involve the addition of an organic solvent, methanol, catalyst and heat to a small amount of dried sample (see [21] and [22] for comprehensive reviews of this). DT has previously, although infrequently, been applied to the quantification of fatty acids in microalgae [24–31], however, no evaluation or comparison to alternative methods has been made.

Transesterification involves the cleaving of an ester bond by an alcohol and can be catalysed by either a base or an acid. Usually a single catalyst is used and the choice is determined by the characteristics of the different catalysts. Alkaline catalysts, such as sodium methoxide (SM), or sodium or potassium hydroxide in methanol, transesterify complex lipids quickly and at lower temperatures than required by acid catalysts, but they do not esterify free fatty acids [21]. Acid catalysts, such as hydrochloric or sulphuric acid in methanol or boron trifluoride (BF_3) methanol, require heating and longer reaction times than basic catalysts [22], but can transesterify complex lipids as well as esterifying free fatty acids [21]. Considering the different capacities of acid and base catalysts, some investigators have used a combination of a basic catalyst or alkaline hydrolysis with NaOH or KOH in methanol, followed by an acid catalyst [21, 22, 32]. This study investigated whether the sequential use of two catalysts would improve the efficiency of DT in microalgae, particularly in the presence of water.

Water is known to interfere with the transesterification reaction [21, 22]. It is a stronger electron donor than methanol and the presence of water in the reaction system can cause hydrolysis, the opposite of esterification. To avoid interference by water, it has been suggested that the sample be dried, or a water scavenger such as 2,2-dimethoxypropane be added [22], however, there are reports which dispute the need for these practices below a critical water content. Lepage and Roy [33], using the catalyst acetyl chloride, found recoveries (>95%) to be unaffected by the presence of water up to 5% of the total reaction volume, while a water content of 10–15% significantly impaired the reaction. Most studies using DT for quantification of fatty acids in microalgae have used freeze-dried biomass, although there has been no investigation as to whether this is necessary.

This study tested and compared the effectiveness of DT to alternative methods of quantifying total fatty acid content in microalgae. The results of DT on three algal species were compared to those obtained by extraction using the Folch, the Bligh and Dyer, and the Smedes and Askland methods. The effects of using a sequential combination of base and acid catalysts, as well as the influence of water, on transesterification efficiency were investigated.

Experimental Procedure

Analytical Reagents

All reagents used were of chromatography standard. Toluene (99.9%) and chloroform (99.8%) were from Sigma-Aldrich (USA) and hexane (98%) and methanol (99.9%) from Merck (Germany). Methanolic base (0.5N), also known as sodium methoxide (SM), and boron trifluoride (BF_3) methanol solution (14%) were obtained from Sigma-Aldrich (USA). Distilled water (dH_2O) from a

Millipore system was used for all analyses. Internal standards used were glyceryl triheptadecanoate (C17-TAG) and methyl nonadecanoate (C19-ME) from Sigma-Aldrich (USA).

Algal Culture and Preparation

Two freshwater Chlorophyta (green algae), *Chlorella vulgaris* (*Cv*) (UTEX 395) and *Scenedesmus* sp. (*Sc*) (obtained from algal culture ponds near Upington, South Africa) and a marine Eustigmatophyte, *Nannochloropsis* sp. (*Nan*) were tested. Culture media for the freshwater species was 3N BBM medium, while the marine alga was grown in F2 medium (UTEX: http://www.sbs.utexas.edu/utex). Airlift reactors with a working volume of 3.2 L were sparged with air (*Cv* and *Sc*) or 4,400 ppm (0.44%) CO_2 (*Nan*) at a gas flow rate of 2 L min^{-1}. Light (80–160 μmol s^{-1} m^{-2}) was provided by three 18 W cool white fluorescent bulbs (Osram). Cells were harvested by centrifugation at 4,000 rpm for 10 min, rinsed in either distilled water (for freshwater cultures) or sterile seawater (marine cultures) and re-centrifuged. Biomass used in the experiments was from a single batch of each species.

Determination of Biomass Water Content

The wet pellet, following centrifugation, was weighed and resuspended in a known volume of distilled water or sterile seawater. A sample of this biomass concentrate corresponding to 0.1 g wet weight was filtered through a pre-weighed 0.45 μm Millipore filter and dried at 80 °C overnight. After cooling to room temperature in a desiccator, filters were weighed to determine the relative dry biomass and water content. The 0.1 g wet weight samples of *Cv*, *Sc* and *Nan* corresponded to 19.6 ± 0.31, 19.8 ± 0.12, and 27.4 ± 0.85 mg dry weight, respectively.

Extraction

All extractions and DTs were performed in triplicate, using samples of 0.1 g wet weight algal biomass. The control for each experiment was 80 μl dH_2O. Total lipid was extracted by the Bligh and Dyer method [15], the Smedes and Askland method [20] and the Folch method [14]. Each sample was extracted three times and the resulting solvent volumes combined. The combined extract was dried at room temperature overnight, transesterified and subjected to GC analysis for quantification of fatty acids. The residual biomass from each extraction was recovered and tested for any remaining fatty acids by DT.

The original protocols were followed as closely as possible, with the following two modifications:

- Sample size was scaled down by a factor of 1,000, with extraction volumes scaled accordingly.
- Homogenisation was replaced by vortexing at maximum speed for 3 min.

According to Folch et al. [14]: "the procedure can be run on any scale that is otherwise technically feasible". In order to verify that the scale of the reaction did not affect the results, the three extraction techniques and DT were repeated in triplicate using 1 g of *Sc* biomass (i.e. volumes scaled down by a factor of 100). Results were found to be very similar to extractions from 0.1 g (data not shown).

Transesterification

For DT, reagents were added directly to either internal standards, olive oil, or algal biomass. For DT of wet algal biomass, negative controls of 80 μl water were included, as well as a control for each algal species containing biomass but no internal standards, to test for the presence of C17 or C19 compounds in the algal cells. For extraction-transesterification, reagents were added to the dried extract or residual biomass from lipid extractions. Two internal standards were used: glyceryl triheptadecanoate (C17-TAG) was added prior to the reaction as a quantitative internal standard, and methyl nonadecanoate (C19-ME) was added in the final solvent extraction step to verify the completeness of the transesterification and efficiency of extraction into the hexane layer. A combination of base followed by acid catalysis was performed as follows: samples were dissolved in 500 μl toluene containing 0.1 mg C17-TAG in glass test tubes with silicon-lined screw-cap lids. One hundred microliters of 2,2-dimethoxypropane (water scavenger) was added. Sodium methoxide (1 ml) was then added and the samples mixed briefly by vortexing before being placed in an incubator at 80 °C, with shaking at 300 rpm for 20 min. Samples were cooled for 5 min to room temperature and 1 ml BF_3 methanol was added before repeating the incubation. After cooling for 5 min to room temperature, 400 μl dH_2O and 400 μl hexane containing 0.1 mg C19-ME were added and tubes mixed by vortexing. Samples were centrifuged at 4,000 rpm for 1 min and the upper hexane-toluene layer, containing the FAME extract, was transferred to vials for GC.

Gas Chromatography

The FAME extract (1 μl), containing internal standards, was injected into a Varian 3900 GC equipped with a flame ionisation detector and SupelcoWax 10 column (30 m × 320 mm × 1.0 μm film thickness) (Supelco, USA). Standard split/splitless injection was used with a split of 100 and an injector temperature of 270 °C. The column

temperature was increased from 180 °C to 260 °C at 2 °C min^{-1}. Nitrogen (2 ml min^{-1}) was used as the carrier gas and the detector temperature was 260 °C. Peaks were identified by retention time using Supelco 37 Component FAME and C14:0 to C22:0 FAME mixtures. Peak areas were used to quantify each FAME relative to the internal standards. Differences in the response factor of the detector to the range of FAMEs in the samples were negligible. The total fatty acid content was calculated by adding all the individual FAME peak areas.

Catalyst Tests

To test the efficiency of transesterification using a single catalyst, as opposed to a combination, C17-TAG samples (0.1 mg) were transesterified with either 1 ml SM, 1 ml BF_3 methanol, or a combination of the two catalysts. The tests were repeated with the addition of 80 µl water (equivalent to the amount of water in the algal pellets), with and without 100 µl of the water scavenger 2,2-dimethoxypropane. The efficiency of transesterification was calculated by dividing the peak area of the resulting C17-ME, by the peak area of the C19-ME added post-reaction. As equal quantities of these two standards were added (the mass of the three methyl esters formed is very similar to that of the TAG), their ratio gave an indication of how much of the C17-TAG was converted to fatty acid methyl esters.

Accuracy, Precision, and Limits of Detection and Quantification

To test the accuracy, precision, linearity, and limits of detection (LOD) and quantification (LOQ) of the assay, triplicate samples of 10, 5, 2.5, 1, 0.5, 0.1, 0.05, 0.01, 0.005 and 0.001 mg 100% extra virgin olive oil (Borges, Spain) were made up in toluene. Negative controls containing no olive oil were included. All samples were transesterified and quantified by GC. To estimate inter-experimental error, fresh 5 and 2.5 mg samples were analysed on three consecutive days. The LOD was defined as the minimum concentration at which distinct peaks could still be discerned above the baseline noise. The LOQ was defined as the lowest concentration of fatty acid that could be quantified with an accuracy and precision (calculated according to Wu et al. [34]) within 15%.

Sensitivity to Water

The effect of water on the two-catalyst reaction was tested using 0.1 mg of the C17-TAG internal standard as substrate, with dH_2O addition up to 50% of the final total reaction volume. Transesterification was carried out using C19-ME as the internal standard, with or without 100 µl of the water scavenger 2,2-dimethoxypropane. Reactions were done in duplicate.

Results

Direct Transesterification Versus Extraction-Transesterification

Total fatty acid content determined by DT and by the three extraction-transesterification methods in *Cv*, *Sc* and *Nan* are shown in Fig. 1. For all three species, DT yielded a higher estimation of fatty acid content than any of the extraction-transesterification methods. Of the extraction methods, the Folch method yielded higher results (77–93% of DT values) than the Smedes and Askland (23–73%) and the Bligh and Dyer (19–63%) methods. The Smedes and Askland method recovered more fatty acid from *Cv* and *Sc* than the Bligh and Dyer method.

DT on the residual biomass after the solvent extractions yielded additional fatty acid, indicating that the extraction procedures did not extract all the fatty acid. The sum of fatty acid extracted plus fatty acid remaining in the residual biomass was similar to that obtained by DT.

Single Catalyst Versus Sequential Combination of Catalysts

The ratio of C17-ME to C19-ME following the sequential combination of a basic catalyst followed by an acid catalyst demonstrated the degree to which C17-TAG was transesterified (Fig. 2). Values greater than 100% were obtained when the area of the C17-TAG peak was greater than that of the C19-ME peak. This could have been due to minor errors in dilution or pipetting of standard solutions.

When the two reagents were used sequentially, 100% conversion of TAG to FAME was obtained in the presence or absence of water. In the absence of water, the acid BF_3 catalyst alone produced an equivalent degree of transesterification to both reagents together, but the basic SM catalyst resulted in only 67% conversion. In the presence of water, no transesterification occurred with SM, while with BF_3 32% conversion was obtained. The addition of a water scavenger to the reaction containing 80 µl water improved the conversion with BF_3 to 55%, but did not improve SM conversion.

Accuracy, Precision and Limits of Detection and Quantification

To test the accuracy, scalability and reproducibility of the DT assay, serial dilutions of olive oil in toluene were

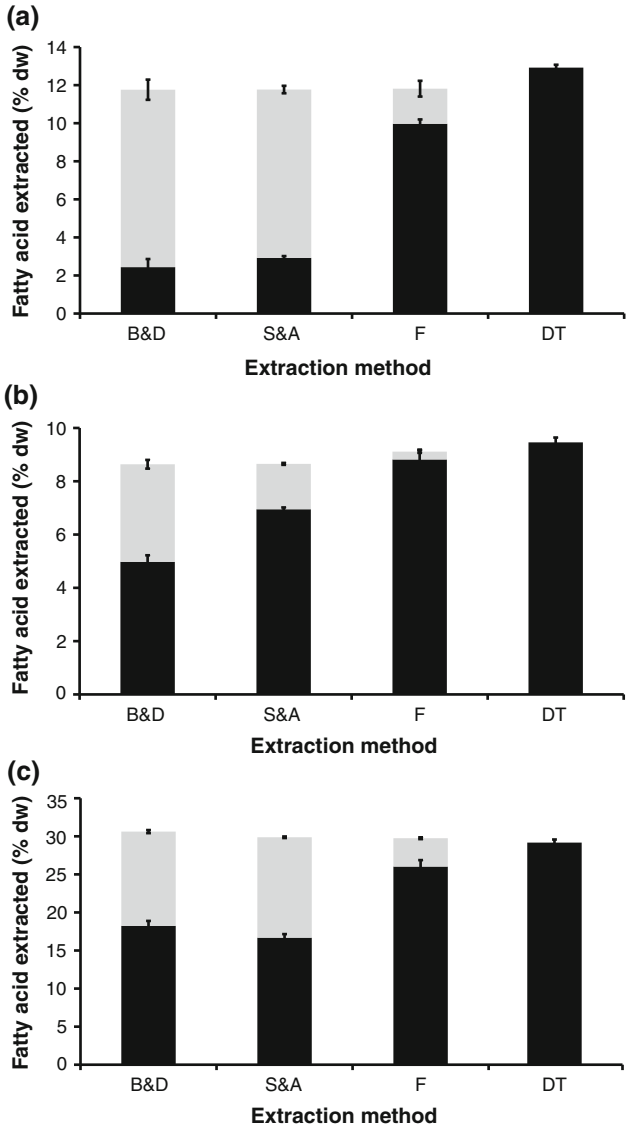

Fig. 1 Fatty acid content (as a percentage of the algal biomass dry weight) of **a** *Chlorella vulgaris*, **b** *Scenedesmus* sp. and **c** *Nannochloropsis* sp. measured by extraction with the Bligh and Dyer (B&D), Smedes and Askland (S&A) or Folch (F) methods, followed by transesterification and GC, or DT of the wet algal pellet. *Black bars* are the fatty acid content measured by the four different methods. *Light grey bars* are the fatty acid obtained by the DT carried out on the biomass residue from the extractions

directly transesterified and quantified by GC. The correlation coefficient of fatty acid concentration determined from the assay to that added to the samples was 0.96 with a linear regression coefficient of 0.9999. The LOD was 5 μg fatty acid, and the LOQ was 50 μg. For olive oil samples between 500 μg and 10 mg, the accuracy and precision of the assay were within 5 and 2.5%, respectively. The inter-experimental accuracy and precision were both within 5%.

Sensitivity to Water

The addition of water up to 10% of the total reaction volume had little effect on the efficiency of the reaction (Fig. 3). With the addition of larger volumes of water, the efficiency decreased dramatically and recovery was variable, as shown by the large error bars with between 20 and 50% water. Results with and without the water scavenger below 10% water were similar. Above 30% water, reactions containing the water scavenger resulted in an increase in the efficiency of transesterification, however, this still represented a substantial under-estimation of the fatty acid content and there was a high degree of variation between samples.

Discussion

This paper presented a rigorous comparison of DT to the most common alternative methods of lipid quantification in microalgae. It was shown, across three algal species, that DT was a simple, accurate and reliable method, capable of determining total fatty acid content more efficiently than traditional solvent extraction methods.

The commonly used extraction method of Bligh and Dyer was the least effective extraction method tested. It significantly underestimated fatty acid content (by up to 81% in the case of *Cv*), accounting for 19–63% of fatty acids quantified by DT. Smedes and Askland [20] investigated the solvent ratios used by Bligh and Dyer and proposed that a greater proportion of methanol would result in a better recovery of lipids. This was true for the green algal species, as the Smedes and Askland method yielded 17–28% more fatty acids than the Bligh and Dyer method (although 6% less fatty acid than the Bligh and Dyer method for *Nan*). However, the Smedes and Askland method still underestimated lipid content, measuring 23–73% of the fatty acid content measured by DT. The Folch extraction method was the most effective, yielding 77–94% of the total extracted by DT. These findings are in agreement with Lepage and Roy [35] who reported that fatty acid recovery from milk and adipose tissue was improved by DT due to the elimination of multiple extraction and purification steps. Fatty acid recoveries from samples of human milk and adipose tissue were 11–16% better than the Folch extraction. Iverson et al. [19] also showed that the Bligh and Dyer method greatly underestimated lipid content compared to the Folch method in fish samples.

DT completely eliminates the need for lipid extraction and purification and can be performed on small sample volumes. Classical lipid extraction techniques are lengthy and involve multiple steps, while DT is rapid and can be

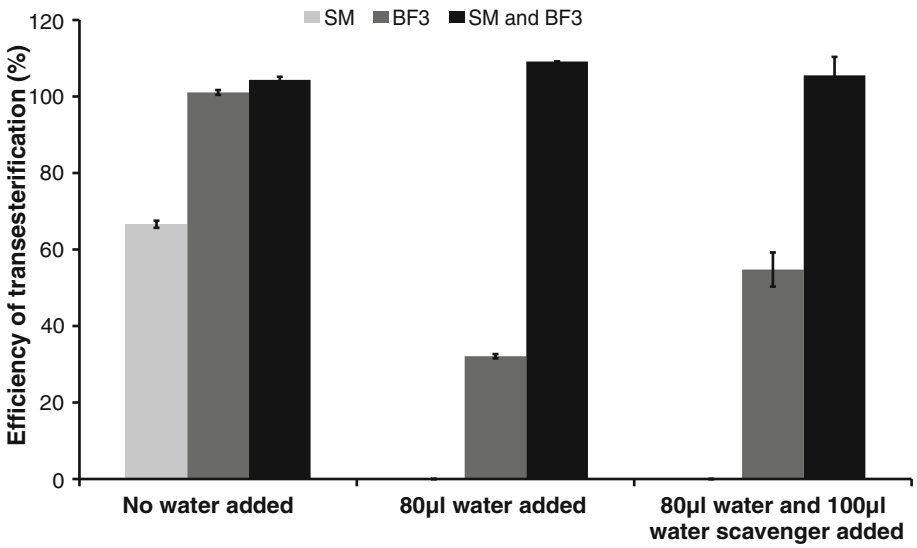

Fig. 2 The efficiency of transesterification of glyceryl triheptadecanoate (C17-TAG) by the basic catalyst sodium methoxide (SM), the acid catalyst boron trifluoride-methanol (BF_3) and a combination of the two (SM and BF_3), compared under three different reaction conditions: anhydrous, with 80 µl water, and with 80 µl water and 100 µl water scavenger

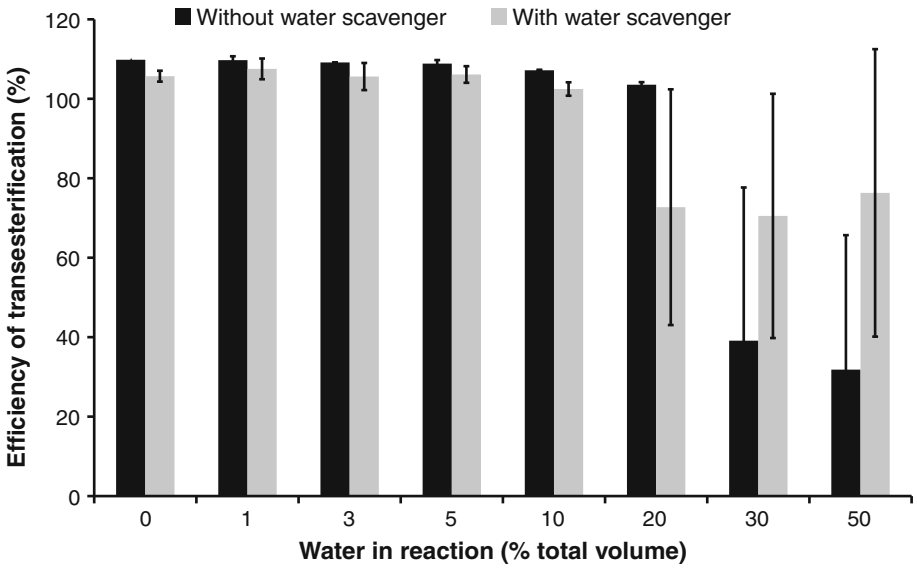

Fig. 3 Efficiency of transesterification, measured by conversion of C17-TAG to C17-ME, as a function of reaction water content, with and without addition of a water scavenger

performed in a single tube, minimising sample losses. The assay was found to be accurate and reproducible to 5% above 0.5 mg and 15% (defined as the LOQ) above 0.05 mg. Assuming a relatively low fatty acid content of 10% dry weight and a biomass concentration of 1 g L^{-1}, this LOQ equates to an algal sample of 0.5 mg dry weight or 2.5 mg wet weight.

The sequential addition of a basic and acid catalyst improved the efficiency of DT, particularly when there was water present in the reaction. With the addition of an amount of water equivalent to that in the centrifuged microalgal samples (80 µl), the basic catalyst SM was completely inhibited and the activity of BF_3 was reduced, while the combination of catalysts yielded complete conversion. This might have been due to the basic catalyst, in the presence of water, resulting in saponification (or alkaline hydrolysis) and cleaving the ester bonds between fatty acids and glycerol. This removed the water and allowed the acid catalyst to esterify the free fatty acids at a faster rate [21]. If dry samples are used, BF_3 on its own is as effective as a combination of catalysts. However, under conditions where there is water present in the reaction, a combination of base and acid catalysts should be used, or alkaline hydrolysis should be performed before methylation.

The majority of previously reported DT protocols for microalgae used lyophilised biomass and a single acid catalyst [25–31]. This study has shown that drying of centrifuged algal biomass was not necessary if a sequential combination of basic and acid catalysts were used. The two-reagent transesterification reaction was unaffected by water up to 10% of the total reaction volume (290 µl). The water content of the algal samples contributed 80 µl of water (3% of total reaction volume) and was well within the acceptable range, thus centrifuged samples could be

processed immediately without drying. It was not necessary to add a water scavenger at water contents less than 10%, although this may have been beneficial at high water contents (>30%). As additional reactants such as 2,2-dimethoxypropane can cause extra peaks in the chromatogram, it is recommended that water scavengers not be used at low water contents (<10%).

The major limitation of this method is that by converting all lipids directly into FAME, lipids can no longer be separated and evaluated as different classes, e.g. polar phospholipids and glycolipids versus non-polar or neutral triacylglycerols. If a study requires the differentiation of lipid classes, solvent extraction of the tissue may be necessary.

As FAME are the components of biodiesel and transesterification is the major method of biodiesel production, DT has potential large-scale application in the rapid, low cost production of biodiesel directly from microalgal cells without the need for oil extraction. Johnson and Wen [36] showed that a one-step method of DT resulted in a higher FAME yield from *Schizochytrium limacinum* (a Thraustochytrid, taxonomically aligned with heterokont microalgae [37]) than oil extraction followed by transesterification, and could produce biodiesel where 8 out of 11 parameters met ASTM fuel standards. Eliminating the step of oil extraction could make the process cheaper, but does not eliminate the need for harvesting and dewatering of the biomass to less than 10%. The analytical procedure described here would need to be further developed to use cheaper and less toxic transesterification reagents, and allow recycling of the solvents. Preliminary data has indicated that sodium hydroxide in methanol (0.5N) and hydrochloric acid in methanol (5%) can be substituted for sodium methoxide and BF_3 methanol, respectively (data not shown).

decomposed to aldehydes during the digestion and absorption processes. Giuffrida et al. [3] detected that low pH promotes breakdown of epoxidized lipids to diols in simulated gastric conditions. Low pH also promotes oxidation of double bonds and as oxygen is present in the stomach in excess, it is likely that the stomach acts as an oxidative bioreactor [4, 5]. Moreover, the ferrous ions that are formed during the digestion of meat products can readily act as catalysts in the oxidation reactions in the stomach [6, 7]. It is difficult to study lipid oxidation during digestion processes, because of the necessity of using animal models and because such research requires complex analytical procedures. However, there are alternatives to animal models. In the current experiment, an artificial digestion model was adopted to analyze the progression of lipolysis and the presence of oxidized lipids [8, 9].

During digestion, triacylglycerols (TAG), which are the main molecular species of refined oils, are hydrolyzed by different enzymes to form free fatty acids (FFA) and monoacylglycerols (MAG). Diacylglycerols (DAG) are also formed in the stomach and in the first part of the small intestine. Lingual lipase and gastric lipase are both active in the acidic environment in the stomach and can hydrolyze from 10 to 30% of the TAG present in the stomach to FFA and DAG [10, 11]. Generally, short and medium-length fatty acids are hydrolyzed more efficiently by gastric lipase than long ones, and the *sn*-3 position is preferred over the *sn*-1 position while the *sn*-2 position is left mostly intact [12]. Different polarities and dipole properties of FFA, MAG, DAG, and TAG result in different distributions inside the lipid droplets formed during digestion. As digestion proceeds, lipid droplets become smaller in size and eventually form mixed micelles with phospholipids, cholesterol, cholesteryl esters and bile salts in the intestine. FFA and MAG are released from the mixed micelles in the duodenum and absorption takes place. Some absorption of FFA also takes place in the stomach [13].

Among the various methods developed to analyze these nonvolatile lipids is high performance liquid chromatography (HPLC) coupled with mass spectrometry (MS). Atmospheric pressure chemical ionization (APCI)–MS [14–18] and electrospray ionization (ESI)–MS [19, 20] have been used to determine e.g. the TAG composition of low erucic acid rapeseed oil. APCI–MS [18] and ESI–MS [21] have also been used to analyze oxidized TAG species of low erucic acid rapeseed oil as ammonium adducts. Simultaneous analysis of different lipid classes is usually performed in a less specific manner e.g. with thin layer chromatography (TLC) [22]. Furthermore, normal phase (NP)-HPLC is frequently used in the crude separation of FFA, MAG, DAG, TAG, phospholipids, and different cholesterol species, followed by more detailed gas chromatography (GC) or HPLC analysis. More specialized NP-HPLC–ESI–MS^n analysis of different lipid classes has recently been developed [23]. Solid phase extraction (SPE) is often used to separate major lipid classes from each other prior to more specific analysis of different molecular species [22].

Once isolated, fatty acids are routinely analyzed by GC as methyl esters. NP-HPLC analysis of fatty acids is usually performed after derivatization to picolinyl or methyl esters, but some work has also been done with underivatized free fatty acids [24, 25]. Orellena-Coca analyzed epoxidized free fatty acids with a reversed phase (RP)-HPLC-evaporative light scattering detector (ELSD)–MS and MS/MS with good resolution between individual molecular species [26]. However, the handling and derivatization of the sample takes time and possibly exposes the sample to further oxidation or other deterioration. Moreover, GC analysis involves elevated temperatures that may affect some of the oxidized molecules such as unstable hydroperoxides.

The purpose of the current study was to develop a method for the simultaneous analysis of FFA, MAG, DAG, and TAG molecular species and their oxidation products from lipid digestion samples. In particular, the aims were to (a) achieve adequate resolution among individual molecular species while reducing the overall workload significantly and (b) reduce the risk of sample oxidation during handling. The developed HPLC–ELSD–ESI–MS method was applied to study lipid digestion and oxidation in an artificial digestion model.

Experimental Procedures

Materials and Methods

All solvents were of HPLC grade or when adequate, *p.a.* grade. HPLC grade water was prepared with Millipore Milli-Q water purification system (Millipore SA, Molsheim, France). Porcine pepsin, lipase, pancreatin, α-amylase from *Aspergillus oryzae*, and bovine serum type II albumin were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Mucin was purchased from Carl Roth GmbH (Karlsruhe, Germany). 12-hydroxyoctadecanoic acid (>98%), 1(3)-monopalmitoyl-*sn*-glycerol (>99%), 1(3)-monostearoyl-*sn*-glycerol (>99%), 1(3)-monooleoyl-*sn*-glycerol (>99%), 1(3)-monolinoleoyl-*sn*-glycerol (>99%), 1(3)-monolinoleoyl-*sn*-glycerol (>98%), 1,2(2,3)-dipalmitoyl-*sn*-glycerol (>99%), 1,3-dipalmitoyl-*sn*-glycerol (>99%), 1,3-dioleoyl-*sn*-glycerol (>99%), 1,3-dilinoleoyl-*sn*-glycerol (>99%), and 1,3-dilinolenoyl-*sn*-glycerol (>99%) were purchased from Larodan Fine Chemicals AB (Malmö, Sweden). Saturated even carbon number free fatty acids (C_{10}–C_{24}), and palmitoleic, oleic, linoleic, and α-linolenic

acids, and trinonadecanoyl-*sn*-glycerol were purchased from Sigma-Aldrich Co. A triacylglycerol mixture (GLC HPLC # G-1) was purchased from Nu-Check Prep Inc. (Elysian, MN, USA). The mixture was composed of saturated TAG from tricaprin to tristearin, and also included tripalmitolein, triolein, trilinolein, and trilinolenin (see Table 2). Oxidized triacylglycerols (1,3-distearoyl-2-(monohydroperoxy)stearoyl-*sn*-glycerol, 1,3-dibehenoyl-2-(monohydroperoxy) oleoyl-*sn*-glycerol, 1,3-distearoyl-2-(monohydroperoxy) oleoyl-*sn*-glycerol, 1,3-dibehenoyl-2-(monoepoxy)stearoyl-*sn*-glycerol, 1,3-distearoyl-2-(diepoxy)stearoyl-*sn*-glycerol, 1,2-(monoepoxy)distearoyl-3-stearoyl-*sn*-glycerol, 1,3-distearoyl-2-(monohydroperoxy)linoleoyl-*sn*-glycerol, and 1,3-dibehenoyl-2-(9-oxo)nonanoyl-*sn*-glycerol) were used from previous experiments [27]. Rapeseed oil (Kultasula, Raisio plc, Finland), milk protein isolate (MAITO90, Func Food Finland Oy, Finland), potato starch (Pirkka, Kesko Corporation, Finland), and fiber preparation (Kuidukas, Myllyn Paras Oy, Finland) were purchased from a grocery store. 3-chloroperoxybenzoic acid and methylene blue were obtained from Sigma-Aldrich Co. Hydrogen peroxide (30%) and formic acid (99%) were obtained from Riedel-de Haën (Riedel-de Haën AG, Seelze, Germany).

Oil Oxidation and Synthesis of Oxidized Reference Compounds

Low erucic acid rapeseed oil was oxidized in a convection oven at 100°C for 48 h. As epoxides are reported to break down to diols in acidic conditions, hydroxylated oil was selected as the second oxidized oil for the digestive experiments [3]. The hydroxylated oil was prepared by chemical oxidation according to Harry-O'Kuru and Carriere from rapeseed oil [28]. Formic acid (370 μL) was mixed with rapeseed oil (3.0 g) while gently mixing with a magnetic stirrer in test tubes. Hydrogen peroxide (3.8 mL) was added slowly while mixing and the temperature was raised to 70°C for 15 h. H_2O (1.8 mL) was added with HCl (250 μL). Mixing was continued for an additional 15 h at 70°C. The mixture was transferred to a separatory funnel with ethyl acetate. The chemically oxidized oil was first washed with saturated NaCl solution, then with saturated $NaHCO_3$ solution, and finally with MQ water. Ethanol (97%) was added to separate the water from the chemically oxidized oil. A rotary evaporator (50°C) was used to dry the oil.

Additionally, linoleic and linolenic acids were oxidized by a photosensitizing method according to Neff et al. [29] and epoxy derivatives were prepared according to Deffense [30]. Briefly, 15 mg of linoleic and linolenic acids in dichloromethane (400 μL) were mixed separately with 3-chloroperoxybenzoic acid (40 mg) to form epoxy derivatives, and linoleic and linolenic acids (30 mg each) in dichloromethane (400 μL) were photo-oxidized in 0.1 mM methylene blue solution (3 mL) under a 250 W UV light (distance from light 20 cm for 15 h) to form hydroperoxides. The solutions in test tubes were kept in an ice bath during the photo-oxidation. In addition, hydroperoxidized monoacylglycerols and diacylglycerols were produced by photo-oxidation from 1(3)-monooleoyl-*sn*-glycerol, 1(3)-monolinoleoyl-*sn*-glycerol, 1(3)-monolinolenoyl-*sn*-glycerol, 1,2(2,3)-dioleoyl-*sn*-glycerol, and 1,2(2,3)-dilinoleoyl-*sn*-glycerol. Peroxide values were measured from the oxidized rapeseed oils according to AOCS method Cd 8-53 [31].

Standard Meal

A standard meal was prepared for the digestion experiments. Potato starch was used as the carbohydrate source, milk protein isolate as the protein source, and fiber was obtained from a bran mixture of oat, rye, and wheat. The carbohydrate, protein, and fiber contents of the standard meal were calculated from the composition information given by the manufacturers. The Finnish nutritional recommendations from the National Nutrition Council [32] and the National FINDIET 2002 survey [33] were used as the basis for the calculations of the macronutrient composition of the standard meal. 50.0% of the energy of the standard meal came from carbohydrates, 16.5% from proteins, and 33.5% from separately added lipids. Three grams of fiber were added for each MJ of energy. Lipids were removed from the milk protein isolate and from the fiber preparation by a exhaustive (40 h) Soxhlet extraction with chloroform and methanol (2:1, v/v). Lipid-free ingredients were dried in a convection oven (60°C) overnight, weighed, and mixed together. The dry standard meal base was stored in a desiccator. The standard meal was prepared from the dry base by adding water and consecutively heating the mixture (100°C for 20 min.) to hydrate the starch. The lipid component was added separately.

Artificial Digestion Model

The artificial digestion model to be developed was based on the Versantvoort et al. [8, 9] comprehensive study on simulation of human digestive processes. The compositions of digestive fluids used here were based on the fed state, in contrast to the fasted state, simulating the conditions during and after meal consumption and digestion. The main differences to Versantvoort's model were the scale and scope and the collection of saliva from volunteers instead of artificially making it. Inorganics were weighed and diluted in 25-mL volumetric flasks which were stored in a refrigerator. Organic fluids were prepared on the same day the digestion model was used. Appropriate amounts were

Table 1 Volumetric composition of the artificial digestion model

Component	Volume (mL)
Food	0.9
Saliva	0.6
Gastric fluid	1.2
Bicarbonate (1 M)	0.2
Bile	0.6
Intestinal fluid	1.2
Total volume	4.7

weighed into 25-mL volumetric flasks and dissolved in deionized water. The collected saliva was centrifuged (1,100×*g*) and the supernatant was used as is on the same day. Saliva was stored refrigerated for a short period of time. The simulated gastric fluid, bile, and intestinal fluid were prepared from organic and inorganic fluids according to Versantvoort et al. [9]. All the liquids were heated to 37°C before use in the artificial digestion model.

The standard meal (900 mg) was weighed in test tubes and the appropriate oil (35 mg) was added, together with an internal standard (5 mg of 12-hydroxystearic acid). Saliva and gastric fluid were added (see Table 1), the test tubes were capped and incubated (pH 2–3) in a shaker for 2 h (700 U/min, 37°C). Finally, bicarbonate, bile, and intestinal fluid were added and the test tubes were incubated for an additional 2 h (pH 6.5–7). Samples (200 μL) were taken for extraction. The pH of the food and digestive fluid mixtures in different digestive phases were checked with a pH meter (WTW inoLab Ph Level 1, Wissenschaftlich-Technische Werkstätten GmbH, Weilheim, Germany).

Extraction

Samples after digestion were extracted according to Folch et al. [34] with minor adjustments. Nitrogen gas was used as an inert atmosphere during the extraction procedures. Samples (200 μL) of digestion fluid were added to disposable glass test tubes and MeOH (1.5 mL) was added. The test tubes were mixed thoroughly and chloroform (3 mL) was added. The test tubes were incubated in a shaker (700 U/min) at room temperature for 1 h. H_2O (1.25 mL) was added, mixed and left to stand. The test tubes were centrifuged at 1,000×*g* for 10 min and the lower phase was carefully transferred into a clean tube. For quantitative extraction, clean lower phase (2 mL) was added to the remaining upper phase, and the test tubes were remixed and centrifuged. The lower phases were combined avoiding any precipitates, evaporated to dryness, and dissolved in isopropanol (1 mL). The samples were not filtered prior to analysis. Extracted samples were stored in a deep freezer (−80°C) for a short period of time until analyzed.

GC Analysis of Fatty Acid Methyl Esters

The fatty acid composition of native rapeseed oil was determined using a GC–flame ionization detector (FID) by comparison to authentic reference compounds. Briefly, 0.3 mg of oil were transferred into test tubes and spiked with 0.1 mg of internal standard trinonadecanoin. Toluene (100 μL) and boron trifluoride in methanol (0.5 mL) were added and the capped test tubes were incubated for 1 h (90°C). After extraction with hexane (0.8 mL) and H_2O (1 mL), the samples were analyzed with a Perkin-Elmer Auto-System Gas Chromatograph (Waltham, MA, USA) with an autosampler and a 60 m × 0.25 mm i.d., 0.25 μm film thickness, J.W. Scientific DB-23 column (Agilent Technologies Inc., Santa Clara, CA, USA). The following temperature program was used. An initial 130°C oven temperature was held for 1 min, then increased to 170°C (6.5°C/min), then to 215°C (2.8°C/min) and held for 12 min, and finally to 230°C (40°C/min) and held for 3 min. The injector was held at 270°C and the detector at 290°C. The injection volume was 1 μL and four replicates were injected per sample.

HPLC–ELSD–ESI–MS Analysis

A Waters Acquity UPLC™ was used as an LC inlet (Milford, MA, USA), and a Macherey-Nagel C18 Nucleodur ISIS column (250 mm × 4.6 mm i.d., 5 μm particle size, Macherey-Nagel inc., Bethlehem, PA, USA) was used for the separation of lipid components. An evaporative light scattering detector (Sedex LT-75, Sedere Inc., Lawrenceville, NJ, USA) was used to detect the separated sample components simultaneously with a Waters Quattro Premier tandem quadruple mass spectrometer used in positive ESI mode. A solvent gradient program was used for the HPLC separation. Solvent A was composed of acetonitrile, H_2O, and formic acid (50:50:0.1, by vol). Solvent B was composed of isopropanol, acetone, and formic acid (90:10:0.1, by vol). Solvent B was increased from an initial level of 10 to 60% in 40 min and to 95% in 85 min. The total flow rate was 1.0 mL/min of which 20% was directed to the mass spectrometer. The ELSD was operated at 40 psi and 70°C.

High water and isopropanol contents of the mobile phases resulted in very high operating pressures. 250 mm × 4.6 mm i.d. columns with 5 μm silica particles can withstand around 5,000 psi of back pressure. Acetone could have been used as pure B solvent but the increase in the low *m/z* background noise in MS was excessive. Instead we modified the existing column oven of the Acquity UPLC system to hold a 250 mm × 4.6 mm i.d. column. After careful insulation, it was possible to decrease the back pressure significantly (approx. to half) by warming up

the column to 60°C. A more modest temperature (30°C) was, however, selected to minimize possible in-column oxidation during the 90 min analysis. This small increase in column temperature when combined with 10% acetone in solvent B was enough to keep the maximum back pressure at less than 5,000 psi.

Free fatty acids can partially ionize during chromatography, resulting in peak broadening and tailing. Different ionization suppressors were tested during optimization. 0.05% trifluoroacetic acid (TFA) gave the sharpest peaks for FFA but resulted in excess noise in the MS detector. Acetic acid and formic acid (0.1%) were similar in the efficiency of ionization suppression during chromatography but not as effective as TFA. Formic acid was selected because of the lowest noise in MS, although some peak broadening still occurred.

Mass calibration of the mass spectrometer was done automatically by Waters MassLynx 4.1 control software. Preliminary calibration was done by infusion of a NaCsI solution. This, however, resulted in small systematic mass error in the higher mass region which was corrected by recalibrating the instrument and all the acquired data. The new calibration was done with the aid of water clusters [35]. Three types of calibrations were performed on each quadrupole: a static scan calibration (50–1,800 Da), a scanning calibration (50–1,800 Da), and a scan speed compensation calibration (200–5,000 amu/s). 31 peaks obtained by the infusion of 0.1% TFA solution were compared to a reference file (calculated monoisotopic cluster peaks of water, $[H_3O + nH_2O]^+$) and calibration curves were obtained. The maximum acceptable deviation of mass differences was set at 0.2, which was not exceeded during the calibration. The mass precision remained good throughout the analyses, and therefore, all the recalibrated data were considered accurate. Tuning was performed by introducing reference compounds via a syringe pump to a tee leading into the ion source, while the solvent flow from the inlet was set at 150 μL/min. Mass spectra from 150 to 1,100 *m/z* were collected in the positive ionization mode. Tuning was optimized for simultaneous analysis of FFA, MAG, DAG, and TAG. The ESI capillary voltage was set at 3.00 kV, the cone voltage at 300 V, the extractor voltage at 2 V, the source temperature at 120°C, the desolvation temperature at 170°C, the desolvation gas (N_2) flow at 600 L/h, and the cone gas flow at 500 L/h. The cone voltage was set at 300 V, because less background noise was observed compared to a smaller and more typical setting of 10–60 V.

Quantitative Calculations

Quantitative calculations were performed from calibration and sample runs. MassLynx 4.1 was used for ELSD and MS data collection and analysis. Origin 8 SR4 (OriginLab Co., Northampton, MA, USA) was used for calibration curve fittings. The quantification was based on calibration curves that were formed by linear fitting of the area of extracted single ion mass chromatogram peaks versus concentration. An internal standard (12-hydroxyoctadecanoic acid) was used to correct for any sample loss during sampling or Folch extraction. Duplicate runs of five different levels of reference compounds were performed to obtain calibration curves. 10, 5, 2.5, 1.25, 0.625 μg loads to column were used for FFA, and one tenth of the amount of FFA for MAG, DAG, and TAG. The saturation of the MS signal limited the accuracy of quantification at higher concentrations. No reliable quantification was performed on the oxidized compounds because the reference compounds acquired were not sufficiently pure.

Results and Discussion

Development of HPLC–ELSD–ESI–MS Method

To develop a comprehensive HPLC method that would be capable of separating FFA, MAG, DAG, TAG, and their oxidized equivalents, a large number of reference compounds was used. Figure 1 shows ELSD and MS chromatograms, as well as a combined full scan mass spectrum of 0–90 min of the unoxidized reference compounds analyzed by the developed method. Analogous chromatograms and a spectrum of oxidized reference compounds are presented in Fig. 2. In addition, oxidized reference compounds were analyzed individually. The assignments, the retention times of the unoxidized and oxidized reference compounds, and the most abundant positive ions formed in ESI–MS are given in Tables 2 and 3, respectively (oxidized molecules are numbered with apostrophes and unoxidized with plain numbers.) Linear fitting equations used in the quantification of some of the MAG, and DAG are shown in Table 4, along the coefficients of determination.

The ELSD served as an auxillary detector and produced similar response profiles as the MS detector for the unoxidized lipids. However, the relative signal intensities of FFA (e.g. peaks 6 and 17 in Fig. 1a) compared to MAG, DAG and TAG were much higher in the ELSD signal compared with the ESI–MS signal in the positive ionization mode (see Fig. 1b). This indicates poor ionization of the FFA in the positive ionization ESI–MS. Also, epoxidized FFA (peaks 1′, 2′, and 4′ in Fig. 2a) had a much higher relative signal intensity in the ELSD. Diacylglycerols formed $[M+23]^+$ ions (sodium adducts) efficiently which corresponded to higher MS signal intensity of DAG (e.g. peaks 19, 22, and 26 in Fig. 1b) compared with MAG (e.g. peak 14 in Fig. 1b). It is worth noting that the flowrate into the ELSD was higher as only 20% of the total flow was

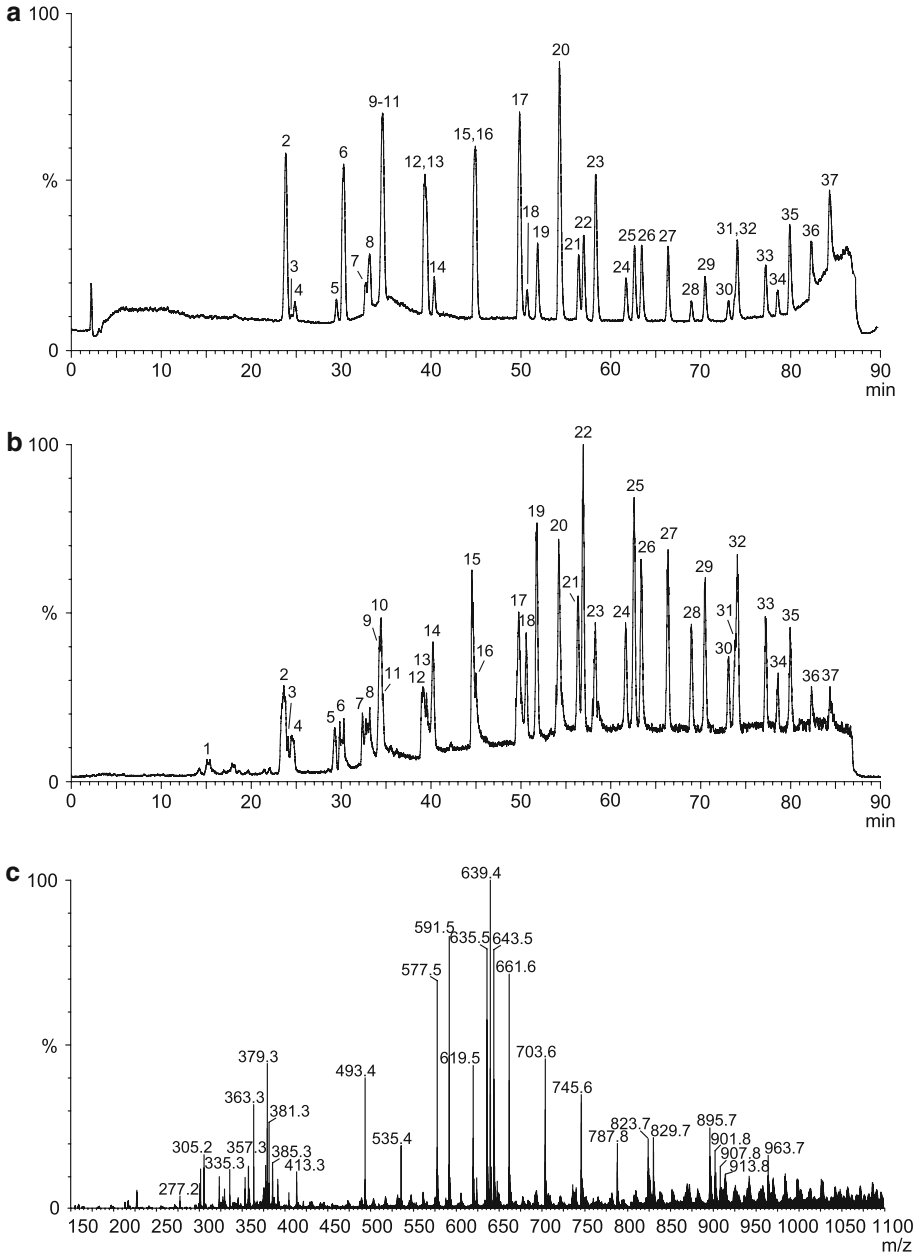

Fig. 1 ELSD chromatogram (**a**), full scan total ion MS chromatogram (**b**), and a combined full scan mass spectrum of 0–90 min (**c**) of unoxidized reference compound mixture. Analyzed as explained in experimental procedures. The amount injected was 5.0 μg of each FFA, 0.5 μg MAG, DAG, and most of the TAG. Refer to Table 2 for peak numbering

directed into the MS detector, and that the amount of FFA injected was ten times the amount of MAG, DAG, and TAG. As expected, the linear range of the response was higher with the ELSD. The total ion current chromatograms include much information that can be extracted and enables the study of closely eluting and unresolved peaks.

As expected, free fatty acids displayed negative $[M-H]^-$ ions when negative ionization mode was used, but as oxidized FFA did not readily form negative ions and since MAG, DAG or TAG did not form negative ions at all, negative ionization was not used. Protonated molecules $[M+H]^+$ were not observed by ESI–MS during analysis, as previously noted by others [17, 18], but instead the analytes formed sodium adducts $[M+23]^+$ and clusters of adducts $[2*M+23]^+$, $[2*M+45]^+$, $[2*M+67]^+$, and $[3*M+89]^+$. Water adducts $[M+18]^+$ were mainly observed with epoxidized FFA. Some protonated molecules and more intense water adducts were seen during tuning, but the flow rate was lower than in actual analyses. Medium length (10:0–16:0) FFA formed mainly $[M+45]^+$ ions and clusters of adducts with minimal $[M+23]^+$ ions. The $[M+45]^+$ ion is probably an adduct of a deprotonated molecule and two sodium atoms. Similarly, ions $[2*M+67]^+$ and $[3*M+89]^+$ probably correspond to clusters of two and

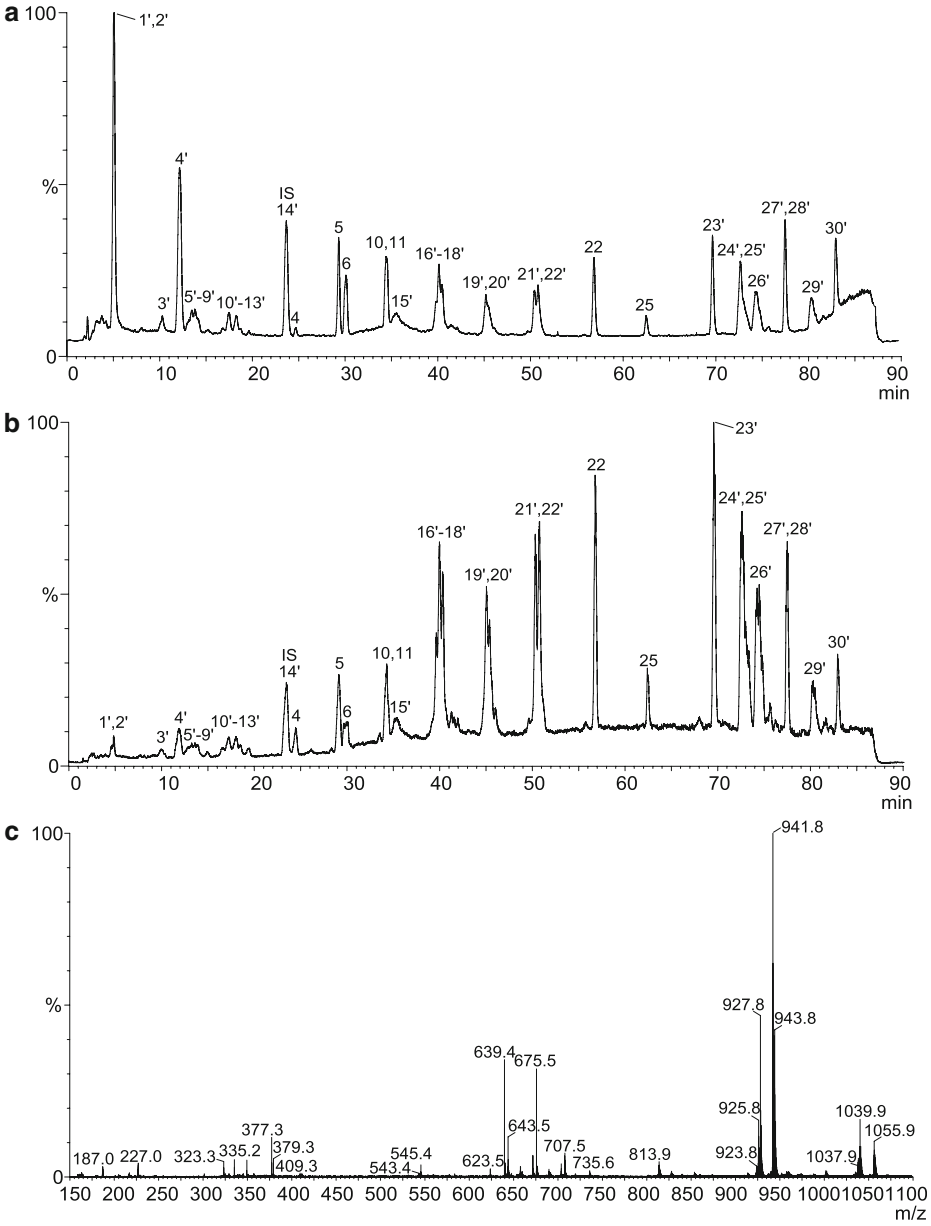

Fig. 2 ELSD chromatogram (**a**), full scan total ion MS chromatogram (**b**), and a combined full scan mass spectrum of 0–90 min (**c**) of oxidized reference compound mixture. Analyzed as explained in experimental procedures. Refer to Tables 2 and 3 for peak numbering

three deprotonated molecules plus three and four sodium atoms. Longer (>18:0) free fatty acids formed more of $[M+23]^+$ adducts. The amount of cluster ions was reduced when the cone gas flow rate was increased to 500 L/h. Possibly conditions in the ion source, such as high cone voltage, facilitated the formation of these somewhat undesirable clusters. Higher weight clusters, however, were of aid in the assignments of some ions.

MAG, DAG, and TAG formed predominantly sodium adducts. Owing to the upper limit of the scanning range (150–1,100 *m/z*), higher molecular weight clusters were observed from glycerolipids only if the $[M+23]^+$ ion was less than *m/z* 538. A distinctive $[M-H_2O+Na]^+$ ion formed from dehydration of the hydroperoxide group was seen in hydroperoxidized MAG, DAG, and TAG when analyzed by ESI–MS. This dehydration phenomenon has also been observed by others [18, 36]. The intensity of the $[M-H_2O+Na]^+$ ion varied from nearly 0% up to 65% compared to $[M+Na]^+$. Hydroperoxidized FFA, instead, formed $[M-H_2O+45]^+$ ions. Synthesized hydroperoxides of FFA, MAG and DAG clearly formed different geometric isomers with different retention times (see Fig. 2). Our RP-HPLC method can separate some of them, but some co-elution still occurred. In order to identify molecular species more reliably, purification by preparative HPLC and consecutive MS/MS and NMR analyses would be needed.

Analysis of Native, Thermally Oxidized, and Chemically Oxidized Rapeseed Oils

Fatty acid composition of the native low erucic acid rapeseed oil determined by GC–FID is shown in Table 5. The FA composition is similar to rapeseed oils used in Sweden [19], the Czech Republic [16], and North America [14], although oils of some Canola varieties have more oleic acid (72%) and much less linoleic (<2%) and α-linolenic (<2%) acids [21]. Typical low erucic acid rapeseed oil is susceptible to autoxidation, as 35% of the fatty acids are polyunsaturated and nearly 60% are monounsaturated. The peroxide values of the oxidized oils were 100 mequiv O_2/kg for the oven-oxidized rapeseed oil and 20 mEq O_2/kg for the chemically oxidized oil. Full scan total ion MS chromatograms of the undigested oils analyzed by the developed HPLC–ELSD–ESI–MS method are presented in Fig. 3 and fingerprint-like, diagnostic, combined spectra of the different oils are given in Fig. 4. Peak assignments and the most abundant positive ions, formed in ESI–MS from undigested native rapeseed, chemically oxidized rapeseed, and oven-oxidized rapeseed oils, are presented in Table 6.

The combined full scan spectra of different oils (Fig. 4) showed that thermally oxidized rapeseed oil and chemically oxidized rapeseed oil clearly differ from each other and from natural unoxidized rapeseed oil. Much of the UFA oxidized to higher molecular weight products but some were also converted to smaller molecular weight molecules, as in oven-oxidized rapeseed oil. These smaller molecular weight oxidation products are probably secondary oxidation products such as core aldehydes as described by Sjövall et al. and others [37–41]. Confirmation of the core aldehydes would have required derivatization with 2,4-dinitrophenylhydrazine and consecutive negative ESI–MS analysis [39, 40]. Moreover, the high temperature during oven oxidation may produce some dimers, trimers and various other oligomers of triacylglycerols as determined by Byrdwell et al. [41] Our HPLC method was not optimized for separating these high molecular weight oxidation products. Chemically oxidized oil contains, as expected, mainly hydroxy triacylglycerols, whereas hydroperoxides [20] are present mainly in the oven-oxidized rapeseed oil.

Artificial Digestion Model and Progression of Lipolysis

Figure 5 represents the full scan MS chromatograms of the digestion products of different oils used in the study. Only small amounts of diacylglycerols and even less triacylglycerols were detected in the model chyme 2 h after the addition of lipases. After 1 h of digestion with lipases, there were still significant amounts of DAG present along

Fatty acid composition was analyzed by GC as methyl esters, $n = 4$

SFA Saturated fatty acids, *MUFA* monounsaturated fatty acids, *PUFA* Polyunsaturated fatty acids

with TAG as well as some MAG and FFA (data not shown). These observations indicate that the overall digestion process was simulating the efficacy of the human digestive system quite well, even though there was no gastric lipase present. It is also worth observing that oxidized oils were digested as efficiently as unoxidized. No substrate specificity in favor of unoxidized oils was detected in the enzymatic processes. Table 7 summarizes the observed and identified digestion products of different oils. Several molecules remained unidentified due to the lack of authentic reference compounds, but some conclusions can be drawn from the mass spectra. Molecules with intense *m/z* 341 and 343 ions are likely to be hydroxylated and epoxidized linoleic and linolenic acids, since the

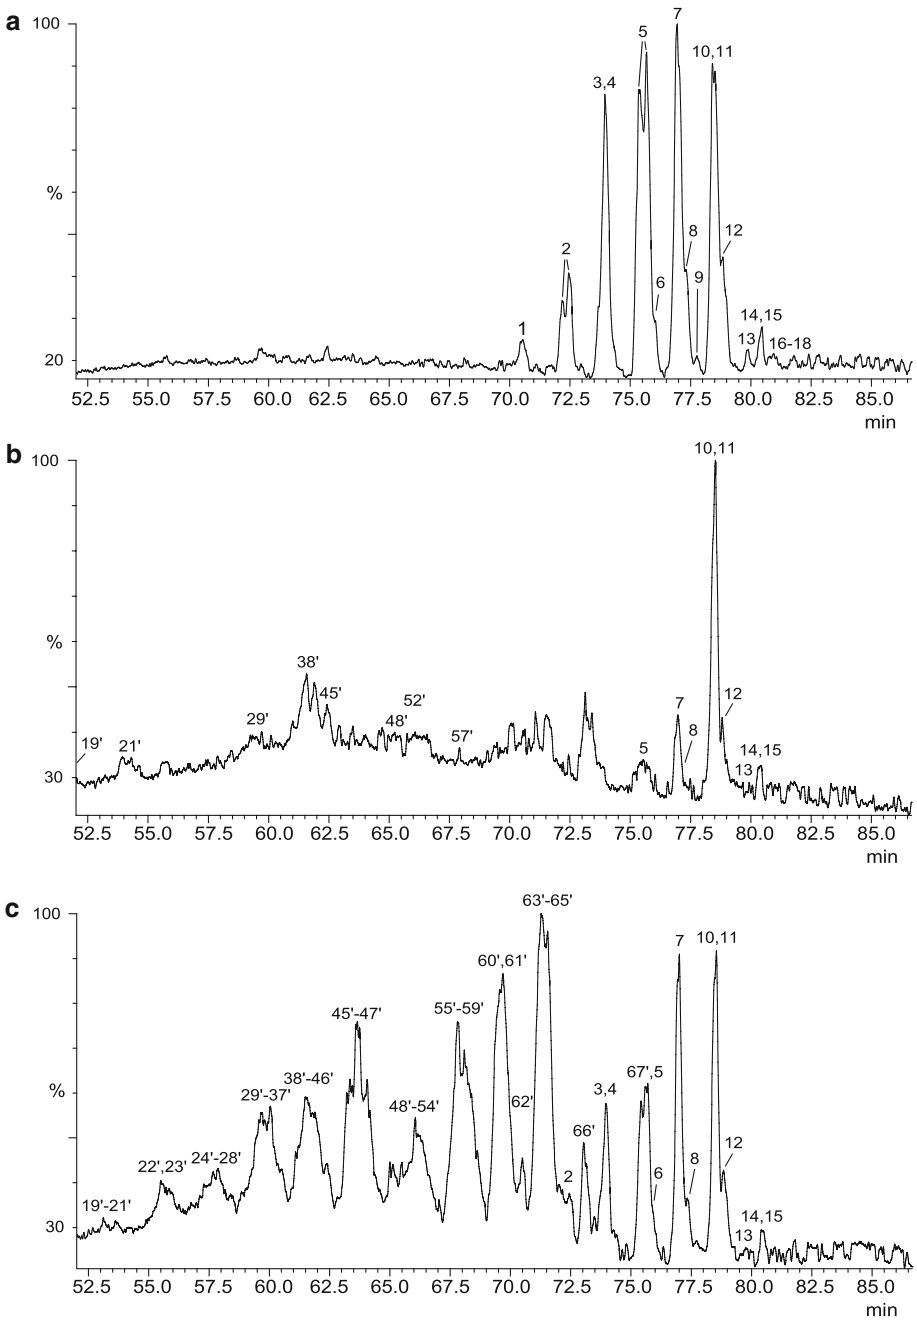

Fig. 3 Full scan total ion MS chromatograms of undigested rapeseed oil (**a**), oven-oxidized rapeseed oil (**b**), and chemically oxidized oil (**c**). Analyzed as indicated in experimental procedures. Refer to Table 6 for peak numbering

calculated values would fit if the formed ion is the expected $[M+45]^+$.

The proportional amounts of regioisomeric *sn*-2 and *sn*-1(3) monoacylglycerol pairs following digestion for 4 h (2 h with lipases) were quite unexpected (Table 8). After the artificial digestion of regular rapeseed oil, 35% of monoolein, 25% of monolinolein and 15% monolinolenin were in the *sn*-1(3) configuration. In the chemically oxidized oil the relative amounts were 30, 21, 20% and in the oven-oxidized oil 13, 0, 0%, respectively. Since pancreatic lipase is thought to be exclusively *sn*-1(3) specific, only the *sn*-2 regioisomer should have been present abundantly. The stereoselectivity of pancreatic lipase has been studied in the past but with limited focus on the formed monoacylglycerol identities in vivo or ex vivo [42]. Constantine et al. [43] observed that some free glycerol was formed when TAG were incubated for extended time. This could be explained by acyl migration of *sn*-2-MAG to *sn*-1(3) and subsequent hydrolysis to FFA and free glycerol. The chemically oxidized oil contained 28% and oven-oxidized oil 11% of the native TAG species present in unoxidized rapeseed oil. This partially explains the smaller amount of

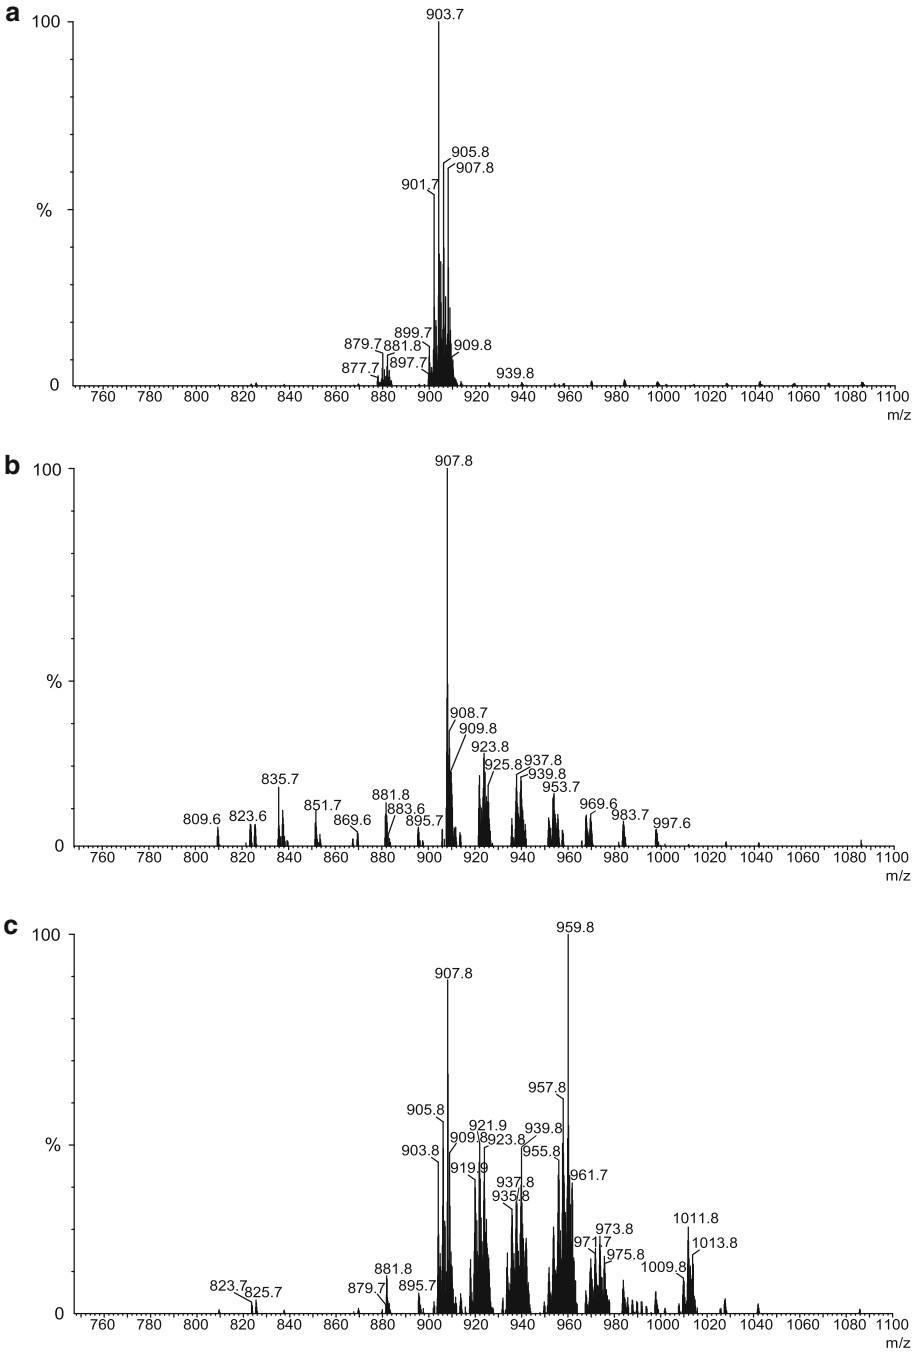

Fig. 4 Combined mass spectra of 50–85 min of undigested rapeseed oil (**a**), oven-oxidized rapeseed oil (**b**), and chemically oxidized oil (**c**). Analyzed as indicated in experimental procedures. Refer to Table 6 for peak listings

sn-1(3)-MAG present in the digested oxidized oils compared to the unoxidized oil.

If the only explanation of the presence of *sn*-1(3)-MAG is nonenzymatic acyl migration, it occurred at a clearly higher rate than previously thought. Although the low pH of the stomach facilitates acyl migration, such a high isomerization was not anticipated due to the addition of bicarbonate to the chyme in the intestinal phase of the artificial digestion model. Furthermore, the substrate specificity of pancreatic lipase should be considered. Again, if only acyl migration was the explanation, the *sn*-1(3)-MAG should have been hydrolyzed to free fatty acids and glycerol by the pancreatic lipase. It is possible that *sn*-1(3)-MAG have a very different affinity to pancreatic lipase as opposed to *sn*-1,2(2,3)-DAG. On-column acyl migration cannot explain the observed *sn*-1(3)-MAG because it would show as a broadening of the observed peaks. Also, sample treatment is minimized and only Folch extraction is done after the artificial digestion. Future experiments should address this interesting observation.

The developed HPLC–ELSD–ESI/MS method was shown to be very useful in the survey of digestion processes of glycerolipids present in an artificial digestion model. The method was capable of separating free fatty acids, monoacylglycerols, diacylglycerols and triacylglycerols and their oxidized equivalents with adequate resolution and, in case of MAG with good resolution, enabling the quantitation of regioisomeric pairs of MAG. Compared to other total lipid profiling techniques, such as capillary gas-liquid chromatography with FID that require derivatization and sample heating [44], this HPLC method has the advantage of minimal sample degradation during analysis. Unprotected hydroperoxy groups are known to isomerize and decompose when heated to high temperatures [45]. Acid-catalyzed methylation techniques have a tendency to isomerize conjugated diene structures and form artifacts [46]. On the other hand, base-catalyzed transesterification is a milder reaction, but cannot derivatize free fatty acids. Shotgun lipidomics with time of flight (TOF) mass spectrometry offers a different route to lipid profiling, but lacks the

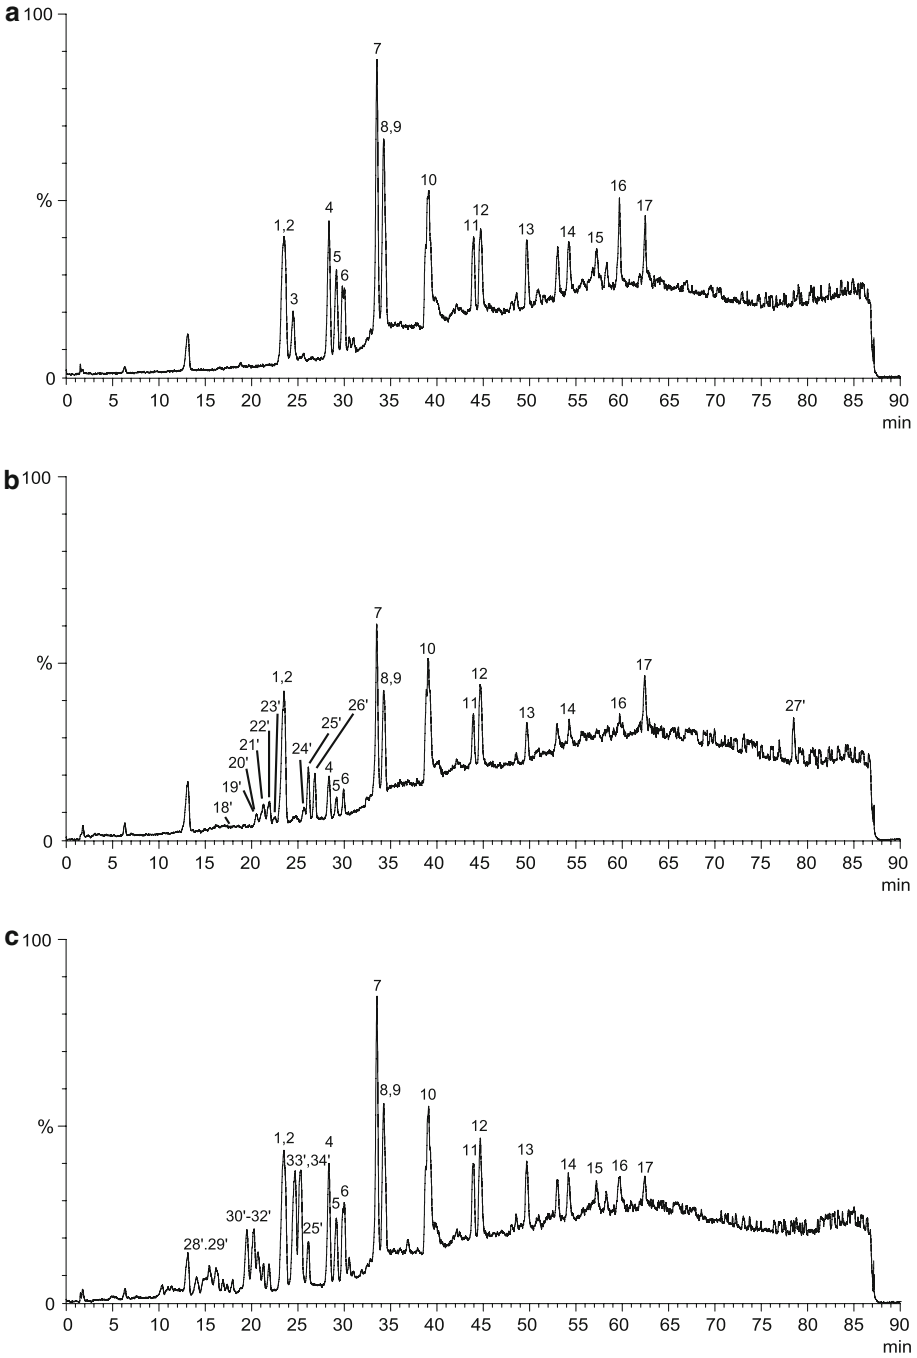

Fig. 5 Full scan total ion MS chromatograms of digested rapeseed oil (**a**), digested oven-oxidized rapeseed oil (**b**), and digested chemically oxidized oil (**c**). Analyzed as indicated in experimental procedures. Refer to Table 7 for peak numbering

separation specificity of liquid chromatography [47]. Ion suppression can be a problem when performing a direct infusion MS analysis. TLC–FID can be used for the quantitative assessment of FFA, MAG, DAG, and TAG species, but the method lacks the specificity of liquid chromatographic separation coupled with mass spectrometric detection [48].

The limitations of the developed method were sensitivity and resolution between some close eluting peaks. Even so, this method does offer a comprehensive view of the molecular structures found in complex lipid samples. If only sensitivity for known molecular species is sought, then selected ion monitoring (SIM) could be used, as full scan mass analysis from 150 to 1,100 *m/z* lowers the sensitivity compared to a narrower mass window. The length of single analysis is also a limiting factor. The chromatography time of 90 min should be shortened to speed up the analysis as a whole. Modern fast LC, UPLC™ and similar ultra high performance LC methods offer the possibility of shortening the time needed for analysis and

simultaneously maintaining or even enhancing resolution and sensitivity. Combined full scan spectra after proper chromatographic separation can produce fingerprint-like, diagnostic profiles of different kinds of samples for such uses as lipid oxidation monitoring, monitoring of lipolysis, and other metabolomic and lipidomic studies. The HPLC solvent gradient separation developed can easily be applied to preparative HPLC to isolate and purify oxidized fractions from different kinds of lipid samples. Nuclear magnetic resonance analysis of different fractions of digestion products could provide accurate information on the structures of oxidized lipid molecules.

Structural information organized by the SC components is essential for knowing the detailed diffusion mechanisms of SC. The role of the intercellular SC lipid bilayer in relation to the barrier function has been investigated by infrared (IR) spectroscopy [7–9] and X-ray diffraction [10, 11]. IR examination showed that the outer layers were less cohesive and the intercellular lipids are disordered compared with the deeper membrane, based on the C–H stretching absorbance of the methyl groups of the lipid acyl chains. The effects of UV irradiation and ethanol perturbations on the SC organization were studied by FTIR and IR imaging microspectroscopy. The X-ray approach is somewhat limited to model lipid membranes containing water or in-vitro SC specimens. Moreover, these methods are have difficulty to obtain information about depth-related changes of the SC.

On the other hand, EPR is a sensitive and nondestructive technique to measure the probe moieties in the lipid bilayers at ambient temperature [1–6]. The EPR probe method can provide an insight into the SC lipid organization as well as its dynamics. Detailed studies of EPR line intensities, linewidths, and line separations with various spin probes may provide the following information: (1) changes in the spin probe's molecular environment as well as nano- to micro-molar probe concentrations, (2) relative reorientation, and (3) lipid structure. The EPR spectroscopic technique could provide more interpretable information, which would allow us to understand the actual SC system further.

In addition, the EPR simulation can potentially provide further insight into skin-lipid structures. The order parameter (S_0) of the spin probe will provide a useful index about structural dependence as a function of the SC depth. The value obtained by the simulation will change by the signal intensity of the sebum secretion and other contribution of SC materials. However, the relative value of the particular SC sample as a function of the depth could provide a useful index of the SC.

In this report, we investigated the lipid structure of hairless mouse SC using aliphatic spin probes together with an EPR slow-tumbling simulation. Hairless mouse SC was used to find the spin-probe permeation effect of terpenes on the SC lipid. EPR spectra were analyzed by a slow-tumbling simulation. The values obtained for the lipid structure are discussed in terms of EPR spectral changes as well as the SC treated with chemical enhancers.

Experimental Sections

SC Cyanoacrylate Glue Stripping

The Institutional Animal Care and Use Committee of NIRS (National Institute of Radiological Sciences) approved the protocols used herein. The sampling method was first utilized by Marks and Dawber [12] to obtain SC sheets. Recently, Yagi et al. [5, 6] developed a process to study SC properties.

A glass plate (7 × 37 mm; Matsunami Glass Ind. Ltd., Tokyo, Japan) was used to strip the SC sheet. A single drop (~12 mg) of a commercially available cyanoacrylate resin had been uniformly spread on the plate. The glass plate was pasted on the back of the hairless mouse (HOS:HR-1, 8-week-old male). The SC specimens were successively removed from the back of the hairless mouse under anesthesia. The SC was stripped consecutively from one to three or four times. Approximately 1 mg of SC sample is required for the measurements.

Once the glue has solidified, no significant signal arises from the cured resin or from the spin probe dissolved in the resin [13]. The only signal observed arises from the spin probe in the attached SC sheet. This method has the advantage of avoiding prior exposure of the SC to enzymes [14]. The EPR signal intensity may depend to a slight degree on how thick a sample is removed by each stripping, but the dependence can be minimized by the amount and area of glue on the glass plate.

Preparation of SC Sheets

The spin probe reagents, 5-doxylstearic acid (5-DSA) and 3β-doxyl-5α-cholestane (CHL), were purchased from Aldrich-Sigma Chemical Co. Inc. and used as received. The molecular structures and coordination of spin probes used in this study of a slow-tumbling simulation are depicted in Fig. 1.

The terpenes, α-terpineol and (+)-limonene, were purchased from Sigma-Aldrich and used as received. The original solution of α-terpineol and (+)-limonene were separately applied on the back of the hairless mouse for 5 min and then the chemicals were wiped off. Then, one piece of stripped SC (~7 × 22 mm^2) was incubated in ~50 μM 5-DSA or CHL aqueous solutions for about 60 min at 37 °C. The probe solution was dropped onto the SC sheet. The SC sheet repels the aqueous solution but the probe goes into the lipid phase during the incubation. After rinsing with deionized water to remove excess spin probe, the SC sample was mounted on an EPR cell. The detailed sample preparations are described elsewhere [6].

EPR Measurements

A JEOL JES-FR30 X-band (9 GHz) EPR spectrometer was used to measure the SC samples at NIRS and analyses of EPR results were mainly performed by Nakagawa. Typical spectrometer settings were as follows: microwave power, 10 mW; time constant, 1 s; sweep time, 8 min;

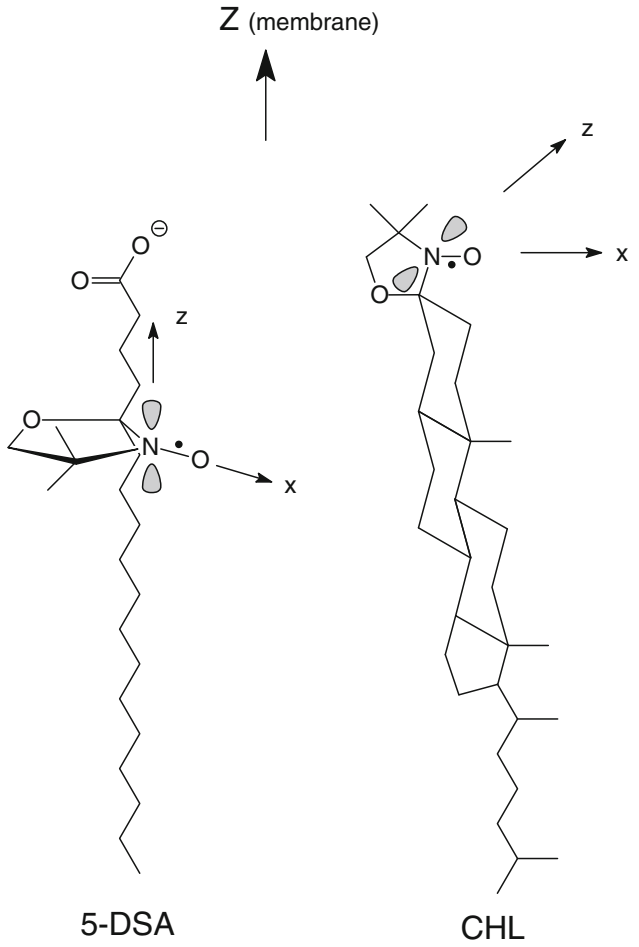

Fig. 1 Coordination of the spin probes, 5-DSA and CHL, for the slow-tumbling calculations are presented. The z-axis is the membrane director

modulation, 0.2 mT; sweep width, 15 mT. All measurements were performed at ambient temperature. The EPR spectra of the SC samples were analyzed using a quantitative simulated order parameter (S_0) [5, 6].

EPR Slow-Tumbling Simulation Analysis

The slow-tumbling motions on the order of 10^{-7} s of the aliphatic spin probes in membranes were evaluated by using the nonlinear least-squares fitting program NLLS to calculate the EPR spectra based on the stochastic Liouville equation [15, 16]. The lipid and 5-DSA molecules in the lipid bilayer experience ordering potentials, which restrict the amplitude of the rotational motion. The ordering potential in a lipid bilayer determines the orientational distribution of molecules with respect to the local ordering axis of the bilayer [17]. The overall orientation of the probe can be expressed by the order parameter (S_0), which is defined as follows [16, 18],

$$S_0 = \left\langle \frac{1}{2}\left(3\cos^2\gamma - 1\right)\right\rangle = \frac{\int d\Omega \exp(-U/kT) D^2_{00}}{\int d\Omega \exp(-U/kT)}, \quad (1)$$

which measures the angular extent of the rotational diffusion of the nitroxide probe moiety. Gamma (γ) is the angle between the rotational diffusion symmetry axis and the z-axis of the nitroxide axis system as shown in Fig. 2. The $\Omega = (\alpha, \beta, \gamma)$ are the Euler angles between the molecular frame of the rotational diffusion tensor, U is the ordering potential, and D is a Winger rotation matrix element.

In calculation based on the experimental spectra, the following principal components, A_{XX}, A_{YY}, A_{ZZ} = (0.66, 0.55, 3.45) mT and g_{XX}, g_{YY}, g_{ZZ} = (2.0086, 2.0063, 2.0025), were used for 5-DSA [19]. The components, A_{XX}, A_{YY}, A_{ZZ} = (0.49, 0.55, 3.31) mT and g_{XX}, g_{YY}, g_{ZZ} = (2.0087, 2.0057, 2.0021), were used for CHL [20].

The local or microscopic ordering of the nitroxide probe in the multilamellar lipid bilayer is characterized by the S_0 value. A larger S_0 value indicates highly ordered structure and a smaller S_0 shows less ordered structure. The modern simulation takes into account EPR intensities, linewidths, and hyperfine coupling values and provides the quantitative information regarding the probe environment. Therefore, S_0-value reflects the local ordering of the lipid structure in the membrane. The error of the spectral simulation is a few percentage points in the case of the dipalmitoylphosphatidylcholine membrane [17].

Results

First, we examined the probe stock solutions. Figure 3 shows EPR spectra of the probe aqueous solutions which were used for incubation of SC sheets. The left-hand EPR spectrum is of a 5-DSA solution and the right-hand

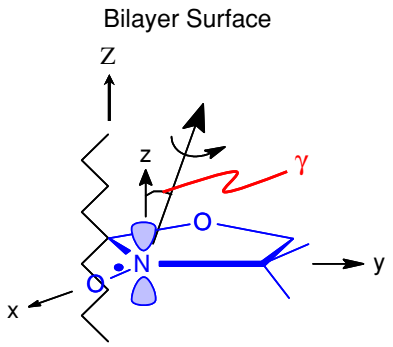

Fig. 2 A schematic representation of a conformation of DSA spin probe in the SC membrane, where the z-axis of the acyl chain is parallel to the z-axis of the nitrogen $2P_z$ orbital

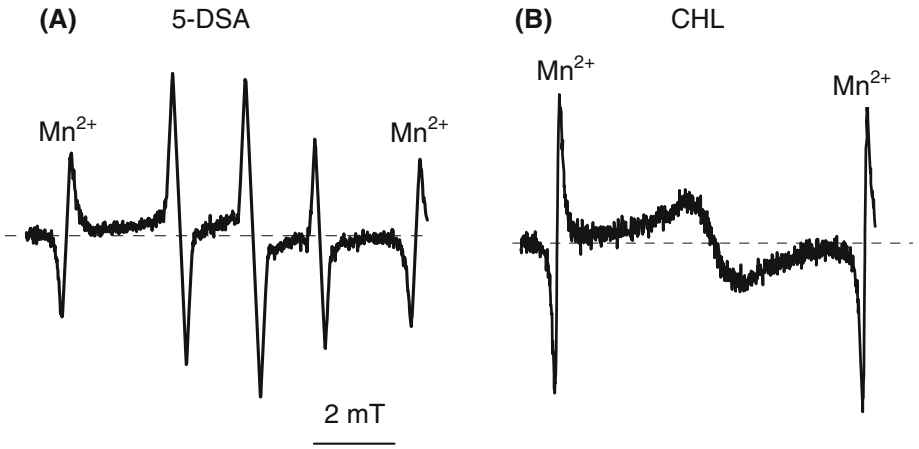

Fig. 3 EPR spectra of spin probes, **a** 5-DSA and **b** CHL, aqueous stock solutions are presented. The EPR spectra were obtained with a single scan

spectrum is of a CHL solution with reference signals for MnO^{2+} (8.69 mT at the distance of the third and the forth peaks). The three-line signal of the 5-DSA aqueous solution was observed. The sharp pattern indicates that 5-DSA is in free tumbling motion in the solution. The one-line signal was observed for CHL aqueous solution.

Figure 4 shows the experimental and simulated EPR spectra of 5-DSA in the SC. The EPR spectra obtained were very stable. The arrow in the spectrum indicates the characteristic peak, which is prominent for the first strip. This peak diminishes in intensity with increasing depth in the SC. It is noteworthy that one can observe the same signal intensity and line-shape at least few hours. The probe may be stable in the lipid bilayer of SC. The top spectrum is the first strip of the SC.

The marked peak appears near the center of the spectrum because the probe embedded in the first sample stripped has greater freedom of motion. The other two lines of the nitroxide probe overlaid the central region of the spectrum. The results imply that signals can originate from sebaceous secretion [6].

Next, we examined the effect of penetration enhancers (terpenes) on the SC lipid. Figure 5 presents the chemical structures of the terpenes, (+)-limonene, and α-terpineol. Figure 6 shows EPR spectra of a terpineol treated SC sheet as a function of depth. The spectra indicate the first and the third stripped SC treated with terpineol. The EPR intensity was very prominent for the first one. The signal intensity of the third stripped SC is a little smaller than that of the first strip.

In addition, we examined the spin probe CHL. Figure 7 shows EPR spectra of CHL from the hairless mouse SC. A relatively broad signal pattern was obtained. The spectral pattern for the second strip was very similar to that of the first strip, except for the intensity. The amplitude of the derivative spectrum for the second strip was about one-half of the amplitude of the first strip.

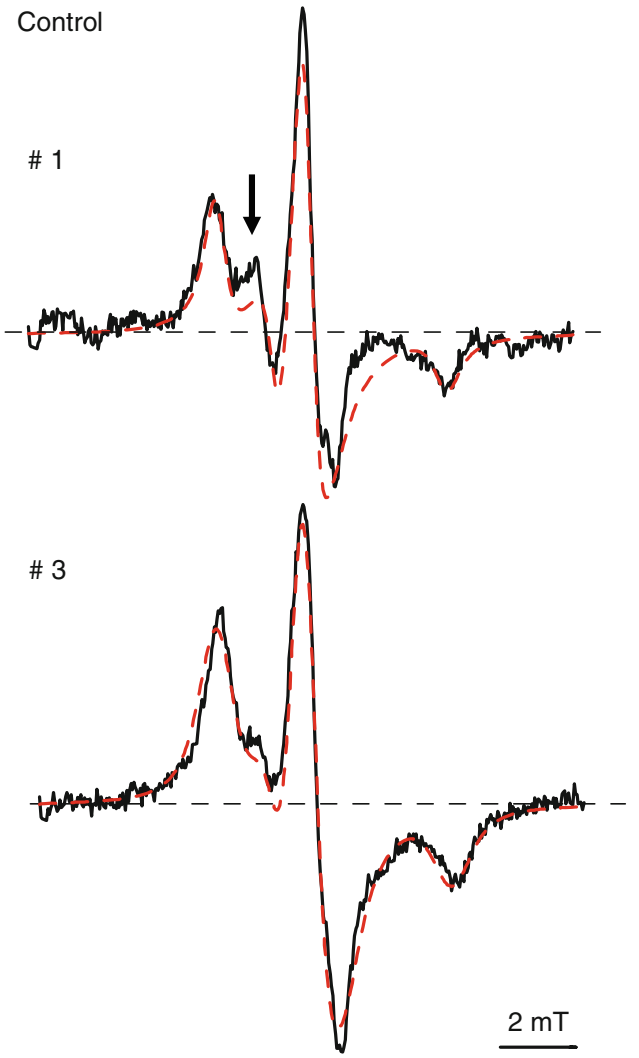

Fig. 4 Experimental (*solid line*) and simulated (*dashed line*) EPR spectra of 5-DSA probe are shown. Stripping numbers show consecutively stripped SC from the surface downwards. The *arrow* of stripping number *1* indicates the characteristic peak. The EPR spectra were obtained with the single scan. The *y*-axes for both spectra range from −800 to +1,200

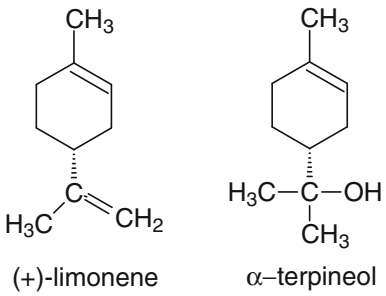

Fig. 5 Chemical structures of the terpenes used in this investigation

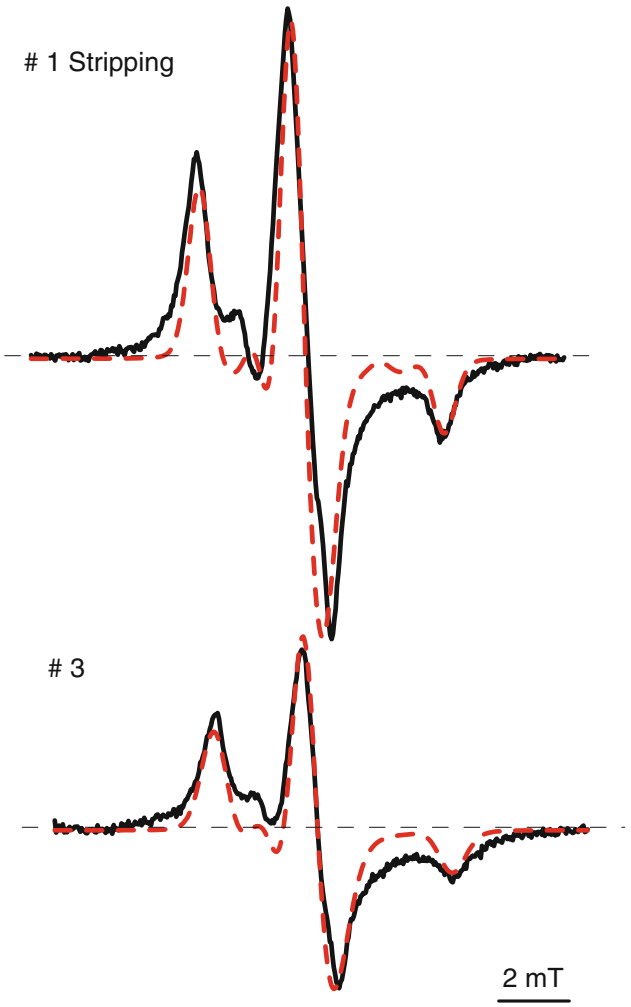

Fig. 6 Experimental (*solid line*) and simulated (*dashed line*) EPR spectra of 5-DSA probe for SC treated with α-terpineol are presented. Stripping numbers show consecutively stripped SC from the surface downwards. The *y*-axes for both spectra range from −2,000 to +2,000

Discussion

Changes in the lipid structural ordering (S_0) of SC can be monitored using the aliphatic probes. The orientation of the spin probe reflects the local molecular environment and the ordering should serve as indicator of conformational changes in the lipid bilayers of the SC. The higher value of the ordering indicates the rigid structure of the SC lipid.

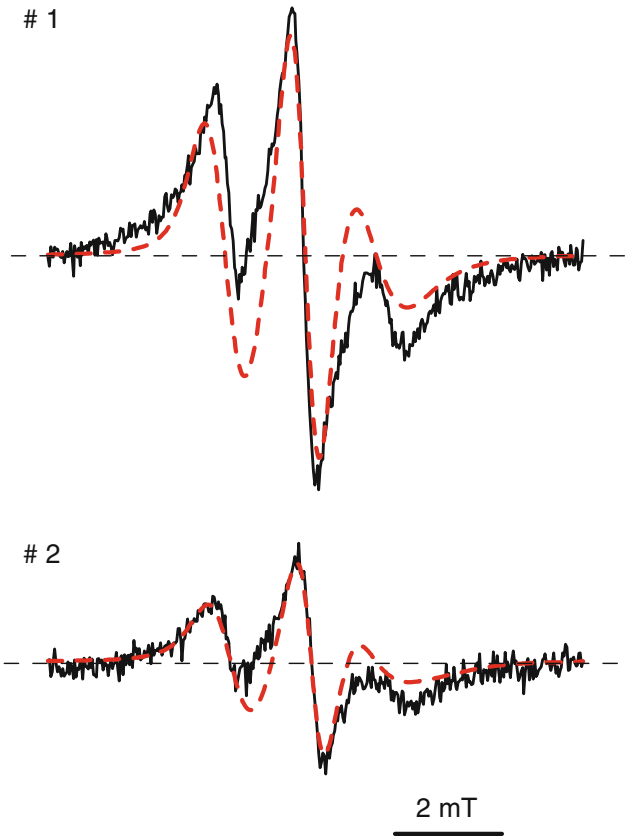

Fig. 7 Experimental (*solid line*) and simulated (*dashed line*) EPR spectra of CHL probe are presented. Stripping numbers show consecutively stripped SC from the surface downwards. The *y*-axes for both spectra range from −1,500 to +1,500

The asymmetric spectral pattern for 5-DSA suggests that 5-DSA is immobile in the SC. The reasonable agreement between the experimental and simulated spectra was obtained as shown in Fig. 4. The simulated S_0 values for the first and third stripped SC were 0.20 and 0.56, respectively. The reasonable agreement suggests that simulation analysis can provide information regarding the quantitative ordering structure of the SC lipids. It is noted that the deviation of the simulated spectrum from the observed spectrum may affect the S_0 value.

One can calculate the angle (γ in Eq. 1 and Fig. 2) between the rotational diffusion symmetry axis (the lipid in SC) and the *z*-axis of the nitroxide axis system [21]. Figure 8 represents the schematic illustration of the bilayer distance in relation to the angle. The simulated S_0 value of 0.20 can be the angle of 69°. The value of 0.55 is the angle of 33°. The angle suggests that the lipids align nearly 33° to the bilayer surface (Fig. 8). Thus, the distance within the bilayer will change because of the S_0 change.

Figure 9 shows a comparison of EPR spectra for control, limonene, and terpineol. The spectra were the first strip. The signal intensity of limonene treated SC is ~1.8 times stronger than that of the control. The signal intensity of terpineol treated SC is ~3.0 times stronger than that of the control. There is significant 5-DSA permeation effect of terpineol on the SC. In the 5-DSA case, the EPR intensity is proportional to the 5-DSA concentration in the SC because of the same EPR linewidth. Thus, the present results suggest that the α-terpineol having an OH-group is more effectively incorporated into the SC lipid than that of limonene.

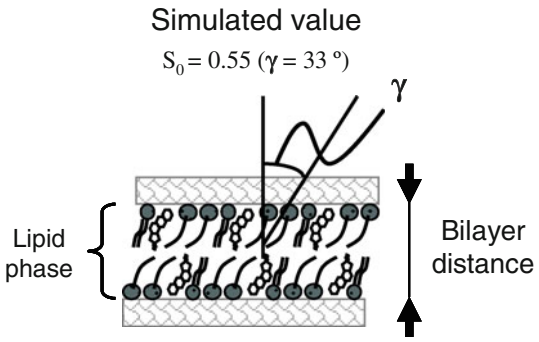

Fig. 8 Schematic illustration of the SC lipid bilayer is presented. The value of simulated order parameter (S_0) related to the angle (γ) between the bilayer surface and the single-chain probe is shown

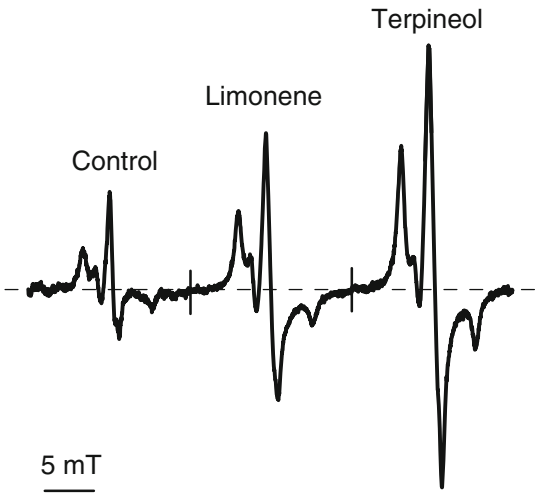

Fig. 9 A comparison of 5-DSA EPR spectra for control, limonene treated, and α-terpineol treated SC is presented. The EPR spectra were obtained for the first stripping of the SC

The simulated S_0 values for the first and the second strip (Fig. 6) were 0.81 and 0.80, respectively. The value for the first one is high even though the discrepancy between the experimental base line and simulated base line. Moreover, the amplitude of the derivative spectrum for the first strip was about two times stronger than that of the third strip (Fig. 6). The permeation of 5-DSA in SC was significant for the first strip. It was also suggested that 5-DSA penetrated the lipids of SC with other penetration enhancers [22]. The EPR spectra were drastically changed by the application of laurocapram in SC after 5–6 h [22] (laurocapram is an unfamiliar chemical in Japan. It was not available commercially at the time of the experiments). The present EPR results showed that EPR intensities increased within 5 min after application of the terpenes.

For CHL, the broad signal without detailed hyperfine splitting was observed. The dotted line is the slow-tumbling simulation of the observed spectra. There is a clear difference between the observed and simulated spectra. The simulated value (e.g. $S_0 \sim 0.3$) may not be reliable because of the discrepancy. The three-line pattern suggests that CHL is probably mobile in the SC.

Moreover, the three-line pattern (the three-line stick spectrum) and the weak outer side peaks were obtained for terpineol treated SC as shown in Fig. 10. The simulation discrepancy and the EPR signal for the terpineol were very different from the results of 5-DSA. Thus, EPR results imply that CHL probe may locate in different parts of the SC.

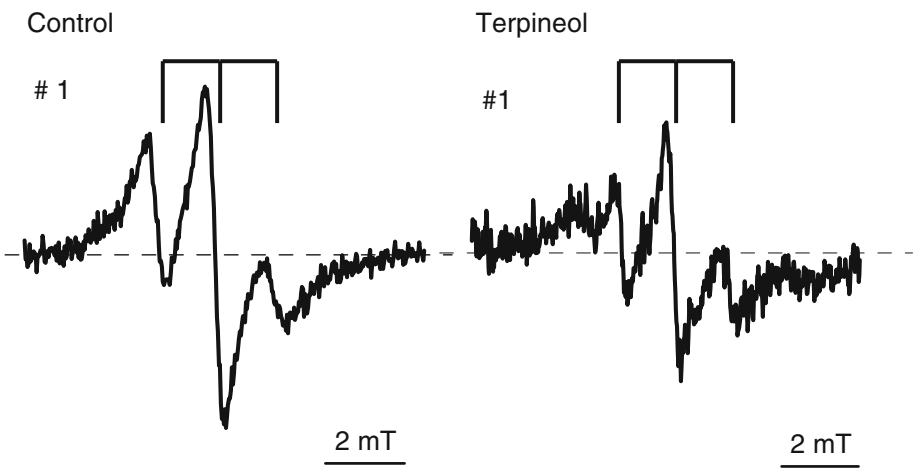

Fig. 10 A comparison of EPR spectra of CHL probe for control (*left side*) and α-terpineol treated SC (*right side*) is shown. The EPR spectra were the first stripping. The *three-line* stick spectrum indicates the signals due to the fast motion of the probe. The *y*-axis for control ranges from −1,500 to +1,500. The *y*-axis for terpineol ranges from −500 to +500

Finally, we made the quantitative evaluation of the effect of terpenes on intercellular lipid structure in SC as a function of skin depth. EPR along with a modern computational analysis provides structural changes of the SC. It was found that α-terpineol significantly enhanced the permeation of the 5-DSA in the SC. Moreover, the bulky CHL molecule showed a quite different behavior to that of 5-DSA in the SC. Therefore, the EPR technique could in turn provide more comprehensive information, which would further the understanding of various SC states. The present results could be useful for percutaneous absorption of drugs.

GβL	G protein β subunit-like protein also known as mLST8
GLUT 4	Glucose transporter 4
IRS	Insulin receptor substrate
LKB	Tumor suppressor protein
LPAAT	Lysophosphatidic acid acyl transferase
MEFs	Mouse embryonic fibroblasts
MGL	Monoacylglycerol lipase
mTOR	Mammalian target of rapamycin (TOR)
mTOR P-S2481	mTOR phosphorylated on serine 2481
mTORC1	Mammalian target of rapamycin complex 1
mTORC2	Mammalian target of rapamycin complex 2
NCS	Newborn calf serum
NEFA	Nonesterified fatty acids
RAPA	Rapamycin
Raptor	Regulatory associated protein of mammalian target of rapamycin
Rheb	Ras homolog enriched in brain
Rictor	Rapamycin-insensitive companion of mTOR
RII	Regulatory subunit II of PKA
TOS	TOR signaling motif
PA	Phosphatidic acid
PDE	Phosphodiesterase
PLD	Phospholipase D
PI3K	Phosphatidylinositol 3-OH kinase
Pol I	Polymerase I
PKA	Protein kinase A
PKB/AKT	Protein kinase B
PPAR γ	Peroxisome proliferator-activated receptor-γ
PTEN	Phosphatase and tensin homologue deleted on chromosome 10
S6K1	p70 ribosomal protein S6 kinase 1
S6K1 P-T389	S6K1 phosphorylated on threonine 389
TAG	Triacylglycerol
TSC	Tuberous sclerosis complex
VLDL	Very low density lipoprotein

Introduction

The mammalian target of rapamycin (mTOR), an evolutionarily conserved Ser/Thr protein kinase, coordinates a signal transduction network that controls a plethora of fundamental cellular functions [1–3]. mTOR forms the catalytic core of at least two functionally distinct signaling complexes, mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2) [3]. The better-understood complex, mTORC1, functions as an environmental sensor to promote anabolic cellular processes such as ribosomal gene transcription, protein synthesis, lipid synthesis, cell growth/size, and cell proliferation in response to sufficient levels of growth factors, nutrients, and hormones [2, 3]. Conversely, adverse cellular conditions rapidly downregulate mTORC1 signaling to promote catabolic functions such as autophagy [4]. mTORC1 and mTORC2 contain shared and unique partner proteins, possess unique cellular functions, and exhibit differing sensitivities to rapamycin, a clinically employed immunosuppressive drug [3]. Rapamycin (clinically known as sirolimus) associates with a cellular protein called FKBP12 [5]. Upon entering the cell, the rapamycin/FKBP12 complex directly binds to the mTOR FRB (FKBP12-rapamycin binding) domain, which lies immediately N-terminal to the kinase domain [5]. Rapamycin/FKBP12 binds assembled mTORC1 but not assembled mTORC2 [5]. Thus, rapamycin acutely inhibits mTORC1 but not mTORC2 signaling. While the mechanisms by which rapamycin allosterically inhibits mTORC1 signaling remain incompletely defined, the drug reduces the affinity between mTOR and raptor, a critical mTORC1 partner protein [5, 6]. Additionally, rapamycin reduces mTORC1 intrinsic kinase activity, as monitored by mTOR S2481 autophosphorylation [7]. The use of rapamycin in clinical medicine underscores the importance of mTORC1 for organismal physiology. Not only does rapamycin reduce organ transplant rejection [8], it reduces the intimal de-differentiation and hyperplasia of vascular smooth muscle cells that often follows coronary artery stent restenosis [9]. Strikingly, rapamycin extends rodent lifespan [10]. Rapamycin analogs and second-generation mTOR catalytic inhibitors also hold therapeutic promise as anti-cancer agents [5].

Rapamycin administration incurs adverse side effects, however. Various clinical trials have documented the development of hypertriglyceridemia or hypercholesterolemia in renal, hepatic, cardiac, and islet transplant patients [11, 12]. Additionally, rapamycin has also been shown to elevate serum free fatty acid (FFA) levels and induce glucose intolerance [13] in transplant patients as well as in mice lacking the mTORC1 downstream target S6K1 [14]. Clinical trials have also documented the occurrence of hyperlipidemia upon the administration of the rapamycin analog CCI-779 (also known as temsirolimus; Wyeth) in the treatment of metastatic melanoma and glioblastoma multiforme [15]. Consistent with rapamycin increasing levels of circulating FFAs and inducing hyperlipidemia, mice lacking S6K1 globally or lacking raptor in adipose are lean with reduced adipose mass and exhibit resistance to diet-induced obesity [14]. Thus, mTORC1 inhibition induced by pharmacological or genetic ablation disrupts lipid homeostasis in vivo.

In this study we set out to better understand how mTORC1 signaling impacts lipid metabolism in cultured adipocytes. Adipose tissue, once considered an inert energy storage depot, is now recognized as an important metabolic and endocrine organ that coordinates energy intake and expenditure critical for energy homeostasis [16]. Adipose tissue removes glucose from the circulation (via the action of the insulin-responsive glucose transporter GLUT4) and stores surplus energy in the form of triacylglycerol (TAG) within lipid droplets. The tissue releases energy as needed via the action of lipolysis, the process by which enzymes known as lipases break down TAG into FFA and glycerol, which are then released into the circulation. Diverse extracellular stimuli regulate lipolysis. Catecholamines (e.g., epinephrine) and glucocorticoids (e.g., cortisol) promote lipolysis while insulin and FFA themselves suppress lipolysis [17]. Starvation or stress triggers the release of catecholamines, which promote lipolysis by activating G protein-coupled adrenergic receptors that activate adenylate cyclase (AC), which lead to increased production of cAMP and activation of protein kinase A (PKA). Several laboratories have established that PKA phosphorylates two lipolytic proteins, perilipin and hormone sensitive lipase (HSL) [18]. Perilipin functions as a master regulator of lipolysis [19, 20]. Under basal conditions, perilipin coats and protects lipid storage droplets. Upon agonist stimulation, PKA phosphorylates perilipin A, which induces a conformational change in the perilipin coating that enables the recruitment of HSL from the cytoplasm to the surface of the lipid droplet [21, 22]. Indeed, perilipin knockout mice have reduced adipose tissue mass and exhibit elevated basal lipolysis with resistance to β-adrenergic-stimulated lipolysis; moreover, the mice display resistance to diet-induced and genetic obesity [18, 22–24].

Our previous work demonstrated that rapamycin administration induces hypertriglyceridemia in organ transplant patients [11], and increases TAG and plasma FFA in guinea pigs [25]. Here, we test the hypothesis that rapamycin promotes TAG lipolysis in cultured murine 3T3-L1 adipocytes. We found that inhibition of mTORC1 signaling with rapamycin augments lipolysis promoted by the β-adrenergic agonist isoproterenol without augmenting cellular cAMP levels. Additionally, we found that rapamycin enhances isoproterenol-induced phosphorylation of HSL. These data indicate that mTORC1 inhibition synergizes with the PKA pathway to promote lipolysis by modulating HSL function. Improved understanding of how mTORC1 inhibition promotes lipolysis to disrupt lipid metabolism may assist clinicians in the future to better handle the deleterious side effects incurred by therapeutic rapamycin treatment during immunosuppression, cancer chemotherapy, or following coronary artery angioplasty.

Experimental Procedures

Materials

Reagents were obtained from the following sources: CHAPS (3-[(3-cholamidopropyl)- dimethylammonio]-1-propanesulfonate) was from Pierce (Rockford, IL, USA); nitrocellulose membrane (0.45 microns) was from Schleicher and Schuell Bioscience Inc. (Keene, NH, USA); autoradiography film (HyBlot CL) was from Denville Scientific Inc. (Metuchen, NJ, USA); reagents for enhanced chemiluminescence (ECL) (Immobilon Western-Chemiluminescent HRP Substrate) were from Upstate/Millipore (Billerica, MA, USA); all standard chemicals were from either Fisher Chemicals (Pittsburgh, PA, USA), Calbiochem/EMD Chemicals (Gibbstown, NJ, USA), or Sigma-Aldrich (St. Louis, MI, USA).

Antibodies

The following antibodies were purchased from Cell Signaling Technology (Danvers, MA, USA): P-S6K1-T389 (rabbit monoclonal 108D2); P-mTOR-S2481, HSL, ATGL, MGL. The perilipin antibody was from Chemicon/Millipore (Billerica, MA, USA) (#AB10200), and the β-actin monoclonal antibody was from Sigma-Aldrich (St. Louis, MI, USA). Antibodies to detect the phosphorylation of PKA on its regulatory subunits RIIα (S96) and RIIβ (S114) were from Upstate/Millipore (Billerica, MA, USA). Custom, affinity-purified anti-peptide antibodies against mTOR and S6K1 were generated in rabbits, as described [7]. Sheep anti-mouse antibodies and donkey anti-rabbit HRP secondary antibodies were from GE-Healthcare (Piscataway, NJ, USA).

Differentiation of 3T3-L1 Fibroblasts into Adipocytes

3T3-L1 fibroblasts (kindly provided by Dr. Ormond MacDougald; University of Michigan Medical School) were cultured in Dulbecco's Modified Eagle Medium (DMEM) that contained high glucose (4.5 g/L), glutamine (584 mg/L), and sodium pyruvate (110 mg/L) supplemented with 10% newborn calf serum (NCS) (Gibco/Invitrogen; Carlsbad, CA, USA) and maintained at 37 °C in 5% CO_2. 3T3-L1 fibroblasts were differentiated into adipocytes by a standard protocol. Briefly, differentiation was induced 2 days post confluency by the addition of DMEM containing 10% fetal bovine serum (FBS) (Hyclone) and dexamethasone (1 μM) (Sigma-Aldrich; St. Louis, MO, USA), 3-isobutyl-1-methylxanthine IBMX (0.5 mM) (Sigma-Aldrich; St. Louis, MI, USA) and insulin (100 nM) (Gibco/Invitrogen; Carlsbad, CA, USA) for 2 days. The cells were further incubated with DMEM/FBS supplemented with

insulin for an additional 2 days. Fully differentiated adipocytes were maintained in DMEM/FBS at 37 °C in a humidified atmosphere containing 5% CO_2 and used 9–14 days after the initiation of differentiation.

Cell Culture, Drug Treatment, Cell Lysis and Western Immunoblotting

3T3-L1 adipocytes were serum deprived for 20 h via incubation in DMEM supplemented with 20 mM Hepes (pH 7.2). Following serum deprivation, adipocytes were drug treated for 30 min by the addition of rapamycin (20 ng/mL) (22 nM) (Calbiochem/EMD Chemicals; Gibbstown, NJ, USA), or wortmannin (100 nM) (Upstate/Millipore; Billerica, MA, USA) prior to the addition of the β-adrenergic agonist isoproterenol (10 μM) (Chemicon/Millipore; Billerica, MA, USA) unless indicated otherwise, insulin (100 nM) (Invitrogen; Carlsbad, CA, USA), or both for 30 min. For cell lysis, adipocytes were washed 2× with ice cold PBS [pH 7.4] and collected in ice cold lysis Buffer A (10 mM KPO_4 [pH 7.2]; 1 mM EDTA; 5 mM EGTA; 10 mM $MgCl_2$; 50 mM β-glycerophosphate; 1 mM sodium orthovanadate (Na_3VO_4); 5 μg/mL pepstatin A; 10 μg/mL leupeptin; 40 μg/mL PMSF) containing the detergent CHAPS (0.3%). Lysates were spun at 13,200 rpm for 5 min at 4 °C, and the post-nuclear supernatants were collected. Bradford assay was used to normalize protein levels for the measurement of triacylglycerol content, lipolysis, cAMP levels, and Western immunoblot analyses. For immunoblots, whole cell lysates were resuspended in 1× sample buffer (50 mM Tris–HCl pH 6.8, 10% glycerol, 2% SDS, 2% β-mercaptoethanol, 0.02% bromophenol blue). Samples were heated at 95 °C for 5 min, resolved on SDS–PAGE gels, and transferred to nitrocellulose membrane using Towbin transfer buffer (25 mM Tris; 192 mM glycine; 10% methanol; 0.02% SDS). Immunoblotting was performed by blocking membranes in TBST (40 mM Tris–HCl pH 7.5; 0.9% NaCl; 0.1% Tween-20) containing 3% nonfat milk and incubating the membranes in TBST with 2% BSA containing primary antibodies or secondary HRP-conjugated antibodies. Blots were developed by enhanced chemiluminescence (ECL).

Measurement of Cellular Triacylglycerol Content

Adipocyte triacylglycerol concentrations were measured by enzymatic methods following manufacturer instructions (Wako Chemicals, Inc.; Richmond, VA, USA) following cellular lysis and normalization of protein content. Briefly, samples and a set of triolein standards were incubated with triacylglycerol reagent A at 37 °C for 5 min followed by addition of triacylglycerol reagent B for 5 min at 37 °C. The colorimetric reaction was then measured at wavelength 590 nm and expressed as mg/mg protein.

Lipolysis Assays

Following serum deprivation and drug treatment, differentiated 3T3-L1 adipocytes were stimulated with isoproterenol for either 1 h or 4 h, as indicated in the figure legends. The media was collected and analyzed for free fatty acid release in the culture media using a NEFA C assay (Wako Chemicals; Richmond, VA, USA) and read by a spectrophotometer at wavelength 540 nm. Free fatty acid release was measured in millimole per microgram protein (mmol/ug) and expressed as relative free fatty acid percent. Glycerol release in the media was measured by colorimetric assay at wavelength 540 nm using a Chemicon lipolysis kit, following the manufacturer's instructions (Chemicon/Millipore; Billerica, MA, USA).

Measurement of Cellular cAMP Levels

Following serum deprivation, drug treatment, and isoproterenol stimulation, cAMP levels were measured using a HitHunter cAMP EFC (enzyme fragment complementation) assay (Amersham/GE-Healthcare; Piscataway, NJ, USA) following the manufacturer's instructions. All samples and standards were run in triplicates, and luminescence was detected using a multimode microplate reader (PerkinElmer, VICTOR 3; Waltham, MA, USA).

Statistics

ANOVA (Analysis of Variance) was used to determine overall statistical significance among various treatment groups. If significance was achieved at $P < 0.05$, then post-hoc secondary LSD (Least Significant Difference) tests were performed.

Results

Insulin-Mediated Activation of mTORC1 Promotes Triacylglycerol Accumulation in 3T3-L1 Adipocytes

To determine whether mTORC1 signaling controls triacylglycerol (TAG) content in adipocytes, we differentiated 3T3-L1 fibroblasts into adipocytes and treated them with insulin in the absence or presence of rapamycin for 18 h after a period of serum deprivation. As expected, chronic insulin treatment promoted triacylglycerol storage (Fig. 1a). We found that rapamycin treatment reduced insulin-stimulated TAG accumulation ~50% in a statistically significant manner ($P < 0.05$), thus demonstrating

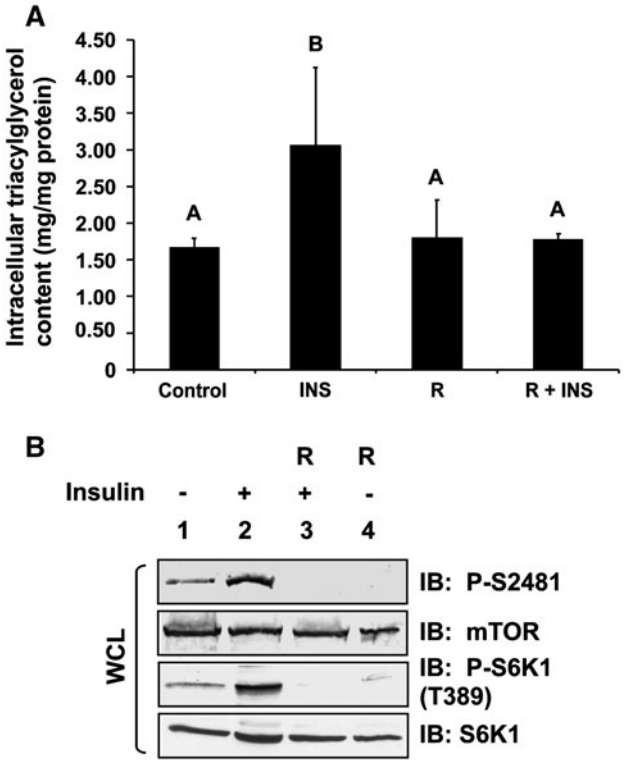

Fig. 1 Insulin-stimulated triacylglycerol (TAG) accumulation in 3T3-L1 adipocytes requires mTORC1 signaling. **a** 3T3-L1 adipocytes were serum-deprived for 20 h (*Control*) and then pre-treated without or with rapamycin (20 ng/mL) for 30 min. Cells were stimulated without (*Control*) or with insulin (INS) (100 nM) in the absence (*R*) or continued presence of rapamycin (*R* + *INS*) for 18 h. Whole cell lysates were analyzed for triacylglycerol content (mg/mg protein) via a colorimetric assay (see "Experimental Procedures") after normalization for protein content. The *graph* represents the mean ± SD of triplicate samples from one experiment but is representative of three independent experiments; thus, each *bar* represents $n = 3$. Differences between treatment groups were analyzed using ANOVA, and differences were considered statistically different at a level of 0.05. *Bars* with different letters are statistically significant. **b** The whole cell lysates analyzed in (**a**) were resolved on SDS–PAGE and immunoblotted with the indicated antibodies to confirm the expected activation and/or inhibition of mTORC1 signaling

that mTORC1 signaling is required for insulin-stimulated TAG storage. To confirm that insulin mediated the activation of mTORC1 and downstream signaling in a rapamycin-sensitive manner in this experiment, we immunoblotted whole cell lysates with mTOR P-S2481 and S6K1 P-T389 antibodies (Fig. 1b). Upon activation, mTOR autophosphorylates on S2481; thus, mTOR P-S2481 immunoblotting monitors intrinsic mTOR catalytic activity [7]. Activated mTORC1 then directly phosphorylates S6K1 on T389 [26]; thus, S6K1 P-T389 immunoblotting monitors mTORC1 downstream signaling. As rapamycin inhibited insulin-stimulated autophosphorylation of mTOR on S2481 and the phosphorylation of S6K1 on T389, these data indicate that rapamycin indeed inhibited the insulin-stimulated activation of mTORC1.

Rapamycin Augments β-Adrenergic-Stimulated Lipolysis in 3T3-L1 Adipocytes

As we found that rapamycin-mediated inhibition of mTORC1 signaling reduces cellular TAG content, we next asked whether rapamycin reduces TAG content by promoting lipolytic rate. As the insulin/PI3K pathway promotes mTORC1 signaling and also suppresses lipolysis (via Akt-mediated activation of phosphodiesterase [PDE], an enzyme that hydrolyzes cAMP to AMP) [27], we measured adipocyte lipolysis in the absence of serum growth factors in order to study lipolysis independently of PDE action. To stimulate lipolysis, we employed the catecholamine isoproterenol, a synthetic β2-adrenergic agonist. By treating serum deprived 3T3-L1 adipocytes with isoproterenol in the absence or presence of rapamycin, we found that inhibition of mTORC1 signaling augments isoproterenol stimulated lipolysis in a statistically significant manner, as measured by the release of FFA (Fig. 2a) into the cell culture media after 1 h of incubation. Based on our preliminary kinetic data (data not shown) as well as reported literature [28], a 1-h time point was optimal for measurements of glycerol release (Fig. 2b) while a 4-h time point was optimal for measurements of FFA release. We thus next measured FFA release utilizing a 4-h time point to determine whether mTORC1 inhibition with rapamycin augments basal lipolysis, whether insulin suppresses isoproterenol-stimulated lipolysis, and whether mTORC1 inhibition using the PI3K inhibitor wortmannin augments isoproterenol-stimulated lipolysis (similar to rapamycin). We found that rapamycin had no effect on basal lipolysis after 4 h of incubation, while, insulin indeed suppressed isoproterenol-stimulated lipolysis, as expected (Fig. 2c). Interestingly, mTORC1 inhibition with rapamycin rescued the suppression of lipolysis caused by insulin, suggesting a novel role for mTORC1 in suppression of lipolysis via the insulin/Akt/PDE pathway (Fig. 2c). Similar to rapamycin, wortmannin treatment augmented isoproterenol-stimulated lipolysis, suggesting a novel role for PI3K as well as mTORC1 in suppression of lipolysis (Fig. 2c). The finding that inhibition of PI3K with wortmannin phenocopies rapamycin treatment to augment isoproterenol-stimulated lipolysis is consistent with the well-known regulation of mTORC1 by PI3K [3]. These data suggest that the PI3K/mTORC1 pathway mediates lipolytic suppression.

Rapamycin Does Not Modulate Cellular cAMP Levels

To begin to understand the mechanism by which mTORC1 inhibition augments isoproterenol-stimulated lipolysis, we

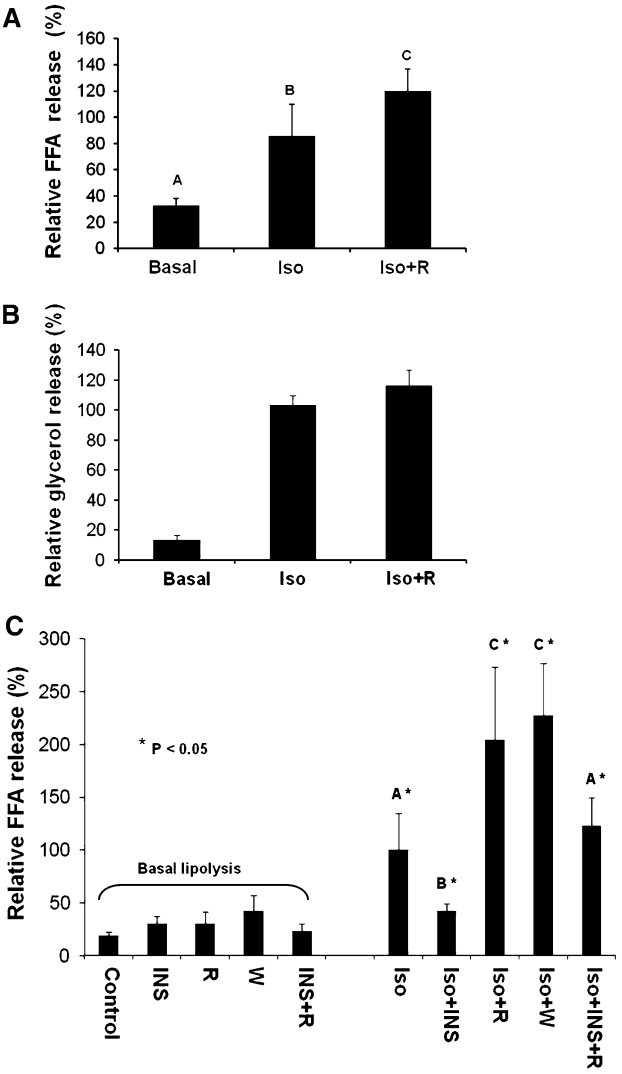

Fig. 2 Inhibition of mTORC1 with rapamycin augments β-adrenergic-activated lipolysis in 3T3-L1 adipocytes. **a, b** 3T3-L1 adipocytes were serum-deprived for 20 h and then pre-treated without or with rapamycin (*R*) (20 ng/mL) for 30 min. Cells were then incubated in the absence (*Basal*) or presence of isoproterenol (*Iso*) (10 μM) for 1 h in the absence or continued presence of rapamycin (*Iso* + *R*). Relative free fatty acid (FFA) release was measured in (**a**) and relative glycerol release was measured in (**b**). In graphs (**a**, **b**) each *bar* represents the mean value ± SD of 5 samples from three independent experiments; thus, each *bar* represents $n = 5$. The value from cells treated with Iso alone was set to 100%, and all other values were normalized to this value. **c** 3T3-L1 adipocytes were treated similarly as in (**a**, **b**) with minor modifications, and relative free fatty acid (FFA) release was measured, as in (**a**). Briefly, serum-deprived cells were pre-treated without or with rapamycin (20 ng/mL) or wortmannin (100 nM) for 30 min. Cells were then incubated in the absence (*Basal lipolysis*) or presence of isoproterenol (10 μM) for 4 h without (*Iso*) or with insulin (100 nM) (*Iso* + *INS*), rapamycin (*Iso* + *R*), wortmannin (*Iso* + *W*), or both insulin and rapamycin (*Iso* + *INS* + *R*), as indicated in the graph. Cells incubated in the absence of isoproterenol (*Basal lipolysis*) were also incubated with insulin (*INS*), rapamycin (*R*), wortmannin (*W*), and insulin and rapamycin (*INS* + *R*) for 4 h. In graph (**c**), each *bar* represents the mean value ± SD of nine samples from three independent experiments; thus, each *bar* represents $n = 9$. As in graphs (**a**, **b**), the value of Iso alone was set to 100%, and all other values were normalized to this value. Differences between treatment groups were analyzed using ANOVA, and differences were considered statistically different at a level of 0.05. *Bars* with different letters are statistically significant

determined whether rapamycin augments isoproterenol-stimulated production of cAMP. Studies in yeast have shown that TOR may function upstream of PKA [29], thus lending support to such a hypothesis. We thus measured cellular levels of cAMP in adipocytes stimulated with isoproterenol in the absence or presence of rapamycin for 15 min (Fig. 3a) and 30 min (Fig. 3b). We found that rapamycin treatment had no effect on cAMP levels during basal or catecholamine-stimulated lipolysis. Thus, these data suggest that mTORC1 inhibition does not augment catecholamine-stimulated lipolysis by leading to increased levels of cAMP.

Rapamycin Does Not Affect PKA Phosphorylation

To begin to study the regulation of PKA activity in intact cells, we investigated the phosphorylation of PKA on its regulatory subunits, RIIα (S96) and RIIβ (S114), utilizing phospho-specific antibodies. Studies have shown that autophosphorylation of S96 on the regulatory subunit RIIα promotes local PKA activity in cardiac muscle [30]. Additionally, point mutation of the S114 autophosphorylation site on RIIβ has been shown to block the nuclear localization of PKA and to inhibit PKA function in T cells both in vitro [31] and in vivo [32]. We found that isoproterenol-stimulated PKA phosphorylation on regulatory subunit RIIα (S96) or regulatory subunit RIIβ (S114) was not altered by rapamycin treatment at various isoproterenol concentrations (Fig. 4a). While by no means conclusive, these data suggest that mTORC1 inhibition may promote isoproterenol-stimulated lipolysis downstream of PKA. Alternatively, it remains possible that mTORC1 inhibition inhibits PKA activity via a mechanism independent of regulatory subunit phosphorylation.

Rapamycin Modestly Augments the Phosphorylation of HSL

To determine whether PKA signaling and mTORC1 inhibition synergistically modulate the activation state of lipolytic targets, we assayed the phosphorylation of two well known PKA dependent targets, hormone sensitive lipase (HSL) and perilipin. In response to starvation and stress, catecholamine induced activation of the cAMP/PKA pathway leads to PKA-mediated phosphorylation of both perilipin and HSL [23]. PKA-induced phosphorylation of perilipin on at least 6 sites triggers a conformational change

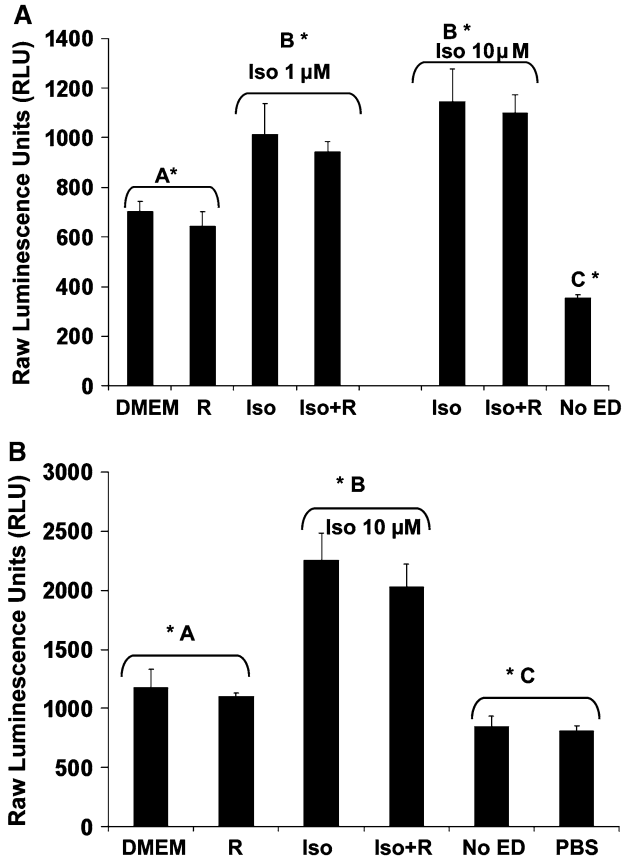

Fig. 3 Rapamycin does not augment cAMP levels over β-adrenergic agonist alone. cAMP levels were measured using the HitHunter cAMP EFC chemiluminescent detection assay (Amersham, Inc.), according to manufacturer's directions. Briefly, 3T3-L1 adipocytes were serum deprived 20 h and pre-treated without or with rapamycin (*R*) (20 ng/mL) for 30 min. Cells were then incubated in the absence (*DMEM*) or presence of isoproterenol (*Iso*) (1 µM or 10 µM) for 15 min (**a**) or (10 µM) 30 min (**b**) in the absence or presence of rapamycin (*Iso* + *R*). "*No ED*" (without enzyme donor) and "*PBS*" represent negative controls for this assay. *Bars* with different letters are statistically significant at a level of 0.05

that disassembles the perilipin protective coat and induces the translocation of HSL from the cytoplasm to the surface of lipid droplet, whereby HSL docks to phosphorylated perilipin [23, 33]. To determine whether rapamycin augments isoproterenol-stimulated phosphorylation of perilipin, we employed a commonly used SDS–PAGE mobility shift assay to determine the phosphorylation state of perilipin. Serum deprived 3T3-L1 adipocytes were pretreated with rapamycin and then stimulated in the absence of isoproterenol or with a series of isoproterenol concentrations ranging from maximal to sub-maximal (10 µM down to 1 nM). As expected, isoproterenol strongly promoted the phosphorylation of perilipin in a dose-dependent manner, as shown by decreased electrophoretic mobility on SDS–PAGE (Fig. 4b). Rapamycin treatment had no effect on isoproterenol-induced perilipin phosphorylation, even at sub-maximal doses (0.1 µM, 10 nM). At the limited resolution of this assay, these data suggest that mTORC1 inhibition with rapamycin does not synergize with catecholamine induced PKA signaling to promote significant phosphorylation of perilipin. Although mobility shift is a commonly used method in detection of perilipin phosphorylation state, we acknowledge the possibility that rapamycin could promote the phosphorylation of individual sites on perilipin whose phosphorylation state may not be measurable by mobility shift. We next investigated the phosphorylation of the lipase HSL, which functions as the rate-limiting enzyme in the lipolytic cascade. To date, three PKA-mediated phosphorylation sites (Ser^{563}; Ser^{659}; Ser^{660}) and one AMPK-mediated phosphorylation site (Ser^{565}) have been identified on rat HSL, as illustrated in Fig. 4c [34, 35]. Phosphorylation of HSL on Ser^{563} by PKA is thought to promote the intrinsic catalytic activity of HSL [36], while phosphorylation of HSL on Ser^{659} and Ser^{660} by PKA are thought to promote the translocation of cytosolic HSL to the surface of the lipid droplet [23]. Conversely, phosphorylation of HSL on Ser^{565} by AMPK is thought to inhibit HSL activity [37]. By treating 3T3-L1 adipocytes with various concentrations of isoproterenol in the absence and presence of rapamycin, we found that rapamycin augmented HSL Ser^{563} phosphorylation (Fig. 4c). On the contrary, there was no additional effect of rapamycin on isoproterenol-stimulated phosphorylation of HSL Ser^{660} (Fig. 4c). Neither isoproterenol nor rapamycin modulated AMPK Ser^{565} phosphorylation, which appears to be constitutively activated under basal conditions [37]. Taken together, these data indicate that mTORC1 inhibition with rapamycin synergizes with PKA signaling to augment the phosphorylation of HSL on Serine 563, which may accelerate lipolysis by augmenting HSL catalytic activity.

Rapamycin Has No Effect on ATGL, HSL, or MGL Protein Expression

To determine whether mTORC1 inhibition with rapamycin additionally promotes lipolysis by modulating the expression of the lipases critical for the breakdown of TAG into FFAs and glycerol, we examined the protein expression of adipose triacylglycerol lipase (ATGL), hormone sensitive lipase (HSL), and monoacyl lipase (MGL). It is currently believed that ATGL initiates basal as well as hormone sensitive lipolysis of triacylglycerol [38, 39] to FFA and diacylglycerol. Subsequently, HSL acts on diacylglycerol particles to release FFA and monoacylglycerol. The final step in lipolysis is catalyzed by the hormone-insensitive MGL, which acts on monoacylglycerol to release FFA and glycerol [39]. Some investigators [40] also suggest a role for triacylglycerol hydrolase (TGH) in lipolysis; the relative contribution of TGH in the lipolytic cascade within the

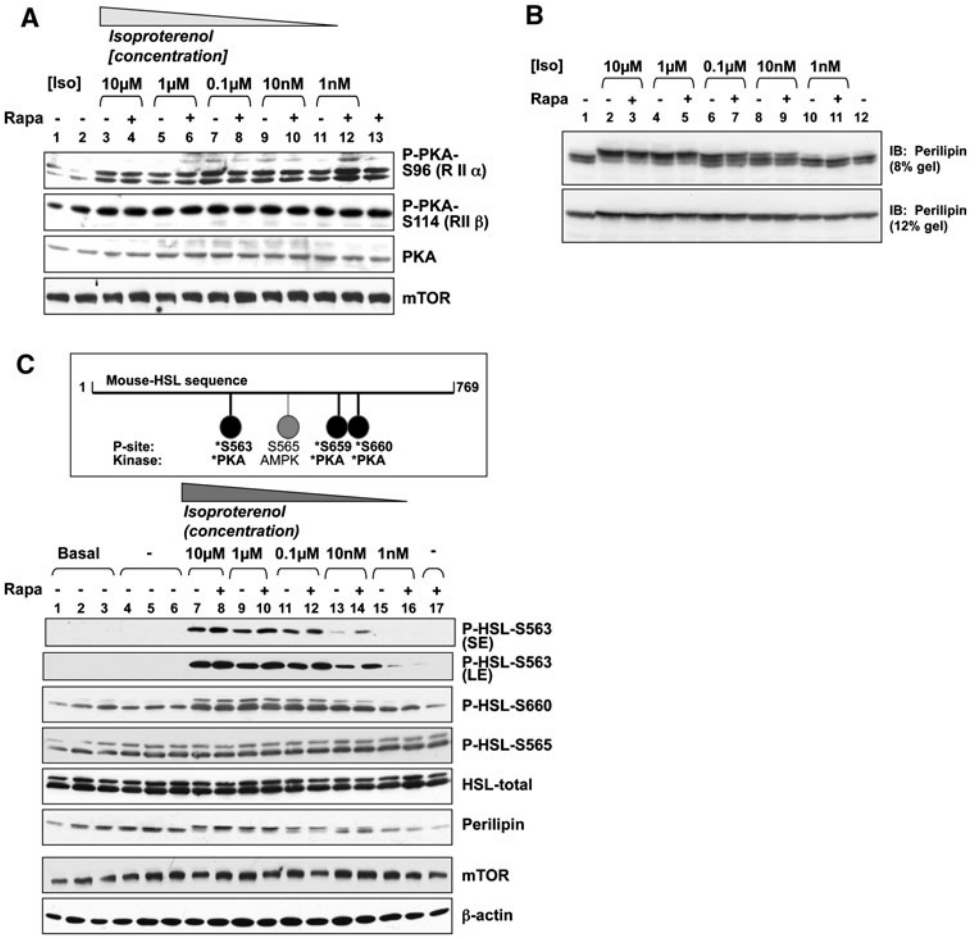

Fig. 4 Rapamycin augments isoproterenol-stimulated phosphorylation of HSL on S563 in the absence of effects on PKA regulatory subunit or perilipin phosphorylation. **a** Rapamycin does not modulate the phosphorylation of PKA on the regulatory subunits RIIα (S196) or RII*β* (S114): 3T3-L1 adipocytes were serum-deprived for 20 h and then pre-treated without (−) or with (+) rapamycin (20 ng/mL) for 30 min. Cells were incubated in the absence (−) or presence of various concentrations of isoproterenol (*Iso*) ranging from 10 μM to 1 nM for 15 min, as indicated. After lysis, whole cell lysate was resolved on SDS–PAGE and immunoblotted with the indicated antibodies. **b** Rapamycin does not augment isoproterenol-stimulated phosphorylation of perilipin: 3T3-L1 adipocytes were serum-deprived for 20 h and pre-treated without (−) or with (+) rapamycin (*Rapa*) (20 ng/mL) for 30 min. Cells were then incubated in the absence (−) or presence (+) of isoproterenol (*Iso*) (10 μM) in the absence or presence of rapamycin for 15 min. After lysis, whole cell lysate was resolved on SDS–PAGE and immunoblotted with perilipin antibodies. Note: To observe perilipin electrophoretic mobility shift, a measure of perilipin phosphorylation, a 21 cm long 8% gel was run for 3:30 h. To visualize total perilipin, a 13-cm long 12% gel was run for 1:45 h. **c** Rapamycin augments isoproterenol-stimulated phosphorylation of HSL on S563 (a PKA phosphorylation site) but not on S565 (an AMPK phosphorylation site): *Upper panel*: Schematic of the HSL sites phosphorylated by PKA and AMPK. *Lower panel*: 3T3-L1 adipocytes were serum-deprived and pre-treated without (−) or with (+) rapamycin, as in (**a**, **b**) above. Cells were then incubated in the absence (−) or presence of various concentrations of isoproterenol (Iso) ranging from 10 μM to 1 nM for 15 min, as indicated. After lysis, whole cell lysates were resolved on SDS–PAGE and immunoblotted with the indicated antibodies. Cells were also lysed immediately after serum deprivation (*Basal*). Two P-HSL-S563 film exposures are shown (SE-short exposure, LE-long exposure)

adipocyte remains unclear, however. We treated 3T3-L1 adipocytes with isoproterenol in the absence or presence of rapamycin for 18 h and measured the protein expression of ATGL, HSL, and MGL by immunoblot (Fig. 5). We found no differences in the abundance of these 3 important lipases under any treatment condition. Thus, these data indicate that mTORC1 inhibition with rapamycin does not augment lipolytic rate by increasing the expression of a critical lipase.

Discussion

Here, we investigated the biochemical mechanism by which mTORC1 inhibition via the immunosuppressive drug rapamycin induces hypertriglyceridemia and increases circulating free FFAs in organ transplant patients [11] as well as in guinea pigs [25]. We report that treatment of 3T3-L1 adipocytes with the mTORC1 inhibitor rapamycin decreases TAG storage by augmenting lipolysis induced by

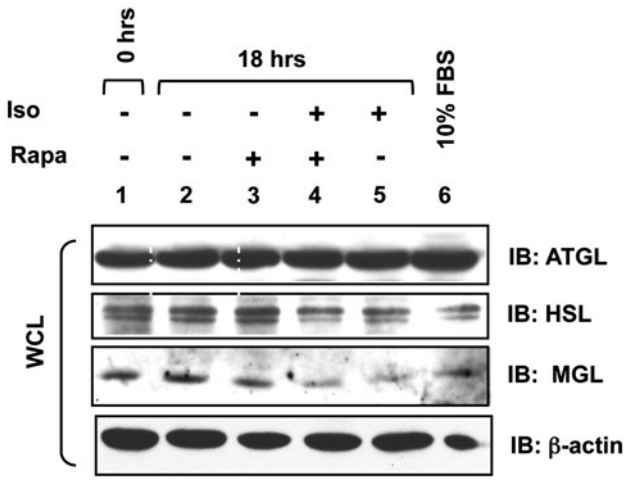

Fig. 5 Rapamycin does not modulate the protein expression of ATGL, HSL, or MGL. 3T3-L1 adipocytes were serum-deprived for 20 h (*lanes 1–5*) and pre-treated without (*lanes 1–2, 5*) or with (*lanes 3, 4*) rapamycin (R) (20 ng/mL) for 30 min. Cells were then incubated in the absence (−) (*lanes 2–3*) or presence (+) (*lanes 4–5*) of isoproterenol (10 μM) for 18 h in the absence or continued presence of rapamycin, as indicated. In lane 1, cells were lysed after the 20 h serum deprivation period ($t = 0$). In *lane 6*, cells were cultured in DMEM/10% FBS (steady-state, non-starved conditions). After lysis, whole cell lysate was resolved on SDS–PAGE and immunoblotted with the indicated antibodies

isoproterenol, a *β*-adrenergic agonist, without altering basal lipolysis. While, the measured effect of rapamycin on hormone-induced lipolysis was modest, the combined effect of increased lipolysis and decreased TAG synthesis incurred by mTOR inhibition likely has a more significant impact on TAG metabolism. Our data further elucidate the mechanism by which mTORC1 inhibition cooperates with PKA signaling to promote lipolysis: We found that rapamycin augments isoproterenol-induced phosphorylation of HSL (on S563) via a mechanism that does not involve increased production of cAMP. These data indicate that mTORC1 inhibition and PKA signaling synergize either downstream of PKA or at the level of PKA to promote lipolysis (Fig. 6). Whether, mTORC1 inhibition and PKA converge on common lipolytic targets (e.g. HSL, ATGL) via parallel pathways or, whether mTORC1 inhibition converges on PKA itself to enhance its function (via increased enzymatic activity, altered subcellular localization, etc.) remains currently unknown (see model in Fig. 6). In support of the former model, TOR and PKA signal via parallel pathways in budding yeast to regulate the transcriptional expression of ribosomal protein genes and stress-responsive genes [41]. In support of the latter model, TORC1 signaling in budding yeast was reported recently to regulate PKA activity [42]. Lastly, we found that rapamycin treatment (18 h) had no effect on the expression of various lipases, including ATGL, HSL, or MGL under basal or isoproterenol-stimulated conditions.

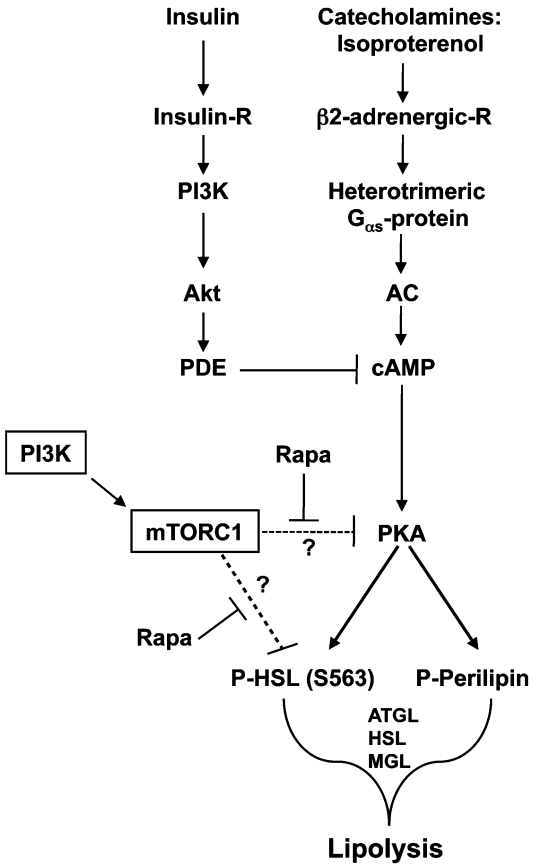

Fig. 6 Model for the role of mTORC1 signaling in suppression of lipolysis in adipocytes. The *β*-adrenergic agonist isoproterenol, a synthetic catecholamine, promotes triacylglycerol (TAG) breakdown (lipolysis) by activating a large heterotrimeric $G_{\alpha s}$-protein that activates adenylate cyclase (*AC*), which converts ATP into cAMP. cAMP binds the regulatory subunits of protein kinase (*PKA*), thus dissociating the repressive regulatory subunits from the catalytic subunits. Catalytically active PKA phosphorylates downstream targets, including perilipin and hormone sensitive lipase (*HSL*), which contribute to initiation of lipolysis together with several other lipases including *ATGL* (adipose triacylglycerol lipase) and MGL (monoacyl lipase), ultimately leading to the breakdown of TAG into free fatty acids (*FFA*) and glycerol. mTORC1 signaling suppresses lipolysis by either acting on common lipolytic targets (e.g., HSL, others?) via a pathway parallel to PKA or by converging on PKA to inhibiting its function. By inhibiting mTORC1 signaling, rapamycin synergizes with the PKA pathway to promote lipolysis, thus reducing TAG storage; therefore, mTORC1 signaling suppresses lipolysis, thus augmenting TAG storage

Our data are consistent with the recent work of Chakrabarti et al., who showed that inhibition of mTORC1 signaling via rapamycin or knockdown of the critical mTORC1 partner raptor decreases TAG storage by increasing lipolysis in 3T3-L1 adipocytes [43]. Consistently, this work demonstrated that overexpression of the mTORC1 activator Rheb augments TAG storage and suppresses lipolysis [43]. Our data differ in that Chakrabarti et al. found that rapamycin also modestly augments

basal lipolysis and modestly reduces the mRNA and protein expression of the lipase ATGL [43]. We found no evidence for alterations in basal lipolytic rate or ATGL expression upon rapamycin treatment. Perhaps differences in experimental conditions account for these apparent discrepancies.

Emerging data identify mTORC1 an important novel controller of both anabolic and catabolic lipid metabolism by regulating lipogenesis and lipolysis, respectively [44, 45]. mTORC1 signaling induces adipogenic differentiation and maintains the adipogenic program by promoting the expression and activation state of the transcription factor PPARγ (peroxisome proliferator-activated receptor-γ), a nuclear hormone receptor that induces the expression of genes that promote fatty acid uptake, synthesis, esterification, and storage [46]. Moreover, mTORC1 signaling promotes lipid biosynthesis by cleaving the transcription factor SREBP-1 (sterol regulatory element binding protein-1) into a mature form that translocates to the nucleus to induce the expression of lipogenic genes that promote fatty acid and TAG synthesis [45, 47].

As increased levels of circulating FFA are well documented as an etiological factor in the development of insulin resistance, the cumulative data suggest that rapamycin administration to patients may exacerbate insulin resistance by promoting TAG lipolysis [48]. Indeed, studies in a diabetic rodent model showed that injection of rapamycin led to worsened hyperglycemia and diabetes [48]. Impaired TOR signaling also appears to promote lipolysis in model organisms. For example, in Drosophila, loss-of-function mutations in *melted* leads to decreased dTOR signaling and a 10% decrease in animal size, consistent with a role of mTOR in cell growth control; strikingly, *melted* flies possess 40% less fat relative to control animals in the fat body, the primary energy storage organ [49]. This phenotype is fat-body autonomous, as re-expression of wild type *melted* in the fat body rescues the leanness of *melted* mutants [49]. Additionally, global knockout of the mTORC1 substrate S6K1 in mice produces animals with increased levels of plasma FFA that exhibit mild glucose intolerance and resistance to diet-induced obesity [14, 50]. Consistently, increased mTORC1 signaling to eukaryotic initiation factor 4E (eIF4E) via global knockout of the eIF4E inhibitors 4EBP-1 and 4EBP-2 leads to increased adipogenesis, decreased lipolysis, and increased FFA re-esterification, which cooperatively induce obesity [51].

In conclusion, these data demonstrate that cellular inhibition of mTORC1 signaling with rapamycin, as well as inhibition of PI3K with wortmannin, synergizes with the PKA pathway to augment the phosphorylation of HSL leading to enhanced hormone-induced lipolysis. Thus, mTORC1 signaling antagonizes the PKA pathway to suppress hormone-induced lipolysis. Many questions remain regarding the molecular mechanism by which mTORC1 signaling impacts lipolytic targets. Does mTORC1 directly or indirectly (via downstream substrates) antagonize PKA signaling? Does mTORC1 signaling suppress PKA activity or does mTORC1 signal along a parallel pathway that converges on a common lipolytic target that lies downstream of PKA? Our data and that of others reveal a novel role for PI3K/mTORC1 signaling in control of cellular TAG and FFA metabolism: mTORC1 signaling reduces lipolytic rate, thus promoting TAG storage. Elucidating the molecular mechanisms by which mTORC1 signaling modulates lipid metabolism may enable clinicians in the future to better manage the deleterious side effects incurred by therapeutic rapamycin or analog treatment employed for immunosuppression, stent restenosis, and cancer. Additionally, as altered lipid homeostasis contributes to diverse human diseases including type II diabetes, obesity, cancer, and cardiovascular disease, elucidation of the biochemical mechanisms by which mTORC1 signaling modulates lipid metabolism is important both biologically and clinically.

Acknowledgments The authors would like to express their gratitude to Drs. Nancy Weigel (Baylor College of Medicine) and Victoria Knutson (University of Texas) for sharing reagents, encouragement, support, and advice. Funding: This work was funded by grants from the National Institutes of Health (K01 DK60654) and the American Heart Association (0750060Z) to GS and NIH-R01 (DK-078135) to DCF.

Conflict of interest Nothing to disclose; there are no commercial or other associations that may pose a conflict of interest.

lipoproteins and bile components, the liver regulates the quantity and quality of lipids available to peripheral tissues. The liver has not evolved as a triacylglycerol (TAG) storage organ, however, hepatocytes transiently or chronically, for physiological or pathological reasons, may sometimes store increased amounts of lipids.

In addition, the liver has remarkable regenerative potential. Liver regeneration after 70% partial hepatectomy (PH) in rodents is considered a paradigm to study the proliferative process that involves multiple intra- and extrahepatic signalling pathways (reviewed in [1–4]). After PH, around 90% of the remaining liver parenchymal cells synchronously re-enter the cell cycle contributing to organ growth. In parallel, there is a rapid accumulation of TAG, possibly linked to the metabolic and structural requirements for hepatocyte proliferation [5, 6]. While the association of liver regeneration after PH with transient steatosis is recognized, there seems to be no agreement concerning whether manipulations of lipid availability and metabolism can alter hepatocyte proliferation and the outcome of liver regeneration [7–10].

Lipids are stored in lipid droplets (LD), dynamic organelles in the cytoplasm of cells. These LD are composed of a hydrophobic core of neutral lipids, mainly TAG and cholesteryl esters (CE), surrounded by a monolayer of phospholipids (PL) and unesterified (free) cholesterol (C), with associated proteins. The lipid composition of LD seems to depend on the cell type and to adapt to the cell environment and pathophysiological context [11]. Such molecular heterogeneity would help provide complexity and plasticity to the organelle, characteristics that enable LD to carry out a range of specific functions in cellular lipid metabolism. There is a high diversity even among the minor lipids in LD. For example, phospholipids are represented by more than 160 different molecular species in CHO cells [12]. Moreover, the dramatic variability in the LD-associated proteins (reviewed in [13]) seems to be related to various aspects of lipid droplet biology, including their biogenesis and regression, the metabolism of stored lipids, interactions with membrane systems for exchange of components, intracellular transport, and structural stabilization in fusion processes [14–20]. It is then logical to expect that LD have cell- and stored lipid-specific functions (reviewed in [21]).

Two paradigms concerning lipid droplets are recognized in animal cells: LD in steroidogenic cells, which are rich in CE and supply a ready source of cholesterol for steroid hormone synthesis [22]; and LD in adipocytes, which are rich in TAG and provide fatty acid substrates for the production of energy and intracellular signalling [14, 23]. As far as we know no data on lipid metabolism of LD in post-PH liver has been reported in the literature. The aim of our work was to evaluate the hypothesis that quiescent and regenerating liver after PH contain LD populations of different sizes and densities with specific characteristic lipid compositions. In addition, we attempted to determine whether liver LD pertained to one of the aforementioned paradigms.

Materials and Methods

Animals and Partial Hepatectomy

Animal care and surgical procedures were approved by the University of the Basque Country Animal Care and Use Committee. Female Sprague–Dawley rats weighing 175–200 g were fed with low fat chow (A04 Panlab, Spain). Animals ($n = 3$) were subjected to 70% PH [24], with removal of the median and left lobes. The resected tissue (quiescent liver) was used as the control sample. The remaining tissue mass (regenerating liver) was removed 24 h later. Tissue pieces were always individually processed.

Histological Staining

Newly obtained liver pieces were frozen in liquid nitrogen-cooled isopentane and 12 μm thick sections were obtained in a cryostat (Microm, HM550) at −25 °C. Sections were rinsed with 60% isopropanol and stained for 15 min with freshly prepared Oil Red O (Sigma) solution (0.5% in isopropanol followed by dilution to 60% with distilled water and filtered). After several rinses in 60% isopropanol and distilled water, slides were counterstained with hematoxylin for 2 min, rinsed with water and mounted (Glycergel, Dako). Digital images were taken with a ProgRes (Jenoptik) camera coupled to a Nikon (Eclipse 50i) microscope.

Isolation of Lipid Droplet Populations from Quiescent and Regenerating Liver Tissue

Liver homogenates were obtained at 4 °C as described previously [25]. Pieces of freshly extracted quiescent and regenerating liver tissue were homogenized using a Potter homogenizer in four volumes of 20 mM Tris–HCl buffer pH 7.4, containing 1 mM EDTA, and protease inhibitors (Roche). LD populations were isolated and characterized separately for each animal as described elsewhere [26]. Briefly, the nuclei were sedimented and the post-nuclear supernatant (PNSN) was adjusted to 20% (wt/vol) sucrose. Then, 1.5 ml PNSN was loaded onto a discontinuous sucrose gradient composed of four phases (1.5 ml each) ranging from 40 to 25% sucrose, and overlaid with three more 1.5 ml phases of 15, 10 and 5% sucrose. The tubes

were centrifuged at 150,000*g* in a TST 41.14 rotor (Kontron) for 4 h. Eight fractions (F1–F8) were harvested from the top of the gradient (Fig. 2). The upper, semisolid, fraction F1 was collected by adsorption on a hydrophobic spatula and dissolved in 60 mM Tris–HCl buffer pH 6.8, containing 10% SDS and 50% sucrose. Fractions F2–F8 was collected by pipetting. Western blot analysis showed that the harvested fractions (F1–F8) were enriched in the LD marker adipophilin and that there was no cross-contamination with endoplasmic reticulum or Golgi marker proteins (Supplementary Fig. 1).

Assessment of Lipid Composition of Lipid Droplets

Lipids were exhaustively extracted from each isolated LD population following the method of Folch et al. [27]. Briefly, a portion of each fraction was mixed with eight volumes of chloroform/methanol/water (2:1:0.0075, v:v:v) and the methanol phase was re-extracted with four volumes of the same mixture. The chloroform phases were aspirated, combined, and washed with 1.5 ml of 0.88% KCl. After centrifugation, the aqueous phase was discarded and the chloroform evaporated. The lipid extract was dissolved in toluene and cholesteryl formate (internal standard) was added.

Lipids were separated using a thin-layer chromatography system composed of six sequential mobile phases as described by Ruiz and Ochoa [28]. Standard curves for all lipid classes were run in each plate. Development allowed sphingomyelin (CerPCho), phosphatidylcholine (PtdCho), phosphatidylinositol (PtdIns), phosphatidylserine (PtdSer), phosphatidylethanolamine (PtdEtn), C, TAG and CE to be separated. The lipid spots were quantified as detailed previously [28] using Quantity One software (Bio-Rad). Analysis was carried out at least twice per extract.

Statistics

Statistical analysis was performed using GraphPad Prism version 5.02 (GraphPad Software, San Diego, CA). Trends along the gradient for each condition were evaluated by one-way analysis of variance (ANOVA) and differences between trends using two-way ANOVA followed by the Bonferroni multiple comparison test. Light and dense fractions were compared by the unpaired Student's *t* test, while correlations between lipid classes were assessed using the Pearson correlation coefficient. A $p \leq 0.05$ was considered statistically significant.

Results

The regenerating liver after 70% PH in rodents is a paradigm of physiological liver steatosis characterized by a massive, transient accumulation of LD [6, 29]. Figure 1 shows Oil Red O-stained sections of rat liver tissue either resected at the time of PH (quiescent, control condition) or 24 h post-PH (regenerating, steatotic condition). In the upper panels, captured at ×400 optical magnifications, the proliferation of LD in regenerating liver can be seen. Lower images (×1000) illustrate the heterogeneity in the LD size distribution in regenerating tissue. In order to analyze the differential lipid composition of LD from quiescent and regenerating liver, and to evaluate if lipid

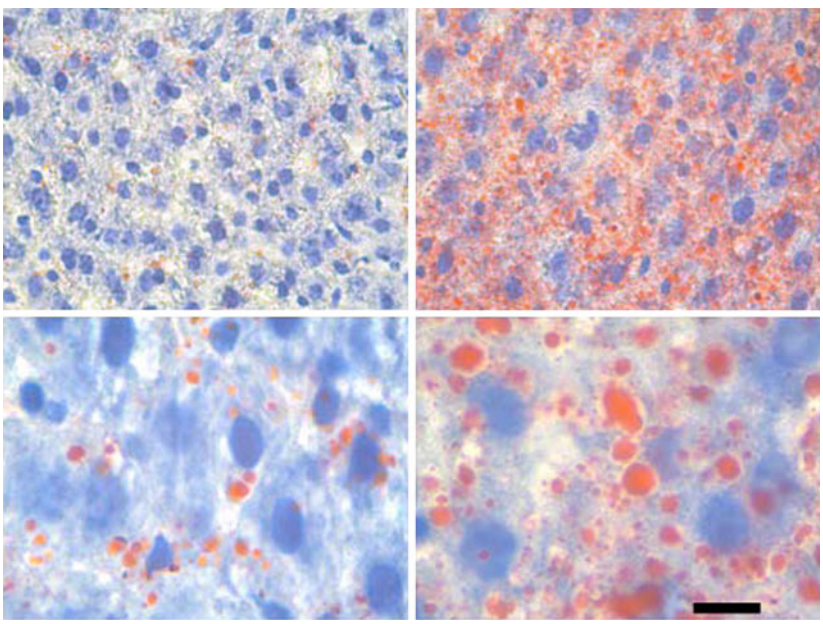

Fig. 1 Lipid droplet distribution in quiescent (*left*) and regenerating (*right*) liver tissue. Frozen liver sections (12 μm) were stained with Oil Red O to visualize lipid inclusions and counterstained with hematoxylin. *Upper* and *lower* images were captured at ×400 and ×1000 magnification, respectively. The *bar* corresponds to 10 μm at ×1000

profiles depend on the size of the particles, we isolated eight LD fractions of different densities, and compared the lipid composition of fractions within each condition and of matched density fractions between the conditions. Western blot analysis, using antibodies against the LD marker adipophilin, the endoplasmic reticulum marker calregulin and the Golgi marker GM-130, confirmed that fractions F1–F8, which float at different sucrose percentage solutions over the sample loading layer, were LD-rich and free of contamination with microsomes (Supplementary Fig. 1).

Of the density-matched LD populations, only F1 differed markedly ($p \leq 0.001$) between tissue conditions (Fig. 2a). The absolute amount of lipids is given in Table 1. Notably, low density LD concentrated in F1, floating above 5% sucrose and with a density <1.02 g/ml, were responsible for the characteristic rise in lipid levels observed after PH.

The molar ratio between the major hydrophobic lipids in the core of the organelle (TAG + CE) and the major amphipathic lipids on the surface (PL + C) is a surrogate index of LD volume (Fig. 2b). The trends in the LD apparent volume across the density gradient fractions differed between quiescent and regenerating liver ($p \leq 0.005$). With the exception of F1 droplets, which were substantially larger in regenerating tissue, the apparent volume of LD was lower in the steatotic than in the control samples.

We determined the molar fraction of each lipid class in LD populations from quiescent (Fig. 3a) and from regenerating liver (Fig. 3b, the grey intensity of *bars* increases with LD density). A one-way ANOVA and linear trend test showed a fall in the molar proportion of TAG as LD population density increased (a, $p \leq 0.05$) in both tissue conditions, more pronounced in regenerating tissue. Furthermore, a significant positive correlation between the increase in the PtdEtn molar fraction and LD density (a, $p \leq 0.05$) was observed in LD populations from the steatotic samples.

There was a negative correlation ($p \leq 0.05$) between the contents of TAG and all of the membrane lipids in LD populations from regenerating liver (Fig. 3b). In addition, positive correlations were found within the phospholipids (at least $p \leq 0.05$) and between them and the C molar fraction ($p \leq 0.05$); however, none of the lipids were found to have significant correlations with the molar ratio of the highly hydrophobic CE. These findings indicate that the density of LD populations isolated from liver tissue is more closely related to TAG than to CE content, especially in conditions of regeneration.

To simplify comparisons isolated LD populations were classified according to the lipid composition. Two LD types were defined in each tissue type, i.e., in quiescent and in regenerating liver tissue: fractions 1–3, corresponding to

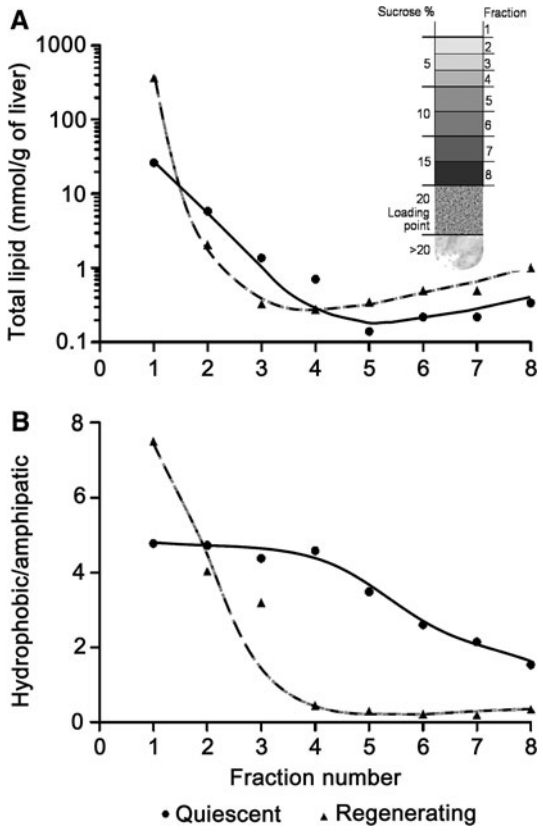

Fig. 2 Basic features of lipid droplet populations from quiescent and regenerating liver tissue. Quiescent and regenerating liver pieces were homogenized, and the post-nuclear supernatant adjusted to 20% sucrose and centrifuged in a density gradient. Fractions 1–8 (F1–F8) above the loading point, ranging from 0 to 15% sucrose (schematized in the insert of panel A), were identified as adipophilin(+) lipid droplets (LD) (Supplementary Fig. 1). **a** Graph showing the total lipid content in F1–F8 from quiescent and regenerating liver is plotted (the individual values are given in Table 1). Note a logarithmic scale is used to make differences between tissues readily visible. **b** The hydrophobic/amphipathic lipid ratio was calculated for each LD population, and represented separately for quiescent and for regenerating liver

LD floating at sucrose ≤5% (density ≤1.02 g/ml) and fractions 5–8, corresponding to sucrose solutions of density ≥1.06 g/ml, were grouped; we refer to these groups as light and dense LD, respectively. Fraction four was not included in either of the groups. This grouping and the exclusion of F4 are in line with the greatest statistically significant differences (Student's t test) in terms of the density between light and dense LD and minimum variance analyzed for both physiological conditions. The mean molar ratios for each lipid class in the two subtypes for quiescent and regenerating tissues are shown in Fig. 3c.

A specific lipid composition pattern was observed for each LD group. Accordingly, it was possible to define four phenotypes of lipid droplets, which do not necessarily coexist in the healthy liver. The main features of these

Table 1 Lipid content of the lipid droplet density fractions F1–F8 isolated from quiescent and regenerating liver

phenotypes, in terms of lipid molar fractions and apparent volumes, are illustrated schematically in Fig. 4. Light particles seem to constitute the LD structures used for fuel storage, and although proportions of TAG in non-steatotic and steatotic livers did not differ statistically their quantity increased considerably during regeneration (Figs. 3c, 4). The two forms of cholesterol are more abundant in the quiescent liver tissue. Results shown in Figs. 2, 4 indicate that there are only moderate differences in apparent volume between light and dense liver LD in the quiescent tissue but that the volumes are dramatically affected by regeneration. Quiescent dense LD (F5–F8) were found to have an apparent volume nearly ten times larger than their counterparts of equal density from regenerating tissue, which corresponds to a hydrophobic/amphipathic ratio up to 20-fold lower. An explanation for such an effect may reside in notably large quantities of CE in the lipid core of the quiescent dense particles.

Discussion

Resection of 70% of a healthy adult liver triggers regenerative mechanisms that result in complete restoration of liver mass and function within a week or so in adult rodents. During this process, the residual mature hepatocytes proliferate [30] and have the capacity to accumulate substantial amounts of lipids in cytoplasmic LD (see liver sections in Fig. 1). By fractionation of quiescent and regenerating rat liver in a discontinuous sucrose gradient, we isolated LD populations from each condition. LD, defined as adipophilin-positive organelles, were localized in a range of fractions lying above the loading point (Supplementary Fig. 1). The scheme in Fig. 4 summarize the features of the four models of LD phenotypes defined in this work considering the lipid composition. The micrographs in Fig. 1 show high heterogeneity in the LD sizes in regenerating tissue consistent with the analysis of lipid composition.

LD are composed of a core of neutral lipids, TAG and CE, surrounded by a coating of amphipathic cholesterol and phospholipids with which specific proteins can be associated permanently or transiently. Our results show that the TAG accumulated in regenerating tissue mostly corresponded to densities below 1.02 g/ml (F1) and probably to the large-sized LD observed in micrographs of stained tissue (Fig. 1). This accumulation seems to be essential to accomplish timely liver regeneration [31], probably providing precursors for membranes and intracellular signalling, and fatty acids for energy production by mitochondrial and peroxisomal oxidation.

Characterization of LD sub-populations was first described by Ontko et al. [32], who showed that the lipid composition of lipid droplets in rat liver varied. The analysis of fibroblasts, lymphocytes and CHO cells by Bartz et al. [12] revealed differences between LD in their lipid composition. These differential characteristics could be connected with specialized behaviors of LD. The lipid content has been related to cell function in hepatic stellate cells that store retinoids for the whole body in their LD [33]; macrophages and neutrophils are important storage sites for arachidonic acid that is a building block for numerous biological mediators, and muscles and plant seeds store TAG for the supply of energy in periods of scarcity [for a review, see [34]).

LD from regenerating tissue, especially those from F1, are similar to adipocyte LD, large and TAG-enriched [14, 35], and practically devoid of cholesteryl esters, lipids

Fig. 3 Lipid composition of lipid droplet populations from quiescent and regenerating liver tissue. Lipid composition was analyzed in lipid droplet (LD) fractions 1–8 (F1–F8) after separation of lipid classes as described in "Materials and Methods". The average molar fraction of neutral and amphipathic lipids in LD fractions from quiescent (**a**) and regenerating (**b**) liver is shown. For each lipid class, fractions 1–8 of increasing density are represented as *bars* of increasing *grey* intensity from left to right. Data were analyzed using the Student's *t* test. $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$: light (F1–F3, taken together) versus dense (F5–F8, taken together) fractions. Statistical analysis of the trends as a function of the gradient for each lipid class was performed by one-way ANOVA: "*a*" indicates $p \leq 0.05$. (**c**) Molar fractions of lipid classes in light (F1–F3) and dense (F5–F8) fractions. Data were analyzed using the Student's *t* test: $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$, as compared to dense fractions within the same condition; and $^{\#}p < 0.05$; $^{\#\#}p < 0.01$; $^{\#\#\#}p < 0.001$, as compared to counterpart fractions of quiescent liver

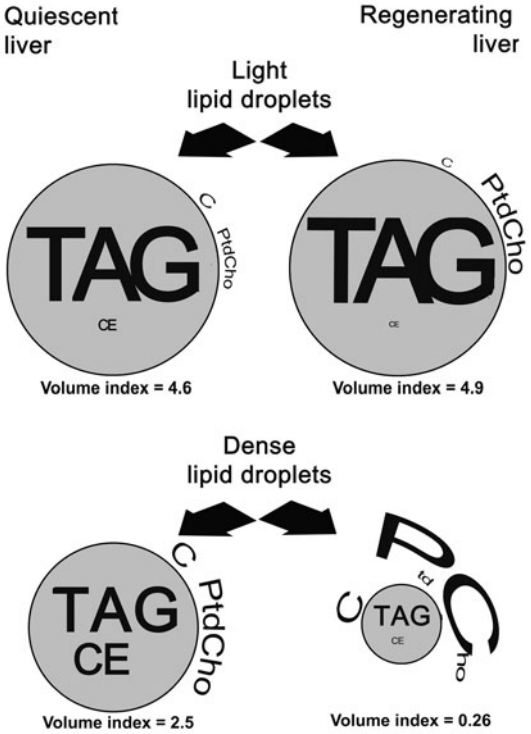

Fig. 4 Schematic representation of light and dense lipid droplets in both quiescent and regenerating livers. We propose four phenotypes of lipid droplets (LD) that occur under physiological conditions on the basis of the molar proportions of the major lipid components. The diameter of the circle representing the LD has been scaled according to the apparent volume calculated by the ratio hydrophobic/amphipathic lipids. The font size of the lipid acronym is proportional to the assessed relative abundance of each lipid (shown in Fig. 3). *TAG* triacylglycerol, *CE* cholesteryl ester, *C* free cholesterol, *PtdCho* phosphatidylcholine

that were found at high levels in all densities LD of quiescent tissue. LD from quiescent liver tissue resemble those of steroidogenic cells, characterized by their high CE content to provide the supply of cholesterol needed for steroid hormone synthesis [34]. In liver parenchymal cells, cholesterol is required for bile acid synthesis and its biliary secretion and also for the assembly of very low density lipoproteins, the secretion rate of which, like that of TAG, is highly dependent on cholesterol availability [36–38]. After PH, the proliferative state is accompanied by profound changes in cholesterol homeostasis [39, 40]. During regeneration, cholesterol metabolism is focused on increasing its cellular availability, which would sustain the formation of new membranes. Limitation of the rate of degradation and secretion of cholesterol, and the activation of its biosynthesis, lead to the maintenance of liver cholesterol levels [40]. Our results suggest that these adaptative changes are accompanied by the mobilization of the CE stored in the LD.

It is well known that metabolic profile changes occur after PH, because of changes in the availability of precursors and enzymatic activities, leading to an increase in the capacity of TAG, PtdCho and PtdEtn synthesis [41–43].

In parallel with the rise of TAG content, these metabolic changes trigger a dramatic increase in the amount of PtdEtn in the liver. Our results show that this is reflected in the percentage of PtdEtn in dense LD only. Such a rise could be related to the need for rapid structural and functional changes involved in LD formation and utilization, for example, to facilitate interactions with proteins. Our data show that the dense LD after PH also became enriched in CerPCho (accounting for 9% of the membrane lipids; data not shown), which is a lipid that tends to segregate forming disordered membrane domains potentially important for lipid–protein specific interactions [44].

In summary, we propose two models of LD in each of the physiological conditions of hepatic tissue analyzed (quiescence and regeneration): one corresponding to light (density $\leq$1.02 g/ml) and one to dense (density $\geq$1.06 g/ml) particles, on the basis of their specific lipid profiles. Our findings provide evidence that hepatic lipid droplets are multifunctional and adaptative structures and support the notion that LD in the liver are complex organelles with probably still unknown roles in lipid metabolism.

resistance is mainly determined by the response of skeletal muscle to insulin. Lipid oversupply is known to play a causative role in the generation of muscle insulin resistance, and lipid signaling molecules derived from free fatty acid (FFA) such as diacylglycerol (DAG) and ceramide were reported to interfere with insulin signal transduction in skeletal muscle (reviewed in [1]).

Recently, dietary monounsaturated fatty acids (MUFA) has been known to have beneficial effect on insulin sensitivity, as compared to a saturated fatty acids (SFA) [2–5]. The associations of dietary SFA with insulin resistance and the development of metabolic syndrome or diabetes were elucidated in several studies [6–9]. Recent studies reported that, compared with unsaturated fatty acids, SFA increased intramuscular accumulation of lipid metabolites (DAG or ceramide) and attenuated insulin-stimulated glucose uptake of skeletal muscle [9, 10].

Insulin receptor substrates (IRS)-1 and -2 are the docking proteins of the insulin receptor; these proteins are recruited to the receptor after insulin binding and play a central role in the translocation of glucose transporter type 4 (GLUT4) through the activation of the phosphoinositol 3-kinase (PI3K) pathway (reviewed in [1]). Although intramuscular lipid metabolites are known to affect the IRS/PI3K pathway, to our knowledge there are few in vivo studies investigating the effect of dietary SFA and MUFA on this pathway. In this study, we compared the effect of dietary SFA and MUFA on the IRS/PI3K pathway and GLUT4 membrane translocation in the skeletal muscle of a type 2 diabetic animal model. The results of this study might provide clues to understanding the mechanism through which dietary fatty acid composition affect skeletal muscle insulin sensitivity and could provide the theoretical background for nutritional advice for T2DM patients.

Materials and Methods

Animals and Experimental Diet

Twenty-nine-week-old male Otsuka Long-Evans Tokushima fatty (OLETF) rats (Otsuka Pharmaceutical, Tokushima, Japan) were kept at ambient temperature (22°C ± 1°C) on a 12-h light–dark cycle with free access to water and diet. Before any experimental intervention, animals were fed a standard rodent chow (Samtako, Osan, Korea). After 1 week, rats were divided into three experimental diet groups. Rats in the control group (chow, $n = 10$) were fed standard rat chow (61.8% carbohydrate, 15.7% fat, 22.5% protein expressed as percentages of the total caloric intake, chow diet) purchased from Samtako; the SFA group (SFA, $n = 10$) was fed a high-fat diet that primarily consisted of saturated fatty acids (24.3% carbohydrate, 52.8% fat, 22.9% protein, lard oil as 79.1% of total fat, SFA diet); and the MUFA group (MUFA, $n = 10$) was fed a high-fat diet that consisted primarily of monounsaturated fatty acids (24.3% carbohydrate, 52.8% fat, 22.9% protein, olive oil as 79.1% of total fat, MUFA diet). We made the high-fat diet by adding olive oil or lard oil to the purchased normal chow diet, and the ingredients of chow diet were as follows; ground corn, dehulled soybean meal, wheat middlings, ground wheat, fish meal, cane molasses, wheat germ, dried beet pulp, brewers dried yeast, dehydrated alfalfa meal, ground oats, dried whey, soybean oil, vitamin premix, and mineral premix. Animals were provided with food and water ad libitum throughout the experimental period. Animals were maintained on their diets for 3 weeks before testing. The animals were euthanized at the end of a dark cycle after overnight fasting for tissue sampling. Blood was collected by cardiac puncture and the vastus lateralis muscle was rapidly dissected out, immediately frozen in liquid nitrogen, and stored at −80°C until analysis. All procedures were approved by the Institutional Animal Care and Use Committee of the Yonsei University College of Medicine.

Insulin Tolerance Test (ITT)

After 3 weeks of experimental diet feeding, an ITT was performed. After a 6-h fast, rats were intraperitoneally injected with 0.75 U/kg human regular insulin (Humulin-R®, Eli Lilly and Company, Indianapolis, IN, USA). Blood samples were obtained at the indicated time by tail snipping, and blood glucose levels were measured with a glucose analyzer (Accu-Check; Roche Diagnostics, Basel, Switzerland).

Oral Glucose Tolerance Test (OGTT)

An OGTT was performed in rats after forced oral administration of a 20% glucose solution (2 g/kg) with a 10-ml syringe followed by an overnight fast. Blood samples were obtained at the indicated time by tail snipping, and blood glucose levels were measured with a glucose analyzer (Accu-Check; Roche Diagnostics).

RNA and cDNA Preparation

Total RNA was isolated from rat skeletal muscle tissue using Trizol reagent (Invitrogen, Carlsbad, CA, USA) and quantified by nano drop (ND-1000, DM Science, Seoul, Korea). Following RNA extraction, 4 μl RNA was treated with 1 U DNase I to remove all contaminating genomic DNA. DNase-treated RNA was subsequently used for cDNA synthesis using MMLV reverse transcriptase (Promega, Madison, WI, USA): 1 μl oligo dT primer was added to 4 μl RNA with 5× MMLV reaction buffer,

2.5 mM each dNTP, 1 U RNasin ribonuclease inhibitor and MMLV reverse transcriptase (200 units). cDNA was stored at −20°C.

Semi-Quantitative RT-PCR

The mRNA levels of IRS-1 and -2 were assessed by semi-quantitative RT-PCR analysis using glyceraldehyde-3-phosphate dehydrogenase (GAPDH) as a control. PCR primers were designed as follows: IRS-1 sense, 5′-ggttttg gtcaaggatgtta-3′; IRS-1 anti-sense, 5′-tgctgaggtcatttaggtc t-3′; IRS-2 sense, 5′-cttttctcccctccacaagc-3′; IRS-2 anti-sense, 5′-caagaacggttgaggagcaa-3′; GAPDH sense, 5′-catt gacctcaactacatggt-3′; and GAPDH anti-sense, 5′-gtgaagac gccagtagactc-3′. RT-PCR products were electrophoresed on a 1% (w/v) agarose gel, stained with ethidium bromide and visualized by UV light.

Plasma Membrane Protein Extraction

The extraction of sarcolemmal membrane protein from skeletal muscle tissue was performed using a commercially available plasma membrane protein extraction kit (#k268-50, BioVision, Mountain View, CA, USA) according to the manufacturer's instructions [11, 12]. For membrane fractionation, skeletal muscle samples of each experimental group were homogenized and processed for extraction of sarcolemmal membrane protein. The protein content in the sarcolemmal membrane fraction was measured by Bradford reagent (Bio-Rad, Hercules, CA, USA). The α1 subunit of the Na^+/K^+-ATPase, a sarcolemmal membrane marker, was measured by immunoblot to document adequate enrichment of membrane fractions.

Immunoblot Analysis

Aliquots of tissue homogenates were denatured under reducing conditions (1.75% SDS, 15 mM 2-mercaptoethanol; 5 min at 100°C), then subjected to SDS-PAGE and immunoblot analyses. To detect IRS-1, nitrocellulose membranes were incubated overnight at 4°C with anti-IRS-1 antibody (rabbit polyclonal IgG, 1:100, Millipore, Billerica, MA, USA) then with goat anti-rabbit IgG conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology, Santa Cruz, CA, USA) for 1 h. Immunolabeling was detected with the ECL Western Blotting Analysis System (Thermo Fischer Scientific, Waltham, MA, USA). All immunoreactivity was normalized to total protein as determined by Bradford assay (Sigma-Aldrich, St. Louis, MO, USA). We used following reagents to detect specific protein we investigated; for phosphorylated IRS-1 (p-IRS-1, Tyr896), anti-p-IRS-1 antibody (rabbit monoclonal IgG, 1:100, Epitomics, Burlingame, CA, USA) and goat anti-rabbit IgG secondary antibody conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology); for IRS-2, anti-IRS-2 antibody (rabbit polyclonal IgG, 1:250, Sigma-Aldrich) and goat anti-rabbit IgG secondary antibody conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology); for phosphorylated IRS-2 (p-IRS-2, Ser731), anti-p-IRS-2 antibody (rabbit polyclonal IgG, 1:1,000, Abbomax, San Jose, CA, USA) and goat anti-rabbit IgG secondary antibody conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology); for phosphorylated p85 subunit of PI3K (p-PI3K p85, Tyr458), anti-p-PI3K p85 antibody (rabbit polyclonal IgG, 1:1,500; Cell Signaling Technology, Danvers, MA, USA) and goat anti-rabbit IgG secondary antibody conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology); for phosphorylated extracellular signal-regulated kinase 1/2 (p-ERK1/2, Tyr204), anti-p-ERK1/2 antibody (mouse monoclonal IgG, 1:1,500, Santa Cruz Biotechnology) and goat anti-mouse IgG secondary antibody conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology); for GLUT4, anti-GLUT4 antibody (mouse monoclonal IgG, 1:500, Cell Signaling Technology) and goat anti-mouse IgG secondary antibody conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology); for Na^+/K^+-ATPase, anti-Na^+/K^+-ATPase antibody (rabbit monoclonal IgG, 1:2,000, Epitomics) and goat anti-rabbit IgG secondary antibody conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology). β-actin immunoreactivity, detected with monoclonal anti-β-actin antibody (1:5,000, Sigma-Aldrich) and goat anti-mouse IgG secondary antibody conjugated to horseradish peroxidase (1:5,000, Santa Cruz Biotechnology), was used as a loading control.

Statistical Analysis

All statistical analyses were performed with SPSS software (version 15.0; SPSS Inc, Chicago, IL, USA). Values were expressed as means ± SD. Statistical analyses were performed using the unpaired Student's t test or one way ANOVA. Data with a p value <0.05 were considered statistically significant.

Results

Insulin Sensitivity was Impaired in OLETF Rats Fed the SFA Diet and Maintained in Those Fed the MUFA Diet

To evaluate the extent of insulin resistance developed in OLETF rats from each group, we performed ITT and OGTT. The glucose disposal rate between 15 and 30 min after insulin administration was significantly reduced in

rats fed the SFA diet, as compared with rats fed the chow diet or the MUFA diet (Fig. 1a). OGTT showed that the blood glucose levels of rats fed the SFA diet were significantly higher than those of rats fed the chow diet or the MUFA diet for all time intervals tested (Fig. 1b).

Dietary SFA Altered the IRS-1/PI3K Pathway and IRS-2 and ERK1/2 Activity

To investigate the effect of dietary fatty acid composition on insulin signal transduction in skeletal muscle, we evaluated the mRNA expression of IRS-1 and -2 in vastus lateralis muscle from OLETF rats in each group. Muscle IRS-1 mRNA expression was significantly reduced in rats fed the SFA diet, as compared with those fed the normal chow diet; however, the MUFA diet did not change the mRNA expression of muscle IRS-1, as compared with the chow diet (chow vs. SFA vs. MUFA, 1.00 ± 0.06 vs. 0.46 ± 0.03 vs. 0.96 ± 0.05 AU, $p < 0.001$) (Fig. 2a). The protein abundance of IRS-1 and phosphorylated IRS-1 in the whole homogenate of skeletal muscle sample showed the same tendency with mRNA expression(IRS-1, chow vs. SFA vs. MUFA, 1.00 ± 0.17 vs. 0.36 ± 0.16 vs. 0.96 ± 0.20 AU, $p < 0.001$; p-IRS-1, chow vs. SFA vs. MUFA, 1.00 ± 0.15 vs. 0.17 ± 0.09 vs. 0.87 ± 0.19 AU, $p < 0.001$) (Fig. 2a and 2b). On the contrary, muscle IRS-2 mRNA expression and protein abundance of IRS-2 and phosphorylated IRS-2 increased in rats fed the SFA diet, as compared with rats fed the chow diet, whereas there was no difference in muscle IRS-2 expression between rats fed the MUFA diet and the chow diet (mRNA, chow vs. SFA vs. MUFA, 1.00 ± 0.05 vs. 1.77 ± 0.04 vs. 1.08 ± 0.08 AU, $p < 0.001$; protein, IRS-2, chow vs. SFA vs. MUFA, 1.00 ± 0.14 vs. 1.72 ± 0.33 vs. 0.87 ± 0.26 AU, $p < 0.001$; protein, p-IRS-2, chow vs. SFA vs. MUFA, 1.00 ± 0.36 vs. 3.97 ± 0.58 vs. 0.57 ± 0.45 AU, $p < 0.001$) (Fig. 3). To investigate the activation of PI3K and ERK1/2, the downstream protein kinases of IRS-1 and -2, we also measured the protein abundance of phosphorylated p85 subunit of PI3K and phosphorylated ERK1/2 in the whole homogenate of skeletal muscle sample. In OLETF rats fed the SFA diet, the level of p-PI3K p85 was decreased and the level of p-ERK1/2 was significantly increased, as compared with rats fed the chow diet, whereas there was no difference in p-PI3K p85 and p-ERK1/2 between rats fed the chow diet and the MUFA diet (p-PI3K p85, chow vs. SFA vs. MUFA, 1.00 ± 0.06 vs. 0.36 ± 0.06 vs. 0.97 ± 0.07 AU, $p < 0.001$; p-ERK1/2, chow vs. SFA vs. MUFA, 1.00 ± 0.08 vs. 5.59 ± 0.54 vs. 1.11 ± 0.16 AU, $p < 0.001$) (Fig. 4).

Dietary SFA Reduced GLUT4 Membrane Translocation in Rat Skeletal Muscle

We investigated the whole cell and sarcolemmal membrane expression of GLUT4 in vastus lateralis muscle from OLETF rats in each group to investigate whether alteration in the IRS-1/PI3K pathway by dietary SFA affected GLUT4 membrane translocation. There was no difference in GLUT4 protein abundance in whole cell lysates of muscle samples from each experimental diet group (Fig. 5a). However, GLUT4 protein abundance in the muscle plasma membrane was significantly reduced by the SFA diet, compared to the normal chow diet (chow vs.

SFA, 1.00 ± 0.23 vs. 0.34 ± 0.15 AU, $p < 0.001$) (Fig. 5b). In contrast, GLUT4 protein abundance in muscle plasma membrane of rats fed the MUFA diet was not different from that in rats fed the chow diet.

Discussion

In this study, we observed the effect of dietary fatty acid composition of a high-fat diet on the insulin signaling pathway and GLUT4 membrane translocation in skeletal muscle of OLETF rats, a type 2 diabetic animal model. Insulin sensitivity measured by ITT was attenuated in the SFA group, whereas the MUFA group showed improved insulin sensitivity, compared with the SFA group. We focused on the insulin sensitivity of skeletal muscle for this study because the skeletal muscle is the major site of insulin-stimulated glucose disposal (reviewed in [1]).

First, we investigated the effect of dietary SFA on the insulin signaling pathway in vastus lateralis muscle of OLETF rats. The association of dietary SFA and insulin resistance of skeletal muscle can be explained by several

mechanisms. The traditional explanation proposes that dietary fatty acid composition affects the composition of cell membranes and membrane function such as GLUT4 translocation or insulin receptor affinity [13]. Recently, several studies reported a direct effect of dietary fatty acid composition or lipid oversupply on gene expression, enzyme activity, and signal transduction associated with insulin sensitivity (reviewed in [1]). Accumulation of lipid metabolites and mitochondrial dysfunction were also reported as possible mechanisms of the SFA-induced insulin resistance [9, 10, 14, 15]. Our results showed that the SFA-rich high-fat diet reduced IRS-1 mRNA expression and protein abundance of total IRS-1 and activated IRS-1, whereas this diet increased IRS-2 and activated IRS-2. IRS-1 and -2 are the docking proteins of the insulin receptor; the proteins are recruited to the receptor after

insulin binding and play a central role in the translocation of GLUT4. In skeletal muscle, IRS-1, and to a lesser extent, IRS-2, appear to be particularly important in the control of glucose metabolism through activation of the PI3K pathway (reviewed in [1]). Recent studies have reported that IRS-1 and IRS-2 have distinct regulatory functions in insulin signaling pathway [16, 17]. Zheng et al. [16] reported that dexamethasone treatment reduced IRS-1 protein and PI3K/Akt signaling and increased IRS-2 protein and MEK/ERK signaling in rat L6 myotubes. Piro et al. reported that palmitate treatment reduced IRS-1/PI3K/Akt signaling and increased IRS-2/ERK signaling in pancreatic α-cell line. Considering that dexamethasone, palmitate and the SFA-rich high-fat diet are responsible for insulin resistance, as well as on the basis of our results showing the different effect of the SFA-rich high-fat diet on skeletal muscle IRS-1 and -2 expressions, we hypothesized that dietary SFA might reduce IRS-1/PI3K signaling and increase IRS-2/ERK signaling in rat skeletal muscle. As expected, our data were consistent with previous studies mentioned above; the protein abundance of activated PI3K was reduced in the skeletal muscle of the SFA group, whereas activated ERK1/2 was increased by dietary SFA. Altogether, our results suggest that the alteration in the IRS-1/PI3K pathway plays a crucial role in SFA-induced insulin resistance in skeletal muscle. In addition, IRS-2 might play a minor role in SFA-induced insulin resistance and the downstream effect of increased IRS-2 appears to be limited to increasing ERK1/2-mediated mitogenic properties, not affecting PI3K-mediated insulin-induced glucose disposal in skeletal muscle. The mechanism underlying this difference in SFA-induced changes in IRS-1 and IRS-2 expression is unclear. Although some clues may be provided by studies showing that Forkhead box O3a (FOXO3a) mediates signaling crosstalk between IRS-1 and -2 during glucocorticoid-induced skeletal muscle atrophy [16], further investigation is needed. We also demonstrated that GLUT4 membrane translocation in skeletal muscle was decreased in SFA diet-fed rats, as compared with those fed the chow diet. This result shows that the alteration in the IRS-1/PI3K pathway by dietary SFA affects the GLUT4 membrane translocation and might, therefore, reduce insulin-stimulated glucose disposal in skeletal muscle.

We also investigated the effect of dietary MUFA in the high-fat diet condition on the insulin signaling pathway in skeletal muscle of OLETF rats. The changes in IRS-1/-2, p-PI3K p85, and p-ERK1/2 induced by dietary SFA completely disappeared when SFA was substituted by MUFA; there was no difference in IRS-1 and -2 expression or in levels of activated PI3K and ERK1/2 between rats fed the MUFA-rich high-fat diet and those fed the chow diet. Our results are consistent with previous findings that the prevention of palmitate-induced insulin resistance by oleate in L6 muscle cells is associated with the ability of oleate to maintain insulin signaling through PI3K [18]. GLUT4 membrane translocation was also preserved in skeletal muscle of the MUFA group. Thus, despite their high-fat diet, the MUFA group had an intact IRS-1/PI3K pathway and maintained GLUT4 membrane translocation and insulin-stimulated glucose disposal in skeletal muscle. Our results are consistent with several randomized controlled clinical studies showing that dietary MUFA improves insulin sensitivity, compared with the SFA-rich diet [2–5]. According to a recent review, consumption of SFA instead of MUFA may worsen glucose-insulin homeostasis, especially among individuals predisposed to insulin resistance [19]. We used a type 2 diabetic animal model for this study; thus, the results of the present study suggest a possible mechanism for the beneficial effect of dietary MUFA, especially in type 2 diabetic patients consuming high-fat diet.

One limitation of this study is that we did not measure the insulin-stimulated glucose disposal of skeletal muscle using radioisotopes. However, to our knowledge, this is the first in vivo study to investigate the effect of dietary fatty acid composition on the insulin signaling pathway and subsequent GLUT4 translocation in skeletal muscle for a type 2 diabetic status under conditions of a high-fat diet. Considering the reality that the majority of diabetic patients fail to reduce the amount of fat or calories in their diet [20–22], this study provides meaningful information that a MUFA-enriched diet could allow diabetic patients to maintain insulin sensitivity even if they continue to consume a high-fat diet.

In conclusion, we showed a beneficial effect of dietary MUFA on insulin sensitivity in a type 2 diabetic model with high-fat diet conditions. This beneficial effect of dietary MUFA, as compared with SFA, is associated with an intact insulin signaling pathway through IRS-1/PI3K and maintenance of GLUT4 membrane translocation in skeletal muscle, both of which were altered by dietary SFA. This study might provide an experimental rationale for dietary advice for type 2 diabetic patients.

address its underlying causes is an important public health priority. Dysregulated lipid metabolism leading to elevated low density lipoprotein (LDL)-cholesterol (C) and low plasma high density lipoprotein (HDL)-C are important CVD risk factors [1–6]. With wider use of the statins, low HDL-C has emerged as the most important lipoprotein disorder for which current therapies are inadequate. The need for new approaches is highlighted by the failed trial of a cholesteryl ester transfer protein (CETP) inhibitor [7]. Although hypertriglyceridemia and low HDL-C are mechanistically linked, the latter is more strongly correlated with CVD mortality [2]. HDL-C and cardioprotection are mechanistically linked by reverse cholesterol transport (RCT), the transfer of cholesterol from macrophages in the subendothelial space to the liver for disposal [8]. The first two RCT steps are macrophage cholesterol efflux and cholesterol esterification in plasma [8]. Thus, an intervention that enhances both of these steps could be a therapeutically useful new approach to improve RCT.

A recombinant (r) virulence determinant from *Streptococcus pyogenes* [9], serum opacity factor (SOF), delipidates human HDL yielding a cholesteryl ester-rich microemulsion (CERM), lipid-free apo A-I and a "neo HDL" [10–12]. Given that neo HDL is more phospholipid-rich than HDL and that cholesterol efflux and esterification are increased by increased phospholipid content of acceptors and substrates, respectively [13–16], we tested the effects of SOF-mediated conversion of HDL in whole plasma to neo HDL on efflux and esterification.

Experimental Procedures

Materials

Total lipoproteins (TLP) and HDL were isolated from human plasma obtained from The Methodist Hospital Blood Donor Center by addition of KBr to $d = 1.21$ g/mL and flotation (48 h at 40,000 rpm, Beckman Ti 50.2 rotor). VLDL, LDL, HDL and lipoprotein-deficient serum (LPDS) were isolated by sequential flotation at $d = 1.012$, 1.063 and 1.21 g/mL, respectively. Lipoprotein purity was verified by size exclusion chromatography (SEC) and SDS-PAGE. Protein was determined with a kit (BioRad DC assay) using BSA as a standard. LDL was stored at 4 °C under nitrogen gas and used within 14 days. OxLDL was prepared by exposing LDL to 5 μmol/L CuSO4 for 24 h at 37 °C [17]. Lipid oxidation was verified by an assay for thiobarbituric acid-reactive substances; precautions were taken to exclude endotoxin. Neo HDL was prepared by incubating HDL (~2 mg/mL) and rSOF (1 μg/mL) in 47.5 mL overnight at 37 °C. The reaction mixture was adjusted to a $d = 1.063$ g/mL with KBr and centrifuged for 18 h at 45,000 rpm (Beckman Ti 50.2 rotor). The upper half of the tube was removed by aspiration. The bottom half was adjusted to a $d = 1.24$ g/mL with KBr and centrifuged as above for 40 h. The neo HDL removed from the top was pure as assessed by SEC [12]. Tris-buffered saline (TBS = 10 mM Tris, 100 mM NaCl, 1 mM EDTA, pH 7.4) was used throughout unless otherwise specified. [^{3}H]Cholesterol was from Amersham Biosciences (Piscataway, NJ, USA). Buffer salts were from Fisher Scientific, Inc., (Rockville, MD, USA). A recombinant polyhistidine-tagged, truncated form of *sof2*, encoding amino acids 38–843 (rSOF) was cloned and expressed in *Escherichia coli* and purified by metal affinity chromatography [10].

Effect of rSOF on LCAT Cholesterol Esterification

HDL was labeled with [^{3}H]cholesterol (~100 μCi) by injection of an ethanolic solution [15] and split into two equal aliquots; rSOF (1 μg/mL) was added to one and an equal volume of saline was added to the other and incubated overnight at 37 °C. On ice, the fractions were recombined as follows: (a) [^{3}H]HDL + (LDL + VLDL) + LPDS, (b) rSOF-treated [^{3}H]HDL + (LDL + VLDL) + LPDS, (c) [^{3}H]HDL + LPDS, and (d) rSOF-treated [^{3}H]HDL + LPDS. TBS was added to each sample to give equal volumes. The samples were incubated at 37 °C for 30 min and transferred to ice. Triplicate aliquots (100 μL) of each incubation were β-counted. Another set of triplicate aliquots were extracted with 4 mL hexane and the phases separated by low speed centrifugation for 5 min; 3-mL aliquots of the upper layer were evaporated under nitrogen and the residue dissolved in 30 μL chloroform. CE and FC were resolved by thin layer chromatography (Whatman TLC silica gel 60A plates) in hexane/diethyl ether/acetic acid (75:35:1, by volume). After spraying the plates with Primuline dye (Sigma–Aldrich, St. Louis, MO, USA), FC and CE bands were identified by comparison with standards. The FC and CE were collected and quantified by β-counting. A 200-μL aliquot of each incubation mixture was analyzed by SEC to determine the distribution of radiolabel into CERM, VLDL, LDL, HDL and neo HDL. SEC profiles of the LCAT reaction products were determined essentially as described [11] using an Amersham Pharmacia ÄKTA chromatography system equipped with two Superose HR6 columns in tandem. Samples were injected into the chromatograph using a 0.2-mL sample loop, and eluted with TBS; 1-mL fractions were collected and analyzed by β-counting.

Effects of rSOF Activity Against Lipoproteins on Cellular Cholesterol Efflux

Plasma, TLP, HDL, and the products of their reactions with rSOF were extensively dialyzed at 4 °C against TBS and

tested as acceptors of cholesterol from the human monocyte-derived macrophage cell line, THP-1 (American Type Culture Collection). THP-1 cells were maintained in RPMI 1640 with 10% FBS, 100 U/mL penicillin, 100 mg/mL streptomycin, 1 mM sodium pyruvate and 2 mM glutamine. Cholesterol efflux was assayed as described previously [15, 16, 18]. In brief, THP-1 cells were seeded and activated with 0.1 μg/mL phorbol 12-myristate 13-acetate for 24 h. Cells were then labeled in serum-containing medium with [1α, 2α(n)-^{3}H]cholesterol (specific radioactivity 1.81 TBq/mmol, final radioactivity 74 KBq/mL) at 37 °C for 48 h in a CO_2 incubator at which time they were ~80% confluent. After labeling, cells were washed twice to remove excess label, and incubated for an additional 18 h in serum-free medium to ensure equilibration of labeled cholesterol into all intracellular pools. During this phase, the THP-1 medium contained the LXR agonist T0901317 (1 μM) to activate the macrophage in a way that increased the activities of ABCA1 and ABCG1 in cells that were not cholesterol-loaded. To initiate the efflux assay, cells were washed and incubated for 0–2 h at 37 °C in serum-free medium containing various concentrations of human plasma (0–8%), TLP, HDL, or neo HDL (10–200 μg/mL). After incubation, the medium was collected, centrifuged, and the supernatant analyzed by β-counting. Cell lipids were extracted with isopropanol and analyzed by β-counting. Cholesterol efflux ($\%E$) was expressed as the percentage of total labeled cholesterol transferred from cells to the medium. Efflux was compared on the basis of acceptor-protein concentration and the data were fitted to the equation $\%E = E_{max} \times (LP)/[K_m + (LP)]$, where LP was the lipoprotein concentration as protein, E_{max} was the maximum efflux and K_m was the lipoprotein concentration at half E_{max} using Systat-Sigma Plot (Point Richmond, CA, USA).

Efflux via ABCA1 and ABCG1

Efflux from ABCA1 and ABCG1-expressing BHK cells under a mifepristone-inducible promoter and MOCK cells transfected with the pGene V5 His plasmid alone were tested as reported by Vaughan and Oram [19]. ABCA1- and ABCG1-expressing BHK cells were labeled with [^{3}H]cholesterol to equilibrium 1 day prior to mifepristone treatment. ABCA1 and ABCG1 receptors were induced by incubating cells for 18–20 h in DMEM with 1 mg/mL fatty acid free bovine serum albumin and 10 nM mifepristone. Unactivated cells (no mifepristone) were used as a negative controls. Transporter-specific efflux was calculated as the difference between efflux from ABCA1 and ABCG1-expressing cells with and without activation.

Comparison of the Effects of HDL and Neo HDL on Inflammatory IL-6 and TNF-α

Mouse peritoneal macrophages were collected from C57Bl/6 J mice 2 days after mineral oil injection and seeded in RPMI-1640 medium supplemented with 5% BSA in 96-well plates at ~10^5cells/well and cultured for 1 day. HDL and neo HDL were preincubated with OxLDL at ratio of 1:1 protein for 1 h at 37 °C. Cells were treated with OxLDL(100 μg/mL), HDL(100 μg/mL) and neo HDL(100 μg/mL), HDL-OxLDL (100 μg/mL each), and neo HDL-OxLDL(100 μg/mL each), respectively. IL-6 and TNF-α concentrations in the media were measured by ELISA kits (BD Bioscience) 18 h after treatment.

Statistical Tests

Statistical analysis of data was done as indicated in the figure legends, using the t test for pairs of means, one-way ANOVA with Tukey's post hoc test for multiple comparisons, and two-way ANOVA with Bonferroni post tests for regression plots, using SPSS and GraphPad Prism statistical software.

Results

Macrophage Cholesterol Efflux

Cholesterol efflux from THP-1 macrophages to plasma (1%) and TLP (25 μg/mL) were linear with time and increased by preincubation with rSOF; efflux to neo HDL formed from treatment of HDL with rSOF was also higher than that to HDL (Fig. 1a–c). The respective ratios of the rates of efflux to the rSOF-derived acceptors to controls were 2.4, 3.3, and 2.6. Increasing the rSOF pre incubation time increased cholesterol efflux and the production of neo HDL and CERM (Supplementary Figs. 1, 2).

[^{3}H]Cholesterol efflux kinetics from THP-1 macrophages to various acceptors with and without rSOF treatment were also measured. The acceptors were, respectively, plasma ± rSOF, TLP ± rSOF, HDL ± rSOF reaction mixtures and isolated HDL and neo HDL (Fig. 2a–d). Efflux from cholesterol-loaded macrophages to plasma was also measured (Fig. 2a, insert). rSOF treatment improved the global parameter of cholesterol efflux, $Cat_{eff} = V_{max}/K_m$(Supplementary Table 1). The Cat_{eff} for acceptors that were rSOF-derived were 2–3 times higher than those of the acceptors from which they were formed (Supplementary Table 1). When measured as mass, macrophage cholesterol efflux to HDL after incubation with rSOF increased with the addition of the LXR agonist

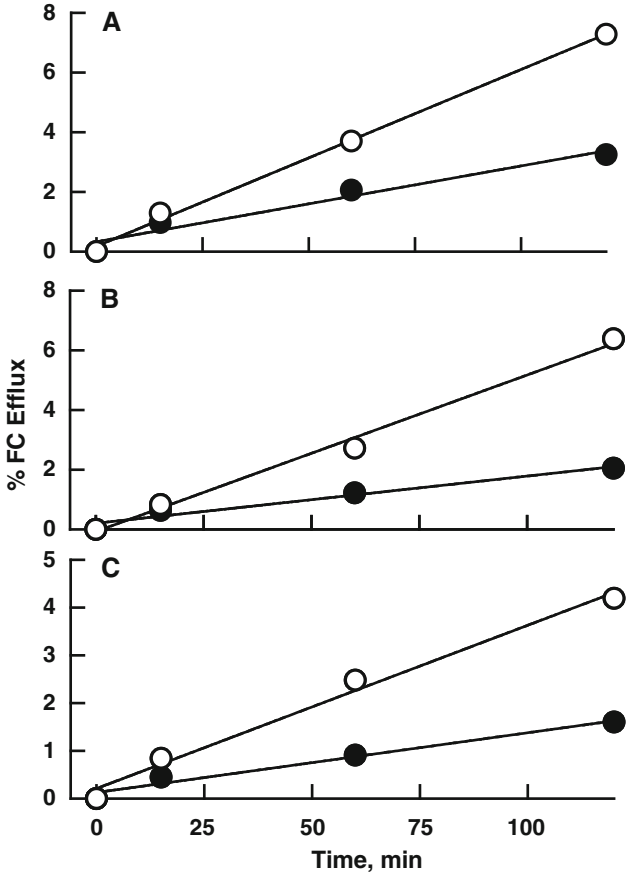

Fig. 1 Time-dependence of cholesterol efflux from THP-1 macrophages. **a** Plasma (1%) and plasma (1%) after overnight incubation with rSOF (1 μg/mL) were incubated with [^{3}H]cholesterol-labeled macrophages for 0–2 h and the amount of radiolabel transferred to media determined. **b** Similar data were collected for TLP (25 μg/mL) and TLP (25 μg/mL) after incubation overnight with rSOF. **c** Similar data for transfer of radiolabel to isolated HDL and neo HDL (both 25 μg/mL). The ratios of the slopes of rSOF derived acceptors to controls in **a**–**c** were 2.4, 3.3, and 2.6, respectively. $r^2 > 0.95$ for all plots. *Closed circles* **a** control plasma, **b** control TLP, **c** HDL. *Open circles* **a** Plasma + rSOF, **b** TLP + rSOF, **c** neo HDL. The efflux values were means ± SD of two experiments in triplicate. In **a**–**c** the error *bars* were smaller than the symbols

(TO-901317) both with and without cholesterol loading (Supplementary Fig. 3).

We identified the plasma acceptors of cellular [^{3}H]cholesterol after 15 min and 2 h efflux times by SEC. After a 15-min incubation of 3% plasma with cells, most of the cell-derived [^{3}H]cholesterol co-eluted with HDL and VLDL (Fig. 3a). In contrast, [^{3}H]cholesterol effluxed to 3% plasma pre-treated for 3 h with rSOF co-eluted with neo HDL and CERM + VLDL (Fig. 3a). After longer incubation (2 h) with macrophages the SEC profiles indicated more transfer to CERM and LDL for rSOF-treated plasma than to VLDL and LDL for control (Fig. 3b). Similar experiments were conducted with TLP, which

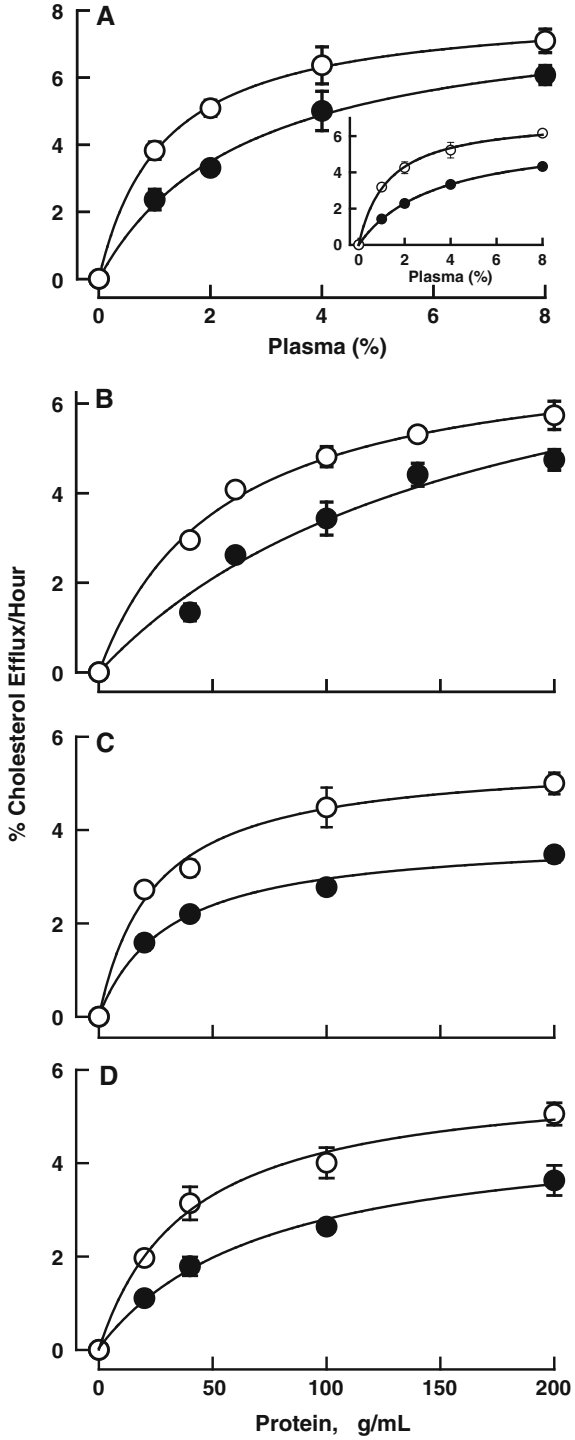

Fig. 2 [^{3}H]Cholesterol efflux from THP-1 macrophages to various acceptors. The acceptors were plasma (**a**), TLP (**b**), and HDL (**c**) each with (*open circles*) and without (*closed circles*) preincubation with rSOF for 18 h. Efflux to isolated HDL (*closed circles*) and neo HDL formed from rSOF + HDL (*open circles*) is shown in (**d**). Insert in **a** shows efflux from cholesterol-loaded macrophages to plasma. Other details are in "Materials" and Fig. 1. Two-way ANOVA analysis of the regression plots indicated that rSOF pretreatment significantly increased efflux to all of the acceptors ($p < 0.001$), and Bonferroni post tests indicated this was true for all the concentrations tested ($p < 0.01$)

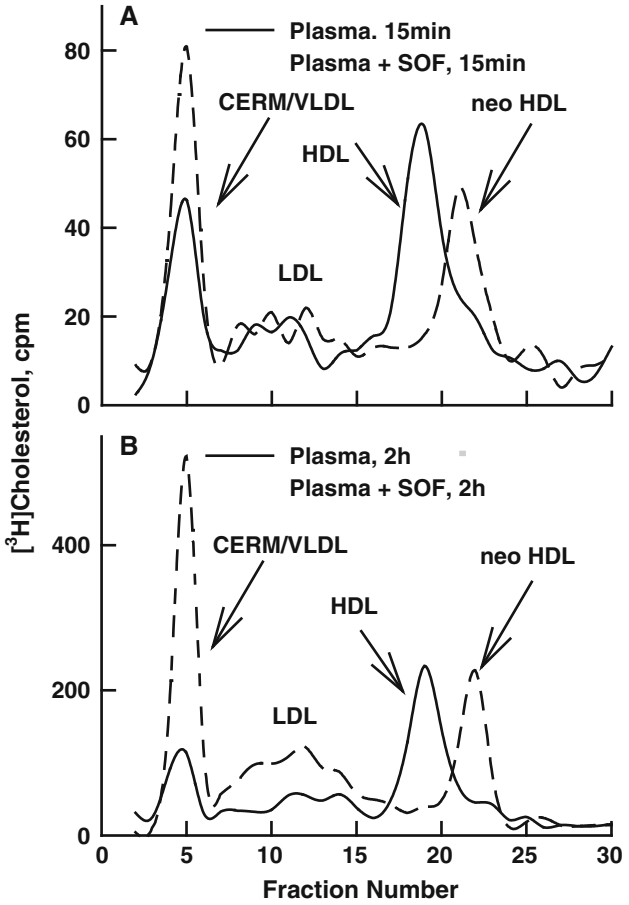

Fig. 3 SEC of 3% plasma, with and without rSOF pretreatment (3 h), after incubation with [^{3}H]cholesterol-labeled THP-1 macrophages. Cells were labeled and treated as in Fig. 1. **a** Fifteen min incubation, **b** 2 h incubation. Plasma (*continuous lines*), plasma post-rSOF (*dashed lines*). Media were transferred to tubes in wet ice and immediately analyzed by SEC in which the effluent was monitored by absorbance at 280 nm (not shown) and by the radioactivity of collected fractions. The peak elution fractions for CERM/VLDL, LDL, HDL, and neo were 4, 12, 19, and 22 mL, respectively

lacks lipid transfer protein and LCAT activities. At 15 min, [^{3}H]cholesterol appeared in all lipoprotein subclasses but at 2 h, a greater fraction was in LDL. (Supplementary Fig. 4). Similarly, SEC showed that cell-derived cholesterol associates with HDL and neo HDL when they were used as acceptors (Supplementary Fig. 5a, c), and efflux to all acceptors was greater at 2 h than at 15 min. When the total rSOF-HDL reaction mixture was used as acceptor, [^{3}H]cholesterol was found in both the neo HDL and the CERM (Supplementary Fig. 5b), and the presence of CERM promoted more total efflux than neo HDL alone at both 15 min and 2 h. Finally, macrophage cholesterol efflux to plasma depleted of apo B-containing lipoproteins increased when the preincubation time with rSOF was increased from 15 to 120 min. With the longer preincubation time, more neo HDL and CERM were formed, and there was a corresponding increase in association of

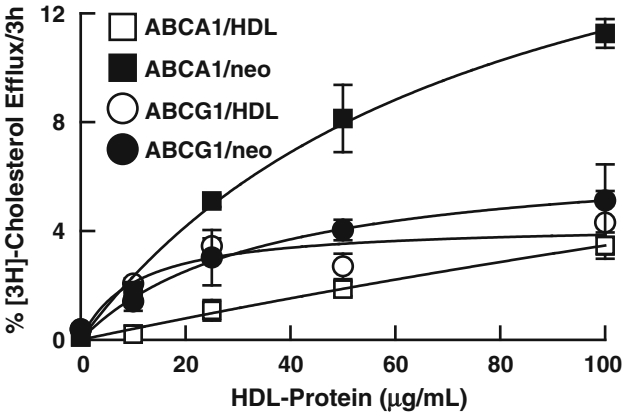

Fig. 4 [^{3}H]Cholesterol efflux from ABCA1- and ABCG1-transfected BHK cells to various protein concentrations of HDL and neo HDL. HDL and neo HDL were incubated with radiolabeled, mifepristone-induced cells for 3 h and the amount of the radiolabel transferred to media determined. The control assays were done with non-induced cells. The efflux values are means ± SD of two experiments in triplicate. Two-way ANOVA analysis of the regression plots indicated that efflux to neo HDL was significantly greater than to HDL for the ABCA1 cells ($p = 0.002$) but that efflux to neo HDL and HDL was not significantly different for the ABCG1 cells

[3H]cholesterol with CERM and neo HDL instead of HDL (Supplementary Fig. 6).

Efflux via ABCA1 and ABCG1

FC efflux from ABCG1-expressing BHK cells to neo HDL and HDL were not significantly different (Fig. 4). In contrast, FC efflux from ABCA1-expressing BHK cells to neo HDL was higher than that to HDL (Fig. 4).

Remodeling of HDL and Neo HDL

HDL-[^{3}H]cholesterol and neo HDL-[^{3}H]cholesterol were incubated with HDL-deficient plasma in amounts that restored the original plasma protein compositions. The LCAT reactivity of neo HDL was higher (+68%) than that of HDL (Fig. 5, left bars). Comparison of the LCAT reactivity of neo HDL and HDL (Fig. 5, right bars), showed CE production from neo HDL was higher than that from HDL (+165%). These samples were also analyzed by SEC, which showed that association of radiolabel with lipoproteins decreased as LDL > HDL > VLDL (Fig. 6a). When the HDL was replaced by rSOF-treated HDL the distribution decreased as LDL > CERM > neo HDL. The experiment with HDL and neo HDL without the apo B-containing lipoproteins showed that most remodeled neo HDL-[^{3}H]cholesterol was associated with CERM while most HDL-[^{3}H]cholesterol remained in the HDL peak (Fig. 6b). The enhancement of cholesterol esterification increased with rSOF dose (Supplementary Fig. 7).

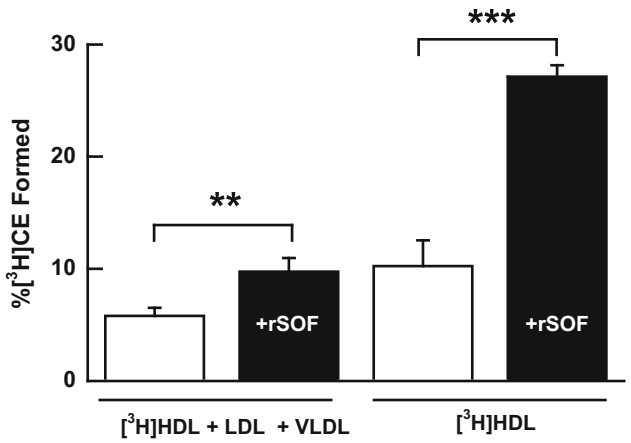

Fig. 5 Effect of rSOF reaction on cholesterol esterification via LCAT. Isolated HDL was labeled with [^{3}H]FC as described in "Materials" and recombined with (LDL + VLDL) and LPDS using amounts that returned all components to their original plasma concentrations. The incubations were for 30 min at 37 °C. The esterification rates are means ± SD of two experiments in triplicate. Statistical analysis by *t* test of HDL versus neo HDL under the same conditions, $^{**}p < 0.01$, $^{***}p < 0.001$

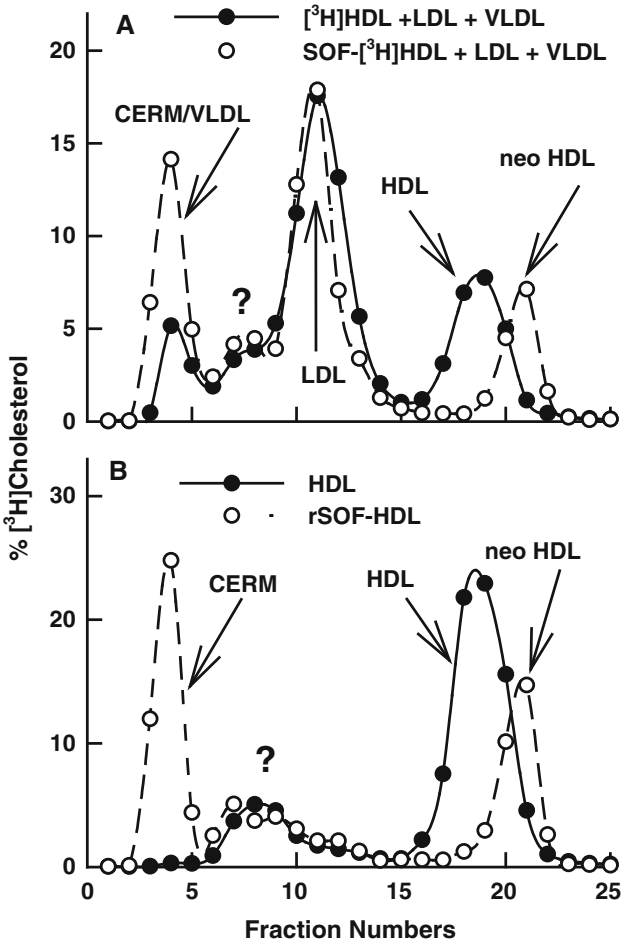

Fig. 6 Distribution of [^{3}H]cholesterol among lipoprotein subclasses after incubation with LPDS for 30 min. Labeling is as in "Materials". **a** Reconstituted whole plasma. SOF treatment of plasma TLP increased non HDL-associated cholesterol from 69 to 86%. **b** HDL or rSOF-HDL plus LPDS. Subtracting the radiolabel in HDL or neo HDL showed that SOF treatment increased the non HDL-associated cholesterol from 22 to 65%. A similar pattern was observed when the incubation with LPDS was reduced to 15 min. Some [^{3}H]cholesterol associated with a peak labeled "?" that was not identified but was likely a component of LPDS because it appears both **a** and **b**

The major fractions from Fig. 6 were used to determine the fraction of cholesterol as ester. HDL-[^{3}H]cholesterol and rSOF-treated HDL-[^{3}H]cholesterol, which contains CERM, neo HDL and lipid-free apo A-I [11], were incubated with HDL-deficient plasma and the distribution of [^{3}H]cholesterol into CE determined (Supplementary Fig. 8a). With rSOF treatment the formation of [^{3}H]CE increases and shifts to the non HDL fractions. The fractions of [^{3}H]CE in the neo HDL and the CERM/VLDL fraction were highest. A similar experiment in which LPDS was incubated with HDL-[^{3}H]cholesterol at their original plasma concentrations showed that at 30 min ~40% of the total cholesterol in HDL was CE (Supplementary Fig. 8b). When HDL-[^{3}H]cholesterol was replaced by rSOF-treated HDL-[^{3}H]cholesterol only 20% of the total cholesterol in neo HDL was esterified. However, more than 60% of the total cholesterol in the coexisting CERM fraction was esterified. Thus, most of the [^{3}H]cholesterol in the CERM peak in Fig. 6a was CE.

Comparative Attenuation of OxLDL-Induced Cytokine Secretion by Mouse Peritoneal Macrophages by HDL and Neo HDL

The effects of HDL and neo HDL on the secretion of the cytokines, IL-6 and TNF-α, by mouse peritoneal macrophages exposed to OxLDL were compared. Both lipoproteins elicited a dose-dependent reduction in IL-6 and TNF-α secretion that was greater for neo HDL (Supplementary Fig. 9). The effects at a single concentration were compared in detail (Fig. 7). These data showed that neither HDL nor neo HDL alone affected cytokine secretion elicited by LDL. In contrast, TNF-α and IL-6 secretion elicited by incubation of macrophages with OxLDL was reduced by coincubation with either HDL or neo HDL, with the effect of the latter being 96 and 103% greater ($p < 0.05$ for both).

Discussion

To simulate a physiological setting, we compared efflux to plasma with and without preincubation with rSOF and found that the parameters for efflux were improved by rSOF treatment and that efflux increased with longer

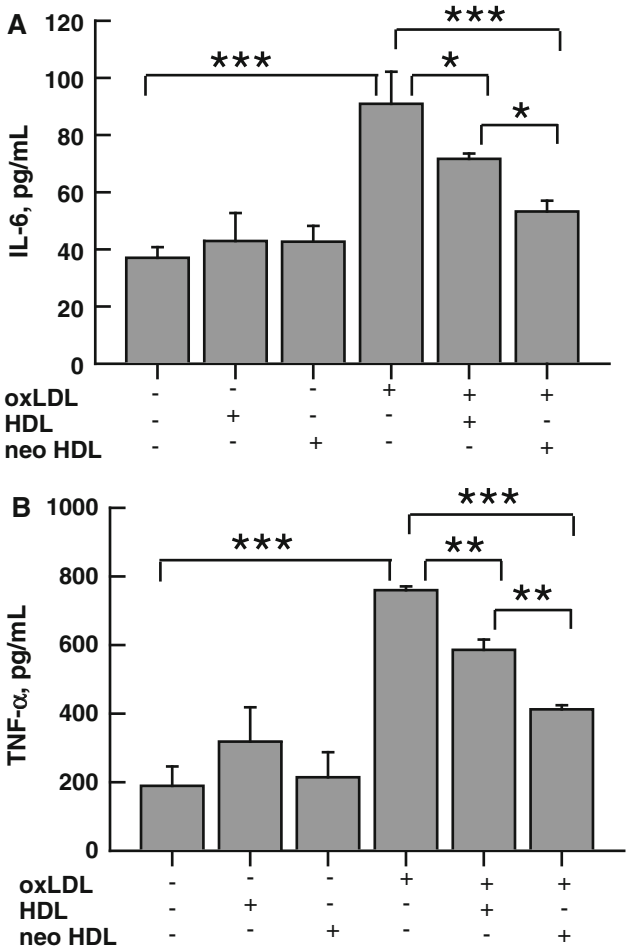

Fig. 7 Comparative attenuation of OxLDL-induced secretion of cytokines by HDL and neo HDL. HDL and neo HDL attenuated OxLDL-induced IL-6 and TNF-α production in a dose-dependent manner (Supplemental Fig. 9). For the data shown here, OxLDL (100 μg/mL) was preincubated with 100 μg/mL of HDL or neo HDL for 1 h at 37 °C. Cells were then incubated with OxLDL, HDL, neo HDL, HDL + OxLDL and neo HDL + OxLDL for 16 h. IL-6 and TNF-α secretion were measured by ELISA. One-way ANOVA analysis with Tukey's post-test indicated the means were significant as indicated ***$p < 0.001$, **$p < 0.01$, *$p < 0.05$

incubation times. Kinetic parameters for efflux to TLP, which lacks the lipid transfer proteins and LCAT of plasma, were similarly improved. In both plasma and TLP, the initial acceptor with and without rSOF-treatment, respectively, appears to be neo HDL and HDL because the fraction of [^{3}H]cholesterol in these particles was higher at 15 min than at 2 h (Fig. 3 and Supplemental Fig. 4). At both 15 min and 2 h, the distribution of [^{3}H]cholesterol was different for plasma and TLP. With plasma as the acceptor, more of the radiolabel was in the VLDL/CERM fraction, while with the TLP acceptor, more radiolabel was in LDL, an effect that was more profound at 2 h than at 15 min. This difference was likely due to the presence of CETP and LCAT activities in plasma but not in TLP. In the absence of LCAT activity, [^{3}H]cholesterol remained unesterified and was spontaneously transferred from HDL or neo HDL to other lipoproteins. In contrast, in plasma [^{3}H]cholesterol was converted to its ester, which requires CETP for transfer to other lipoproteins, a process that was much slower than that of spontaneous [^{3}H]cholesterol transfer from HDL [20–23].

[^{3}H]Cholesterol efflux to rSOF-treated HDL and isolated neo HDL was greater than that to HDL. This finding further supports the hypothesis that the increased efflux to plasma and TLP post-rSOF treatment is due to a more rapid initial transfer to neo HDL than to HDL (Supplementary Fig. 5a, c). Notably, a large fraction of the [^{3}H]cholesterol efflux to rSOF-treated HDL appeared in the CERM fraction (Supplementary Fig. 5b). As with TLP, the fraction of [^{3}H]cholesterol in the CERM was greater at 2 h than at 15 min. This further supported our hypothesis that [^{3}H]cholesterol transfer to non-neo HDL fractions in TLP was spontaneous free cholesterol transfer and that cholesterol desorbs more rapidly from neo HDL than from HDL. This was consistent with data showing that spontaneous lipid transfer rates increase with decreasing particle size according to the Kelvin equation [21].

Differences in the size, charge, apo composition and PL content of neo HDL and HDL might be mechanistically linked to differences in cholesterol efflux. Size probably does not play an important role in the rate differences. When normalized to PL content, there was no difference in efflux to rHDL of varying size and when normalized to particle number at constant PL concentration, cellular FC efflux to larger particles was more efficient [22], the opposite of our observations. Although HDL can have either α or pre β mobility and the latter was a preferred plasma acceptor of cholesterol, there was little evidence that charge was an important efflux discriminator. In contrast, the higher PL and apo A-II content of neo HDL compared to HDL [10, 11] could underlie the differences. Other studies support this; normalized to PL content ABCG1-mediated FC to rHDL efflux is more highly correlated with apo A-II ($r^2 = 0.7$) than with apoA-I ($r^2 = 0.5$); the underlying mechanism for this has not been identified. On the other hand, both spontaneous and ABCG1-mediated efflux increases with HDL-PL [24, 25]. This is supported by numerous studies with both rHDL and modified plasma HDL [13–16]. Indeed, the similar increases in efflux to neo HDL and to rSOF-treated plasma versus HDL and untreated plasma, respectively, are compelling evidence that neo HDL and not lipid-free apo A-I, which is also formed by rSOF [10], is the mechanistic link to increased efflux in plasma.

The studies of efflux from cells expressing ABCA1 and ABCG1 provide clues to the source of the increased efflux to neo HDL (Fig. 4). The higher efflux to neo HDL versus

HDL again showed that neo HDL was a superior acceptor. More importantly, the higher efflux from the ABCA1-expressing cells suggests that this transporter mediates the efflux to neo HDL. A role for lipid-free apo A-I cannot be excluded in the efflux from plasma and TLP. However, the similar increases in Cat_{eff} for efflux to plasma, TLP and isolated neo HDL, which contains no lipid-free apo A-I, suggests that neo HDL and not lipid-free apo A-I was the major acceptor. Although it has been suggested that ABCG1 is an important mediator of efflux to lipidated species [26], other studies have not supported this and have shown that pre β_1-HDL is an efficient FC acceptor via ABCA1 [27]. Given the similarity between neo HDL and pre β_1-HDL particles with respect to size, smaller than HDL, efficient efflux via ABCA1 was not unexpected. This finding was interesting in the context of the report that cholesterol efflux to plasma correlates better with the concentration of pre β_1-HDL than with that of HDL [28].

LCAT Reactivity of HDL and Neo HDL

CE formation via LCAT was higher (+68%) in plasma treated with rSOF than in untreated control plasma. LCAT catalyzed CE formation in neo HDL, the product of rSOF, was even higher (+165%) than that of HDL. The smaller increase in whole plasma may be due to some binding of LCAT to other lipoproteins such as LDL which is a poorer substrate [29]. Similarly, the higher rate of CE formation from neo HDL than from HDL suggests that higher neo HDL-reactivity underlies the differences observed in plasma. The higher rate of esterification in both rSOF-treated plasma versus control plasma and isolated HDL versus neo HDL, may be due to the higher PL content of neo HDL versus HDL [10, 11] and the transfer of CE to CERM which could produce some modest relief of product inhibition. The more likely explanation is that neo HDL has a lower FC/PL ratio than HDL and that high cholesterol concentrations are inhibitory; the optimal FC/PL ratio for LCAT activity is 12.5 mol%, above which activity declines [30]. This optimum is considerably lower than the FC/PL ratio of native HDL, ~25 mol% [31].

According to SEC of the respective products of the LCAT reaction against HDL and rSOF-treated HDL in whole plasma, most of the radiolabel occurs with LDL + VLDL and LDL + VLDL/CERM. However, the radiolabel in the VLDL/CERM fractions was higher than that of the VLDL (Fig. 6a). A similar experiment in which the reaction mixture does not contain VLDL or LDL also showed increased radiolabel in the CERM (Fig. 6b) suggesting that the increased radiolabel seen in the void volume of Fig. 6a was bound to CERM as CE and not to VLDL (Fig. 6). Whether the appearance of additional cholesterol in apo B lipoproteins is beneficial cannot be stated with certainty. One view is that any increase in cholesterol in VLDL and LDL is atherogenic. However, others opine that transfer to the apo B lipoproteins helps clear more cholesterol via the non-HDL receptors. New work in our laboratory shows that the CE transferred from HDL to CERM by rSOF is rapidly taken up by hepatocytes in vitro [32] and in vivo in mice, cleared from plasma into the liver (Rosales et al., unpublished work).

Enhanced Reduction of Cytokine Secretion by Neo HDL Versus HDL

Hypercholesterolemia is associated with increased numbers of arterial macrophage foam cells, a hallmark of an inflammatory state. HDL has anti inflammatory properties that oppose the inflammatory properties of OxLDL, an effect that may be due to enhanced cholesterol efflux to HDL [33, 34]. Our data, which compare the effects of HDL and neo HDL on the OxLDL-induced secretion of TNF-α and IL-6, show neo HDL producing nearly twice the suppression of these two markers of inflammation. Thus, the rSOF reaction has the potential to reduce inflammation via the formation of neo HDL.

rSOF: A Path to Improved RCT

Thus, rSOF activity against plasma might improve key steps in RCT, which comprises macrophage cholesterol efflux that forms nascent HDL and esterification of nascent HDL-cholesterol by LCAT. First, rSOF treatment increased cholesterol efflux under all conditions, plasma, TLP, and isolated HDL. Cholesterol accumulation in macrophage foam cells induces an inflammatory response, apoptosis, and other adverse effects associated with atherogenesis [35]. Cholesterol efflux from macrophages to HDL and apoA-I is one mechanism of atheroprotection [36, 37].

Second, neo HDL was a better LCAT substrate than HDL even in whole plasma. Although recent studies have shown that LCAT may be less important in RCT than once thought [38], in the context of rSOF the LCAT reaction may be important to the final RCT step, hepatic CE uptake, because a major fraction of HDL-cholesterol was transferred to the CERM mostly as its ester. Future studies in vivo will determine the feasibility of an SOF-based therapy, and provide a rationale for finding small molecules or peptides that catalyze the SOF reaction.

Acknowledgments Dr. Urbain Tchoua dedicates this publication to his father, Jean-Pierre Tchoua, who passed away during its preparation. We thank Dr. Joshua S. Wooten for help with statistical analyses. Supported by grants-in-aid from the National Institutes of Health (HJP, HL-30914 and HL-56865), the Merck-UNCF Science Inititative (UT) and the Department of Veterans Affairs (HSC).

Abbreviations

CVD	Cardiovascular disease
Milk	Milk protein
Soy−	Isoflavone-poor soy
Soy+	Isoflavone-rich soy
TC	Total cholesterol
TAG	Triacylglycerol
Apo B-100	Apolipoprotein B-100
Apo A-I	Apolipoprotein A-I
FDA	Food and Drug Administration
VLDL	Very-low density lipoprotein
AUC	Area under the curve
BMI	Body mass index
HDL-C	High density lipoprotein cholesterol constituent
NEFA	Non-esterified fatty acids
ANOVA	Analysis of variance
LDL-C	Low density lipoprotein cholesterol constituent
RLP-C	Remnant-like particle-cholesterol
TRL	Triacylglycerol rich lipoprotein
LDL	Low density lipoprotein
HDL	High density lipoprotein
LCAT	Lecithin:cholesterol acyltransferase

Introduction

The efficacy of soy product consumption in reducing the risk factors for cardiovascular disease (CVD) owing to constituents beyond vegetarian diet benefits, such as fiber content and the degree of saturation of fat, has recently been questioned [44]. The US Food and Drug Administration (FDA) used a meta-analysis by Anderson et al. [4] as the basis for the food labeling health claim that: "Diets low in saturated fat and cholesterol that include 25 g of soy protein a day may reduce the risk of heart disease". According to the US FDA's health claim report card, this claim receives a letter grade of "A" on account of "significant scientific agreement". While a plethora of randomized control trials demonstrate a salubrious effect of soy protein [3, 32, 57, 62], other studies controvert these benefits [20, 30, 31]. Of particular interest and for comparison are the limited findings in recent meta-analyses regarding the efficacy of soy protein and isoflavone constituents in altering the traditional blood lipid profile (i.e., total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, and triacylglycerol) [42, 53, 61]. Furthermore, it is not clear whether these modest findings are due to the isoflavone constituents as once postulated, or to other innate components of *Glycine max* (Linnaeus) Merrill such as phytate, saponins, and storage proteins (i.e., conglycinin and glycinin; 7s and 11s globulins, respectively) [13, 18, 21, 28, 55]. Other complications in the soy controversy include differences in the method employed to extract soy protein and processing techniques on the bioavailability of soy constituents (e.g., isoflavones, fiber, saponins, and fat), study design (e.g., parallel vs. crossover), population studied (e.g., normo- vs. hyper-cholesterolemic; ethnicity), geographic area of cultivation, cultivar used, and length of intervention [6, 11, 15, 29, 41, 50, 53]. Moreover, the inter-individual contradistinction of gastrointestinal microflora conversion of daidzein to a more potent isoform, equol, affects the bioavailability and potency (e.g., responders vs. non-responders) of ingested isoflavones [29, 46, 50]. However, this intimation has recently been challenged [7, 16, 54].

Conventional laboratory analysis of blood lipids requires the patient to fast for 8–12 h prior to drawing blood, however, most individuals spend their time ostensibly in a postprandial state, which may partially explain the disparities regarding the salubrious effect of soy [1]. Zilversmit [63] first postulated that the etiology of atherogenesis may be more wholly explained by analyzing triacylglycerol-rich lipoproteins (i.e., chylomicrons + VLDL) and subsequent metabolic remnants. Three decades later, research has progressively expounded upon this intimation by demonstrating that the postprandial state may be an over-looked, independent risk factor for future cardiac events [5, 8, 22, 26, 35, 36, 52]. Intriguingly, several studies have found that triacylglycerol-rich lipoproteins and apolipoprotein B-48 (a constituent protein marker identifying fats that are intestinally derived) are elevated in patients with normal fasting concentrations of TAG but who present with CVD compared with matched healthy subjects after ingesting a high-fat meal (i.e., lipid challenge) [17, 23, 39, 47]. Thus, studies involving soy consumption and its effect on the traditional lipid profile may be missing a more favorable, metabolic processing of exogenous lipids. The first study to evaluate the effect of a soy protein isolate on postprandial remnant-like particles showed no change in fasting lipid concentrations but a significant and more favorable decrease in postprandial, remnant-like cholesterol concentration and area under the curve (AUC) compared with an atherogenic control (i.e., casein); after 3 weeks of supplementation in 11 Japanese males [48]. It is plausible then, that the salubrious effect of soy may be more detectable during the postprandial state rather than following an overnight fast and may be more representative of an individual's normal metabolic state. Therefore, postprandial concentrations of lipoprotein

constituents may be more sensitive and more indicative factors of CVD risk.

The primary purpose of this study was to determine if measuring postprandial concentrations of lipoprotein constituents were more sensitive than the traditional lipid profile for detecting any salubrious effects of consuming soy protein with and without isoflavones. A secondary purpose was to evaluate apolipoprotein B-100 and A-I concentrations as potential mechanisms responsible for any beneficial effects. Since soy studies have mostly been myopic with respect to gender, we sought to describe the effects of Soy− and Soy+ in normolipidemic, sedentary males.

Materials and Methods

Participants

This study was approved by the University at Buffalo's Human Subject's Review Committee. Thirty-five men, with mean ± SD values of 24.2 ± 2.3 years, 175.7 ± 6.6 cm, 73.9 ± 14.6 kg, and 23.8 ± 3.7 kg/m^2 for age, height, weight, and body mass index (BMI), respectively, were recruited to participate voluntarily in a study investigating the effects of soy on CVD risk factors from the Western New York community. Informed consent was obtained prior to participation in the screening process. Participants were included in the study if they met the following criteria: not taking cholesterol reducing medications, BMI between 18 and 26 kg/m^2, non-habitual soy consumers, non-extremist dietary practitioners (i.e., high protein and/or fat intakes), and non-smokers. Participants were also screened for fasting lipid (TC, HDL-C, and TAG) and glucose concentrations using the Cholestech L·D·X® (Cholestech Corporation, Hayward, CA) and Accu-Chek Advantage Analyzers (Roche Diagnostics Corporation, Indianapolis, IN), respectively. A physician recorded the participant's medical history and performed a physical examination to exclude those participants with a known history of cardiovascular, pulmonary, and metabolic diseases.

Anthropometric Measurements

Data for age, height, weight, BMI, body composition, circumferences, and blood pressure were recorded and previously published [45].

Dietary Procedures and Analyses

A double-blind, parallel-arm design was used to compare the effects of a milk protein isolate (Milk, as the control group; atherogenic equivalent) an isoflavone-poor soy protein isolate (Soy−), and an isoflavone-rich soy protein isolate (Soy+) on postprandial lipid and glucose concentrations. Each participant was randomly assigned by a trained research assistant to one of the three protein supplement groups: Milk, Soy− or Soy+. The supplements were donated by The Solae Company (St. Louis, MO, USA) and consisted of 25 g of powdered protein isolate packaged in a vacuum sealed envelope; constituents have previously been reported [45]. The protein powder was mixed with a beverage of the participant's choice (including milk) and taken daily for 28 days. All unused and/or empty packets were returned in the large envelopes to the lab as an indicator of compliance.

A registered dietitian collected 3-day diet records and analyzed them using Nutritionist Pro Software (First Databank, San Bruno, CA, USA); data have been previously published [45].

Test Meal

Participants visited the laboratory, at baseline and approximately 28 days later, and were given a 998.6 kcal (239.5 kJ) liquid meal consisting of approximately 40.0% carbohydrate, 40.2% fat, and 19.8% protein. Ingredients were mixed together in a blender on "liquefy" for 2 min and included 350.6 g of skim milk, 141.034 g of Hershey's Lite Chocolate Syrup© (The Hershey Company, Hershey, PA, USA), 82.775 g of Wegmans' Natural Creamy Peanut Butter© (Wegmans Food Markets, Rochester, NY, USA), and 11.84 g of Optimum Nutrition's chocolate-flavored Whey protein© (Optimum Nutrition, Inc., Aurora, IL, USA). Subjects were given approximately 15 min to consume the liquid meal.

Fasting and Postprandial Blood Draws

Fasting and postprandial blood samples were taken at baseline and approximately 28 days later. Participants visited the laboratory after a 12-h fast and a registered nurse placed an IV-catheter in an antecubital vein. A 7-mm microbore extension was connected to the catheter and secured with sterile Tegaderm™ (3M Health Care, St. Paul, MN). These collectively remained in place for the duration of the laboratory visit (i.e., ~6.5 h). For blood draws, an 18-gauge needle was attached to a 10-mL syringe and approximately 3 mL of blood was placed into a 5-mL serum vacutainer tube; allowed to clot at room temperature. 3 mL of 0.9% saline solution was used between blood draw samples as a flush to prevent coagulation in the microbore extension/catheter setup. 5 mL of blood/saline was drawn and discarded before each blood draw to minimize contamination of the sample from the flush. Serum samples were centrifuged within 30 min of collection at

3,000 r/min (1,875*g*) for 30 min at 4°C (Sorvall RT60000B Refrigerated Centrifuge, Newton, CT). Serum samples were stored at −80 °C until analysis. After participants ingested the test meal, postprandial blood samples were taken at 30, 60, 120, 240, and 360 min using the blood draw procedures aforementioned. Participants were instructed not to consume any food or participate in any moderate to vigorous physical activity during the 6 h of postprandial blood draws. Water was provided ad libitum.

Blood Sample Analysis (Lipids and Glucose)

Blood was analyzed for triacylglycerol (TAG), total cholesterol (TC), non-esterified fatty acids (NEFA), apolipoproteins B-100 and A-I (Apo B-100 and Apo A-I, respectively), and glucose using commercially available kits from Wako Chemicals USA, Inc. (Richmond, VA). In addition, all procedures were followed as directed in the application parameters obtained from Wako for the Cobas Fara centrifugal analyzer for Automated Chemistry Analysis (Model # 22-2081, Roche Diagnostic Systems, Nutley, NJ). All assays for each participant were run in duplicate on the same day with the same reagent batch. External calibrators were included on all assays on every run, and the range of concentrations in the calibration curves encompassed the range of expected sample values. Two controls were used, Accutrol and Cardiolipid, that were run ten times throughout the duration of each test to ensure intra-assay reproducibility.

Triacylglycerol

TAG was measured by the enzymatic colorimetric endpoint method (Kit #s 999-37491 and 995-37591). Serum plasma samples were first combined with the Enzyme color A reagent (50 mmol/L Good's buffer, pH 7.0 containing 0.45 mmol/L *N*-(2-hydroxy-3-sulfopropyl)-3,5-dimethoxyaniline, 30 IU/mL glycerol kinase from *Cellulomonas* sp., 4.0 mmol/L adenosine-5′-triphosphate, 3.8 IU/mL glycerol-3-phosphate oxidase from *Streptococcus* sp., 200 IU/mL catalase from bovine liver and 2.4 IU/mL ascorbate oxidase from *Acremonium* sp.) to decompose free glycerol so as not to interfere with the assay. Enzyme color B reagent (50 mmol/L Good's buffer, pH 7.1 containing 150 IU/mL lipoprotein lipase (LPL) from *Pseudomonas* sp., 13.5 IU/mL peroxidase from horseradish, 3.4 mmol/L 4-aminoantipyrine and 0.1% sodium azide) was then added to hydrolyze TAG into glycerol and free fatty acids by LPL. The liberated glycerol was phosphorylated by adenosine-5′-triphosphate and underwent oxidation by glycerol-3-phosphate oxidase which resulted in the release of hydrogen peroxide. *N*-(2-hydroxy-3-sulfopropyl)-3,5-dimethoxyaniline and 4-aminoantipyrine underwent quantitative oxidative condensation catalyzed by peroxidase due to the presence of hydrogen peroxide. The resultant blue pigment from these reactions was measured for absorbance and was directly correlated with TAG concentrations.

Total Cholesterol

TC concentrations were measured by using the enzymatic colorimetric method (Kit # 276-64909). Serum samples were combined with a working color reagent (0.15/150 M Tris buffer solution, 0.13 U/mL cholesterol oxidase, 0.13 U/mL cholesterol ester hydrolase, 2.4 U/mL peroxidase, and 0.015% 4-aminoantipyrine) and allowed to incubate for 5 min at 37°C. The cholesterol esters in the serum were hydrolyzed to free cholesterol and fatty acids in a reaction catalyzed by cholesterol ester hydrolase. The cholesterol produced and the free cholesterol already present in the serum were oxidized in a reaction catalyzed by cholesterol oxidase that generated hydrogen peroxide. The hydrogen peroxide formed participated in quantitative oxidative condensation between *p*-chlorophenol and 4-aminoantipyrine in the presence of peroxidase. The product of the reaction was a red quinone pigment. The total amount of cholesterol in the test sample was determined by measurement of the absorbance of the red color at its maximal absorption wavelength of 505 nm.

Non-esterified Fatty Acids

NEFA was measured using the enzymatic colorimetric method (Kit # 994-75409E). Serum samples were first combined with color reagent A (acyl-coenzyme A synthetase, ascorbate oxidase, coenzyme A (CoA), adenosine triphosphate, 4-aminoantipyrine, 0.05 mol/L phosphate buffer, 3 mmol/L magnesium chloride, surfactant, and stabilizers) and incubated for 10 min at 37 °C. NEFA in serum, when treated with acyl-CoA synthetase in the presence of adenosine triphosphate, magnesium cations and CoA, formed the thiol esters of CoA known as acyl-CoA as well as the byproducts adenosine monophosphate and pyrophosphate. The samples/solutions were then mixed with color reagent B [acyl-coenzyme A oxidase, peroxidase and 1.2 mmol/L 3-methyl-*N*-ethyl-*N*-(*β*-hydroxy- ethyl)-aniline] and incubated for 10 min at 37 °C. In the second portion of the procedure, the acyl-CoA was oxidized by added acyl-CoA oxidase to produce hydrogen peroxide which in the presence of added peroxidase allowed the oxidative condensation of 3-methyl-*N*-ethyl-*N*-(*β*-hydroxy-ethyl)-aniline with 4-aminoantipyrine to form a purple colored adduct with an absorption maximum at 550 nm. Hence, the amount of NEFA in the sample was determined from the optical density measured at 550 nm.

Ascorbic acid existing in the sample would be expected to cause significant interference due to its biological role as an antioxidant and known ability to react with hydrogen peroxide. Therefore, ascorbate oxidase was added to the reaction mixture at the outset to remove all ascorbic acid from the sample.

Apolipoprotein B-100

Apolipoprotein B-100 was measured by a turbidimetric immunoassay procedure (Kit # 993-27401). Serum samples were mixed with a buffer (100 mmol/L phosphate buffer and 0.1% sodium azide) and an anti-human antibody (11.5 mg Ag/mL anti-human apolipoprotein B isolated from goat and 0.1% sodium azide) specific for apo B-100. The binding of apo B-100 to the anti-human antibody yielded an insoluble aggregate that caused increased turbidity. The degree of turbidity was measured optically and was proportional to the amount of apo B-100 in the sample.

Apolipoprotein A-I

Apolipoprotein A-I was measured by a turbidimetric immunoassay procedure (Kit # 991-27201). Serum samples were combined with a buffer (100 mmol/L phosphate buffer and 0.1% sodium azide) and an anti-human apo A-I antibody (1.15 mg Ag/mL prepared from goat and 0.1% sodium azide) that yielded an insoluble aggregate that caused increased turbidity. The extent of the turbidity was then measured optically and was proportional to the amount of apo A-I in the sample.

Glucose

Glucose was measured by using an enzymatic colorimetric method (Kit # 994-90902). Serum samples were combined with the working reagent (60 mmol/L phosphate buffer, 5.3 mmol/L phenol, 0.13 U/mL mutarotase, 9.0 U/mL glucose oxidase, 0.65 U/mL peroxidase, 0.50 mmol/L 4-aminoantipyrine, and 2.7 U/L ascorbate oxidase) and incubated for 5 min at 37 °C. The equilibrium of D-glucose in solution was maintained in the ratio of α-D-glucose 36.5% and β-D-glucose 63.5%. Glucose oxidase reacted only with β-D-glucose. The existing α-D-glucose in the sample was converted rapidly to the β-isomer by the action of mutarotase and was then oxidized by glucose oxidase to produce hydrogen peroxide. In the absence of mutarotase, the reaction proceeded slowly because β-D-glucose was first consumed by glucose oxidase as α-D-glucose was gradually converted to β-D-glucose. When mutarotase was added, α-D-glucose was rapidly converted to β-D-glucose, so that glucose oxidase action was facilitated. The hydrogen peroxide produced induced oxidative condensation between phenol and 4-aminoantipyrine in the presence of peroxidase, so that a red color was produced. The amount of glucose contained in the test sample was determined by measuring the absorbance of the red color.

Area Under the Curve

AUC was calculated in increments to determine temporal differences. The summation of intervals (i.e., 0 + 30 min; 30 + 60 min; 60 + 120 min; 120 + 240 min; 240 + 360 min) was divided by two followed by the subtraction of fasting values to normalize the data. To normalize the data for hours, incremental AUC values were multiplied by 0.5, 1.0, and 2.0 for the 0 + 30 min and 30 + 60 min intervals, the 60 + 120 min interval, and the 120 + 240 min and 240 + 360 min intervals, respectively. The total AUC was calculated as the summation of normalized intervals.

Statistics

A general linear model, two-way repeated measures analysis of variance (ANOVA) was used to determine significant differences in variables listed in Table 1 and Figs. 1, 2, and 3 after protein supplementation. The Bonferroni (all pair-wise) multiple comparison test was used to determine the main effects of diet collapsed across time (Milk pre plus Milk post vs. Soy− pre plus Soy− post vs. Soy+ pre plus Soy+ post) and time collapsed across diet (Milk pre plus Soy− pre plus Soy+ pre vs. Milk post plus Soy− post plus Soy+ post) and to determine any diet by time interactions (pre vs. post within groups). A p value <0.05 was considered statistically significant. The data were analyzed with Number Cruncher Statistical Systems software (NCSS 2000, Kaysville, UT). Protein group identification was not revealed to the principle investigator until after they performed all biochemical and statistical analyses.

Results

Participants

Owing to poor study compliance and subsequent data outliers, 5 participants were eliminated leaving 9, 11, and 10 participants for the Milk, Soy−, and Soy+ groups, respectively.

Postprandial Serum Concentrations

Baseline and post-intervention data are presented in Table 1 and Figs. 1, 2, and 3. After 4 weeks of supplementation with 25 g/day of Soy− protein, TAG increased by 90.7 mg/dL at 240 min and TAG total AUC increased

Values with the same letters are not significantly different ($p < 0.05$)

Soy− Isoflavone-poor soy protein isolate, *Soy*+ Isoflavone-rich soy protein isolate

[A] Values with an * are significantly different from pre values; main effect of time ($p < 0.05$)

[B] Data for the 30 and 60 min time points are unavailable

by 271.1 mg/dL ($p = 0.012648$ and $p = 0.007190$, respectively; pre vs. post within group). NEFA decreased by 0.1 mg/dL at 360 min after protein supplementation ($p = 0.025743$; main effect of time collapsed across diet). Soy+ supplementation resulted in higher apo A-I at 240 min compared with the Milk group (189.7 vs. 149.8 mg/dL; $p = 0.044964$; post vs. post between groups).

Discussion

This study examined the effect of 28 days of Milk, Soy−, and Soy+ supplementation on select fasting and postprandial blood lipid and glucose concentrations in normocholesterolemic, sedentary males. Our data support the hypothesis that the postprandial state is more sensitive than the traditional lipid profile for detecting changes associated with soy consumption in this study population, which is in concurrence with previous data [48]. While fasting blood lipid and glucose concentrations did not change significantly, postprandial TAG concentration was surprisingly higher after Soy− consumption. In addition, there was a trend for reduced postprandial TAG concentration after Soy+ consumption. These data suggest that the dearth of isoflavones in Soy− may deleteriously alter postprandial processing of TAG such that over time risk for CVD potentially increases. Together, with a previous report, our data show support for measuring blood lipids in a postprandial state in order to detect changes with soy ingestion [48]. However, these changes are minimal at best in the normocholesterolemic, sedentary male, which provides credence to a recent statement by the American Heart Association; which iterated that the ingestion of soy products provides little additional, salubrious benefit beyond the typical vegetarian diet [44].

Postprandial metabolism has been increasingly recognized as an important, but crudely defined tool in the assessment of CVD risk factors. The well-established traditional lipid profile standardizes CVD risk factors by utilizing a fasting blood sample which controls for diurnal flux in plasma lipids, utilizes the Friedewald formula for LDL-C estimation, and compares patient samples to population norms [8]. While these analytical attributes are desirable, most individuals spend the majority of their day processing exogenous nutrients, which supports the ideology that postprandial metabolism may be more sensitive to their usual metabolic state and therefore might allude to occult CVD risk factors. Recent large, prospective studies and others support the foregoing intimation by demonstrating that postprandial TAG concentration was associated with an increased risk for CVD and a subsequent cardiovascular incident independent of the traditional lipid profile [5, 14, 22, 33, 35]. In contrast to fasting studies evaluating TAG's role in CVD risk factor assessment, postprandial TAG concentration maintained a strong, prognostic relationship with CVD despite adjusting for fasting TC and HDL-C concentrations [5, 10, 25, 33]. In the first study to analyze the postprandial state in conjunction with a soy treatment, Shige et al. [48] reported that remnant-like particle-cholesterol (RLP-C) was significantly reduced compared with a casein treatment after 3 weeks of supplementation in 11 Japanese males. Additionally, AUC for RLP-C decreased by 7.7 mg/dL (0.20 mmol/L) after the soy protein treatment compared to the casein treatment which increased significantly by 5.4 mg/dL (0.14 mmol/L). Since RLP-C has been demonstrated to be an independent predictor of future cardiac events, these data suggest that soy protein may reduce this innate risk [24]. In the present study, we did not observe any significant changes in fasting or postprandial cholesterol concentrations. However, it is important to note that we did not discern between TRLs containing Apo B-48 (intestinally derived) and Apo B-100 (hepatically derived) lipoproteins, which limits the analytical density range of these lipoproteins and thus may ameliorate our sensitivity to the favorable changes observed by Shige [24]. In contrast to Shige, we observed a significant increase of 83% from baseline values in AUC postprandial TAG concentration after Soy− consumption but not in the Milk or Soy+ fed groups; suggesting that the absence of isoflavones in this supplement leads to undesirable changes in TAG and may have clinical implications for CVD. It is noteworthy that the Soy+ group

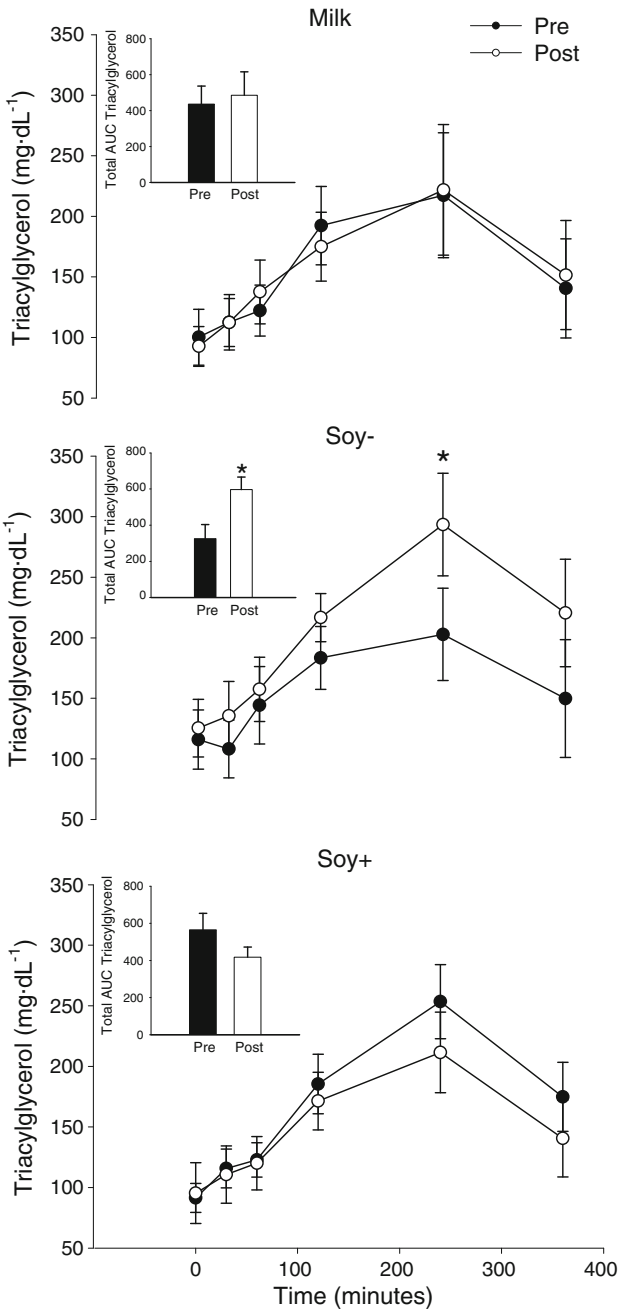

Fig. 1 Triacylglycerol serum concentration after a 12-h fast and ingestion of a high calorie mixed meal before and after 28 days of supplementation with a milk protein isolate (*Milk*), isoflavone-poor soy protein isolate (*Soy*−) or an isoflavone-rich soy protein isolate (*Soy*+) ($n = 9$, $n = 11$, and $n = 10$, respectively). Values are the average of 30 sedentary males ± the standard error of the mean. Significant difference between pre and post values ($^*p < 0.05$)

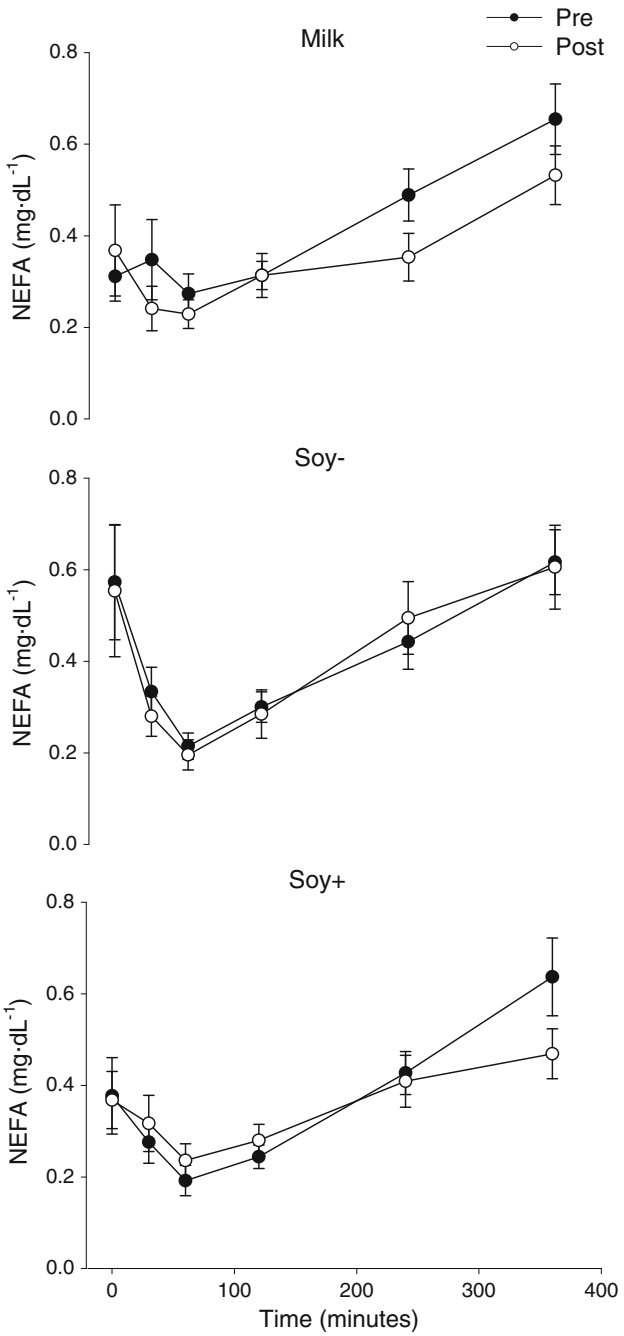

Fig. 2 Non-esterified fatty acid (*NEFA*) serum concentration after a 12-h fast and ingestion of a high calorie mixed meal before and after 28 days of supplementation with a milk protein isolate (*Milk*), isoflavone-poor soy protein isolate (*Soy*−) or an isoflavone-rich soy protein isolate (*Soy*+) ($n = 9$, $n = 11$, and $n = 10$, respectively). Values are the average of 30 sedentary males ± the standard error of the mean

showed a decreasing trend of 26% in AUC postprandial TAG concentration. Although not statistically significant, these data are suggestive of a modulating role for soy isoflavones as previously reported [7]. Furthermore, these differences were significantly greatest 240 min after ingestion of the test meal with a similar trend at 360 min. Cohn et al. [9] reported that TAG concentration peaks approximately 3–4 h post-absorption of a singular meal and returns to fasting concentrations within 6–8 h in disease-free individuals, which was nearly observed in the present study.

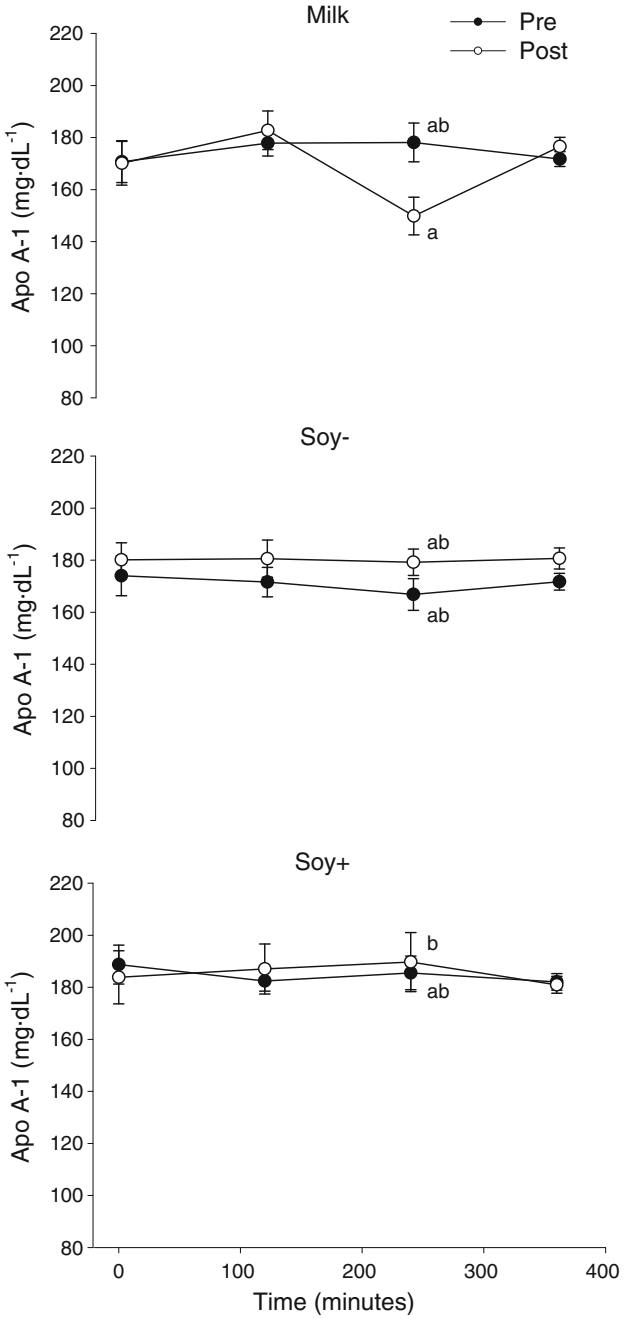

Fig. 3 Apolipoprotein A-I serum concentration after a 12-h fast and ingestion of a high calorie mixed meal before and after 28 days of supplementation with a milk protein isolate (*Milk*), isoflavone-poor soy protein isolate (*Soy*−) or an isoflavone-rich soy protein isolate (*Soy*+) ($n = 9$, $n = 11$, and $n = 10$, respectively). Values are the average of 30 sedentary males ± the standard error of the mean. Values with the same letters are not statistically significant ($p < 0.05$)

It is interesting to note that we observed a significant decrease of 15.5% in NEFA at 360 min after protein consumption regardless of the protein source. Interpretation of this observation is not clear, however, a discussion regarding dietary intake may partially explain this finding. Collection of dietary data in free-living participants is desirable but presents an immutable challenge of study compliance. Previously, we reported dietary analysis data on the current study population and the difficulty in interpretation owing to poor study compliance with recording data; thus, we were forced to analyze our results with ten fewer participants compared with other reported data [45]. Despite this limitation, it is interesting to note that Soy− increased their saturated fat intake by 14.2%, as a percentage of the total identifiable lipid, and 3.0%, if calculated as a percentage of total kilocalories after supplementation. It is putative that a higher than recommended chronic ingestion of saturated fat results not only in higher fasting levels of TAG but also exacerbates the postprandial response in TAG [12, 19, 27, 34, 56, 58]. Therefore, it is plausible that the significant increase observed in postprandial TAG in Soy− may be due to higher exogenous consumption of foods containing a greater proportion of saturated fat. We also reported that saturated fat intake, calculated as a percentage of the total identifiable lipid, increased by 4.0% after protein supplementation regardless of the protein source in the current study population. These data may imply that the release of NEFA from adipose tissue (i.e., lipolysis) was reduced at 360 min owing to greater amounts of available exogenous fats. It is important to reiterate that these interpretations and any subsequent clinical significance are mere hypotheses based on the available literature to date and warrant better control for future investigation.

Apolipoproteins B-48 and B-100 are substantive constituents of chylomicrons and VLDL and LDL particles, respectively. Chylomicrons are intestinally derived lipoproteins that contain one apolipoprotein B-48 per chylomicron particle and serves as the hepatic cell receptor ligand [38]. Similarly, one apolipoprotein B-100 is found per VLDL and LDL particle and functions as a cell receptor ligand [38]. As such, studies have used apolipoprotein B-48 and B-100 as direct measurement of the number of chylomicron, VLDL and LDL particles in circulation [40, 51]. Since the penetration of the endothelium by lipoprotein particles is a gradient-driven process, fewer, potentially atherogenic particles would succumb to oxidation and therefore subsequent vascular damage and succeeding risk for CVD diminished [59]. In the present study we did not observe any clinically remarkable changes in apolipoprotein B-100, which is in agreement with our previously published nuclear magnetic resonance (NMR) data [45].

TAG concentration during the postprandial state is dependent upon the total amount of ingested lipid, hepatic and lipoprotein lipase activity, and LDL receptor expression [38]. As previously discussed, TRLs contain one apolipoprotein ligand per lipoprotein particle which binds

to the LDL receptor and results in the physical removal of the particle from circulation [37, 43]. Hepatic and lipoprotein lipase serve to reduce the size of these particles in circulation by hydrolyzing the TAG into its constituents, glycerol and fatty acids, and subsequently results in the delivery of the fatty acids to tissues such as muscle and adipose [60]. While direct measurement of lipoprotein particle size and number is highly desirable, the size of TRL particles can be inferred via the TAG to apolipoprotein ratio [2]. In the present study, we did not observe a significant difference in the TAG/apolipoprotein B-100 ratio but a decreasing trend was apparent 240 min postprandially. We speculate that hepatic and lipoprotein lipase activities may have been altered owing to Soy− and Soy+ consumption resulting in the respective, observed TAG concentrations. Unfortunately, it is difficult to quantify TAG concentration and lipase activity concomitantly without introducing analytical error and therefore we were unable to do so in the present study. Previously, we reported that hepatic lipase concentration increased by 19.2% after Soy− consumption in a fasted state which resulted in an increase in the number of small, dense HDL particles (TAG-rich from interacting with TRLs) which would theoretically increase CVD risk [45]. It is plausible that hepatic and/or lipoprotein lipase activity may be altered as a result of isoflavone presence in products containing soy protein resulting in changes similar to those observed in the present study. The dearth of information regarding isoflavone effect on lipid remodeling via hepatic and lipoprotein lipase activity warrants further investigation as a potential mechanism.

Apolipoproteins A-I and A-II constitute the major structural protein of HDL particles and play a key role in HDL metabolism. In particular, apolipoprotein A-I serves as the select acceptor of cell cholesterol, as a lecithin:cholesterol acyltransferase (LCAT) cofactor, as a promoter of reverse cholesterol transport, and as a ligand for the HDL receptor [49]. Although we did not see any fasting or postprandial changes in total cholesterol, we did observe that apolipoprotein A-I was significantly higher by 21% in Soy+ post supplementation compared with Milk post supplementation at 240 min after the test meal ingestion. Furthermore, apolipoprotein A-I concentration after Milk supplementation showed a non-significant decreasing trend of 27.7% at 240 min after the test meal ingestion (i.e., pre vs. post within group difference). We speculate that these data may indicate lower HDL particle concentration and subsequent cholesterol constituent, which is in agreement with the atherogenic diet. It is noteworthy that TC showed a non-significant decreasing trend after Milk supplementation, which seemingly supports our data; however, caution is warranted in this interpretation as we did not measure HDL-C or HDL particle size and number in the postprandial state. Future studies are needed to elucidate lipoprotein particle remodeling in the postprandial state as a result of soy consumption utilizing NMR analysis of lipoprotein particle size and number.

In summary, we have demonstrated that the postprandial state is a viable and more sensitive indicator of CVD risk compared with the traditional lipid profile with respect to the potential salubrious effects of consuming soy protein for 28 days in sedentary, normocholesterolemic males. Our data suggest that soy isoflavones may play a role in postprandial TAG processing and that removing these phytochemicals from soy products may obviate any cardioprotective effect and may even have a deleterious consequence if ingested chronically. However, these data and subsequent interpretations are limited and should be viewed as preliminary data owing to the low number subjects within each group. Further research is warranted to clarify the use of the postprandial state as a means of investigating potential cardio-protective effects of soy protein consumption on TAG processing after ingestion of a test meal.

Acknowledgments The authors would like to thank The Solae Company (St. Louis, MO, USA) for donating the protein supplements used in this study. Special gratitude is warranted to our colleagues Amy Miracle and Jack Young for their input in the final review of this manuscript.

fasting serum TAG concentration is very important for patients with HTG, atherosclerosis, cardiovascular disease or T2DM, etc.

1,3-Diacylglycerol (DAG), which has been consumed for many years, is a natural component (2–10%) of some edible fats and oils [6]. A cooking oil product manufactured by Kao Corporation containing about 83% (w/w) DAG has been approved as a "Food for Specified Health Use" by the Ministry of Health, Labour and Welfare of Japan since 1999 [7]. In 2000, the Food and Drug Administration also granted this product a status of generally recognized as safe [8].

DAG supplementation was previously reported to reduce the fasting serum TAG concentration compared with TAG [9, 10]. However, this efficacy was not consistently accepted by all past studies. In a study conducted by Nagao et al., after 16 weeks supplementation, the fasting serum TAG concentration of DAG group decreased from 1.16 to 1.04 mmol/L while that of TAG group decreased from 1.31 to 1.10 mmol/L [11]. So it is still in doubt whether DAG is efficacious for reducing the fasting serum TAG concentration.

Meta-analysis is a statistical technique in which results of separate studies are combined to increase statistical power and clarity, and to estimate the size of treatment effects more accurately. This method has some inherent weaknesses such as the sources of bias are not controlled and the heavy reliance on published studies [12]. Despite these weaknesses, meta-analysis is still employed in many clinical settings to evaluate the efficacy and safety of a variety of therapeutic interventions due to its advantages [13, 14]. We have already examined the effects of DAG on body weight control and the postprandial serum TAG concentration in our previous studies [13, 14]. In this study, we performed a meta-analysis of randomized controlled trials to assess the association between DAG intake and the fasting serum TAG concentration.

Methods

Selection of Studies

Potential papers were initially searched from electronic databases of Medline (1966–2010), Embase (1984–2010) and Cochrane library using the standardized subject terms and search strategy in Table 1. The references of all located papers were searched for further studies.

Inclusion Criteria

A trial was included if it was randomized controlled designed in humans, used DAG supplementation as the only intervention and used the fasting serum TAG concentration as one of the endpoints. No restrictions were imposed on the daily dose of test oil and the physiological conditions of subjects.

Table 1 Search strategy and search terms used to identify studies on diacylglycerol supplementation and fasting serum triacylglycerol concentration

(10)	Hyperlipidemia
(11)	(7) or (8) or (9) or (10)
(12)	(6) and (11)

Validity Assessment

The methodological quality of included papers was evaluated using the scoring system developed by Jadad (Table 2) [15].

Information Extraction

The detailed information was extracted independently by two reviewers in a standardized manner according to the predefined protocol. Any discrepancies were resolved by discussing them with an additional reviewer. The extracted characteristics included the study design (i.e., parallel or crossover, open, single- or double-blinded), number of subjects, daily dose of test oil, duration of supplementation, fasting serum TAG concentrations at baseline and final, the net change of concentration in along with corresponding standard deviations (SD). For studies that reported multiple time points for the same subjects, only the last points of the supplementation were extracted for analysis.

In the study conducted by Yasunaga et al., the safety aspects of high-dose dietary DAG were separately tested in males and females, so the data of the males and that of the females were extracted and included as two independent studies. The influence of these two studies on the overall results was tested by sensitivity analysis [16]. Similar extraction methods were also used in meta-analysis conducted by He et al. [17] in which two separate studies from study conducted by Joshipura et al. were extracted and included as independent trial [18]. In the study conducted by Yanagisawa et al., TAG concentration was reported as

Table 2 Quality of included studies

Li 2008 [28]	1	1	1	1	4

mg/dL which was transformed to mmol/L according to the formula mg/dL $\times$ 0.01129 = mmol/L [19]. In the study conducted by Yanagisawa et al., TAG concentrations were reported in the form of figures, so the specific data were obtained by measuring the corresponding figures and sensitivity analysis was performed to test the influence of this study on the overall results [19]. In the study conducted by Nagao et al., the concentrations were reported as means $\pm$ standard errors (SE) which were transformed to means $\pm$ SDs. In some studies, the SDs of mean change in fasting serum TAG concentration were not reported. The authors were contacted for detailed data but no reply was received. Therefore, the missing SDs were imputed using methods provided by the Cochrane Handbook [20].

Statistical Analysis

The validity of random design was tested by meta-analysis in advance. The net change of fasting serum TAG concentration was used as the endpoint to assess the effect of DAG supplementation. The influence of each study on the result of meta-analysis was weighted by the inverse of variance, and studies with narrower confidence intervals (CI) were given more weight. A random effect model was adopted to calculate the weighted mean difference (WMD) and 95% CI because of the heterogeneity in daily dose, duration of supplementation and initial characteristics of subjects among all studies. Meta-analysis was conducted using the software of Review Manager 4.2 (Update Software Ltd, Oxford, England). Sensitivity analysis was conducted to determine whether conclusions were robust to decisions made during the review process [20]. In this study, sensitivity analysis was performed to test the robustness of the overall result during the inclusion/exclusion of paper in which TAG concentrations were reported in the form of figure and paper in which two independent studies were extracted. A funnel plot was used to test the possibility of publication bias and fail-safe number analysis was used to determine the number of studies with null effects that would have to exist to nullify the reported reduction efficacy [14, 21]. All studies were divided into three groups (healthy, diabetic and diabetic with HTG groups) according to the physiological conditions of subjects. Sub-group analysis was performed to determine whether the physiological conditions influence the effect of DAG. The influences of daily dosage and the initial fasting serum TAG concentration on the effect of DAG were assessed using weight estimation in SPSS 12.0.

Results

Of the 13 publications identified after title and abstract evaluation, one did not provide the detailed data [22], two did not take DAG as the only intervention [23, 24], three were designed without placebo control [25–27], one lasted only for 2 days [28]. Finally, six papers with seven independent studies (298 subjects) were included into the statistic pooling [9–11, 16, 19, 29] (Fig. 1). Validity assessment showed that three studies got 4 points and four studies got 3 points (Table 2). The detailed information of included studies is shown in Table 3. The preparations of test oil are shown in Table 4 and there were no significant differences in the fatty acid composition between two test

RD(S)BCP Random double (single)-blind control parallel design, *H* healthy; *T2DM* Type 2 diabetes mellitus; *HTG* Hypertriglyceridemia, *Sample size* (M:F) of the DAG group/(M:F) of the TAG group, Data were reported in mean ± SD

oils in all studies. Three studies reported whether the supplementation of DAG can induce adverse effect to subjects [9, 16, 29]. In the study conducted by Yamamoto et al. [9] and the study conducted by Li et al. [29], no aggravation of physical conditions or adverse reaction were noted after ingestion of the test oils throughout the study period. In the study conducted by Yasunaga et al., some adverse effects were reported during the treatment period. However, there was no significant change in any group when compared with background records. In addition, the number of definite complaints in DAG group was smaller than that of the TAG group and no serious adverse effects were reported during the treatment [16].

Meta-analysis showed that there was no significant difference in the initial fasting serum TAG concentration between DAG and TAG groups (WMD: 0 mmol/L; 95% CI: −0.11 to 0.11 mmol/L; $P = 0.95$) (Fig. 2).

Meta-analysis with random effect model showed that there was no significant difference in the net change of fasting serum TAG concentration between DAG and TAG groups after test oil supplementation (WMD: −0.07 mmol/L; 95% CI: −0.21 to 0.08 mmol/L; $P = 0.37$) (Fig. 3). Funnel plot analysis showed that all studies distributed in the 95% CI except for the study conducted by Yamamoto et al. (Fig. 4) [10]. Fail-safe number analysis indicated that 18 studies with positive effect were necessary to reverse the reported non-significant efficacy of DAG.

Sensitivity analysis was performed to determine the robustness of meta-analysis. The first tested whether the removal of two studies extracted from the paper conducted by Yasunaga et al affect the overall outcome. Results showed that there still was no significant difference between two groups (WMD: −0.15 mmol/L; 95% CI: −0.38 to 0.08 mmol/L; $P = 0.20$) [16]. The second showed that the removal of study in which the data was reported in the form of figure did not affect the overall results significantly (WMD: −0.10 mmol/L; 95% CI: −0.30 to 0.10 mmol/L; $P = 0.31$) [19]. In the third one, the removal of study which distributed out of the 95% CI did not affect the overall result (WMD: −0.02 mmol/L; 95% CI: −0.10 to 0.07 mmol/L; $P = 0.74$) [10]. Finally, the removal of all above studies did not change the direction of the overall results (WMD: −0.10 mmol/L; 95% CI: −0.34 to 0.14 mmol/L; $P = 0.41$) [10, 16, 19].

Sub-group analysis showed that DAG reduced the fasting serum TAG concentration in diabetic subjects with HTG (WMD: −0.87 mmol/L; 95% CI: −1.71 to −0.02 mmol/L; $P = 0.04$) [9, 10], but not in healthy (WMD: 0.02 mmol/L; 95% CI: −0.06 to 0.11 mmol/L; $P = 0.58$) [11, 16, 19] and diabetic subjects (WMD: −0.17 mmol/L; 95% CI: −0.39 to 0.05 mmol/L; $P = 0.12$) [29] (Fig. 3). However, as far as the sub-group of

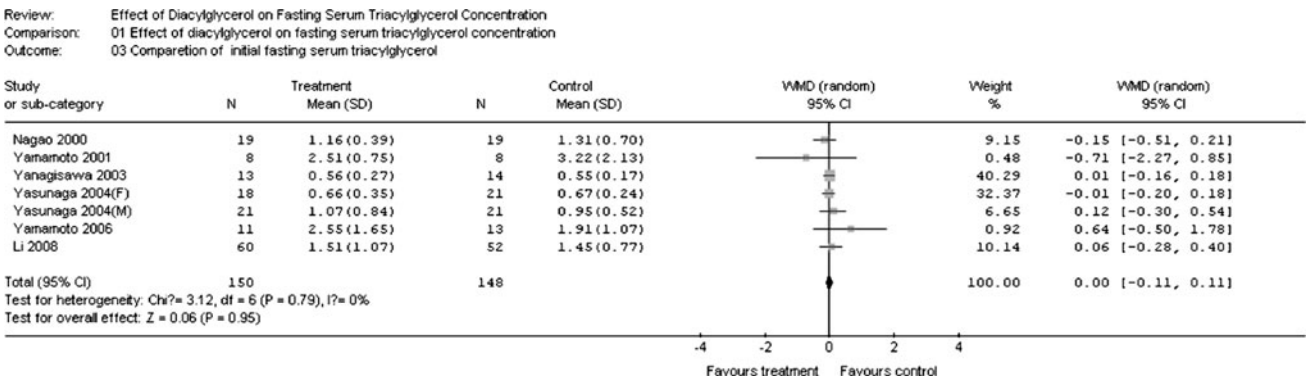

Fig. 2 Comparison in initial fasting serum TAG concentration between DAG and TAG groups (random effect model)

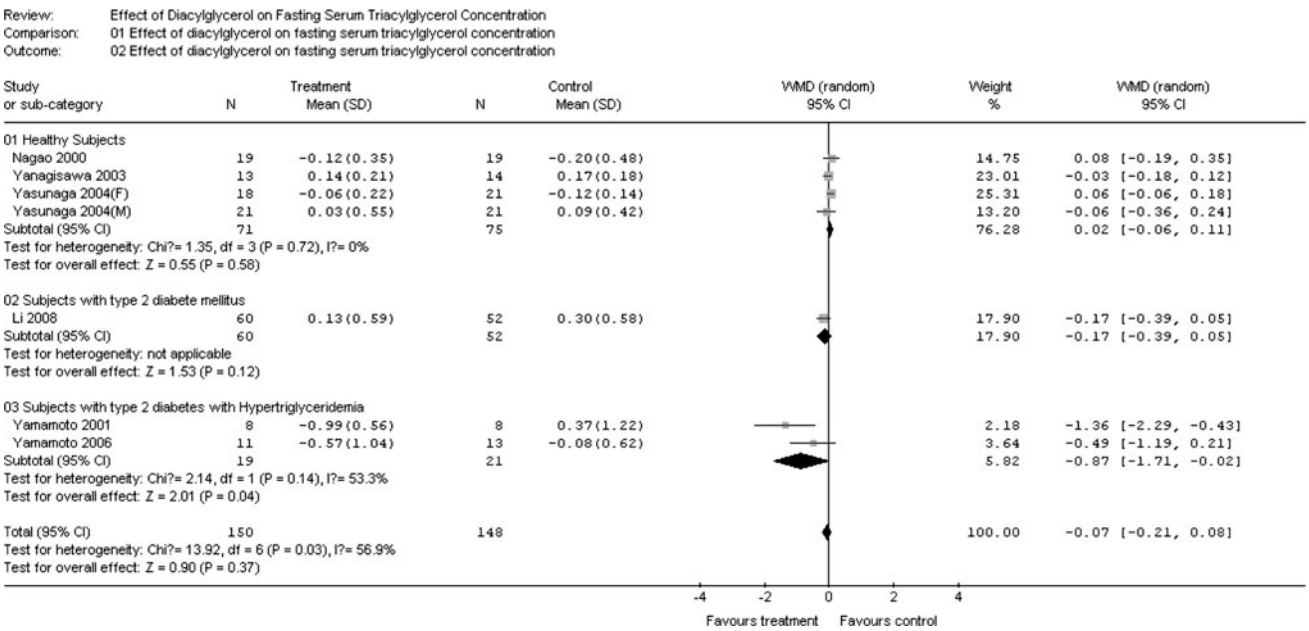

Fig. 3 Sub-group analysis of the effect of DAG on fasting serum TAG concentration (random effect model). All studies were divided into three groups according to the physiological conditions of subject (healthy, diabetic, diabetic with HTG groups)

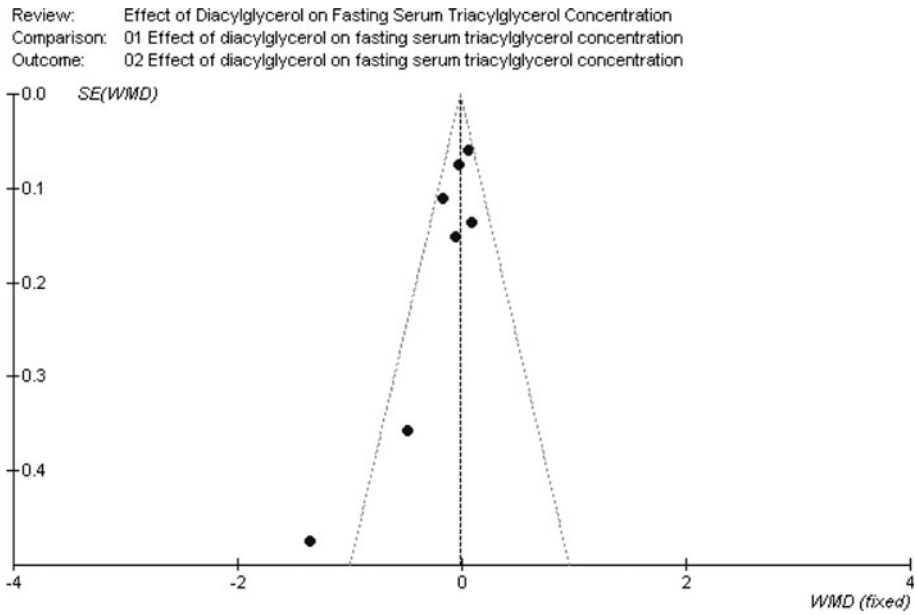

Fig. 4 Funnel plot of the mean difference in fasting serum TAG concentration reduction plotted against 1/SE. The distribution of studies was relatively symmetric except for the study conducted by Yamamoto et al. which means the possibility of publication bias [10]

T2DM patients with HTG concerned, analysis was based only on 40 patients and a moderate I square had been obtained.

Weight estimation analysis of all the studies included indicated that the effect of DAG was influenced to some extent by the initial fasting serum TAG concentration, although this trend did not reach the significant level ($P = 0.328$). However, this efficacy was not influenced by the daily dose ($P = 0.996$).

Discussion

In meta-analysis of continuous outcomes, the influences of initial values on the overall results were usually not taken into account because all included studies were randomly designed. But evidence shows that although the subjects were assigned into two groups randomly at the beginning of experiments, there is significant difference incidentally in some variables between two groups [11]. The effect of dietary intervention might be correlated with the initial values, such as subjects with abundance of visceral fat area tended to achieve larger reduction in visceral fat after body weight loss [30]. In fact, a weak but significant correlation between the initial values and the losses of visceral fat have been already observed in the study conducted by Nagao et al. [11]. So whether there were significant differences in initial values of tested variables should be examined. As far as current study concerned, the differences in initial fasting serum TAG concentration were relatively great in two studies conducted by Yamamoto et al., although all subjects were assigned into two groups randomly [9, 10]. However, these two studies were given small weights (0.48 and 0.92%, respectively) during the meta-analysis because of their great SDs. Their influences on the overall result were reduced greatly and non-significant result was obtained (Fig. 2).

Meta-analysis indicated that DAG oil supplementation did not reduce the fasting serum TAG concentration significantly compared with TAG oil. This result was consistent with four papers that had been included [11, 16, 19, 29] but not consistent with two papers published by Yamamoto et al. [9, 10]. In these two studies, the fasting serum TAG concentrations of DAG groups decreased 0.99 mmol/L and 0.57 mmol/L respectively which were significantly greater than those of TAG group (−0.37 and 0.08 mmol/L, respectively) after test oil supplementation. However, these two studies were given small weights (2.18 and 3.64%, respectively) because of their great SDs. Their influences on the overall result were reduced greatly and non-significant result had been obtained (Fig. 2).

Positive results were reported in two studies [9, 10] and negative results were reported in five studies [11, 16, 19, 29]. This inconsistency might be caused by the differences in initial physiological conditions of subjects. So all studies were divided into three groups (healthy, diabetic and diabetic with HTG groups) and sub-group analysis was used to determine the effect of DAG in each group. Results showed that DAG did not reduce the fasting serum TAG concentration significantly in healthy group compared with TAG. In the diabetic group in which the initial fasting serum TAG concentrations were higher than those of healthy group, the effect of DAG seemed to be enhanced to some extent according to the greater WMD and lower P value. In the diabetic with HTG group, the effect of DAG was increased furthermore and reached significant level. These

results indicated that effect of DAG might be influenced by the initial fasting serum TAG concentration of subjects. Furthermore, weight estimation analysis showed that the effect of DAG was influenced to some extent by the initial fasting serum TAG concentration, although this influence did not reach the significant level. All these results indicated that DAG supplementation was more efficacious in reducing the fasting serum TAG concentration in subjects with higher initial concentrations.

It was conceived that DAG supplementation could reduce the increment of postprandial TAG concentration compared with TAG supplementation. The different structure of DAG from TAG was regarded as the major contribution. The initial products of digested TAG are free fatty acids (FFA) and 2-monoacylglycerol (MAG) and those for 1,3-DAG are mainly FFA and 1(3)-MAG [31]. The resynthesis of TAG in small intestinal epithelial cells from 2-MAG is faster than that from 1(3)-MAG because the later involves the phosphatidic acid pathway, a slow turnover pathway than 2-MAG pathway, which interpreted the less increment of postprandial TAG concentration after DAG consumption compared with TAG [32]. This effect of DAG has also been proved in our former meta-analysis in which DAG supplementation reduced the increment of TAG concentration at postprandial 2, 4 and 6 h [14]. However, more studies are needed to elucidate whether DAG supplementation affect the fasting serum TAG concentration.

There were several limitations in this study. Firstly, it was conceivable that some trials were not uncovered although systematic efforts were made to locate and retrieve them. In this study, the fail-safe number indicated the light possibility of publication bias. The distorting effects arising from publication bias and location bias have repeatedly been reported [33–35]. Secondly, there was great heterogeneity among all included studies, especially in the initial fasting serum TAG concentration. Although the validity of random design was verified beforehand and random effect model was adapted to reduce the influence of heterogeneity, the great differences in initial fasting serum TAG concentrations might have influenced the result of meta-analysis [9, 10]. Thirdly, all located studies were conducted with Asian subjects. This restriction limits the application of current study to American and European people. So, more studies are needed with Western subjects. Finally, the number of patients included in this meta-analysis is very small which might due to the specialism of this topic. The subsequent sub-group analysis was performed based even smaller number of patients. As far as the T2DM patients with HTG sub-group concerned, the analysis was performed based on only 40 patients and had a moderate I square statistic although a significant result had been obtained. This significant effect should be viewed with caution and more studies are needed to establish this efficacy. In spite of these limitations, the high methodological quality of all the studies included (such as randomized, double-blind, TAG controlled design) and the high consistency of sensitivity analysis indicated the robustness of this meta-analysis.

Compared with TAG oil, supplementation of DAG oil did not cause significant adverse reactions which might be due to the similarity in fatty acids composition, energy values and bioavailability between them [36].

In conclusion, DAG supplementation did not reduce the fasting serum TAG concentration significantly compared with TAG in this meta-analysis of seven randomized controlled trials, but some effects were suggested in diabetic patients with HTG.

fish and marine mammals of different species, brands and grades by using the FAME profiles and PCA. The GC FAME profiles from plant oils such as rapeseed, linseed and soy oils and seven different brands of n-3 supplements are also used in the discrimination process. The discrimination between and within animal oils is studied by using three different data analysis strategies: firstly, the analysis of the full FAME profiles from plant, supplement and animal oils; secondly, the analysis of selected FAME profiles from plant, supplement and animal oils with levels higher than 0.5% of the total composition; thirdly, the analysis of the full FAME profiles from animal oils. It must be mentioned that discrimination studies of n-3 rich oils derived from fish and marine mammals have not been previously reported.

Experimental

Reagents and Samples

Sodium hydroxide, hexane, methanol, boron trifluoride in methanol (20% w/v) and chloroform were purchased from Merck (Darmstadt, Germany). Butylated hydroxytoluene (BHT) and boron trichloride in methanol (14%) were purchased from Sigma–Aldrich Co., USA. FAME pure standards and also model mixture standards 2A and 2B (18:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:4n-6), 3A (18:2n-6, 18:3n-3, 20:4n-6, 22:6n-3), 4A (6:0, 8:0, 10:0, 12:0, 14:0) 6A (16:0, 18:0, 20:0, 22:0, 24:0), 7A (16:1n-7, 16:1n-9, 20:1n-9, 22:1n-11, 24:1n-9) and 14A (13:0, 15:0, 17:0, 19:0, 21:0) were purchased from Nu-Chek Prep (Elysian, MN, USA). Nonadecanoic acid methyl ester (19:0) internal standard was from Fluka (Buchs, Switzerland). De-ionized water was purified in a Milli-Q system (Milli-Q system Millipore, Milford, MA, USA). The fish oils were cod liver oil from Peter Möller, Lysaker, Norway and salmon oil from Havnegater, Sortland, Norway. The two brands of harp seal oils (*Pagophilus groenlandicus*) were from Rieber Skinn A/S, Bergen, Norway (two refined samples from different batches, designated as RSA1 and RSA2, and one crude sample designated as CSA were provided) and from JFM Sunile A/S, Os, Norway (one refined sample designated as RSB was provided). Whale oil (*Balaenoptera acutorostrata*) conventionally (WC) and molecularly (WM) distilled were from Myklebust Trading AS, Myklebost, Norway. The plant oils analyzed were soy oil (Mills DA, Sofienberg, Norway), linseed and rapeseed oils (Kinsarvik Naturkost, Bergen, Norway). The seven commercial n-3 supplements obtained from a local pharmacy were Fri Flyt (Vesterålens Naturprodukter AS, Sortland, Norway), Natur-Omega (Naturhuset AS, Vøyenenga, Norway), Møllers dobbel (Peter Möller, Lysaker, Norway), Pikasol (Axellus A/S, Oslo, Norway), Omega-3 Forte (Vitamed, Sarpsborg, Norway), Omega-3 høykonsentrert (Sunkost, Oslo, Norway), El Dorado (Probio Nutraceuticals, Tromsø, Norway). The supplements were designated as K1, K2, K3, K4, K5, K6 and K7, respectively.

FAME Preparation

The FAME preparation protocol has been published elsewhere [48]. Briefly, 50 mg of the sample are mixed with 2 ml BF_3/CH_3OH and 5 mg of the 19:0 internal standard. The mixture is heated at 100 °C for 1 h and cooled down to room temperature. Aliquots of 1 ml of hexane and 2 ml of H_2O are added, vortex-mixed for 15 s, placed in a centrifuge at 3,000 rpm for 2 min and the FAME are then extracted from the upper hexane phase. Depending on the fat content the sample is either concentrated under nitrogen or diluted with hexane and subsequently subjected to GC analysis.

The FAME for every kind of oil (fish, marine mammal and plant) were prepared in triplicate and for the n-3 supplements in duplicate.

Gas Chromatography Instrumentation

Analysis of the FAME was performed on a Perkin-Elmer AutoSystem XL gas chromatograph (Perkin-Elmer, Norwalk, Connecticut) equipped with a liquid autosampler and a flame ionization detector. The FAME samples were analyzed on a CP-Sil 88 capillary column (50 m × 0.32 mm ID 0.2 μm film thickness, Varian, Courtaboeuf, France). Data collection was performed by the Perkin-Elmer TotalChrom Data System software version 6.3. The temperature program was as follows: the oven temperature was held at 60 °C for 1 min, ramped to 160 °C at 25 °C/min, held at 160 °C for 28 min, ramped to 190 °C at 25 °C/min, held at 190 °C for 17 min, ramped to 220 °C at 25 °C/min and finally held at 220 °C for 10 min. Direct on-column injection was used. The injector port temperature was ramped instantaneously from 50 to 250 °C and the detector temperature was 250 °C. The carrier gas was ultra-pure helium at a pressure of 82 KPA. The analysis time was 60 min. This time interval was sufficient to detect FAME with chains from 10 to 24 carbons in length. The FAME peaks were identified by comparison of their retention times with the retention times of highly purified FAME standards. Since the concentration of the internal standard (19:0) is known and its recovery in the different oils was constant, the comparison of the various FAME peak areas with 19:0 peak area is used to calculate the concentration of the FAME in the various oils and supplements.

Principal Component Analysis

Principal component analysis (PCA) is a well documented multivariate method for reducing the dimensionality of a data set by rotating and constructing orthogonal linear combinations of the original variables and projecting the maximum variability onto a new axis also known as principal components (PCs). The results are classified according to the level of information produced by the various combinations of the original variables in a way that the first component (PC1) is the major axis of the points in the p-dimensional space that accounts for the largest variation

SFA saturated fatty acids, *MUFA* monounsaturated fatty acids, *PUFA* polyunsaturated fatty acids

matrices where *m* represents every prepared oil sample and *n* represents every analyzed fatty acid. The matrices submitted to PCA are standardized by subtracting their means and dividing by their standard deviations in order to construct linear combinations of the predictor variables *n* that contains the greatest variance. The PCA score and loading plots of the FAME profiles from the various oils were computed with the software package Statgraphics Plus 5.1 (Statistical Graphics Corp.).

Results

The fish, marine mammal and plant oils were prepared in triplicate and the n-3 supplements in duplicate. The triplicate and duplicate lipid profiles from the various injected oil samples, expressed as mg FAME/g sample, are presented in Tables 1, 2, 3, 4 and 5. The individual profiles were arranged in a data matrix consisting of 47 rows representing the various analyzed oils with their respective

replicates and 34 columns representing the individual FAME detected by GC. The 34 individual FAME profiles were: 14:0, 14:1n-9, 15:0, 16:0, 16:1n-9, 16:1n-7, 17:0, 16:2n-4, 18:0, 16:3n-3, 18:1n-11, 18:1n-9, 18:1n-7, 16:4n-3, 18:2n-6, 20:0, 18:3n-3, 20:1n-11, 20:1n-9, 20:1n-7, 18:4n-3, 20:2n-6, 20:3n-6, 22:0, 20:3n-3, 20:4n-6, 22:1n-11, 22:1n-9, 20:4n-3, 20:5n-3, 24:0, 24:1n-9, 22:5n-3, 22:6n-3.

Discrimination by Using the Full FAME Profiles from Plant, Supplement and Marine Animal Oils

The 47 × 34 matrix was submitted to PCA as a data exploration technique and a total of six components (PCs) were extracted and grouped in decreasing order of variance. The first component (PC1) which explains 41.91% of the total variation can be used to discriminate the oils according to their nature as is shown in Fig. 1. A plot of the scores of the two first components (Fig. 2), which explain 66.35% of the data variation, differentiates basically the same number of groups and sub-groups found in Fig. 1. Besides, the loadings of the two first components, were plotted to investigate the relationship between the various FAME (Fig. 3).

The six PCs computed by using the 47 × 34 matrix were plotted against each other to produce two and three dimensional PC scores graphs and consequently explore the capability of these PCs to discriminate confidently within the marine animal oils. Unfortunately, clear and well-defined patterns that allow one to differentiate the various oils and grades were not observed in any of the graphical representations, hence a data reduction, based on selected FAME profiles, was implemented.

Discrimination by Using Selected FAME Profiles from Plant, Supplement and Marine Animal Oils

FAME data reduction has been used in the discrimination of oils derived from one fish species (cod liver oil) by selecting the 15 FAME with levels higher than 1% of the total composition [42]. Considering that in the present study the 34 FAME or variables are given in mg/g and arranged in columns for PCA purposes (47 × 34), it was decided to discard all the FAME columns with average values <5 mg/g (<0.5% of the total averaged FAME profile), in that way 19 FAME profiles were retained (14:0, 16:0, 16:1n-7, 18:0, 18:1n-11, 18:1n-9, 18:1n-7, 18:2n-6, 18:3n-3, 20:1n-11, 20:1n-9, 18:4n-3, 20:4n-6, 22:1n-11, 20:4n-3, 20:5n-3, 24:1n-9, 22:5n-3, 22:6n-3). A new data matrix of size 47 × 19 was submitted to PCA and three PCs, explaining 85.29% of the total data variability, were computed. The three PCs were used to generate various two and pseudo-three dimensional score plots which essentially showed a clear

SFA saturated fatty acids, *MUFA* monounsaturated fatty acids, *PUFA* polyunsaturated fatty acids

discrimination between plant, supplements and marine animal oils as already observed in Figs. 1, 2.

Discrimination by Using Full FAME Profiles from Marine Animal Oils

The contribution of the supplement and plant oils was removed as an alternative approach to discriminate the various marine oils. A 24 × 34 matrix was constructed by using the data presented in Tables 1, 2 and submitted to PCA. A considerable percentage of the variability of this matrix (97.58%) was explained by four extracted PCs (49.80, 22.65, 20.08 and 5.05%). The score plot of PC1 and PC4 (Fig. 4) indicates that it is possible to discriminate within the four different types of animal oils by using these two components.

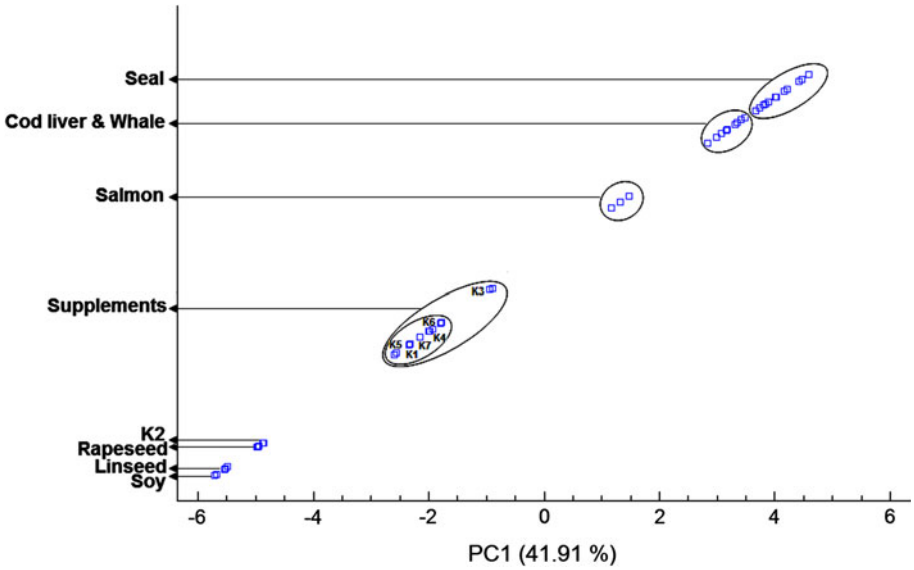

Fig. 1 PC1 score plot for the different kinds of oils obtained after computing a 47 × 34 (samples × FAME profiles) data matrix. The different supplements and providers are designated by *numbered letter Ks*. For details regarding the providers see "Experimental"

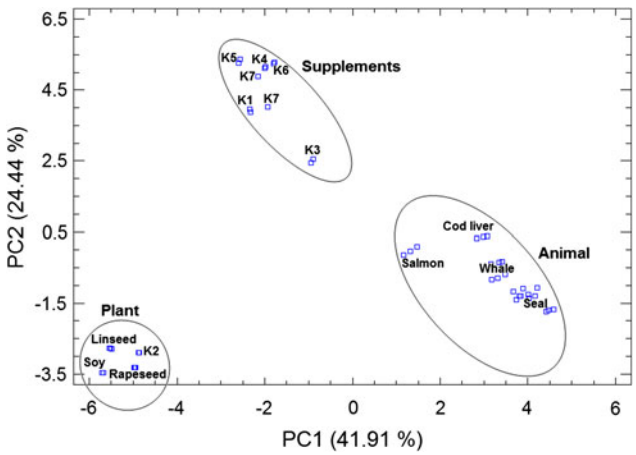

Fig. 2 PC1 and PC2 score plot for the different kinds of oils obtained after computing a 47 × 34 (samples × FAME profiles) data matrix. The different supplements and providers are designated by *numbered letter Ks*. For details regarding the providers see "Experimental"

Discrimination Between Genuine and Adulterated Oils

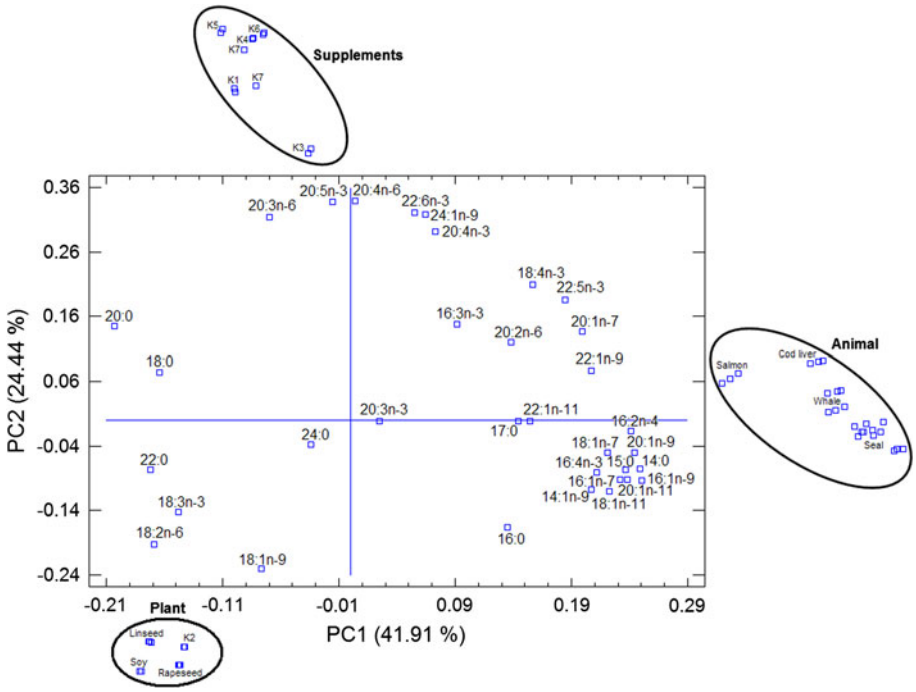
Further assessment of the capability of GC for discriminating between pure and adulterated oils, was achieved using conventionally distilled whale oil (WC) debased by cod liver oil in the proportions 90:10, 80:20 and 50:50. The FAME profiles of the mixtures prepared in triplicate (Table 5) along with the profiles of the marine animal oils described in Tables 1 and 2 were submitted to PCA and four PCs extracted, explaining 47.05, 25.08, 20.19 and 5.36% of the data variability, respectively.

Discussion

Discrimination by Using the Full FAME Profiles from Plant, Supplement and Marine Animal Oils

A graph of PC1 for the various oil samples (Fig. 1) shows that different kinds of oils can be basically differentiated along the PC1 axis. Specifically, the scores of the analyzed plant and animal oils grouped themselves at opposite ends of the PC1 axis while the scores of six supplements (K1 and K3–7) in the middle of this axis. The scores for K2 overlaps those from rapeseed oil, hence it is likely that this supplement contains this particular oil. In addition, the supplements as well as the animals exhibit some subgroups which discriminate supplement K3 in the former and salmon oil in the latter. These latent sub-structures are attributed to the consistently high levels of 16:0 and 16:1n-7 in supplement K3 (on average three times higher compared to the others supplements of this group) and the high levels of 18:1n-9, 18:2n-6 and 18:3n-3 in the salmon oil (on average 1.7, 4.7 and 5.0 times higher than the rest of marine animal oils, respectively).

The score plot of the first two PC (Fig. 2) which explained 41.91 and 24.44%, respectively, of the total variability of the different types of oil FAME profiles allowed concluding that PC1 discriminates in effect between animal and plant oils while PC2 differentiates between supplements and plant oils. Besides, this score plot revealed that in addition to rapeseed oil, supplement K2 also contains linseed oil due to the proximity of their scores. This proximity was constantly observed when the scores of any of the six PCs were plotted against each



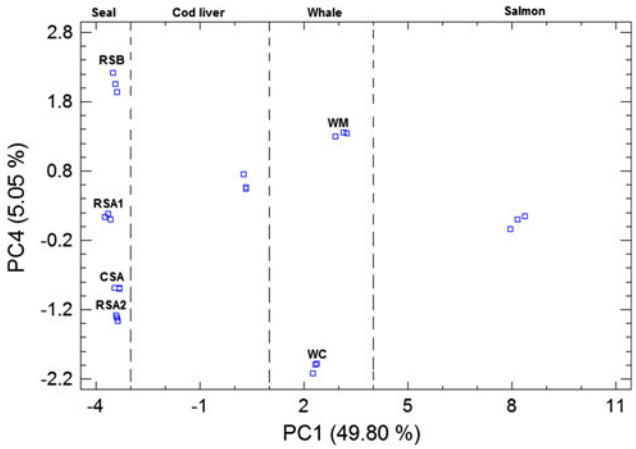


Fig. 4 PC1 and PC4 score plot for the fish and marine mammal oils obtained after computing a 24 × 34 (samples × FAME profiles) data matrix. RSA1 and RSA2 are refined seal oils from provider A and from different batches. CSA is crude seal oil from provider A. RSB is refined seal oil from provider B. WM and WC are molecularly and conventionally distilled whale oils from the same provider. For details regarding the providers see "Experimental"

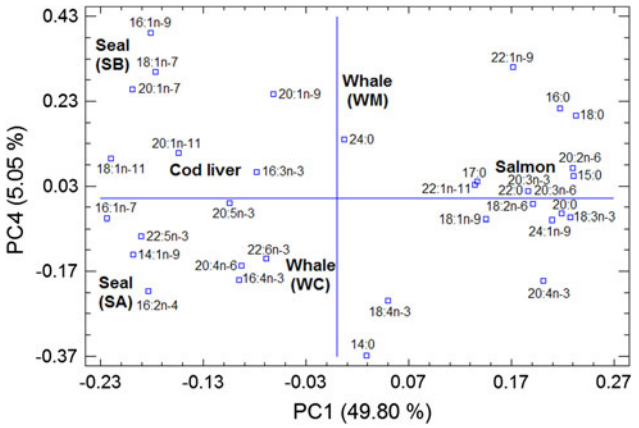

Fig. 5 FAME loading plot for PC1 and PC4 and its relationship to the scores portrayed in Fig. 4

other. The presence of rapeseed and linseed oils in the composition of K2 was confirmed by searching the webpage of the manufacturer of this particular supplement. The PC1 versus PC2 plot (Fig. 2) revealed some variability in the individual scores for K7 which could be attributed to experimental errors, indicating the importance of replication in discrimination studies.

The plot of the loadings of the two first components, expressing the relationship between the various FAME (Fig. 3) showed the lack of correlation between 20:5n-3 and 18:1n-9 on the PC2 axis, indicating that none of the plant oils studied in the present investigation are present in the composition of supplements K1, K3, K4, K5, K6 and K7. These observations are in agreement with the various manufacturers who have reported some special developed oils (name not disclosed), refined fish oil (from non-specified origin), gelatin from pork, etc. among the various constituents of their supplements rather than plant oils.

The superimposition of the three main clusters from Fig. 2 on the loading plot (Fig. 3) demonstrates unequivocally that the observed inverse correlation between 20:5n-3 (positive PC2 loading value) and 18:1n-9 (negative PC2 loading value) is responsible for the discrimination between supplements (with scores highly associated to

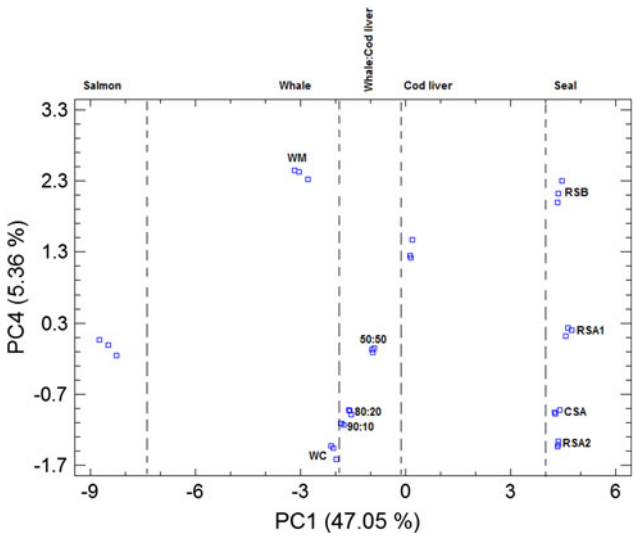

Fig. 6 PC1 and PC4 score plot for the various genuine marine oils and three samples of adulterated whale oil (WC) with cod liver oil at different proportions (90:10, 80:20 and 50:50). The PCs were obtained after computing a 33 × 34 data matrix. RSA1 and RSA2 are refined seal oils from provider A and from different batches. CSA is crude seal oil from provider A. RSB is refined seal oil from provider B. WM and WC are molecularly and conventionally distilled whale oils from the same provider. For details regarding the providers see "Experimental". PC1 and PC4 score plot for genuine and adulterated fish and marine mammal oils by using the full FAME profiles

20:5n-3) and plant oils (with scores highly associated to 18:1n-9). Similarly, the lack of correlation between 16:1n-9, 14:0, 20:1n-9, 16:2n-4 (positive PC1 loading values) and 22:0, 18:2n-6 (negative PC1 loading values) is responsible for discriminating between animal and plant oils.

Discrimination by Using Selected FAME Profiles from Plant, Supplement and Marine Animal Oils

The discrimination patterns of the various two and pseudo-three dimensional score plots obtained after performing PCA on selected FAME profiles were basically similar to those obtained by using the full FAME profiles (Figs. 1, 2). However, the graphs consistently misclassified supplement K2 as containing a mixture of the three plant oils (soy, linseed and rapeseed oil) while in fact only linseed and rapeseed oil are present in this particular supplement. This result indicates that PCA on full FAME profiles outperforms the proposed data reduction approach for supplement classification. The various plots generated with the aforementioned three PCs were also unable to establish a clear distinction between the various species, brands and grades of animal oils; hence a further discrimination study was carried out by using only the full FAME profiles derived from marine oils.

Discrimination by Using Full FAME Profiles from Marine Animal Oils

The PC1 and PC4 score plot (Fig. 4) shows that PC1 can discriminate between the four different types of animal oils, namely seal oil, cod liver oil, whale oil and salmon oil and that PC4 can discriminate effectively within every animal oil species and their alleged qualities. For instance, it is observed that the two different batches of refined seal oils from manufacturer-A (designated as RSA1 and RSA2 in Fig. 4) display positive and negative PC4 score values, respectively, indicating some differences between them. In addition, the crude and the refined seal oils from the same manufacturer and designated as CSA and RSA2 in Fig. 4, exhibit negative scores values, indicating a correlation between these two oils regardless their alleged qualities. The discrimination between the seal oils from different manufacturers namely Rieber Skinn (SA) and JFM Sunile (SB) is observed in Fig. 4. The variables responsible for the discrimination between the manufactures are visualized by means of the PC1 and PC4 loading plot (Fig. 5). The higher contents of 16:1n-9, 18:1n-7, 20:1n-7 and the lower contents of 16:2n-4 in SB compared to SA are the main fatty acids that contribute to distinguish SA from SB. Similarly, Fig. 4 shows the unmistakably differentiation between molecularly distilled whale oil (WM) from conventionally distilled whale oil (WC) which is mainly due to the slightly higher levels of 20:1n-9, the lower levels of 22:6n-3 and 18:4n-3 as well as the lack of 16:4n-3 in WM compared to WC. The clear-cut distinction between cod liver and salmon oil along the PC1 axis (Fig. 4) is mainly attributed to the contribution of several fatty acids such as 18:1n-11 and 16:1n-7 at negative PC1 values and 20:2n-6 and 18:3n-3 at positive PC1 values as indicated in Fig. 5.

Discrimination Between Genuine and Adulterated Oils

The PC1and PC4 score plot (Fig. 6) demonstrates that it is possible to discriminate adulterated from genuine whale oil samples. The information retained by PC1 is mainly connected with the nature of the various oils. For instance, five specific regions can be visualized along the PC1 axis (salmon, whale, whale + cod liver, cod liver and seal) while the information retained by PC4 is mainly connected with the discrimination within animal oil species, their alleged qualities and the various proportions of cod liver oil used to adulterate genuine whale oil.

In conclusion, the different approaches used in the discrimination process indicated that PCA on the full FAME profiles is the best strategy to discriminate between the various oils considered in this study. Considering that n-3 rich oils derived from animals are highly regarded as alternative medicines worldwide, the potentiality of

unexplored single or coupled techniques for authentication and discrimination of these kinds of oils should be investigated to prevent fraudulent practices.

Acknowledgments The European Commission in the context of the Erasmus Mundus Program and The Norwegian Research Council (SIP project NRF 173534/I30) are gratefully acknowledged for financial support of Y.Z and Z.D, respectively.
