ORIGINAL ARTICLE

Early and Sustained Enrichment of Serum n-3 Long Chain Polyunsaturated Fatty Acids in Dogs Fed a Flaxseed Supplemented Diet

Brent L. Dunbar · Karen E. Bigley · John E. Bauer

Received: 15 September 2009 / Accepted: 13 October 2009 / Published online: 5 November 2009

Abstract A study was conducted in dogs to assess n-3 long chain polyunsaturated fatty acid incorporation after feeding an α-linolenic (ALA)-rich flaxseed supplemented diet (FLX) for 84 days. Serum total phospholipids (PL), triacylglycerol (TG), and cholesteryl esters (CE) were isolated at selected times and fatty acid methyl esters were analyzed. Increased LA was seen in the FLX-PL fraction after 28 days and an expected decrease in PL–AA. Enrichment of ALA, eicosapentaenoic acid (EPA) and docosapentaenoic acid n-3 (DPAn-3) in the FLX-group occurred early on (day 4) in both PL and TG fractions but no docosahexaenoic acid (DHA) was found, consistent with data from other species including humans. In contrast, no accumulation of DPAn-3 was seen in serum-CE, suggesting that this fatty acid does not participate in reverse-cholesterol transport. The accumulation of DPAn-3 in fasting PL and TG fractions is likely due to post-absorptive secretion after tissue synthesis. Because conversion of DPAn-3 to DHA occurs in canine neurologic tissues, this DPAn-3 may provide a circulating reservoir for DHA synthesis in such tissues. The absence of DPAn-3 in serum-CE suggests that such transport may be unidirectional. Although conversion of DPAn-3 to DHA is slow in most species, one-way transport of DPAn-3 in the circulation may help conserve this fatty acid as a substrate for DHA synthesis in brain and retinal tissues especially when dietary intakes of DHA are low.

Abbreviations

AA	Arachidonic acid
ALA	Alpha-linolenic acid
CE	Serum cholesteryl ester fraction
DHA	Docosahexaenoic acid
DPAn-3	Docosapentaenoic acid, n-3
EDTA	Ethylenediaminetetraacetic acid
EPA	Eicosapentaenoic acid
FLX	Flax seed supplemented diet
LA	Linoleic acid
PL	Serum phospholipid fraction
SUN	Sunflower seed supplemented diet
TG	Serum triacylglycerol fraction

Introduction

Long chain n-3 fatty acids, notably eicosapentaenoic acid (EPA) and docosapentaenoic acid (DHA), are documented to have important health benefits including cardioprotective effects [1–3] as well as roles in neurological development [4–6] and the inflammatory response [7–9]. While many studies have emphasized EPA and DHA, naturally occurring fish oils are additionally enriched in docosapentaenoic acid (DPAn-3), an important intermediate in

DHA synthesis [10]. Consequently, recommendations have been made for the general public to increase their dietary intakes of fatty fish rich in these compounds [11]. However, cost, availability, heavy metal concerns, and dietary preferences may limit fish and fish-oil intake among certain populations [12]. Metabolically, α-linolenic acid (ALA) is a precursor of EPA, DPAn-3, and DHA. Studies in several mammalian species have found that DPAn-3 is the main ALA metabolite in cell membranes of most herbivores and carnivores [13]. As such it may be an important plasma or tissue reservoir for either EPA or DHA synthesis.

Dietary ALA has been shown to increase blood concentrations of cardioprotective fatty acids in humans and to exert benefits in post-myocardial infarction patients [2]. High ALA diet also reduces lipid and inflammatory cardiovascular disease risk factors in patients with hypercholesterolemia [14] and certain inflammatory mediators in free-living subjects [15]. The cardioprotective effects of ALA appear to be due, in part, by reduction in the production of inflammatory cytokines [16]. It is unknown whether ALA is cardioprotective in its own right although there is an ever growing body of research supporting this possibility (reviewed in [17]).

The canine species has served as a model demonstrating that intravenously infused EPA and DHA reduces the risk of cardiac arrhythmias [18]. Because dogs, like humans, can convert either ALA or stearidonic acid to longer chain n-3 derivatives [19, 20], the ability of dietary ALA to provide enough EPA to be similarly cardioprotective is unknown. Knowledge of dietary ALA metabolism in dogs will therefore provide a basis for future investigations of the canine arrhythmic model using dietary interventions with n-3 fatty acids.

It should also be mentioned that dogs, although relatively expensive, are a species of choice for human drug development including compounds affecting lipid metabolism and especially where serial blood sampling is performed. Furthermore, because many of the commercial foods fed these animals during such testing now contain increased amounts of flaxseed or linseed oil, it has become necessary to understand effects that such background diets may have on lipid metabolism per se. Thus, the canine species is an important animal species with which to investigate the time course and extent of incorporation of long chain n-3 fatty acids in plasma or tissues when ALA-enriched diets are fed. Seed oils rich in ALA such as flaxseed, canola, or corn show promise for providing functional enrichment of cell membranes with EPA, DPAn3, and, under some conditions, DHA. They may provide an alternative to fish and fish oil, which may be less available and sustainable globally.

The present study was performed to evaluate the early time course and extent of accumulation of long chain n-3 derived fatty acids in the major serum lipid subfractions of dogs fed an ALA enriched diet over a 12 week feeding period. Serum total phospholipid fatty acids are generally used as a biomarker of tissue enrichment; serum triglyceride fatty acids reflect the post-absorptive state of fasted samples; and cholesteryl ester fatty acid profiles demonstrate important metabolic preferences during their return to the liver via reverse cholesterol transport. Analysis of each of these serum lipid subfractions under conditions of a single dietary modification provides a complete metabolic picture of the dynamics of fatty acid metabolism and allows a thorough evaluation of lipid metabolic alterations in this canine model.

Experimental Procedures

Flaxseed and Sunflower Seed Supplements

Whole flax and sunflower seeds were ground and screened (200 mesh, ENRECO, Manitowoc, WI, USA) to improve digestibilities. The composition of the ground seeds is shown (Table 1). The flaxseed contained 52.7% ALA and the sunflower seed contained 68.2% LA while the other fatty acids were distributed nearly equivalently between these two oilseeds.

Animals and Diets

A commercially available canine dry, extruded diet (basal diet; Hill's®, Canine Senior, single lot number) was lightly sprayed with up to 1% (w/w) distilled water in a bakery mixer (Model L800, Hobart Industries, Inc, Troy, OH, USA) and the ground seeds were coated onto the expanded food particles at 3% by weight of the basal diet. Two diets were thus produced varying in fatty acid composition reflecting the supplement used. The diets were allowed to dry completely, stored at 4°C in their original bags, then placed in plastic drums fitted with lids until the time of

Values are the average of two determinations

feeding. Complete fatty acid profiles of the two supplemented diets have been previously reported [21]. Dietary treatments were such that the fatty acid profiles of the two supplemented diets varied predominately between 18-carbon n-6 and n-3 fatty acid series.

The basal diet contained approximately 23.8% energy as fat (about 97 g fat/kg diet), 7.8% energy as linoleic acid (LA). On an as-fed basis this diet contained 17.0% protein, 58.5% carbohydrate, 3.0% fiber, 10.8% moisture and 3552 kcal/kg diet. The supplemented diets contained 25% of energy total fat (about 102 g fat/kg diet). The sunflower seed supplemented diet (SUN) contained 9.3% kcal as LA and 0.43% kcal as ALA. It also contained 17.0% protein, 56.9% carbohydrate, 4.2% fiber, and 10.8% moisture (as-fed). By contrast, the flaxseed supplemented diet (FLX) contained 7.3% kcal as LA and 2.5% kcal as ALA with 17.2% protein, 57.0% carbohydrate, 3.7% fiber, and 10.8% moisture on an as-fed basis. Because the LA contents of each diet were between 7.3 and 9.3% energy, it was anticipated that tissue levels would be saturated with LA [22, 23]. Thus, a comparison between a low ALA (0.43% kcal) diet (SUN) and an enriched ALA (2.5% kcal) diet (FLX) was made at saturating dietary concentrations of LA.

The protocol for this study was approved by the Texas A&M University Laboratory Animal Use Committee. Dogs were individually maintained in kennels according to the American Physiological Society Guidelines for Animal Research. Eighteen adult, mixed breed dogs, ranging in body weight from 10 to 20 kg were divided into 2 groups of 9 each. To begin the study, feeding periods were staggered over three successive days so that 3 animals from each group (6 animals per day) were fed the supplemented diets assuring feeding and sample collections in a timely manner.

The basal diet was fed, unsupplemented, for a 2 week diet acclimation period prior to blood sample collection on day 0. The dogs were then randomly assigned to either the SUN or FLX group and fed their respective diets for 84 days. Because the animals were fed to maintain their starting body weights and monitored weekly, all animals were observed to readily and consistently consume all food offered. All dogs were weighed weekly during the feeding period. Blood samples were obtained via jugular vena puncture with no anticoagulant after withholding food overnight (day 0) just prior to starting the feeding period. Thereafter, the animals were fed their respective diet and blood samples again collected after withholding food at 4, 7, 14, 28, 56, and 84 days.

Sample Analyses

Serum was freshly harvested from the blood samples on the day of collection and total lipids were extracted and sub-fractionated via thin layer chromatography [21]. After visualization with iodine vapor, the phospholipids (PL), triacylglycerol (TG), and cholesteryl ester (CE) fractions were scraped from the plates, placed in screw-capped glass tubes fitted with Teflon caps, and 4% sulfuric acid in methanol added for trans-methylation prior to capillary gas chromatography [21]. Fatty acid profiles were determined using an Omegawax^{TM} 320 fused silica capillary column (0.25 μm thickness, 30 m long, and 0.32 mm ID) (Supelco, Inc. Bellafonte, PA) with a Hewlett Packard Series II 5890 Gas Chromatograph (Hewlett Packard Co., Palo Alto, CA) with a 50:1 split ratio and helium as carrier gas at 30 ml/min initial velocity. The column oven was temperature programmed starting at 180°C, held for 15.5 min, then heated to 210°C at 12°C/min and held for 19 min. The injection and detector temperatures were held constant at 250 and 260°C respectively. Flame ionization detection was used and results generated with HP Chem Station® software package (Hewlett Packard Co, Palo Alto, CA, USA). Authentic fatty acid methyl ester standards (68-B, 20-A, Nu-Check Prep, Elysian, MN, USA) and fish oil standards were used to identify the samples via retention time comparisons. [21]. In addition, a standard for 20:3n5 (Δ5,8,11) via lipid extraction and trans-methylation of *Podocarpus nagi* seeds rich in this fatty acid was prepared and used to provide a preliminary identification of this fatty acid triene when observed in the samples. When present, it was tentatively identified as a 20:3n-6 isomer that awaits confirmation of its more precise molecular configuration. The seeds were generously provided by Shigeru Matsutani (Kyoto Botanical Garden, Kyoto, Japan).

Statistics

Statistical analyses of all data were performed using the Microsoft Windows® version of SAS/STAT Version 6 (SAS Institute, Cary, NC, USA). The Shapiro–Wilks test was performed and nearly all the data were normally distributed. Repeated measures ANOVA using a general linear model was performed with the diet as a between-subject factor and time as a within-subject factor. Friedman's test was used for the non-normally distributed data. Main effects of time and diet as well as the interaction of time with diet were therefore determined. When diet or diet × time effects were found, student's *t* test was used to identify differences between the two dietary treatments at the same time.

In all cases, significance was set at $P < 0.05$. Fatty acid profiles of lipid fractions obtained on Days 0, 4 and 84 have been previously reported in abstract form [21]. Results of the complete repeated measures ANOVA analyses of samples collected at all sample times are now presented.

Results

Statistically significant time effects were seen with the majority of fatty acids in this study. This finding was not unexpected due to lipid modification of the basal diet in which the day 0 values were compared with those obtained at subsequent sampling periods after feeding the two supplements. Also, it should be noted that the fatty acid profiles of the serum PL, TG, and CE in the SUN group were essentially unchanged over time after day 4 (Tables 2, 3, and 4). These findings were not unexpected because the relative fatty acid compositions of both the basal diet and SUN supplemented basal diet were nearly identical. However, where diet and diet × time interactions were observed, comparisons between the SUN and FLX groups were made and a number of important differences were observed. The diet*time interactions are shown in the footnotes to Tables 2, 3, and 4 and included the n-3 polyunsaturated fatty acids except for DHA in all fractions and 22:4n-6 in the PL fraction (Table 2). Interactions between diet and time indicated that the duration of feeding interacts with the diet per se to provide an additional effect on a particular fatty acid beyond any main diet effect seen.

Enrichment of serum n-3 polyunsaturated fatty acids in the FLX group occurred early on (day 4) in each lipid subclass examined. Specifically, PL fractions were significantly enriched in ALA and EPA beginning on day 4 and remained so during the entire feeding period (Table 2). At the end of the feeding period, serum PL fatty acid changes included significant elevations of ALA (254% increase), EPA (195% increase), and DPAn-3 (68% increase) and significant decreases of AA, in the FLX group (Fig. 1). It is especially noteworthy, however, in the FLX group, that PL–DHA was unchanged during the entire period demonstrating the lack of serum DHA accumulation in the FLX (i.e. ALA) supplemented dogs. Also, increased PL–LA was seen in the FLX group and this increase reached statistical significance on days 28 and 84 while numerical elevations of PL–LA in this group were also seen at every sample time after day 0 (Table 2). On day 28 the anticipated decrease in PL–AA was observed within the FLX group which remained so for the duration of the study. Of additional interest was that when the FLX diet was fed, 22:4n-6 was decreased as early as 7 days relative to the SUN group which appeared to be modestly increased, but not significantly so, with time. Serum TG fractions of FLX fed dogs were similarly enriched in ALA (217% increase), EPA (171% increase), and DPAn-3 (122% increase) and again no DHA was found (Table 3).

In the serum CE fraction, flaxseed supplementation resulted in a significant increase in ALA at day 4 and throughout the feeding period. This change was followed beginning on day 7 with a statistically significant accumulation of EPA (Table 4). Percentage increases of ALA and EPA were greatest among all lipid fractions analyzed with 300% increases seen in ALA at day 7 and in EPA at day 14. These statistically significant accumulations culminated on day 84 with a 423% increase of ALA and 410% increase in EPA (Table 4). However, no appreciable accumulation of either DPAn-3 or DHA was seen in this fraction at any time point studied.

Discussion

Rapid accumulation of EPA, but not DHA, was seen in serum PL and TG lipid fractions in the canine model when a 3% (w/w) whole ground flaxseed supplement was added to a moderately high LA containing diet (7.3% of energy as LA). Notably, early and significant increases in ALA, EPA, and DPAn-3 were all seen with the exception of DHA. Similar enrichments of EPA and DPAn-3 have been observed in human plasma using a 4 week feeding period [24]. For that matter, this phenomenon has been observed in humans and various other animal species (reviewed in [25]) and is consistent with other evidence that plasma enrichment of DHA after ALA supplementation is less efficacious than providing smaller dietary amounts of preformed DHA per se [25, 26]. It should be noted that studies in rats have shown the conversion of ALA all the way to DHA to be effective in liver and plasma [27]. By contrast, however, there is resistance for serum DHA levels to increase in dogs fed ALA at the dietary amounts employed in this study given the observation that PL–DHA was unchanged in the FLX group during the entire dietary period. This finding is more similar to results seen in humans [25].

The accumulation of DPAn-3 seen in both fasting PL and TG fractions is consistent with secretion after tissue synthesis from dietary ALA. Conversion of DPAn-3 to DHA has been reported in canine neurologic tissues [28] and likely occurs after uptake of fatty acid precursors from the circulation. These findings suggest that production of DPAn-3 from ALA may serve as an important circulating reservoir for tissue DHA synthesis as DPAn-3 is transported via plasma lipids to neurological tissues [29].

It should be noted that conversion of ALA to longer chain derivatives is largely affected by the relative amounts of LA present in the diet and thus the LA/ALA ratio [25]. However, many human studies using n-3 fatty acid supplementation have been unable to accurately document n-6 intakes which may explain, in part, variability of results seen. In the present study, using dogs, the LA/ALA ratio of the FLX supplemented diet was 3.1:1 while that of the SUN group was 23.3:1 both of which are within the range

of values recommended by the 2006 National Research Council for canine diets [30]. The recent report by Marangoni et al. found similar increases of EPA and DPAn-3 in a small group of normal humans supplemented with walnuts containing 4.4 g LA/day and 1.2 g ALA per day at a LA/ALA ratio of 3.6:1 [24]. In that study, amounts of LA and ALA from other dietary sources were not strictly controlled although participants were instructed to specifically limit their consumption of other ALA containing foods and fish during the short study period. Given these similar findings, it is of interest that the FLX group LA/ALA ratio in the present study is essentially equivalent to

Table 3 Serum triacylglycerol fatty acid composition during the feeding period

human recommendations from a 1999 National Institutes of Health Workshop that diets contain no more than 6.7 g of LA and 2.2 g of ALA per day yielding an LA/ALA ratio of 3.0:1 [31] as well as those from the International Society for the Study of Fatty Acids and Lipids in which diets containing 2% of energy from LA and 0.7% energy from ALA are noted resulting in an LA/ALA ratio of 2.9:1 [32]. Hence, the canine data presented here may provide a reasonable model to study the effects of LA and ALA, per se or in combination, with incremental amounts of EPA and/or DHA for human lipid metabolism. Future investigations of canine responses to n-3 fatty acids are thus warranted.

As in the other lipid fractions, the observed changes in the CE fraction appeared to achieve a steady state after approximately 28 days of supplementation. It is of interest, however, that while there were significant increases of EPA in the flaxseed group, essentially no DPAn-3 or DHA was found in the serum CE fraction of these dogs. By contrast, in an earlier study, when we fed fish oil to dogs, we also observed that DPAn-3 was not present in the CE fraction. DHA was found, but only to a small extent relative to the PL and TG fractions [33]. Previous studies investigating lecithin:cholesterol acyl transferase (LCAT) in various species have also reported CE-DPAn-3 to be absent in

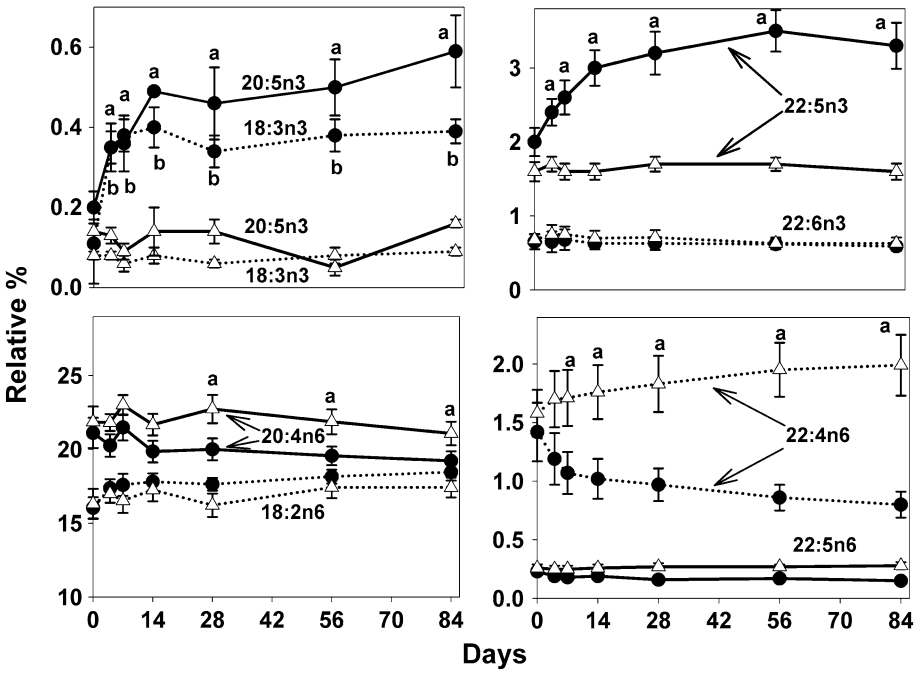

Fig. 1 Time course of the accumulation of selected n-3 and n-6 fatty acids in the serum phospholipid fractions of dogs fed diets supplemented with whole ground sunflower and whole ground flax seed. *Filled circles* represent values from dogs fed the flax seed supplement; *open triangles* correspond to those animals fed the sunflower seed supplement. Fatty acid species are as indicated on each plot; values are relative % ± SD; letters *a* and *b* each indicate a statistically significant difference between diet groups for the same fatty acid at time points indicated, $p < 0.05$

canines [34, 35]. Taken together, these findings indicate that this fatty acid, and perhaps 22 carbon fatty acids in general, may not be preferred substrates for cholesterol esterification via reverse cholesterol transport as mediated by the LCAT enzyme. Also because no appreciable accumulation of DHA occurred in the CE fraction with flaxseed feeding, this fatty acid is apparently seen only in the presence of a sufficient preformed dietary source. Given that DHA in human plasma CE is present in low concentrations as well, the importance of this finding in the canine model is that CE-DHA may serve as a potential biomarker of dietary DHA sufficiency in both dogs and humans and should be investigated further.

It is particularly noteworthy that the fatty acid profiles in the present work show differential metabolic enrichment of lipid fractions with the derived n-3 LCPUFA after ALA feeding in the canine. Enrichment of post-absorptive serum PL and TG with DPAn-3 suggests the possibility of transport and delivery of this fatty acid into tissues without its return via reverse cholesterol transport in the CE fraction. We hypothesize that while conversion of DPAn-3 to DHA is slow in dogs, humans, and other species, one-way transport of DPAn-3 via the circulation may serve to physiologically conserve this fatty acid as a substrate for DHA synthesis in tissues such as brain and retina and especially when dietary sources of DHA are scarce. Furthermore, because DPAn-3 is absent in serum CE, such transport may be unidirectional.

Observations relating to the metabolism of n-6 fatty acids in dogs were also made in this study. The significant increase of PL–LA in the FLX group, even at lower total LA dietary content, may be the result of a reported preference of delta-6 desaturase for ALA versus LA [18]. As such, competition between these two fatty acids for conversion to longer chain derivatives may result in LA accumulation providing a sparing effect when ALA is fed. Alternatively, this finding may be a consequence of the reduction of AA in this fraction due not only to n-3 polyunsaturated fatty acid incorporation but also some competition between LA and AA in the process of phospholipid esterification. In any case, this accumulation of LA in fur-bearing animals such as dogs may subsequently participate in skin and hair coat improvements previously observed in canine species fed polyunsaturated fatty acid supplements [36, 37]. Finally, decreased amounts of 22:4n-6 seen with flaxseed supplementation resulted in a statistically significant difference as early as 7 days which remained decreased thereafter. By contrast, a nearly constant amount of PL–AA was seen in the SUN group providing substrate for chain elongation to 22:4n-6. Competition between n-3 and n-6 fatty acids for incorporation into the serum PL pool may have made more AA available for 22:4n-6 synthesis thereby resulting in the modest increase in this fatty acid species. Such AA chain elongation may, in part, help minimize the accumulation of excessive amounts of AA in cell membranes for eicosanoid synthesis when high n-6 diets are fed.

Overall, the results of this study have demonstrated that aspects of canine fatty acid metabolism are more similar to humans than rodent species and thus offer a useful model for investigations in several areas including not only cardiac arrhythmia studies but also spontaneous models of

carcinogenesis and cognitive decline which develop more rapidly due to shorter canine life spans. One direct finding of relevance to human health from this study is the potential for CE-DHA as a biomarker of DHA status for human health. Furthermore, establishment of a metabolic steady state with respect to serum fatty acid accumulation appeared as early as 28 days Knowledge of these phenomena permits future investigations of the canine model, where appropriate, to take advantage of shorter term feeding studies in which a metabolic steady state is desired given the expense and sometimes ethical concerns with this species.

Abstract Based on mechanistic and epidemiological data, we raise the question of the relationship between qualitative dietary polyunsaturated fatty acids (PUFA) changes and increase in obesity. In this double-blind trial, we studied the effects on 160 overweight volunteers (body mass index, BMI >30) of a 90 days experimental diet rich principally in animal fat with a low PUFA/saturated fatty acid (SFA) ratio but a low n-6/n-3 ratio, using animal products obtained from linseed-fed animals. The control diet provided less animal fat, a higher PUFA/SFA ratio and a higher n-6/n-3 ratio. Both diets excluded seafood. In the experimental group, we observed a significant increase in red blood cell (RBC) α-linolenic acid content and a slight increase in EPA and DHA derivatives, while in the control group we observed a significant reduction in EPA and DHA content. Between groups now, the difference in the three n-3 fatty acids changes in RBC was significant. This demonstrates that plasma EPA and DHA levels can be maintained without fish if products from linseed-fed animals are used. During the diets, we noted a significant reduction in weight, BMI and hip circumference within both groups of volunteers. However, no significant difference was observed between the control group and the experimental group. Interestingly, 150 days after the end of the trial (i.e., day 240), we noted a significant weight gain in the control group, whereas no significant weight gain was observed in the experimental group. This was also observed for the BMI and hip circumference. Moreover, significant differences in BMI ($P < 0.05$) and weight ($P = 0.05$) appeared between the two groups, showing in both cases a smaller increase in the experimental group. During the 90 days trial, we did not observe any differences between groups in terms of total cholesterol, HDL cholesterol, LDL cholesterol or triglycerides, suggesting that the saturate content and the P/S ratio are not as important as the n-6 and n-3 fatty acid composition.

Keywords n-3 Fatty acids · Linseed · Red blood cell · Fatty acid composition · Obese

Abbreviations

BMI	Body mass index
PUFA	Polyunsaturated fatty acids
FA	Fatty acid
SFA	Saturated fatty acid
LNA	Linoleic acid
ALA	α-Linolenic acid

Introduction

In only a few decades, obesity has become a major health concern, which also increases the risk of type 2 diabetes

and cardiovascular disease. Obesity is a multifactorial disease. Excessive adipose tissue development is primarily due to an imbalance between caloric intake and caloric expenditure, this imbalance being related to changes in dietary habits and to more sedentary lifestyles. However, in addition to the energy imbalance, different aspects of lipid metabolism such as lipid synthesis, transport, storage and catabolism are also implied in obesity development. Amongst nutrients involved in this metabolism, all fatty acids play obviously a major role from a quantitative point of view, but polyunsaturated fatty acids (PUFA) may also play a qualitative role, which is less well established. Indeed, recent data show that PUFA from the n-6 or n-3 series do not play identical roles. While n-6 PUFA are now well known as activators of adipose tissue development [1] and their dietary excess is suspected to favor childhood adiposity [2] and adult adiposity [3–5], n-3 PUFA seem to play a more favorable role, acting against different mechanisms leading to obesity. Thus in humans, n-3 PUFA seem somewhat to limit metabolic syndrome and type 2 diabetes [6–8]. A negative correlation has been described between abdominal obesity and n-3 PUFA content of adipose tissue [9]. Moreover, n-3 fatty acid intake limits fat accumulation in mice [10] and rats [11].

The fatty acid (FA) composition of the diet has changed significantly since the 1960s, when obesity began to increase. The first change was the increase in the PUFA/(saturated fatty acid) SFA ratio, due to the increase in consumption of vegetable oils rich in PUFA rather than animal fat which are richer in SFA. The second change was the subsequent increase in n-6 PUFA content, while n-3 PUFA content decreased or remained constant. This is due to the very high levels of n-6 PUFA in the most common vegetable oils (soybean, corn, sunflower, etc.) used in human nutrition as well as in animal feeds. Consumption data show that the linoleic acid (LNA) to α-linolenic acid (ALA) ratio increased by approximately three times to reach a range of 12–25 in most of the western diets during this period [12, 13]. These dietary ratio values are consistent with other values in humans, measured in breast milk [14, 15] and in subcutaneous adipose tissue [16, 17].

Thus, based on both mechanistic and epidemiological data, we raise the question of the relationship between these qualitative changes in dietary PUFA and increase in obesity, and more precisely when the increase in the dietary PUFA/SFA ratio is always associated with a large increase in the dietary n-6/n-3 FA ratio.

In this double-blind trial, we studied the effects on volunteers of a 90 days experimental diet rich in animal fat with both low PUFA/SFA and low n-6/n-3 ratios, using principally animal products obtained from linseed-fed animals. The control diet provided less animal fat, a higher value for the PUFA/SFA ratio and a higher value for the n-6/n-3 ratio. The volunteers were overweight or obese (body mass index, BMI $\approx$ 31). The main results were: (1) Plasma EPA and DHA levels can be maintained without fish, if using products from linseed-fed terrestrial animals. (2) During the diets, we noted a significant reduction in weight, BMI, and hip circumference within both groups of volunteers, but no significant difference was observed between the control group and the experimental group. However, the experimental diet limited weight recovery after the end of the trial. (3) No comparative deleterious effect (on plasma lipid parameters) was observed between diets, suggesting that the n-6/n-3 ratio is as important as the SFA level.

Materials and Methods

Volunteers

One hundred and sixty volunteers with metabolic syndrome (78 men and 82 post-menopausal women) between 18 and 65 years old were selected from those responding to local press recruitment (293 volunteers were evaluated). Inclusion criteria were waist circumference $\geq$80 cm for women and $\geq$94 cm for men, plus at least two other risk factors: triglycerides (TG) $\geq$1.5 g/l; fasting plasma glucose (FPG) $\geq$1.0 g/l; HDL cholesterol $\leq$0.4 g/l for men and $\leq$0.5 g/l for women; systolic blood pressure (BP) $\geq$130 mmHg; diastolic BP $\geq$85 mmHg or treatment for hypertension. The average body weight, BMI and hip circumference were respectively, 88.5 $\pm$ 15.6 kg, 31.5 $\pm$ 4.3 kg/m^2 and 109 $\pm$ 7.6 cm. Exclusion criteria included diabetes, any treatment for hypercholesterolemia and any disease judged incompatible with the study by the investigator. During a visit, the purpose and method of the study was explained to the selected volunteers; written informed consent was obtained from those willing to participate and a prescription was given. Inclusion and exclusion criteria were checked during a medical visit. The proposed diets were then explained to the volunteers and some menu examples were given to help them to adhere to the nutritional advice given during an individual consultation with a dietitian. The diets were given to volunteers from day 0 to day 90. At day (D) 90, 137 volunteers remained in the trial: 72 in the experimental group and 65 in the control group. The others decided to stop the trial between D0 and D90. All statistical analyses at D90 were carried out with these 137 volunteers. At day 240, 98 volunteers (72%) came back for the last anthropometric measurements: 50 in the experimental group (69%) and 48 in the control group (74%).

Study Design

Subjects were randomly assigned to one of two different diets. As regards animal products, the experimental diet included products with a high level of n-3 originating from linseed-fed animals while the control group diet included standard animal products. The feeds of animals that supplied the experimental products (dairy products, meats and eggs) contained an average of 5% of extruded linseed and are described in details in other publications [18]. As regards plant products, the experimental group volunteers received 5 g/day of extruded linseed flour, while the control group volunteers received the same amount of extruded wheat/soybean (90/10) flour. Moreover, the experimental group's bread included 4% extruded linseed flour. In the experimental diet, flour plus bread represent 40% of the total ALA intake while animal products provide long-chain derivatives (EPA plus DHA), and account for 60% of ALA. The control group volunteers received margarine with a high n-6 content (rich in sunflower oil) instead of the butter that the experimental group received.

The macronutrient content of the two diets was similar. The overall composition and energy intake of the two diets did not differ. The proposed energy intake was 1,667 kcal for women and 1,931 kcal for men. Subjects were asked not to consume any fish or seafood products or products containing more than 5% fat. Products containing linseed or products with a high n-3 content were also forbidden. The only authorized oil was olive oil (10 g a day). Male and female diets only differed by the amount of carbohydrates and meat (+50 g and +40 g for men, respectively).

The fat spread was butter for the experimental group and margarine for the control group, which mainly explains the difference in the proportion of lipids of animal origin between the two diets. The recommended weekly intake of eggs was ten. Sugar (sucrose) was requested to be reduced or excluded from the diet in order to reduce total calorie intake and reduce weight.

Subjects undertook an adjustment period of 2 weeks during which they had to follow the prescribed diet, consuming their own usual products (usual meats, eggs, dairy products, and fat spread). Afterward, at day 0, experimental or control products were provided for the whole family. They were delivered every week to a local shop where subjects collected them, presenting their volunteer card. Compliance was verified by checking the collection of the products with the help of local shop managers. Each member of the family was given 1,050 ml of milk, 10 eggs, 250 g of fat spread, 210 g of hard cheese, 7 slices of ham, 50 g of diced bacon fat, 2 sausages, 2 loaves of bread, 2 pork chops plus occasionally beef, chicken or veal. Small quantity adaptations were necessary according to the number of persons in the family and the packaging size. Flour (linseed or wheat/soybean) were provided for the volunteers only and not for the whole family.

During the experimental period, from D0 to D90, the volunteers met a dietitian to receive nutritional advice at least once a month. Compliance with the diet was evaluated by weekly recording of consumption. From D90 to D240, the volunteers returned to a free diet with the reintroduction of fish and previously forbidden products and had no visits with any member of the dietitian's team.

Anthropometry and Assays

The following anthropometric and plasma lipids parameters were measured at the hospital at D0 and D90: body weight and BMI were measured by TANITA TBF 300 MA, and hip circumferences were measured with an automatic rubber band. Blood lipids (total cholesterol, HDL cholesterol and triglycerides) were analyzed with an enzymatic technique using Advia1650-Siemens, and LDL cholesterol was calculated by the Friedwald formula [19]. After the end of the trial (D90), volunteers were requested to come back 5 months later (D240) for additional anthropometric measurements only.

Lipid Extraction and Fatty Acid (FA) Analysis

RBC lipids were extracted from 0.5 ml of samples with a mixture of hexane/isopropanol (3:2 v/v), after acidification with 1 ml HCl 3 M [20]. Total lipid extracts were saponified for 30 min at 70 °C with 1 ml of 0.5 M NaOH in methanol and methylated with 1 ml BF_3 (14% w/v in methanol) for 15 min at 70 °C. Fatty acid methyl esters were extracted twice with pentane and analyzed by GC using an Agilent Technologies 6890N (Bios Analytic, Toulouse, France) with a split injector (20:1) at 250 °C and a bonded silica capillary column (BPX 70, 30 m × 0.25 mm; SGE, Villeneuve-St Georges, France) with a polar stationary phase of 70% cyanopropyl polysilphenylene-siloxane (0.25 µm film thickness). Helium was used as a carrier gas (average velocity 24 cm/s). The column temperature program started at 150 °C, increased by 2 °C/min to 220 °C and held at 220 °C for 10 min. The flame ionization detector temperature was 250 °C. Identification of FA methyl ester was based on retention times obtained for FA methyl esters prepared from FA standards.

Statistical Analysis

Analyses of covariance, with terms for the treatment group and the baseline value were used to compare least square means and to test for differences in baseline to endpoint changes between treatments. Paired *t*-tests are also performed within each treatment group. Different analyses

were performed using stratifications by sex and the value of each metabolic syndrome risk factor. All analyses were conducted using SAS® version 8.2. The study was designed as an intend-to-treat analysis. The difference was considered significant when $P < 0.05$ and a tendency when $0.05 < P < 0.10$.

Results

Effects of Changes in Animal Feeding on Animal Products Composition and on FA Composition of Volunteers Diets

The main lipid sources used in the volunteers' diets are shown in Table 1. In the two diets, lipids provided 33% of the total caloric intake. Animal products used in the experimental diet originated from animals fed 5% extruded linseed, which provides C18:3n-3 (ALA) to the animals. In the control diet, animal products came from standard French breeding farms. This variable fraction represents 77% of the volunteers' lipid intake. The diets given to the volunteers are described in Tables 2 and 3. The real consumption of each volunteer is not known very precisely as meals were taken at home. The two diets were iso-caloric and iso-lipidic. In addition to the animal lipids presented above, margarine was used in the control diet. This margarine is a commercial product, the composition of which is close to the composition of French lipid intakes (Table 1). The experimental diet was rich in animal lipids (76% of total lipids). It provided high levels of n-3 PUFA, (not only ALA but also long-chain derivatives EPA and DHA) and low levels of n-6 PUFA. 40% of ALA is provided by linseed flour plus bread, in the experimental diet. Compared with the experimental diet, the control diet was richer in plant lipids (animal fats provided only 49% of lipids) and was richer in total PUFA (17.3 vs. 9.1 g/day in the experimental diet). Moreover, LNA content was much higher in the control diet (16.0 vs. 5.5 g/day in the experimental diet). As a result, the following ratios were very different between the two diets: PUFA/SFA values were 0.7 in the control diet versus 0.3 in the experimental diet, and C18:2n-6/C18:3n-3 values were 22.9 in the control diet versus 2.3 in the experimental diet.

Change in Volunteers' RBC FA Composition

The two diets produced clear changes in the content and ratios of numerous FAs in the RBC (Table 4). For n-3 PUFA, we observed in the volunteers receiving the experimental diet (animal products from linseed-fed animals plus a small amount of linseed flour and bread) a significant increase in ALA content between day 0 and day 90 and a significant increase in the total n-3 fatty acids. In the control group of volunteers, no effect was observed as regards ALA content, but the EPA and DHA content and total n-3 fatty acids decreased significantly. Between groups, the differences in the ALA, EPA and DHA changes (D90-D0) were significant.

Table 1 Fatty acid (FA) composition (% of total FA) of main lipid sources given to volunteers

[d] Fatty acids from industrial products, starchy vegetables and fruits (no qualitative difference between both groups)

[e] Consumption of fish and seafood products was prohibited during the experiment

* Products in the standard group were standard products, while products in the experimental group came from (1) animals (beef, chicken and pork) fed a linseed-enriched diet (5% of cooked linseed) or (2) linseed-enriched bread (5% of cooked linseed)

The n-6 PUFA content increased between D0 and D90 in the RBC of the control group, the increase being significant for LNA and for total n-6 fatty acids, but not significant for arachidonic acid (C20:4n-6). In the experimental group, we did not observe any significant change in the n-6 fatty acid content of the RBC. Between groups, the difference in the LNA and total n-6 fatty acid changes (D90–D0) was significant.

We noted also that the LNA/ALA ratio increased significantly in the control group and decreased significantly in the experimental group. The difference in changes between groups was also significant. This was equally true for the Σn-6/Σn-3 ratio.

More generally, the total PUFA content increased significantly in the control group and did not change in the experimental group. Furthermore, an increase in stearic acid content was noted in the experimental group, whereas oleic acid content was reduced in both groups.

Changes in Anthropometric Parameters

From D0 to D90, i.e., over the period of the diets, we noted a significant reduction in weight, BMI, and hip circumference in both groups of volunteers (Table 5). However, no significant difference was observed between the control group and the experimental group. Interestingly, from D90 to D240, i.e., after the end of the trial, we noted a significant weight gain in the control group, whereas no significant weight gain was observed in the experimental group. This was equally true for the BMI and hip circumference, which both increased solely in the control group. Between the two groups, from D90 to D240 we showed a significant difference for the BMI ($P < 0.05$), and a difference at the limit of significance for weight ($P < 0.06$), showing in both cases a smaller increase in the experimental group.

Changes in Plasma Lipid Parameters

These parameters were studied at D0 and D90. In Table 6, we first observed within each of the two groups a general deterioration in all the parameters, with an increase in LDL cholesterol in both groups and an increase in TG in the experimental group. However, the main result was that no significant difference between the groups was noted in total cholesterol, HDL cholesterol, LDL cholesterol or triglycerides over the period from D0 to D90. These parameters were not measured at D240. This is an interesting and novel result when considering the dietary characteristics

Table 3 Estimation of the mean fatty acid consumption by volunteers (g/volunteer/day)

other than the n-3 fatty acids. Indeed, the high level of SFA (44% fatty acid = 14.6% energy) in the experimental diet did not lead to any deleterious effect on plasma lipid parameters, as compared with the control diet (35% fatty acid = 12% energy). Moreover, the experimental diet was also low in n-6 fatty acids (8.2 vs. 23.6% fatty acid), low in total PUFA (13.1 vs. 25.2% fatty acid) and none of these characteristics caused any deleterious effect on the plasma lipid parameters.

Discussion

The fatty acid content of RBC is considered to be a tissue marker for dietary fatty acid composition [21, 22]. The first result of this study is the increase in the ALA content of RBC in the experimental group, whereas it did not vary in the control group. This increase in ALA is mainly due to the dietary animal products obtained from linseed-fed animals but also from linseed flour and bread included in the experimental diet. All together the ALA supply was about 2.4 g/day, which is a little higher than the French recommended intake [23]. We noted in the control group that ALA intake corresponded to the French average consumption [13, 17] and that this intake was sufficient to maintain its levels in the RBC during the study. More interesting is the effect of the diet on EPA and DHA content in the RBC. These contents decreased significantly

in the control group, whereas they were maintained in the experimental group. Maintaining the EPA and DHA levels in the RBC in the experimental group, without consuming fish and other seafood during the trial, constitutes the major result of this study. This demonstrate the efficiency of the terrestrial animal vector for providing EPA and DHA to humans, when the animals receive small amounts of the precursor ALA alone (linseed-fed animals). This can be mainly explained by the direct intake of EPA + DHA contained in the animal products of the experimental diet (Table 3), since these derivatives are synthesized from ALA by the linseed-fed animals during their growth. In addition, it is likely that low conversion of ALA to EPA + DHA also took place in the volunteers during the trial, but conversion in humans is known to be very low to EPA, and extremely low (less than 0.5% ALA) to DHA [24](for a review on ALA conversion and supplementation). Moreover, for these reasons, ALA provided by flour and bread in the experimental diet, could account only modestly for EPA synthesis and not for DHA synthesis, in volunteers.

Before the trial, the volunteers consumed a varied diet including fish and other seafood, and were recruited in a marine area (large fishing harbor) where a high consumption of n-3 fatty acids from fish and other seafood was described in a previous study [25]. Although fish and other seafood remain the main source of n-3 derivatives (EPA + DHA) for the population, the supplies of fish are limited whereas people have been encouraged to increase their intake [26]. We show here that improving the feeds of terrestrial animals by incorporating linseed is quantitatively capable of maintaining the EPA and DHA levels in the RBC of a population. In an earlier study, only EPA was increased by a similar experimental diet [18], but this previous study was performed with healthy volunteers exhibiting a high level of DHA in the RBC (4.8%), whereas the present study was performed with obese subjects having only 2.6% DHA in the RBC. This low level of DHA observed here also suggests a low DHA consumption by obese volunteers or a reduced conversion of α-linolenic precursor or even a higher catabolism (β-oxidation) of this fatty acid, and raises the question of larger requirement of n-3 to maintain tissues in obese. Finally, we showed here a decrease in EPA and DHA derivatives in the control group, suggesting (at least in the absence of fish consumption) that the average ALA intake in France is not sufficient to maintain correct EPA + DHA levels by ALA conversion alone, especially with a high dietary LNA/ALA ratio .

As regards n-6 fatty acids, we observed an increase in LNA content in the RBC of the control group, which reflects the control diet, characterized by standard animal products and sunflower-margarine. This increase inside the control group explains the significant difference observed for LNA between the two groups, since no significant change in LNA content was observed inside the experimental group. Although the dietary LNA content was three times lower in the experimental group than in the control group, it was sufficient to maintain the LNA and arachidonic acid levels in the RBC.

One of the goals of this work was: to evaluate the effect of the experimental diet, rich in n-3 fatty acids, on various anthropometric parameters of obesity. The results showed clearly that the volunteers from both groups lost weight and that no significant difference of weight was observed between the two groups over the period of the diets. This is probably due to the fact that both diets were normo-caloric; in other words probably hypo-caloric (for obese individuals) when compared with the diet consumed before the trial. This suggests that the reduction in caloric intake may have masked any qualitative effects relating to the diet's fatty acid composition. However, the results obtained at day 240 (in only 72% of the day 90 population) showed a weight gain in the control group, whereas no weight gain was determined in the experimental group. This interesting result suggests that the experimental diet, provided between day 0 and day 90, was able to limit the weight gain recovery. The changes in BMI and hip circumference confirmed the effect on weight, between day 90 and day 240, within the groups. Between groups, the BMI was significantly lower at day 240 in the experimental group and weight tended to be lower in the experimental group than in the control group. Our results suggest that n-3 fatty acids may have several metabolic effects. More precisely, we can suppose that the enrichment of the tissues in n-3 fatty acids improves various metabolic syndrome parameters, which is consistent with the literature [10, 11, 27–29], and reduces the weight gain recovery phenomenon. One can also suggest a different energy expenditure, implying membrane processes, which are known to be modulated by membrane fatty acid composition [30, 31]. A very recent study showed that plasma n-3 PUFA were negatively associated with obesity [32]. Finally, we can also suppose that the high n-6 fatty acid levels in the control diet could also explain the difference between groups, since LNA is considered to be very adipogenic [1, 4, 5]. Moreover, the weight gain observed in the control group is in good agreement with the work by Dayton et al. [3] showing an even stronger effect but with longer exposure to the same type of diet rich in LNA. In any case, the n-6/n-3 balance seems to be involved, whereas the proportion of saturated fatty acids does not appear to be a determinant of weight gain, since the experimental diet was the richest in saturated fatty acids. Lastly, observing the inhibiting effect on weight gain recovery in the long term after the end of the trial is a new and very interesting observation, since this long-term period is frequently subject to dramatic weight recovery as is often described in the literature in humans [33]. However, the effects reported here on anthropometric parameters at D240 can be considered only as preliminary results for further investigations.

Finally, we studied the plasma lipid parameters in the volunteers. Surprisingly, the plasma lipid parameters tended to worsen within each group although volunteers lost weight. In the literature, weight loss generally improves plasma lipid parameters [34–37] but this occurs after caloric restriction, which is not the case in the present study. However, our results suggest at least that content and duration of both diets are unable to stop the lipid parameter evolution in obese persons. Interestingly, between groups, we observed no significant difference in total cholesterol, HDL cholesterol, LDL cholesterol or triglycerides during the trial (D0–D90). In other words, the experimental diet was much richer in saturated fatty acids, but did not alter the plasma lipid parameters during the 90 days as compared with the control group. This suggests that the level where saturated fatty acids are deleterious remains to be determined and probably should be re-evaluated [38], depending on the diet composition in n-3 and n-6 PUFA. If we consider the PUFA/SFA ratio, the experimental diet exhibited the lower value, without any deleterious effects on the plasma lipid parameters (as compared with the control diet), which is in good agreement with a previous work with different values of the PUFA/SFA ratio in humans [39]. This suggests that the PUFA/SFA ratio is less relevant than the balanced composition of the experimental diet in both n-6 and n-3 fatty acids, as compared with the excess of n-6 fatty acid in the control diet. Finally, the results in terms of plasma lipid parameters also suggest that a diet containing 76% animal lipids (experimental diet) does not appear to be more deleterious than a diet containing 49% animal lipids only (control diet).

Dietary Source of Stearidonic Acid Promotes Higher Muscle DHA Concentrations than Linolenic Acid in Hybrid Striped Bass

Anant S. Bharadwaj · Steven D. Hart · Billie J. Brown · Yong Li · Bruce A. Watkins · Paul B. Brown

Received: 29 June 2009 / Accepted: 30 October 2009 / Published online: 22 November 2009

Abstract Rapid expansion of aquacultural production is placing increasing demand on fish oil supplies and intensified the search for alternative lipid sources. Many of the potential alternative sources contain low concentrations of long chain n-3 fatty acids and the conversion of dietary linolenic acid to longer chain highly unsaturated fatty acids is a relatively inefficient process in some species. A 6-week study was conducted to compare tissue fatty acid (FA) concentrations in hybrid striped bass fed either 18:3n-3 (α-linolenic acid; ALA) or 18:4n-3 (stearidonic acid; SDA). Hybrid striped bass were fed either a control diet containing fish oil, or diets containing ALA or SDA at three different levels (0.5, 1 and 2% of the diet). There were no significant differences in whole animal responses between fish fed ALA or SDA. Liver and muscle concentrations of ALA and SDA were responsive to dosages fed. However, only 22:6n-3 concentrations in muscle were significantly affected by dietary source of 18 carbon precursors. Muscle 22:6n-3 concentrations were significantly higher in fish fed SDA compared to fish fed ALA. Based on these data, it appears that feeding SDA can increase long chain n-3 fatty acid concentrations in fish muscle.

Introduction

A significant proportion of the global fish oil supply is used as a dietary lipid and fatty acid (FA) source for propagation

of aquatic animals [1]. The rapid increase in aquacultural production and the associated demand for fish oil may create a shortage of this commodity in the near future. The supply of lipid sources from oilseed crops is larger than the supply of fish oil and regarded as a logical choice for replacing fish oil, either partially or completely, in dietary formulations [2]. Plant-derived lipid sources have been fed to fish without significantly compromising growth or health, but their use has generally resulted in lower muscle concentrations of n-3 fatty acids, thereby reducing the potential health benefits to humans from the consumption of fish [2, 3]. Terrestrial plant-based lipids contain relatively high concentrations of linoleic acid (18:2n-6), oleic acid (18:1n-9) and to a lesser extent, linolenic acid (ALA; 18:3n-3), and do not contain long chain highly unsaturated fatty acids of the n-3 family (LC-n-3 HUFA; ≥20 C) [4].

Fish are unable to synthesize either linoleic or ALA acid and have a dietary requirement for n-3 and/or n-6 FA [5]. Turchini et al. [5] recently reviewed most of the published data on EFA requirements in fish and concluded that, in general, marine fish require a dietary supply of LC-n-3 HUFA such as 20:5n-3 (eicosapentaenoic acid; EPA) or 22:6n-3 (docosahexaenoic acid; DHA), whereas species with a freshwater life history stage require either ALA, ALA and 18:2n-6 or only 18:2n-6 to satisfy their essential fatty acid (EFA) requirements [5–7]. The n-3 family remains a focal point for research efforts because they can have significant impacts on human health. ALA is metabolized through a series of desaturation and elongation reactions to form long chain n-3 HUFA. In the first step, ALA is converted to 18:4n-3 (stearidonic acid; SDA) by the action of Δ6 desaturase, which is considered an inefficient and rate limiting process in vertebrates [8–10]. Providing a dietary source of SDA might be a viable method of increasing n-3 FA concentrations in fish [11].

Metabolism of n-3 FA varies among fish species. Marine fish such as gilthead seabream *Sparus aurata*, turbot *Scophthalmus maximus*, golden gray mullet *Liza aurata* and European sea bass *Dicentrarchus labrax* have limited ability to convert 18 C FA to LC-n-3 HUFA [12–17]. Freshwater fish, or those with a freshwater life history stage, such as tilapia *Oreochromis niloticus*, zebrafish *Danio rerio*, brown trout *Salmo trutta*, rainbow trout *Oncorhynchus mykiss*, and Atlantic salmon *Salmo salar* are able to elongate and desaturate ALA to EPA and DHA [12, 13, 18–21].

Stearidonic acid has been evaluated in both mammals and fish. In humans, ingestion of SDA increased plasma and erythrocyte EPA and 22:5n-3 (docosapentaenoic acid; DPA) [22]. In rats fed SDA, an increase in liver and plasma EPA was observed [9], whereas in mice an increase in plasma and splenocyte 20:4n-3 (eicosatetraenoic acid; ETA), EPA, and DHA concentrations were reported [23]. Similarly, increases in red blood cell and heart EPA concentrations were observed in beagles fed SDA [24]. In turbot and Atlantic salmon cell lines, SDA was metabolized to EPA and DPA, with only low concentrations of DHA being formed [25, 26]. Echium oil, a rich source of SDA, has been fed to Atlantic cod *Gadus morhua*, Arctic charr *Salvelinus alpines*, and Atlantic salmon, but the comparisons were with fish oil [27–29]. There does not appear to be a formal comparison of ALA to SDA as a source of n-3 FA in fish.

The hybrid striped bass is a cross between the anadromous striped bass and strictly freshwater white bass with a reported requirement for LC-n-3 HUFA [30]. However, there is little information on n-3 FA metabolism in this hybrid. Lane et al. [31] and Trushenski et al. [32, 33] reported effects of feeding various lipid sources on fillet composition over time and effects on various lipid classes, but there have been no reports of feeding selected n-3 precursors and resulting downsteam effects on LC-n-3 HUFA. We hypothesized that the hybrid striped bass would efficiently use SDA as a source of n-3 FA as both parental species have a freshwater life history stage and this hybrid might be a good model for formal comparison of ALA to SDA. Specific objectives were to: (1) determine if dietary SDA would promote higher concentrations of LC-n-3 HUFA than dietary ALA; and, (2) determine if high dietary concentrations of SDA and ALA would promote increased tissue retention of n-3 HUFA.

Experimental Procedures

Fish Husbandry

Juvenile hybrid striped bass (*Morone saxatilis* × *M. chrysops*) were obtained from Keo Fish Farms (Keo, AR, USA), and transported to the Purdue University Aquaculture Facility. Procedures used during transport, quarantine, and the experimental period were approved by the Purdue Animal Care and Use Committee. Fish were acclimated to laboratory conditions for 10 weeks before being used in the study and fed a commercial diet during that period (Nelson and Sons, Murray, UT, USA).

A semi-closed, recirculating system comprising 32 individual, 190-L aquaria were used in this study. Each aquarium was constantly aerated via an airstone connected to a regenerative blower. The experimental system was equipped with four submerged filtration tanks for solid material removal and a submerged biological filtration tank for oxidation of nitrogenous waste products. Water was pumped through a sand filter to each aquarium at a rate of ~4 L/min. Water temperature was maintained at 26 ± 1 °C during the study.

Groups of 10 fish were randomly stocked into individual aquaria and acclimated to the experimental system for 2 weeks prior to the experiment. Fish were fed a commercial diet (Nelson and Sons, Murray, UT, USA) for the first week and their respective experimental diets for 1 week thereafter. Triplicate groups of fish were randomly assigned a dietary treatment. Fish were fed to satiation twice daily during both the acclimation and experimental portions of the study. Before the start of the study, the number of fish per tank was reduced to five. The average initial weight in each tank was 208 g/fish. Water quality was monitored daily throughout the study and maintained within acceptable limits. Ammonia- and nitrite-N concentrations did not exceed 0.5 and 0.05 mg/L, respectively. Dissolved oxygen concentrations did not fall below 7 mg/L. The study was conducted for 6 weeks.

Diets

The basal diet was formulated to contain 40 g/100 g crude protein and 10 g/100 g lipid. All diets contained 400 g/kg solvent extracted, dehulled soybean meal, 150 g/kg corn gluten meal, 150 g/kg fish meal, 100 g/kg ground, whole wheat, 20 g/kg mineral premix, 30 g/kg vitamin premix, 1 g/kg ascorbyl-polyphosphate, 1 g/kg choline-Cl, 10 g/kg soybean lecithin, and 38 g/kg α-cellulose. Seven different experimental diets were formulated by varying the dietary lipid source (Table 1). The control diet contained 10 g/100 g menhaden oil and the remaining diets contained either flaxseed oil as a source of ALA (55% wt:wt) or a purified source of SDA (60% ethyl ester, wt:wt) at 0.5, 1 and 2 g/100 g of the diet. High-oleic acid safflower oil was used to balance the lipid content of the ALA and SDA containing diets.

Stearidonic acid, flaxseed oil, and high-oleic safflower oil were obtained from commercial producers (K. D. Pharma Bexbach GmbH, Bexbach, Germany; U.S. Soy, Mattoon, IL, USA; and, Oilseeds International, San Francisco, CA, USA, respectively). Soybean meal, and fish meal were obtained from the Purdue University Animal Sciences Research and Education Facility Feed Mill (Montmorenci, IN, USA). Corn gluten meal, menhaden oil, and flax oil were obtained from commercial suppliers (A. E. Staley Mfg. Co., Lafayette, IN, USA; Omega Protein, Reedville, VA, USA; and, U.S. Soy, Mattoon, IL, USA, respectively). L-ascorbyl polyphosphate (a source of vitamin C, 35% active ingredient) was obtained from Roche Inc. (Nutley, NJ, USA). Vitamin (U.S. Fish and Wildlife Service #30) and mineral (U.S. Fish and Wildlife Service #3) premixes were obtained from feed manufacturers (Zeigler Bros., Inc., Gardners, PA, USA, and Nelson and Sons, Inc., Murray, UT, USA, respectively). All diets used in this study were manufactured at the Purdue University Aquaculture Facility [34]. Dry ingredients were mixed in a V-mixer (Patterson-Kelley, East Stroudsburg, PA, USA), then transferred to a Hobart mixer (Hobart Corporation, Troy, OH, USA) and mixed with water and lipid. Choline chloride was dissolved in water and mixed into each of the diets [35]. Diets were adjusted to pH 7 ± 0.2 with saturated sodium hydroxide. Diets were pelleted with a 3.1-mm die attached to the Hobart mixer. The resulting strands were chopped into pellets of uniform length and air dried for 72 h. The dried diets were sealed in airtight bags, flushed with nitrogen gas and stored at −20 °C.

Sample Collection

At the end of 6 weeks, fish were euthanized with tricaine methanosulfonate (Argent Chemicals, Redmond, WA, USA) and weighed. The final weights of fish were used along with initial weights to calculate weight gain over the duration of the study. Three fish from each replicate were weighed and livers and intraperitoneal fat (IPF) dissected and weighed. Muscle samples were collected from the region below the dorsal fin, ~1 cm anterior to the center of the fish.

Livers and IPF weights were used to calculate relative liver weights (RLW) and IPF ratio, respectively. Muscle and liver samples were stored in polyethylene bags containing water. All sample bags were flushed with nitrogen gas, sealed and stored at −20 °C. All fatty acid analyses were completed within 4 weeks of sample collection.

Lipid Extraction and Fatty Acid Analysis

Diet, liver, and muscle samples were homogenized in a 2:1 chloroform–methanol solution and lipids extracted [36]. Total lipids were then saponified and fatty acid methyl esters (FAME) synthesized by esterification with boron trifluoride (BF_3) in methanol (14% w/v; Supelco, Bellfonte,

Table 1 Lipid composition of experimental diets (g/kg) fed to hybrid striped bass

Ingredient	Control	ALA0.5	ALA1	ALA2	SDA0.5	SDA1	SDA2
Menhaden oil	100						
High oleic safflower oil		90.9	81.8	63.6	91.6	83.2	66.4
Flaxseed oil (55% ALA)		9.1	18.2	36.4			
Stearidonic acid (60% SDA)					8.4	16.8	33.6

PA, USA). These FAME were analyzed using a GC (Agilent 6890 Series GC System, 7683 Series Injector; Agilent Technologies, Palo Alto, CA, USA), equipped with a DB-23 column (30 m, 0.53 mm i.d., 0.5 μm film thickness; J&W Scientific, Folsom, CA, USA). The GC was operated at 140 °C for 2 min and temperature was increased 1.5 °C/min to 198 °C and held for 7 min. Helium was used as carrier gas. The injector and FID temperatures were 225 and 250 °C, respectively. The FAME were identified by comparison of retention times with those of pure standards (GLC-422, GLC-87, GLC-68A, GLC 76; Nu-Chek-Prep, Elysian, MN, USA) and FAME prepared from menhaden oil. The fatty acid composition of total lipids in diets was determined as described above. The fatty acid composition of diet, liver and muscle samples was identified in terms of area % and reported as g/100 g of fatty acids in lipids.

Statistical Analysis

All data were analyzed as both an unbalanced (with control diet) and balanced (without control diet) 2 × 3 factorial design using each aquarium as the experimental unit and dietary treatment as the independent variable. All tabular presentations were of the balanced statistical analysis with designated symbols indicating differences between fish fed the control diet and those fed the experimental diets. All percentage data were arc sine transformed prior to analysis [37]. All data were subjected to two-way ANOVA using Statistical Analysis System release 8.0 Software (SAS Institute, Cary, NC, USA). Main effects were dietary fatty acid type and dietary fatty acid level. If significant differences were detected, Student–Newman–Keuls test was used to separate means. Differences were considered significant at $p < 0.05$.

Results

Relatively low concentrations of ALA and SDA (1.6 and 1.7 g/100 g total lipids, respectively) were found in the control diet (Table 2). The ALA and SDA diets both contained lower concentrations of saturated fatty acids than the control diet, but contained higher concentrations of monounsaturated fatty acids. The ALA diets (ALA0.5, ALA1 and ALA2) contained 5.2, 10.2, and 20.1 g/100 g ALA, respectively. The SDA diets (SDA0.5, SDA1, and SDA2) contained 5.0, 10.0 and 19.9 g/100 g SDA, respectively.

There were no mortalities during the study. Weight gain, feed intake and feed conversion ratio were not significantly affected by dietary treatment, FA level or the interaction of the two main effects (Table 3). Relative liver weights and IPF ratios were also not significantly affected by dietary treatment, FA level or interaction.

Dietary sources of ALA and SDA significantly affected liver concentrations of ALA and SDA (Table 4) Liver ALA concentrations were significantly higher in fish fed the ALA series of diets and liver SDA concentrations were significantly higher in fish fed the SDA series of diets. Further, increasing dietary concentrations resulted in increasing concentrations in liver samples. Concentrations (and range of mean values) of 14:0 (1.3–1.4), 15:0 (0.1–0.2), 16:1n-7 (2.4–2.6), 17:0 (0.3), 18:0 (3.0–3.4), 18:1n-9 (44.5–47.6), 18:2n-6 (13.8–14.2), 20:1n-9 (1.6–2.0), 20:4n-6 (0.5–0.6), 20:5n-3 (1.8–2.2), 22:5n-6 (0.2), 22:5n-3 (0.6–0.7), 22:6n-3 (4.1–5.3), total monounsaturates (50.7–53.9), total n-6 HUFA (1.4–1.5), the n-6/n-3 HUFA ratio (0.2) and ARA/DHA ratio (0.1) in liver were not significantly affected by dietary lipid source, level or the interaction of the two variables (data not shown). Concentrations (and mean value) of 14:0 (4.2), 16:0 (15.0), 16:1n-7 (7.5), 20:4n-6 (1.3), 20:4n-3 (1.1), 20:5n-3 (7.6), 22:5n-6 (0.5), 22:5n-3 (2.3), 22:6n-3 (23.2), total, n-6 HUFA (2.9), and total n-3 HUFA (0.1) in liver of fish fed the control diet were significantly higher than in fish fed other dietary treatments.

Table 3 Mean initial weight (W_i, g/fish), weight gain (W_g g/fish/6 weeks), feed intake (FI, g/fish/6 weeks), feed conversion ratio (FCR), relative liver weight (RLW), and intraperitoneal fat index (IPF) of juvenile hybrid striped bass fed varying concentrations of linoleic acid (ALA) or stearidonic acid (SDA)

Muscle concentrations of ALA and SDA were significantly affected by the interaction of FA type and level (Table 5). There were no other significant interactions in muscle samples. Mean muscle concentrations of SDA and DHA were significantly higher in fish fed SDA compared to fish fed ALA. There were no other significant affects of FA type. Mean concentrations of ALA and SDA were significantly affected by FA levels in diets.

Mean concentrations (and range of mean values) of 14:0 (1.1–1.5), 15:0 (0.2), 16:0 (16.1–17.5), 16:1n-7 (2.2–3.0), 17:0 (0.2–0.3), 18:0 (4.8–5.5), 18:1n-9 (19.1–24.4), 18:1n-7 (1.5–1.6), 20:1n-9 (0.9–1.1), 20:3n-6 (0.7), 20:4n-6 (2.0–2.2), 20:4n-3 (0.3–0.4), 20:5n-3 (6.6–7.1), 22:5n-6 (0.5–0.6), 22:5n-3 (1.3–1.4), total unsaturates (22.9–23.7), total monounsaturates (27.3–29.9), total n-6 HUFA (3.4–3.6), and the ratios of ARA/EPA and ARA/DHA in muscle samples were not significantly affected by dietary FA source or level (data not shown).

Discussion

These data indicate that feeding hybrid striped bass a dietary source of SDA promotes higher muscle SDA and DHA concentrations than fish fed a dietary source of ALA. Further, concentrations in both liver and muscle were responsive to the dosage fed. However, increases in DHA or other LC-n-3 HUFA were not of the same magnitude as the increases in ALA and SDA. Thus, while the increased DHA concentrations in muscle of fish fed SDA appears consistent with the inefficient rate limiting step associated with the Δ-6 desaturase, there are other factors contributing to LC-n-3 HUFA concentrations in the muscle of hybrid striped bass. This appears to be the first evaluation of a concentrated source of SDA in diets fed to fish compared to a source of ALA; thus, there are no direct comparisons with other studies. However, there are comparisons to in vitro studies.

Atlantic salmon cells treated with SDA contained higher concentrations of SDA, 20:4n-3 and EPA compared to cells that were supplemented with ALA [38]. In a separate study, SDA was metabolized to EPA in both Atlantic salmon and turbot cell lines, but more efficiently in salmon [25]. In both cell lines, only a small amount of DHA was detected, although there was significant production of DPA in both. In another study with Atlantic salmon cell cultures, SDA was converted to EPA and DPA, but not to DHA [26]. The developing picture in fish appears to support the inefficient Δ-6 desaturase step in FA metabolism, but also appears to indicate considerable variation in further metabolism of n-3 FA across species. The Atlantic salmon and hybrid striped bass have qualitatively different FA requirements [39], which may be influencing this comparison.

Mean muscle concentrations of ALA were 1.8, 2.4 and 4.3 g/100 g FA in fish fed the ALA series of diets, respectively and 0.9, 1.1 and 1.3 g/100 g FA in fish fed the SDA series, respectively. Mean SDA concentrations in muscle of fish fed the SDA series of diets were 0.8, 1.4 and 2.8 g/100 g, respectively and 0.8, 0.5 and 0.5 g/100 g FA in fish fed the ALA series of diets, respectively. Thus, differences appear related to dose. It is not known if higher dietary levels of ALA and SDA would promote higher muscle retention of n-3 HUFA and is an area for future study.

Neither dietary fatty acid type nor level significantly affected weight gain, feed intake, FCR, HSI, or IPF in the present study. Similar results have been reported in fish fed echium oil compared to fish and other lipid sources. In Arctic charr fed either fish oil or echium oil, no significant differences in growth, mortality, feed efficiency, or tissue lipids were observed [28]. Similarly, cod fed either fish oil or echium oil did not exhibit significant differences in growth, feed efficiency, RLW, or liver and muscle lipid concentrations [27]. Lipid classes in muscle or liver were not affected by dietary lipid type in cod. In Atlantic salmon parr fed fish oil, echium oil, canola oil or a 1:1 mixture of canola and echium oils, dietary lipid did not significantly affect growth, feed efficiency, feed consumption or RLW [29]. Lipid classes of red and white muscle were also not affected by dietary lipid. However, the FA composition of liver and muscle lipids in these species of fish, as with the hybrid striped bass in the present study, was affected by dietary lipid source. In all previous studies with fish fed echium oil, the comparison was with fish oil and virtually all fatty acids were significantly affected by lipid source, whereas the minority of fatty acids were significantly changed in this study.

Results from our study lead us to speculate that the initial Δ-6 desaturase reaction step may be rate limiting in the metabolism of 18 C FA in muscle of the hybrid striped bass as DHA concentrations are higher when a dietary source of SDA was provided compared to a source of ALA. However, other steps in the elongation and desaturation of SDA appear to be influencing LC-n-3 HUFA concentrations as the dose dependent increases from dietary SDA did not result in dose dependent increases in DHA or any other n-3 FA.

Acknowledgments This study was supported by Purdue Agriculture Research Programs.

ORIGINAL ARTICLE

Mitochondrial Cholesterol Transporter, StAR, Inhibits Human THP-1 Monocyte-Derived Macrophage Apoptosis

Received: 13 October 2009 / Accepted: 10 November 2009 / Published online: 28 November 2009

Abstract Steroidogenic acute regulatory protein (StAR) plays an important role in the maintenance of intracellular lipid homeostasis. Macrophages are the key cellular player in the pathophysiology of atherosclerosis. Imbalance of macrophage lipid homeostasis causes cellular apoptosis, which is the key process in the initiation of atherosclerosis. The present study has investigated the effects of StAR in the apoptotic process of human THP-1 derived macrophages induced by serum withdrawal or Ox-LDL. Overexpression of StAR significantly decreased the number of apoptotic macrophages by decreasing the expression of pro-apoptotic genes Caspase-3 and Bax mRNA and protein levels, as well as through increasing expression of anti-apoptotic gene Bcl-2 mRNA and protein levels in the absence and presence of Ox-LDL. The results indicate that StAR plays an important role in macrophage and foam cell apoptotic processing, which may provide a potential method for preventing atherosclerosis.

Introduction

Macrophages are central to the initiation and progression of atherosclerosis. In certain circumstances, macrophages accumulate modified low-density lipoproteins (LDLs), especially oxidized LDL (Ox-LDL). These modified LDLs can be metabolized into free cholesterol and cholesterol

esters leading to foam cell formation, which is a critical step for macrophage apoptosis and atherosclerosis progression [1–4]. Intracellular free cholesterol is considered to be a potent inducer of macrophage apoptosis, and subsequently necrosis, which could contribute to lesion necrosis, plaque destabilization, and disruption leading to acute atherothrombotic cardiovascular events [5–7]. Apoptotic and necrotic death of macrophages and foam cells lead to accumulation of insoluble lipids and other cellular contents, a characteristic of advanced lesions [8]. Therefore, decreasing intracellular cholesterol and cholesterol ester levels may prevent macrophages from foam cell formation and apoptosis.

Steroidogenic acute regulatory protein (StAR), one of the mitochondrial cholesterol delivery proteins, could deliver cholesterol from the outer mitochondrial membrane (OMM) into the inner mitochondrial membrane (IMM), which plays an important role in the maintenance of intracellular lipid homeostasis [9–11]. Our previous studies demonstrated that overexpression of StAR in THP-1 macrophages activates liver X receptor alpha (LXRα) and proliferation peroxysome activator receptor gamma (PPARγ), and increases ATP-binding cassette transporter G1 (ABCG1) and sterol 27-hydroxylase (CYP27A1) expression. Subsequently, it decreases intracellular lipid levels and the secretion of inflammatory factors, such as TNFα [12]. Furthermore, overexpression of StAR in ApoE−/− mice also decreases serum and tissue lipids [13]. Both free cholesterol accumulation and inflammatory factors are major pathogens for macrophage apoptosis [5, 14, 15]. Thus, StAR or StAR-like cholesterol transporters may be involved in the regulation of apoptosis. We hypothesized that StAR inhibits macrophage and foam cell apoptosis and necrosis.

In the present study, we provided convincing evidence that StAR plays an important role in the prevention of macrophage apoptosis, which may have therapeutic value for the prevention of atherosclerosis.

Experimental Procedure

Materials and Reagents

Culture media and reagents, TRIZOL reagent and a SuperScript™ III First-Strand Synthesis System for RT-PCR were purchased from Invitrogen (Carlsbad, CA). The SYBR® Green real-time PCR Master Mix was from the Toyobo Company (Osaka, JP). Primary antibodies against StAR and β-actin were purchased from Abcam Ltd. (Cambridge Science Park, Cambridge, UK). Antibodies against Caspase-3, Bax and Bcl-2 were purchased from SantaCruz Biotechnology, Inc (Santa Cruz, CA). Second antibodies against rabbit and mouse IgG were obtained from Kirkegaard and Perry Laboratories (Guildford, UK). The Annexin V-PE apoptosis detection kit (containing PE-conjugated Annexin V, 7-AAD and 10× binding buffer) was purchased from BD Biosciences (San Jose, CA). Lipoproteins were prepared from 80 ml blood of healthy donors by gradient ultracentrifugation as previously described [16]. The recombinant adenovirus encoding StAR (Ad-StAR) was prepared as described [17]. The control adenovirus expressing the enhanced green fluorescence protein (Ad-EGFP) was purchased from Vector Gene Technology Company Ltd. (Beijing, China). All other reagents were from Sigma-Aldrich Chemical Co (St. Louis, MO) unless stated otherwise.

Cell Line and Cell Culture

THP-1, a human monocytic cell line, was purchased from the American Type Culture Collection (Manassas, VA). Cells were cultured in RPMI 1640 medium with 25 mM HEPES buffer (supplemented with 10% fetal bovine serum, 2 mM L-glutamine (Invitrogen), 100 U/ml of penicillin, and 100 μg/ml of streptomycin) at 37 °C in a humidified incubator with 5% CO_2. THP-1 monocytic cells were differentiated to macrophages by addition of 50 nM phorbol 12-myristate 13-acetate (PMA) for 48 h. After being differentiated to macrophages, the PMA-containing medium was removed, and replaced with serum-free media, the cells were cultured for another 24 h before treatment. The macrophages were converted to foam cells by incubation with Ox-LDL (25 μg/ml) for 48 h as previously described [3].

Infection of Macrophages with Adenovirus Encoding Human StAR

THP-1 derived macrophages were infected with recombinant adenovirus encoding Ad-StAR at a multiplicity of 50 pfu/cell for 48 h in the absence and presence of Ox-LDL as previously described [18]. The adenovirus encoding Ad-EGFP were used as controls.

Morphological Assessment of Apoptosis by Electron Microscopy

A method of uranyl acetate and lead citrate staining was used to detect morphological changes as previously described [19]. In short, THP-1 derived macrophages were infected with Ad-StAR or Ad-EGFP in the absence and presence of Ox-LDL for 48 h. The cells were digested with pancreatin and fixed with 3% glutaraldehyde precooled at 4 °C for 2 h. After washed with PBS twice, the cells were fixed with 1% osmic acid for one more hour, dehydrated by acetone, and embedded in epoxide resin. After stained with

uranyl acetate and lead citrate, the cells were observed under transmission electron microscope.

Agarose Gel Electrophoresis for DNA Fragmentation Detection

Selected apoptotic DNA was extracted from the treated cells and analyzed by agarose gel electrophoresis according to the manufacturer's instructions. In short, 4 μg of specific DNA was loaded to 1% agarose gel, and fragments were visualized by ethidium bromide staining.

Quantification of Apoptosis by Flow Cytometry

THP-1 cells were seeded in a six-well plate at 1×10^6 cells/well density, differentiated, and infected as described above. The media were changed with fresh serum-free RPMI 1640 media in the presence or absence of 25 μg/ml Ox-LDL. Forty eight hours after the change, apoptotic cells were assessed by flow cytometry as previously published [20]. In brief, the harvested cells were washed twice with cold PBS, then resuspended in 1× binding buffer at a concentration of 1×10^6 cells/ml, incubated with Annexin V-PE (Phycoerythrin) and 7-ADD (7-amino-actinomycin) for 15 min at room temperature in the dark. The positive cells were analyzed by flow cytometry within one hour.

Determination of Total mRNA by Real-Time Fluorescent Quantitative RT-PCR

Total RNA was extracted according to the manufacturer's instructions. 2 μg of total RNA were reversely transcribed and amplified. The relative mRNA levels were measured by real-time PCR using SYBR-Green real-time PCR Master Mix (Toyobo, Osaka, Japan) with SYBR-Green I. Specific primer pairs for StAR, Caspase-3, Bax, Bcl-2, GAPDH were designed based on published sequences in GenBank and are listed in Table 1.

Determination of Relative Protein Levels

After infection or treatment, total cell lysates were harvested in RIPA sample buffer. Thirty micrograms of protein was loaded to 12% SDS-PAGE to detect Caspase-3, Bax, Bcl-2 using β-actin as loading control, and Western blot analysis was performed as previously described [21].

Statistic Analysis

Data are expressed as means ± SD and evaluated by independent-samples t test and the Games–Howell post-test using SPSS 11.5 software. A value of $P < 0.05$ was considered statistically significant.

Results

StAR Gene was Successfully Overexpressed in THP-1 Derived Macrophages by Infection with Recombinant Adenovirus

THP-1 derived macrophages were infected with recombinant adenovirus encoding Ad-EGFP at a multiplicity of 0, 10, and 50 pfu/cell respectively. All of these cells were incubated for another 48 h. Transfection efficiency was detected by fluorescence microscope and flow cytometry as shown in Fig. 1a–d. The cells infected with Ad-EGFP at a multiplicity of 50 pfu/cell for 48 h had the highest infection efficiency (about 50%). This condition was used in the following experiments unless otherwise mentioned.

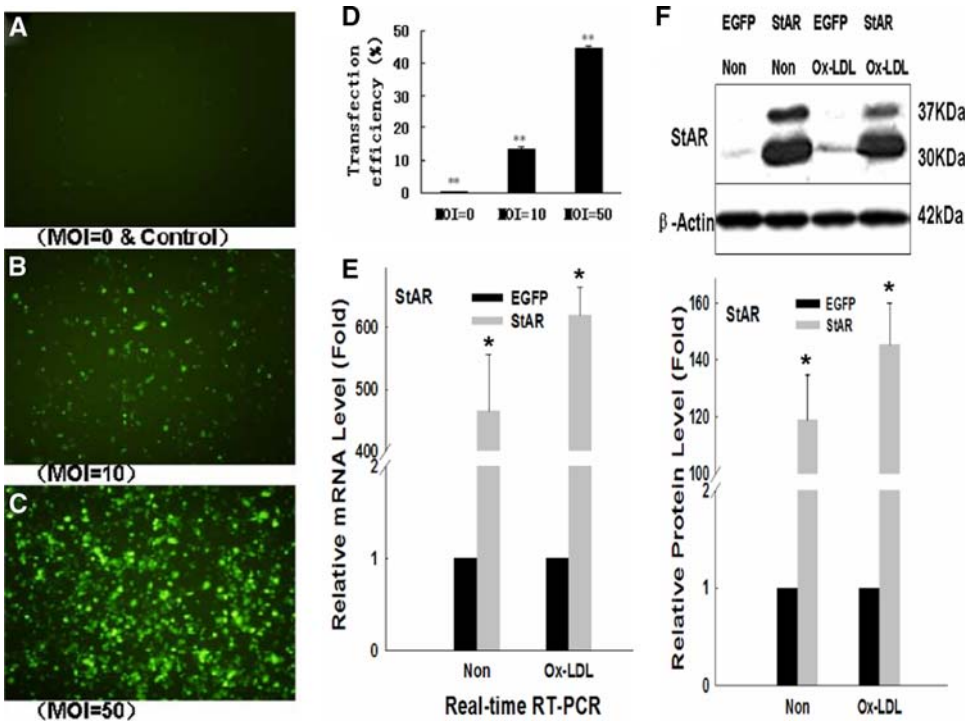

Fig. 1 StAR gene was successfully overexpressed in THP-1 derived macrophages. THP-1 derived macrophages were transfected with recombinant adenovirus encoding Ad-StAR and Ad-EGFP. Then, the transfection efficiency of StAR gene in THP-1 macrophages was detected by fluorescence microscope (**a**–**c**) and flow cytometry (**d**). The levels of StAR mRNA (**e**) and protein (**f**) were determined by real-time RT-PCR and Western blot. Cells infected with Ad-EGFP were the controls; *Non* cells incubated in serum-free media without Ox-LDL; *Ox-LDL* with 25 μg/ml Ox-LDL in serum-free media. $*P < 0.05$; $**P < 0.01$

THP-1 derived macrophages that were infected with recombinant adenovirus encoding Ad-StAR at a multiplicity of 50 pfu/cell for 48 h expressed high levels of StAR mRNA and protein but did not exhibit evidence of cell toxicity. Real-time RT-PCR analysis showed that infection with Ad-StAR increased StAR mRNA levels by 460-fold in the absence of Ox-LDL and 620-fold in the presence of Ox-LDL respectively in the THP-1 cells (Fig. 1e). Western blot analysis showed one major immunoreactive band with a molecular weight of 30 kDa (lower band), which was consistent with StAR mature protein, and a second band with the molecular weight of 37 kDa (upper band), which was consistent with a precursor form (Fig. 1f). It showed that Ad-StAR infection increased the StAR protein levels about 120-fold in the absence of Ox-LDL and 145-fold in the presence of Ox-LDL respectively. A summary of the data normalized to β-actin is shown in the lower panel of Fig. 1f.

Effect of StAR Overexpression on Morphology of THP-1 Derived Macrophages and Foam Cells

Morphology changes of the cells with StAR overexpression in the presence or absence of Ox-LDL were assessed by electron microscope. As shown in Fig. 2a–d, compared with the cells infected with Ad-EGFP, chromatin condensation, margination, apoptotic body and lipid droplet in the cells infected with Ad-StAR were significantly decreased.

Effect of StAR Overexpression on Apoptosis in THP-1 Macrophages and Foam Cells Detected by DNA Fragmentation

As shown in Fig. 2e, overexpression of StAR in THP-1 derived macrophages with or without Ox-LDL showed much weaker "DNA laddering" representing integer multiples of the internucleosomal DNA length (about 180–200 bp), which is indicative of apoptosis, compared with the control cells infected with Ad-EGFP. It suggested that StAR could inhibit THP-1 macrophage apoptosis.

Effect of StAR Overexpression on Apoptosis and Necrosis in THP-1 Derived Macrophages Detected by Flow Cytometric

THP-1 derived macrophages were randomized into the following groups: negative control (no infection and no staining); negative control used for detection of transfection efficiency (infected with Ad-EGFP but no staining); control groups (infected with Ad-EGFP in the presence or absence Ox-LDL, and staining with Annexin V-PE and 7-AAD); experiment groups (infected with Ad-StAR in the presence or absence of Ox-LDL, and stained with Annexin V-PE and 7-AAD). The number of apoptotic cells was determined by flow cytometry as shown in Fig. 2f. Ad-StAR infected cells without Ox-LDL dramatically inhibited the apoptosis both in the early and end stage of apoptosis (Fig. 2g). However, Ad-StAR infected cells

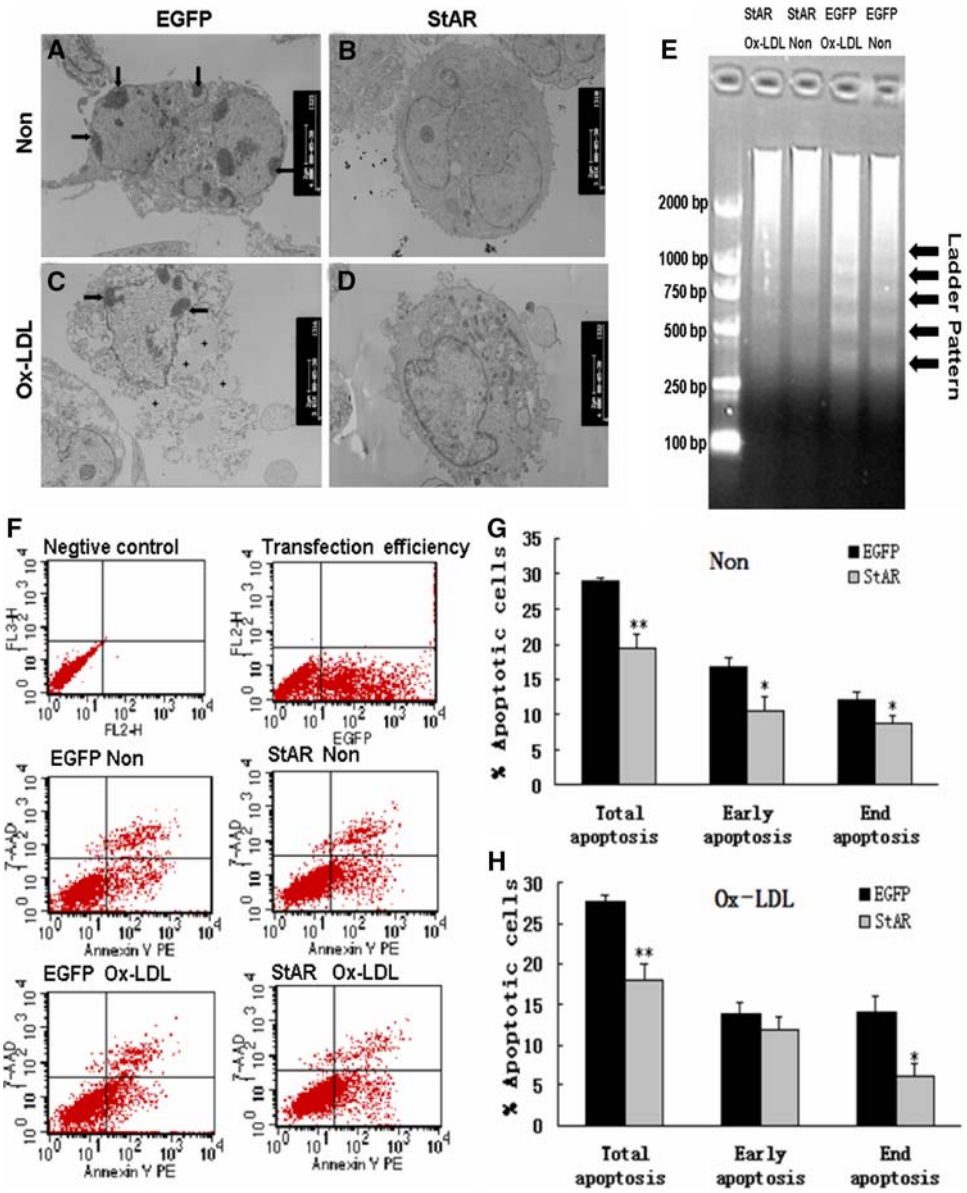

Fig. 2 Effect of StAR on THP-1 macrophages and foam cells apoptosis. THP-1 derived macrophages were incubated with or without 25 μg/ml Ox-LDL for 24 h following infection with recombinant adenovirus encoding Ad-CMV-EGFP and Ad-CMV-StAR at a multiplicity of 50 pfu/cell. Then, THP-1 macrophages and foam cells morphological changes were analyzed by electron microscope (**a**–**d**) and DNA ladder fragmentation was detected on 1% agarose gel electrophoresis (**e**). The number of THP-1 macrophages apoptosis was assessed by FCM (**f**–**h**). *Arrow* chromatin condensation, margination and apoptosis body. *Plus* lipid droplet or blebbing. *Non* cells incubated in serum-free media without Ox-LDL; *Ox-LDL* with 25 μg/ml Ox-LDL in serum-free media. $^{*}P < 0.05$ versus EGFP. $^{**}P < 0.01$ versus EGFP

treated with 25 μg/ml Ox-LDL mainly inhibited apoptosis at the end stage (Fig. 2h).

Effect of StAR Overexpression on Pro- and Anti-Apoptotic Genes' Protein Expression

The protein levels of Caspase-3 (Fig. 3b), Bax (Fig. 3c), Bcl-2 (Fig. 3d) following StAR overexpression in THP-1 derived macrophages were detected by Western blot analysis as shown in Fig. 3a. The pro-apoptosis protein Caspase-3 and Bax were decreased consistently by 0.6- (Non), 0.5- (Ox-LDL), and 0.7- (Non), 0.6- (Ox-LDL) fold respectively, while anti-apoptosis protein Bcl-2 was increased by 1.6- (Non) and 2.1- (Ox-LDL) fold in Ad-StAR infected macrophages in the presence or absence of Ox-LDL.

Effect of StAR Overexpression on Pro- and Anti-Apoptotic Genes' mRNA Expression

The mRNA levels of the genes related to apoptosis were determined by real-time RT-PCR after the cells had been infected with the recombinant adenovirus for 48 h as indicated. As shown in Fig. 4, the pro-apoptosis gene Caspase-3 (Fig. 4a) and Bax (Fig. 4b) were decreased by 0.6- (Non), 0.7- (Ox-LDL), and 1.0- (Non), 0.4- (Ox-LDL) fold respectively, while anti-apoptosis protein Bcl-2 (Fig. 4c) was increased by 1.4- (Non) and 1.5- (Ox-LDL) fold in the Ad-StAR infected macrophages with or without Ox-LDL. Because the Bax gene in the Ad-StAR infected macrophages without Ox-LDL had no dramatic change, the Bax/Bcl-2 ratio was assessed, and the result was shown in

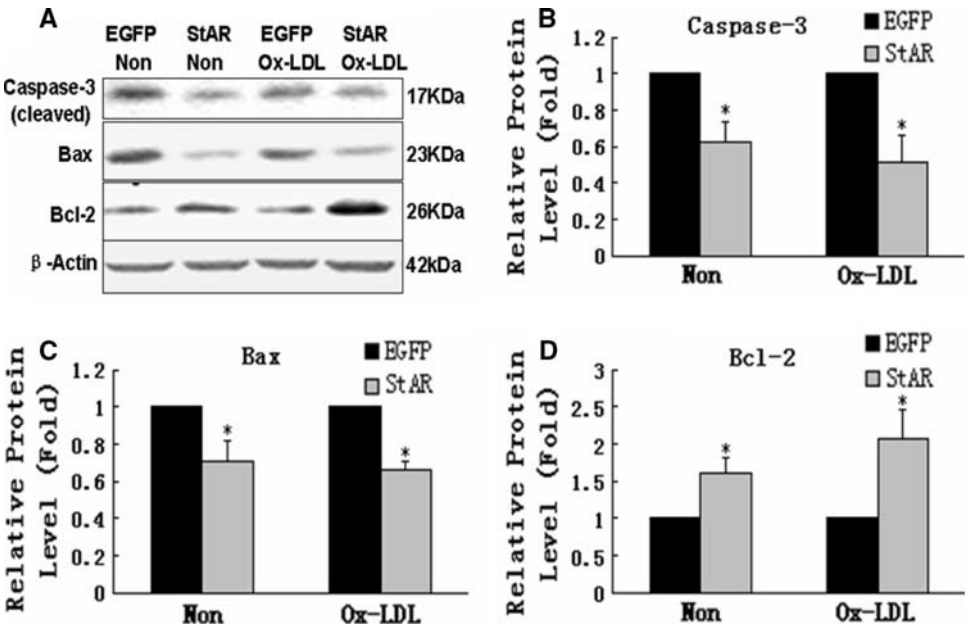

Fig. 3 Effect of StAR on Caspase-3, Bax and Bcl-2 protein expression. After transfection and treatment with or without Ox-LDL, total cell lysates of THP-1 derived macrophage were extracted for determination the protein levels of Caspase-3, Bax and Bcl-2. *Non* cells incubated in serum-free media without Ox-LDL; *Ox-LDL* with 25 μg/ml Ox-LDL in serum-free media. $*P < 0.05$ versus EGFP

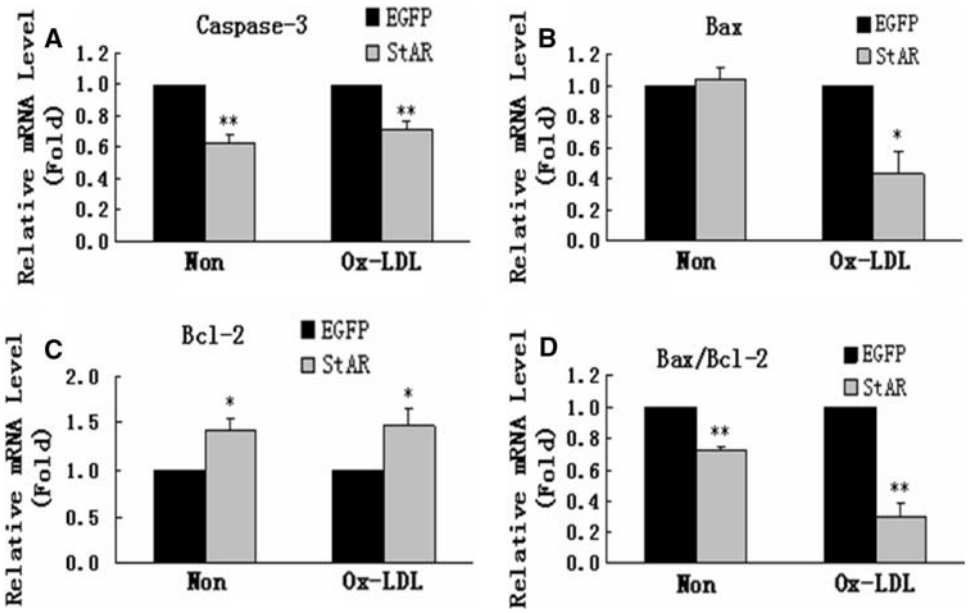

Fig. 4 Effect of StAR on Caspase-3, Bax and Bcl-2 mRNA expression. After transfection and treatment with or without Ox-LDL, total RNA of THP-1 derived macrophage was extracted for determination the mRNA levels of Caspase-3, Bax and Bcl-2. *Non* cells incubated in serum-free media without Ox-LDL; *Ox-LDL* with 25 μg/ml Ox-LDL in serum-free media. $*P < 0.05$ versus EGFP. $**P < 0.01$ versus EGFP

Fig. 4d. The Bax/Bcl-2 ratio was decreased to 0.7- (Non) and 0.3- (Ox-LDL) in the Ad-StAR infected macrophages with or without Ox-LDL.

Discussion

Macrophages play a key role in the initiation and progression of atherosclerosis. Lipid-laden cells (foam cells), predominantly of monocytic origin, are a hallmark feature of atherosclerotic plaques [4, 22, 23]. In advanced plaques, necrotic lipid-filled cores are formed following the death of macrophages and foam cells. Cytotoxic substances released from these cells are thought to contribute to plaque destabilization, which could then result in a clinical event such as a heart attack or stroke [22, 24]. Therefore, targeting the inhibition of apoptosis and necrosis of macrophages and foam cells may present a therapeutic strategy for atherosclerosis.

The StAR was first found in steroidogenic tissues. It could transport cholesterol from the OMM into the IMM, where the cholesterol side-chain cleavage enzyme, P450scc, is located. This enzyme catalyzes the first and rate-limiting step in steroidogenesis converting insoluble cholesterol to soluble pregnenolone [11, 25, 26]. In recent years, it was reported that StAR was also expressed in the non-steroidogenic tissues such

as liver, vascular endothelial cells and macrophages, and it plays an important role in the maintenance of intracellular lipid homeostasis [10, 21, 27]. Overexpression of StAR in these tissues decreases lipid levels (both cholesterol and triglyceride) and inflammatory factors. However, the effect of StAR on apoptosis is still not clear yet.

In the current research, we provided convincing evidence that StAR inhibits macrophage and foam cell apoptosis, the number of apoptotic cells was significantly lower compared with the control groups after overexpression of StAR, which was consistent with the TUNEL results of Ning et al. [12]. Apoptotic cells had typical morphological and biochemical characteristics, including shrinkage of the cells, chromatin condensation, margination, apoptosis body, and oligonucleosomal fragmentation of nuclear DNA as shown in Fig. 2a–d [28, 29].

Ox-LDL is taken up by macrophages, leading to the accumulation of high levels of intracellular cholesterol and the transformation of macrophages into lipid-laden foam cells [1, 4, 30]. Increasing numbers of reports indicate that Ox-LDL is cytotoxic to macrophages and contributes to macrophage apoptosis [31–33], which may relate to down-regulating expression of the anti-apoptotic genes Bcl-2 and up-regulating the pro-apoptotic genes Bax and Caspases [34–37]. However, in the present study, the apoptotic index, including morphology, DNA ladder, and the quantity of apoptotic and necrotic cells, in groups treated with or without Ox-LDL were not obviously different. Fewer THP-1 macrophages undergoing apoptosis both in the early and the end stage were observed in the cells infected with Ad-StAR without Ox-LDL. However, the apoptosis in the cells infected with Ad-StAR with Ox-LDL only occurred in the end stage (Fig. 2f–h), which can partly be explained by the difference in transfection efficiency between the groups with and without Ox-LDL.

To better understand the mechanism of StAR overexpression inhibiting apoptosis in the THP-1 macrophages and foam cells, we determined the protein and mRNA expression of the genes related to apoptosis by Western blot and real-time RT-PCR. The results showed that compared with the control groups, the expression of pro-apoptotic proteins including Caspase-3 and Bax were lowered 0.6- (without Ox-LDL), 0.5- (with Ox-LDL) and 0.7- (without Ox-LDL), 0.6- (with Ox-LDL) fold respectively, while the anti-apoptotic protein Bcl-2 level increased to 1.6- (without Ox-LDL) and 2.1- (with Ox-LDL) fold. The change of mRNA levels was consistent with that of protein levels.

As a cholesterol delivery protein, StAR regulates the formation of oxysterols in the mitochondria [38]. The generated oxysterols, including 27-hydroxycholesterol (27HC) and 25-hydroxycholesterol (25HC), have been implicated in the regulation of lipid metabolism. Li et al. [39] reported cholesterol was delivered into mitochondria and hydroxylated to 25HC and subsequently 3β-sulfated to form sulfated 25-hydroxycholesterol (25HC3S). Ma et al. has shown that the 25HC3S increased cell proliferation and decreased apoptosis in macrophages [40, 41]. Taking other reports and our results together, we can state that the mechanism of StAR inhibiting apoptosis in THP-1 macrophages and foam cells is as follows: when cellular cholesterol levels are increased in cells, cholesterol is delivered by StAR protein to mitochondria, where it is hydroxylated to 25HC, then sulfated to 25HC3S, which decreases apoptosis by decreasing the expression of pro-apoptotic genes including Caspase-3 and Bax and increasing the expression of the anti-apoptotic gene Bcl-2.

ORIGINAL ARTICLE

HOCl-Mediated Glycerophosphocholine and Glycerophosphoethanolamine Generation from Plasmalogens in Phospholipid Mixtures

Jacqueline Leßig · Beate Fuchs

Received: 21 October 2008 / Accepted: 3 July 2009 / Published online: 25 November 2009

Abstract Many mammalian tissues and cells contain, in addition to (diacyl) phospholipids, considerable amounts of plasmalogens, which may function as important antioxidants. Apart from the "scavenger" function mediated by the high sensitivity of the vinyl-ether bond, the functional role of plasmalogens is so far widely unknown. Furthermore, there is increasing evidence that plasmalogen degradation products have harmful effects in inflammatory processes. In a previous investigation glycerophosphocholine (GPC) formation was verified as a novel plasmalogen degradation pathway upon oxidation with hypochlorous acid (HOCl), however these investigations were performed in simple model systems. Herein, we examine plasmalogen degradation in a more complex system in order to evaluate if GPC generation is also a major pathway in the presence of other highly unsaturated glycerophospholipids (GPL) representing an additional reaction site of HOCl targets. Using MALDI–TOF mass spectrometry and ^{31}P NMR spectroscopy, we confirmed that the first step of the HOCl-induced degradation of GPL mixtures containing plasmalogens is the attack of the vinyl-ether bond resulting in the generation of 1-lysophosphatidylcholine (lysoPtdCho) or 1-lysophosphatidylethanolamine. In the second step HOCl reacts with the fatty acyl residue in the *sn*-2 position of 1-lysoPtdCho. This reaction is about three times faster in comparison to comparable diacyl-GPL. Thus, the generation of GPC and glycerophosphoethanolamine (GPE) from plasmalogens are relevant products formed from HOCl attack on the vinyl-ether bond of plasmalogens under pathological conditions.

Introduction

Plasmalogens represent a glycerophospholipid (GPL) class with a vinyl-ether moiety in the *sn*-1-position of the glycerol backbone [1]. The marked reactivity of this group renders plasmalogens subject to oxidation and imparts potentially strong antioxidative properties to these phospholipids [1, 2]. Compared to their 1-acyl analogues, plasmalogens are more susceptible to oxidative damage [3, 4]. Therefore, their supposed function as "scavengers" [5] can be explained by the direct reaction between atmospheric oxygen or—in particular—reactive oxygen species (ROS) and the vinyl-ether moiety [5, 6]. In binary mixtures of plasmenylcholine (PlsCho) and phosphatidylcholine (PtdCho), selective oxidation of PlsCho by hypochlorous acid (HOCl) followed by the formation of lysophosphatidylcholine (lysoPtdCho) is obvious. The rate constant of the reaction of plasmalogens with HOCl is approximately ten times higher than the rate constant of the reaction of alkenes with HOCl [7]. Double bonds of the fatty acyl residue present in the *sn*-2 position of the resulting lysoPtdCho are secondary HOCl targets leading to the production of lysoPtdCho-chlorohydrins. Unsaturated lysoPtdCho species are also more susceptible to oxidative attack than unsaturated PtdCho [4].

The preferred destruction of plasmenyl-phospholipids in membranes under oxidative stress is one possible explanation of the physiological function of these compounds in membranes: Plasmalogens are supposed to protect animal cells against oxidative damage [2, 5, 6, 8–11], and are regarded as natural antioxidants in lipoproteins [2].

Plasmalogens are also lipids involved in brain signal transduction and synaptic function [12]. It has been shown that a plasmalogen-selective phospholipase A_2 (PLA_2) exists in the brain and that it is probably involved in the regulation of the K^+ channels [13, 14]. The contribution of plasmalogens to signal transduction was also demonstrated in the heart where a special PLA_2 selectively hydrolyzes plasmalogen substrates [15], resulting in the production of lysoplasmalogens and prostacyclin, important bioactive products [16]. Furthermore, PlsCho vesicles are characterized by changed molecular dynamic properties in comparison to their diacyl analogues underscoring the biological significance of plasmalogens [17]. Experiments using ethanolamine glycerophospholipids containing either an ester or a vinyl-ether linkage at the *sn*-1 position indicated that introduction of the vinyl-ether group increased the tendency to give hexagonal phases [18].

Cellular membranes contain often 20%, in some cases even more than 50%, of plasmalogen glycerophospholipids [10]. There is a preponderance of plasmalogens in cardiac sarcolemma [19]. In some sperm plasma membranes, highly unsaturated compounds, such as 1-*O*-1′-palmitenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine ($PDHPC_{plasm}$) and 1-*O*-1′-palmitenyl-2-docosapentaenoyl-*sn*-glycero-3-phosphocholine ($PDPPC_{plasm}$) are very abundant [20, 21].

In different mammalian tissues, the plasmalogen concentration decreases upon aging. A similar behaviour has also been observed in patients with Alzheimer's disease (AD) [10, 22–25]. Plasmalogen deficiency may, thus, play an important role in AD pathogenesis and altered plasmalogen content may contribute to neurodegeneration, synapse loss and synaptic dysfunction in AD [25].

Concomitantly, an accumulation of plasmalogen oxidation products such as α-hydroxyaldehydes and plasmalogen epoxides is detectable [10, 24, 26, 27]. Finally, neuropathological conditions (e.g. ischemia, spinal cord injury) and chronic diseases such as atherosclerosis and myocardial infarction are also characterized by membrane instability and increased oxidative damage [9, 23].

Although plasmalogen GPL can be basically regarded as efficient antioxidants in vivo [11, 28–30], it is not known so far, if the removal of reactive oxygen species compensates the negative effects mediated by the plasmalogen decrease and the related accumulation of plasmalogen oxidation products [31].

At an inflammatory locus, HOCl is generated by myeloperoxidase (MPO), a heme-enzyme released from polymorphonuclear leukocytes (PMNL) [32]. HOCl reacts with a variety of molecules including amino acids, proteins, carbohydrates, nucleic acids and lipids [33–38]. Chlorohydrins are generated as the primary products when HOCl reacts with the double bonds of unsaturated PtdCho [38–40]. Additionally, α-chlorofatty aldehydes and 2-lysophosphatidylcholines (2-lysoPtdCho) are characteristic products of reactive chlorinating species produced by MPO (or its products) targeting the vinyl-ether bond of plasmalogens in cellular membranes [41–45].

Plasmalogens containing a polyunsaturated fatty acyl residue at the *sn*-2 position are more sensitive to oxidative modifications than their monounsaturated counterparts [7, 11, 46]. Free radical-induced oxidation of plasmalogen GPL with esterified docosahexaenoic acid (DHA) at the *sn*-2 position occurs at both, the *sn*-1 and *sn*-2 position, accompanied by the formation of glycerophosphocholine (GPC) [47]. Combined plasmalogen and 1-lysoPtdCho degradation and subsequent GPC generation could be demonstrated in artificial plasmalogens after HOCl-treatment, whereby marked GPC formation occurred only in the case of highly unsaturated 1-*O*-1′-stearenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine ($SDHPC_{plasm}$) and 1-*O*-1′-stearenyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine ($SAPC_{plasm}$) [47]. However, these investigations are limited because there was only a single artificial plasmalogen as target for HOCl whereas under in vivo conditions there are many targets [47].

Therefore, the aim of this study was to extend the results of our previous study [47], where the preferred reactivity of the plasmalogen vinyl-ether group in comparison to olefinic residues was demonstrated. It is not yet known, whether the unsaturated 1-lysoPtdCho or an intact diacyl PtdCho exhibits a higher reactivity against HOCl. It was also not known which role phosphatidylethanolamine (PtdEtn) species—that are normally present in biological systems—presumably play and which products may be expected in their presence. To address these questions, we examined the HOCl-induced plasmalogen degradation in an artificial model mixture of polyunsaturated plasmalogen-ChoGpl and PtdCho using a combination of MALDI–TOF mass spectrometry and high resolution ^{31}P-NMR spectroscopy. We confirmed our results using a complex biological lipid mixture from boar spermatozoa. Boar spermatozoa were chosen because they contain large amounts of polyunsaturated GPL (particularly DHA and docosapentaenoic acid, DPA) as well as plasmalogens. Under conditions of HOCl attack, we demonstrated a marked increase in GPC formation from PlsCho in boar spermatozoa, confirming that our model system is replicated in a lipid mixture mimicking in vivo conditions.

Experimental Procedures

Chemicals and Samples

All chemicals for NMR spectroscopy (sodium cholate, EDTA, and deuterated water with an isotopic purity of 99.6%), buffer preparation ($NaH_2PO_4 \times H_2O$, $Na_2HPO_4 \times 2H_2O$ and trishydroxymethylaminomethane, TRIS), and matrix preparation (*p*-nitroaniline, PNA) as well as all solvents (chloroform and methanol) and taurine (2-aminoethane-1-sulfonic acid) were obtained in the highest commercially available purity from Fluka Feinchemikalien GmbH (Taufkirchen, Germany). 1-*O*-1′-stearenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine ($SDHPC_{plasm}$), 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (SDHPC) and 1-*O*-1′-stearenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphoethanolamine ($SDHPE_{plasm}$), 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphoethanolamine (SDHPE) as well as the internal standards 1-myristoyl-2-lyso-*sn*-glycero-3-phosphocholine (1-M-2-LPC), 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) and 1,2-dipalmitoyl-*sn*-glycero-3-phosphate (DPPA) were purchased from Avanti Polar Lipids (Alabaster, MA, USA) as solutions in $CHCl_3$ and used without further purification.

Boar spermatozoa lipid extracts were kindly provided by Dr. Karin Müller and co workers from the Leibnitz Institute for Zoo and Wildlife Research (Berlin, Germany). Boar semen was obtained from different fertile animals of a breeding station (Hermitage Deutschland GmbH Besamungseberstation Golzow, Germany). After the removal of seminal fluid by centrifugation (8 min, 700×*g*, 22 °C), the sperm pellets were pooled and extracted according to the method of Bligh and Dyer [48].

HOCl Incubation and Lipid Extraction

Two aliquots of the phosphatidylcholine (SDHPC) and the corresponding plasmalogen glycerophosphocholine

($SDHPC_{plasm}$) dissolved in chloroform were mixed in an equimolar ratio (each lipid 2 mM) and evaporated to dryness. Vesicles (4 mM GPL in total) were prepared by suspending the lipid film in a 50-mM phosphate buffer (pH 7.4) and vortexing vigorously for 30 s. A stock solution of NaOCl was kept in the dark at 4 °C. Its concentration was determined at pH 12 using $\varepsilon_{290} = 350\ M^{-1}\ cm^{-1}$ for ^{-}OCl [49]. NaOCl was diluted with phosphate buffered saline (50 mM) immediately prior to use. Liposomes were incubated with varying concentrations of $HOCl/ClO^{-}$ for 1 h at pH 7.4. Adding an excess of taurine stopped the reaction. Subsequently, twice the volume of a chloroform/methanol mixture (2:1, v/v) was added in comparison to the aqueous phase in order to extract the lipids [48]. Both, the organic and the aqueous layer were used for further analysis. Experiments with plasmalogen glycerophosphoethanolamine were performed in the same way. For the investigation of the boar spermatozoa lipid extracts 4 mM lipid vesicles (whole lipid extract; corresponding to approximately 0.6 mM plasmalogen-ChoGpl) were incubated with NaOCl and processed as described above.

MALDI–TOF Mass Spectrometric Measurements

Positive ion MALDI–TOF mass spectra were acquired on a Bruker Daltonics Autoflex workstation (Bremen, Germany). The system utilizes a pulsed nitrogen laser emitting at 337 nm. The extraction voltage was 20 kV and 200 single laser shots were averaged for each mass spectrum. In order to enhance the spectral resolution, spectra were recorded in the reflector mode under "delayed extraction" conditions [50, 51]. Internal standards were added for quantitative analysis [50–52]. Known amounts of DPPC and 1-M-2-LPC were added to the organic phases of interest prior to MALDI–TOF MS. Furthermore, GPC amounts were estimated by comparison with the intensities of selected matrix peaks [51, 53]. The organic or aqueous phases of the reaction mixtures were applied to the MALDI target using PNA as matrix [54]. For the investigation of the organic and aqueous phases the "low mass gate" (matrix suppression) was set to $m/z = 400$ and 150, respectively. All spectra were processed using the software "Flex analysis" version 2.2 provided by Bruker Daltonics.

^{31}P-NMR Spectroscopic Measurements

The dried organic and aqueous layers of the reaction mixtures were combined and solubilized [55, 56] in 50 mM TRIS (pH 7.65) containing 200 mM sodium cholate and 5 mM EDTA. DPPA was added as the concentration and frequency standard. After intense vortexing of the 0.5-ml samples ^{31}P-NMR spectra were recorded in 5-mm NMR tubes on a Bruker DRX-600 spectrometer operating at 242.88 MHz for ^{31}P. All measurements were performed using a direct $^{31}P/^{1}H$-NMR probe at 30 °C (303 K) with composite pulse decoupling (Waltz-16) to eliminate ^{31}P-^{1}H coupling. ^{31}P-NMR spectra of the boar spermatozoa extracts were additionally recorded at 60 °C (333 K). At this temperature the sphingomyelin (CerPCho) resonance is shifted to lower ppm values [57] and the GPC resonance can be clearly resolved whereas the GPC and CerPCho resonances overlap in the spectra recorded at 30 °C.

Other NMR parameters were as follows: experiment time: 2–8 h, data size: 8 k, 60° pulse (6.7 μs), pulse delay 2 s, and a line broadening of 1 Hz.

All peak assignments were confirmed by comparison with the shift of commercially available reference compounds. Spectra were processed using the software "1D WIN NMR" version 6.2® (Bruker Analytische Messtechnik GmbH, Rheinstetten, Germany) including the deconvolution (II) routine for peak area determination [58].

Results

Artificial Lipid Model System

In order to start with a simple model system, an artificial mixture of different commercially available GPL was used.

Artificial Mixture of Choline Glycerophospholipids

The plasmalogen glycerophosphocholine 1-*O*-1′-stearenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine ($SDHPC_{plasm}$) and the PtdCho 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (SDHPC) were investigated in the presence of different amounts of hypochlorous acid. Plasmalogens and PtdCho with highly unsaturated fatty acyl residues in the *sn*-2-position were chosen because of their extreme sensitivities to oxidative stress and their significant abundance in many cells, particularly spermatozoa. Both species possess six double bonds in the *sn*-2 position of their glycerol backbones but have different linkage types in the *sn*-1 position.

Selected examples of the positive ion MALDI–TOF mass spectra of the extracts of the reaction mixture are shown in Fig. 1. Spectra of untreated ChoGpl are shown in trace 1a. $SDHPC_{plasm}$ gives two major peaks at $m/z = 818.6$ and 840.6 corresponding to the H^{+} and Na^{+} adducts, respectively. Similarly, SDHPC shows also two peaks at $m/z = 834.6$ and 856.6 corresponding to the H^{+} and Na^{+} adducts. Spectra in Fig. 1 also exhibit additional peaks at $m/z = 468.3$ and 490.3 corresponding to 1-M-2-LPC. This compound was added to the organic phase as internal standard to allow reliable quantitative evaluation of the reaction products. POPC ($m/z = 760.6$ and 782.6)

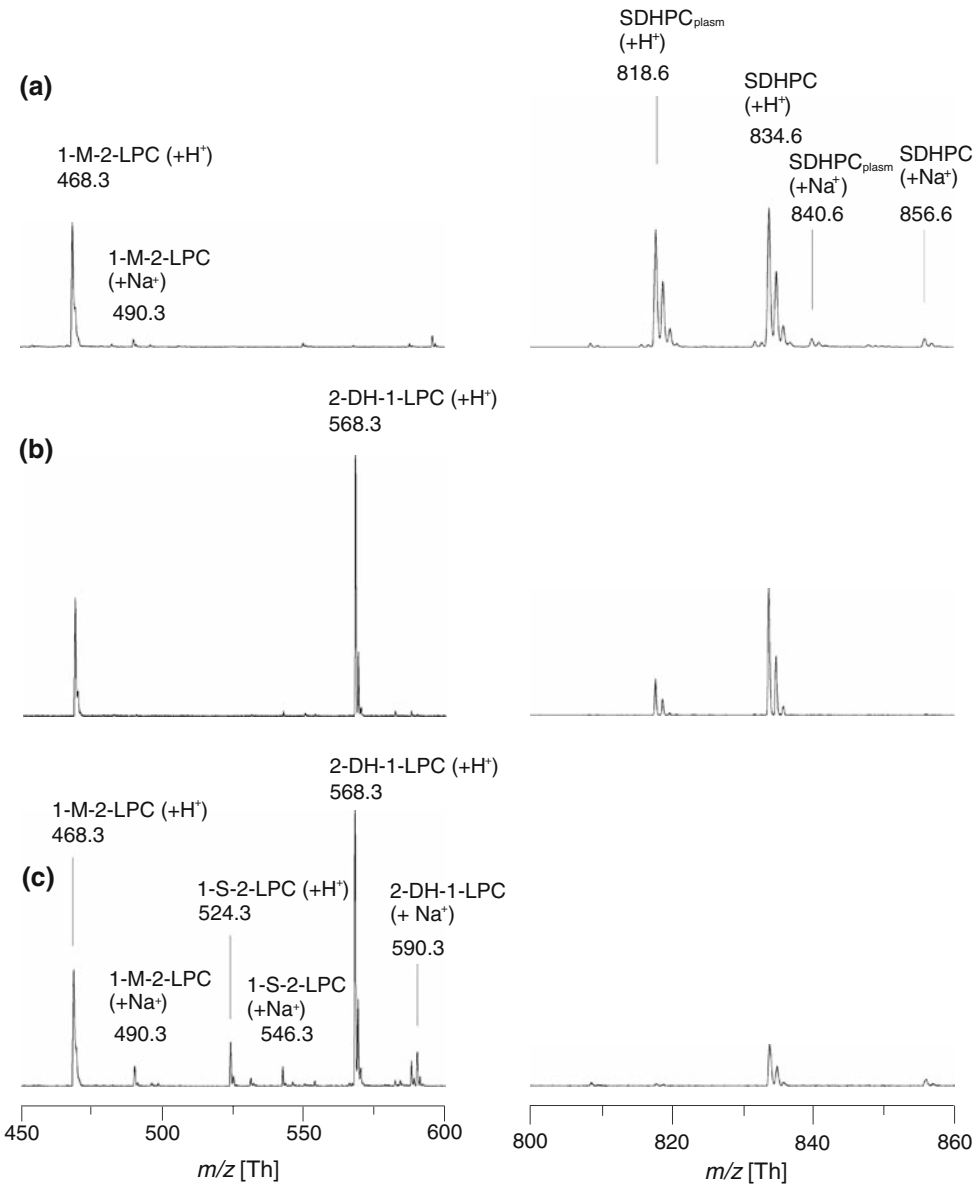

Fig. 1 Positive ion MALDI–TOF mass spectra of the organic extracts of a mixture of $SDHPC_{plasm}$ and SDHPC (2 mM each) after incubation with **a** buffer, **b** 2.5 and **c** 10 mM HOCl for 1 h at room temperature (~25 °C). The decrease of the plasmalogen-ChoGpl ($SDHPC_{plasm}$) and the phosphatidylcholine (SDHPC) with increasing HOCl concentrations is shown at the right hand side while the lysophosphatidylcholine generation (2-DH-1-LPC and 1-S-2-LPC) is shown at the left hand side. Spectra were scaled according to the integral intensity of the 1-M-2-LPC standard and the *m/z* values as well as the peak assignments are indicated. Spectra were split for clarity

was also added as internal standard for the quantitative assessment of the higher mass range (data not shown). Two different standards were used because compounds with higher masses are characterized by more marked contributions of heavier isotopes that lead to diminished peak intensities. Spectra were scaled along the *y* axis with respect to the intensity of 1-M-2-LPC. The POPC standard is not shown because spectra were split to emphasize the mass regions of interest.

The plasmalogen peaks were strongly diminished upon treatment with 2.5 mM HOCl, whereas the peak intensities of SDHPC remained nearly constant (trace 1b). Additional peaks became detectable in the low mass region at $m/z = 568.3$ and 590.3 corresponding to the H^+ and Na^+ adduct of 1-lyso-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (2-DH-1-LPC).

After treatment with 10 mM HOCl (i.e. a fivefold molar excess over the plasmalogen) the plasmalogen peaks (trace 1c) disappeared completely whereas the SDHPC peak is still detectable. The peak intensities of the 2-DH-1-LPC remained nearly constant, whereas additional peaks at $m/z = 524.3$ and 546.3 corresponding to the H^+ and Na^+ adduct of 1-stearoyl-2-lyso-*sn*-glycero-3-phosphocholine (1-S-2-LPC) were generated. However, the intensities of 2-DH-1-LPC were much higher in comparison to 1-S-2-LPC. This is a clear indication of the much higher reactivity of the vinyl-ether bond of the plasmalogens in comparison to the ester linkages of common GPL. Chlorohydrin formation (indicated by various 52 amu shifts as there are several reaction sites [38]) is marginally observed from SDHPC using HOCl concentrations of 5 mM and higher (data not shown).

The aqueous phases of the extracts of the incubation mixture were also analyzed by MALDI–TOF MS (data not shown). New peaks corresponding to GPC appeared at m/z = 258.1 and 280.1 in the HOCl-treated samples [47] but were completely absent in the control sample (data not shown). This clearly indicates that GPC is a major oxidation product of plasmalogens particularly if an excess of HOCl is used. The GPC generation will be discussed below in more detail.

In order to evaluate the relative contributions of 1-S-2-LPC, 2-DH-1-LPC and GPC, these products were quantified in dependence on the concentrations of HOCl used (data not shown, but see data obtained by ^{31}P-NMR as given below). Intensities of the peaks of interest were related to the intensities of the internal standards, i.e. the sum of the intensities of the H^+ and Na^+ adducts of 1-myristoyl-2-lyso-*sn*-glycero-3-phosphocholine (m/z = 468.3 and 490.3) for 1-lyso-2-acyl-glycerophosphocholines (Fig. 1), and the sum of the intensities of the H^+ and Na^+ adducts of 1-palmitoyl-2-oleoyl-*sn*-glycero-phosphocholine (m/z = 760.6 and 782.6) for the plasmalogen-ChoGpl and the PtdCho.

There are significant reactivity differences between $SDHPC_{plasm}$ and SDHPC with HOCl. The peaks of the plasmalogen $SDHPC_{plasm}$ decrease continuously with increasing HOCl concentrations whereby the contribution of 2-DH-1-LPC increases (Fig. 1). No plasmalogen could be detected anymore at HOCl concentrations higher than 7.5 mM, whereas the SDHPC peaks did not decrease significantly up to HOCl concentrations of 2.5 mM (Fig. 1, trace b). The conversion of SDHPC into the chlorohydrinated fatty acid and 1-S-2-LPC started at HOCl concentrations of about 5 mM, whereas the formation of GPC from plasmalogen was observed already at smaller HOCl concentrations and increased continuously if higher HOCl concentrations were used (data not shown). The proposed three-stage pathway of the reactions of HOCl with the PlsCho/PtdCho mixture relevant to Fig. 1 is schematically shown in Fig. 2. The sequential oxidation of plasmalogens to lysoPtdCho, which are important targets for the subsequent HOCl-attack leading to the generation of lysoPtdCho-chlorohydrins, is illustrated in this schema [4].

The reaction products of the $SDHPC_{plasm}$/SDHPC mixture subsequent to incubation with HOCl were additionally analyzed by ^{31}P-NMR spectroscopy. For that purpose, the aqueous and the organic phases were evaporated to dryness, recombined and solubilized in aqueous sodium cholate. Selected ^{31}P-NMR spectra of the mixture of $SDHPC_{plasm}$ and SDHPC after incubation with different amounts of HOCl are shown in Fig. 3. In trace a, the ^{31}P-NMR spectrum of the mixture of both GPLs (incubated with pure buffer in the absence of HOCl) is shown as reference. There is only one peak representing the combined resonances of $SDHPC_{plasm}$ and SDHPC at $\delta = -0.62$ ppm because no differentiation in dependence on the acyl or alkenyl residues can be made under the applied experimental conditions. A survey of the spectral resolution achievable by ^{31}P NMR using the mixed micelle approach is available in [58]. This spectrum (3a) unequivocally proves the absence of even small amounts of lysoPtdCho and GPC in the starting material.

^{31}P-NMR spectra of the $SDHPC_{plasm}$/SDHPC mixture after treatment with HOCl are shown in traces b and c. The intensities of the resonances of 2-DH-1-LPC and GPC detected at −0.18 and 0.03 ppm, respectively, are increasing in the presence of 2.5 mM HOCl (trace b). A further increase of the 2-DH-1-LPC and GPC resonances was observed if an increased excess of HOCl was used and an additional peak corresponding to 1-S-2-LPC appeared at −0.15 ppm (trace c). This compound is generated by the release of oxidatively-modified docosahexaenoic acid from the *sn*-2-position of SDHPC. Please note that a partial migration of the fatty acyl residue from the *sn*-2 to the *sn*-1 position (minor peak at −0.33 ppm) takes place in mixed detergent-GPL micelles [59]. Thus, a second very minor resonance of the corresponding lysoPtdCho isomer is detectable at −0.33 ppm but with much lower intensity than the "real" lysoPtdCho. This has nothing to do with the HOCl effect but is caused by a methodological reason [59].

The quantitative evaluation of the ^{31}P-NMR data is given in Fig. 4 whereby 0.5 mM DPPA was used as internal standard (the ^{31}P-NMR chemical shift is $\delta = 3.15$ ppm i.e. this resonance is outside the presented spectral range in Fig. 3). With increasing HOCl concentrations, the concentration of the $SDHPC_{plasm}$/SDHPC mixture decreases slowly (Fig. 4a, triangles). The concentration of 2-DH-1-LPC (Fig. 4a, rectangles) reaches a maximum at about 5 mM HOCl. The decrease of the $SDHPC_{plasm}$/SDHPC resonance for about 1.25 mM correlates with the 1.25 mM increase of the 2-DH-1-LPC at 5 mM HOCl. The subsequent slight decrease of the 2-DH-1-LPC resonance at HOCl concentrations of 7.5 and 10 mM is consistent with the simultaneously detected GPC generation (Fig. 4, trace b) and confirms the sequential formation of 2-DH-1-LPC and GPC even in the presence of an additional highly unsaturated PtdCho target. At the highest HOCl concentrations (7.5 and 10 mM), the generation of small amounts of 1-S-2-LPC derived from SDHPC is evident (Fig. 4a, circles). The loss of $SDHPC_{plasm}$/SDHPC (1.9 mM) at 10 mM HOCl is consistent with the sum of the concentration increase of 2-DH-1-LPC (1 mM), 1-S-2-LPC (0.3 mM) and GPC (0.6 mM). Thus, NMR data indicate a comparable behaviour as already evidenced by MALDI–TOF MS (cf. Fig. 1). Even if the detailed reasons of slight deviations between both methods are not yet clear, it seems likely that chlorohydrin

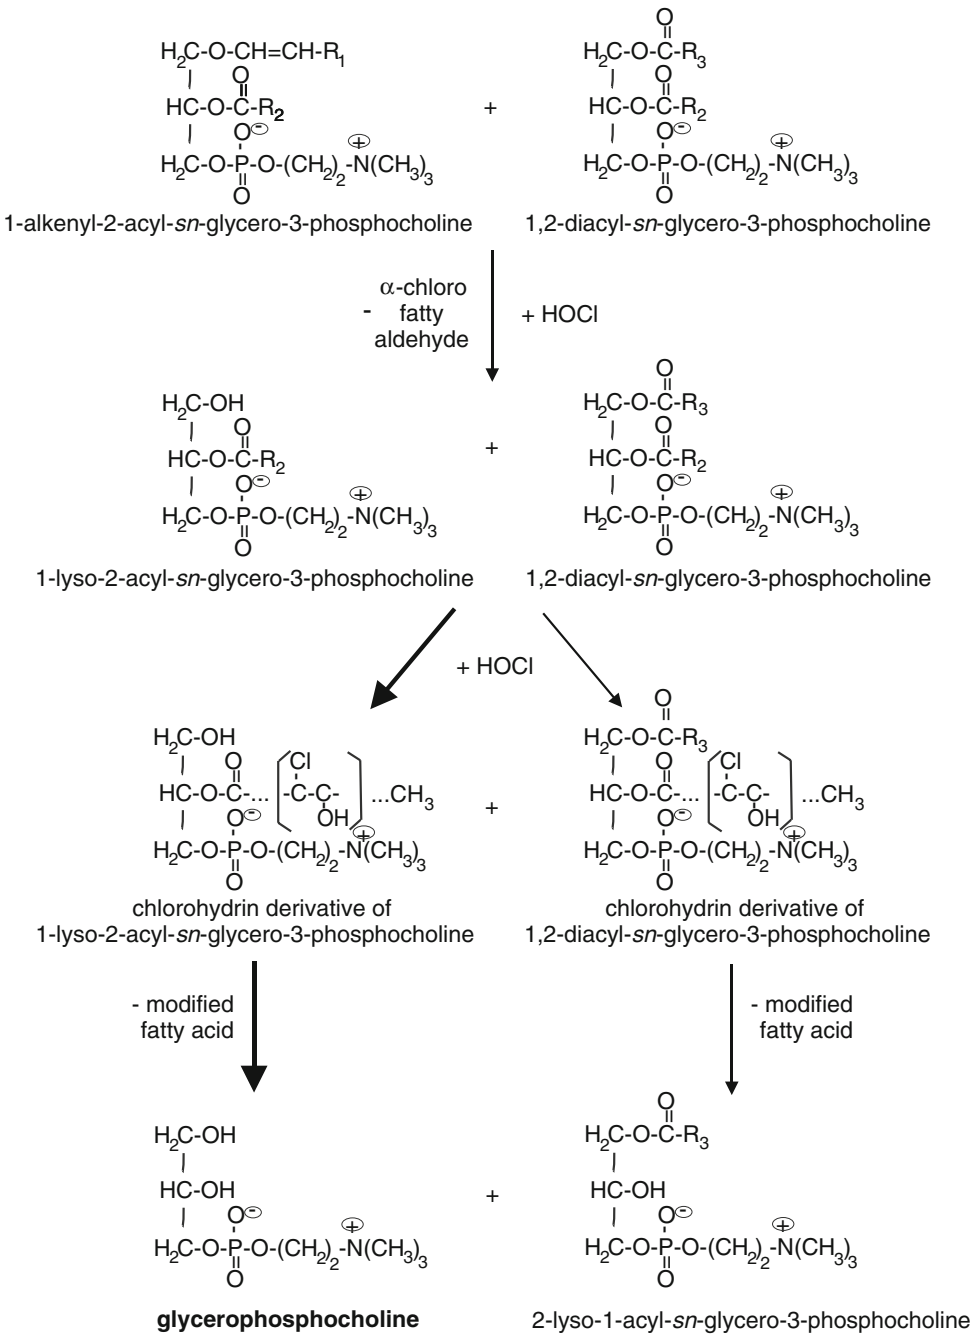

Fig. 2 Proposed three-stage pathway of the preferred cleavage of the *sn*-1 plasmalogen ChoGpl accompanied by the generation of 1-lyso-2-acyl ChoGpl and α-chloro fatty aldehydes in a plasmalogen/phosphatidylcholine mixture. In the second step, the formation of chlorohydrin derivatives of the polyunsaturated fatty acyl residues in the *sn*-2 position takes place leading finally (in the third step) to the generation of GPC in the case of the plasmalogen and 2-lyso-1-acyl glycerophosphocholine in the case of the phosphatidylcholine. R_1 stearenyl residue, R_2 docosahexaenoyl residue, R_3 palmityl residue

formation contributes to the observed differences: As previously shown [44], chlorohydrin formation is reflected by many different peaks of rather low intensities if MALDI–TOF MS is used, whereas in the case of NMR only broadening of the GPL resonance under retention of the integral intensity is observed.

Artificial Mixture of Phosphatidylethanolamines

For initial investigations of the HOCl-induced degradation of GPL of boar spermatozoa lipid extracts that contain a mixture of GPL, including PlsCho and PlsEtn, some selected plasmalogen species were also investigated on a model level after HOCl incubation by ^{31}P-NMR spectroscopy. Selected ^{31}P-NMR spectra of 1-*O*-1′-stearenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphoethanolamine ($SDHPE_{plasm}$) after incubation with different concentrations of HOCl are shown in Fig. 5. In order to prevent the aggregation of the PlsEtn in the reaction mixture, these incubations were performed in the presence of completely saturated DPPC ($\delta = -0.61$ ppm) that does not react at all with HOCl. In trace a, the ^{31}P-NMR spectrum of $SDHPE_{plasm}$ incubated with pure buffer in the absence of HOCl is shown as control and the resonance of $SDHPE_{plasm}$ is obvious at $\delta = -0.04$ ppm.

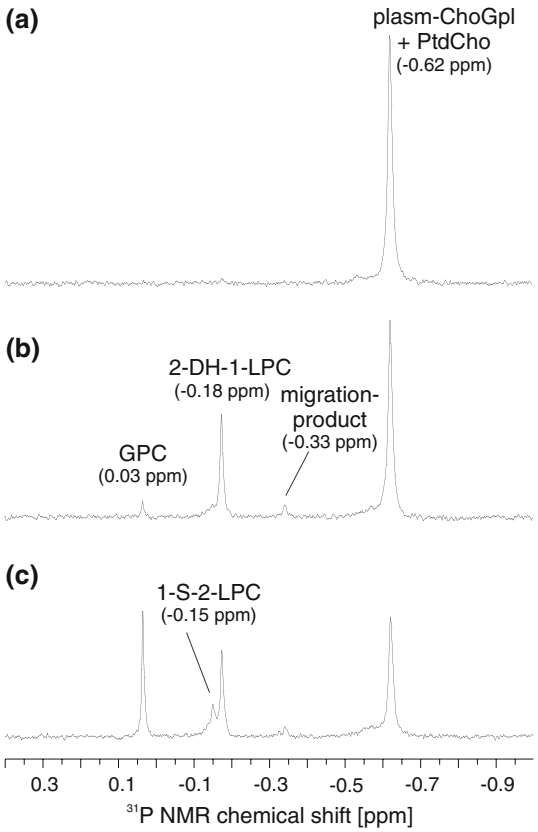

Fig. 3 242.88 MHz ^{31}P-NMR spectra of the combined organic and aqueous extracts of an $SDHPC_{plasm}$/SDHPC mixture after incubation with **a** buffer, **b** 2.5 mM and **c** 10 mM HOCl for 1 h at room temperature. The plasmalogen and PtdCho concentrations were each 2 mM in all cases. Spectra were scaled according to the intensity of the DPPA standard resonance (peak outside the shown chemical shift range at 3.15 ppm). Peak assignments and the related chemical shifts are indicated. Further methodological details are available in [58]

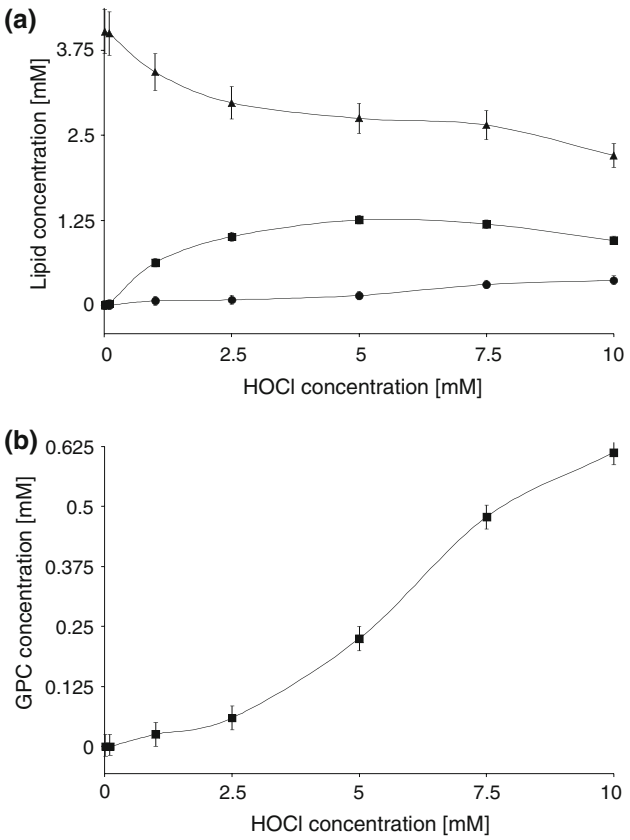

Fig. 4 Quantitative analysis of the integral peak intensities determined from the ^{31}P-NMR spectra provided in Fig. 3: The absolute $SDHPC_{plasm}$/SDHPC (*triangles*), 2-DH-1-LPC (*rectangles*) and 1-S-2-LPC (*circles*) concentrations (**a**) as well as the GPC concentrations (**b**) calculated by comparison with the integral intensity of the internal standard (DPPA) are shown. *Error bars* represent standard deviations of three independent measurements. The *drawn lines* were not derived from a mathematical model but only represent spline curves to guide the eye

With increasing HOCl concentrations (2.5 mM) the intensity of the $SDHPE_{plasm}$ resonance decreases continuously whereby 2-DH-1-LPE (0.37 ppm) and GPE (0.57 ppm) are generated (trace b). At the highest HOCl concentration (10 mM, trace c) the $SDHPE_{plasm}$ resonance has completely disappeared whereas the GPE resonance increased concomitantly with a decrease of the 2-DH-1-LPE resonance. This is in agreement with the sequential formation of 2-DH-1-LPE and GPE upon HOCl-treatment of polyunsaturated fatty acid containing PlsEtn.

It is rather surprising that basically the same products are obtained equally if plasmalogen-ChoGpl or -EtnGpl species react with HOCl. In contrast to the plasmalogen-ChoGpl, the -EtnGpl (as well as the lysoPtdEtn and the GPE) contain an additional "free" amino group that possesses high reactivity with HOCl [60]. The resulting mono- and dichloramines, however, are not very stable compounds and decompose slowly under generation of further compounds such as aldehydes or nitriles [60]. As the chemical shifts of lysoPtdEtn and GPE do not markedly change under the influence of HOCl, the question whether there is the intact plasmalogen-EtnGpl and/or potentially chlorinated species cannot be convincingly answered by means of ^{31}P NMR. Unfortunately, however, the detectability of chloramines by MALDI–TOF MS is also difficult [61]. Therefore, this question was not further addressed in this work.

ChoGpls and EtnGpls in a Model Mixture

For more detailed investigations of the HOCl-induced degradation of GPLs in complex lipid mixtures such as spermatozoa extracts, which contain not only plasmalogen-ChoGpls and plasmalogen-EtnGpls but also their GPLs mixtures mimicking a more complex lipid system, were finally investigated by ^{31}P-NMR spectroscopy. Selected ^{31}P-NMR spectra of an equimolar mixture of $SDHPE_{plasm}$, $SDHPC_{plasm}$, 1-stearoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphoethanolamine (SDHPE) and SDHPC after

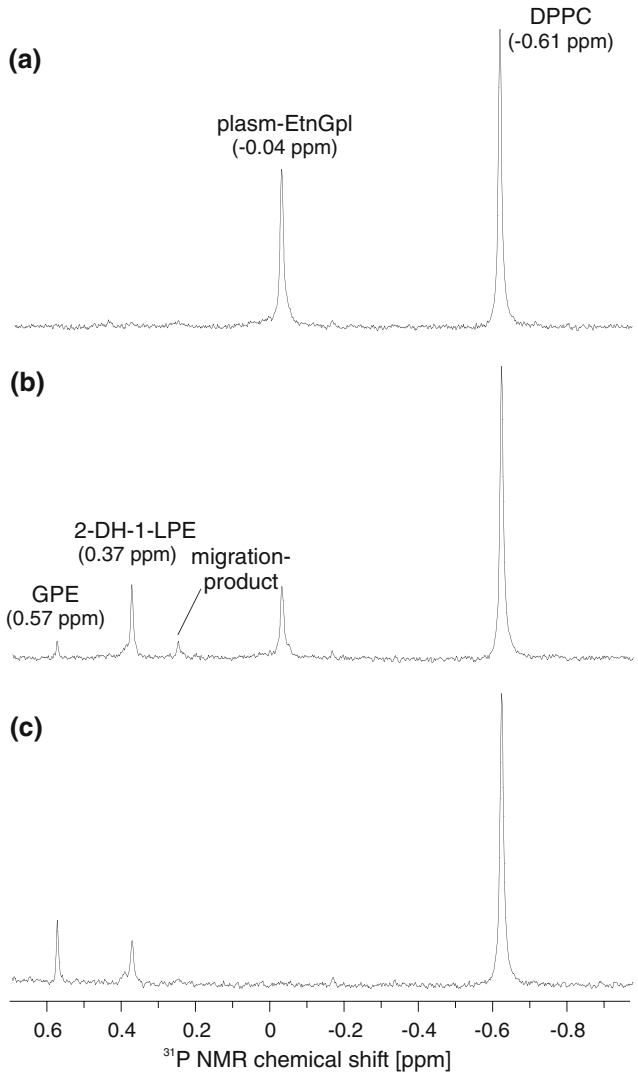

Fig. 5 242.88 MHz ^{31}P-NMR spectra of the combined organic and aqueous extracts of plasmalogen glycerophosphoethanolamine (in combination with DPPC that was added to suppress the aggregation of large EtnGpl aggregates) after incubation with **a** buffer, **b** 2.5 mM and **c** 10 mM HOCl for 1 h at room temperature. The plasmalogen concentration was 2 mM in all cases. Spectra were scaled according to the intensity of the DPPA standard resonance (peak outside the shown range at 3.15 ppm). All peak assignments and the corresponding ^{31}P-NMR chemical shifts are indicated

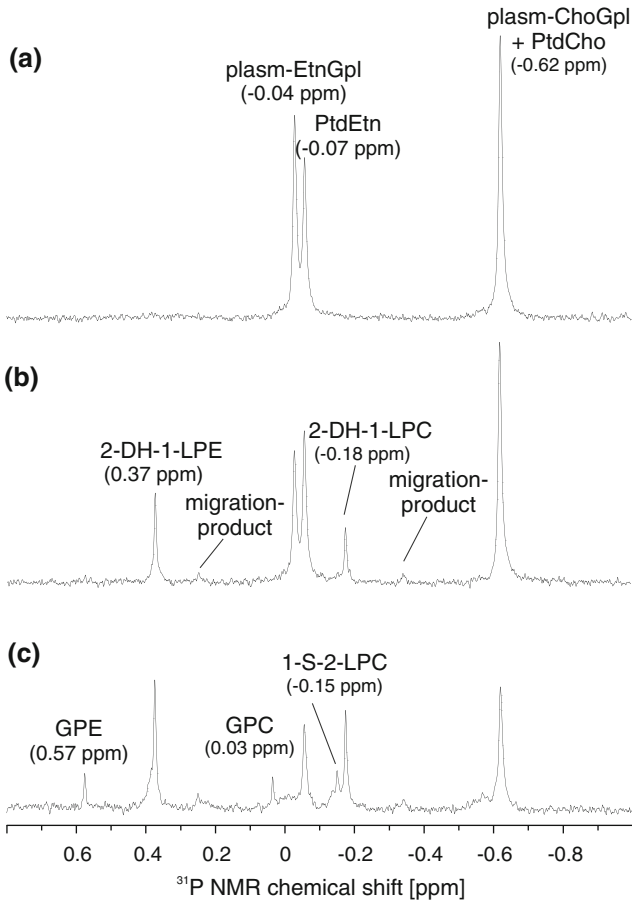

Fig. 6 242.88 MHz ^{31}P-NMR spectra of the combined organic and aqueous extracts of an $SDHPC_{plasm}$/SDHPC and $SDHPE_{plasm}$/SDHPE mixture after incubation with **a** buffer, **b** 2.5 mM and **c** 10 mM HOCl for 1 h at room temperature. The plasmalogen, PtdCho and PtdEtn concentrations accounted for 1 mM in all cases. Further methodological details are available in [58]

incubation with different concentrations of HOCl are shown in Fig. 6. In trace a, the ^{31}P-NMR spectrum of the reaction mixture incubated with pure buffer in the absence of HOCl is shown as control. The peaks appearing beside the resonances of $SDHPC_{plasm}$ and SDHPC at $\delta = -0.62$ ppm represent the resonances of $SDHPE_{plasm}$ (−0.04 ppm) and SCPE (−0.07 ppm). With increasing HOCl concentrations (2.5 mM) the intensities of the $SDHPE_{plasm}$ and the $SDHPC_{plasm}$/SDHPC resonance decrease continuously whereby 2-DH-1-LPE (0.37 ppm) and 2-DH-1-LPC (−0.18 ppm) are generated (trace b). At the highest HOCl concentration (10 mM, trace c) the $SDHPE_{plasm}$ resonance has completely disappeared whereas the GPE resonance increased concomitantly with the GPC resonance. This proves the sequential formation of 2-DH-1-LPE and GPE concomitantly with 2-DH-1-LPC and GPC upon HOCl-treatment of polyunsaturated plasmalogen-EtnGpls and ChoGpls in the same reaction mixture.

A quantitative evaluation of the ^{31}P-NMR data is given in Fig. 7. As already outlined above, 0.5 mM DPPA served as internal reference. With increasing HOCl concentrations, the concentration of the $SDHPC_{plasm}$/SDHPC resonance decreases slowly (Fig. 7a, black triangles). The concentration of 2-DH-1-LPC (Fig. 7a, black rectangles) reaches a maximum at about 5 mM HOCl. The decrease of the $SDHPC_{plasm}$/SDHPC resonance for about 0.7 mM correlates with the 0.7 mM increase of the 2-DH-1-LPC in the presence of 5 mM HOCl. The subsequent decrease in the 2-DH-1-LPC resonance at HOCl concentrations of 7.5 and 10 mM is consistent with the pronounced GPC

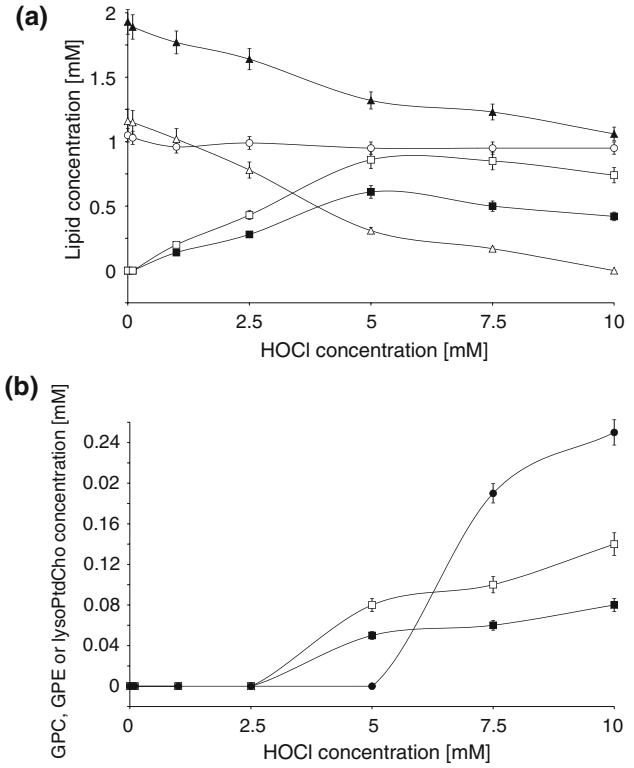

Fig. 7 Quantitative analysis of the integral peak intensities of the ^{31}P NMR resonances provided in Fig. 6: The absolute $SDHPC_{plasm}$/SDHPC (*black triangles*) and 2-DH-1-LPC (*black rectangles*) concentrations as well as the absolute $SDHPE_{plasm}$ (*white triangles*), SCPE (*white circles*) and 2-DH-1-LPE (*white rectangles*) concentrations (**a**) as well as the GPC (*black rectangles*), GPE (*white rectangles*) and 1-S-2-LPC (*black circles*) concentrations (**b**) calculated by comparison with the integral intensity of the internal standard (DPPA) are shown. *Error bars* represent standard deviations of three independent measurements. The *drawn lines* were not derived from a mathematical model but do only represent spline curves to guide the eye

generation (Fig. 7, trace b, black rectangles) and confirms the sequential formation of 2-DH-1-LPC and GPC from the plasmalogen even in the presence of additional highly unsaturated GPLs. At the highest HOCl concentrations (7.5 and 10 mM) the generation of small amounts of 1-S-2-LPC derived from SDHPC is also evident (Fig. 7b, black circles). The $SDHPC_{plasm}$/SDHPC concentration decrease by 0.8 mM at 10 mM HOCl concentration agrees well with the sum of the concentration increase of 2-DH-1-LPC (0.5 mM), 1-S-2-LPC (0.25 mM) and GPC (0.07 mM).

Furthermore, the concentration of the $SDHPE_{plasm}$ resonance decreases with increasing HOCl concentrations (Fig. 7a, white triangles). The concentration of 2-DH-1-LPE (Fig. 7a, white rectangles) reaches a maximum at about 5 mM HOCl. The decrease of the $SDHPE_{plasm}$ resonance by about 0.8 mM correlates with the 0.8 mM increase of the 2-DH-1-LPE at 5 mM HOCl. The subsequent decrease of the 2-DH-1-LPE resonance at the highest HOCl concentrations of 7.5 and 10 mM is consistent with the pronounced GPE generation (Fig. 7, trace b, white rectangles) and confirms the sequential formation of 2-DH-1-LPE and GPE even in the presence of further highly unsaturated GPLs. The intensity of the SDHPE resonance remains nearly constant upon HOCl treatment (Fig. 7a, white circles). The $SDHPE_{plasm}$ concentration decrease by 1 mM at 10 mM HOCl concentration agrees well with the sum of the concentration increase of 2-DH-1-LPE (0.85 mM) and GPE (0.14 mM).

Overall, the NMR data indicate only a slightly higher reactivity of $SDHPE_{plasm}$ in comparison to $SCPC_{plasm}$.

Boar Spermatozoa Extracts

Boar spermatozoa are characterized by a very high content of ether linked and plasmalogen GPL. The most important constituents are 1-*O*-1′-palmitenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine ($PDHPC_{plasm}$) and 1-*O*-1′-palmitenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphoethanolamine ($PDHPE_{plasm}$) [20, 62].

Important ether-linked glycerophospholipids are 1-*O*-1′-palmityl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine ($PDHPC_{ether}$), 1-*O*-1′-palmityl-2-docosapentaenoyl-*sn*-glycero-3-phosphocholine ($PDPPC_{ether}$) and 1-*O*-1′-palmityl-2-docosapentaenoyl-*sn*-glycero-3-phosphoethanolamine ($PDPPE_{ether}$) [20]. Furthermore, boar spermatozoa contain significant amounts of sphingomyelin (CerPCho) and diacyl-PtdChos. However, a detailed investigation of the reactivity of these compounds with HOCl was outside the scope of this paper.

The ^{31}P-NMR spectra of boar spermatozoa lipid extracts after incubation with different concentrations of HOCl measured at 303 K (left hand side) and 333 K (right hand side) are shown in Fig. 8. These different temperatures were chosen in order to demonstrate the significant resolution increase under slightly different conditions. In trace a, the spectrum of a boar spermatozoa lipid extract incubated with pure buffer in the absence of HOCl is shown as reference. This spectrum exhibits six major resonances representing PlsCho and PtdCho (−0.62 ppm), PakCho (−0.56 ppm), two different CerPCho resonances (CerPCho 14:0 $\delta = -0.06$ and CerPCho 16:0 $\delta = 0.01$ ppm), plasmalogen–EtnGpl (−0.03 ppm) and ether–EtnGpl (0.02 ppm). This is in agreement with the known GPL composition of boar spermatozoa [20].

After incubation of the spermatozoa extracts with increasing HOCl concentrations (2.5 mM, i.e. about fourfold excess over the PlsCho, the PlsCho and PlsEtn resonances decreased significantly and resonances corresponding to the expected degradation products, the 2-DH-1-LPC (−0.18 ppm) and 2-DH-1-LPE (0.37 ppm), became detectable (Fig. 8, trace b). Furthermore, the PakCho resonance (−0.56 ppm) decreases slightly and ether-lysoPtdCho

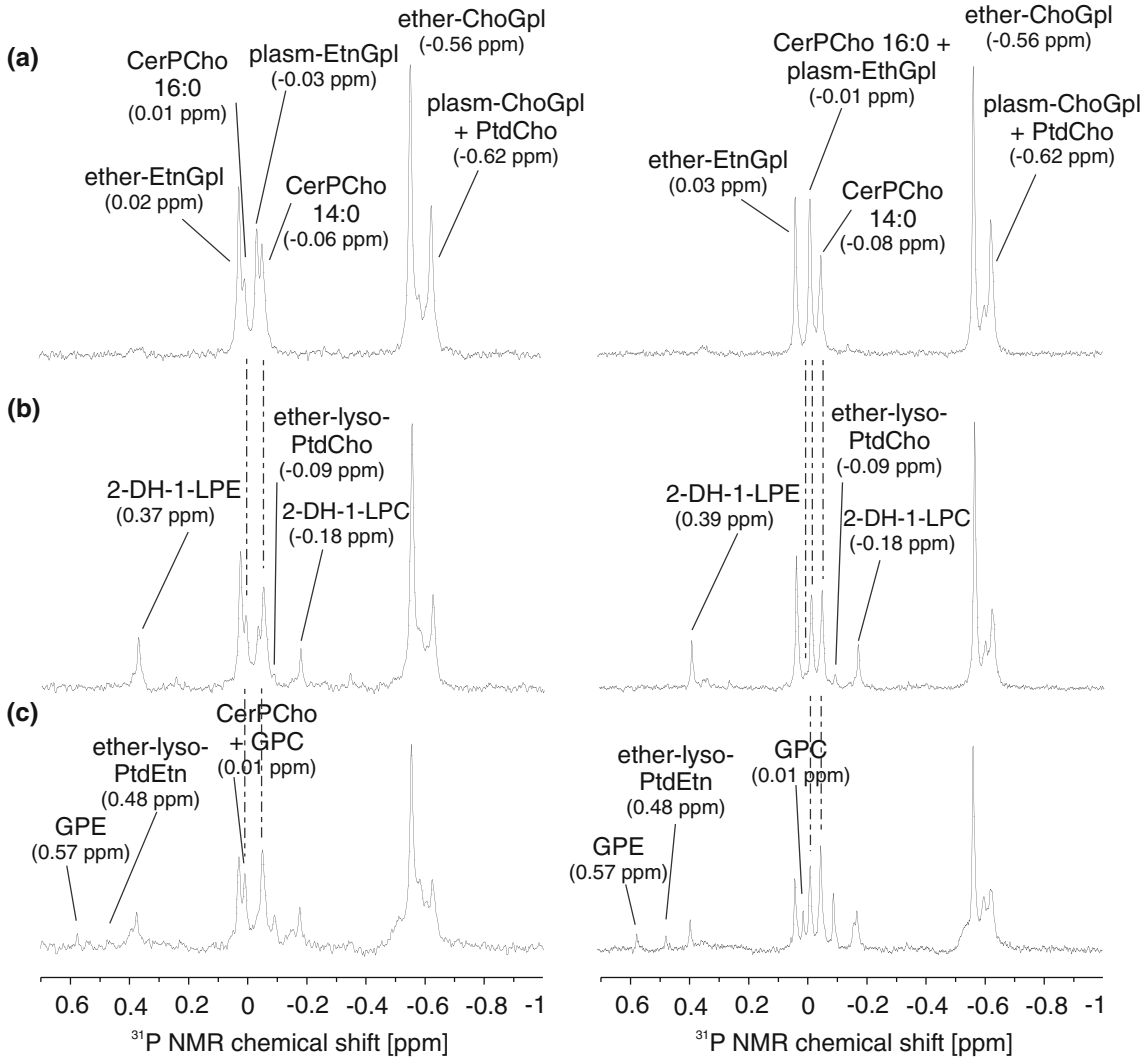

Fig. 8 242.88 MHz ^{31}P-NMR spectra of the combined organic and aqueous extracts of boar spermatozoa after incubation with **a** buffer, **b** 2.5 mM and **c** 10 mM HOCl for 1 h at room temperature. The spectra at the left side were acquired at 303 K whereas spectra at the right side were recorded at 333 K. The boar phospholipid concentration was about 4 mM in all cases. Spectra were scaled according to the resonance of the used DPPA standard (peak outside the shown frequency range at 3.15 ppm) and all peak assignments and the chemical shifts are indicated. *Vertical dotted lines* indicate the resonances undergoing the most pronounced changes

(−0.09 ppm) appears as a weak resonance. The intensities of PlsCho and PlsEtn as well as PakCho and PakEtn were additionally diminished after incubation with 10 mM HOCl (Fig. 8, trace c), whereby the intensities of the ether derived lysoPtdCho and lysoPtdEtn resonances increased slightly. In contrast, the 2-DH-1-LPC and 2-DH-1-LPE resonances remain nearly constant or decrease only slightly, respectively. This observation can be explained by the formation of GPC (0.01 ppm) and GPE (0.57 ppm) from unsaturated 1-lysoPtdCho and 1-lysoPtdEtn. Unfortunately, the resonance of GPC overlaps with the peak of CerPCho 16:0 if the ^{31}P-NMR spectra are recorded at 303 K. Therefore, all ^{31}P-NMR spectra were additionally acquired at 333 K (Fig. 8 right hand side). At 333 K the GPC peak can be differentiated from the resonance of CerPCho containing 16:0, whereby, however CerPCho containing 16:0 overlaps with PlsEtn (Fig. 8, trace a, right hand side). From the spectra recorded at 333 K it is evident that weak GPC formation is observed already after incubation with 2.5 mM HOCl (trace b, right hand side). At HOCl concentrations of 10 mM the GPC resonance reaches its maximum intensity (trace c, right hand side). This confirms the sequential formation of 2-DH-1-LPC and GPC as well as of 2-DH-1-LPE and GPE also upon HOCl-treatment of biologically relevant boar spermatozoa lipid extracts, not only in simplified model systems.

Additionally, the incubation of boar spermatozoa lipid extracts with different HOCl concentrations was also studied by MALDI–TOF MS. We focussed on $PDHPC_{plasm}$ in order to confirm the ^{31}P-NMR data. The $PDHPC_{plasm}$

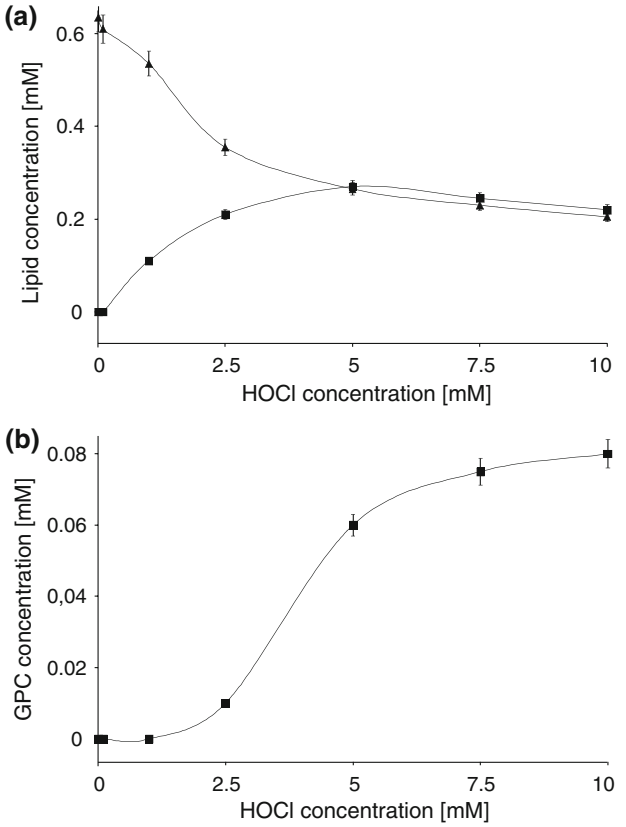

Fig. 9 Quantitative analysis of the integral peak intensities of the ^{31}P NMR spectra shown in Fig. 8. The absolute plasmalogen-ChoGpl (*triangles*) and the 2-DH-1-LPC concentrations (*rectangles*) (trace a) as well as the absolute GPC concentrations (*rectangles*) (trace b) determined by ^{31}P-NMR spectroscopy and calculated according to the known concentration of the DPPA internal standard are shown in dependence on the HOCl concentration. *Error bars* represent standard deviations of three independent measurements. In the case of the 2-DH-1-LPC the *error bars* are in the range of the symbol size. The *drawn lines* were not derived from a mathematical model but do only represent spline curves to guide the eye

peaks at $m/z = 790.6$ and 812.6 (initial concentration about 0.6 mM) disappeared nearly completely upon treatment with 2.5 mM HOCl (data not shown). New peaks were detectable in the low mass range at $m/z = 568.3$ and 590.3 corresponding to the H^+ and Na^+ adduct of 1-lyso-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (2-DH-1-LPC). After incubation with 10 mM HOCl the 2-C-1-LPC peaks disappeared. Concomitantly, the peaks of GPC ($m/z = 258.1$ and 280.1) appeared in the spectra of the aqueous phases and increased with increasing HOCl concentrations (data not shown).

A quantitative evaluation of the data obtained by ^{31}P NMR is shown in Fig. 9. Only the fate of the PlsCho and their related degradation products were quantitatively analyzed. Unfortunately, however, the PlsCho resonance overlaps with the PtdCho resonance in the ^{31}P-NMR spectra and, thus, both compounds can not be individually analyzed. However, the intensity loss of PlsCho was accompanied by an increase of the corresponding 2-DH-1-LPC resonance. With increasing HOCl concentrations, the PlsCho concentration decreases slowly (trace a, triangles), whereby HOCl concentrations of 2.5 mM and higher lead to marked degradation of PlsCho. The concentration of 2-DH-1-LPC (trace a, rectangles) reaches a maximum at about 5 mM HOCl. The subsequent decrease of the 2-DH-1-LPC concentration in the presence of 7.5 and 10 mM HOCl is consistent with marked GPC generation (trace 9b). However, please note that GPC formation starts already at HOCl concentrations of about 2.5 mM. This result unequivocally proves the degradation of the initially formed 2-DH-1-LPC from plasmalogen-ChoGpl and the subsequent formation of GPC under the influence of HOCl. This obviously also holds for complex biological lipid mixtures where highly unsaturated GPL "substrates" are additionally available for reaction with HOCl.

Discussion

The high sensitivity of plasmalogens—in particular their vinyl-ether bond—to different ROS has been well documented [3]. In a previous study the degradation of PlsCho by HOCl, a highly oxidative and chlorinating reagent produced by MPO, a heme-enzyme which is released by stimulated PMNL under inflammatory conditions could be demonstrated. PlsCho containing highly unsaturated fatty acyl residues (e.g. DHA) at the *sn*-2-position of the glycerol backbone are degraded by HOCl to a higher extent than PtdCho resulting in 1-lysoPtdCho as well as glycerophosphocholine [47]. This confirms that the vinyl-ether bond is the most oxidation-sensitive double bond in GPL leading to 1-lysoPtdCho, whereas the highly unsaturated acyl residue in the *sn*-2 position is less sensitive to ROS and results in GPC generation. This holds at least for isolated PlsCho model systems.

However, oxidative stress affects not only one substrate or one particular GPL class. From the chemical view of lipid oxidation all highly unsaturated acyl residues are sensitive targets for HOCl. Consequently, the aim of this study was to investigate which highly unsaturated acyl chain is oxidatively modified to which extent by HOCl treatment of a PlsCho and PtdCho mixture containing both the same highly unsaturated fatty acyl residue, DHA, in *sn*-2 position.

In addition to the expected 2-DH-1-LPC generation from $SDHPC_{plasm}$ in a $SDHPC_{plasm}$/SDHPC mixture, a secondary reaction product—GPC—resulting from further degradation of 2-DH-1-LPC can be easily observed if only a slight excess of HOCl is used. In contrast, only minor 1-S-2-LPC generation (resulting from HOCl-induced degradation of

SDHPC) could be detected. The GPC generation from $SDHPC_{plasm}$ or its degradation product, 2-DH-1-LPC, is about three times more pronounced than the 1-S-2-LPC generation from SDHPC in an equimolar mixture of $SDHPC_{plasm}$/SDHPC. This is remarkable because both contain the same fatty acyl residue in the *sn*-2 position but in complete agreement with former investigations [63].

Obviously, HOCl cleaves the unsaturated fatty acyl chain preferentially in 2-DH-1-LPC rather than in SDHPC. One possible explanation is the fact that the fatty acyl chain in the *sn*-2 position of SDHPC is sterically shielded against ROS attacks in comparison to the acyl chain in the *sn*-2 position of 2-DH-1-LPC. In contrast, the *sn*-2 position of 2-DH-1-LPC seems easily accessible for HOCl (leading finally to GPC generation) when the residue in *sn*-1 position is previously hydrolyzed by HOCl. However, it is so far unknown if this in vitro effect is primarily caused by the much smaller vesicular size of 2-DH-1-LPC in comparison to SDHPC [58]. The generation of chlorohydrins as transients between the educt and the corresponding lyso compound was also expected. As lipids with polyunsaturated fatty acyl residues were exclusively used in this study, many different chlorinated products can be expected. High numbers of chlorination sites induce the cleavage of the modified fatty acyl residues due to the considerable electronegativity of the added chlorine [44]. Therefore, the negligible generation of chlorohydrins is caused by simultaneous generation of lysolipids. Additionally, the large variety of chlorinated products results in very low peak intensities per single product and, thus, poor detectability.

Additionally, PlsEtn exhibited a similar reaction behavior as PlsCho upon HOCl-treatment leading to 2-DH-1-LPE and further GPE generation, whereby PlsEtn exhibited apparently slightly higher reactivity than ChoGpl.

Subsequent to the evaluation of artificial GPL systems, a more complex lipid system mimicking the complex lipid mixtures of biological membranes was also investigated. Many tissues and cellular membranes contain significant amounts of plasmalogens. Spermatozoa membranes, especially boar spermatozoa [20], contain elevated amounts of PlsCho and PlsEtn. Furthermore, they contain considerable amounts of other highly unsaturated GPL, for instance PakCho and PakEtn. The detection of alterations in the concentration of selected lipid-derived metabolites can be beneficial in the management of various pathological conditions, including infertility in males [64], whereby the GPC concentration in mammalian semen is considerable and much higher than in other body fluids [65]. For this reason, boar spermatozoa membrane lipid extracts were investigated to translate the results of the PlsCho/PtdCho mixture into a more complex, but also more relevant biological lipid mixture.

GPC is known as a water-soluble phosphodiester acting as lysophospholipase inhibitor and represents, therefore, a compound that decreases the phospholipid turnover [65, 66]. The GPL content of spermatozoa does not significantly change but the GPC concentration increases during their passage through the female genital tract [65]. Thus, decreased plasmalogen levels are likely to result in enhanced GPC concentrations that in turn enable lysophospholipid reacylation and reduce the need of de novo GPL synthesis [65]. Nevertheless, GPC accumulation is efficiently regulated by the enzyme GPC: choline phosphodiesterase [67].

Aging or chronic inflammatory processes are characterized by a significant decrease in the plasmalogen content and concomitantly an accumulation of oxidation products that are likely to disturb the sensitive balance between apoptosis and necrosis [22, 68]. Exceedingly high necrosis rates may result in spermatozoa damage and infertility. Thus, the role of accumulated plasmalogen degradation products under conditions of oxidative stress must be studied in more detail. GPC and GPE are presumably also relevant but so far underestimated oxidation products.

Summarizing, we were able to demonstrate that the formation of GPC and GPE from PlsCho and PlsEtn, respectively, occurs under in vitro and in vivo conditions also in the presence of further highly unsaturated GPL. The first step of the HOCl-induced degradation of GPL mixtures containing plasmalogens is surely the oxidation of the vinyl-ether group resulting in the generation of 1-lysoPtdCho and 1-lysoPtdEtn. It could be shown that HOCl subsequently affects the fatty acyl residue in the *sn*-2 position of 1-lysoPtdCho about three times more efficiently than that of diacyl-GPLs.

Consequently, the generation of GPC and GPE from plasmalogen-ChoGpls and -EtnGpl and their degradation products (1-lysoPtdCho and 1-lysoPtdEtn) must be considered as highly relevant in biological membranes and particularly under inflammatory conditions.

Acknowledgment This work was supported by the German Research Council (DFG Schi 476/5-1, FU 771/1-1 and Gl 199/4-3) and the Federal Ministry of Education and Research (Grant BMBF 0313836). The kind gift of boar spermatozoa samples by Dr. Karin Müller and Ulrike Jakop is gratefully acknowledged. We would also like to thank the Translational Centre for Regenerative Medicine (TRM) Leipzig for the possibility to use the selective ^{31}P dual NMR probe. Finally, we are greatly indebted to Dr. Jürgen Schiller for careful proof-reading of the final manuscript version.

Abstract Atherosclerosis contributes to disruption of neuronal signaling pathways by producing lipid-dependent modifications of brain plasma membranes, neuroinflammation and oxidative stress. We investigated whether long-term (11 weeks) consumption of refined- (ROO) and pomace- (POO) olive oil modulated the fatty acid composition and the levels of membrane signaling proteins in the brain of apolipoprotein E (apoE) knockout (KO) mice, an animal model of atherosclerosis. Both of these oils are rich in bioactive molecules with anti-inflammatory and antioxidant effects. ROO and POO long-term consumption increased the proportion of monounsaturated fatty acids (MUFAs), particularly of oleic acid, while reducing the level of the saturated fatty acids (SFAs) palmitic and stearic acid. As a result, the MUFA:SFA ratio was higher in apoE KO mice brain fed with ROO and POO. Furthermore, both oils reduced the level of arachidonic and eicosapentaenoic acid, suggesting a decrease in the generation of pro- and anti-inflammatory eicosanoids. Finally, ROO and POO induced an increase in the density of membrane proteins implicated in both the Gαs/PKA and Gαq/PLCβ1/PKCα signaling pathways. The combined effects of long-term ROO and POO consumption on fatty acid composition and the level of signaling proteins involved in PKA and PKC activation, suggest positive effects on neuroinflammation and brain function in apoE KO mice brain, and convert these oils into promising functional foods in diseases involving apoE deficiency.

Keywords Apolipoprotein E knockout mice · Dietary olive oils · Brain · Fatty acid composition · Signaling proteins

Abbreviations

AA	Arachidonic acid
apoE	Apolipoprotein E
BHT	2,6-di-*tert*-butyl-*p*-cresol
COX	cyclooxygenase
CNS	Central nervous system
DHA	Docosapentaenoic acid
EPA	Eicosapentaenoic acid
FAMEs	Fatty acid methyl esters
KO	Knockout
MUFA	Monounsaturated fatty acid
PKA	Protein kinase A
PKC	Protein kinase C
PLA2	Phospholipase A2
PLC	Phospholipase C
POO	Pomace olive oil
PUFA	Polyunsaturated fatty acid
ROO	Refined olive oil
SDS	Sodium dodecyl sulfate
SFA	Saturated fatty acid

Introduction

Atherosclerosis, a main risk factor for ischemic stroke, is today considered as a chronic inflammatory state [1]. A critical event promoting atherosclerosis involves accumulation and oxidation of LDL-derived lipids in the vascular wall triggering a subsequent inflammatory response. The release of pro-inflammatory cytokines and activation of phospholipase A2 (PLA2) by macrophage foam cells in developing atherosclerotic lesions alters brain lipid metabolism and stimulates production of eicosanoids and reactive oxygen species thereby favoring injuries in the central nervous system (CNS) [2, 3].

Apolipoprotein E (apoE) is the main lipoprotein transporter of cholesterol, phospholipids and polyunsaturated fatty acids in the brain and mediates the binding of lipoproteins to cell surface receptors. Deregulated lipid metabolism due to deficiencies in apoE may be of particular importance for CNS injuries and disorders, such as Alzheimer's disease (AD), as abnormalities in lipid metabolism and peroxidation may contribute to the progression of neurodegeneration [4]. For this reason, apoE knockout (KO) mice, originally developed for studies on the pathogenesis of atherosclerosis, have become an attractive animal model for studying the consequences of an imbalance in lipid metabolism on brain function [5, 6]. Accordingly, brains from apoE KO mice show alterations in the phospholipid and fatty acid composition when compared with control mice [7], which could in part explain the impairment in neurotransmitter-associated signaling reported in these mice [8]. In this context, impaired coupling of neurotransmitter receptors (e.g., muscarinic M1 receptors) to G proteins as well as reductions in protein kinase A (PKA), phospholipase C (PLC) and protein kinase C (PKC) activities have been observed in brain tissues from both patients with AD [9, 10] and apoE KO mice [11].

The Mediterranean diet is characterized by the consumption of olive oil (OO), which contains a high proportion of the natural monounsaturated fatty acid (MUFA) oleic acid (about 80%). The so-called "orujo" or pomace olive oil (POO) is a sub-product of OO that is traditionally commercialized in Spain and also rich in oleic acid (about 74%). The importance of high-oleic acid oils as an integral component of the Mediterranean diet and its beneficial influence on cardiovascular parameters is well known [12]. Indeed, there is evidence to suggest that OO is fundamental for the beneficial influence of this diet on inflammatory parameters [13]. In addition to fatty acids, ROO and POO contain also minor quantities of other compounds in their unsaponifiable fraction, such as tetra- and penta-cyclic triterpenes (e.g., oleanolic and maslinic acid, erythrodiol and uvaol), sterols and tocopherols. Several important biological activities, e.g., antioxidant, anti-inflammatory, vasodilatory and anti-tumoral effects, have been recently attributed to these minor nutritional components [14–17]. Moreover, new improved procedures for POO extraction, through centrifugation and additional refining, permit us to concentrate significant amounts of them in the final product [18]. Accordingly, long-term consumption (>8 weeks) of diets enriched in OO and POO delayed the progression of atherosclerosis in apoE KO mice by modifying plasma lipids and pro-inflammatory parameters as well as by increasing antioxidant defenses [19–22]. Nevertheless, little is known about the influence of these dietary oils on the pathologically altered fatty acid composition in the brain and the signaling proteins implicated in neurotransmission in this animal model.

Therefore, the purpose of the present study was to examine the changes in lipid composition and pivotal signaling proteins in the brain of apoE KO mice. The content of the different fatty acid types was measured in this model after long-term consumption of refined OO (ROO) and POO (Table 1). Furthermore, we also analyzed whether the observed changes in lipid composition were accompanied by variations in membrane proteins implicated in G protein signaling pathways that lead to activation of PKA and PKC in the brain.

Table 1 Composition of the refined (ROO) and pomace olive oil (POO)

Component	ROO	POO
Erythrodiol + Uvaol	0.0017	0.050
Maslinic acid	0	0.011
Squalene	0.26	0.25
Total phytosterols	0.112	0.224
Total tocopherols	0.022	0.098
Waxes	0.012	0.34
Fatty acids		
Myristic (14:0)	0.02	0.02
Palmitic (16:0)	10.98	10.29
Stearic (18:0)	3.53	2.95
Arachidic (20:0)	0.42	0.45
Behenic (22:0)	0.12	0.17
Lignoceric (24:0)	0.05	0.07
Palmitoleic (16:1)	0.82	0.76
Oleic (18:1)	77.80	74.27
Gadoleic (20:1)	0.25	0.33
Linoleic (18:2n-6)	4.52	8.07
Linolenic (18:3n-3)	0.62	0.70
Saturated	15.12	13.95
Monosaturated	78.87	75.36

Dietary components are expressed as g% (w/w). Values are means ± SEM of three determinations. SEM values were less than 0.01%

Experimental Procedures

Animals and Diets

Homozygous apolipoprotein E knockout mice (apoE KO), hybrids of C57BL/6J and 129Ola strains, were bred at the 'Unidad Mixta de Investigación', Zaragoza. Twenty-six males, aged two months were fasted overnight, anesthetized with isofluorane, and blood samples were obtained by retroorbital bleeding to estimate the initial plasma cholesterol and triglycerides. Three random groups with equivalent plasma cholesterol and triglycerides were housed in sterile filter-top cages in rooms maintained on a 12-h light/12-h dark cycle. Animals had ad libitum access to food and water. The study protocol was approved by the Animal Research Ethical Committee at the University of Zaragoza. Body weights and food intake were recorded throughout the experiment.

Mice were maintained on normal chow: Teklad Mouse/Rat Diet no. 2014 (Harlan Teklad, Harlan Ibérica, Barcelona, Spain). Three study groups were set up: (a) a control group fed on chow alone (n = 9), (b) a group that received freshly prepared refined olive oil (ROO, 10% w/w) from our pilot plant along with chow diet ($n = 9$), and (c) a group that received pomace olive oil (POO, 10% w/w) in their diet (also called "orujo olive oil") ($n = 8$) as described previously [20]. All diets were prepared weekly and stored in N_2 atmosphere at −20 °C, fresh food was provided daily. Animals were fed on experimental diets for 11 weeks and all diets were well tolerated. To determine their composition, both olive oils were analyzed following the standard regulations of the European Union [23]. Briefly, phytosterols and triterpenic dialcohols (erythrodiol + uvaol) were separated by thin-layer chromatography, whereas the pentacyclic triterpene acid fraction (maslinic acid) was isolated by solid-phase extraction [18]. Afterwards, the compounds were analyzed by gas chromatography. Total tocopherols were determined by the IUPAC 2432 method [24]. Table 1 shows the composition of the different olive oils. At the end of the experimental period and after fasting overnight, animals were sacrificed by suffocation in CO_2 and left brain tissue was rapidly frozen in liquid N_2.

Analysis of Total Brain Fatty Acids

To analyze fatty acids, lipids were extracted from 100 mg of brain tissue as described elsewhere [25] using 2,6-di-*tert*-butyl-*p*-cresol (BHT) as an antioxidant. The extracted lipids were redissolved in 1 mL of chloroform:methanol (2:1, v/v) and maintained at −20 °C until use. Lipids were transmethylated and the resulting fatty acid methyl esters (FAMEs) were analyzed by gas chromatography as described previously [26]. Individual FAMEs were identified by comparing the retention times with that of standards.

Immunoblot Analysis and Quantification of Membrane-Associated Signaling Proteins in the Brain

Quantitative immunoblotting of G proteins, PLCβ1 and protein kinases (PKA and PKCα) was carried out in brain homogenates. Briefly, total brain proteins were solubilized and fractionated by SDS–polyacrylamide (10%) gel electrophoresis, and then transferred to membranes by western blotting. The following primary antibodies were used to detect the distinct proteins: anti-Gαs (1:350), anti-Gαq/11 (1:5,000) and anti-Gαo (1:5,000) all from Santa Cruz Biotechnology (USA), and anti-PKAcatα (1:1,000), PKARIIα (1:1,000), PKARIIβ (1:5,000), anti-PLCβ1 (1:1,000) and anti-PKCα all from BD Transduction Laboratories (Heidelberg, Germany). The quantification of the labelling was performed by image analysis using at least four standard curves of different protein contents loaded on the same gels (i.e., total protein loaded vs integrated optical density) [see 27, 28]. This quantification procedure was repeated at least three times for each sample on different gels. Values obtained from the groups supplemented with ROO and POO were normalized to the protein content of the control group (taken as 100%).

Statistical Analysis

Results are expressed as means ± SEM. One-way analysis of variance (ANOVA) followed by Bonferroni's test was used for the statistical evaluations. Differences between experimental groups were considered statistically significant at a value of $P < 0.05$.

Results

Effect of Chronic ROO and POO Consumption on Brain Fatty Acid Composition

Long-term consumption of ROO and POO induced changes in the fatty acid content of total lipids isolated from apoE KO mice brain. After the 11-week period of ROO and POO consumption, MUFA proportion had increased by 5.7 and 2.9%, respectively. When compared to control animals, these changes meant relative increases of 23 and 12% in the ROO and POO groups, respectively (Table 2). The difference was mainly due to an increase in the proportion of oleic acid (18:1n-9). In contrast, ROO and POO consumption decreased the amount of polyunsaturated fatty acids

(PUFAs) by about 3.4%. This corresponded to a relative decrease of at least 10% in both experimental groups when compared to control animals (Table 2). Moreover, ROO and POO consumption significantly decreased the content of the saturated fatty acids (SFAs), stearic (18:0) and palmitic (16:0) acid. These SFA's diminished in the order of 1.5–2.7%, respectively, which represented a relative change of 8–14% when compared to the control group. As a result, after ROO and POO consumption the ratios of MUFAs:PUFAs and MUFAs:SFAs were higher in apoE KO mice brain (Table 2). Prior to ROO and POO consumption, the proportion of araquidonic acid (AA) (20:4n-6), a precursor in the production of pro-inflammatory eicosanoids, was 10.85 ± 0.05% of the total fatty acids. In contrast, ROO and POO consumption decreased AA proportion by 19%, when compared to control animals. Interestingly, the proportion of eicosapentaenoic acid (EPA) (20:5n-3) and docosapentaenoic acid (DHA) (22:6n-3), which are metabolized to potent anti-inflammatory mediators, also decreased by around 10 and 16%, respectively, in both experimental groups (Table 2).

Effects of Chronic ROO and POO Consumption on Membrane Signaling Proteins in the Brain

To determine whether the changes in lipid composition induced by long-term ROO and POO consumption affected membrane-associated proteins, we measured the brain levels of G proteins, PKA (IIα and IIβ), PLCβ1 and PKCα by quantitative immunoblotting. These proteins are major intracellular signaling proteins regulating brain function and their interaction with membranes is sensitive to membrane lipid composition. Long-term ROO consumption induced a significant increase in the overall levels of Gαs and Gαq/11 in apoE KO mice brain when compared to controls (75 ± 15 and 27 ± 5%, respectively, Fig. 1a, b). Likewise, POO consumption also produced a significant increase of these G protein levels (60 ± 10% for Gαs, Fig. 1a; and 59 ± 4% for Gαq/11, Fig. 1b). Interestingly, a further increase in the levels of Gαq/11 was observed when the diet was supplemented with POO (26 ± 3% when compared to the ROO group, Fig. 1b). In contrast, no significant changes were observed in brain Gαo levels after ROO or POO consumption (Fig. 1c).

Having observed that ROO and POO consumption increased Gαs and Gαq/11 levels, we set out to determine whether proteins downstream of these G proteins were also influenced by these dietary supplements. Hence, we analyzed the effects of ROO and POO consumption on PKA (downstream of Gαs), and on PLCβ1 and PKCα (downstream of Gαq/11) levels. In agreement with the Gαs protein data, we observed increased levels of the catalytic (catα; 141 ± 7%) and the regulatory RIIα (134–141%) and RIIβ (149–152%) PKA subunits after chronic ROO and POO consumption, when compared to control animals (Fig. 2). Similarly, brain PLCβ1 and PKCα levels also increased significantly in both groups. The levels of PLCβ1 augmented by 16 ± 6% in the ROO group and 21 ± 6% in the POO group when compared to control animals (Fig. 3a). Finally, PKCα levels were equally up-regulated, albeit to a much higher extent, increasing 61 ± 9 and 109 ± 8% in ROO and POO groups, respectively (Fig. 3b). As observed for Gαq/11 (Fig. 1b), long-term POO consumption further increased brain PKCα levels (30 ± 5%) when compared to ROO group (Fig. 3b).

Discussion

Deficiencies in apolipoprotein E (apoE) alter lipid homeostasis and produce lipid modifications of plasma membranes in the brain, in this way contributing to

neurodegeneration [4]. ApoE knockout (KO) mice, an animal model for studies on the pathogenesis of atherosclerosis, develop cognitive deficits resembling those of Alzheimer's disease (AD) and have become an attractive animal model for studying the consequences of an imbalance in the lipid metabolism on brain function [6, 29]. Indeed, important changes in cholesterol or phospholipid membrane content, cholesterol membrane leaflet distribution, and degree of FA saturation, have been reported in apoE KO mice brain [7, 30]. Interestingly, these alterations could in turn affect cognitive performance of these mice [8]. Furthermore, the brain of atherosclerotic apoE KO mice is believed to be particularly vulnerable to oxidative stress as it has lower antioxidant and anti-inflammatory defenses, which leads to progressive brain cell damage and decline in cerebral function [31].

In this work, we have analyzed the changes in both fatty acid composition and membrane-signaling protein levels induced by long-term (11 weeks) ROO and POO consumption in apoE KO mice brain. These two olive oils contained high concentrations of bioactive molecules, such as tetra- and penta-cyclic triterpenes (erythrodiol + uvaol and maslinic acid), tocopherols and phytosterols (Table 1), which are known to be essential for the beneficial influence of the Mediterranean diet on inflammatory [15, 32] and cardiovascular parameters [33], and which were recently associated with a delay of atherosclerosis development in apoE KO mice [20, 34]. In this context, particularly triterpenes, such as oleanolic acid, improved not only brain anti-inflammatory defenses but also ameliorated malfunctioning neurological signs in an experimental animal model for multiple sclerosis [35]. For these reasons, we

hypothesized that dietary ROO and POO supplementation may also have positive effects on neuroinflammation and brain function by modulating lipid composition and the levels of signaling proteins in apoE KO mice brain.

After long-term ROO and POO consumption, the most apparent difference in brain fatty acid composition was a significant increase in the total amount of MUFA. This increase was mostly due to a rise in the proportion of oleic acid (Table 2), probably as a result of the high amount of oleic acid present in both olive oils (Table 1). It is known that higher MUFA:SFA ratio reduces membrane microviscosity (i.e., increase membrane fluidity), thereby enabling proteins involved in cellular signaling to function together. In this context, the increase in the MUFA:SFA ratio observed after ROO and POO could account for some cognitive benefits by reverting the pathologically altered membrane fluidity seen in the brain of apoE KO mice [30]. On the other hand, dietary fatty acids can also influence the production of eicosanoids, which are implicated in inflammatory processes. The activation of PLA2 in atherosclerotic lesions releases arachidonic acid (AA), eicosapentaenoic acid (EPA), and docosapentaenoic acid (DHA). Whereas AA is metabolized to pro-inflammatory eicosanoids through the COX pathway, a major pathway promoting inflammation, EPA and DHA are mainly processed to molecules that have important roles as inflammation inhibitors (e.g., resolvins) [36]. Interestingly, ROO and POO consumption decreased not only the level of AA, but also that of EPA and DHA (Table 2), which most probably result in a decline of the production of pro-inflammatory and compensatory anti-inflammatory eicosanoids, suggesting a general reduction in the degree of neuroinflammation in apoE KO mice brain.

The effects on lipid composition observed in apoE KO mice brain fed with ROO and POO enriched diets were accompanied by alterations in membrane-associated proteins that influence the activation of brain PKA and PKC. Significant increases in Gαs/PKA levels were found in apoE KO mice brain of both dietary groups (Figs. 1, 2). Likewise, the levels of proteins, which participate in the phosphoinositide signaling cascade, namely the Gαq/11 protein and the enzymes PLCβ1 and PKCα, were also up-regulated after long-term ROO and POO consumption. Interestingly, POO increased brain Gαq/11 and PKCα levels to a higher extent than ROO, which could be related to the higher concentrations of triterpenes in POO [37]. PKA and PKC have been implicated in the phosphorylation of many proteins, as well as in neurotransmitter release and dopaminergic neurotransmission. Thus, the effect of the intake of both oils on the levels of membrane proteins that participate in cellular signaling (including G proteins, PKA, PLCβ1 and PKCα), suggests that they should improve GPCR-induced neuronal signaling in apoE KO mice. This would counteract the impaired neurotransmitter-mediated signal transduction that has been reported in apoE KO mice [8]. Indeed, reductions in the level and/or activity of GPCR and their corresponding G proteins, as well as of their down-stream effectors, such as PLC/PKC have been reported in both neurodegenerative disorders associated with apoE deficiency [9, 10] and in apoE KO mice [11]. Nevertheless, the participation of additional mechanisms in these processes cannot be excluded.

In summary, long-term ROO and POO consumption modulates brain fatty acid composition in apoE KO mice and influences the levels of pivotal membrane proteins implicated in the activation of PKA and PKC, suggesting positive effects on neuroinflammation and brain function. The combination of these two molecular effects might convert ROO and POO oils into valuable functional foods in diseases involving apoE deficiency. Further studies are needed to evaluate in a direct way the efficacy of olive oil consumption on cognitive function in such neurodegenerative diseases.

Acknowledgments We thank Angel Beltrán, Jesús Navarro, Carmen Navarro and Elena Santa Clotilde of the *Unidad Mixta de Investigación* for their invaluable help in maintaining the animals and Dr. Pablo V. Escribá of the University of the Balearic Islands for the helpful discussions. The Spectrum of Plant and Animal Sterols in Different Oil-Derived Intravenous Emulsions

Maria Luisa Forchielli · Germana Bersani · Sara Tala · Gabriele Grossi · Cristina Puggioli · Massimo Masi

Received: 28 February 2009 / Accepted: 27 October 2009 / Published online: 22 November 2009

Abstract Intravenous lipid constituents have different effects on various biological processes. Some of these effects are protective, while others are potentially adverse. Phytosterols, in particular, seem to be implicated with parenteral nutrition-associated cholestasis. The aim of this study is to determine the amount of plant and animal sterols present in lipid formulations derived from different oil sources. To this end, animal (cholesterol) and plant (β-sitosterol, campesterol, and stigmasterol) sterols in seven different commercially available intravenous lipid emulsions (ILEs) were quantified by capillary gas chromatography after performing a lipid extraction procedure. The two major constituents of the lipid emulsions were cholesterol (range 14–57% of total lipids) and β-sitosterol (range 24–55%), followed by campesterol (range 8–18%) and stigmasterol (range 5–16%). The fish oil-derived formulation was an exception, as it contained only cholesterol. The mean values of the different sterols were statistically different across ILEs ($P = 0.0000$). A large percentage of pairwise comparisons were also statistically significant ($P = 0.000$), most notably for cholesterol and stigmasterol (14 out of 21 for both), followed by campesterol (12 out 21) and β-sitosterol (11 out 21). In conclusion, most ILEs combined significant amounts of phytosterols and cholesterol. However, their phytosterols:cholesterol ratios were reversed compared to the normal human diet.

Introduction

Intravenous lipid emulsions (ILEs) are the source of fat within total parenteral nutrition (TPN). The principal idea behind their use is the prevention of essential fatty acid deficiency. Only recently, due to the increasing interest in lipids for therapeutic purposes, have new ILEs been essayed and marketed, to offer potential new health benefits or to modify metabolic derangements in diseases. ILEs have been found to have positive effects in gastrointestinal, pulmonary, cardiovascular, autoimmune, oncologic, and critical care diseases. At the same time, they have been blamed as possible causes of TPN-associated complications. Phytosterols, in particular, have been included in the

list of toxic substances responsible for parenteral nutrition-associated cholestasis (PNAC) [1–5].

So far, little is known on the main sterol components of commercially available ILEs. The literature and the manufacturers have focused on fatty acid composition and possibly on other lipophilic substances such as diacylglycerols, egg phosphatide, and α-tocopherol. Phytosterols, in contrast, are often not even included in the list of main ILE components, as their amounts have been reported as minimal.

The aim of this study is to analyze the contents of the most representative ILEs in great detail and to identify their sterol profiles, including phytosterols.

Materials and Methods

Samples

Seven ILEs were selected based on their principal lipid constituents (soy, safflower, olive oil, and fish oil): Structolipid®, Intralipid®, Lipovenos®, Omegaven® (Fresenius Kabi AG, Germany), Clinoleic® (Clintec, France), Lipofundin MCT,® and Lipofundin S® (Braun, Germany), all at 20% lipid concentration with the exception of Omegaven®, which contains a 10% lipid amount. All the ILEs have various long-chain triglycerides (LCT) from plant or marine sources. In Lipofundin MCT®, medium-chain triglycerides (MCT) are combined with LCT. Table 1 shows the composition of each product.

Reagents, Solvents, and Standards

Chloroform (analytical reagent grade), *n*-hexane (analytical reagent grade), methanol (Lichrosolv), diethyl ether, anhydrous sodium sulphate, potassium chloride, and potassium hydroxide were supplied by Merck (Darmstadt, Germany). Acetone (AnalaR®) was purchased from BDH (VWR International Ltd., Leicestershire, UK). Bidistilled water and silylating agents (pyridine, hexamethyldisilazane and trimethylchlorosilane) were supplied by Carlo Erba (Milano, Italy).

(24*R*)-Ethylcholest-5-en-3β-ol (β-sitosterol) (purity: 60% β-sitosterol and 30% (24*R*)-methylcholest-5-en-3β-ol (campesterol)) was purchased from Research Plus (Bayonne, NJ, USA). (24*S*)-Ethylcholest-5, 22-dien-3β-ol (stigmasterol) (purity: 93%), cholest-5-en-3β-ol (cholesterol) (purity: 99%), and 5α-cholestane (purity: 97%) were purchased from Sigma (St. Louis, MO, USA). The purity of the standards was controlled by gas chromatography (GC).

Lipid Extraction

Lipid extraction was performed using a modified version [6] of the method by Folch et al. [7]. Two 10-ml volumes of each ILE were sampled and homogenized with 200 ml

Table 1 Composition of the tested intravenous lipid emulsions

Name	Composition
Structolipid® 20%	Purified soy bean oil structured triglycerides 200 g/1,000 ml
	Excipients: purified egg phospholipids, glycerol
Intralipid® 20%	Soybean oil 200 g/1,000 ml
	Egg yolk phospholipids 12 g/1,000 ml
	Excipients: glycerol 22.5 g/1,000 ml
Clinoleic® 20%	Mixture of purified olive oil (approximately 80%) and purified soybean oil (approximately 20%) 200 g/1,000 ml
	Excipients: purified egg phosphatides 12 g/1,000 ml, glycerol 22.50 g/1,000 ml, sodium oleate 0.30 g/1,000 ml
Lipovenos® 20%	Soybean oil 200 g/1,000 ml
	Egg phospholipids 12 g/1,000 ml [75–81%(3-*sn*-phosphatidylcholin)]
	Glycerol 25 g/1,000 ml
	Excipients: sodium oleate
Lipofundin MCT® 20%	Soybean oil 100 g/1,000 ml, α-tocopherol
	Medium-chain triglycerides (coconut) 100 g/1,000 ml
	Excipients: egg yolk lecithin, sodium oleate, α-tocopherol
Lipofundin S® 20%	Soybean oil 200 g/1,000 ml
	Excipients: egg yolk lecithin, glycerol, sodium oleate, α-tocopherol
Omegaven 10%	Purified fish oil 100 g/1,000 ml
	Excipients: egg yolk lecithin, glycerol, sodium oleate, α-tocopherol

of a chloroform:methanol solution (1:1, v/v) in a glass bottle with screw-cap. Successively, the bottle was placed at 60 °C for 20 min before adding 100 ml of chloroform. After a 3-min homogenization, the content of the bottle was filtered through filter paper. The filtrate was mixed thoroughly with 100 ml of a 1 M KCl solution and left overnight at 4 °C in order to achieve phase separation. The lower phase was collected and transferred into another Sovirel bottle. To dry the sample completely, 3–4 spoons of anhydrous sodium sulfate were added. The bottle was sealed and placed in darkness for 2 h at 4 °C. The organic phase was further filtered through a layer of anhydrous sodium sulfate with chloroform on filter paper, collected into a pre-weighed flask, and dried using a vacuum rotary evaporator (Buchi Rotavapor R, Switzerland) with a water bath at 40 °C. The fat content was determined gravimetrically. The extracted fat was dissolved in hexane:isopropanol (4:1, v/v) and was held at −20 °C until analysis. The lipid extraction procedure was performed three times per sample.

Determination of Sterols

A 50-µl amount of the internal standard solution (1 mg of 5α-cholestane/ml) was added to a 250-mg lipid subfraction of the Folch extract. Subsequently, the sample was dried under nitrogen and treated with 10 ml of 1 N KOH solution in methanol, in order to obtain a saponification at room temperature for 18 h, in darkness and under continuous agitation [8]. To extract the unsaponifiable matter, 10 ml of water and 10 ml of diethyl ether were added to the samples, which were vigorously shaken. The diethyl ether fraction was then separated; the extraction with 10 ml of diethyl ether was repeated three times.

The three portions of diethyl ether were pooled, washed twice with 5 ml of a 0.5 N KOH solution, washed once with 5 ml of a 20% NaCl solution to remove any residual emulsion, and extracted. A correct washing procedure must lead to washing water having a pH <8. The ether extract was added with anhydrous sodium sulfate, kept at 4 °C for 2 h, filtered using Whatman No. 1 filter paper, and extracted again with 10 ml diethyl ether. The resulting ether extract was evaporated using a vacuum rotary evaporator, dissolved in 1 ml of hexane:isopropanol (4:1, v/v) and held at −20 °C until analysis.

One-fifth of the unsaponifiable matter was dried and silylated, according to Sweeley et al. [9]. After 20 min at 40 °C, the sample was dried under a nitrogen stream and dissolved in 100 µl of hexane. One microliter of the silylated sample was analyzed by capillary gas chromatography (cGC) for the sterol determination. The gas chromatograph (HRGC 5300 Mega Series, Fisons, Rodano, Italy) was equipped with a split/splitless injector and a flame ionization detector. A fused-silica capillary column (30 m × 0.32 mm i.d. × 0.25 µm film thickness) coated with 100% dimethyl-polysiloxane (CP-Sil 5 CB Low Bleed/MS, Chrompack-Varian, Middelburg, The Netherlands) was used. The oven temperature was programmed to rise from 250 to 325 °C at a rate of 3 °C/min and held for 10 min at 325 °C. The injector and detector temperatures were both set at 325 °C. Helium was used as the carrier gas at a flow rate of 3 ml/min; the split ratio was 1:15.

Sterols were identified by comparing their retention times with those of commercial sterol standards and by spiking the silylated samples with a small amount of silylated sterol standards.

Sterols were then quantified by comparing the peak areas of the internal standard (5α-cholestane) and its concentration with the peak areas of the sample sterols. The GC response factors of sterols with respect to the internal standard were considered equal to 1.

Data Analysis

Two samples of each ILE underwent lipid extraction. For each lipid extraction, in turn, sterol determination was performed three times. GC data were stored and processed with a Turbochrom Navigator acquisition system (Ver. 6.1.1.0.0:K20) (Perkin Elmer Instruments, Norwalk, CT, USA). The means, standard deviations (SD), and coefficients of variability (CV) were then computed for the sterol contents.

STATA Software v.3 (Santa Monica, CA, USA) was used to perform one-way analysis of variance (ANOVA) with multiple-comparison tests (using both the Bonferroni and Scheffe' options to validate results) at a 95% confidence level ($P < 0.05$) to identify differences among ILEs.

Results

The amount of extracted lipids was quantified and classified by type of sterols (animal: cholesterol, and plant: β-sitosterol, campesterol, and stigmasterol). Animal and plant sterols were differently represented across solutions, with the latter generally accounting for a greater share than the former. Chromatograms of the identified sterols are shown in Fig. 1. For each ILE, Table 2 reports the presence of each sterol as a percentage of the total amount of sterols; Table 3 does the same with respect to phytosterols only; Table 4 reports the presence of each sterol relative to the overall quantity of fat as well as the ratio of plant to animal sterols. Finally, Table 5 shows the mean content of each sterol in each ILE, as well as the standard deviation and the percent coefficient variation.

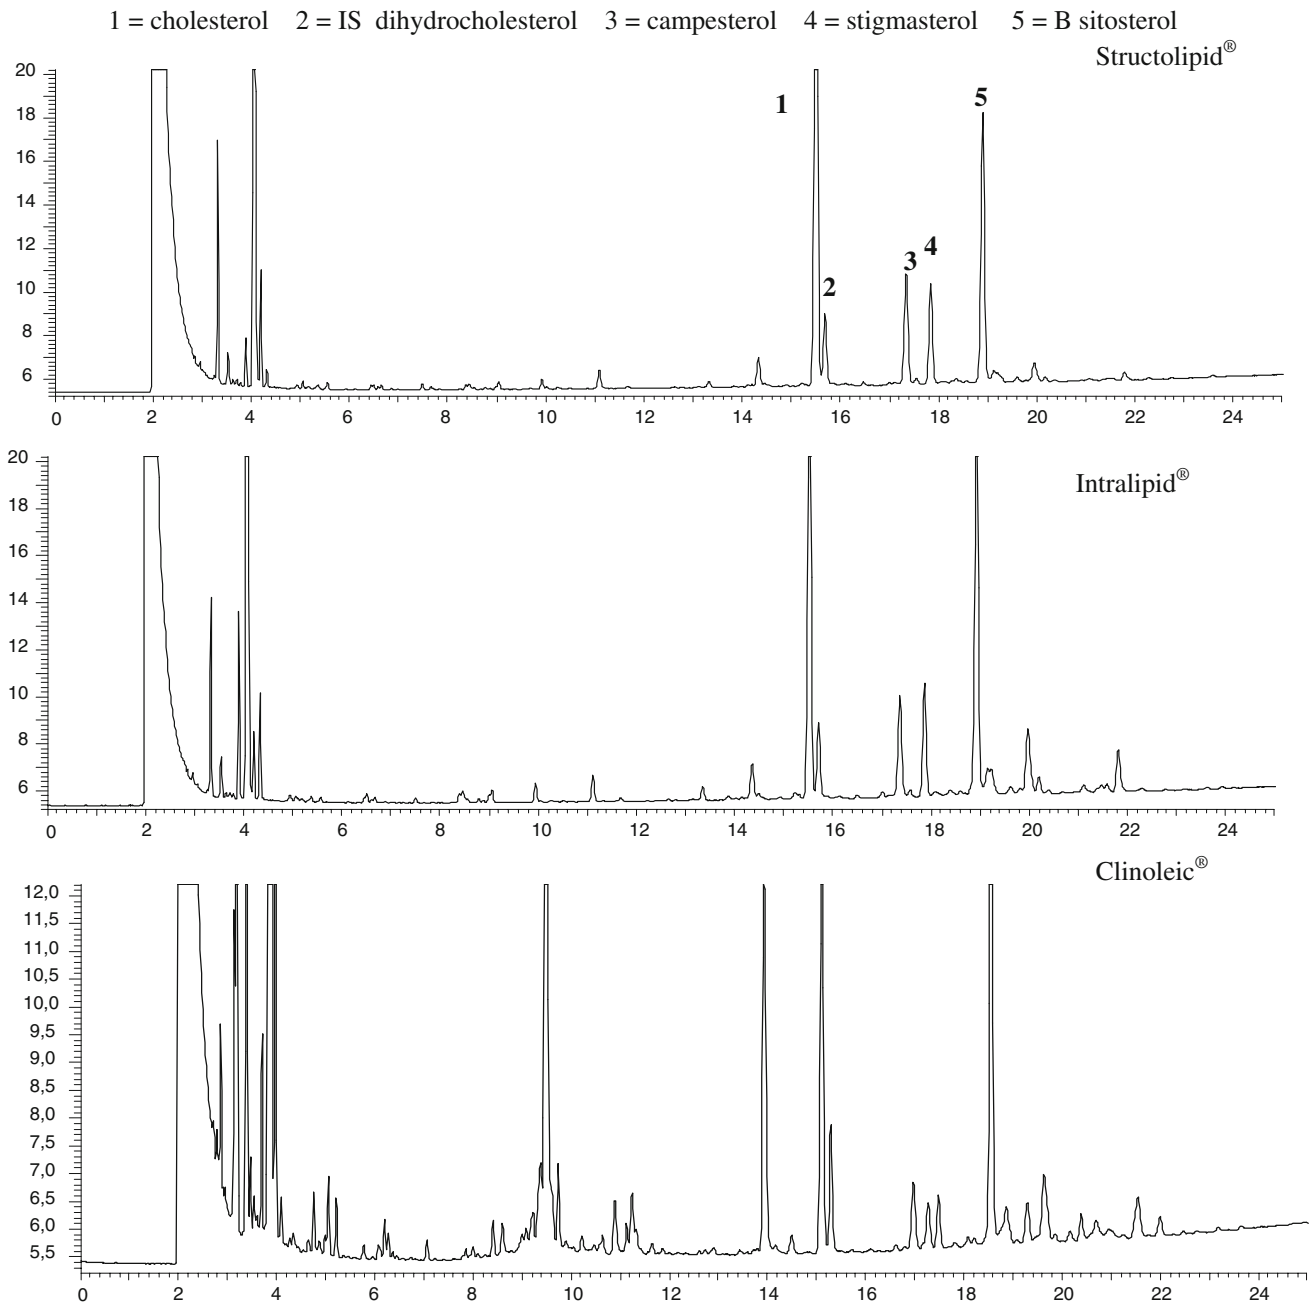

Fig. 1 Chromatograms of plant and animal sterols identified in the intravenous lipid emulsions *1* cholesterol *2* IS dihydrocholesterol, *3* campesterol, *4* stigmasterol, *5* B sitosterol

Of the seven ILEs, Omegaven® is peculiar in that it contains only cholesterol. Among the other six, cholesterol and β-sitosterol were the main components, followed by campesterol and stigmasterol, with the only exception being Lipofundin S®. Structolipid® was the only solution with more animal sterols than plant ones (56.6 vs. 43.4%). Structolipid® and Intralipid® were the two ILEs with the highest percentages of cholesterol (56.6 and 43.4%, respectively) and the lowest percentages of β-sitosterol (24.2 and 36.5%, respectively). Conversely, the ILEs with the lowest percentages of cholesterol and the highest percentages of β-sitosterol were Clinoleic® (32.2 and 55.2%, respectively), Lipovenos® (21.8 and 50.6%) and Lipofundin S® (14 and 52%). Clinoleic® had the lowest quantities of campesterol (7.8%) and stigmasterol (4.9%).

The average quantities of each sterol were found to be statistically different across the ILEs (P 0.0000). The coefficients of variation were small for all ILEs with the exception of Lipofundin S®, whose variation coefficients were large for all animal and plant sterols. With respect to

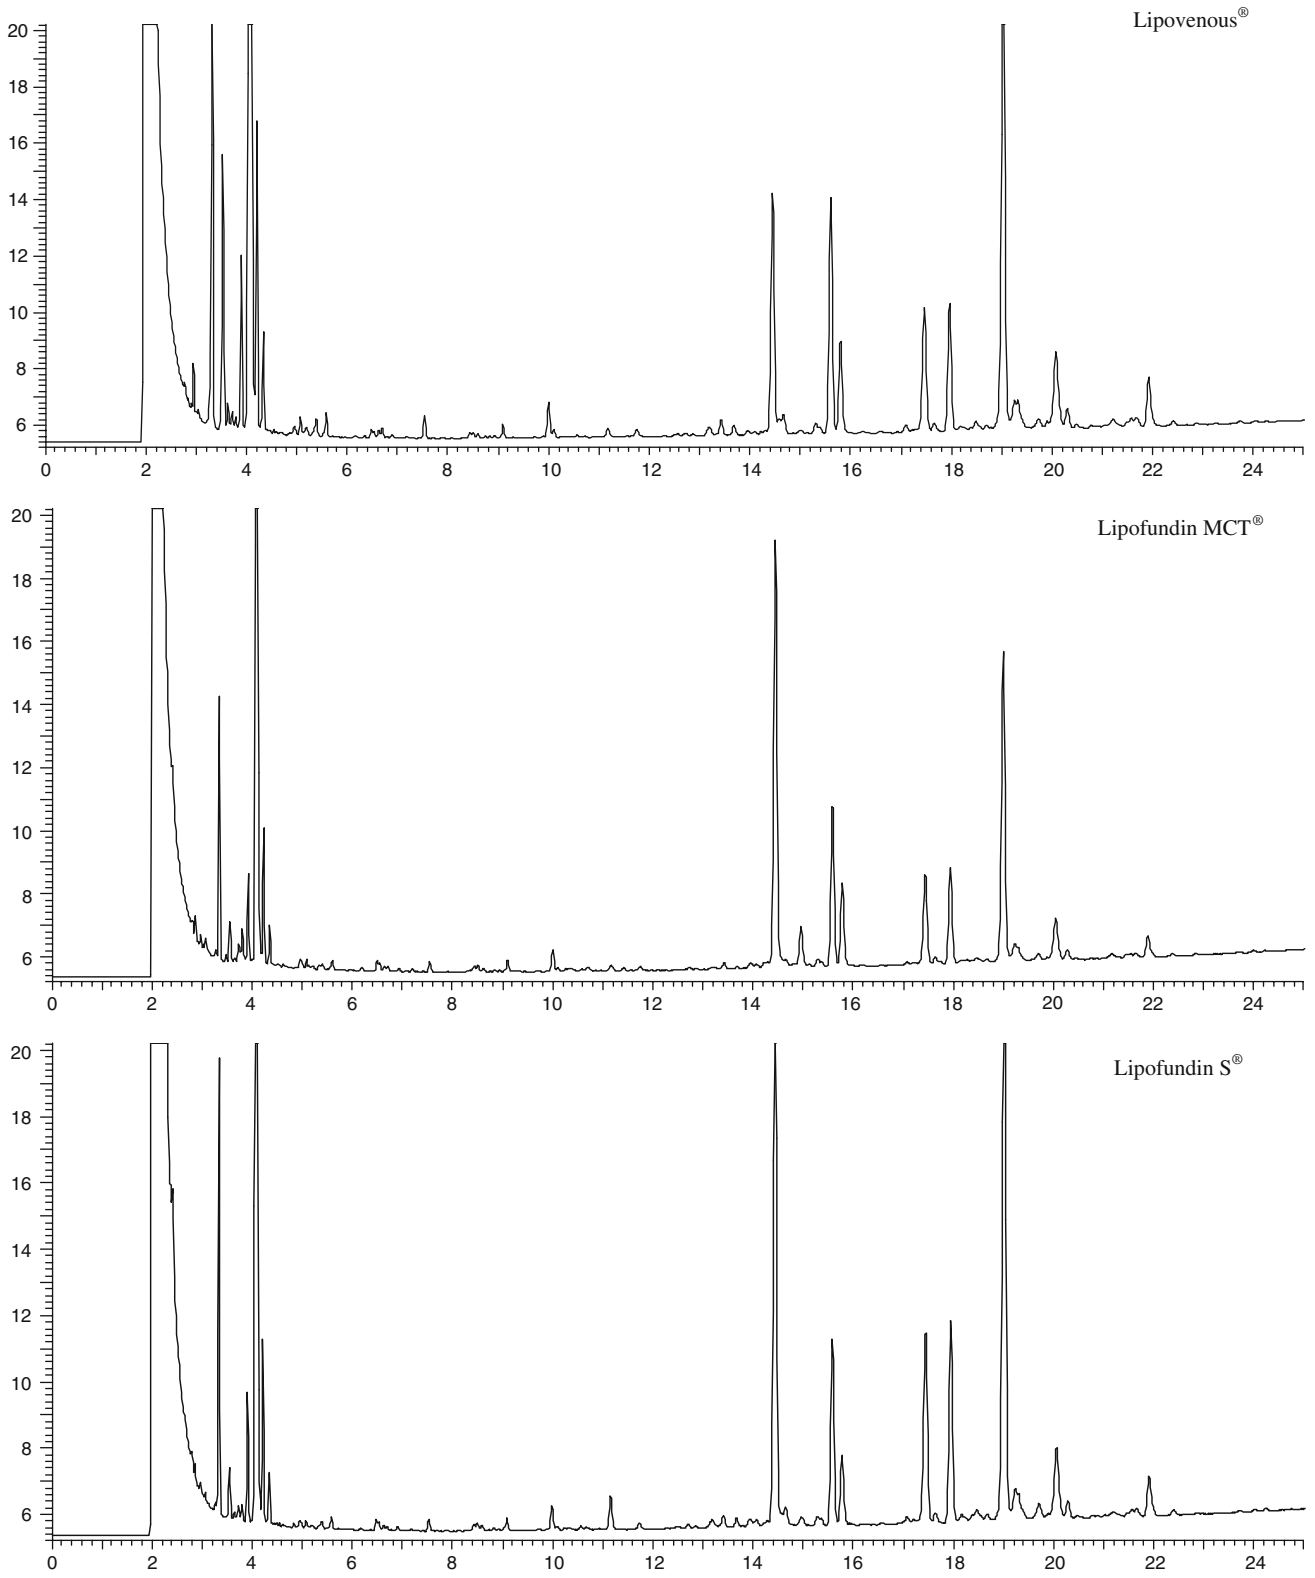

Fig. 1 continued

each sterol, a multiple pairwise comparison between ILEs confirmed statistically significant pairwise differences (P 0.000) with few exceptions. Nonstatistically significant pairwise comparisons between ILE means were particularly frequent for β-sitosterol (10 out of 21, involving Structolipid® Intralipid® Clinoleic® Lipovenos® and Lipofundin MCT®),

Table 2 Distribution of animal and plant sterols in intravenous lipid emulsions (average amounts)

Name	% Cholesterol (over total sterols)	% Campesterol (over total sterols)	% Stigmasterol (over total sterols)	% β-Sitosterol (over total sterols)
Structolipid® 20%	56.6	10.5	8.7	24.2
Intralipid® 20%	43.4	9.8	10.2	36.5
Clinoleic® 20%	32.2	7.8	4.9	55.2

followed by campesterol (9 out 21) and by cholesterol and stigmasterol (both 7 out 21). The pairwise comparisons which did not reach statistical significance are summarized and included in Table 5.

Discussion

Scattered reports in the literature have linked PNAC to the vegetable sterol components of ILEs [1–5]. Information on the sterol contents of ILEs, however, is currently scanty. The purpose of this paper has thus been to collect and present some data on the sterols contained in the most representative ILEs.

To this end, seven ILE formulations were selected as being representative in terms of their main oil component (soy, olive oil, fish oil variably combined with medium- or long-chain fatty acids, and purified triglycerides). These products were chemically analyzed to identify and quantify their animal and plant sterol contents.

Table 5 Summary statistics for sterol content in the intravenous lipid emulsions

Name	Cholesterol		Campesterol		Stigmasterol		β-Sitosterol	
	Mean (SD) (mg/100 ml solution)	CV (%)	Mean (SD) (mg/100 ml solution)	CV (%)	Mean (SD) (mg/100 ml solution)	CV (%)	Mean (SD) (mg/100 ml solution)	CV (%)

The symbols identify nonstatistically significant pairwise comparisons between ILE means for each sterol with

[a] Compared to Structolipid®

[b] Compared to Intralipid®

[c] Compared to Clinoleic®

[d] Compared to Lipovenos®

[e] Compared to Lipofundin MCT®

All formulations had both animal and plant sterols, with the exception of Omegaven®, which contained only cholesterol. The source of cholesterol in these ILEs is egg yolk. The relative weight of each sterol varied significantly across formulations ($P = 0.0000$), with a large percentage of pairwise comparisons being statistically significant ($P = 0.000$), most notably for cholesterol and stigmasterol (14 out of 21 for both). Only one solution (Structolipid®) was found to have more animal (56.6%) than plant sterols, but a large presence of cholesterol (43.4%) was also detected in Intralipid®. Overall, the detection of large cholesterol contents was a surprise, since egg phospholipids were intended as a minor constituent of ILEs. Conversely, Clinoleic®, Lipofundin S®, Lipovenos®, and Lipofundin MCT® showed to be rich in β-sitosterol, with quantities ranging between 47.9 and 55.2% of total sterols.

The phytosterol contents of some ILEs differed from those detected in other studies, in which a smaller range of products and/or sterols was looked at. For Intralipid®, the plant sterol concentrations we found are similar to Ellegard's [10], but lower than those reported in two other studies [3, 11]. For Clinoleic®, phytosterols and cholesterol quantities were once again similar to Ellegard's. For Structolipid®, however, we found twice as much cholesterol as Ellegard (373 vs. 200 mg/l). No comparisons were possible for the other ILEs due to lack of data in the literature.

Within each set of extractions and determinations, the measurements were highly consistent, although some minimal differences did emerge. The small values of most coefficients of variation suggest that the analyses were executed appropriately. The occasionally high variation coefficient can thus be ascribed not to methodological issues, but to actual differences in quantities of sterols, unsaturated fat, and tocopherols across batches of the same product. Cross-batch variability may stem from both the quality of the oil source and the extraction process itself. Overall time and year of harvest, geographical source, and climate may affect the amount of sterols present in the ILEs. This amount may be further modified by refinement, with a reduction of free sterols by up to 30% of their original quantity [12]. Quantities of unsaturated fat and tocopherols may change the ratio of free to esterified sterols. The relatively high variation coefficient found in Clinoleic® and Lipofundin S® may stem respectively from the high content of oleic acid, which has been proven to be unstable [13], and of tocopherols. Conversely, those ILEs which are fully synthetized in a laboratory (e.g. Structolipid®) or semisynthetic (e.g. Lipofundin MCT®) are more stable. This is again reflected by the low variation coefficient. In addition, final cholesterol content of ILEs seems to be strongly affected by the amount of egg phospholipids added to the ILEs. This quantity has never been specified by producers. Appropriate storage is another key factor in

the fat variability of ILEs, which must be kept at a temperature below 25 °C. In our case, the ILEs tested were maintained below this temperature at all times. For this reason, we did not check for sterol variability and peroxidation over time. Finally, it is possible that the use of ethyl ether in the lipid extraction may have caused sterol peroxidation. This possibility was not further investigated because we believe that, ethyl ether being part of a cold saponification, the use of low temperatures should have prevented sterol oxidation.

We had an excellent separation of fats and the quantification of stigmasterol, which previous studies had left undetermined. In Plat et al. [14], the presence of stigmasterol was considered insignificant, and only sitosterol and campesterol were identified. On the contrary,in our study, stigmasterol was very well represented, to the point that its level was close to that of campesterol in most solutions. Stigmasterol is a potent antagonist of some hepatic nuclear receptor families, leading to the development of biliary injuries, while sitosterol and campesterol had minimal or insignificant inhibitory effects in a human-derived liver cell line HepG2 [15]. In addition, stigmasterol disrupts cholesterol homeostasis. Whether ILEs with a high content of stigmasterol are crucial to the development of PNAC is yet to be proven.

In humans, there is evidence of wide individual variations in plant sterols [16]. Plasma levels of campesterol and sitosterol (24-methyl and 24-ethyl analogue of cholesterol, respectively) are high, followed by minimal amounts of stigmasterol, ergosterol, avenasterol, and brassicasterol. β-sitosterol is secreted as neutral sterol into bile more rapidly than cholesterol and other plant sterols [17]. This more rapid fractional turnover of β-sitosterol may indirectly indicate that the rigorous exclusion of sterols other than cholesterol in vertebrates may be essential for the maintenance of normal cholesterol homeostasis. It is therefore particularly critical that, in all the solutions we analyzed, the ratio of cholesterol to phytosterols is highly skewed toward phytosterols, when compared to the amounts absorbed by a healthy person on a standard diet. For a 70-kg adult on a standard diet, the content of sterols is approximately 200–400 mg/day for phytosterols and 1,200–1,700 mg/day for cholesterol. Of these, only 10–20 mg/day of phytosterols and 300–500 mg/day of cholesterol are taken up by the gastrointestinal system and brought to the liver, where they are secreted into the bile. When the recommended intake of 1 g/(kg day) of fat is provided intravenously to a 70-kg adult, on the other hand, the data presented in Table 4 translate into an intake of phytosterols in the range of 119–241 mg/day (about 10 times the normal amount absorbed through the diet) and an intake of cholesterol in the range of 26–129 mg/day (about one tenth of the amount absorbed through the diet). This may explain why, in a study performed in short-bowel patients with and without parenteral nutrition and in controls, higher serum levels of phytosterols were detected in those on parenteral nutrition compared to those on oral intake or the controls [10]. Compared to controls, all the patients with short-bowel syndrome appeared to have lower serum levels of cholesterol, but higher endogenous cholesterol and bile acid synthesis. In another case, a person with short-bowel syndrome who had received home-parenteral nutrition for over 27 years with soy-based ILE [18], serum cholesterol remained surprisingly low (80–140 mg/dL; normal range <200) even though phytosterols had not been determined.

The fish oil-based ILE is the only formulation without plant sterols. This could explain its beneficial effects on liver functions, in terms of the reversal of PNAC in humans, regularity of bile flow, and prevention of hepatic lipogenesis in animals [19, 20]. These beneficial effects, however, may also stem from the presence of cholesterol, which may be more naturally suited to the human body. Another explanation could be the lower supplementation of lipids, in line with the recommended dosage of 1 g/(kg day). If cholesterol is indeed beneficial, structured lipids could be another option in the presence of PNAC. In our analysis, we found a cholesterol to plant sterol ratio of 1:0.8, confirming a cholesterol predominence. However, the absolute values of both sterols were high.

Our study is the first to determine the animal and plant sterol quantities in ILEs originating from different oils. The quanti-qualitative determinations of animal and plant sterols will require further confirmation, especially in terms of sample type and storage time, but they already suggest the need for future research looking at the phytosterols:cholesterol ratio and its association to liver dysfunction during ILE infusions.

Acknowledgments We are particularly grateful to Dr. Maria Rodriguez Estrada and Mr Stefano Savioli at the Food Science Department directed by Prof. Lerker, University of Bologna, for their expertise and technical assistance offered for accurate laboratory determinations.

Lipid Abnormalities in a Never-Treated HIV-1 Subtype C-Infected African Population

Carla Maria T. Fourie · Johannes M. Van Rooyen · Annamarie Kruger · Aletta E. Schutte

Received: 7 August 2009 / Accepted: 23 October 2009 / Published online: 15 November 2009

Abstract Dyslipidemia has been documented worldwide among human immunodeficiency virus-infected (HIV) individuals and these changes are reminiscent of the metabolic syndrome (MetS). In South Africa, with the highest number of HIV infections worldwide, HIV-1 subtype C is prevalent, while HIV-1 subtype B (genetically different from C) prevails in Europe and the United States. We aimed to evaluate if HIV infection (subtype C) is associated with dyslipidemia, inflammation and the occurrence of the MetS in Africans. Three hundred newly diagnosed HIV-infected participants were compared to 300 age, gender, body mass index and locality matched uninfected controls. MetS was defined according to the Adult Treatment Panel III (ATP III) and International Diabetes Federation (IDF) criteria. The HIV-infected group showed lower high density lipoprotein cholesterol (1.23 vs. 1.70 mmol/L) and low density lipoprotein cholesterol (2.60 vs. 2.80 mmol/L) and higher triglycerides (1.29 vs. 1.15 mmol/L), C-reactive protein (3.31 vs. 2.13 mg/L) and interleukin 6 (4.70 vs. 3.72 pg/L) levels compared to the uninfected group. No difference in the prevalence of the MetS was seen between the two groups (ATP III, 15.2 vs. 11.5%; IDF, 21.1 vs. 22.6%). This study shows that HIV-1 subtype C is associated with dyslipidemia, but not with a higher incidence of MetS in never antiretroviral-treated HIV-infected Africans.

Keywords HIV-1 subtype C · South Africa · African · Metabolic syndrome · Dyslipidemia · Never-treated · Inflammation

Abbreviations

AIDS	Acquired immunodeficiency syndrome
ARV	Antiretroviral
ATP III	Adult Treatment Panel III
BMI	Body mass index
CI	Confidence intervals
CVD	Cardiovascular disease
DBP	Diastolic blood pressure
FG	Fasting glucose
HDL-C	High-density lipoprotein cholesterol
HIV	Human immunodeficiency virus
HR	Heart rate
hs-CRP	High sensitivity C-reactive protein
hs-IL-6	High sensitivity interleukin-6
IDF	International Diabetes Federation
LDL-C	Low-density lipoprotein cholesterol
MetS	Metabolic syndrome
OR	Odds ratios
PP	Pulse pressure
PURE	Prospective urban and rural epidemiological
SBP	Systolic blood pressure
TC	Total cholesterol
TG	Triglycerides
WC	Waist circumference

Introduction

Southern Africa accounts for almost a third of all new human immunodeficiency virus (HIV) infections and acquired immunodeficiency syndrome (AIDS) related deaths worldwide, and an estimated 5.5 million people are living with HIV in South Africa [1]. The predominant virus responsible for these infections in South Africa is HIV-1, group M (major), subtype C [2, 3], which accounts for 55–60% of all HIV-1 infections worldwide [4, 5], and differ as much as 30% in its genomes from HIV-1 subtype B, responsible for the infections in North America, Europe and Australia [2, 5, 6]. The clinical consequences of these subtype variations still remain unclear [7].

Cardiovascular involvement in various forms, such as dyslipidemia [8], lipodystrophy [9, 10], endothelial dysfunction [11], accelerated atherosclerosis [12] and coagulation disorders [13] have been documented worldwide among HIV-infected individuals. This involvement can be associated with various factors, such as the infection itself, opportunistic infections, the therapy or non HIV related cardiovascular risk factors like smoking and age [14]. It is well known that the lipid profile of HIV-infected individuals changes, and these changes include increased levels of triglycerides (TG), and decreased levels of total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C) and high-density lipoprotein cholesterol (HDL-C) [12, 15–18]. It remains unclear what the relative contribution of the HIV infection and the ongoing inflammation are to the blood lipids [7, 19].

Some of the changes seen in HIV-infected individuals—in particular low HDL-C levels, hypertriglyceridemia, increased levels of visceral adipose tissue, plasma glucose and insulin—are reminiscent of the metabolic syndrome (MetS) [10]. The MetS has been identified as a significant and multifaceted risk factor for cardiovascular disease (CVD) [10, 20]. The above metabolic abnormalities are among the most significant side effects experienced with highly active antiretroviral (ARV) therapy, in particular with protease inhibitors [10, 14, 21]. On the other hand, the long term effects of the infection itself (as ARV therapy can not completely eradicate HIV-1) have become increasingly challenging [22] and may play a role in these metabolic changes. This is seen in the study of Bonfanti et al. [23] where the prevalence of the MetS was higher in the HIV-infected individuals compared to the general population, but was similar in treated and untreated HIV-infected individuals.

Even though South Africa is the country with the largest number of HIV infections in the world [1], to the best of the authors's knowledge, no study to date has been done to specifically evaluate whether the HIV-1 (subtype C) infection itself, prevalent in South Africa [3], leads to the same metabolic changes and inflammatory state seen in HIV-1 (subtype B), prevalent in Europe, United States, Australia and South America [5].

The aim of this study was therefore to evaluate whether HIV-1 (subtype C) infection itself is associated with dyslipidemia, inflammation and the occurrence of the MetS in newly identified HIV-infected participants who had never received ARV therapy.

Methods

Study Design and Participants

This sub-study is embedded in the larger international PURE (Prospective Urban and Rural Epidemiological) study. The overarching PURE study is a longitudinal multi national study that will track changes in lifestyles, CVD risk factors and chronic diseases over a period of 12 years, using periodic standardized data collection in urban and rural areas of developing countries in transition, including South Africa. The South African leg of the study was performed in the North West province where a total of 2,000 black South Africans (1,000 urban and 1,000 rural) were randomly recruited from a rural and urban setting and screened during the baseline phase in 2005. The inclusion criteria were volunteers older than 35 years that were non users of any chronic medication and with no self-reported diseases. For this sub-study the 300 newly identified HIV-infected participants of the baseline PURE study population were individually matched with 300 HIV-uninfected participants (case-control design), according to age, gender, body mass index (BMI) and locality (urban and rural). The methodology appropriate to this sub-study will be discussed.

Ethical Considerations

All participants provided signed informed consent after all the procedures had been explained to them in their home language. The study protocol complies with the Declaration of Helsinki as revised in 2004 [24] and was approved by the Ethics Committee of the North-West University, Potchefstroom, South Africa.

Experimental Protocol

Permission to execute the PURE study was obtained from the provincial Department of Health, local authorities and from the Tribal Chief in the rural area. For about 12 weeks 30–35 participants arrived at the research locality of the rural or urban areas at about 07:00 each morning after a 10–15 min drive (provided by the research team) from their

communities. The participants were introduced to the setup and after the procedures were explained they signed the informed consent forms and received HIV pre-counseling given by trained counselors. The HIV status of the participants was revealed during post-counseling and the infected participants were referred to their local clinic or hospital for follow-up and CD4 cell count determination. During the course of the morning demographic, lifestyle and food frequency questionnaires were completed with the help of the specially trained field workers in the subject's home language. Lifestyle data included self reported current tobacco use, alcohol intake as well as medical history.

Anthropometric Measurements

Height, weight, hip and waist circumference (WC) were measured (Precision Health Scale, A & D Company, Japan; Invicta Stadiometer, IP 1465, UK; Holtain unstretchable metal tape) using standardized procedures [25].

Cardiovascular Measurements

Systolic blood pressure (SBP), diastolic blood pressure and heart rate were obtained with a validated OMRON HEM-757 device. After a 10-min rest period, blood pressure measurements were performed twice (5 min apart) on the right arm (brachial artery), while the participants were seated upright and relaxed with his/her right arm supported at heart level. Appropriate cuffs were used for obese participants.

Blood, Serum and Plasma Samples

Blood was drawn from the antebrachial vein using a sterile winged infusion set and syringes. Serum was prepared according to appropriate methods and stored at −80 °C in the laboratory. In the rural area serum was stored at −18°C (no longer than 5 days) until it could be transported to the laboratory facility and was then stored at −80 °C until analysis.

Biochemical Analyses

Quantitative determination of the cholesterol, HDL-C, TG, glucose (GOD-POD), high sensitivity C-reactive protein (hs-CRP) and creatinine concentration in the serum of the participants was done with the Konelab20i™ auto analyzer (Thermo Fisher Scientific Oy, Vantaa, Finland), a clinical chemistry analyzer for colorimetric, immunoturbidimetric and ion-selective electrode measurements. LDL-C was calculated by using the Friedewald formula [26]. The creatinine clearance rate was estimated using the Cockcroft-Gault formula [27]. Serum concentrations of high sensitivity interleukin-6 (hs-IL-6) were measured using human enzyme-linked immunosorbent assays (Quantikine® HS ELISA, R&D Systems, Minneapolis, USA). HIV status was determined with the First Response (PMC Medical, India) rapid HIV card test using whole blood. If tested positive, the test was repeated with the Pareeshak (BHAT Bio-tech India) card test. The card test distinguishes between HIV-1 and HIV-2, but not between subtypes. The HIV-1 subtype C epidemic prevalent in South Africa has been established by serotyping and genotyping [1–3].

The Metabolic Syndrome

The MetS in the sub-study was identified according to the definition of the Third Report of the National Education Program Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults (ATP III) [20], and according to the definition of the International Diabetes Federation (IDF) [28].

Statistical Analysis

All data were statistically analyzed by means of Statistica v.8 (Statsoft Inc., OK, USA, 2008). Mean values and standard deviations were calculated. The distribution of hs-CRP, CRP:HDL ratio and hs-IL-6 were normalized by logarithmic transformation before analysis, reporting the geometric mean and 5–95% percentiles. Independent *t* tests were used to compare the characteristics of the continuous variables of the HIV-infected and uninfected groups. The Chi-square tests were done to compare data of categorical variables. An analysis of covariance (ANCOVA) was performed to compare the cardiovascular parameters, lipid profile, glucose, hs-CRP and hs-IL-6 of the HIV-infected and uninfected participants, whilst adjusting for tobacco and alcohol use.

Odds ratios (OR), as estimates of risk, with 95% confidence intervals (CI), were calculated using 2×2 frequency tables for HIV-infected versus uninfected participants. Since very few participants met the cut-off values for the MetS (for both the ATP III and IDF definitions), especially for WC in African men, the median was used as cut-off value for the calculation of OR. Frequency tables were used to determine the number of subjects that were classified according to each specific MetS definition (ATP III and IDF), thereby determining the prevalence of the MetS in both the HIV-infected and control groups. The Chi-square test was used to obtain the *P* values. *P* values ≤ 0.05 are regarded as significant.

Results

Characteristics of HIV-infected participants and matching controls are reported in Table 1. Due to individual

Table 1 Characteristics of the HIV-infected and uninfected African participants ($N = 600$)

	HIV infected ($N = 300$)	HIV uninfected ($N = 300$)	P
Age (years)	44.0 ± 8.04	44.0 ± 7.81	0.97
Height (cm)	161 ± 9.88	161 ± 8.37	0.62
Weight (kg)	59.5 ± 13.5	58.9 ± 13.9	0.61
BMI (kg/m^2)	22.9 ± 5.59	22.8 ± 5.48	0.92
Waist (cm)	75.9 ± 10.6	75.9 ± 10.1	0.98
Hip (cm)	92.6 ± 13.8	93.0 ± 13.9	0.71
Waist:hip ratio	0.83 ± 0.11	0.82 ± 0.10	0.62
SBP (mm Hg)	124 ± 21.8	129 ± 21.8	0.003
DBP (mm Hg)	84.0 ± 14.7	85.9 ± 14.3	0.09
PP (mm Hg)	40.2 ± 11.5	43.7 ± 13.1	0.0005
HR (beats/min)	76.4 ± 15.0	72.2 ± 15.2	0.0009
TC (mmol/L)	4.42 ± 1.25	5.02 ± 1.33	<0.0001
HDL-C (mmol/L)	1.23 ± 0.58	1.70 ± 0.71	<0.0001
LDL-C (mmol/L)	2.60 ± 1.01	2.80 ± 1.14	0.01
TG (mmol/L)	1.29 ± 0.77	1.15 ± 0.75	0.03
TG:HDL-C ratio	1.41 ± 1.47	0.86 ± 1.21	<0.0001
Glucose (mmol/L)	5.35 ± 1.26	5.50 ± 1.10	0.13
hs-CRP (mg/L)	3.31 (0.32–50.4)	2.13 (0.23–29.2)	0.0006
CRP:HDL-C ratio	2.94 (0.21–62.0)	1.36 (0.13–18.5)	<0.0001
hs-IL-6 (pg/ml)	4.70 (1.29–20.9)	3.72 (1.11–16.9)	0.0004
Creatinine (μmol/L)	83.8 (46.0–376)	76.5 (46.4–372)	0.83
eCrCl (ml/min)	73.5 (15.1–160)	79.7 (16.1–157)	0.15
Calorie intake (kJ)	1,879.0 ± 953	1,836.1 ± 1,003	0.59
Total fat intake (g/day)	51.3 ± 33.4	50.4 ± 38.4	0.78
Tobacco users N (%)	127 (42.3)	137 (45.6)	0.41
Alcohol users N (%)	96 (32.0)	103 (34.3)	0.54

Data are expressed as arrhythmic means ± standard deviation, geometric mean (5–95 percentiles) or % of N

N indicates number of participants, *BMI* body mass index, *SBP* systolic blood pressure, *DBP* diastolic blood pressure, *PP* pulse pressure, *HR* heart rate, *TC* total cholesterol, *HDL-C* high-density lipoprotein cholesterol, *LDL-C* low-density lipoprotein cholesterol, *TG* triglycerides, *hs-CRP* high-sensitivity C-reactive protein, *hs-IL-6* high-sensitivity interleukin 6, *eCrCl* estimated creatinine clearance

All *P* values were obtained with independent *t* tests, except for tobacco and alcohol users where the Chi-square test was used

matching, age and BMI values, as well as the other anthropometric measurements were almost identical in the two groups. HIV-infected participants had a lower SBP, pulse pressure, TC, HDL-C and LDL-C, whereas the heart rate, TG, TG:HDL-C ratio, hs-CRP, CRP:HDL-C ratio and hs-IL-6 were higher in the HIV-infected group. After adjusting for tobacco and alcohol use, similar results were obtained, which were expected as the percentage tobacco and alcohol users did not differ. There were no differences in the calorie and fat intake between the HIV-infected and uninfected groups. Separate analyses as in Table 1 were performed for each gender and similar results were obtained.

The OR of the HIV-infected group versus the uninfected group is shown in Table 2. In this study population having a lower HDL-C is five times more likely when being a HIV-infected man and three times more likely in women. The Odds ratio for having a higher TG, hs-CRP and hs-IL-6 level is respectively 1.7, 1.8 and 1.7 times more when being HIV infected.

The MetS defined according to the ATP III and IDF criteria are shown for HIV-infected and uninfected participants in Table 3. In comparison with the controls no difference (15.2 vs. 11.5%; $P = 0.18$) in the MetS was seen in the HIV-infected, never-ARV-treated participants according to the ATP III definition. Similar results were shown for the IDF definition (21.1 vs. 22.6%; $P = 0.65$).

Discussion

In this study HIV-1- (subtype C) infected, never-ARV-treated, participants showed dyslipidemia and inflammation. These results are in agreement with documented data on HIV-infected individuals of other population groups [12, 18, 29] where HIV-1 (subtype B) prevails [5].

A low HDL-C concentration increases the risk for coronary heart disease [30] and for every 1 mg/dl increase in serum HDL-C, a 2% reduction in CVD is estimated [31]. Duprez et al. found that lower HDL levels were associated with a higher risk of CVD in HIV-infected patients and Jericó et al. found smoking and HDL cholesterol to be the main cardiovascular risk factors in their HIV-infected study population [32, 33]. In our study population a HIV-infected man is seven times, and a woman three times more likely to have low HDL-C levels which should increase

Table 2 Odds Ratios of HIV-infected ($N = 300$: M = 116, F = 184) participants versus uninfected ($N = 300$: M = 116, F = 184) participants

	OR	
	HIV infected versus HIV uninfected	95% CI
WC		
M (≥73 cm)	0.93	0.6–1.6
F (≥75 cm)	0.94	0.6–1.4
TG (≥1.0 mmol/L)	1.70	1.2–2.3*
HDL-C		
M (<1.4 mmol/L)	5.25	2.9–9.2*
F (<1.3 mmol/L)	2.92	1.9–4.5*
SBP (≥124 mm Hg)	0.72	0.5–1.0*
DBP (≥84 mm Hg)	0.72	0.5–1.0*
FG (≥5.3 mmol/L)	0.64	0.5–0.9*
hs-CRP (≥2.7 mg/L)	1.78	1.3–2.5*
hs-IL-6 (4.2 pg/ml)	1.67	1.2–2.3*

N indicates number of participants, *M* male, *F* female, *WC* waist circumference, *TG* triglycerides, *HDL-C* high-density lipoprotein cholesterol, *SBP* systolic blood pressure, *DBP* diastolic blood pressure, *FG* fasting glucose, *hs-CRP* high sensitivity C-reactive protein, *hs-IL-6* high sensitivity interleukin 6

Median of the total group was used as cut-off value. Significance is indicated by *

their risk for CVD. Even though Africans normally exhibit lower fasting triglyceride and higher HDL-C levels than Caucasians [34], HDL-C levels of our HIV-infected participants (1.23 ± 0.58 mmol/L) were below the level of 1.28 mmol/L (50 mg/dl), which is seen as an increased risk for CVD [35].

Because the contribution of HIV to dyslipidemia is difficult to distinguish from those of classic cardiovascular risk factors, control participants were carefully matched by gender, age, BMI and locality to minimize the confounding effect of these non HIV related conditions on the results of this study. Furthermore, the participants in this study were newly identified and had never received ARV therapy. It could therefore be speculated that the metabolic changes seen have been influenced by HIV-1, subtype C, infection itself.

To identify the MetS in our study population, the criteria of the most frequently used ATP III definition and more recent IDF definition were used. Although our infected participants never received ARV treatment, the prevalence of MetS of 15% (ATP III definition) and 21% (IDF definition) is higher of that found by Badiou et al. [36] in HIV-positive individuals (7.3 vs. 11.2%; 80% treated by combined ARV therapy) and in agreement with the study by Samaras et al. [37] (14 vs. 18%), where 93% of the participants had received ARV therapy at some time. The TG:HDL-C ratio, which is closely linked to lipid disorders associated with MetS, was higher in our HIV-infected participants, as observed previously in HIV-infected individuals [38] and in type 2 diabetes patients [39]. The most prevalent lipid abnormalities seen in our study were the low HDL-C levels and higher TG levels exhibited by the HIV-infected participants. This was also seen in the SIMONE study where the diagnosis of MetS in HIV-infected individuals was mainly due to reduced HDL-C and high serum TG levels [40].

Much controversy still exist whether HIV-infected individuals have a higher prevalence of MetS (with or without therapy). In the study of Mondy et al. [41] the researchers found the prevalence of MetS to be similar among the HIV-infected participants (25.5%), who received ARV therapy, and the matched NHANES control participants (26.5%). On the other hand, in the cohort of HIV-infected individuals of Samaras et al. [37], the prevalence of the MetS was less in HIV positive adults (all received ARV therapy at some time) than in the general population. Our study, where the participants never received ARV therapy, shows that the prevalence of the MetS (both according to the ATP III and IDF definition) does not differ between the HIV-infected and the matched uninfected participants. This finding is in contrast with the finding of Bonfanti et al. [23] which reported a higher prevalence of MetS in never-treated HIV-infected individuals than in the general population.

Abdominal obesity, an essential component of the MetS, seems to occur less frequently in HIV-infected individuals (treated), and they seldom meet the cut-off value of the MetS criteria [37, 42]. Furthermore, there are no specific population group WC cut-off value available for sub-Saharan Africans and in this study the cut-off value for Europeans were used, as suggested by the IDF definition, when identifying the prevalence of MetS using the IDF criteria. It is known that abdominal obesity is more prevalent among African women than men [43] and very few male participants met the WC cut-off value whether HIV infected (0.88% ATP III and 2.63% IDF) or not (0% ATP III and 0.88% IDF), suggesting that these WC cut-off values might influence the outcome of the prevalence of the MetS in our study. The fact that the participants of our study were matched according to BMI to differentiate between the contribution of the infection itself and classical risk factors, could therefore not address this problem. Although more women met the WC cut-off value, it has also been shown that there is a clear difference regarding body composition between African and Caucasian women and Schutte et al. [44] suggested that these differences should be incorporated by the IDF definition when establishing a WC cut-off value for Africans. They also suggested that different HDL-C and TG cut-off values be used

Table 3 Comparison of the prevalence of the MetS between the HIV-infected ($N = 300$: M = 116, F = 184) and uninfected participants ($N = 300$: M = 116, F = 184)

	ATP III			IDF		
	HIV infected	HIV uninfected	*P*	HIV infected	HIV uninfected	*P*
WC						
M	0.88	0.00	0.32	2.63	0.88	0.31
F	18.33	18.68	0.93	33.9	40.1	0.22
TG	18.2	14.3	0.19	17.6	14.3	0.28
HDL-C						
M	47.4	12.1	<0.0001	46.5	11.2	<0.0001
F	62.6	33.7	<0.0001	62.6	33.7	<0.0001
BP	50.0	59.0	0.03	50.0	59.0	0.03
FG	22.7	25.1	0.49	36.6	43.7	0.08
MetS	15.2	11.5	0.18	21.1	22.6	0.65

Data are expressed as % of *N*

ATP III definition of MetS requires three or more of the following criteria: abdominal obesity, WC, men > 102 cm, women > 88 cm; hypertriglyceridemia ≥ 1.69 mmol/L; low HDL-C, men < 1.04 mmol/L, women < 1.29 mmol/L; blood pressure ≥ 130/85 mm Hg, or fasting glucose ≥ 6.1 mmol/L

IDF definition of MetS requires abdominal obesity, WC, men ≥ 94 cm, women ≥ 80 cm, and two or more of the following criteria: hypertriglyceridemia ≥ 1.7 mmol/L; low HDL-C, men < 1.03 mmol/L; women < 1.29 mmol/L; blood pressure ≥ 130/85 mm Hg, or fasting glucose ≥ 5.6 mmol/L

N indicates number of participants, *M* male, *F* female, *WC* waist circumference, *TG* triglycerides, *HDL-C* high density lipoprotein cholesterol, *BP* blood pressure, *FG* fasting glucose, *MetS* metabolic syndrome

All *P* values were obtained via the Chi-square test

for Africans to determine the prevalence of MetS in an African population as they mostly show more favorable lipid values than Caucasians [44].

HIV lipodystrophy is characterized by dyslipidemia, visceral adiposity and a loss of abdominal and peripheral subcutaneous fat [45]. Lipodystrophy is seen in only a small portion of HIV-infected individuals not receiving ARV therapy [46]. The HIV-infected and uninfected participants in this study were matched according to BMI and no differences were seen in waist or hip circumference or waist:hip ratio. Odds ratios also showed no increase in risk for an increase in WC when being HIV infected. The participants were newly identified as being HIV infected and therefore it is not known how long the participants have been infected. However, it seems that no fat redistribution took place in our never-treated HIV-infected participants.

The fasting glucose levels were similar between the HIV-infected and the control groups. The use of fasting glucose level alone to diagnose impaired tolerance is likely to underestimate the prevalence of insulin resistance, advocated as a causative factor of the MetS [47].

Both low serum HDL-C levels and high serum hs-CRP levels are seen as independent risk factors for CVD [37, 48], and the concentration of CRP is seen as a predictor of cardiovascular events [49]. A study by Wadham et al. [50] showed that HDL-C inhibits the inflammatory effect of CRP. In the general population the MetS is associated with inflammation and the IDF consensus group has highlighted elevated CRP as apparently being related to the MetS. The hs-CRP levels differ between the HIV-infected and control group (3.31 vs. 2.13 mg/L; $P = 0.0006$) and the OR for having a higher hs-CRP is 1.78 when HIV infected. The latter did not seem to influence the risk for MetS in this study. However, it is not known for how long the participants have been infected, and the duration of infection might be an important determinant of inflammatory status and its consequences.

Although hypertension is very common in black South Africans [51, 52] and 59% of the HIV uninfected participants had a high blood pressure (according to both the ATP and IDF definition for MetS), the SBP as well as the prevalence of high blood pressure were lower in the HIV-infected group. This seems to be consistent with previous studies [53], as hypertension in the HIV population is mostly associated with the use of ARV therapy, the MetS, insulin resistance and/or anthropometric disorders [54].

Kidney function is often compromised in the HIV-infected population, and HIV-associated nephropathy is frequently seen in immunosuppressed individuals of black ethnicity [55]. In our study no difference in serum creatinine or estimated creatinine clearance rate was seen between the HIV-infected and uninfected participants.

These results suggest that identification of the MetS in HIV-1 subtype C infected Africans should not be the main focus for the identification of individuals at risk for CVD. Low HDL-C and elevated TG levels seem to be the most prevalent abnormalities and therefore emphasis should be placed on determining the HDL-C and TG levels and to treat the metabolic abnormalities present, thereby reducing the probable cardiovascular risk faced by these individuals.

This study should be interpreted within the context of its strengths and limitations. We applied a case–control design and carefully matched the control subjects according to age, gender, BMI and locality. When viewing previous studies regarding HIV and cardiovascular risk, our study population is unique in specifically two aspects: they were infected with the subtype C virus instead of subtype B, and they were unaware of their infected status and therefore have never received ARV treatment. Thus the differences found could probably be attributed to the infection itself. Furthermore, the data as obtained in this study is limited in HIV-infected South Africans. A limitation of the study is that the duration of the HIV infection is unknown as the participants were newly identified being HIV infected. Also, some of the participants chose not to visit the local clinic or hospital for follow-up (CD4 cell count determination and possible subsequent treatment) after they were informed of their HIV-infected status. This is probably due to stigmatization which still exists among South African individuals [56, 57]. Thus, we were only able to obtain CD4 cell count data from a limited group of participants ($N = 72$) and those results were not used in the study due to the small sample size.

In conclusion, the results of this study provide evidence that HIV-1, specifically subtype C, is associated with dyslipidemia and an inflammatory state of newly identified HIV-infected, never-treated, African individuals that may increase their risk for CVD. The study therefore shows that HIV-1 subtype C, though genetically different from subtype B, seems to influence the MetS components in the same way as HIV-1 subtype B, but does not increase the prevalence of the MetS in Africans.

Acknowledgments The authors would like to thank the PURE-SA research team, especially Dr. M Watson, who was responsible for the HIV testing and counseling, the field workers and office staff in the Africa Unit for Transdisciplinary Health Research (AUTHeR), North-West University, South Africa. Use of Comparative Proteomics to Identify Key Proteins Related to Hepatic Lipid Metabolism in Broiler Chickens: Evidence Accounting for Differential Fat Deposition Between Strains

Jianzhen Huang · Xue Tang · Jiming Ruan · Haitian Ma · Sixiang Zou

Received: 7 August 2009 / Accepted: 28 October 2009 / Published online: 29 November 2009

Abstract In order to investigate differences in fat metabolism during embryonic development, a comparative proteomics strategy was employed using Arbor Acres (AA) and San Huang (SH) broiler chickens with different growth and fat deposition characteristics. These birds were floor-reared and fed identical diets, and embryonic livers were collected from AA and SH chicken embryos on days 9, 14 and 19 of incubation and hatching. Proteins were extracted and fractionated by two-dimensional electrophoresis (2-DE), Neuhoff's colloidal Coomassie Blue G-250 staining was carried out, and stained gels were scanned and analyzed using PDQuest7.3 software (Bio-Rad). In-gel trypsin digestion of the differential protein spots and matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF-MS) were subsequently assessed. Peptide mass fingerprinting of the differentially expressed proteins was performed using the server from MASCOT or either Prospector or ProFound, and 37 proteins were successfully identified. In the present study, embryo and liver weights showed a trend toward enhanced growth during embryonic development. Of the 37 identified differential proteins, phosphoenolpyruvate carboxykinase (PEPCK), apolipoprotein A-I (Apo A-I), fatty acid-binding protein (L-FABP) and 3-hydroxy-3-methylglutaryl-Coenzyme A synthase (HMG-CoA synthase) were up-regulated in SH chickens to a greater extent than they were in AA chickens. These observations suggest that the lipid metabolic proteins and enzymes are inherent characteristics that contribute to the apparent differences in fat deposition between the two strains.

Keywords Embryonic development · Broilers · Proteomics · Lipid metabolism

Abbreviations

AA	Arbor Acres
SH	San Huang
2-DE	Two-dimensional electrophoresis
MALDI-TOF-MS	Matrix-assisted laser desorption/ionization-time of flight mass spectrometry
Apo	Apolipoprotein
L-FABP	Fatty acid-binding protein
PEPCK	Phosphoenolpyruvate carboxykinase
HMG-CoA synthase	3-Hydroxy-3-methylglutaryl-Coenzyme A synthase
ME	Malic enzyme
FAS	Fatty acid synthetase
ACC	Acetyl-CoA carboxylase
DTT	Dithiothreitol
PMSF	Phenylmethanesulfonyl
CHAPS	3-(3-Cholamidopropyl-dimethylammonio)-1-propanesulfonate

Introduction

Over the past several decades, an unintended consequence of the increased growth rates that have been achieved in commercial poultry production has been the development of excessive abdominal fat deposits. This trait represents a major drawback for the industry, as it reflects reduced feed efficiency during rearing and decreases the yield of lean meat after processing [1]. It is, therefore, of particular interest to better understand avian lipid metabolism and to further elucidate the genetic mechanisms involved in the regulation of fat deposition in poultry. Unlike mammalian species, in birds, the liver is the main site of de novo fatty acid synthesis, accounting for 95% of all lipid production in young chicks, with the adipose tissue serving only as a lipid storage site [2, 3].

Considerable metabolic and physiological research has been conducted on liver tissue, and some studies have shown that the main source of variability between fat- and lean-type chicken lines can be attributed to differences in liver fatty acid metabolism [1, 4–6]. It is known that gene expression and the activity of lipogenic enzymes differ between fat- and lean-line chickens during fat deposition. Some of the genes involved in fatty acid synthesis, such as malic enzyme (ME), ATP citrate lyase and Acetyl-CoA carboxylase (ACC), have been found to be differentially expressed in the two lines [7].

The San Huang (SH) broiler chicken is a well-known Chinese indigenous breed that displays uniform body fat, high intramuscular fat, and excellent meat quality, while Arbor Acres (AA) chickens display less favorable meat quality characteristics, caused by excessive abdominal fat deposition. Thus, these two species of broiler chickens provide good models for the study of hepatic lipid metabolism differences. Zhao et al. [8, 9] reported that genes related to lipid metabolism, such as fatty acid synthetase (FAS), ACC and apolipoprotein B100 (ApoB100), display different mRNA expression profiles during embryonic liver development in the two lines. However, little information is available relative to liver protein expression in the pathways and mechanisms that contribute to adiposity variability in both lean and fat lines, especially in chicken embryos. To date, the proteomic approach provides a powerful tool to study various biological and medical mechanistic phenomena and has been focused on characterizing the diseased liver [10, 11]. A global protein expression analysis of the chicken embryo liver will aid in the identification of differentially expressed proteins involved in lipid metabolism, provide new insight into the mechanism of fat deposition in embryonic broiler chickens, and pave the way toward a new framework for future studies.

Therefore, the aim of the current study was to identify differences in fat deposition between AA and SH chicken lines, to describe and compare protein profiles in the embryonic livers, and to identify those differential proteins that are of particular importance in the control of hepatic lipid metabolism and fat deposition. Achievement of this latter goal will provide the basic molecular information necessary to understand the regulation of fat deposition in embryonic broiler chickens.

Materials and Methods

Reagents

Immobilized pH gradient gel (IPG) strips, urea, thiolurea, dithiothreitol (DTT), 3-(3-cholamidopropyl-dimethylammonio)-1-propanesulfonate (CHAPS), ampharmalyte pH 3–10, phenylmethanesulfonyl (PMSF), and iodoacetamide were all purchased from Bio-Rad (Richmond, CA, USA), while Coomassie Brilliant Blue G-250 was purchased from Amresco (Solon, OH, USA) and trypsin was purchased from Promega (Madison, WI, USA). All chemicals for SDS-PAGE were of electrophoresis grade.

Animals

A total of 120 AA and SH female broilers (42-weeks-old) were obtained and housed in the Wuxi Breeding Company (Jiangsu, China). The birds were divided into two groups (AA and SH, 60 birds per group), and each group was kept in three pens, with 20 broilers per pen. All birds were fed identical diets and floor-reared under natural lighting at constant temperature (20 ± 3 °C) and humidity (50 ± 3%). They were placed under dietary restriction but they had free access to drinking water. Nutrient levels within the diet (Table 1) were based on NRC (1994) recommendations. Animal care and use were approved by the Institutional Animal Care and Use Committee of Nanjing Agricultural University.

Before the initiation of the experiment, the birds were acclimatized to the environmental conditions for at least 2 weeks. Eggs from each of three pens for each group were collected, numbered and weighed, and placed in an electric forced-draft incubator at 37.5 ± 0.5 °C and 60% relative

[b] Metabolizable energy in kilojoules per kilogram

humidity. Only un-chipped and intact eggs were used in the experiment prior to incubation. The start of the incubation period was referred to as "E1d" (1-day-old embryos), and after hatching, the term used was "H1" (1-day-old birds). Embryonic livers were collected from AA and SH chicken embryos on days 9, 14 and 19 of incubation and hatching, and then washed twice with cold physiological saline (0.9% NaCl solution) to remove blood and other possible contaminants. Samples were then flash-frozen in liquid nitrogen and stored at −80 °C prior to homogenization.

Protein Sample Preparation and Two Dimensional Gel Electrophoresis

Tissues were homogenized in a lysis buffer consisting of 7 mol/L urea, 2 mol/L thiolurea, 2% (w/v) CHAPS, 50 mmol/L DTT, 0.8% (w/v) ampharmalyte pH 3–10 and 1 mmol/L PMSF, using a glass homogenization vessel in an ice bath. The resultant homogenate was swirled for 20 min and centrifuged for 20 min at 15,000×*g* at 4 °C. Supernatant was collected and fractionated into aliquots. The protein concentration for each of the final supernatants was measured by the Bradford assay [12] using bovine serum albumin (BSA) as the standard. Eight hundred micrograms of each protein extract were separated by iso-electrophoresis using IPG strips (pH 3.0–10.0 NL, 17 cm) in the protean system (Bio-Rad). Focusing was performed through 1 h at 250 V, 1 h at 500 V, 1 h at 2,000 V, 2 h at 8,000 V, and then holding at 8,000 V until a total of at least 60,000 Vh was reached. The second dimension was run on a 12.5% polyacrylamide SDS gel using the Multiphor system (Amersham Biosciences). The 2-DE for each sample was repeated four times. Neuhoff's colloidal Coomassie Blue G-250 stain was carried out according to the method described by Candiano et al. [13]. Stained gels were scanned and analyzed using PDQuest7.3 software (Bio-Rad). After alignment, spots between gels were first automatically matched. The matched spots were then re-examined manually to ensure accuracy. Generally, only those spots, with a quality of over 50, were chosen for further analysis. Spot quantity normalization was conducted in the 'total quantity of valid spots' mode.

MALDI-TOF-MS Analysis and Database Queries

In-gel trypsin digestion of protein spots, and MALDI-TOF-MS (Reflex III, Bruker-Daltonics, Germany) analyses were based on procedures described by Wang et al. [14]. MS fingerprinting data searches were performed by search engines of ProFound (http://129.85.19.192/ profound_ bin/WebProFound.exe) and MS-fit (http://prospector.ucsf.edu/uscfhtml3.4/ms-fit.htm) against the NCBInr database in the taxa of *Gallus gallus* (Chicken) with the parameter sets of trypsin digestion, two missed cleavages, complete modification of iodoacetamide (Cys), partial modification of methionine oxidation, protein mass = ±20% of the observed protein mass, *p*I = ±1 of observed *p*I, and a mass tolerance for monoisotopic data of 100 ppm. Protein identification was assigned when the following criteria were met: at least four matching peptides and >20% sequence coverage.

Functional Annotation of Identified Proteins

Functions of proteins identified through MS fingerprinting data were annotated by querying against the protein function database Pfam (http://www.sanger.ac.uk/Software/Pfam/; [15]) or Inter-Pro (http://www.ebi.ac.uk/interpro/; [16]).

Statistical Analysis

The effect of embryonic development age (days) on embryo weight and liver weight were analyzed by two-way ANOVA (with developmental age as the main effect) using the general linear models approach. Differences among individual means were evaluated. Analysis of variance (ANOVA) and correlation coefficient estimates for protein

expression changes were conducted using JMP 5.1 (SAS Institute). The statistical significance level was set at $P < 0.05$.

Results

Changes in Embryo Weight and Liver Weight in AA and SH Broiler Chickens at Various Embryonic Stages and at Hatching

Both body weight and absolute liver weight were significantly higher in AA broiler chickens than in SH broiler chickens starting on day 14 of embryonic development and continuing to hatching ($P < 0.05$). However, body weight and absolute liver weight both exhibited trends toward increases in both species.

Comparative Analysis of Liver Proteins between AA and SH Broiler Chickens

Good separation of protein spots was apparent in the 2D gel electrophoresis, except in the base area (Fig. 1). After auto-matching and a manual quality check of the detected spots, 326 valid spots were identified in this experimental series. To determine the repeatability among gels of the same sample, spot to spot correlation coefficients were estimated. Results showed that they varied from 0.81 to 0.92, with all being significant at $P \geq 0.0001$. In each sample, at least one of the three correlation coefficients was over 0.85, while the difference in spot volume among replicates was not significant, based on ANOVA.

In general, the protein profiles in embryo livers from AA and SH broiler chickens during the four development stages were similar. However, certain spots displayed obvious differences in volume or abundance. A total of 40 spots, which reflected a two-fold difference in volume as compared to the two breeds during the four development stages, were subjected to detailed identification. Spots 1, 2, 3, 4, 5, 6, 7, 13, 15, 16, 17, 23, 24, 25, 28, 29, 30, 31, 32, 33, 35 and 36 displayed down-regulation in SH broiler chicken embryo liver, among which, spots 6, 7, 13, 15, 16, 17, 23, 24, 25, 33 and 36 showed a greater than three-fold difference in volume. The remainder of the 40 spots displayed up-regulation in SH broiler chicken embryo liver, and spots 8, 9, 11, 12, 18, 20, 21, 22, 34 and 39 showed a greater than three-fold difference in volume.

Proteins from all 40 spots were subjected to in-gel digestion and analyzed by MALDI-TOF-MS. Protein identification using the MS fingerprint data was conducted by querying the Swiss-Prot, NCBInr protein and chicken polypeptide databases. Positive identifications were obtained for all 40 spots, except for spots 3, 6 and 23. Thus, only the data for the remaining 37 spots were used for further analysis, and the protein identity for each of the 37 spots is listed in Table 2.

Proteins identified successfully were sorted into six main functional classes based on the KOG database comparison. A large group of proteins (spots 17, 27, 29, 34, 35, 36, 38, 39 and 40) were categorized as important in metabolism, such as PEPCK, ApoA-I, L-FABP, HMG-CoA synthase, enolase, sulfotransferase, etc. Some proteins (spots 7, 8, 9 and 28) were found to be involved in signal transduction, while others (spots 11, 12, 14, 30, 32, 34 and 37) are known to participate in energy metabolism, protein synthesis and disease/defense. The remaining proteins were not related to any KOG based function (Table 3).

Discussion

Hamburger and Hamilton [17] described a series of stages to categorize the entire 21-day development period of the chicken embryo, based on external characteristics. These stages can be divided into three phases. The two earlier phases form a period during which the organs and systems of the body are formed, while the last phase, from day 13 until hatching, is characterized by the maturation and growth of the organ systems. Embryonic development is an energy consuming process. During the two earlier phases, glucose within the yolk sac supplies energy, but about 90% of the total energy required by the embryo for growth comes from β-oxidation of fatty acids derived from yolk lipids [18, 19]. Previous studies have indicated that differences in lipid metabolism exist during the embryonic stage of development among the different lines of broiler breeders [20, 21]. In the current study, we found that body weight and absolute liver weight in AA broiler chickens were slightly higher than in SH birds during the last phase of embryonic development, which indicates that there was a difference in lipid metabolism between the breeds.

Using a proteomic approach, 37 proteins that exhibited differential changes in profile when taken from AA and SH chicken embryonic livers were identified. Some of these were involved in important aspects of metabolism and, in particular, lipid metabolism.

Phosphoenolpyruvate carboxykinase (PEPCK) is a rate-controlling enzyme in gluconeogenesis which catalyzes the synthesis of phosphoenolpyruvate (PEP) from oxaloacetate (OAA). It is expressed primarily in liver, kidney and adipose tissue, where its synthesis is highly regulated by insulin, glucocorticoids, thyroid hormone and glucagon at the level of transcription. PEPCK exists as two different isozymes in vertebrate tissues (PEPCK-C and PEPCK-M), which show remarkable similarity in protein secondary structure. PEPCK-C is the major form evident in

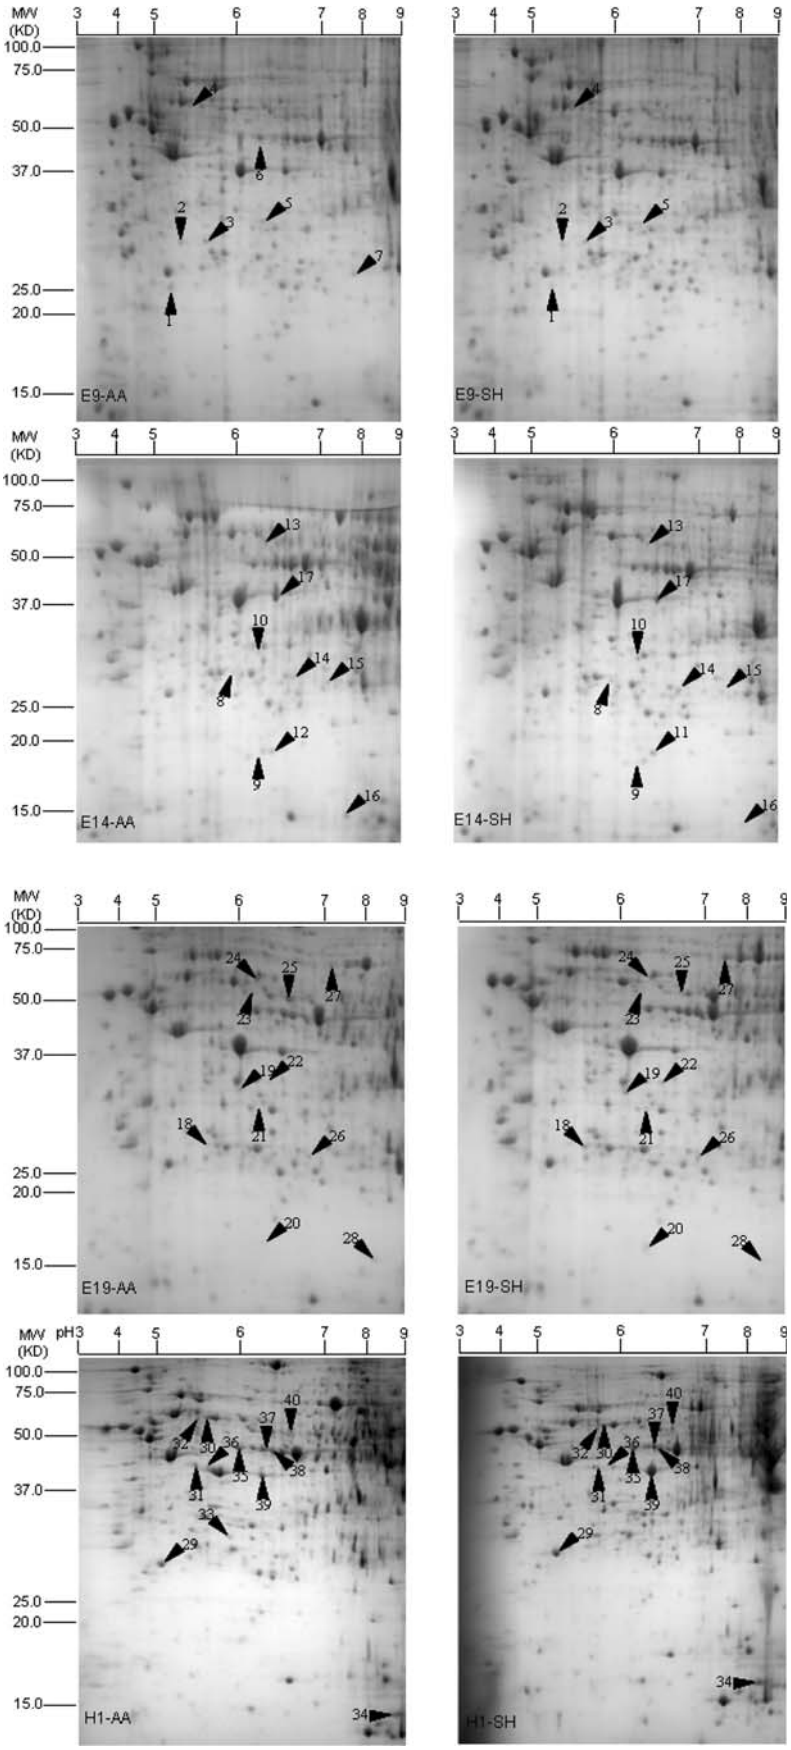

Fig. 1 Proteins profiles of AA chicken and SH chicken embryo liver at the stage of E9, E14, E19, H1. *Arrows* indicate the proteins with at least a 2.0-fold change in the four development stages

embryonic chicken liver tissue, while PEPCK-M only exists in the liver of adult chickens [22]. Tordjman et al. [23] have reported that fatty acids stimulate PEPCK-C gene expression, and recent studies have suggested that PEPCK is also important in the maintenance of blood glucose concentration and insulin resistance. In this paper, PEPCK resulted from up-regulation in SH chicken embryonic liver, which indicates that gluconeogenesis was more pronounced in SH chicken embryonic liver than in AA chicken embryonic liver, indirectly suggesting that fatty acid oxidation in SH chicken embryos provides enhanced levels of non-carbohydrate substrate for gluconeogenesis.

ApoA-I, the major protein component of high-density lipoprotein (HDL), has diverse physiological functions, including lipid binding and solubilization, activation of lecithin: cholesterol acyl transferase (LCAT), modulation of HDL rearrangement during metabolism and lipid transfer, and interaction with HDL receptors on cell surfaces. Douaire et al. [24] reported that the mRNA levels of genes coding for lipogenic enzymes (acetyl-coenzyme A carboxylase, fatty acid synthase, malic enzyme, Δ9-desaturase) and apoproteins (apoB and apoPVLDL-II) did not differ significantly between fat and lean birds, while the mRNA levels for genes coding for apoA-I were significantly different. We found that apoA-I was expressed to a greater extent in SH chicken embryonic liver than in AA birds. This observation could indicate that cholesterol metabolism was enhanced by higher levels of apoA-I in SH chicken embryonic liver.

HMG-CoA synthase is the rate-limiting enzyme for ketone body formation and the catalyst for the condensation of acetoacetyl-CoA and acetyl-CoA to form HMG-CoA plus free CoA. The activity of HMG-CoA synthase is located in both the cell cytosol and in the mitochondria. The HMG-CoA produced by cytosolic HMG-CoA synthase is the starting point for the isoprenoid pathway which, in addition to producing cholesterol as its main end product, yields other important isoprenoids. Control of ketogenesis is exerted by transcriptional regulation of mitochondrial HMG-CoA synthase. Mitochondrial and cytosolic HMG-CoA synthase are encoded by two different genes. Hegardt [25] reported that fasting, cAMP, and fatty acids increase the transcriptional rate of mitochondrial HMG-CoA synthase, while re-feeding and insulin repress it. In the present study, we observed that HMG-CoA synthase protein levels were significantly higher in SH broiler chickens than they were in AA broiler chickens. Therefore, ketogenesis was enhanced, and this reflected, at least in part, an increased acetyl-CoA level in the liver, which resulted from the high rate of fatty acid beta oxidation in SH broiler chickens.

Fatty acid-binding proteins (L-FABP) are small molecular weight proteins with high binding affinities for long-chain fatty acids [26], and they are members of a super family of lipid-binding proteins that occur intra-cellularly in invertebrates and vertebrates. In mammals, the intracellular or cytoplasmic FABP form a group of at least nine distinct proteins, with molecular weights ranging from 14 to 15 kDa. They are named according to the tissues from which they are isolated [26], and they are involved in intracellular fatty acid movement, cell growth and differentiation, cellular signaling, gene transcription, and protection of enzymes from the toxic effects of free fatty acids [27]. Ceciliani et al. [28] isolated a FABP from chicken liver which had an isoelectric point of 9.0, whereas other L-FABPs have isoelectric points near 6.0. It has been documented that the ontogeny of FABP in turkey liver is associated with fatty acid metabolism in turkey embryos and poults [29]. Martin et al. [30] reported that L-FABP gene ablation dramatically enhances many of the effects of dietary cholesterol to significantly induce hepatic cholesterol and triacylglycerol accumulation as well as to potentiate BW gain (primarily as fat tissue mass). Cogburn et al. [31] reported that L-FABP gene expression was higher (1.66-fold) in hyperthyroid (lean) chickens than in hypothyroid (fat) chickens. Wang et al. [32] have also reported that chicken liver tissue L-FABP mRNA levels vary among different breeds, with the Baier layers (a Chinese local breed) having higher levels than meat-type broilers. They indicated that L-FABP gene assessment was used as an important candidate gene in chicken QTL detection programs, focusing on phenotypes related to fat traits. In this study, the results showed that L-FABP protein expression was significantly higher in SH broiler chickens

than in AA birds. The higher expression level for L-FABP in the embryonic liver of SH broiler chickens might result in increased fatty acid transportation into the mitochondria or peroxisomes and, thus, enhanced fatty acid oxidation and reduced fat deposition.

Taken together, it can be concluded that PEPCK, apoA-I, FABP, HMG-CoA synthase were up-regulated in the embryonic liver of SH broiler chickens, which suggests that gluconeogenesis, cholesterol metabolism and fatty acid oxidation were functional in the embryonic liver of SH broiler chickens prior to their occurrence in the embryonic livers of AA broiler chickens. It also suggests that the observed differences in lipid metabolism between AA and SH birds might, in part, be attributed to this differential expression of proteins in embryonic liver. However, given the limitations of the proteomics approach relative to immobilized pH gradients and pH intervals, we cannot extrapolate this conclusion to total protein synthesis and/or degradation without further study.

In conclusion, expression of the proteins and enzymes related to hepatic lipid metabolism in broiler chickens exhibited specific breed characteristics during embryogenesis. The data suggest that these proteins were associated with fat traits and that they contributed to the apparent differences in fat deposition observed between SH and AA broiler chickens. The data also strongly suggest that the regulation of adiposity in chickens derived from lean and fat lines was linked to the regulation of the key proteins and enzymes screened in the present study.

Electron Paramagnetic Resonance Investigation of Stratum Corneum Lipid Structure

Kouichi Nakagawa

Received: 14 September 2009 / Accepted: 6 November 2009 / Published online: 29 November 2009

Abstract Electron paramagnetic resonance (EPR) in conjunction with a slow-tumbling simulation was utilized for defining stratum corneum (SC) lipid structure. We found that ordering calculated from the simulation is an appropriate index for evaluating SC lipids structure. The SC from two sites (mid-volar forearm and lower-leg) of human volunteers was stripped consecutively from one to three times using a glass plate coated with a cyanoacrylate resin. Aliphatic spin probes, 5-doxylstearic acid (5-DSA) and 3β-doxyl-5α-cholestane (CHL), were used to monitor SC ordering. EPR spectrum of 5-DSA incorporated in the SC demonstrated a characteristic peak for the first strip. However, EPR spectra of CHL in the SC did not show a clear difference for each strip, except for the peak intensity. The results imply that CHL is not incorporated into the lipid phase as easily as 5-DSA is. A slow-tumbling simulation of the EPR spectrum was performed to analyze the detailed lipid structure. The simulation results for 5-DSA show differences in values of the SC ordering as a function of depth. Thus, these results along with the simulation analysis provide a detailed SC layer structure.

Introduction

Electron paramagnetic resonance (EPR) is useful for elucidating structural aspects of stratum corneum (SC) [1–5]. Non-invasive spectroscopic characterization of the outermost layer of the SC is an important subject in dermatology and cosmetology. The SC, a heterogeneous structure composed of corneocytes embedded in the intercellular lamellar lipid bilayer, acts as the main epidermal barrier against chemicals, oxidative stress, the UV component of sunlight, and other invasive environmental factors, as well as regulating transepidermal water loss (TEWL) to prevent dehydration of viable cells underneath the SC. The intercellular lamellar lipid bilayers play a critical role in these barrier functions.

It is essential to know the composition of SC lipids as well as their structure in relation to depth. The various components, such as ceramides, cholesterol, and free fatty acids of SC lipids have been investigated by thin-layer chromatography (TLC) [6, 7]. It was also pointed out that the levels of SC lipids in a group of women aged 41–50 showed a decrease in SC lipid levels [8].

At present, no quantitative method is available to evaluate the structures and motions of the molecular components of the intercellular lamellar lipid bilayers. TEWL

measurement is the only non-invasive method which indirectly provides knowledge of the status of the lipid layers in relation to water permeation, but the measurement itself does not provide direct information regarding the state of the SC. The ordering of the lipid bilayer can be studied by X-ray analysis only for in vitro SC specimens or model lipid membranes composed of water. Structural information can be obtained by analysis of aliphatic spin probes incorporated into the lamellar lipids using EPR [1–5]. Therefore, EPR can potentially detect the skin-lipid structures as well as their dynamics.

The EPR spin probe method has been utilized to characterize the skin-lipid structures [1, 2], as well as fluidity [3]. The physicochemical properties of intercellular lipids of SC were investigated as a function of various surfactants [4], and water content [5]. These studies provided information about the fluidity-related behavior of SC under various conditions by measuring EPR signal intensities and hyperfine values. Recently, we recognized that the conventional method of calculating the chain ordering using hyperfine values cannot differentiate subtle EPR spectral changes [1, 2]. Changes in the probe behavior are reflected in the EPR line width as well as the line shape, besides the hyperfine values. Precise analysis of EPR spectra can be performed by spectral simulation to extract quantitative ordering of the lipid structures [9, 10]. Therefore, EPR in conjunction with a simulation method should be useful to obtain direct information regarding skin-lipid structures. Such knowledge of the SC structural changes and mobility would be important in understanding the mechanism of irritant dermatitis and other SC diseases.

This paper describes an EPR investigation of the lipid ordering of SC using aliphatic spin probes together with a slow-tumbling simulation. EPR spectra were analyzed both by conventional calculation and slow-tumbling simulation. The obtained values of the order parameter are discussed in terms of EPR spectral changes in relation to the lipid moieties.

Experimental Section

Sample Preparations of Stripped SC from Volunteers and Spin Labeling of the SC

The Fukushima Medical University Internal Review Board approved all protocols used herein. The ethical principles for non-clinical biomedical research involving human subjects as stated in the Declaration of Helsinki Guidelines were adhered to in every respect. SC was removed from the mid-volar forearm of volunteers, who had given informed consent to the procedure, with a single drop of cyanoacrylate resin, and placed on quartz glass (7×37 mm^2; Matsunami Glass Ind. Ltd., Japan). The time interval was approximately 2 min between successive strippings. The spin probe agents, 5-doxylstearic acid (5-DSA) and 3β-doxyl-5α-cholestane (CHL), were purchased from Aldrich-Sigma Chemical Co. Inc. and used as received. A schematic representation of the configuration of the spin probes in a membrane is shown in Fig. 1. SC samples were incubated in $\sim$50 μM probe aqueous (H_2O) solutions for $\sim$60 min at 37 °C. After rinsing with deionized water to remove excess spin probe, the SC sample was mounted in the EPR cavity. Sample preparation has been described in detail elsewhere [1, 2].

EPR Measurements

EPR measurements were performed with an EMX EPR spectrometer from Bruker Instruments Inc. (Billerica, MA). First derivative, X-band spectra were recorded in a high sensitivity microwave cavity using a microwave power, 5 mW; time constant, 0.1 s; sweep time, 120 s; modulation, 0.1 mT; sweep width, 12.5 mT. Each spectrum used in the data analysis is an average of 2–5 scans. All measurements were performed at ambient temperature. The

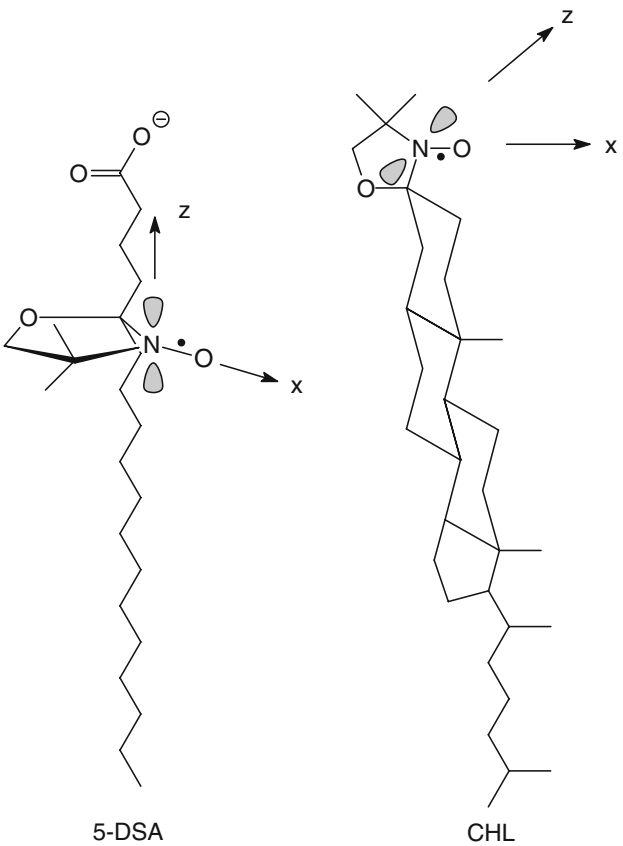

Fig. 1 A schematic representation of the configuration of the aliphatic spin probes in a membrane, where the *Z*-axis of the acyl chain is parallel to the *z*-axis of the membrane

resulting EPR spectra of 5-DSA in the SC samples were analyzed using two methods: conventional calculation of the order parameter and spectral simulation [9].

Conventional EPR Analysis

The inclination of the principal axis of the nitroxide radical to the rotational axis of the long-chain probe molecule represents a measure of the order–disorder of the molecular assemblies of a membrane. The order parameter indicates the membrane chain dynamics and microenvironment of the medium in which the spin probe is incorporated. The conventional order parameter (S) is determined from the hyperfine coupling of the EPR signals according to the following relations [11]:

$$S = \frac{A_{\parallel} - A_{\perp}}{A_{ZZ} - \frac{1}{2}(A_{XX} + A_{YY})} \times \frac{a}{a'}, \tag{1}$$

$$a' = \frac{A_{\parallel} + 2A_{\perp}}{3}, \tag{2}$$

where a is the isotropic hyperfine value, $(A_{XX} + A_{YY} + A_{ZZ})/3$; A_{XX}, A_{YY}, and A_{ZZ} are the principal values of the spin probe. In calculation based on the experimental spectra, the following principal components were used for 5-DSA [12].

$$A_{XX}, A_{YY}, A_{ZZ} = (0.66, 0.55, 3.45)\ \text{mT} \tag{3}$$

$$g_{XX}, g_{YY}, g_{ZZ} = (2.0086, 2.0063, 2.0025) \tag{4}$$

The experimental hyperfine couplings of $2A_{\parallel}$ and $2A_{\perp}$ are obtained from the EPR spectrum. The order parameter indicates that the S value increases with increasing anisotropy of the probe site in the membrane. On the other hand, the S value becomes zero for completely isotropic rotation of the nitroxide radical. Since the spin probe is incorporated into the highly oriented intercellular lipid structure in normal skin, in which the probe cannot move freely due to the rigidity of the lipid structure, its EPR spectrum represents the microscopically oriented profile. When the normal structure is completely destroyed by chemical and/or physical stress, the EPR spectral profiles changes to three sharp lines because the probe mobility is unrestricted. Therefore, the EPR spectral profile reflects the rigidity of the environment of the probe moiety. However, the conventional analysis measuring $2A_{\parallel}$ and $2A_{\perp}$ gives limited information concerning the probe moiety in the membrane, and may not reveal subtle differences in the overall spectra related to the membrane chain ordering [9].

EPR Slow-Tumbling Simulation Analysis

The slow-tumbling motions of the aliphatic spin probes were calculated using the nonlinear least-squares fitting program called NLSL (2000 version for Windows) to analyze the EPR spectra based on the stochastic Liouville equation [13–15]. The simulation of the EPR spectra for spin probes incorporated into multilamellar vesicles was performed using a microscopically ordered but macroscopically disordered (MOMD) model introduced by Meirovitch et al. [16]. This model is based on the characteristics of the dynamic structure of lipid dispersions. For example, lipid molecules are preferentially oriented by the local structure of the bilayer, but the lipid bilayer fragments are overall distributed randomly. The spectrum from the sample can be regarded as a superposition of the spectra from all of the fragments.

The lipid and DSA molecules in the bilayer membrane experience ordering potentials, which restrict the amplitude of the rotational motion. The orienting potential in a lipid bilayer, $U(\Omega)$, determines the orientational distribution of molecules with respect to the local ordering axis of the membrane bilayer. It can be expressed as an expansion in generalized spherical harmonics [17, 18],

$$-U/kT = c_0^2 D_{00}^2(\Omega) + c_2^2\left(D_{02}^2(\Omega) + D_{0-2}^2(\Omega)\right) + \cdots, \tag{5}$$

where $\Omega = (\alpha, \beta, \gamma)$ are the Euler angles between the molecular frame of the rotational diffusion tensor and the local director frame. The c_0^2 and c_2^2 are dimensionless potential energy coefficients, k is the Boltzmann constant, and T is the absolute temperature.

The order parameter, S_0, is defined as

$$S_0 = \langle D_{00}^2 \rangle = \left\langle \frac{1}{2}(3\cos^2\gamma - 1) \right\rangle = \frac{\int d\Omega \exp(-U/kT) D_{00}^2}{\int d\Omega \exp(-U/kT)}, \tag{6}$$

which measures the angular extent of the rotational diffusion of the nitroxide moiety. Gamma (γ) is the angle between the rotational diffusion symmetry axis and the z-axis of the nitroxide axis system; z is the axis of the nitrogen $2p_z$ atomic orbital, and the x-axis lies along the N–O bond, as shown in Fig. 2. The local or microscopic ordering of the nitroxide spin probe in the membrane is characterized by the S_0 value. A larger S_0 value indicates more restricted motion. Therefore, S_0 reflects the local ordering of bilayer molecules in the membrane. The A and g of Eqs. 3 and 4 were used for the simulation of 5-DSA, respectively.

Results

Figure 3 shows the experimental and simulated EPR spectra of 5-DSA in the SC. The reasonable agreement of the experimental and simulated spectra suggests that

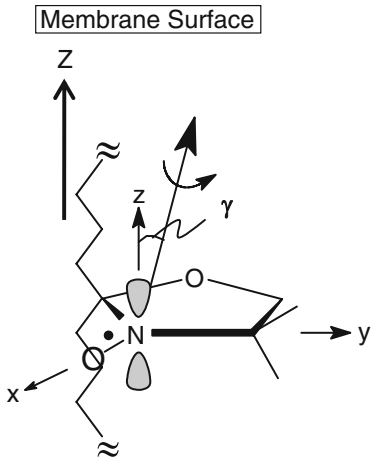

Fig. 2 A schematic representation of a conformation of DSA spin probe in the SC membrane, where *Z*-axis of the acyl chain is parallel to *z*-axis of the nitrogen $2P_z$ orbital

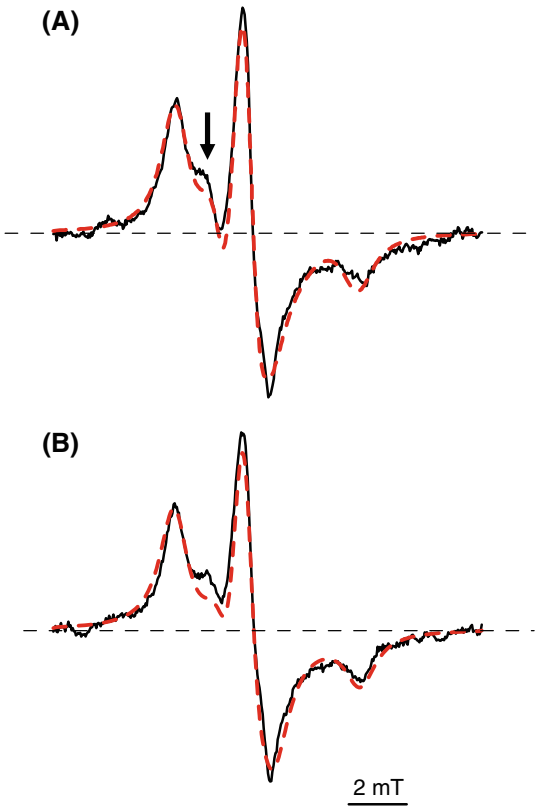

Fig. 3 The experimental (*solid line*) and simulated (*dotted line*) EPR spectra of 5-DSA in stripped SC from human mid-volar forearm (M, 79). The *arrow* indicates the characteristic peak for the first strip. The S_0 values obtained by the simulation were **a** 0.25 and **b** 0.74

simulation analysis can provide detailed information regarding the SC lipids. The S_0 value changes from 0.25 to 0.74, while the *S* value is in the range of 0.56–0.59. The conventional *S* value was calculated using the hyperfine values ($2A_{\|}$ and $2A_{\perp}$) from the observed spectrum in Eq. 1.

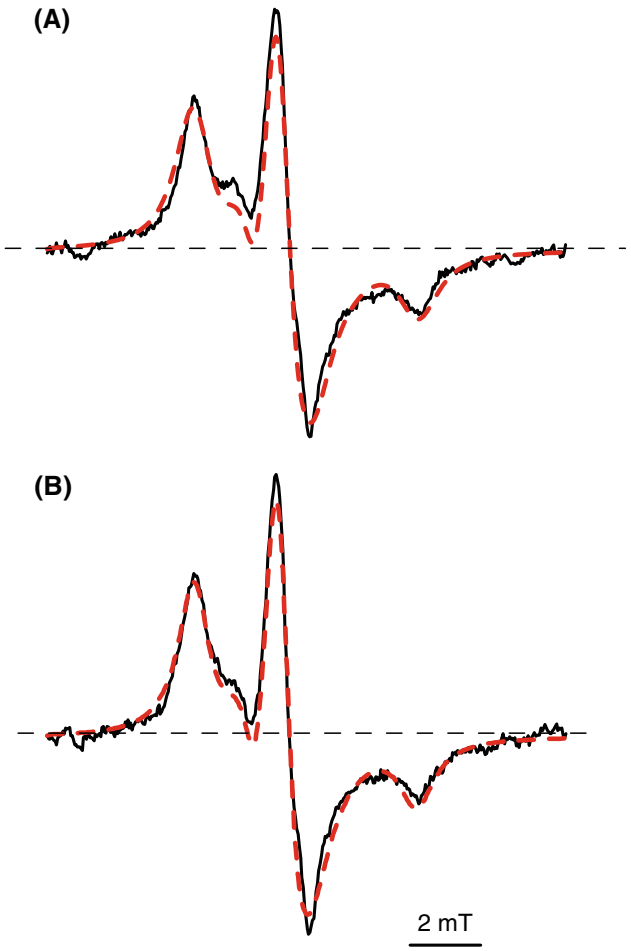

Fig. 4 The experimental (*solid line*) and simulated (*dotted line*) EPR spectra of 5-DSA in stripped SC from human lower-leg. Parallel and perpendicular hyperfine components are indicated for the conventional calculation. The S_0 values obtained by the simulation were **a** 0.28 and **b** 0.60

The arrow in the spectrum (**a**) indicates the characteristic peak, which is prominent only for the first strip (Fig. 3). This peak mainly does not belong to the slow probe motion in the SC. The peak diminishes in intensity with increasing depth in the SC. The marked peak appears near the center of the spectrum because the probe embedded in the first sample stripped has greater freedom of motion. The other two lines of the nitroxide probe overlaid the central region of the spectrum. The results imply that the probe signal can originate from sebaceous secretion where the probe is relatively mobile [2].

Figure 4 shows that human SC stripped from lower-leg presents typical EPR spectra of 5-DSA incorporated in the SC lipids. The EPR spectrum of stripping number 1 slightly differs from number 3. The characteristic peak indicated the arrow in the spectrum is prominent only for the first strip. This peak diminishes in intensity with increasing depth in the SC. Satisfactory agreement between the

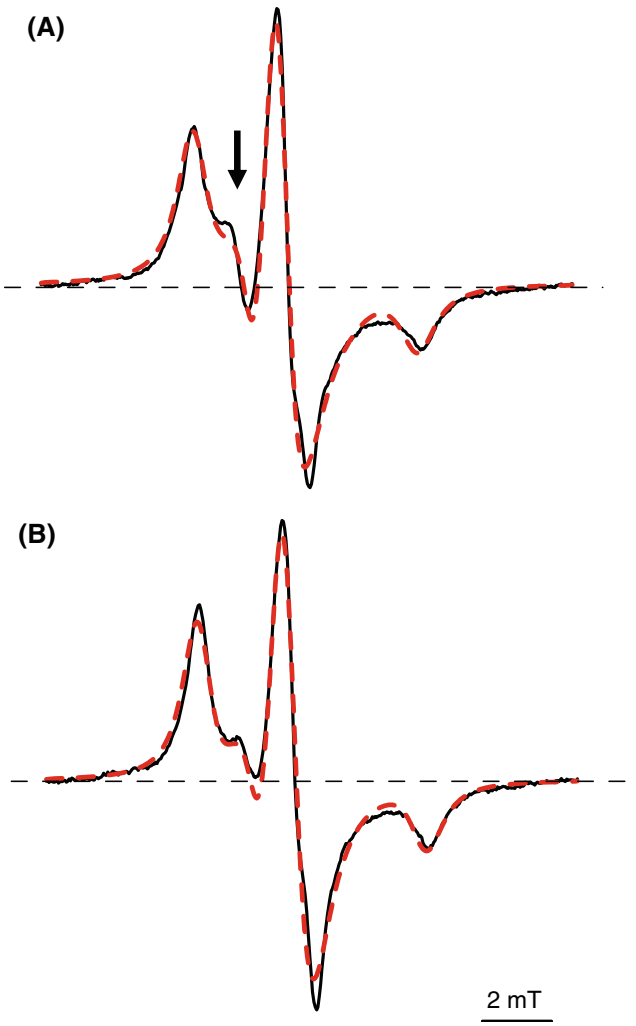

Fig. 5 The experimental (*solid line*) and simulated (*dotted line*) EPR spectra of 5-DSA probe in stripped SC from human mid-volar forearm (F, 51). The *arrow* indicates the characteristic peak for the first strip. The S_0 values obtained by the simulation were **a** 0.34 and **b** 0.36

experimental and calculated spectra can provide a quantitative S_0, which reveals the microscopic ordering in association with the structure of the SC lipids.

Figure 5 presents typical EPR spectra of 5-DSA incorporated in the SC lipids from human mid-volar forearm (F, age 51). The characteristic peak indicated by the arrow is prominent only for the first strip. The reasonable agreement of the simulated and experimental spectra suggests that simulation analysis can provide comprehensive information regarding the SC lipids.

Discussion

The modern EPR slow-tumbling simulation reveals detailed SC lipid structure. Significant differences exist

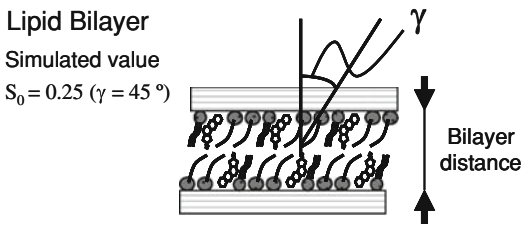

Fig. 6 Schematic illustration of relative lipid bilayer distances and the values of simulated order parameter related to the angles between the bilayer surface and the single-chain probe. The angle (γ) reflects the bilayer distance

between the conventional and simulated order parameters in Fig. 3. Because the slow-tumbling simulation calculates the total line-shape of the spectrum, it is able to extract more detailed information about the SC structure than the conventional analysis, which is normally ambiguous in distinguishing the two hyperfine components (parallel and perpendicular) from the experimental spectrum due to the presence of weak and broad signals [5]. Thus, the S_0 values (0.2–0.9) obtained by the simulation suggest that the outermost SC layers are less rigid (or more mobile), while the deeper lipid layers (S_0–0.9) have more rigid and oriented structures.

One can calculate the angle (γ in Fig. 2) between the rotational diffusion symmetry axis (the lipid in SC) and the z-axis of the nitroxide axis system [19]. Figure 6 represents the schematic illustration of the bilayer distance in relation to the angle. The simulated S_0 value of 0.25 can be the angle of 45°. The value of 0.74 is the angle of 25°. The angle suggests that the SC lipids align nearly perpendicularly to the bilayer surface. The larger S_0 value yields larger distance between the lipid bilayer. The analysis implies that the longer distance of the lipid bilayer can be related to the oriented SC structure.

The S_0 value changes from 0.28 to 0.60, while the S value is in the range of 0.63–0.64 in Fig. 4. The S_0 value of 0.60 is the angle of 31°. The higher S_0 value implies that the lower SC lipids have better-ordered structure than those of the upper SC lipids. Similarly, the S_0 value was 0.34, while the S value was 0.54. The simulated S_0 value of 0.34 can be the angle of 42° in Fig. 5.

Figure 7 shows EPR spectra of CHL from the mid-volar forearm of a male subject. A relatively broad 3 line pattern was obtained. The spectral pattern was very similar to that of the first strip, except for the intensity. The intensity of the second stripped sample was weak under the same experimental procedure for the probes. The weaker intensity than that of 5-DSA and the broad 3 line signal suggest that CHL probe may not be easy to incorporate with the SC lipid. Moreover, the weak intensity implies that the broadening may not be due to the spin–spin interaction.

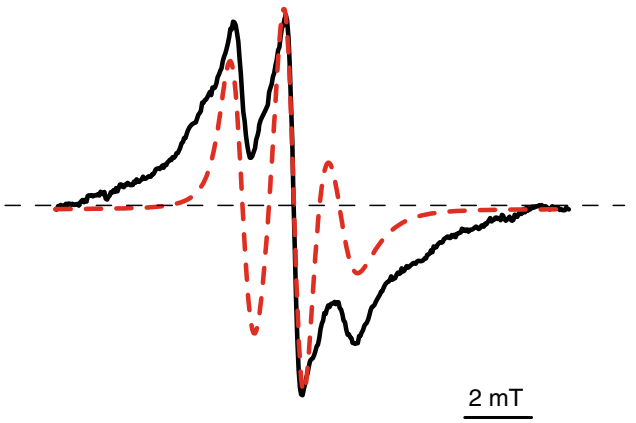

Fig. 7 The in vitro experimental (*solid line*) and simulated (*dotted line*) EPR spectra of CHL probe from human mid-volar forearm (M, 79)

The dotted line is the slow-tumbling simulation of the CHL spectrum in Fig. 7. There is a clear difference between the observed and the simulated spectrum. The discrepancy suggests that CHL moieties might be quite different orientations as well as motions in the SC. The EPR and the simulation results imply that CHL probe is difficult to incorporate into the SC lipids and the probe may locate into different parts in the SC.

EPR spectroscopy along with a modern computational analysis provides quantitative insight into the SC structure as a function of the depth. The EPR spectral pattern contains information regarding the probe mobility as well as the lipid structure. Satisfactory agreement between the experimental and calculated spectra can provide a quantitative S_0, which reveals the microscopic lipid chain ordering in the SC. In addition, the EPR method recognizes sebaceous exudates [2]. Thus, EPR together with computational analysis could in turn provide more comprehensive information, which would result in the understanding of various SC.

High Dietary Fat Exacerbates Weight Gain and Obesity in Female Liver Fatty Acid Binding Protein Gene-Ablated Mice

Received: 21 August 2009 / Accepted: 24 November 2009 / Published online: 25 December 2009

Abstract Since liver fatty acid binding protein (L-FABP) facilitates uptake/oxidation of long-chain fatty acids in cultured transfected cells and primary hepatocytes, loss of L-FABP was expected to exacerbate weight gain and/or obesity in response to high dietary fat. Male and female wild-type (WT) and L-FABP gene-ablated mice, pair-fed a defined isocaloric control or high fat diet for 12 weeks, consumed equal amounts of food by weight and kcal. Male WT mice gained weight faster than their female WT counterparts regardless of diet. L-FABP gene ablation enhanced weight gain more in female than male mice—an effect exacerbated by high fat diet. Dual emission X-ray absorptiometry revealed high-fat fed male and female WT mice gained mostly fat tissue mass (FTM). L-FABP gene ablation increased FTM in female, but not male, mice—an effect also exacerbated by high fat diet. Concomitantly, L-FABP gene ablation decreased serum β-hydroxybutyrate in male and female mice fed the control diet and, even more so, on the high-fat diet. Thus, L-FABP gene ablation decreased fat oxidation and sensitized all mice to weight gain as whole body FTM and LTM—with the most gain observed in FTM of control vs high-fat fed female L-FABP null mice. Taken together, these results indicate loss of L-FABP exacerbates weight gain and/or obesity in response to high dietary fat.

Abbreviations

L-FABP	Liver fatty acid binding protein
FTM	Fat tissue mass
LTM	Lean tissue mass
WT	Wild-type
DEXA	Dual emission X-ray absorptiometry
LCFA	Long chain fatty acids
rtPCR	Real-time PCR
ACO-1	Palmitoyl CoA oxidase-1
ACO-2	Branched chain CoA oxidase-2
ACO-3	Pristanoyl CoA oxidase-3
PBE	L-peroxisomal bifunctional enzyme
CpT1-l	Carnitine palmitoyl CoA acyltransferase-1
MCAD	Mitochondrial medium chain acyl CoA dehydrogenase
HMG-CoA Syn	HMG-CoA synthase
CYP4A3	Cytochrome p450, family 4, subfamily A, polypeptide 3

Introduction

Liver fatty acid binding protein (L-FABP) is a small 14-kDa soluble protein highly expressed in tissues active in long chain fatty acid (LCFA) uptake, oxidation and metabolism—especially liver, intestine, and kidney (0.1–0.4 mM; rev. in [1]). L-FABP is unique among the fatty acid binding protein family in that it has two known (rather than one) ligand binding sites, a broad

range/promiscuity for a variety of ligands, and high affinity for long chain fatty acids (LCFAs) or their CoA thioesters (LCFA-CoAs) [1–6]. Demonstration of LCFA and LCFA-CoA binding to L-FABP provided the first insight that this protein may be involved in LCFA uptake and intracellular targeting to metabolic organelles for oxidation and esterification. This expectation has since been borne out by multiple studies performed in vitro, in cultured cells, and mice as follows:

Purified L-FABP extracts LCFA/LCFA-CoA from membranes and protects LCFA-CoAs from hydrolysis [7–11]. Also in vitro, L-FABP removes palmitoyl CoA induced substrate inhibition of carnitine palmitoyltransferase-1, the rate limiting step in mitochondrial LCFA oxidation [12, 13], and serves as a LCFA donor protein for peroxisomal and LCFA-CoA donor protein for mitochondrial LCFA oxidation [14, 15]. Finally, L-FABP facilitates presentation of bound LCFA-CoA for esterification to phosphatidic acid and cholesteryl ester by purified liver microsomes [7–11]. Thus it was expected that L-FABP should alter LCFA oxidation and esterification in living cells and in animals.

In L-FABP overexpressing transformed cells, L-FABP enhanced LCFA uptake [1, 16–19], intracellular transport/diffusion [1, 17], oxidation (especially with branched-chain fatty acids selectively oxidized in peroxisomes [20], and esterification [16, 18, 21]. Initial physiologic studies suggested that L-FABP may function in LCFA metabolism. For example, L-FABP concentration in rat tissues was directly related to the oxidative capacity (liver or other L-FABP expressing tissues) [22, 23]. Further, peroxisomal proliferators induced expression of L-FABP and peroxisomal β-oxidation in primary rat hepatocyte cultures [24, 25]. More recently, the relevance of L-FABP to LCFA/LCFA-CoA oxidation and esterification was more firmly established by studies with genetically engineered mice, in which L-FABP gene ablation inhibited hepatic LCFA uptake and LCFA oxidation in vivo, and reduced hepatic cytosol binding capacity for LCFA and LCFA-CoA [26–29]. Cultured primary mouse hepatocytes from L-FABP knockout (KO) and wild-type (WT) mice also confirmed that loss of L-FABP reduced LCFA uptake, intracellular transport/diffusion, and oxidation [30].

Thus in-vitro, cultured-cell, and animal studies have indicated that L-FABP is involved in hepatic uptake of LCFAs derived from diet or adipose tissue. In the liver, L-FABP may target bound LCFA and/or LCFA-CoA to intracellular organelles for oxidation (mitochondria, peroxisomes) or esterification [endoplasmic reticulum (ER)] for storage (lipid droplets) or secretion (VLDL). Since the net effect of L-FABP would elicit rapid hepatic uptake and removal of LCFAs—primarily by oxidation since hepatic storage of esterified LCFAs is limited—it was hypothesized that L-FABP gene ablation would enhance high fat diet induced weight gain and obesity. This hypothesis was tested in male and female and L-FABP KO and WT mice pair-fed a defined isocaloric high fat versus control diet. Absence of L-FABP exacerbated weight gain and obesity induced by high dietary fat.

Materials and Methods

Materials

RNeasy mini kits were from Qiagen (Valencia, CA). Probes and primers used in the real-time PCR experiments on mouse liver RNA were purchased from Applied Biosystems (Foster City, CA). Protein was quantified by Protein Assay Dye Reagent (Bio-Rad Laboratories, Hercules, CA).

Animals

L-FABP gene-ablated mice were generated using a construct strategy that deleted all four exons of the L-FABP gene as described earlier [26]. Since the L-FABP KO mice were backcrossed to normal C57BL/6NCr mice (Charles River Wilmington, MA obtained through the National Cancer Institute, Frederick Cancer Research and Development Center, Frederick, MD) to the N6 generation (98.4% genetic homogeneity), C57BL/6NCr mice of matching sex/age were used as control animals for the feeding studies. Mice were housed in ventilated microisolator cages, temperature was maintained at 25 °C, and lighting was a constant 12-h light/dark cycle. For the first 7 weeks of life mice were given water and fed standard chow (4.4% gm% fat, Harlan Teklad Rodent Diet 8604, Madison, WI) ad libitum. The Animal Care and Use Committee of Texas A&M University approved all animal protocols.

Composition of Experimental Diets

Defined high fat and control pelleted diets were obtained commercially (Research Diets, Inc., New Brunswick, NJ). The defined control diet (# D12450B, Research Diets, Inc., New Brunswick, NJ) was comprised of 20, 70, and 10 kcal% protein, carbohydrate and fat, respectively, with caloric value of 4,057 kcal/1,055 g or 3.85 kcal/g diet (Table 1). The control diet contained 10 kcal% (4.3 gm%) as fat comprised of soybean oil and lard in nearly equal weight proportions. The isocaloric high-fat diet (# D12451, Research Diets, New Brunswick, NJ) was comprised of 20, 35, and 45 kcal% protein, carbohydrate and fat, respectively, with caloric value of 4,057 kcal/858 g or 4.73 kcal/g

Table 1 Ingredient and fatty acid group percent composition in control and high fat diets

Group	Control diet	High fat diet
Ingredient gm% (kcal%)		
Protein	19.2 (20)	24 (20)
Carbohydrate	67.3 (70)	41 (35)
Fat	4.3 (10)	24 (45)
Fatty acid (%)		
Saturated	25.1	36.3
Monounsaturated	34.7	45.3
Polyunsaturated	40.2	18.5

(Table 1). Fat was increased to 45 kcal% (24 gm%) by increasing the amount of lard (but not soybean oil) and decreasing the amount of carbohydrate. Both control and high-fat diets had very low cholesterol, 0.002 and 0.02%, respectively, by weight. Fatty acids in the control diet were 25.1, 34.7, and 40.2% saturated, monounsaturated, and polyunsaturated fatty acids, respectively (Table 1), while fatty acid composition in the high-fat diet was comprised of 36.3, 45.3, and 18.5% saturated, monounsaturated, and polyunsaturated fatty acids, respectively (Table 1). Thus, the high-fat diet had more saturated and monounsaturated concomitant with less polyunsaturated fatty acids.

Dietary Study

One week before beginning the dietary studies, male and female mice (7 weeks old, 20–30 g) were switched to a pelleted defined control diet (10 kcal% fat; # D12450B, Research Diets, Inc., New Brunswick, NJ) described above (Table 1), a diet free of significant amounts of phytoestrogens or cholesterol [31] that could complicate any high-fat effect and sex-based comparisons [32]. Each mouse was housed individually in Tecniplast Sealsafe IVC cages equipped with external water bottles and lid holders with wire bars for holding food pellets. After 1 week of acclimation on the control diet, pair-feeding of the high-fat diet for 12 weeks was accomplished as follows: male and female WT and L-FABP KO mice were divided into four groups of 14 mice each: male L-FABP KO, male L-FABP WT, female L-FABP KO, and female L-FABP WT mice. On day one of the feeding study, the amount of control diet consumed as determined by weight and calorie content was measured in one half of the mice in each group. On day two, the other half of each group were pair-fed (1 day offset) the defined high-fat diet based on the amount of control diet consumed by the first half. Each day in the 12-week study body weights of mice from each group were recorded and the amount of high fat and control diet consumed was measured to ensure that each paired group was given food that by weight and calorie was similar to within a non-significant margin of the control group from the previous day. Briefly, at mid-morning daily, each mouse was weighed, and food intake was measured by weighing remaining pellets in the food holder plus any gathered from bedding. The latter were easily recovered since the food was color-coded (yellow for control food, red for high-fat food). At the end of 12 weeks, mice were fasted overnight 12 h, to assure that liver was not influenced by recent digestion and to give more uniform liver weights. Mice were then anesthetized by intraperitoneal (IP) injection of a mixture of ketamine and xylazine (0.01 mL/g body weight; 10 mg ketamine/mL and 1 mg xylazine/mL in 0.9% saline solution), weighed, and examined for whole body phenotype (see below). The anesthetized mice were then euthanized by cervical dislocation, serum collected, and livers harvested, weighed, snap-frozen on dry ice, and stored at −80 °C for mRNA analyses as described [33].

Whole-Body Phenotype

The whole body phenotype was analyzed at the beginning and end of the study by dual-energy X-ray absorptiometry (DEXA) utilizing a Lunar PIXImus densitometer (Lunar Corp., Madison, WI). DEXA determined the relative proportion of fat tissue mass (FTM) and bone-free lean tissue mass (LTM) as described earlier [34]. Prior to PIXImus analysis each mouse was anesthetized as described in the previous section. To facilitate recovery after the procedure, mice were injected with yohimbine (0.11 μg/g body weight), as well as with warm saline solution for rehydration. Mice were kept warm during recovery with heat pads to minimize heat loss, and checked every 10 min until recovery was complete. Whole body composition was determined by exposing the mouse (except the head region) to sequential beams of low- and high-energy X-rays with image acquisition of the X-rays impacting a luminescent panel. Bone mass was separated from soft tissue mass by measurement of the ratios of signal attenuation at the different energy levels. Soft tissue mass was further resolved into lean tissue mass (LTM) and fat tissue mass (FTM) for accurate measurement of whole body composition. Calibration was performed using a phantom mouse with known bone mineral density and FTM as described in Refs. [33, 34]. Data were expressed as gain in FTM and LTM at the end of the dietary study compared to the beginning as described earlier [34].

Serum β-Hydroxybutyrate Measurement

Serum levels of the ketone body β-hydroxybutyrate, a product of acetyl CoA produced from fatty oxidation, can be used to measure fatty acid oxidation in the liver [26, 28,

29, 34]. Serum levels of β-hydroxybutyrate (3-HB) were measured with high sensitivity and specificity according to the manufacturer's directions (Autokit 3HB, Wako Diagnostics, Richmond, VA) by measuring the rate of Thio-NADH (β-thionicotinamide adenine dinucleotide) production spectrophotometrically at 405 nm upon oxidation of 3-HB.

Liver Lipid Content

Liver lipids were extracted, resolved into individual lipid classes, and quantitated as described earlier [34].

Real-Time PCR of Mouse Liver RNA

Real-time PCR (rtPCR) was performed on total RNA from liver isolated and purified with RNeasy mini kits (Qiagen, Valencia, CA) according to the manufacturer's instructions. Total concentration of RNA extracts was determined spectrophotometrically followed by confirmation of RNA integrity by agarose electrophoresis and ethidium bromide staining. Expression patterns were analyzed by quantitative real-time PCR using an ABI PRISM 7000 Sequence Detection System (Applied Biosystems, Foster City, CA), TaqMan® One Step PCR Master Mix Reagent kit, as well as gene specific TaqMan® PCR probes and primers. Thermal cycler protocol was as follows: 48 °C for 30 min, 95 °C for 10 min before the first cycle, 95 °C for 15 s, and 60 °C for 1 min, repeated 40 times. TaqMan® One Step chemistry was used for total RNA reverse-transcription in the first step of the thermal cycler protocol (48 °C for 30 min) prior to amplification. Specific probes and primers were Assay-on-Demand® products for mouse: (i) Peroxisomal fatty acid oxidative enzymes: palmitoyl CoA oxidase-1 (ACO-1, Mm00443579_m1), branched chain CoA oxidase-2 (ACO-2, Mm00446408_m1), pristanoyl CoA oxidase-3 (ACO-3, Mm00446122_m1), and L-peroxisomal bifunctional enzyme (PBE, Mm00470091_m1); (ii) Mitochondrial fatty acid oxidative enzymes: carnitine palmitoyl CoA acyltransferase 1 (CpT1, Mm00550438_m1) and mitochondrial medium chain acyl CoA dehydrogenase (MCAD; Mm00431617_m1); and (iii) ER lipid metabolic enzymes including cytochrome p450, family 4, subfamily A, polypeptide 3 (CYP4A3, Mm00484132_m1). Probes and primers were from Applied Biosystems (Foster City, CA). Experiments were performed in triplicate and analyzed with ABI Prism 7000 SDS software (Applied Biosystems) to determine the threshold cycle (C_T) from each well. Primer concentrations and cycle number were optimized to ensure that reactions were analyzed in the linear phase of amplification. The mRNA expression levels of ACO-1, ACO-2, ACO-3, PBE, CPT-1, MCAD, and CYP4A3 determined in all groups were normalized to the housekeeping gene coding for 18S RNA. All mRNA data were expressed relative to the control male wild type mouse group on control diet). Relative expression levels were determined by the comparative $2^{-\Delta\Delta C_T}$ method [35] where $\Delta\Delta C_T = [C_T \text{ of target gene} - C_T \text{ of 18 s}]_{\text{different mice groups}} - [C_T \text{ of target gene} - C_T \text{ of 18 s}]_{\text{control mouse group}}$ as described in User Bulletin 2, ABI Prism 7000 Sequence Detection System (Applied Biosystems, Foster City, CA).

Statistical Analysis

Data analysis was performed on eight dietary groups consisting of seven mice/group: male control-fed WT, female control-fed WT, male control-fed L-FABP KO, female control-fed L-FABP KO, male high fat control WT, female high fat control WT, male high fat L-FABP KO, and female high fat L-FABP KO mice. All data were analyzed by analysis of variance (ANOVA) combined with the Newman-Keuls multiple comparisons test (GraphPad Prism, San Diego, CA). Values represent the mean ± SEM, with $p < 0.05$ considered statistically significant.

Results

Effect of High-Fat Diet and L-FABP Gene Ablation on Food Consumption

To ensure that any alterations in weight gain were not due to potential differences in food preference, mice were pair-fed as described in "Materials and Methods". Under pair-feeding conditions, one half of the mice in each group were provided access to the same amount of the high-fat diet as consumed each previous day by the other half of the mice on the control diet. The overall result was that total food consumption was similar whether the mice were fed the high-fat or the control diet.

Since the caloric densities of the control and high fat diet were similar, each paired group was given food that by weight and calorie content was similar to within a non-significant margin of the control group from the previous day. Total food consumption of each mouse was measured daily and summed over the 12-week dietary to show that total gram mass and kcal of control or high-fat diets consumed by WT males did not differ from that of WT females (data not shown). Likewise, L-FABP gene ablation did not significantly affect total gram mass or total kcal of control or high-fat diet consumed by either male or females. Thus, all groups consumed the same amount of food and any differences in weight gain or obesity were not due to differences in food consumption.

Effect of High-Fat Diet and Sex on Weight Gain and Body Weight in Wild-Type Mice

While control-fed WT male (Fig. 1a, solid circles) and female (Fig. 1c, solid circles) mice gained weight with increasing time on the control defined diet, weights were higher for males (0.093 ± 0.008 g/day) than females (0.067 ± 0.007 g/day). The final body weight of WT males (Fig. 2a) was 1.3-fold significantly higher than that of females (Fig. 2b), but males started with higher initial body weights such that there was only a slight difference in weight gain when expressed as a percent gain (Fig. 2c).

On the high-fat diet, both WT males (Fig. 1b, solid circles) and females (Fig. 1d, solid circles) also gained weight with increasing time, with males gaining markedly more weight than on control food. WT males on the high-fat diet gained weight at nearly twofold faster rate (0.18 ± 0.01 g/day) than on the control diet (0.09 ± 0.01 g/day). In contrast, WT females on the high-fat diet gained weight at a similar rate (0.063 ± 0.004 g/day) to control diet (0.067 ± 0.007 g/day). Consequently, at the end of the 12-week study, WT males weighed much more, regardless of whether expressed as total body weight (Fig. 2a) or as % change in weight (Fig. 2c), than their WT female counterparts (Fig. 2b, d). However, these changes were not due to differences in food consumption (data not shown). Thus, WT males gained weight faster, regardless of control or high-fat diet, and were more sensitive to weight gain induced by high-fat diet than their WT female counterparts.

Effect of High-Fat Diet and Sex on Weight Gain and Body Weight in L-FABP Knockout Mice

L-FABP gene ablation did not significantly affect the rate of weight gain in males (Fig. 1a, solid triangles) fed the control diet. While L-FABP gene ablation trended to slightly decrease the rate of weight gain in females (Fig. 1c, solid triangles) on the control diet, this effect did not achieve statistical significance. The lack of effect of L-FABP gene ablation on rate of weight gain on control diet was reflected in only slight or no differences in final body weight (Fig. 2a, b) and % change in body weight (Fig. 2c, d) in male or female L-FABP KO mice as compared to their WT counterparts. In contrast, L-FABP gene ablation significantly increased weight gain in response to the high fat diet, most prominently in females (Fig. 1d, solid triangles) where significant differences were observed in weeks 9–12 between the high-fat fed female KO versus WT mice. However, while weight gain in L-FABP KO males trended higher than for WT males, the rate did not achieve statistical significance at $p < 0.05$ (Fig. 1b). In contrast, L-FABP KO females gained weight nearly 1.8-fold faster than WT females on the same high fat, 12-week diet (Fig. 1d). As a result, at the end of the 12-week high-fat diet, L-FABP KO females weighed significantly

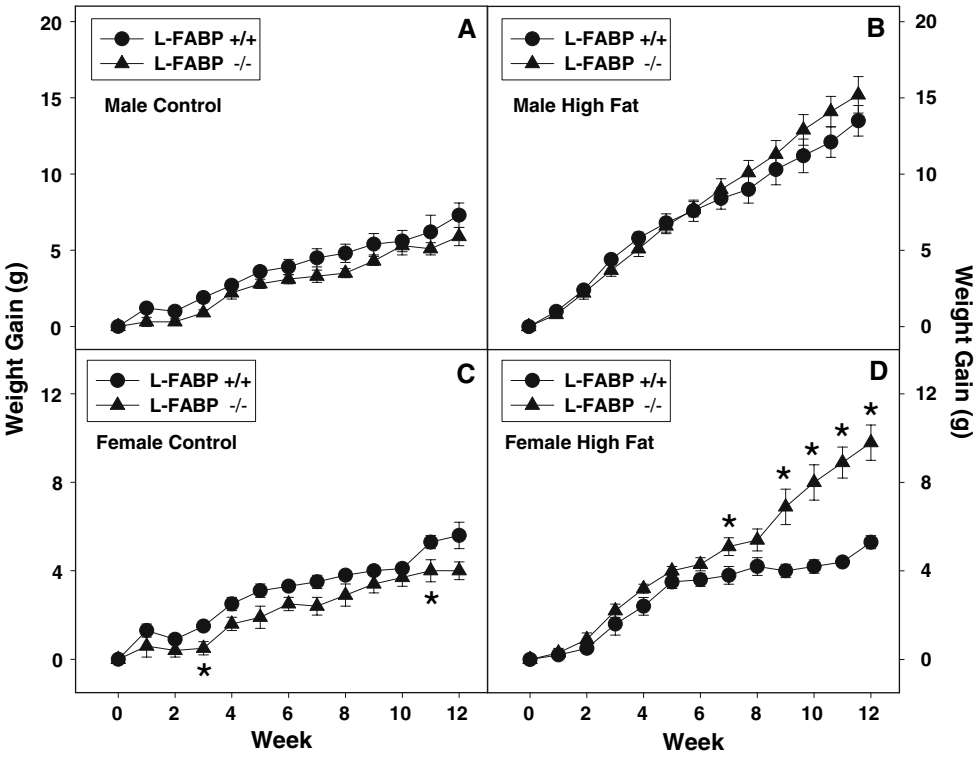

Fig. 1 Weekly weight gain in response to high-fat diet and L-FABP gene ablation. Weight gain of male (**a**, **b**) and female (**c**, **d**) WT and L-FABP KO mice fed a defined control-diet (**a**, **c**) or high-fat diet (**b**, **d**) was measured daily and summed weekly as described in "Materials and Methods". Solid circles refer to WT mice while solid triangles refer to L-FABP KO mice. Values represent the mean ± sem, $n = 5$–7. Statistical analysis was as follows: * $p \leq 0.05$ versus WT mice on high fat diet

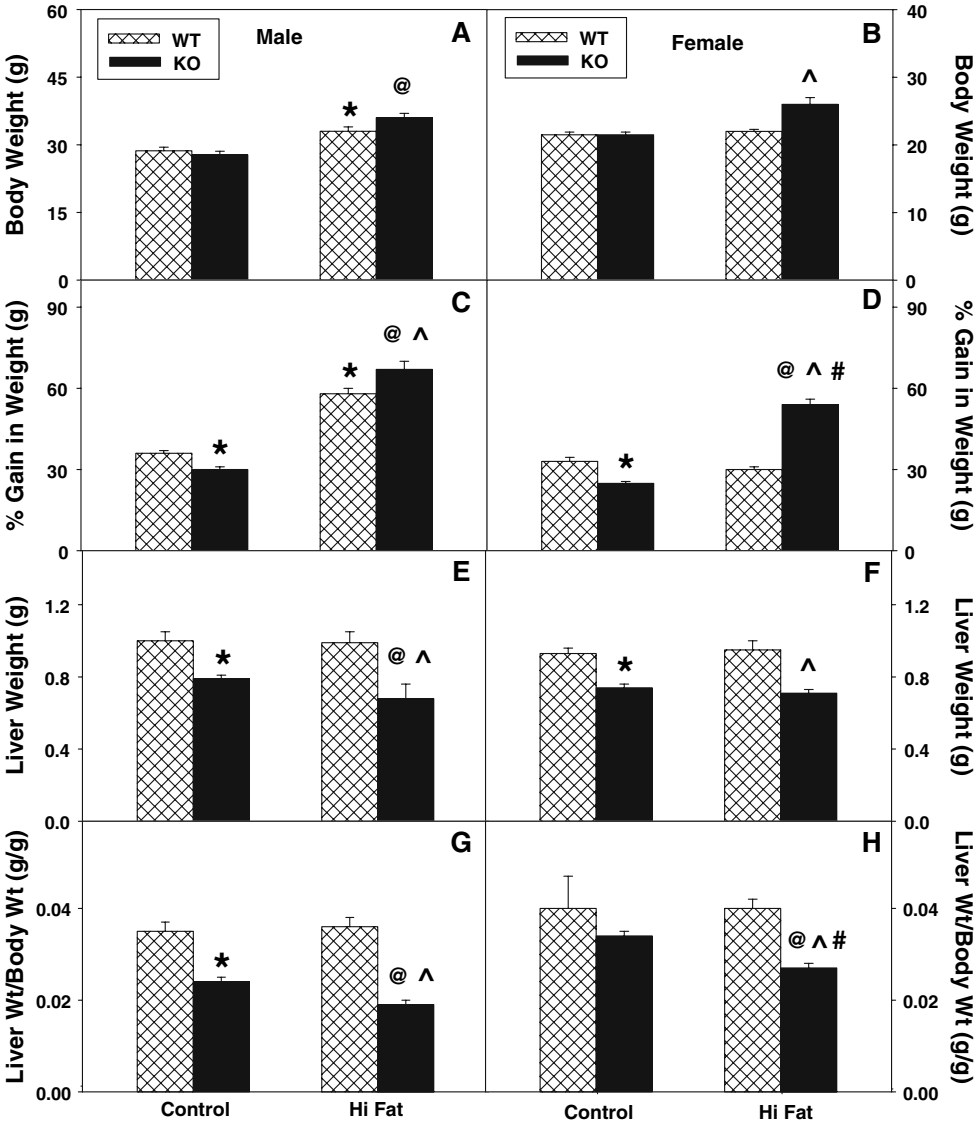

Fig. 2 Effect of L-FABP gene ablation and high-fat diet on final body weight and liver weight. Final body weight (**a**, **b**) and % gain in body weight (**c**, **d**) were determined for male (**a**, **c**) and female (**b**, **d**) WT (*hatched bar*) and L-FABP KO (*solid bar*) mice fed defined control-diet or high-fat diet for 12 weeks as described in "Materials and Methods". After killing, liver weights (**e**, **f**) and liver weight/body weight (**g**, **h**) were determined for male (**e**, **g**) and female (**f**, **h**) WT and L-FABP KO mice as in "Materials and Methods". Values represent the mean ± sem, $n = 5$–7. Statistical analysis was as follows: * $p \leq 0.05$ versus WT mice on control-diet; @ $p \leq 0.001$ versus L-FABP KO mice on control-diet; ^ $p \leq 0.001$ versus WT mice on high-fat diet; and # $p \leq 0.003$ versus male L-FABP KO on high-fat diet

more than their WT female counterparts, expressed as total body weight (Fig. 2b) and as % change in weight (Fig. 2d). However, as previously noted, because the dietary study was pair-fed, weight gain differences were not due to differences in food consumption.

Taken together, these data indicate that L-FABP gene ablation increases sensitivity, particularly of female mice, to high-fat diet induced weight gain.

Effect of High-Fat Diet and Sex on Liver Weight

While high-fat diet did not affect liver weights (Fig. 2e, f) or the ratio of liver weight/body weight (Fig. 2g, h) in either male or female WT mice, L-FABP gene ablation significantly altered these parameters. In control-fed mice, L-FABP gene ablation decreased the liver weight in both males and females (Fig. 2e, f), and the ratio of liver weight/body weight was also decreased in males (Fig. 2g) as compared to their WT counterparts. The high-fat diet further decreased liver weight (Fig. 2e, f) slightly and decreased the ratio of liver weight/body weight (Fig. 2g, h) in both L-FABP KO males and females as compared to their respective control-fed groups. Thus, L-FABP gene ablation decreased absolute liver mass (g) in both males and females on the control diet. The high-fat diet exacerbated these decreases in both L-FABP KO males and females.

Although high fat diet and/or L-FABP gene ablation elicited small changes in content of several individual lipid classes, there was little effect on the total level of liver lipids indicative of steatosis, primarily the neutral lipids (triglyceride + cholesterol ester). Neither isocaloric pair feeding of high fat diet nor L-FABP gene ablation significantly elevated the total level of neutral lipids indicative of steatosis in male mice (Table 2). Neutral lipid content of

Table 2 Effect of high fat diet and L-FABP gene ablation on liver lipid content

Sex	Gene type	Diet	Lipid mass (nmol/mg protein)					
			PL	C	FFA	TG	CE	Neutral lipids
Male	WT	Control	433 ± 23	32 ± 3	45 ± 4	454 ± 45	30 ± 4	484 ± 45
Male	KO	Control	392 ± 30	25 ± 4	30 ± 5	353 ± 33	28 ± 4	381 ± 33
Male	WT	High fat	417 ± 22	36 ± 4	23 ± 2	429 ± 28	46 ± 5	476 ± 29
Male	KO	High fat	446 ± 43	37 ± 3	25 ± 2	469 ± 37	46 ± 6	515 ± 38
Female	WT	Control	486 ± 45	30 ± 3	35 ± 5	907 ± 144	104 ± 14	1,012 ± 145
Female	KO	Control	546 ± 63	43 ± 5	31 ± 4	720 ± 62	135 ± 25	856 ± 67
Female	WT	High fat	467 ± 33	37 ± 3	19 ± 2	885 ± 53	101 ± 8	987 ± 54
Female	KO	High fat	459 ± 22	43 ± 3	24 ± 2	1,069 ± 112	143 ± 14	1,212 ± 113

Lipids were extracted and composition determined as described in "Materials and Methods". Values represent the mean ± SE (n = 5–8)
PL phospholipid, *C* cholesterol, *FFA* unesterified (free) fatty acid, *TG* triacylglyceride, *CE* cholesterol ester, *Neutral Lipids* TG + CE

livers from female mice, regardless of diet or genotype, was generally about twofold higher in female than male mice (Table 2). However, neither isocaloric pair feeding of high fat diet nor L-FABP gene ablation significantly elevated these lipids in female mice (Table 2). Thus, pair-feeding of isocaloric high fat diet did not induce hepatic steatosis in either male or female mice. Likewise, L-FABP gene ablation did not induce hepatic steatosis—regardless of the diet.

Effect of High-Fat Diet and Sex on Fat and Lean Tissue Mass in Wild-Type Mice

To determine if the above changes in body weight were due to altered fat tissue mass (FTM), lean tissue mass (LTM), or both, dual emission X-ray absorptiometry (DEXA) was performed on each mouse at the beginning and end of the dietary study as described in "Materials and Methods". Quantitative analysis and comparison of multiple DEXA images taken at the end versus the beginning of the dietary study showed that control-fed male WT mice (Fig. 3a) exhibited a greater proportion of weight gain as FTM than their female counterparts (Fig. 3b). Furthermore, high-fat fed WT males and females had 3.6- and 3.7-fold higher fat gain, respectively (Fig. 3a), as compared to control diet animals. In addition, the control-fed wild-type males gained much more LTM than their female counterparts (Fig. 3d).

In summary, these data indicated that both WT male and female mice were more susceptible to fat weight gain on a high-fat diet than control diet.

Effect of L-FABP Gene Ablation on Fat and Lean Tissue Mass in Response to A High-Fat Diet

DEXA analysis revealed that the gain in FTM in L-FABP KO male and female mice exhibited a similar qualitative pattern as their WT counterparts on the control diet (Fig. 3), but L-FABP gene ablation increased FTM in control and high-fat fed female mice with a trend towards increase observed for the male KO mice (Fig. 3a). LTM was also increased in the control and high-fat female (Fig. 3d) but not male (Fig 3c) KO mice.

Thus with a control diet, L-FABP gene ablation increased both fat and lean tissue mass in both males and females as compared to WT mice on the same diet. In response to high-fat diet, both L-FABP KO males and females gained more weight as fat, as well as lean tissue mass than their WT counterparts, with more gain observed in females (Fig. 3b) than males (Fig. 3a). The absolute gain observed in FTM was highest for high-fat fed WT and L-FABP KO males (Fig. 3a). In contrast, the largest fold increase in FTM was measured in high-fat fed L-FABP null females (4.5-fold) when compared to fold increases observed with male counterparts (3.4–3.7-fold). In LTM, the high-fat fed L-FABP KO males and females gained similar amounts as compared to control-fed L-FABP KO counterparts.

Effect of High Fat Diet and L-FABP Gene Ablation on Fatty Acid Oxidation: Serum β-Hydroxybutyrate Level

In control-fed WT females, serum β-hydroxybutyrate levels were about 50% higher than males (Fig. 4a), indicating higher hepatic fatty acid oxidation. The high-fat diet increased serum β-hydroxybutyrate levels in male mice to levels indistinguishable from control-fed WT female mice, but similar results were not observed with high-fat fed WT females (Fig. 4b). In control-fed mice, L-FABP gene ablation resulted in decreased serum β-hydroxybutyrate levels in both males and females (Fig. 4), and the high-fat diet produced further decreases, most markedly in females.

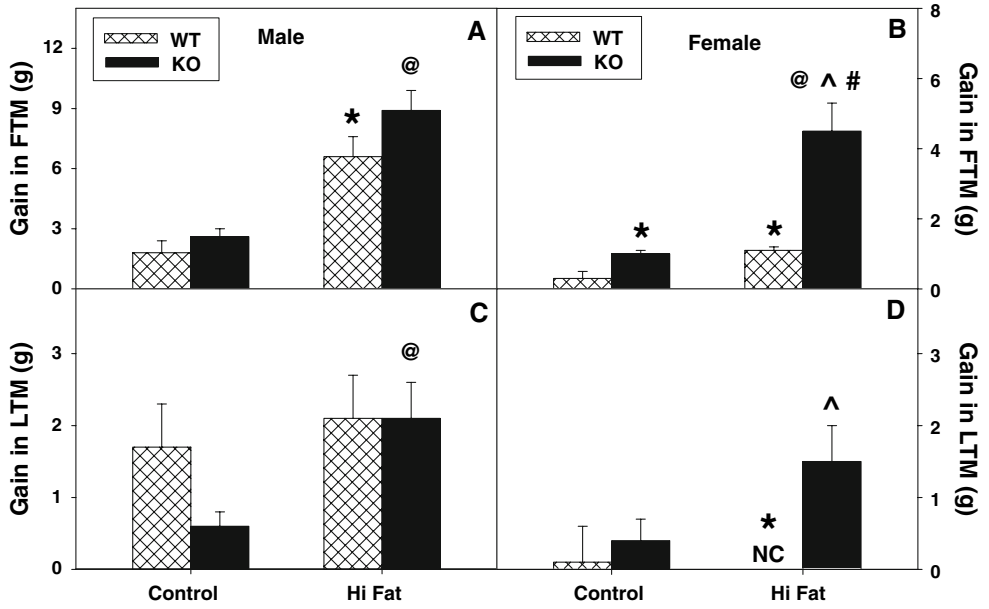

Fig. 3 Effect of L-FABP gene ablation and high-fat diet on whole body phenotype: Gain and percent gain in fat tissue mass (FTM) and lean tissue mass (LTM). At the beginning and end of the 12-week dietary study, FTM and LTM was determined by dual emission X-ray absorptiometry (DEXA) in male and female WT (*hatched bar*) and L-FABP KO (*solid bar*) mice fed control- and high-fat diets as described in "Materials and Methods". Changes in initial and final FTM (**a**, **b**) and LTM (**c**, **d**) for male (**a**, **c**) and female (**b**, **d**) WT and L-FABP KO mice were reported as gain in respective tissue mass. Values represent the mean ± sem, $n = 5$–7. Statistical analysis was as follows: * $p \leq 0.02$ versus WT mice on control-diet; @ $p \leq 0.02$ versus L-FABP KO mice on control-diet; ^ $p \leq 0.006$ versus WT mice on high-fat diet; and # $p \leq 0.001$ versus male L-FABP KO mice on high-fat diet

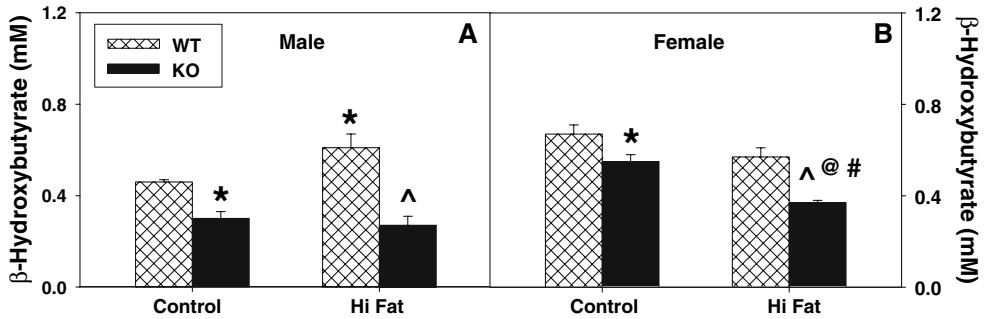

Fig. 4 Effect of L-FABP gene ablation and high-fat diet on serum β-hydroxybutyrate levels. At the end of the dietary study, serum was collected and levels of β-hydroxybutyrate were determined for male (**a**) and female (**b**) WT and L-FABP KO mice as described in "Materials and Methods". *Cross-hatched* and *solid bars* refer to WT and KO mice, respectively. Values represent the mean ± sem, $n = 5$–7. Statistical analysis was as follows: * $p \leq 0.03$ versus WT mice on control-diet; @ $p \leq 0.002$ versus L-FABP KO mice on control-diet; ^ $p \leq 0.007$ versus WT mice on high-fat diet; and # $p \leq 0.05$ versus male L-FABP KO mice on high-fat diet

Taken together, these data indicated that L-FABP gene ablation decreased fatty acid oxidation—an effect magnified by a high-fat diet.

Effect of High-Fat Diet and L-FABP Gene Ablation on Hepatic Levels of Peroxisomal Enzymes Involved in Fatty Acid Oxidation

Since decreased serum levels of β-hydroxybutyrate indicated that L-FABP gene ablation reduced fatty acid oxidation, especially in response to high-fat diet, mRNA levels of four key enzymes involved in peroxisomal fatty acid oxidation were examined: acyl CoA oxidase-1 (ACO-1, the key enzyme in peroxisomal β-oxidation of straight-chain fatty acids); acyl CoA oxidase-2 (ACO-2, involved in branched-chain fatty acid oxidation); acyl CoA oxidase-3 (ACO-3, involved in oxidation of pristanoyl-CoA—a branched-chain acyl CoA), and peroxisomal bifunctional enzyme (PBE). In control-fed wild-type mice, peroxisomal levels of ACO-1 (Fig. 5a, b), ACO-3 (Fig. 5c, d) and PBE (Fig. 5g, h) were significantly lower (about twofold each) in females versus males. The high-fat diet did not increase

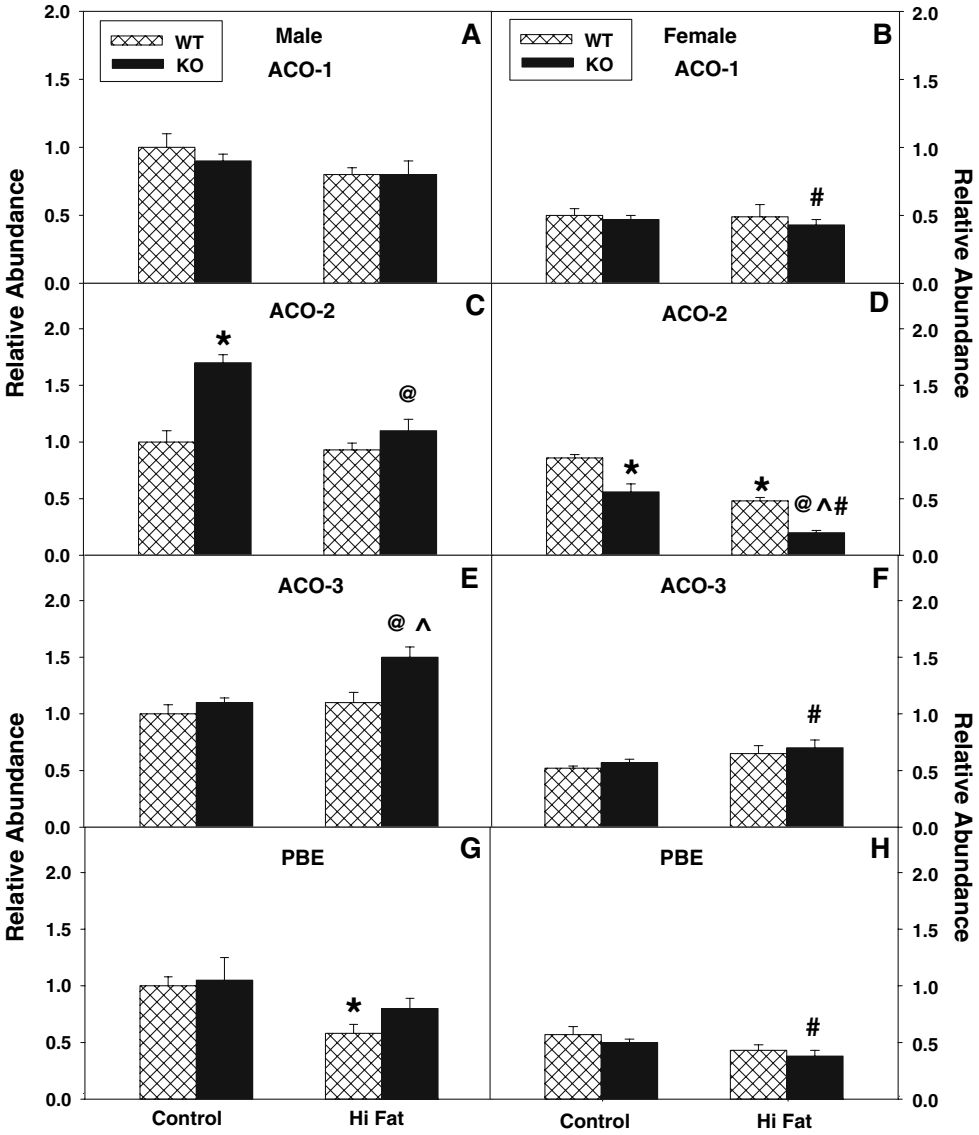

Fig. 5 Effect of L-FABP gene ablation and high-fat diet on key enzymes in hepatic peroxisomal fatty acid oxidation. At the end of the 12-week dietary study, livers were harvested and expression of the key peroxisomal enzymes involved in peroxisomal fatty acid oxidation was measured by real time PCR as described in "Materials and Methods". Acyl CoA oxidase-1 (ACO-1, **a**, **b**); acyl CoA oxidase-2 (ACO-2, **c**, **d**); acyl CoA oxidase-3 (ACO-3, **e**, **f**); and bifunctional enzyme (PBE, **g**, **h**) were determined for male (**a**, **c**, **e**, **g**) and female (**b**, **d**, **f**, **h**) mice as described in "Materials and Methods". *Cross-hatched* and *solid bars* refer to WT and KO mice, respectively. Values represent the mean ± sem, $n = 5$–7. Statistical analysis was as follows: * $p \leq 0.02$ versus WT mice on control-diet; @ $p \leq 0.002$ versus L-FABP KO mice on control-diet; ^ $p \leq 0.03$ versus WT mice on high-fat diet; and # $p \leq 0.01$ versus male L-FABP KO mice on high-fat diet

the levels of these proteins in either sex as compared to their control-fed, sex-matched counterparts.

L-FABP gene ablation did not significantly alter levels of ACO1 in control-fed or high-fat fed mice (Fig. 5a, b). In contrast, L-FABP gene ablation increased the level of ACO-2 in control-fed male mice (Fig. 5c), but decreased the level of ACO-2 in control-fed and high-fat fed females (Fig. 5d) when compared to the correspondingly fed WT mice. ACO-3 level was increased by L-FABP gene ablation in high-fat fed L-FABP KO male mice (Fig. 5e). Levels of PBE were not significantly altered by L-FABP gene ablation in either male (Fig. 5g) or female (Fig. 5h) mice fed control (or high-fat) diet as compared to similar diet fed wild-type mice.

Taken together, these data indicated that, regardless of diet, the male WT and L-FABP KO mice exhibited a greater abundance of several key peroxisomal enzymes (ACO-1, ACO3, PBE) involved in fatty acid oxidation as compared to their female counterparts. L-FABP gene ablation upregulated the expression of several of these oxidative enzymes (ACO-2 in control-fed males; ACO-3 in high-fat fed males), but did not change or slightly decreased the levels of these and other fatty acid oxidative enzymes depending on diet. Thus, the decreased fatty acid oxidation indicated by decreased serum levels of β-hydroxybutyrate in L-FABP KO mice was not associated with decreased expression of most peroxisomal proteins involved in fatty acid oxidation.

Effect of High-Fat Diet and L-FABP Gene Ablation on Hepatic Levels of Mitochondrial Enzymes Involved in Fatty Acid Oxidation

Carnitine palmitoyl transferase-1 (CPT-1, located at the outer mitochondrial membrane), is the rate-limiting enzyme involved in import of straight-chain fatty acids into

mitochondria for β-oxidation, while medium chain acyl CoA dehydrogenase (MCAD) is a key enzyme involved in β-oxidation of straight-chain fatty acids within mitochondria. MCAD (Fig. 6a, b) and CPT-1 (Fig. 6c, d) levels were substantially lower in control-fed WT females than males. The high-fat diet decreased expression of MCAD (Fig. 6a) and CPT1 (Fig. 6c) in males, but not females. L-FABP gene ablation did not significantly affect MCAD (Fig. 6a, b) or CPT-1 (Fig. 6c, d) in control-fed males or females. On the high-fat diet, similar findings were obtained with L-FABP KO females, while MCAD (Fig. 6a), but not CPT-1 (Fig. 6c), was increased in the L-FABP KO males. Therefore, decreased fatty acid oxidation shown as decreased serum levels of β-hydroxybutyrate in L-FABP gene-ablated mice on control and high-fat diets was also not associated with diminution of key enzymes involved in mitochondrial fatty acid β-oxidation.

Effect of High-Fat Diet and L-FABP Gene Ablation on Hepatic Levels of Microsomal Enzymes Involved in Lipid Metabolism

The relative abundance of Cytochrome P450 4A3 (CYP4A3), an important ER enzyme participating in microsomal lipid oxidation, was also measured. High-fat diet and L-FABP gene ablation decreased levels of CYP4A3 in both male and female mice (Fig. 6e, f) showing that L-FABP gene ablation did not increase levels of a key ER enzyme involved in lipid oxidation.

Discussion

A major role of liver is to take up and effectively metabolize dietary long chain fatty acids (LCFAs) after intestinal absorption (rev. in [1, 22, 23]). LCFAs as well as their CoA thioesters are known to be potent detergents that dissolve membranes and inhibit the action of multiple receptors and enzymes (rev. in [1, 7, 36, 37]). To prevent these adverse effects, mammals have evolved a family of cytosolic proteins with sufficiently high affinity for these ligands that intracellular levels of unbound free fatty acid and fatty acyl CoA are maintained at a low level, i.e. nM range (rev. in [1, 37–40]). High levels of liver fatty acid binding protein (L-FABP) representing 2–5% of cytosolic protein (0.1–0.4 mM) are expressed in tissues very active in long chain fatty acid (LCFA) uptake, oxidation and metabolism—especially liver, intestine, and kidney (rev. in [1]). Studies performed in vitro show that L-FABP facilitates uptake of fatty acids from membranes [7–11], removes

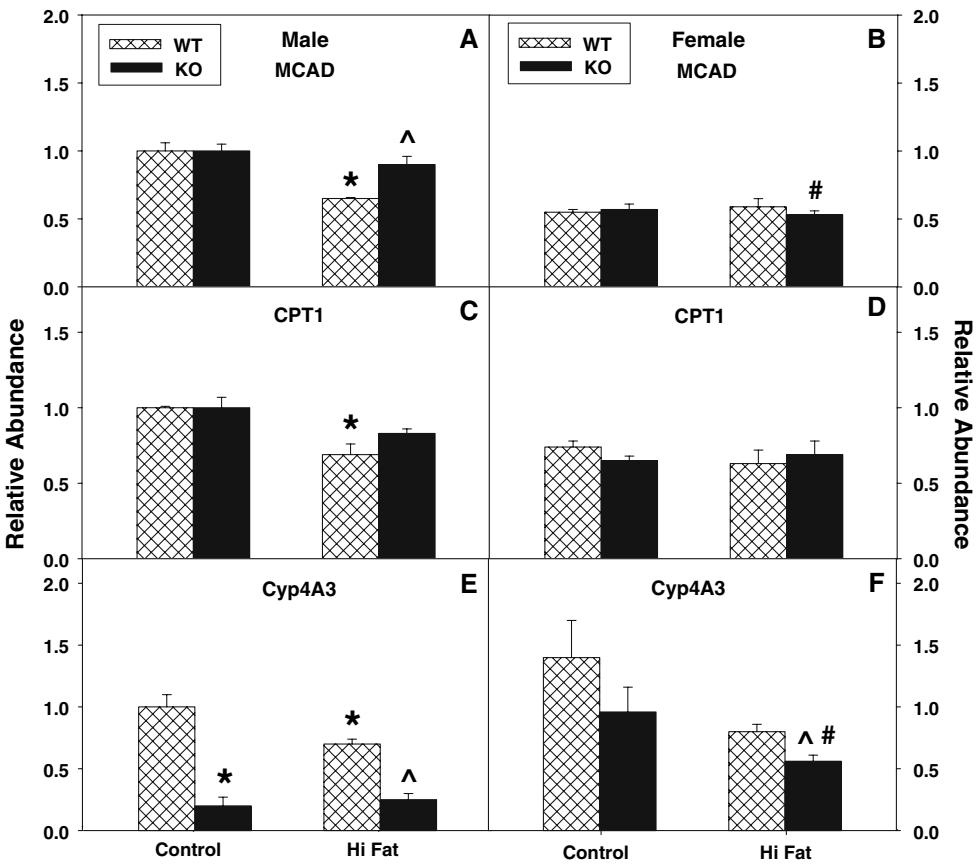

Fig. 6 Effect of L-FABP gene ablation and high-fat diet on liver levels of key enzymes in mitochondrial fatty acid oxidation and microsomal lipid oxidation. At the end of the 12-week dietary study, livers were harvested and expression levels of two key enzymes involved in mitochondrial fatty acid oxidation: medium chain acyl CoA dehydrogenase (MCAD, **a**, **b**), carnitine palmitoyl transferase-1 (CPT-1, **c**, **d**), and a key microsomal enzyme involved in lipid oxidation: cytochrome p4A3 (CYP4A3, **e**, **f**) were measured by real time PCR in male (**a**, **c**, **e**) and female (**b**, **d**, **f**) mice as described in "Materials and Methods". *Cross-hatched* and *solid bars* refer to WT and KO mice, respectively. Values represent the mean ± sem, $n = 5$–7. Statistical analysis was as follows: * $p \leq 0.04$ versus WT mice on control-diet; ^ $p \leq 0.009$ versus WT mice on high-fat diet; and # $p \leq 0.005$ versus male L-FABP KO mice on high-fat diet

substrate inhibition of carnitine palmitoyltransferase-1 (rate limiting step in mitochondrial LCFA oxidation) by palmitoyl CoA [12, 13], and functions as a LCFA donor protein for both peroxisomal and mitochondrial LCFA oxidation in vitro [14, 15]. Other studies with L-FABP overexpressing transformed cells have further established the potential functional significance of L-FABP in facilitating LCFA uptake [1, 16–19], intracellular transport/diffusion [1, 17], oxidation [20], and esterification [16, 18, 21]. The physiological significance and relevance of L-FABP to LCFA and LCFA-CoA oxidation and esterification was confirmed by numerous studies utilizing L-FABP gene-ablated mice where hepatic LCFA uptake in vivo and in cultured hepatocytes exhibited reduced hepatic cytosolic binding capacity for LCFAs and LCFA-CoAs, reduced intracellular LCFA transport/diffusion, and decreased hepatic LCFA oxidation [26–30]. Since liver stores relatively little esterified LCFA as lipid droplets, the net effect of these actions of L-FABP would be to facilitate rapid removal and oxidation. On this basis it was hypothesized that L-FABP gene ablation would enhance weight gain and obesity in a high-fat diet situation. To avoid potential complications due to preference for high fat diet, this hypothesis was addressed by pair feeding L-FABP KO mice compared to WT mice on a defined control diet versus isocaloric high-fat diet for 12 weeks as described in "Materials and Methods". The results provided the following new insights:

First, isocaloric pair feeding of high fat diet elicited sex-dependent body weight gain in male, but not female, mice. Because the mice were pair fed, the greater weight gain of male vs female mice was not due to differences in food consumption. While it was previously established that ad libitum feeding high fat diet itself markedly increases food consumption (as much as 40%) and consequently body weight gain [41–47], the present findings clearly established that weight gain was also greater (at least in males) when the mice were pair fed an isocaloric high fat diet. Thus, consuming the same number of calories as fat (high fat diet) rather than carbohydrate (low fat diet) resulted in increased weight gain in male mice. The greater increase in male mouse body mass was associated with about threefold greater increase in FTM than LTM while female mice isocaloric pair fed high fat diet exhibited increased FTM but not LTM. The molecular basis for the differential response of male versus female mice to isocaloric pair fed high fat diet may be related in part to the sex dependent difference in hepatic L-FABP expression in rodents [31, 48]. Consistent with these findings, sex dependent differences in response to other types of diet (e.g. phytol rich, cholesterol rich, cholestatic, etc.) have also been observed in mice [31, 42–45, 49]. Taken together, these data indicated that the male wild type mice were more efficient in converting both control diet and isocaloric pair fed high fat diet into increased body mass, both FTM and less so LTM.

Second, L-FABP gene ablation elicited sex-dependent body weight gain in female more than male mice. L-FABP gene ablation modestly increased weight gain (primarily as FTM) in control-fed female, but not male, mice. A similar pattern of increased weight gain was also observed in older (>6 mo) female L-FABP KO mice fed ad libitum standard rodent chow [43, 45] or pair-fed a different defined control-diet [42, 43]. Isocaloric pair feeding high fat diet dramatically exacerbated this effect in female, but not male, mice. The increased weight gain in high-fat fed female L-FABP KO mice was not due to differences in food consumption. The molecular basis for the gender dependent effect of L-FABP gene ablation may be related in part to the inter-dependent relationship between L-FABP and PPARα. The promoter of L-FABP contains a PPRE, L-FABP induces expression of PPARα, and L-FABP transports fatty acids into the nucleus to ligand activate PPARα and induce expression of more L-FABP [39, 40, 50, 51]. Roles for PPARs in sex dependent differences in mouse lipid metabolism have also been shown with PPARα null and PPARβ null mice [50, 52, 53].

Third, the effect of L-FABP gene ablation on diet induced obesity and hepatic steatosis appears to be dependent on both feeding regimen and susceptibility of the mouse background strain to diet induced obesity. Isocaloric pair feeding high fat diet (current study) as well as ad libitum feeding standard rodent chow (low fat) or isocaloric pair-feeding different types of low fat defined control diets [42–45] indicated that L-FABP gene ablation did not protect mice from high-fat diet induced weight gain. In addition, isocaloric pair fed high fat diet mice, regardless of sex of L-FABP expression, did not exhibit hepatic steatosis. In contrast to these studies with wild type C57BL/6NJ mice and L-FABP KO mice backcrossed to the C57BL/6NJ mice, ad libitum feeding of high fat diet to the more obesity susceptible C57BL6J strain induced hepatic steatosis [46, 47]. Surprisingly, ad libitum feeding of high fat diet to L-FABP KO mice backcrossed to the more obesity susceptible C57BL6J strain resulted in protection from high fat diet induced obesity and from hepatic steatosis [46, 47]. The marked differences in response to high fat diet between the two L-FABP KO mouse models were not due to differences in back-cross generation number [54]. Instead, these difference in phenotype may be attributed in part to several factors: (i) Wild type mice fed high fat diet ad libitum consume up to 40% more food and gain as much as 50% more weight [46, 47]. While isocaloric pair feeding high fat diet did not upregulate L-FABP in wild type mice determined by western blotting (data not shown), ad libitum feeding high fat diet is known to

activate PPARα—a nuclear receptor that induces transcription of multiple genes in fatty acid metabolism including L-FABP (rev. in [50, 55, 56]). Thus, ad libitum feeding high fat diet may upregulate L-FABP expression in the wild type mice, but not the L-FABP KO mice. (ii) The two independently generated L-FABP KO mice were backcrossed to a different C57BL/6 mouse strains differing markedly in susceptibility to high fat diet induced obesity. The C57BL/6J (Jackson Labs) used to backcross independently generated L-FABP KO mice are more susceptible to high fat diet induced obesity (higher weight gain, impaired glucose tolerance) than mice used for backcrossing in the current study (C57BL/SNJ from Charles River) (JAX NOTES, Issue 511, Fall, 2008, http://jaxmice.jax.org/jaxnotes/511/511n.html) [57–59]. The mechanistic basis for the difference in obesity susceptible of these strains is partly due to the C57BL/6J mouse strain exhibiting a null mutation in the NAD nucleotide transhydrogenase (Nnt) gene which codes for an enzyme that regulates NADH/NAD ratio—an important contributor to LCFA synthesis (JAX NOTES, Issue 511, Fall, 2008, http://jaxmice.jax.org/jaxnotes/511/511n.html). (iii) Overexpression of the green fluorescent protein (GFP) in the independently generated L-FABP KO mouse, but not the wild type control [29, 46, 47]. GFP was recently shown to function as a potent electron donor to several cofactors important in lipid metabolism including cytochrome c, FAD, FMN, and NAD in vitro [60]. Taken together, these findings demonstrate the importance of sex, high fat dietary regimen (pair fed, ad libitum fed), L-FABP KO background strain, and overexpression of GFP as each being important potential contributors to the whole body and hepatic phenotype of L-FABP KO mice fed high fat diet.

Fourth, the finding that L-FABP gene ablation did not induce hepatic steatosis in mice fed either control diet or pair fed high fat diet was consistent with the existing literature of known functions established for L-FABP in vitro, in cultured transformed cells, in cultured primary hepatocytes, and mice. L-FABP KO reduces hepatic uptake of dietary LCFA in vivo [26, 28] and in cultured L-FABP KO hepatocytes [30]. LCFA uptake directly correlates with L-FABP expression level in cultured transfected transformed cell lines [16, 19]. Further support comes from the fact that L-FABP gene ablation reduces LCFA oxidation in vivo as shown by reduced serum β-hydroxybutyrate in mice pair fed high fat diet (current study) and in L-FABP KO mice fed control chow [26, 28, 29], by reduced LCFA oxidation in cultured primary hepatocytes from L-FABP KO [30], and by increased LCFA oxidation in cultured transfected transformed cell lines [16, 19]. Regardless of the back-cross strain utilized to generate the two distinct L-FABP KO mice, inhibition of LCFA β-oxidation was observed in response to L-FABP gene ablation and this inhibition was not associated with major changes in levels of most of the key proteins/enzymes involved in peroxisomal and mitochondrial oxidation.

In summary, the present findings demonstrated that ablation of all four exons of the L-FABP gene and backcrossing to the C57BL/6NJ strain (resistant to high fat diet induced obesity) decreased fatty acid β-oxidation and increased weight gain (especially in fat tissue mass)—effects exacerbated by pair-feeding a defined isocaloric high-fat diet. This phenotype was consistent with predictions based on in vitro and cultured cell studies demonstrating L-FABP increases LCFA uptake (rev. in [1, 26]), LCFA intracellular transport [1, 17, 30, 61, 62], and both mitochondrial and peroxisomal LCFA oxidation [20, 30]. Thus, L-FABP gene ablation did not protect mice from weight gain and obesity induced when fed either control diet or isocaloric pair fed high fat diet, but instead exacerbated weight gain and obesity. While L-FABP gene ablation appeared to protect mice fed high fat diet ad libitum, interpretation of this phenotype is more complex due to much greater food consumption and weight gain concomitant with likely L-FABP upregulation in wild type mice, more obesity sensitive background strain, and presence of GFP in the KO but not wild type mice. Resolving the relative contributions of these factors is an important challenge. It is of interest to note that the pattern of higher weight gain and obesity in L-FABP mice fed high fat diet was also exhibited by adipocyte fatty acid binding protein (A-FABP) gene-ablated mice, which show increased body weight gain as compared with their WT counterparts when fed a high-fat diet [63]. Likewise, intestinal fatty acid binding protein (I-FABP) gene ablation resulted in mice with a higher weight gain than their WT counterparts when fed either a low-fat or a high-fat diet [64]. These findings suggested that in L-FABP KO mice pair fed a high-fat diet, LCFAs are more available for storage (weight gain) rather than hepatic uptake and oxidation (or storage).

Abstract Hepatic lipidosis is a common pathological finding in the American mink (*Neovison vison*) and can be caused by nutritional imbalance due to obesity or rapid body weight loss. The objectives of the present study were to investigate the timeline and characterize the development of hepatic lipidosis in mink in response to 0–7 days of food deprivation and liver recovery after 28 days of re-feeding. We report here the effects on hematological and endocrine variables, body fat mobilization, the development of hepatic lipidosis and the alterations in the liver lipid classes and tissue fatty acid (FA) sums. Food deprivation resulted in the rapid mobilization of body fat, most notably visceral, causing elevated hepatosomatic index and increased liver triacylglycerol content. The increased absolute amounts of liver total phospholipids and phosphatidylcholine suggested endoplasmic reticulum stress. The hepatic lipid infiltration and the altered liver lipid profiles were associated with a significantly reduced proportion of n-3 polyunsaturated FA (PUFA) in the livers and the decrease was more evident in the females. Likewise, re-feeding of the female mink resulted in a more pronounced recovery of the liver n-3 PUFA. The rapid decrease in the n-3/n-6 PUFA ratio in response to food deprivation could trigger an inflammatory response in the liver. This could be a key contributor to the pathophysiology of fatty liver disease in mink influencing disease progression.

Introduction

Fatty liver or hepatic lipidosis is a common pathological finding in carnivores such as the American mink (*Neovison vison*), where fat accumulation in the liver often occurs due to metabolic or nutritional causes [1]. Fatty liver is also frequently found in mink dams diagnosed with nursing sickness [2], which is often fatal and only diagnosed post-mortem [3]. In mink, the hepatic lipid infiltration may be caused by several factors, including amino acid or fatty acid (FA) imbalances, excess dietary carbohydrate intake, choline and vitamin B deficiency, poor feed quality, obesity, restricted feeding or food deprivation [1, 4–6]. The body weight (BW) of the mink fluctuates greatly over the production cycle due to seasonal changes in the plane of nutrition [7] as well as hormonal status [8]. However, food deprivation aggravates these normal metabolic responses resulting in the rapid mobilization of body fat and lipid infiltration in the liver [5, 6]. During the production cycle, the risk of development of fatty liver may be elevated due to excessive fattening during the fall, rapid slimming prior to breeding, stress during pregnancy and mid-late lactation and rapid mobilization of body fat reserves for milk production [1, 7].

In humans, hepatic steatosis (lipidosis) is a common finding in (visceral) obesity and type 2 diabetes and it is considered to be the hepatic manifestation of the metabolic syndrome with strong evidence of an unfavorable n-3/n-6 polyunsaturated FA (PUFA) ratio [9, 10]. The FA manifestations and liver histology of mink nursing sickness and the associated fatty liver syndrome show evident similarity to type 2 diabetes [11] and the non-alcoholic fatty liver disease (NAFLD) of humans [10]. It has recently been shown in members of the *Mustelidae* family (e.g. mink, European polecat *Mustela putorius*) that during rapid BW loss the intra-abdominal body fat depots are more efficiently hydrolyzed in relation to adipose tissue mass than subcutaneous fat [6, 12, 13] with the preferential mobilization of n-3 PUFA leading to a potentially unfavorable n-3/n-6 PUFA ratio [14, 15]. The depletion of n-3 PUFA has been proposed to favor FA and triacylglycerol (TAG) synthesis over hydrolysis and FA oxidation, and may impair lipid export from the liver by suppressing very-low-density lipoprotein (VLDL) secretion [9]. The most consistent endocrine responses associated with food deprivation in mustelids include decreased concentrations of plasma leptin, insulin and triiodothyronine (T_3) [12, 16], while hematological changes suggesting immunosuppression have been reported [6, 17]. The human NAFLD presents significant similarities in phenotype to the fasting-induced fatty liver in mustelids [15], despite the different principal correlates, i.e. obesity versus rapid BW loss. Therefore, the mink may serve as a useful animal model to study the biochemical manifestations of human liver steatosis with potential applications to NAFLD.

Previously, the precise time scale of the biochemical manifestations in the development of fasting-induced hepatic lipidosis has not been described in mustelids. It can be hypothesized that the manifestations of lipidosis would appear at specific points of time during fasting and that the induced fatty liver would be reversible after a recovery period. The objectives of the present study were to investigate the development and characterize the fatty liver syndrome in mink in response to 0–7 days of food deprivation and liver recovery with the normal feeding regime resumed for 4 weeks. This study reports the effects on the mobilization of body fat depots, the development of hepatic lipidosis and the subsequent alterations in the liver lipid classes and tissue and plasma FA profiles as well as in the hematological and endocrine variables.

Experimental Procedures

The time scale of the development of hepatic lipidosis in the mink was studied by exposing 60 standard black mink (5 males, 5 females per group, age 9 months) to 0, 1, 3, 5, or 7 days of fasting. In addition, one group was fasted for 7 days followed by a normal feeding regime for 4 weeks [re-fed (RF)]. The fasting experiment was carried out from 10 January through 16 January and re-feeding from 16 January until 13 February 2007. The animals were weighed prior to the study and at the end of each experimental procedure. The RF group was also weighed prior to re-feeding at the end of the fasting period. The experiment was carried out at the Canadian Centre for Fur Animal Research, Nova Scotia Agricultural College, in Truro, Nova Scotia, Canada (45.37°N, 63.27°W). The mink were housed individually in standard-sized cages, provided with a nest box and adequate bedding. The experimental protocols were approved by the Animal Care and Use Committee of the

Nova Scotia Agricultural College and carried out in accordance with the guidelines of the Canadian Council on Animal Care [18]. During the fasting regimes the mink were isolated from the rest of the herd and therefore not subjected to the normal daily feeding routines in order to alleviate potential stress due to food deprivation. Post-approval monitoring during the experiment included twice daily general health checks and a veterinary inspection by two licensed veterinarians of all mink on the morning of the designated days of the fasting regimes. No morbidity or mortality occurred during the course of the experiment. However, based on veterinary consultation, two female mink were sampled on day 6 of fasting due to their rapidly declining BW during the unexpectedly cold weather. Also, for the remaining females in the RF group the normal feeding routine was resumed on day 6 of fasting. The post-fast diet was the same as was fed to all experimental mink before the start of the experiment and contained 32.31% dry matter, 3.34% ash, 13.54% protein, 6.73% lipid and 8.70% carbohydrate of fresh weight, and 5.65 MJ metabolizable energy kg^{-1}. The FA composition (mol%, mean ± SD, $n = 6$) of the lipid fraction was as follows: saturated FA (SFA) 30.85 ± 0.96; monounsaturated FA (MUFA) 49.75 ± 0.94; n-6 PUFA 14.11 ± 0.70; n-3 PUFA 4.91 ± 0.40. The diet was stored frozen in −20 °C and thawed in the refrigerator prior to feeding.

The control group (0 day) was fasted for 12 h prior to euthanasia. To accomplish this, the feeding and feed removal were staggered for mink in this test group according to their planned sampling schedule. At the end of the fasting periods, the animals were anaesthetized with a combination of xylazine (Rompun 3.4 mg kg BW^{-1}) and ketamine hydrochloride (Ketalean 8.5 mg kg BW^{-1}) given as intramuscular injections. The mink were sampled for blood using cardiac punctures (Vacutainer EDTA tubes) and euthanized with an intracardiac injection of pentobarbital sodium (Euthanyl 105.6 mg kg BW^{-1}). Immediately following euthanasia, samples were obtained from various internal organs and tissues. The intermuscular fat sample was obtained from the region of the gluteal muscle and the skeletal muscle tissue from the gastrocnemius muscle. The excised tissues were placed in cryovials and plastic bags and snap-frozen in liquid nitrogen. The samples were kept on dry ice until transferred to long-term storage at −80 °C. The organ and fat depot masses were determined using quantitative dissection. The body mass indices (BMI) indicating adiposity of mustelids [6] were calculated with the formula: BMI = BW (kg) [body $length^3$ (m)]$^{-1}$ and the hepatosomatic indices (HSI) as liver weight in percent of final BW.

The whole blood was analyzed for hematological parameters (SCIL Vet abc Animal Blood Counter; Vet Novations Canada Inc., ON, Canada) by the diagnostic services laboratory of Fundy Veterinarians (Murray Siding, NS, Canada). The plasma glucose, total cholesterol, creatinine, TAG, total protein, urea and total bilirubin concentrations and creatine kinase and alanine aminotransferase (ALT) activities were determined as previously outlined in Mustonen et al. [6, 19]. The glucagon, ghrelin and total T_3 analyses were determined as described in Mustonen et al. [12] and the rest of the endocrinological assays and catecholamines as in Mustonen et al. [16]. The instrument used was a Wizard 1480 Gamma Counter by Wallac (Turku, Finland). The homeostasis model assessment (HOMA) index, as a measure of insulin resistance applied also previously to mustelids [12], was calculated based on the fasting plasma insulin and glucose concentrations [20]; where HOMA = fasting insulin ($\mu U\ mL^{-1}$) × fasting glucose (mmol L^{-1})/22.5.

The liver lipids were extracted according to Folch et al. [21]. The liver lipid classes were analyzed with thin layer chromatography (TLC–FID, Iatroscan new Mark V, Iatron Laboratories Inc., Tokyo, Japan [22]), and the tissue FA composition using gas chromatography mass spectrometry (GC–FID and GC–MS, 6890N network GC-system, Agilent Technologies Inc., Palo Alto, CA, USA). For a more detailed description of FA analyses, see Nieminen et al. [14, 23].

Statistical Analysis

The experimental design used was 2 × 6 factorial with two sexes and six treatment groups. The data were analyzed using the General Linear Models procedure in SAS® v.9.1 (SAS Institute Inc., Cary, NC, USA) to examine the effects of the sex and the fasting regimes and their interaction on the measured variables. A multiple means comparison test (PDiff) was used to identify where differences existed when these effects were found significant. Statistical significance was set at $P < 0.05$. The results are presented as lsmeans ± standard error of the mean (SEM).

Results

BW Loss, Liver Lipid Content and Body Fat Mobilization

In comparison to the non-fasted control, both males and females had significantly lower final BW during 5–7 days of fasting, whereas the 1- to 3-day groups did not differ from the control (0 day; Table 1). Also, the final BW of the RF group were not different during the preceding fast from the mink fasted for 7 days. During the 4-week re-feeding period, the mink recovered some of their BW; at the end of the experiment the RF males weighed 2396.8 ± 130.8 g and the RF females 1148.8 ± 146.2 g. The females

Table 1 Body weight (BW), body length, body mass index (BMI), liver weight, and the weights of the body fat depots in male and female mink in response to fasting for 0 (control), 1, 3, 5, and 7 days, and re-feeding (RF) for 28 days after a 7-day fast

Presented are lsmeans ± SEM

[a–e] Fasting regimes differ within row ($P < 0.05$)

[f] For RF group calculated after the 7-day fast. All other values of RF group measured after the re-feeding period

[g] Calculated as the sum of mesenteric, omental, diaphragmatic and perirenal fats

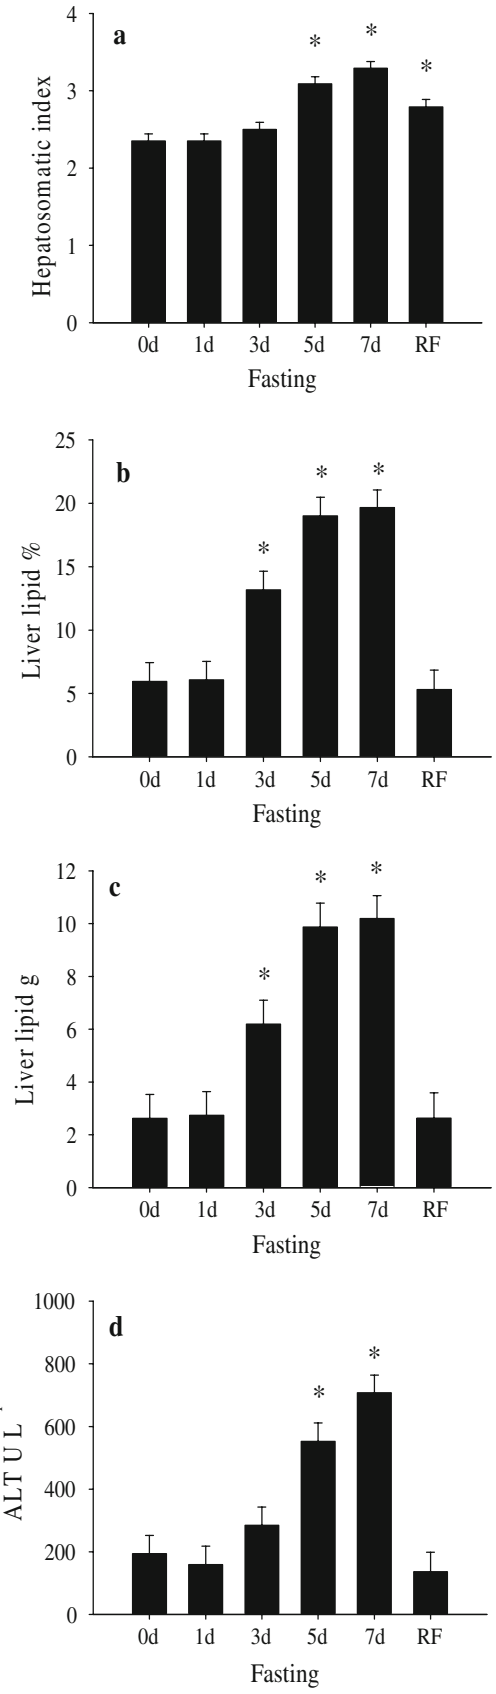

Fig. 1 Changes in the **a** hepatosomatic index, **b** liver lipid %, **c** liver lipid mass (g), and **d** plasma alanine aminotransferase (*ALT*) activity (U L^{-1}) in mink in response to fasting for 0 (control), 1, 3, 5, and 7 days, and re-feeding (*RF*) for 28 days after a 7-day fast. Reported are lsmeans + SEM, both sexes combined. *Asterisk* differs from control ($P < 0.05$). Total $n = 60$. *P* values: **a** fasting <0.001, sex 0.003, F × S 0.471; **b** fasting <0.001, sex 0.384, F × S 0.630; **c** fasting <0.001, sex <0.001, F × S 0.490; and **d** fasting <0.001, sex 0.038, F × S 0.028

showed a more pronounced loss in % BW and BMI. Overall, the HSI was elevated in comparison to the control in the 5-, 7-day and RF groups, whereas the 0- to 3-day groups did not differ (Fig. 1). The females exhibited significantly higher HSI values than the males (2.84 vs. 2.62%, SEM = 0.05). Food deprivation of 3–7 days increased the liver lipid percentage and liver lipid mass (g) in comparison to the control animals in both male and female mink. The liver lipid percentages for the 0-, 1-, 3-, 5-, 7-day, and RF groups were on average 5.9 ± 1.5, 6.1 ± 1.5, 13.2 ± 1.5, 19.0 ± 1.5, 19.7 ± 1.4, and 5.3 ± 1.6%, respectively. The test groups had the following absolute amounts of total liver lipids: 0 day, 2.6 ± 0.9 g; 1 day, 2.7 ± 0.9 g; 3 days, 6.2 ± 0.9 g; 5 days, 9.9 ± 0.9 g; 7 days, 10.2 ± 0.9 g; and RF, 2.6 ± 1.0 g; the males had higher absolute amounts (7.4 ± 0.5 g) than the females (4.1 ± 0.5 g).

In response to food deprivation, the following internal organs reduced in absolute mass: pancreas, small intestine, kidneys, testes and the female reproductive organs, whereas no change was observed in the masses of the spleen, stomach, heart, and the thyroid and adrenal glands (data not shown). The absolute and relative weights of the total intra-abdominal body fat depots declined significantly in response to food deprivation, however, they did not attain the levels of the non-fasted control animals after the re-feeding period (Table 1). Notably, the relative (% BW) combined weight of the omental and mesenteric adipose depots declined in response to the fasting regimes as follows: 0 day, 7.4 ± 0.5%; 1 day, 7.2 ± 0.5%; 3 days, 6.8 ± 0.5%; 5 days, 5.4 ± 0.5%; and 7 days, 5.0 ± 0.4%; while these two visceral fat depots did not recover once normal feeding was resumed (RF, 5.0 ± 0.5%; $P < 0.001$). The females had less subcutaneous fat in absolute and relative mass, however, the relative mass of the total intra-abdominal adipose depots was higher in the female mink in comparison to the males (8.2 ± 0.3% vs. 7.2 ± 0.3%). Overall, the male mink had an average estimated body fat content (% BW) of 34.8% and the females 31.3% (SEM = 0.86; $P < 0.005$). The body fat content ranged between 33.3 and 37.6 ± 1.5% during 0–3 days of fasting, declined to 31.1–31.2 ± 1.4% during 5–7 days, and was 29.9 ± 1.6% after re-alimentation ($P < 0.006$).

Liver Lipid Classes

The majority of liver lipids were in the form of TAG, the relative amount of which increased during 1–7 days of fasting (Fig. 2). The absolute quantities of TAG within the livers in the non-fasted control (0 day) and 1 day fasted mink were on average 1.2–1.5 g, while the total liver TAG contents were 3.9 g at 3 days and 6.7–6.9 g at 5–7 days, and declined to 0.8 g upon re-feeding. On the contrary, the relative amounts of phosphatidylcholine (PtdCho) and total phospholipids (PL) were lower within 3–7 days of fasting. However, when taking into account the liver mass and lipid content, the absolute quantities of total PL were the lowest during 0–1 days (0.93–1.03 g), and elevated within 3 days of fasting (3 days, 1.58 g; 5 days, 2.12 g; 7 days, 2.57 g), while at the end of the 4-week re-feeding period 1.27 g of total PL was present in the liver (SEM = 0.20, $P < 0.001$). The total quantities of PtdCho were the lowest during 0–3 days (0.85–0.99 g), elevated during 5–7 days of food deprivation (5 days, 1.76 g; 7 days, 2.09 g), and returned to pre-fasting levels after re-feeding (0.92 g; SEM = 0.20; $P < 0.001$). Lower relative percentages were also observed in free FA (FFA), diacylglycerols and cholesterol during fasting. In response to re-alimentation, significantly higher percentages of cholesteryl esters, diacylglycerols, cholesterol, sphingomyelin, and total PL were present in the liver lipids in comparison to the control animals. Concomitantly, the RF mink exhibited a significantly lower fraction of TAG in the total liver lipids.

Hematology, Clinical Chemistry and Endocrinology

Overall, the red blood cell count showed lower levels after the re-feeding period (Table 2). This differed from all other treatments except 0 day. The males had on average higher red blood cell counts than the females (9.2 ± 0.1 vs. 8.7 ± 0.1 10^{12} L^{-1}). The hemoglobin concentrations were elevated on day 5 of food deprivation and the males showed higher hemoglobin levels than the females (18.7 ± 0.2 vs. 17.8 ± 0.2 g dL^{-1}) throughout the study. The mean corpuscular hemoglobin concentration increased in both sexes during fasting returning to day 0–1 levels after re-alimentation while the red cell distribution width declined and the mean platelet volume showed minor changes during the fasting regimes. A significant response to food deprivation was observed in the white blood cells, where the lymphocyte percentage declined significantly over the duration of 7 days of fasting with recovery to pre-fasting levels during the re-feeding period, and the granulocyte percentage showed an overall increase during the

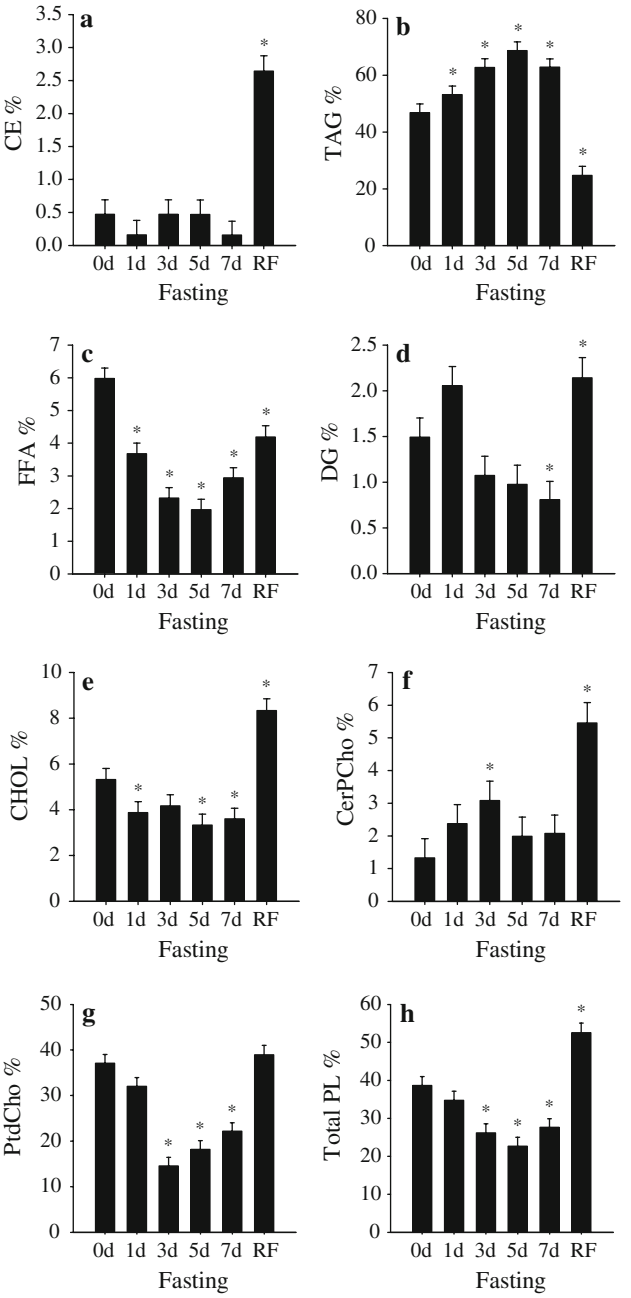

Fig. 2 Alterations in the proportions (%, lsmeans + SEM, both sexes combined) of mink liver lipid classes **a** cholesteryl esters (*CE*) **b** triacylglycerols (*TAG*) **c** free fatty acids (*FFA*) **d** diacylglycerols (*DG*) **e** cholesterol (*CHOL*) **f** sphingomyelin (*CerPCho*) **g** phosphatidylcholine (*PtdCho*) and **h** phospholipids (*PL*) in response to fasting for 0 (control), 1, 3, 5, and 7 days, and re-feeding (*RF*) for 28 days after a 7-day fast. *Asterisk* differs from control ($P < 0.05$). [a–d] Fasting regimes differ within row ($P < 0.05$)

P plasma, *ADR* adrenal

fasting regimes with return to day 0–3 levels in response to re-alimentation. The monocyte percentage, on the other hand, showed a more variable response with peak values on days 3 and 7 of fasting.

The plasma TAG concentrations showed a significant increase in response to food deprivation during days 1–7 in comparison to the non-fasted control animals and the RF mink (Table 3). The cholesterol levels varied in the different experimental regimes with the highest values observed in the RF group. Lowest values for both sexes were observed on days 3 and 7 of fasting. Overall, the males had higher plasma total protein concentrations than the females (64.5 ± 0.7 vs. 62.1 ± 0.7 g L^{-1}). In both sexes, the plasma protein levels declined during 3–7 days of food deprivation and remained low upon re-feeding. Concurrently, no change was observed in the plasma urea levels throughout the experimental regimes. For plasma ALT, a significant fasting × sex regime interaction was found, where the female mink showed higher values on day 5 of fasting than the males. The plasma ALT levels increased during 5–7 days of fasting and returned to 0- to 3-day levels in response to re-alimentation (Fig. 1).

A significant decline was observed in the plasma insulin levels during fasting and the concentration remained low thereafter (Table 3). This was accompanied by a decrease in the HOMA index. The plasma leptin concentrations were significantly lower during days 3–7 of fasting in comparison to the 0- to 1-day groups; they also remained low after feeding was resumed. The females had on average lower circulating plasma leptin levels than the males (2.220 ± 0.077 vs. 2.555 ± 0.076 ng mL^{-1}). For plasma ghrelin a significant fasting × sex interaction was found indicating the highest levels in the female mink fasted overnight (0 day), whereas for the males the highest plasma ghrelin concentrations were seen on day 7 of fasting and the lowest on day 3. The plasma T_3 levels declined within 7 days of fasting and returned to pre-fasting levels when feeding was resumed. Generally, the females exhibited higher concentrations of dopamine (10.29 ± 0.56 μg g^{-1}) and noradrenaline (145.00 ± 6.71 μg g^{-1}) in their adrenal glands in comparison to the males (7.44 ± 0.56 μg g^{-1}; 115.54 ± 6.67 μg g^{-1}).

Tissue FA Profiles

A rapid shift was observed in the liver FA profiles in response to food deprivation and re-feeding (Fig. 3; Table 4). In the female mink, significantly lower hepatic n-3/n-6 PUFA ratio was present within 1 day of food deprivation, whereas the males responded within 3 days. The RF mink showed complete recovery of the hepatic total n-3 PUFA and n-3/n-6 PUFA ratio, with the females having significantly higher values compared to the males.

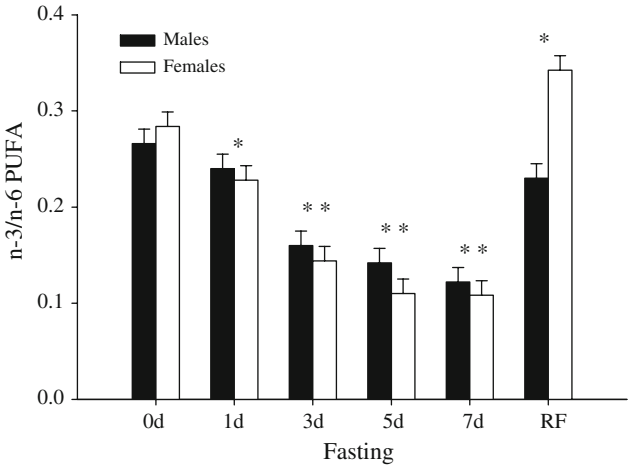

Fig. 3 Changes in the hepatic n-3/n-6 polyunsaturated fatty acid (*PUFA*) ratio (lsmeans + SEM) in male and female mink in response to fasting for 0 (control), 1, 3, 5, and 7 days, and re-feeding (*RF*) for 28 days after a 7-day fast. *Asterisk* females differ from control, *double asterisk* both sexes differ from control ($P < 0.05$). Total $n = 60$. P values: fasting <0.001, sex 0.231, F × S <0.001

In addition, a significant decline was observed in the liver SFA levels after 1 day of fasting, while total MUFA and the unsaturated FA (UFA)/SFA ratio increased during 3–7 days. For these variables, the RF group did not differ from the 0-day mink.

For the other tissues, the FA data (Table 4) are presented by fasting regime only as no interaction (fasting × sex) was observed. The intermuscular adipose tissue exhibited lower concentrations of n-3 PUFA and n-3/n-6 PUFA ratios during food deprivation. Overall, the females had lower n-3 PUFA % ($P = 0.013$) and n-3/n-6 PUFA ratios ($P = 0.008$) than the males in their intermuscular adipose tissue. In the mesenteric fat during the fasting regimes, total SFA were shown to decline while total MUFA increased. Although the UFA/SFA ratio increased in response to food deprivation, the n-3 PUFA % and n-3/n-6 PUFA ratios declined. These changes in the FA composition were reversed when feeding was resumed for 4 weeks. In the perirenal fat, total SFA declined during fasting and subsequently the UFA/SFA ratio increased. Again, a significant decrease was observed in n-3 PUFA as well as n-3/n-6 PUFA ratios during the course of food deprivation. The RF animals were not significantly different in their perirenal PUFA profiles from the controls. However, the SFA proportions of perirenal adipose tissue depots remained low in the RF group while the UFA/SFA ratio remained high. Overall, the females had lower n-3 PUFA % in this adipose depot than the males ($P = 0.036$). In the ventral subcutaneous adipose tissue, a significant decline was once again observed in n-3 PUFA as well as in the n-3/n-6 PUFA ratios during the course of food deprivation.

The typical decline in the n-3/n-6 PUFA ratio in response to food deprivation was also observed in the FA profiles of the skeletal muscle (Table 4). Overall, the females had higher levels of total SFA ($P = 0.019$), total n-3 PUFA ($P = 0.009$) and higher n-3/n-6 PUFA ratios ($P = 0.002$), but lower total MUFA ($P = 0.039$) and UFA/SFA ratios ($P = 0.016$) than the males. Finally, regarding the plasma FA profiles, total MUFA increased while total n-6 and n-3 PUFA declined in response to food deprivation. A significant sex difference was observed ($P = 0.034$) where the female mink had higher plasma n-3/n-6 PUFA ratios in comparison to the males.

Discussion

BW Loss, Fat Mobilization, HSI and Liver Fat Content

It is evident from the current study that fasting of mink for as few as 3 days results in considerable BW loss and a significantly increased liver lipid content primarily present as TAG. These findings are in agreement with previous studies on the effects of food deprivation in mink [5, 6], polecats [15] and sables (*Martes zibellina*) [17]. Furthermore, a 28-day period of re-feeding after a 7-day fast resulted in moderate recuperation of BW and return to normal liver fat percentage, indicating liver recovery. The rapid BW loss during fasting [6, 12] is most likely an outcome of (1) the energetically demanding body shape with a high surface-area-to-volume ratio [24] and (2) the inability of small mustelids to utilize, e.g., torpor or related hypometabolic adaptations [12, 25]. This necessitates rapid mobilization of the adipose tissue depots during food deprivation.

On average, the females lost more % BW than the males. This is likely caused by the significant sexual dimorphism exhibited by the species [26] where, due to its smaller body size, the female mink would be energetically more challenged during times of food deprivation, especially in cold weather. In addition to their smaller BW, the anatomic difference that the female mink seem to deposit relatively more adipose tissue in the intra-abdominal depots may be worth considering. Having more intra-abdominal adipose tissue may, under conditions of preceding obesity, e.g., as a result of autumnal fattening, predispose the female mink to a more rapid onset of hepatic lipidosis. In this regard, the visceral (omental, mesenteric) adipose tissue poses a far greater health risk than subcutaneous fat in humans [27], as the FFA hydrolyzed from these depots are released directly into the hepatic portal circulation [28]. Based on the estimated body fat content (>33% BW), the mink in this study could be considered obese at the start of the food deprivation period. It is also

evident from the current data that the mink were largely unable to recover their body fat depots during winter once they had been mobilized due to food deprivation.

Hematology, Endocrinology and Clinical Chemistry

Similar to earlier findings in mink [6], sables [17] and American marten (*Martes americana*) [13] the blood lymphocyte percentage declined in response to 7 days of food deprivation, while in the RF group, the lymphocyte percentage did not differ from the pre-fasted levels. This suggests that prolonged food deprivation could lead to immunosuppression in mink and that this would be reversed once normal feed intake is resumed.

The plasma leptin concentrations were significantly lowered in the mink in response to 3–7 days of food deprivation not dissimilar to earlier observations [16] and remained low thereafter. Our results are also in a close agreement with findings by Mustonen et al. [12] on the European polecat where a drastic decline was observed in plasma leptin concentrations in response to 5-day food deprivation. It is noteworthy that in the American marten and the sable, food deprivation of 2 and 4 days, respectively, did not influence the plasma leptin levels [13, 17]. In these species, the plasma ghrelin concentrations increased in response to short-term food deprivation, whereas no clear response was observed in the current study, where the female mink showed the highest levels when fasted overnight and the males after 7 days. Likewise, the plasma ghrelin levels of the European polecat and male American mink remained unaffected by food deprivation [12, 16]. The different responses observed in these two key endocrine regulators of body energy homeostasis may reflect the different degrees of adiposity among the members of the weasel family. The mink [6] and the European polecat [12] represent species with a propensity to unnatural obesity under captive conditions, whereas the American marten [23] and the sable [17] do not have a tendency to accumulate excessive adipose tissue depots.

During food deprivation, the observed lower T_3 concentration could contribute to the down-regulation of metabolism resulting in reduced energy expenditure when food supply is limited [29]. Since insulin is required for the conversion of thyroxine (T_4) to T_3, the down-regulation of metabolism is a direct outcome of suppression of insulin release in response to food deprivation and the accompanying low blood glucose levels [30]. The characteristic decline in the insulin levels was observed in the mink in the current study similar to our recent findings in the polecats and male American mink, where the plasma insulin levels decreased markedly in response to fasting and coincided with the lower T_3 concentrations and T_3/T_4 ratios [12, 16].

The elevated circulating TAG concentrations may reflect the rapid mobilization of body fat reserves during food deprivation. The increased influx of FFA from the visceral fat depots into the liver may promote hepatic insulin resistance which leads to an accelerated synthesis of VLDL causing elevated plasma TAG levels [27]. This increases the hepatic TAG influx posing an overwhelming challenge to the liver's ability to metabolize these lipids [9, 10] resulting in a perpetuating cycle. The liver lipid metabolism is further challenged in strictly carnivorous mammals [31–33], which rely on gluconeogenesis for blood sugar provision and are unable to conserve nitrogen by down-regulating the urea cycle during fasting [34]. In mustelids, food deprivation is accompanied by decreased plasma arginine levels [12, 35], causing the accumulation of orotic acid [33]. Orotic acid is an intermediary metabolite in the pyrimidine ribonucleotide synthesis, the first step of which is the formation of carbamoyl phosphate, and

it is directly hepatotoxic interfering with the liver's ability to assemble and secrete VLDL [36]. Carbamoyl phosphate, formed from ammonia and bicarbonate, is also required for the urea cycle where it participates in the important step of citrulline synthesis from ornithine maintaining the cycle [37].

In carnivores, a dietary source of arginine is required for the proper functioning of the urea cycle, where arginine is converted to urea yielding ornithine [38]. Shortage of arginine may further compromise the liver lipid metabolism in carnivores as the urea cycle function declines. Arginine is also required for the synthesis of apolipoprotein E, which has a facilitating role in hepatic lipid mobilization increasing the number of VLDL particles secreted by the liver [39]. The rapid depletion of arginine [35] may be an outcome of competing requirements coinciding at the time of extensive body fat mobilization; namely meeting the demands for accelerated VLDL synthesis and eliminating increasing amounts of waste nitrogen resulting from augmented gluconeogenesis. Arginine deficiency, therefore, appears to be a significant constraint for the liver lipoprotein metabolism during food deprivation, when there is no dietary supply of arginine, its synthesis is inadequate [32] and its amount in muscles diminishes as a result of stimulated proteolysis [35]. It is evident that complex biochemical interactions exist among the different physiological systems during food deprivation exerting pathophysiological linkages between the liver lipid metabolism, gluconeogenetic pathways and the urea cycle function. This may help explain the rapidity by which hepatic lipidosis develops in carnivores.

The severity of the fatty liver disease is further exacerbated due to the effects it may have on the central nervous system. It is not known if urinary orotic acid or blood ammonia levels are increased in mink females diagnosed with nursing sickness (DB Hunter, personal communication). However, hepatic lipidosis and coma are among the most prevalent findings in the advanced stage of the disease [2, 40, 41]. In humans [42] and carnivore companion animals [34], hepatic encephalopathy and hyperammonemic coma are commonly associated with fulminant liver failure. The human hepatic encephalopathy is also characterized by low-grade cerebral edema, swelling of astrocytes, hyponatremia and the depletion of organic osmolytes in the brain cells [43]. It is probable that the mortality that often accompanies nursing sickness and the associated hepatic lipidosis in the mink may be an outcome of the decline in the urea cycle function, and ultimately caused by the accumulation of toxic levels of ammonia leading to suppression of the functions of the central nervous system. The hyponatremia in mink dams [41] may also be a significant contributor to mortality as it further exacerbates the pathogenesis of hepatic encephalopathy as seen in humans [43]. In mink farming, electrolyte therapy has been successfully used to treat mink dams in the early stages of nursing sickness [3, 44]. This, in addition to maintaining kidney function [11], may help prevent the development of cerebral edema in subjects with impaired liver function effectively reducing mortality.

Liver Lipids and Tissue FA Profiles

It is evident based on our findings that the significant increase in the HSI would be caused by TAG accumulation as a result of fat mobilization and increased FFA influx into the liver. On the other hand, the relative decrease of lipid components mostly present in cellular membranes may be indicative of liver cell damage supported by the elevated ALT activities, while their relative increase in the RF group may be evidence for hepatocyte regeneration. However, the significantly elevated absolute quantities of total PL during 3–7 days, and of PtdCho during 5–7 days, suggest that as the liver enlarges in size there would be also accelerated synthesis of membrane PL in the endoplasmic reticulum (ER) most likely triggered by ER stress and the unfolded protein response (UPR) [45]. Chronic ER stress has been shown to underlie the physiological responses in obesity, including inflammation and insulin resistance [46]. In liver disease, oxidative stress and ER dysfunction have been proposed as causative factors in the formation of Mallory-Denk bodies [47]; a morphologic hallmark in the transition from simple steatosis (lipidosis) to the more severe steatohepatitis. Possibly, the observed alterations in the liver lipid composition of the 3–7 days fasted mink could be associated with ER stress and the UPR contributing to the development of liver pathology.

The FA data of the various adipose tissue depots clearly show a rapid loss of the n-3 PUFA and a significant decline in the n-3/n-6 PUFA ratio in response to food deprivation. The over-representation of the n-6 PUFA in the body, caused by the selective mobilization of n-3 PUFA during fasting [14, 15], is known to result in increased percentages of these FA in the cell membranes of blood cells and hepatocytes [48]. This in turn results in augmented synthesis of the arachidonic acid (20:4n-6)-derived eicosanoids shifting the physiological state of the body to pro-inflammatory and pro-thrombotic and increasing blood clotting, vasospasms and vasoconstriction. The findings of the present experiment are similar to previous studies on carnivores [14, 15, 19, 23] where the FA profiles indicated lower n-3 PUFA proportions in the livers of fasted animals. The complete recovery of the hepatic n-3/n-6 PUFA ratio in response to re-feeding as seen for the first time in the current experiment is clear evidence of the liver's ability to regenerate and recover from injury caused by lipid accumulation when normal feeding is resumed. The rapid

decrease in the n-3/n-6 PUFA ratio in response to food deprivation could be significant in triggering an inflammatory response in the liver tissue [48]. This could be a key contributor to the pathophysiology of fatty liver disease in mink and may influence the disease progression.

It is noteworthy that the plasma n-3/n-6 PUFA ratio appeared relatively constant throughout the experiment and did not respond to the fasting and re-feeding regimes. The higher circulating levels of the n-3 in relation to the n-6 PUFA indicate augmented mobilization of n-3 PUFA in the female mink, suggesting an elevated physiological demand compared to the males. The resulting more pronounced depletion of the n-3 FA from the adipose tissue depots and the liver may predispose the female mink to the development of metabolic disorders arising from such FA imbalance, such as poor glycemic regulation [49, 50], nursing sickness [11] and fatty liver disease [9].

Mustelids would be suitable models to study NAFLD, as several similarities have been observed in the manifestations of hepatic lipidosis between these species and NAFLD patients. The most obvious are the increased liver TAG content, histological findings of steatosis and potentially increased plasma transaminases [9, 10, 15, 48]. Both NAFLD patients and fasted mustelids display decreased tissue n-3 PUFA proportions and n-3/n-6 ratios [9, 15, 48]. Additional similarities could be liver inflammation [10, 48], oxidative stress [9, 10] and ER stress [47], but these remain to be confirmed in further studies. Finally, mustelids could also be very useful models to study liver recovery avoiding the logistical challenges associated with human subjects, e.g., liver biopsies and long follow-up periods [10]. In the mink, the recovery was relatively rapid, as most of the manifestations of lipidosis had disappeared after 28 days of re-feeding.

The key findings of our study are that (1) the development of hepatic lipidosis in mink is rapid and occurs within only a few days of fasting, (2) the principal manifestations in mink are similar to the human NAFLD making the mink a potentially useful animal model for studies on liver steatosis, and that (3) the hepatic lipidosis and the associated biochemical manifestations are reversible when normal feeding is resumed for 4 weeks. In summary, food deprivation of mink resulted in the rapid mobilization of body fat, most notably visceral, causing elevated HSI, liver TAG content and plasma ALT activities. The hepatic lipid infiltration and the altered liver lipid profiles were associated with a significantly reduced n-3 PUFA proportion in the livers and this decrease was more evident in the females. Likewise, re-feeding of the female mink resulted in a more pronounced recovery of the liver n-3 PUFA. The rapid decrease in the n-3/n-6 PUFA ratio in response to food deprivation could trigger an inflammatory response in the liver tissue. This could be a key contributor to the pathophysiology of fatty liver disease in mink and may influence the disease progression.

Acknowledgments This study was supported by the Natural Sciences and Engineering Research Council of Canada (Discovery Grant to KRW, NSERC Undergraduate Student Research Award to CP and RC), the Canada Mink Breeders' Association, the Nutricia Research Foundation, the Finnish Fur Breeders' Association, the Academy of Finland (A-MM and PN), the Mink Farmer's Research Foundation, Fur Commission USA and the Heger Company. Abstract Plasma phospholipid transfer protein (PLTP) mediates both net transfer and exchange of phospholipids between different lipoproteins. Animal studies have shown that it is closely related to the development of atherosclerosis. Although many studies have indicated that PLTP activity is increased in diabetes mellitus, the role of PLTP in diabetes is still unclear. To evaluate the influence of a high-fat meal on PLTP activity, 50 non-diabetic patients with coronary heart disease (CHD), 50 insulin-treated Type 2 diabetics, and 50 healthy controls were included. We determined PLTP activity before and 4 and 8 h after a high-fat meal. As expected, serum PLTP activity was significantly higher in CHD patients than in healthy controls (71.0 ± 46.2 vs. 54.0 ± 33.8 pmol/μl/h, $P = 0.032$) at baseline. More importantly, we found that serum PLTP activity increased to its maximum 4 h after fat loading and then decreased to nearly basal levels after 8 h both in controls and CHD patients. In contrast, PLTP activity continuously increased during this time period in the diabetic patients. With regards to the data from this study we hypothesize that serum PLTP is involved in the clearance of postprandial lipoproteins and this process is attenuated in diabetes. Since postprandial lipoproteins are atherogenic, the delay in clearance of these particles could play an important role in the development of atherosclerosis in patients with diabetes mellitus.

Keywords Phospholipid transfer protein · Diabetes mellitus

Abbreviations

ACE	Angiotensin converting enzyme
BLp	ApoB-containing lipoprotein
CAD	Coronary artery disease
CHD	Coronary heart disease
CRP	C-reactive protein
HDL	High density lipoprotein
HDL-C	High density lipoprotein-cholesterol
OGTT	Oral glucose tolerance test
PLTP	Phospholipid transfer protein
RLP	Remnant-like particle
TG	Triglycerides
VLDL	Very low density lipoprotein

Introduction

The plasma phospholipid transfer protein (PLTP) is primarily involved in high density lipoprotein (HDL) metabolism. PLTP mediates both net transfer and exchange of phospholipids between lipoproteins [1].

PLTP's proatherogenic potency has been clearly demonstrated in atherogenic mouse models: PLTP deficiency resulted in markedly decreased atherosclerosis due in part to decreased production and lower levels of apoB-containing lipoproteins (BLp) [2] and increased bioavailability of vitamin E in atherogenic lipoproteins [3]. PLTP overexpression resulted in markedly increased atherosclerosis due in part to decreased HDL levels [4] and increased VLDL secretion [5].

The role of PLTP in atherosclerosis in humans is still the subject of controversy, however. We have previously shown that high plasma PLTP activity is a risk factor for coronary heart disease (CHD) [6]. In contrast, other authors showed that low PLTP activity was a risk factor for peripheral atherosclerosis [7]. Furthermore, we found that serum PLTP activity was higher in hemodialysis patients than in matched controls and represents a further aspect of uremic dyslipidemia in end-stage kidney disease. However, PLTP activity was not related to survival in this patient group [8]. On the other hand, we found in a recent publication that PLTP is a not only a risk marker but a risk factor for CAD-patients under statin treatment [9]. Thus, the significance of PLTP in atherogenesis is still an open issue.

Patients suffering from diabetes mellitus are at high risk for atherosclerotic diseases. Interestingly, several reports have shown that plasma PLTP activity is elevated in Type 2 [10–12] and Type 1 [13] diabetes mellitus. Furthermore, plasma PLTP decreased in response to exogenous insulin and these effects of insulin were impaired in obese type II diabetic patients. This forms the basis for the hypothesis that plasma PLTP is regulated by insulin [14].

To further investigate possible linkages among PLTP activity, diabetes, and atherosclerosis, we measured serum PLTP activity in insulin-treated patients with diabetes mellitus, patients suffering from coronary heart disease, and healthy controls at baseline and 4 and 8 h after eating a high-fat meal.

Experimental Procedure

Study Population

This prospective study was designed to evaluate postprandial lipoprotein metabolism with a focus on the postprandial kinetics of PLTP activity. We included 50 patients with insulin-treated Type 2 diabetes mellitus (approximately 2/3 of patients suffered from CHD and patients with Type 1 diabetes were excluded), 50 patients with angiographically proven CHD without diabetes mellitus, and 50 subjects with no clinical or anamnestic evidence of atherosclerosis or diabetes mellitus recruited in a general practitioner's office in Timmendorfer Strand. A diabetes mellitus or impaired glucose tolerance in patients with CHD and controls was excluded by standard methods of the Curschmann Clinic Timmendorfer Strand (measurement of fasting glucose, OGTT).

All study subjects were of German nationality and the patients were recruited in the Curschmann Clinic for Rehabilitation, Timmendorfer Strand, Germany. The study was approved by the ethics committee of the University of Lübeck, Germany. Participation was voluntary and each participant gave written informed consent.

Laboratory Methods

Blood samples were taken from all subjects under standardized conditions after an overnight period of fasting. After this first blood sample was taken, subjects ate in a period of approximately 15 min, a meal high in fat, consisting of a total of 1,265 kcal/m^2 body surface area (105 g of fat, consisting of 52 g saturated fat and 300 mg cholesterol, with 48 g carbohydrates and 32 g protein). Subjects were instructed not to eat any other food until after the last blood sample was taken. Further blood samples were taken after 4 and 8 h. All blood samples were immediately centrifuged at 4,000 rpm for 10 min and divided into aliquots. All aliquots were stored at −80 °C until analysis.

Before eating the meal, patients with diabetes mellitus received a dosage of subcutaneous insulin individually adapted to the meal described above. Glucose levels were measured every 2 h until the end of study period to diagnose severe hypo- or hyperglycemia. Indeed, additional insulin administration was required to treat blood glucose levels above 250 mg/dl in three patients (each 4 IU of rapid-acting insulin after 4 h). In another three patients additional carbohydrates were administered to increase blood glucose levels that were lower than 80 mg/dl (all asymptomatic).

PLTP activity was measured by using an assay kit (Cardiovascular Target, NY, USA). Basically, the kit includes donor and acceptor particles. Upon incubating donor and acceptor with 3 µl of human plasma PLTP mediates the transfer of fluorescent phospholipid, which is present in a self-quenched state when associated with the donor. The transfer is determined by the increase in fluorescence intensity as the fluorescent lipid is removed from the donor and transferred to the acceptor. The interassay coefficient of variation in PLTP activity was 3.3 ± 0.5%.

The linear range of PLTP activity in this assay was between 1 and 7 μl of plasma. Three freeze–thaw cycles of plasma did not influence the assay. The PLTP activity was analyzed concurrently in cases and controls, and the laboratory personnel was unaware of the individual group allocation.

C-reactive protein and serum lipoprotein levels were measured by standard methods used at the Institute of Clinical Chemistry and Laboratory Medicine, Johannes Gutenberg University, Mainz, Germany (Roche Diagnostics GmbH, Germany and Rolf Greiner GmbH, Germany).

Statistical Analysis

Continuous variables are presented as mean ± standard deviation, categorical variables in %. The distributions for serum concentrations of triglycerides, HDL-C and CRP were skewed and all analyses were calculated with log-transformed values; however, exponential values were presented. For all analyses log-transformed values of triglycerides, HDL-C and CRP for each group individually were used. Mean levels of variables were compared by ANOVA with post hoc analyses. Pearson's correlation coefficient was used to perform correlation analysis. All analyses were carried out using SPSS 11.5 (SAS Institute Inc., Cary, NC).

Results

Baseline Data

BMI and sex did not differ between insulin-treated diabetic patients and CHD patients and controls; however, the diabetics were older. As expected, active smokers were found more frequently among the controls than in the two patient groups, and medical treatment with statins, ACE inhibitors, β-blockers, diuretics, angiotensin-receptor—blockers, and classic risk factors were more often found in the two patient groups (Table 1). In 33 diabetics (66%) a history of coronary heart disease was known.

Pre- and Post-Prandial PLTP Activity, Total Cholesterol, HDL Cholesterol, Triglycerides, and CRP

As shown in Fig. 1a, at basal level, serum PLTP activity was significantly higher in CHD patients than in controls (71.0 ± 46.22 vs. 54.0 ± 33.8 pmol/μl/h, $P = 0.032$). This result confirmed our previous observations [6]. Furthermore, such a difference is also found when comparing CHD patients and insulin-treated diabetic patients (71.0 ± 46.2 vs. 46.6 ± 35.2 pmol/μl/h, $P = 0.007$).

Table 1 Baseline variables in healthy controls, patients with coronary heart disease, and patients with insulin-treated diabetes are shown. Continuous variables are presented as mean ± standard deviation (statistical comparison by ANOVA), categorical variables in % (statistical comparison by chi-square test)

	Controls	CHD patients	Diabetics
Age (years)	52.7 ± 11	55.5 ± 9	64.0 ± 8.7

Diuretics (%)	10	20	42

FH of CHD family history of coronary heart disease, *CHD* coronary heart disease, *Diabetics* patients with insulin-treated diabetes

To investigate the influence of potential confounders on group comparison of PLTP activity we adjusted the analysis regarding group comparisons of PLTP activity at baseline and found also in a regression analysis including the variables age, sex and BMI that PLTP at baseline was significantly different in the comparison of subgroups independent on these potential confounders ($P < 0.001$) as presented above.

Four hours after the high-fat meal, serum PLTP activity had more than doubled in both controls (134.0 ± 66.0 vs. 54.0 ± 33.8 pmol/μl/h, $P < 0.001$) and CHD patients (149.3 ± 81.3 vs. 71.0 + 46.22 pmol/μl/h; $P < 0.001$). In contrast, PLTP activity had only increased by 23% in diabetic patients and this effect was not statistically significant (62.1 ± 39.8 vs. 46.6 ± 35.2 pmol/μl/h, $P = 0.051$). Eight hours after the high-fat meal, serum PLTP activity was significantly decreased both in controls and CHD patients ($P < 0.001$ in both groups compared to 4 h after the meal), whereas in diabetics serum PLTP activity tended to increase as compared to measurements 4 h after the meal (72.3 ± 42.5 vs. 62.1 ± 39.8 pmol/μl/h, $P = 0.198$. In other words, postprandial serum PLTP activity was blunted in insulin-treated diabetes patients (see Fig. 1a).

We showed in an additional analysis that the prolonged increase of PLTP activity in insulin-treated diabetic patients during the study period could have been shown both in insulin-treated diabetic patients with or without known CHD (see Table 2). Interestingly, serum PLTP activity was not significantly increased in insulin-treated diabetic patients with known CHD in comparison to insulin-treated diabetic patients without known CHD, which is

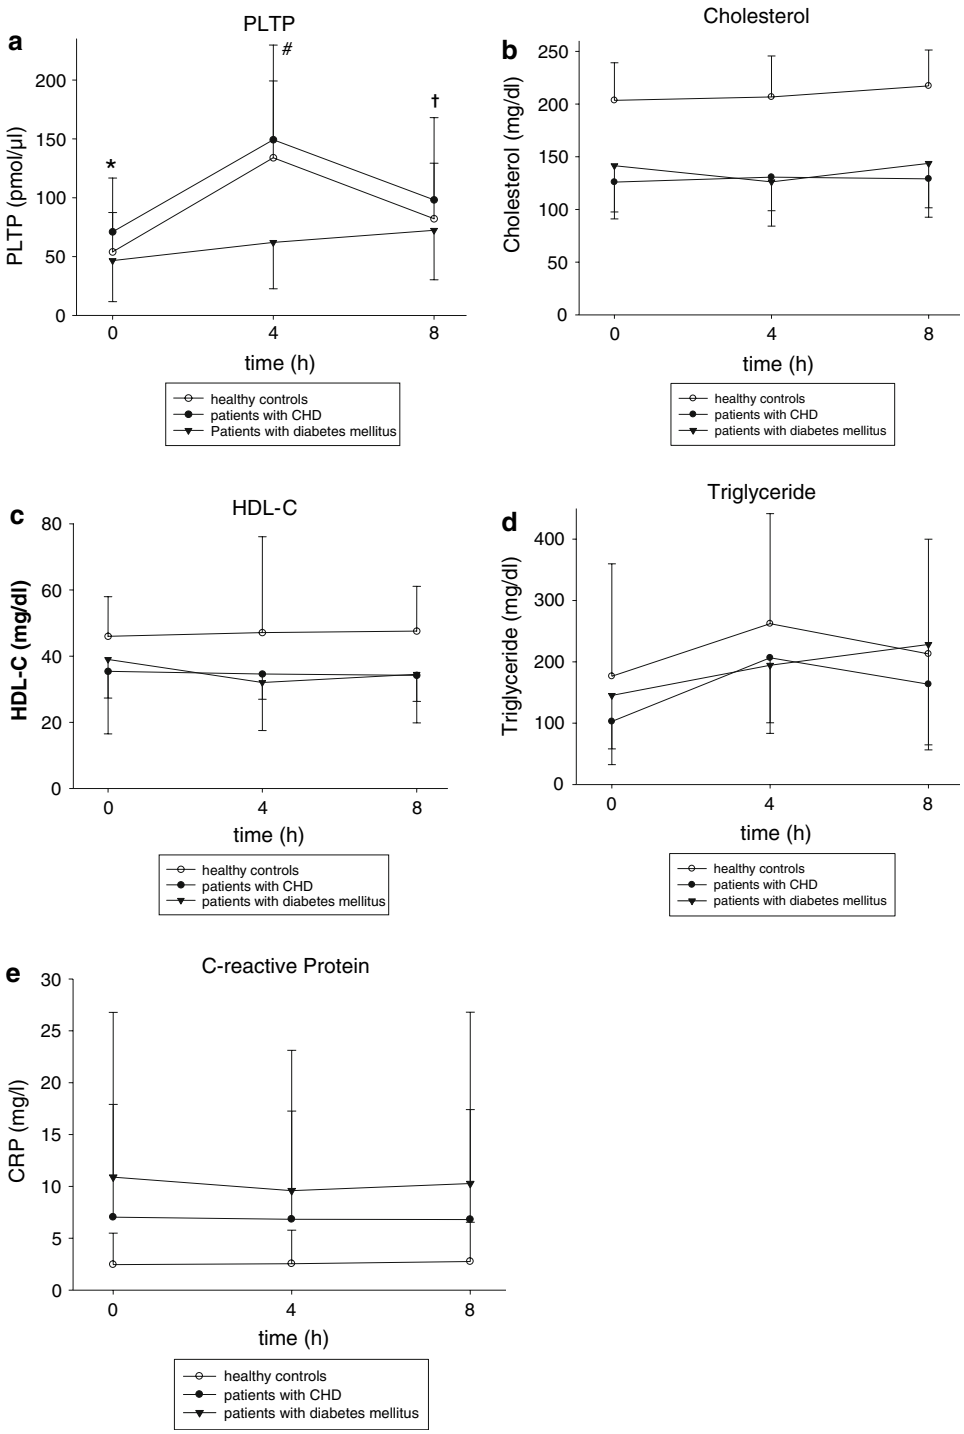

Fig. 1 Pre- and postprandial PLTP activity (**a**), total cholesterol (**b**), HDL cholesterol (**c**), triglyceride (**d**), and CRP (**e**) levels 4 and 8 h after intake of a high-fat meal as described in the material and methods section. All results are presented as mean ± standard deviation. **a** *Asterisk* CHD versus control $P = 0.032$. CHD versus insulin treated diabetic patients $P = 0.007$. *Hash* PLTP activity in CHD and control patients at 0 versus 4 h $P < 0.001$. *Dagger* PLTP activity in CHD and control patients at 4 versus 8 h $P < 0.001$. **b** Control vs. CHD and Control versus insulin treated diabetic patients $P < 0.05$ at 0, 4 and 8 h. **c** Control versus CHD and Control versus insulin treated diabetic patients $P < 0.05$ at 0, 4 and 8 h. **d**, **e** CHD versus control and insulin treated diabetic patients versus control $P < 0.05$ at 0, 4 and 8 h

in concordance with the increase of PLTP activity shown in CHD patients in comparison to insulin-treated diabetic patients in our study (see Table 2).

Next, we measured triglyceride levels, a well-known marker of postprandial lipoprotein catabolism. As expected, both controls and CHD patients showed a bell-shaped curve, indicating accumulation and clearance of postprandial lipoproteins in the circulation after a high-fat loading. To our surprise, such a curve did not exist in insulin-treated Type 2 diabetes patients (Fig. 1d). Like PLTP activity, triglyceride levels were continuously increased in the period of 8 h after the high-fat meal, suggesting that PLTP activity may be responsible for the clearance of postprandial lipoprotein clearance.

We also measured HDL cholesterol and total cholesterol levels. Here, no bell-shaped curve could be observed,

Table 2 Serum PLTP activity in comparison of insulin dependent diabetic patients with or without known CHD. Statistical comparison by *T* test

	PLTP0 pmol/μl/h, mean ± SD	PLTP4 pmol/μl/h, mean ± SD	PLTP8 pmol/μl/h, mean ± SD
Insulin dependent diabetics without known CHD ($n = 17$)	35.8 ± 37.7	47.6 ± 39.6	58.9 ± 38.6
Insulin dependent diabetics with known CHD ($n = 33$)	52.1 ± 33.0	69.1 ± 38.6	78.9 ± 43.4
P-value	0.121	0.076	0.124

0 fasting, *4* 4 h after a high-fat meal, *8* 8 h after a high-fat meal, *SD* standard deviation

which we also reported previously in another study [15]. Moreover, controls had significantly higher HDL cholesterol and total cholesterol levels at all time points than the patients in both groups (Fig. 1c, d all P-values < 0.05). We also measured CRP levels and found that CRP was significantly increased in both patient groups at all time points in comparison to healthy controls (Fig. 1e, all P-values < 0.05).

Correlation Analyses

Interestingly, PLTP was not correlated to triglycerides in any subject at any time point (all P-values > 0.05, data not presented). However, we found a significant association between fasting triglycerides and PLTP activity 8 h after the meal in diabetics or 4 h afterwards in CHD patients, but not in other subgroups (Table 3).

Glucose Levels

Glucose levels were measured in insulin-treated diabetic patients during the study period. We found at baseline a fasting glucose of 145.7 ± 29.7 mg/dl (mean ± SD). Then, glucose levels increased to its maximum 2 h after the meal (182.9 ± 42.0 mg/dl) and continuously decreased during the next 6 h (162.3 ± 58.9 mg/dl 4 h, 128.8 ± 43.9 mg/dl 6 h, 108.9 ± 33.3 mg/dl 8 h after the high fat meal, respectively).

Moreover, we found no significant correlation of PLTP with glucose levels at all time points. Correlations were: PLTP0-Gluc0: $r = -0.207$, $P = 0.222$, PLTP4-Gluc4: $r = -0.272$, $P = 0.094$, PLTP8-Gluc8: $r = -0.204$, $P = 0.213$.

Discussion

In the present study we confirmed our previous observation that plasma PLTP activity is significantly higher in CAD patients than in controls [6]. Furthermore, we demonstrated the following for the first time: (1) postprandial serum PLTP activity levels, like serum TG levels, show a bell-shaped curve with a peak at 4 h in healthy controls and CHD-patients; (2) in insulin-treated patients with diabetes mellitus, postprandial PLTP activity, with a linear line, was significantly lower than that in controls and CAD patients; and (3) postprandial PLTP activity correlates with serum TG levels 8 h after the high-fat meal in diabetic patients. Thus, we hypothesize that serum PLTP is involved in the clearance of postprandial lipoproteins, which is attenuated in insulin-treated Type 2 diabetes.

Table 3 Pearsons coefficients of correlation between PLTP activity and fasting triglycerides in all subgroups. For all analyses, log-transformed values of triglycerides were used

	PLTP0	PLTP4	PLTP8
Controls	$r = -0.231$	$r = 0.014$	$r = 0.088$
TRIGL0	$P = 0.118$	$P = 0.942$	$P = 0.655$
CHD patients	$r = 0.207$	$r = -0.293$	$r = -0.226$
TRIGL0	$P = 0.154$	$P = 0.041$*	$P = 0.123$
Diabetics	$r = 0.085$	$r = 0.071$	$r = -0.298$
TRIGL0	$P = 0.556$	$P = 0.631$	$P = 0.039$*

TRIG triglyceride, *0* fasting, *4* 4 h after a high-fat meal, *8* 8 h after a high-fat meal

*$P < 0.05$ was considered as significant

Based on our observation, serum PLTP activity levels have a typical postprandial rhythm after a high-fat loading, which is mainly affected by the predisposing metabolic conditions. However, our results are different from those published in two previous reports [16, 17], in which postprandial PLTP activity remained nearly unchanged. The obvious difference between the present study and the others is the size of the population. We included 150 persons, whereas not even 15 persons were included in the two previous studies. Moreover, in another study with healthy controls an infusion highly concentrated with triglycerides increased PLTP from 8 h to its maximum after 24 h [15], which may further underline the hypothesis of a regulatory effect of postprandial triglycerides on PLTP.

Furthermore, PLTP mediates the net transfer of phospholipids from apoB-containing particles (postprandial lipoproteins are a major part of them) to HDL, promotes transfer of phospholipids from VLDL and chylomicron into HDL-particles [18], and without PLTP activity HDL levels are dramatically reduced [18]. Thus, it is conceivable that

PLTP activity is necessary to catabolize postprandial lipoproteins.

Although the risk factors for atherosclerotic diseases are well established in diabetes mellitus [19, 20], we hypothesize that PLTP may represent an additional one in these patients.

In diabetes mellitus PLTP is considered to be a determinant of carotid intima-media thickness, an important prognostic marker for patients with CHD [21]. Furthermore, PLTP is increased in patients with impaired glucose tolerance, type II diabetes, and type I diabetes [10–14, 22, 23]. However, in the present study we could not confirm these observations. We found that PLTP activity was not different in diabetics in comparison to healthy controls (54.0 ± 33.8 vs. 46.6 ± 35.2 pmol/μl/h, $P = 0.339$) (Fig. 1a). This may be partly explained by the quiescent disease state predominant in our rehabilitation patients.

The topic of PLTP regulation has been discussed extensively. On the one hand, PLTP secretion may be up-regulated by glucose in vitro; on the other, plasma PLTP activity is decreased by exogenous hyperinsulinemia and glucose-induced hyperinsulinemia in vivo [14, 24, 25].

In our study PLTP increased in the subgroup of insulin-treated diabetics from the fasting state to 4 and 8 h after the meal, although insulin in an adapted dosage was subcutaneously administered before eating the high-fat meal. This means that all diabetics in our study had a peak glucose level accompanied by a peak insulin level approximately 1–2 h after the meal. Then, blood glucose levels decreased slightly in all patients, which was accompanied by a short peak after administering long-acting insulin and also followed by a slight decrease in plasma insulin levels until the end of the 8-hour study period without taking any other food. This underlines the hypothesis that PLTP is not regulated by hyperglycemia and hyperinsulinemia [26]; otherwise, we would expect the same increase in PLTP after 4 h followed by a decrease to 8 h in the diabetic patients that was found in nondiabetic CHD patients and healthy controls in our study.

This finding is supported by correlation analyses in the diabetic subgroup: we found no significant correlation of PLTP with glucose levels at all time points (see "Results" section). However, the interpretation of these data is limited by the fact that we didn't measured glucose in the other groups. On the other hand the different results of our and the previous studies regarding association of PTLP with glucose may be explained by different designs [14, 24–26].

In a subanalysis comparing the diabetics with unknown CHD with diabetics suffering from CHD, the increase of PLTP activity from baseline to 4 and 8 h after the high fat meal was found in both subgroups. Thus, increase of PLTP in the diabetic subgroup was independent on CHD.

Regulation of PLTP under physiological or pathophysiological conditions is still an open issue. As PLTP plays a key role in (postprandial) lipoprotein metabolism [27], other factors related to lipoprotein markers may regulate PLTP activity. Triglycerides are markers of proatherogenic postprandial remnant-like particles (RLP) [28]. Furthermore, it is well known that RLP receptors are downregulated in diabetics and atherosclerotic diseases [28], and in the present study triglycerides increased from fasting to 4 and 8 h after the high-fat meal in the diabetic subgroup; therefore, we hypothesize that serum PLTP activity is related to abnormal RLP metabolism. To confirm this hypothesis, we performed correlation analyses but we found no correlation between fasting triglycerides and PLTP in the total cohort or in healthy controls. However, we did find a significant and negative association between fasting triglycerides and postprandial PLTP activity after eight hours in diabetics ($r = -0.293$, $P = 0.041$) and postprandial PLTP activity after 4 h in CHD patients ($r = -0.298$, $P = 0.039$). Thus, we hypothesize that serum triglycerides and, as a consequence, RLP concentrations may be involved in PLTP regulation under atherosclerotic conditions, which is more prolonged in diabetics than in patients with CHD in our study. However, the negative correlations between PLTP activity and TG levels found in patient groups (at 0 and 8 h) reflects the known alteration of postprandial triglyceride lipolysis in patients with Type 2 diabetes mellitus and CHD rather than RLP clearance [29, 30].

In summary, our study suggests that PLTP is involved in postprandial lipoprotein clearance and this ability is diminished in insulin-treated diabetes. This phenomenon is possibly related to abnormal postprandial clearance of remnant-like particles in these patients.

Acknowledgments Part of this study was taken from the thesis of Kirsten Fingscheidt. The study was partially supported by National Institute of Health grant HL69817.

Abstract The composition of fatty acids in abdominal subcutaneous adipose tissue and the correlation of fatty acid values of plasma and erythrocytes had not been reported in Japan. The aim of the present study was to investigate the fatty acid composition and correlation of plasma and erythrocyte phospholipids (PL) and adipose triacylglycerols (TG) in 75 adult patients admitted for non-malignant diseases. We also examined the relationship of n-3 and n-6 polyunsaturated fatty acid (PUFA) with patients' characteristics. The total n-3 PUFA were 11.2, 11.8 and 1.9%, and the ratios of n-6/n-3 were 2.41, 1.87 and 8.20 in plasma and erythrocyte PL and adipose TG, respectively. There were the highest correlations for total n-3 PUFA and the n-6/n-3 ratio between plasma and erythrocyte PL and adipose TG. There was a positive correlation between n-3 PUFAs and age, but a negative correlation was found between n-6 PUFAs and age. There was no significant difference in the values of PUFAs in plasma and erythrocyte PL and adipose TG between men and women. The patients with cholesterol cholecystolithiasis showed a significantly lower proportion of eicosapentaenoic acid in plasma and erythrocyte PL than those of the other patients. Our findings suggest that PUFA in plasma and erythrocyte PL may be good biomarkers and more acceptable for studying participants than adipose TG.

Introduction

In Japan, dietary habits and lifestyle have changed greatly, and nutritionally related diseases are rapidly approaching the levels of Western countries [1–7]. A review of data published by the Japan Ministry of Health, Labour and Welfare for the national nutritional survey in Japan for the years between 1955 and 2004 [6] showed that the total energy intake had changed little. However, the intake of fat has been increasing markedly. In 1955, carbohydrates

accounted for nearly 80% of the total energy intake, but there has been a gradual decrease year by year, and the decrease in the percentage of energy from carbohydrates was balanced by an increase in the percentage of energy from fat intake. Furthermore, the components of dietary fat also changed in Japan between 1955 and 2004. The presence of sea foods rich in eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in the traditional Japanese diet helped to provide a diet with relatively low ratios of n-6 to n-3 polyunsaturated fatty acids (PUFAs). The fat intake from those sources has remained almost the same since 1955, while the intake of animal and vegetable fats rapidly increased up to 1975, with a further slow increase being evident from 1975 to 1995, and a relatively slow decrease afterward. Clearly, the increased fat intake in Japan has been due to the increased consumption of animal and vegetable fats, and not fish oil. This is an obvious reflection of the westernization of Japanese dietary habits, and it has had a negative impact. Dietary intake of fat is related to cardiovascular disease [4, 7, 8], obesity [9, 10] and some cancers [2, 3]. Greater emphasis has been placed on the potential health benefit of maintaining good nutritional practices.

The fatty acid composition of serum lipids has been considered a reliable index reflecting dietary intake of fatty acids over periods of weeks or months [11, 12]. The rate at which fatty acid changes occur in red blood cells is slower than that for plasma lipids [13, 14]. The fatty acid composition of subcutaneous adipose tissue changes much more slowly than that of the other lipid fractions, e.g., plasma lipids and the erythrocyte membrane. The individual level of fatty acid composition of adipose tissue is a valid index for the habitual dietary fatty acid composition over the preceding two and half years in free living adults [15, 16], and this means that subcutaneous adipose tissue biopsies can be particularly useful for studying the long-term effects of dietary fat quality [17]. However, taking blood samples is more acceptable to study patients than adipose tissue excision or aspiration, and fatty acid measurement in plasma or erythrocyte membrane lipids may be more feasible in large-scale epidemiological studies if plasma or red blood cells could be substituted for subcutaneous fat.

In Japan, there is a long history of eating fish, but the Japanese diet continues to become more westernized, especially among the younger generation. We therefore examined the fatty acid composition of these lipids and the association between plasma and erythrocyte phospholipid (PL) and abdominal subcutaneous adipose triacylglycerol (TG) in adults patients admitted for non-malignant diseases. We also examined the role of several personal characteristics (such as age, sex, BMI and patients with cholesterol gallstones etc.) in terms of fatty acid composition of plasma and erythrocyte PL and adipose TG.

Experimental Procedures

Subjects

Seventy-five adult patients who had been admitted for elective surgery to Kansai Medical University Hospital for non-malignant disease; 39 inguinal hernia, 28 cholesterol cholecystolithiasis, 6 abdominal aortic aneurysm, and 2 varicosis patients were entered into this study, of whom 48 were men and 27 were women. Patients with previously reported metabolically important disease (diabetes, hepatic or renal dysfunction, and those undergoing drug treatment for hyperlipidemia) were excluded. Body mass index (BMI) was calculated as weight in kilograms divided by the square of the height in meters.

The protocol was approved by the ethical committee of Kansai Medical University, and all study participants gave their informed consent for use of blood samples and subcutaneous fat for research purposes.

Fasting blood samples obtained after 12–14 h overnight fasting were collected and placed in plastic tubes containing EDTA as an anticoagulant, mixed, and centrifuged for 15 min at room temperature. Plasma and packed red blood cells were obtained from EDTA-anticoagulated blood. Plasma was then transferred to smaller tubes for storage at −80 °C until analysis. RBCs were washed twice with saline and frozen at −80 °C until analysis.

A fragment of adipose tissue was removed from abdominal subcutaneous fat during surgery. Each fragment was rinsed with saline, immediately frozen on dry ice and stored at −80 °C until analysis.

Fatty Acid Analysis

The fatty acid composition of the total phospholipid fraction of washed red blood cells and plasma was determined as follows: Total lipids were extracted by the method of Bligh and Dyer [18]. The total phospholipid fraction was separated by thin-layer chromatography and after transmethylation with HCL–methanol, the fatty acid composition was analyzed by gas chromatography (GC14A Shimadzu Corporation, Kyoto, Japan) with a capillary column DB-225 (0.25 mm, 30 m length id, 0.25 μm; J&M Scientific, Folsom, CA, USA). The column temperature was kept at 170 °C for the first 1 min, raised to 220 °C at a rate of 4 °C/min, and kept at this temperature for 22 min. The whole system was controlled with gas chromatography software, CLSS-GC10 ver. 1.3 (Shimadzu Corporation, Kyoto, Japan).

The fatty acid composition of the triacylglycerol fraction of subcutaneous adipose tissue was determined in a similar manner, except that the TG fraction separated by thin-layer chromatography was used. We adopted the area

percentage of each fatty acid in all detected fatty acids as a measurement value.

The laboratory was blind to the sample origin (disease, sex, age etc.).

Statistical Analysis

Data are expressed as means ± SD. Statistical analysis for the subject characteristics between sex and age groups was performed by the Mann–Whitney test. The correlation for some PUFAs between plasma and erythrocyte PL and adipose TG was calculated using Spearman's method. Univariate regression and multivariate analyses were performed to assess the relationship between plasma PL EPA + DHA, erythrocyte PL EPA + DHA and adipose TG EPA + DHA and characteristics (age and BMI) of participants. Associations between plasma PL linoleic acid (LA) + arachidonic acid (ARA), erythrocyte PL LA + AA and adipose TG LA + AA and some characteristics of the subjects were also analyzed in the same way. In the case of multivariate analysis, age and BMI were included into the calculation as independent predictors. The association of the area percentage of PUFAs for plasma and erythrocyte PL and adipose TG in men and women was analyzed by the ratio test. All statistical analyses were performed with JMP 2005 by the SAS institute Inc., Cary, NC., USA. Significance was taken as $P < 0.05$.

Results

Subjects

The mean age of the men was 58 years (range 27–81 years) and that of the women 58 years (range 33–74 years). The mean BMI value of patients was 23.3 ± 3.7 (range 16.5–37.8). There were no significant differences in the number of the patients and BMI between sex and age groups. Characteristics of the study subjects and body mass indices are shown in Table 1.

Table 1 Characteristics of study subjects

Age (years)	Male		Female	
	n	BMI	*n*	BMI
≤49	14	24.0 ± 4.4[a]	5	21.1 ± 3.1
50–69	22	22.4 ± 2.7	17	25.1 ± 4.5
≥70	12	22.1 ± 2.5	5	24.3 ± 3.6
	48	22.8 ± 3.3	27	24.2 ± 4.3

[a] All values are expressed as means ± SD. *BMI* Body mass index (kg/m^2)

There were no significant difference in the number of the patients and BMI between sex and age groups

Fatty Acid Analysis

The mean fatty acid compositions of plasma and erythrocyte PL and adipose TG fractions are presented in Table 2. In plasma and erythrocyte PL fractions, the greatest proportion of fatty acids was saturated fatty acids, 47.7 ± 1.4 and 45.1 ± 1.4%, respectively, followed by polyunsaturated ones (38.2 ± 1.5 and 33.9 ± 1.4%, respectively). However, in adipose TG fraction the highest proportion of fatty acids was monounsaturated (53.2%), followed by saturated (29.6%) and polyunsaturated fatty acids (17.2%). Palmitic acid (16:0) had the highest proportion of all fatty acids in plasma and erythrocyte PL fraction, and oleic acid (18:1n-9) had the highest in adipose TG fraction. Among PUFA, linoleic acid (LA 18:2n-6, 16.3%), arachidonic acid (AA 20:4n-6, 10.5%) and LA (18:2n-6, 14.2%) accounted for the greatest proportions in plasma PL, erythrocyte PL and adipose TG fractions, respectively. The total n-6 fatty acids were 27.0, 22.1 and 15.3% in plasma PL, erythrocyte PL and adipose TG fractions, respectively. As for the total n-3 fatty acids, they were 11.2, 11.8, and 1.9% in plasma PL, erythrocyte PL and adipose TG fractions, respectively. The ratios of n-6/n-3 were 2.4, 1.9 and 8.2 in plasma PL, erythrocyte PL and adipose TG fractions, respectively.

Fatty Acid Analysis for Cholesterol Gallstone Patients

The fatty acid composition of plasma and erythrocyte PL and adipose TG fractions was compared between the patients with cholesterol cholecystolithiasis and those with inguinal hernia or varicosis. The proportion of plasma PL EPA was 2.0 ± 0.9 and 2.8 ± 1.7 in cholesterol gallstone patients and other patients, respectively ($P < 0.05$). The EPA proportion in the erythrocyte PL fraction was 1.6 ± 0.6 and 2.1 ± 0.9 in cholesterol gallstone patients and the other patients, respectively ($P < 0.001$). However, there were no differences in the EPA proportion in adipose TG fraction in either group. There were no particular differences in the other fatty acids between the groups.

Correlations of Fatty Acid Profile in Plasma and the Erythrocyte PL and Adipose TG Fraction

Significant positive correlations were found for several fatty acids. The correlations were highest for EPA in all three types of comparison. A strong significant positive correlation was found for nearly all PUFAs; LA ($r = 0.81$, $P < 0.001$), AA ($r = 0.74$, $P < 0.001$), EPA ($r = 0.84$, $P < 0.001$), DHA ($r = 0.74$, $P < 0.001$) and total saturated fatty acids in a comparison between plasma and erythrocyte

Table 2 Fatty acid composition of plasma and erythrocyte phospholipids and adipose triacylglycerols

Fatty acid	Plasma phospholipids	Erythrocyte phospholipids	Adipose triacylglycerols
Saturated			
16:0	29.8 ± 1.5	24.6 ± 1.4	21.8 ± 2.2

Total saturated[c]	47.7 ± 1.4	45.1 ± 1.4	29.6 ± 2.9

All values are expressed as means ± SD

AA arachidonic acid, *EPA* eicosapentaenoic acid, *DHA* docosahexaenoic acid, *LA* linoleic acid, *PUFA* polyunsaturated fatty acid

[a] Total n-6 is the sum of 18:2n-6, 18:3n-6, 20:3n-6, 20:4n-6, 22:4n-6 and 22:5n-6

[b] Total n-3 is the sum of 18:3n-3, 20:5n-3, 22:5n-3 and 22:6n-3

[c] Total saturated is the sum of 16:0, 18:0, 20:0, 22:0 and 24:0

PL fractions. In a comparison between erythrocyte PL and adipose TG fractions, correlation coefficients were weak or absent for LA (18:2n-6), AA (20:4n-6), DHA (22:6n-3) and saturated fatty acids. Likewise, in a comparison between plasma PL and adipose TG fractions, significant positive correlations were found only for EPA ($r = 0.57$, $P < 0.001$), AA ($r = 0.32$, $P < 0.001$) and LA ($r = 0.27$, $P < 0.05$), but not for DHA or saturated fatty acids. The highest correlations in all three types of comparison were found for the total n-3 fatty acids, the ratio of n-6/n-3 and EPA/PUFA.

Differences in Fatty Acid Composition Due to Sex

The differences in the values of PUFAs in plasma and erythrocyte PL and adipose TG fractions due to sex are shown in Fig. 1. There was no significant difference in the values of PUFAs in plasma and erythrocyte PL and adipose TG fractions between men and women.

Changes in PUFAs with Age

Univariate and multivariate analyses of EPA + DHA in plasma and erythrocyte PL and adipose TG fractions and age are shown in Table 3. Those of LA + AA are shown in Table 4. There was a significantly positive correlation between EPA + DHA in plasma and erythrocyte PL fractions and age, but not n-3 PUFA in the adipose TG fraction and age on both univariate and multivariate analyses, respectively. LA + AA in plasma and erythrocyte PL fractions showed a significant inverse correlation with age, but not between those in the adipose TG fraction and age.

Correlations Between EPA + DHA, and Age and BMI

Univariate and multivariate analyses of EPA + DHA values, and age and BMI are shown in Table 3. There were significantly positive correlations between EPA + DHA in the plasma and erythrocyte PL fractions and age. No significant correlations were found between EPA + DHA and BMI.

Correlations Between LA + AA, and Age and BMI

Univariate and multivariate analyses of LA + AA values, and age and BMI are shown in Table 4. LA + AA values in both PL fractions were inversely correlated with age. Those values in the plasma PL fraction were also inversely correlated with BMI. Otherwise no correlations were found

Discussion

Because monounsaturated and saturated fatty acids are endogenously synthesized, their proportions are not expected to represent the proportion of dietary fatty acids, but at least the essential fatty acids in plasma [19–22], the erythrocyte membrane [22, 23] and adipose tissue [23–26] provide useful information on fatty acid intake. James et al. [27] investigated the relationship between dietary linoleic

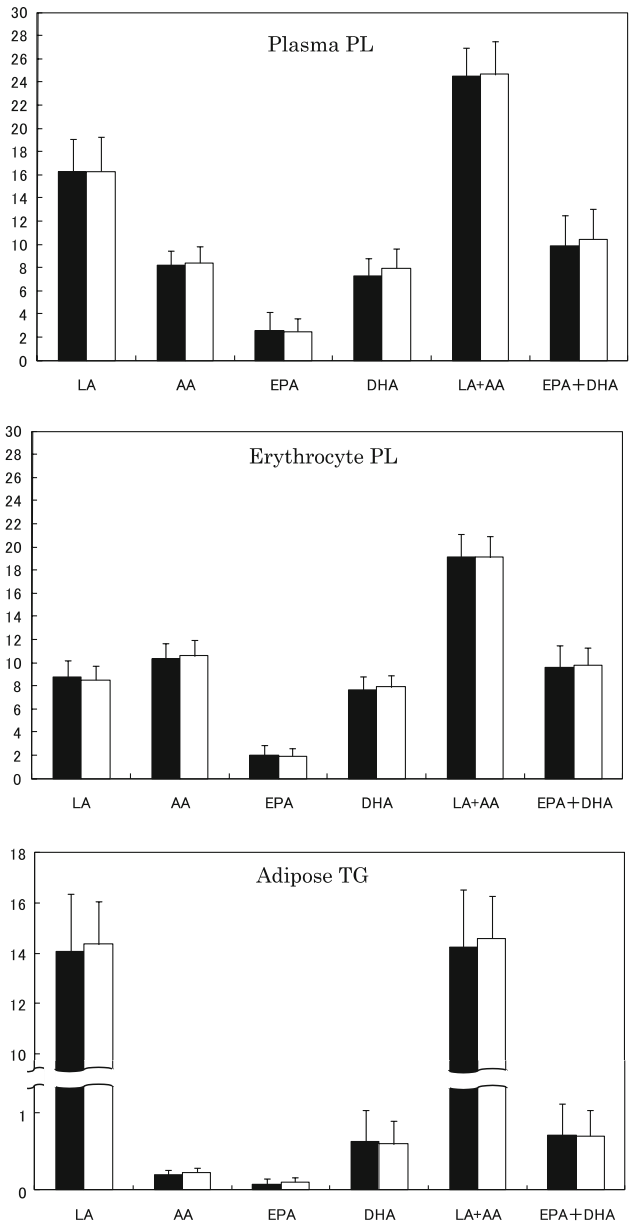

Fig. 1 Area percentage contents of some PUFA for plasma and erythrocyte PL and adipose TG in men and women. *LA* linoleic acid, *AA* arachidonic acid, *EPA* eicosapentaenoic acid, *DHA* docosahexaenoic acid, *PL* phospholipid, *TG* triacylglycerol. *Men* closed columns, *women* open columns. All values are expressed as means ± SD and *bars* indicate one SD. Statistical analysis were done using the ratio test. There were no significant difference between men and women in the values of PUFAs of plasma and erythrocyte PL and adipose TG fractions

acid intake of 2.5–17.5% of energy and the tissue concentration of arachidonic acid in healthy male volunteers. They found a positive linear relationship between dietary LA and the LA concentration in neutrophil phospholipids, plasma triacylglycerols, and plasma cholesteryl esters. By contrast, differences in dietary LA within a broad range were not associated with differences in concentrations of AA in those neutrophil and plasma fractions. They also investigated the effects of n-3 PUFA on AA concentration in neutrophil and plasma PL. The AA concentrations in neutrophil and plasma PL were lowered by 17.6 and 18.1% on supplementation of the diet with 4 g fish oil (1.6 g EPA, 0.3 g DHA), respectively. They concluded that a reduction in dietary linoleic acid by using standard dietary strategies is not likely to lead to a reduction in tissue AA, whereas this can be accomplished by EPA-rich fish-oil supplementation. On the other hand, Harris et al. [28] reported the effects of 16 weeks' intake of fish or fish-oil capsules on the fatty acid composition of erythrocyte and plasma phospholipids. They found that DHA-rich fish oil from either oily fish or fish-oil capsules enriched blood lipids with n-3 fatty acids, but that arachidonic acid concentrations decreased in plasma phospholipids only by 6–7% during the first month, and did not change noticeably thereafter or in erythrocytes at any time. In Japan the average intakes of EPA and DHA are about 0.4 and 0.7 g per day, respectively [29]. Although we did not measure fatty acid intake, considerable intake of EPA in our subjects appeared to affect AA contents in both erythrocyte and plasma PL fractions. This is why we found a very significant correlation in AA values between erythrocyte and plasma PL fractions ($r = 0.74$).

Recently, Beydoun et al. [30] reported the fatty acid composition of plasma phospholipids in 2,251 adults aged 50–65 years in the USA. The percentage of women and age distribution of the subjects were similar to those of our study. Comparing their data with our results, the proportion of total saturated fatty acids, oleic acid, the highest proportion in monounsaturated fatty acids and total unsaturated fatty acids were essentially the same. However, the proportions of n-3 and n-6 fatty acids in plasma phospholipids were very different. Total n-6 PUFA, LA and AA values in their study were 1.4 times, 1.4 times and 1.3 times higher than ours, respectively. Total n-3 PUFA, alpha-linolenate EPA and DHA values in our subjects were 3.1 times, 2.6 times, 4.4 times and 2.6 times higher, respectively, than theirs. The Japanese diet has become more westernized, but Japanese still consume more fish than Western countries such as the USA where the median EPA and DHA intake is 0.25 g per day [31].

Hodson et al. [32] calculated the mean values of 13 fatty acids in various blood fatty acid fractions using 9–19 studies in Western countries. The mean fatty acid composition of adipose tissue was surprisingly similar to our data. The n-3 fatty acids do not accumulate in the adipose tissue, probably because those fatty acids are too "soft" (non-viscous) [33] to keep the adipose tissue more or less solid. A very small accumulation of n-3 fatty acids in the adipose

LA + AA is the area percentage of LA and AA in the total PL fraction in plasma and erythrocyte, and total TG fraction in subcutaneous adipose tissue

AA arachidonic acid, *BMI* body mass index (kg/m^2), *LA* linoleic acid, *PL* phospholipid, *TG* triacylglycerol

tissue in our Japanese subjects appeared to exert no sizable competitive effects on n-6 PUFA value. As expected, in the plasma and erythrocyte PL fractions, increased n-3 fatty acids and decreased n-6 fatty acids were found in our subjects compared with those of Hodson et al. [32].

Cholesterol gallstone disease is a common disease in western countries and also in Japan. A number of dietary factors are involved in the pathogenesis of cholesterol cholelithiasis [34, 35]. It has been reported that populations consuming a diet rich in n-3 FUPA exhibit a low incidence of cholesterol cholelithiasis [36]. In our study, the patients with cholesterol gallstones showed a significantly lower level of EPA in the plasma and erythrocyte PL fraction than those in the other patients.

Concerning sex-related differences in fatty acid composition, a higher proportion of LA and DHA in subcutaneous adipose tissue was reported in Scottish women than in Scottish men [37]. Similar results were also found in serum in middle-aged Finnish [38] and Dutch (>20 years younger than our subjects) [39] subjects. In the present study, there were no significant differences between men and women in any PUFAs of the plasma and erythrocyte PL and adipose TG fractions. Similarly, no sex difference in long chain n-3 PUFAs in serum among over 1,200 Japanese subjects aged 40–79 years was reported [40]. These differences among various studies may be due to differences in hormonal balance, age, dietary intake or disease status.

In the present study, age was positively correlated with n-3 PUFAs in the plasma and erythrocyte PL and adipose TG fractions, but negatively correlated with n-6 FUFAs, especially in the plasma and erythrocyte PL fractions. Itomura et al. [41] investigated the factors influencing EPA + DHA levels in the erythrocyte PL fraction in Japan. They found a significant positive relationship between EPA + DHA in erythrocytes and dietary EPA + DHA %, and also a significant positive relationship between EPA + DHA in the erythrocyte PL fraction and age. Furthermore, in a national nutrition survey in Japan [42], a positive correlation between n-3 PUFAs intake and age was reported, while a negative correlation between n-6 PUFAs intake and age was also reported. Consequently, these correlations were mainly explained by dietary factors.

Not many fatty acid values correlated with BMI in our measured fractions, as reported by Itomura et al. [41]. However, n-3 PUFAs were found to be negatively associated with obesity in Australia [43]. In the Australian study, the exclusion criteria for participation induced consumption of fish-oil supplements and consumption of more than two fatty fish meals per week. On the other hand, almost 60% of people in Japan eat fresh fish more than 3 times per week [40]. Furthermore, there was a big difference in average BMIs between the two studies' subjects. These might explain the different results.

The relationship between types of fat intake and BMI were investigated in Spain [44]. It was reported that energy from fat does not play an important role in the development of obesity. On the other hand, the Nurses' Health Study Cohort showed that dietary lipids other than vegetable fat were positively associated with BMI, and vegetable fat was inversely related to BMI [45]. Waresjo et al. [46] investigated the relationship between the fatty acid composition of serum cholesteryl esters and obesity. They found a positive and significant association between BMI and 20:4n-6 and 20:5n-3, and a strong and inverse association of LA. Taking into consideration that fish oils reduced obesity in rats but had no effects in humans [47], the positive relationship between EPA and BMI was surprising. In our study, an inverse correlation was found between LA + AA in the plasma PL fraction and BMI. The reason for this is not clear.

Adipose tissue PUFA may best reflect the long-term PUFA composition in the diet, but is rarely used as a biomarker because of the invasive sample collection protocol. In our study, PUFAs showed significant and strong correlations between the plasma and erythrocyte PL and adipose TG fractions.

In conclusion, our findings suggest that PUFA in plasma and erythrocyte PL may be a good biomarker and a more acceptable method to study participants than adipose tissue TG.

Acknowledgments We thank all the participants in this study and the staff at the Hematological Examination Section, Central Laboratory for Clinical Investigation, Kansai Medical University Hospital for expert laboratory assistance. We are grateful to Ms. Hiroko Hamatani (University of Toyama) and Ms. Shizuko Takebe (University of Toyama) for their technical assistance in fatty acid analysis.

DGAT1, DGAT2 and *PDAT* Expression in Seeds and Other Tissues of Epoxy and Hydroxy Fatty Acid Accumulating Plants

Runzhi Li · Keshun Yu · David F. Hildebrand

Received: 12 December 2008 / Accepted: 1 January 2010 / Published online: 27 January 2010

Abstract Triacylglycerol (TAG) is the main storage lipid in plants. Acyl-CoA: diacylglycerol acyltransferase (DGAT1 and DGAT2) and phospholipid: diacylglycerol acyltransferase (PDAT) can catalyze TAG synthesis. It is unclear how these three independent genes are regulated in developing seeds, and particularly if they have specific functions in the high accumulation of unusual fatty acids in seed oil. The expression patterns of *DGAT1*, *DGAT2* and a *PDAT* in relation to the accumulation of oil and epoxy and hydroxy fatty acids in developing seeds of the plant species *Vernonia galamensis*, *Euphorbia lagascae*, *Stokesia laevis* and castor that accumulate high levels of these fatty acids in comparison with soybean and *Arabidopsis* were investigated. The expression patterns of *DGAT1, DGAT2* and the *PDAT* are consistent with all three enzymes playing a role in the high epoxy or hydroxy fatty acid accumulation in developing seeds of these plants. *PDAT* and *DGAT2* transcript levels are present at much higher levels in developing seeds of epoxy and hydroxy fatty acid accumulating plants than in soybeans or *Arabidopsis*. Moreover, *PDAT, DGAT1* and *DGAT2* are found to be expressed in many different plant tissues, suggesting that these enzymes may have other roles in addition to seed oil accumulation. *DGAT1* appears to be a major enzyme for seed oil accumulation at least in *Arabidopsis* and soybeans. For the epoxy and hydroxy fatty acid accumulating plants, *DGAT2* and *PDAT* also show expression patterns consistent with a role in the selective accumulation of these unusual fatty acids in seed oil.

Keywords *Vernonia galamensis* · *Stokesia laevis* · *Euphorbia lagascae* · Castor (*Ricinus communis*) · *Arabidopsis thaliana* · Soybean · Diacylglycerol acyltransferase · Phospholipid: diacylglycerol acyltransferase · Epoxy and hydroxy fatty acids · Oil accumulation · Seed development

Introduction

Seed oils are an important source of fatty acids for human nutrition and hydrocarbon chains for industrial products.

Most seed oils of plants such as soybean, canola, sunflower, oil palm and maize are stored largely in the form of triacylglycerol (TAG), as the major carbon and energy reserve [1]. TAG in common oilseeds is predominantly composed of five fatty acids, the saturated palmitic (C16:0) and stearic (C18:0) acids, monounsaturated oleic acid (C18:1), the polyunsaturated linoleic (C18:2) and α-linolenic (C18:3) acids. However, a very large diversity of fatty acids exists in the reserve TAG of seeds. A number of plant species have been found to contain high levels of unusual fatty acids such as hydroxy, epoxy and acetylenic fatty acids [2]. For example, castor (*Ricinus communis*) oil is as much as 90% ricinoleate, a hydroxy fatty acid (12-hydroxy-octadec-*cis*-9-enoic acid). The seed oils from *Vernonia galamensis*, *Euphorbia lagascae* and *Stokesia laevis* can accumulate 60–80% of an epoxy fatty acid known as vernolic acid (*cis*-12-epoxyoctadeca-*cis*-9-enoic acid) [3–6]. These unusual fatty acids have properties that make them valuable as renewable raw materials for the chemical industry, being used in making plastics, paints, other coatings, adhesives and composites.

The synthesis of TAG and the high accumulation of a single unusual fatty acid in seed oils have attracted considerable interest, both in functional and applied areas of plant biology. In seeds, TAG biosynthesis occurs in certain membranes of the endoplasmic reticulum (ER) and accumulates in oil bodies, which are generated through budding of the outer ER membrane [7]. TAGs are synthesized by the enzymes of the Kennedy pathway, which sequentially transfer acyl chains from acyl-CoAs to *sn*-1, -2 and -3 positions of a glycerol backbone [8]. Acyl-CoA: diacylglycerol acyltransferase (DGAT; EC 2.3.1.20), a transmembrane enzyme, functions in the final step of the pathway by catalyzing the acylation of *sn*-1,2-diacylglycerol (DAG) at the *sn*-3 position using an acyl-CoA substrate. DGAT has been proposed to be the rate-limiting enzyme in plant storage lipid accumulation [9, 10]. It was discovered that many organisms have two distinct classes of DGATs with no homology to each other, designated DGAT1 and DGAT2 [11–14] and a third soluble DGAT has also been described [15]. Genes encoding DGAT1 have been cloned and characterized from several plant species [16–19]. In addition to DGAT, another mechanism of TAG synthesis has been recently reported in plants and yeast [20, 21]. This is an acyl-CoA independent reaction where a phospholipid such as phosphatidylcholine or phosphatidylethanolamine can donate its *sn*-2 acyl group to DAG, resulting in the formation of TAG. This transacylase activity is termed phospholipid: diacylglycerol acyltransferase (PDAT; E.C.2.3.1.158). *PDAT* genes have also been isolated and identified in plants [22, 23].

Although the current literature shows that DGAT1, DGAT2 and PDAT, encoded by three separate gene families, are all capable of catalyzing the final acylation step during TAG synthesis, it remains poorly understood as to how they contribute to the overall accumulation of TAG in seed oils and how they are regulated in developing seeds. The specific functions of DGAT1, DGAT2 and PDAT in the high accumulation of unusual fatty acids such as epoxy and hydroxyl fatty acids in seed oils are only recently beginning to be elucidated and recent studies indicate an important role for DGAT2. In 2006 [24] reported that DGAT2 appeared to be of importance in castor oil biosynthesis and [25] presented good evidence that DGAT2 may be involved in the selective accumulation of the unusual fatty acid, eleostearic acid, in tung (*Vernicia fordii*) oil. Subsequently [26] showed that castor DGAT2 can nearly double hydroxy fatty acid accumulation in *Arabidopsis* seeds (from ~17 to ~30%) co-expressing this gene along with the castor hydroxylase compared to the hydroxylase gene alone.

In the present paper, we report our studies on transcript levels of *DGAT1, DGAT2* and *PDAT* expression during the seed development of *Vernonia galamensis*, *Euphorbia lagascae*, *Stokesia laevis,* castor (*Ricinus communis*), soybeans (*Glycine max* cv. Jack) and *Arabidopsis.* We also examined the correlation between these three gene expression patterns and oil/target fatty acid accumulation in the seeds. Our current data suggest that DGAT2 and PDAT play important roles in epoxy and hydroxy fatty acid accumulation in seed oils of source plants, although DGAT1 appears to be a major enzyme for oil accumulation in all the plants studied, especially soybean and *Arabidopsis*.

Materials and Methods

Plant Materials

Developing seed samples were collected from both the source plants and common oilseed plants. The source plants included *Vernonia galamensis, Euphorbia lagascae, Stokesia laevis* and castor (*Ricinus communis*), which can accumulate high levels of epoxy and hydroxy fatty acids in their seed oils. Soybean and *Arabidopsis thaliana* represent a common oilseed and a model plant for comparison in this study. *Arabidopsis* plants were grown in a growth chamber under a 16 h light 20 °C/8 h dark 15 °C cycle. *Euphorbia*, castor and soybean plants were grown in a greenhouse at 16/8 day/night and 25/21 °C. *Vernonia* and *Stokesia* plants were grown in outdoor plots in Lexington, KY.

Dicot embryogenesis is divided into five general stages: globular, heart, cotyledon, maturation, and dormancy [27–30]. In this study, we focused on cotyledon to maturation stages and further classified them based on six different developmental phases, including: days after flowering (DAF), seed size (length), seed coat color, fresh weight and other morphological traits of seeds. Simply, the days after

Table 1 Classification of 6 different stages of the developing seeds. The numbers indicate days after flowering (DAF) and single seed fresh weight (wt), DAF/seed (wt)

Species	Stage 1	Stage 2	Stage 3	Stage 4	Stage 5	Stage 6

For *Arabidopsis*, the seed weight was not measured

flowering/pollination, which represent each developmental stage of the tested plant seeds, are listed in Table 1.

Northern Blots

Total RNA was isolated from roots, stems, leaves, young developing embryos (between stage 1 and 3) and mid-late maturation seeds (between stage 3 and 4) of all the test plants. The Trizol reagent was used for this isolation according to manufacturer's instructions (Invitrogen). Based on the alignment of the known sequences for each *DGAT1*, *DGAT2* and *PDAT* gene, a conserved region was identified for each gene. Then, conserved regions of *Arabidopsis DGAT1* (At2g19450), *DGAT2* (At3g51520) and *PDAT* (At5g13640) cDNAs were amplified and labeled with digoxigenin (DIG)-UPT by a PCR DIG Probe Synthesis Kit (Roche Applied Science). RNA was separated on 1% denaturing formaldehyde gel and transferred onto a Zeta-Probe Blotting Membrane (Bio-Rad Laboratories). Equalized loading of RNA was checked by ethidium bromide staining of rRNAs. The hybridization was performed at 60 °C overnight using the DIG Easy Hyb kit (Roche Applied Science). The final washing step was performed at 65 °C in 0.1 × SSC and 0.1% SDS under constant agitation. The hybridized mRNA was detected with alkaline phosphatase conjugated anti-DIG antibody (Roche Applied Science) and its chemiluminescent substrate, CDP-Star (Roche Applied science), following the manufacturer's protocol.

Real-Time PCR Quantification

Total RNA was extracted from the developing seeds at six developmental stages using the methods described above. After extraction, RNA samples were treated with DNaseI (Promega Co.) to remove contaminating DNA. First-strand cDNA was synthesized with the SuperScript II RT kit (Invitrogen), using equal amounts of oligo (dT) and random primers, according to the manufacturer's instructions. All Real-time reactions were performed in an iCycler iQ detection system (Bio-Rad) using the intercalation dye SYBR Green I master mix kit (Applied Biosystems) as a fluorescent reporter.

PCR reactions were performed in triplicate in 25-μL volumes using 1 μL of each forward and reverse primers (500 nM), 12.5 μL of SYBR green master mix, 5 μL of a 1:10 (v/v) dilution of cDNA and 5.5 μL of DEPC treated water. Reactions were performed in MicroAmp 96-well plates (Applied Biosystems) covered with optical adhesive covers (Applied Biosystems). The following program was applied: initial polymerase activation at 95 °C for 10 min; then a two-temperature thermal cycle consisting of denaturation at 95 °C for 15 s, followed by anneal extension at 60 °C for 1 min, totally 40 cycles.

The quantification of PCR products was performed via a calibration curve procedure using 18S RNA as an internal standard. PCR products were analyzed using melting curves as well as agarose gel electrophoresis to ensure single product amplification. The ratio of gene-specific expression to 18S signal was defined as relative expression. PCR controls were performed in the absence of added reverse transcriptase to ensure RNA samples were free of DNA contamination. Primers for specific amplification of each cDNA were designed using the Primer Express software (Applied Biosystems), taking into account criteria such as product length (around 500 bp), optimal PCR annealing temperature, and likelihood of primer self-annealing (Table 2).

Fatty Acid Analysis

Seed samples collected at the six different development stages were frozen in liquid N_2, stored at −80 °C and then

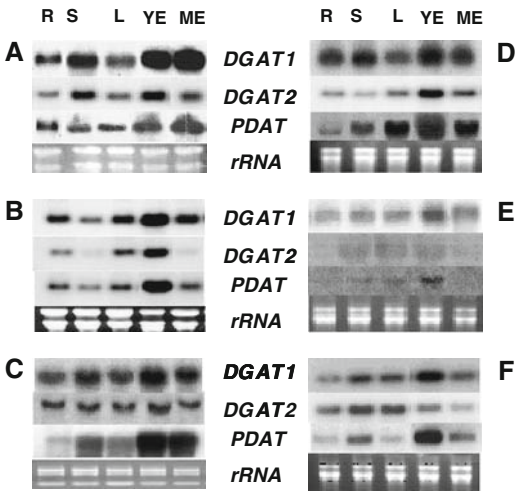

Fig. 1 Northern blot analysis of *DGAT1, DGAT2* and *PDAT* expression in different tissues of plants. Total RNA was extracted from root (*R*), stem (*S*), leaf (*L*), young developing embryo (*YE*) and early maturing seed (*ME*). Total RNA (15 μg) was loaded for Northern blot and hybridized separately to the DIG-labeled cDNA probes of *DGAT1, DGAT2* and *PDAT*. Ethidium bromide staining (*lowest panel*) is shown for equalized loading. The figure shows results typical of those obtained in three independent experiments. **a** *Vernonia galamensis*, **b** *Euphorbia lagascae*, **c** *Stokesia laevis*, **d** Castor (*Ricinus communis*), **e** Soybean (*Glycine max*) (cv. Jack), **f** *Arabidopsis thaliana*. In **a**, the same membrane was used for the blotting (exposure for 5–5 min 15 s), and the same was in **b**. In **d**, DGAT1 and PDAT blots were performed using the same membrane (exposure for 5 min 30 s), and DGAT2 using another membrane (exposed for 5 min). In **e**, the same membrane was used for DGAT2 (exposure for 5 min 30 s) and PDAT (exposure for 6 min), but another membrane for DGAT1 (exposure for 5 min). In **f**, a membrane was used for DGAT1 (5 min exposure), and another membrane for both DGAT2 and PDAT (5 min 20 s exposure)

lyophilized. Weighed samples were transferred the samples to glass test tubes containing 0.5 mL of sodium methoxide after addition of tri-heptadecanoin (tri-17:0) (25 μg/mg in chloroform) as a standard. The seed samples were finely ground and the samples incubated for at least 15 min with shaking. 0.5 mL of isooctane containing 0.001% BHT was added to each tube and mixed well. Phase separation was obtained with centrifugation. The top layer was extracted and transferred into GC auto-sampler vials. The fatty acid methyl esters were analyzed with gas chromatography on a Varian CP-3800 GC with a 24 m × 0.25 mm ID CP-Select CB for FAME (http://www.varianinc.com/cgi-bin/nav?products/consum/gccolumns/select/selfame&cid=KLOJINIPFP) fused silica column with a 0.25 μm film thickness. The temperature program was 90 °C for 1 min., then to 155 °C at 20 °C/min. with no hold, then to 175 °C at 3.6 °C/min. with no hold and finally to 250 °C at 12 °C/min. holding for one min. The areas for each fatty acid including tri-17:0 standard was collected and then used to calculate total oil content (μg/mg) and each fatty acid level (% total fatty acids).

Results

Expression of *DGAT1, DGAT2* and *PDAT* in Different Plant Tissues

To obtain information about the expression patterns of *DGAT1, DGAT2* and *PDAT* genes through a range of tissue types, total RNA was isolated from root, stem, leaf, young developing embryos (between stage 2 and 3) and early maturing seeds (between stage 3 and 4). Northern blot was performed using the conserved regions of *Arabidopsis DGAT1, DGAT2* and *PDAT* cDNA as probes. All three genes were highly expressed in young developing embryos and/or early maturing seeds from the tested epoxy and hydroxy fatty acid accumulating plant species (*Vernonia galamensis*, *Euphorbia lagascae*, *Stokesia laevis* and castor) although they showed variable expression in root, stem and leaf tissues (Fig. 1a–d). For soybeans (Fig. 1e), a common oil crop, stronger expression of *DGAT1* was found in developing seeds (between stage 2 and 4) compared to the level in other tissues. The weak expression of *DGAT2* and *PDAT* was present in stem, leaf and young developing embryos (between stage 2 and 3). No *DGAT2* and *PDAT* transcript was detected in roots, and only trace signals were found in the late maturing seeds (between stage 3 and 4). In *Arabidopsis* (Fig. 1f), a model plant, both *DGAT1* and *PDAT* were clearly expressed in all tissues tested, although their levels were slightly higher in young developing seeds

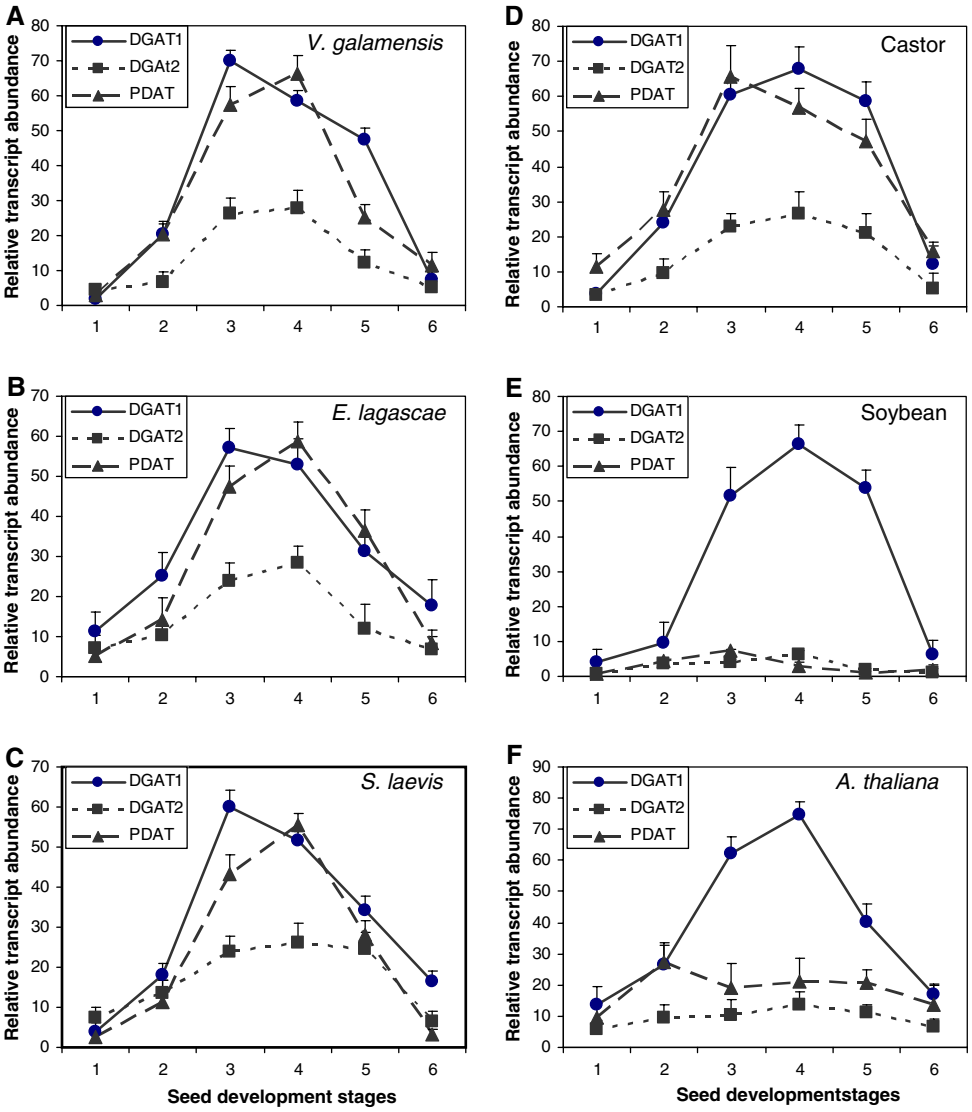

Fig. 2 Expression patterns of *DGAT1, 2* and *PDAT* transcripts during seed development. Expression levels were normalized with respect to the internal control *18 s RNA*. *Data bars* represent the mean ± STD level of relative transcript abundance from five experiments with independent RNA extractions. **a** *Vernonia galamensis*, **b** *Euphorbia lagascae*, **c** *Stokesia laevis*, **d**. Castor, **e**. Soybean (cv. Jack), **f**. *Arabidopsis thaliana*

(between stage 2 and 3). The level of *DGAT2* mRNA was less in seeds than in other tissues.

Temporal Expression Patterns of *DGAT1, DGAT2* and *PDAT* Transcripts During Seed Development

The RNA blots above show that *DGAT1, DGAT2* and *PDAT* are highly expressed in the young developing seeds of the tested plants, except for the weak expression of *DGAT2* in the seeds of soybean and *Arabidopsis*. To determine the relative transcript abundance of these three genes during seed development stages and maturation, relative mRNA expression patterns of these three genes were investigated by quantitative real-time PCR. RNA samples were extracted from seeds at six different developmental stages (stage 1–6) and gene-specific primers were designed to amplify the conserved region (about 400–500 bp) for each gene.

As shown in Fig. 2, the mRNAs of *DGAT1, DGAT2* and *PDAT* accumulated basically in a coordinated manner during seed development of *Vernonia galamensis*, *Euphorbia lagascae*, *Stokesia laevis* and castor. Their transcripts were clearly detectable at an early embryonic phase (stage 2), increased to a maximum at late embryonic phase (stage 3) or early seed maturing phase (stage 4), and declined thereafter, suggesting that the mRNAs have similar stabilities and kinetics of synthesis. Furthermore, the transcript levels were different from each other at their peaks (Fig. 2a–d). The *DGAT1* expression level was similar to that of *PDAT*, and both of them were approximately two to threefold higher than *DGAT2*. These findings suggest that the increased expression of these three genes at late embryonic phase and early seed maturing stage might functionally contribute to seed oil accumulation in these high epoxy or hydroxy source plants. These gene expression studies were repeated with gene specific primers for

DGAT1, *DGAT2* and *PDAT* in castor (Fig. 4) and *DGAT1* and *DGAT2* in *Vernonia* [68] and the same expression patterns were seen as reported in this manuscript.

However, only the *DGAT1* transcript accumulated to high levels with a peak at stage 4 in soybean developing seeds (Fig. 2e), while the transcripts of *PDAT* and *DGAT2* were present at very low levels throughout seed development. For *Arabidopsis* (Fig. 2f), the mRNA accumulation of *DGAT1* reached its maximum at stage 4 while the *PDAT* transcripts peaked at stage 2. *DGAT1* expression was three- to four-folds higher than that of *PDAT* in seed development. Again, *DGAT2* expression was very low during seed development.

Taken together, *DGAT1* had the highest transcript level of these three genes in all tested plant seed development. *PDAT* and *DGAT2* transcripts are present at much higher levels in epoxy and hydroxy accumulating plants than in soybean and *Arabidopsis*.

Developmental Changes in Seed Oil Content

For the purpose of examining the time course of oil accumulation during developing and maturing seeds, the total oil content and fatty acid composition at each stage was determined. As shown in Fig. 3, total oil content (μg/mg) started to increase at stage 3, and reached its peak at stage 6 in the seeds of *Vernonia* (Fig. 3a), *Stokesia* (Fig. 3b), *Euphorbia* (Fig. 3c) and castor (Fig. 3d). The maximum rate of oil accumulation occurred from stage 4 to stage 5 or from stage 3 to stage 4; after that, oil accumulation slowed.

In soybean seed (Fig. 3e), oil accumulation increased at the most rapid rate between stage 2 (25 DAF) and stage 4 (45 DAF), which was followed by a slow increase through stage 6 (65 DAF). Similarly, the rate of oil synthesis began to increase at stage 2 (9 DAF), peaked from stage 3 (12 DAF) to stage 4 (15 DAF), and then gradually declined in *Arabidopsis* seed development (Fig. 3f).

Fatty Acid Profiles Through Seed Development

The fatty acid of particular interest is vernolic acid for *Stokesia*, *Vernonia* and *Euphorbia*, and ricinoleic acid for castor. To understand how the accumulation of these unusual fatty acids is regulated in seeds, we measured fatty acid profiles at each stage of seed development using soybean and *Arabidopsis* for comparison.

Fatty acid profiles were determined for each stage of the developing seeds. Like total oil content, the unusual fatty acid levels also began to elevate sharply from stage 4 to stage 5 or from stage 3 to stage 4, and approached its maximum level at stage 6, whereas the relative amounts of common fatty acids such as 16:0, 18:1 and 18:2 were reduced after stage 3 in the seed development of these source plants (Fig. 3a1, b1, c1, d1).

Following seed development (Fig. 3e1), 18:2, a major fatty acid in soybean seed oil, began to increase from stage 2 though stage 6 at a stable rate while other fatty acids exhibited no dramatic changes, except for 18:3 which decreased. In *Arabidopsis* (Fig. 3f1), 18:1 and 18:2 levels increased by the same pattern with the maximum rate between stage 3 and stage 4. However, levels of other fatty acids declined throughout seed development and maturation.

Coordinate Expression of *DGAT1, 2* and *PDAT* is Consistent with High Epoxy and Hydroxy Fatty Acid Accumulation in Seeds

In this study, we investigated whether the developmental regulation of *DGAT1*, *DGAT2* and *PDAT* expression had functions in the accumulation of oil and target fatty acids of the source plants which contain high levels of unusual fatty acids in seed oil. In Fig 2, it is clearly seen that the three genes were concomitantly expressed throughout the seed development of *Vernonia*, *Stokesia*, *Euphorbia* and castor, with the highest rate of expression between stage 2 and 3. As shown in Fig 3, the temporal patterns of total oil content were basically consistent with the accumulation patterns of the target fatty acids in the source plant seeds. Their maximum rate of increase in vivo was between stages 3 and 5 in seed development. In comparison of patterns of the mRNA levels and oil/fatty acid accumulation, it was found that the maximum expression rate of the three genes was in close parallel to the maximum increased rate of oil and target fatty acid accumulation in the seed development, although the former was one or two developmental stage ahead of the latter. It is understood that accumulation of the transcripts precedes accumulation of the enzymes and enzymatic products. However, only the *DGAT1* transcript was largely increased during the active period of TAG and major fatty acid accumulation in the seeds of soybeans and *Arabidopsis* (Figs. 2, 3). A relationship between oil accumulation and *DGAT2* and *PDAT* function in soybean seeds is unlikely, because these two genes are expressed at low levels at stages of high oil synthesis. In *Arabidopsis* seeds, *DGAT2* also exhibited weak expression. The *PDAT* transcript peaked at an early stage (DAF 9), and was much lower than the maximum *DGAT1* level, suggesting that *PDAT* expression is not closely related to oil accumulation during *Arabidopsis* seed development.

Overall, the present data indicate that *DGAT1*, *DGAT2* and *PDAT* all show expression patterns consistent with roles in oil accumulation in high epoxy or hydroxy fatty acid accumulators.

Discussion

Triacylglycerols (TAGs) are quantitatively the most important storage form of energy for eukaryotic cells. During the past few years, the biosynthesis of TAG has received much attention. To date, three independent gene families, *DGAT1, DGAT2* and *PDAT* have been described and encode unique proteins with the capacity to form TAG, and all three genes are present in the genomes of eukaryotes [16, 17, 20, 22, 23, 31, 32]. It has also been reported that these three genes could contribute to oil accumulation in plant seeds [33, 34]. However, it is still unclear how they determine the final TAG accumulation in seeds.

DGAT1 has been quite extensively studied in *Arabidopsis*. Two mutants, AS11 [13, 35, 36] and ABX45 [12] have been analyzed, and these studies show that a

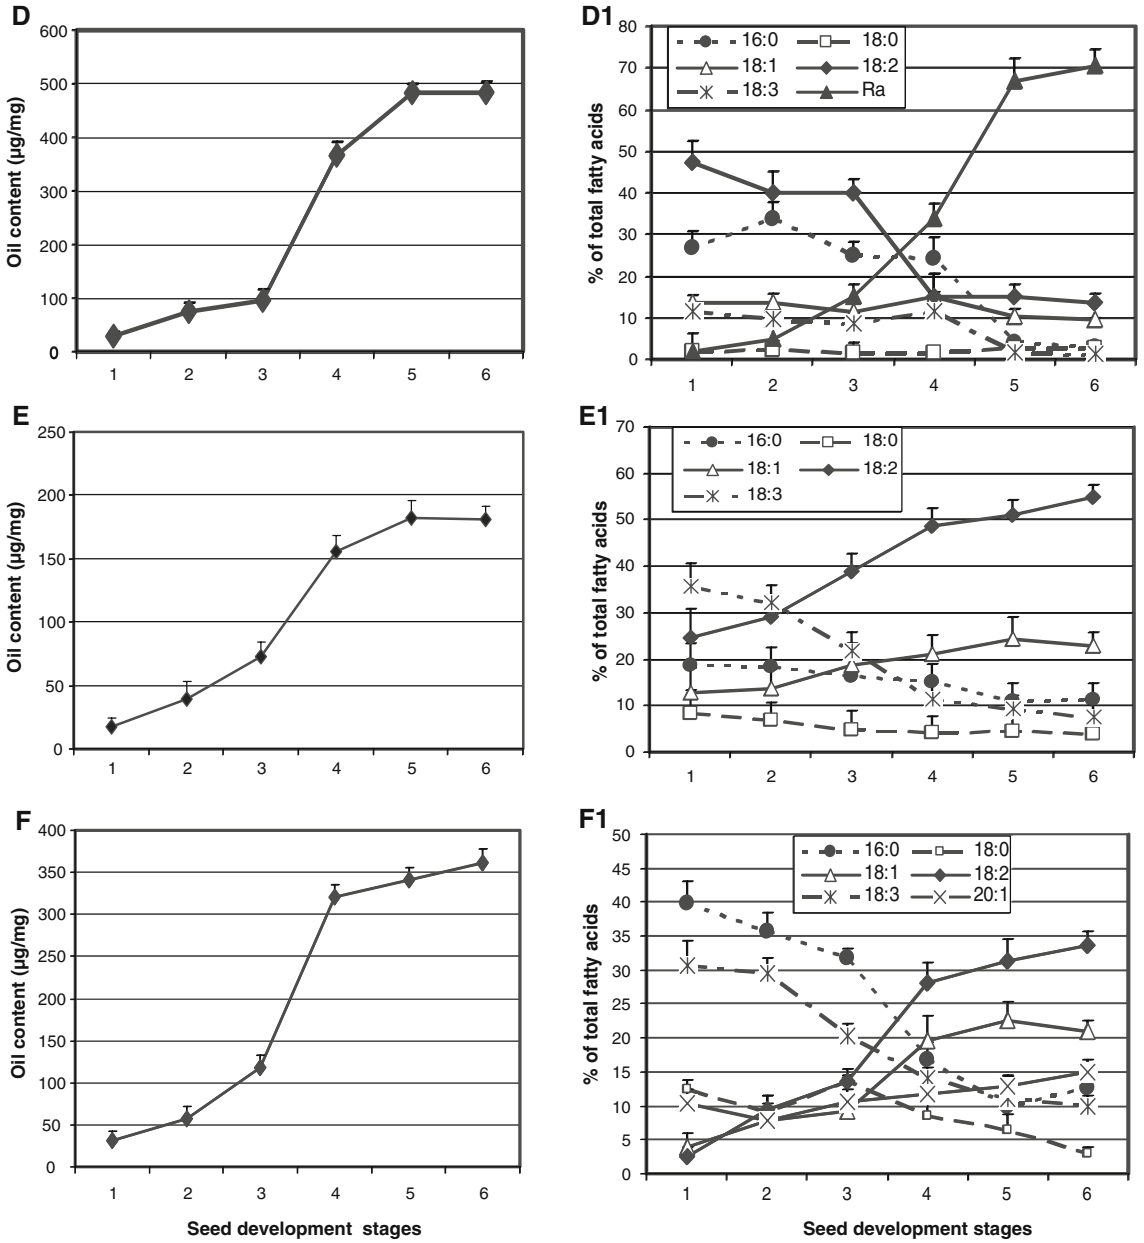

Fig. 3 continued

dysfunctional DGAT1 protein results in a decrease in stored TAG and a modified TAG fatty acid profile. Seed-specific over-expression of an *Arabidopsis DGAT1* gene enhances oil deposition and average seed weight, suggesting that DGAT1 catalyzes a rate-limiting step in TAG biosynthesis [35]. These results provide strong evidence that DGAT1 is an important enzyme in catalyzing TAG formation in plant seeds. However, the seeds of these two mutants still synthesize TAGs at 55–75% of the normal level, indicating that other enzymes also contribute to TAG accumulation in *Arabidopsis* seeds [12, 20, 31, 37].

Research on other oil plants also indicates an important role of DGAT1 for oil synthesis and accumulation in seeds. It is found that the critical stage for castor oil biosynthesis is between 19 DAP and 26 DAP, where castor DGAT1 (RcDGAT) protein and activity significantly increases. The close correlation between profiles of RcDGAT activity and oil accumulation is consistent with a role of RcDGAT in castor oil biosynthesis [38, 39]. Kroon et al. [24] indicate this is apparently mainly due to DGAT2. High expression of *DGAT1* is reported during development of oilseed rape (*Brassica napus*) seeds [16]. A tight correlation between

DGAT activity and oil deposition is also reported by other groups [40, 41]. By silencing the expression of *DGAT1* in tobacco, Zhang et al. [42] found that the expression level of *DGAT1* is correlated with oil content in the seeds, and reduction of *DGAT1* transcript also results in decreased seed weight. In addition, the seeds with *DGAT1* silenced still accumulate some TAG.

During soybean (cv. Amsoy 71) seed development, the rate of lipid biosynthesis was reported to increase markedly between 15 and 45 DAF [43] or from 20 to 50 DAF [44]. Our data show that the period of highest oil accumulation in soybean cv 'Jack' grown under the conditions stated in the materials and methods is between 25 and 45 DAF (Fig 3e, e1), a period where *DGAT1* transcript levels were maximal (Fig 2e). For *Arabidopsis*, the rate of oil synthesis peaked at 9–15 DAF (Fig. 3f, f1), and the highest level of *DGAT1* transcript occurs at this period of seed development (Fig. 2f). It has previously been reported that oil is synthesized at maximum rates between 7 and 13 DAF [45], and that the DGAT1 protein peaks at 7–9 DAF during *Arabidopsis* embryo development [46]. Moreover, our current data also shows that *DGAT1* transcript levels accumulate to a higher level than *DGAT2* and *PDAT*, and the peak of the *DGAT1* transcript level is consistent with the maximum increase of oil and fatty acid accumulation during seed development of *Vernonia, Euphorbia, Stokesia,* castor, soybeans and *Arabidopsis*.

Many of the more than 300 naturally occurring unusual fatty acids that have been described in seeds to date have high-valued properties for industrial utilization. The main component of seed oil in *Vernonia galamensis*, *Crepis palaestina*, *Euphorbia lagascae* and *Stokesia laevis* is the epoxy fatty acid vernolic acid whereas a hydroxy fatty acid, ricinoleic acid, is the major component in castor seed oil. The accumulation of unusual fatty acids in TAG can be divided into two major steps. First is the insertion of the functional group into the acyl chain, followed by the incorporation of the unusual fatty acid into TAG. In unusual fatty acid accumulating plants, these fatty acids are found almost exclusively in TAG and are excluded from membrane lipids, most likely because they are deleterious to membrane function [47]. Therefore, at least two enzymes are needed for these unusual fatty acids to accumulate in seed oil. One is for the synthesis of the unusual fatty acid and others are for specifically incorporating the unusual fatty acid into TAG. Several genes have been identified that code for enzymes involved in the synthesis of some unusual fatty acids [48]. For example, epoxygenase genes responsible for epoxidizing linoleic acid have been cloned from several accumulators of vernolic acid [49–52]. However, transgenically expressing these synthesis enzymes only result in low levels of the unusual fatty acid accumulation in seed oil [50, 52–55]. Low-level accumulation of unusual fatty acids in transgenic plants may be from the failure to efficiently incorporate them into TAGs, leading to their rapid degradation through the β-oxidation cycle [56–58]. These findings suggest that besides the synthesis enzyme, the enzymes catalyzing the final acylation step of TAG synthesis such as DGAT1, DGAT2 and PDAT might be other major contributors for selective accumulation of unusual fatty acids in native plant seed oil.

PDAT activity has been identified in microsomal preparations from castor and *Crepis palaestina* plants [20]. It is proposed that PDAT is involved in the transfer of the oxygenated acyl groups from phospholipids into TAGs. Stahl et al. [22] demonstrated that *Arabidopsis* PDAT (AtPDAT, At5g13640) utilized different phospholipids as acyl donor and accepted acyl groups ranging from C10 to C22. AtPDAT exhibited highest activity for acyl groups containing several double bonds, epoxy, or hydroxyl groups. AtPDAT has similar acyl specificity for vernoloyl and ricinoleoyl groups as the PDAT activity assayed in the microsomal preparations from developing castor endosperm, indicating that the plant PDAT acyl specificities are general and not limited to plants producing unusual fatty acids. Furthermore, the transformants over-expressing *AtPDAT cDNA* had tenfold higher PDAT activity than the wild type, and did not have any alteration in fatty acid composition in either vegetative parts or in the oil accumulating seeds. Expression of *PDATs* from other plants may show specificity not seen with this *Arabidopsis PDAT*. Mhaske et al.'s [23] work on a knockout mutant of *Arabidopsis* in the *PDAT* gene (locus At5g13640) shows that this knockout has no effect on either the fatty acid content or composition of seed. PDAT activity encoded by this gene is not a major determinant of TAG synthesis in *Arabidopsis* seeds. This is contrary to the situation in yeast where PDAT is a major contributor to TAG accumulation in exponential growth phase [59]. Stahl et al. [22] reported that *Arabidopsis* has six ORFs with significant homology to either lecithin: cholesterol acyltransferase (LCAT) or ScPDAT. They demonstrated that At5g13640 has PDAT activity but At3g44830 is mainly expressed in developing seeds. This has lead Stahl et al. (2004) to hypothesize that At3g44830 has a specific role in TAG deposition in developing seeds but confirmation of this awaits further experimentation.

Several *DGAT2* genes have been recently cloned and characterized from animal [32], fungi [31] and plants [19, 31]. In yeast, the DGAT2 enzyme is dominant in the stationary growth phase when the yeast is storing significant amounts of TAG [59, 60]. In animals, the temporal-spatial expression of the *DGAT2* gene is different from *DGAT1*, and therefore has different physiological functions in vivo [61–63]. Recent experiments indicate a particularly

important role for *DGAT2* expression and conjugated and hydroxy fatty acid accumulation in seed oil and that DGAT2 can function different from DGAT1 in plants [24–26].

In our present study, the expression pattern of *DGAT2* was consistent with a role in the accumulation of oil and epoxy or hydroxy fatty acids during seed development. Only very low levels of *DGAT2* transcript were detected in soybean and *Arabidopsis* developing seeds, suggesting a correspondingly small role (if any) in TAG synthesis. Similarly, *PDAT* expression in developing seeds is high for epoxy and hydroxy fatty acid accumulating plants and weak for soybean and *Arabidopsis.* The *PDAT* expression data in this study also suggest that *PDAT* might play an important role in epoxy and hydroxyl fatty acid accumulation, which is consistent with the results obtained in the functional analysis of PDAT from castor and *Crepis palaestina* plants [20].

The primary role of DGAT1, DGAT2 and PDAT is to catalyze the final step of storage TAG synthesis. It is expected that these three genes would mainly be expressed in developing seeds of oil plants. However, it has been suggested that their expression is not restricted to the embryos. DGAT activity has been found in spinach leaves [64] and germinating soybean cotyledons [65]. *DGAT1* transcripts have been detected in many tissues in *Arabidopsis* including developing siliques, flowers, germinating seeds and young seedlings [13]. Using RNA gel blot analysis, Hobbs et al. [16] detected low levels of *DGAT1* expression in leaves and stems as well as its strong expression in embryos and flowers in *Brassica napus*. In *Arabidopsis* seedlings, *DGAT1* is expressed in shoot and root apical regions, correlating with rapid cell division and growth [46]. In addition, *DGAT1* gene expression is up-regulated by glucose and associated with glucose-induced changes in seedling development [46]. *DGAT1* transcripts are expressed in different tobacco tissues including leaves, stems, roots, petals and developing seeds [42]. Roles in fatty acid mobilization and senescence in leaves have also been reported [66, 67]. These observations suggest that the *DGAT1* gene may also be involved in physiological activities other than its "classical" role for storage fatty acid accumulation in plants or TAG synthesis occurs at least transiently in many plant tissues.

The *AtPDAT* (At5g13640) gene is also found to express in leaves, root, flowers and developing seeds of *Arabidopsis* [22]. Some PDATs may possibly play a general protective role by removing oxidized fatty acids from phospholipids, or function in the removal of DAG, a product of the phosphatidylinositol signaling pathway [23]. Preliminary information on *DGAT2* expression in plant tissues is just emerging. In animals extensive information on its expression in different types of cells and tissues has already been reported.[24–26, 61, 62, 68].

Our data provide evidence that *DGAT1*, *DGAT2* and *PDAT* expression in leaves, stems and roots as well as in developing seeds is different between unusual and normal fatty acid accumulating oilseeds. Consistent with previous knowledge, our results also suggest that *DGAT1, DGAT2* and *PDAT* genes might be involved in other physiological activities of plants.

It should be noted that *Arabidopsis* genome contains only one *DGAT1* [15], one *DGAT2* (NM_115011) and six *PDATs* [21]. The other species tested here may contain one or multiple isoforms for each of the three classes of genes. We previously isolated two *DGAT1* cDNA clones from *Vernonia* (EF653277 and EF653276) [69] and soybean (AF257589 and AF257590). We also cloned one full-length cDNA of Vernonia *DGAT2* (FJ652577). It was reported that the castor genome contains one *DGAT1* [37], one *DGAT2* [23] and two *PDATs* [70]. In the present study, the conserved region of each gene family was used for the probe and primer design, which allows detection of the expression levels of each gene family or at least one isoform expression (if one more isoforms present in the genome). The three gene expression patterns in *Arabidopsis* and DGTA1 expression pattern in castor obtained by this study are in agreement with the previous reports [15, 21, 23, 34, 45], indicating our experiments provide useful information on expression of TAG biosynthetic genes in these plants although the primers are heterologous for some plants tested here. In castor seeds, our data shows *DGAT1* expression is higher than *DGAT2*, whereas *DGAT2* level is higher than *DGAT1* reported by Kroon et al. [23]. This discrepancy might be due to differences in castor genotype and sampling. Interestingly, compared to *DGAT2* expressions in soybean and *Arabidopsis*, we concluded DGAT2 is important for unusual fatty acid accumulation that is consistent with their conclusion, supported by transgenic experiments in *Arabidopsis* [25]. We also characterized *DGAT1* and *DGAT2* cDNA clones [69] and conducted the transgenic experiments [71], which confirms the suggestion from this study that both DGATs function in unusual fatty acid accumulation in *Vernonia* seeds. Further QPCR was also performed with castor gene specific primers for *DGAT1*, *DGAT2* and *PDAT* (Fig. 4) and *Vernonia DGAT1* and *DGAT2* specific primers in Li et al. [68] and the same expression patterns were seen as reported in this manuscript.

Developing an understanding of the control of TAG synthesis in seeds and how plants can accumulate high levels of certain fatty acids (particularly unusual fatty acids) in seed oil is a significant challenge if yields are to be increased and unusual fatty acids are to be engineered for high production in common oilseed plants. The present study was carried out with the aim of investigating *DGAT1*, *DGAT* and *PDAT* transcript levels in relation to the

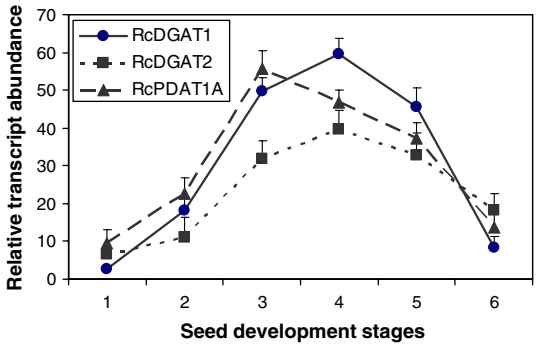

Fig. 4 Expression patterns of *DGAT1, 2* and *PDAT* transcripts during castor (*Ricinus communis*) seed development using castor gene specific primers. Expression levels were normalized with respect to the internal control *18 s RNA*. *Data bars* represent the mean ± STD level of relative transcript abundance from five experiments with independent RNA extractions. Real-time PCR was performed as described in "Materials and Methods" (and legend of Fig. 2). Gene-specific primers were designed based on the ORF of each gene. Primers for *RcDGAT1 (AY366496)* were 5′-tgttaacagcaggctcatcatt-3′ (*forward*) and 5′-ccatacaagcaagttccatcaa-3′ (*reverse*). Primers for *RcDGAT2 (EU391592)* were 5′-tttggttatgagccacattcag-3′ (*forward*) and 5′-caagggtttacccatctccata-3′ (*reverse*). Primers for *RcPDAT1A* [70] were 5′-gacatcagtgtgctgatggttt-3′ (*forward*) and 5′-tgctcaaacttt ggtccctaat-3′ (*reverse*)

accumulation of oil and epoxy and hydroxy fatty acids in developing seeds of *Vernonia galamensis*, *Euphorbia lagascae*, *Stokesia* and castor in comparison with soybean and *Arabidopsis*. For all plants examined, *DGAT1* appears to be a major enzyme gene for seed oil accumulation. For the epoxy and hydroxy fatty acid accumulating plants, *PDAT* and *DGAT2* also appear to play significant roles in the selective accumulation of these unusual fatty acids in the seed oil. We provide the first evidence that *DGAT2* is expressed in different tissues including developing seeds of the tested plants. Consistent with other reports, *PDAT* and *DGAT1* are found to be expressed in different plant tissues.

Acknowledgments This research was supported by the United Soybean Board, Ashland Chemicals, the Kentucky Science and Engineering Foundation, the Consortium for Plant Biotechnology Research, and the Kentucky Soybean Promotion Board. We gratefully acknowledge John Johnson for his technical support.

Facile and Stereoselective Synthesis of (*Z*)-15-Octadecenoic Acid and (*Z*)-16-Nonadecenoic Acid: Monounsaturated Omega-3 Fatty Acids

Tristan Rawling · Colin C. Duke · Pei H. Cui · Michael Murray

Received: 29 October 2009 / Accepted: 25 November 2009 / Published online: 13 January 2010

Abstract Facile syntheses of the monounsaturated omega-3 fatty acids, (*Z*)-15-octadecenoic acid and (*Z*)-16-nonadecenoic acid, are presented. Commercially available hydroxy fatty acids were esterified and oxidised, followed by the Wittig reaction to introduce the omega-3 olefinic bond; hydrolysis yielded the omega-3 fatty acids in high purity. An examination of different reaction conditions for the Wittig step found that THF as solvent and coupling temperatures of −78 °C gave optimal stereoselectivity, affording the omega-3 olefins in *Z*:*E* ratios ≥97:3. The syntheses have overall yields of ∼43%, and utilise straightforward, robust chemistry, that may be readily scaled up and reproduced. Also presented is a method for accurately determining the double bond geometry and isomeric purity of the fatty acid products using ^{1}H–^{13}C-HSQC NMR and GC–MS, respectively.

Keywords Omega-3 · Fatty acid · Wittig reaction · Stereoselectivity

Abbreviations

DCM	Dichloromethane
DMF	*N*,*N*-dimethylformamide
FAME	Fatty acid methyl ester
$NaN(TMS)_2$	Sodium bis(trimethylsilyl)amide
PCC	Pyridinium chlorochromate
PUFA	Polyunsaturated fatty acid
THF	Tetrahydrofuran

Introduction

Omega-3 polyunsaturated fatty acids (PUFAs) have been the subject of intense recent interest because their beneficial actions in cells and in vivo are biologically distinct from those of their omega-6 counterparts. Thus, omega-3 fatty acids possess anti-inflammatory and anti-cancer effects, and have also been shown to inhibit platelet aggregation, promote neuronal cell survival, increase membrane fluidity and to modulate the expression of genes that regulate lipid metabolism [1]. Populations with a high intake of omega-6 PUFAs exhibit an increased risk of breast, colon and prostate cancer, compared to those with a high consumption of omega-3-containing oils [2–5]. Moreover, in vivo and in vitro studies have shown that omega-6 PUFAs stimulate carcinogenesis and tumour growth and metastasis, while omega-3 PUFAs repress tumourigenesis [2, 6, 7]. PUFAs undergo biotransformation to eicosanoid derivatives catalysed by cyclooxygenase, lipoxygenase and cytochrome P450 enzymes; these eicosanoids mediate many of the cellular effects of PUFAs [8, 9]. Because omega-3 and omega-6 PUFAs give rise to parallel series of eicosanoids with differing potency, the omega-3 olefinic bond is strongly implicated in the beneficial properties of the parent omega-3 PUFAs.

Most studies of the biological effects of omega-3 fatty acids have focussed on naturally occurring PUFAs, such as α-linolenic acid and eicosapentaenoic acid. However, the

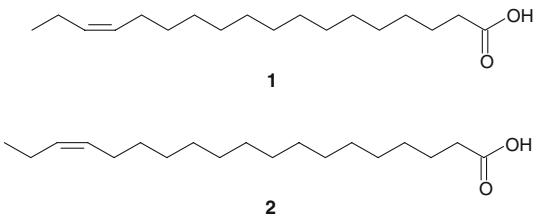

Fig. 1 The (*Z*)-monounsaturated omega-3 fatty acids prepared in this work

assignment of particular cellular actions to the omega-3 bond is confounded by possible interference from other double bonds in these molecules. Indeed, with the exception of the omega-3 double bond, the olefinic bonds in eicosapentaenoic acid are analogous to those in the major omega-6 PUFA arachidonic acid. Surprisingly, there has been little work done to date on the synthesis of monounsaturated omega-3 fatty acids, which may serve as probes to clarify some of the biological properties of the omega-3 double bond.

Syntheses of the monounsaturated omega-3 fatty acid (*Z*)-15-octadecenoic acid (**1**) (Fig. 1) have been reported. Klok et al. [10] reported a seven step synthesis starting from 1,12-dodecanediol, in which hydrogenation of 15-octadecynoic acid is used to prepare the omega-3 bond. An alternative eleven step synthesis has been reported by Gunstone et al. [11], starting from undec-10-enoic acid. In the present article, we describe a four step synthesis of (*Z*)-15-octadecenoic acid (**1**), as well as (*Z*)-16-nonadecenoic acid (**2**), in high isomeric purity. The synthetic procedure employs straightforward, robust, quick and inexpensive reactions, and may be readily scaled up. **1** occurs naturally and has been detected in, but not isolated from, animal products including beef [12], pork [13], cows milk and butter [14], and in human blood [15] and human milk [16, 17]. As well as being useful probes for studying the properties of the omega-3 double bond in fatty acids of naturally and non-naturally occurring chain lengths, these compounds may permit the convenient synthesis of metabolites, such as epoxides derived from reactions of the omega-3 bond. The preparation of corresponding metabolites from polyunsaturated fatty acids leads to complex mixtures that require extensive purification [18].

Experimental Procedures

Instrumentation

Preparative liquid chromatography was performed using Dry Column Vacuum Chromatography (DCVC) with Merck Silica Gel 60H (5–25 μm) as the stationary phase. A 70-mm (ID) column was used, and 50-mL fractions were collected. TLC was carried out on Merck silica gel 60 F_{254} TLC plates. ^{1}H-NMR (400 MHz), ^{13}C-NMR (100.5 MHz), and ^{1}H–^{13}C-HSQC-NMR spectra were recorded using a Varian 400-MR instrument. Spectra were referenced internally to NMR solvent ($CDCl_3$; ^{1}H δ 7.26 ppm, ^{13}C δ 77.10 ppm). High Resolution Mass Spectra (HRMS) were obtained by the Mass Spectrometry Unit at the School of Chemistry, The University of Sydney, on a Bruker 7T Fourier Transform Ion Cyclotron Resonance Mass Spectrometer. Melting points were measured on a Stuart SMP10 melting point apparatus.

GC–MS was performed on a PolarisQ GC–MS–MS ion trap mass spectrometer coupled to a Trace GC, which was fitted with a ZB Wax column (30 m × 0.25 mm × 0.25 μm). Automated injections were performed on an AS2000 Autosampler. The injection port temperature was 190 °C and 1.0-μL injections were made in splitless mode, with the split valve opened after 1 min. Helium was used as carrier gas, at a flow rate of 1 mL/min. The GC oven temperature was programmed as follows: initial temperature of 100 °C for 2.5 min, then ramped at 5 °C/min to 280 °C, and held for 6.5 min giving a total run time of 45 min. Eluted compounds were subjected to methane chemical ionisation and detection was made in full scan mode scanning the MS from 100 to 600 amu in 2 μs. Compounds **1** and **2** were converted to their methyl esters using acetyl chloride/methanol prior to GC–MS analysis.

Chemicals

The following were purchased from the indicated commercial suppliers and were used as received: 15-hydroxypentadecanoic acid (97%), 16-hydroxyhexadecanoic acid (98%), 1 M sodium bis(trimethylsilyl)amide in THF, *n*-propyltriphenylphosphonium bromide, anhydrous THF and acetyl chloride (Aldrich, Castle Hill, NSW, Australia); pyridinium chlorochromate (PCC) and iodomethane (Fluka, Castle Hill, NSW, Australia), and potassium carbonate and sodium hydroxide (Ajax Finechem, Taren Point, NSW, Australia).

General Procedure for the Synthesis of the Methyl Esters **5** and **6**

To a solution of the hydroxy fatty acid (**3** or **4**, 7.87 mmol) in acetone (160 mL) was added water (8 mL), potassium carbonate (23.60 mmol) and iodomethane (39.33 mmol). The resulting mixture was refluxed for 4 h, and then concentrated in vacuo. The residue was dissolved in water (60 mL), and the solution was acidified with 1 M HCl. The aqueous phase was extracted with DCM (3 × 60 mL), and the combined extracts were washed with brine (100 mL), dried over Na_2SO_4, and concentrated in vacuo, affording methyl esters **5** and **6**.

Methyl 15-hydroxypentadecanoate (**5**)

White solid (72%). m.p. 49–50 °C (lit. m.p. 49.8 °C (19)). CI–MS: *m/z* (%): 273 ($[M + H]^+$, 6), 255 (39), 241 (29), 223 (95), 205 (100), 163 (14), 149 (39), 135 (39), 121 (42), 107 (26). The ^{1}H- and ^{13}C-NMR spectra of the product were in good agreement with previously reported data [19].

Methyl 16-hydroxyhexadecanoate (**6**)

White solid (70%). m.p. 53–54 °C (lit. m.p. 54.5–56 °C (20)). The ^{1}H- and ^{13}C-NMR, and MS spectra of the product were in good agreement with previously reported data [20].

General Procedure for the Synthesis of Aldehydes **7** and **8**

To a suspension of PCC (6.68 mmol) and Celite (1.440 g) in anhydrous DCM (20 mL) under nitrogen, was slowly added the methyl ester (**5** or **6**, 3.93 mmol) in anhydrous DCM (6 mL). The mixture was stirred for 2 h under nitrogen, after which diethyl ether (50 mL) was slowly added. The resulting mixture was stirred for 10 min, and then filtered over Celite. The Celite was washed with ether (2 × 20 mL), and the filtrate concentrated in vacuo. The residue was purified on silica gel by stepwise gradient elution with dichloromethane/hexane (40:60 to 100:0).

Methyl 15-oxopentadecanoate (**7**)

White solid (86%). m.p. 39–41 °C. CI–MS: *m/z* (%): 271 ($[M + H]^+$, 8), 239 (36), 221 (68), 203 (100), 175 (11), 161 (21), 147 (39), 133 (40), 121 (46), 107 (28). The ^{1}H- and ^{13}C-NMR spectra of the product were in good agreement with previously reported data [21, 22].

Methyl 16-oxohexadecanoate (**8**)

White solid (78%). m.p. 41–43 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.76 (t, J_{HH} = 2.0 Hz, 1H, C**H**O), 3.67 (s, 3H, C**H**$_3$O), 2.42 (td, J_{HH} = 7.6, 2.0 Hz, 2H, CHOC**H**$_2$), 2.30 (t, J_{HH} = 7.2 Hz, 2H, C**H**$_2$COO), 1.66–1.58 (m, 4H, C**H**$_2$CH$_2$COO and C**H**$_2$CH$_2$CHO), 1.36–1.24 (m, 20H, C**H**$_2$). CI–MS: *m/z* (%): 285 ($[M + H]^+$, 8), 253 (52), 235 (96), 217 (100), 175 (16), 151 (16), 147 (34), 135 (43), 121 (47), 107 (24). The ^{13}C-NMR spectrum of the product was in good agreement with previously reported data for a crude product [23].

General Procedure for the Synthesis of Omega-3 Fatty Acid Methyl Esters **9** and **10**

To a suspension of *n*-propyltriphenylphosphonium bromide (7.07 mmol) in anhydrous THF (10 mL) at 0 °C under a nitrogen atmosphere, was added NaN(TMS)$_2$ (1.0 M in THF, 6.43 mmol). The resulting orange mixture was stirred for 40 min at room temperature. The mixture was then cooled to −78 °C, and the aldehyde (**7** or **8**, 3.21 mmol) in THF (5 mL) was added dropwise by syringe. Stirring at −78 °C was continued for 30 min after which the reaction mixture was allowed to warm to room temperature. After further stirring for 2 h the reaction was quenched with saturated aqueous NH_4Cl (20 mL), and extracted with DCM (3 × 40 mL). The combined extracts were dried over Na_2SO_4, and the DCM removed in vacuo. The residue was purified on silica gel by stepwise gradient elution with dichloromethane/hexane (20:80 to 50:50).

Methyl (*Z*)-15-octadecenoate (**9**)

Colorless oil (80%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.40–5.28 (m, 2H, C**H**C**H**), 3.66 (s, 3H, OC**H**$_3$), 2.30 (t, J_{HH} = 7.6 Hz, 2H, C**H**$_2$COO), 2.08–1.98 (m, 4H, C**H**$_2$CHCHC**H**$_2$), 1.62 (quin, J_{HH} = 7.6 Hz, 2H, C**H**$_2$CH$_2$COO), 1.38–1.20 (m, 20H, C**H**$_2$), 0.95 (t, J_{HH} = 7.6 Hz, 3H, C**H**$_3$). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 174.32 (**C**OO), 131.47 (**C**H), 129.34 (**C**H), 51.40 (O**C**H$_3$), 34.10 (**C**H$_2$COO), 29.77, 29.62 (3C), 29.56, 29.53, 29.43, 29.28, 29.24, 29.14, 27.08 (CH**C**H$_2$), 24.95 (**C**H$_2$CH$_2$COO), 20.48 (CH**C**H$_2$), 14.37 (**C**H$_3$). CI–MS: *m/z* (%): 297 ($[M + H]^+$, 100), 265 (94), 247 (68), 191 (10), 178 (12), 163 (17), 149 (24), 135 (24), 121 (25), 107 (15). R_t = 25.43 min. *Z*:*E* ratio = 97.0:3.0. HRMS (APCI) calculated for $C_{18}H_{33}O$ ($[M + H–MeOH]^+$) 265.25259, found 265.25307.

Methyl (*Z*)-16-nonadecenoate (**10**)

Colorless oil (76%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.40–5.28 (m, 2H, C**H**C**H**), 3.66 (s, 3H, OC**H**$_3$), 2.30 (t, J_{HH} = 7.6 Hz, 2H, C**H**$_2$COO), 2.06–1.98 (m, 4H, C**H**$_2$CHCHC**H**$_2$), 1.62 (quin, J_{HH} = 7.2 Hz, 2H, C**H**$_2$CH$_2$COO), 1.38–1.22 (m, 22H, C**H**$_2$), 0.95 (t, J_{HH} = 7.6 Hz, 3H, C**H**$_3$). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 174.33 (**C**OO), 131.48 (**C**H), 129.35 (**C**H), 51.41 (O**C**H$_3$), 34.11 (**C**H$_2$COO), 29.77, 29.65 (2C), 29.62 (2C), 29.58, 29.54, 29.44, 29.29, 29.24, 29.14, 27.09 (CH**C**H$_2$), 24.95 (**C**H$_2$CH$_2$COO), 20.49 (CH**C**H$_2$), 14.38 (**C**H$_3$). CI–MS: *m/z* (%): 311 ($[M + H]^+$, 97), 279 (100), 261 (68), 191 (12), 177 (15), 163 (18), 149 (23), 135 (28), 121 (27), 109 (19). R_t = 26.98 min. *Z*:*E* ratio = 98.5:2.5. HRMS (APCI) calculated for $C_{19}H_{35}O$ ($[M + H–MeOH]^+$) 279.26824, found 279.26856.

General Procedure for the Synthesis of Omega-3 Fatty Acids **1** and **2**

To a solution of the omega-3 fatty acid methyl ester (**9** or **10**, 1.66 mmol) in ethanol (25 mL) was added 1.5 M

NaOH (12 mL). The mixture was heated to 40 °C for 5 min to obtain a clear solution. Stirring was continued at room temperature for 2 h. The volume of the reaction mixture was reduced to 20 mL by rotary evaporation, and the solution was adjusted to pH 3 with 1.0 M HCl. The white solid was collected by filtration, thoroughly washed with water, and dried under vacuum to yield the omega-3 fatty acids **1** and **2**.

(*Z*)-15-octadecenoic acid (**1**)

White solid (96%). m.p. 41–42 °C (lit. m.p. 40.5–41.5 °C (11)). ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.43–5.27 (m, 2H, C**H**C**H**), 2.35 (t, $J_{HH} = 7.6$ Hz, 2H, C$\mathbf{H}_2$COO), 2.08–1.98 (m, 4H, C$\mathbf{H}_2$CHCHC$\mathbf{H}_2$), 1.63 (quin, $J_{HH} = 7.2$ Hz, 2H, C$\mathbf{H}_2$CH$_2$COO), 1.38–1.22 (m, 20H, C$\mathbf{H}_2$), 0.95 (t, $J_{HH} = 7.4$ Hz, 3H, C$\mathbf{H}_3$). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 179.94 (**C**OO), 131.48 (**C**H), 129.35 (**C**H), 34.03 (**C**H$_2$COO), 29.77, 29.62 (3C), 29.57, 29.54, 29.42, 29.29, 29.23, 29.05, 27.09 (CH**C**H$_2$), 24.68 (**C**H$_2$CH$_2$COO), 20.49 (CH**C**H$_2$), 14.38 (**C**H$_3$). CI–MS (FAME derivative): *m/z* (%): 297 ([M + H]$^+$, 92), 265 (100), 247 (80), 191 (13), 178 (16), 163 (24), 149 (32), 135 (33), 121 (33), 107 (19). R_t (FAME derivative) = 25.54 min. *Z*:*E* ratio = 97.0:3.0. HRMS (ESI) calculated for $C_{18}H_{33}O_2$ ([M–H]$^-$) 281.24751, found 281.24832.

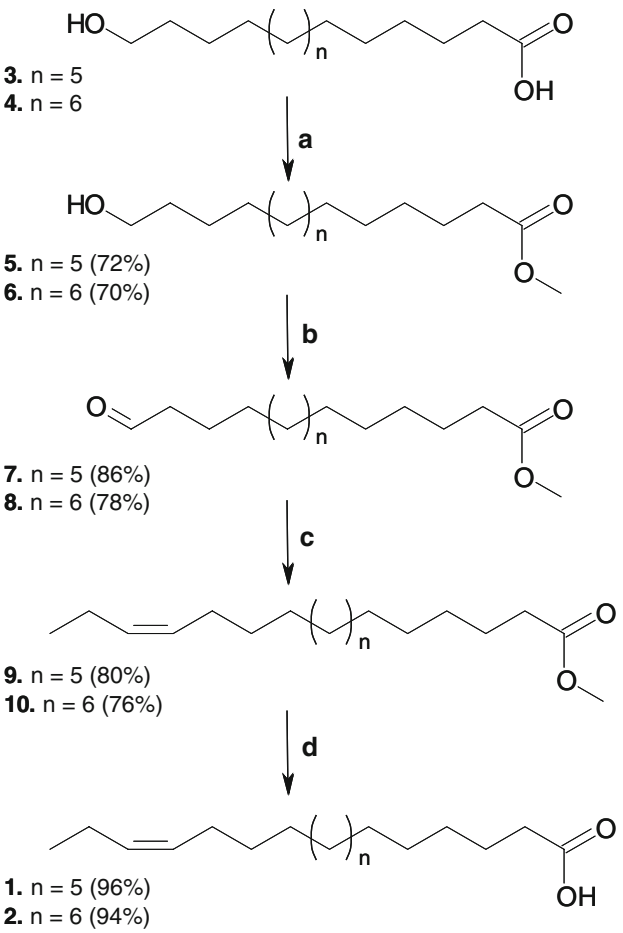
(*Z*)-16-nonadecenoic acid (**2**)

White solid (94%). m.p. 52–53 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.43–5.28 (m, 2H, C**H**C**H**), 2.34 (t, $J_{HH} = 7.6$ Hz, 2H, C$\mathbf{H}_2$COO), 2.08–1.96 (m, 4H, C$\mathbf{H}_2$CHCHC$\mathbf{H}_2$), 1.61 (quin, $J_{HH} = 7.2$ Hz, 2H, C$\mathbf{H}_2$CH$_2$COO), 1.38–1.20 (m, 22H, C$\mathbf{H}_2$), 0.95 (t, $J_{HH} = 7.6$ Hz, 3H, C$\mathbf{H}_3$). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 179.81 (**C**OO), 131.48 (**C**H), 129.35 (**C**H), 34.07 (**C**H$_2$COO), 29.77, 29.65 (2C), 29.63 (2C), 29.58, 29.55, 29.43, 29.29, 29.24, 29.07, 27.09 (CH**C**H$_2$), 24.70 (**C**H$_2$CH$_2$COO), 20.49 (CH**C**H$_2$), 14.38 (**C**H$_3$). CI–MS (FAME derivative): *m/z* (%): 311 ([M + H]$^+$, 94), 279 (100), 261 (68), 191 (10), 177 (15), 163 (17), 149 (24), 135 (24), 121 (27), 109 (15). R_t (FAME derivative) = 27.24 min. *Z*:*E* ratio = 98.5:2.5. HRMS (ESI) calculated for ([M–H]$^-$) $C_{19}H_{35}O_2$ 295.26316, found 295.26399.

Results and Discussion

Synthesis

The synthesis of compounds **1**–**2** is shown in Scheme 1. An important step in the synthesis was the Wittig reaction of aldehydes **7** and **8** with *n*-propyltriphenylphosphonium bromide to form the omega-3 double bond. The Wittig reaction was selected as there is no ambiguity as to the positioning of the double bond and, through careful control of the reaction conditions, high stereoselectivity may be achieved. This allowed for the preparation of fatty acids in high isomeric purity, without the need for time-consuming preparative HPLC purification.



Scheme 1 Synthesis of the model (*Z*)-monounsaturated omega-3 fatty acids. Reaction conditions: **a** MeI, K_2CO_3, acetone/water, reflux, 4 h; **b** PCC, DCM, rt, 2 h; **c** [Ph_3PPr]Br, NaN(TMS)$_2$, THF, −78 °C to rt, 2.5 h; **d** NaOH, ethanol/water, rt, 2 h

The first step in the synthesis was esterification of 15-hydroxypentadecanoic acid (**3**) and 16-hydroxyhexadecanoic acid (**4**), which was done to facilitate the purification of subsequent compounds by chromatography on silica gel. Initially, esterification of **3** and **4** was attempted following the Fischer protocol (1 g of **3** or **4**, 5 equiv acetyl chloride, 50 mL methanol). ^{1}H-NMR spectra of the products isolated after liquid–liquid extraction contained a weak triplet at 4.05 ppm that was attributed to a methylene ester group i.e. –COOC$\mathbf{H}_2$CH$_2$–, from the product of intermolecular esterification of two hydroxyfatty acid molecules. Additional resonances attributable to this product were not observed, possibly because they may be obscured by the stronger resonances of the target products. The

intermolecular esterification products could not be removed by silica gel chromatography. Subsequent attempts using more dilute reaction conditions (1 g of **3** or **4** in 200 mL of methanol), which might reduce the rate of intermolecular esterification, also failed to yield a pure product. Reaction conditions were therefore sought under which intermolecular esterification could not occur. Thus, **3** and **4** were esterified using iodomethane, and the triplet attributed to the intermolecular esterification product was absent from the ^{1}H-NMR spectra of the isolated products. Oxidation of the thus obtained **5** and **6** with PCC proceeded smoothly, affording the aldehydes **7** and **8,** respectively, in good yield.

With **7** and **8** in hand we set out to prepare the (*Z*)-omega-3 double bond. Wittig reactions using amide bases such as $NaN(TMS)_2$ are reported to yield exclusively the (*Z*)-isomer [24–26]. The reaction was initially performed following a literature procedure [24] (Table 1, entry 2), however GC–MS and ^{13}C-NMR analysis of the product isolated from silica chromatography indicated that the reaction had not proceeded with absolute (*Z*) selectivity (*Z*:*E* = 95.5:4.5). The stereoselectivity of the Wittig reaction is dependent on several factors, including the nature of the aldehyde and ylide, and the reaction conditions [27, 28]. Thus, the influence of the temperature at which the ylide and aldehyde were combined and the role of different solvent systems were tested in attempts to improve the stereoselectivity (Table 1). It emerged that dimethylformamide (DMF) decreased the reaction yield and, consistent with previous findings, THF was found to give optimum (*Z*) selectivity [27, 28]. Higher reaction temperatures improved the reaction yield, however a concurrent increase in formation of the (*E*) isomer was observed. Thus, to obtain optimal stereoselectivity, the Wittig reaction was performed in THF at −78 °C, to afford **9** and **10** (*Z*:*E* ≥ 97.0:3.0).

Table 1 Yield and *Z*:*E* ratio obtained from the Wittig reaction of **7** and *n*-propyltriphenylphosphonium bromide[a]

Solvent	Temperature (°C)[b]	*Z*:*E* ratio[c]	Yield (%)[d]
THF + DMF (12:1)	Room Temperature	92.5:7.5	70
THF + DMF (12:1)	0	95.5:4.5	65
THF	0	95.5:4.5	75
THF	−78	97.0:3.0	69
Toluene	−78	95.5:4.5	69

[a] All reactions performed under conditions analogous to those reported in the general procedure used to prepare **9** and **10**. Only the solvent system and temperature at which **7** was added to the ylide were changed

[b] Temperature at which **7** was added to ylide

[c] *Z*:*E* ratio determined by GC–MS

[d] Isolated yield based on the aldehyde

Hydrolysis of **9** and **10**, to afford the omega-3 fatty acids **1** and **2** in excellent yields, was achieved using NaOH. Under the mild reaction conditions employed, pure products were obtained without the need for subsequent chromatography. In addition, no change in the *Z*:*E* ratio was observed upon de-esterification, indicating base catalysed isomerisation [29] of (*Z*) double bonds did not occur under the reaction conditions.

Omega-3 Olefinic Bond Characterisation

Previously, identification of double bond geometry and isomeric purity of synthetically prepared, unsaturated fatty acid derivatives has been achieved using ^{1}H-NMR spectroscopy [10, 26, 30, 31]. In the ^{1}H-NMR spectra of **1** and **2**, as well as their precursors **9** and **10**, the olefinic proton resonances were found to be coincident. Consequently, ^{1}H-NMR spectroscopy did not provide reliable data regarding the double bond geometry or isomeric purity of these compounds. A similar observation had been made in the synthesis of (*E*)-vaccenic acid [32].

The double bond configurations in **1**, **2**, **9,** and **10** were identified using the chemical shifts of the signals arising from the carbons adjacent to the double bond. Assignment of these resonances was achieved using ^{1}H–^{13}C-HSQC NMR spectroscopy, where coupling of these signals to the proton resonances at 2.02 ppm, which arise from the protons adjacent to the double bond, was observed. Using this approach, resonances arising from the carbon atoms adjacent to the double bond in the ^{13}C-NMR spectra of **1**, **2**, **9**, and **10** were identified at ∼27 and 20 ppm. Similar shifts have been reported in the ^{13}C-NMR spectra of a series of unbranched omega-3 (*Z*)-alkenes [33], and the chemical shifts of these resonances may be considered diagnostic for the omega-3 (*Z*) configuration. In the case of the (*E*) isomers, deshielding shifts these resonances to ∼32 and 25 ppm, respectively [33]. Weak resonances at ∼32 and 25 ppm, attributed to the (*E*) isomers, were observed in the ^{13}C-NMR spectra of **1**, **2**, **9**, and **10**.

In addition to the configurations of double bonds, the chemical shifts of the adjacent carbons atoms indicate the position of the double bond. Thus, chemical shifts of ∼20 and 27 ppm are typical for omega-3 (*Z*) compounds [33] but shift significantly when the position of the double bond is changed. For example, they appear at ∼29 and 27 ppm in the ^{13}C-NMR spectra of omega-4 (*Z*) alkenes [33]. The double bond position is also confirmed by the chemical shift of the methyl group protons which appear at 0.95 ppm in the ^{1}H-NMR spectra of **1**, **2**, **9**, and **10**; these lie within the 0.93–1.03 ppm range reported to be characteristic of omega-3 fatty acids [34].

The isomeric purity of the olefinic compounds was determined by GC–MS. Gas chromatograms of **9** and **10**,

and the FAME derivatives of **1** and **2**, displayed two peaks with identical mass spectra. Based on order of elution [35], the first minor compound to elute was identified as the (*E*) isomer, and the second major compound as the (*Z*) isomer. That the (*Z*) isomer is the major constituent of the olefinic compounds is supported by the ^{13}C-NMR data. Using a Zebron ZB-Wax column and relatively long run times of 45 min, baseline separation was achieved, and the *Z*:*E* ratio was then calculated from the peak areas. Under the GC conditions described, the FAME derivatives of **1** and **2** had retentions times of 25.54 and 27.24 min, respectively, with those of the corresponding (*E*) isomers at 25.25 and 26.94 min, respectively.

Conclusions

This article presents a convenient synthesis of two (*Z*)-monounsaturated omega-3 fatty acids with a high degree of isomeric purity. The four-step synthetic procedure beginning with the hydroxy fatty acids has an overall yield of ~43%, and may be readily scaled up to prepare gram quantities. The fatty acids described will be valuable model compounds for researchers to evaluate the functional importance of the omega-3 double bond in the cellular actions of naturally-occurring omega-3 PUFAs.

Abstract A very long chain polyunsaturated hydrocarbon, hentriacontanonaene (C31:9), was detected in an eicosapentaenoic acid (EPA)-producing marine bacterium, which was isolated from the mid-latitude seashore of Hokkaido, Japan, and was tentatively identified as mesophilic *Shewanella* sp. strain osh08 from 16S rRNA gene sequencing. The geometry and position of the double bonds in this compound were determined physicochemically to be all *cis* at positions 3, 6, 9, 12, 15, 19, 22, 25, and 28. Although C31:9 was detected in all of the seven EPA- or/and docosahexaenoic acid-producing bacteria tested, an EPA-deficient mutant (strain IK-1Δ8) of one of these bacteria had no C31:9. Strain IK-1Δ8 had defects in the *pfaD* gene, one of the five *pfa* genes responsible for the biosynthesis of EPA. Although *Escherichia coli* DH5α does not produce EPA or DHA inherently, cells transformed with the *pfa* genes responsible for the biosynthesis of EPA and DHA produced EPA and DHA, respectively, but not C31:9. These results suggest that the Pfa protein complex is involved in the biosynthesis of C31:9 and that *pfa* genes must not be the only genes responsible for the formation of C31:9. In this report, we determined for the first time the molecular structure of the C31:9 and discuss the possible biosynthetic pathways of this compound.

Introduction

A unique very long straight-chain polyunsaturated hydrocarbon (PUHC) with an odd number of carbon atoms, hentriacontanonaene (C31:9), was first discovered in marine Antarctic bacteria [1]. The same compound was reported in a deep-sea bacterium [2]. These C31:9-producing bacteria are psychrophilic and produce eicosapentaenoic acid (EPA) and/or docosahexaenoic acid (DHA) [1]. However, the molecular structure of C31:9 has not been determined, and the relationship between these *n*-3 polyunsaturated fatty acids (PUFAs) and C31:9 biosynthesis is not clear, although bacterial EPA and DHA are synthesized by the Pfa protein complex encoded by the *pfaA, pfaB, pfaC, pfaD*, and *pfaE* genes [3].

Another straight-chain PUHC with an odd number of carbons, all *cis*-3,6,9,12,15,18-heneicosahexaene (C21:6), is distributed in marine planktonic algae and animals [4, 5]. The biosynthesis of C21:6 may occur through the decarboxylation of DHA [4] because the marine organisms possessing C21:6 contain DHA [4, 5] as well as the hydrocarbon derived from DHA (Δ4, 7, 10, 13, 16, 19) by decarboxylation. C21:6 from DHA should have double bonds at 3, 6, 9, 12, 15, and 18. Eukaryotes have a decarboxylation pathway to synthesize odd-carbon-number alkanes from even-carbon-number counterpart fatty acids via fatty aldehyde formation [6]. However, no biochemical or molecular evidence on the biosynthesis of C21:6 is available, and information about C31:9, which is recognized as a biomarker of Antarctic bacteria [1], is limited.

We isolated an EPA-producing bacterium from the surface of seaweed collected at the mid-latitude seashore of Hokkaido, Japan. This isolate (designated strain osh08) included, in addition to low levels of EPA, a hydrocarbon suspected to be C31:9. In this study, we describe the physicochemical determination of the molecular structure of this compound including the position and geometry of the double bonds. We investigated the distribution of C31:9 using various types of marine and nonmarine microorganisms, including EPA- or DHA-producing bacteria and eukaryotes, a genetically engineered EPA-deficient mutant of *Shewanella* species, and *Escherichia coli* that had been transformed with the *pfa* genes responsible for the biosynthesis of EPA or DHA. We discuss the possible biosynthetic pathways of C31:9 with regard to the distribution of EPA, DHA, C31:9, and *pfa* genes in bacteria.

Experimental Procedures

Strains and Culture Conditions of Bacteria and Eukaryotes

Bacterial strains isolated from seaweed samples that had been collected at the mid-latitude seashore of Oshoro, Hokkaido, Japan (43.19N, 141.00E) were screened for their ability to produce long-chain PUFAs such as EPA and DHA in moderate-temperature environments. The seaweed fragments (approximately 2 × 3 cm) soaked in seawater were vortexed. Portions (200 μL) of the seawater sample were spread on the plates containing ZoBell agar medium (1 g/L peptone, 1 g/L yeast extract, 0.1 g/L $Fe_3(PO_4)_2$, and 0.15 g/L agar in 50% (by vol) seawater; [7]). Sea water used in this study was natural seawater that had been filtered using filter paper (type No. 02, Advantec, Tokyo, Japan). Plates were then incubated at 20 °C for several days. Bacterial colonies were subjected to methanolysis using 10% (by vol) acetyl chloride in methanol, as described below. One strain (osh08) capable of producing EPA was isolated, purified by repeated streaking of cells on the agar plates, and utilized for further investigations.

Strain osh08 was cultivated in the ZoBell liquid medium with shaking at 180 rpm at 25 °C for 1 day, unless otherwise stated. To investigate effects of temperature on growth and production of C31:9, strain osh08 was cultivated at 0, 4, 15, 20, 25, 30, 37, 40, and 43 °C.

The following strains were used: *Colwellia maris* ABE-1^T [8], *Moritella marina* MP-1^T (ATCC15381^T), *Shewanella marinintestina* IK-1^T [9], *Shewanella pneumatophori* SCRC-2738^T [10], *Shewanella benthica* (ATCC43992), *Pseudomonas alcaliphila* AL15-21^T [11] as marine bacteria; *Pseudomonas psychrophila* E-3^T [12], *Vibrio rumoiensis* S-1^T [13], *Shewanella oneidensis* MR-1^T (ATCC 700550^T), *Pseudomonas aeruginosa* WatG [14], *Rhodococcus erythropolis* (laboratory strain isolated from soil), *E. coli* DH5α (Takara Bio, Tokyo, Japan), and *Stenotrophomonas maltophilia* (laboratory strain from soil) as nonmarine bacteria; a thraustochytrid-like microorganism

strain 12B [15] and *Schizochitrium limacinum* SR21 [16] as marine eukaryotes; and a terrestrial eukaryote, *Saccharomyces cerevisiae* (baker's yeast). Nonmarine and marine bacteria were grown in a Luria–Bertani (LB) medium and a LB medium containing 30 g/L NaCl, respectively. Strain 12B, *S. limacinum* SR21, and yeast were grown in F medium, as described previously [15].

Extraction and Analysis of Lipids

Hydrocarbons of osh08 were first extracted with hexane from the fatty acid methyl ester (FAME) fraction after methanolysis of dry cells (approximately 15 mg) using 1 mL of 10% (by vol) acetyl chloride in methanol at 100 °C for 1 h. A mixture of 10 μg each of heneicosanoic acid (21:0, Sigma–Aldrich, Tokyo) and *n*-tetracosane (C24:0, Sigma–Aldrich) was used as an internal standard. To avoid coextraction of FAMEs, hydrocarbons were directly extracted from dry cells (approximately 10 mg) with 20 mL of a mixture of methanol/hexane (1:1, by vol) after sonic oscillation at 70 watts for 10 s in an ice bath using a sonic disruptor (model, W-185; Branson, Danbury, CT). This procedure was repeated three times. The combined hexane extracts were used as crude hydrocarbon fraction.

The crude hydrocarbon fraction was applied to thin-layer chromatography (TLC) on silica gel plates (type 5721, Merck, Darmstadt, Germany) using a mixture of hexane/ethyl ether/acetic acid (90:10:1, by vol) as solvent. Squalene (Kanto Chemical, Tokyo), and squalane (Tokyo Kasei Kogyo, Tokyo), were used as standards.

Purification of C31:9 was performed by reversed-phase high-performance liquid chromatography (HPLC). Crude hydrocarbon extracts (1.5 mg aliquots) were dissolved in 1 mL of acetonitrile. The solution was filtered through a Millex-HV filter (pore size 0.45 μm, Millipore, Billerica, MA). A 300-μL aliquot of the filtrate was subjected to HPLC on a liquid chromatography system (model CCMP, Tosoh, Tokyo) equipped with an ODS column (type TSKgel ODS-80Ts, 15 cm long, 2.0 mm I.D., Tosoh) and an ultraviolet detector (model UV-8010, Tosoh), which had been equilibrated with acetonitrile. C31:9 was eluted with the same solvent at a flow rate of 1.0 mL/min, and absorbance at 210 nm of the eluate was monitored. The retention time of C31:9 was around 16.2 min. C31:9 with a purity of more than 99%, which was evaluated by gas-liquid chromatography (GLC; see below), was subjected to further analysis.

The *cis* and *trans* configurations of double bonds of C31:9 were determined using HPLC-purified hydrocarbon fraction (approximately 500 μg) by infrared spectrometry (IR; model FT/IR 660 Plus, Jasco, Tokyo) by the potassium bromide method. Assignment of individual peaks of C31:9 in IR was referred to [17–19].

The purified hydrocarbon fraction dissolved in hexane at 3.5 μg/mL was fully hydrogenated using H_2 gas at room temperature for 40 min. Platinum(IV) oxide at 5 mg/mL was used as a catalyst. Hydrogenated hydrocarbon was extracted with hexane. Partial hydrogenation was performed using hydrazine [20]. The hydrocarbon fraction (approximately 20 μg) was dissolved in 1 mL methanol and then mixed with 0.1 mL hydrazine and 0.1 mL 30% H_2O_2 (by vol). The reaction mixture was stirred for 90 min at 50 °C. To stop the reaction, 1 mL 5 M HCl was added, and the mixture was extracted with hexane. The extract was applied to silver nitrate TLC on silica gel (no. 5721, Merck), as described previously [21] with a solvent system composed of hexane/benzene (1:1, by vol). Silica gels corresponding to spots whose mobility was close to that of authentic 1-dodecene (C12:1, Sigma–Aldrich) were scraped off the plate and extracted with a mixture of methanol/water/hexane (1:1:2, by vol). A hexane fraction containing hydrocarbons with one double bond was recovered. The location of double bonds in each monounsaturated hydrocarbon was determined by chemical ionization (CI) ion-trap mass spectrometry using acetonitrile as a regent gas (see below and [22–24]).

The FAME fraction including hydrocarbon, crude and purified hydrocarbons, and hydrogenated hydrocarbons were analyzed by GLC as described [25] on a gas chromatograph (model GC-353B, GL Sciences, Tokyo) equipped with a polar capillary column (type BPX70, 25 m long, 0.22 mm I.D., 0.25 μm film thickness, SGE Japan, Yokohama, Japan) unless otherwise stated, and flame ionization detection with nitrogen as the carrier gas. The GLC oven temperature was 80 °C initially and programmed up to 240 °C at a rate of 4.0 °C/min. The oven temperature was held at the maximum for 60 min. The injector and detector temperatures were set at 221 °C. The data were analyzed using a D-2500 Chromato-Integrator (Hitachi, Tokyo). In order to detect PUFAs and PUHCs with very long retention times, GLC analysis was also performed using a nonpolar capillary column (type TC-1, 30 m long, 0.25 mm I.D., 0.1 μm film thickness) obtained from GL Science. The injector and detector temperatures were set at 250 and 340 °C, respectively. The oven temperature was first set at 50 °C, and then raised to 330 °C at the rate of 10 °C/min. The maximum oven temperature was held for 10 min. Triacontanoic acid methyl ester (30:0) and tetratriacontane (C34:0) from Sigma–Aldrich were used as internal standards.

Relative fatty acid and hydrocarbon composition was expressed as weight percentage of the total combined weight of these compounds. The hydrocarbons and FAMEs were also analyzed by ion-trap mode gas chromatography–mass spectrometry (GC/MS) on a Varian system (model CP-3800 gas chromatograph and Saturn 2200 ion trap mass

spectrometer, Varian Technologies Japan, Tokyo) under the same conditions as described previously [25]. Data were analyzed using a Saturn™ Software Workstation Version 5.52. In GC/MS analysis, two modes of electron impact ionization (EI) and CI were utilized and abbreviated as EI-GC/MS and CI-GC/MS, respectively. In CI-GC/MS, acetonitrile was used as an ionization reagent.

FAMEs were identified by comparing their retention times with those of authentic standards in GLC and by their EI-GC/MS analysis. To determine the position of double bonds of monounsaturated fatty acids, the FAME fraction was subjected to the I_2-catalyzed reaction for the formation of adducts with dimethyl disulfide according to the procedure of Shibahara et al. [26] The resultant dimethyl disulfide adducts were analyzed by EI-GC/MS, as described above. The position of double bonds of EPA was determined by EI-GC/MS analysis of its pyrrolidide derivative prepared, as previously [27].

DNA Procedures

For PCR amplification of 16S rRNA genes, osh08 cells were cultivated as described above. Genomic DNA was isolated by the method of Marmur [28]. PCR was performed using a Mastercycler® ep gradient Thermal Cycler (Eppendorf AG, Hamburg, Germany) in a total volume of 50 μL using *Ex Taq* DNA polymerase (Takara Bio) in the supplied buffer. For the amplification of the full length of 16S rRNA genes, primers 9F (5′-GAGTTTGATCCTGG CTCAG-3′) and 1541R (5′-AAGGAGGTGATCCAGCC-3′) were used. PCR was carried out according to the following program, an initial denaturation at 95 °C for 5 min followed by 30 cycles of 1 min at 95 °C, 1 min at 57 °C, and 2 min at 72 °C, concluding with a 5 min extension at 72 °C for the amplification of the 16S rRNA gene. PCR products were analyzed by electrophoresis on 10 g/L agarose gels and were visualized by a UV transilluminator after staining with ethidium bromide (Nippon Gene, Tokyo).

PCR products that had been ligated to the pCR2.1-TOPO® vector using the TOPO TA cloning® Kit (Invitrogen) were subjected to cycle sequencing according to the manufacturer's protocol. Recombinant vectors were used to transform *E. coli* DH5α and transformants were selected by blue/white colony screening. Individual white colonies were grown at 37 °C overnight with rotary shaking in LB medium. Plasmid pCR2.1-TOPO carrying 16S rRNA gene from osh08 was isolated with the mini-preparation method [29]. Cycle sequencing was performed as described previously [30]. The sequence comparative searches were performed using the NCBI (http://www.ncbi.nlm.nih.gov/) databases. The osh08 16S rRNA gene sequence has been deposited in DDBJ/GenBank/EMBL with the accession number of AB447987.

[a] Fatty acids are abbreviated, as in 16:1(9), where the number before the colon shows the number of carbon atoms and after the number of double bonds in the fatty acid. The distance of the double bond from the carboxylic end of the fatty acid is indicated in parenthesis. iso13:0 and iso15:0 are iso-branched fatty acids. C31:9 is hentriacontanonaene

[b] Fatty acids and hydrocarbons were separately quantified using 21:0 and C24:0, respectively, as internal standards, and the sum of these compounds was regarded as 100%. The data indicated are mean ± standard errors for three independent experiments

Results

Extraction and Cellular Contents of Polyunsaturated Hydrocarbons and Fatty Acids

The compound suspected to be a very long chain hydrocarbon with multiple double bonds was extracted with hexane in the FAME fraction after methanolysis of osh08 cells grown at 25 °C. As described below, this compound was identified as a PUHC with 31 carbons and 9 double bonds (hentriacontanonaene; C31:9). Δ9-Hexadecenoic acid (28.8 ± 0.7%) and hexadecanoic acid (14.5 ± 1.0%) were the major fatty acids and pentadecenoic, hexadecenoic, heptadecenoic and octadecenoic acids included two isomers with a double bond at different positions (Table 1). C31:9 was the sole hydrocarbon detected in the fraction. The contents of C31:9 and EPA (20:5) were 3.0 ± 0.6 and 0.5 ± 0.2%, respectively.

C31:9 was extracted directly from dry cells in the hexane fraction with a mixture of hexane and methanol (1:1, by vol). The content of this compound was 0.63 ± 0.02 μg/mg of dry cells for cells grown at 20 °C for 18 h (3.15 μg/mL of culture). The content of C31:9 after methanolysis was calculated to be 0.49 ± 0.01 μg/mg of dry cells (2.45 μg/mL of culture) for cells grown under the same conditions.

Effects of Temperature on the Growth of Strain osh08 and Content of EPA and C31:9

The osh08 cell grew in the temperature range of 4 to 40 °C, and the optimum growth occurred at 30 °C. No growth was observed at 0 °C or 43 °C. According to Wiegel's definition [31], this type of strain should be regarded as mesophilic bacteria that are tolerant to a temperature around 5 °C rather than as psychrotrophs, which can grow at 0 °C.

Table 2 shows the contents of C31:9 and EPA in the total FAME fraction including hydrocarbons after methanolysis of osh08 cells grown at various temperatures. The maximum production of C31:9 and EPA was at 25 and 4 °C, respectively. It is interesting that the content of C31:9 and EPA changed in an antiparallel mode with regard to their biosynthetic pathways (see below). To our knowledge, the highest temperature at which EPA is produced in bacteria is 28 °C for *Shewanella japonica* [32] and *S. pacifica* [33]. Although EPA comprises around 0.2% of total fatty acids, osh08 produced EPA at 37 °C, and the maximum temperature at which C31:9 was produced was also 37 °C (Table 2).

Physicochemical Analysis of C31:9

In EI-gas chromatographic analysis of the FAME fraction including hydrocarbons, C31:9 occurred at a retention time of about 34 min (Fig. 1a), and no peak was detected after C31:9. The mass spectrum of C31:9 in EI-GC/MS was similar to that of the methyl esters of PUFAs such as arachidonic acid, EPA, and DHA, where fragment ions at an *m/z* of 79 and 91 were dominant (Fig. 2a), suggesting that the hydrocarbon contained multiple methylene-interrupted double bonds in the straight aliphatic chain. In CI/MS analysis of the C31:9 peak, an ion of $[M + 54 + H]^+$ at *m/z* 473 was prominent (Fig. 2b). The molecular weight of H_2-hydrogenated C31:9 (C31:0), whose retention time was around 30 min in an EI-gas chromatogram (Fig. 1b), was determined to be 436 by the occurrence of an $[M + 40 + H]^+$ ion at *m/z* 477 in CI/MS (Fig. 2c). These results indicate that the hydrocarbon comprises 31 carbon atoms with 9 double bonds (C31:9, molecular weight, 418).

In GLC analysis of the total FAME fraction using a nonpolar capillary column, EPA and C31:9 appeared around 22 and 28.5 min, respectively, and the retention times of 30:0 and C34:0 used as internal standards were about 26 and 34 min, respectively. However, no peaks suspected to be 32:9 fatty acid were detected (data not shown).

The EI-gas chromatogram of partially hydrogenated hydrocarbons gave five peaks (peaks 1, 2, 3, 4, and 5 in Fig. 3) with the same molecular weight of 434, suggesting that the fraction was a mixture of hydrocarbons with one double bond at different positions.

The CI-mass spectrum of one isomer (peak 1 in Fig. 3) was shown in Fig. 4a, where fragment ions at *m/z* 264 (a) and 278 (b) were evident. This result indicates the location of a double bond at 15 (or 16 when counted from the opposite end). Peak 2 was that of an isomer having a double bond at 12 or 19, because fragment ions at *m/z* 222 (a) and 320 (b) were detected (Fig. 4b). Peaks 3, 4, and 5 were determined to be isomers having double bonds at 9 or

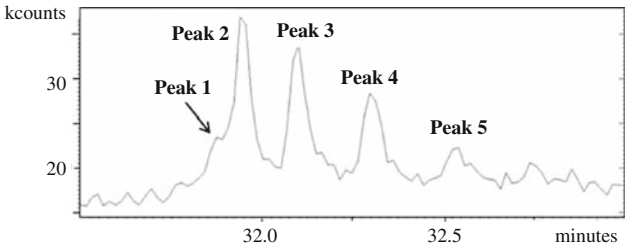

Fig. 3 EI-gas chromatogram of a C31:1 mixture prepared from partially hydrogenated C31:9. Five peaks of the C31:1 isomers were numbered

22, 6 or 25, and 3 or 28, respectively (Fig. 4c–e). The results are summarized together with the relative intensity of each diagnostic ion in Table 3. The double bonds at 3, 6, 9, and 12 are equivalent to the locations at 28, 25, 22, and 19, respectively.

The infrared spectrum of HPLC-purified C31:9 is shown in Fig. 5. There were intense peaks at 2,963 and 2,855 cm^{-1} corresponding to C–H stretching of CH_3 groups, intense peaks at 2,921 and 2,360 cm^{-1} corresponding to C–H stretching of CH_2 groups, and peaks at 1,457 and 1,337 cm^{-1} corresponding to C-CH_2 and C-CH_3 groups, respectively [18]. A peak at 1,391 cm^{-1} corresponded to CH bending of the HC=CH *cis* double bond [19]. However, there was no peak at 970 cm^{-1} corresponding to CH bending of the HC=CH *trans* double bond. The intense peaks around 3,015 and 1,670 cm^{-1} are regarded as those corresponding to CH stretching and C=C stretching, respectively, of the HC=CH *cis* double bond [17, 19]. The relatively intense peak at 1,731 cm^{-1} is considered to correspond to C=O and C–O stretching of

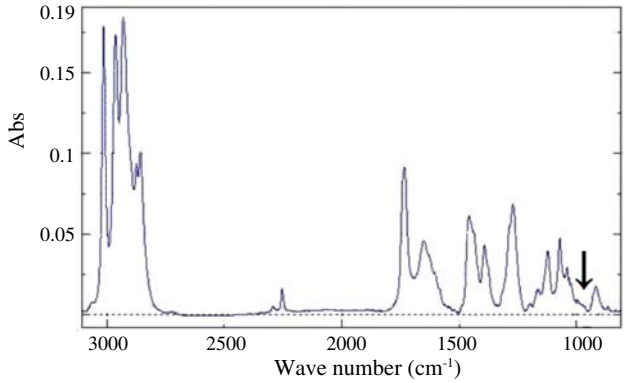

Fig. 5 IR spectrum of C31:9. There was no characteristic peak at 970 cm^{-1} corresponding to CH bending of the HC=CH *trans* double bond (a region indicated by *arrow*)

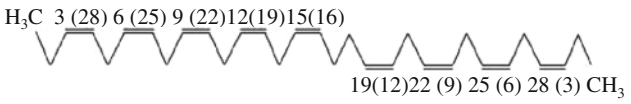

Fig. 6 Proposed structure of C31:9. The position of the double bonds of C31:9 (product) was counted from both methyl ends

carboxylate ester of the contaminating fatty acid methyl esters [17, 19]. Considering all these data together, we identified the compound as all *cis*-3, 6, 9, 12, 15, 19, 22, 25, 28-hentriacontanonaene (C31:9) (Fig. 6). The position and geometry of double bonds of C31:9 were determined for the first time in this study.

Distribution of C31:9 in Various Microorganisms and its Possible Biosynthetic Pathways

Table 4 shows the distribution of EPA, DHA, C31:9, and *pfa* genes in bacteria and some eukaryotic microorganisms. C31:9 was found in all tested marine bacteria that produce EPA or DHA, as also found by Nichols et al. [1]. The *pfa* genes responsible for the biosynthesis of EPA and DHA have been cloned from *S. pneumatophori* SCRC-2738, *S. marinintestina* IK-1, and *M. marina* MP-1 [3]. *Shewanella oneidensis* MR-1^T grown at 20 °C for 18 h contained both EPA and C31:9 at 0.2 ± 0.1 and $2.0 \pm 0.7\%$, respectively, of the total FAME and hydrocarbon fraction, although this strain, which was isolated from sediments of a freshwater lake, does not require NaCl for growth [34] and is recognized as mesophilic [35]. The chromosome of this bacterium (AE014299; see [36]) included *pfa* genes (Table 4). However, the marine bacterium *P. alcaliphila* AL15-21^T and nonmarine yeast produced neither PUFA nor C31:9. Two marine eukaryotes, which are known to produce very high levels of DHA and other PUFAs [15, 16], produced no C31:9. These eukaryotic microorganisms are expected to have *pfa*-like genes that are responsible for the biosynthesis of PUFAs because such genes have been cloned from *Schizochytrium* sp. ([37] and see accession numbers AF378327, AF378328, and AF378329). Although *E. coli* DH5α does not inherently produce EPA or DHA, the cells transformed with the *pfa* genes responsible for the biosynthesis of EPA and DHA produced EPA and DHA, respectively, but not C31:9 (Table 4 and see [3]). In contrast, the EPA-deficient mutant (strain IK-1Δ8) of *S. marinintestina* IK-1, in which one of the five *pfa* genes, *pfaD* gene, responsible for biosynthesis of EPA is defective [38], produced neither EPA nor C31:9. These results suggest that five *pfa* genes are involved in the biosynthesis of C31:9. However, *pfa* genes must not be the only genes responsible for the formation of C31:9 because *E. coli* recombinants carrying *pfa* genes had no C31:9 (Table 4).

Tentative Identification of Strain osh08

The 1,534 bp nucleic acid sequence of the 16S rRNA gene of osh08 was determined and was 99.8 and 98.4% similar to that of *Shewanella basaltis*^{T} (EU143361) and *S. hafniensis*^{T} (AB205566), respectively. The strain was identified tentatively as *Shewanella* sp. strain osh08. Detailed characterization of this strain is in progress.

Discussion

In this study, an EPA-producing mesophilic strain (*Shewanella* sp. strain osh08) was isolated from the mid-latitude seashore of Hokkaido, Japan. This strain included a long-chain PUHC, hentriacontanonaene (C31:9), which has never been reported in bacteria other than psychrophiles [1, 2]. The geometry and position of the double bonds in this compound were determined to be all *cis* (Fig. 5) at positions 3, 6, 9, 12, 15, 19, 22, 25, and 28 (Table 3 and see Fig. 6). The same compound (C31:9) was detected in marine and nonmarine, and psychrophilc and mesophilic bacteria, which contained EPA and/or DHA (Table 4).

[a,b] Present and absent, respectively

[c] Present but only the *pfaD* gene is deficient

[d,e] *E. coli* DH5α carrying pEPAΔ1 that contains *pfaA–E* genes responsible for the biosynthesis of EPA and *E. coli* DH5α carrying pDHA3 that contains *pfaA–pfaD* genes and *pfaE* gene responsible for the biosynthesis of DHA, respectively

Based on our present results, previous studies on the bacterial distribution of PUFAs and *pfa* genes [3], and data on the predicted biosynthetic pathway of PUFAs in the polyketide synthesis mode [37, 39, 40], we will discuss the biosynthetic routes of C31:9.

When hydrocarbons are produced from fatty acids, decarboxylation of the precursor is necessary. Aliphatic hydrocarbons can be produced in eukaryotes by decarboxylation of corresponding fatty acids [6]. Some marine and freshwater algae produce a C21:6 hydrocarbon with double bonds at 3, 6, 9, 12, 15, and 18, and this PUHC is thought to be formed by decarboxylation of DHA [5], although no biochemical or molecular evidence is available. This speculation is acceptable because (1) the positions of the double bonds of C21:6 are consistent with the view of the decarboxylation of DHA with double bonds at Δ4, 7, 10, 13, 16, and 19; and (2) most organisms that have C21:6 also contain DHA [5].

Two biosynthetic routes can be proposed for the formation of C31:9 (see Fig. 7). One pathway is that C31:9 is synthesized by a head-to-head condensation mechanism, in which two molecules of Δ4, 7, 10, 13-hexadecatetraenoic acid (16:4) are condensed in a head-to-head mode. An additional double bond can be formed by the condensation of two fatty acid molecules, which releases CO_2 (Fig. 7a). The head-to-head formation of long chain nonisoprenoid hydrocarbons from fatty acids has been reported in both in vivo [41] and in vitro [42] systems of *Sarcina lutea*, where a monounsaturated long chain hydrocarbon can be formed from two saturated fatty acid molecules by the following equation [41–43].

$$RCH_2COOH + R'CH_2COOH \rightarrow RCH = CHCH_2R' + CO_2$$

In the in vitro system, the head-to-head condensation requires coenzyme A, Mg^{2+}, ATP, NADPH, and either

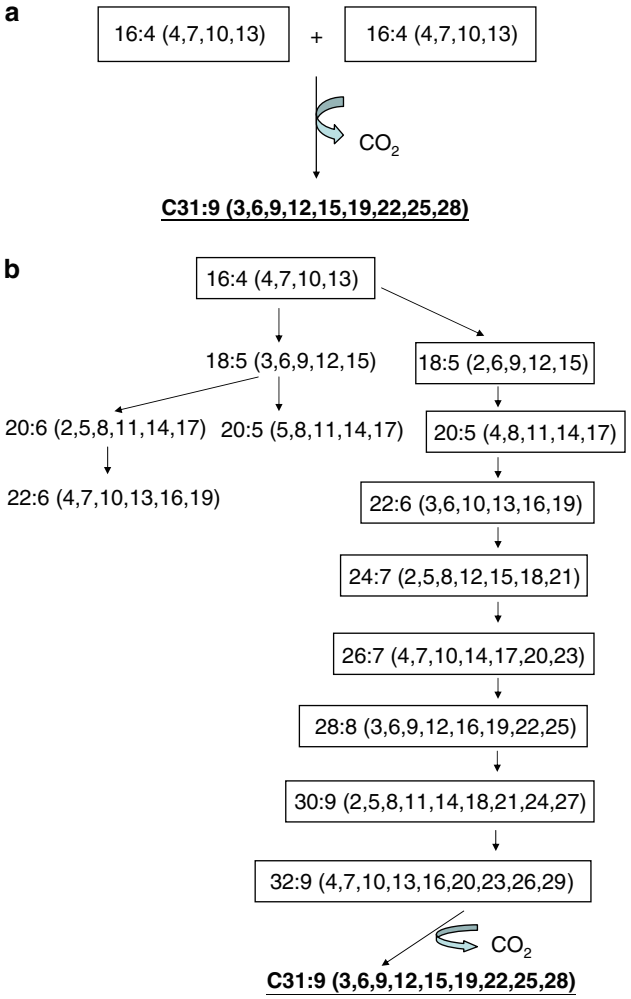

Fig. 7 Possible biosynthetic pathways of C31:9. **a** C31:9 formation by head-to-head condensation of two Δ4,7,10,13-hexadecatetraenoic acid (16:4) molecules. **b** C31:9 formation by decarboxylation of a hypothetical very long chain polyunsaturated fatty acid, Δ4,7,10,13,16,20,23,26,29-dotriacontanonaenoic acid (32:9), which may be synthesized by the Pfa protein complex using 16:4 as a precursor. Fatty acids in this figure are abbreviated, as in 16:4(4,7,10,13), where the number before the colon shows the number of carbon atoms and after the number of double bonds in the fatty acid. The distances of the double bonds from the carboxylic end of the fatty acid are indicated in parentheses. Fatty acid intermediates before 16:4 (4,7,10,13) are not shown. Compounds other than 16:4(4,7,10,13), 20:5(4,8,11,14,17) (EPA), 22:6(4,7,10,13,16,19) (DHA), and hentriacontanonaene (C31:9) are hypothetical. Boxed fatty acids are regarded as intermediates in the formation of C31:9

pyridoxal phosphate or pyridoxamine phosphate as cofactors [43]. Although we have no direct biochemical evidence on the role of this mechanism in the formation of C31:9, the number and positions of double bonds in C31:9, the antiparallel occurrence of EPA and C31:9 in osh08 cells (below 25 °C, Table 2), and the detection of 16:4 in EPA-producing recombinant *E. coli* [44] support this hypothetical pathway.

The other proposed biosynthetic pathway of C31:9 may occur by decarboxylation of a hypothetical very long chain PUFA, Δ4, 7, 10, 13, 16, 20, 23, 26, 29-dotriacontanonaenoic acid (32:9), which may be synthesized by the Pfa protein complex using 16:4 as a precursor (Fig. 7b). At the final step in this hypothetical biosynthetic process of C31:9, decarboxylation of the 32:9 fatty acid is necessary. No intermediate fatty acids other than 16:4 would be overlapped after 16:4 in the biosynthetic pathways of 32:9 and EPA (and DHA) because of the antiparallel occurrence of EPA and C31:9 in osh08 cells grown at various temperatures. However, no fatty acid corresponding 32:9 has been detected in the FAME fraction of osh08 under different GLC conditions using polar and non polar columns (see above). In both proposed pathways, the C31:9 molecule could have an ethylene-interrupted double bond between C15 and C19 (or C12 and C16) (see Figs. 6 and 7). With regard to the decarboxylation activity to synthesize C31:9, such activity would be present only in bacteria carrying *pfa* genes, because there was no C31:9 detected in two PUFA-producing marine eukaryotes, which are expected to have eukaryote type *pfa* genes ([37] and Table 4).

Acknowledgments The infrared analysis of C31:9 was carried out using the apparatus of the OPEN FACILITY, Hokkaido University Sousei Hall with extensive assistance by and discussion with Dr. Y. Matsuo. The authors would like to express their appreciation to Drs. K. Shimazu and K. Nakata of the Faculty of Environmental Earth Science, Hokkaido University for their discussions throughout the work. This work was partly supported by a grant from the National Institute of Polar Research and a Grant-in-Aid from Hokkaido Innovation through Nanotechnology Support (HINTS).

Abstract An acclimation to the changing physicochemical conditions and high amount of Δ^{12}-unsaturated fatty acids of the Antarctic *Chlorella vulgaris* NJ-7 prompted us to speculate about the involvement of Δ^{12}-fatty acid desaturases (FAD) in its adaptation to the extremely unfavorable ambience. A full-length cDNA sequence, designated CvFAD6, was isolated from *C. vulgaris* NJ-7 via RT-PCR and RACE methods. Sequence alignment showed that the gene was homologous to corresponding Δ^{12}-FAD from other eukaryotes. Phylogenetic analysis showed that it was grouped with plastidial Δ^{12}-FAD with conserved histidine boxes. Yeast cells transformed with a plasmid construct containing CvFAD6 coding region accumulated a considerable amount of linoleic acid ($18{:}2\Delta^{9,12}$), normally not present in wild-type yeast cells, suggesting that the isolated gene encodes a functional Δ^{12} enzyme. The correlation between the accumulation of CvFAD6 and temperature has been examined by real time PCR. The analysis showed a constant expression of CvFAD6 from 25 to 15 °C whereas a fourfold increased from 25 to 4 °C. Moreover, CvFAD6 transcription was more sensitive to saline stress since a 20-fold increase at 6% NaCl was detected. Our data demonstrate that CvFAD6 is the enzyme responsible for the Δ^{12} fatty acids desaturation involved in low temperature and high salinity acclimation for Antarctic *C. vulgaris* NJ-7.

Introduction

Cold-adapted organisms are able to acclimate rapidly to the changing physicochemical conditions within the brine channel systems. The capability of responding to rapid changes in a host of external stresses including, temperature and salinity, is therefore an intrinsic characteristic of life in sea ice and just as important as being able to survive freezing temperatures [1]. *Chlorella vulgaris* NJ-7 grow

well at temperatures between 4 and 30 °C [2]. Compared with other well studied cold-adapted chlorophytes that failed to grow at temperatures above 20 °C [3, 4], it has retained a higher versatility in response to environmental changes. *C. vulgaris* NJ-7 would seem to be the first candidate for research on acclimation to dramatic temperature and salinity shifts.

Organisms have evolved a number of adaptive mechanisms to counteract the effects of temperature change such as, loss of membrane fluidity, decrease in enzymatic activity, and a decline in protein stability [5]. Total fatty acids of *C. vulgaris* NJ-7 showed variations for different treatments. It is highest at 4 °C (71.09 ± 2.09 mg/g) while lowest at 25 °C (53.99 ± 3.07 mg/g). They are 70.14 ± 2.740020, 60.87 ± 2.82 and 60.73 ± 1.48 mg/g at 15 °C, 25 °C + 3% NaCl and 25 °C + 6% NaCl, respectively (our data). Cold adaptation has always been linked to high levels of membrane-associated polyunsaturated fatty acids (PUFA). Moreover a higher degree of unsaturated fatty acids (UFA) in the membrane lipids is also an adaptive advantage under high-salinity stress [6]. The total amount of Δ^{12} UFA (16:2, 16:3, 18:2 and 18:3) was 37.49 and 34.53% in Antarctic microalgae *Chlamydomonas raudensis* Ettl (UWO241) and *Chlorella* BI, respectively [4]. Otherwise, it was about twice as much in *C. vulgaris* NJ-7 (73.7%) [7]. C18:2, normally 20–30 mg/g (our data), is high while the amount of C18:1 is only a trace (0.03 mg/g) in *C. vulgaris* NJ-7. On the other hand, researches on fatty acid distributions of *C. vulgaris* NJ-7 under different treatments revealed the linkage between fatty acids alteration and stresses. Percentages of 18:2 in total fatty acids by mass increased in response to exposure to lower temperature and higher salinity [7].

Fatty acid desaturases (FAD) play an essential role in fatty acid metabolism and the maintenance of biological membranes [8]. High amount of Δ^{12}-UFA of *C. vulgaris* NJ-7 prompted us to speculate about the involvement of Δ^{12}-FAD in its adaptation to the extreme unfavorable ambience. FAD can be divided into two groups: soluble and membrane-bound desaturases. Of the latter, Δ^{12} FAD catalyze the desaturation at Δ^{12} position to introduce the second hydrogen bond and anchor to the endoplasmic reticulum (ER) and plastidial membrane as two different isoforms: FAD2 and FAD6 [9, 10].

In order to clarify the involvement of Δ^{12} FAD in freezing and salt tolerance and further explore the regulatory mechanism of oleate desaturation, we isolated a novel plastidial oleate desaturase (FAD6) gene in Antarctic microalga, *C. vulgaris* NJ-7 and demonstrated its function by expression in yeast. Meanwhile, the expression pattern of this gene was investigated at different temperature or salt stresses.

Materials and Methods

Strains and Growth Conditions

Chlorella vulgaris NJ-7 was grown in batch cultures in a salt medium (BG11) [11], and initially maintained at a temperature of 25 °C with 12 h of incandescent light and 12 h of darkness.

DNA and RNA Isolation and cDNA Synthesis

Chlorella vulgaris NJ-7 in the exponential growth phase were harvested. The dried mass was frozen in liquid nitrogen, ground with a mortar and pestle into a fine powder. Genomic DNA was isolated following the protocol described by Sambrook et al. [12]. Total RNA was extracted from the powder according to the method of Li et al. [13]. The RNA samples were used for the first-strand cDNA synthesis after being treated with DNaseI to remove DNA. It was synthesized with a reverse transcription polymerase chain (RT-PCR) reaction kit (Takara) according to the manufacturer's instructions. A 500-μg amount of total RNA was used in a 20-μL reaction system. Controls received water instead of reverse transcriptase to assess any contamination from genomic DNA as described by Zhou et al. [14].

PCR with Degenerate Primers

First-strand cDNA was used as a template. Available sequences of Δ^{12}-acyl lipid desaturases from the GenBank database [15] were used to design two degenerate primers, F1/R1 (Table 1). F1 and R1 corresponded to the highly conserved regions FVVGHDC and FWMSTF.

PCR contained 1 × PCR Ex Taq buffer (Mg^{2+} plus), 0.2 mM of each dNTP, 0.4 μM of each primer, and 1 U of Ex-Taq (Takara) per 25 μL reaction. Amplification run on a Tpersonal Thermocycler 118 (Biometra, Germany) following parameters: an initial 5-min denaturation step at 94 °C, followed by 30 cycles of 94 °C for 30 s, 55 °C for 30 s, and 72 °C for 1 min, finally extended at 72 °C for 7 min. The PCR fragments were cloned into a pMD-18-T vector (Takara) and sequenced.

Full-Length cDNA and Genomic Sequences Isolation

The nucleotide sequences of the 3′ and 5′-ends of CvFAD6 were amplified by the RACE method [12]. Amplifications were carried out using the SMART RACE cDNA Amplification Kit (BD-Clontech) according to the manual. 3′ and 5′RACE were performed using gene-specific primers (3GSP1, 3GSP2, 5GSP1 and 5GSP2, Table 1). PCR was carried out using the formulation described in the manual.

Table 1 Primers used in experiment

F Forward, *R* reverse

The program was performed as follows: 5 min at 94 °C, followed by 30 s at 94 °C, 3 min at 72 °C, for 5 cycles, 30 s at 94 °C, 30 s at 70 °C and 3 min at 72 °C, for 5 cycles, 30 s at 94 °C, 30 s at 68 °C and 3 min at 72 °C, for 25 cycles, finally extended at 72 °C for 7 min. Nested PCR was carried out using the nested universal primers and gene-specific primers. Secondary PCR fragments were subcloned into pMD-18-T vector and nucleotide sequences were determined.

Based on the information of 3′- and 5′-ends sequences, two gene-specific primers F2 and R2 (Table 1) were designed to amplify the full-length cDNA and genomic sequence. PCR was performed with the GC-Rich PCR system (Takara) using 1 × GC buffer (Mg^{2+} plus), 0.2 mM dNTP, 0.5 μM F2 and R2, 1 U of LA-Taq per 25 μL reaction. Reaction conditions were as follows: 5 min denaturation at 94 °C, followed by 30 cycles of 94 °C for 30 s, 55 °C for 30 s and 72 °C for 1 min/kb, finally extended at 72 °C for 7 min. The PCR fragments of the expected length (1.4 and 3.1 kb) were cloned into pMD-18-T vector and sequenced.

Sequence Analysis

A BLAST search program (http://www.ncbi.nlm.nih.gov/blast/) was used. Multiple sequence alignment of putative CvFAD6 was performed with Clustalx1.81 [16]. The distribution of the hydrophobic amino acids was analyzed using the Kyte-Doolittle hydropathy scale [17]. Transmembrane (TM) regions of the protein were predicted with TMHMM (Transmembrane Hidden Markov Model) [18]. The signal sequence analysis was done using a signal peptide prediction server [19].

Phylogenetic affiliation of the CvFAD6 was examined by comparing it to the confirmed and putative plastidial and microsomal Δ^{12} FAD obtained from public databases. Amino acid sequences were aligned using the ClustalX program with the implanted BioEdit [16, 20]. Phylogenetic trees were constructed using neighbor-joining methods, as implemented in the program MEGA4 [21]. Minimum evolution and maximum parsimony analyses were also performed. Bootstrap support was estimated using 1,000 replicates for distance analyses. Default program parameters were used.

Expression in Yeast

The open reading frames was amplified with specific primers, F5 and R5 (Table 1), and subcloned behind the GAL1 promoter of the yeast expression vector pYES2.0 (Invitrogen). The 5′ ends of the F5 and R5 contain an *Eco*RI or an *Xho*I restriction site (underlined) respectively to facilitate subsequent manipulation. The sequence orientation and identity were confirmed by sequencing and the resulted plasmid was designated pYFAD6.

Saccharomyces cerevisiae INVSc1 was transformed and selected according to the manual. Yeast cultures were grown to logarithmic phase at 30 °C in synthetic minimal medium (SC-Ura). The cells were then induced as described by Robert et al. [22], and were incubated at 15 °C for a further 48 h. The cells were harvested by centrifugation, and washed three times with sterile distilled water and then dried by lyophilization. The total lipids were extracted and analyzed according to the method described by Hsiao [23].

Growth Under Various Stresses and Quantification Real Time PCR (qRT-PCR)

Algae at the logarithmic phase were divided into five treatments for a further 14 days. The treatments are as follow: 25 °C, 0% (w/v) NaCl (control); 15 °C, 0% NaCl; 4 °C, 0% NaCl; 25 °C, 3% NaCl; 25 °C, 6% NaCl. Turbulence was monitored by determining OD_{730} every 24 h. Values were calculated with the mean of three independent samples. For real-time PCR, algae at the logarithmic phase were divided into the same five treatments. After an interval of 36 h, algae were harvested by centrifugation at 5,000 rpm for 5 min at 4 °C and washed with sterile,

distilled, deionized water to remove salts before they were centrifuged again.

Two pairs of gene-specific primers were designed according to the CvFAD6 cDNA (F3 and R3) and β-actin sequences (F4 and R4, Table 1). Standard curves for CvFAD6 and β-actin genes were generated by tenfold serial dilutions (10^5–10^{10} copies/μL) of each plasmid DNA to select the optimum dilution degree for qRT-PCR. PCR products were quantified continuously with ABI 7900 Real-Time PCR System (Applied Biosystems) using SYBR Green fluorescence (Takara) according to the manufacturer's instruction. Control reactions were amplified with an RNA template but without reverse transcriptase. The relative amounts of CvFAD6 RNA were normalized to the respective β-actin transcripts. The $2^{-\text{delta delta CT}}$ method [24] was used to analyze qRT-PCR data.

Nucleotide Sequencing and Accession Number

The nucleotide sequences of CvFAD6 genomic and cDNA have been deposited and assigned the accession number GQ175317 and FJ774004 in the EMBL/GenBank/DDBJ database.

Results

Cloning and Characterization of the CvFAD6 Gene

A 470 bp cDNA fragment was generated by RT-PCR with degenerate primers. The amplicon shared a 69% sequence similarity to chloroplast Δ^{12} FAD genes from *Chlamydomonas* sp. W80 and *Polytomella parva*. It indicated that a partial putative FAD6 had been isolated. Gene-specific primers were further designed to obtain the full-length CvFAD6. A 640 bp 5′-RACE product and an 843 bp 3′-RACE product were amplified. The nucleotide sequences of both products from RACE experiments shared an overlap on flanking regions of the 5′ or 3′ ends of the partial putative CvFAD6 cDNA fragment, suggesting that these fragments are portions of the same gene. Sequence analysis revealed that the cloned CvFAD6 cDNA was 1,615 bp in length, which contained a 1,272 bp open reading frame, a 56 bp 5′-untranslated region, and a 287 bp 3′-untranslated region with the characteristics of the poly (A) tail. An ATG translation initiation codon was identified in the sequence of the 5′ terminus (57–59 bp), and a TAA termination codon was found 1,270 nucleotides downstream of the initiation site.

BlastX and BlastN searches combined with alignments between CvFAD6 genome and CvFAD6 cDNA sequences allowed us to identify the genomic organization. The result indicated that CvFAD6 genomic sequence of 3,112 bp was interrupted by nine introns. The sizes and splicing sites of the exons were summarized in Fig. 1. There were canonical GT/AG splicing signals at the ends of the putative introns. The 3′ acceptor splice site is also preceded by pyrimidine-rich sequences as is a common feature of mRNA 3′ splice sites.

Comparison with Other Desaturases

CvFAD6 encoded 423 amino acid residues with an estimated molecular mass of 48.3 kDa and a theoretical isoelectric point of 8.78. A Blast search revealed that the primary structure of CvFAD6 showed 29 and 32% similarity to its (EU596474) [7] and *Chlorella* C-27 microsomal Δ^{12} FAD (BAB78716) [25], respectively. However, it was more similar to these of known plastidial Δ^{12} FAD, with a 65% identity to *C. reinhardtii* (XP_001693068), 63% to *Mesostigma viride* (ABD58898), 53% to *Descurainia Sophia* (ABI73993) and 54% to *Arabidopsis thaliana* (NP_194824). Thus, we deduced that CvFAD6 encoded a plastidial Δ^{12} desaturase rather than a microsomal one.

The distribution of the hydrophobic amino acids of CvFAD6 was typical for a membrane protein, as identified using the Kyte-Doolittle hydropathy scale [17]. The prediction of TM helices by TMHMM indicated that the deduced protein contained five hydrophobic domains between amino acids 102–124, 129–148, 218–240, 255–277 and 282–304, which would be long enough to span the membrane bilayer twice, with the N-terminus facing the cytosol. In addition, CvFAD6 had a transit peptide at the N-terminus, which was a feature of plastidial desaturases as represented by soybean gmFAD6 [26]. All these observations suggested that CvFAD6 encoded a plastidial, rather than a microsomal, Δ^{12} FAD.

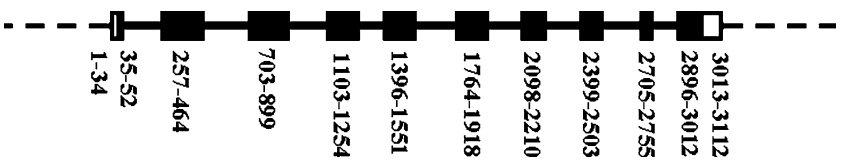

Fig. 1 The complete gene structures of *C. vulgaris* NJ-7 FAD6. Exons are shown as *boxes*: *black boxes* are open reading frames, *empty boxes* are 5′- or 3′-untranslated regions

A multiple sequence alignment of CvFAD6 against similar plastidial Δ^{12} FAD highlighted conserved motifs including FVVGHDC and FWMSTF against which the degenerate primers were designed. Otherwise conserved histidine boxes, HXXXXH (147–151), HXXHH (183–187, 345–349), HXXXXXH (234–239) and HHXXXH (302–307), were found to located in hydrophilic regions separated by long hydrophobic or membrane spanning regions. The histidine-rich motifs, which were highly conserved among membrane-bound acyl-CoA and acyl-lipid desaturases, were proposed as forming the potential diiron active site [27].

Phylogenetic Analysis

All tree topologies were highly congruent. Two major clades were very well supported based on bootstrap values (Fig. 2). All of the microsomal Δ^{12} FAD were grouped. CvFAD6 was clustered within plastidial Δ^{12} FAD group.

Functional Analysis in *S. cerevisiae*

To validate the protein activity, pYFAD6 and empty vector, pYES2.0 (control), were expressed in *S. cerevisiae* INVSc1. Compared with fatty acid profiles derived from the control, pYFAD6 transformants showed a novel peak. The novel peak corresponded to 18:2 which was produced by Δ^{12} desaturation of 18:1Δ^{9}. No 16:2 was detected, indicating that CvFAD6 recognized only one substrate (18:1) in yeast (Fig. 3). Different TM topologies of Δ^{12}-FAD were proposed which lead to different regioselectivity [28]. Δ^{12}-FAD from the *Lentinula edodes* [29] and *Rhizopus arrhizus* [28] recognized only one substrate (18:1)

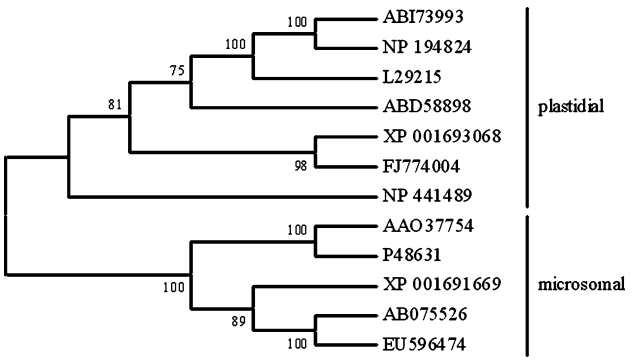

Fig. 2 Neighbor-joining phylogram showing relation of Δ^{12} FAD and related desaturases based on amino acid sequences. Bootstrap analysis of 1,000 randomized sequence replicates was performed; Sequences shown are: ABI73993-*D. Sophia*, NP_194824-*A. thaliana*, L29215-*Glycine max*, ABD58898-*M. viride*, XP_001693068-*C. reinhardtii*, FJ774004-CvFAD6, NP_441489-*Synechocystis* sp. PCC 6803 DesA, AAO37754-*Punica granatum*, P48631-*Glycine max*, XP_001691669-*C. reinhardtii*, AB075526-*Chlorella* C-27, EU596474-CvFAD2

whereas Δ^{12}-FAD from *Phaeodactylum tricornutum* [30], *Sapium sebiferum* [31] and *Chlorella* C-27 [25] recognized two substrates (16:1 and 18:1) while 18:1 was the preferred substrate. Furthermore, the amount of 18:1 was found to be reduced which can be explained by the conversion of 18:1 into 18:2 (Table 2). These results demonstrate directly that CvFAD6 gene encodes a Δ^{12} fatty acid desaturase, which converts 18:1 to 18:2.

Yeast is known to be the model of choice for the functional characterization of microsomal FAD, because it contains a physiological electron donor system (cytochrome b5 and NADH-cytochrome b5 reductase) required by such desaturases. However, it is surprising that a plastidial oleate desaturase (FAD6), that uses ferredoxin as the physiological electron donor, can be functionally expressed in *S. cerevisiae*, where no ferredoxin is present. Nevertheless, the low desaturation levels evident from Fig. 3b suggest activity of desaturases of plastidial origin. The possible reason is that ferredoxin and NADPH-ferredoxin reductase, are supplied to some extent with reducing equivalents in yeast cells. It is consistent with the finding in *P. tricornutum* [30].

Effects of Temperature and Salt Stress on the Growth of *C. Vulgaris* and CvFAD6 Expression

Algal cells at the logarithmic phase were transformed with different treatments: 4 °C + 0% NaCl, 15 °C + 0% NaCl, 25 °C + 0% NaCl, 25 °C + 3% NaCl, and 25 °C + 6% NaCl, with the starting optical density $OD_{730} = 0.8$, each of these in triplicate. Cell density was monitored turbidometrically at 730 nm daily, and specific growth rates were calculated using the equation $\mu = (\ln Xt - \ln X0)/t$, where $X0$ is the initial cell density, and Xt is the cell density after t days [2]. The results signified that low temperature and high salinity slowed down the growth of *C. vulgaris* NJ-7. The growth rate at 4 °C + 0% NaCl was lower than that at 15 °C + 0% NaCl, and the latter was lower than that at 25 °C + 0% NaCl (Fig. 4a); meanwhile, the growth rate at 25 °C + 6% NaCl was lower than that at 25 °C + 3% NaCl while the latter was lower than that at 25 °C + 0% NaCl (Fig. 4b). And 25 °C + 6% NaCl had the most serious effects on its growth. Next were 4 °C + 0% NaCl, and 25 °C + 3% NaCl (Fig. 4c).

Considering the changing profiles of 18:2 fatty acid and the preliminary experiments [7], we chose an interval of 36 h for stress treatment. Then algae were harvested for first strand cDNA synthesis.

The gene expression patterns of CvFAD6 in *C. vulgaris* NJ-7 were analyzed by qRT-PCR. β-Actin [7] was used as a reference for total RNA. β-Actin PCR product was not detected when reverse transcriptase was omitted, indicating that the RNA template was free of genomic DNA. The data

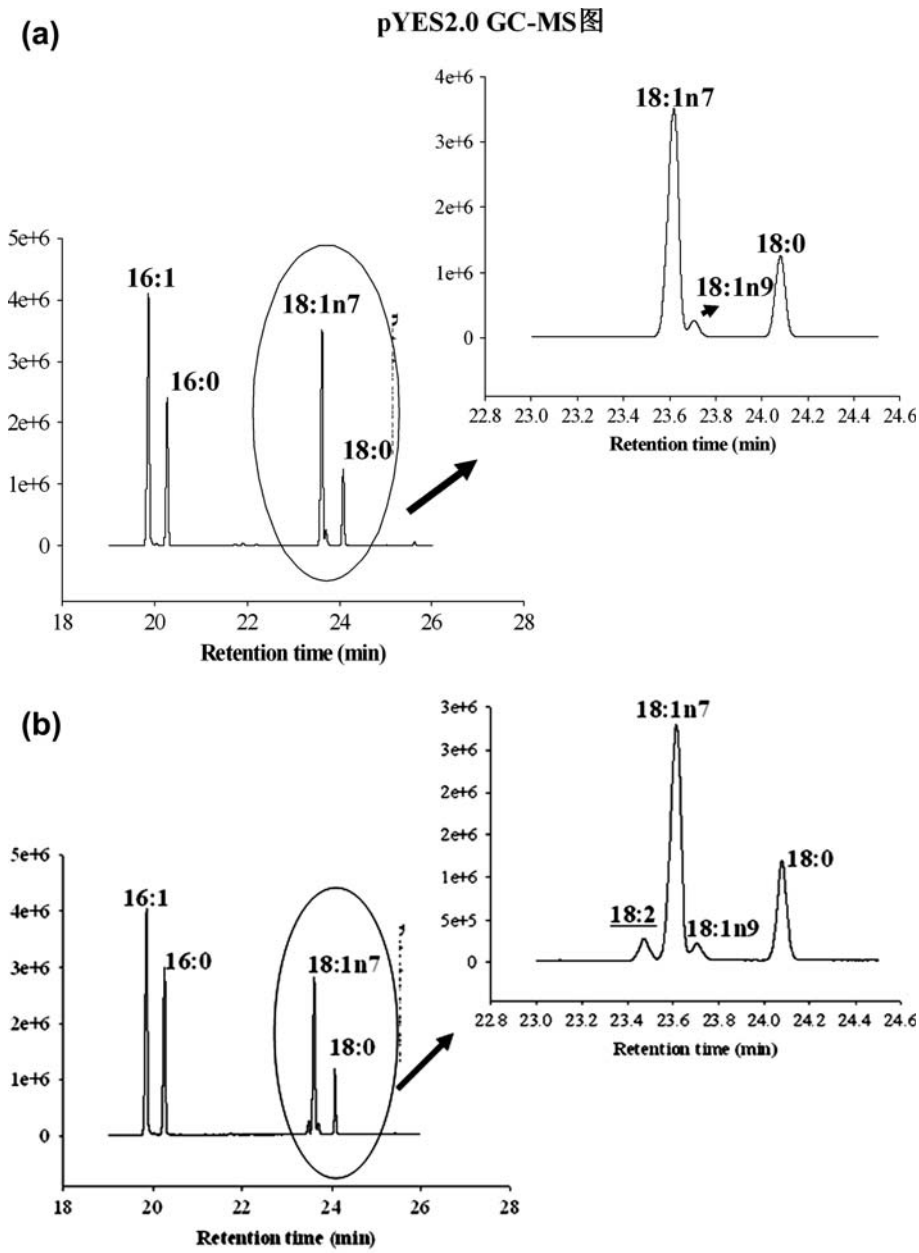

Fig. 3 GC of FAME of recombinant yeast harboring pYES2 (control, **a**) and pYFAD6 containing the CvFAD6 gene (**b**). The transformants at logarithmic phase were grown for 48 h at 15 °C, and FAME from whole cells were prepared and analyzed by gas chromatography (GC) as indicated in "Materials and Methods". The experiment was repeated twice and results of a representative experiment are shown

revealed that temperature and salt concentration regulated the accumulation of CvFAD6 gene transcripts. Transcript accumulations remained relatively constant when algae at 25 °C were transferred to 15 °C. However, transcript accumulation increased significantly at 4 °C, more than fourfold than that at 25 °C (Fig. 5). CvFAD6 was expressed abundantly under salt stress, twofold at 3% NaCl and 20-fold at 6% NaCl (Fig. 5). Thus NaCl was related to the upregulation of CvFAD6 mRNA levels. A higher expression pattern under salt stress suggested a correlation between the level of membrane desaturation and salt concentration.

Discussion

A novel plastidial Δ^{12} fatty acid desaturase from Antarctic *C. vulgaris* NJ-7 was isolated using RT-PCR with degenerate primers designed from conserved motifs and RACE methods. The isolated protein was found to contain features

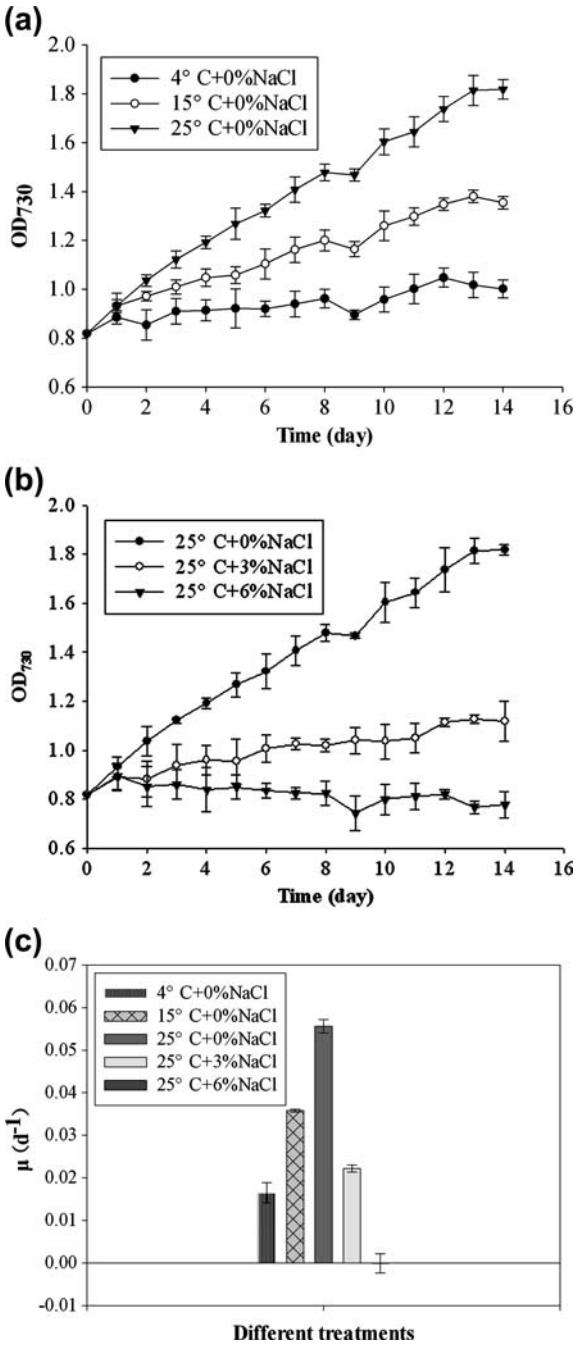

Fig. 4 Effects of temperature and salinity on the growth of *C. vulgaris* NJ-7. Algae at the logarithmic phase were divided into five treatments. The treatments are as follow: 25 °C, 0% (w/v) NaCl (control); 15 °C, 0% NaCl; 4 °C, 0% NaCl; 25 °C, 3% NaCl; 25 °C, 6% NaCl. Turbulence was monitored by determining OD_{730} every 24 h. **a** growth curve at different temperature; **b** growth curve at different concentration of NaCl; **c** growth rates of *C. vulgaris* NJ-7 which were calculated using the equation $\mu = (\ln Xt - \ln X0)/t$, $X0$ is the initial cell density, and Xt is the cell density after t days. characterizing membrane-bound Δ^{12} FAD including membrane-spanning regions separating conserved histidine boxes.

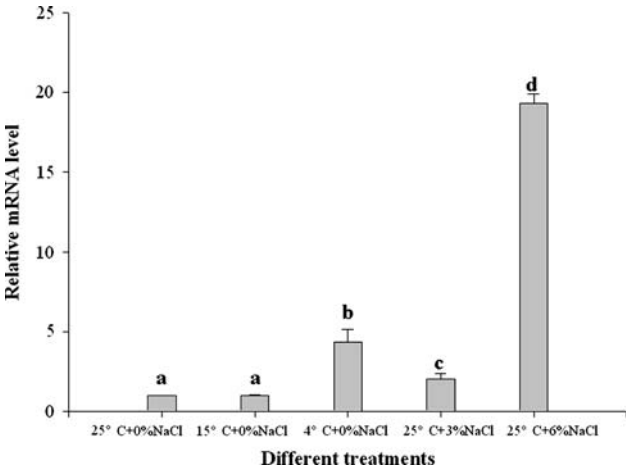

Fig. 5 Real-time-PCR quantification of the CvFAD6 mRNA levels under different stresses. Algae at logarithmic phase were divided into five treatments: 25 °C, 0% (w/v) NaCl (control); 15 °C, 0% NaCl; 4 °C, 0% NaCl; 25 °C, 3% NaCl; 25 °C, 6% NaCl. After an interval of 36 h, algae were harvested and the real-time PCRs were employed to quantify the relative amounts of CvFAD6 transcripts. Data are presented as the mean ± SD ($n = 3$). *Bars* with *different letter* indicate that means are significantly different ($P < 0.05$)

Phylogenic analysis suggested that CvFAD6 was a group with confirmed and putative plastidial Δ^{12} FAD. The result was further supported by the predication of a transit peptide at the N-terminus. Moreover DesA from *Synechocystis* sp. PCC 6803 was found to be closely related with plastidial Δ^{12} FAD (Fig. 2). Though the peptide length of DesA was dramatically shortened, FVVGHDC and FWMSTF motifs and four of the five histidine boxes were conserved. Thus we believe that plastidial Δ^{12} FAD in eukaryotes have a prokaryotic origin.

To validate the protein activity, the putative Δ^{12} FAD was expressed in *S. cerevisiae*. Linoleic acid (18:2), normally not present in wild-type yeast cells, was detected in pYFAD6 transformants. It indicated that the isolated gene encodes a functional Δ^{12} enzyme.

qRT-PCR analysis clarified that the transcripts of CvFAD6 accumulated at different rates during the changes of temperature and salinity. Both cold and high salinity stress led to a higher amount of transcripts. Although the temperature change from 25 to 4 °C resulted in fourfold increase of transcripts, 25 to 15 °C had no effects on the accumulation of CvFAD6. It signified that CvFAD6 played roles in lower temperature around the freezing point. Additionally it implied that the microalga employed other mechanisms to overcome intermediate temperature shifts [7]. The response profile of CvFAD6 is different from that of the microsomal Δ^{12} FAD, CvFAD2 [7]. Its mRNA increased when alga was transfer from 25 to 15 °C or 4 °C after 36 h. Moreover, growth of *C. vulgaris* NJ-7 was most seriously affected by 6% NaCl whereas CvFAD6 mRNA

accumulated more than 20-fold at 6% NaCl. mRNA of CvFAD6 accumulated more dramatically than CvFAD2 (8.5-fold) for 6% NaCl induction. It signifies that they respond differently to stresses, at least in different degree. CvFAD2 initiates transcription accumulation in response to major or intermediate temperature shifts whereas CvFAD6 was only upregulated under freezing temperature stress [7]. Otherwise, the latter is more sensitive to salinity change. In addition, high salinity showed more notably stimulative to CvFAD6 expression than low temperature though the change of 18:2 was not so dramatic. It may be because of low translation rate or a decrease of enzyme activity at high salinity. Sea water freezes at approximately −1.8 °C (salinity of 3.4%), and the salts contained within the water are expelled from the growing ice crystal matrix. When ice forms from freshwater, the result is a hard brittle solid with the primary inclusions being gas bubbles. In contrast when sea water freezes the resultant ice is a semisolid matrix, permeated by a labyrinth of brine filled channels and pores. The volume of ice occupied by the brine channels is directly proportional to the temperature of the ice, as are the brine concentrations within the channels. The higher concentration the salt is, the lower the ice-point is. Brine channel walls constitute large surface areas that can be colonized by algae and used as sites for attachment and locomotion [1]. Thus high salinity slows down the ice formation of ambient sea water meanwhile high salinity impedes the formation of an ice crystal matrix within Antarctic *C. vulgaris* NJ-7. Salt stress induced increases in the UFA was also observed in fungus for the sake of adaptation to a wide range of NaCl concentrations [32]. Decreases in the palmitic fatty acid (C16:0), together with increases in the linoleic fatty acid resulted in the maintenance the correct membrane fluidity at high salinity [33]. To our knowledge, it is the first time that a plastidial Δ^{12} desaturase gene has been found that is induced by both low temperature and high salinity. Therefore the CvFAD6 of plasma membrane involved in the acclimation to the dramatically changing ambience of Antarctic *Chlorella* NJ-7. Moreover, CvFAD6 could be further utilized in plant genetic engineering to enhance cold and high salinity tolerance [34] and improve the oleic acid content [35–37].

In conclusion, we isolated the salinity- and cold-inducible fatty acid desaturase CvFAD6. CvFAD6-expressing transgenic yeast showed a novel peak of 18:2. Real-time PCR analysis revealed that CvFAD6 was involved in different stress responses in a different manner. The changing profile of CvFAD6 mRNA levels is not coincident with the change of 18:2 fatty acid. We believe that the response process of *C. vulgaris* NJ-7 to stresses is a network where CvFAD6 is involved. Stresses alter gene expression positively or negatively in a regulatory network with synergistic and antagonistic effects. Stress responses require the coordinated interaction of many factors. Several players regulate crosstalk and allow the alga to fine-tune specific responses to different stimuli. The functions of stress-related genes are not unvaried and are stress- and time-dependent. However, we only concentrated on transcripts accumulation, the result cannot be used to determine the change of enzyme activity. Further research should consider the FAD profiles from post-transcription and translation levels. Large scale studies of the genome sequences of cold or high salinity-adapted organisms [38–42] will step up the clarification of the role of fatty acids in freezing and salt tolerance.

Acknowledgments We thank Pro. Xu Xudong (Institute of Hydrobiology, Chinese Academy of Sciences) for providing the Antarctic microalga strain *C. vulgaris* NJ-7. Chemical Structure of *Bacteriovorax stolpii* Lipid A

Sebastian Beck · Frederic D. Müller · Eckhard Strauch · Lothar Brecker · Michael W. Linscheid

Received: 16 December 2009 / Accepted: 4 January 2010 / Published online: 22 January 2010

Abstract *Bdellovibrionales* is a phylogenetically diverse group of predatory prokaryotes, which consists of the two families *Bdellovibrionaceae* and *Bacteriovoracaceae*. We describe LPS and lipid A of the type strain *Bacteriovorax stolpii* DSM 12778, representing the first characterized endotoxin of a *Bacteriovoracaceae* member. It has a smooth form LPS, which was identified by SDS-polyacrylamide gel electrophoresis. The lipid A structure was determined by combined gas chromatography–mass spectrometry, electrospray ionization mass spectrometry and NMR spectroscopy. Its backbone consists of two β-(1 → 6)-linked 2,3-diamino-2,3-dideoxy-D-glucopyranoses (Glc*p*N3N) carrying a pyrophosphoethanolamine at O-4′ of the non-reducing sugar and a phosphate group linked to O-1 of the reducing Glc*p*N3N. Positions 2, 3, 2′ and 3′ of the two Glc*p*N3N are acylated with primary 3-hydroxy fatty acids and one of those carries a secondary fatty acid.

Introduction

Bdellovibrionales, also referred to as *Bdellovibrio*-and-like organisms (BALOs), are predatory prokaryotes causing lysis of other Gram-negative bacteria by invading and replicating within their periplasm [1–3]. Despite this unique and similar predatory lifestyle as well as common morphological features among predatory prokaryotes, genetic analyses revealed distinct differences. At present the two families Bdellovibrionaceae and Bacteriovoracaceae constitute the order *Bdellovibrionales* [4–8]. The type strain *Bdellovibrio bacteriovorus* HD100 (DSM 50701) is a well-studied representative of Bdellovibrionaceae [3, 6–10]. It is an obligate predator with an essential requirement of living prey cells for growth and replication [9]. Its lipid A is very different from other bacteria, since charged groups are completely lacking. This uncommon structure is supposed to be the main reason for the unique biophysical properties and a decreased endotoxic activity of the lipopolysaccharide (LPS) [10]. As the encounter of predators with prey bacteria occurs through surface structures of the outer membrane, the unusual lipid A could also be a prerequisite for the predatory lifestyle.

In contrast, the type strain *Bacteriovorax stolpii* (DSM 12778), a typical representative of the family *Bacteriovoracaceae*, is a facultative predator capable of growing intracellularly within prey bacteria or extracellularly in rich media [11, 12]. Without the obligate need of living prey cells, *B. stolpii* is an interesting candidate for therapeutic applications. It has been shown that the cell wall of *B. stolpii* possesses unusual sphingophosphonolipids [13–15]. Furthermore, outer membrane proteins show some high strain specificities in comparison to other predators like *B. bacteriovorus* or *Peredibacter starrii* [16]. Thus, structure determination of the *B. stolpii* lipid A is of special interest. In particular, comparison with the *B. bacteriovorus* lipid A might allow identification of specific motives in taxonomically distinct groups of predatory bacteria and enable a better understanding of processes involved in the attachment and penetration of predatory prokaryotes. In continuation of our previous work we now examined the LPS and lipid A of the facultative predatory strain *B. stolpii*.

Experimental Procedures

Bacterial Growth and Lipopolysaccharide Extraction

Bacteriovorax stolpii (DSM 12778, ATCC 27052) was grown in peptone yeast extract medium (ATCC 526) at 30 °C for 3–5 days. Each batch was checked by 16S rDNA amplification, followed by restriction pattern analyses of the resulting amplicons [8]. Cells were harvested by centrifugation, washed twice in 2% phenol, ethanol and acetone and dried in a rotary concentrator. The yield was 12.8 g bacteria (dry weight) from 27 L culture. The pellet was resuspended in 100 mL bidistilled water and nucleic acids were degraded by addition of RNAse A, DNAse I and incubation at 37 °C for 16 h with gentle stirring. Additionally, Proteinase K was added and the mixture was incubated for 8 h at 37 °C. The resulting suspension was dialyzed for 48 h at room temperature and lyophilized. The phenol/chloroform/light petrol ether (2:5:8, v/v/v) method was used for LPS extraction [17]. Crude LPS was precipitated from the extract by dropwise addition of ethanol. The precipitate was further purified by addition of RNase A, DNase I and incubation at 37 °C for 16 h and additionally treated with Proteinase K. The resulting suspension was dialyzed against bidistilled water and lyophilized to yield 645 mg of LPS.

Gel Electrophoresis of LPS

For gel electrophoresis of LPS, the gel system according to Laemmli was used [18]. Samples were suspended in loading buffer, boiled for 10 min, and separated at 20 mA on a 12% (w/v) polyacrylamide gel at 8 °C. Gels were stained by the oxidative silver staining protocol [19].

Isolation and Derivatisation of Lipid A

Lipid A of *B. stolpii* was obtained by mild acidic hydrolysis of LPS. One hundred and eighty milligrams of LPS were suspended in 1% acetic acid to a final concentration of 7 mg mL^{-1} and heated to 100 °C for 120 min. The mixture was cooled on ice, followed by centrifugation at 4 °C for 10 min at 12,000×*g*. The precipitate was washed in bidistilled water and acetone, resuspended in bidistilled water and lyophilized to yield 63 mg of lipid A. Dephosphorylated lipid A was obtained by suspending 50 mg of lipid A in 10 mL of hydrofluoric acid (48%) and stirring for 48 h at 4 °C. The reaction mixture was directly dialyzed against bidistilled water and lyophilized to yield 38 mg of dephosphorylated lipid A.

Fatty Acid Analysis

Fatty acids were analyzed as their corresponding methyl esters. A 1-mg sample of lipid A or LPS was dissolved in 2 M HCl in methanol (500 µL) and heated to 100 °C for 16 h. The mixture was dried using a gentle stream of compressed nitrogen and fatty acid methyl esters were extracted by partitioning between bidistilled water (50 µL) and chloroform and extraction with chloroform (three

times, 100 μL each). The combined extracts were dried and redissolved in 50 μL chloroform. A 1-μL sample was analyzed by gas chromatography–mass spectrometry (GC–MS).

Gas chromatography–mass spectrometry was performed on an electron impact ionization Hewlett Packard mass spectrometer G1800A with a fused silica capillary column (HP-5MS, 30 m, inner diameter 0.25 mm, film thickness 0.25 μm). Hydrogen was used as the carrier gas at a flow rate of 1 L h^{-1} and the initial GC temperature was 150 °C for 3 min, then raised to 320 °C at 5 °C min^{-1}. Relative abundances were determined from the corresponding peak areas, while the fatty acid methyl ester Mix GLC-80 (Supelco) was used as external standard.

Sugar Analyses

For qualitative analyses, the sugars were converted into their alditol acetates after hydrolysis of lipid A, reduction with sodium borohydride and peracetylation, according to previously described procedures [20]. Determination of the absolute configuration of sugars was carried out by analyses of the corresponding acetylated (*S*)-2-butylglycosides [21, 22]. The temperature program for sugar analyses was identical as in the case of fatty acid methyl ester analyses.

Mass Spectrometry

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-ToF MS) of intact LPS was performed on a Voyager DE mass spectrometer (Applied Biosystems) in delayed extraction mode. LPS was dispersed in bidistilled water to a concentration of 10 mg mL^{-1} and directly mixed on target with an equal volume of saturated dihydroxy benzoic acid solution in water/acetonitrile (1:1, v/v). Mass spectra were calibrated externally by using LPS preparations from *Escherichia coli* K-12 (DSM 423) with known chemical structure [23].

Electrospray ionization-Fourier transform ion cyclotron resonance mass spectrometry (ESI-FTICR MS) was performed on a Finnigan LTQ FTMS (Thermo Electron) equipped with a 6-T superconducting magnet. Samples were dissolved in a mixture of chloroform/methanol/water (100:75:15, v/v/v) to a concentration of about 10–20 μg mL^{-1}, treated with Amberlite IR-120 cation exchanger, a flow rate of 3 μL min^{-1} was used. The spray voltage was 4.3 kV (positive ESI) or 4.0 kV (negative ESI). The nitrogen sheath gas flow rate was 15 arb and the transfer capillary temperature remained at 200 °C during all measurements. Transfer optics and lenses were optimized by automatic tuning. All spectra were acquired with a resolution of 100,000.

Nuclear Magnetic Resonance Spectroscopy

Fully protonated lipid A was obtained by suspending 2.0 mg lipid A in 2 mL distilled water, increasing the pH to ~9 by addition of 0.36 M aqueous triethylamine, and decreasing of the pH to ~2 by addition of 0.1 M HCl. The precipitate was isolated by centrifugation (2,000×*g*, 10 min) and dissolved in 3 mL chloroform/methanol (4:1, v/v). After washing three times with 5 mL distilled water and removal of the solvent at ~20 mbar, all exchangeable protons were replaced by deuterium dissolving lipid A in 3.0 mL of chloroform-*d*/methanol-d_4 (2:1, v/v) and drying in a stream of nitrogen. The lipid A was dried over P_4O_{10} (~0.1 mbar) and dissolved in 0.5 mL chloroform-*d*/methanol-d_4 (2:1, v/v). The dephosphorylated lipid A was treated in the same way and dissolved in 0.5 mL pyridine-d_5/methanol-d_4 (2:1, v/v).

NMR spectra were measured at 315 K ± 0.05 K on Bruker AV600 and DRX600 spectrometers using the XWINNMR 2.6 and Topspin 1.3 software, respectively. Irradiation and measurement frequencies were 600.13 MHz (^{1}H), 242.94 MHz (^{31}P) and 150.1 MHz (^{13}C). One dimensional ^{1}H, ^{31}P, and ^{13}C spectra were recorded and Fourier transformed to spectra with 7,250 Hz (^{1}H), 25,000 Hz (^{31}P), and 32,000 Hz (^{13}C). Two dimensional spectra (COSY, NOESY, ROESY, TOCSY and HMQC) were recorded with a spectral width of 7,250 Hz for ^{1}H and 32,000 Hz for ^{13}C. Selected parameters for 2D NMR experiments: TOCSY, mixing time 70–100 ms. NOESY, mixing time 200 and 400 ms. ROESY, mixing time 225 ms. Tetramethylsilane (δ_H 0.00 ppm, δ_C 0.0 ppm), methanol (δ_H 3.35 ppm, δ_C 49.0 ppm) or DMSO (δ_H 2.25 ppm, δ_C 39.4 ppm) were used as internal standards.

Results

SDS-PAGE and Mass Spectrometry of LPS

The *B. stolpii* lipopolysaccharides (LPS) showed an S-form pattern in SDS-PAGE analyses (see Supplementary Material). In addition to the typical O-antigen ladder, two major abundant bands were apparent from the gel separation. These two bands likely correspond to R-forms of the isolated LPS. Furthermore, the LPS was subjected to ESI-FTICR MS, however, no conclusive data was obtained in positive as well as in negative ionization mode. This was most likely caused by the high chemical diversity of the LPS, as apparent from the SDS-PAGE analyses. The negative MALDI-ToF spectrum of the LPS (see Supplementary Material) showed lipid A derived signals in the range of *m*/*z* 1,500–1,800 as the most abundant signals, as identified by ESI–MS experiments of lipid A (see below).

The high abundance of lipid A derived signals in MALDI-ToF analyses most probably resulted from laser-induced fragmentations of LPS species.

Compositional Analysis of *B. stolpii* Lipid A

The analyses of alditol acetates in combination with the analyses of acetylated (*S*)-2-butylglycosides of sugars revealed that the lipid A exclusively harbors 2,3-diamino-2,3-dideoxy-D-glucopyranoses (Glc*p*N3N) as sugar moieties, similar to the lipid A of *B. bacteriovorus* [10]. The GC–MS analyses of fatty acid methyl esters confirmed that non-hydroxylated and 3-hydroxy fatty acids are present in the LPS of *B. stolpii*. No unsaturated fatty acids or other hydroxy fatty acids were present in the LPS. For the non-hydroxylated fatty acids, dodecanoic acid (12:0), 11-methyl dodecanoic acid (*iso*-13:0), tetradecanoic acid (14:0) and 13-methyl tetradecanoic acid (*iso*-15:0) were identified. While 11-methyl dodecanoic acid is the most abundant non-hydroxylated fatty acid, a wider distribution was found for the 3-hydroxylated fatty acids (Table 1). No 3-hydroxy dodecanoic acid was found in these experiments. All fatty acid analyses were performed with lipid A and LPS of *B. stolpii*, while no differences were detected.

Mass Spectrometry of *B. stolpii* Lipid A

In the mass spectrum of negative ions (Fig. 1a) several groups of signals differing in the mass of one methylene group (CH_2, 14.015 u) were detected. The most intense signals, those of the singly charged ($[M–H]^-$) group of signals around *m/z* 1,612.075, were assigned to lipid A consisting of a 2,3-diamino-2,3-dideoxyglucopyranose (Glc*p*N3N) disaccharide carrying two phosphate groups and five fatty acids ($LA_{penta}P^{I}P^{II}$). The signals around *m/z* 1,735.085 correspond to the deprotonated species ($[M–H]^-$) of the penta-acylated lipid A carrying two phosphate groups and one phosphoethanolamine (*P*EtN) group ($LA_{penta}P^{I}P^{II}$*P*EtN). The fatty acid distribution for the $LA_{penta}P^{I}P^{II}$*P*EtN species is shown in Table 2. A series of ions around *m/z* 1,627.090 could be identified as penta-acylated lipid A with one phosphate group and a *P*EtN group ($LA_{penta}P^{II}$*P*EtN). The signals around *m/z* 1,532.114 resulted from penta-acylated lipid A species substituted with one phosphate group only ($LA_{penta}P^{I}$ or $LA_{penta}P^{II}$). $LA_{penta}P^{I}P^{II}$, $LA_{penta}P^{II}$*P*EtN and $LA_{penta}P^{I}P^{II}$*P*EtN could also be detected as doubly charged ions. The base signals for these three groups were *m/z* 805.538 for $LA_{penta}P^{I}P^{II}$, *m/z* 813.047 for $LA_{penta}P^{II}$*P*EtN and *m/z* 867.042 for $LA_{penta}P^{I}P^{II}$*P*EtN.

Collision induced dissociation (CID) of the negatively charged species at *m/z* 1,735.086 ($LA_{penta}P^{I}P^{II}$*P*EtN) resulted in the loss of a phosphoethanolamine residue (*P*EtN, $C_2H_6NO_3P$, 123.008 u) or of a phosphate group (H_3PO_4, 97.976 u), while fragmentation of the species around *m/z* 1,612.075 ($LA_{penta}P^{I}P^{II}$) only resulted in the dominant loss of a phosphate group (H_3PO_4, 97.976 u). Additionally, in all these fragmentation experiments the loss of 214.193 u, corresponding to the elimination of a 13:0 fatty acid, was observed. For CID of the cluster at *m/z* 1,532.114 ($LA_{penta}P^{I}$/$LA_{penta}P^{II}$) the elimination of a 13:0 fatty acid residue has been the most abundant fragmentation, while in no cases additional fragmentations were apparent that allowed the unambiguous determination of the fatty acid distribution.

In the positive ion spectrum (Fig. 1b), the same molecular species, apart from $LA_{penta}P^{I}$/$LA_{penta}P^{II}$, could be identified as protonated $[M + H]^+$ or sodiated ions $[M + Na]^+$. The signals around *m/z* 1,516.117 originated from fragmentation of the $LA_{penta}P^{I}P^{II}$ ions [loss of a phosphate group (H_3PO_4, 97.976 u)]. Additionally to these signals, singly charged ions in the range of *m/z* 850–1,050 could be detected and were assigned to the corresponding B-ions. The ions around *m/z* 1,026.652 represented the non-reducing sugar part of the lipid A of *B. stolpii*, consisting of the Glc*p*N3N^{II} sugar moiety carrying three fatty acids, one phosphate and one *P*EtN group ($B_{tri}P^{II}$*P*EtN). Based on these findings the *P*EtN group of the lipid A of *B. stolpii* could clearly be located at the non-reducing sugar of the disaccharide backbone. The signals around *m/z* 903.643 originated from B-ion fragment ions carrying one phosphate group and three fatty acids ($B_{tri}P^{II}$) (B-fragment nomenclature according to Domon et al. [24]).

MS/MS experiments of B-ions in positive ESI–MS proved that a secondary fatty acid, which is linked to the 3-hydroxy group of a primary fatty acid, is present at the non-reducing sugar part of the lipid A. Furthermore, these analyses showed that 11-methyl dodecanoic acid (*iso*-13:0) is the dominant secondary fatty acid in the investigated lipid A, since in all these experiments the loss of 196.182 or 214.193 u has been the most abundant fragmentation for

Table 1 Relative abundances of fatty acids in LPS of *B. stolpii* as determined by GC–MS analyses of fatty acid methyl esters

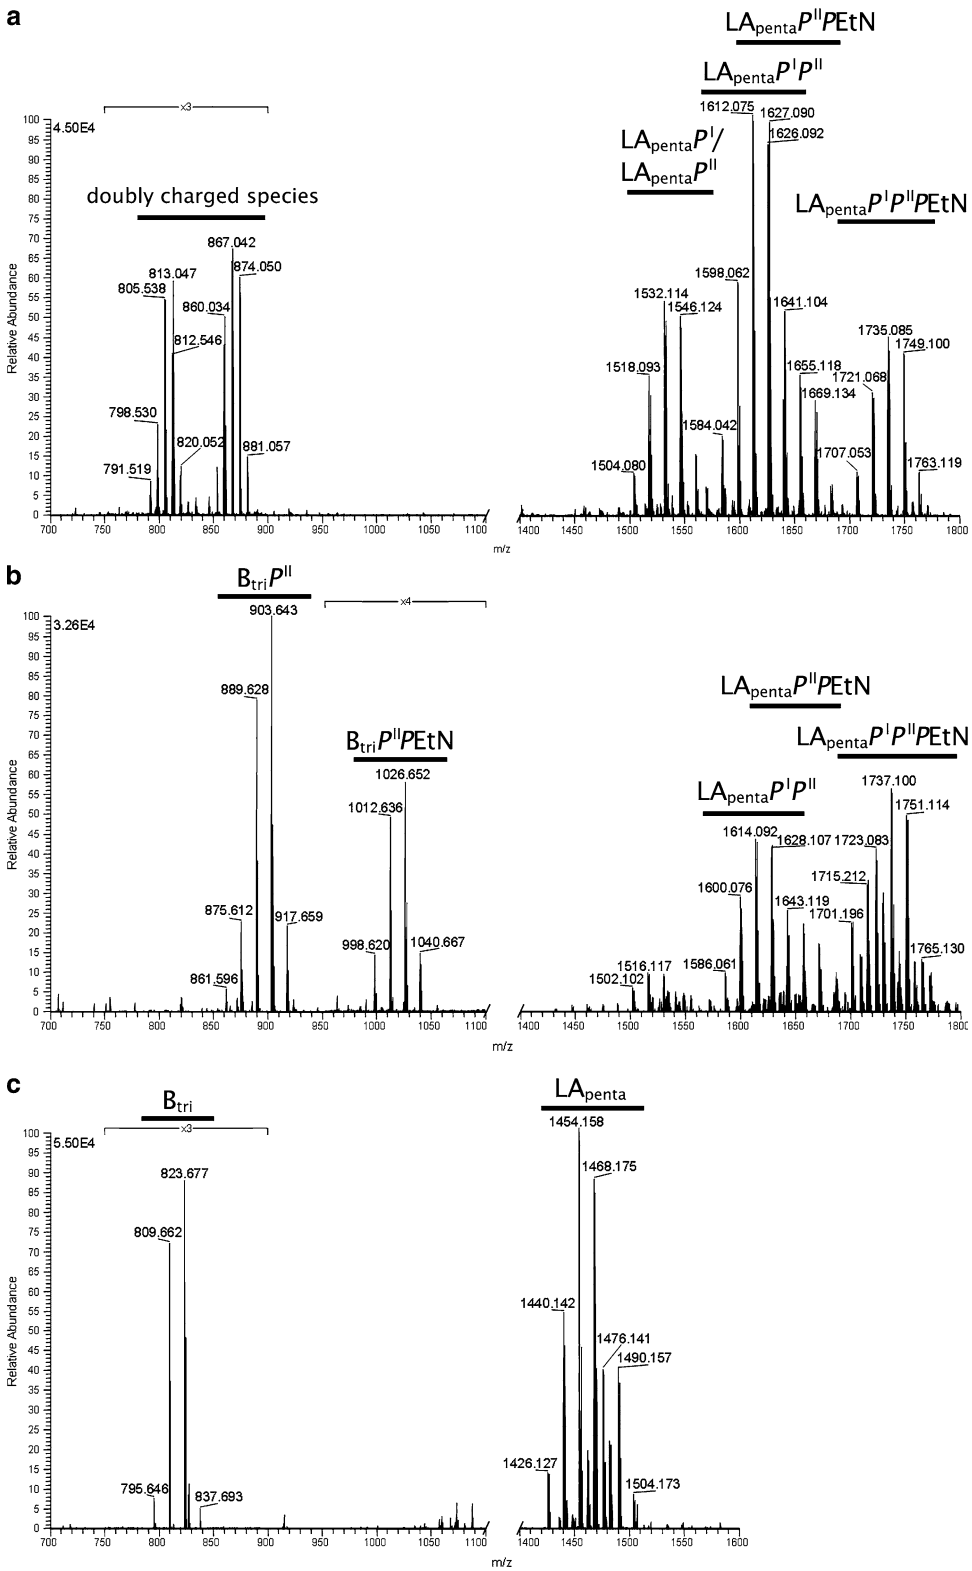

Fig. 1 ESI-FTICR mass spectra of *B. stolpii* lipid A: negative (**a**) and positive (**b**) ions, as well as the positive ions ESI-FTICR mass spectrum of dephosphorylated lipid A of *B. stolpii* (**c**)

B-ions. Fragmentation experiments of the $[M + H]^+$ signals around *m/z* 1,737.100 ($LA_{penta}P^{I}P^{II}PEtN$) resulted in the dominant formation of the corresponding B-ions (Table 2). In the positive ion spectrum of the dephosphorylated lipid A of *B. stolpii* (Fig. 1c), only two groups of ions were present: LA_{penta} (*m/z* 1,454.158) and B_{tri} (*m/z* 823.677).

An unambiguous assignment of the primary fatty acid residues linked to the amino groups at positions 2 and 3 of the two Glc*p*N3N was not possible as previously reported

[a] Experimental and theoretical values (in *brackets*) are given

[b] Relative abundances of B-ions were estimated from MS/MS experiments of positive ions

[c] Secondary fatty acid distributions were deduced from fragmentation experiments of B-ions, primary fatty acid distributions of Glc*p*N3N^{II} were calculated from most abundant B-ions (*italics*) of the corresponding molecular species and the fatty acid distribution of Glc*p*N3N^{I} was determined from neutral losses in MS/MS experiments

[25, 26]. Nevertheless, an assignment of fatty acid residues according to accurate masses from ESI-FTICR MS measurements could be made (Table 2). In agreement with the GC–MS analyses of fatty acid methyl esters (Table 1), the two primary fatty acids bound to Glc*p*N3N^{II} were assigned from the masses of B-ions in FTICR MS experiments. Additionally, the two primary fatty acids bound to Glc*p*N3N^{I} were assigned from the determined neutral losses in MS/MS experiments, being in good agreement with the data of the chemical component analyses.

NMR Spectroscopy of *B. stolpii* Lipid A

NMR spectra of unmodified lipid A showed relative poor line resolution independent of the used solvent systems [27, 28]. In particular, solvents generally suitable for measurements of lipid A carrying phosphoethanolamine groups (*P*EtN) caused signals with relatively large line widths at half height (>10 Hz) [29, 30]. In order to circumvent this problem, the sugar moiety and the fatty acid substitution pattern have been analyzed on dephosphorylated lipid A, prepared by reaction with hydrofluoric acid. The dephosphorylation was verified by ESI-FTICR MS (Fig. 1c) and the NMR spectra have been performed in pyridine-d_5/methanol-d_4 (2:1, v/v) at 315 K with reasonable resolution. The sugar moiety of *B. stolpii* lipid A was proven to consist of two Glc*p*N3Ns with a β-(1 → 6) interglycosidic linkage. ^{1}H and ^{13}C chemical shifts of Glc*p*N3N^{II} indicated a 2,3-diamino-2,3-dideoxy glucopyranose structure, which is diacylated in positions 2 and 3 (Table 3). The $^3J_{H–H}$ coupling constants of H-2′, H-3′, H-4′ and H-5′ in Glc*p*N3N^{II} were in the range of 10–12 ppm, thus, proving the β-glucopyranose configuration. The β-anomeric conformation was assigned from the $^3J_{H1'–H2'}$ coupling constant (8.7 Hz) and the (1 → 6) interglycosidic linkage was determined by ^{13}C chemical shift of C-6 in Glc*p*N3N^{I} (Table 3). The reducing Glc*p*N3N^{I} also showed typical shifts (Table 3) and $^3J_{H–H}$ coupling constants of a 2,3-diacylated 2,3-diamino-2,3-dideoxy glucopyranose structure. Remarkable, although the anomeric position of Glc*p*N3N^{I} was dephosphorylated, over 90% of the lipid A was present in the α-anomeric form ($^3J_{H1–H2}$ = 3.2 Hz). ^{1}H and ^{13}C chemical shifts of the Glc*p*N3N^{II} (1 → 6)Glc*p*N3N^{I} sugar moiety are listed in Table 3 and spectra are shown in Fig. 2.

The integral of ca. 150 aliphatic protons in the ^{1}H spectrum indicated the presence of five fatty acids which correlated with results from GC–MS and ESI-FTICR MS. An assignment of the complete fatty acids by NMR was not possible due to overlapping signals. However, ^{1}H NMR shifts of protons in position 2, 3, and 4 of all 3-hydroxy fatty acids were assigned (Table 4). Thereby the absolute configuration of position 3 is most likely to be (*R*) in all cases, comparable to all other yet studied lipid As [31]. Integrals over the signals of the hydroxy fatty acids of the dephosphorylated lipid A indicated about 60% to be 3-hydroxy fatty acids with a free OH-group, ~20% to be 3-hydroxy fatty acids carrying a secondary fatty acid,

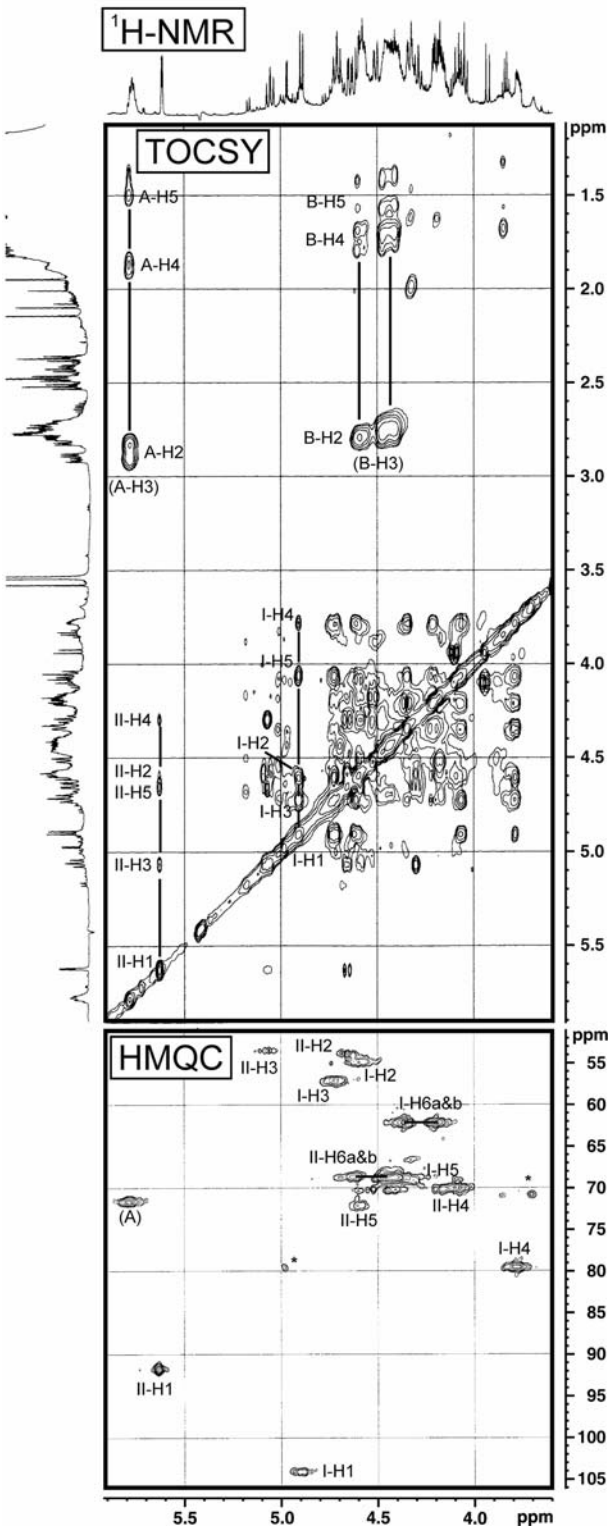

Fig. 2 Parts of ^{1}H, TOCSY, and $^{1}H/^{13}C$ HMQC spectra of dephosphorylated *B. stolpii* lipid A. Assignment of the signals are given according the common carbohydrate nomenclature (I = Glc*p*N3N^{I}; II = Glc*p*N3N^{II}). Signals of hydroxy fatty acids with acylated OH-group are indicated with "*A*" and signals of hydroxy fatty acids with free OH-group are indicated with "*B*". The according shift values are listed in Tables 3 and 4

Table 3 Proton and carbon chemical shifts of the sugar backbone of the dephosphorylated lipid A of *B. stolpii*

	H1/C1	H2/C2	H3/C3	H4/C4	H5/C5	H6a/C6	H6b

Table 4 Proton chemical shifts [δ ^{1}H (ppm)] of position 2, 3, 4, and 5 in all primary 3-hydroxy fatty acids (FA-1–FA-4) of the dephosphorylated lipid A of *B. stolpii*

	H2a/b	H3	H4a/b	H5a&b
3-OH fatty acids carrying a secondary fatty acid				
FA-1	2.91/2.81	5.78	1.87/1.83	1.52
3-OH fatty acids with free OH functionalities				
FA-2	2.71/2.70	4.58	1.79/1.70	1.43
FA-3	2.70/2.64	4.48	1.76/1.70	1.43
FA-4	2.69/2.63	4.40	1.76/1.70	1.42

and ~20% to be non-hydroxy fatty acids. This is in good agreement with the mass spectrometric results. The non-hydroxy fatty acids showed four different signal groups, which indicated variations in their conformation and configuration.

Additionally, chemical shifts of the different terminal ends of the fatty acids were determined. In branched fatty acids the CH_3 groups (ω) had $\delta_H = 0.80$ ppm and $\delta_C = 13.4$ ppm, while the neighboring CH groups ($\omega - 1$) had a $\delta_H = 1.19$ ppm and $\delta_C = 38.1$ ppm. These shifts differed from the ones of the unbranched fatty acids (CH_3 (ω): $\delta_H = 0.78$ ppm and $\delta_C = 13.2$ ppm; CH_2 ($\omega - 1$): $\delta_H = 1.44$ ppm and $\delta_C = 37.0$ ppm). Comparison of the different ^{1}H NMR signal intensities of these partly overlapping signal groups proved the nearly equal occurrence of branched and unbranched fatty acids (Table 1, Fig. 3).

1D and 2D ^{1}H spectra as well as 1D ^{31}P spectra have been recorded in $CDCl_3$/methanol-d_4 (4:1) at 305 K for further analysis of the intact lipid A. Although spectra showed a relatively poor line resolution, they allowed completion of the structure determination. The anomeric signal of Glc*p*N3N^{I}, identified in COSY had the characteristic down field shift of a phosphorylated α-anomeric form (~5.5 ppm) and the phosphate group (P^{I}, –O–PO_3H) had therefore to be located in this position (α-D-Glc*p*N3N^{I}-(1 → P^{I})). In Glc*p*N3N^{II} the positions 1, 2 and 3 were occupied by the interglycosidic linkage to Glc*p*N3N^{I} and

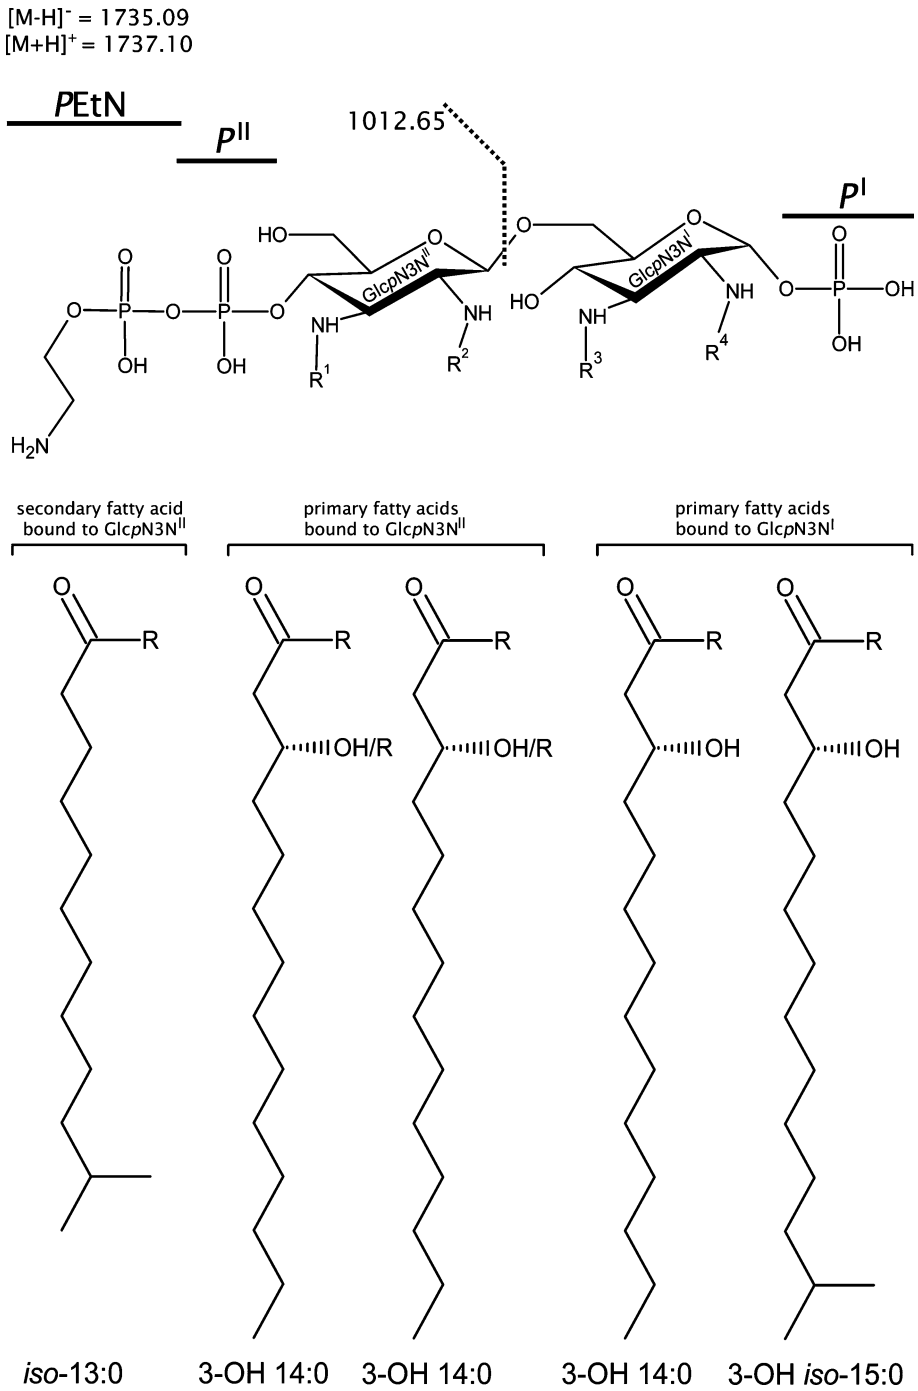

Fig. 3 Chemical structure of the lipid A of *B. stolpii*. *Upper part* structure of the backbone with two β-(1 → 6)-linked D-Glc*p*N3Ns, being substituted at C1 and C4′ with a phosphate group (P^{I}) and a pyrophosphoethanolamine (P^{II}*P*EtN) group, respectively. Corresponding *m*/*z* value for B-ion fragments in positive ionization mode is given. *Lower part* structure and distribution of the fatty acid residues. The exact position of each fatty acid residue could not be determined from the results of the analyses

by two acyl groups, respectively. A hydroxy function in position 6 represented the binding position for the O-specific chain. Thus, the remaining position 4 is carrying the two phosphate groups and the ethanolamine. ^{31}P spectra indicated these groups to be pyrophosphoethanolamine ($\delta(^{31}P)$ = ca. −10 ppm), as it has been reported in a few other lipid A structures.[23, 30, 32–34].

The resulting lipid A backbone structure was determined to (*P*EtNP^{II} → 4)-β-D-Glc*p*N3N^{II}-(1 → 6)-α-D-Glc*p*N3N^{I}-(1 → P^{I}), as shown in Fig. 3 for the species with highest molecular weight ($LA_{penta}P^{I}P^{II}$*P*EtN) observed in mass spectra (*m*/*z* 1,737.100 $[M + H]^+$ and *m*/*z* 1,735.085 $[M–H]^-$). Therein, each 2,3-diamino-2,3-dideoxy-glucopyranose is substituted with two primary 3-hydroxy fatty acids linked to the amino groups at positions 2 and 3. The non-reducing sugar (Glc*p*N3N^{II}) additionally carries a non-hydroxy secondary fatty acid linked to the 3-hydroxy group of a primary fatty acid.

Discussion

The two *B. stolpii* and *B. bacteriovorus* strains possess a S-form LPS [10]. Lipid As of both *Bdellovibrionales*, however, harbor only a few common structural features, which set them apart from most other lipid A structures. They possess β-(1 → 6)-linked 2,3-diamino-2,3-dideoxy-D-glucopyranoses in their backbone. Similar structures have been found in *Brucella*, *Rhodopseudomonas*, *Leptospira*, and *Mesorhizobium* species [35–37], while lipid A of most other Gram-negative bacteria have two β-(1 → 6)-linked 2-amino-2-deoxy-D-glucopyranoses in their backbone [38–40]. Another common feature of the two lipid As is the presence of *iso*-branched fatty acids [10], which are also rarely found in other bacteria. It remains to be determined, whether these structural features are related to the distinct biological activity of the *Bdellovibrionales* and could be important for their unique lifecycle.

The significant differences between the lipid A structures are numerous. *B. bacteriovorus* possesses the only yet isolated uncharged lipid A [10]. In contrary, the now investigated lipid A of taxonomically related *B. stolpii* has a phosphate and a *PP*EtN group in its backbone. Hence it owns several functionalities, which are able to carry negative as well as positive charges. A further difference between the lipid As is the absence of unsaturated fatty acids or dihydroxy fatty acids in *B. stolpii*. These variations coincide with genetic differences and might portend variations in their mechanisms to penetrate other bacteria [4–8].

Bacteriovorax stolpii lipid A has a strong amphiphilic character, likely caused by intermolecular ionic interactions between protonated primary amines and deprotonated phosphate functionalities. This strong tendency of forming aggregates is accompanied by a molecular dynamic between different conformations. Such chemical exchanges were indicated by weak and broad in phase EXSY cross peaks in ROESY spectra. Aggregation due to the strong amphiphilic character of *B. stolpii* lipid A and the resulting short transversal relaxation times (T_2) have hence not been the only reason for the line broadening in NMR spectra. The dynamic effects of the molecules rather cause the presence of more than one conformation in energetic minima. Disaggregation of *B. stolpii* lipid A in non-natural environments as reported for some other lipid As does hence not automatically lead to enhancement of NMR-spectral resolution [27–30].

Such molecular motion of pyrophosphoethanolamine (*PP*EtN) groups has been described to cause stability changes in the outer membrane under different environmental conditions. The possibility of having different lipid A conformations might be applied by the *B. stolpii* to change the outer membrane structure. These variations might be used to change forms from a non-predatory style to a predatory style, when necessary or possible. Hence, it is of interest to discover the *B. stolpii* lipid A structures and dynamics in membranes, in particular in dependence on the presence of other lipid A membranes. An investigation of the endotoxic potential of *B. stolpii* lipid A in different environments is also interesting in this context [41].

More analyses of other *Bdellovibrionales* (e.g. *Peredibacter* or other *Bacteriovorax*/*Bdellovibrio* species) are necessary for the assignment of conserved structures within the lipid As and LPS of predatory prokaryotes. Such studies will help to identify building blocks or conserved components of the outer membrane and will increase the understanding of the mechanisms involved in prey cell recognition and invasion. The current study resolves the second structure of an endotoxin of a predatory bacterium and confirms once again that the unique predatory lifestyle is associated with special structures.

METHODS

An Improved Method for Determining Medium- and Long-Chain FAMEs Using Gas Chromatography

Zhidong Xu · Kevin Harvey · Thomas Pavlina · Guy Dutot · Gary Zaloga · Rafat Siddiqui

Received: 24 November 2009 / Accepted: 21 December 2009 / Published online: 16 January 2010

Abstract The existing protocols for analyzing fatty acid methyl esters (FAMEs) using a one-step acetyl chloride (AC) catalyzed transesterification and extraction procedure cannot accurately determine the medium- and long-chain fatty acids simultaneously in clinical (enteral, parenteral) formulations. For example: (1) addition of AC at room temperature generates an exothermic reaction that often results in loss of sample and possible injury to the analyst; (2) certain polyunsaturated fatty acids (PUFAs) are less stable at elevated temperatures during the transesterification and contribute to the over-estimation of the C16:0 and C18:1 fatty acids; and (3) the flame-ionization detector (FID) response varies depending on the carbon chain length of the fatty acids, that consequently impacts the underestimation of medium-chain fatty acid (C6–C10) recoveries. To overcome these deficiencies and accurately determine FAMEs, we have developed an improved one-step transesterification method that employs the addition of AC in tubes kept on a dry ice bath, the transesterification at room temperature, and the data analysis using relative response factors. Using this modified protocol, we determined the fatty acid composition of lipid emulsions (Omegaven® and Lipidem®) on a Shimadzu GC2010 gas chromatography (GC) system using a capillary GC column (Zebron ZB-WAX plus, 30 m, 0.25 mm ID, 0.25 μm). Our data suggest that the improved method can be easily used to accurately determine fatty acids (C6–C24) in functional foods and lipid emulsions.

formulations contain a wide variety of fatty acids differing in chain length, degree of unsaturation and position, and configuration of double bonds. Although a gas chromatography/mass spectrometry method has been developed to quantitatively determine C8–C26 chain length fatty acids [1], the GC analysis of FAMEs with FID remains the most frequently used method [2, 3]. The results from GC/FID are often expressed as a relative percentage of total fatty acids, which may potentially contribute to error in data interpretation [1]. The accurate quantification of FAs in biological samples depends on proper extraction, methylation of FAs into FAMEs, optimized GC run conditions and calculation of their concentration using internal and external standards [4–6].

The one-step digestion, extraction and esterification of biological samples, which is referred to as "direct transesterification," is widely used because of its simplicity, rapidity and higher accuracy [7–9]. This method has some complications. For example: addition of acetyl chloride at room temperature generates an exothermic reaction that often results in loss of sample and possible injury to the analyst; adding the acetyl chloride slowly with stirring is often cumbersome for large numbers of samples; certain polyunsaturated fatty acids are less stable at temperatures of 100 °C during the transesterification process; and the generation of molecular species that may contribute to the over-estimation of fatty acids [10]. Furthermore, the FID response varies with carbon-chain variation. The FID response is based on ionization of alkyl carbon entities, whereas the carboxyl carbon is not ionized during the combustion [11, 12]. To accurately determine FAMEs with a FID, a correction factor is normally applied based on a theoretical relative response factor ($RRF_{(Theo)}$) to compensate for the unionized carboxyl carbon [11, 13]. The widely used $RRF_{(Theo)}$ was originally calculated based on "active atom" theory without considering the instrument conditions [6, 14]. However, it has been realized that the instrument parameters, sample running conditions and the fatty acid composition in samples can influence the RRF and hence may affect the analysis [15–20].

To overcome these deficiencies and accurately determine medium- and long-chain FAMEs, we have developed an improved one-step transesterification method that employs the addition of acetyl chloride in a dry ice bath, transesterification at room temperature and data analysis using the experimental relative response factor ($RRF_{(Exp)}$) based on relative peak area ratios of the individual fatty acid to the internal standard (IS), C23:0, under optimized GC run conditions. Our data suggest that our improved protocol for FAME analysis accurately determines both medium- and long-chain fatty acids in a one-step transesterification and extraction procedure. This procedure can easily be adopted to perform an accurate FAME analysis on large numbers of clinical and research samples on a routine basis in less time and without any threat of hazards to the analyst.

Materials and Methods

Materials

Fatty acid standards, the internal standard, and FAME mixture (GLC-461A) were purchased from Nu-Chek (Nu-Chek Prep, Inc., USA). The purity of all fatty acid standards was at least 99%. Benzene (CHROMASOLV® Plus, for HPLC, ≥99.9%), hexane (CHROMASOLV®, for HPLC, ≥97.0%), chloroform (anhydrous, ≥99%), methanol (anhydrous, 99.8%) and acetyl chloride (Puriss. p.a., ≥99.0%) were purchased from Sigma–Aldrich (St Louis, MO, USA). A FocusLiner for the GC-2010 system was purchased from Supelco (Sigma–Aldrich), and a Zebron ZB-WAX plus (30 m, 0.25 mm ID, 0.25-μm film thickness) capillary GC column was purchased from Phenomenex (Torrance, CA, USA). Lipid emulsions: Lipidem® and Omegaven®, were from B. Braun Melsungen AG (Germany) and Fresenius Kabi Deutschland GmbH (Germany), respectively. The internal standard of C23:0-M (tricosanoate-methyl ester) was dissolved in the hexane solution at a concentration of 0.982 mg/ml, and the internal standard of C23:0-acid (C23:0-A) was dissolved in the methanol-benzene (4:1, v/v) solution at a concentration of 0.989 mg/ml. All fatty acid standards were flushed with N_2 and stored at −20 °C.

Instrumentation

GC chromatography was performed with a Shimadzu GC2010 chromatography system (Shimadzu Scientific Instruments, Columbia, MA, USA) equipped with an auto sampler and a flame ionization detector. Helium was used as carrier and make-up gas. The injection volume was 1 μl, which was used with a split ratio of 1:50, or alternative ratios as reported elsewhere in the text. The injection port and detector temperatures were 240 and 250 °C, respectively. The column temperature program was as follows: temperature was held at 30 °C for 2 min, increased to 180 °C at 20 °C/min, held at 180 °C for 2 min, increased to 207 °C at 4 °C/min, held at 207 °C for 3 min, increased to 220 °C at 2 °C/min, held at 220 °C for 2 min, and then increased to 240 °C at 2 °C/min before finally being held at 240 °C for 2 min.

Optimization of the One-Step Extraction Transesterification Process

Method A

A 50-μl lipid sample was placed in 10 × 130 mm Pyrex tubes (10 ml) which had Teflon-lined screw caps, and then mixed with 40 μl of the internal standard and 2 ml of methanol-benzene (4:1, v/v). A small magnetic stirring bar

was placed in each tube and, while stirring, 200 µl of acetyl chloride was slowly added over a period of 1 min. The tubes were tightly closed and subjected to transesterification at 100 °C for 1 h. The tubes were allowed to cool in an ice bath, and then 5 ml of 6% K_2CO_3 solution was added slowly to stop the reaction and neutralize the mixture. The tubes were briefly vortexed and then centrifuged at 900×*g* for 10 min (at 25 °C). The top layer was collected and transferred to a sample vial for GC analysis.

Table 1 Fatty acid standard mixture

FA	(mg/ml)	FA	(mg/ml)
C6:0	1.67	C16:1n-7	2.38
C8:0	1.77	C18:1n-9	2.38
C9:0	0.71	C18:2n-6	1.50
C10:0	1.18	C18:3n-6	2.17
C12:0	0.96	C18:3n-3	2.49
C14:0	1.15	C22:6n-3	2.30
C16:0	1.04		

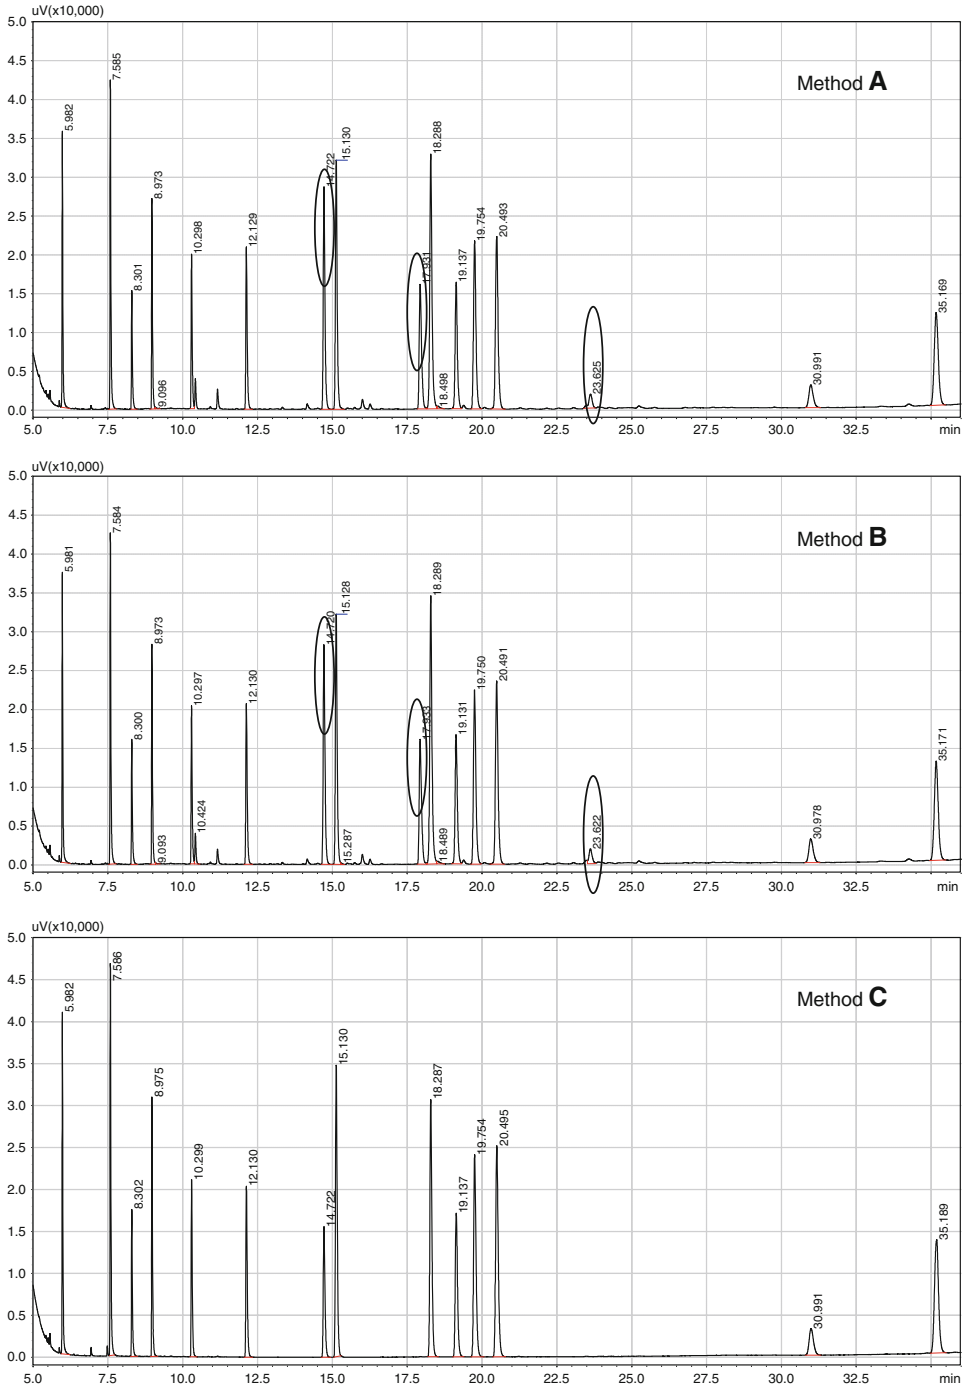

Fig. 1 Comparison of transesterification methods. Standard mixture (listed in Table 1) is used to prepare FAMEs using transesterification Methods A, B or C, as described in the text. The major extra peaks are marked by *black circles*. The GC chromatogram is a representative of three experiments performed in triplicate ($n = 9$)

Method B

A 50-µl sample of the lipid mixture was placed in 10 × 130 mm Pyrex tubes (10 ml) which had Teflon-lined screw caps, and then mixed with 40 µl of the internal standard and 2 ml of methanol-benzene (4:1, v/v). The tubes were gently vortexed, and then placed in a dry ice bath for 10 min. Then 200 µl of acetyl chloride was added to the tubes quickly; the tubes were flushed with N_2, tightly closed, and subjected to transesterification at 100 °C for 1 h. The samples were further processed as described in "Method A".

Method C

The samples were prepared and acetyl chloride was added to each tube as described in "Method B". The tubes were then kept in the dark at room temperature for 24 h. The samples were further processed as described in "Method A".

Data Quantification

The concentration of individual fatty acids ($C_{(GC)}$) were calculated using the expression $C_{(GC)} = A_{(FA)}/A_{(IS)} \times C_{(IS)}$, where $A_{(FA)}$ is the GC peak area of the fatty acid whose concentration is to be determined, $A_{(IS)}$ is the GC peak area of the internal standard, and $C_{(IS)}$ is the concentration (mg/ml) of the internal standard.

Determination of the Relative Response Factor

Theoretical Relative Response Factor

Theoretical relative response factor for each fatty acid (C6–C24) relative to the C23:0 internal standard was calculated according to the active carbon theory [12].

Experimental Relative Response Factor

For determining the $RRF_{(Exp)}$, 130 µl of the GLC-461A reference standard in hexane was mixed with 20 µl of internal standard (C23:0-M; 0.982 mg/ml in hexane) and subjected to the GC analysis. The ratio of the fatty acid to the internal standard, and the instrument parameters, were as indicated elsewhere in the text. Each experiment was done in triplicate. The relative response factor was calculated based on the equation: $RF = C_{(Theo)}/C_{(GC)}$, where $C_{(Theo)}$ is the concentration of the fatty acid based on its weighed amount, and $C_{(GC)}$ is the concentration of the fatty acid calculated based on the GC peak area and internal standard (C23:0) concentration.

Results and Discussion

Optimization of GC Parameters

Based on the recommendations proposed in the official method of the association of analytical chemists (AOAC) [21], we employed C23:0-M as the internal standard, and a wax-type capillary gas chromatograph column to perform the fatty acid analysis. We initially compared the GC analysis of fatty acids with the splitless and split injection modes, using different inlet liners (including no wool, wool-packed, gooseneck and FocusLiner). Our results (not shown) demonstrated that GC analysis with split injection at 250 °C using a FocusLiner inlet yields optimal fatty acid resolution. Most of the analyses were performed using a 1:50 split ratio based on optimization described below.

Optimization of a One-Step Transesterification

In order to develop a safe, simple and highly reproducible transesterification method for accurately determining FA concentrations for routine analysis, we modified and optimized the original Lepage and Roy one-step transesterification method [8, 9]. A standard mixture containing C6 to C22 fatty acids, as shown in Table 1, was used to optimize the transesterification using three different approaches, referred to as Methods A, B and C. "Method A" is the original Lepage and Roy method wherein the addition of acetyl chloride for transesterification is usually done very

Table 2 Recovery of fatty acids using different transesterification methods

FA	$RRF_{(Exp)}$	Method A %, mean ± SD	Method B %, mean ± SD	Method C %, mean ± SD
C6:0	1.44	94.1 ± 1.4	92.2 ± 2.7	100.4 ± 2.3
C8:0	1.20	91.6 ± 2.0	90.1 ± 2.9	97.4 ± 2.4
C9:0	1.19	93.4 ± 1.8	92.3 ± 2.6	97.7 ± 2.2

C18:3n-6	1.07	97.3 ± 1.7	96.5 ± 2.3	102.2 ± 2.2
C18:3n-3	1.08	95.9 ± 1.5	95.3 ± 2.4	100.8 ± 2.2
C22:6n-3	1.16	94.1 ± 2.5	93.0 ± 2.4	100.1 ± 2.1

The concentration of the fatty acid was calculated based on the internal standard peak area and corrected with $RRF_{(Exp)}$, as describe in the text. The recovery was calculated by formula $[C_{(Exp)}/C_{(Theo)} \times 100]$

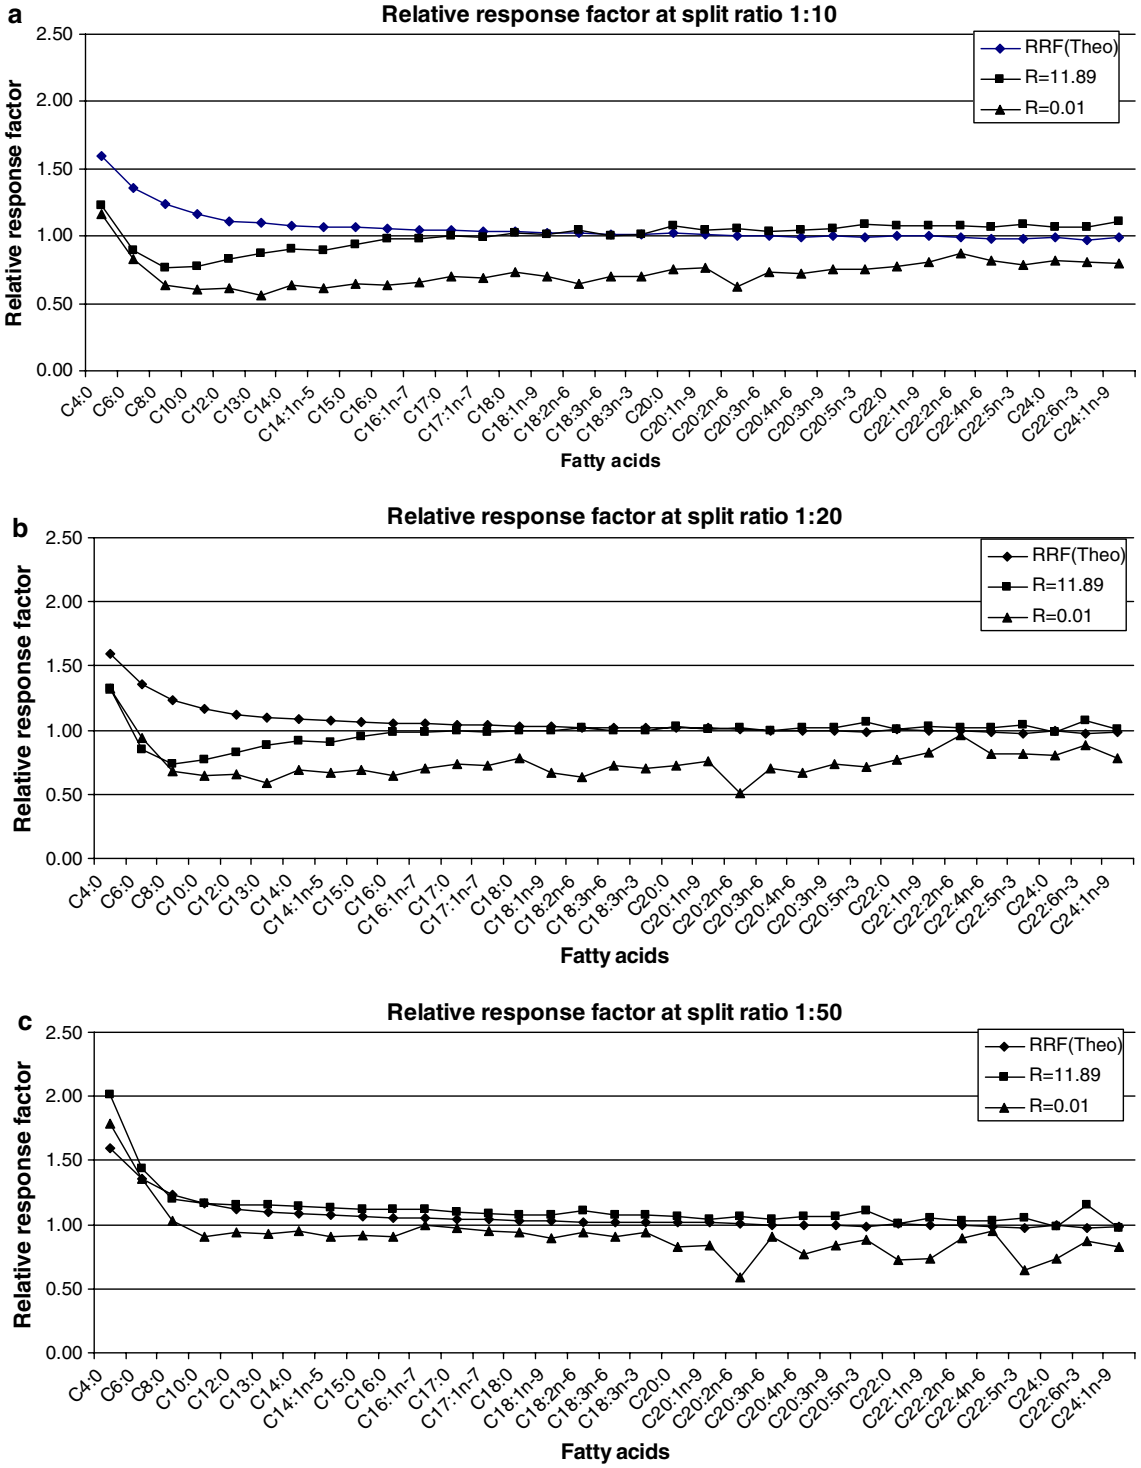

Fig. 2 Effect of injector split ratio on the relative response factor in the presence of variable fatty acid-to-internal standard ($FA_{(Sample)}/FA_{(IS)}$) ratio. Fatty acid-methyl esters from GLC-461A standard mixture (FA_{sample}) and C23:0-M (FA_{IS}) internal standard (0.982 mg/ml) was prepared in hexane to obtained variable (0.01–11.86) $FA_{(Sample)}/FA_{(IS)}$ ratios (*R*) as shown in Table 3. Each mixture ($FA_{(Sample)}/FA_{(IS)}$) was applied for GC analysis using an injector split ratio of **a** 1:10, **b** 1:20, or **c** 1:50, while keeping all other GC run parameters conditions constant. The curves representing the lowest (0.01) and the highest (11.89) *R* are shown for simplicity. All other curves (data not shown) fall within the lowest and the highest *R* curves. Each *point* represents a mean of three experiments

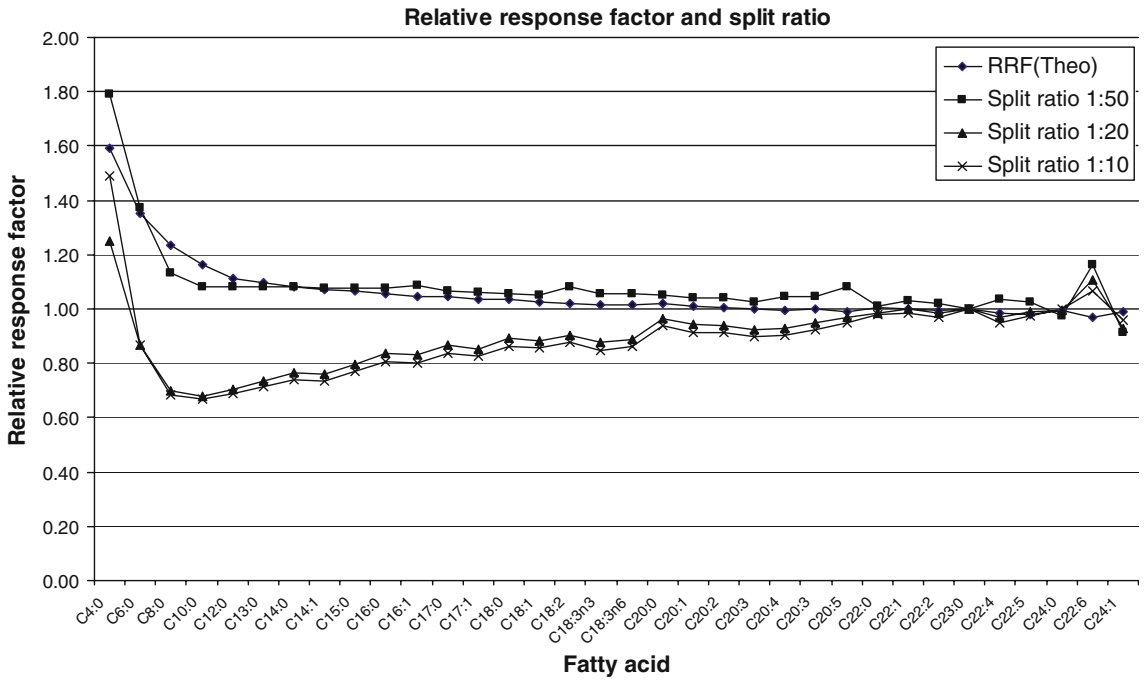

Fig. 3 Effect of injector split ratio on the relative response factor in the presence of a fixed fatty acid-to-internal standard ($FA_{(Sample)}$/$FA_{(IS)}$) ratio. The GLC-461A standard mixture and internal standard (C23:0-M, 0.982 mg/ml) was prepared in hexane to obtained a fixed (0.44) $FA_{(Sample)}/FA_{(IS)}$ ratio. Samples were run using a split ratio of 1:5, 1:10, 1:20, or 1:50, while keeping all other GC run parameters constant. Each *point* represents a mean of three experiments

carefully and slowly to avoid an exothermic reaction. This is usually done while the reaction contents are kept stirring, which takes approximately 1 min to complete. The exothermic nature of the reaction sometimes results in loss of sample because of the splatter, and may also pose a threat of possible injury to the analyst. This procedure is not only cumbersome when a large number of samples are to be analyzed, but transesterification using "Method A" also resulted in the formation of extra peaks, as shown in Fig. 1a. We therefore modified the method and incubated the tubes for transesterification on a dry ice bath for 10 min prior to adding acetyl chloride ("Method B"). The results shown in Fig. 1b also resulted in the formation of extra peaks, as in "Method A". We further modified the procedure, and in "Method C", after adding acetyl chloride in the reaction mixture on a dry bath, the transesterification was performed at room temperature for 24 h. Results shown in Fig. 1c clearly indicate that the extra peaks were no longer present on the chromatogram. These results suggest that the extra peaks may have resulted from side reactions at an elevated temperature. The recoveries of the individual fatty acids using Methods A, B, or C are shown in Table 2. The data demonstrate that the presence of extra peaks induced by transmethylation at 100 °C (Methods A and B) interfere with the estimation of fatty acids, and resulted in overestimation of particularly C16:0 and C18:1n-9. Comparing the data from Methods A and B, it appears that there are no significant differences between acetyl chloride added at room temperature or at low temperature; however, addition of acetyl chloride at low temperature avoids the need of its dropwise addition and constant stirring. We also evaluated the effect of the amount of water present (1–5%) in the transesterification reaction using "Method C". Our results demonstrate that the water content (up to 5% in the transesterification) does not significantly affect fatty acid analysis of the standard mixture or biological samples (data not shown).

Relative Response Factor

Accurate determination of fatty acid concentration by GC using FID not only depends on the optimized extraction/transesterification and instrument parameters, but is also contingent on the signal response of the FID detector to FAMEs of different composition. The early pioneer work by Ackman and Sipos [12], and Bannon [13], proposed using a theoretical relative response factor ($RRF_{(Theo)}$), based on the ionized carbon atoms, to correct the FID response to FAMEs of different composition. We realized from the previously published results [16–20], and also from our preliminary analysis, that the RRF for different FAMEs can be varied depending upon the GC run conditions, and therefore may cause an error in the determination of fatty acid concentrations in a given sample. The data shown in Fig. 2 indicates that when the $FA_{(Sample)}$:$FA_{(IS)}$ is varied, there was a variation in $RRF_{(Exp)}$, and this variation

in $RRF_{(Exp)}$ was also influenced by the split ratio used for injection (Fig. 2a–c). It is obvious from these results that there are differences between $RRF_{(Exp)}$ and $RRF_{(Theo)}$ values, which are more pronounced for medium-chain FAs, and become smaller as the carbon-chain length increases. The effect of injection split ratios on $RRF_{(Exp)}$ was also determined using a fixed (0.44) fatty acid to internal standard ($FA_{(Sample)}/FA_{(IS)}$) ratio. The data reported in Fig. 3 indicate that as the split ratio increases, the $RRF_{(Exp)}$ value becomes closer to that of $RRF_{(Theo)}$. Data from Figs. 2 and 3 demonstrated that the optimal $RRF_{(Exp)}$ could be obtained when a split ratio of 1:50 was used; however, the $RRF_{(Exp)}$ was still influenced by the $FA_{(Sample)}$:$FA_{(IS)}$ ratio. We therefore determined $RRF_{(Exp)}$ over a wide range of $FA_{(Sample)}$:$FA_{(IS)}$ ratios for each fatty acid. The data presented in Table 3 indicate that as the $FA_{(Sample)}$:$FA_{(IS)}$ ratio varied, the RRF is also varied. Short- to medium-chain fatty acids (C4–C10), in particular, have much variation between $RRF_{(Theo)}$ and $RRF_{(Exp)}$, and may have potential for underestimation when only the $RRF_{(Theo)}$ is used to calculate their concentration. Based on these results, we suggest the GC analyst should first determine the $RRF_{(Exp)}$

value under optimum GC run conditions for each fatty acid, and should use the $RRF_{(Exp)}$ closest to the $FA_{(Sample)}$:$FA_{(IS)}$ ratio for accurately computing each FA concentration.

Comparison of Methods for Data Calculation

Different approaches are used to quantify fatty acid compositions from the GC chromatograph. The concentration calculation based on the internal standard concentration and peak area offers reasonably accurate values, particularly for long-chain saturated and unsaturated fatty acids; but, this method would not give an accurate concentration for medium-chain fatty acids. One way to overcome this problem is to use multiple internal standards for FAs of different carbon chain lengths [6, 22, 23]. These data can be further corrected using a $RRF_{(Theo)}$ to get an estimation of fatty acid concentrations, including those of the medium-chain fatty acids. However, we realized that if an accurate estimation of short- to long-chain fatty acids is desired in a given sample, and accuracy is the ultimate priority, then concentrations corrected with a $RRF_{(Exp)}$ and/or calculated with an external standard curve combined with the using of internal standard would be superior to calculating FA concentrations, as described above. We, therefore, compared FA data analysis methods inclusive of: Calc. I Fatty acid concentration calculated based on internal standard and peak area; Calc. II Fatty acid concentration calculated with Calc. I and corrected with the theoretical RRF; Calc. III Fatty acid concentration calculated with Calc. I and corrected with the experimental RRF; and Calc. IV Fatty acid concentration calculated based on the internal standard and external standard curves. Data representing fatty acid recovery were calculated with the four data calculation methods (shown in Table 4). The data indicate that Calc. III and IV calculations produced similar results, which are the most consistent relative to the theoretical concentration of fatty acids.

Total Fatty Acid Analysis of Two Lipid Emulsions

Based on our current data, we suggest that our modification of a one-step transesterification process ("Method C") and use of Calc. III ($RRF_{(Exp)}$ instead of $RRF_{(Theo)}$) would yield a superior analysis of FAs. In order to confirm our data, we used two known lipid emulsions. Omegaven® contains 10% lipids as triglycerides enriched in n-3 PUFAs, whereas Lipidem® contains 20% lipids as triglycerides enriched in medium-chain fatty acids. Using these emulsion we further evaluated Methods A, B and C for transesterification. Fatty acid concentrations were calculated based on Calc. III, using $RRF_{(Exp)}$ obtained from Table 3 according to the $FA_{(Sample)}$:$FA_{(IS)}$ ratio of the samples. From the data presented in Table 5, we found that transesterification using Methods A and B resulted in a higher C16:0, C18:0 and C18:1n-9 concentration than that using "Method C". The "Method C" also produced a better recovery of n-3 PUFA. These results further confirmed that transesterification at 100 °C produces extra peaks that interfere with the estimation of some fatty acids. Furthermore, heating during transesterification also resulted in loss of the PUFAs, particularly C20:5n-3 and C22:6n-3.

In conclusion, an improved protocol collectively using "Method C" for a one-step transesterification and $RRF_{(Exp)}$ for data analysis accurately determined both medium- and long-chain fatty acids in commercial lipid emulsion

The lipid emulsions were analyzed at a split ratio of 1:50. The concentration of the fatty acid was calculated based on the internal standard peak area, and subsequently corrected with the $RRF_{(Exp)}$

samples. Transesterification with Methods A and B resulted in higher C16:0 and C18:1n-9 concentrations than using "Method C", due to side reactions. Furthermore, "Method C" also produced a better recovery of n-3 polyunsaturated fatty acids (EPA and DHA). This procedure can be easily adopted for analyzing large quantities of lipid samples for routine analysis in less time and without any threat of hazards imparted to the analyst.

REVIEW

Elevated Production of Docosahexaenoic Acid in Females: Potential Molecular Mechanisms

Alex P. Kitson · Chad K. Stroud · Ken D. Stark

Received: 8 September 2009 / Accepted: 15 January 2010 / Published online: 12 February 2010

Abstract Observational evidence suggests that in populations consuming low levels of n-3 highly unsaturated fatty acids, women have higher blood levels of docosahexaenoic acid (DHA; 22:3n-6) as compared with men. Increased conversion of alpha-linolenic acid (ALA; 18:3n-3) to DHA by females has been confirmed in fatty acid stable isotope studies. This difference in conversion appears to be associated with estrogen and some evidence indicates that the expression of enzymes involved in synthesis of DHA from ALA, including desaturases and elongases, is elevated in females. An estrogen-associated effect may be mediated by peroxisome proliferator activated receptor-α (PPARα), as activation of this nuclear receptor increases the expression of these enzymes. However, because estrogens are weak ligands for PPARα, estrogen-mediated increases in PPARα activity likely occur through an indirect mechanism involving membrane-bound estrogen receptors and estrogen-sensitive G-proteins. The protein kinases activated by these receptors phosphorylate and increase the activity of PPARα, as well as phospholipase A_2 and cyclooxygenase 2 that increase the intracellular concentration of PPARα ligands. This review will outline current knowledge regarding elevated DHA production in females, as well as highlight interactions between estrogen signaling and PPARα activity that may mediate this effect.

Abbreviations

ALA	Alpha-linoleic acid
AMPK	AMP-activated protein kinase
Ca^{2+}-PLA_2	Calcium-dependent phospholipase A_2
CE	Cholesteryl esters
COX	Cyclooxygenase
CREB	cAMP response element binding
D5D	Delta-5 desaturase
D6D	Delta-6 desaturase
DHA	Docosahexaenoic acid
DPAn-3	Docosapentaenoic acid, n-3
ELOVL	Elongase of very long chain fatty acids
EPA	Eicosapentaenoic acid
ER	Estrogen receptor
ERK-MAPK	Extracellular receptor kinase-mitogen activated protein kinase
FABP	Fatty acid binding proteins
GPR30	G-protein receptor 30
HUFA	Highly unsaturated fatty acids
LNA	Linoleic acid
MAPK	Mitogen-activated protein kinase
PC	Phosphatidyl choline
PE	Phosphatidyl ethanolamine
PL	Phospholipids
PLA_2	Phospholipase A_2
PPAR	Peroxisome proliferator activated receptor
PPRE	Peroxisome proliferator response element
PS	Phosphatidyl serine
PUFA	Polyunsaturated fatty acids

Introduction

The dietary intake and blood content of omega-3 polyunsaturated fatty acids (n-3 PUFA, ≥18 carbons, ≥2 double bonds), particularly the highly unsaturated fatty acids (HUFA, ≥20 carbons, ≥3 carbon–carbon, double bonds) eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:3n-3), are associated with a reduced risk of sudden cardiac death when incorporated into cardiac membranes as phospholipids or free fatty acids [1–4]. Also, the incorporation of DHA into brain phospholipids is associated with improved neurological development [5] and performance on spatial tasks [6]. EPA and DHA can either be obtained directly from the diet or produced within the body from dietary precursors such as alpha-linolenic acid (ALA, 18:3n-3). As reviewed recently, it appears that in humans, increasing ALA intakes can significantly increase levels of EPA and n-3 docosapentaenoic acid (DPAn-3), but not DHA in various blood measures [7]. However, even limited production of EPA, DPAn-3 and DHA from dietary ALA may be clinically relevant. The anti-arrhythmic benefit of EPA and DHA is estimated to have a very steep dose–response curve that plateaus at an EPA + DHA consumption of 750 mg/day [8], much higher than the estimated North American intakes of EPA + DHA of approximately 100 mg/day [9–12]. It has recently been suggested that 250–500 mg/day of EPA + DHA should be established as a dietary reference intake [13]. Therefore, even a small contribution to tissue EPA and DHA through ALA conversion could have a significant impact on sudden cardiac death risk reduction.

Dietary ALA intakes are inversely associated with sudden cardiac death in women [14] but not in men [15] in North American populations. North American intakes of ALA are approximately 1,500 mg/day [9–12]. Increased ALA conversion to EPA and DHA has been observed in women consuming <200 mg EPA + DHA/day as compared with men and women consuming >500 mg EPA + DHA/day [16, 17] and may partially explain the inverse association with sudden cardiac death. Increased conversion of ALA to DHA [16, 18, 19] and higher levels of DHA in various lipid fractions of liver, erythrocytes, plasma and whole blood [16, 20–24] have been observed in females consuming typical Western diets as compared with males.

An increased capacity to biosynthesize DHA in women is possibly an evolutionary adaptation to attempt to provide a supply of DHA for maternal–fetal transport during the fetal brain growth spurt [7, 12, 25]. Observational results suggest that pregnant women undergo metabolic adaptations to maintain DHA in blood for placental transport [12, 26–28]. Changes in n-3 HUFA have also been associated with both endogenous and exogenous changes in circulating estrogen [21, 29–32], however, the potential mechanisms for this enhanced biosynthesis has not been elucidated.

The biosynthesis of DHA is mediated by elongases and desaturases in the endoplasmic reticulum and acyl-CoA oxidase and multifunctional protein 2 in the peroxisome. Estrogen-response elements have not been associated with the genes of any of these enzymes to date despite our efforts (unpublished observations). This is despite the fact that estrogen response elements are well characterized [33] and can be identified using a variety of tools. Peroxisome-proliferator receptor α (PPARα), a nuclear receptor that increases the expression of desaturases [34, 35] is a potential target for an estrogen mediated effect, but it also lacks an estrogen response element [36]. However, PPARα activity may be increased by indirect estrogen mediated phosphorylation. Several of the protein kinase systems activated by membrane-bound estrogen receptors, including mitogen-activated protein kinase (MAPK) and protein kinase A, phosphorylate and increase the activity of PPARα [37–39]. We presently review evidence supporting sex differences in the conversion of ALA to DHA and suggest a potential mechanism involving interaction between PPARα and estrogen signaling.

Dietary Sources of DHA

Preformed DHA

Blood levels of DHA are strongly correlated with the dietary intake of DHA [40]. In North America, salmon is a dominant source of dietary EPA and DHA due to its high popularity (ranked 4th in consumption frequency among marine foods after shrimp, tuna and breaded fish, respectively), and a high content of EPA and DHA [8, 9, 41]. Salmon provides 1,100–2,100 mg EPA + DHA/100 g as compared with 130–860 mg from tuna, 320–550 mg from shrimp, and 0–210 mg from breaded fish (per 100 g cooked) [42]. Alternative sources that can provide significant amounts of dietary n-3 HUFA include fish oil capsules and novel EPA and DHA enriched functional foods [43, 44]. All these strategies are largely dependent on fish stocks and fish-farming practices that may not be sustainable [45]. Non-fish sources of preformed dietary DHA include fat extraction from species of microalgae such as *Crypthecodinium cohnii* and *Schizochytrium* [46, 47]. The production of DHA by microalgae varies with some species relying on alternating desaturases and elongases while others utilize polyketide synthase systems [48, 49]. There are ongoing efforts to develop genetically modified organisms capable of producing n-3 HUFA [50, 51].

Dietary Precursors of DHA

The primary dietary precursor of long chain n-3 PUFA that is consumed in North America is ALA, which is found in a variety of plant foods and oils, particularly in flaxseed oil. Canola and soybean oil also contain significant amounts of ALA, but also typically contain relatively higher amounts of linoleic acid (LNA, 18:2n-6). Supplementing with relatively low levels of dietary ALA (2.4 g ALA/day in flaxseed oil) can increase erythrocyte EPA [52] with higher doses of ALA resulting in further increases in blood levels of EPA and DPAn-3, but often not DHA as reviewed extensively [7]. There is no evidence that ALA interventions result in increased DHA in blood, however these studies have been done predominantly with males only [52–55] or with mixed sex groups without specific sex group analyses [56–59]. Recently, we demonstrated that DHA levels in free living females was significantly higher than free living males, and that increases in DHA status is much slower than changes in EPA with fish oil supplementation [24]. Therefore, acute intervention studies may not be appropriate to detect DHA biosynthesis and accumulation in human blood. There are some longer ALA intervention studies that suggest DHA blood measures may possibly increase (for example, 52 weeks) [60]. It is also important to note that blood measures of EPA, DPAn-3, and DHA may only reflect hepatic ALA conversion, while there is evidence suggesting tissue specific ALA conversion with brain capable of synthesizing DHA from ALA, while the heart appears to only convert ALA to EPA and DPAn-3 [61].

Mammalian DHA Biosynthesis

The discovery that dietary ALA was the precursor of DHA was made in 1950 by Widmer and Holman [62] by feeding fat-deficient rats isolated ALA and observing the tissue deposition of DHA. Klenk and Mohrhauer [63] later elucidated the pathway of DHA formation from ALA to be: 18:3n-3 → 18:4n-3 → 20:4n-3 → 20:5n-3 → 22:5n-3 → 22:6n-3. It was then determined that the pathway took place in the endoplasmic reticulum [64]. Testing of the assumption that a delta-4 desaturase was responsible for the conversion of 22:5n-3 into 22:6n-3 revealed no microsomal formation of 22:6n-3, but rather two novel fatty acids were microsomally produced: 24:5n-3 and 24:6n-3 [65]. It was later determined that 22:6n-3 was formed by peroxisomal β-oxidation of the microsomally produced 24:6n-3 (Fig. 1) [66].

The first enzyme in the conversion of ALA to longer chain n-3 HUFA is delta-6 desaturase (D6D) [67]. D6D catalyzes the desaturation of both n-6 and n-3 PUFA, and also appears to act on both 18- and 24-carbon PUFA, representing a significant metabolic "bottle-neck" [68]. A D6D knockout mouse has been demonstrated to lack the ability to make arachidonic acid (20:4n-6) from LNA and to lack the ability to make docosapentaenoic acid (22:5n-6) from dietary arachidonic acid [69]. In addition, the competition between ALA and 24:5n-3 for D6D results in EPA accumulation and limited synthesis and accumulation of DHA in Hep-G2 phospholipids [70]. As a result, the expression and activity of D6D, and substrate competition are considered primary determinants of DHA production rate. However, the large induction of both D6D and delta-5 desaturase (D5D), but not elongases, observed in HepG2 cells in response to essential fatty acid deficiency suggests that HUFA production is dependent on the concentration of both of these enzymes [71]. Additionally, these two genes are located only 11 kb apart on chromosome 11 in humans (chromosome 19 in mice) in a head-to-head orientation, suggesting that the transcription of these two genes may be regulated similarly [67]. A thorough review of the desaturases is available [67].

Sex Differences in DHA Status and Metabolism

Several studies have observed sex differences in blood and tissue DHA content in humans and rats (summarized in Table 1). While consuming a habitual diet, women possess significantly higher levels of DHA in total plasma lipids, as well as plasma non-esterified fatty acids, triacylglycerols, and phosphatidyl choline [23]. Sex specific responses to fish-oil supplementation have been observed including higher levels of DHA in erythrocytes and whole blood at baseline and after 8 weeks washout post-supplementation in women as compared with men [24]. Also, female sex has been significantly associated with increased DHA in studies examining various lifestyle and physiological parameters on fingertip prick whole blood in Italians [72] and serum phospholipids and cholesteryl esters in New Zealanders [22]. Higher levels of DHA in the blood of women as compared with men could be the result of differences in DHA mobilization and partitioning, dietary intake and male–female differences in body mass rather than differences in biosynthesis. However, increased ALA to DHA conversion rates in women relative to men have been determined using fatty acid stable isotope tracer studies [16, 18, 19].

The net fractional conversion of an orally ingested bolus of $U^{13}C$-ALA into EPA and DHA in women capable of bearing children has been observed to be approximately 21 and 9.1%, respectively [18] as compared with conversion rates in men of 7.9% for EPA and DHA production that was undetectable by the investigators means [19]. In these

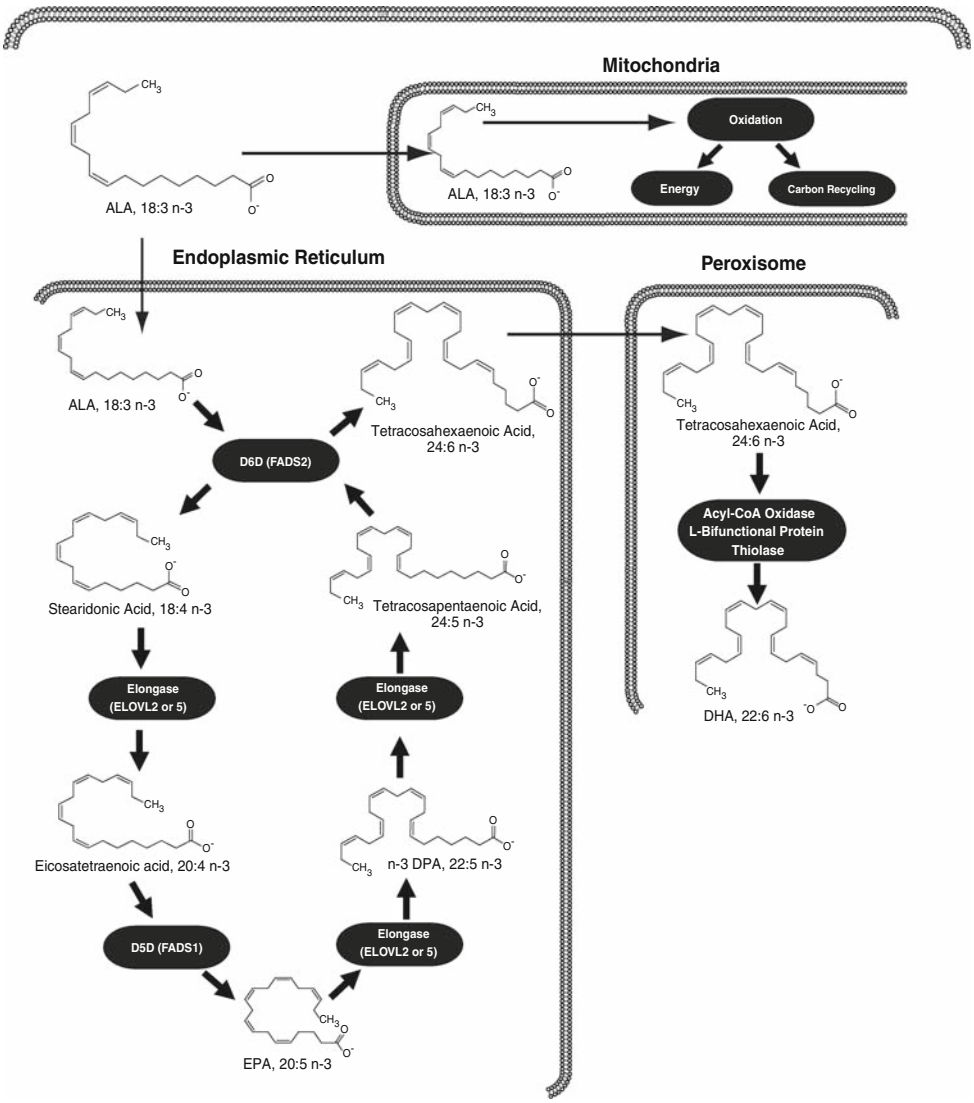

Fig. 1 Two main metabolic fates of alpha-linolenic acid: conversion to longer-chain n-3 polyunsaturated fatty acids in the endoplasmic reticulum and peroxisomes, and mitochondrial oxidation. *ALA* alpha-linolenic acid, *D6D* delta-6 desaturase, *FADS* fatty acid desaturase, *ELOVL* elongase of very long chain fatty acids, *EPA* eicosapentaenoic acid, *D5D* delta-5 desaturase, *DPA* docosapentaenoic acid, *DHA* docosahexaenoic acid

studies, ^{13}C-EPA and DHA primarily appeared in plasma phosphatidyl choline. Labelled U^{13}C-DHA has also been detected in plasma triacylglycerol and phospholipid fractions in women (no men comparison group) after treatment with dietary U^{13}C-ALA [73]. Compartmentalized modeling of ^{2}H-ALA metabolism through examining ^{2}H-HUFA appearance in plasma total lipids has isolated the sex difference to the conversion of labeled 22:5n-3 to labeled 22:6n-3, and that this sex difference was present only when participants consumed a beef-based diet low in n-3 HUFA and not a fish-based diet [16, 17]. Additionally, there may be increased partitioning of ALA towards DHA synthesis in women, as oxidation and carbon-recycling of ALA into saturated and monounsaturated fatty acids are much lower as compared with men [18, 19, 74]. In animal models, elevated DHA has also been observed in the liver phosphatidyl choline and phosphatidyl ethanolamine of mature female relative to male rats [20] and feeding male rats a high-ALA diet containing no EPA or DHA results in elevated liver and heart phospholipid EPA and DPAn-3, but not DHA [75].

In a model of dietary n-3 repletion, increased hepatic expression of D5D and D6D was observed in female rats as compared with male rats that corresponded to higher D5D protein content [76]. An increased expression of D5D only [20] and no differences in D5D and D6D [77] have also been reported. We have observed increased D5D and D6D mRNA expression in females as compared with males at 14 week of age on a standard chow diet (Kitson and Stark, unpublished observations). These results tend to suggest a greater capacity for DHA biosynthesis in females as compared with males. Sexual maturity may contribute to some of the disparity in these studies but this has not been elucidated.

Age may influence DHA accumulation [78]. There are reports of an association between age and DHA levels in

Table 1 Summary of studies investigating sex differences in DHA content or metabolism

Author [references]	Number of subjects	Dietary fatty acid treatment	Results
Rat studies			
Burdge et al. [20]	Wistar, male and female ($n = 24$ for each)	Maternal = 5.9 g ALA/kg diet	Increased DHA in PC and PE (% total fatty acids) in females
		Lactation/weaning = 0.7 g ALA/kg diet	Increased hepatic D5D expression in females.
Extier et al. [76]	Wistar male and female ($n = 6$ for each sex/time point)	Maternal = 0.05 g ALA/kg diet.	Increased DHA in plasma PC and liver PC, PS, and PE in females
		Weanling = 0.2 mg ALA/kg diet.	Increased D5D and D6D and lower PPARα and FABP7 hepatic expression in females
			Increased hepatic D5D protein content in females
			No DHA or gene expression differences in cerebral cortex
Childs et al. [77]	Wistar male and female ($n = 6$ for each sex/diet group)	Low soybean = 1.6 g ALA/kg diet	Increased DHA in plasma PC, liver PC and PE in females in all diets
		High fat soybean = 9.1 g ALA/kg diet	No differences in gene expression
		High fat linseed = 50.2 g ALA/kg diet

adult human blood. Although dietary intake of DHA is a potential confounder, age was positively associated with DHA in plasma phospholipids [79, 80], serum phospholipids and cholesteryl esters [22], plasma total lipids [40] and erythrocytes [40, 81] after controlling for DHA intakes. However, no differences in DHA content between subjects over 75 years of age and control subjects between 20 and 48 years of age were observed in plasma phospholipids,

non-esterified fatty acids, triacylglycerides, cholesteryl esters, and erythrocytes [82]. To our knowledge, a direct examination of the effect of age and sex on biosynthesis and accumulation of DHA has not been completed.

Role of Estrogen in DHA Biosynthesis

Sex differences in DHA levels appear to be mediated by circulating sex hormones, particularly estrogen (studies investigating hormone status or hormone manipulations, and DHA are summarized in Table 2). Elevated DHA content of female blood is possibly an evolutionary adaptation meant to provide fetal tissues with sufficient DHA for neural development. During pregnancy, the concentration of DHA in maternal blood is significantly elevated in the third trimester, when circulating levels of estrogen are highest [12, 26, 83]. Presumably, this increase in maternal DHA supports the fetal brain growth spurt in the third trimester, as the fetus' capacity to produce DHA from ALA may be insufficient to meet the extreme demand [25, 84]. With postpartum, maternal estrogen and circulating maternal DHA levels decrease [12, 26].

Blood levels of DHA have been associated with exogenous sex hormone interventions. Postmenopausal women have been observed to have decreased DHA in erythrocyte phospholipids [85], and postmenopausal women undergoing hormone replacement strategies including both direct hormone replacement and selective estrogen-receptor modulators have increased circulating DHA relative to postmenopausal women not using hormone therapies [86, 87]. Women taking an estradiol-based contraceptive pill also have elevated blood and erythrocyte DHA levels as compared to women not taking oral contraceptives [21, 88]. Similarly, DHA increased in the plasma cholesteryl esters of male-to-female transsexuals receiving oral ethinyl estradiol, while plasma cholesteryl ester DHA decreased in the blood of female-to-male transsexuals receiving testosterone treatment [21].

In rats, EPA and DHA in plasma phosphatidyl choline correlate strongly with female sex hormones (estrogen and progesterone), and plasma, liver, and adipose EPA and DHA content vary inversely with testosterone [89]. DHA in liver phospholipids and plasma phosphatidyl choline have been observed to be higher in females as compared with males after n-3 deficiency/repletion [76]. Higher DHA has also been seen in female rat plasma and liver phospholipids in different diets containing varying levels of total fat and ALA [77]. Decreased erythrocyte DHA has been observed after ovariectomization as compared with sham-operated controls [90]. In addition, neuroblastoma cells incubated with ALA and estradiol exhibit higher EPA and DPAn-3 in phosphatidyl ethanolamine and increased expression of D5D as compared with cells incubated with ALA alone [91, 92]. Interestingly, treating neuroblastoma cells with dehydrotestosterone decreases EPA and DHA in phosphatidyl ethanolamine, and decreases D5D expression [91].

Based on current evidence, it appears that sex influences the concentration of circulating DHA, resulting in higher levels in females. This difference is associated with estrogen, and appears to involve increased conversion of ALA to DHA, in particular the conversion of 22:5n-3–22:6n-3, and only during low dietary intake of n-3 HUFA. It is possible that estrogen may increase the concentration or activity of DHA synthesis enzymes, including desaturases, elongases, and peroxisomal β-oxidation enzymes resulting in enhanced DHA biosynthesis.

Estrogen Signalling Mechanisms

Estrogen exerts many effects on a variety of different tissue types, and its actions are mediated by both direct interaction with the genome and nongenomic mechanisms [93]. The effects of estrogen are mediated primarily by estrogen receptors (ERα and ERβ in mammals) which exhibit a variety of subcellular localizations depending on tissue type [94, 95]. For example, in endometrial cells, ERα is primarily found at the cell membrane, whereas in breast cancer cells it is in the nucleus [95].

In direct genomic estrogen signaling, the binding of estrogen to estrogen receptors results in dimerization with another estrogen receptor (ERα or ERβ) followed by binding to an estrogen response element in the promoter of a target gene, causing altered transcription of that gene. In "nongenomic" estrogen signaling, estrogen binds to and activates estrogen receptors anchored to the plasma membrane [96], or a G-protein known as G-protein receptor 30 (GPR30) [97]. Dimerization to another estrogen receptor can also occur with this mechanism [98], however the signal transduction that results from the activation of these membrane bound receptors involves a number of second messenger protein kinases and calcium signaling mechanisms, rather then direct genomic interaction (some are presented below, and are extensively reviewed in [93]).

The observational link between circulating estrogen and DHA production suggests that estrogen increases the expression of the enzymes involved in DHA production from shorter-chain n-3 PUFA. However, to our knowledge, no estrogen response elements have been identified to date that influence the expression of any of the genes involved in DHA synthesis (D6D, D5D, acyl-CoA oxidase), suggesting that the estrogen dependent induction of these genes occurs through indirect mechanisms. Several reliable techniques exist for determining the presence of estrogen

Table 2 Summary of studies investigating effects of exogenous estrogen and menopause on DHA content or metabolism

Author [reference]	Cell/subjects	Treatment	Effects of gender or steroids on measurements
Cell culture			
Alessandri et al. [92]	SH-SY5Y neuroblastoma ($n = 3$ for each condition)	10 nM 17β-estradiol 30 μM of ALA alone 10 nM 17β-estradiol with 30 μM of ALA	Increased EPA and n-3 DPA in PE with 17β-estradiol treatment
Extier et al. [91]	SH-SY5Y neuroblastoma (n = 4 for each condition)	7 μM ALA, LA, or ALA/LA, 10 nM 17β-estradiol, dehydrotestosterone, progesterone or control.	Increased EPA and n-3 DPA and increased D5D expression with ALA, and 17β-estradiol treatment Decreased EPA and DHA and decreased PPARα and D5D expression with ALA and dehydrotestosterone treatment Decreased D6D expression with progesterone treatment
Human			
Stark et al. [29]	Females (43–69 years)	Premenopausal ($n = 19$) Postmenopausal taking hormone therapy ($n = 40$) Postmenopausal not taking hormone therapy ($n = 34$)	Increased DHA and n-3 DPA in plasma PL in postmenopausal women not taking hormone therapy
Sumino et al. [87]	Postmenopausal women (43-63 years)	Taking conjugated equine estrogen and medroxyprogesterone acetate ($n = 59$) Not taking hormone therapy ($n = 45$)	Increased plasma DHA and EPA total lipids in women taking hormones
Giltay et al. [21]	Male-to-female transsexuals (eugonadal)	Cyproterone acetate alone ($n = 16$) Cyproterone acetate with oral ethinyl estradiol ($n = 15$) Transdermal 17β-estradiol ($n = 15$)	Increased DHA in serum CE with cyproterone acetate with oral ethinyl estradiol
	Female-to-male transsexuals (ovariectomized)	Testosterone esters plus anastrozole ($n = 16$) Placebo ($n = 14$) Testosterone esters alone ($n = 17$)	Decreased DHA in serum CE with testosterone esters alone
	Females	Using oral contraceptives ($n = 32$) No oral contraceptive use ($n = 71$) Controlled diet, free from fish	Non-significant increase in DHA in serum CE with oral contraceptive use ($P = 0.08$)
Giltay et al. [86]	Postmenopausal females (47–59 years) Males (60–70 years)	Females 60 mg raloxifene/day ($n = 23$) Females 150 mg raloxifene/day ($n = 20$) Females conjugated equine estrogen with medroxyprogesterone acetate ($n = 17$) Females placebo ($n = 23$). Males 120 mg raloxifene/day ($n = 15$) Males placebo ($n = 15$)	Increased DHA in plasma CE in post-menopausal women taking 150 mg/day raloxifene and in women taking equine estrogens with medroxyprogesterone acetate at 24 months compared to baseline
Stark and Holub [30]	Postmenopausal females (45–70 years)	Postmenopausal taking hormone therapy ($n = 18$) Postmenopausal not taking hormone therapy ($n = 14$) 2.8 g algal DHA vs. placebo in crossover design	Increased estimates of retroconversion of DHA to EPA in plasma phospholipids of women not taking hormone therapy

response elements on any gene on a genome-wide basis [99, 100], however genome-wide screening for these elements in DHA-producing genes has not been reported.

Peroxisome Proliferator-Activated Receptor α (PPARα)

The structure, ligand-binding, DNA-binding and metabolic actions of PPARs have been reviewed [101, 102]. PPARs are ligand-activated transcription factors belonging to the nuclear steroid receptor superfamily. Inactive PPARs are bound to corepressor proteins which are released upon ligand binding to the PPAR through a conformational change to the PPAR. This conformational change allows the PPAR to bind to the retinoid-x-receptor and co-activator proteins that facilitate binding of the complex to DNA through a number of different mechanisms including histone acetylase activity [103]. This activated complex then interacts with peroxisome proliferator response elements (PPRE; nucleotide regions with an imperfect direct repeat-1 motif) in the promoter region of target genes, and gene transcription is modulated.

Three distinct PPARs have been discovered with varying tissue expression, genomic targets, and ligands: PPARα, PPARγ (PPARγ$_1$ and PPARγ$_2$ are produced from the same gene by different promoters), and PPARβ/δ. All three subtypes bind to the direct repeat-1 motif, however, each PPAR subtype distinguishes its targets by differences in the region directly upstream of this motif [101].

PPARα is expressed in metabolically active tissues such as liver, heart, kidney, skeletal muscle and brown adipose tissue [104, 105] and is known to regulate the expression of genes involved in PUFA desaturation (D6D, D5D) [35, 106], peroxisomal β-oxidation (acyl-CoA oxidase, D-bifunctional protein) [107, 108], and fatty acid transport (cytosolic fatty acid binding protein, fatty acid transport protein, acyl-CoA binding protein) [109, 110], all of which are involved in DHA formation (a review of PPARα responsive genes is available [111]). PPARα plays a large role in lipid homeostasis by increasing peroxisomal and mitochondrial β-oxidation rates, and producing energy and acetyl units for ketone body formation in periods of fasting and/or low carbohydrate intake [112].

Natural ligands for PPARα include PUFA (n-3 and n-6), monounsaturated fatty acids, and eicosanoids such as leukotriene B4 and hydroxyeicosatetraenoic acids [36]. Fibrates such as clofibrate, fenofibrate, and bezafibrate are synthetic ligands for PPARα and are effective lipid-lowering agents in humans, while in rodents fibrates cause increased hepatic peroxisome number, hepatomegaly, and carcinogenesis at higher doses [111].

PPARα can be phosphorylated at multiple sites, resulting in increased activity (reviewed in [113]). The mechanism by which phosphorylation increases PPARα activity has not been elucidated, however, some evidence suggests that phosphorylation of PPARα results in a decreased affinity for corepressor proteins [114]. This finding is significant, as it suggests that phosphorylated PPARα is more likely to be activated at a biological concentration of PPARα ligands, such as PUFA.

Estrogen and PPARα

There is strong evidence that estrogen signaling interacts with PPARα-dependent gene transcription particularly with regards to lipid metabolism. For example, mice deficient in aromatase, and therefore unable to synthesize estrogen, succumb to hepatic steatosis resulting from elevated hepatic lipid accumulation and deficient β-oxidation [115]. However, estrogen supplementation prevents this effect by increasing mitochondrial and peroxisomal β-oxidation rates via increased expression of mitochondrial and peroxisomal β-oxidation enzymes (acyl-CoA oxidase, medium chain acyl-CoA dehydrogenase) [115, 116], similar to the effect of PPARα activation. Additionally, the expression of stearoyl-CoA desaturase 1, a PPARα-induced gene, is significantly increased in female mouse livers and results in elevated hepatic oleate production [117]. Also, mitochondrial β-oxidation is increased in women but not in men fed a high oleate diet (31.4% of energy), indicating a sex difference in the metabolic response to oleate, a weak PPARα ligand [118]. Treating ovariectomized rats with 17β-estradiol increases PPARα content and expression of PPARα-dependent lipid oxidation genes in red gastrocnemius muscle [119]. Significant increases in the expression and transcriptional activity of PPARβ/δ, and an increase in the expression of lipid oxidation genes under transcriptional control of PPARα, independent of an increase in PPARα expression in liver, muscle, and adipose tissue has been demonstrated using a similar approach [120]. Reduced fat accumulation in female but not male mice has also been observed after treatment with phytol, a peroxisome proliferator [121].

The expression of fatty acid binding proteins (FABP), which is increased following PPARα activation [122], is also much higher in females than in males [123, 124]. FABP transports fatty acids to the nucleus and has been observed to co-localize with and possibly increasing the activity of PPARα in fibroblasts and primary mouse hepatocytes [125–127]. However, transient transfection of fibroblasts with FABPs decreased tetradecylthioacetic acid stimulated PPAR activity [128].

Similarly, estrogen administration causes peroxisome proliferation in the uropygial glands of male and female mallard ducks, accompanied by an increase in the peroxisome-dependent production of 3-hydroxy fatty acid

diesters [129]. In humans, the rate of DHA retroconversion to EPA, a process dependent on peroxisomal activity, is increased in postmenopausal women receiving hormone replacement therapy as compared with postmenopausal women not receiving this treatment [30]. Additionally, phospholipids and long chain PUFA in the brain are increased in female but not male PPARβ knockout mice suggesting sexual dimorphisms and a role of PPARβ in paroxysmal acyl-CoA use in the brain [130]. Considerable differences exist in the response of PPARα and PPARβ/δ to some natural ligands (particularly 8(*S*)-HETE) [131], and that generalizing in vivo results between different PPARs should be done with caution. Nonetheless, it seems that sex differences exist in other PPARs, as well as PPARα.

In a transgenic luciferase-$^{5\times}$PPRE mouse, it was shown that liver exhibited significantly lower PPARα transcriptional activity in females as compared with males in response to oral fibrate administration, food withdrawal, and reversal of feeding schedule [132]. These sexual dimorphisms remained despite ovariectomization and castration that suggests gonadal hormones are not involved. These observations may also be a dependent on the presence of the 5 PPREs in this model as similar observations have not been confirmed in mice with intact genomes. However, this transgenic model does support the notion that sex differences exist in PPARα-dependent gene transcription. Similarly, male as compared with female mice express more PPARα-dependent genes in response to 2 weeks of daily oral trichloroethylene treatment, suggesting a sex specific response to exogenous activators of PPARα [133].

Observations in PPARα-null mice strongly illustrate the interaction between estrogen and PPARα. Normally, ovariectomization results in significant gains in adipose tissue mass, while subsequent treatment with exogenous estradiol relieves this effect. However, in PPARα-null mice, no significant changes in adipose tissue are observed upon ovariectomization and subsequent estradiol administration, suggesting that the effect estrogen has on fat oxidation is dependent on the presence of PPARα [134]. Circulating leptin concentrations decrease in PPARα-null mice as compared with control mice, with a sex-specific effect in the leptin response to feeding as leptin was increased in female PPARα-null mice as compared with male PPARα-null mice [135].

The evidence presented above infers that a significant biological interaction exists between estrogen signaling and PPARα activity, and is present in several animal models. Accordingly, understanding the mechanism by which estrogen regulates PPARα may provide a better understanding of observations of sexual dimorphisms in n-3 PUFA metabolism. Interestingly, in vitro ligand binding analysis has shown that 17-β estradiol is a weak direct activator of PPARα, suggesting that it is not a PPARα ligand [36]. However, many interactions exist between estrogen signaling and PPARα, including protein kinases and other mechanisms, which suggest that estrogen acts on PPARα indirectly.

Estrogen Increases PPARα Activity by Phosphorylation

It is known that the phosphorylation (and corresponding activity) of PPARα is enhanced by several of the protein kinase systems activated by membrane bound estrogen receptors. By phosphorylating PPARα, estrogen will enhance DHA formation by increasing the transcription of enzymes involved in this pathway (Fig. 2).

Estrogen binding to membrane bound estrogen receptors activates extracellular receptor kinase-mitogen activated protein kinase (ERK-MAPK) in a variety of tissue types/cell lines. Injection of 17-β-estradiol increases ERK-MAPK activity in several rat brain structures [38] and the addition of estrogen to male derived hypothalamic nuclei in vitro results in significant elevations in the activity of MAPK [39]. Furthermore, the addition of estrogen to cultured muscle cells [136] and breast cancer cells [137] also results in elevated ERK-MAPK activity, illustrating that this effect is shared by a variety of tissues.

Phosphorylation and increased activity of PPARα resulting from MAPK-mediated signal transduction has been well documented in a variety of cellular processes. Hepatic PPARα is known to be phosphorylated at two serine residues in response to insulin signaling via the ERK-MAPK system, resulting in increased PPARα-dependent gene transcription [114, 138]. The incubation of cultured myotubes with adiponectin results in elevated activity of ERK-MAPK and corresponding phosphorylation of PPARα, resulting in increased target gene expression and lipid catabolism [139]. Similarly, phosphatidyl inositol supplementation also increases PPARα activity via ERK-MAPK-dependent phosphorylation in human hepatocyte cell lines [140], resulting in PPARα-dependent production and secretion of apolipoprotein A-1.

Estrogen also activates protein kinase A phosphorylation systems. In vitro research with hippocampal neurons indicates that estrogen causes significant protein kinase A activation that is dependent on the presence of membrane-bound estrogen receptors [37]. Estrogen has been observed to cause protein kinase A dependent phosphorylation of *N*-methyl-D-aspartic acid receptors in rat spinal neurons, lessening the perception of pain by the animal [141]. In rat liver tissue, estrogen interaction with GPR30 results in activated protein kinase A signal transduction and prevention of apoptosis following organ injury [142]. Activation of protein kinase A signaling by cholera toxin has also been shown to increase the phosphorylation and transcriptional

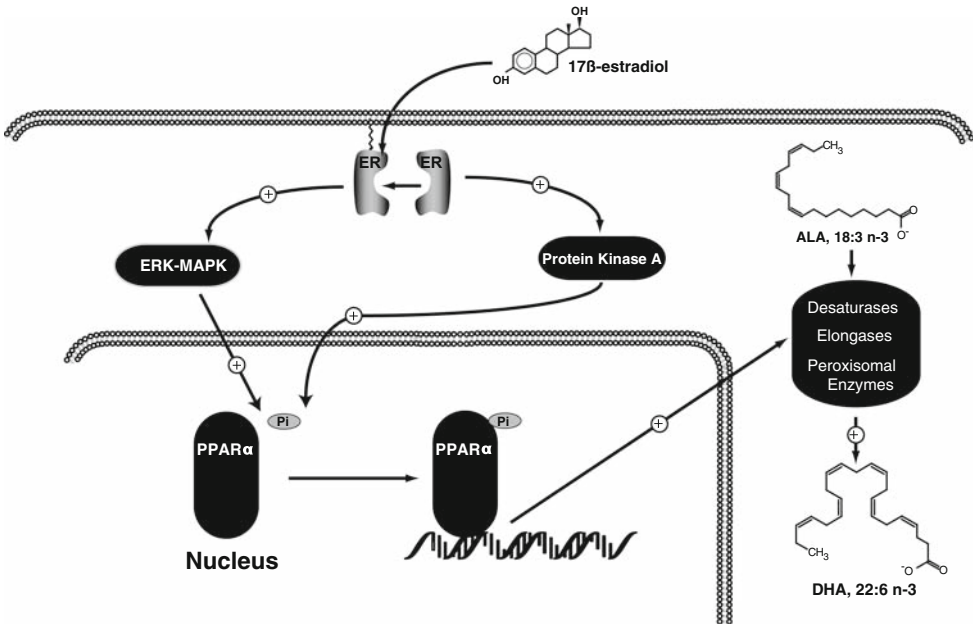

Fig. 2 Proposed mechanism of increased peroxisome-proliferator activated receptor α phosphorylation by estrogen. *ER* estrogen receptor, *ERK-MAPK* extracellular receptor kinase-mitogen activated protein kinase, *Pi* inorganic phosphate, *PPARα* peroxisome-proliferator activated receptor α, *ALA* alpha-linolenic acid, *DHA* docosahexaenoic acid

activity of PPARα [143]. Protein kinase A phosphorylates several enzymes in lipid-utilization systems and metabolism, including diacylglycerol lipase in the brain [144].

Phosphorylation of 5′AMP-activated protein kinase has also been observed in response to 17β-estradiol supplementation in the skeletal muscle of ovariectomized rats. Lipid oxidation in white adipose tissue [145] and skeletal muscle [146] is increased during AMP-activated protein kinase (AMPK) activation, and it has been found that siRNA inhibition of PPARα prevents this response [146].

Phosphorylation of PPARα via activation of membrane bound estrogen receptors is likely similar to the estrogen mediated phosphorylation and increased activity of cAMP response element binding (CREB) protein. Activation of CREB protein results in the increased expression of anti-apoptotic proteins, including the Bcl-2 family [147]. It has been well established that estrogen binding to membrane bound estrogen receptors results in the phosphorylation and increased activity of CREB protein. The precise protein kinase that mediates this phosphorylation varies by tissue, as protein kinase A is responsible in ZR-75 breast cancer cells [148], and protein kinase B/Akt and ERK-MAPK mediate this response in neuronal cells [149]. The increased CREB protein activity that results from phosphorylation has anti-apoptotic effects in all cell types, indicating increased CREB protein-dependent transcription.

Increased Concentration of Intracellular PPARα Ligands

Despite not being a PPARα ligand, estrogen may increase the intracellular concentrations of effective PPARα ligands, particularly PUFA and eicosanoids (Fig. 3). PUFA are most often found in the inner membrane leaflet of cells, in the *sn-2* position of phosphatidyl ethanolamine [150]. Hydrolytic release of PUFA from this position for cell signaling or eicosanoid synthesis is catalyzed by phospholipase A_2 (PLA_2). Upon phosphorylation, the activity and a calcium-dependent isoform of PLA_2 (Ca^{2+}-PLA_2) is increased, and the enzyme becomes localized in the cell membrane and nuclear envelope regions. By localizing in these regions, Ca^{2+}-PLA_2 functions to release PUFA from biological membranes for cell signaling and eicosanoid synthesis.

Similarly to PPARα, activation of the ERK-MAPK signaling cascade has been observed to phosphorylate Ca^{2+}-PLA_2 in HeLa cells [151, 152]. Because estrogen has been observed to activate the ERK-MAPK system [38], as well as IP_3-dependent calcium signaling cascades [153–155], estrogen would be expected to increase the activity of Ca^{2+}-PLA_2. Indeed, in pregnant rats uterine Ca^{2+}-PLA_2 activity is elevated near gestation in response to increased estradiol concentrations [156]. Estradiol-administration also enhanced the activity of Ca^{2+}-PLA_2 of mussel (*Mytilus galloprovincialis*) blood cells [157].

Eicosanoids are known to be involved in atherosclerosis, bronchial asthma, and many other inflammatory conditions [158]. Prostaglandins are produced in most tissue types, and are known to activate PPARα [36]. These cytokines are produced by enzymes known as cyclooxygenases (COX) of which there are two types: COX-1, which is constitutively expressed in most tissue types, and COX-2, the expression of which is induced during periods of inflammation. With regards to estrogen, increased COX-2 expression has been observed in response to elevated estrogen in human

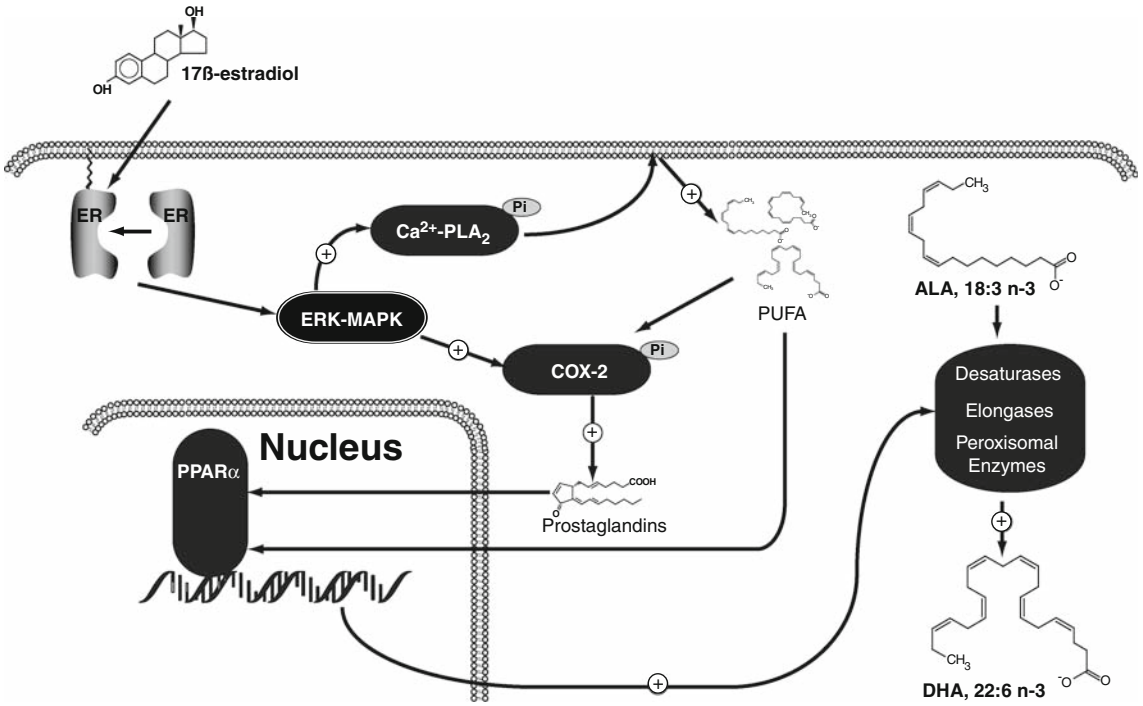

Fig. 3 Proposed mechanism by which estrogen increases intracellular concentration of ligands for peroxisome-proliferator activated receptor α. *ER* estrogen receptor, *ERK-MAPK* extracellular receptor kinase-mitogen activated protein kinase, *Ca^{2+}-PLA_2* calcium-dependent phospholipase A_2, *COX-2* cyclooxygenase-2, *Pi* inorganic phosphate, *PUFA* polyunsaturated fatty acids, *PPARα* peroxisome-proliferator activated receptor α, *ALA* alpha-linolenic acid, *DHA* docosahexaenoic acid

amnion, resulting in elevated prostaglandin E_2 production [159].

Conclusions

The current knowledge of sex differences in n-3 PUFA metabolism is presently outlined and various likely mechanisms mediating the elevated n-3 HUFA synthesis observed in females have been indicated. Women have higher circulating concentrations of DHA as compared with men that is associated with estrogen, and is a result of increased conversion of ALA into DHA. This increased conversion likely involves the increased expression/activity of DHA synthesis enzymes, highlighting possible interaction between estrogen signaling mechanisms and the expression of enzymes responsible for the synthesis of DHA. Two likely mechanisms by which estrogen increases PPARα activity and subsequent DHA formation are presented: (1) estrogen increases the activity of ERK-MAPK and protein kinase A, which phosphorylate and increase the activity of PPARα, and/or (2) estrogen increases the intracellular concentration of both PUFA and eicosanoids, PPARα ligands, via elevated Ca^{2+}-PLA_2 and COX-2 activities, resulting in activation of PPARα. By increasing the activity of PPARα, estrogen likely causes elevated transcription of the enzymes involved in DHA synthesis, including desaturases, elongases, and peroxisomal β-oxidation enzymes. The increased activity of these enzymes results in the increased production of DHA, contributing to the elevated tissue DHA content observed in females.

A more complete understanding of these interactions is required to understand the health benefits of individual n-3 PUFA and to assist in the determination of dietary recommendations for ALA, EPA, DPAn-3 and DHA. The impact of hormonal status on n-3 PUFA metabolism may be important for DHA availability for maternal–fetal transport during pregnancy. In addition, subtle differences in DHA production may be contributing to observed sexual dimorphisms in sudden cardiac death. The interaction between estrogen and fatty acid metabolism requires further research including an examination of the effects of various gonadal hormones, the impact of fluctuations in hormones throughout the life cycle including physiological challenges such as pregnancy, and the impact of the dietary intake of specific fatty acids. In addition, an enhanced understanding of the regulation and control of DHA biosynthesis may assist in efforts to produce alternative food sources of DHA and aid in the challenge of meeting the potential global demand for EPA and DHA.

Received: 20 October 2009 / Accepted: 26 January 2010 / Published online: 18 February 2010

Abstract Lysophosphatidylcholine is known to be a lipid mediator in various cellular responses. In this study, we examined the anti-inflammatory actions of lysophosphatidylcholine containing docosahexaenoic acid esterified at the *sn*-1 position. First, in RAW 264.7 cells, DHA-lysoPtdCho suppressed the LPS-induced formation of NO concentration-dependently. However, ARA-lysoPtdCho showed a partial suppression, and LNA-lysoPtdCho had no significant effect. Additionally, DHA-lysoPtdCho also reduced the level of TNF-α or IL-6, but not PGE_2. In animal experiments, the i.v. administration of ARA-lysoPtdCho (150 or 500 μg/kg) prevented zymosan A-induced plasma leakage remarkably with a maximal efficacy (Emax) of 50%, in contrast to no effect with LNA-lysoPtdCho. Remarkably, DHA-lysoPtdCho suppressed zymosan A-induced plasma leakage with an ED_{50} value of 46 μg/kg and an Emax value of around 95%. Additionally, mechanistic studies indicated that the anti-inflammatory action of DHA-lysoPtdCho was partially related to the reduced formation of LTC_4, TNF-α, and IL-6. When the interval time between lysoPtdCho administration and zymosan A challenge was extended up to 2 h, such a suppressive action of DHA-lysoPtdCho was augmented, suggesting that a DHA-lysoPtdCho metabolite is important for anti-inflammatory action. In support of this, 17-HPDHA-lysoPtdCho showed a greater anti-inflammatory action than DHA-lysoPtdCho. Furthermore, a similar anti-inflammatory action was also observed with i.p. administration of DHA-lysoPtdCho or a 17(*S*)-hydroperoxy derivative. Additionally, oral administration of DHA-lysoPtdCho also expressed a significant anti-inflammatory action. Taken together, it is proposed that DHA-lysoPtdCho and its metabolites may be anti-inflammatory lipids in vivo systems.

LOX	Lipoxygenase
ED_{50}	50% effective dose
IC_{50}	50% inhibitory concentration
PLA_2	Phospholipase A_2
LTC_4	Leukotriene C_4
PGE_2	Prostaglandin E_2
IL-6	Interleukin-6
TNF-α	Tumor necrosis factor alpha
NO	Nitric oxide

Introduction

Previously, certain families of lipid-derived mediators were reported to be implicated in inflammatory diseases such as asthma, rheumatoid arthritis, or inflammatory bowel disease [1–6]. Although much is known about the molecular basis of initiating signals and pro-inflammatory chemical mediators in inflammation, it has recently become apparent that endogenous lipid mediators participate in events of inflammatory or anti-inflammatory events [7, 8]. Arachidonic acid (ARA), released from PLA_2-catalyzed hydrolysis of phosphatidylcholine, is converted to leukotrienes or lipoxins via the lipoxygenase enzymatic pathway, and to prostaglandins via the cyclooxygenase enzymatic pathway. Especially, prostaglandin E_2 (PGE_2) and leukotriene B_4 (LTB_4) are well known to be representative pro-inflammatory lipid mediators [9], whereas lipoxins have recently been reported to show an anti-inflammatory action [7]. Remarkably, arachidonate-derived eicosanoids in inflammatory exudates include lipoxins in addition to prostaglandins and leukotrienes. 5-Lipoxygenase (5-LOX) is crucial for the formation of leukotrienes and lipoxins, while 12/15-lipoxygenase is important for the formation of lipoxin [7, 9–12]. Furthermore, resolvins, which are generated from the oxygenation of eicosapentenoic acid at C-15, and protectins, derived from oxygenation of docosahexaenoic acid (DHA) at C-17 have also been reported to be potent anti-inflammatory lipid molecules.

Meanwhile, lysophosphatidylcholine (lysoPtdCho), another product from PLA_2-catalyzed hydrolysis of phosphatidylcholine, has been reported to be pro-inflammatory [1–3, 6, 13]. The pro-inflammatory action of lysoPtdChos, saturated or monounsaturated, may be due to the generation of reactive oxygen species or nitric oxide in various types of cells [14–17]. Additionally, our recent study also indicated that LNA-lysoPtdCho showed a cytotoxic effect, accompanied by ROS formation [18]. Previous studies reported that lysoPtdChos with a polyunsaturated acyl group were present in animal sources. In plasma, LNA-lysoPtdCho, ARA-lysoPtdCho, and DHA-lysoPtdCho existed at a substantial level in plasma [19–21]. In addition, DHA-lysoPtdCho was one of the major lipid components in shark liver extract [22]. Noteworthy, our recent studies demonstrated that polyunsaturated-lysoPtdChos containing linoleoyl, arachidonoyl, or docosahexaenoyl group was efficiently oxygenated by reticulocyte 15-LOX or leukocyte 12/15-LOX [23–25]. Therefore, it was supposed that lysoPtdChos with polyunsaturated acyl groups could affect the formation of lipid mediators such as lipoxin [7]. Separately, in our study, ARA-lysoPtdCho and DHA-lysoPtdCho were found to strongly inhibit mammalian 5-LOX activity [26], responsible for the generation of pro-inflammatory leukotrienes [9]. Meanwhile, DHA, a hydrolysis product of DHA-lysoPtdCho, is known to show anti-inflammatory action [27] while ARA, the hydrolysis product of ARA-lysoPtdCho, is converted to lipid metabolites, pro-inflammatory or anti-inflammatory. Nonetheless, there has been no knowledge about the effect of polyunsaturated-lysoPCs on inflammation in vivo system. In this regard, we examined anti-inflammatory effects of lysoPtdChos containing polyunsaturated acyl group in vitro as well as in vivo system.

Materials and Methods

Materials

Dilinoleoyl phosphatidylcholine, diarachidonoyl phosphatidylcholine, and didocosahexaenoyl phosphatidylcholine (purity, 99%) were from Avanti Polar Lipid (Alabaster, AL, USA). 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT), soybean lipoxygenase-1 (Type I-B), phospholipase A_2 (PLA_2) (honey bee venom), lipopolysaccharide (LPS) (from *Escherichia coli* serotype 0111:B4; purity >99%) and zymosan A (from *Saccharomyces cerevisiae*) were purchased from Sigma-Aldrich Corp (St. Louis, MO, USA). PGE_2 and LTC_4 EIA kit were procured from Cayman Chemical (Ann Arbor, MI, USA). TNF-α ELISA kit was from Invitrogen Corp (Camarillo, CA, USA) and IL-6 ELISA kit was obtained from Ebioscience Inc Co (California, USA). LNA-lysoPtdCho, ARA-lysoPtdCho, DHA-lysoPtdCho were prepared from PLA_2-catalyzed hydrolysis of the corresponding phosphatidylcholines as described previously with a slight modification [23–26]. In brief, didocosahexaeonyl-phosphatidylcholine (2.5 mg), dissolved in chloroform, was dried under N_2, and then rapidly dispersed in 10 ml of 50 mM borax buffer (pH 9.0) containing 10 mM $CaCl_2$. The hydrolysis was started by adding PLA_2 (100 units), and allowed to continue under N_2 with constant stirring for 2 h at 25 °C. The reaction mixture was partially purified by a Sep-pack column (2 × 1 cm) and the lysophospholipid

product was further purified by silica gel TLC in the solvent system (chloroform: methanol: water: 65:25:4). Finally, the spot containing DHA-lysoPtdCho was scraped off, extracted with methanol, dried under nitrogen and kept at −80 °C until use and 17-HPDHA-lysoPtdCho was prepared as described previously [26]; briefly, soybean LOX-1 (200 units/ml) was incubated with DHA-lysoPtdCho (200 μM) in borax buffer (50 mM, pH 9.0) for 30 min. Subsequently, the mixture was passed through a C_{18} column (2 × 1 cm), and the products were eluted with methanol and concentrated under N_2 gas.

Measurement of Polyunsaturated LysoPtdCho Induced Cytotoxicity in RAW 264.7 cells

RAW 264.7 cells were cultured in DMEM supplemented with penicillin (100 units/ml), streptomycin (100 μg/ml) and heat-inactivated FBS (10% v/v) at 37 °C in 5% CO_2 (19). Cells with passages from 6 to 13 were harvested, and seeded in 96-well plate (5×10^4 cells/well), followed by 24 h incubation. Then, cells were pre-incubated with each polyunsaturated lysoPtdCho (0–60 μM) in the medium for 2 h, and then incubated in the presence or absence of LPS (1 μg/ml) at 37 °C for 20 h. Cell viability was examined by the assay using MTT [18]; briefly, RAW cells (5×10^4 cells/well) were exposed to MTT reagent (500 μg/ml) at 37 °C for 4 h. After the removal of the medium, the formazan was extracted from cells by disrupting the cell membranes with dimethylsulfoxide. The cell viability was measured by determining the absorbance at 570 nm with a reference at 690 nm.

Preventive Effect of LysoPtdCho on LPS-Induced NO Production in RAW 264.7 Cells

RAW 264.7 cells (5×10^4 cells/well) were preincubated with polyunsaturated lysoPtdCho (0–60 μM) at 37 °C for 2 h, and then the production of NO (nitric oxide) was stimulated with LPS (1 μg/ml) during further incubation for 20 h. The production of NO was determined by using the Griess reagent consisting of 1% sulfanilamide and 0.1% *N*-(1-naphthyl) ethylenediamine dihydrochloride in 2.5% H_3PO_4 [18].

Effect of DHA-lysoPtdCho on LPS-Induced TNF-α, IL-6, and PGE_2 Formation in RAW 264.7 Cells

To investigate the effect of DHA-lysoPtdCho on TNF-α, IL-6, and PGE_2 formation in LPS-treated cells, RAW 264.7 cells (5×10^4), seeded on 96-well plate, were pre-incubated with DHA-lysoPtdCho (0–40 μM) 2 h prior to treatment with LPS (1 μg/ml) for 20 h at 37 °C, in a 5% CO_2 incubator. The cell-free supernatants were collected for the determination of TNF-α, and IL-6 by ELISA kit and PGE_2 by EIA kit according to the manufacturers' manuals.

Effect of Polyunsaturated LysoPtdCho on Zymosan A-Induced Peritonitis in Mice

ICR mice (male, 6 weeks) were housed under a 12 h: 12 h light–dark cycle and fed with unlimited commercial food and water. Peritoneal inflammation was induced in ICR mice according to a previously reported method [28, 29] with some modifications. For the measurement of plasma leakage, polyunsaturated PtdChos, polyunsaturated lysoPtdChos (0–500 μg/kg) or their derivatives were administrated intravenously, intraperitoneally or orally 30–60 min prior to intravenous injection of 0.5% Evans blue dye (200 μl), dissolved in PBS, and intraperitoneal injection of zymosan A (100 mg/kg), prepared freshly in PBS. Then 30 min later, mice lightly anesthetized were decapitated and blood was collected to obtain serum as described previously [30]. Meanwhile, peritoneal lavages were performed with 4 ml of ice cold PBS followed by the brief centrifugation to get supernatant. Subsequently, the concentration of Evans blue dye in peritoneal lavage fluid and in serum was determined by measuring absorbance at 620 nm, and calculating the amount to (μg/μl) using an Evan Blue standard curve. The volume of plasma leakage (μl) for 30 min after zymosan A i.p. injection was calculated by dividing the amount of Evans blue dye in the peritoneal lavage fluid (μg) by the concentration of Evans blue dye in the serum (μg/μl) [31].

For the measurement of leukocyte infiltration, lysoPtdChos and their derivatives were administered i.v. 30 min prior to i.p. administration of zymosan A as described above. Total cell counting were performed for lavage fluid collected at the 90 min time point using light microscopy together with trypan blue staining [31, 32].

Determination of LTC_4, TNF-α, and IL-6 Levels in Peritoneal Lavage Fluid

In order to determine the level of LTC_4, TNF-α, and IL-6 in exudates, 1 ml of peritoneal lavage fluid was transferred to microcentrifuge tubes, and centrifuged (15,000 rpm, 5 min). The supernatant was used directly for the analysis of TNF-α and IL-6 by ELISA kit, and analysis of LTC_4 by enzyme immunoassay (EIA) kit according to the manufacture's instructions [31–33].

Effect of DHA-LysoPtdCho on Leukotriene C_4-Induced Plasma Leakage

DHA-lysoPtdCho (0–150 μg/kg) was injected into the tail vein of mice, and 60 min later, 0.2 ml of 0.5% Evans blue

dye dissolved in saline was intravenously injected just before intraperitoneal (i.p.) administration of LTC_4 (100 μg/kg). Samples of blood and peritoneal fluid were collected as described above [34].

Statistical Analysis

Results were expressed as means ± SD. Statistical significance was evaluated using ANOVA and Student's *t* test, and $P < 0.05$ was considered statistically significant.

Results

Our previous study indicated that polyunsaturated lysoPtdChos strongly inhibited mammalian 5-LOX activity [9], an initial enzyme in the biosynthesis of inflammatory LTC_4 [26]. In the present study, we evaluated the anti-inflammatory actions of polyunsaturated lysoPtdChos by determining the effect of lysoPtdChos on LPS-induced formation of inflammatory mediators such as NO, PGE_2, TNF-α, or IL-6.

Effects of Polyunsaturated LysoPtdChos on LPS-Induced Production of Mediators in RAW 264.7 Cells

It is well known that the stimulation of macrophages by LPS results in high-level production of nitric oxide [35] through the expression of inducible nitric oxide synthase (iNOS) in some cells such as macrophages [36]. First, to see the effect of lysoPtdCho on LPS-induced NO formation, each lysoPtdCho (3–60 μM) was pre-incubated with RAW 264.7 cells for 2 h, and then LPS (1 μg/ml) was included in the same incubation. As shown in Fig. 1b, LNA-lysoPtdCho had no significant suppressive effect on LPS-induced NO formation up to 60 μM. Additionally, ARA-lysoPtdCho also showed no significant inhibition of LPS-induced NO formation at lower concentrations (1–20 μM), although it had some suppressive effect at 60 μM. In contrast, DHA-lysoPtdCho diminished the production of NO in a concentration-dependent manner (12–200 μM), and the 50% effective concentration (EC_{50}) of DHA-lysoPtdCho was estimated to be 18.2 ± 2.1 μM (Fig. 1b). Meanwhile, DHA at 20 μM suppressed LPS-induced NO production by approximately 18% (data not shown), much smaller than the suppression (~50%) achieved with DHA-lysoPtdCho at 20 μM. In a separate experiment to see whether the suppressive effect of DHA-lysoPtdCho on LPS-induced NO production was related to its cytotoxic action, the effect of DHA-lysoPtdCho on the viability of RAW 264.7 cells was measured, based on the MTT assay. Figure 1a indicates that DHA-lysoPtdCho and DHA-lysoPtdCho had no remarkable cytotoxic effect within the concentrations used, whereas linoleoyl-lysoPC showed a significant reduction of viability at 6 μM or higher concentrations. Thus, the suppressive effect of DHA-lysoPtdCho on LPS-induced NO production was expressed at non-cytotoxic concentrations. Subsequently, we turned to the effect of DHA-lysoPtdCho on the level of TNF-α or IL-6 in RAW 264.7 cells stimulated with LPS. Again, DHA-lysoPtdCho expressed a dose-dependent suppression of TNF-α or IL-6 formation (Fig. 2). Next, we examined the effect of DHA-lysoPtdCho on PGE_2 formation in RAW 264.7 cells stimulated with LPS. However, DHA-lysoPtdCho up to 200 μM failed to diminish the level of PGE_2 (779 pg/ml) in RAW 264.7 cells stimulated with LPS (1 μg/ml) only (data not shown).

Effects of Polyunsaturated LysoPtdChos on Zymosan A-Induced Plasma Leakage

Since DHA-lysoPtdCho exhibited a remarkable anti-inflammatory action in vitro models, we examined whether

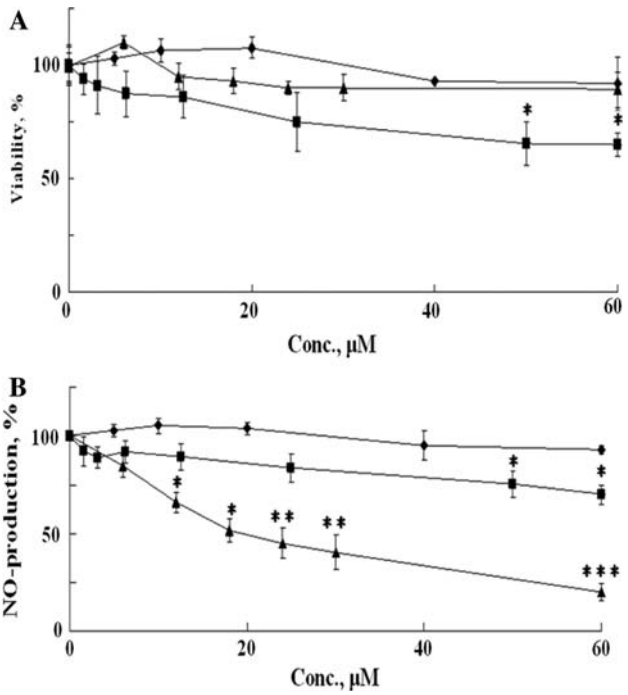

Fig. 1 Effect of polyunsaturated lysoPtdChos on cell viability or LPS-induced NO production. RAW 264.7 cells were preincubated with each polyunsaturated lysoPtdCho (LNA-lysoPtdCho, *filled squares*; ARA-lysoPtdCho, *filled diamonds*; DHA-lysoPtdCho, *filled triangles*) at various concentration (0–60 μM) for 2 h, and then stimulated with LPS (1 μg/ml) for another 20 h. Cell viability (**a**) and LPS-induced NO production (**b**) were determined as described in "Materials and Methods". Data were expressed as a percentile value (%) of the LPS-treated group, which were pre-incubated with LPS (1 μg/ml) in the absence of polyunsaturated-lysoPCs, and were displayed as mean ± SE values of triplicate determinations. *$P < 0.05$ and **$P < 0.01$ versus LPS-treated group

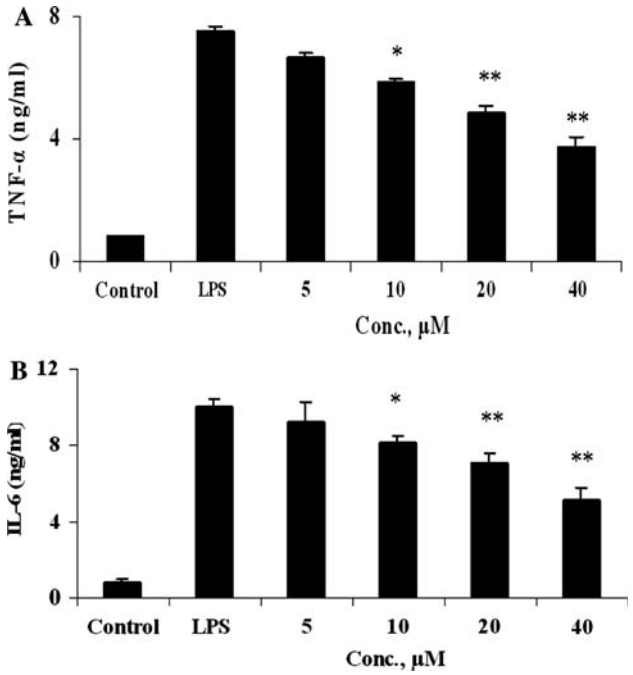

Fig. 2 Effects of DHA-lysoPtdCho on LPS -induced TNF-α (**a**) and IL-6 (**b**) production in RAW 264.7 cells. RAW 264.7 cells (5×10^4 cells/well) were incubated with DHA-lysoPtdCho (5–40 μM) for 2 h and then LPS (1 μg/ml) was treated for another 20 h. TNF-α and IL-6 in the cell-free cultured supernatant were measured by an ELISA kit. Data were expressed as mean ± SEM values of triplicate determinations. $*P < 0.05$ and $**P < 0.01$ versus LPS-treated group

polyunsaturated lysoPtdChos might attenuate zymosan A-induced peritonitis in an animal model. In this study, each lysoPtdCho was tested for the suppression of zymosan A-induced plasma leakage into the peritoneum in mice, based on extravasation of Evans blue dye indicative of vascular permeability. As shown in Fig. 3a, the i.v. administration of LNA-lysoPtdCho up to 500 μg/kg did not reduce the level of exudate infiltration induced by zymosan A, when it was administered 30 min before i.p. administration of zymosan A (100 mg/kg). Meanwhile, ARA-lysoPtdCho (150 μg/kg) was observed to decrease the level of exudate infiltration induced by zymosan A, but the elevation of ARA-lysoPtdCho dose to 500 μg/kg failed to further enhance the suppressive effect (Fig. 3b). Furthermore (Fig. 3c), DHA-lysoPtdCho expressed a remarkable suppression of zymosan A-induced plasma leakage in a dose-dependent way up to 500 μg/kg; a significant decline of zymosan A-induced plasma leakage into the peritoneum was observed with DHA-lysoPtdCho at a dose as small as 15 μg/kg ($P < 0.05$). Further, the administration of DHA-lysoPtdCho at a higher dose (500 μg/kg) almost completely suppressed the zymosan A-induced plasma leakage into the peritoneum, and the ED_{50} value was estimated to be approximately 46 μg/kg. However, zymosan A-induced plasma leakage was not suppressed significantly or remarkably (<10%) by didocosahexaenoyl-phosphatidylcholine (15–50 μg/kg) (data not shown). From these data, it was found that DHA-lysoPtdCho was the most efficient among phospholipids tested in preventing zymosan A-induced plasma leakage. To prove the anti-inflammatory action of DHA-lysoPtdCho in vivo, we examined the effect of DHA-lysoPtdCho on inflammatory mediators such as interleukin-6 or TNF-α in peritoneal exudates. As indicated in Fig. 4, DHA-lysoPtdCho, administered i.v. significantly inhibited zymosan A-induced formation of IL-6 and TNF-α in dose-dependent manner, supporting anti-inflammatory role of DHA-lysoPtdCho. In further study, the effect of DHA-lysoPtdCho on infiltration of leukocytes into the peritoneum was evaluated. Figure 5 showed that DHA-lysoPtdCho prohibited the infiltration of leukocytes into the peritoneum, providing further support for the anti-inflammatory action of DHA-lysoPtdCho.

In the subsequent study, a time-dependent effect of DHA-lysoPtdCho on zymosan A-induced plasma leakage was examined. For this study, DHA-lysoPtdCho (50 μg/kg) was administered 10, 30, 60, or 120 min before i.p. administration of zymosan A, and a time-dependent suppression of plasma leakage was evaluated. As exhibited in Fig. 6, the 10-min interval between administration of DHA-lysoPtdCho and zymosan A challenge was not sufficient to express a remarkable suppression of plasma leakage. Meanwhile, both the 30-min interval and the 60-min interval were sufficient to inhibit zymosan A-induced plasma leakage, although there was no significant difference between two experimental conditions. This may suggest that the same mechanism may apply for anti-inflammatory action of DHA-lysoPtdCho between 30- and 60-min intervals. Meanwhile, the extension of interval time to 120 min augmented the inhibitory effect to some extent. Taken together, it is supposed that anti-inflammatory action of DHA-lysoPtdCho may involve multiple mechanisms. Previously, DHA-lysoPtdCho was observed to inhibit 5-lipoxygenase, an initial enzyme in the biosynthetic pathway responsible for the formation of LTC_4 [9]. Therefore, the accumulation of DHA-lysoPtdCho in the peritoneum may lead to the reduction of LTC_4 formation in the peritoneum. To test this possibility, the effect of DHA-lysoPtdCho administration on the formation of LTC_4 in the peritoneum was investigated [34]. As indicated in Fig. 7, the formation of LTC_4 in peritoneal exudates was suppressed by DHA-lysoPtdCho, i.v. administered in a dose-dependent manner. However, the suppression of leukotriene C_4 formation by DHA-lysoPtdCho at 150 μg/kg was approximately 50%. From this, it is suggested that anti-inflammatory action of DHA-lysoPtdCho may be ascribed at least partially to the inhibition of 5-lipoxygenase. However, the suppressive effect of DHA-lysoPtdCho on

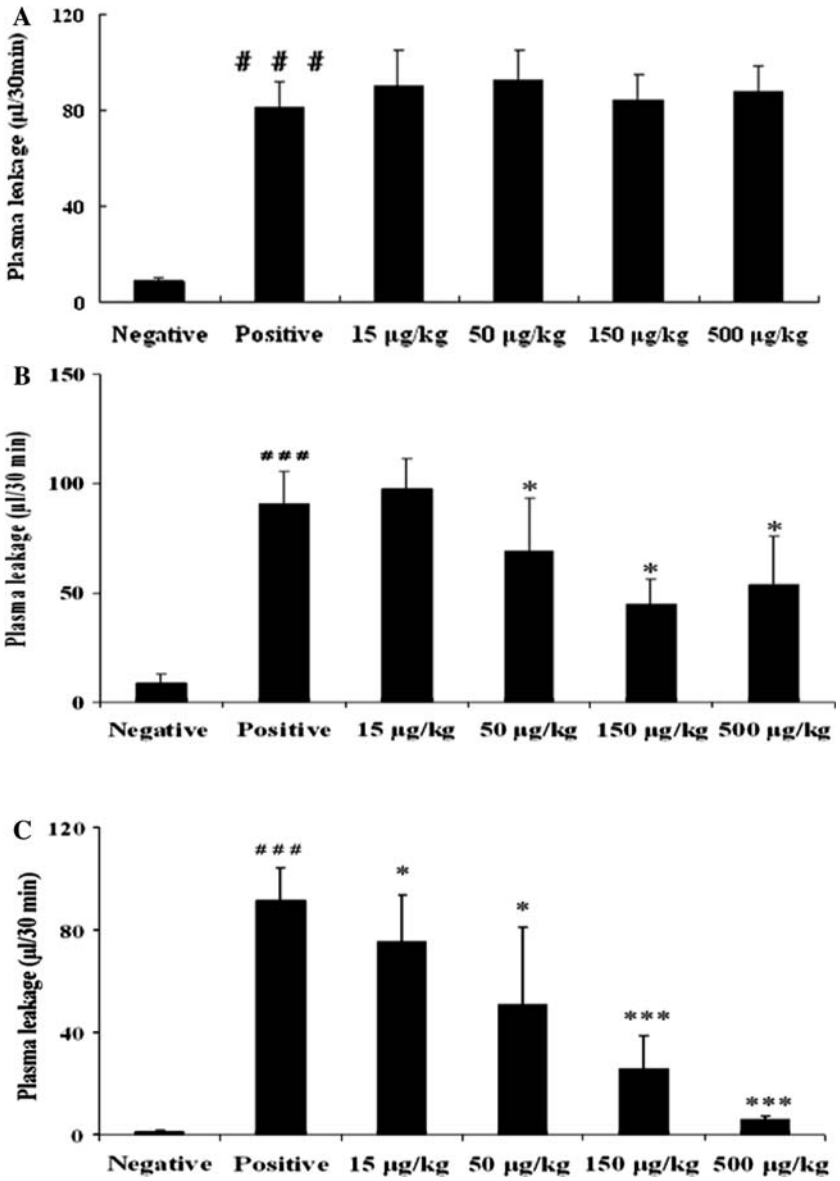

Fig. 3 Effects of polyunsaturated lysoPtdCho, administered i.v. on Zymosan A-induced plasma leakage in mice. LNA-lysoPtdCho (**a**), ARA-lysoPtdCho (**b**) DHA-lysoPtdCho (**c**) was administered i.v. to mice (0–500 μg/kg) 30 min prior to i.p. administration of zymosan A (100 mg/kg), and the plasma leakage was determined as described in Materials and Methods. The *column* and *bar* represent the means ± SEM of results from each group of >10 mice. $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ versus positive group (zymosan A); $^{\#\#\#}P < 0.001$ versus negative group (PBS)

zymosan A-induced LTC_4 formation was smaller than zymosan A-induced plasma leakage (Fig. 3c). This led to the assumption that a process responsible for the change of vascular permeability might be directly affected by DHA-lysoPtdCho or its metabolites. To test this possibility, we examined the effect of DHA-lysoPtdCho on plasma leakage caused by LTC_4, an inflammatory mediator. Figure 8 demonstrates that LTC_4-induced inflammation was suppressed remarkably by DHA-lysoPtdCho. This may support a notion that a mechanism other than the inhibition of LTC_4 formation may also be responsible for the anti-inflammatory action of DHA-lysoPtdCho. In support of this, a time-dependent action of DHA-lysoPtdCho indicates that the metabolism of DHA-lysoPtdCho may be crucial for its anti-inflammatory action. One metabolic pathway is the hydrolysis of DHA-lysoPtdCho to produce DHA. And the other may be a lipoxygenation process to give rise to HPDHA-lysoPtdCho. With this in mind, DHA and 17-HPDHA-lysoPtdCho were examined for their anti-inflammatory action. As demonstrated in Fig. 9, 17-HPDHA-lysoPC, a product from the oxygenation of DHA-lysoPtdCho by 15-lipoxygenase, showed a remarkable anti-inflammatory effect, greater than that of DHA-lysoPtdCho. From this, it is suggested that the anti-inflammatory action of DHA-lysoPtdCho may involve the formation of 17-HPDHA-lysoPtdCho as an intermediate in the metabolic activation of DHA-lysoPtdCho. Meanwhile, the treatment with DHA or 17(*S*)-hydroperoxy-4,7,10,13,15,19-DHA at 50 μg/kg did not show any significant anti-inflammatory action (Fig. 9).

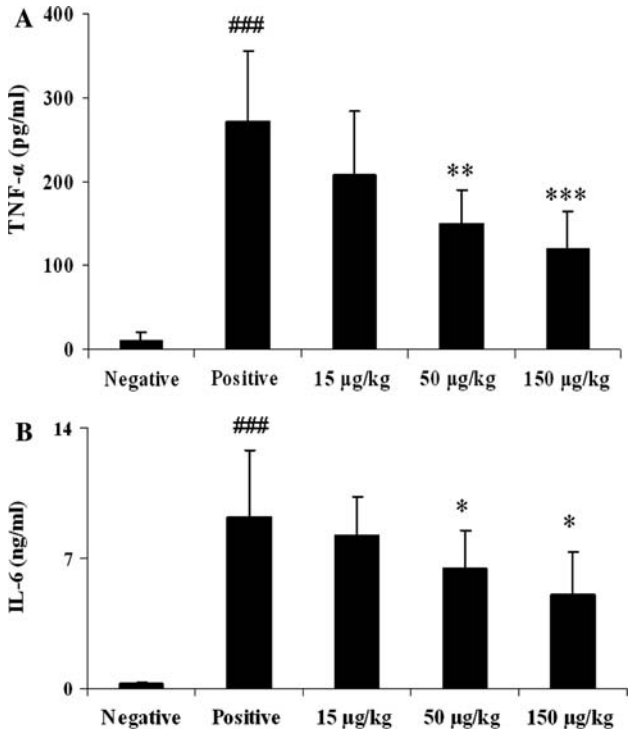

Fig. 4 Effect of DHA-lysoPtdCho, administered i.v. on zymosan A-induced TNF-α and IL-6 formation in mice. DHA-lysoPtdCho was administered i.v. to mice (0–150 μg/kg) 30 min prior to i.p. administration of zymosan A (100 mg/kg). Plasma lavage was performed with 4 ml PBS followed by brief centrifugation (15,000 rpm, 5 min), and cell-free lavage supernatant was used directly for determination of TNF-α and IL-6 levels by ELISA kit. The *column* and *bar* represent the means ± SEM of results from each group of ten mice. $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ versus positive group (zymosan A); $^{\#\#\#}P < 0.001$ versus negative group (PBS)

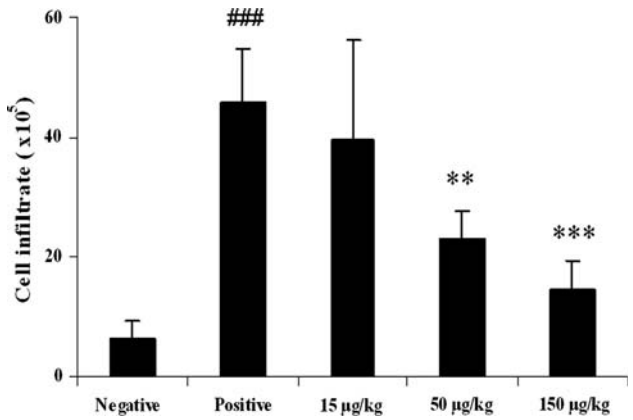

Fig. 5 Effect of DHA-lysoPtdCho, administered i.v. on zymosan A-induced leukocyte infiltration in mice. DHA-lysoPtdCho was administered i.v. 30 min prior to i.p. administration of zymosan A (100 mg/kg). Total cell counts were performed for the lavage fluid collected at the 90-min time point using light microscopy together with trypan blue staining

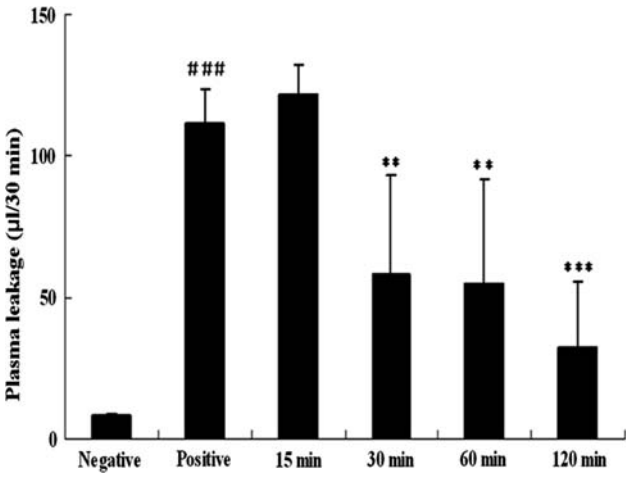

Fig. 6 Time-dependent suppressive effect of DHA-lysoPtdCho, administered i.v. on Zymosan A-induced plasma leakage in mice. DHA-lysoPtdCho was administered i.v. to mice (50 μg/kg) 15 min, 30 min, 60 min or 120 min prior to i.p. administration of zymosan A (100 mg/kg), and the plasma leakage was determined as described in "Materials and Methods". The *column* and *bar* represent the means ± SEM of results from each group of >10 mice. $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ versus positive group (zymosan A); $^{\#\#\#}P < 0.001$ versus negative group (PBS)

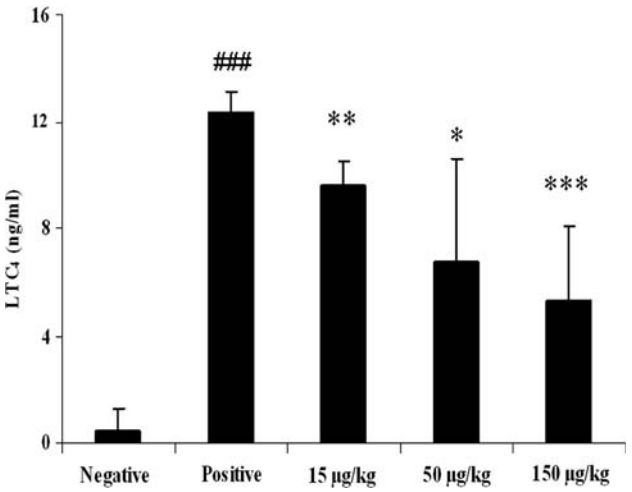

Fig. 7 Effect of DHA-lysoPtdCho, administered i.v. on zymosan A-induced LTC_4 formation in mice. DHA-lysoPtdCho was administered i.v. to mice (0–150 μg/kg) 30 min prior to i.p. administration of zymosan A (100 mg/kg). Plasma lavage was performed with 4 ml PBS followed by brief centrifugation (15,000 rpm, 5 min), and the cell-free lavage supernatant was used directly for determination of LTC_4 level by EIA kit. Effect of DHA-LysoPtdCho, Administered i.p. on Zymosan A-Induced Plasma Leakage

In a separate experiment to see anti-inflammatory action of lysoPtdCho administered by other administration routes,

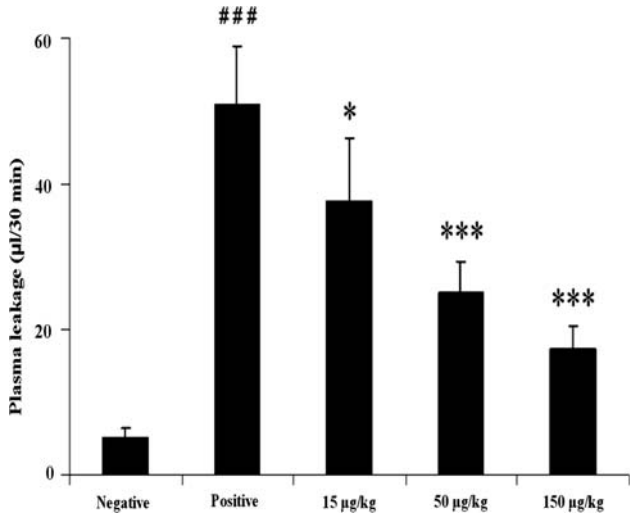

Fig. 8 Effect of DHA-lysoPtdCho, administered i.v. on LTC_4-induced plasma leakage in mice. DHA-lysoPtdCho (0–150 µg/kg) was administered i.v. into tail vein of mice 60 min before i.p. administration injection of LTC_4 (100 µg/kg), and the plasma leakage was determined as described in "Materials and methods". The *column* and *bar* represent the mean ± SEM of results from each group of 10 mice. $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ versus positive group (LTC_4); $^{\#\#\#}P < 0.001$ versus negative group (PBS)

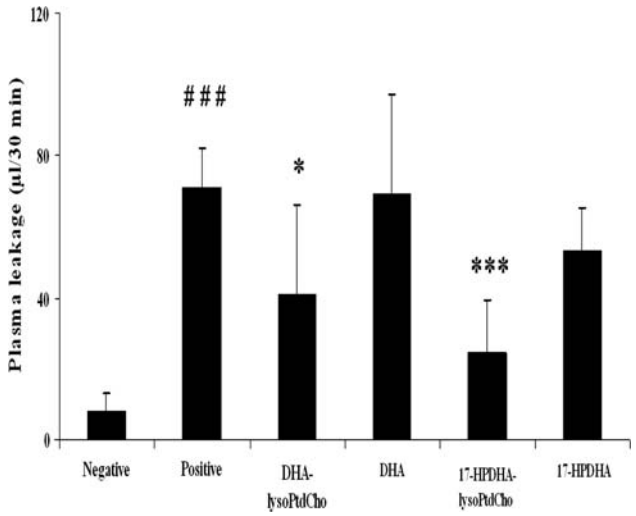

Fig. 9 Effects of DHA, 17-HPDHA, DHA-lysoPtdCho or 17-HPDHA-lysoPtdCho, administered i.v. on zymosan A-induced plasma leakage in mice. Lipids were administered i.v. to mice (50 µg/kg) 30 min before i.p. administration injection of zymosan A (100 mg/kg), and the plasma leakage was determined as described in "Materials and Methods". The *column* and *bar* represent the mean ± SEM of results from each group of >10 mice. $^{*}P < 0.05$, $^{**}P < 0.01$ versus positive group (zymosan A); $^{\#\#\#}P < 0.001$ versus negative group (PBS)

DHA-lysoPtdCho, and 17-HPDHA-lysoPtdCho were administered i.p. 60 min prior to zymosan A challenge, and its suppressive effect was evaluated. As demonstrated in Fig. 10, the i.p. administration of DHA-lysoPtdCho or

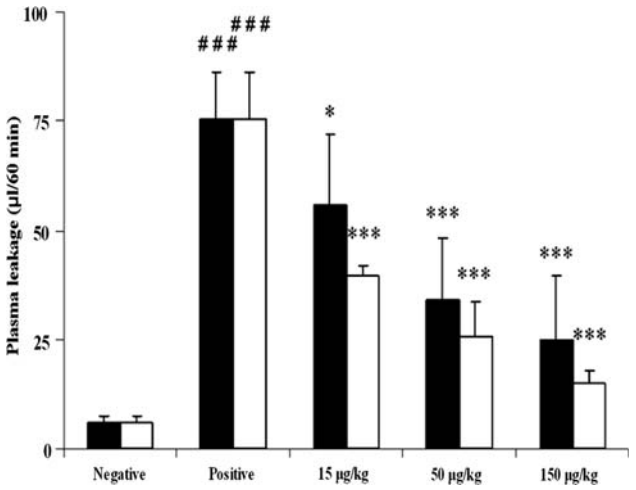

Fig. 10 Effect of DHA-lysoPtdCho or 17-HPDHA-lysoPtdCho, administered i.p. on zymosan A-induced plasma leakage in mice. DHA-lysoPtdCho (*filled bars*) or 17-HPDHA-lysoPtdCho (*open bars*) was administered i.p. (50 µg/kg) to mice 60 min before an i.p. injection of Zymosan A (100 mg/kg), and the plasma leakage was determined as described in "Materials and Methods". The *column* and *bar* represent the mean ± SEM of results from each group of >10 mice. $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ versus positive group (zymosan A); $^{\#\#\#}P < 0.001$ versus negative group (PBS)

17-HPDHA-lysoPtdCho produced a dose-dependent anti-inflammatory action. In comparison, 17-HPDHA-lysoPtdCho was more efficacious than DHA-lysoPtdCho, similar to the finding with the i.v. administration (Fig. 9). Thus, DHA-lysoPtdCho was suggested to be transformed to 17-HPDHA-lysoPtdCho, more bioactive.

Effect of DHA-LysoPtdCho, Administered Orally on Zymosan A-Induced Plasma Leakage

In a further experiment, the anti-inflammatory effect of DHA or DHA-lysoPtdCho, orally administered, was examined. As shown in Fig. 11, oral administration of DHA-lysoPtdCho showed an apparent suppressive effect on zymosan A-induced plasma leakage, although oral administration was less effective than i.p. or i.v. administration. In contrast, the anti-inflammatory action of docosahexaenoic acid, orally administered, was not significant up to 150 µg/kg. Thus, the structure of DHA-lysoPtdCho is suggested to be important for anti-inflammatory action in vivo.

Discussion

Although there have been reports on the anti-inflammatory actions of DHA metabolites in vitro and in vivo [37–39], there has been no report on the anti-inflammatory action of DHA-lysophospholipids. Recently, our previous study

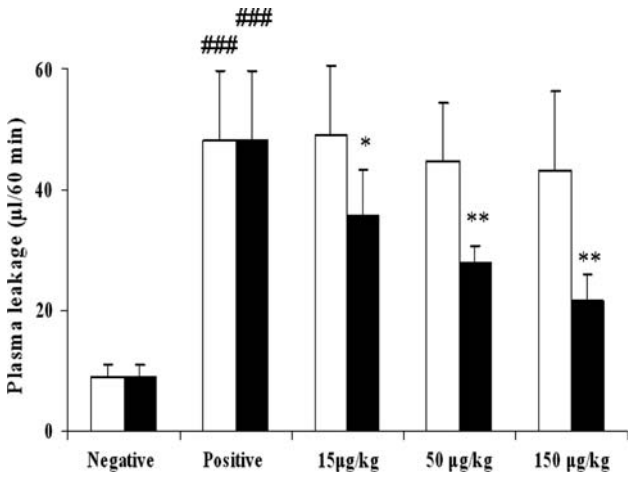

Fig. 11 Effect of DHA-lysoPtdCho or DHA, administered orally, on zymosan A-induced plasma leakage in mice. DHA (*open bars*) or 17-HPDHA-lysoPtdCho (*filled bars*) was administered orally (50 µg/kg) to mice 60 min before i.p. injection of zymosan A (100 mg/kg), and the plasma leakage was determined as described in "Materials and Methods". The *column* and *bar* represent the mean ± SEM of results from each group of >10 mice. $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ versus positive group (zymosan A); $^{\#\#\#}P < 0.001$ versus negative group (PBS)

showed that DHA-lysoPtdCho and its oxygenation products strongly inhibited mammalian 5-LOX activity [26], responsible for the generation of inflammatory lipid mediators such as leukotriene B or cysteinyl-leukotrienes. Very recently, we observed that ARA-lysoPtdCho and its 15-hydroperoxy derivative expressed an anti-inflammatory action in zymosan A-induced peritonitis [40]. Present studies indicate that DHA-lysoPtdCho is more efficient than ARA-lysoPtdCho in LPS-induced production of NO in RAW cells. Moreover, the effective concentrations (5–10 µM) of DHA-lysoPtdCho in inhibiting 5-LOX activity [26] as well as LPS-induced NO production are relatively low. Noteworthy, such an action seems to be peculiar to DHA-lysoPtdCho, since other lysoPtdCho species such as ARA-lysoPtdCho or LNA-lysoPtdCho had no remarkable reduction of NO level. Furthermore, DHA-lysoPtdCho also decreased the level of inflammatory mediators such as TNF-α or IL-6 induced by LPS, supporting the anti-inflammatory action of docosahexaenoyl-lysoPC.

Consistent with its anti-inflammatory action in vitro, DHA-lysoPtdCho, i.v. administered, suppressed zymosan A-induced peritonitis in mice at relatively low doses (15–50 µg/kg). In comparison, DHA-lysoPtdCho, i.v. or i.p. administered, was much more effective than ARA-lysoPtdCho in suppressing zymosan A-induced peritonitis. Even oral administration of DHA-lysoPtdCho exhibited some suppressive effect on zymosan A-induced peritonitis, although it was less efficient than i.v. or i.p. administration. Thus, DHA-lysoPtdCho is supposed to be one of endogenous anti-inflammatory lipids. In support of this, DHA-lysoPtdCho was observed to reduce the levels of TNF-α or IL-6 as well as infiltrated leukocytes in vivo system. In the time course of anti-inflammatory action, a prior administration of DHA-lysoPtdCho seemed to be important for a maximal anti-inflammatory action; the administration of DHA-lysoPtdCho at least 30 min before the zymosan A challenge expressed a remarkable inhibition, but the administration 10 min before the zymosan A challenge did not succeed in showing a noticeable inhibition. From this, it is suggested that the anti-inflammatory action of DHA-lysoPtdCho in the peritoneum may require some delay process. Thus, the appearance of DHA-lysoPtdCho or its metabolites in peritoneal cells, where the mediators responsible for plasma leakage could be generated, may require a transport process. This might be consistent with the previous observation [41] that the appearance of labeled DHA, administered i.v. in peritoneal exudates required approximately a 1-h to 2-h delay for a maximal level. Earlier it had been reported that early vascular permeability, followed by subsequent infiltration of neutrophils into the peritoneum, depended largely on cysteinyl-leukotrienes, derived from 5-lipoxygenation of ARA, released by resident peritoneal macrophages, and to a lesser extent, on mast cell histamine and prostaglandin E_2 of multiple cellular origins [42, 43]. In this respect, the suppressive effect of DHA-lysoPtdCho on zymosan A-induced peritonitis might be partially related to the direct inhibition of 5-LOX [26], an initial enzyme implicated in the biosynthetic pathway of cysteinyl-leukotrienes responsible for vascular permeability [43]. Support for this comes from the finding that the i.v. administration of DHA-lysoPtdCho partially reduced the formation of LTC_4 in peritoneal exudates, reaffirming the notion that one mechanism, responsible for the anti-inflammatory effect of DHA-lysoPtdCho on zymosan A-induced peritonitis, may be related to the reduction of LTC_4 through the inhibition of 5-lipoxygenase. However, a complete inhibition of LTC_4 formation was not achieved using DHA-lysoPtdCho under the conditions used. This led us to the assumption that a process responsible for the change of vascular permeability might be directly affected by DHA-lysoPtdCho or its metabolites. In support of this assumption, the plasma leakage caused by LTC_4 was successfully prevented by DHA-lysoPtdCho administration, confirming that DHA-lysoPtdCho or its metabolites may exert an anti-inflammatory action. Concerned with this, the requirement of the time interval between lysoPC administration and zymosan A challenge may suggest that a metabolism of DHA-lysoPtdCho may be crucial for the maximal expression of anti-inflammatory action at the inflammation site, i.e. the peritoneum. There may be two possible metabolic pathways of DHA-lysoPtdCho; one is the formation of DHA,

and the other, the formation of HPDHA-lysoPtdCho [24]. In the former process, DHA is released from the enzymatic hydrolysis of DHA-lysoPtdCho in vivo. However, this hydrolytic metabolic process may not be directly related to the anti-inflammatory action of DHA-lysoPtdCho in peritoneal cells as suggested from no remarkable effect of DHA administered in this experiment. Rather, HPDHA-lysoPtdCho may more likely be a metabolic intermediate accountable for anti-inflammatory action. In support of this, 17-HPDHA-lysoPtdCho showed greater anti-inflammatory effect than DHA-lysoPtdCho in i.v. administration as well as i.p. injection. The similarity of DHA-lysoPtdCho action between two administration routes may support the idea that the metabolic activation of DHA-lysoPtdCho may occur commonly in vivo. This could be explained by the notion that DHA-lysoPtdCho might be primarily subjected to lipoxygenation by 15-lipoxygenase to generate 17-HPDHA-lysoPtdCho, which could be further utilized for the formation of potent anti-inflammatory mediators such as protectin D type derivative [38]. Alternatively, secondary metabolites such as maresin type derivative [37], derived from 14-HPDHA-lysoPtdCho, may be implicated in the anti-inflammatory action. Taken together, it is likely that the primary metabolites such as 17-HPDHA-lysoPtdCho or 14-HPDHA-lysoPtdCho may be finally converted to bioactive products directly responsible for anti-inflammatory action. This might be well supported by the previous finding [24] that DHA-lysoPtdCho was enzymatically converted to 14-HPDHA-lysoPtdCho derivative or 17-HPDHA-lysoPtdCho derivative. In turn, 14-hydroperoxydocosahexaenoyl derivative and 17-hydroperoxydocosahexaenoyl derivative could be transformed finally to maresin [37] or protectin D [38]. Thus, it is supposed that another mechanism for anti-inflammatory action of DHA-lysoPtdCho may involve a series of metabolic activation pathways. Previous studies showed that in zymosan A-induced peritonitis, protectin D significantly reduced PMN infiltration at very low doses, showing an apparent maximal response approximately in the 50% range [9]. In our present study, meanwhile, an almost complete inhibition of zymosan A peritonitis was achieved with DHA-lysoPtdCho at a dose of 500 μg/kg, indicating that DHA-lysoPtdCho might be more efficient in showing a maximal efficacy. This could be explained by the assumption that DHA-lysoPtdCho might express anti-inflammatory activity through multiple actions, such as suppression of the formation of nitric oxide or TNF-α, inhibition of 5-lipoxygenase activity as well as formation of maresin or protectin D.

Once the *sn*-2 position of phosphatidylcholine is hydrolyzed by PLA_2, unsaturated fatty acids are released, and then metabolized to form bioactive lipid mediators, inflammatory or anti-inflammatory [44]. Meanwhile, the remaining lysoPtdChos with saturated acyl chains or oleoyl group have been found to have cytotoxic effects on various cell systems [14–18]. As a part of the inflammatory actions of lysoPtdChos, lysoPtdChos brought about the superoxide production in neutrophils [17] and nonphagocytic cells [16, 17], and LNA-lysoPtdCho caused oxidative stress in RAW 264.7 cells [18]. In addition, lysoPtdChos elicited the production of pro-inflammatory cytokines in human monocytes and rat aortic smooth muscle cells [45], and played a role as a chemotactic factor for monocytes and T cells [3, 46]. The diverse properties of lysoPtdChos suggest that the functions of this class of lipids are highly dependent on the type of lysoPtdChos. A recent report showed that transcellular secretion of group V phospholipase A_2 from the epithelium induced the synthesis of leukotriene C_4 through the generation of lysoPtdChos in eosinophils [47]. In this regard, it will be of great interest whether or how DHA-lysoPtdCho affects the secretory group V PLA_2-induced formation of LTC_4 in eosinophils.

An apparent advantage with DHA-lysoPtdCho, compared to other types of lysoPtdCho, is that it exhibits anti-inflammatory actions at non-cytotoxic concentrations. Moreover, DHA-lysoPtdCho still exhibits a significant anti-inflammatory action after oral administration. In this respect, it is conceivable that administration of DHA-lysoPtdCho will help ameliorate the pro-inflammatory state, caused by various inflammatory agents including pro-inflammatory lysoPtdChos.

In this respect, DHA-lysoPtdCho therapy is possible if these lipids are introduced through appropriate administration routes in the inflammation progress. For this purpose, the upper limit of DHA-lysoPtdCho dosage, showing anti-inflammatory action selectively, is to be established in further studies.

Abstract Insulin resistance is the central defect in type 2 diabetes and obesity. During the development of insulin resistance a lipid accumulation is accompanied by increased PTP-1B expression in the muscle. The aim of this study was to examine the effects of PTP-1B knockdown on insulin signaling and insulin resistance in the presence or absence of palmitate in C2C12 skeletal muscle cells. A stable C2C12 cell line was established using short hairpin RNA (shRNA) to knockdown protein expression of PTP1B. Analysis of PTP-1B protein expression and phosphorylation and protein levels of IRS-1 and Akt were detected by western blot. The effects of PTP-1B knockdown on the glucose uptake was also measured in C2C12 cells. The stable C2C12 cell line harboring the PTP-1B shRNA showed 62% decrease in the PTP-1B protein levels. 0.5 mM palmitate significantly induced insulin resistance in both control (26%) and PTP-1B knockdown cells (16.5%) compared to the untreated cells. Under treatment with palmitate, insulin stimulated phosphorylation of IRS-1 (Tyr632) and Akt (Ser473) in knockdown cells was significantly 1.55- and 1.86-fold, respectively, greater than the controls. In the presence of palmitate, insulin dependent glucose uptake was significantly about 3-fold higher in PTP-1B knockdown stable C2C12 cells compared to the control cells. Our data showed that decreasing the PTP-1B protein level by shRNA can enhance the activity of important elements of insulin signaling. The improvement in insulin action persisted even in palmitate treated insulin resistant myotubes.

Keywords Protein tyrosine phosphatase-1B · Short hairpin RNA interference · Insulin resistance · Knockdown · Glucose uptake · Palmitate

Abbreviations

BSA	Bovine serum albumin
2-DOG	2-Deoxyglucose
IR	Insulin receptor
IRS-1	Insulin receptor substrate-1
LAR	Leukocyte antigen related phosphatase
PTP-1B	Protein tyrosine phosphatase-1B
ShRNA	Small hairpin RNA

Introduction

Insulin resistance precedes the diagnosis of type 2 diabetes [1]. It appears that the plasma free fatty acid (FFA) levels contribute to impaired insulin signaling leading to reduced

insulin sensitivity and glucose uptake [2, 3] in insulin responsive tissues. Among FFAs, palmitate is the most predominant FFA in the circulation [3]. In vivo and in vitro studies have shown that palmitate causes insulin resistance in insulin target tissues [4–6]. Skeletal muscle is the most important tissue for insulin action [7, 8], where almost 80% of insulin dependent glucose uptake occurs in this tissue. However, the connection between high concentration of plasma FFA and the development of insulin resistance in skeletal muscle is not clearly known. The first theory was glucose-fatty acid cycle, suggested by Randle et al. [9, 10]. Other mechanisms underlying fatty acid-induced insulin resistance have also been proposed. Accordingly, the elevation of plasma FFA inhibits insulin stimulated glucose transport activity, associated with reduced insulin receptor (IR) and insulin receptor substrate-1 (IRS-1) tyrosine phosphorylation [11, 12]. Furthermore, several different phosphatases as inhibitors of insulin action have been suggested to have a role in the development of insulin resistance in the muscle.

PTPases are a large family of enzymes that have a major role in many cellular functions. Enhanced activity of one or more PTPases has been reported in several insulin resistance states, such as obesity and some models of diabetes [13–15]. Specifically, some PTPases such as protein tyrosine phosphatase-1B (PTP-1B), leukocyte antigen related phosphatase (LAR) [16], and SH2-containing protein-tyrosine phosphatase-2 (SHP2) have been implicated in the regulation of normal IR signaling and/or in insulin resistance [17, 18]. Among them, PTP-1B is the main negative regulator of insulin signaling pathway that has received significant attention during the recent years [19, 20]. This enzyme is widely expressed in insulin-sensitive tissues [21]. PTP-1B binds to the IR and efficiently dephosphorylates it in vitro. Early studies have shown that PTP-1B overexpression inhibits phosphorylation of IR and IRS-1 leading to insulin resistance [16, 17, 22–25]. Conversely, deletion of PTP-1B in fat, liver, and muscle tissues increases insulin sensitivity [26–28]. Human and animal studies have also demonstrated that insulin resistance is accompanied by an abnormal increase in PTP-1B activity and protein levels in skeletal muscle [29, 30]. Particularly, animals on a high fat diet showed an enhancement of the expression of PTP-1B in the muscle [31]. However, little is known regarding the role of PTP-1B in palmitate-induced insulin resistance in the muscle. Therefore, in the present study we aimed to investigate the effects of PTP-1B knockdown on the key molecules of insulin signaling in the presence or absence of palmitate in C2C12 skeletal muscle cells. To this end, we assessed glucose uptake and some critical elements of the insulin signaling pathway in PTP-1B knockdown and control C2C12 cells.

Materials and Methods

Plasmid Preparation

shRNA constructs against Mus musculus *Ptpn1* (four *ptpn1*-specific shRNA expression pRS vectors) and one pRS vector (pRS-5) without shRNA cassette sequence (as a negative control) were purchased from OriGene (Rockville, MD, USA). The pRS vectors were transformed into the competent *E. coli* DH5α bacteria. After ampicillin selection, the purified plasmid DNAs (Miniprep Kit, QIAGEN, Hilden, Germany) were tested for identification of the vectors by bidigestion of the clones with *Eco*RI and *Hin*dIII (Fermentas, St. Leon-Rot, Germany) restriction enzymes. Once the requirement was met, the mid-scale preparations of the plasmids were performed.

Cell Culture

C2C12 myoblast (ATCC Number CRL 1772) was purchased from the Pasteur Institute of Iran. Myoblasts were maintained at 37 °C (in an atmosphere of 5% CO_2) in Dulbecco's modified Eagle's Medium (DMEM) (Gibco, Berlin, Germany) containing 10% fetal bovine serum (FBS), 2 mM glutamine, 100 unit/ml penicillin, and 100 μg/ml streptomycin. Differentiation of myoblasts into myotubes was induced when the cells had achieved 70–90% confluence by replacing the media with DMEM containing 2% horse serum, 2 mM glutamine, 100 unit/ml penicillin, and 100 μg/ml streptomycin. Four days after fusion, the differentiated myotubes were used for the experiments.

Myoblast Transient Transfection

C2C12 myoblasts were transiently transfected with shRNA and control plasmids using the calcium phosphate precipitation technique [32] modified by Okayama [33]. In brief, a day prior to transfection, 5×10^5 cells per well were seeded in 0.1% gelatin-coated six-well cluster plates. Six-well plates were transfected with 15 μg of shRNA plasmids (pRS-1–pRS-4), pRS-5 vector without shRNA cassette sequence (negative control) and pEGFP-C1 plasmid (as a control for transfection efficiency).

Stable Transfection

After selecting the pRS-1 (AATTGCACCAGGAAGAT AATGACTATATC) as the best vector silencing the *ptpn1* gene and pRS-5 as negative control, stable transfection was performed. Forty-eight hours after transfection, myoblasts were trypsinized and were divided into a fresh medium containing 4 μg/ml puromycin (Sigma-Aldrich, Munich,

Germany). Cells were divided such that they are no more than 25% confluent, and were nourished with a selective medium every 3–4 days. In the next step, the puromycin-resistant colonies were picked up and expanded in 96-well plates and were nourished with the selection medium for 2 weeks. Stable myoblasts were harvested and assessed for the PTP-1B protein level using western blot. To demonstrate the fact that pRS-1 vector specifically targeted for PTP-1B gene, and does not affect the expression of a similar PTPase, the lysates were also immunoblotted for the expression of leukocyte antigen-related (LAR) gene.

Western Blot Analysis

C2C12 cell lysate was prepared by homogenization in modified RIPA buffer (50 mM Tris–HCl pH 7.4, 1% Triton X-100, 0.2% sodium deoxycholate, 0.2% SDS, 1 mM Na-EDTA, 1 mM PMSF) supplemented with protease inhibitor cocktail (Roche, Mannheim, Germany). For detection of phospho protein, a buffer consisting of 50 mM HEPES pH 7.5, 150 mM NaCl, 100 mM NaF, 10 mM EDTA, 10 mM $Na_4P_2O_7$, 2 mM $NaVO_4$, and protease inhibitor cocktail was used. Protein concentration was determined using Bradford's method [34]. 20–30 μg of total protein was fractionated by SDS-PAGE according to Laemmli method [35]. The gel was transferred onto a PVDF membrane (Millipore, Schwalbach, Germany). The membrane was blocked overnight in blocking buffer (5% skimmed milk in TBST buffer) and then incubated for 1 h with primary antibodies diluted in TBST containing 1% BSA. Primary antibodies used were as follows: PTP-1B, LAR, p-IRS-1 (Tyr632), and IRS-1 (Santa Cruz Biotechnology, Santa Cruz, USA), Akt, and phospho-Akt (Ser473) (Cell Signaling Technology, Beverly, MA, USA), β-actin (Abcam, Cambridge, MA, USA). The membrane was then incubated with secondary antibody conjugated to HRP (Santa Cruz Biotechnology, Santa Cruz, USA) for 1 h and detection was performed using ECL reagents (Amersham Pharmacia Corp, Piscataway, NJ, USA). Films were scanned and protein bands were quantified using Scion Image software. Each experiment was performed at least three times.

Muscle Creatine Kinase (MCK) Assay

MCK activity, which indicates myogenic differentiation over the culture period, was determined using the NADPH-coupled assay following the protocol supplied by the manufacturer (Biomerieux SA, Lyon, France). Briefly, the cells were washed twice with cold calcium–magnesium free PBS, and homogenized in 0.5 ml of cell lysis buffer (1 M NaCl, 1 mM EGTA, 1% Triton X-100, 10 mM Tris–HCl, pH 7.2). The lysate was centrifuged for 10 min at 15,000 rpm and the supernatant was applied to the assay. Creatine kinase levels were normalized to milligram of total protein.

Palmitate Treatment

Palmitate was administered to cells as a conjugate with fatty acid free-BSA. Briefly, sodium palmitate was dissolved in 50% (v/v) ethanol, diluted in DMEM containing 1% (w/v) fatty acid-free BSA to final concentration and was incubated in 37 °C for 2 h while being shaken. Two hours before the experiments, the experiments, myotubes were placed in serum free-DMEM containing 1% BSA and then the cells were incubated in the presence or absence of 0.5 mM palmitate for 16 h.

Glucose Uptake Assay

Glucose uptake was assayed using [^{3}H]2-DOG ([^{3}H]2-deoxyglucose) (Amersham Pharmacia Corp, Piscataway, NJ, USA). Glucose uptake measurements were performed in triplicate and in three independent experiments. In brief, C2C12 cells were seeded on plates. After 4 days of differentiation, myotubes were treated with 0.5 mM palmitate for 16 h followed by a serum starvation of 2–3 h in DMEM plus 0.1% BSA. Myotubes were then treated with or without 100 nM insulin for 30 min and washed two times with wash buffer [20 mM HEPES (pH 7.4), 140 mM NaCl, 5 mM KCl, 2.5 mM $MgSO_4$, and 1 mM $CaCl_2$]. Myotubes were then incubated in the transport buffer (wash buffer containing 0.5 mCi [^{3}H]2-DOG/ml and 10 μM 2-DOG) for 10 min. Cells were lysed in 0.05 M NaOH and [^{3}H]2-DOG levels were counted in the cell lysate using a scintillation counter. Nonspecific uptake was determined by incubating the cells in the presence or absence of 10 μM cytochalasin B.

Statistical Analysis

All statistical analyses were performed using SPSS 13.0. (SPSS, Chicago, IL). Comparisons among all groups were performed with the one-way analysis of variance (ANOVA) test. If statistical significance was found, the Tukey post hoc test was performed. Values of $p < 0.05$ were considered statistically significant.

Results

Confirming Silencing of the PTP-1B in C2C12 Cells

We were able to successfully deliver pRS and pEGFP-C1 plasmids to myoblasts with high efficiency using calcium

phosphate precipitation method. Western blot results showed that the pRS-1 vector caused the highest *ptpn1* gene silencing in transient transfection experiments (Fig. 1). Thus, pRS-1 and pRS-5 vectors (negative control) were selected for stable transfection of C2C12 cells. Our results demonstrated a 62% decrease of PTP-1B protein levels in the C2C12 stable cell line harboring PTP-1B shRNA (Fig. 2a). Figure 2b shows that pRS-1 transfection into C2C12 myoblasts does not affect the expression of LAR suggesting that the pRS-1 vector specifically silence the expression of PTP1B gene.

No Difference in Muscle Creatine Kinase Activity in PTP-1B Knockdown Stable and Control Cell Lines

In order to assess the role of PTP-1B in C2C12 differentiation, muscle creatine kinase (MCK) activity assay was performed. According to our findings, while the MCK activity was undetectable in myoblasts, it was measurable after 24 h of differentiation and gradually increased until 96 h. In the present study, we did not observe any meaningful differences in the activity of MCK in PTP-1B knockdown stable and control C2C12 cells during the differentiation period (Fig. 3).

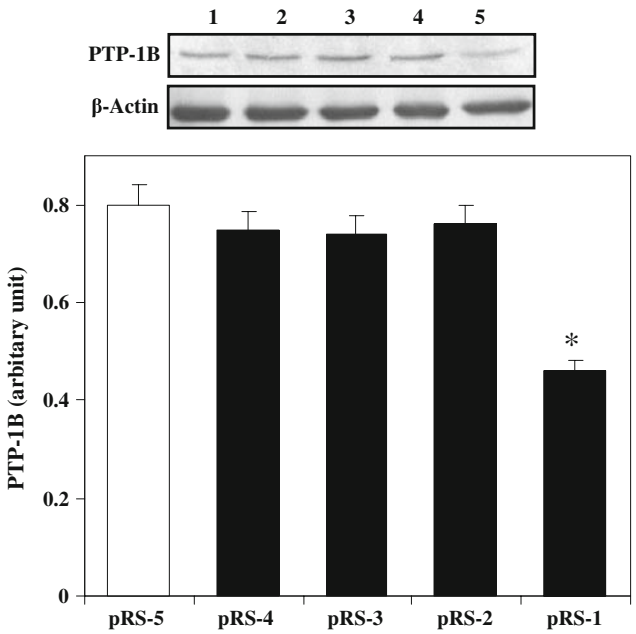

Fig. 1 Knockdown of PTP-1B in C2C12 cells following transient transfection with shRNA expression pRS vectors. C2C12 cells were transfected with 20 μg of pRS-1 to pRS-4 (1–4) and pRS-5 (5) as negative control. Forty-eight hours post-transfection, western blot was performed using antibodies against PTP-1B and β-actin as internal control. Protein level of PTP-1B was normalized to the level of β-actin protein. The figure shows representative data gained from mean ± SD of three independent experiments, $^{*}p < 0.01$

Enhancement of Insulin Signaling by PTP-1B Knockdown in the Presence of Palmitate

The results showed that the insulin-induced phosphorylation of IRS-1 was reduced by palmitate in both control and knockdown cell lines by 22.8% ($p = 0.01$) and 28.3% ($p = 0.008$), respectively. While PTP-1B knockdown stable cells in the basal state had slightly higher IRS-1 (Tyr632) phosphorylation with respect to the control, the presence of insulin caused a greater difference in IRS-1 phosphorylation in PTP-1B knockdown stable cells compared to the controls (1.8-fold, $p = 0.001$) (Fig. 4). 0.5 mM palmitate reduced IRS-1 phosphorylation in both cells, whereas the PTP-1B knockdown cells still had 1.55 fold ($p = 0.01$) higher IRS-1 phosphorylation level than the controls.

We also assessed the effects of palmitate on Akt phosphorylation in both PTP-1B knockdown stable and control cells (Fig. 5). The phosphorylation of Akt in the presence of insulin was decreased by palmitate in both control and knockdown cell lines by 29.2% ($p = 0.009$) and 33.2% ($p = 0.005$), respectively. In the presence of insulin, Akt phosphorylation (Ser473) in PTP-1B knockdown cells was significantly greater than the control cells (2.42-fold, $p < 0.001$). Insulin induced Akt phosphorylation was reduced by palmitate in both cell lines, whereas the knockdown cells still significantly had a higher Akt phosphorylation (1.86-fold, $p = 0.004$) than the control cells. Taken together, these findings suggest that PTP-1B downregulation enhances the activity of key elements of insulin signaling. Increased the activity of insulin signaling pathway remained significant even when palmitate is present in the media. There was no significant difference in the IRS-1 and Akt protein levels of the PTP-1B knockdown stable cells in comparison with the control cells in the presence or absence of palmitate and insulin.

Enhancement of Glucose Uptake in the PTP-1B Knockdown Cells Treated With Palmitate

To determine whether PTP-1B is functional in glucose uptake process,[^{3}H]2-DOG uptake was measured. In the basal condition, PTP-1B knockdown stable and control cells did not show a significant difference in the uptake of glucose (Fig. 6). Insulin stimulation led to a significantly increase in glucose uptake in both cell lines, whereas the PTP-1B knockdown cells showed much higher sensitivity to insulin than the control cells (3.3-fold vs. 1.75-fold, $p = 0.001$). Insulin-stimulated glucose uptake was decreased by palmitate in both control and knockdown cell lines by 26% ($p = 0.01$) and 16.5% ($p = 0.01$), respectively. In the simultaneous presence of insulin and palmitate, PTP-1B knockdown cells remained sensitive to insulin

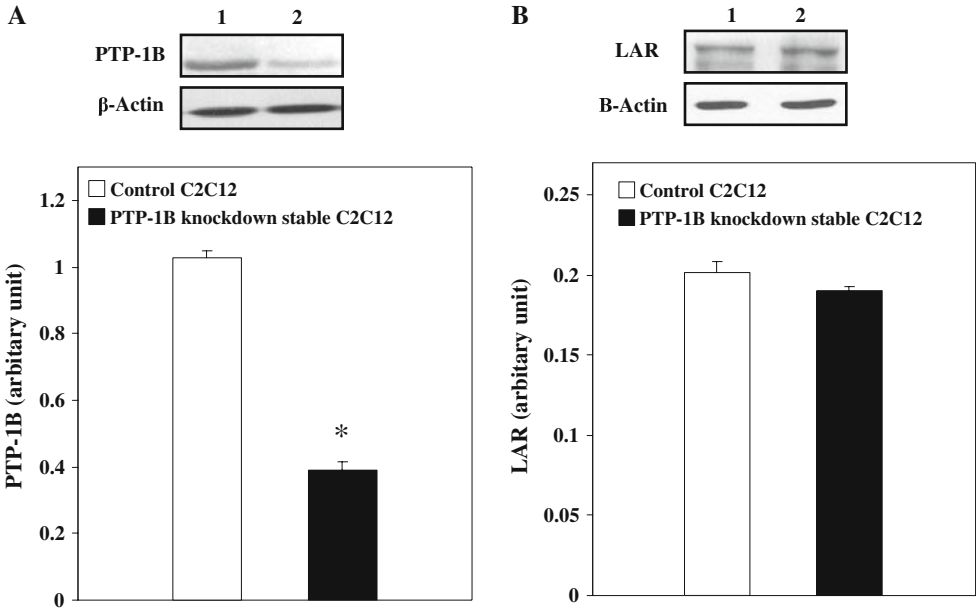

Fig. 2 Knockdown of PTP-1B in C2C12 cells following stable transfection with shRNA expression pRS-1 plasmid. After selection of stable clone. **a** Western blot was performed with antibodies against PTP-1B and β-actin. **b** Western blot was performed with antibodies against LAR and β-actin. Protein levels of PTP-1B and LAR were normalized by protein level of β-actin. The figure shows representative data obtained from mean ± SD of three independent experiments, $^*p < 0.01$. 1 = Control C2C12 cells; 2 = PTP-1B knockdown stable C2C12 cells

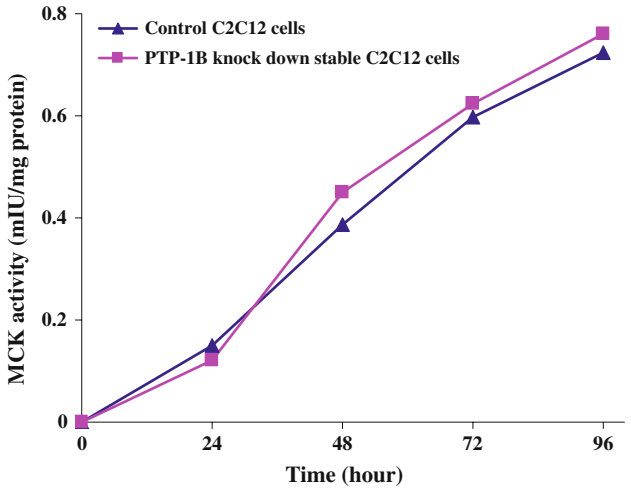

Fig. 3 Muscle creatine kinase (MCK) activity assay for PTP-1B knockdown stable and control C2C12 cells. MCK activity is depicted versus time (h) of differentiation. The figure shows representative data gained from mean ± SD of three independent experiments

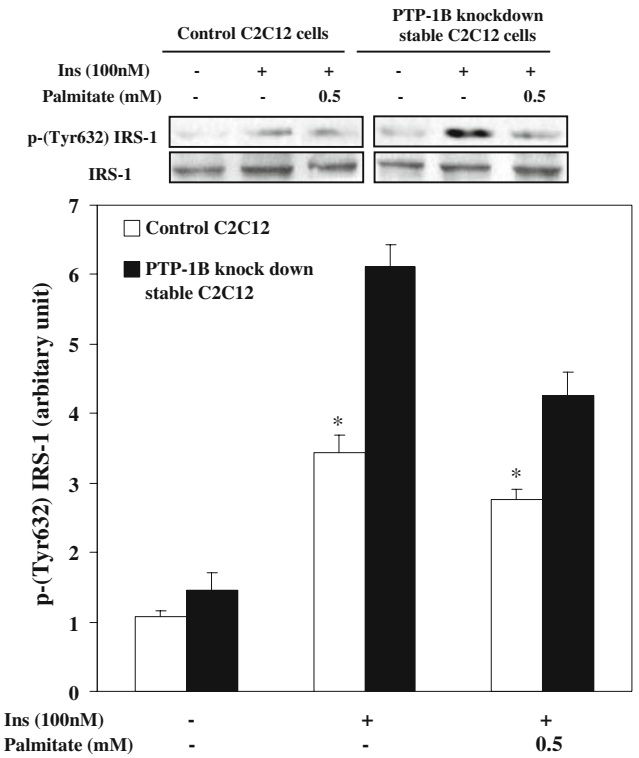

Fig. 4 The effect of palmitate on tyrosine 632 phosphorylation status of IRS-1 in PTP-1B knockdown stable and control C2C12 cells. Palmitate treatment was performed as described in the "Materials and Methods". Before harvesting, the cells were incubated in the presence or absence of 100 nM insulin (INS) for 15 min. Cell lysates were prepared and subjected to western blot using specific antibodies. The figure shows representative data gained from the means ± SD of three independent experiments, $^*p < 0.01$

with about 2.8-fold ($p < 0.001$) increase in glucose uptake in comparison with the control cells. These results indicate that knockdown of PTP-1B improves glucose uptake in C2C12 cells even in the presence of palmitate.

Discussion

Protein Tyrosine Phosphatase-1B is thought to be a negative regulator of insulin signaling through dephosphorylating the activated IR and/or IRSs. Animal with the disrupted PTP-1B gene exhibit enhanced insulin sensitivity [26, 36, 37]. Increased tyrosine phosphorylation of IR in homozygous null mice is detected in muscle and liver but not in adipose tissue [26]. Moreover, the PTP-1B deficient mice show resistance to weight gain on a high fat diet

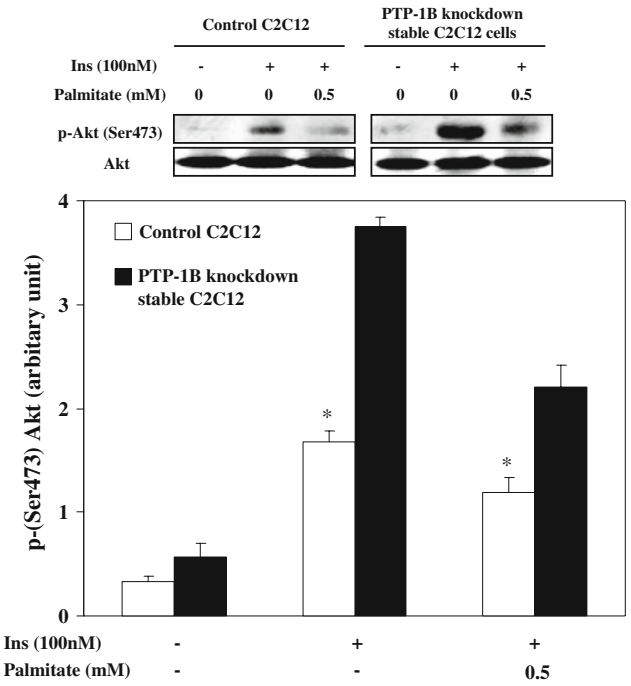

Fig. 5 The effect of palmitate on serine 473 phosphorylation status of Akt in PTP-1B knockdown stable and control C2C12 cells. Palmitate treatment was performed as described in the "Materials and Methods". Before harvesting, the cells were incubated in the presence or absence of 100 nM insulin (INS) for 15 min. Cell lysates were subjected to western blot using specific antibodies. The figure shows representative data gained from means ± SD of three independent experiments, $*p < 0.01$

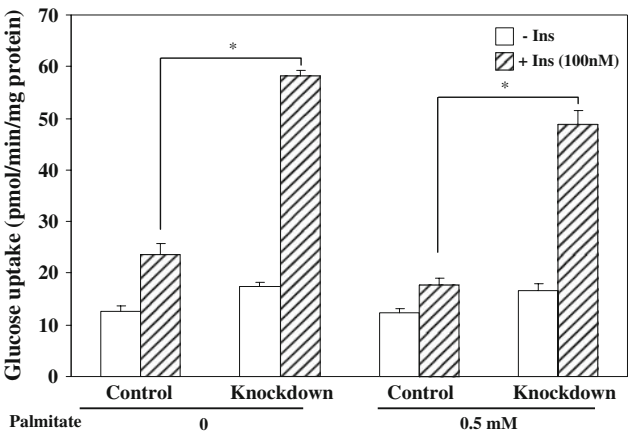

Fig. 6 The effect of 0.5 mM palmitate on glucose uptake in PTP-1B knockdown stable and control C2C12 cells. Myotubes were grown in the absence and presence of 0.5 mM palmitate for 16 h, followed by serum starvation for 2 h in 1% FBS–DMEM. Then, glucose uptake was measured in the presence or absence of insulin (INS) and cytochalasin B, as described in "Materials and Methods". The figure shows representative data gained from mean ± SD of three independent experiments, $*p < 0.01$

[26, 27]. Furthermore, human and animal studies have manifested an abnormal increase in PTP-1B activity and protein levels in skeletal muscle of insulin resistant individuals [29, 30]. Animals on a high fat diet also showed an enhancement in PTP-1B levels in the muscle [31]. Considering the importance of palmitate in inducing insulin resistance and the role of PTP-1B in negatively regulating insulin signaling pathway, we aimed to investigate the effects of PTP1B inhibition on insulin signaling in the presence and absence of palmitate in C2C12 cell line.

Several in vivo studies have been conducted to show the improving effect of PTP-1B deletion on insulin signaling and insulin resistance induced by high fat diet, however, little is known about the direct role of PTP-1B downregulation on the insulin signaling pathway when a fatty acid is present. One recent study by Liu et al. noted that knockdown of PTP-1B in 293HEK cells significantly increased GLUT4 translocation in the presence of palmitate. However, the study findings resulted from a cell line that does not normally exhibit insulin-mediated glucose uptake [38]. The results of our study on a relevant cell line provide more evidence of the effect of PTP1B knockdown on palmitate-induced muscle insulin resistance. In the present study we hypothesized that the knocking down of PTP-1B using shRNA could enhance insulin signaling through benefitting phosphorylation of key signaling molecules, and finally could increase glucose uptake even in the presence of palmitate. In order to be able to study the significance of PTP-1B knockdown on palmitate induced insulin resistance in the muscle, we generated a stable knockdown of PTP-1B gene in C2C12 cells with the protein level 38% of the control C2C12 cell line.

Several PTPases such as PTP-1B and LAR have been implicated in negatively regulating insulin signal transduction [16]. Both LAR and PTP-1B are expressed in insulin-responsive tissues such as muscle, liver, brain and adipose [18, 39–41]. LAR and PTP-1B are both involved as IR and IRS phosphatases [23, 39, 42]. To ensure that silencing was specific for PTP-1B and does not lead to change the expression of LAR, western blot was performed. We did not observe a significant change in LAR protein levels in PTP-1B knockdown stable cells suggesting a specifically downregulation of PTP-1B in our model.

Some studies have shown a role of PTP-1B and other PTPases such as SHP-2 in cellular differentiation in non-muscle tissues [43–45]. To the best of our knowledge, there is no study on the importance of PTP-1B in muscle differentiation. To ensure that PTP-1B knockdown does not interfere with C2C12 differentiation, creatine kinase activity a metabolic marker characteristic of differentiated myotubes was measured. Our data showed no change in MCK activity in PTP-1B knockdown stable cells during the C2C12 differentiation.

To investigate the influence of PTP-1B on the insulin signaling pathway, two key molecules of this pathway were targeted. As expected, insulin stimulated the phosphorylation

of Akt and IRS-1 in the knockdown and control cells. IRS-1 phosphorylation indirectly leads to activation of Akt by activating PI 3-kinase [46]. Phosphorylation of Akt is an important factor in insulin-induced glucose metabolism in the muscle and liver [47]. Our results demonstrating the inhibitory effect of palmitate on insulin signaling molecules are in concordance with the previous studies showing that palmitate induces insulin resistance in skeletal muscle by inhibiting the phosphorlyation of Akt and IRS-1 [4, 48]. Study on downregulating the PTP-1B led to enhanced sensitivity to insulin action even in the insulin resistant myotubes. Several studies have shown that palmitate inhibits insulin-mediated glucose transport mainly in skeletal muscle [49, 50]. Our data showed that PTP-1B knockdown improves glucose uptake in the presence of palmitate. This finding is in the line with the other in vivo studies demonstrating an improvement in the glycemic state in PTP-1B null mice [26, 27].

Conclusion

In the present study we have provided the evidence showing that PTP-1B downregulation may have an insulin sensitizing effect in both the presence and absence of palmitate. Activation of important elements of insulin signaling accompanied by increased glucose uptake in PTP-1B knockdown cells would favor this important enzyme as a therapeutic target for treatment of patients with insulin resistance, dyslipidemia and metabolic syndrome.

Abstract The *trans* fatty acid (TFA) patterns in the fats of ruminant meat and dairy products differ from those found in other (processed) fats. We have evaluated different TFA isomers in human breast milk as an indicator of dietary intake of ruminant and dairy fats of different origins. Breast milk samples were collected 1 month postpartum from 310 mothers participating in the KOALA Birth Cohort Study (The Netherlands). The study participants had different lifestyles and consumed different amounts of dairy products. Fatty acid methyl esters were determined by GC-FID and the data were evaluated by principal component analysis (PCA), ANOVA/Post Hoc test and linear regression analysis. The two major principal components were (1) 18:1 *trans*-isomers and (2) markers of dairy fat including 15:0, 17:0, 11(*trans*)18:1 and 9(*cis*),11(*trans*)18:2 (CLA). Despite similar total TFA values, the 9(*trans*)18:1/11(*trans*)18:1-ratio and the 10(*trans*)18:1/11(*trans*)18:1-ratio were significantly lower in milk from mothers with high dairy fat intake (40–76 g/day: 0.91 ± 0.48, $P < 0.05$) compared to low dairy fat intake (0–10 g/day: 1.59 ± 0.48), and lower with strict organic meat and dairy use (>90% organic: 0.92 ± 0.46, $P < 0.05$) compared to conventional origin of meat and dairy (1.40 ± 0.61). Similar results were obtained for the 10(*trans*)18:1/11(*trans*)18:1-ratio. We conclude that both ratios are indicators of different intake of TFA from ruminant and dairy origin relative to other (including industrial) sources.

Keywords *Trans* fatty acids · Vaccenic acid · Conjugated linoleic acid · Human milk · Partially hydrogenated fats

Abbreviations

TFA	*trans* fatty acids
EFA	Essential fatty acids
PHVO	Partially hydrogenated vegetable oils
LCPUFA	Long-chain polyunsaturated fatty acids
FFQ	Food frequency questionnaire
MDOO	Meat and/or dairy of organic origin
PCA	Principal component analysis
SAT	Saturated fatty acids
MUFA	Monounsaturated fatty acids
CLA	Conjugated linoleic acid isomer

Introduction

Changes in the Western diet have led to increased values of *trans* fatty acids (TFA, mainly 18:1 isomers with a double bond located between positions 4 and 16 but also minor amounts of 16:1, 18:2, and 18:3 isomers) in human milk

[1, 2]. In humans, TFA have been associated with adverse effects on essential fatty acids (EFA) and long-chain polyunsaturated fatty acids (LCPUFA) metabolism [3], oxidative stress [4], infant development [5] as well as low density lipoprotein cholesterol levels [6]. These negative effects of TFA are mainly associated with isomers from partially hydrogenated vegetable oils (PHVO), such as 6/7/8(*trans*)18:1, 9(*trans*)18:1, 10(*trans*)18:1 [7], and only weakly with TFA of natural sources like ruminant fats such as 11(*trans*)18:1 [8]. The industry reacted to these observations by optimizing the processes for fat production and fat hardening, which led to a significant reduction in the TFA content in food [9, 10]. The discussion about adverse effects of TFA led to the labeling of total TFA content in food in the USA, Canada and Denmark. In contrast, the European Food Safety Agency decided against a general labeling of TFA in Europe due to inconsistent epidemiologic data [11].

In the randomized, double-blind, controlled, cross-over design TRANSFACT study, a consumption of 11–12 g/day of TFA (5% of energy intake) of either natural or PHVO source led to a significant reduction in HDL-cholesterol only in women [12]. It is also known that a high TFA diet leads to increased TFA amounts in human milk [10]. We evaluated the TFA composition of human milk samples from 310 women participating in the Dutch KOALA study, a prospective birth cohort study, which analyses the effect of diet and life-style (i.e. consumption of organic vs. conventional food) on the occurrence of atopic diseases in children [13]. We were able to show that the 11(*trans*)18:1 (vaccenic acid) and its metabolite 9(*cis*),11(*trans*)18:2 (a conjugated linoleic acid isomer, CLA) significantly increased in human breast milk following a diet of >90% meat and/or dairy products of organic origin, even after correcting for the amount of daily ruminant fat intake, suggesting that organic food provides lower TFA and higher CLA intakes [14].

At the moment, it is not possible to quantitatively estimate the TFA intake of natural and industrial sources (e.g. PHVO) from analytical data. Additionally, comparable data on the TFA isomer distributions in various food matrices are not available. In this study, we have searched for the full spectrum of TFA present in the human mother milk and evaluated whether certain TFA patterns can be used as indicator(s) for the mother's intake of TFA from ruminant products and other sources.

Experimental Procedures

Subjects and Collection of Breast Milk

Breast milk samples were donated by breastfeeding participants of the KOALA study, a prospective birth cohort study described elsewhere [15]. Briefly, we recruited pregnant women with varying lifestyles (conventional and alternative). Pregnant women with a conventional lifestyle ($n = 2{,}343$) were recruited from an ongoing prospective cohort study on pregnancy-related pelvic girdle pain in the Netherlands. During the same recruitment period (December 2002–August 2003) pregnant women with an alternative lifestyle, which often includes the use of organic food, were recruited through several channels, such as organic food shops, anthroposophic doctors and midwives, Rudolf Steiner schools, and relevant magazines. A total of 312 mothers agreed to donate milk samples which were collected 1 month post partum (146 from the conventional and 166 from the alternative lifestyle group without further preselection criteria [16], both groups were recruited from December 2002 to August 2003). The study was approved by the Medical Ethical Committee of Maastricht University/Academic Hospital Maastricht, Maastricht, The Netherlands.

Breast Milk Sampling and Fatty Acids Analysis

Collection and processing of the breast milk samples occurred on the same day. Fractions used for fatty acids analysis were preserved by mixing approximately 2 ml of milk with 2 µl methanol containing 500 mg butylated hydroxytoluene (BHT) per liter. The samples were stored at −80 °C in plastic storage vials (Sarstedt, Nümbrecht, Germany) at the European Biobank in Maastricht (the Netherlands), until analysis. Analyses of the fatty acids composition were completed in milk samples from 310 of 312 subjects. Lipids were extracted from the milk samples with chloroform/methanol (2/1, v/v + 0.001% BHT) in duplicate and fatty acid methyl esters were prepared for GC-FID analysis (Agilent 6890, Agilent, Waldbronn, Germany) on a 100 m × 0.25 mm 0.2 µm CP Sil 88 column (Varian, Darmstadt, Germany). The derivatisation procedure included a saponification step with 0.5 M potassium hydroxide solution in methanol with subsequent acidic esterification with 1 M sulphuric acid in methanol. Standard components for identification and calculation of response factors were obtained as fatty acid methyl esters from Sigma (Munich, Germany). TFA were identified on the basis of the elution order given in [17]. In total, 36 fatty acids were used in the final data analysis. The chosen methodology gives a reasonable separation of the major 18:1-TFA. Co-elutions are indicated in the tables (e.g. co-eluting 6(*trans*), 7(*trans*)- and 8(*trans*)18:1 are labelled as 6/7/8(*trans*)18:1. 16:1 *trans* and *cis* isomers were less well resolved (also due to chromatographically interfering 17:0 isomers) and are presented as total (*trans*)16:1 and total (*cis*)16:1 the elution order of other fatty acids methyl esters was confirmed by their retention times and positive

electron impact ionization GC–MS (Trace GC coupled to a PolarisQ ion trap mass spectrometer, both Thermo Electron, Dreieich, Germany) as described elsewhere [18].

Food Frequency Questionnaire

The food frequency questionnaire (FFQ) was included in a self-administered questionnaire in week 34 of pregnancy. The questionnaire was based on an existing validated FFQ [19], which was extended and modified to meet the specific aims of this study, including products frequently used by people with alternative life styles. The FFQ consisted of approximately 160 food items, for which the frequency of consumption in the last month and portion size were to be estimated by the participants. In addition, the participants were asked to approximate the amounts of consumed food of conventional, organic and biodynamic origin, representing three different types of food production. Biodynamic food is a special type of organic food which is produced according to anthroposophic guidelines. Based on the consumption of organic food, subjects were classified into three groups. The conventional group ($n = 185$) consisted of persons who claimed to consume less than 50% "meat and dairy products of organic origin" (MDOO), whereas people in the other two groups consumed substantial amounts of organic products: Thirty-three persons used 50–90% MDOO and 37 used >90% MDOO; 55 women reported other combinations of meat and dairy products from different categories of organic origin (e.g. conventional dairy and >90% organic meat) [14]. The study participants were also grouped according to the amount of the daily intake of dairy fat, as calculated from the FFQ: 55 women consumed 0–10 g/day, 106 10–20 g/day, 117 20–40 g/day and finally 32 women consumed 40–76 g/day of dairy products. The characteristics of the study participants in these groups have been described in detail elsewhere [14, 16]. The fat intake in these groups was calculated using the data from the FFQ and the Dutch Food Composition Table [20].

Statistical Methods

Duplicate values of fatty acids (expressed as weight percentage (wt%) of total fatty acids in breast milk fat) were averaged for each subject, and the resulting mean values were used for further calculations. Principal component analysis (PCA) was performed to evaluate correlations between groups of fatty acids using breast milk levels. In the PCA a varimax rotation was used in order to maximize the intersubject variance, and the limit of the eigenvalue for meaningful components was set at 1.5. In a first PCA, all measured fatty acids were included, and in a second PCA only compounds known to be enriched in dairy fat and PHVO: 18:1 and 18:2 isomers, and 15:0, 17:0 and 18:0 as markers for ruminant fat intake [7, 14, 21–23]. Both PCAs yielded 2 first components with similar factor loadings and therefore we only present the second PCA. For comparisons between groups, mean wt% of breast milk fatty acid levels and TFA markers were computed for groups of subjects classified by dairy fat intake, and by MDOO intake, using the Tukey–Kramer test for multiple comparisons between groups of unequal size. Linear regression analysis was used to test whether TFA concentrations increased or decreased over the categories of dairy fat intake (categories 0–10, 10–20, 20–40 and 40–76 g/day, respectively) and of MDOO intake (conventional, 50–90% MDOO and >90% MDOO, respectively). All statistical analyses were done in SPSS 12.0 for Windows [24].

Results and Discussion

Our results show that the total TFA content of mothers' milk in the compared groups ranged between 3 and 3.3% of total fatty acids (Table 1), which is lower than the values previously measured in the human milk of German mothers in 1992 (4.4% [25]) and in 1999 (3.8% [26]). The total TFA content in milk from American and Canadian woman has declined since obligatory TFA labeling was introduced in these countries and recent studies [10, 27] revealed a total TFA amount of 7.0% in the United States of America and 4.6% in Canada. Since no significant differences in the total TFA content between groups of organic intake and dairy fat intake could be observed in the present study, we have concluded that the total TFA content is not suitable as a "quality" descriptor for human milk.

Alternatively, the data on the fatty acids composition of the various samples were evaluated by PCA, to detect groups (components) of fatty acids with high correlations within each component and low (or negative) correlations between the components (Table 2). Three components were found, that together explain 61% of the variance of fatty acids included in this analysis. Component 1 represents 18:1 *trans*-isomers with double bonds between positions 6 and 14, with highest factor loadings (>0.80) for 6/7/8(*trans*), 9(*trans*), 10(*trans*), 12(*trans*) and 13/14(*trans*)18:1. Component 2 shows the highest factor loadings for 15:0, 16:0, 17:0, 9(*cis*),11(*trans*)CLA (rumenic acid) and 11(*trans*)18:1. Whereas there is a considerable clustering of TFA known to be typical for PHVO in component 1, component 2 comprises fatty acids typically found in ruminant fats (C15:0 and C17:0) as well as 11(*trans*)18:1 and rumenic acid. This interpretation of the PCA loadings table is further corroborated by the component plot in Fig. 1. PHVO fatty acids form one distinct cluster whereas fatty acid associated with dairy fat such as

Table 1 Most abundant TFA in breast milk (as wt% of total milk fat) by daily dairy fat intake and origin of meat and dairy

[a,b] Groups sharing the same letter for the respective fatty acids are significantly different (Tukey–Kramer test for multiple comparisons between groups of unequal size, $P < 0.05$). Only fatty acids present in amounts higher than 0.04% of total milk fat are shown. Data are shown as average ± SD. Total TFA include: (*trans*)16:1, 6/7/8(*trans*)18:1, 9(*trans*)18:1, 10(*trans*)18:1, 11(*trans*)18:1, 12(*trans*)18:1, 13/14(*trans*)18:1 and (*trans,trans*)18:2

[c] May include 6/7/8(*cis*)18:1

Table 2 Principal component analysis of marker fatty acids in human milk ($n = 310$)

	Component

[a] May include 6/7/8(*cis*)18:1

[b] May include 15(*trans*)18:1 and 10(*cis*)18:1

11(*trans*)18:1, C15:0 and rumenic acid form a second cluster. Possible markers for TFA from PHVO would be therefore 6/7/8(*trans*)-, 9(*trans*)-, 10(*trans*)- and 13/14(*trans*)18:1 (or the sum of them). The fact that 11(*trans*)18:1 is associated with component 1 as well as with component 2 probably reflects its presence in both natural fat of ruminant origin and in PHVO [28, 29]. Component 3 includes *cis* and *trans* 16:1 fatty acids, as well as 9(*cis*)18:1 (oleic acid) and 11(*cis*)18:1, which are mainly of dietary origin, but can also be synthesized by the stearoyl-desaturase from 16:0 and 18:0. Note that 11*(cis)*18:1 fatty acids can as well derive from the elongation of 7*(cis)*16:1 by means of fatty acid elongation. The PCA suggests that the major variation between the study participants was caused by differences in the intake of ruminant fats and probably other (including industrial) sources of TFA. Therefore, we analyzed our data depending on the intake of MDOO and dairy fat. Unfortunately, it was not possible to assess the intake of PHVO with our FFQ mainly because of the lack of available data on the TFA isomer composition of different food.

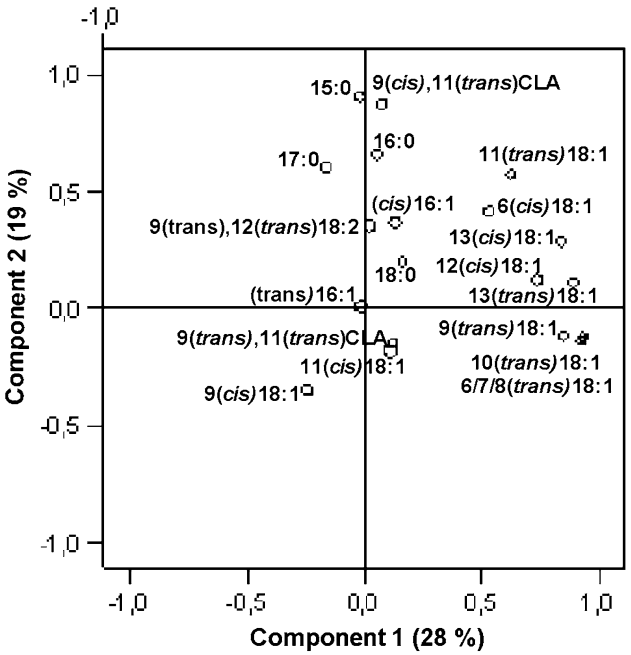

Fig. 1 PCA component plot for marker fatty acids in human milk ($n = 310$)

The amounts of 6/7/8(*trans*)18:1, 9(*trans*)18:1 and 10(*trans*)18:1 in human milk decrease with the dairy fat intake calculated from the FFQ. The amounts of these PHVO-characteristic TFA are the highest in the group with the lowest dairy intake of 0–10 g/day and decrease with increasing amounts of dairy fat intake. The opposite is true for fatty acids known to be present in relatively high amounts in dairy products such as 11(*trans*)18:1 and 9(*cis*),11(*trans*)CLA (Table 1). When the levels of the various TFA-isomers were compared between groups of different MDOO intake, a similar pattern emerged, as can also be seen in Table 1. The PHVO-characteristic 9(*trans*)18:1 and 10(*trans*)18:1 are highest in the conventional group and are significantly lower in the group of >90% MDOO. By contrast, the levels of the dairy products characteristic TFA—11(*trans*)18:1 and 9(*cis*),11(*trans*)CLA—increased with the amount of consumed MDOO. Interestingly, no significant differences of total TFA have been observed among groups of increasing intake of MDOO or among the groups with increasing dairy intake (Table 1), although the isomer distribution differed significantly. Not only were several single TFA considered possible markers either for dairy- or for PHVO-intake, also two ratios between these fatty acids were considered in our work: 10(*trans*)18:1/11(*trans*)18:1 and 9(*trans*)18:1/11(*trans*)18:1 (Table 1). The 9(*trans*)18:1/11(*trans*)18:1 ratio shows a significantly lower value in the groups with either higher dairy fat or higher MDOO intake (Table 1). The same ratios were calculated for the subjects groups consuming different amounts of MDOO: 9(*trans*)

18:1/11(*trans*)18:1 ratio was significantly lower in the group with 50-90% MDOO (0.96 ± 0.40, $P < 0.05$) and >90% MDOO (0.92 ± 0.46, $P < 0.05$) compared to the conventional group (1.40 ± 0.61). Comparable trends were observed for the ratios including 10(*trans*)18:1, which seems to be the most abundant isomer in PHVO in the US [27], relative to 11(*trans*)18:1 (Table 1). These ratios were calculated alternatively for further comparisons.

The observed changes in the TFA patterns and the calculated TFA ratios suggest major differences between TFA intakes of food with different TFA isomer compositions, e.g. TFA from ruminant/dairy fat versus TFA from industrial sources. A previous biomarker study has shown that 6/7/8/9(*trans*)18:1 and 10(*trans*)18:1, but not 11(*trans*)18:1, from PHVO were increased in plasma phospholipids of high margarine consumers compared to groups with high butter intake [7]. Our results from the PCA corroborate that these fatty acids are suitable indicators for TFA intake from PHVO. In order to find a single descriptor of TFA intake, the 9(*trans*)18:1/11(*trans*)18:1-ratio was evaluated as a alternative descriptor for TFA composition in human milk samples in comparison to the total TFA value. This value was significantly lower in both groups with organic meat and dairy intake. Previous work revealed that 11(*trans*)18:1 was the predominant 18:1 isomer in human milk from German women (with a 9(*trans*)18:1/11(*trans*)18:1-ratio of 0.54 and a 10(*trans*)18:1/11(*trans*)18:1-ratio of 0.47) [26]. By contrast, the main isomer in the milk of American mothers was 10(*trans*)18:1, with a 10(*trans*)18:1/11(*trans*)18:1-ratio of 1.36. [27]. The 9(*trans*)18:1/11(*trans*)18:1-ratio was calculated from Mosley's data to be 0.59, revealing the differences in TFA isomer distribution in milk samples from the US and from Europe. Note that the corresponding values in our conventional- and low dairy intake-group were 0.84 (9(*trans*)18:1/11(*trans*)18:1-ratio) and 1.01 (10(*trans*)18:1/11(*trans*)18:1-ratio), respectively. This suggests that milk from American women not only contained higher amounts of total TFA but also that these TFA are derived to a great extent from industrial sources. To estimate the amount of dairy intake, the amounts of other markers of ruminant fat such as 15:0, 17:0 and 9(*cis*), 11(*trans*)CLA could in principle be used as well, but they are only partially correlated to total TFA. The 9(*cis*),11(*trans*)CLA would have the disadvantages of showing seasonal variation [21] and being a metabolite of 11(*trans*)18:1 [30].

We can conclude from our data that a diet rich in dairy products and/or MDOO is strongly associated with a lower 9(*trans*)18:1/11(*trans*)18:1-ratio in human milk, whereas a diet low in dairy products and/or MDOO (and probably higher in TFA of PHVO origin) leads to a high ratio. This isomer ratio is therefore worthy of being taken into account when studying the health-related impact of TFA levels in food [31, 32]. Since it allows the qualitative discrimination between TFA from natural (ruminant) and industrial (partially hydrogenated) origin, it can be used as a tool to relate these two types of product-groups in the diet of the mothers to different health-outcomes in their children.

Received: 6 July 2009 / Accepted: 19 January 2010 / Published online: 21 February 2010

Abstract Two tunicates, *Eudistoma* sp. and *Leptoclinides uniorbis*, collected from the tropical waters off Djibouti were investigated for lipids and phospholipid (PL) fatty acids. PL accounted for 38.2% of the total lipids in *Eudistoma* sp. and for 30.2% in *L. uniorbis.* PL classes were quantified by normal-phase high-performance liquid chromatography using an evaporative light-scattering detector and revealed essential differences. *Eudistoma* sp. contained mainly phosphatidylcholine (PC, 70.3% of total PL) and lysophosphatidylcholine (LPC, 11.9%) and was devoid of phosphatidylserine (PS), whereas the major PL of *L. uniorbis* was PS (59.1%) followed by PC (22.5%) and LPC (8.8%). Gas chromatography–mass spectrometry analyses of fatty acid (FA) derivatives revealed 38 FA in *Eudistoma* sp., and 35 FA in *L. uniorbis*, ranged from C_{12} to C_{24} chain lengths. Polyunsaturated FA accounted for 25.9% in *Eudistoma* sp. and for 32.3% in *L. uniorbis*. Interestingly, *L. uniorbis* contained a high percentage (16.7%) of the 20:5n-3 acid (8.9% in *Eudistoma* sp.) and the 18:4n-3 acid (4.1%). Significant levels of the 20:4n-6 acid were observed in both organisms (7.8 and 6.0% respectively). *Eudistoma* sp. contained the rare 20:3n-7 acid (2.3%) only recorded to date in hydrothermal vent animals. The cyclopropane dihydrosterculic acid was identified in both tunicates (0.7 and 0.5% respectively). These latter FA, together with some unusual branched saturated and monounsaturated FA, revealed the occurrence of associated bacteria in the tunicates. Another noticeable feature was a series of eight C_{16} to C_{18} aldehyde dimethylacetals revealing the presence of plasmalogens at 5.0% in *Eudistoma* sp. and 14.2% in *L. uniorbis*. The results of this study were compared with those previously published for other tunicates regarding mainly PL content and FA composition.

Introduction

Tunicates are marine invertebrates present in almost every marine community and particularly abundant in coastal regions [1–4]. Tunicates and Ascidians (class Ascidiacea) are now well-known to be rich sources of unique and biologically active metabolites including lipids and lipophilic compounds [5, 6], in particular those from the *Eudistoma* genus (family Polycitoridae) [7, 8], and those from the apparently less documented genus *Leptoclinides* (family Didemnidae) [9, 10]. New amino acid derivatives have been isolated from a polar cytotoxic extract (P-388 cells) of the ascidian *Leptoclinides dubius* [11]. A series of halogenated pyridoacridine alkaloids was isolated from ascidians including a *Leptoclinides* species [12].

In spite of this interesting ascidian chemistry, only a few studies have been directed towards the ascidian lipids and fatty acids (FA). Seasonal changes in the FA composition of the ascidian *Halocynthia roretzi* were reported a long time ago [13]. Other pioneering studies described the phospholipid (PL) FA composition of several ascidian and pelagic tunicate species [14, 15]. A new phytosphingosine type cerebroside and two new carotenoids were isolated from Mediterranean tunicates [16]. New glucosphingolipids were obtained and characterized from the Ascidian *Phallusia fumigata* [17]. Lipid and FA compositions of the pelagic tunicate *Doioloetta gegenbauri* were determined [18]. The lipophilic extract of a tunicate from the Indian Ocean, *Aplidium savignyi*, contained unusual antioxidant isoprenoid hydroquinones [19]. The FA composition of polar lipids from benthic ascidians was reported [20, 21]. The FA composition of the tunicate *Botryllus schlosseri* was compared with those of two associated bacterial strains [22]. High levels of EPA (up to 25% of total FA mixture) and DHA (up to 20%) were reported from total lipids, neutral lipids and polar lipids of the edible tunicate *H. roretzi* [23]. Seasonal changes in thermotropic behavior of particular PL classes, and their fatty acyl chain compositions, were studied in different organs of the ascidian *Halocynthia aurantium* revealing high levels of 20:5n-3 (EPA) and 22:6n-3 (DHA) in almost all samples [24]. New lipids from a *Cystodytes* tunicate were recorded including sphingosines as phospholipase PLA2 inhibitors and inactive ceramides [25]. Interestingly, high levels of DHA were observed in glycolipids (up to 12% of the FA mixture) and especially in PL (38.2%) from the pelagic colonial tunicate *Pyrosoma atlanticum* [26]. Ether-linked glycerophospholipids in muscle and viscera, a major PL subclass of *H. roretzi*, were investigated [27]. Interestingly, the *sn*-2 glycerol positions of these ether lipids contained high levels polyunsaturated FA (PUFA) including EPA and DHA as major components. Several new glycosphingolipids were isolated from the marine ascidian *Microcosmus sulcatus* [28, 29]. Several fractions of a dichloromethane extract obtained from an *Eudistoma* ascidian displayed a cytotoxic activity attributed to heterocyclic aromatic amines [30]. Unprecedented serinolipids were identified from the tunicate *Didemnum* sp. [31]. Recently, some known lipid molecules have been identified in the methanolic extract of the ascidian *Didemnum psammatodes* including sterols, FA, methyl esters and glyceryl ethers [32]. The mixture of three methyl esters from the latter organism showed antiproliferative and cytotoxic effects against human leukemia cell lines. Lipids of Antarctic zooplankton including tunicates were investigated [33]. The lipid contents of the pelagic tunicate *Oikopleura vanhoeffeni* were reported showing PL as the major lipid class [34].

As part of our ongoing studies of lipids from marine invertebrates, tunicates [21], sponges [35–39], and gorgonians [40], we investigated two tropical ascidian species for lipids and PL FA. This work aims at extending knowledge on ascidian lipids and PL FA in comparison with data published for other species living at different places.

Materials and Methods

Animals

Both tunicates studied are classified as Tunicates, Ascidians, order Aplousobranchia. *Eudistoma* sp. belongs to the Polycitoridae family, while *Leptoclinides uniorbis* to the Didemnidae family. Specimens were collected during a scuba diving campaign in October 1998 (Ardoukoba scientific expedition) in the Ghoubbet Bay (Ghoubbet al-Kharab, Djibouti) at approximately 10–20 m depth.

Animals were then kept in sea water and frozen (−20 °C). They were stored at this temperature since the harvesting site up to the laboratory with the technical support of the French army. Voucher specimens were deposited at the Muséum National d'Histoire Naturelle, Paris, France (*L. uniorbis* Monniot C. & F., 1996, registration number n° A2 LEP 111—*Eudistoma* sp., number of collected specimen: D33).

Extraction, Isolation and Analysis of PL

The tunicates were extracted with CH_2Cl_2/CH_3OH (1/1, v/v) at room temperature for 2–3 days in closed bottles. The combined extracts yielded the crude total lipids. PL were separated from other lipids by column chromatography on silica gel (70–230 mesh) using dichloromethane (neutral lipids), acetone (glycolipids) and methanol (PL) as successive eluents. The general methods used for isolation and analysis of lipid mixtures have been described previously [35, 38–40].

Standards of PL [phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylglycerol (PG), phosphatidylinositol (PI), lysophosphatidylcholine (LPC), sphingomyelin (SPH)] were purchased from Sigma-Aldrich Co. (Saint-Quentin Fallavier, France). PL separations were performed on a modular UltiMate® 3000 RS HPLC System (Dionex, France) coupled to an evaporative light scattering detector Sedex 85 (Sedere S.A., Alfortville, France). Chromeleon® Chromatography Management Software (Dionex) was used for system control and data processing.

Chromatographic analysis of PL was carried out according to the method of Stolyhwo et al. [41]. The nebulizer gas pressure (dried and filtered air) was maintained at 3.5 bar and the drift tube temperature was set at 50 °C. The analytical column (150 mm × 4.6 mm, i.d. 3 µm) was packed with a silica normal-phase Previal (Alltech Associates Inc., Lokeren, Belgium). A precolumn with the same packing and internal diameter was used.

The chromatographic separation was carried out using a binary gradient according to the following scheme: t_0 min: 0% B, t_3 min: 20% B, t_{12} min: 100% B, and finally isocratic conditions (100% B) for 3 min. Eluent A consisted of chloroform and eluent B of methanol/28% ammonia in water/chloroform (92:7:1, v/v/v). The mobile phase was brought back to the initial conditions and the column was allowed to equilibrate until the next injection. The total chromatographic run time was 20 min per sample. The flow rate was maintained at 1.5 mL/min. Samples were dissolved in chloroform (2 mg/mL) and the injection volume was 10 µL per sample. The samples and the column were thermostatized at 10 and 25 °C, respectively. The lipids extracted were injected three times.

The PL identification was carried out by comparison with the retention time of pure standards. To obtain a quantitative evaluation of the PL, calibration curves were determined from the area values obtained by injecting 10 µL of chloroform serial diluted solutions of PE, PC, SPH, LPC (1–10 µg) and PI, PS (0.5–5 µg). Calibration curves were calculated by applying the equations of the power model to the area and concentration values. The sum of the PL concentrations was regarded as total PL concentration. PL species were expressed as % of the total PL.

Preparation and GC–MS Analyses of FA Methyl Esters and *N*-Acyl Pyrrolidides

The PL fatty acids were converted to methyl esters by the reaction (30 min under reflux) with methanolic hydrogen chloride. *N*-Acyl pyrrolidides (NAP) were prepared by direct treatment of methyl esters with pyrrolidine/acetic acid (10/1, v/v) under reflux (2 h) [42].

Fatty acid methyl esters (FAME) and NAP were analyzed using a Agilent model 689 series II gas chromatograph linked to an Agilent 5973 series network mass selective detector (e.i. at 70 eV) equipped with an Agilent model 5973N selective quadrupole mass detector. Separation was achieved with a CP-Sil 5 CB low bleed MS capillary column (60 m × 0.25 mm i.d., 0.25 µm phase thickness; Chrompack, Middelburg, The Netherlands). The temperatures of injector and interface were maintained at 250 °C and helium was used as the carrier gas under a constant flow rate (1 mL/min). For FAME and NAP analyses, the oven temperature was programmed from 200 to 340 °C at a rate of 8 °C/min. The temperature was maintained for 15 min then allowed to drop immediately to 285 °C.

Mass spectral data for the rare icosatrienoic acid pyrrolidide are presented below.

7,10,13-icosatrienoic acid pyrrolidide. MS *m/z* (rel. intensity): 359 (M^+, 29.4), 344 (1.6), 330 (2.4), 316 (2.4), 302 (3.2), 288 (4.5), 274 (7.1), 260 (4.8), 248 (6.3), 234 (5.6), 220 (4.8), 208 (15.9), 194 (5.6), 180 (8.8), 168 (15.9), 154 (8.7), 140 (10.3), 126 (85.7), 113 (100), 98 (42.9), 85 (26.3) 72 (59.4), 70 (61.1), 55 (48.4).

Results

Lipid Content and Lipid Class Composition

The tunicates *Eudistoma* sp. and *L. uniorbis* were composed of respectively 0.86 and 0.82% of lipids (related to dry matter). Neutral lipids (40.20%) and PL (38.17%) were predominant lipid classes for *Eudistoma* sp., while *L. uniorbis* possessed almost similar proportions of neutral lipids, glycolipids and PL (35.78, 33.97 and 30.25%, respectively) (Fig. 1).

Furthermore, the separation and quantification of PL classes were carried out by high-performance liquid chromatography using an evaporative light-scattering detector [41, 43], and showed that the main PL class in *Eudistoma*

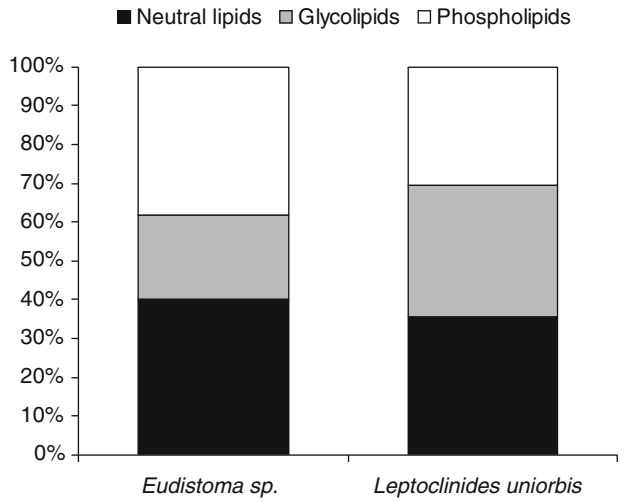

Fig. 1 Lipid class composition of *Eudistoma* sp. and *Leptoclinides uniorbis*

Table 1 Phospholipid class composition of *Eudistoma* sp. and *Leptoclinides uniorbis*

Phospholipid class	*Eudistoma* sp.	*L. uniorbis*
Phosphatidylglycerol	9.4 ± 3.1	4.0 ± 0.9
Cardiolipin	7.8 ± 1.9	3.0 ± 0.8
Phosphatidylinositol	–	2.6 ± 0.2
Phosphatidylserine	–	59.1 ± 2.2
Phosphatidylethanolamine	0.6 ± 0.0	–
Phosphatidylcholine	70.3 ± 3.9	22.5 ± 1.9
Lysophosphatidylcholine	11.9 ± 2.8	8.8 ± 1.0

Traces (<0.5%) of sphingomeylin were observed in *L. uniorbis*

Values expressed as mean ($n = 3$) ± standard deviation

sp. was PC at 70.3%, whereas it was PS at 59.1% in *L. uniorbis*. All PL components are shown in Table 1.

Eudistoma sp. was devoid of PS and contained 11.9% of LPC, and relatively noticeable amounts of PG and cardiolipin (CL). *L. uniorbis* contained 22.5% of PC and lower amounts of LPC (8.8%), PG, CL and PI. *Eudistoma* sp. contained only 0.6% of PE, and *L. uniorbis* contained trace amounts of SPH.

PL Fatty Acid Composition

Thirty-eight FA in PL of *Eudistoma* sp., and 35 FA in PL of *L. uniorbis*, were identified by gas chromatography–mass spectrometry (GC–MS) analyses as methyl esters (FAME) and NAP derivatives. Most of the FA listed in Table 2 were identified as FAME by comparing their equivalent chain length (ECL) values with those previously described or using commercial mixture.

For many compounds, GC–MS data of the NAP derivatives allowed to confirm their structures and to determine the double bond and branching positions [42].

Saturated FA

The PL of *Eudistoma* sp. contained 42.9% of saturated fatty acids (SFA) whereas those of *L. uniorbis* contained only 29.2% of SFA. The SFA were ranged from C_{14} to C_{22} for both organisms. Major SFA were palmitic (15.9%), stearic (8.2%) and myristic (6.5%) acids for *Eudistoma* sp., and myristic (8.2%), palmitic (4.9%) and stearic (3.7%) acids for *L. uniorbis*. A C_{20} isoprenoid FA, phytanic acid, occurred at 2.1% in *Eudistoma* sp. and at 0.8% in *L. uniorbis*.

Monounsaturated FA

Monounsaturated FA (MUFA) of PL from *Eudistoma* sp. represented 31.2% of the total FA identified, with the predominant part consisting of palmitoleic (9.7%), oleic (9.4%) and vaccenic (6.4%) acids. MUFA accounted for 38.5% of the total FA in PL of *L. uniorbis*, with a wide part of vaccenic (15.6%), palmitoleic (12.0%) and oleic (5.8%) acids. The 7-methyl-6-hexadecenoic acid, often found in marine organisms, accounted for 0.8% in *Eudistoma* sp. and 0.4% in *L. uniorbis*. The rare 15-methyl-6-hexadecenoic and 15-methyl-9-hexadecenoic acids occurred as traces only in PL of *Eudistoma* sp. Another interesting MUFA was detected by GC–MS as methyl ester only in *Eudistoma* sp. It was eluted just after the 9–19:1 methyl ester (ECL value of 18.92), and its mass spectrum, showing a molecular ion at *m/z* 310 corresponding to a 19:1 acid structure, was identical to those previously presented [42, 44, 45]. Other diagnostic peaks were the relatively intense peak at *m/z* 278 ($[M-32]^+$, loss of methanol), and peaks at *m/z* 236 ($[M-74]^+$ and *m/z* 194 ($[M-116]^+$, loss of COOMe plus 4 CH_2 from the chain) [45]. This cyclopropane FA, namely 9,10-methyleneoctadecanoic acid, has been recorded for the first time in tunicates to the best of our knowledge.

Polyunsaturated FA

Polyunsaturated FA accounted for 25.9% of total PL FA mixture in *Eudistoma* sp., while they were the most part of PL FA (32.3%) from *L. uniorbis*. The predominant PUFA were 20:5n-3 (EPA, 8.9%), 20:4n-6 (arachidonic, 7.8%) acids in *Eudistoma* sp., and EPA (16.7%), 20:4n-6 (6.0%) and 18:4n-3 (stearidonic, 4.1%) acids in *L. uniorbis*. Thus, arachidonic acid occurred at significant levels in both organisms. The 22:6n-3 acid (DHA) was found at low levels in both organisms (3.0 and 2.5% respectively).

[b] Minor FA identified in *Eudistoma* sp. (<0.3%): 12-methyltetradecanoic (14.72), 15-methyl-6-hexadecenoic (16.30), 15-methyl-9-hexadecenoic (16.53), 9-heptadecenoic (16.76), 2-hydroxy-octadecanoic (19.12), tricosanoic (23.00) and tetracosanoic (24.00); and in *L. uniorbis*: tricosanoic (23.00), 2-hydroxydocosanoic (23.10) and tetracosanoic (24.00)

[c] Total DMA accounted for 5.0% of the FA mixture in *Eudistoma* sp. and for 14.2% in *L. uniorbis*

Interestingly, the quite rare 7,10,13-icosatrienoic acid was readily identified as NAP (see "Materials and Methods"). The mass spectrum of its methyl ester (ECL 19.50) had a molecular ion peak at *m/z* 320, suggesting a 20:3 acid structure. Other major fragment ions were at *m/z* 289 (loss of MeO), 222, 150, 136, 122, 107, 93, 79 (base peak), 67 and 55 (peaks at *m/z* 74 and 87 of low intensity). The NAP showed an intense molecular ion at *m/z* 359 (20:3 acid structure) and the Δ7, Δ10 and Δ13 unsaturations were proved by a difference of 12 amu (instead of the expected gap of 14 amu) between homologous fragment ions at *m/z* 168 and 180, at *m/z* 208 and 220, and at *m/z* 248 and 260, respectively. This rare PUFA has been found for the first time in a shallow-water organism to the best of our knowledge.

Fatty Aldehydes (Dimethylacetals)

Eight fatty aldehydes, characterized as their resulting dimethylacetals, were also present in small amounts in the FA mixture from both ascidians (Table 2). All mass spectra of dimethylacetals displayed a typical base peak at *m/z* 75 $[C_3H_7O_2]^+$ and an appreciable fragment ion $[M\text{-}MeO]^+$. Thus, *Eudistoma* sp. and *L. uniorbis* contained dimethylacetals displaying, in addition to the *m/z* 75, several characteristic fragment ions at respectively *m/z* 255, 269 and 283 ($[M\text{-}MeO]^+$) corresponding to $C_{16:0}$, $C_{17:0}$ and $C_{18:0}$ aldehydes [44]. Such compounds are known to arise from methanolysis of particular PL named plasmalogens containing a vinyl–ether bond at the *sn*-1 position of the glycerol backbone (1-*O*-alk-1-enyl-2-acyl phospholipids) whose biological interest was recently reviewed [46–48].

Discussion

Tunicates seem to be among the least investigated invertebrates for lipids. The lipid content and lipid class distribution of our ascidian species can be compared to those previously published. A recent study showed that *Cystodytes violatinctus* possessed quite similar amount of lipids (1.00%) to those found in the present work (around 0.8%), while another *Eudistoma* species, *E. bituminis*, possessed 4.22% of them [21]. The lipid content of the edible parts of *H. roretzi* was studied monthly and found to be between 0.78 and 2.67% [16]. Other results were obtained using a similar extraction procedure for ascidians such as *H. roretzi* (0.3% of lipids [27]), *A. savignyi* (0.6% of lipids [19]), *Styela* sp. (1.0% of lipids [20]), *P. atlanticum* (5.0–7.0% of lipids [26]). The ascidian *Vanadis antarctica* was characterized by a relatively high lipid content (1.2%) in contrast with the other gelatinous zooplanktonic species (less than 0.1%) [33]. The mean lipid content of *O. vanhoeffeni* was around 5% before the bloom and 7.5% after the bloom (dry weight) [34]. Thus, the lipid contents found in the present work are generally comparable to those published, excepted for a few cases given above.

It was reported that the predominant lipid class in ascidians is mostly PL, which are well-known to be major constituents of the cell membrane. Hence, PL in ascidians ranged from 30 to 90% of the total lipids [21, 25–27, 33, 34]. Nevertheless, knowledge of the PL distribution in tunicates is still limited. In a recent report, the PL contents of *C. violatinctus* and *E. bituminis* accounted for 14.3 and 20.7% of the total lipids [21]. The PL of *P. atlanticum* accounted for 73.7% of the total lipids, and the major PL class was PC (62% of PL), PS being a minor component with PG not reported [26]. Several gelatinous zooplanktonic species also had high PL contents between 40 and 98%, while the non-gelatinous benthic *Distaplia cylindrinca* had 75% of PL [33]. The muscle and viscera of *H. roretzi* contained 39.9 and 28.0% of polar lipids respectively, mainly PL [27]. In this report, the most abundant PL was PC at around 49% followed by PE and SPH. The data obtained in the present work (38.2% of PL

in *Eudistoma* sp. and 30.2% in *L. uniorbis*) are in relatively good agreement with those on other tunicates and ascidians regarding PL contents.

The possible factors determining the PL class distribution in marine organisms were early reviewed [48]. It seemed that the PL pattern of a marine organism is mainly determined by taxonomic position but other factors have to be into account such as the environmental conditions [48]. PL composition has been considered to be an indicator of evolutionary level [14, 15]. PC is the major PL class in a lot of marine organisms including tunicates [26], sponges [37, 38, 48], mollusks and echinoderms [48] and *Eudistoma* sp. in the present study. The second most abundant PL class is often PE, while the acid PS has not been found as the major PL class in any marine organisms to the best of our knowledge.

It is rather surprising to find such a weak content of palmitic acid in *L. uniorbis*, in comparison with other tunicates for which it was found to be 13–40%, including those from the Indian Ocean (40.0% for *E. bituminis* and 21.2% for *C. violatinctus*) [21]. The occurrence of *iso*-branched odd SFA, such as *i*-15:0, *i*-17:0 and *i*-19:0 acids seems to indicate a possible presence of associated bacteria [49] as previously observed in marine sponges [50]. Phytanic acid was reported in *E. bituminis* with a high proportion (16.5%) [21]. It was previously identified as NAP in low amounts in African gorgonians [40]. It is generally assumed to originate from the phytol moiety of chlorophyll, and probably exogenous owing to the ubiquity of photosynthetic organisms in oceans [36].

As reported previously, the predominant MUFA were palmitoleic, oleic and vaccenic acids in both tunicates. They are commonly observed as being abundant in tunicates (13–25% of PL FA), for example, those from the Indian Ocean [21]. The methyl-branched Δ6 MUFA such as 7-methyl-6-hexadecenoic acid are often found in marine organisms. The presence of this FA in tunicates was reported for the first time and these Δ6 unsaturated FA were linked to bacterial origin [21]. This compound was identified in gorgonians [40, 51] and in sponges [52]. Branched short-chain MUFA such as the rare 15-methyl-6-hexadecenoic and 15-methyl-9-hexadecenoic acids were found in gorgonians [40] and in the sponge *Dysidea fragilis* [53], and probably also originated from associated bacteria [54]. The 9,10-methyleneoctadecanoic acid was observed in both tunicates. It has not yet been recorded from tunicates. Cyclopropane FA were observed in marine invertebrates such as sponges [50, 55], and it is known that they are widely distributed among both Gram-positive and Gram-negative bacteria [56].

Interesting results were the occurrence of EPA at the high proportion in *L. uniorbis* (16.7%), and the presence of the 18:4n-3 acid (4.1%). Surprisingly, the 22:6n-3 acid (DHA) was found at low levels in this study and not recorded in *C. violatinctus* and *E. bituminis* [21], whereas it was found in high levels in other tunicates, such as *B. schlosseri* (15.5%, [22], *H. aurantium* (up to 32%, [24]) and *H. roretzi* (13–20%, [23]. Striking results of this study were the unexpected proportion of the 20:5n-3 acid (EPA) in *L. uniorbis* (16.7%) and the occurrence of the 18:4n-3 acid (4.1%) inducing interesting potentialities for this species. These n-3 PUFA are generally attributed to marine photosynthetic phytoplankton. Intense research effort on the role of n-3 long-chain FA in human health and nutrition has continuously increased as shown by a number of recent works [6, 57, 58]. Another result of interest was the identification of the rare 20:3n-7 acid. This FA was quite recently identified (as dimethyloxazoline derivative) in deep-sea cold-seep mussels among several unusual n-4 and n-7 methylene interrupted PUFA but not in shallow-water mussels [59]. Such unusual FA probably originate from chemosynthetic bacteria. Thus, it had been previously found in hydrothermal vent mussels [60] and in vent worms [61], and clearly attributed to thiotrophic symbiotic bacteria.

As revealed by identification of dimethylacetals, both organisms contained plasmalogens. Biological activities of plasmalogens were recently reviewed including their roles in the structure and function of biological membranes [46, 47]. These compounds may protect cells against oxidative stress, since their vinyl–ether bond is preferentially oxidized which protects PUFA at the *sn*-2 position from oxidation. Such compounds have also been described i.e. in sponges [35, 39], gastropods [44], and hydrothermal vent worms [60].

As concluding remarks, the lipid and PL contents of *Eudistoma* sp. and *L. uniorbis* were relatively similar to those published for other tunicates. But the PL class distribution and the PL FA composition of our species were quite different than those reported for other tunicates. The most striking result seems to be the PL class distribution that revealed PC as the major PL in *Eudistoma* sp. whereas it was PS in *L. uniorbis*. Such a strong proportion of PS was not found in any marine invertebrate to date to the best of our knowledge. PL FA composition was different than those previously reported, even for the tunicates of the same genus such as *Eudistoma* sp. (the present study) and *E. bituminis* [21]. Regarding the PL FA, interesting findings of this work seem to be the high content of EPA, the occurrence of the 18:4n-3 acid in *L. uniorbis*, and the identification of the rare 20:3n-7 acid in *Eudistoma* sp. Several FA, such as *iso*-branched odd chain saturated FA, branched MUFA, cyclopropane FA and the 20:3n-7 itself can originate from different types of associated bacteria. Interestingly was the occurrence of plasmalogens among PL of both organisms.

Acknowledgments Organisms were caught during the European Programme "Marine Science and Technology" MAST III, PL950054, 1996–1999, *Bioactive Marine Natural Products in the field of Anti-tumoral, Antiviral and Immunomodulant Activity*. We thank the Ardoukoba association for the assistance during the harvesting of the tunicates. We are indebted to Drs Jean-Pascal Bergé and Jean-Paul Gouygou, the Ifremer Research Center, Nantes, France, where GC-MS analyses were carried out.

ORIGINAL ARTICLE

Fatty Acyl-CoA Reductase and Wax Synthase from *Euglena gracilis* in the Biosynthesis of Medium-Chain Wax Esters

Prapapan Teerawanichpan · Xiao Qiu

Received: 6 November 2009 / Accepted: 2 February 2010 / Published online: 2 March 2010

Abstract *Euglena gracilis*, a unicellular phytoflagellate, can accumulate a large amount of medium-chain wax esters under anaerobic growth conditions. Here we report the identification and characterization of two genes involved in the biosynthesis of wax esters in *E. gracilis*. The first gene encodes a fatty acyl-CoA reductase (*EgFAR*) involved in the conversion of fatty acyl-CoAs to fatty alcohols and the second gene codes for a wax synthase (*EgWS*) catalyzing esterification of fatty acyl-CoAs and fatty alcohols, yielding wax esters. When expressed in yeast (*Saccharomyces cerevisiae*), EgFAR converted myristic acid (14:0) and palmitic acid (16:0) to their corresponding alcohols (14:0Alc and 16:0Alc) with myristic acid as the preferred substrate. EgWS utilized a broad range of fatty acyl-CoAs and fatty alcohols as substrates with the preference towards myristic acid and palmitoleyl alcohol. The wax biosynthetic pathway was reconstituted by co-expressing *EgFAR* and *EgWS* in yeast. When myristic acid was fed to the yeast, myristyl myristate (14:0–14:0), myristyl palmitoleate (14:0–16:1), myristyl palmitate (14:0–16:0) and palmityl myristate (16:0–14:0) were produced. These results indicate EgFAR and EgWS are likely the two enzymes involved in the biosynthesis of medium-chain wax esters in *E. gracilis*.

Keywords *Euglena* · Fatty acyl-CoA reductase · Fatty alcohol · Wax ester · Wax synthase

RACE	Rapid amplification of cDNA ends
WS	Wax synthase

Introduction

Euglena gracilis is a unicellular phytoflagellate protist that can grow photoautotrophically in a minimal medium as well as heterotrophically in an organic carbon-rich medium. Under light or aerobic conditions, *Euglena* accumulates polysaccharides (mainly β-1,3 glucan, known as paramylon) and wax esters as energy reserves [1, 2]. Once the cell culture is switched from light to dark or from aerobic to anaerobic conditions, the polysaccharide reserve is converted to wax esters in the cytosol and the accumulated wax esters can reach up to 62% of the total lipid content [3]. Wax esters produced in *Euglena* are in a range of the 20- to 36-carbon chains comprised of saturated fatty acids and alcohols of 12–18 carbon chains with myristyl myristate (14:0–14:0) as the major species [4]. Under aerobic growth, *Euglena* mainly accumulates even-numbered wax esters, however an anaerobic growth condition promotes the accumulation of odd-numbered wax esters in some *Euglena* strains [3–6]. In addition to light and oxygen, other environmental factors, such as nutrients and temperature can also affect the production and composition of storage wax esters in *Euglena* cells. The production of wax esters is more efficient when the culture medium contains organic carbon source [7] or when the culture is shifted from low to high temperature (15 °C to 33 °C) [8]. Supplementation of

the medium with unsaturated fatty acids (oleic acid, linoleic acid, linolenic acid) and unusual fatty acid (ricinoleic acid) leads to the accumulation of these fatty acids in both acyl and alcohol moieties of wax esters [6].

The wax ester biosynthetic pathway consists of two successive steps: conversion of fatty acyl-CoA to fatty alcohol and esterification of fatty acyl-CoA and fatty alcohol [9]. The enzymes responsible for these reactions are fatty acyl-CoA reductase (FAR) and acyl-CoA:fatty alcohol acyltransferase or wax synthase (WS), respectively. The genes encoding FARs have been identified from a variety of living organisms, including mouse [10], human [10], silkmoth [11], bean borer moth [12], jojoba [13], *Arabidopsis* [14, 15] and wheat [16]. BmFAR, a fatty acyl-CoA reductase from silkmoth (*Bombyx mori*), is responsible for production of sex pheromone bombykol, (*E,Z*)-10,12–hexadecadien-1-ol [11], whereas OsFARXIII, another fatty acyl-CoA reductase from bean borer moth (*Ostrinia scapulalis*), catalyzes the production of (*Z*)-11-tetradecenol, which can be further converted to acetate or aldehyde pheromones [12]. ScFAR, a fatty acyl-CoA reductase from jojoba (*Simmondsia chinensis*), is responsible for producing storage wax esters in developing seeds [13]. *Arabidopsis* fatty acyl-CoA reductase AtCER4 (At4g33790) is involved in the synthesis of cuticular wax lipids [15]. *TaTAA1a*, *TaTAA1b* and *TaTAA1c*, three orthologs of the jojoba *ScFAR*, were isolated from wheat [16]; they are involved in producing the lipid component in the outer pollen wall.

Wax synthases have also been isolated and characterized from a wide range of living organisms. Some show only wax synthase activity such as mouse WS, human WS [17], jojoba ScWS [18] and petunia PhWS1 [19], while the other exhibit both wax synthase and acyl-CoA:diacylglycerol acyltransferase (DGAT) activities, including *Acinetobacter* WS/DGAT [20] and *Arabidopsis* WSD1 [21]. Mouse and human *WSs* (*MmWS* and *HsWS*) are highly expressed in sebaceous-rich tissues, such as preputial glands and eyelids [17]. Jojoba *ScWS* was isolated from developing seeds and is involved in the synthesis of liquid waxes that accumulate in seeds [18]. *Arabidopsis AtWSD1* (*At5g37300*) is involved in synthesis of stem epicuticular wax esters as shown by a severe reduction of the wax ester content (44 and 46 carbons) in *Arabidopsis wsd1* mutants [21]. Petunia *PhWS1* is highly expressed in petals and involved in the production of very long chain fatty acid esters of methyl, isoamyl and short to medium straight chain alcohols (4–12 carbons) [19].

In *E. gracilis*, the activities of both FAR and WS were found in the microsomal fraction of cultures grown in the dark [22]. The biochemical assays showed that FAR used 14:0, 16:0 and 18:0 as substrates and required NADH as a cofactor [22, 23]. Although the biosynthesis of wax esters in *Euglena* has been extensively studied, the genes encoding these enzymes have not been described. Here we report the identification and characterization of two genes, *EgFAR* and *EgWS*, involved in the biosynthesis of wax esters in *E. gracilis*. Heterologous expression of these genes in yeast revealed the unique properties of the enzymes—preferential utilization of medium chain fatty acyl and alcohol as substrates for synthesis of wax esters.

Experimental Procedures

Isolation of Putative *Euglena Fatty Acyl-CoA Reductase* (*EgFAR*) and *Euglena Wax Synthase* (*EgWS*)

Euglena gracilis was grown aerobically in a TSY medium (0.1 g/l sodium acetate, 0.1 g/l beef extract, 0.2 g/l peptotryptone, 0.2 g/l yeast extract, 0.2 μg vitamin B12, 1 μg/l biotin, 100 μg/l thiamine-HCl, 0.1 μg/l niacinamide, pH 7.0 [24]) at 25 °C for 16 h (120 μE m^{-2} s^{-1})/8 h (light/dark) regime. The *Euglena* cells can accumulate up to 28% wax ester under these conditions. Total RNA was extracted from the *E. gracilis* culture using TRIZOL® reagent (Invitrogen). The full length cDNAs of *EgFAR* and *EgWS* were obtained using Marathon™ cDNA Amplifcation kit under conditions detailed by the supplier (Clontech). The gene-specific primers used for 5′- and 3′-RACE of *EgFAR* are ACR1 (5′-GGCTGGTTGGAGTTGACGTAGCA-3′) and ACF1 (5′-GCCATGAACGATTTCTACGCGGG-3′) primers, respectively. The gene-specific primers used for 5′- and 3′-RACE of EgWS are WSR2 (5′-CTCCGGGTG ACCTTTCGGC-3′) and WSF2 primers (5′-CCAGCCC TACTTTTCCACATCTCTGAG-3′), respectively.

DNA Sequencing and Analysis

All synthesis and sequencing work was performed by the DNA Technologies Unit at the Plant Biotechnology Institute, National Research Council of Canada. Nucleotide sequence and amino acid sequence comparisons were conducted using Lasergene7 (DNASTAR).

Amino Acid Sequence Alignment and Phylogenetic Analysis

Phylogenetic analysis of functionally characterized FARs and WSs were performed as previously described [25].

Construction of Yeast Expression Vectors Harboring *EgFAR*, *EgWS* and *EgFAR-EgWS*

The *EgWS* open reading frame (ORF) was amplified using primers WSFLF (5′-TTCGCGATGGATTTTTTGGGG-3′) and WSFLR (5′-GCCACCCAAGGCACTTGGCCT-3′)

and cloned into pYES2.1/V5-His/lacZ vector (Invitrogen), yielding plasmid pPT504. The *EgFAR* ORF was amplified using primers PT0037 (5′-GATCGGATCCATGAACGAT TTCTACGCG-3′)-PT0041 (5′-ATCAGCTAGCCTATCA CAGCATGGCCCGC-3′) and digested with *Bam*HI and *Nhe*I. The amplified fragment was subsequently cloned into the corresponding restriction sites of a yeast expression vector pESC-URA (Stratagene), yielding pPT515. The amplification was performed using 2.5 units of Platinum® *Pfx* DNA polymerase (Invitrogen) in the presence of 5% (v/v) DMSO. PCR conditions for *EgFAR* were 35 cycles of 94 °C for 15 s, 55 °C for 30 s, 68 °C for 1 min with the final extension at 68 °C for 5 min. PCR conditions for *EgWS* were identical to *EgFAR*, except that the extension time was 30 s instead of 1 min. For the co-expression study, the *EgWS* ORF was amplified from pPT504 using primers PT0049 (5′-GATCATCGATATGGATTTCTTAG GTTTTCCTGAC-3′)-PT0050 (5′-CTGTAGATCTCTAT CAGACAGACAGACCTAGC-3′). The amplified fragment was digested with *Cla*I and *Bam*HI and subsequently cloned into the corresponding sites of pPT515, yielding pPT516.

Functional Analysis of *EgFAR* and *EgWS* in Yeast

pPT515 (*EgFAR*) and pPT504 (*EgWS*) plasmids were transformed into yeast (*Saccharomyces cerevisiae*) strain H1246 (*MATα*; *are1*-Δ::*HIS3 are2*-Δ::*LEU2 dga1*-Δ::*KanMX4 lro1*-Δ::*TRP1 ADE2*) [26] using S.c. Easy-Comp™ transformation kit (Invitrogen). Yeast strains transformed with pPT515 (*EgFAR*), pPT504 (*EgWS*), pPT516 (*EgFAR* + *EgWS*), pESC-URA or pYES2.1 plasmids were grown at 30 °C for 2 days in 10 ml of the synthetic dropout medium containing 0.17% (w/v) yeast nitrogen base, 0.5% (w/v) ammonium sulfate, 2% (w/v) glucose and 0.06% (w/v) dropout supplement lacking uracil (DOB + GLU-URA). After two washes with 10 ml of sterile distilled water, the expression of transgene in yeast were induced by culturing the yeast at 20 °C for 4 days for pPT515 (*EgFAR*) and 30 °C for 2 days for pPT504 (*EgWS*) in 10 ml of the synthetic dropout medium containing 2% (w/v) galactose (DOB + GAL-URA) with or without substrate supplementation in the presence of 0.1% (v/v) tergitol (Nonidet P-40). Two-hundred fifty micromolar of fatty acid was used as a substrate for the pPT515 (*EgFAR*) expression, whereas 250 μM of fatty acid and 250 μM of fatty alcohol were used as substrates for the pPT504 (*EgWS*) expression. After induction, the cultures were washed once with 10 ml of 1% (v/v) tergitol and once with 10 ml of distilled water, and then subjected to fatty acid analysis. For the yeast feeding experiment, fatty acid and fatty alcohol substrates were initially prepared as stock solutions in ethanol at the concentration of 500 mM and the appropriate amount of the stock was then diluted in 10% tergitol at the final concentration of 50 mM used for feeding the yeast.

In Vitro Assays of *EgFAR* and *EgWS*

To investigate substrate specificity of EgFAR and EgWS in vitro, the microsomal fractions of yeast expressing *EgFAR* and *EgWS* were prepared as previously described [27, 28]. For the EgFAR assay, the enzyme reaction (500 μl) contained 200 μg of microsomal proteins, 0.3 M sucrose, 0.1 M MOPS (pH 6.5) or 0.1 M Tris–HCl, (pH 7.4), 1 mM EDTA, 2.5 mM DTT, 5 mM $MgCl_2$, 1 mM PMSF, 100 μM acyl-CoA, 2.5 mM NADH, 2.5 mM NADPH. The reaction was carried out at 30 °C with gentle shaking for 30 min to 2 h. For the EgWS assay, the same amount of protein and the reaction buffer (pH 7.4) were used. One-hundred micromolar of acyl-CoA and 100 μM fatty alcohol were added as substrates. The reaction was carried out at 30 °C with gentle shaking for 2 h. The enzyme reactions were terminated by addition of 100 μl of 6 M HCl. After adding 1 ml of phosphate buffered saline and 1 ml of 0.9% (w/v) NaCl solution, lipids were extracted twice with 2 ml hexane. The known amount of methyl eicosanoate (20:0-ME) was added as the internal standard. The solvent was subsequently removed under a nitrogen stream and the lipid samples were resuspended in 20 μl of hexane, which was derivatized with bis(trimethylsilyl)-acetamide (TMS) and analyzed by GC for the EgFAR assay or was directly analyzed by GC for the EgWS assay (see below). Acyl-CoA stock solutions were prepared in 10 mM sodium acetate buffer (pH5.2)/ethanol (1:1, v/v) at a concentration of 50 mM.

Co-Expression of *EgFAR* and *EgWS* in Yeast

To reconstitute the *Euglena* wax biosynthesis pathway in yeast, the plasmid pPT516 harboring the two-gene cassette (*EgFAR* and *EgWS*) was transformed into the yeast strain H1246. The transformants were grown in the DOB + GLU-URA medium at 30 °C for 2 days and the expression of *EgFAR* and *EgWS* was induced in the DOB + GAL-URA medium supplemented with 500 μM 14:0 in the presence of 0.1% (v/v) tergitol at 20 °C for 4 days. The yeast cells were harvested and analyzed for fatty alcohol and wax monoester production as described above.

Analysis of Fatty Acids, Fatty Alcohols and Wax Esters of Yeast Transformants

Fatty acids of yeast cells were transmethylated with 2 ml of methanol/HCl (3 M) at 80 °C for 2 h and the reaction was terminated by adding 1 ml of 0.9% NaCl solution. Total fatty acid methyl esters (FAMEs) and fatty alcohols were

then extracted twice with 2 ml of hexane and the hexane phase was transferred to a new tube, evaporated under a nitrogen stream and resuspended in 200 μl of hexane. Fifty microliters of samples were derivatized with 50 μl of TMS/pyridine (1:1, v/v) at 80 °C for 30 min and the derivative was analyzed by gas chromatography (GC). For wax ester analysis, the total lipid was extracted by homogenizing yeast cells in the presence of 6 ml of chloroform/methanol (2:1, v/v). The organic phase was dried under a stream of nitrogen gas, resuspended in 50 μl of hexane and analyzed by GC, GC–mass spectrophotometry (MS) and thin layer chromatography (TLC).

GC, GC–MS and TLC Analysis

Fatty acids (10:0, 12:0, 14:0, 16:0, 16:1n-9, 18:0, and 18:1n-9), fatty alcohols (10:0Alc, 12:0Alc, 14:0Alc, 16:0Alc, 16:1n-9Alc, 18:0Alc and 18:1n-9Alc), wax esters (14:0–12:0, 14:0–14:0, 14:0–16:0, 14:0–16:1n-9, 14:0–18:0, 14:0–18:1n-9, 12:0–14:0, 16:0–14:0, 16:1n-9–14:0, 18:0–14:0, 18:1n-9–14:0) and TLC reference standard (cholesterol, cholesteryl oleate, triolein, oleic acid, methyl oleate) with 99% purity were purchased from Nuchek-Prep, Inc. For GC analysis, one-microliter samples were analyzed on an Agilent 6890 N GC equipped with a DB-5 column (10 m × 0.25 mm) (J&W Scientific). The following temperature programs were employed: 70 °C for 1 min, then 10 °C/min to 300 °C, and 300 °C for 10 min with H_2 as the carrier gas. For MS analysis, the mass selective detector was run under standard electron impact conditions (70 eV), scanning an effective *m/z* range of 40–700 at 2.26 scans/s. Identities of FAMEs, fatty alcohols-TMS derivatives and wax esters were identified by comparing their retention times with those of the standards and confirmed by GC–MS on the basis of their fragmentation patterns. For TLC analysis, total lipid samples and standards were spotted on 60-Å silica gel SIL G-25 plates (Macherey–Nagel) and resolved in hexane/diethylether/acetic acid (90:7.5:1, v/v/v) [21]. The plate was air-dried and the lipid metabolites were detected by primuline spraying (0.05% w/v; Sigma) and the pictures were taken under UV light at 254 nm.

Results

Isolation of Two cDNAs Encoding Putative Fatty acyl-CoA Reductase and Wax Synthase from *E. gracilis*

The partial cDNA sequences of *Euglena* putative fatty acyl-CoA reductase *EgFAR* and wax synthase *EgWS* were obtained by a homology search of the *Euglena* EST database using jojoba ScFAR and ScWS as query sequences and the full-length putative *EgFAR* and *EgWS* cDNAs were obtained by 5′- and 3′-RACE using *Euglena* cDNAs as the template. Sequence analysis indicated putative *EgFAR* encodes a polypeptide of 514 amino acids in length with the predicted molecular mass of 56.5 kDa. The deduced protein EgFAR contains a Rossmann-fold NAD/NADP binding domain (NABD; 289 amino acids) [29] linked with a Male Sterile 2 domain (MS2, 97 amino acids) [30] at the carboxyl end (Fig. 1a). A conserved motif (I/V/F)-X-(I/L/V)-T-G-X-T-G-F-L-(G/A), found in other fatty acyl-CoA reductases, was also observed in the NABD domain of EgFAR (Fig. 1b). The hydropathy analysis indicated that the putative EgFAR contains five high hydrophobic regions; one located at the N-terminus and the rest present in the central portion of the protein. Phylogenetic analysis of the putative EgFAR and related sequences reveals that EgFAR is more closely related to plant fatty acyl-CoA reductases, including *Arabidopsis* AtCER4 [15], wheat TaTAA1 [16] and jojoba ScFAR [31], whereas the insect and mammalian fatty acyl-CoA reductases [10] form a distant group (Fig. 2a). Sequence analysis of the putative *EgWS* indicated that it encodes a polypeptide of 368 amino acids with the predicted molecular mass of 41.2 kDa. The deduced protein EgWS contains six distinct hydrophobic regions. Phylogenetic analysis of EgWS and related sequences reveals that *Euglena* EgWS clusters with jojoba ScWS [18], which is distantly related to the rest members of wax synthases, including the mammalian WSs [17], *Acinetobacter* AcWS/DGAT [20], *Arabidopsis* AtWSD1 [21] and petunia PhWS1 [19] (Fig. 2b).

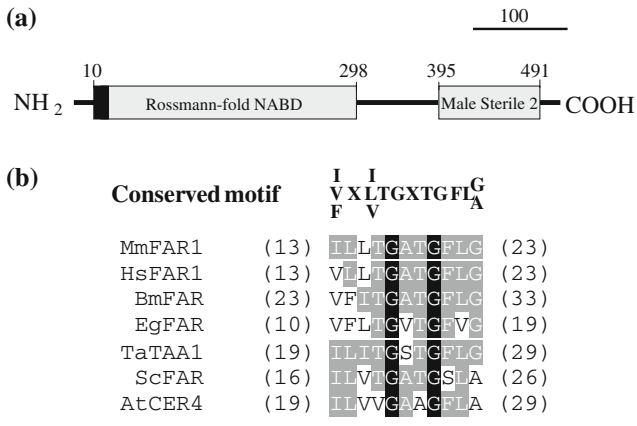

Fig. 1 A schematic diagram illustrating the functional domains (**a**) and a conserved motif (**b**) of EgFAR and other related sequences. The *numbers* indicate amino acid positions. The accession numbers of these sequences are indicated in Fig. 2

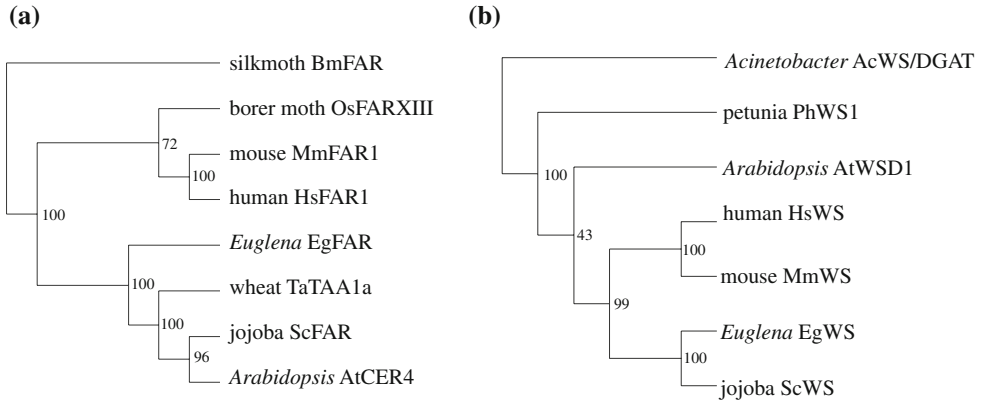

Fig. 2 Phylogenetic analysis of EgFAR (**a**) and EgWS (**b**) and their related sequences. The GenBank accession numbers of the sequences are as follows: mouse MmFAR1, BC007178; mouse MmFAR2, BC055759; human HsFAR1, AY600449; human HsFAR2, BC022267; silkmoth BmFAR, AB104896; borer moth OsFARXIII, EU817405; wheat FAR (TaTAA1a), AJ459249; jojoba ScFAR, AF149917; *Arabidopsis* AtCER4, AY070065-At4g33790; mouse MmWS, AY611032; human HsWS, AY605053; *Arabidopsis* AtWSD1, NM_123089-AT5G37300; *Acinetobacter* AcWS/DGAT, AF529086; jojoba ScWS, AF149919; petunia PhWS1, DQ093641

Functional Analysis of *EgFAR* and *EgWS* in Yeast

To determine the function of putative *EgFAR* and *EgWS*, the full-length cDNAs were cloned into the yeast expression vectors separately and the recombinant plasmids were transformed into the *Saccharomyces cerevisiae* quadruple mutant strain H1246 [26], in which four acyltransferase genes involved in the triacylglycerol (TAG) and sterol ester biosynthesis were disrupted. This strain appeared to have diminished capacity for wax ester biosynthesis (Fig. 3b), thus can serve as a good host system to examine the function of genes involved in the biosynthesis of wax esters.

The activity of the putative *Euglena* fatty acyl-CoA reductase was investigated by feeding the yeast strain carrying *EgFAR* with a variety of probable fatty acid substrates. Analysis of total fatty alcohols in the cells indicated that the transformant expressing *EgFAR* produced new peaks only when myristic acid (14:0) and palmitic acid (16:0) were used as substrates, compared with the vector control (Fig. 3a). The chemical structures of these new peaks were determined as myristyl alcohol (14:0Alc) and palmityl alcohol (16:0Alc) by GC–MS. The conversion efficiencies of the two alcohols were 34 ± 4 and 24 ± 3%, respectively. No other alcohol products were detected when the yeast strain was fed with other saturated fatty acids (10:0, 12:0 and 18:0) or unsaturated fatty acids (16:1n-9, 18:1n-9 and 18:2n-6). A similar result was obtained when *EgFAR* was expressed in yeast strain INVSc.

The activity of the putative EgWS was investigated by feeding the yeast strain expressing *EgWS* with 14:0 and 14:0Alc substrates. The total neutral lipids including triacylglycerols and wax esters in the transformant were first analyzed by TLC. In contrast to the vector control, the yeast expressing *EgWS* produced wax esters in presence of 14:0 and 14:0Alc that were detected on the TLC plate (Fig. 3b). Like the control, the transformant expressing *EgWS* did not produce any triacylglycerols, indicating EgWS possess wax synthase activity, but not diacylglycerol acyltransferase activity as seen in bacterial WS/DGAT [32]. Wax composition analysis by GC and GC–MS indicated that the major components of wax esters produced in the transformant were myristyl myristate (14:0–14:0), myristyl palmitate (14:0–16:0) and myristyl pamitoleate (14:0–16:1) (Fig. 3c). It was also noted that the vector control could produce a trace amount of myristyl myristate (14:0–14:0) when the yeast was fed with substrates (Fig. 3b, c).

To examine the fatty acid substrate specificity of EgWS, the yeast strain was fed with 14:0Alc in combination with a range of fatty acids including 10:0, 12:0, 14:0, 16:0, 16:1n-9,18:0, and 18:1n-9. The wax analysis showed that EgWS could incorporate 12:0, 14:0, 16:0 and 16:1–9 fatty acids into wax esters, but it could not use 10:0, 18:0 or 18:1n-9 as the substrate. Quantitative analysis of the ratio of products versus substrates indicated that the highest conversion efficiency of fatty acids was observed on 14:0, which was followed by 12:0, 16:0 and 16:1n-9 (Table 1). In order to examine fatty alcohol substrate specificity, the yeast strain was fed with 14:0, the most preferred acyl-CoA substrate for EgWS in combination with a range of fatty alcohols including 10:0Alc, 12:0Alc, 14:0Alc, 16:0Alc, 16:1n-9Alc, 18:0Alc and 18:1n-9Alc. Wax analysis indicated that EgWS could utilize 12:0Alc, 14:0Alc, 16:0Alc and 16:1n-9Alc fatty alcohols, but not 10:0Alc, 18:0Alc and 18:1n-9Alc as the substrates. The preferred fatty alcohol was 16:1n-9Alc, which was followed by 14:0Alc, 12:0Alc and 16:0Alc (Table 1).

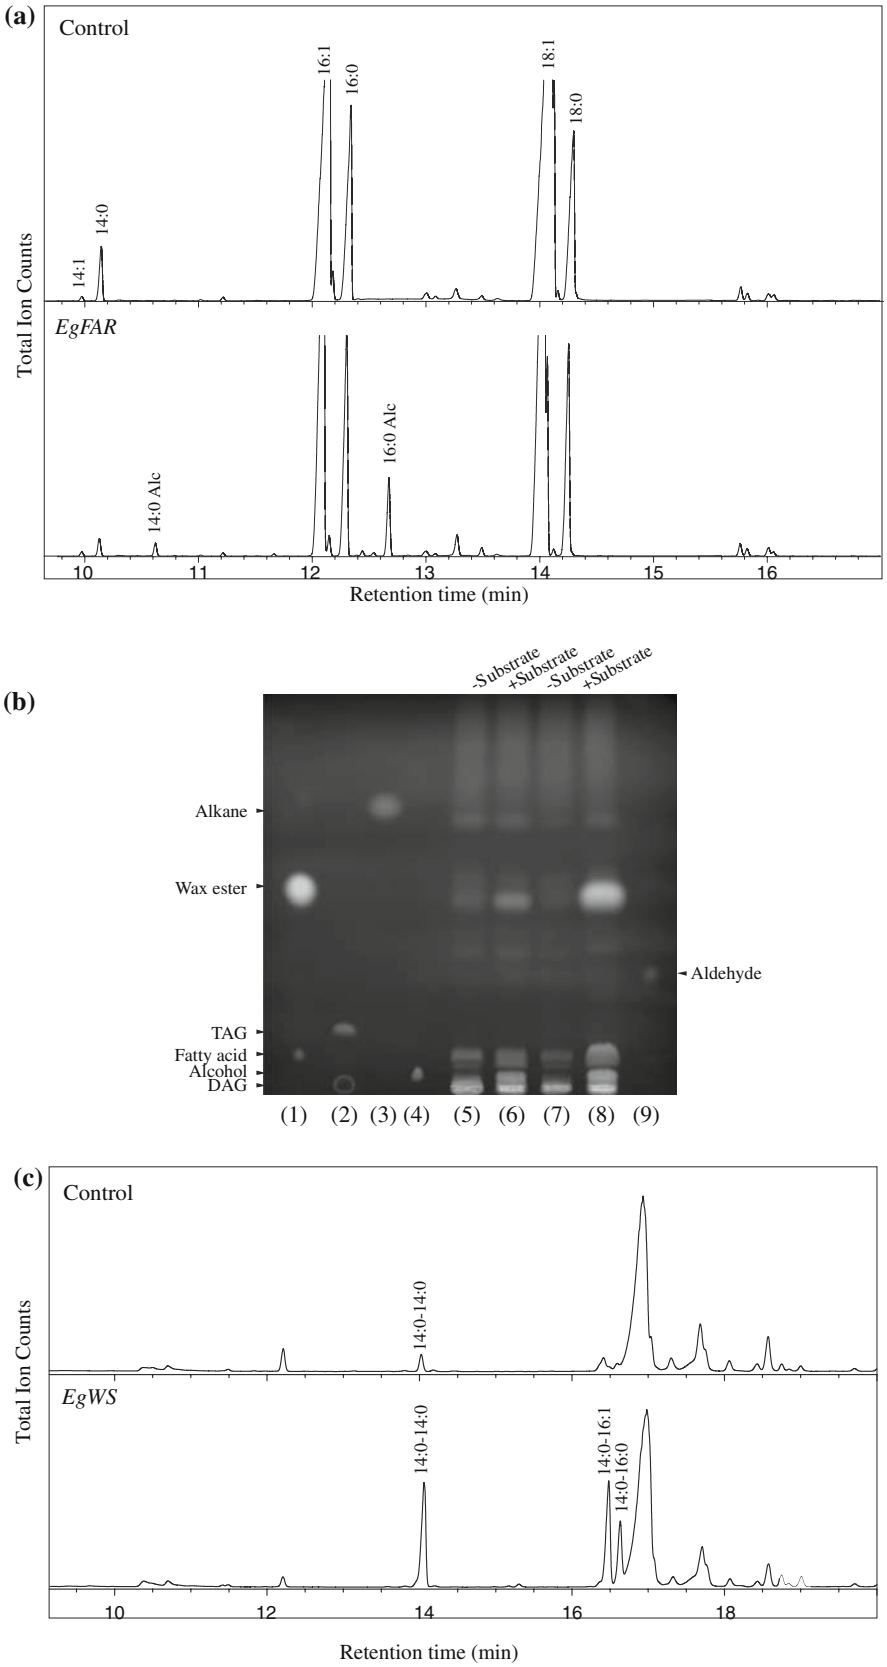

Fig. 3 Activity of EgFAR (**a**) and EgWS (**b**, **c**) in yeast. **a** GC analysis of fatty acid methyl esters and fatty alcohol TMS ethers prepared from the yeast transformed with the pESC-URA vector control or *EgFAR*. **b** TLC analysis of the total lipid of the yeast transformed with the pYES2.1 vector control (*lanes 5* and *6*) or *EgWS* (*lanes 7* and *8*) in the absence (*lanes 5* and *7*) and presence (*lane 6* and *8*) of substrates (14:0 and 14:0Alc). *Lane 1–4*, *9* are standards: *DAG* diacylglycerol, *TAG* triacylglycerol (**c**) GC analysis of the total lipid prepared from yeast transformed with *EgWS* or the pYES2.1 vector control and fed with 14:0 and 14:0Alc substrates

Table 1 Substrate specificity of EgWS for fatty acids and fatty alcohols

Substrate	Conversion efficiency (%)	
	Fatty acid	Fatty alcohol
12:0	37 ± 8	21 ± 2
14:0	47 ± 4	47 ± 6
16:0	31 ± 1	25 ± 2
16:1n-9	33 ± 3	68 ± 5
18:0	n.d.	n.d.
18:1n-9	n.d.	n.d.

The transformant yeast was fed with 14:0Alc in combination with different fatty acids to examine the fatty acid specificity and fed with 14:0 in combination with different fatty alcohols to examine the fatty alcohol specificity. The conversion efficiencies (%) of wax esters were calculated as [(product)/(substrate + product)] × 100 using the values corresponding to the weight percent of fatty alcohol substrates and the wax ester products inside the yeast cells. The values are the average derived from triplicates ± standard deviation (SD)

n.d. not detected

To study the substrate specificity of EgFAR and EgWS in vitro, the microsomal fractions of yeast expressing *EgFAR* or *EgWS* were incubated with a series of fatty acids or fatty acid and alcohol combinations. However, only small activity of wax ester synthesis was detected in the in vitro assay of EgWS, which was basically in agreement with the result from the in vivo experiment. Furthermore, we could not detect any fatty acyl-CoA reductase activity in the in vitro assay of EgFAR with all possible substrates. The reason why the in vitro EgWS and EgFAR activities in yeast were low is unknown. It is noteworthy that so far only three reports have described the in vitro fatty acyl-CoA reductase and wax synthase activities in heterologous systems, including mammalian FARs and WSs in the HEK293 human cell line [10, 17] and *Acinetobacter* WS/DGAT in *E. coli* [20]. The difficulty in the yeast in vitro assays of EgFARs and EgWSs might be related to the nature of this type of enzymes or simply the low activities of the two enzymes in yeast.

Reconstitution of the *Euglena* Wax Biosynthetic Pathway in Yeast

To reconstitute the *Euglena* wax biosynthetic pathway in yeast, *EgFAR* and *EgWS* were cloned into a yeast expression vector, pESC-URA, in which the expression of *EgFAR* and *EgWS* were driven by *GAL1* and *GAL10* inducible promoters, respectively. The recombinant plasmid was then transformed into the yeast strain H1246 and the transformants were grown in the selective medium supplemented with 14:0, a common preferred substrate for both EgFAR and EgWS. Wax ester analysis indicated that the co-expressing yeast, like the *EgFAR*-expressing yeast, could convert 14:0 and 16:0 to 14:0Alc and 16:0Alc, respectively (Fig. 4). In addition, the co-expressing yeast produced three new wax ester peaks which were not detected in either *EgFAR*-expressing yeast or vector control yeast. Identities of these peaks were determined by comparing their retention times and mass spectra to those of standards. Peak 1 had the identical retention time and mass spectrum to

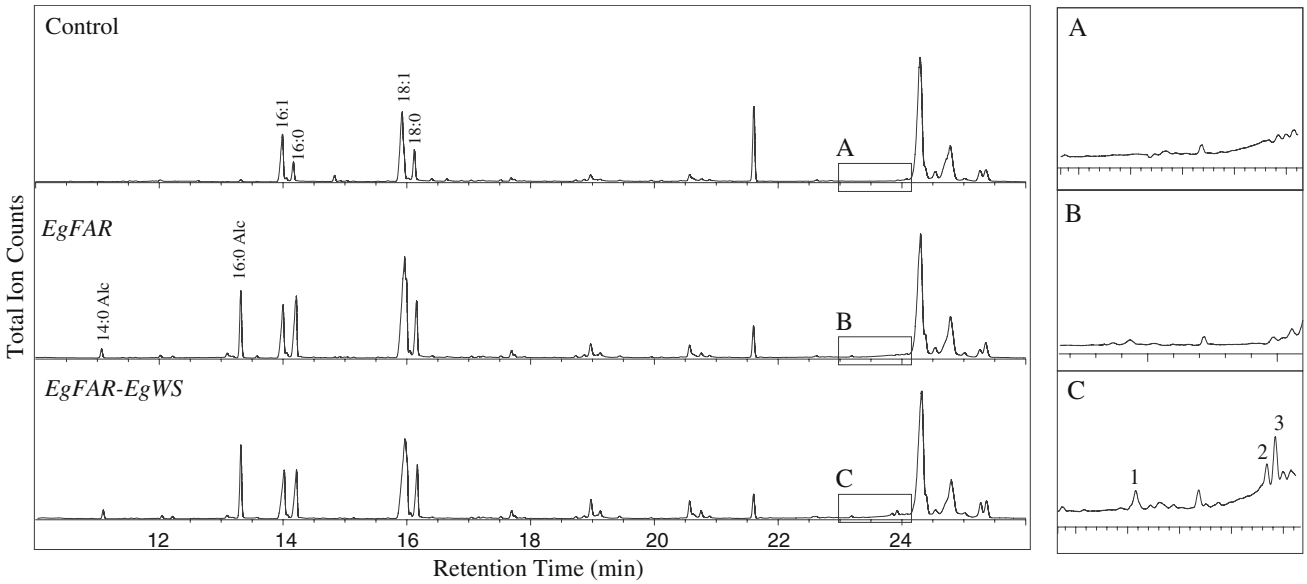

Fig. 4 Co-expression of *EgFAR* and *EgWS* in yeast. GC analysis of the total lipid showing wax ester production prepared from yeast transformed with pESC-URA (empty vector), *EgFAR* and *EgFAR-EgWS* and fed with 14:0 substrate. *Peak 1* myristyl-myristate (14:0–14:0), *Peak 2* myristyl-palmitoleate (14:0–16:1), *Peak 3* myristyl palmitate (14:0–16:0) and palmityl myristate (16:0–14:0). Selected regions of the chromatograms of control, *EgFAR* and *EgFAR-EgWS* expressing yeast are magnified in boxes *A*, *B* and *C*, respectively

myristyl myristate (14:0–14:0) which accounted for ~23% of total wax esters (Fig. 5a) while peak 2 had the identical retention time and mass spectrum to myristyl palmitoleate (14:0–16:1) (Fig. 5b) which accounted for ~22% of total wax esters. Peak 3 appeared to contain two wax ester products, myristyl palmitate (14:0–16:0) and palmityl myristate (16:0–14:0) together they accounted for ~55% of total wax esters. GC and GC–MS analysis showed that it had the same retention time as myristyl palmitate (14:0–16:0) and palmityl myristate (16:0–14:0) and possessed the mass spectrum (Fig. 5c) with diagnostic ions representing the mass spectra of both myristyl palmitate (14:0–16:0) (Fig. 5d) and palmityl myristate (16:0–14:0) (Fig. 5e). Based on the abundance of the diagnostic fragments and the relative response factors of 14:0–16:0 (*m/z* 257) and 16:0–14:0 (*m/z* 229), peak 3 contained ~58% of 14:0–16:0 and ~41% of 16:0–14:0. Collectively, these results indicated that EgWS in the co-expressing yeast could esterify 14:0Alc and 16:0Alc produced by EgFAR with 14:0, 16:0 and 16:1n-9 fatty acids, producing medium chain wax esters, myristyl myristate (14:0–14:0), myristyl palmitate (14:0–16:0), myristyl palmitoleate (14:0–16:1) and palmityl myristate (16:0–14:0).

Discussion

The biosynthesis of wax esters comprises two consecutive catalytic steps, reduction of fatty acyl-CoA to fatty alcohol and subsequent esterification of fatty acyl-CoA and fatty

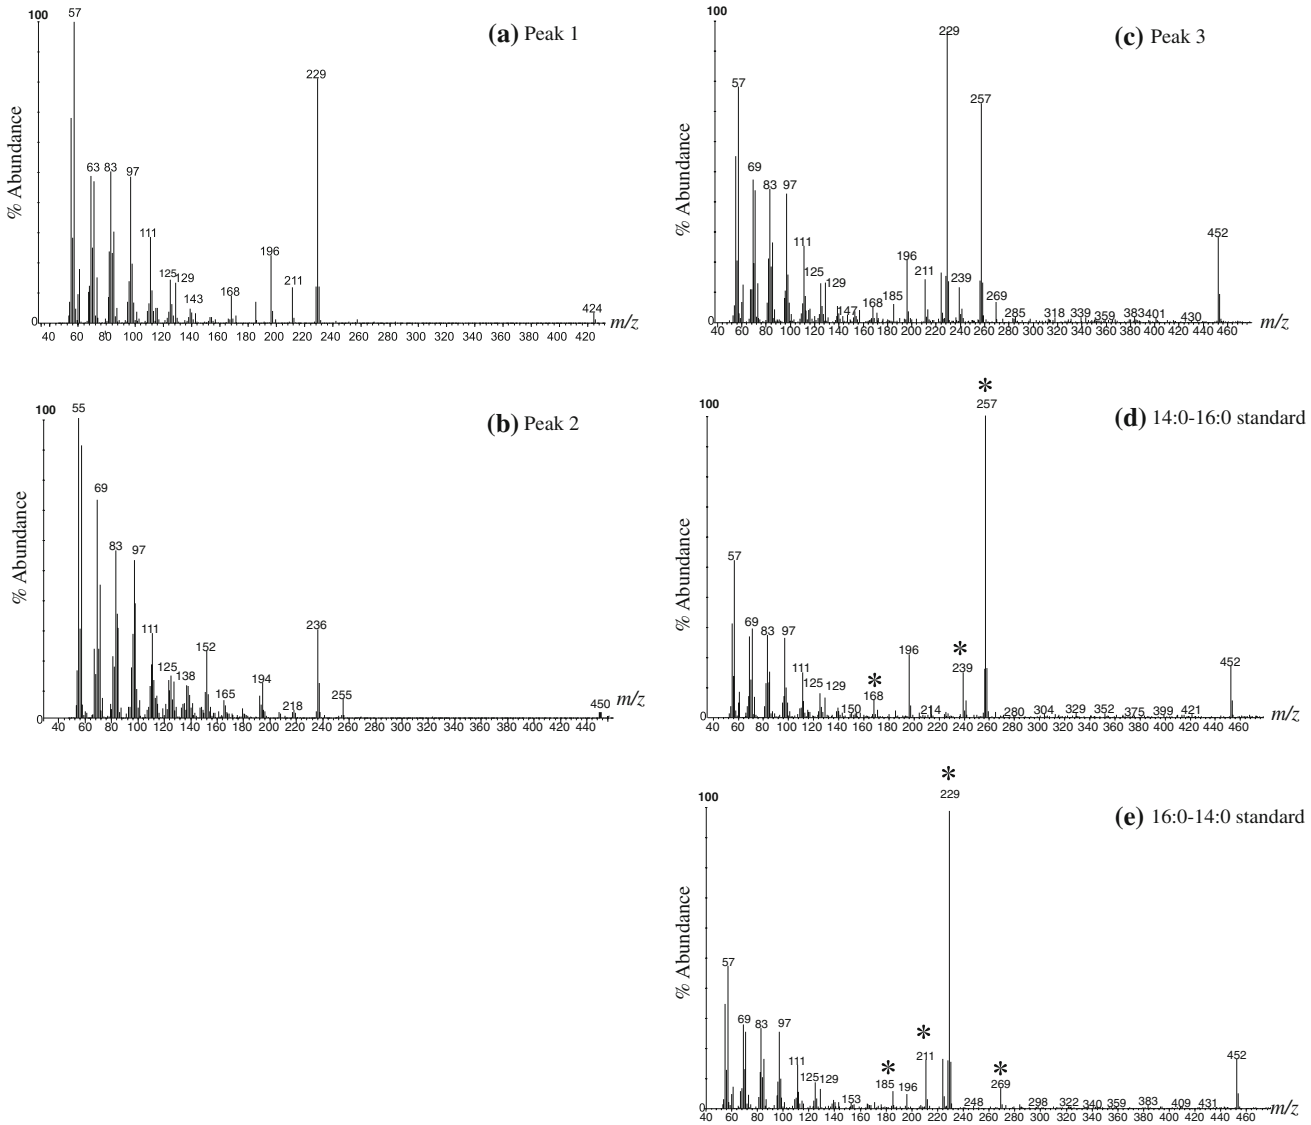

Fig. 5 GC/MS analysis of wax ester peak 1 **a**, peak 2 **b** and peak 3 **c** in Fig. 4, myristyl palmitate (14:0–16:0) standard (**d**) and palmityl myristate (16:0–14:0) standard **e**. *Asterisks* indicate diagnostic ions of the wax esters

alcohol. The reduction of fatty acid to fatty alcohol occurs through aldehyde intermediate and is catalyzed by either one or two enzyme reactions. In the two-enzyme reaction, acyl-CoA reductase first converts the fatty acyl-CoA to aldehyde and then the aldehyde reductase catalyzes the reduction of the aldehyde to alcohol. Evidence supporting the two-step reaction came from the early identification of aldehyde reductase from *Brassica oleracea* [33] and the recent isolation of the *acyl-CoA reductase* gene from *Acinetobacter*, catalyzing the production of fatty aldehyde [34]. However, support for the existence of the two-enzyme reduction is scarce in eukaryotes. In fact, a single enzyme reaction for the fatty acid reduction appears to occur widely in nature where the FAR catalyzes reduction of fatty acyl-CoA to fatty alcohol directly, although aldehyde intermediates could be detected by indirect trapping assays [23]. This type of fatty acyl-CoA reductases has been identified from jojoba cotyledon, pea leaves [23, 35, 36] and many others [37–39], including the one we describe here from *Euglena*.

Although *E. gracilis* has long been known to accumulate a large amount of medium-chain wax esters under dark and anaerobic growth conditions, the genes involved in the biosynthesis of these wax esters have yet to be identified. In this study, we report the isolation and characterization of two cDNAs, *EgFAR* and *EgWS*, from *E. gracilis* encoding two enzymes involved in the biosynthesis of medium chain wax esters. The pairwise sequence comparison of EgFAR and previously identified FARs revealed that EgFAR shares low amino acid identity with other FARs (23–27.4%). Functional analysis of EgFAR in yeast indicated that it could effectively convert 14:0 and 16:0 fatty acids to their corresponding alcohols. Compared with other biochemically characterized FARs, EgFAR possesses a narrower substrate range, only using saturated fatty acids with 14 and 16 carbon chains as substrates with the preferred fatty acid being 14:0 when expressed in yeast.

The pairwise sequence comparison of EgWS and related wax synthases revealed that EgWS also shares low amino acid identity to its related enzymes (in the range of 13–27%). It was noted that EgWS does not contain an *N*-terminal domain with the proposed active site (HHXXXD) found in *Acinetobacter* AcWS/DGAT [20], *Arabidopsis* AtWSD1 [21] and petunia PhWS1 [19]. This domain was believed to be essential for their acyl-CoA acyltransferase activities for the synthesis of wax esters and TAGs [20]. It will be interesting to know how EgWS functions without this domain. To date, three wax synthases including EgWS we report here have been functionally characterized in yeast. AtWSD1 mainly synthesizes wax esters with 16:0 fatty acid and 18:0Alc, 24:0Alc and 28:0Alc alcohols, and PhWS1 produces wax esters with very long chain fatty acids and methyl, isoamyl short to medium chain alcohols (4–12 carbons), whereas EgWS prefers 14 carbon chain fatty acid as the substrate.

Wax esters consisting of medium chain saturated fatty alcohols are sporadically found in animals and microorganisms [40–43]. *E. gracilis* can accumulate up to 28 or 62% of the total lipid as wax esters when grown in aerobic or anaerobic conditions [3] and the major molecular species of the wax esters accumulated is myristyl myristate [4, 6]. Functional expression of *EgFAR* and *EgWS* separately in yeast revealed that both enzymes could use 14 and 16 fatty acid substrates and the co-expression of *EgFAR* and *EgWS* in yeast resulted in production of medium-chain wax esters. These results are consistent with the composition of wax esters naturally present in *Euglena*, suggesting an important role of EgFAR and EgWS in synthesizing the wax esters in *Euglena*. *EgFAR* and *EgWS* were identified by the homology search of an EST database using jojoba *ScFAR* and *ScWS* as query sequences and only one EST of each EgFAR and EgWS was found in the database. However, it could not be excluded that there are additional genes involved in the biosynthesis of medium-chain wax esters in *Euglena* that were not present in the EST database. It should also be noted that *Euglena* can accumulate unsaturated fatty acid (e.g. 18:1n-9) wax esters when the culture medium is supplemented with such fatty acid [6]. Although we have not observed any activity of EgFAR and EgWS towards 18:1n-9 when they were expressed in yeast, this should not exclude the possibility that the difference of the cellular microenvironment between the native host and yeast could have effect on the substrate specificity of the enzymes. Alternatively, there might be additional FARs and WSs present in *Euglena* that can utilize unsaturated fatty acids as substrates.

Medium- and long-chain wax esters have been widely used in food, pharmaceuticals, textiles, perfumes and flavoring. They can also be used in the production of fatty sulfate salts and alcohol ethoxylates in the detergent industry. The current supply of wax from natural sources is limited due to the high production cost and cannot meet the growing demand for its widespread uses. Metabolic engineering of oilseed plants to produce wax esters has been viewed as an attractive alternative to provide cost-effective sources for biological wax. The first attempt of wax metabolic engineering in plants was undertaken by expressing jojoba *ScFAR* and *ScWS*, along with *Lunaria annua β-ketoacyl-CoA synthase* (a component of fatty acid elongase) resulting in the production of very long chain wax esters in *Brassica napus* seeds [18]. Here, we describe two genes *EgFAR* and *EgWS* from *Euglena* encoding fatty acyl-CoA reductase and wax synthase that have a substrate preference towards medium chain substrates. It will be interesting to see how these genes perform in the production of industrially important medium-chain wax esters in oil seed crops.

Acknowledgments We are very grateful to Patricia Vrinten for technical assistance in gene isolation. We thank Devin Polichuk, Darwin Reed and Valerie Catinot for technical help and discussions. This work is part of ICON, a European Community Seventh Framework Programme.

Received: 13 October 2009 / Accepted: 11 January 2010 / Published online: 4 February 2010

Abstract Fetal bovine serum (FBS) is an important factor in the culture of *Trypanosoma cruzi*, since this parasite obtains and metabolizes fatty acids (FAs) from the culture medium, and changes in FBS concentration reduce the degree of unsaturation of FAs in phosphoinositides. When *T. cruzi* epimastigotes were cultured with 5% instead of 10% FBS, and stearic acid was used as the substrate, Δ^9 desaturase activity decreased by 50%. Apparent K_m and V_m values for stearic acid, determined from Lineaweaver–Burk plots, were 2 μM and 219 pmol/min/mg of protein, respectively. In studies of the requirement for reduced pyridine nucleotide, Δ^9 desaturase activity reached a maximum with 8 μM NADH and then remained constant; the apparent K_m and V_m were 4.3 μM and 46.8 pmol/min/mg of protein, respectively. The effect of FBS was observed only for Δ^9 desaturase activity; Δ^{12} desaturase activity was not affected. The results suggest that decreased FBS in culture medium is a signal that modulates Δ^9 desaturase activity in *T. cruzi* epimastigotes.

Keywords *Trypanosoma cruzi* · Δ^9 Desaturase · Δ^{12} Desaturase · Fetal bovine serum

Abbreviations

ATP	Adenosine triphosphate
FBS	Fetal bovine serum
EDTA	Ethylenediaminetetraacetic acid
FAME	Fatty acid methyl esters
FFA	Free fatty acid
FAs	Fatty acids
HPLC	High performance liquid chromatography
HEPES	(4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid
NADH	Nicotinamide adenine dinucleotide
NADPH	Nicotinamide adenine dinucleotide phosphate
NL	Neutral lipid
PL	Phospholipid
PMSF	Phenylmethylsulphonyl fluoride
PUFAs	Polyunsaturated fatty acids
PC	Phosphatidylcholine
SEM	Standard error of the mean
TLC	Thin layer chromatography

Introduction

Protozoan parasites often encounter unpredictable changes in their environment. Modification of their membrane lipid composition helps maintain the biophysical properties for optimal membrane function, allowing them to cope with environmental changes [1, 2]. *Trypanosoma cruzi*, the etiological agent of Chagas' disease, is an intracellular protozoan that undergoes a complex life cycle between a hematophagous insect vector, *Triatoma infestans*, and a mammalian host. In the intestinal tract of the vector, the replicative non-infectious epimastigotes differentiate to the infectious non-dividing metacyclic forms, a process denominated metacyclogenesis.

It is well known that differentiation of these parasites involves changes in the shape of the cell; consequently the membrane fluidity might be essential for trypanosome

transmission. In *T. cruzi*, it has been demonstrated that the oleic acid present in the intestinal extracts of *T. infestans* induce cell differentiation of *T. cruzi* epimastigotes into the infective metacyclic form [3]. As part of a strategy for surviving in these different environmental conditions, *T. cruzi* adjusts the balance between saturated and unsaturated fatty acids (FAs) in certain membrane lipids [4, 5]. Desaturases are key enzymes in FA metabolism required to regulate physical and biochemical properties of membranes [6]. Desaturases are present in most living cells, and play critical roles in the biosynthesis of polyunsaturated fatty acids (PUFAs). PUFAs serve as precursors of biologically active molecules involved in the activation of a variety of signalling mechanisms that affect cellular functions [7].

The endoplasmic reticulum contains membrane-bound enzymes that remove two hydrogen atoms from the aliphatic chain of a FA to produce a *cis* double bond [8]. Δ^9 Desaturase is of particular interest since FAs that contain a double bond at the central C9–C10 position have a maximal disordering effect on membrane physical properties [9]. Since FAs are the main constituents of membrane glycerolipids, modulation of the number and position of double bonds in acyl chains by individual FA desaturases helps maintain the proper dynamic state of the membrane bilayer during environmental impacts [10]. Temperature changes have been shown to modulate the ratio of saturated to unsaturated FAs in *T. cruzi* [5]. The concentration of fetal bovine serum (FBS) in the culture medium also affects the degree of unsaturation. When the FBS concentration in the culture medium is reduced from 10 to 5%, the proportion of linoleic acid in phosphoinositides decreases [4], suggesting that desaturase activity may be modulated by FBS concentration.

We showed previously that the ratio of unsaturated to saturated FAs increases with growth in culture, as indicated by an increased percentage of linoleic acid (18:2), and that carbamoylcholine increases [^{14}C] labelling of triacylglycerols and diacylglycerols [11]. These findings indicate that unsaturated FAs are important factors during parasite aging and response to environmental stimuli. Initial studies from our laboratory demonstrated de novo biosynthesis of palmitic acid in *T. cruzi* [12], and we showed later that epimastigotes of *T. cruzi* are able to incorporate and metabolize exogenous FAs; palmitic acid is elongated to stearic acid and then desaturated to oleic acid and linoleic acid. These data support the existence of Δ^9 and Δ^{12} desaturases [12, 13]. Molecular characterization of oleate desaturase was conducted in *T. brucei* by Petrini et al. [14], using heterologous expression, and in *T. cruzi* by Maldonado et al. [15].

Genomic analysis of trypanosomatids revealed the presence of front-end desaturase genes, tentatively designated as $\Delta^8\Delta^5\Delta^6$ desaturases for *Leishmania major* and Δ^6 for *T. brucei and T. cruzi*, on the basis of sequence similarity. The desaturases were later characterized as $\Delta^6\Delta^5\Delta^4$ for *L. major,* while only Δ^4 is present in *Trypanosoma*. Functional predictions are never conclusive for desaturases; i.e., biochemical characterization is essential for correct assignment of enzyme regioselectivities [16]. Study of biochemical properties of a parasite's desaturases helps provide insight into their role in parasite response to environmental conditions. Since *T. cruzi* is able to sense changes in FBS concentration, and consequently modulate the degree of unsaturation of phosphoinositide FAs, we used FBS concentration change as a tool to elucidate Δ^9 and Δ^{12} desaturase activities. Reduction of FBS concentration in the parasite culture medium decreased Δ^9 desaturase activity by 50%. Therefore we suggest that the Δ^9 desaturase activity would play a possible role as a regulator of oleic acid level and could be implied in the regulation of membrane fluidity necessary for parasite transmission. Partial biochemical characterization of *T. cruzi* Δ^9 and Δ^{12} desaturases using subcellular fractions and radioactive FAs is also described.

Experimental Procedure

Materials

Solvents were either analytical or HPLC grade. Lipid standards were from Sigma Chemical Co. (St Louis, MO, USA). Culture media were from Merck (Germany) or Difco (USA). FBS was from Natocor (Argentina).

Parasite Strain and Growth Conditions

The Tulahuen strain of *T. cruzi* was used. Epimastigote forms were grown at 28 °C in modified Warren's medium [17] as described by Racagni et al. [18]. The medium was supplemented with 5 or 10% FBS and 1,000,000 U penicillin per 4×10^7 parasites. Cells in the logarithmic growth phase (5 days old) were harvested by centrifugation at 4,500*g* for 10 min. The weight of harvested cells and the number of mobile cells per mL culture medium was measured.

Enzyme Extraction

Cells were weighed, frozen at −180 °C and thawed three times. Broken cells were homogenized 1:5 (w/v) in 50 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), pH 7.4 containing 0.25 M sucrose, 5 mM KCl, 1 mM ethylenediaminetetraacetic acid (EDTA), and protease inhibitors (1 μg/mL leupeptin, 1 mM phenylmethylsulphonyl fluoride (PMSF), 1 μg/mL aprotinin). The

homogenate was centrifuged using three sedimentation steps: 1,000*g* for 10 min, 25,000*g* for 12 min, and 105,000*g* for 60 min. Supernatants of 25,000*g*, and 105,000*g*, and the pellet of the 105,000*g* centrifugation, were used for determination of desaturase activity.

Enzymatic Assays

Δ^9 desaturation of [1-^{14}C]palmitic acid or [1-^{14}C]stearic acid was estimated in subcellular fractions of *T. cruzi* by measuring the formation of [1-^{14}C]palmitoleic acid or [1-^{14}C]oleic acid, respectively. The reaction mixture consisted of 41.7 mM potassium phosphate buffer (pH 7.4), 0.25 M sucrose, 0.15 M KCl, 41.7 mM NaF, 5 mM $MgCl_2$, 1.6 mM *N*-acetyl-cysteine, 60 μM CoA (sodium salt), 1.3 mM adenosine triphosphate (ATP), 0.87 mM nicotinamide adenine dinucleotide (NADH), 3.1 μM of [1-^{14}C] palmitic or stearic acid, and 0.2 mg microsomal protein, in a total volume of 750 μL [19]. For determination of Δ^{12} desaturase activity, [1-^{14}C]oleic acid as substrate and 0.8 mg protein were used. After 1 min preincubation at 37 °C, the reaction was initiated by addition of microsomal protein, and mixtures were incubated in open tubes for 15, 5, or 25 min, respectively, for stearic, palmitic, or oleic acid as substrate. The desaturation reaction was stopped by:

(a) 10% KOH in ethanol, followed by saponification at 80 °C for 45 min under N_2 atmosphere. The unsaponified fraction was extracted twice with 2 mL petroleum hydrocarbon (b.p. 30–60 °C), and discarded. After acidification with HCl, FAs were extracted three times with petroleum hydrocarbon, solvent was evaporated under N_2, and FAs were dissolved in 50 μL petroleum hydrocarbon. Finally, FAs were separated on thin layer chromatography (TLC) plates of silica gel G impregnated with 4% $AgNO_3$ (w/v), using toluene as solvent.

(b) Alternatively, the enzyme reaction was stopped by the addition of an appropriate volume of chloroform/methanol (2:1, by vol) [20] if phospholipids (PL) were to be isolated. The lower phase was dried down under stream of nitrogen and PL were isolated from this total lipid extract by TLC.

Lipid Extraction

Total lipids were extracted from washed parasites by the acidified extraction procedure of Bligh and Dyer [20], and 0.1 M KCl in 50% methanol was added to obtain a lower chloroform phase and an upper phase. The lower phase, containing lipids, was washed once with KCl solution, dried under N_2, and dissolved in an appropriate volume of chloroform/methanol (2:1, by vol).

Processing of Radioactive Samples

Separation and Analysis of PL and Neutral Lipids

Aliquots of the total lipid extracts were subjected to TLC to separate the total PL fraction from the neutral lipid (NL), using hexane/ethyl ether/acetic acid (80:20:1, by vol) as solvent. Following TLC, lipids were located by exposing the plates either to iodine vapour (for radioactivity analysis), or to UV light after spraying with 2,7′dichlorofluorescein in methanol (for further analysis of FAs).

Separation and Analysis of Labelled Fatty Acids from Lipids

Fatty acid methyl esters (FAME) were prepared from the lipid fractions separated by TLC with 10% BF_3 in methanol [21], or from FAs saponified with 10% KOH in ethanol. Labelled FAME were resolved according to their degree of unsaturation on TLC plates of silica gel G impregnated with 4% $AgNO_3$ (w/v), using toluene as solvent. FAME bands were located under UV light after spraying the plates with dichlorofluorescein, eluted [22], and evaporated to dryness at 35 °C, in counting vials. Then, 3 mL of Optiphase Hisafe 2 (PerkinElmer, USA), liquid scintillant was added to each vial, and the radioactivity was measured using a liquid scintillation counter (Beckman LS 60001 C, USA) [23].

Analysis of FBS Fatty Acids

Aliquots of FBS total lipids were subjected to methanolysis as described for labelled samples, in order to prepare FAME from FAs. BF_3 in methanol was added to lipids previously evaporated to dryness in screw-cap tubes. Tubes were added with N_2, sealed, and kept overnight at 45 °C. The resulting FAME were purified by TLC using hexane/diethyl ether (95:5, by vol), on plates of silica gel G pre-washed with methanol/diethyl ether (75:25, by vol). FAME were recovered from the silica support by agitation with water/methanol/hexane (1:1:1, by vol), followed by centrifugation, hexane extraction was repeated three times. FA analysis was performed using a Varian 3700 gas chromatograph equipped with two glass columns (2 m × 2 mm) packed with 15% SP 2330 on Chromosorb WAW 100/120 (Supelco Inc., Bellefonte, PA) and two flame ionization detectors. The column oven temperature was programmed from 155 to 230 °C at a rate of 5 °C/min. Injector and detector temperatures were 220

and 230 °C, respectively; the carrier gas was N_2 with a flow rate 30 mL/min.

Statistical Analysis

Results are shown as the means ± SEM for at least three independent experiments. Statistical analysis of data was carried out using Origin Pro 8 Copyright © 1991–2008.

Results

Effect of FBS on Δ^9 and Δ^{12} Desaturase Activities

FBS is essential for culturing *T. cruzi* epimastigote forms. The parasite obtains and metabolizes FAs from the culture medium, and a decrease in FBS concentration alters the degree of FA unsaturation of the signalling lipid [4]. In order to test the hypothesis that FBS concentration modulates desaturase activities, we first determined the FA composition of FBS. The major FAs were palmitic acid (16:0; 23.56%), stearic acid (18:0; 12.33%), and oleic acid (18:1n-9; 23.92%). Arachidonic acid (20:4n-6) and other long-chain FAs were detected in small amounts. To assess the effect of FBS concentration on desaturase activities, parasites were cultured with 5 or 10% FBS (control). 5% FBS decreased Δ^9 desaturase activity by 50% when stearic acid was used as the substrate. The FBS concentration had no effect on activities of Δ^9 with palmitic acid or Δ^{12} with oleic acid as substrates (Fig. 1). Specific activity of Δ^9 desaturase with 5% FBS and stearic acid as substrate was lower than that with 10% FBS, and was higher in the 105,000*g* pellet than in the supernatant (Table 1). The

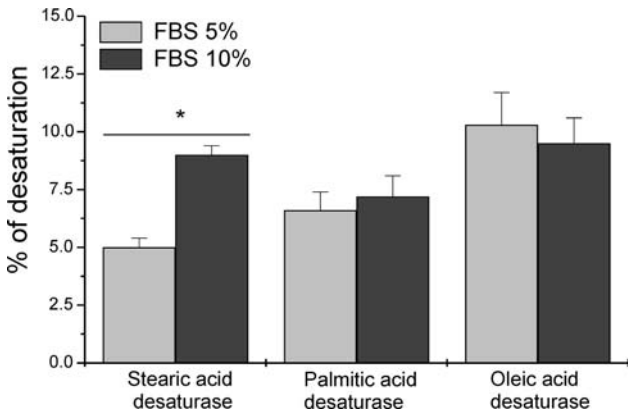

Fig. 1 Effect of fetal bovine serum (FBS) concentration on *T. cruzi* desaturase activities. Parasites were grown with 5 or 10% FBS and harvested at the logarithmic phase of growth (5 days). Δ^9 Desaturase was determined using [1-^{14}C]palmitic acid or [1-^{14}C]stearic as substrate. Δ^{12} Desaturase was assayed using [1-^{14}C]oleic acid as substrate. Results are expressed as percent of desaturation ± SEM, $n = 4$, * $P < 0.05$, *t* test

number of parasites decreased by 30% when they were cultured with 5% instead of 10% FBS (data not shown).

Kinetic Parameters of Desaturases

Δ^9 Desaturase

In view of our previous finding that palmitic acid is elongated to stearic acid and then desaturated to oleic acid and linoleic acid when these substrates are added to culture medium [13], we tested the possibility that both palmitic and stearic acids are substrates of Δ^9 desaturase. Δ^9 Desaturase activity increased up to 140 pmol/min/mg of protein within a stearic acid concentration range of 2.5–3.0 μM (Fig. 2). Apparent K_m and V_m values, determined from a Lineaweaver–Burk plot, corresponded to 2 μM and 219 pmol/min/mg of protein, respectively (Fig. 2, inset). In a study of requirement for reduced pyridine nucleotide, Δ^9 desaturase activity reached a maximum value with 8 μM NADH, and then remained constant (Fig. 3). Apparent K_m and V_m were 4.3 μM and 46.8 pmol/min/mg of protein (Fig. 3, inset). Reduced coenzyme nicotinamide adenine dinucleotide phosphate (NADPH) had the same effect as NADH; both formed 38% of oleic acid. Δ^9 Desaturase required a shorter incubation time when the substrate was palmitic acid; desaturase activity increased until 5 min, and decreased at longer times (data not shown). For palmitic acid, apparent K_m and V_m were 1.33 μM and 58.8 pmol/min/mg of protein (data not shown).

Δ^{12} Desaturase

In view of our finding that the level of diunsaturated FAs was altered by 5% FBS in phosphoinositides, we examined the possibility that Δ^{12} desaturase could be responsible for these changes and be affected by FBS. Δ^{12} Desaturase activity as a function of substrate concentration is shown in Fig. 4. Enzyme activity deviated from Michaelis–Menten kinetics at oleic acid concentrations above 10 μM; however, such an effect is unlikely to occur in vivo since the endogenous substrate concentration is much lower. Apparent K_m and V_m values determined from a Lineweaver–Burk plot were 1.03 μM and 2.8 pmol/min/mg of protein (Fig. 4, inset). There was no difference between NADPH and NADH requirements (data not shown).

Effects of Protein Concentration and Preincubation Time on Desaturase Specific Activities

The effects of the variation in microsomal protein concentration on enzyme activity were tested at 3.02 μM for stearic acid and at 2.6 μM for oleic acid. When the

microsomal protein concentration increased, Δ^9 desaturase activity increased linearly up to 0.2 mg, and Δ^{12} desaturase activity increased up to 0.8 mg, beyond these protein concentrations, a linear relationship was no longer observed (Fig. 5a, b).

Activity of Δ^9 desaturase required a shorter preincubation time than that of Δ^{12} desaturase. Δ^9 desaturase activity increased up to 15 min, and decreased thereafter (Fig. 6). For Δ^{12} desaturase, maximum activity was observed at 35 min (data not shown). However, it is possible that

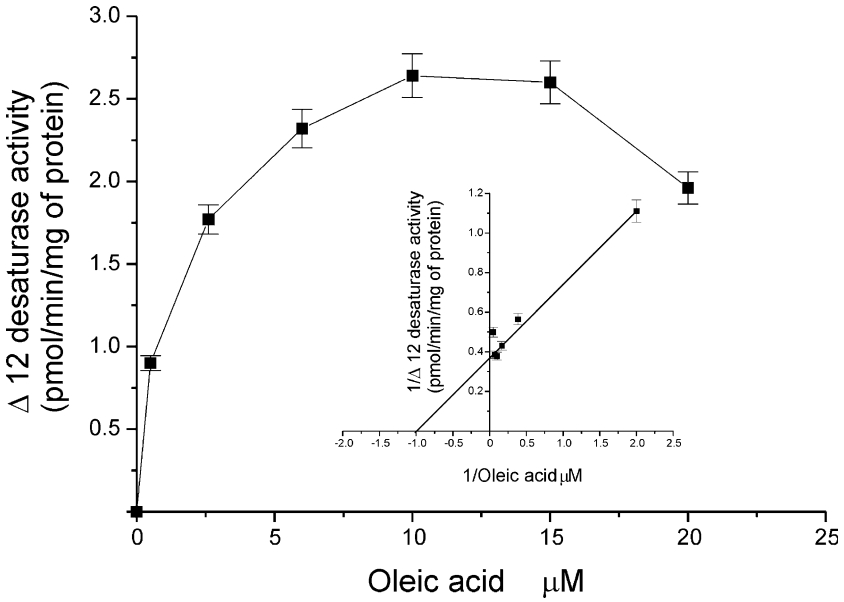

Fig. 4 Effect of [1-^{14}C]oleic acid concentration on *T. cruzi* Δ^{12} desaturase activity. Incubation was performed at 37 °C for 25 min, under the conditions described in "Experimental Procedure". Fig. 5 Effects of 105,000*g* pellet protein concentration on *T. cruzi* Δ^9 (**a**) and Δ^{12} (**b**) desaturase activities. Protein concentration varied from 0.05 to 0.4 mg for Δ^9 desaturase activity, and from 0.2 to 1 mg for Δ^{12} desaturase activity. Incubation was performed at 37 °C for 15 min and 25 min, for Δ^9 and Δ^{12} desaturase, respectively. Reaction conditions are described in "Experimental Procedure". Values are means ± SEM of three separate experiments

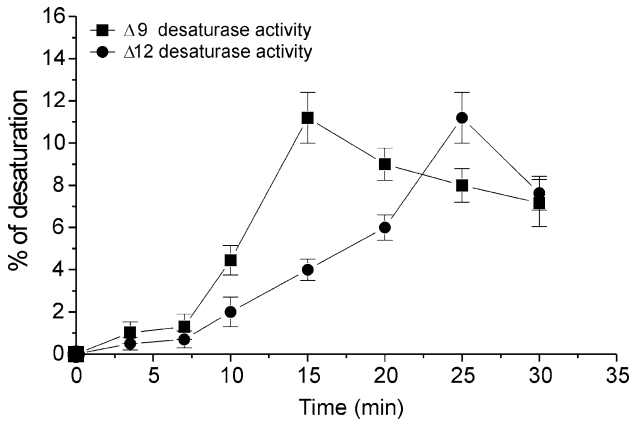

Fig. 6 Effect of incubation time on desaturase activities, determined as described in "Experimental Procedure". 18:0 and 18:1n-9 were used as substrates to test Δ^9 and Δ^{12} desaturase activity, respectively. Values are means ± SEM of three separate experiments

products of non-specific elongation of oleate, linoleate, or FA with the double bond in different positions were formed at this time, giving rise to other desaturase activities. For this reason, Δ^{12} desaturase activity was assayed at 25 min in subsequent experiments.

Other Biochemical Properties of Δ^9 Desaturase

In view of our previous finding that palmitic acid added to the culture medium is metabolized and incorporated into complex lipids by *T. cruzi* epimastigotes [13], we tested the behavior of palmitic acid with the microsomal fraction enzyme source.

Table 2 Effect of time on incorporation of [1-^{14}C] palmitic acid in lipids

Time (min)	Incorporation of radioactive substrate (%)		
	2	5	10
Lipid fractions			
FFA	63.0 ± 1.5	55.6 ± 1.1	45.5 ± 1.7
NL	21.5 ± 1.9	24.8 ± 1.5	24.6 ± 0.1
PL	15.5 ± 1.1	19.5 ± 0.4	29.8 ± 1.8

Incorporation of [1-^{14}C] palmitic acid in neutral lipids (NL) and phospholipids (PL) was followed for 2, 5, and 10 min. Lipids were extracted as described by Bligh and Dyer [20], and different fractions were obtained by TLC. Values represent means ± SEM of three independent experiments

Incorporation of [1-C^{14}]palmitic acid in lipids was dependent on incubation time. We observed different effects on the radioactivity detected in free fatty acid (FFA), NL and PL fractions, especially at 2 vs. 10 min incubation time (Table 2). The greatest radioactivity increase in PL (from 15.5 ± 1.1 to 29.8 ± 1.8%, $n = 3$, $P < 0.05$) and the greatest decrease in FFA (from 63.0 ± 1.5 to 45.5 ± 1.7%, $n = 3$, $P < 0.05$) were found at 10 min. In the presence of reduced coenzymes, a 26% increase in radioactivity incorporation in PL was observed at 10 min (data not shown). FFA showed the highest radioactivity at all times tested. Since [1-^{14}C]palmitic acid was incorporated in PL, the function of phosphatidylcholine (PC) as substrate of *T. cruzi* desaturases was confirmed using 1,2 di [1-^{14}C] palmitoylphosphatidylcholine.

Since it is possible that 1,2 di [1-^{14}C] palmitoylphosphatidylcholine is hydrolyzed before serving as a substrate of desaturases, levels of radioactivity on complex lipids and FFA were tested at various incubation times. Over 93% (93.6 ± 2.2, $n = 12$) of total radioactivity was recovered in PL at 30 min, indicating that hydrolysis did not occur. After testing desaturase activity using 1,2 di [1-^{14}C] palmitoylphosphatidylcholine as substrate, FAs were saponified, FAME were obtained, and analyzed by $AgNO_3$ TLC. When the reaction time was 5 min, 17% of the radioactivity was observed in monounsaturated FAs, and the amount of label increased by 29.1% at 10 min. As a consequence, radioactivity in saturated FAs decreased from 64 to 51% between 5 and 10 min. About 19% of radioactivity was found in the diunsaturated FA fraction, suggesting that 1,2 di [1-^{14}C] palmitoylphosphatidylcholine may also be a desaturase substrate in *T. cruzi*.

Discussion

Our previous biochemical studies showed that the FA composition of *T. cruzi* phosphoinositides is significantly altered by decreased FBS concentrations in culture medium [4], and that the FBS concentration is a key factor for growth of *T. cruzi* epimastigote forms in culture. In the present study, we examined the effect of FBS concentration on Δ^9 and Δ^{12} desaturase activities in *T. cruzi* epimastigotes, in relation to our previous findings. When stearic acid was the substrate and the FBS concentration was lowered from 10 to 5%, epimastigotes were able to modify Δ^9 desaturase; consequently, oleic acid levels were also lower than at 10% FBS. Thus, a smaller amount of substrate was available for Δ^{12} desaturase. This could explain the decreased level of linoleic acid in phosphoinositides we had observed previously [4]. Modulation of desaturase activity occurs only in the presence of FAs that serve as substrates of the enzyme. In *T. cruzi*, a decrease in FBS leads to a reduction in Δ^9 desaturase activity, since a decrease in the stearic acid level from FBS occurred when the concentration was 5%. In contrast, when palmitic acid was the substrate, FBS was not able to modify Δ^9 desaturase activity. Since the palmitic acid level is twice that of stearic acid in FBS, its variation in the culture medium may affect Δ^9 desaturase activity for palmitic acid to a lesser extent. The low susceptibility of Δ^{12} desaturase to FBS concentration suggests a significant role of this enzyme in the synthesis of linoleic acid. Availability of oleic acid may be responsible for the decrease in diunsaturated FAs when parasites are cultured with 5% FBS [4].

Furthermore, since the decrease in FBS concentration also implicates a decrease in the oleic acid level, we alternatively considered that the oleic acid level produce by Δ^9 desaturase activity could also be a signal for triggering the differentiation in the parasite [3].

Modification in the degree of unsaturation of FAs in *T. cruzi* was also observed by Florin-Christensen et al. [5] when epimastigotes were transferred from 28 to 37 °C, reflecting a response to environmental conditions. In the present study, desaturase activity was detected in all fractions studied, indicating a complex distribution pattern as shown for *Tetrahymena pyriformis* [24]. In *T. cruzi* epimastigotes, Δ^9 desaturase showed highest specific activity in the 105,000*g* pellet, similarly observed in mammals and yeast [25–27]. K_m values obtained for *T. cruzi* desaturases show that the same amounts of palmitic, stearic, and oleic acids are required for both desaturases to reach 50% of the maximum velocity. However, once K_m is reached, desaturation of stearic acid by Δ^9 desaturase occurs 3.7 times faster than for palmitic and 78 times faster than for oleic acid by Δ^{12} desaturase. Thus, Δ^9 desaturase is capable of using palmitic acid CoA and stearic acid CoA in spite of the differences in the V_m value. This is consistent with results in mice, where four Δ^9 desaturase isoforms capable of using palmitic acid and stearic acid CoA were reported [28]. Palmitic acid desaturation increased up till 5 min,

whereas enzyme activity increased until 15 min when stearic acid was the substrate. These findings suggest that desaturases use palmitic acid first, the product of de novo synthesis in *T. cruzi,* and then stearic acid. These time courses are consistent with a normal precursor–product metabolic relationship, implying sequential synthesis.

In addition to acyl-CoA desaturases as found in animals and fungi, FAs in plants and cyanobacteria are desaturated by acyl-lipid desaturases [29].

The phylogenetic relationships among Δ^4/Δ^5 desaturases in lower eukaryotes and Δ^6 desaturase from cyanobacteria were analyzed by Tripodi et al. [16]. Our results suggest that *T. cruzi* can desaturate FAs esterified to a phosphoglycerolipid, similarly to *Synechococcus*. In this algal genus, the acyl-lipid Δ^9 desaturase also uses palmitic acid esterified to phosphoglycerides [30]. In contrast, in *Synechocystis*, acyl-lipid Δ^9 desaturases are specific to stearic acid esterified at the C-1 position of a glycerolipid [29].

Both mono and diunsaturated FAs were produced when 1,2 di [1-^{14}C] palmitoylphosphatidylcholine was used as substrate. Desaturation by *T. cruzi* is comparable to the oleic acid desaturation systems in yeast [31] and in *Tetrahymena pyriformis* [32], in that one substrate may be a phospholipid. The *Acanthamoeba castellanii* desaturase, on the other hand, uses only FAs linked to phospholipids [33]. FAD2 microsomal Δ^{12} desaturases in higher plants use FAs esterified to a phosphoglycerolipid backbone, although the FAD2 enzyme does not display a preference for either *sn*-1 or *sn*-2 position [25]. Biochemical characterization of Δ^{12} desaturases from insects indicates that they use acyl-CoA substrates [34]. In *T. cruzi*, desaturation of stearic acid increased up to 15 min and formation of linoleic acid from oleic acid increased up to 35 min, at a much slower rate, suggesting that the activities of the two enzymes are coupled. Gabrielides et al. [35] obtained similar results for *Neurospora.*

T. cruzi desaturases appear to be related to other microsomal Δ^9 and Δ^{12} desaturases, since they show substrate requirements similar to those of microsomal desaturases in higher plants and fungi [36, 37]. Regarding the influence of microsomal protein concentration, the activities of both enzymes showed the same behavior: a breakdown in the linearity in the same concentration range. Since either stearic acid or oleic acid was rapidly incorporated into phospholipids, less substrate may be available for Δ^9 or Δ^{12} desaturation. This could explain the observation that an increase in microsomal protein above 0.2 mg for Δ^9 desaturase, or 0.8 mg for Δ^{12} desaturase, produces a decrease in conversion of stearic acid to oleic acid, or oleic acid to linoleic acid. It is possible that incorporation of the FA substrate in microsomal lipids competes with the desaturation reaction, as suggested by Irazú et al. [38]. Reduced coenzymes NADH and NADPH showed similar effects on desaturation, indicating that they both yield electrons in similar amounts for the enzymatic system. Similar requirements have been reported by Fukushima et al. [39] for *T. pyriformis* MT-1, and by Shipiro and Prescott [24] for *T. pyriformis* W. In *T. pyriformis* W, NADH is three times more efficient than NADPH as an electron donor for this reaction.

We observed that the decreased percentage of radioactivity in free palmitic acid was due to its incorporation into complex lipids, which depended on incubation time (Table 2). These results are consistent with those for *T. cruzi* by Florin-Christensen et al. [5]. These authors explained the process as part of a mechanism for adaptation to different temperatures, and proposed a role of triacylglycerides and sterol esters for storage of FAs in membrane lipids. In our study, incorporation of radioactivity from [1-^{14}C]palmitic acid into PL was at a maximum at 10 min, and was enhanced in the presence of reduced coenzymes. This increase could have resulted from an increase in (1) desaturase activities that form unsaturated FAs efficiently; those would then be incorporated into PL by specific acyl transferases; (2) activity of elongases, which also require an electron donor, and whose products (FAs with a chain length greater than that of palmitic acid) would be incorporated by specific acyl transferases; (3) acyl transferase activities resulting from an increased concentration of FA substrates formed during NADH-dependent reactions. In view of previous and present findings, possibility (1) seems most likely.

In summary, the present results demonstrate the participation of *T. cruzi* Δ^9 desaturase in responses to environmental changes, which enhance our understanding of lipid metabolism in this parasite. Since 18:1n-9 induces cell differentiation to infective forms in *T. cruzi* [3], Δ^9 desaturase can be a potential target to attack parasite transmission and consequently, the determination of Δ^9 desaturase activity provides information that may also lead to improved design of chemotherapy drugs against Chagas' disease.

Abstract Long-chain saturated fatty acids such as palmitic acid induce insulin resistance and NF-κB activation in skeletal muscle cells. Here we investigated the effects of long-chain fatty acid (FA) saturation and configuration on NF-κB activity and insulin sensitivity in cultured skeletal muscle cells. Of all tested unsaturated FAs, only elaidic acid (3-fold), *cis*9,*trans*11-CLA (3-fold) and *trans*10,*cis*12-CLA (13-fold) increased NF-κB transactivation in myotubes. This was not accompanied by decreased insulin sensitivity (measured as insulin-induced glucose uptake and GLUT4 translocation). We therefore conclude that FA-induced NF-κB activation is not sufficient for the induction of insulin resistance in skeletal muscle cells.

Introduction

Although the molecular mechanisms underlying the pathogenesis of insulin resistance are still not fully understood, different lines of evidence support the notion that elevated concentrations of plasma free fatty acids (FA) play an important role [1–3]. A relation between the activation of the transcription factor-κB (NF-κB) and FA-induced insulin resistance in skeletal muscle in humans has been proposed [1]. In addition, studies in cultured skeletal muscle cells have shown that the saturated FA palmitate (C16:0) not only induces insulin resistance [4–7] but also activates the NF-κB pathway, which results in the production of pro-inflammatory cytokines such as interleukin-6 (IL-6) and tumor necrosis factor (TNF)-α [8–10]. Still, a causal relationship between NF-κB activation and FA-induced skeletal muscle insulin resistance is disputable [11–15]. Recently, we reported that the differential effects of SFAs on NF-κB activation and insulin resistance in

skeletal muscle cells depend on FA chain length [16]. Incubation with palmitic acid (C16:0) and stearic acid (C18:0) resulted in insulin resistant skeletal muscle cells showing increased NF-κB activation, while incubation with the shorter saturated FAs caprylic acid (C8:0) and lauric acid (C12:0) did not trigger these effects. Effects of individual FAs with the same long-chain length, but with differences in the degree of saturation or in *cis–trans* configuration have not yet been systematically evaluated. To investigate if the association between long-chain SFA-induced NF-κB activation and insulin resistance in skeletal muscle cells can be generalized to all long-chain FAs (≥16 carbon atoms), we investigated the effect of saturation and configuration on long chain FA-induced NF-κB activity in relation to insulin sensitivity in cultured skeletal muscle cells.

Materials and Methods

Cell Culture

The C2C12 murine skeletal muscle cell line (ATCC CRL1772; Manassas, VA), stably transfected with the 6κB-TK-luciferase, was used for the assessment of NF-κB transcriptional activity as described previously [16–18].

The L6 rat skeletal muscle cell line, stably transfected with a construct encoding GLUT4 with an exofacial *myc* epitope (L6-GLUT4*myc*) was kindly provided by Dr. Amira Klip from the Hospital for Sick Children, Toronto, ON, Canada. Cells were cultured and [^{3}H]-deoxyglucose uptake, GLUT4 translocation and NF-κB DNA binding by electrophoretic mobility shift analysis (EMSA) was determined as described previously [16]. All experiments for both cell lines were performed in 5-day differentiated myotubes.

Fatty Acid Incubations

Stock solutions of 40 mmol/l were made in ethanol for all FAs (palmitic, palmitoleic, stearic, oleic, elaidic, vaccenic, linoleic, α-linolenic, arachidonic acid, EPA, DHA (all from Sigma, St. Louis, MO) and *cis*-9, *trans*-11 CLA and *trans*-10, *cis*-12 CLA (Bio-connect, The Netherlands). FAs were conjugated to bovine serum albumin (BSA) [16] prior to addition to the cells. For every type of measurement, the experimental set-up was chosen to include all comparisons between saturated and unsaturated FA as reported.

Statistical Analysis

SPSS (version 16.0) was used for statistical analysis. Values for NF-κB transcriptional activity and [^{3}H]-deoxyglucose uptake measurements were analyzed by one-way ANOVA, and the various treatment groups ($N = 3$) were compared post hoc with Bonferroni correction, in which a p value of ≤0.05 was considered significant.

Results and Discussion

To test whether the previously reported effects of long-chain SFAs on NF-κB activation in skeletal muscle [9, 11, 16] are also present after incubation with monounsaturated (MUFAs) and polyunsaturated FAs (PUFAs), we incubated C2C12 myotubes, stably transfected with an NF-κB sensitive reporter construct, with a variety of FAs. The concentrations FA used in this study are within the range of those found in the plasma of healthy and diabetic subjects [19–21].

The incubation time and FA concentration were optimized for palmitic acid [16] and used for all other FAs tested. In contrast to palmitic acid (C16:0) and stearic acid (C18:0), their mono-unsaturated counterparts [palmitoleic (C16:1) and oleic (C18:1) acid] did not induce NF-κB transactivation in C2C12 skeletal muscle cells (Fig. 1a). Also poly-unsaturated FAs with the same chain length as stearic acid [linoleic (C18:2) and α-linolenic (C18:3) acid] did not show these effects. The absence of activation of NF-κB for these FAs was confirmed in another skeletal muscle cell line, by performing an EMSA for the assessment of RelA DNA binding in L6 myotubes (Fig. 1b).

Deoxyglucose uptake increased ∼4-fold following insulin stimulation of vehicle treated myotubes (Fig. 1c). Pretreatment with the different mono- and polyunsaturated FAs resulted in a similar increase in insulin-induced deoxyglucose uptake (between 3.5- and 4-fold increase compared to their respective vehicle controls), while C16:0 and C18:0 decreased insulin-stimulated deoxyglucose uptake by ∼60 and ∼80%, respectively, compared with vehicle control. These results were confirmed by GLUT4 translocation measurements (Fig. 1d) and are in line with the notion that NF-κB activation and the occurrence of insulin resistance occur simultaneously, suggesting that NF-κB activation may be causally related to long-chain SFA induced insulin resistance.

These results are supported by several in vitro studies in L6 cells, C2C12 cells or primary myotubes, where no insulin desensitizing and NF-κB activating effects were found for C16:1, C18:1 and C18:2 [4–6, 10, 22]. However, Sinha et al. [11] reported an increased NF-κB DNA binding and insulin resistance in L6 myotubes after incubating with C16:0 or C18:2, whereas no effects were found for C18:3 incubation. A possible explanation for this discrepancy may lie in the fact that the experiments by Sinha and co-workers were performed for 6 h, while the other studies

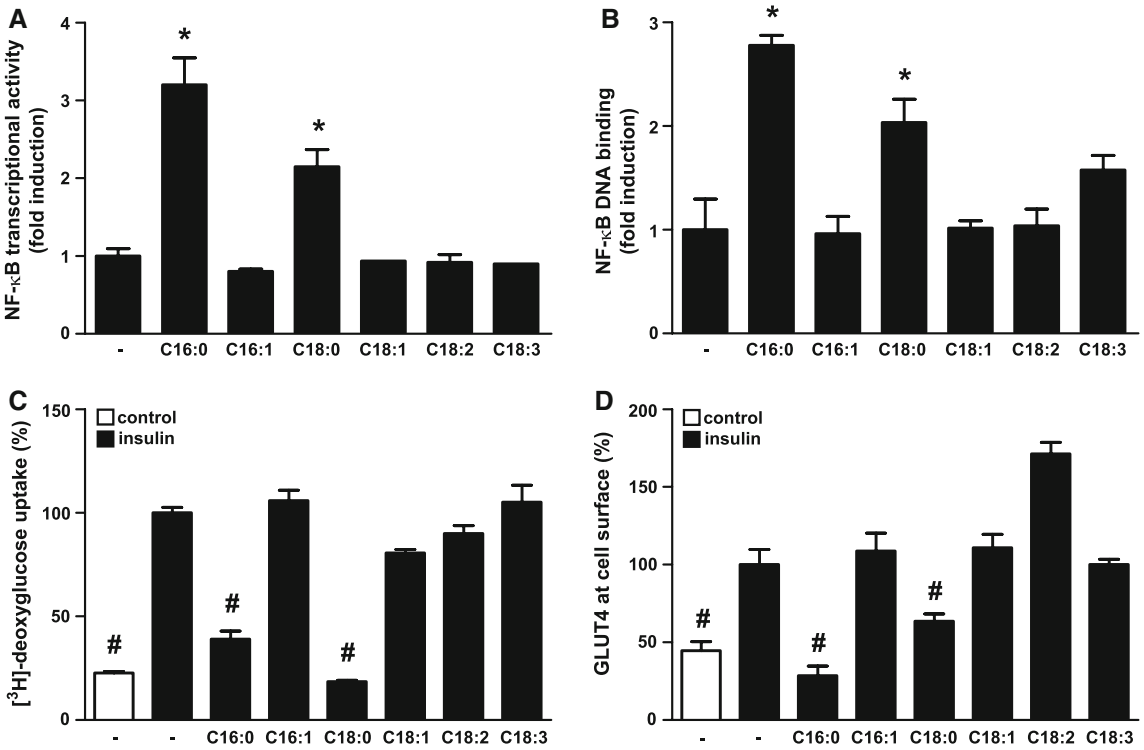

Fig. 1 NF-κB transcriptional activity and insulin sensitivity in skeletal muscle cells after incubation with C16 or C18 FAs differing in degree of saturation. C2C12 myoblasts stably transfected with the 6κB-TK-luciferase construct were differentiated for 5 days and incubated with 400 μmol/l of the indicated FAs for 24 h (**a**). Lysates were prepared for assessment of luciferase activity. Values were corrected for protein content and expressed as fold-induction over control. Alternatively, 5 days differentiated L6-GLUT4myc myotubes were incubated with and without the indicated fatty acids (200 μmol/l, 16 h). Nuclear extracts were prepared and assessed for RelA DNA binding activity to a consensus NF-κB oligonucleotide by EMSA (**b**). Relative DNA binding activity was determined by phosphor-imager analysis and expressed as fold induction. Furthermore, 2-deoxyglucose uptake (**c**) and GLUT4 translocation (**d**) were measured after stimulation with 25 nmol/l insulin for 15 min in 5 days differentiated L6-GLUT4myc myotubes. Data are expressed as percentage of insulin-stimulated glucose uptake or GLUT4 translocation in absence of FA. Basal and insulin-stimulated conditions are represented by the *white* and *black bars*, respectively. $^{*}p < 0.05$ versus control. $^{\#}p < 0.05$ versus insulin-stimulated control. Data shown are representative examples of three independent experiments

mentioned, including ours, evaluated effects after longer exposure time points.

Besides the *cis*-unsaturated FA described so far, unsaturated FA in our diet can have a *trans* configuration. The main sources of dietary *trans*-MUFA include industrially hydrogenated oils, and dairy products and meat containing ruminant fat. The most abundant MUFA *trans*-FAs found in these groups are elaidic acid (*trans*-9 C18:1) and vaccenic acid (*trans*-11 C18:1), respectively [23]. Of these two tested *trans* isomers of oleic acid, only the incubation of myotubes with elaidic acid resulted in an increased (∼3-fold) NF-κB transactivation compared with vehicle-treated myotubes (Fig. 2a). This might suggest that the position of the *trans* double bound determines the potential of a specific FA to activate NF-κB.

Well-known isomers of linoleic acid are the geometric and positional isomers *cis*-9, *trans*-11 conjugated linoleic acid (CLA) and *trans*-10, *cis*-12 CLA. We found an increased NF-κB transactivation (∼3-fold) after culturing the cells with *cis*-9, *trans*-11 CLA, which was comparable with the magnitude of the effects of C16:0 and C18:0. Since a single double bound at the *cis*-9 (oleic acid) or *trans*-11 (vaccenic acid) position of the C18-backbone did not result in an increased NF-κB transactivation, it is remarkable that the combination of these two double bounds in *cis*-9, *trans*-11 CLA caused an increased NF-κB transactivation. Strikingly, *trans*-10, *cis*-12 CLA provoked a ∼13-fold increase in NF-κB transcriptional activity, which is even higher than could maximally be achieved with the pro-inflammatory cytokine TNF-α (10 ng/ml), the prototypical inducer of NF-κB (routinely 5 to 10-fold induction after 4 h incubation, data not shown). In addition, activation of NF-κB after incubation with *trans*-10, *cis*-12 CLA was confirmed by performing an EMSA for the assessment of RelA DNA binding in L6 myotubes (Fig. 2b).

The fact that elaidic acid and *cis*-9, *trans*-11 CLA did not reveal increased DNA binding might be due to transient

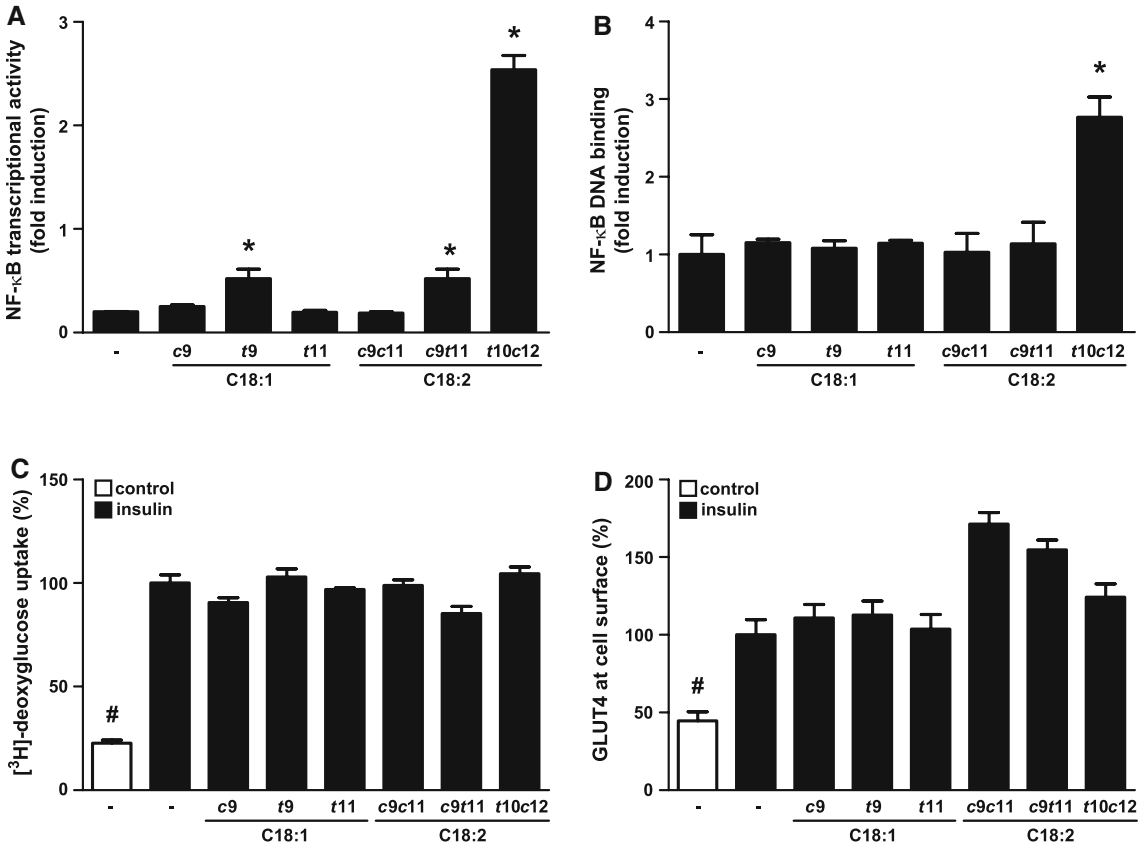

Fig. 2 NF-κB transcriptional activity and insulin sensitivity in skeletal muscle cells after incubation with geometric and positional C18:1 or C18:2 isomers. C2C12 myoblasts stably transfected with the 6κB-TK-luciferase construct were differentiated for 5 days and incubated with 400 μmol/l of the indicated FAs for 24 h (**a**). Lysates were prepared for assessment of luciferase activity. Values were corrected for protein content and expressed as fold-induction over control. Alternatively, 5 days differentiated L6-GLUT4myc myotubes were incubated with and without the indicated fatty acids (200 μmol/l, 16 h). Nuclear extracts were prepared and assessed for RelA DNA binding activity to a consensus NF-κB oligonucleotide by EMSA (**b**). Relative DNA binding activity was determined by phosphor-imager analysis and expressed as fold induction. Furthermore, 2-deoxyglucose uptake (**c**) and GLUT4 translocation (**d**) were measured after stimulation with 25 nmol/l insulin for 15 min in 5 days differentiated L6-GLUT4myc myotubes. Data are expressed as percentage of insulin-stimulated glucose uptake or GLUT4 translocation in absence of FA. Basal and insulin-stimulated conditions are represented by the *white* and *black bars*, respectively. $^{*}p < 0.05$ versus control. $^{\#}p < 0.05$ versus insulin-stimulated control. Data shown are representative examples of three independent experiments

DNA binding, as bi-phasic NF-κB activation in skeletal muscle has been reported, and the use of a reporter construct is less sensitive to transient changes in NF-κB transactivation [24]. Another explanation could be that the demonstrated increase in NF-κB transactivation is based on a mechanism independent from increased DNA binding, for example protein kinase A induced phosphorylation of NF-κB [25].

In spite of the considerable differences in NF-κB activity between the tested C18 *cis* and *trans*-FAs, and in particular between *cis*-C18:2 and C18:2 *trans*-10, *cis*-12 CLA, differential effects were not observed on insulin-stimulated glucose uptake (Fig. 2c) or GLUT4 translocation (Fig. 2d), which were not affected by any of these isomers.

Altogether, our results are in agreement with recent in vitro data, showing no effects on insulin signaling at the level of p-Akt, after incubation of C2C12 myotubes with elaidic and vaccenic acid [26]. The same authors showed that diets enriched in *trans* MUFAs of dairy or industrial origin did not impair muscle insulin sensitivity in Wistar rats. Nevertheless, opposing effects of CLA on insulin sensitivity have been described in rodents: many studies in the obese Zucker rat model describe positive effects on insulin sensitivity [27–29], while studies in mice showed that CLA, and in particular the *trans*-10, *cis*-12 isomer, induces insulin resistance [30–33]. Little is known on the effects of CLA on insulin sensitivity and inflammation in humans. In healthy young men, a diet rich in CLA (5.5 g/day, 5 weeks) did not affect inflammatory and diabetic risk markers [34]. In obese men with metabolic syndrome, supplementation with (3.4 g/day) *trans*-10, *cis*-12 CLA or *cis*-9, *trans*-11 CLA for 12 weeks resulted in an increased insulin resistance [35, 36] and supplementation with

trans-10, *cis*-12 CLA also resulted in increased levels of inflammatory biomarkers in serum [37]. Considering the latter observation and the striking induction of NF-κB by *trans*-10, *cis*-12 CLA in the cultured muscle cells in our study, it appears that *trans*-10, *cis*-12 CLA may initiate systematic inflammatory signaling in multiple tissues, and it remains to be determined if this does have pathological consequences. Finally, we also evaluated the effects of the n-3 FAs eicosapentaenoic acid, docosahexaenoic acid and the n-6 FA arachidonic acid, but none of these FAs affected NF-κB activity or insulin sensitivity (data not shown).

Our results show that the apparent association between SFA-induced NF-κB activation and insulin resistance in skeletal muscle cells cannot be generalized to all long chain FAs. Therefore, the proposed causal role of NF-κB activation in the induction of SFA-induced insulin resistance requires further investigation. It has been proposed that intramuscular accumulation of FA metabolites like diacylglycerol (DAG) [2, 4, 38–40] plays a role in inducing insulin resistance. Increased FA oxidation results in a decreased accumulation of FA metabolites like DAG and a protection against palmitate-induced insulin resistance in skeletal muscle cells [41]. Furthermore, it has been shown that the oxidation rate of FAs in muscle increases proportionally with the number of double bonds [42, 43]. This may explain why C16:0 and C18:0 did [16], but the C16-MUFA and C18-MUFA/PUFAs did not induce insulin resistance.

In conclusion, the results reported here reveal that FA-induced NF-κB activation is not sufficient for the induction of insulin resistance in skeletal muscle cells.

Abstract In the brain, polyunsaturated fatty acids (PUFA), especially arachidonic acid and docosahexaenoic acid (DHA), are required for regulating membrane fluidity, neuronal survival and signal transduction. Since the brain cannot synthesize n-6 and n-3 PUFA de novo, they must be supplied from the blood. However, the methods of PUFA entry into the brain are not agreed upon. This study tested the necessity of CD36, a candidate transporter of unesterified fatty acids, for maintaining brain PUFA concentrations by comparing brain PUFA concentrations in $CD36^{-/-}$ mice to their wild-type littermates. Because $CD36^{-/-}$ mice have been reported to have impaired learning ability, the PUFA concentrations in different brain regions (cortex, hippocampus, cerebellum and the remainder of brain) were investigated. At 9 weeks of age, the brain was separated into the four regions and fatty acid concentrations in total and phospholipid classes of these brain regions were analyzed using thin layer and gas chromatography. There were no statistical differences in arachidonic acid or DHA concentrations in the different brain regions between wild-type and $CD36^{-/-}$ mice, in total or phospholipid fractions. Concentrations of monounsaturated fatty acids were decreased in several phospholipid fractions in $CD36^{-/-}$ mice. These findings suggest that CD36 is not necessary for maintaining brain PUFA concentrations and that other mechanisms must exist.

Introduction

The brain is enriched with long chain polyunsaturated fatty acids (PUFA) especially arachidonic acid (20:4n-6) and docosahexaenoic acid (DHA; 22:6n-3) [1]. These PUFA are considered essential for normal development and function of the brain as they regulate membrane fluidity, neuronal survival [2–4], and neurotransmission [5]. In addition to these functions, altered brain PUFA metabolism has been associated with psychiatric disorders including schizophrenia [6], bipolar disorder [7], and depression [8]. Whereas dietary PUFA deprivation leads to an upregulation of liver arachidonic acid and DHA synthesis via desaturation/elongation of their 18 carbon precursors, linoleic (18:2n-6) and α-linolenic acid (18:3n-3), respectively, synthesis rates within the brain remain low and unchanged [9–11]. As a result, it is important that PUFA are

transported to the brain from the plasma where they are found as unesterified fatty acids, or esterified fatty acids in lipoproteins derived from the liver or diet [12–14].

While the mechanisms of PUFA uptake in the brain have not been fully characterized [15, 16], two models for PUFA entry into the brain through endothelial cells of the blood–brain barrier (BBB) have been proposed: (1) passive diffusion or transporter-mediated uptake of unesterified fatty acids [17–20], and (2) lipoprotein receptor-mediated endocytosis of lipoprotein particles [20, 21]. It has been shown that the low density and very low density lipoprotein receptors are not necessary for maintaining brain PUFA levels, suggesting that other mechanisms exist and are sufficient [22, 23]. Recently the rates of uptake of DHA and arachidonic acid into brain phospholipids from the plasma unesterified pool have been shown to approximate their respective rate of consumption by the brain, suggesting that plasma unesterified fatty acids are a major pool for brain fatty acid uptake [24–26].

Despite evidence for the uptake of plasma unesterified fatty acids into the brain, whether unesterified fatty acids cross the BBB via passive diffusion or via an active transporter is not agreed upon [18, 19]. Consistent with the Hamilton Model [27–29], Ouellet et al. [30] demonstrated that the brain transport coefficient (Clup, $\mu l\ g^{-1}\ s^{-1}$) of [^{14}C]-DHA and [^{14}C]-eicosapentaenoic acid (EPA) was not saturable at super-physiological concentrations, up to 100 μM, suggesting that DHA and EPA cross the BBB by simple diffusion. It was also reported that, upon crossing the BBB, EPA is rapidly β-oxidized possibly explaining its low concentration within the brain [31].

Several proteins facilitate fatty acid transport in various cell types [32–35]; however, the relevance of these proteins to brain PUFA uptake has yet to be explored. CD36 is an integral membrane glycoprotein expressed on the surface of a wide variety of cells including platelets, monocytes, adipocytes, myocytes, hepatocytes, enterocytes, retinal and mammary epithelial cells, microvasculature endothelial cells, and microglia and microvascular endothelial cells of the brain [36, 37]. CD36 is a 'pattern recognition' receptor, dependent on the intracellular concentrations of its ligands [38–40]. Based on its role in fatty acid binding and uptake in other types of cells, BBB endothelial cell CD36 [41–43] is a putative fatty brain acid transporter [12]. In 1999, Febbraio et al. [44] created a CD36 null mutation in mice by targeted homologous recombination. In 2005, Abumrad et al. [12] found that CD36$^{-/-}$ mice have normal activity, anxiety and exploration of novel environments, but have impaired learning ability, which they hypothesized may occur due to an impaired supply of essential PUFA to the brain. This hypothesis is supported by several studies demonstrating that rodents deprived of n-3 PUFA have impaired learning [45–50]. The purpose of this study was therefore to explore the involvement of CD36 in maintaining brain fatty acid concentrations. To do this, total phospholipid fatty acid concentrations of CD36$^{-/-}$ and wild-type mice within specific brain regions were compared. We hypothesized that if CD36 is necessary for maintaining brain PUFA concentrations, then CD36$^{-/-}$ mice will have decreased brain PUFA concentrations. After not finding a difference in total phospholipid fatty acid concentrations, we examined phospholipid classes to assess if specific pools may have been altered.

Materials and Methods

Animals and Treatments

All procedures were carried out in accordance with the policies set by the Canadian Council on Animal Care, and were approved by the Animal Ethics Committee at the University of Toronto (protocol #2000721) and the Cleveland Clinic IACUC. The brain samples of ten male wild-type and ten male CD36$^{-/-}$ mice were provided by the Cleveland clinic (Cleveland, OH). All mice were ten generations backcrossed to C57Bl/6 and littermate derived wild-type mice were used as controls and genotyped as previously described [51]. The mice were raised until 9 weeks of age in the Cleveland clinic in which temperature, humidity, and light cycle were controlled; the animals had ad libitum access to water and food (Teklad 2018S 18% Rodent Diet with Fenbendazole, Madison, WI). The fatty acid percentage compositions of the mouse diet, as measured by gas chromatography, were as follows: 16:0, 15.2%; 18:0, 3.5%; 18:1n-9, 19.6%; 18:2n-6, 51.8%; 18:3n-3, 5.6%; and fatty acids longer than 20 carbons accounted for less than 1% of total fatty acids. By 9 weeks of age, mice have an intact BBB [52], an adult size brain [21], and plateaued brain PUFA concentrations [53, 54]. Hence, mice were euthanized at 9 weeks of age with carbon dioxide and the cortex, cerebellum, hippocampus, and remainder of the brain were extracted. Brain regions were then frozen in liquid nitrogen prior to storage at −80 °C until further analysis.

Brain Lipid Extraction and Gas Chromatography/Flame Ionization Detection

Total lipids were extracted from the brain regions according to the method of Folch, Lees, and Sloane Stanley [55]. Thin layer chromatography (TLC) plates were activated by heating at 100 °C for 1 h. Total lipids were then loaded on a TLC plate and the plate was placed in a tank with solvents. Total phospholipid was separated along with authentic standards in heptane/diethyl ether/glacial acetic

acid (60:40:2, v/v). Phospholipid fractions were separated along with authentic standards in chloroform/methanol/2-propanol/KCl (0.25%, w/v)/triethylamine (30:9:25:6:18, v/v). Bands corresponding to total phospholipid, choline glycerophospholipid (ChoGpl), ethanolamine glycerophospholipid (EtnGpl), phosphatidylserine (PtdSer), phosphatidylinositol (PtdIns), and ceramide phosphocholine (CerPCho) were visualized under ultraviolet light, after lightly spraying with 8-anilino-1-naphthalene sulfonic acid (0.1%, w/v). Bands were scraped into a test tube containing a known amount of unesterified heptadecanoic acid (Nu-Chek Prep, Elysian, MN, USA), and converted to fatty acid methyl esters with 14% boron trifluoride/methanol at 100 °C for 1 or 1.5 h for CerPCho. Fatty acid methyl esters were quantified on a Varian-430 gas chromatograph (Varian, Lake Forest, CA, USA) equipped with a Varian Factor Four capillary column (VF-23 ms; 30 m × 0.25 mm i.d. × 0.25 μm film thickness), and a flame ionization detector (FID). Samples were injected in splitless mode. The injector and detector ports were set at 250 °C. Fatty acid methyl esters were eluted using a temperature program set initially at 50 °C and held for 2 min, increased at 20 °C/min and held at 170 °C for 1 min, then increased at 3 °C/min and held at 212 °C for 10 min to complete the run. The carrier gas was helium, set to a 0.7 ml/min constant flow rate. Peaks were identified by retention times of fatty acid methyl ester standards (Nu-Chek-Prep, Elysian, MN). Fatty acid concentrations (nmol/g brain) were calculated by proportional comparisons of the gas chromatography peak areas with that of the heptadecanoic acid internal standard. The 2018 Teklad Global 18% Protein Rodent Diet was measured in quadruplicate according to the method described above.

Brain Cholesterol Analysis by Gas Chromatography/Mass Spectrometry

A portion of the total lipid stock solution containing total lipids of cortex, cerebellum, hippocampus, or rest of brain, along with 5-α-cholestane as an internal standard were dried down under nitrogen and saponified in 1 M methanolic NaOH at 90 °C for 1 h. The non-saponifiable material containing sterols and glycerol was separated from saponifiable materials by adding saline and hexane, centrifuging (275 g) for 4 min and removing the upper hexane phase containing sterols. The hexane extraction process

and centrifugation was repeated one more time, in order to maximize the cholesterol yield. The sterol fraction containing cholesterol was dried under nitrogen and subsequently derivatized in trimethylsilyl chloride (Pierce, Rockford, IL, USA) at 60 °C for 30 min. The trimethylsilyl chloride was completely evaporated under nitrogen and the remaining derivatized cholesterol fraction was reconstituted with 150–300 µl of hexane for analysis by gas chromatography/mass spectrometry (GC/MS).

Cholesterol was determined by GC/MS using a HP-5 ms capillary column (30 m 9 0.25 mm i.d. 9 0.25 lm film thickness; Agilent Technologies) in an Agilent 6890 series Gas Chromatograph system equipped with an Agilent 5973 Network Mass Selective Detector (Agilent Technologies, Wilmington, DE, USA). The flow rate of helium carrier gas was 1 ml/min. The oven temperature was programmed as follows: 100 °C held initially for 1 min, increased at 15 °C/min to 280 °C and held for 17 min at 280 °C (total run time 30 min). The temperature of the injection port, ion source, and interface were 250, 230, and 280 °C, respectively. The injection volume was 1 µl and a splitless insert was adapted. A mass range from 50 to 700 amu was scanned using an electron ionization energy of 70 eV. Cholesterol trimethylsilyl ester and 5-α-cholestane (internal standard) were quantified on the basis of selected mass fragments.

Statistics

Results are expressed as means ± SD. Means were compared by unpaired, two-tailed *t* tests, with statistical significance set at $P < 0.05$.

Results

Cortex, Hippocampus, Cerebellum and Remainder of Brain Esterified Fatty Acid Concentrations

With the exception of 22:5n-3 in remainder of brain total phospholipids (Table 1) and 20:3n-3 in cortical PdtIns (Table 2) which were statistically lower in CD36$^{-/-}$ mice as compared to controls, no other significant differences in PUFA concentrations were detected (Tables 1, 2, 3, 4, 5). Total phospholipid 18:1n-7 was lower in the cortex of

CD36$^{-/-}$ mice as compared to controls (Table 1), whereas hippocampal EtnGpl 16:0 (Table 3) was significantly lower in CD36$^{-/-}$ mice as compared to controls. In the cerebellum, 16:1n-7 was significantly lower in total phospholipids of CD36$^{-/-}$ mice as compared to wild-type controls (Table 1). 16:1n-7 was also significantly lower in the remainder of brain PtdSer in CD36$^{-/-}$ compared to wild-type (Table 5).

Cortex, Hippocampus, Cerebellum and Remainder of Brain Cholesterol Concentrations

There were no statistically significant differences ($P > 0.05$) in cholesterol concentrations between CD36$^{-/-}$ mice as compared to wild-type controls in the four brain regions measured (Fig. 1).

Discussion

The cortical, cerebellar, hippocampal, and remainder of brain total phospholipid and phospholipid fraction esterified fatty acid as well as cholesterol concentrations from wild-type mice in this study are consistent with other reports [22, 23, 53, 56] and slight discrepancies may be due to differences in diet and brain region analysis [1, 57]. Although the majority of fatty acids were not statistically different, small decreases in monounsaturated fatty acids were detected in total phospholipids and the major phospholipid classes of CD36$^{-/-}$ mice. Although we cannot rule out that these minor differences in monounsaturated fatty acids could have been caused by random chance most of the observed changes were a decrease in the fatty acid concentration within CD36$^{-/-}$ mice, suggesting that the results maybe due to genetic ablation of CD36.

In 2009, Mitchell et al. [43] examined the permeability of oleate (18:1n-9) across primary human brain microvessel endothelial cells (HBMEC) using confluent cells grown on Transwell inserts. The necessity of CD36 in transporting oleate across the HBMEC monolayer was tested by knocking-down CD36 with siRNA. After transfecting with CD36 siRNA for 48 h (the expression of CD36 mRNA on HBMEC was reduced by 52%), the radioactivity of [^{14}C]-18:1n-9 transported into the basolateral medium was

significantly reduced by 42% in 20 min, suggesting that CD36 is involved in the movement of oleate across the HBMEC. Interestingly in our study, although the level of 18:1n-9 was not decreased in CD36$^{-/-}$ mice, levels of 16:1n-7 were decreased in several phospholipid fractions within several regions. The lack of change in 18:1n-9 concentrations in our study is difficult to interpret as the brain is capable of synthesizing 18:1n-9 de novo which may be upregulated to compensate for a decrease in plasma 18:1n-9 uptake in CD36$^{-/-}$ mice. It would be of interest to directly test the uptake rate of plasma unesterified mono- and polyunsaturated fatty acids in CD36$^{-/-}$ and wild-type controls [56, 58–60].

In 2005, Abumrad et al. [61] examined the learning ability of CD36$^{-/-}$ mice using the eight radial arm maze. The maze consisted of multiple arms at the end of which contained a sweetened milk reward. Revisiting an arm where the reward was already obtained was considered an error. Unlike their wild-type littermates, CD36$^{-/-}$ mice showed substantially more errors, indicating a deficit in learning [12]. Since n-3 PUFA deprivation is associated with impaired learning in rodents [45–50] we examined PUFA concentrations in 4 major brain regions of CD36$^{-/-}$ and wild-type mice. There were no significant differences in brain DHA concentrations between wild-type and CD36$^{-/-}$ mice. Therefore, it is not clear if a change in brain DHA concentration may be related to the behavioral deficits in CD36$^{-/-}$ mice.

The lack of a significant difference in brain arachidonic acid or DHA concentrations between CD36$^{-/-}$ and wild-type mice suggests that CD36 is not necessary for maintaining brain PUFA concentrations. Since the brain cannot synthesize n-3 or n-6 PUFA de novo, PUFA likely enter the brain through CD36-independent mechanisms such as passive diffusion [18, 30], lipoprotein receptors including the high density lipoprotein receptor [62], or other fatty acid transporters that have not yet been characterized in the brain endothelium. From our study, it is not possible to conclude that CD36 does not play a role in fatty acid transport. It is possible that CD36 is normally involved in fatty acid transport, but previously mentioned

mechanisms, including changes respective plasma pools or kinetics, or other compensatory mechanism including a decrease in brain PUFA catabolism compensated for a lack of CD36-mediated transport. Cardiomyocytes from CD36$^{-/-}$ have a one-fold increase in fatty acid transport protein 1 (FATP1) which could be a compensatory mechanism in the absence of CD36 [63]. In addition, esterified PUFA might be cleaved from lipoproteins at the BBB by enzymes such as lipoprotein lipase [20] or endothelial lipase [64–66], thus providing another pool from which PUFA can enter the brain.

In conclusion, CD36 has been implicated as a candidate fatty acid transport protein in several tissues. CD36$^{-/-}$ mice have decreased levels of monounsaturated fatty acids in several brain phospholipid pools, but it is not clear if these changes are related to the altered behavior previously reported in these mice. By examining CD36$^{-/-}$ mice, we have demonstrated that brain PUFA levels, especially arachidonic acid and DHA, are not altered, suggesting that other mechanisms to transport PUFA into the brain must exist and are sufficient.

ORIGINAL ARTICLE

Trans-Membrane Uptake and Intracellular Metabolism of Fatty Acids in Atlantic Salmon (*Salmo salar* L.) Hepatocytes

Jishu Zhou · Ingunn Stubhaug · Bente E. Torstensen

Received: 14 September 2009 / Accepted: 3 February 2010 / Published online: 27 February 2010

Abstract To elucidate if the trans-membrane uptake of fatty acids is protein-mediated, the uptake of oleic acid (18:1n-9), linoleic acid (18:2n-6), alpha-linolenic acid (18:3n-3), eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) was investigated in vitro in Atlantic salmon (*Salmo salar* L.) primary hepatocytes. Firstly, optimal fatty acid incubation time and concentration were established for trans-membrane 18:n-9 uptake. Based on saturation kinetics, a 2-h incubation time and 37.5 μM were used for the following experiments. Secondly, in order to identify whether trans-membrane fatty acid uptake in hepatocytes was mainly passive or protein mediated, hepatocytes were pre-incubated with membrane protein inhibitors followed by 2 h of incubation with [1-^{14}C] labelled 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3 and 22:6n-3. Fatty acid uptake into hepatocytes was highest with 20:5n-3 and 22:6n-3 and lowest with 18:1n-9. Phloretin was the most potent fatty acid uptake inhibitor, inhibiting uptake in the following order: 20:5n-3 > 18:3n-3 = 22:6n-3 > 18:2n-6 > 18:1n-9. The uptake of FA in Atlantic salmon hepatocytes seem to be due to both saturable and inhibitable protein mediated uptake, as well as passive uptake processes with more unsaturated and long fatty acids (20:n-3 > 22:6n-3 = 18:3n-3 > 18:2n-6) being more dependent on membrane protein mediated uptake compared to 18:1n-9.

Keywords Fatty acid · Trans-membrane uptake · Fatty acid transport protein (FATP) · Fatty acid translocase (FAT/CD36) · Fatty acid binding protein in plasma membrane (FABPpm) · Transport · Passive diffusion · Atlantic salmon · Hepatocytes · Inhibitors

Abbreviations

DAG	Diacylglycerol
DIDS	Diisothiocyanodisulfonic acid
FABPpm	Fatty acid binding protein in plasma membrane
FATP	Fatty acid transport protein
FAT/CD36	Fatty acid translocase
FFA	Free fatty acid
HEPES	4-(2-Hydroxyethyl)-1-piperazineethane-sulfonic acid
OA	Oleic acid
LCFA	Long-chain fatty acid
MAG	Monoacylglycerol
PBS	Phosphate buffered saline
PL	Phospholipids
SSO	Sulfo-*N*-succinimidyl 4-maleimido-oleic acid ester
SSMB	Sulfo-*N*-succinimidyl 4-maleimido-butyric acid ester
TAG	Triacylglycerol

Introduction

Fatty acids are key nutrients associated with energy production- and storage, gene regulation [1] and essential components in cell membrane phospholipids [2]. With their hydrophobic nature, LCFAs have long been thought to transverse the lipid bilayer of the cell membrane by simple, non-facilitated diffusion [3–8] then by "flip–flop" in the phospholipid bilayer [9, 10]. However, there are several indications of active protein mediated fatty acid (FA) uptake being present in cells. Energy dependency and an ATP-driven pump have been reported to be involved in FA transport across 3T3F4424 adipocytes [11] and rat hepatocyte membranes [12]. Furthermore, there are a number of FA transport proteins identified in the cell membrane of a variety of tissues, such as fatty acid transport proteins 1 to 6 (FATP1–FATP6) [13–15], plasma membrane associated fatty acid binding protein (FABPpm) [16, 17] and fatty acid translocase (FAT/CD36) [18], which are all thought to function as trans-membrane FA uptake proteins.

Protein modifying agents or membrane protein inhibitors has been found to inhibit cellular LCFAs uptake suggesting the existence of membrane protein dependent transport. Examples of such membrane protein modifying agents are phloretin and sulfo-*N*-succinimidyl oleate (SSO) which have been found to inhibit the LCFAs uptake [19, 20]. Both SSO and phloretin have been reported to decrease 18:1n-9 uptake in rat heart and skeletal muscle [21, 22] and SSO has been found to decrease 18:1n-9 uptake in rat adipocytes [23]. Diisothiocyanodisulfonic acid (DIDS), being a non-permeable anion exchange inhibitor [24], and SSO have been reported to decrease palmitate uptake in rainbow trout (*Oncorhynchus mykiss*) red and white muscle vesicles [25]. Furthermore, methyl-β-cyclodextrin is reported to decrease fatty acid uptake by >50% in COS cells through depletion of cholesterol [26].

In Atlantic salmon hepatocytes, FA uptake has been found to significantly decrease when fish were fed dietary vegetable oil based diets compared with fish oil [27], indicating an effect of dietary fatty acids on the expression or activity of fatty acid uptake associated membrane proteins. Furthermore, the mRNA expression of FAT/CD36 and FATP in Atlantic salmon liver, muscle and adipose tissues have been identified and reported to be significantly affected by dietary fatty acid composition in white muscle but not in liver [28]. However, the mechanism of fatty acid uptake in Atlantic salmon tissues and the relative importance among these membrane proteins have not previously been investigated. The aim of the present study was to elucidate the uptake mechanisms and the following intracellular metabolic fate in Atlantic salmon hepatocytes of18:1n-9, and compared to other long chain fatty acids typical for vegetable- and fish oils; i.e. 18:2n-6, 18:3n-3, 20:5n-3 and 22:6n-3 to give indications of the possible relationship between fatty acid uptake rate and metabolism as a driving force for uptake.

Materials

Atlantic salmon were obtained from the Institute of Marine Research (IMR) and fed a commercial diet containing about 48% crude protein, 25% lipid, 13% nitrogen-free extracts (Skretting, Spirit HH200-75A, Stavanger, Norway). Fetal bovine serum (FBS) and GlutaMax were bought from Gibco-brl/Life Technologies (Gaithersburg, MD, USA). Leibovitz L-15, antibiotics (mixture of penicillin, streptomycin and amphotericin B), metacain (MS222), unradiolabelled fatty acids, laminin, butylated hydroxytoluene (BHT), collagenase (Type VIII), fatty acids free bovine serum albumin (BSA) and 4-(2-hydroxyethyl)-1-piperazineethane-sulfonic acid (HEPES), perchloric acid, diethylether, methyl acetate, isopropanol, isohexane, acetic acid, chloroform, methanol, sodium chloride (NaCl), potassium chloride (KCl), ethylenediaminetetraacetic acid (EDTA), were all obtained from Sigma Chemical Co. (Poole, UK). Nylon gauze (100 μm) and chamber slides were bought from BD Bioscience (Erembodegem, Belgium). Phosphate buffered saline solution (PBS) and trypan blue were supplied by Bio-Whittaker (MD, USA). High-performance thin layer chromatography (HPTLC, silica gel 60) plates were obtained from Merck (Darmstadt, Germany). Radiolabelled [1-^{14}C] fatty acids (50 μCi/mmol) was purchased from American Radiolabelled Chemicals Inc. (Laborel, Oslo, Norway). Scintillation fluid and a TRI-CARB 2000CA scintillation counter were bought from Ecoscint A, National Diagnostics (Atlanta, GA, USA) and United Technologies Packard (UK) respectively. Complete L-15 medium was composed of Leibovitz L-15 supplemented with 10% FBS, 2 mM GlutaMax, 100 U penicillin mL^{-1}, 100 μg streptomycin mL^{-1} and 0.25 μg amphotericin B mL^{-1}. Semi-complete L-15 medium was composed of complete L-15 medium without FBS.

Cyclodextrin, phloretin, diisothiocyanodisulfonic acid (DIDS) and sulfo-*N*-succinimidyl 4-maleimido-butyric acid ester (SSMB) were purchased from Fluka Chemicals (Sigma–Aldrich, Oslo, Norway). Sulfo-*N*-succinimidyl 4-maleimido-oleic acid ester (SSO) was synthetized according to a modified procedure [29] originally described by Staro [30]. Briefly, oleic acid (0.25 mmol), HOSu (SO_3)Na (0.25 mmol), and dicyclohexylcarbodiimide (DCC) (0.275 mmol) were dissolved in 0.5 mL of dry *N,N*-dimethylformamide (DMF) and stirred at room temperature overnight. The precipitated dicyclohexylurea was removed by filtration (Whatman No. 1). The filtrate was

kept at 3 °C for 4 h. Eight volumes of ethyl acetate were added and the precipitated product was collected by filtration (Ultipor Nylon 66, 45-μm pore size) under nitrogen and then stored in a vacuumed desiccator over phosphorus pentoxide. The chemicals and materials for synthesizing SSO were all purchased from Fluka Chemicals (Sigma–Aldrich, Oslo, Norway).

Methods

Preparation of Hepatocytes

Atlantic salmon (500 ± 143 g) were randomly selected and placed in a 50-L bucket with oxygenated seawater. After the fish were sedated with 0.1 g L^{-1} MS222 in water, hepatocytes were isolated by a two-step perfusion essentially as described by Dannevig and Berg [31]. Through the hepatic vein, the liver was first cleared of blood by perfusion with HEPES buffer (NaCl 8.4 g L^{-1}, KCl 0.5 g L^{-1}, EDTA 0.0074 mg L^{-1}) then digested with HEPES-buffer containing collagenase (0.1 mg mL^{-1}). The digested liver was then removed gently put into a sterile Petri-dish on ice, filled with PBS and the hepatocytes were dispersed by using two tweezers. The tissue suspension was subsequently filtered through 100 μm nylon gauze. The cells were collected by centrifugation at 50*g* for 5 min at 4 °C and washed twice more with PBS followed by the same centrifugation. Finally, the cells were resuspended in 20 mL complete L-15 medium. The cell viability was routinely measured by the trypan blue excluded method and >85% of unstained cells was the criterion for further use of the cells. Cells were plated onto 25-cm^2 cell culture flasks (TPP, Trasadingen Switzerland), pre-coated with 2 μg cm^{-2} laminin, at a density of 2 million cells mL^{-1} (5-mL cell suspension $flask^{-1}$) and cultured at 12 °C overnight. Duplicate flasks were cultured from each fish and three fish per treatment were used if not otherwise stated (total $n = 6$).

18:1n-9 Uptake Depending on Time and Concentration

All experiments performed to measure 18:1n-9 uptake were done 12 h after seeding the cells when the hepatocytes were attached. In the first experiment, 5 mL semi-complete L-15 medium was added 60 μM 18:1n-9 together with 1 μM [1-^{14}C] 18:1n-9, and this was incubated with the hepatocytes (0.2 μCi $flask^{-1}$) for 0, 0.5, 1, 2, 4, 6, 12, 24 h. 18:1n-9 bound to BSA with a molar ratio of 2.5:1 were prepared as previously described by Ghioni et al. [32]. In the second experiment, 5 mL of semi-complete L-15 medium was added 0, 37.5, 75, 150, 300, 600 μM 18:1n-9 and [1-^{14}C] 18:1n-9 with the unradiolabelled and radiolabelled 18:1n-9 M ratio of 30:1 were incubated with the cell for 2 h (0, 0.13, 0.24, 0.49, 0.98, 1.98 μCi $flask^{-1}$, respectively). The FA uptake was terminated by removing the medium. The medium was centrifuged at 500*g* for 5 min, 4°C and the supernatant was collected. The cell layer was collected by using a cell scrape and PBS. The cells pellets were washed twice with PBS and centrifuged at 500*g* for 5 min, 4°C before the cells were re-suspended in 0.5 mL 0.88% KCl solution. 50 μL of cell suspension and 500 μL of the medium were mixed with 8 mL scintillation fluid in scintillation vials to count the radioactivity in the scintillation counter. Lipids were extracted from the cell and medium samples as described below.

Inhibition of Fatty Acid Uptake

Hepatocytes were pre-incubated with inhibitors, 10 mM cyclodextrin, 250 μM phloretin, 250 μM DIDS, 200 μM SSO or 200 μM SSMB, in 0.05% DMSO-semi-complete L-15 medium respectively for 0.5 h. Then the medium was removed and the fatty acid uptake study was carried out by adding semi-complete L-15 medium containing 37.5 μM 18:1n-9 and 1.25 μM [1-^{14}C] 18:1n-9 (0.3 μCi $flask^{-1}$) for 2 h including various inhibitors mentioned above. For studying the inhibition of phloretin on the uptake of 18:1n-9, 18:2n-6), 18:3n-3, 20:5n-3 and 22:6n-3, 250 μM phloretin was added to the hepatocytes for 0.5 h. Then the medium was removed and the fatty acid uptake was carried out by adding semi-complete L-15 medium containing 37.5 μM of the different fatty acids and 1.25 μM [1-^{14}C] fatty acid (0.3 μCi $flask^{-1}$) for 2 h including 250 μM phloretin. In addition, hepatocytes (controls) with 0.05% DMSO and (cold and radiolabelled) fatty acids but without inhibitors were run concurrently with experimental treatments. Cell and incubation medium samples were harvested and radioactivity was measured as described above. For fatty acid uptake and metabolism data after 2 h of incubation this was corrected for with a time-zero sample with radiolabelled fatty acids added to correct for background radioactivity.

Incorporation of Fatty Acids into Lipid Classes

Recovery of [1-^{14}C] fatty acids in lipid classes was analyzed by thin-layer chromatography (HPTLC). Lipids were extracted from cells and the medium by adding four to five volumes of chloroform:methanol (2:1) described by Folch et al. [33] with 0.05% BHT in it. After mixing well and centrifugation at 450*g* for 5 min, the lower chloroform phase was transferred carefully and totally into another glass tube and dried under a stream of nitrogen. The lipid was re-suspended in 50 μL of chloroform and applied as a 1-cm line on HPTLC plates alongside 5 μL of a mixed

lipid standard (5 mg mL^{-1}). Lipid classes were separated by an isohexane:diethyl ether:acetic acid (80:25:1.5 v/v/v) solvent system and visualized by exposure to iodine vapor. The plate was marked and the iodine was removed under vacuum. The individual lipid class, total phospholipids (PLs), neutral lipids (NLs including monoacylglycerol, MAG; diacylglycerol, DAG; triacylglycerols, TAG; cholesterol and sterol ester) and free fatty acids (FFA) was scraped into scintillation vials and 8 mL of scintillation fluid was added respectively before radioactivity was measured by the scintillation counter.

Assay of Hepatocytes β-Oxidation Activity

The analysis of ^{14}C-acid soluble fatty acid oxidation products (ASPs) and $^{14}CO_2$ in the hepatocytes and medium samples were determined as described previously by Tocher et al. [34] and Stubhaug et al. [27]. A 100-μL quantity of the sample was transferred into a 2-mL centrifuge tube then 50 μL of BSA solution (6 g mL^{-1}) was added to bind the remaining fatty acids. After the mixture was mixed well, 500 μL of ice-cold perchloric acid (4 M) was added to precipitate the protein-bound un-oxidized FAs. After further mixing well, the mixture was centrifuged at 3,500*g* for 10 min. Then 250 μL of the supernatant was taken to mix with 8 mL scintillation fluid to determine the radioactivity using the scintillation counter.

Apoptosis Test: MTT Test and Hoechst Staining Test

The potential toxicity of the fatty acid uptake inhibitors was investigated either by staining the nucleus using the DNA specific dye Hoechst 33342 (Sigma–Aldrich, Oslo, Norway) or by the MTT based in vitro toxicology assay kit according to the manufacturers protocol (Sigma–Aldrich, Oslo, Norway). Hepatocytes isolated from Atlantic salmon was cultured overnight in 96-well plates (0.4 million cells cm^{-2}) (MTT) and chamber slides (Hoechst), followed by incubation with inhibitors for 2.5 h as described above. For the visualization of the nucleus, hepatocytes were fixed in 4% buffered paraformaldehyde (pH 7.4) for 15 min after 24 or 48 h exposure. Subsequently, the cells were incubated for 3 × 5 min with PBS/1 mM glycine, 1 min in PBS/0.1% Triton X-100 and washed for 3 × 5 min with PBS prior to staining with 1 μg mL^{-1} of the DNA specific dye Hoechst 22242 for 15 min. Apoptosis was scored by assessing the nuclear status of at least 200 cells in each exposure group using a Bx51 Olympus Fluorescence microscope (Olympus Europa GmbH, Hamburg, Germany). The resulting data from the MTT-test on the primary culture used in the experiments presented here are not shown since they revealed no differences; rather they were used to verify the findings from the nucleus staining.

Statistical Analysis

All data are presented as means ± SD. A nonlinear regression model was used to describe the effect of changes in 18:1n-9 concentration on 18:1n-9 uptake by the hepatocytes and to determine the K_m and V_{max} constants of fatty acid membrane transport (Excel, version 2007). Significant differences between treatments and controls were determined using one way ANOVA, followed by the Turkey post-hoc test. All statistical analyses were performed using the STATISTICA 6.1 software (StatSoft Inc., Tulsa, USA). Result were considered significant at $P < 0.05$.

Results

Fatty acids taken up by hepatocytes can either be esterified into cellular lipids, β-oxidized for energy production or further secreted as esterified lipids incorporated into lipoproteins, as very low density lipoprotein (VLDL). Theoretically, uptake should be calculated by the sum of total radioactivity recovered in the cells and radioactivity of esterified lipids and β-oxidation products recovered in the incubation medium. However, neither radioactive esterified lipids nor radioactive β-oxidation products was found accumulated in the incubation medium compared to 0 h control hepatocytes. Therefore 18:1n-9 uptake was first calculated by the radioactivity recovered in the cell (dpm) and then it was transferred into the value of nmol by the specific activity of radiolabelled 18:1n-9 (μCi $mmol^{-1}$). Finally the net total uptake of 18:1n-9 including radiolabelled and unlabelled 18:1n-9 was calculated by the molar ratio of radiolabelled and unlabelled 18:1n-9.

18:1n-9 Uptake-Time Course Study

Incubation of 61 μM 18:1n-9 with 1×10^7 hepatocytes at 12 °C revealed that the uptake was fast and linear over the first 6 h (Fig. 1a). It gradually reached a saturated state after 12 h with no difference in uptake between 12 and 24 h. During the 24 h incubation study the uptake rate was the highest around 2 h (2 nmol h^{-1} million $cells^{-1}$). Therefore this incubation time was chosen for the following experiments.

18:1n-9 Uptake-Concentration Study

Uptake of 18:1n-9 by hepatocytes increased linearly with increasing 18:1n-9 concentration up to 150 μM followed by a saturated state (Fig. 1b) according to the Michaelis–Menten equation (Fig. 2). K_m for this process as a function of the total 18:1n-9 concentration was calculated to be 46.4 ± 0.6 μM, while the V_{max} amounted to 2.25 ± 0.03 nmol h^{-1}

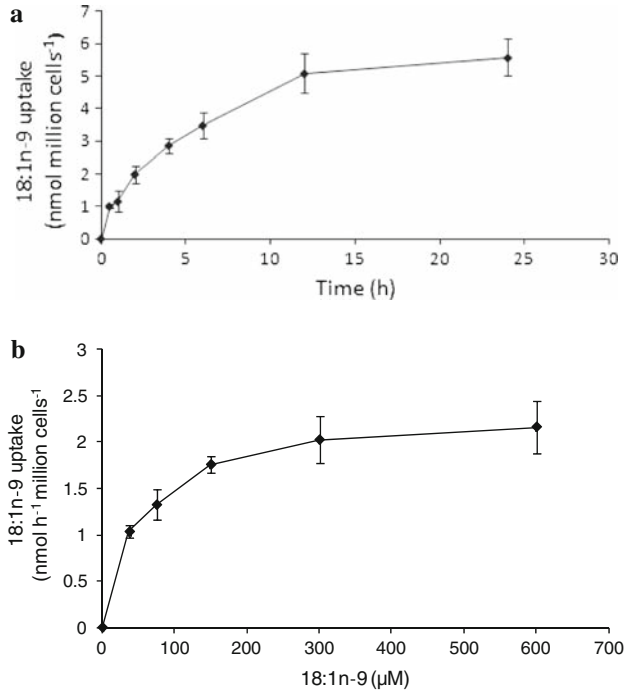

Fig. 1 **a** Uptake of 18:1n-9 from 0 to 24 h in Atlantic salmon hepatocytes during incubation of 61 μM 18:n-9 with the radiolabelled:nonlabelled 18:1n-9 M ratio of 1:60, bound to BSA (18:1n-9: BSA; 2.5:1). Data are presented as means ± SD ($n = 3$). **b** Atlantic salmon hepatocyte 18:1n-9 uptake with increasing 18:1n-9 concentration. Hepatocytes were incubated with 18:1n-9, where the radiolabelled:unradiolabelled 18:1n-9 M ratio was 1:30. The uptake was measured 2 h after addition of the 18:1n-9 substrate. Data are presented as means ± SD ($n = 6$)

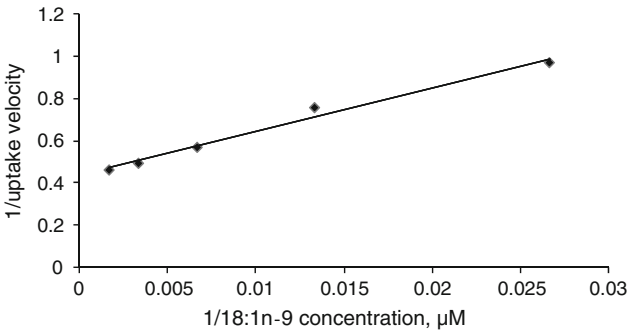

Fig. 2 Lineweaver–Burk plot of rate of 18:1n-9 uptake versus 18:1n-9 concentration. The kinetic parameter was generated from a weighted least-squares fit of the individual data points from each experiment to a rectangular hyperbola (K_m 46.37 ± 0.58 μM; V_{max} 2.25 ± 0.03 nmol h^{-1}million cells^{-1}, $n = 6$). The regression equation and correlation coefficient was $y = 20.61x + 0.437$; $R^2 = 0.985$, $P < 0.05$

million cells^{-1}. Of the concentrations tested, 37.5 μM 18:1n-9 was closest to the K_m value and this concentration was chosen for the following experiments.

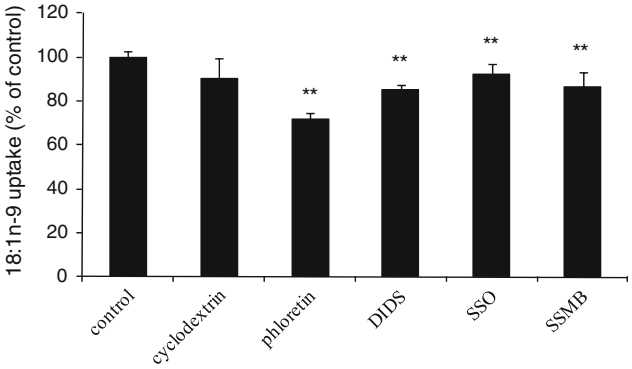

Fig. 3 Inhibition of 18:1n-9 uptake by inhibitors in Atlantic salmon hepatocytes. Data are presented as means ± SD ($n = 6$) and are expressed relative to untreated control (100%). *Asterisks* denote very significant difference compared to control ($P < 0.01$). *DIDS* diisothiocyanodisulfonic acid, *SSO* sulfo-*N*-succinimidyl 4-maleimido-oleic acid ester, *SSMB* sulfo-*N*-succinimidyl 4-maleimido-butyric acid ester

Effects of Different Membrane Protein Inhibitors on 18:1n-9 Uptake

To further clarify whether 18:1n-9 uptake into hepatocytes of Atlantic salmon was mediated by membrane proteins, the effects on fatty acid uptake of membrane protein inhibitors were studied (Fig. 3). Treatment of hepatocytes with phloretin resulted in the highest inhibition of 18:1n-9 uptake by 28.2 ± 2.6% of control. DIDS and SSMB revealed lower inhibition by 14.5 ± 1.7 and 13.4 ± 6.6%, respectively. The lowest inhibition was found in the presence of SSO, inhibiting the uptake by 7.8 ± 4.7%.

Uptake of Vegetable- and Fish Oil Fatty Acids into Hepatocytes

The uptake of FAs was measured respectively as total radioactivity recovered in hepatocytes and further expressed as % of the initially added FAs. Uptake of different FAs ranged between 9.5 and 15% (Fig. 4) with 20:5n-3 being most efficiently taken up (15%), followed by 22:6n-3 (13%), 18:1n-9, 18:2n-6 and 18:3n-3. The most potent membrane protein inhibitor, phloretin, revealed in the first 18:1n-9 study (Fig. 3) inhibited the fatty acid uptake in the following order; 20:5n-3 > 18:3n-3 = 22:6n-3 > 18:2n-6 > 18:1n-9 with the 20:5n-3 uptake being lowered by 67%. This was in contrast to 18:1n-9 revealing the lowest inhibition of phloretin compared to all the other fatty acids tested (Fig. 5).

Incorporation of Fatty Acids into Hepatocyte Lipids

The cellular lipid distribution of fatty acids was calculated by the radioactivity recovered in cellular PLs, NLs and free FAs (% of cellular lipid; Fig. 6). Fatty acids were mainly

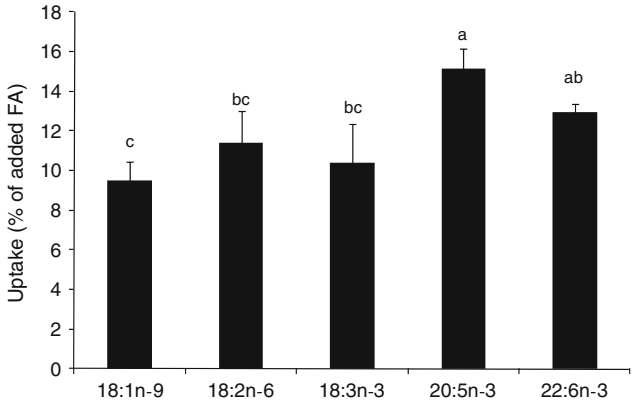

Fig. 4 Trans-membrane uptake of 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3 and 22:6n-3 by hepatocytes of Atlantic salmon given as % fatty acid taken up of the total fatty acid added. Cells were incubated for 2 h with 37.5 μM radiolabelled and unlabelled fatty acids respectively with molar ratio of 1:30. Data are presented as means ± SD, $n = 10$ for 18:1n-9, $n = 6$ for 18:3n-3 and 18:2n-6, and $n = 4$ for 20:5n-3 and 22:6n-3. Statistical differences analyzed by one-way ANOVA are denoted by *different letters*

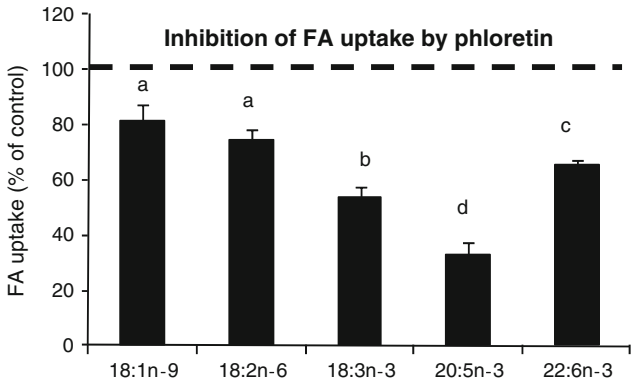

Fig. 5 Inhibition of trans-membrane fatty acid uptake by phloretin in Atlantic salmon hepatocytes given as % of control (no inhibitor added). Data are presented as means ± SD, $n = 6$. Statistical differences between the control and inhibitors are denoted by an *asterisk*

recovered as FFAs (50–70% of cellular lipid), whereas ~30% was recovered esterified into cellular PL and ~6% esterified into NLs. The 22:6n-3 was mainly incorporated into cellular PLs (38% of cellular lipid), followed by 20:5n-3 (27%), and 18:1n-9, 18:2n-6, 18:3n-3 with approximately 20% being recovered in PLs. The incorporation into NLs was not significantly different between the fatty acids, ranging from 5 to 7% of the cellular lipids. The recovery of 18:1n-9, 18:2n-6, 18:3n-3 and 20:5n-3 into cellular FFA was not significantly different, varying from 61 to 68% of the cellular lipids, which was significantly higher than the recovery of 22:6n-3 in cellular FFA, being 50% of the cellular lipids.

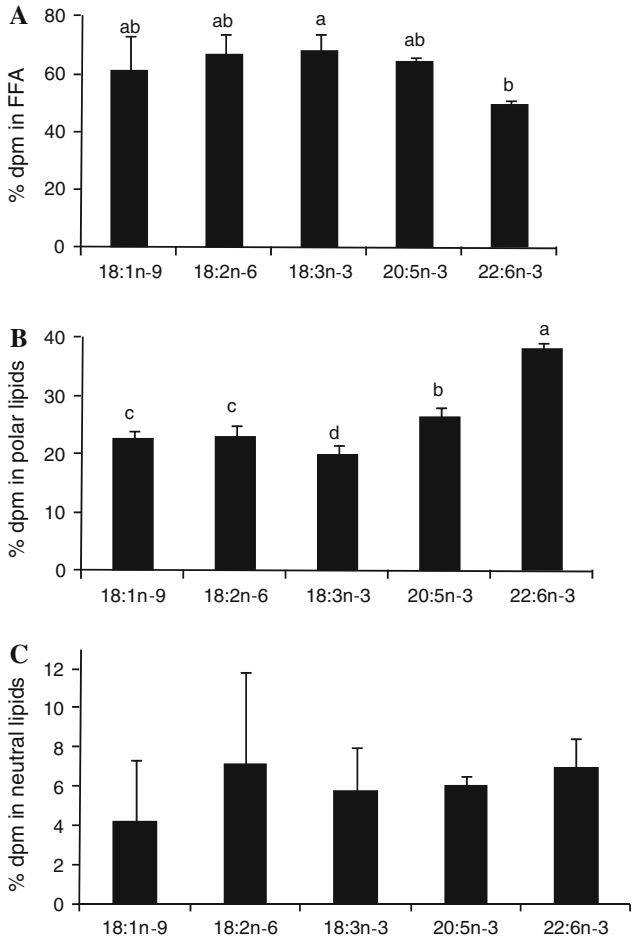

Fig. 6 Recovery of [1-^{14}C] 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3 and 22:6n-3 in cellular lipid classes given as % dmp in FFA (**a**), polar (**b**) or neutral (**c**) lipids of the total cellular lipids dpm. Neutral lipids includes monoacylglyceride, diacylglyceride, triacylglyceride and sterol ester. Data are presented as means ± SD, $n = 12$ for 18:1n-9 and $n = 6$ for 18:2n-6 and 18:3n-3; $n = 4$ for 20:5n-3 and 22:6n-3. Statistical differences between fatty acids are denoted by *different letters*

Fatty Acid Catabolism

The β-oxidation of fatty acids by the hepatocytes is presented relative to the total radiolabelled fatty acids taken up. The β-oxidation of 18:3n-3 was significantly higher (7%) compared to all the other fatty acids analysed. The β-oxidation of 18:1n-9 was the lowest (<1% of total 18:1n-9 taken up) followed by 18:2n-6 < 20:5n-3 < 22:6n-3 being increasingly more β-oxidation (Fig. 7).

Cell Viability

In order to evaluate if the addition of inhibitors affected the hepatocytes viability or stress resulting in apoptosis of the cells, a chemical (MTT) and morphological (Hoechst staining) test were applied. The cell viability ranged from

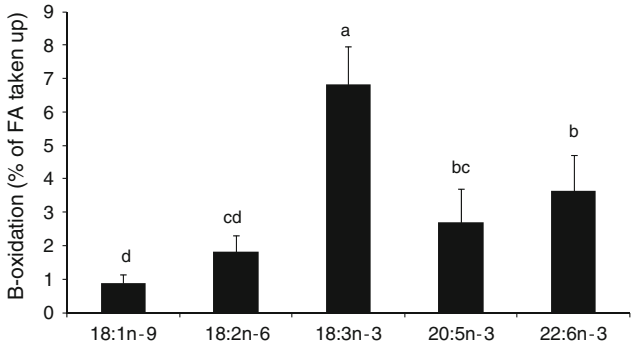

Fig. 7 β-Oxidation of fatty acids given as % dpm recovered in acid soluble products relative to the total fatty acids (dpm) taken up into the cells. Data are presented as means ± SD, $n = 12$ for 18:1-9, $n = 6$ for the other fatty acids. Statistical differences between different fatty acids are denoted by *different letters*

90 to 113% in the presence of inhibitors and no significant difference was found compared with the control by MTT-test (data not shown) and this was further documented by the Hoechst staining test (data not shown), pointing to the fact that neither the cell integrity nor the physiologic state was affected by treating hepatocytes with inhibitors for 2.5 h.

Discussion

Atlantic salmon hepatocytes is an established in vitro system and has been used in a range of lipid metabolic studies [27, 34–38]. The present report is the first to study the fatty acid uptake mechanisms across hepatocyte membranes of Atlantic salmon over a time span relevant to metabolic studies. A previous study by Richards et al. [25] measured fatty acid uptake within seconds, whereas in the present study, the uptake of fatty acids was measured for several hours. The 18:1n-9 uptake occurred through a saturable, transport mechanism, which is in line with Richards and co-workers [25], with uptake being the highest during the first 2 h of incubation. It has been suggested that intracellular metabolism is the driving force and regulator of fatty acid uptake over the cell membranes [39]. Hence, the current results of fatty acid uptake represent not only an isolated uptake across the membrane (s), but the fatty acid uptake over the membrane within a time span which may be more relevant for metabolic studies (h). In line with the present results, previous studies using hepatocytes as well as adipocytes and cardiac myocytes isolated from rat, have shown that 18:1n-9 uptake followed saturation kinetics indicating protein mediated uptake when measured over a longer time span [40]. Saturation kinetics has also been reported to be valid for uptake of the saturated fatty acid palmitate (16:0) into skeletal muscle [41], and for 18:1n-9 uptake into mammalian adipocytes [16, 42], cardiac myocytes [43], and hepatocytes [44]. The ratio of fatty acid:albumin was maintained at 2.5:1 being similar to what was used in previous metabolic and fatty acid uptake studies in Atlantic salmon hepatocytes [38, 45] and rainbow trout muscle membrane [25] where the ratio varied was reported to vary from 8–11:1, 2.5:1 to 0.2–5:1.

Previously, the molar ratio between fatty acid and albumin in the medium has been found to affect the uptake kinetics of fatty acids in rat hepatocytes [40]. Lower FA:albumin ratio than 2.0:1 has been found to decrease the uptake of FA [40], and with a high uptake rate of FA this situation may theoretically occur since the concentration of albumin in the medium would increase relative to the fatty acid concentration as the fatty acids were taken up by the hepatocytes. However, in the current experiments the total fatty acids uptake found never exceeded 15% of the amount of fatty acids added and consequently the molar ratio of FA:BSA was never lower than 2.2:1. The molar ratio of FA:albumin initially being 2.5:1 was safely above the highest ratio used by Sorrentino et al. [40] who tested FA:BSA ratios from 0.1:1 to 2:1. Hence, based on previous 18:1n-9:BSA ratio data, the observed saturation kinetics was unlikely to be due to a sub-optimal 18:1n-9:albumin ratio.

Increasing the concentration of 18:1n-9 adds complexity to the interpretation for the 18:1n-9 uptake and saturation due to the fact that net accumulation of fatty acids within the cells can be a result of changes in fatty acid metabolism and cellular influx. Metabolic demand for fatty acids has been suggested to be the driving force for fatty acid uptake through conversion of fatty acids to acyl-CoA by the action of acyl-CoA synthetases and the regulation of the membrane-bound transport proteins [39]. This has also been exemplified by the finding that with stable over-expression of the initial and rate limiting enzyme in glycerolipid synthesis, glycerol-3-phosphate acyl transferase in CHO cells, the fatty acid uptake increased [46]. Hence, if the intracellular fatty acid metabolism was lower than any other fatty acid transport pathways, especially the transmembrane process, the saturation of fatty acid uptake could also be apparent and firm conclusions on a passive diffusion or a protein mediated uptake mechanism could not be made [47–49]. In the present study of 18:1n-9, low levels of β-oxidation products (>1%) were found when corrected for background activity, using a time-zero sample and approximately 20% of 18:1n-9 taken up was incorporated into PL. This indicates that intracellular metabolism of 18:1n-9 was low compared to especially 18:3n-3, selectively being β-oxidized and 22:6n-3 being esterified into PL approximately twofold higher than 18:1n-9. Therefore the present 18:1n-9 uptake with a saturation curve could also be explained as passive diffusion in combination with

a rate limitation in the subsequent intracellular fatty acid metabolism. Overall, the relative levels of secreted fatty acids (esterified lipids in medium) and ß-oxidation products was lower compared to previously published papers on Atlantic salmon hepatocyte metabolism [27, 34, 38]. This is, however, the first time the results are being corrected for background activity using a time-zero sample in the experimental design. This resulted in lower actual activity data compared to without a zero-sample correction. Furthermore, results expressed as relative amount of radioactivity of the total added or taken up is highly dependent on the total concentration of fatty acids added to the cells. When lower concentrations are used, the relative amount is higher whereas the absolute amount of fatty acids taken up was actually lower in the results of Stubhaug et al. [27] study compared to ours as outlined below. Another important factor influencing metabolic rate is temperature. The lower incubation temperature (12 °C) used in the current study will slow down the overall metabolism compared to incubation at 20 °C used in previous studies [27, 34, 37]. The incubation time used in the current study was identical (2 h) to most previously published studies [27, 34]. Decreased incubation time will naturally result in less total metabolism. Furthermore, the cell viability measurements (by MTT and Hoechst) showing overall no indications of decreased viability further supports the fact that the lower relative metabolism was due to the inclusion of time zero-sample correction and higher fatty acid concentrations, rather than decreased viability and cell integrity.

The efficiency of uptake and the metabolic fate of 18:1n-9, 18:2n-6, 18:3n-3, 20:5n-3 and 22:6n-3 was demonstrated to be significantly different in Atlantic salmon hepatocytes supporting previous studies performed with hepatocyte suspensions [27]. Especially 18:1n-9 and 20:5n-3 seemed to represent the opposites with regards to uptake and degree of inhibition. 18:1n-9 was the least efficiently taken up with the uptake inhibited by phloretin the least, whereas 20:5n-3 was the most efficiently taken up and inhibition by phloretin was the highest of the fatty acids studied. Previously, 20:5n-3 was reported to be the most efficiently taken up fatty acid in hepatocytes from FO fed Atlantic salmon [27] with as much as 90% of added fatty acids being taken up. In the current study 9–15% of the fatty acids added were taken up. However, Stubhaug et al. [27] added 2 μM fatty acids in contrast to 37.5 μM in the current study. When calculating the total amount of fatty acids taken up, actually 3.75 μM fatty acids in the current study was taken up by the cells compared to 1.8 μM reported by Stubhaug et al. [27].

Intracellular metabolism has been suggested to be the driving force and regulator of fatty acid uptake over the cell membranes [39, 50]. However, our results indicate that metabolism alone is not the determining factor. The metabolism of 18:3n-3 and 20:5n-3 was comparable when combining the relative amount being β-oxidized and incorporated into polar lipids. However, 20:5n-3 was significantly more efficiently taken up compared to 18:3n-3. Furthermore, a major proportion of all fatty acids tested were recovered in cellular FFA (50–70% of lipids), suggesting that the amount of fatty acids taken up was sufficient for subsequent intracellular metabolism, esterification or β-oxidation, and that trans-membrane uptake was the primary regulating step of fatty acids uptake in the current study. Furthermore, the metabolic fate of 22:6n-3 differed slightly from the other fatty acids, with more 22:6n-3 being recovered in the polar lipids (mainly phospholipids) and less in FFA and β-oxidation products. Supporting previously published data [27] this confirms that 22:6n-3 has an important role in structural lipids as part of the cell membranes.

It is generally considered that the membrane proteins, FABPpm, FAT/CD36 and FATP, are responsible of the uptake of long and very long chain fatty acids [Reviewed by Frohnert and Bernlohr; 51]. The FA uptake inhibitors used in the current study either inhibits one specifically (e.g. SSO) or all of these membrane bound proteins (phloretin). The 18:1n-9 uptake was differently inhibited by the five inhibitors used with the maximal degree of inhibition by phloretin being 28%, which was lower than earlier studies using rat cardiac myocytes [49, 50, 52], rat adipocytes [24, 29] (varying from 60 to 90%) and trout muscle sarcolemma (about 40%) [25], indicating that salmon hepatocytes are less dependent on protein mediated 18:1n-9 uptake compared to mammalian and trout cells. In line with these previous results, the present study was not able to inhibit fatty acid uptake completely. Considering that phloretin was reported to be a potent non-specific inhibitor of membrane transport proteins [53, 54] and phloretin-containing buffer has also been used as a "stop solution" to suppress the efflux or influx of FAs rapidly and completely [42], the maximal degree of inhibition by phloretin, about 30%, was postulated as the contribution of these FA uptake associated membrane proteins, FABPpm, FAT/CD36 and FATPs. The present remaining 18:1n-9 uptake not being inhibited accounted for about 70% and it can be assumed to be attributed to passive diffusion. In contrast to 18:1n-9, the uptake of 20:5n-3 was inhibited by 70% followed by 18:3n-3 and 22:6n-3 at approximately 50% inhibition. This suggests that FA uptake by Atlantic salmon hepatocytes is accomplished by both passive and carrier-mediated trans-membrane transport, and that the omega-3 fatty acids are more dependent on membrane bound protein mediated uptake than 18:1n-9 and 18:2n-6. When Atlantic salmon are fed diets increasingly replacing fish oil with vegetable oils their dietary fatty acid

composition will be dominated by 18:1n-9 and 18:2n-6 fatty acids [55]. These differences in the mechanisms for fatty acid uptake may have implications when dietary fatty acid compositions are changed in such a manner.

Compared to previous published reports on rainbow trout muscle sarcolemma, the magnitude of inhibition by phloretin of 18:1n-9 uptake was approximately 10% lower compared to the present study. On the other hand, the pattern was similar with phloretin being the most potent inhibitor and SSO being the least [25] indicating the uptake mechanisms being similar between trout muscle sarcolemma and Atlantic salmon hepatocytes. SSO was reported to have the specificity towards FAT/CD36 by specifically inhibiting FAT/CD36 without indicating an effect on FATP or FABPpm [20], hence inhibition of 7.8% 18:1n-9 uptake by SSO can be attributed to the function of FAT/CD36. FABPpm has also been reported to function in conjunction with FAT/CD36 [reviewed by Bonen et al. 56] therefore the two proteins might collaborate to increase the rates of fatty acid transport across membrane [57] and accounted for 8% in the present 18:1n-9 uptake. Considering that 18:1n-9 uptake mediated by total membrane proteins was 28%, 18:1n-9 uptake mediated by another assumed membrane transport protein, FATP, would account for 20%. Cyclodextrin did not significantly lower the 18:1n-9 uptake compared to the control. However, cyclodextrin has previously been reported to disrupt the lipid raft by lowering the cholesterol levels in the lipid raft [reviewed by Ikonen et al. 58], and the 10% of the 18:1n-9 uptake inhibition by cyclodextrin suggested that lipid raft was also included in Atlantic salmon hepatocytes fatty acid uptake and its attribution to fatty acid uptake would be 10%. SSMB is an analogue of SSO, and is an agent with protein modifying properties. SSMB showed higher inhibition on 18:1n-9 uptake compared to SSO suggesting that SSMB can function as a more potent inhibitor than SSO of fatty acid uptake associated membrane proteins.

When the fatty acids are taken up by cells, they may be bound to intracellular fatty acid-binding proteins (FABPs) and transported from the cell surface to the various sites of metabolism or storage [Stoch and Thumser 59]. The main proportion of fatty acids taken up was recovered in FFA probably bound to intracellular FABPs, whereas less than 10% was recovered in TAG. This was in contrast to Stubhaug et al. [27] who reported that the main proportion of fatty acids was recovered in TAG and less than 5% was recovered as FFA. This may likely be due to differences in incubation temperature with decreased temperature (12 °C) in the current study resulting in slower metabolism and incorporation of fatty acids into TAG compared to hepatocytes cultured at 20 °C in the study of Stubhaug et al. [27].

In conclusion, the uptake of fatty acids by Atlantic salmon hepatocytes was shown to be time- and concentration dependent, and to be partly inhibited by membrane protein inhibitors. 20:5n-3, 18:3n-3 and 22:6n-3 seems to be more dependent on membrane bound proteins compared to 18:1n-9 and 18:2n-6, and intracellular metabolism did not seem to be a main regulating factor or driving force for fatty acid uptake in cultured Atlantic salmon primary hepatocytes.

Acknowledgments Thanks are due to Mrs. Betty Irgens and Ms Thu Thao Nguyen for technical assistance. The study was financed by the Norwegian Research Council (158930/I10) and the China Scholarship Council. J. Zhou was the recipient of grant from the China Scholarship Council and the National Institute of Nutrition and Seafood Research (NIFES).

The Influence of n-3 PUFA Supplements and n-3 PUFA Enriched Foods on the n-3 LC PUFA Intake of Flemish Women

Isabelle Sioen · Jolien Devroe · David Inghels · Ruth Terwecoren · Stefaan De Henauw

Received: 9 November 2009 / Accepted: 1 March 2010 / Published online: 18 March 2010

Abstract Food consumption data of Flemish women of reproductive age collected in 2002 showed a large deficit for ALA and n-3 LC PUFA compared to the recommendations (mean ALA and EPA + DHA intake 1.4 g/day and 209 mg/day, respectively) and indicated a need to tackle the problem of low n-3 PUFA intake. Another recent Belgian study demonstrated that enrichment of commonly eaten food items with n-3 PUFA provides the opportunity to increase the n-3 PUFA intake up to 6.5 g/day and decrease the n-6/n-3 ratio. Since a large supply of n-3 PUFA supplements and n-3 PUFA enriched foods exists on the Belgian market, this study aimed at assessing the influence of these products on the n-3 LC PUFA intake for Flemish women of reproductive age. It was found that n-3 supplements are consumed by 5% of the Flemish women. Of all the n-3 PUFA enriched foods on the Flemish market, margarines and cooking fat are most frequently consumed by young women. The results indicated that a big gap remains between the EPA&DHA intake (mean = 276 mg/day) and the recommendation. Seafood remains the most important source of EPA&DHA. Only 11.6% of the population sample reached an intake level of 500 mg EPA&DHA per day. The study showed that other strategies will be needed to increase the EPA&DHA intake in the long term.

ISSFAL	International society for the study of fatty acids and lipids
LA	Linoleic acid
LC	Long-chain
PUFA	Polyunsaturated fatty acids

Introduction

An adequate intake of n-3 long chain (LC) polyunsaturated fatty acids (PUFA), in particular of docosahexaenoic acid (DHA) during pregnancy and lactation is important to support optimal visual and cognitive development in the foetus and the neonate [1, 2]. Furthermore, consumption of eicosapentaenoic acid (EPA) and DHA, the most important n-3 LC PUFA, during pregnancy reduces the risk of early premature birth [1–3]. In addition, epidemiological studies have clearly shown that n-3 LC PUFA lower the risk of cardiovascular diseases (CVD) in adults [1–4].

To achieve an adequate n-3 LC PUFA intake, appropriate dietary habits are needed. The food source naturally richest in n-3 LC PUFA is fish and other seafood,

particularly oily fish [4]. However, in most European countries, the estimated intake of fish is too low to meet the recommendation for n-3 LC PUFA [4–9]. Moreover, due to negatively perceived messages in the media about contaminants in seafood, people tend to decrease their fish consumption and possibly look for alternatives. In addition, since it is not clear whether the world's oceans could meet the seafood demand, alternatives will be of even bigger interest in the future in view of a sustainable food supply. These alternatives can be found in n-3 PUFA enriched foods as well as in n-3 PUFA supplements based on sustainable sources e.g. algae. The market of foods and supplements containing n-3 PUFA is rapidly growing [10].

Data on food consumption of women of reproductive age living in Flanders (the northern, Dutch speaking part of Belgium) collected in 2002 showed a large deficit for alpha-linolenic acid (ALA) and n-3 LC PUFA compared to the recommendations and indicated a need to tackle the problem of low n-3 PUFA intake [5]. Another recent Belgian study demonstrated that enrichment of commonly eaten food items with n-3 PUFA provides the opportunity to increase the n-3 PUFA intake and to decrease the n-6/n-3 ratio in the diet to around 3.3 [11]. These facts together with the increasing supply of n-3 FA supplements and n-3 FA enriched foods, created the interest to investigate the consumption level of these foods and supplements as well as their effect on the n-3 LC intake of Flemish women of reproductive age. A good reason to focus on this subgroup of the population lies in the importance of n-3 LC PUFA during pregnancy and lactation. Moreover, the development of appropriate dietary habits of this subgroup of the population will (1) influence the dietary habits of their children and (2) influence the dietary habits of themselves and their partners in the future, which can help to prevent both for CVD during later life.

So, the two specific objectives of this study were (1) to collect data on the consumption of n-3 PUFA supplements, n-3 PUFA enriched foods and foods naturally rich in n-3 LC PUFA for Flemish women of reproductive age and (2) to calculate and evaluate the overall intake of n-3 LC PUFA, i.e. the sum of EPA and DHA, and assess the influence of the supplements and enriched foods on the overall EPA&DHA intake for Flemish women of reproductive age.

Materials and Methods

Very few dietary assessment methods are available to adequately assess the intake of n-3 LC PUFA [12, 13]. Since fish is the most important source of n-3 LC PUFA and fish is episodically consumed, a long term dietary assessment method is needed. In Australia, a 28-item semi-quantitative food frequency questionnaire (FFQ) has recently been developed and compared with a 3 day dietary record as well as with the n-3 LC PUFA content of red blood cells and plasma [12, 14]. This FFQ was found to be a valid and reproducible method that can be used to estimate the n-3 LC PUFA intake of healthy adults and is available online. However, since the food items of this FFQ are not representative of the Flemish and Belgian market and the Belgian food habits, it was not useful for this study. Therefore, a new FFQ was developed.

Market Study

In order to include all relevant supplements and food items in the FFQ, a market study was made to list all n-3 PUFA food supplements and all food products containing a labelling on the package indicating the presence of and/or enrichment with n-3 PUFA. During the months August, September, and October 2008, all important supermarket chains in two provinces of Flanders were visited and the relevant food items for this study were listed together with their n-3 PUFA content. In addition, different pharmacies, drugstores and bio-shops were visited as well. At the same time, photos of the relevant products were made for use in the FFQ.

Food Frequency Questionnaire

Based on the knowledge of the market study, a semi-quantitative FFQ was developed with the objective of collecting data on the consumption of n-3 PUFA supplements, food items enriched with n-3 PUFA, and food items naturally rich in n-3 LC PUFA (seafood and seaweed). This type of FFQ assesses the type of product consumed as well as the amount by asking the respondent to indicate the portion they regularly consume in a list of portion size options.

The FFQ started with questions on some socio-demographic and personal characteristics: year and country of birth, number of family members, weight, height, highest level of education, smoking behavior, presence of some diseases (high cholesterol, cardiovascular diseases, cancer, high blood pressure, food allergies, obesity, diabetes) for themselves or family members, pregnancy and/or lactation, taking part in sports regularly, paying attention to what they eat, and following a diet. In a second part of the FFQ, the use of n-3 PUFA supplements during the last 2 months was probed, including the amount and frequency, as well as the person who advised them to take n-3 PUFA supplements. Next, the habitual consumption of foods naturally rich in n-3 LC PUFA and foods enriched with n-3 PUFA was probed, divided in eight different categories: (1) seafood and seaweed, (2) eggs, (3) bread, (4) meat, meat

products and vegetarian substitutes, (5) margarines, (6) cooking/frying fat, (7) mayonnaise and dressings, (8) dairy and soy products. Before finalizing the FFQ, a pre-test was performed with 40 participants, of whom 37 completed and returned the questionnaire, to test the comprehensiveness of the questionnaire.

It was decided to work with an FFQ in paper version (not online). The FFQ was developed with Teleform Designer version 10.1 for an automatic scanning. The FFQ was distributed together with a letter explaining the purpose of the study, instructions on how to complete the FFQ and some photos to illustrate the products about which questions were asked. The FFQ was self-administered by the subjects.

Population Sample

Study volunteers were recruited in February 2009 via a convenience sample strategy, using relatives, colleagues and friends. There were no exclusion criteria, other than the fact that the participants needed to be women between 18 and 39 years old living in Flanders. After the first week of data collection, extra efforts were made to make sure that all age categories were equally divided in the study sample group. In total, 500 FFQs were distributed and needed to be returned within a period of 2.5 weeks.

The questionnaire and the study protocol were approved by the Ethical Committee of the Ghent University Hospital. All participants signed an informed consent form before completing the questionnaire.

Fatty Acid Composition

The second objective of this study was to calculate the intake of LC n-3 PUFA. For this, only EPA and DHA were considered (not DPA, since there is a lack of composition data for this fatty acid). In order to achieve this objective, concentrations of EPA and DHA for the different food items in the FFQ were needed. For the first food group in the FFQ, i.e. fish and other seafood, EPA&DHA concentrations for four different subgroups were determined: (1) lean fish (<2% fat), (2) half-fatty fish (2–10% fat), (3) fatty fish (>10% fat), and (4) crustaceans and mollusks. For each subgroup, mean EPA&DHA concentrations were calculated according to the concentration in the Dutch food composition database as well as data provided by the Belgian Health Council and using a weighting factor to represent the relative frequency of consumption of each fish species by the Belgian population, determined through the pan-European SEAFOODplus consumer survey and by the Belgian Health Council [15–17]. The EPA&DHA concentrations of two types of seaweed (wakame and kelp) were found in the American food composition database [18], for a third type (nori) data were received from the Japanese scientist Dr. Onishi (personal communication). For margarines and eggs, the only available n-3 enriched foods containing EPA&DHA, the EPA&DHA concentrations indicated on the package were used.

To calculate the contribution of the n-3 PUFA supplements to the EPA&DHA intake, the concentrations indicated on the packages were used for those women who indicated the brand name of the supplement they used. For those women who did not give these details, a mean EPA&DHA concentration of all the available supplements was used.

Evaluating the EPA&DHA Intake

Different recommendations exist for evaluating the intake of EPA&DHA. The International Society for the Study of Fatty Acids and Lipids (ISSFAL) recommends a minimum intake of EPA&DHA of 500 mg/day in view of cardiovascular health [19]. For recommendations to pregnant and lactating women, ISSFAL refers to the work recently done by the Perinatal Lipid Intake Working Group (PeriLip), that recommends a dietary intake of n-3 LC PUFA that supplies a DHA intake of at least 200 mg/day [3]. The Belgian Health Council recommends for adults an EPA&DHA intake equal to 0.3% of the total energy intake [20]. It is, however, hard to translate this recommendation for the current study since we have no information on the energy intake of the respondents. Therefore, the ISSFAL and PeriLip recommendations are used for the evaluation.

Statistics

The normality of the continuous variables was tested using a Kolmogorov–Smirnov test (P value <0.01). To investigate correlations between two continuous variables, of which at least one was not normally distributed, Spearman's correlations were used (P value <0.05). To look for significant differences between two groups for a non-normal, continuous variable, a Mann–Whitney U test was used (P value <0.05). To test for significant differences between more than two groups, a Kruskal–Wallis test (P value <0.05) was used. To study associations between two discontinuous variables, a Pearson χ^2- test was used (P value < 0.05).

Results

Market Study

In total, 202 food items were found on the Belgian market carrying on the package an indication that they contained

n-3 PUFA. Of these, 50 (23%) were fish and other seafood, 25 (11%) were ALA-containing oils. The others were margarines ($n = 35$; 16%), vegetarian substitutes ($n = 18$; 8%), soy drinks and soy desserts ($n = 17$; 8%), mayonnaise and dressings ($n = 14$; 6%), yoghurts ($n = 13$; 6%), meat products ($n = 11$; 5%), butter ($n = 3$; 1%), eggs ($n = 5$; 2%), milk ($n = 2$; 1%), cream ($n = 2$; 1%), cheese ($n = 2$; 1%), and five others (e.g. including biscuits and chocolate spread). Of these food items, only one brand of eggs and four brands of margarine contained EPA&DHA, besides ALA.

In addition, 139 different n-3 PUFA supplements were found, produced by 46 different producers. These supplements were found in the form of oils, capsules and tablets. Several brands had also a special supplement for children.

Participation Rate and Sample Characteristics

Of the 500 distributed FFQs, 421 were returned after completion, leading to a response-rate of 84.2%. However, seven of them were excluded since (1) they were completed by men, (2) they were completed by women younger than 18 or older than 39, (3) they did not complete the question about the n-3 PUFA supplement use, or (4) they did not complete the question about the fish and other seafood consumption. This led to a total study population of 414 women, of which 18 were pregnant and five were breastfeeding.

The sample characteristics are shown in Table 1. This table shows that the younger age category (<25 years old) is oversampled, as well as the part of the population following or have followed higher education. As a consequence, 62% of the population is still studying.

Consumption of n-3 PUFA Supplements, n-3 PUFA Enriched Foods and Foods Naturally Rich in n-3 LC PUFA

The first objective of this study was to collect data on the consumption of n-3 PUFA supplements, n-3 PUFA enriched foods (eggs, bread, meat (products) and vegetarian substitutes, margarines, cooking/frying fat, mayonnaise and dressings and dairy and soy products) and foods naturally rich in n-3 LC PUFA (fish, other seafood and seaweed) by Flemish women of reproductive age. Figure 1 shows the percentage of users within the study population for these supplements and food items. The results indicate that fish and other seafood are consumed by the majority of the study population, whereas seaweed is only consumed by 7% of the participating women. Of the total population, only 12 women (3%) never consumed any fish or seafood. Concerning the n-3 PUFA enriched foods, margarine and cooking/frying fat are the most frequently used products, while n-3 PUFA enriched eggs are the least popular. n-3 PUFA containing supplements are only consumed by 5% of the participating women ($n = 21$). Of these 21 women, 12 used it on own initiative, 6 on medical advice, and 3 for other reasons (e.g. advice of parents or pharmacist). Within this group of supplements users, four women were pregnant (i.e. 22% of the pregnant women in this population sample) and one woman was breastfeeding. The Pearson χ^2- test found significant associations between n-3 PUFA supplement usage and (1) being pregnant (P value = 0.001), (2) being on a diet (p-value = 0.022), (3) having a food allergy (P value = 0.028), and (4) paying attention to what they eat (P value = 0.022). Only 4.6% (19 women) never used any n-3 PUFA enriched food or n-3 PUFA containing supplement.

The Intake of EPA&DHA

The second objective of this study was to calculate the intake of EPA&DHA, two n-3 LC PUFAs, via foods

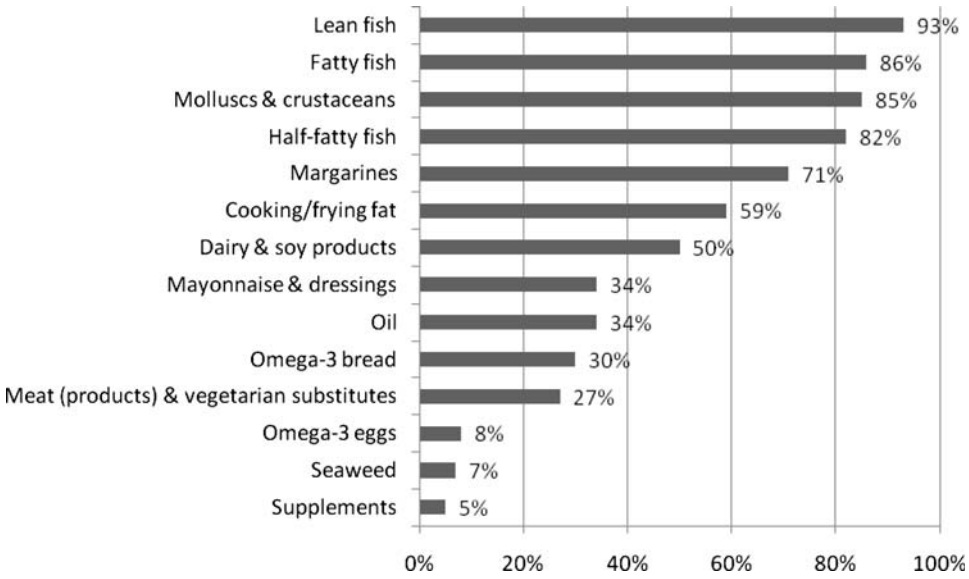

Fig. 1 The percentage of users of foods naturally rich in n-3 LC PUFA, n-3 PUFA enriched foods and n-3 PUFA supplements

naturally rich in these fatty acids (fish, other seafood and seaweed), via n-3 enriched foods containing EPA&DHA (margarines and eggs), and via n-3 PUFA supplements. The results are shown in Table 2. The contribution of each EPA&DHA source is shown in Table 3, in absolute values (mg/day) and percentage, together with the mean and median consumption level of each EPA&DHA source. The EPA&DHA intake was found to be non-normally distributed (P value <0.001), which is also illustrated by the difference between the mean and median intake (276 vs. 199 mg/day). A significant and positive correlation was found between the EPA&DHA intake and the age (correlation coefficient = 0.181, P value <0.001). No correlation was found with BMI. The Mann–Whitney U test found a

significant difference in the EPA&DHA intake for (1) the supplement users (P value <0.001), (2) the consumers of fish and other seafood (P value <0.001), (3) those paying attention to what they eat (P value = 0.014), (4) those doing sports regularly (P value = 0.017), (5) those having a high cholesterol (P value = 0.018) and (6) those who are currently suffering from cancer or had done so in the past (P value = 0.046). No significant difference in EPA&DHA intake were found according to BMI category, being a student versus working, education level, number of family members, smoking, and certain diseases within the family.

The intake of EPA&DHA was compared to the ISSFAL recommendation of 500 mg/day [19]. The ISSFAL recommendation was only achieved by 48 of the 414 women (11.6%) participating in this study. Another 11.6% had an intake between 375 and 500 mg/day, whereas, respectively, 18.6, 22.9, and 35.3% had an intake between 250 and 375 mg/day, 125 and 250 mg/day and 0 and 125 mg/day.

Discussion

This study investigated the consumption level of n-3 PUFA supplements, n-3 PUFA enriched foods and foods naturally rich in n-3 LC PUFA of Flemish women of reproductive age (18–39 years old). With the collected consumption data, the intake of n-3 LC PUFA, EPA&DHA, was calculated and evaluated against the ISSFAL recommendation. Two important limitations of the study are (1) that due to time and budget constraints, it was impossible to work with a random sample and (2) there was no validated FFQ available that was applicable for the Belgian population. As alternative, a convenience sample strategy and a newly developed FFQ was used. This FFQ was pretested before to ensure the comprehensiveness and the quality of the collected data. It is, however, difficult to generalize the results based on a convenience sample to the overall population of Flemish women of reproductive age. Nevertheless, we tried to collect a large sample of women (n = 414) from different age categories and with a different working status and education level (see Table 1).

During the start of this study, an important problem was encountered, i.e. identifying the n-3 enriched foods. The market study had as objective to list all available n-3 PUFA supplements as well as all n-3 PUFA enriched foods. For the latter, the criterion was that the package of the food items contained a label indicating the presence of and/or enrichment with n-3 PUFA. When considering n-3 PUFA enriched food, it is good to differentiate food items enriched in a direct and in an indirect way. In direct enriched food items, an extra nutrient, e.g. ALA or EPA&DHA, is added to the product at the end of the production process. Examples are bread and mayonnaise enriched with ALA by using ALA-rich oils in the production process, or margarines enriched with EPA&DHA. Direct enrichment with EPA&DHA became possible as technology made it achievable to produce high quality, deodorized, and stabilized oils enriched with LC n-3 PUFAs [21]. Indirect enrichment is performed via modification of animals' diet. In this respect, research efforts to increase the n-3 (LC) PUFA content of terrestrial animal products by enriching the animals' feed contributed to improving the overall intake of n-3 (LC) PUFAs [22]. Examples are chickens partially fed with fish meal that produce eggs containing EPA&DHA, cows fed with linseed enriched feed producing ALA-rich milk and meat. Producers of these directly and indirectly enriched foods indicate the presence of these n-3 PUFA on the packages of their food items. However, during the market study we experienced that also food items naturally rich in n-3 PUFA, e.g. ALA-rich oils and soy based desserts—thus, foods that did not undergo a modification—contained a label indicating the presence of n-3 PUFA. This made it difficult to really separate the enriched ones from the others.

In addition, it was found that most of the n-3 PUFA enriched foods available on the Belgian market are enriched with ALA and not with EPA&DHA. Eggs and margarines were the only available directly enriched food items containing EPA&DHA, so the only food items that could contribute to the n-3 LC PUFA intake of the studied women.

Another problem encountered was to find data on the EPA&DHA content of seaweed. Food composition tables as well as the scientific literature lack data on this issue. If these kinds of alternative EPA&DHA sources were to become more important in the future, these data would be very relevant. Moreover, for enriched margarines and eggs, EPA&DHA contents as reported on the packages were used. However, since inaccurate reporting on some labels exists, these data include a factor of uncertainty.

The results of this study showed that n-3 PUFA supplements are used by 5% of the Flemish women of reproductive age. A significant association was found between those who are pregnant, those who follow a diet, those who have a food allergy and those who report that they pay conscious attention to what they eat. This can be linked with the conclusion of Reinert et al. [23] that using dietary supplements is in general related to a healthier lifestyle.

This study also indicated that, although the supply of n-3 PUFA enriched foods is increasing, there still remains a big gap between the actual EPA&DHA intake and the one recommended. Of the women of reproductive age, 58.2% do not even reach 50% of the recommended intake. Although the mean and median EPA&DHA intake of the

pregnant and breastfeeding women is a bit higher than the overall mean and median intake, their intake is still far removed from the ISSFAL recommendation as well as from the advice of the PeriLip working group who recommended an intake of DHA only equal to at least 200 mg/day. When comparing the calculated EPA&DHA intake of this study to the calculated EPA&DHA intake of Flemish women in 2002, a slight increase is found over the 7 years, from 209 to 276 mg/day, which can be explained by an increased fish and seafood consumption as well as by the use of n-3 PUFA supplements and eggs and margarines enriched with EPA&DHA. Moreover, the results can also be influenced due to an oversampling of more highly educated women.

EPA&DHA intake was positively correlated with age, which means that older women (within the groups of women between 18 and 39 years old) tend to have a higher EPA&DHA intake. In addition, a significant association was found between the EPA&DHA intake on the one hand and suffering from high blood cholesterol, using supplements, doing sports regularly and reportedly paying conscious attention to what they eat on the other hand. These findings show that, in the future, efforts aiming to increase the EPA&DHA intake should focus on those people who do not tend to change their dietary habits on their own initiative and need extra support and information to convince them to change their diet.

Finally, it was also found that fish and other seafood remain the most important source of EPA&DHA intake. Accordingly, appropriate fish and other seafood consumption is the most probable solution to attaining a diet that would meet the recommendations for EPA&DHA. Within fish and seafood, small fatty fish species (e.g. herring, anchovy, sardine, sprat) are most likely to increase the intake of EPA&DHA in a safe way, due to their high LC n-3 PUFA and low contamination load. In the light of the depletion of fish stocks, other (sustainable) strategies are needed to help increase the EPA&DHA intake without creating an ecological problem. In this study, it was found that n-3 PUFA enriched foods do not really help to fill the gap between EPA&DHA intake and recommendation because (1) most of the n-3 PUFA enriched foods contain solely ALA and (2) those that contain EPA&DHA (eggs and margarine) only contribute very marginally to the overall intake. Enriching more foods with EPA&DHA would be an option, with the condition that sustainable sources of EPA&DHA are used, e.g. algae. In contrast, this study indicated that the use of n-3 PUFA supplements in general leads to a much higher EPA&DHA intake and helps to reach a an intake higher than the one recommended. However, these supplements are quite expensive, most of them rely on fish oil (and are therefore not a sustainable source) and as most nutritionists think, they should not be considered as magic bullets to convert an unhealthy diet into a healthy one. Therefore, diet-based approaches increasing the supply of n-3 LC PUFA in the food chain are preferable to the use of supplements. However, supplements based on sustainable sources can be a solution for specific subgroups with an increased need e.g. vegetarian women, pregnant women or patients with cardiovascular diseases.

A first promising and more sustainable solution to increase EPA&DHA supply and intake is to cultivate algae for supplements and direct and indirect enrichment. Algae are the original source of n-3 LC PUFA in fish and, as stated by Winkler [24], the option exists to use them directly for human consumption. Another option is the production of microbial oils, otherwise referred to as single cell oils (SCO), based on a DHA-producing organism that can grow in large-scale industrial fermenters. For example, *Crypthecodinium cohnii* produces a triacylglycerol oil in which DHA can reach levels between 40 and 50% of the total fatty acids and, moreover, occurs as the sole PUFA. Currently, the major application of these SCOs is in the form of a supplement for infant nutrition [25]. A third alternative way to increase the supply of n-3 LC PUFAs is through metabolic engineering in plants which manipulates the lipid metabolism and leads to the production of novel plant oils [26, 27]. It is also worth mentioning that recent studies report on the development of transgenic pigs able to convert n-6 PUFAs to n-3 PUFAs [28, 29]. However, long period of research and a long regulatory path will be needed before they will be able to enter the food chain, that is if ever they do, because a lot of controversy still exists with regard to the presence of transgenic foods on the market.

Conclusion

Although a variety of n-3 PUFA supplements and n-3 PUFA enriched foods are on the market and although a lot of media attention is paid to these n-3 PUFA, this study illustrated that an important gap remains between the actual EPA&DHA intake and that recommended within the group of Flemish women of reproductive age. However, these women are responsible for the health of the next generation, partly during the pregnancy and lactation period and partly during the first decades of their children's lives when they highly influence the dietary habits of their offspring. New and sustainable strategies will be needed to help all people (including the less health-consciousness) to increase their EPA&DHA intake in a sustainable way and to improve public health during the next decades.

Acknowledgments The dietician Mrs. M. Bellemans (Department of Public Health, Ghent University) is thanked for her contribution during the creation of the food frequency questionnaire and during the evaluation of the results. All participants who completed the questionnaire are gratefully acknowledged for their participation in this study.

Abstract Oxidized low-density lipoprotein (ox-LDL) plays a key role in the progression of atherosclerosis and diabetes complications. The aim of this study was first, to evaluate the association between ox-LDL and diabetes duration, and second, to examine serum level of ox-LDL in patients with prolonged diabetes and a desirable LDL-cholesterol level. A total of 36 type-2 diabetic patients with a diabetes duration of more than 5 years, 36 newly diagnosed diabetic patients, and 36 age-, sex- and BMI-matched healthy participants were recruited. Healthy participants and newly diagnosed patients were not receiving any treatment. All patients with prolonged diabetes had desirable LDL-cholesterol levels (<100 mg/dL), according to the adult treatment panel-III guidelines. While LDL-cholesterol was significantly lower in patients with diabetes duration >5 years, in comparison to newly diagnosed patients ($P < 0.01$), ox-LDL was significantly higher in patients with prolonged diabetes ($P < 0.001$). The ox-LDL-to-LDL ratio was dramatically higher in patients with diabetes duration >5 years in comparison to newly diagnosed patients and healthy participants ($P < 0.001$). Ox-LDL was significantly associated with diabetes duration ($r = 0.519, P = 0.001$). In multivariate analysis, this association remained significant ($\beta = 0.501$, $P = 0.003$) after adjustment for potential confounders. In conclusion, this study showed that the serum ox-LDL level increases with the length of diabetes, even though the patients' LDL-cholesterol level is maintained at a desirable level. Our findings highlight that possibly more attention should be focused on markers of oxidative stress in the management of lipids in diabetic patients.

Introduction

Oxidation of low density lipoprotein (LDL) is a key process in the early progression of atherosclerotic diseases and diabetes complications [1–3]. Oxidized LDL (ox-LDL), derived from LDL-cholesterol under oxidative stress, encompass many atherogenic properties. Several studies have reported the strong association of increased serum ox-LDL level, high serum malondialdehyde and presence of auto-antibodies against ox-LDL, with atherosclerosis, diabetes and its complications [4–7]. Ox-LDL is an independent predictor of endothelial dysfunction [8], with pro-inflammatory, prothrombotic, and pro-apoptotic properties in individuals suffering from oxidative stress, such as diabetic patients [9].

It is widely encouraged to maintain serum LDL-cholesterol below certain levels in diabetic patients [10]. It has been demonstrated that statins can have an influence on the ox-LDL level [11]. However, the efficacy of this function is not well documented in vivo [12]. It is yet to be examined whether maintaining serum LDL-cholesterol at a desirable level is sufficient to reduce the most atherogenic derivates of LDL-cholesterol, i.e. ox-LDL.

Guidelines for the management of the lipid profile in diabetic patients are mainly focused on controlling LDL-cholesterol, triglycerides (TG), high density lipoprotein-cholesterol (HDL) and total cholesterol [10]. Yet, no account is taken of some other important atherogenic lipids such as ox-LDL. It was decided that it would be interesting to evaluate how the ox-LDL level changes in our routine practice for lipid control in diabetic patients. In this study, we decided to evaluate two important subjects: first, to evaluate the association between ox-LDL and diabetes duration, and second, to examine serum level of ox-LDL in patients with prolonged diabetes and a desirable LDL-cholesterol level.

Methods

Participants

This cross-sectional hospital-based study was conducted from February 2008 to April 2009 in the outpatient diabetes clinic of a university general hospital. A total of 36 type-2 diabetic patients with a diabetes duration of more than 5 years, 36 newly diagnosed type-2 diabetic patients, and 36 age-, sex- and BMI-matched healthy participants were recruited. Diabetes mellitus was diagnosed according to the criteria of the American Diabetes Association [13]. Newly diagnosed diabetic patients were not taking oral hypoglycemic agents, aspirin, insulin, statin, and anti hypertensive medications. All patients with diabetes duration >5 years had a desirable LDL-cholesterol level (<100 mg/dL), according to the adult treatment panel (ATP) III guideline [10]. Smokers, patients with proteinuria or renal involvement (creatinine > 1.5 mg/dL or GFR < 70 cc/min), patients receiving anti-oxidants and those with evidence of glomerulonephritis, congestive heart failure, hypo and hyperthyroidism were not included. Demographic and anthropometric data including age, sex, duration of diabetes, height, weight in light clothing and blood pressure (in sitting position after 10 min rest) were recorded. Blood pressure was re-measured twice after 5 min and averaged. The body mass index (BMI; kg/m^2) was calculated according to the Quetelet formula.

The research was carried out according to the principles of the Declaration of Helsinki. The local ethics review committee of Tehran University of Medical Sciences approved the study protocol. All participants gave written informed consent before participation.

Blood Samples

Blood samples were collected after almost 12 h of fasting and, serum creatinine, fasting plasma glucose, total cholesterol, TG, HDL-cholesterol, LDL-cholesterol and HbA1C were measured. Glucose measurements [intra-assay coefficient of variants (CV) 2.1%, inter-assay CV 2.6%] were carried out using the glucose oxidase method. Cholesterol, HDL-cholesterol, LDL-cholesterol and TG were determined using direct enzymatic methods (Parsazmun, Karaj, Iran). HbA1C was estimated by High-Pressure Liquid Chromatography (HPLC) Method. Ox-LDL was measured using a commercially available sandwich enzyme-linked immunosorbent assay (ELISA, Mercodia, Uppsala, Sweden). The intra- and inter-assay coefficient of variation for the assay ranged between 4.5 and 7%. The detection limit was ≤0.03 U/L.

Statistical Analysis

Data were analyzed using SPSS software (version 16.0; SPSS Inc., Chicago, USA). Continuous variables are expressed as means ± standard errors of mean (SEM). Comparison between the three groups was performed using analysis of variance (ANOVA) with Scheffé post hoc. Adjusted partial correlation coefficients were calculated among variables. Multivariate regression analysis, with ox-LDL as the outcome, was used to evaluate the independent association between ox-LDL and the duration of diabetes. $P < 0.05$ was considered statistically significant.

Results

Characteristics of the study participants are presented in Table 1. There were no significant differences between

Table 1 Characteristics of participants in the three groups

Variables are expressed as means ± standard errors of mean (SEM)

[a] The P values are derived from analysis of variances (ANOVA) among the 3 groups

[b] Groups are matched for age, sex and BMI

* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$ when comparing new cases of diabetes and healthy participants

† $P < 0.05$, $^{\ddagger}P < 0.01$, $^{\dagger\ddagger}P < 0.001$ when comparing new cases and patients with a diabetes duration of more than 5 years

groups with respect to systolic and diastolic blood pressure, HbA1C, creatinine, cholesterol and HDL-cholesterol. Serum TG level was significantly higher in diabetic patients. In patients with a diabetes duration of more than 5 years, 4 patients were not receiving anti-diabetic treatments, 29 patients were using oral hypoglycemic agents (Metformin and/or Glibenclamide), and 8 were on insulin treatment. Fourteen patients (38.9%) with diabetes duration more than 5 years were on antihypertensive treatment (angiotensin converting enzymes inhibitors, angiotensin receptor blockers and/or beta blockers) and 12 patients (33.3%) were using statin. While LDL-cholesterol was significantly ($P < 0.01$) lower in patients with diabetes duration of more than 5 years (89.95 ± 4.47) in comparison to newly diagnosed (116.63 ± 4.32) patients, ox-LDL was significantly higher in patients with prolonged diabetes versus newly diagnosed patients (81.43 ± 1.65 vs. 45.50 ± 1.49; $P < 0.001$). The ox-LDL-to-LDL ratio was significantly ($P < 0.001$) higher in patients with a diabetes duration >5 years (0.94 ± 0.05) in comparison to newly diagnosed (0.42 ± 0.02) patients and healthy (0.42 ± 0.02) participants (Fig. 1). There were no significant differences in ox-LDL in patients receiving statins or not.

After adjustment for age, sex and BMI, ox-LDL was significantly ($P < 0.05$) associated with fasting plasma glucose ($r = 0.337$) and TG ($r = 0.312$) in healthy participants. In diabetic patients, ox-LDL was significantly associated ($r = 0.519$, $P = 0.001$) with diabetes duration (Fig. 2). In multivariate regression analysis, the association between diabetes duration and ox-LDL remained significant ($\beta = 0.536$, $P < 0.001$) after adjustment for age, sex, BMI, cholesterol, LDL-cholesterol, systolic and diastolic blood pressure, HbA1c, creatinine and fasting plasma glucose. In all the three groups, there was no significant association between ox-LDL and LDL-cholesterol.

Discussion

In this study, we showed that ox-LDL is significantly associated with the duration of diabetes. Multivariate regression analysis revealed that the association between

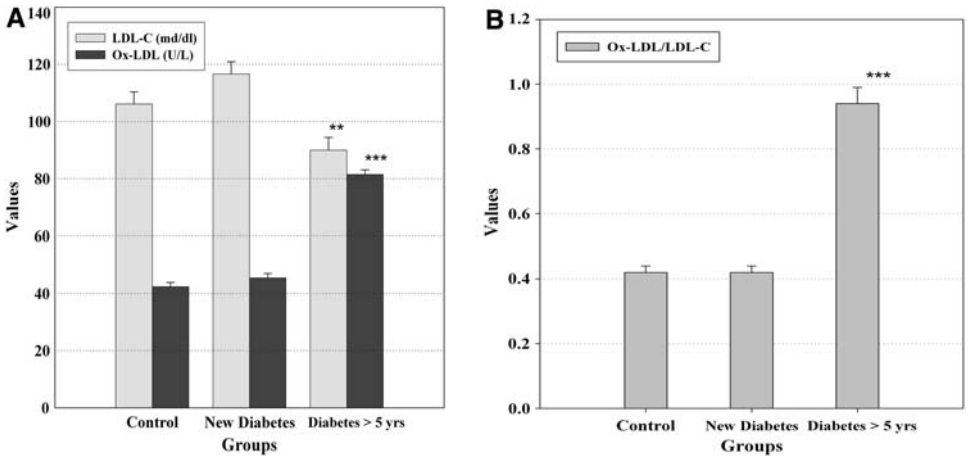

Fig. 1 Mean values of ox-LDL (U/L), LDL-cholesterol (mg/dL), and ox-LDL to LDL-cholesterol ratio (ox-LDL/LDL-C) in the three groups. Although LDL-cholesterol was kept in the desirable range (<100 mg/dL) in patients with diabetes duration of more than 5 years, the serum level of ox-LDL was still escalating (**a**). The contribution of the oxidized form of LDL to the total LDL-cholesterol was significantly higher in patients with prolonged diabetes (**b**). Groups were matched for age, sex and BMI. $*P < 0.05$, $**P < 0.01$, $***P < 0.001$ when comparing patients with prolonged diabetes versus newly diagnosed patients. *Handles* represent standard error of mean

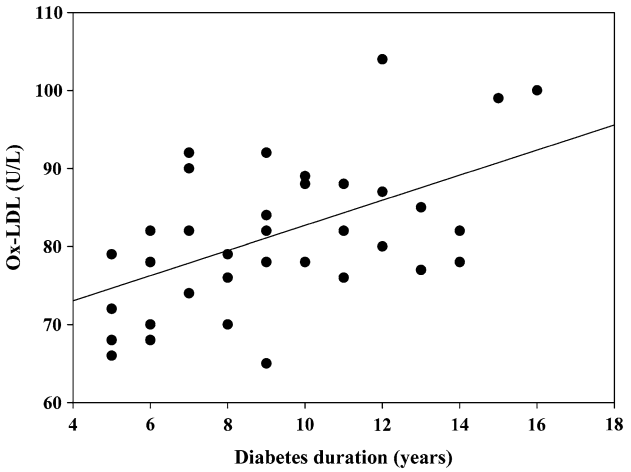

Fig. 2 Scatter plot demonstrating the significant correlation ($r = 0.519$, $P = 0.001$) between diabetes duration and ox-LDL

ox-LDL and diabetes duration was independent of age, sex, BMI, serum lipids, glycemic control and creatinine. Interestingly, our results suggested that maintaining an optimized level of LDL-cholesterol, according to guidelines for management of lipids in diabetic patients [10], does not sufficiently influence the ox-LDL level. Furthermore, we showed that ox-LDL levels corrected for LDL-cholesterol concentrations (ox-LDL/LDL-cholesterol: the proportion of oxidatively modified LDL to total LDL-cholesterol particles) significantly correlates to the diabetes duration.

In agreement with our findings, it has been shown that ox-LDL is associated with fasting plasma glucose [14, 15]. It was reported that serum ox-LDL levels are significantly higher in diabetic patients than healthy individuals [8, 16, 17]. In a study by Gokulakrishnan et al. [18] the mean level of ox-LDL in diabetic patients was higher than subjects with impaired glucose tolerance. Our results showed the association in patients with different durations of diabetes. Ox-LDL (or oxidation ratio of LDL-cholesterol) is reported to have a significant association with diabetes macro- and microvascular complications [6, 19–22]. Our findings, alongside with the results of the previous studies showing that high plasma ox-LDL levels are predictors of subclinical and clinical atherosclerosis [23–25], indicating that controlling ox-LDL level, may prevent the progression of atherosclerotic complications at an early stage.

The origin of ox-LDL is not completely understood. It has been suggested that ox-LDL could be formed enzymatically and/or by metal ion-catalyzed reactions within the circulation [26]. Nevertheless, relative importance of enzyme-mediated and non-enzyme-mediated LDL-cholesterol oxidation remains unclear [27]. These mechanisms are enhanced in diabetic status and progress with diabetes elongation. Increased sensitivity of LDL-cholesterol to oxidation in diabetic patients has been shown in several studies [28, 29]. LDL-cholesterol glycation may represent a predisposing event that facilitates subsequent oxidative modification [28, 29]. Advanced glycosylated end-products (AGEs) may induce the production of ox-LDL from macrophages, even though they do not directly cause oxidation of LDL-cholesterol [30]. Our results support the mechanisms for enhancement of oxidative stress in parallel with an increase in diabetes duration.

Diabetes is a progressive inflammatory condition. As the disease becomes prolonged, elevated free radical formation, elevated inflammatory cytokines and an overwhelming

endogenous anti-inflammatory response, propagate the oxidative stress in diabetic patients [31, 32]. It can be hypothesized that, alongside with the progression of the inflammatory status, ox-LDL increases with the chronicity of diabetes [33]. It was shown that ox-LDL is associated with hypercholesterolemia and high serum LDL-cholesterol [34, 35]. Surprisingly, in our results, we found a significant increase in the ox-LDL level in parallel with a decrease in the LDL-cholesterol level in patients with prolonged diabetes. Our findings can suggest that possibly the chronicity of diabetes is a potential mechanism that can independently increase the level of ox-LDL in diabetic patients. It has already been shown that a change in the ox-LDL level certainly does not occur in parallel with a change in the LDL-cholesterol level. As described by Holvoet [36], impaired glycemic control is associated with an in vivo increase in LDL-cholesterol oxidation irrespective of decreased or stable LDL-cholesterol levels. It has also been reported that a reduction in LDL-cholesterol can occur along with an unchanged ox-LDL level [37].

Maintaining LDL-cholesterol at less than 100 mg/dL is widely encouraged in patients with diabetes [10]; however, our results showed that keeping LDL-cholesterol in the aforementioned range does not guarantee a safe level of ox-LDL in diabetic patients as the disease becomes prolonged. As ox-LDL possesses its own consequences on the progression of diabetic complications [6, 7], it would be wise to try to reduce ox-LDL, alongside with controlling the plasma lipid profile in a healthy state.

Many studies have shown the effects of statins, 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, in lowering LDL-cholesterol and oxidative stress [11]. Of note, it has been demonstrated that statins reduce ox-LDL production [38, 39], and decrease total body fat oxidation [40]. A study by Van Tits et al. [41] reported a decrease of 35–43% in ox-LDL by therapeutic intervention with statins in patients with familial hypercholesterolemia. Statins posses well-documented beneficial effects on vascular redox state [42] and exert anti-inflammatory effects [38, 43–45]. Nevertheless, it should be taken into account that most of the studies on effects of statins on oxidative stress are confined to in vitro researches and there are still doubts about the in vivo effects of these agents. For example, Bredie et al. [12] reported no changes in the oxidative susceptibility of LDL-cholesterol after Simvastatin therapy. In our study, approximately one-third of patients with prolonged diabetes were receiving statins for optimizing their serum LDL-cholesterol levels. There were no significant differences in ox-LDL in patients receiving statins or not. Regardless of statin treatment, patients with prolonged diabetes had dramatically higher ox-LDL in comparison to newly diagnosed patients. Here lies an interesting finding of this study. It can be inferred from our results that independent of the effect of keeping LDL-cholesterol below 100 mg/dL, or using statins, there are other more-influential mechanisms (possibly the chronicity of diabetes) which increase ox-LDL on prolongation of diabetes.

In reviewing this study, one should pay attention to the limitations regarding using cross-sectional data, which precludes a determination of the direction of causality. Using the same ELISA kit as our study, it has been reported that ox-LDL significantly correlates with LDL-cholesterol [34, 41]. In our study, we were unable to show this association in any of our three groups. It should be noted that because of the limited statistical power, this non-significant association should be interpreted with caution. Further prospective studies are paramount to evaluate the effects of lipid lowering agents and/or anti-oxidants in lowering ox-LDL in patients with different durations of diabetes.

In conclusion, this study showed that the serum ox-LDL levels increase with the length of diabetes, even though the patients' lipid profiles are maintained at a desirable level. Our findings highlight that possibly more attention should be focused on markers of oxidative stress in the management of lipids in diabetic patients.

Conflict of interest statement The authors declare that they have no conflict of interests.

Abstract The aim of this study was to determine the impact of pitavastatin on low-density lipoprotein cholesterol (LDL-C) and lectin-like oxidized LDL receptor-1 (LOX-1) in patients with hypercholesterolemia. Twenty-five hypercholesterolemic patients (8 male, 17 female; age 66 ± 13, 21–80 years) who had not received anti-dyslipidemic agents and had LDL-C levels of more than 160 mg/dL were examined. Biochemical factors were measured at baseline and after treatment with pitavastatin (2 mg/day) for 6 months. Serum levels of LOX-1 with apolipoprotein B-100 particle ligand and a soluble form of LOX-1 (sLOX-1) were measured by ELISA. All subjects completed the study with no adverse side effects. Total-C (268 ± 26 vs. 176 ± 17 mg/dL), LDL-C (182 ± 21 vs. 96 ± 14 mg/dL), and LOX-1 ligand (867 ± 452 vs. 435 ± 262 ng/mL) were reduced with pitavastatin treatment ($P < 0.0001$ for each). Significant decreases in triacylglycerols were noted ($P < 0.0001$), but there were no changes in high-density lipoprotein cholesterol. After 6 months, there were no significant changes in high-sensitivity CRP or soluble LOX-1. At baseline, there were no significant correlations between LOX-1 ligand and either LDL-C or sLOX-1. The decrease in LOX-1 ligand was not correlated with the decrease in LDL-C, but was correlated with the decrease in sLOX-1 ($r = 0.47$, $P < 0.05$). In conclusion, pitavastatin therapy had beneficial effects on markers of oxidative stress in hypercholesterolemic subjects. Serum

levels of LOX-1 ligand may be a useful biomarker of the pleiotropic effects of statins.

Keywords Pitavastatin · Lectin-like oxidized low-density lipoprotein receptor-1 (LOX-1) · Pleiotropic effects

Abbreviations

LOX-1	Lectin-like oxidized LDL receptor-1
sLOX-1	Soluble LOX-1
LDL-C	Low-density lipoprotein cholesterol
HDL-C	High-density lipoprotein cholesterol
OxLDL	Oxidized low-density lipoprotein
CRP	C-reactive protein
ELISA	Enzyme-linked immunosorbent assay
TAG	Triacylglycerol
TC	Total cholesterol

Introduction

Numerous clinical studies on statin therapy have demonstrated that a reduction in plasma levels of low-density lipoprotein cholesterol (LDL-C) prevents atherosclerotic progression and decreases cardiovascular risk [1–3]. There is a growing body of evidence that the oxidative modification of LDL is involved in the progression of atherosclerosis. It has been reported that plasma levels of oxidized LDL (OxLDL) were elevated in patients with coronary artery disease, and were associated with plaque instability in coronary artery disease [4, 5]. However, the clinical study of LDL oxidation has been hampered by the difficulty of a specific assay for plasma levels of OxLDL. It has been shown that statins reduce the production of reactive oxygen species through pleiotropic effects independent of cholesterol reduction [6–8]. The effects of statins on various circulating biomarkers of oxidative stress have been reported in clinical studies.

Lectin-like OxLDL receptor-1 (LOX-1) is a receptor for OxLDL that is mainly expressed in vascular endothelial cells, and OxLDL uptake through this receptor may be involved in endothelial dysfunction in atherogenesis [9, 10]. More recently, a novel sandwich enzyme immunoassay for LOX-1-ligand, which uses a recombinant soluble form of LOX-1 and anti-apoB antibody, has been developed to detect circulating modified LDL via specific binding to LOX-1 [11].

Pitavastatin is a strong statin similar to atorvastatin and rosuvastatin [12–14], and has been shown to have pleiotropic effects in vitro. To date, there have been no reports on the relations between the effects of pitavastatin on LDL levels and LDL oxidation in humans. Thus, we examined the effects of pitavastatin on serum levels of LOX-1 ligand activity and soluble LOX-1 (sLOX-1), and their relationships in patients with hypercholesterolemia.

Methods

Study Patients

Twenty-five subjects, between the ages of 21 and 80 years, with a baseline LDL-C between 160 and 220 mg/dL who were not receiving lipid-lowering therapy were recruited. Exclusion criteria included exposure to cholesterol-reducing drugs within the previous 6 weeks, coronary artery disease, congestive heart failure, significant renal or hepatic disease, familial hypercholesterolemia, and pregnant or lactating women.

Protocol

After informed consent was obtained from all participants before the study, pitavastatin was administered at a dose of 2 mg/day for 6 months. Data obtained before and after 6 months of treatment with pitavastatin included fasting blood work, adverse events, and the results of a physical examination. Laboratory analyses of blood work included lipid analyses and the assessment of other biomarkers. All assays were carried out by personnel who did not know the clinical characteristics of the patients.

Measurement of Biomarkers

Blood samples for measuring the plasma or serum concentrations of parameters were collected from the peripheral vein at the time of the patient visit. The blood samples were immediately placed on ice and centrifuged at −30 °C until assay.

Lipid parameters [total cholesterol (TC), LDL-C, high-density lipoprotein cholesterol (HDL-C), and triacylglycerol (TAG)] were analyzed from ethylenediaminetetraacetic acid-treated plasma, and determined by commercially available enzymatic-colorimetric methods. Serum levels of high-sensitivity CRP were determined by a sensitive nephelometric assay (Dade, Behring, Japan). Fasting blood sugar, hemoglobin A1c, creatinine, uric acid, and creatine kinase, and a liver function test were measured by standard techniques.

Measurement of sLOX-1

According to a previous report [15], serum sLOX-1 levels were determined by a sandwich ELISA. Forty microliter of

standard recombinant human LOX-1 (61-273) or fourfold-diluted sera were applied to 384-well plates immobilizing anti-human LOX-1 antibody (TS92, 0.25 μg/well) [9]. Bound sLOX-1 was detected by the combination of another anti-human LOX-1 antibody (HUC5-40) and a peroxidase-conjugated donkey anti-chicken IgY (AP194P, Chemicon, MA) with TMB solution.

Measurement of LOX-1 Ligand Activity

LOX-1 ligand activities in plasma were determined according to a previous report [11]. Recombinant LOX-1 (0.4 μg/well) was immobilized on 96-well plates (Maxisorp, Nunc) by incubating overnight at 4 °C in 50 μL of PBS. After being washed twice with PBS, the plates were blocked with 0.3 mL of 20% (v/v) ImmunoBlock (DS Pharma) for 8 h at 4 °C. After being washed three times with PBS, the plates were incubated with 0.1 mL of the standard OxLDL or plasma diluted 40-fold with EDTA–HEPES buffer [10 mM HEPES (pH 7.0), 150 mM NaCl, 2 mM EDTA]. The plates were then washed three times with PBS, and incubated for 1 h at room temperature with 0.5 μg/mL HUC20, a chicken monoclonal antibody that recognizes mouse and human ApoB, in PBS containing 1% (w/v) BSA. After being washed three times with PBS, the plates were incubated for 1 h at room temperature with peroxidase-conjugated goat anti-chicken IgG (H + L) (KPL, Gaithersburg, MD) diluted 2,000-fold with PBS containing 1% (w/v) BSA. After being washed five times with PBS, a substrate solution containing 3,3′, 5,5′-tetramethylbenzidine (TMB solution, Bio-Rad Laboratories, Hercules, CA) was added to the plates and incubated at room temperature for 30 min. The reaction was terminated by the addition of 50 μL of 2 M sulfuric acid. Peroxidase activity was determined by the measurement of absorbance at 450 nm.

Statistical Analysis

Data are expressed as the mean values ± SD. To analyze the effects of treatment with pitavastatin for 6 months, the paired Student's *t* test was applied to paired data. Linear regression analyses were carried out to detect correlations between continuous valuables. A value of $P < 0.05$ was considered statistically significant.

Results

Subject Characteristics

The characteristics of the study population are shown in Table 1. The mean age of the study population was 63 ± 13 years and most of the subjects were female (68%). The subjects enrolled in this study had hypertension ($n = 16$, 64%) and diabetes mellitus ($n = 1$, 4%). Similar medical treatments were continued throughout the study period. Systolic and diastolic arterial pressures and pulse rate did not change during the study period (Table 1). All subjects completed the 6-month study protocol without any adverse side effects, and no clinical disorder developed during the study period.

Effects of Pitavastatin on Biochemical Profiles

Table 1 shows the lipid parameters before and after pitavastatin treatment. Before pitavastatin treatment, TC and LDL-C levels were abnormally high (268 ± 26 and 182 ± 21 mg/dL, respectively). TC (268 ± 26 vs. 176 ± 17 mg/dL) and LDL-C (182 ± 21 vs. 96 ± 14 mg/dL) significantly decreased after pitavastatin treatment ($P < 0.0001$ for each) (Table 1; Fig. 1a). Although pitavastatin treatment significantly decreased TAG from 145 ± 65 to 104 ± 40 mg/dL ($P < 0.0001$), it did not significantly change HDL-C (before, 57 ± 14 mg/dL; after, 58 ± 15 mg/dL; P = ns) (Table 1). Fasting blood sugar, hemoglobin A1c, uric acid, and creatinine phosphokinase were unchanged during the study period (Table 1). Other biochemical markers including liver function were unchanged (data not shown).

Measurement of LDL Ligands, sLOX-1, and High-Sensitivity CRP

LOX-1 ligands remarkably decreased with pitavastatin treatment (867 ± 452 vs. 435 ± 262 ng/mL, $P < 0.0001$)

Table 1 Hemodynamic and biochemical parameters before and after pitavastatin treatment

	Before	After

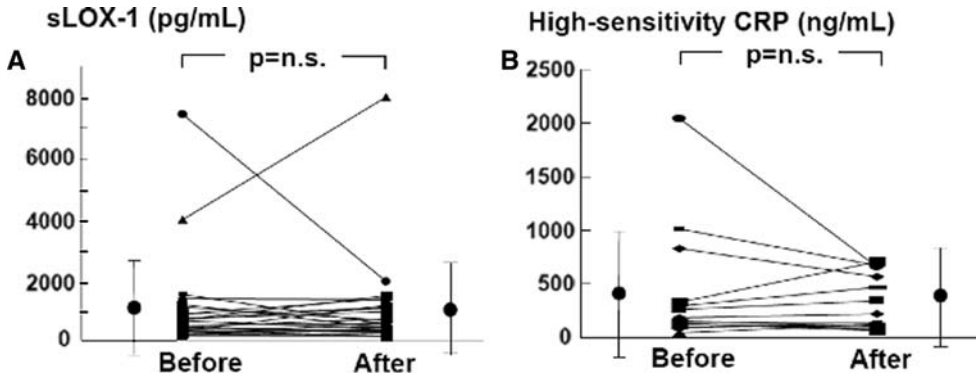

Fig. 2 Levels of soluble LOX-1 (sLOX-1) (**a**) and high-sensitivity CRP (**b**) before and after 6 months of treatment with pitavastatin

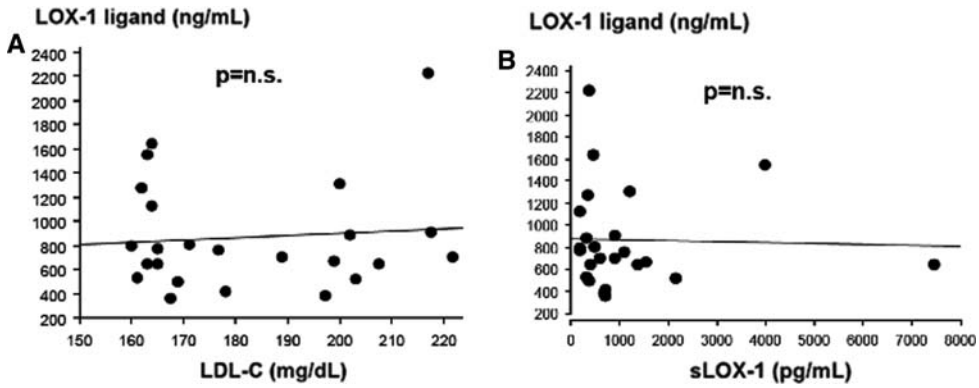

Fig. 3 Relationship between LOX-1 ligands and LDL-C before pitavastatin treatment (**a**). Relationship between LOX-1 ligands and sLOX-1 before pitavastatin treatment (**b**)

(Fig. 1b). Meanwhile, soluble LOX-1 (1,059 ± 1,530 vs. 1,022 ± 1,526 pg/mL) (Fig. 2a) and high-sensitivity CRP (0.42 ± 0.59 vs. 0.39 ± 0.45 mg/L) (Fig. 2b) did not change with pitavastatin treatment. In a 73-year-old woman with hypertension and stable angina pectoris, a marked increase in soluble LOX-1 levels was observed after treatment with pitavastatin (3,980–8,010 pg/mL). Her clinical characteristics and medical treatments did not change during the study period.

Before pitavastatin treatment, there was no significant linear correlation between LOX-1 ligands and LDL-C (Fig. 3a), or between LOX-1 ligands and sLOX-1 (Fig. 3b). In two subjects, basal sLOX-1 levels were far higher (>3,000 pg/mL) than those in the other 22 subjects. In the remaining 22 subjects, the degree of the reduction in LOX-1 ligands correlated with that in sLOX-1 (Fig. 4a), but not that in LOX-1 ligands (Fig. 4b).

Discussion

We first demonstrated that treatment with pitavastatin reduced LOX-1 ligands as well as TC, LDL-C, and TAG in hypercholesterolemic patients. The measurement of LOX-1 ligands may be useful as a tool for estimating pleiotropic effects of statins.

Statin therapy can ameliorate future cardiovascular events, and this improvement has been ascribed not only to

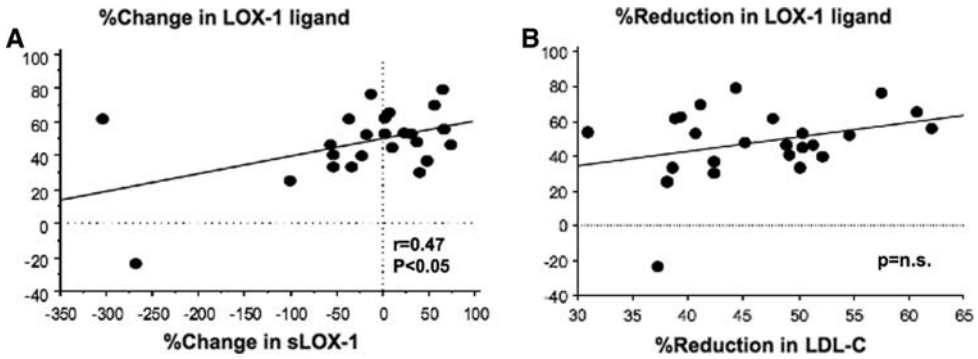

Fig. 4 Relationship between the degree of reduction in LOX-1 ligands and that in sLOX-1 (**a**). Relationship between the degree of reduction in LOX-1 ligands and that in LDL-C (**b**)

reductions in LDL cholesterol but also to the antioxidant properties of statins [6, 8, 16]. Different statins have different antioxidative capacities for LDL oxidation, and it is speculated that pitavastatin hinders the development of atherosclerosis by reducing the oxidative modification of LDL.

OxLDL is implicated in endothelial dysfunction as well as the formation and progression of atherosclerosis [10, 17]. It has been shown that plasma levels of OxLDL were elevated in patients with coronary artery disease, and were associated with the severity of acute coronary syndrome and coronary artery disease [4, 5]. We previously reported that plasma levels of OxLDL were a useful measure of coronary endothelial dysfunction [18]. However, the clinical importance of circulating OxLDL has not yet been fully elucidated.

Several receptors for OxLDL have been identified over the past few years [19–21]. LOX-1 is one such receptor for OxLDL and is expressed in atherosclerotic lesions, including endothelial cells, macrophages, and smooth muscle cells [9, 22]. OxLDL binds to LOX-1, resulting in NADPH oxidase activation and eNOS downregulation, and the atherogenic properties induced by OxLDL are mainly mediated via LOX-1 [10]. LOX-1 can be cleaved at its membrane proximal extracellular domain and released as soluble forms of LOX-1 [23]. It has been reported that serum levels of sLOX-1 are elevated in coronary artery disease [24, 25]. In the present study, soluble LOX-1 did not change after pitavastatin treatment. The expression of LOX-1 could be enhanced by risk factors for atherosclerosis such as hyperlipidemia, hypertension, and diabetes mellitus [22]. In the present study, arterial pressures and biochemical profiles other than lipid levels remained unchanged during the study.

LOX-1 recognizes multiple ligands such as OxLDL, apoptotic cells, bacteria, and platelets [10, 22]. The precise OxLDL epitope recognized by LOX-1 is not known. OxLDL is not one homogeneous entity, but rather represents multiple chemical and immunogenic modifications of the lipid and apoB-100 on LDL. ApoB-containing lipoproteins and their oxidized form play an important role in the pathogenesis of atherosclerosis. We previously demonstrated that plasma levels of LOX-1 ligands were increased in ApoE-deficient mice fed a high-fat diet and there was a link between the level of LOX-1 ligands and the progression of atherosclerosis in mice [11]. Recently, LOX ligands have been shown to be associated with the incidence of cardiovascular disease [15].

In the present study, we showed that pitavastatin can reduce LOX-1 ligands but not sLOX-1. Circulating levels of sLOX-1 may not change after pitavastatin treatment, although the vascular expression of LOX-1 was decreased with pitavastatin treatment. As for pitavastatin, the reduction in LOX-1 ligand levels was similar to that in LDL-cholesterol levels. The changes in LOX-1 ligands were correlated with those in sLOX-1, suggesting a potent link between sLOX-1 and LOX-1 ligands. Before pitavastatin treatment, LOX-1 ligands showed no significant correlation with plasma LDL-C levels. In addition, the degree of the reduction in LOX-1 ligands was not significantly correlated with that in LDL-C levels. Numerous trials have shown that statins can lower LDL-C levels. In addition, LOX-1 ligand levels may be a suitable biomarker for estimating the pleiotropic effects independent of the cholesterol-lowering effects of statins. In previous studies using WHHL rabbits, fluvastatin significantly reduced plasma levels of both LOX-1 ligands and TC, as well as the atherosclerotic lesion area and the cholesterol content of aortic arches [26].

In the present study, treatment with pitavastatin did not change plasma levels of CRP. CRP is produced predominantly in the liver as part of the acute-phase response, and is also expressed in smooth muscle cells within diseased atherosclerotic arteries [27]. CRP and LOX-1 share a range of biological functions. CRP can induce LOX-1 expression [28], and the binding of CRP to LOX-1 enhances the binding affinity of OxLDL to LOX-1 [29]. Statin therapy reduces high-sensitivity CRP by a mechanism beyond LDL reduction [14]. Koshiyama et al. [30] reported that pitavastatin lowered high-sensitivity CRP in patients with hypercholesterolemia. Our modest sample size might have limited the observed effects of pitavastatin on serum high-sensitivity CRP levels. Further studies are needed to

address whether serum levels of LOX-1 ligands are associated with anti-inflammatory, anti-thrombotic, and vascular endothelial effects.

In conclusion, pitavastatin therapy reduces both LDL-C and LOX-1 ligands in hypercholesterolemic subjects. Serum levels of LOX-1 ligands may be a useful biomarker for monitoring the pleiotropic effects of statins, and the reduction of LOX-1 ligands by statins, other antioxidants, or lifestyle modifications may be a promising therapeutic strategy against atherosclerosis and future cardiovascular events.

Study Limitations

Several important questions remain regarding the impact of pitavastatin on LOX-1 in hypercholesterolemic subjects. For example, our findings are limited by the fact that this was an uncontrolled study with a modest number of subjects. Furthermore, we did not address the question of the dose–response effects of pitavastatin on LOX-1. We must validate our findings in randomized, well-controlled and larger human studies. In addition, further analyses must be performed to examine whether patients with risk factors for atherosclerosis have higher levels of LOX-1 ligand activity than healthy subjects.

Abstract Exercise (EXE) and amino-bisphosphonates (BP) are both considered as useful strategies in the prevention of post-menopausal bone loss. Exercise reduces lipid levels, and BP may induce increase in high-density lipoprotein cholesterol (HDL-C). We hypothesized that combined effects of BP and exercise would produce a better improvement of lipid profile. We studied the specific and combined effects of zoledronic acid (Z) and EXE on lipid profile and bone remodeling in mature ovariectomized (OVX) rats. Six-month old female rats were randomly assigned to either a sham-ovx group ($n = 12$) or one of four OVX groups ($n = 12$): vehicle-treated sedentary (OVX); OVX + EXE (OVX-E, running on a treadmill for 12 weeks); OVX + Z (20 μg/kg, i.v.), (OVX-Z); OVX + Z+EXE (OVX-ZE). Total cholesterol (TC), HDL-C and bone remodeling markers were measured at baseline and at the end of the study. We demonstrated that both Z and EXE prevented the increase in bone resorption resulting from OVX, and individually improved the atherosclerotic risk index. Therapy with Z resulted in significant increase (39.00 ± 0.03 vs. 53.6 ± 0.01 mg/dl; +37.4%, $P < 0.05$) in serum concentration of HDL-C and a non significant decrease in TC (135.30 ± 0.03 vs. 144.80 ± 0.05 mg/dl; −5.8%) in the OVX-Z group compared to the OVX group. Post-menopausal women have elevated risk of CVD and bone resorption, hence, these data ultimately demonstrate (except for the elevated ratio in the combined group) that exercise and zoledronic acid are useful in minimizing the impact of these two processes in women and the combination of the two may be clinically relevant.

Introduction

In post-menopausal women, amino-bisphosphonates represent one of the pharmacologic options for the prevention and treatment of osteoporosis [1]. Among bisphosphonates one can distinguish medication by their molecular mechanisms of action. Etidronate, clodronate, tiludronate inhibit osteoclast function and induce osteoclast apoptosis by incorporation into intracellular analogs. These compounds do not interfere with intracellular sterol biosynthesis [2]. Amino-bisphosphonates inhibit the prenylation and function of GTP-binding proteins required for osteoclast function [3]. These last compounds inhibit squalene synthase and hence may be cholesterol lowering agents in animal [4]. Recently, it has been shown that high doses of zoledronic acid given in patients with smoldering myeloma may modify their lipid profile [5]. There was an improvement in the atherosclerotic risk index with an increase in the HDL-C/LDL-C ratio (high-density lipoprotein cholesterol/low density lipoprotein cholesterol ratio) and a decrease in the TC/HDL-C ratio (Total cholesterol/high-density lipoprotein cholesterol ratio).

Non pharmacological prevention of osteoporosis fracture by physical activity and particularly regular exercises (EXE) characterized by impact or loading is currently recommended [6]. The effect of regular exercise on the lipid profile has been developed in a lot of studies [7–9]. It has been recently demonstrated that increasing steps walked may have beneficial effects on serum lipids and thus may decrease the cardio vascular disease risks [10].

There is a large body of evidence that bisphosphonates reduce the bone turnover and particularly inhibit bone resorption [11, 12], the target cell being the osteoclast. Conversely, physical activity, and more specifically mechanical stress, has been shown to induce an osteogenic effect mediated by osteocytes and osteoblasts [13–15]. Based on these assumptions, the present study aims at investigating both specific and combined effects of zoledronic acid and treadmill exercise on bone turnover and the lipid profile in mature ovariectomized (OVX) rats.

Materials and Methods

Rat Groups and Treatment

Sixty 6-month old Wistar female rats (Animal Production Center, Olivet, France) were maintained and acclimatized for 2 weeks on a 12-h light/12 h dark cycle at 22 ± 2 °C during the experiment. Rats were housed in standard cages (two animals to a cage) with ad libitum access to food [a commercial standard diet (A04, SAFE, France)] and water. Rats were randomized to either sham-operated (sham; $n = 12$) or bilateral OVX ($n = 48$). We did not ration OVX rats in order to mimic real life conditions in postmenopausal women, knowing that this is usually recommended as obesity induced by OVX may protect against osteopenia [16].

Among the rats randomly selected in the the OVX group, a second randomization procedure was done leading to four groups of 12 animals each in addition to the sham-operated group (SH): OVX sedentary controls (OVX); OVX-exercise (OVX-E); OVX-zoledronic acid (OVX-Z); OVX- zoledronic acid exercise- (OVX-ZE).

Based on a previous dose-ranging study, we selected a single i.v. dose of 20 μg/kg zoledronic acid, as it has been demonstrated, it is the minimum dose required to provide long-term bone protection against the effects of OVX [17]. We injected the drug or a physiological saline solution 2 days before the OVX surgery. Sham operations were performed by exteriorizing the ovaries. Bilateral ovariectomies were performed under ketamine-xylazine anesthesia. This experiment was conducted in conformity with the Public Health Service Policy on Human Care and Use of Laboratory Animals. The procedure for the care and killing of the animals was in accordance with the European Community Standards on the care and use of the laboratory animals (Ministère de l'Agriculture, France, Authorization Inserm 45-001).

Exercise Regimen

The exercise regimen (EXE) consisted of running in an especially home made motor-driven treadmill, which allowed eight rats to exercise together. The running program was initiated gradually. The exercise regimen consisted of daily training. During the first 4 weeks, the speed of the treadmill and the duration of each running were gradually increased from 8 m/min for 3–30 min to 12 m/min for the first 2 weeks. In the two following weeks, the speed and duration of the running session were gradually increased to 15 m/min for 60 min. This speed and duration were maintained for 5 days per week for the rest of the experiment (8 weeks more).

Lipids and Bone Turnover Biomarkers

At baseline and at the end of the study, blood was obtained by venous puncture at the tail. Blood samples were allowed to clot at 4 °C for 20 min before centrifugation at 3,000 rpm for 10 min. Sera were stored at −20 °C for 24 h and then stored at −80 °C until analysis. Analyses of total serum cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), and low density lipoprotein cholesterol (LDL-C) were determined using a high performance

cholesterol colorimetric assay (Hitachi). The inter and intra-assays were in our laboratory <10%.

Osteocalcin (OC) and C terminal collagen cross-links (CTx) which are respectively biomarkers of bone formation and resorption were assayed in duplicate by ELISA (Nordic Bioscience Diagnostics, Herlev Hoved-Gade, Denmark). The within-assay and between assay CVs were <10% in our laboratory. The intra-assay CVs were 5.5 and 5.6% respectively for OC and CTx. The inter-essays CV were 5.0 and 5.6% respectively for OC and CTx.

An uncoupling index (UI) was calculated to assess the relative balance of the formation and resorption processes of bone remodeling, as previously described [18]. First, the means ± SE of the baseline CTx and OC values were determined in each rat. Using the values of the SHAM group, OC and CTx Z-score [(rat value − mean baseline)/SD baseline] were calculated by subtracting the Z-score of the resorption marker from the Z-score of the formation marker. A positive UI indicates bone remodeling unbalanced in favor of bone formation, whereas a negative UI reflects an unbalanced favoring bone resorption.

Plasma Cytokine TNF-α

In order to assess the expression of proinflammatory cytokines potentially induced by the zoledronic acid or the exercise regimen, cytokine TNF-α was measured using an immuno assay ELISA (IBL Hamburg, Deutschland). The intra-essays CV and inter-essays were respectively <5% and <10%.

Body Weight, Fat Mass, Lean Mass and Bone Mineral Content (BMC) Measurements

All analyzes were conducted with the Discovery A densitometer (Hologic, Inc., Bedford, MA) calibrated daily in accordance with the manufacturer's recommendations. The rat whole body (WB) module was used to provide WB fat mass and WB lean mass. At baseline and at 12 weeks (4 weeks of gradually increased exercise and 8 weeks at full regimen, i.e. paragraph exercise regimen described above) lean and fat masses were measured by DXA. The root-mean square CV of in vivo WBBMC, WBBMD and WB fat mass were respectively 1.2, 0.87, and 3.8%. These CVs were determined from two repeated measures with repositioning on 30 animals.

Statistical Analysis

Data are presented as means ± standard deviations (SD) for body weight and body mass; they are presented as mean ± standard error of the mean (SEM) for serum chemistry. Normal distributions (Gaussian) of the data were assessed by a Kolmogorov–Smirnov test. The effect of ovariectomy was determined by comparing the sham-OVX and OVX groups using *t* test. To compare the main and combined effects of exercise and zoledronate between the OVX groups for longitudinal data, a two-way ANOVA with repeated measures was performed. In the event of a significant interaction, exercise and zoledronate effects were considered synergistic. A one-way ANOVA with post hoc, pair-wise comparisons using Fisher's protected least-significant difference [19] was used in case of significant interactions. In the event of a non-significant interaction, the main effect for each intervention (zoledronate, EXE) was explored by Newman–Keuls test and intervention effects were considered additive. The level of significance was set at $P \leq 0.05$. All statistical analyses were performed with software PCSM (OPTIMA-Deltasoft, France).

Results

All the data followed a normal distribution. Significant interaction were found in lipid parameters, serum CTX and uncoupling index between exercise and zoledronic acid.

Anthropometrics and Densitometry Parameters

Body weight in the OVX group was significantly greater than in sham operated rats 12 weeks post-surgery 386 ± 33 versus 333 ± 22 g; $P = 0.002$. There was a significant difference in body weight between the OVX-Z group and the two exercised groups (Table 1). Percentage of fat mass was found significantly higher in the OVX-Z group compared to all the OVX groups (Table 1). There was a higher percentage of fat mass in the OVX group (27.7%) as compared to the one in the SH group (19%), $P < 0.005$. There were no significant differences observed between the groups for WB lean mass. We have found a significant difference for whole body BMC between the OVX-Z group and the OVX, OVX-E and OVX-ZE groups (Table 1).

Lipid Profile

The OVX group had a higher serum total cholesterol and LDC-C levels compared with the SH group (Table 2). The OVX-E group displayed a significantly lower TC (127.2 mg/dl) than in the OVX group (144.8 mg/dl) ($P < 0.05$). We observed a 37.4% higher HDL-C level in the OVX-Z group (53.6 mg/dl) than in the OVX group (33 mg/dl) ($P < 0.05$). Exercise also markedly increased the HDL-C (+25.4%) in the OVX-E group as compared to the OVX group ($P < 0.05$). However, the OVX-ZE group

Table 1 Changes in anthropometric and bone parameters in WBBMC in sham-operated (SH) or ovariectomized (OVX) mature rats treated or not by zoledronic acid (Z) (a single injection 20 μg/kg), exercising on a treadmill or not (E) for 12 weeks

[a] OVX differences versus SH

[b] Differences versus OVX

[c] Differences versus OVX-Z

[d] Differences versus OVX-E

[e] Interactions between treatment and exercise

LDL-C low-density lipoprotein cholesterol, *HDL-C* high-density lipoprotein cholesterol, *TC* total cholesterol, *TNF α* tumor necrosis factor alpha

displayed lower levels of HDL-C than in the OVX-E and OVX-Z groups (Table 2). There was a trend to a higher TC/HDL-C ratio between baseline and the end of the study in the OVX-group $P = 0.06$. However, this ratio was significantly lower in the OVX-Z and the OVX-E groups respectively 2.53 and 2.54 than in the OVX group ($P < 0.05$). Conversely, the TC/HDL-C ratio in the OVX-ZE group was not significantly different from in the OVX-group and was higher (3.54) than in the OVX-Z and the OVX-E groups (Table 2). Likewise, the HDL-C/LDL-C ratio decreased significantly in the OVX groups between baseline and the end of the study (0.774 vs. 0.416; $P < 0.01$). This latter ratio significantly increased the OVX-Z and OVX-E versus the OVX group and there was a trend to a higher HDL-C/LDL-C ratio in the OVX-Z group than in the OVX group ($P = 0.058$) (Table 2).

Plasma Cytokine TNF-α

Ovariectomy was characterized by an increase in TFN-α between the baseline and at the end of the study (534.8 ± 14 vs. 678.9 ± 9 pg/ml; $P < 0.001$). There was an interaction between exercise and zoledronic acid concerning the levels of plasma TFN-α. As indicated in Table 2 we have found higher values of TNF-α at the end of the study in the OVX-Z, OVX-E and OVX-ZE groups than in the OVX group ones. The highest level of the TNF-α was found in the OVX-ZE group and it was significantly higher than in the OVX-E group, respectively 721.5 ± 12.5 versus 697 ± 7 pg/ml; $P < 0.01$.

Bone Turnover

The CTx level was 27.7% higher in the OVX group (23.8 ng/ml) than in the SH group (18.6 ng/ml), $P < 0.0005$. The CTx levels were significantly lower in OVX-Z and OVX-E groups as compared to the OVX group ($P < 0.05$). However, the CTx levels in the OVX-ZE were not statistically different from those in the OVX group but were significantly higher than in the OVX-Z and OVX-E groups (Table 3). In contrast, at the end of the study, serum osteocalcin levels were not significantly different between the SH group and the OVX group. The OVX-ZE group displayed higher osteocalcin level than in the OVX, the OVX-Z and the OVX-E groups. The osteocalcin level was significantly higher in the OVX-E group (178.27 ng/ml) versus the OVX and OVX-Z groups (respectively, 117.83 and 139.32 ng/ml) (Table 3). As expected the uncoupling index moved from −0.26 at baseline to −4.43 at the end of the study in the OVX group. In the OVX-E group the UI increased from −0.22 at baseline to +3.42 at the end of the study. Results of the UI in the OVX-Z groups are indicated in Table 3.

Table 3 Changes in OC, CTX and uncoupling index (UI) in sham-operated (SH) or ovariectomized (OVX) mature rats treated or not by zoledronic acid (Z) (a single injection 20 μg/kg), exercising on a treadmill or not (E) for 12 weeks

Discussion

The main findings of the present study were that the therapy with zoledronic acid (a single injection) resulted in a significant increase (+37.4%) in serum concentration of HDL-C and a trend toward lower TC (−5.8%) as compared to the vehicle-treated ovariectomized mature rats. Moreover, these changes were associated with a significant decrease in the TC/HDL-C ratio and a trend toward an increase in the HDL-C/LDL-C ratio. Such parameters are recognized indicators of atherosclerosis risk. These last results on the lipid profile might have a positive effect on cardiovascular risk if one considers their extrapolation to human.

However, it is noteworthy that, if specific effects of exercise and zoledronic acid were beneficial for atherosclerotic risk, the additive effects of these two interventions had produced a paradoxically negative impact.

To our knowledge, there is only one study in rats with such a consideration, i.e. assessment of blood lipids rodent treated with bisphosphonates [20]. In the latter study, female Sprague–Dawley rats ovariectomized at 11 weeks were treated by alendronate and the authors did not observed any effect on the serum cholesterol levels after 3 weeks of treatment. At the same time, there was a 1.2–1.5 fold higher serum cholesterol level in the OVX group as compared with the sham group. It has been demonstrated that the rat model would be useful for studying the pharmacological effects of estrogen on total serum cholesterol [21]. Differences might be observed concerning the mechanisms for the hypocholesterolemic effect of estrogen between rats and humans. Estrogen lowers cholesterol by up-regulation of the hepatic LDL receptor [22]. In addition, in the rat, both HDL-C and LDL-C may be reduced because rat HDL-C contains apoprotein E (which is not found in human HDL-C) [23]. Hence, the amazing results displayed in the OVX-ZE group might be explained by differences between lipid metabolism in humans and rats (our rat model might not be the more appropriate).

In early postmenopausal women, exercise programs may reduce lipid levels [24]. In addition, it has been noticed that IV amino-bisphosphonates induced, in post-menopausal women with moderate to severe osteoporosis, a significant increase in HDL-C [25]. In our study in mature ovariectomized rats, we investigated the separate and combined effects of treadmill running exercise and zoledronic acid on the lipid profiles. Papers aiming to describe the lipid profile when using bisphosphonates for metabolic bone disorders are scarce and sometimes conflicting. In human it has been recently reported that in smoldering multiple myeloma patients zoledronic acid may have an effect on lipid metabolism with a decrease in both TC and LDL-C [16]. Guney et al. [26] have also recently reported data suggesting in 49 patients treated for osteoporosis with alendronate a beneficial effect on lipid metabolism. Two other studies have shown respectively in patients treated by IV pamidronate for Paget's bone disease [27] and in postmenopausal women with osteoporosis treated by IV neridronate [25] a reduction in LDL-C and an increase in HDL-C. Specific mechanisms leading to the effects of bisphosphonates on lipid metabolism are still unknown. However some bisphosphonates inhibit the squalene synthase enzyme and cholesterol biosynthesis [4] as it has been demonstrated for the first time in vivo by Amin et al. [28]. Indeed squalene synthase is one of the key enzyme in cholesterol biosynthetic pathway but reduction of plasma cholesterol can also be achieved by inhibiting hydroxymethyl-glutaryl-coenzyme A reductase (HMG-CoAR); which is also a key rate-limiting enzyme involved in the cholesterol biosynthesis and the development of such inhibitors of the HMG-CoAR has led to the family of statins [29]. Recent studies have highlighted the role of the farnesyl pyrophosphate synthetase (FPPS) as the molecular target of nitrogen-containing bisphosphonates [11, 12]. The FPPS is a distal enzyme of the mevalonate–squalene pathway and the ability of aminobisphosphonates to inhibit this enzyme is also a possible mechanism in lowering cholesterol.

Physical exercise was also able in our study to significantly decrease TC (−12%) and increase HDL-C (+34%) in trained rats as compared to the ovariectomized sedentary rats. Consequently, the TC/HDL-C and HDL-C/LDL-C ratios were respectively lower and higher in EXEd rats than in sedentary rats as expected [21, 26].

Because exercise and zoledronic acid may have different ways of producing an action on lipid metabolism (i.e. increase in aerobic metabolism, oxygen uptake and fatty acid use for muscular energy supply during exercise [30] and actions on cholesterol biosynthesis with zoledronic acid), we hypothesized in this study that, it was possible to observe additive effects of exercise and zoledronic acid on the lipid profile. This was not the case in our study as we noticed both for TC and HDL-C no statistical differences between ovariectomized rats treated with vehicle and ovariectomized rats practicing exercise treated with zoledronic acid. We cannot explain this effect, it is possible that the expression of certain antioxidant enzyme stimulated by the treadmill running exercise may have been counteracted by the inflammatory effects induced by the injection of zoledronic acid [31]. Indeed it has been shown that bisphosphonates may have pro inflammatory effects and clinicians do know the acute-phase response following the first injection of IV aminobisphosphonates in human. We do not assess in this study the oxidative stress indicators and oxidant status resulting of the exercise regimen

and the bisphosphonate therapy. Furthermore, we only assess the plasma inflammatory cytokine TNF-α. In the present study, the highest value of TNF-α at the end of the study was found in the OVX-ZE group. The TNF-α results found in this group (exercise training is supposed to reduce inflammation by decreasing TNF-α [32]) might be a possible explanation of our paradoxical lipid profile results in this group. Conversely, bisphosphonates are also described to have anti-inflammatory effects [33] and clodronate has been shown to inhibit the in vitro production of super oxide free radicals by polynuclear cells [33]. In turn these last effects may have been counterbalanced by some characteristics of the exercise regimen applied to the animals. Exercise training may rather reduce TNF-α but it has been shown sometimes that TNF-α level was not altered by exercise [10]. We have found a mild but significant increase in the TNF-α level at the end of the study in the OVX-E group as compared to the OVX group ($P = 0.04$).

At the end of the experiment the CTx levels were respectively 18.8 and 19.1% lower in the OVX-E and OVX-Z groups as compared to the OVX group. However, we can easily distinguish the effects of EXE and zoledronic acid on the bone turnover as there was a strong negative UI indicating an imbalance favoring resorption in the OVX group, a strong positive UI in the OVX-E group indicating that bone remodeling was unbalanced in favor of formation and a mild positive UI in the OVX-Z group indicating that zoledronic acid effects in this ovariectomized mature rats study prevented the deleterious effects of OVX, i.e. (increase in bone resorption parameters). Theoretically, it is an attractive hypothesis that a concurrent combination of exercise and zoledronic acid would be superior to either intervention alone as they act on different target sales. In the present study, the lack of additive effect of the combination exercise and zoledronic acid on the bone turnover might be explained by the potency of the antiresorptive effect of the zoledronic acid. The response to the osteogenic effects of exercise might be blunted by the powerful effect of zoledronic acid. Such a hypothesis has been mentioned to explain the lack of efficacy in combining parathyroid hormone with alendronate, the capacity of the antiresorptive drug being superior to a capacity of formation associated with the PTH treatment [34]. To our knowledge there have been two studies aiming at combining a bisphosphonate therapy with exercise in rats [35, 36]. Unfortunately none of them have investigated the effects on bone turnover markers.

We observed an increase in weight in the OVX-Z group as compared to the OVX-E and OVX-ZE groups. However it has been demonstrated that although differences in body weight are often cited as the reason for a better lipid profile between active and inactive persons, some data support an influence of physical activity on lipid profiles independently of the metabolic effect of weight variations [30] and this may be also the case with the action of zoledronic acid on lipid metabolism.

In this study, we aimed to analyze the individual and combined effects of zoledronic acid and treadmill exercise on lipid profile and bone remodeling ovariectomized rats. The present results confirmed that both zoledronic acid and physical exercise prevent the increase in bone resorption resulting from the ovariectomy. However we did not find any positive additive effect when combining these two interventions despite the different mechanisms and action pathways involved.

Both exercise and zoledronic acid were shown to individually improve the atherosclerotic risk index.

Our finding that zoledronic acid given in OVX-rats may interfere with lipid metabolism (mild reduction in TC and a large increase HDL-C) has not yet been reported in animal studies. Several studies [5, 25–27] in humans show that some amino bisphosphonates including zoledronic acid [5] seem to be able to induce effects on lipid metabolism with a profile that might be clinically relevant as amino bisphosphonates are largely used for the treatment of several bone disorders. Our results are hypothesis generating and further studies are needed to corroborate our findings.

Expression of Genes Associated with Bone Resorption is Increased and Bone Formation is Decreased in Mice Fed a High-Fat Diet

Ying Xiao · Jue Cui · Ya-Xin Li · Yong-Hui Shi · Guo-Wei Le

Received: 10 September 2009 / Accepted: 11 February 2010 / Published online: 7 March 2010

Abstract A high-fat diet (HFD) leads to an increased risk of osteoporosis-related fractures, but the molecular mechanisms for its effects on bone metabolism have rarely been addressed. The present study investigated the possible molecular mechanisms for the dyslipidemic HFD-induced bone loss through comparing femoral gene expression profiles in HFD-fed mice versus the normal diet-fed mice during the growth stage. We used Affymetrix 430A Gene Chips to identify the significant changes in expression of the genes involved in bone metabolism, lipid metabolism, and the related signal transduction pathways. Quantitative RT-PCR was carried out on some significant genes for corroboration of the microarray results. At the conclusion of the 12-week feeding, the down-regulation of most of the genes related to bone formation and the up-regulation of most of the genes related to bone resorption were observed in the HFD-fed mice, consistent with the changes in plasma bone metabolic biomarkers. Together, the HFD induced a decrease in the majority of the adipogenesis-, lipid biosynthesis-, and fatty acid oxidation-related gene expression, such as PPARg and APOE. Furthermore, some genes engaged in the related signal transduction pathway were strongly regulated at the transcript level, including IGFBP4, TGFbR1, IL-17a, IL-4, and P53. These results indicate that an HFD may induce inhibitory bone formation and enhanced bone resorption, thus causing adverse bone status.

Keywords Bone mass · High-fat diet · Hyperlipidemia · Gene expression profiles · Bone metabolism

Abbreviations

BMD	Bone mineral density
HFD	High-fat diet
RT-PCR	Reverse transcription-polymerase chain reaction
P1CP	Propeptide of I collagen C-propeptide
NTx	Cross-linked N-telopeptides of bone type I collagen
ROS	Reactive oxygen species

Introduction

A high-fat diet (HFD) has been recognized as a risk factor for a person's health being involved in conditions such as dyslipidemia, atherosclerosis, obesity, and osteoporosis [1–5]. The intake of lard rich in highly saturated fat is pervasive and consequently results in the increasing prevalence of dyslipidemia in China [5]. Dietary saturated fat intake has been recognized as contributing to the likelihood of osteoporosis-related fractures [4, 6]. Moreover, children treated with a high-fat low-carbohydrate diet could have a worse bone mineral status [7]. In growing animal models, an HFD or high-energy diet could deleteriously affect bone mineral content, structure, and mechanical properties [8–10]. Lac et al. [11] found that significant correlations were noted between body composition, adiponectin, and bone parameters in growing rats fed an HFD. Parhami et al. [12] have pointed out that an atherogenic diet inhibits bone formation by blocking differentiation of osteoblast in growing mice, possibly resulting from lipid oxidation

products. In addition, a recent study has suggested that an HFD may induce an increase in bone resorption in mice [13]. However, none of these studies addressed the effects of HFD on global gene expression profiles of bone.

A gene microarray can provide a broad view of gene expression. Thus, for the first time, we used an Affymetrix GeneChip 430A, which contains over 22,000 probe sets for 12,960 different genes, to study the changes in mRNA expression of the proximal femur of growing C57BL/6 mice fed a dyslipidemic HFD. Genes were categorized as related to lipid metabolism, bone metabolism, and the related signal transduction mainly with the aid of Gene Ontology analysis. The analysis on femoral gene expression profiles will help to elucidate more completely the possible molecular basis for the HFD-induced low bone mass.

Materials and Methods

Animals

The experiment was conducted with male C57BL/6 mice (4 weeks old) from Shanghai Slac Laboratory Animal Co. Ltd. (Shanghai, China). The animals were housed under conditions of controlled temperature (23 ± 2 °C) and humidity (60%) with natural light. The experimental protocol was developed according to the institution's guideline for the care and use of laboratory animals.

Experimental Design and Samples Preparation

Test animals were initially fed standard diets for 3 days for adaptation after arrival. Mice were randomly assigned to two groups ($n = 8$ for each group). Group control received only a normal diet containing 4.8% (w/w) fat. Group HFD received an HFD containing 21.2% fat (additional 17.5% lard and 0.5% cholesterol). This HFD has been found to cause significant dyslipidemia in C57BL/6 mice [5]. All mice were allowed free access to the test diets and deionized water throughout the 12-week test period.

At the end of the experimental periods, mice were deprived of food for 12 h. After mice were anesthetized with aether, blood was collected by removing eyeball, and then mice were sacrificed immediately by cervical vertebra dislocation. The visceral fat pads (perirenal and abdominal) and subcutaneous fat pads (subscapular) were immediately excised and weighed. Plasma was obtained from blood samples after centrifugation (500*g* for 10 min at 4 °C), and then the plasma samples were frozen and stored at −20 °C until analysis. The proximal femur (right) of four mice per group was dissected out immediately and stored in RNA-later solution at −20 °C until used for RNA extraction, and other femur bones (left) were dissected for measurement of bone mineral density and mechanical testing and then stored at −20 °C.

Bone Metabolic Biomarkers in Plasma

The plasma levels of propeptide of I collagen C-propeptide (P1CP) and cross-linked N-telopeptides of bone type I collagen (NTx) were determined by a mouse-P1CP Elisa Kit and a mouse-NTx Elisa kit (USCN Life Science & Technology Company, Missouri City, TX, USA), respectively.

Bone Mineral Density and Mechanical Testing

On the day of testing, femur bones were thawed (20–25 °C). The bone mineral density (BMD) in the left femur was measured by dual-energy X-ray absorptiometry (GE Healthcare, Milwaukee, WI, USA) in animal mode and was analyzed in accordance with the manufacturer's manual.

The maximum load in the central left femur was testing in three-point bending by Texture Analyzer XT (Stable Micro Systems, Haslemere, Surrey, UK). Bones were temperature equilibrated (37 °C) in a physiological buffer solution (PBS, pH 7.4) for at least 1 h prior to testing. A testing systems loaded each bone in three-point bending (10 mm min^{-1}) until failure. The three-point intersupport distance for the femurs was 6 mm, and they were loaded anterior to posterior. For three-point bending, we calculated a maximal load of the bone at the center.

DNA Microarray Procedure

The RNA was prepared from the proximal one-third of the whole right femur including bone marrow using Trizol (P/N 15596-018; Invitrogen Life Technologies, Carlsbad, CA, USA). Subsequently, four samples at each group were pooled. RNA was further purified using Qiagen RNeasy (P/N 74104; RNeasy Mini Kit, Qiagen) columns and the quality verified by the laboratory by a chip analysis (Bioanalyzer 2100; Agilent, Amstelveen, The Netherlands). Ten micrograms of RNA was used for one-cycle cRNA synthesis (Affymetrix, Santa Clara, CA, USA). Hybridization, washing, and scanning of Affymetrix GeneChip mouse genome 430A arrays, which consist of more than 22,000 probe sets for 12,960 different genes, was done according to standard Affymetrix protocols.

DNA Microarray Data Analysis

The GeneArray™ scanner 3000 (Affymetrix) was used to scan and quantitatively analyze the scanned image, and the

data were globally scaled to all the probe sets with an identical target intensity value. Once the probe array had been scanned, GeneChip software automatically calculated intensity values for each probe cell and ascribed a presence or absence call for each mRNA. Algorithms in the software used probe cell intensities to calculate an average intensity for each set of probe pairs representing a gene that directly correlated with the amount of mRNA. The statistical algorithms were implemented in Affymetrix Microarray Suite 5.0. Expression patterns for the HFD group were compared with those of the control group. When the difference between two different RNA samples was assessed, the fold changes from side-by-side comparisons on the same lot of microarrays were compared directly. We set up cut-off values to 1.5 ($P > 0.05$) for the fold change in ratio. These genes were classified into different groups according to their biological functions and analyzed mainly by GenMAPP2 as an assistant analysis tool.

Quantitative Real-Time Reverse Transcription-Polymerase Chain Reaction

Quantitative real-time reverse transcription-polymerase chain reaction (RT-PCR) was carried out to validate our microarray results ($n = 4$ for each group). Total RNA was reverse-transcribed to cDNA according to the manufacturer's instructions (MultiScribe Reverse Transcriptase, Applied Biosystems, Foster City, CA, USA). We used Platinum *Taq* polymerase (Invitrogen Life Technologies) and EvaGreen dye (Biotium, Hayward, CA, USA) to employ real-time quantitative PCR. In this system, the increase in the concentration of EvaGreen dye fluorescent is proportional to the increase in PCR products; the reaction product can be accurately measured in the exponential phase of amplification by the ABI prism 7000 Sequence Detection System. The sequences of the primers are listed in Table 1. The relative expression levels of the target genes were calculated as a ratio to the housekeeping gene β-actin. Melting curve analysis was performed to assess the specificity of the amplified PCR products.

Statistical Analysis

Data of physiological and biochemical markers were reported as means ± standard deviations. Comparisons across groups were performed by analysis of the two sided Student t Test. $P < 0.05$ was considered statistically significant. Analysis was done with SPSS 15 (SPSS, Inc., Chicago, IL, USA).

Results

Food Intake, Body Weight, and Fat Mass

The food intake, body weight change, and fat mass at each group are shown in Table 2. The HFD group exhibited significantly lower food intake but higher energy intake than the control group ($P < 0.05$). A significant increase in body weight gain and fat mass was observed in the HFD group ($P < 0.01$).

Table 1 Sequences of primers used in quantitative real-time reverse transcription polymerase chain reaction

Gene symbol	Gene (full name)	Forward primer (5′–3′)	Reverse primer (5′–3′)
β-actin	Beta-actin	GGGTCAGAAGGACTCCTATG	GTAACAATGCCATGTTCAAT

Table 2 Food intake, body weight, and fat mass

Group	Food intake (g/day)	Energy intake (g/day)	Initial body weight (g)	Final body weight (g)	Fat mass (g/g body weight)
Control	3.01 ± 0.16	11.82 ± 0.52	14.98 ± 0.97	23.56 ± 1.53	0.085 ± 0.010
HFD	2.74 ± 0.13*	13.43 ± 0.55*	14.81 ± 0.99	26.44 ± 1.67**	0.117 ± 0.012**

Values are expressed as means ± SDs for eight animals

* $P < 0.05$, ** $P < 0.01$ versus control

Table 3 BMD and bone mechanical testing

Group	Femur BMD (mg/cm^2)	Femur maximum load (N)
Control	75.3 ± 1.3	27.9 ± 3.1
HFD	71.6 ± 2.1*	24.1 ± 2.6*

Values are expressed as means ± SDs for eight animals

* $P < 0.05$ versus control

BMD and Mechanical Testing

As shown in Table 3, the HFD caused a moderate decrease in both BMD and maximum load of femur ($P < 0.05$). Feeding of the HFD for 12 weeks resulted in the development of osteoporosis in the HFD-fed mice.

Bone Metabolism and Related Gene Expression Profiles

The transcript levels of the femora genes related to bone metabolism in the HFD group compared with the control group are presented in Table 4. It is evident that the magnitude of osteoblast-specific genes except Osteopontin (SPP1) were down-regulated in femora of HFD-fed mice and that the majority of osteoclast-specific genes were up-regulated, such as cathepsin K (CTSK), integrin beta 3 (ITGB3) and calcitonin receptor (CALCR). Collagens are the major components of the bone matrix and the extracellular matrix, and matrix metalloproteinases (MMPs) play a role in bone formation and in bone resorption by degrading the bone matrix [14, 15]. The expression levels of the listed genes encoding collagens (type I, II, V, IX and XI) were diminished in femur of HFD-fed mice. The transcription levels of some genes encoding MMP2, MMP9, and MMP13 were slightly increased in the HFD-fed mice, but MMP1a and MMP14 were 9.2- and 1.6-fold down-regulated in the HFD group, respectively. The listed genes engaged in the related regulation factors of bone metabolism were found to be differentially regulated, indicating that the HFD can induce increased bone resorption and decreased bone formation. Moreover, bone metabolic biomarkers were assayed and are shown in Fig. 1. As expected, the HFD significantly reduced plasma levels of P1CP ($P < 0.01$) as a biomarker of bone formation and increased plasma levels of NTx ($P < 0.05$) as a biomarker of bone resorption, supporting the evidence of gene expression profiles.

Lipid Metabolism- and Antioxidant System-Related Gene Expression Profiles in Femur

As presented in Table 4, the majority of the genes engaged in adipogenesis and lipid biosynthesis, such as peroxisome proliferator activated receptor gamma (PPARg), CCAAT/enhancer binding protein beta (CEBPb), twist gene homolog 1 (TWIST1), and stearoyl-coenzyme A desaturase 2 (SCD2), were down-regulated in the HFD group compared with the control group. Also, HFD caused a decrease in most of the gene expression of those engaged in fatty acid oxidation, such as PPARg, apolipoprotein E (APOE), acetyl-Coenzyme A acetyltransferase 1 (ACAT1), and lipase (LIPE). In addition, the transcription levels of genes encoding antioxidant enzymes superoxide dismutase 2 (SOD2), glutathione peroxidase 3 (GPx3), and thioredoxin reductase 1 (TXNRD1) in the HFD group were lower than those in the control group.

Signal Transduction-Related Gene Expression Profiles in Femur

Signal transduction pathway plays a key role in differentiation, proliferation, and the function of bone cells. The changes in the expression of the selected genes involved in signal transduction are listed in Table 4. The genes encoding insulin-like growth factor 1 (IGF1), IGF1 receptor, and some insulin-like growth factor binding proteins (IGFBPs) were down-regulated in the HFD group versus the control group. An increase in the majority of cases of gene expression related to p53 signal pathway associated with osteoblast apoptotic [16] was found in the HFD mice. In addition, the magnitude of genes encoding transforming growth factors, interleukins, and their receptors were up-regulated, especially those transforming growth factor, beta receptor I (TGFbR1, 13.9 folds) and IL-17a (9.8 folds). In contrast, IL-4, a proinflammatory cytokine, was found to be down-regulated by 2.5 fold.

[a] The mRNA levels in the HFD group were compared with the control group. Fold-change calculations are based on means of signal values in each group of four mice after background subtraction ($P < 0.05$), with a negative fold change representing down-regulated expression

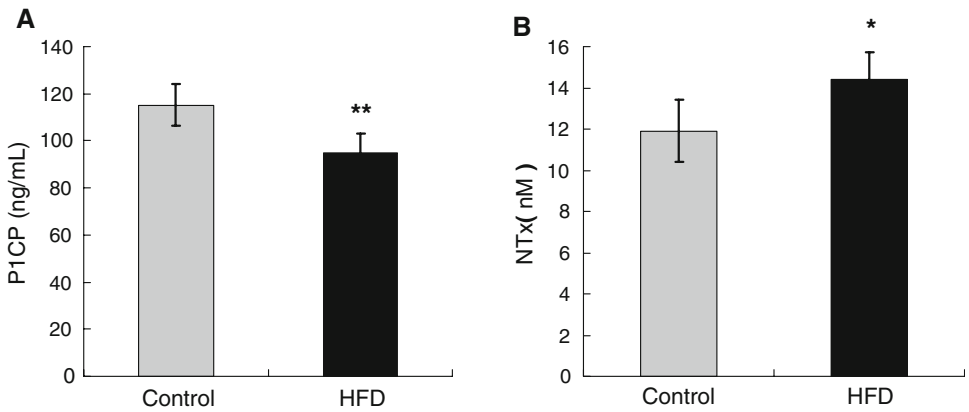

Fig. 1 Comparison of bone metabolic markers including plasma P1CP (**a**) and plasma NTx (**b**) in mice fed a normal diet and an HFD. Values are expressed as means ± SDs ($n = 8$ for each group). *$P < 0.05$, **$P < 0.01$ versus control

Confirmation of Differential Expression of Selected Genes by Real-Time RT-PCR Analysis

We validated our microarray findings by conducting real-time PCR assays on the selected genes. When gene expression profiles obtained by microarray analysis and quantitative RT-PCR were compared, their patterns were very similar with regard to the direction (up- or down-regulation), despite some slight variations (Fig. 2). Collectively, the quantitative PCR results demonstrated the reliability of the microarray analysis.

Discussion

The present study provides gene transcript profiles of the femur bone of growing C57BL/6 mice fed a dyslipidemic HFD for 12 weeks to help to reveal further the molecular mechanisms underlying the HFD-induced bone loss. Our emphasis was primarily on genes engaged in lipid metabolism, bone metabolism, and the related signal transduction pathway mainly through Gene Ontology analysis. Furthermore, the validity of our microarray findings was confirmed by conducting real-time RT-PCR assays on the selected genes.

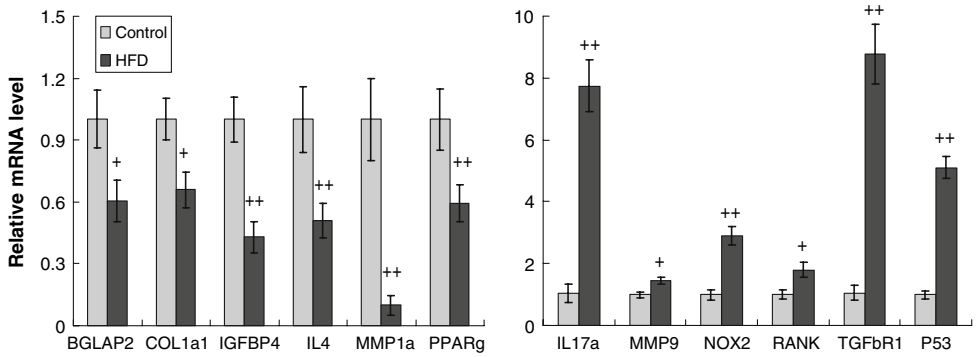

Fig. 2 Verification of the expression changes of BGLAP2 (osteocalcin), COL1a1, IGFBP4, IL4, MMP1a, PPARg, IL17a, MMP9, NOX2, RANK, TGFbR1, and P53 using quantitative RT-PCR. The relative expression level of each sample was calibrated by the comparative threshold cycle method, using β-actin as an endogenous control. Data are expressed as fold changes (means $\pm$ SDs, $n = 4$ for each group), normalized to β-actin mRNA expression, where the values for the control mice were set at 1.0. $^{+}P < 0.01$ and $^{++}P < 0.001$ compared with the control mice

C57BL/6 mice were used as a model for HFD-induced low BMD in our study since the lipid metabolism and bone metabolism changes in these animals are similar to those that occur in humans [17, 18]. Lac et al. [11] have demonstrated that fat mass is negatively correlated with bone mineral density. As expected, the dyslipidemic HFD induced significantly more body weight gain and fat mass but significantly lower femoral BMD and maximum mechanical load. Bone is primarily comprised of collagen and mineral, which together provides its mechanical properties [19]. Accordingly, this finding suggests that both the matrix and mineral content of femurs were affected by the HFD. In addition, the HFD-induced poor mechanical properties suggest that cortical bone was influenced since the three-point bending test evaluates changes in a substantial quantity of cortical bone. This finding is similar to others reports for bone status influenced by other high-fat diets [8, 9, 11].

In the terms of bone formation, the HFD down-regulated most genes engaged in bone mineralization, corresponding to decreased levels of plasma P1CP, a bone formation biomarker. Runx2 and Osterix (OSX), a series of transcriptional activation events, are essential for osteoblast differentiation [20]. Runx2 knockout or OSX knockout mice show the complete lack of both intramembranous and endochondral ossification due to the absence of osteoblast differentiation [20]. In our microarray data, the HFD brought about a 1.5-fold decreased regulation of OSX but no significant change in Runx2 expression. In addition, FOS and other regulators were down-regulated in the HFD group, suggesting that the HFD could depress osteoblastic differentiation and bone formation [20, 21]. Conversely, the HFD up-regulated the majority of genes engaged in osteoclast activity, corresponding to the increased plasma levels of NTx, a bone resorption biomarker. In addition, expression levels of most of the collagens and tissue inhibitors of metalloproteinase were decreased, but some genes encoding matrix metalloproteinase (MMPs) were up-regulated in the HFD-fed mice, such as MMP9 which plays an important role in bone matrix degradation [15, 22]. Interestingly, MMP1a mRNA was strongly decreased by 9.2 folds in the HFD-fed mice. MMP1 is known as a collagenase predominantly expressed in osteoblasts, and it can play a role in bone formation by cleaving the native triple helix of type I collagen [23, 24]. Therefore, the strong down-regulation of MMP1 may reflect the diminished osteoblastic activity in the HFD-fed mice. Overall, the above-mentioned results indicate that the HFD can not only inhibit bone formation but also enhance bone resorption in growing mice.

In some previous studies, HFD was shown to cause inhibitory bone formation and osteoblastic differentiation in mice and in vitro evidence [12, 25–27], but its effects on bone resorption and on osteoclastic proliferation and differentiate had never been observed. However, a new study from Cao et al. [13] has indicated that an HFD may bring about increased bone resorption and osteoclast activity in mice without effects on bone formation. These differences between the previous study results and our results may be attributed to the variations in physiological stages, dietary compositions, feeding periods, and experimental method. In our study, the microarray approach provides an opportunity to examine the effects of HFD on bone metabolism in a global manner, but further studies will be necessary to validate this speculation.

Lipid metabolism is closely associated with bone metabolism, since osteoblasts and adipocytes appear to be derived from a common mesenchymal stem cell pool [28, 29]. HFD-induced LDL oxidation products promote osteoporotic loss of bone by directing progenitor marrow stromal cells to undergo adipogenic instead of osteogenic differentiation through activating PPARg [25]. Indeed, it has been

reported that PPARg plays an important role in lipid metabolism and bone development. PPARg activation has been demonstrated to decrease osteoblastic and osteoclastic formation [30, 31] and to increase adipogenesis and lipid catabolism [31–33]. However, the majority of the examples of gene expression involved in adipogenesis, lipid biosynthesis, and fatty acid oxidation were down-regulated by the HFD in our data, such as PPARg, CEBPb which cooperates with PPARs to induce adipogenesis [34], lipase, and APOE. This gene expression profile is not consistent with the previous reports that HFD could promote lipogenesis and inhibit osteogenesis via PPARg activation [25–27]. This discrepancy may result from differences in pathologic processes or fatty acid compositions of diets. Indeed, HFD provides a higher dietary energy density and consequently can induce obesity [35], several unsaturated fats have been demonstrated to activate PPARs to regulate adipogenesis [36], and high ratios of omega3/omega6 polyunsaturated fatty acids can decrease PPARg mRNA levels [37, 38]. Moreover, a decrease in lipid anabolism profile may be a response to excessive adipogenesis to resist obesity in the present study. On the other hand, the present data indicate that the HFD may cause enhanced osteoclastic function and depressed lipid catabolism through decreased PPARg activation. Some previous similar observations in rodents have also shown that a diet rich in saturated fats brought about high plasma levels of triglyceride and cholesterol together with a small decrease in apolipoproteins [39, 40]. Furthermore, the $APOE^{-/-}$ mice fed an HFD have been demonstrated to enhance reduction of bone formation and vascular atherosclerotic lesions [41]. Accordingly, we presume that the dyslipidemic HFD-induced bone loss may be partially attributed to the impaired lipid catabolism capacity.

Another notable gene engaged in bone resorption was 2.6-fold up-regulated NADPH oxidase 2 (NOX2). NOX has been known to generate large quantities of mitochondrial reactive oxygen species (ROS) during bone resorption [42]. ROS, which specifically regulates signaling pathways by reversible oxidation of proteins [43], not only augments osteoclastic differentiation and function, but also is essential for osteoclastic differentiation [42, 44]. Moreover, in the present data, the genes encoding antioxidant enzymes including SOD2, GPx3, and TXNRD1 were down-regulated in the HFD group, indicating that the HFD could result in bone oxidative stress, an imbalance between free radicals and antioxidant system. Other studies have shown that lipid oxidation caused by excessive levels of ROS may have opposite effects on bone formation [12, 25]. Furthermore, an increasing number of studies have provided evidence for a strong relationship between oxidative injury and osteoporosis in diabetes mellitus and at postmenopause [45–47]. Thus, the HFD-induced bone loss may also be associated with oxidative stress.

Besides changes in bone metabolism- and lipid metabolism-related gene expression, the differential alternations in transcript levels of many genes related to signal transduction in the HFD-fed mice compared with the control were found in our microarray data. There were the down-regulated genes encoding IGF1, IGF1 receptor and some IGFBPs in the HFD group. Previous studies suggested that IGF1 can stimulate osteoblastic proliferation and bone formation [48] and that decreased IGF1 predisposes to osteoporosis [49]. Bielohuby et al. [50] also reported that low-carbohydrate/high-fat diets impaired longitudinal growth, possibly mediated by reductions in IGF-1 in rats. IGFBPs play modifying roles in IGF action by regulating both IGF half-life and access to IGF receptors [51]. IGFBP4 has been shown to increase bone formation in mice upon systemic administration [52]. The decreased IGFBP4 mRNA expression in the HFD mice may therefore have inhibited bone formation in this study.

Hirasawa et al. [41] suggested that APOE gene deficiency enhances the reduction of bone formation induced by an HFD through the stimulation of transformation related protein 53 (P53)-mediated apoptosis in osteoblasts. It is well known that P53 negatively regulates osteoblastic differentiation and bone formation [16, 53]. The strong up-regulation of the gene encoding P53 was observed in the HFD group, indicating that P53 dependent osteoblastic apoptotic may be one of causative factors for the HFD-induced inhibitory bone formation.

On the other hand, there is an increase in mRNA levels of receptor activator of nuclear factor-kB (RANK) and receptor activator of nuclear factor-kB ligand (RANKL) in our data without changes in osteoprotegerin (OPG) expression. Growth transforming factors [54] and cytokines [55–57] have been known to stimulate osteoclastogenesis and bone resorption by RANK/RANKL pathway, such as IL-1, IL-6, IL-17, and TNF-a. In fact, some studies have shown that HFD-induced hypolipidemia and/or obesity is often associated with elevated levels of inflammatory markers [58, 59]. Our microarray data show a large up-regulation of TGFbR1 and IL-17a expressed primarily in T cells[60] in the HFD-fed mice, which can contribute to enhanced bone resorption, despite a small decrease in TGFb1 expression and no significant changes in TNF-a, IL-1, and IL-6 expression.

Another notable observation was the decreased IL-4 mRNA expression in HFD mice, which is secreted by activated Th2 cells [61]. IL-4 has been shown to inhibit bone resorption through inhibiting NF-κB and Ca^{2+} signaling [62] or through a direct action on osteoclast precursors via PPARg [61] in an in vitro model. In atherosclerotic lesions of $Apoe^{-/-}$ mice, Th1 cells are dominant, as the cytokines IFN-γ, IL-2, and TNF-a are highly expressed, whereas low amounts of the Th2

cytokines IL-4, IL-5, and IL-10 can be detected [63]. Indeed, there is a decrease in IL-4, PPARg and APOE expression in the HFD-fed mice in the present data, although the undeterminable changes in expression levels of other cytokines were found, such as IFN-γ and IL-10. Therefore, the HFD-induced decreased IL-4 transcript in bone may have adverse effects on preventing bone loss.

In summary, the present results from various bone parameters indicate that the HFD induces alterations to skeletal growth and consequently causes an adverse bone status in C57BL/6 mice. The changes in global gene expression profiles of proximal femur suggest that the HFD may cause negative effects on bone formation and promotive effects on bone resorption, together with abnormal lipid metabolism as reflected by the decreased transcript levels of most of the genes engaged in adipogenesis and fatty acid oxidation. Furthermore, the HFD-induced inhibitory bone formation maybe due to the changes in gene expression involved in the IGF-1 signaling pathway and P53 apoptotic pathway. The great up-regulation of TGFbR1 and IL-17a and the down-regulation of IL-4 in bone of mice fed HFD may lead to a stimulation of bone resorption through the RANK/RANKL pathway associated with low PPARg expression.

Our study is the first time microarray data has been provided for an opportunity to gain a better understanding of the basis for the impacts of HFD on bone physiological function and to identify the related signal transduction pathway. However, it is necessary to obtain further confirmation at the protein level and with functional analysis.

Acknowledgments The authors thank Mr. Xiao-Jia Pu (Nuclear Medicine Section, Wuxi People's Hospital) for the technical support on BMD measurement and for providing the technical equipment. Enantioselective Analysis of Chiral Anteiso Fatty Acids in the Polar and Neutral Lipids of Food

Simone Hauff · Georg Hottinger · Walter Vetter

Received: 13 January 2010 / Accepted: 18 February 2010 / Published online: 12 March 2010

Abstract Anteiso fatty acids (*a*FA) are substituted with a methyl group on the antepenultimate carbon of the straight acyl chain. This feature leads to a stereogenic center. The 12-methyltetradecanoic acid (*a*15:0) and the 14-methylhexadecanoic acid (*a*17:0) are the most common *a*FA found in food, although they occur only in very small quantities. In this study we used gas chromatography in combination with a chiral stationary phase to determine the enantiomeric distribution of both *a*15:0 and *a*17:0 in the neutral and polar lipids of aquatic food samples and cheese. The best suited column was selected out of four custom-made combinations of heptakis(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl)-*β*-cyclodextrin (*β*-TBDM) with different amount and polarity of an achiral polysiloxane. After separation of polar and neutral lipids of the food samples by solid phase extraction, fatty acid methyl esters were prepared and the fatty acid methyl esters were fractionated by reversed phase high performance liquid chromatography. Measurements of fractions high in *a*FA by enantioselective GC/MS in the selected ion monitoring mode verified the dominance of the (*S*)-enantiomers of *a*15:0 and *a*17:0 in both lipid fractions. However (*R*)-enantiomers were detectable in all samples. The relative proportion of the (*R*)-enantiomers was up to fivefold higher in the polar lipids than in the neutral lipids. The higher proportions in the polar lipids indicate that microorganisms might be involved in the formation of (*R*)-*a*FA.

Keywords Methyl branched fatty acids · Anteiso fatty acids · Chirality · Enantiomer separation · Dairy products · Fish

Abbreviations

β-TBDM	Heptakis(6-*O*-*tert*-Butyldimethylsilyl-2, 3-di-*O*-methyl)-*β*-cyclodextrin
*a*FA	Anteiso fatty acids
*a*15:0	12-Methyltetradecanoic acid
*a*16:0	13-Methylpentadecanoic acid
*a*17:0	14-Methylhexadecanoic acid
CSP	Chiral stationary phase
ee	Enantiomeric excess
ELSD	Evaporative light scattering detector
FAME	Fatty acid methyl ester
FID	Flame ionization detection
GC	Gas chromatography
GC/EI-MS	Gas chromatography electron ionization mass spectrometry
HPLC	High performance liquid chromatography
NL	Neutral lipids
PL	Polar lipids
RP-HPLC	Reversed phase high performance liquid chromatography
SIM	Selected ion monitoring mode
SPE	Solid phase extraction

Introduction

Anteiso fatty acids (*a*FA) bear a methyl substituent on the antepenultimate carbon of the acyl chain. Consequently, the carbon bearing the methyl branch is stereogenic. The

12-methyltetradecanoic acid (*a*15:0) and the 14-methylhexadecanoic acid (*a*17:0) are the most prominent *a*FA in food. In marine biota and dairy products they contribute with ~1% to the fatty acid patterns [1, 2]. In contrast, these *a*FA are dominant in the lipid bilayer (phospholipids) of several *gram*-positive bacteria [3, 4], where they are involved in keeping the membrane fluid when these organisms are exposed to cold temperatures [5–7]. Additionally, *a*FA have even been reported to suppress the proliferation of human cancer cells [8, 9].

Chirality is a specific feature of biomolecules which impinges on the biological properties. Biochemical processes are prevalently enantioselective and usually only one enantiomer exhibits full biological activity. Hence, knowledge of the absolute stereo-configuration of chiral biomolecules—including the *a*FA—is essential for the proper assessment of their bioactivity. However, the chromatographic enantioseparation of the long-chain *a*FA is a challenge, because it becomes the more difficult the larger the distance is between the stereogenic center and the functional group [10–12].

So far, an indirect enantiomer separation of long chain *a*FA has been achieved by high performance liquid chromatography (HPLC) [10, 12, 13]. In addition, gas chromatography (GC) in combination with modified cyclodextrins as the chiral stationary phase (CSP) was used for the enantioseparation of food-relevant *a*FA [14]. Several capillary columns coated with different CSP dissolved in diverse polysiloxanes were tested, and *β*-TBDM was the only CSP which allowed for the partial resolution of these *a*FA [14]. Using a capillary column coated with 50% heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-*β*-cyclodextrin (*β*-TBDM) in OV-1701, it was shown that *a*15:0 and *a*17:0 were virtually (*S*)-enantiopure in dairy products although the presence of traces of the respective (*R*)-enantiomers could not be excluded [14]. In fact, small amounts of (*R*)-enantiomers were detected in marine oils [14]. It is noteworthy that *a*FA were higher concentrated in the polar lipids of fish than in its neutral lipids, while no significant differences were found in the lipids of dairy products [15].

Here, we wished to explore whether there are differences in the enantiomeric distribution of *a*FA in neutral and polar lipids of cheese and fish. With this goal in mind, we first attempted to improve the enantioresolution of *a*FA by variations in the ratio between the CSP and the achiral polysiloxane of *β*-TBDM columns. The effect of different ratios of CSP and polysiloxanes on the stereoselectivity has been shown for flavor compounds by Mosandl and coworkers [16]. Nevertheless, further chiral capillary columns varying in terms of the amount of chiral selector, the polarity of the polysiloxane as well as the film thickness of the stationary phase were tested. The best column was finally applied to the enantioselective determination of *a*FA in food. For this purpose, polar (PL) and neutral lipids (NL) were fractionated by solid phase extraction (SPE) [17]. After conversion of the lipid fatty acids into methyl esters (FAME), *a*FA were enriched by means of reversed phase HPLC [18].

Materials and Methods

Chemicals and Standards

Ethyl acetate (purest, Acros Organics, Geel, Belgium) and cyclohexane (purest, VWR, Darmstadt, Germany) were combined (1:1, v/v) and distilled to gain the azeotropic mixture (54:46, v/v). Methanol, *n*-hexane (both HPLC gradient grade), silica gel 60 (particle size 0.063–0.2 mm, 70–230 mesh) and methanolic BF_3 (~10%) were from Fluka (Taufkirchen, Germany). Individual racemic *a*FA were from Larodan (Malmö, Sweden), whereas (*S*)-enantiomers of *a*FA were synthesized by Thurnhofer and Vetter [19].

Food Samples

The following six food samples were selected because they were known to contain *a*FA both in PL and NL [14, 15]: gilthead seabream (*Sparus aurata*) fillet, brown trout (*Salmo trutta fario*) fillet, see bass (*Dicentrarchus labrax*) fillet (all from local supermarkets) and seal oil (*Pusa sibirica*; from a local market on the Lake Baikal), as well as cow mozzarella (made from pasteurized milk, Italy) and camembert (made from raw milk, Germany) cheeses.

Extraction of Food Samples

Lipids of food samples were gained by means of accelerated solvent extraction (ASE 200, Dionex, Idstein, Germany) as recently described [17, 20]. Briefly, ~1 g of the homogenized freeze dried sample was loaded into 11-mL stainless steel cells, and the extraction was performed with three portions of 40 mL of ethyl acetate/cyclohexane (54:46, v/v) followed by two portions of 40 mL of methanol/ethyl acetate (1:1, v/v) [17]. Extracts were combined, concentrated by rotary evaporation (180 mbar, 30 °C water bath temperature) and were then adjusted to a defined volume (10–25 mL).

Solid Phase Extraction

Lipid fractionation was performed as recently described [19]. In summary, approximately 5 mg of food lipids diluted in 100 µL ethyl acetate/cyclohexane/methanol

(45:45:10 by volume) were loaded onto a SPE column containing 350 mg of deactivated silica (20%). NL were eluted with 23 mL cyclohexane/ethyl acetate (1:1, v/v) whereas PL were eluted with ethyl acetate/methanol (1:1, v/v), methanol and methanol/water (98:2, v/v) into another flask [17]. The two lipid fractions were rotary evaporated to about 1 mL, transferred into derivatization tubes, and were finally evaporated to dryness under a gentle stream of N_2 (35 °C). Fatty acids in the dry lipid fractions were transformed into the corresponding FAME using the boron trifluoride method [1].

Enrichment of Anteiso FAME by Reversed Phase High Performance Liquid Chromatography (RP-HPLC)

RP-HPLC analyses of FAME were carried out with a Varian solvent pump and a Varian ProStar 325 UV-vis detector (dual wavelength mode using 206 and 234 nm) serially connected with a PL-ELS 2100 evaporative light scattering detector (ELSD, Polymer Laboratories) (all Varian, Darmstadt, Germany). The N_2 nebulizer temperature was set at 40 °C and the ELSD drift tube flow was set at 1.2 mL/min.

One milligram of FAME diluted in 50 µL methanol was injected via a Rheodyne 7010 injector equipped with a 100-µL sample-loop.

Three serially connected 250 mm × 4.6 mm C_{18} columns (ET 250/8/4 Nucleosil 7 C_{18}; (7 µm particle size), Supelcosil LC-18-DB (5 µm particle size), and ET 250/8/4 Nucleosil 5 C_{18}-AB (5 µm particle size)) served as stationary phase while pure methanol was used as the mobile phase (flow rate 0.9 mL/min) [18]. For the isolation of *a*FA, the ELSD was disconnected and the fractions were manually collected for 30 min, at time intervals of 0.5 min. All HPLC fractions containing the individual *a*FA in highest purity (*a*15:0 ~15 min; *a*16:0 ~17 min; *a*17:0 ~19 min) were combined and concentrated to ~10–150 µL for subsequent GC/EI-MS analysis. Purity of the respective fractions was determined by achiral GC/EI-MS (see below).

Gas Chromatography in Combination with Electron Ionization Mass Spectrometry (GC/EI-MS)

An HP GCD Plus system (Hewlett-Packard, Waldbronn, Germany) was used to perform enantioselective GC/EI-MS analyses. One microliter of standard or sample solution was splitless injected (split opened after 2 min) at 250 °C via an HP 6890 autosampler (Hewlett-Packard). Helium (purity 5.0, Sauerstoffwerke, Friedrichshafen, Germany) was used as the carrier gas at a constant flow rate of 1.0 mL/min. The transfer line temperature and ion source temperatures were set at 280 and 165 °C, respectively. Enantioselective determinations of *a*FA in food samples were performed by GC/EI-MS in the selected ion monitoring (SIM) mode. The six fragment ions *m/z* 74, *m/z* 87 [17, 21], *m/z* 256 (M^+ of 15:0 ME isomers), *m/z* 270 (M^+ of 16:0 ME isomers), *m/z* 284 (M^+ of 17:0 ME isomers), and *m/z* 282 (M^+ of 17:1 ME isomers) were recorded throughout the run.

Frequently, the required low isothermal elution temperatures of *a*15:0, *a*16:0 and *a*17:0 resulted in retention times longer than the maximum run time on our GC/MS system (i.e. 650 min). Thus, a second run was immediately started at the end of the first run (the column equilibration time was set to 0 s, air was injected, the new run started isothermal with the final temperature of the first run). The GC oven program of the first run started at 60 °C, which was held for 1 min; then the temperature was ramped with 20 °C/min to 112 °C (held 455 min) and thereafter with 1 °C/min to 132 °C (held for further 171 min). The GC oven program of the second run started at 132 °C for 115 min, and then the temperature was raised with 30 °C/min to 200 °C (held 15 min). The total run time was 782 min. In this way, *a*17:0 eluted after ~730 min (650 min first run plus ~80 min in the second run).

Achiral GC/EI-MS measurements of HPLC fractions were performed with an HP 5971/5890 combo previously described [21, 22] except for the following modifications: A 60 m × 0.25 mm × 0.20 µm film thickness (d_f) SP 2331 column (Supelco, Bellefonte, PA, USA) was installed in the GC oven and the temperature program started at 60 °C (held 1 min), was then ramped with 7 °C/min to 180 °C (hold time 2 min), afterwards with 3 °C/min to 200 °C (hold time 2 min), and finally at 3 °C/min to 220 °C (held for 10 min). The total run time was 45.5 min.

Heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-*β*-cyclodextrin (*β*-TBDM) Columns Tested

The chiral stationary phase was synthesized as previously described [14]. The following combinations of the CSP with 14% cyanopropylphenyl, 86% dimethyl polysiloxane (OV-1701) or 5% phenyl, 95% methyl polysiloxane (DB-5) were prepared according to Blum and Aichholz [23]: (1) 50% *β*-TBDM in OV-1701 (2) 66% *β*-TBDM in OV-1701 (3) 50% *β*-TBDM in DB-5 (all 30 m long, 0.25 mm i.d., 0.2 µm d_f), as well as (iv) 66% *β*-TBDM in OV-1701 (30 m, 0.25 mm i.d., 0.18 µm d_f).

Initial tests of the *β*-TBDM columns were performed by flame ionization detection (FID) as described elsewhere [14]. For each column, isothermal temperatures (108–125 °C) were stepwise lowered (1 °C steps), until the best resolution was obtained for racemic *a*15:0 and *a*17:0 standards. Temperature changes showed the same effects for both *a*FA (and also *a*16:0), so that final column optimization was carried out with only the *a*15:0. The best

suited column was then transferred to the GC/EI-MS system, making sure that the linear velocity of the carrier gas was equal on both the GC/FID and the GC/EI-MS system. In this way, retention time shifts were marginal (<10 min).

Method Validation and Mode of Evaluation

The enantiomeric distributions of *a*FA in food samples were expressed by the enantiomeric excess (*ee*), which was calculated with formula 1:

$$ee\% = \frac{(S)\text{-}a\text{FA} - (R)\text{-}a\text{FA}}{(S)\text{-}a\text{FA} + (R)\text{-}a\text{FA}} \times 100 \quad (1)$$

with (*S*)-*a*FA and (*R*)-*a*FA being the peak area and (*S*)-*a*FA being the major enantiomer.

Determination of small amounts of (*R*)-*a*FA was carried out as follows. Gas chromatograms from pure (*S*)-*a*FA were superimposed with those containing small amounts of (*R*)-*a*FA and the excess of peak area from the latter was calculated. Repeated integration (n=3) resulted in an accuracy of the *ee*% determination of ±0.5%. Final verification was obtained by weighing the cut chromatograms from prints on 80-g paper. The gravimetric results were generally within the ±0.5% frame assessed by integration. To ensure the absence of potential memory peak from previous runs which could falsify the enantioselective measurements, three runs with fast temperature programs (started at 60 °C (held 1 min) and ramped with 10 °C/min to 200 °C (held 15 min)) were carried out before the analysis of the next sample. The characteristic GC/EI-MS-SIM ions traces (see "Material and Methods") *m/z* 74, *m/z* 87 as well as M^+ were normalized to the same peak high [14]. While the ion traces of the two anteiso enantiomers showed exactly the same peak shape, this feature was not observed for other fatty acids including *i*FA. Additionally, random samples were spiked with racemic standards, which again confirmed the presence of both enantiomers. The GC/EI-MS-SIM method enabled the non-interfered enantioselective analysis of the *a*FA obtained from the NL and PL fractions. Chromatograms with low abundant/noisy peaks were smoothed by using the method of Savitzki and Golay [24].

Results and Discussion

Analysis of Racemic *a*FA as Methyl Esters on Different Chiral Capillary Columns

The enantioselectivity of a CSP is affected by both the type and amount of the CSP and the achiral polysiloxane [16, 25]. Previously, several β-TBDM columns were tested, and columns containing 50% β-TBDM in OV-1701 gave better results than those with lower amounts of the CSP [14]. Starting from the 50% β-TBDM column used in our previous studies [14, 26] two new β-TBDM columns were produced by (a) decreasing the polarity of the polysiloxane from OV-1701 to DB 5 or (b) increasing the amount of the CSP from 50 to 66%. Results from columns with such high amounts of β-TBDM (i.e. 66%) in a polysiloxane have not been published before. The columns were initially installed in a GC/FID system and tested by isothermal elution of *a*15:0-*a*17:0. The temperature was subsequently lowered by 1 °C until the best resolution (i.e. the deepest valley between the two enantiomers) was obtained (see Materials and Methods). Retention times of analytes are known to increase with increasing amounts of the CSP [16, 27], and this was also observed for the racemic *a*FA. At similar retention times, the elution temperature for *a*15:0 was 3 °C lower on the 50% β-TBDM than on the 66% β-TBDM. Nevertheless, the resolution was much better for the 66% β-TBDM column (33 vs. 16% valley between both enantiomers on 50% β-TBDM, Table 1).

On the 50% β-TBDM in DB-5, the elution temperatures even increased by ~8 °C at a given temperature and the resolution was worse than on the 50% β-TBDM in OV-1701 (12 vs. 16%) (Table 1). This is in contrast with chiral flavor compounds where the best enantioresolution

Table 1 Elution temperature and retention time regimes of the enantioseparation of racemic *a*15:0 methyl ester on different heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin (β-TBDM) columns and corresponding resolution expressed in form of the valleys between the two isomers (c ≈ 10 ng/μL)

Column parameters	Isothermal temperature (°C)	Retention time t_{R1}/t_{R2} [min]	Valley (%)[a]
50% β-TBDM in DB-5 (0.2 μm d_f)	117	536.5/541.3	12
50% β-TBDM in OV-1701 (0.2 μm d_f)	109	550/555.5	16
66% β-TBDM in OV-1701 (0.2 μm d_f)	112	526.5/532.5	33
66% β-TBDM in OV-1701 (0.18 μm d_f)	112	430.5/435	35
66% β-TBDM in OV-1701 (0.2 μm d_f)	110	604/611	30
66% β-TBDM in OV-1701 (0.18 μm d_f)	110	491.5/497.5	30

[a] Ratio between the (mean of the) peak maxima of the two enantiomers and the minimum between them

on β-TBDM was obtained in combination with less polar polysiloxanes [16]. The better resolution of *a*FA on the more polar polysiloxane could be due to the fact that OV-1701 provides the best mixing properties with cyclodextrins [16], which is the more difficult the higher the amount of the cyclodextrin (here: 66%), and the lower the operating temperature is [20].

The best results were obtained with 66% β-TBDM in OV-1701 but the retention times of the *a*FA on this column were rather long. We thus attempted to reduce the retention of *a*FA at a given elution temperature by a new column with lower film thickness (0.18 µm instead of 0.2 µm). The thinner film of the 66% β-TBDM in OV-1701 decreased the retention times at a given temperature (e.g. 110 °C) by more than 100 min without loss of enantiomeric resolution (see Table 1). As expected, the enantiomeric resolution waned with increasing chain length of the *a*FA. For *a*15:0 and *a*17:0 the maximum enantiomeric excess that could be established was $ee > 97.5\%$ and $ee = 95\%$, respectively (see below). This resolution was sufficient for the determination in samples with non-racemic composition of the analytes (Fig. 1). Consequently, this column (66% β-TBDM in OV-1701, 30 m, 0.25 mm i.d., 0.18 µm d_f) was used for the analysis of *a*FA in food samples by GC/EI-MS-SIM.

Enrichment of Anteiso Fatty Acids from Food Samples

*a*FA are minor fatty acids in food (<0.6% of total lipids [15]) which need to be enriched before the enantioselective GC analysis can be commenced [14]. Thurnhofer et al. [14] used urea complexation in combination with silver ion liquid chromatography for this purpose. However, these procedures are time consuming and accompanied with significant loss of the analytes (especially during urea complexation). Therefore, we chose to perform the sample fractionation by RP-HPLC (see "Materials and Methods"). In RP-HPLC, retention times of saturated FAME increased with the chain length while the retention decreased the more double bonds were present at a given chain length (e.g. 18:3 < 18:2 < 18:1 < 18:0) [22]. Methyl branches had only a small effect on the retention, so that *a*15:0 and *i*15:0 (longest chain C_{14}, respectively) eluted into the same RP-HPLC fractions as 14:0 (and *a*17:0/*i*17:0 as 16:0) [18]. In dependence of the concentration in the sample, FAME were distributed over 2–5 HPLC fractions with *a*FA mainly targeted in two fractions. Fractions with *a*FA (see "Materials and Methods") contained no further relevant fatty acids than those mentioned and could be subjected to enantioselective analysis by GC/EI-MS on the 66% β-TBDM column. The RP-HPLC enrichment was suited for *a*15:0 and *a*17:0 in NL and PL. Moreover, *a*16:0 was detected in the PL of sea bass and could be studied as well

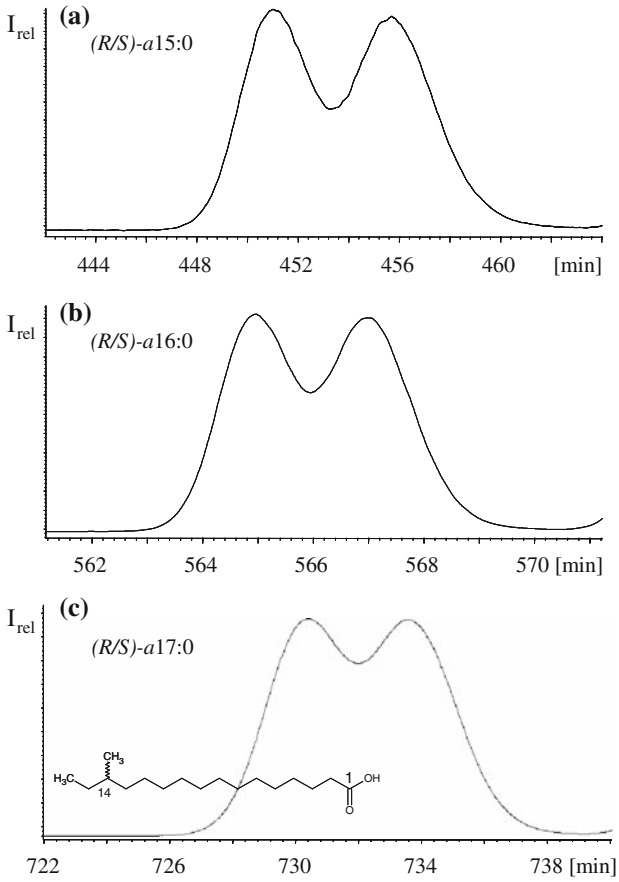

Fig. 1 Gas chromatographic enantioseparation (66% β-TBDM in OV-1701, 30 m, 0.25 mm i.d., 0.18 μm d_f) of racemic standards of methyl esters of *a*15:0, *a*16:0 and *a*17:0 (c $\approx$ 10 ng/µL)

(see below). Before, this even-numbered *a*FA has only been detected after selective enrichment by urea complexation [14]. In the sea bass, the concentration of *a*16:0 was ~0.9% of 15:0 (84 mg/100 g PL [15]) and thus in the 0.8 mg/100 g range. Obviously, the RP-HPLC fractionation provided a similar enrichment effect for branched chain fatty acids as urea complexation.

Enantioselective GC/EI-MS-SIM Analysis of *a*FA in Food Samples after Conversion into Methyl Esters and Enrichment by RP-HPLC

Injections of enantiopure *a*FA standards [19], verified that the (*R*)-enantiomer eluted prior to the (*S*)-enantiomer [14]. We also checked the retention times of other compounds in the HPLC fractions and observed no co-elutions with *a*FA on the 66% β-TBDM in OV-1701 column. However, the elution order of anteiso and iso isomers on β-TBDM was reversed in comparison with achiral stationary phases (e.g. OV-1701, DB-5 or the polar 100% cyanopropyl polysiloxane [15]). Thus, the effect must originate from the interaction of the branched chain fatty acid isomers with

Table 2 Enantiomeric distribution of anteiso fatty acids (*a*FA) in the neutral and polar lipids of food samples, expressed as the enantiomeric excess %(*ee*) and the proportion of the (*R*)-enantiomers

	Sample name	Sea bass	Trout	Gilthead seabream	Seal oil	Camembert	Mozzarella
*a*FA	Lipid class	Enantiomeric excess (%*ee*); proportion of (*R*)-enantiomer					
*a*15:0	NL	>90[a]; <5	93; 3.3	92; 4.1	87; 6.6	96; 2.2	97.5; 1.2
	PL	88; 6.0	88; 5.6	87; 6.5	68; 15.9	75; 12.3	77; 11.4
*a*16:0	NL	n.d.[b]	n.d.	n.d.	n.d.	n.d.	n.d.
	PL	84; 8.2	n.d.	n.d.	n.d.	n.d.	n.d.
*a*17:0	NL	>95[c]; <2.5	>95; <2.5	95; 2.5	89; 5.7	>95; <2.5	>95; <2.5
	PL	86; 7.1	>95; <2.5	95; 2.5	71; 14.5	88; 6.0	>95; <2.5

[a] *ee* could not be determined exactly, due to low signal-to-noise ratio

[b] n.d. = not detected: <0.8 mg/100 g

[c] Detection limit of the (*R*)-enantiomer of *a*17:0 was 2.5% (*ee* > 95%)

the CSP, most likely due to the three-dimensional geometry of the *β*-TBDM.

Fish und Seal Oil

In the sea bass sample, *a*15:0 and *a*17:0 were detected in both the neutral and the polar lipids. In all occasions the (*S*)-enantiomers were predominant. However, low amounts of the (*R*)-enantiomers were detected as well (Table 2).

Interestingly, the (*R*)-*a*17:0 was much more abundant in the PL (*ee* = 86%, 7.1% (*R*)-*a*17:0) than in the NL (*ee* > 95%, <2.5% (*R*)-*a*17:0). This result was observed for *a*15:0 (*ee* = 88% in PL vs. >90% in the NL) as well (see Table 2). As mentioned previously, traces of *a*16:0 were detected in the PL (but not in the NL) of the sea bass sample. The (*S*)-enantiomer dominated over the (*R*)-16:0 (*ee* = 84%) similarly to (*S*)-*a*17:0 in the PL of sea bass (Table 1 and Fig. 2a). One presumed biosynthesis pathway of *a*FA involves isoleucine-derived 2-methyl-butanoyl-CoA as primer instead of acetyl-CoA [28]. While this pathway can explain the formation of odd numbered *a*FA (i.e. *a*15:0 and *a*17:0), it does not fit for *a*16:0. Hence, there must be either a different biosynthesis pathway for even-numbered *a*FA, or the low amounts of *a*16:0 may originate from α-oxidation of *a*17:0. For instance, myxobacteria are able to convert odd-numbered iso-FA (e.g. *i*17:0) into even-numbered iso-FA (e.g. *i*16:0) by α-oxidation [29]. Since *a*16:0 and *a*17:0 (but also *a*15:0) showed almost the same enantiomeric excess of the (*S*)-enantiomer in the PL (Fig. 2b, c; Table 1), *a*16:0 might indeed be formed by oxidative degradation of *a*17:0.

Higher proportions of (*R*)-*a*15:0 in PL than in NL were also measured in trout and gilthead sea bream (Fig. 3) while (*R*)-*a*17:0 was absent or found in traces only in both the PL and the NL (*ee* ≥ 95%) (Table 2). However, the highest relative amounts of (*R*)-*a*FA were determined in the seal oil with 15.9% (*R*)-*a*15:0 (*ee* = 67%) and 14.5% (*R*)-*a*17:0 (*ee* = 71%).

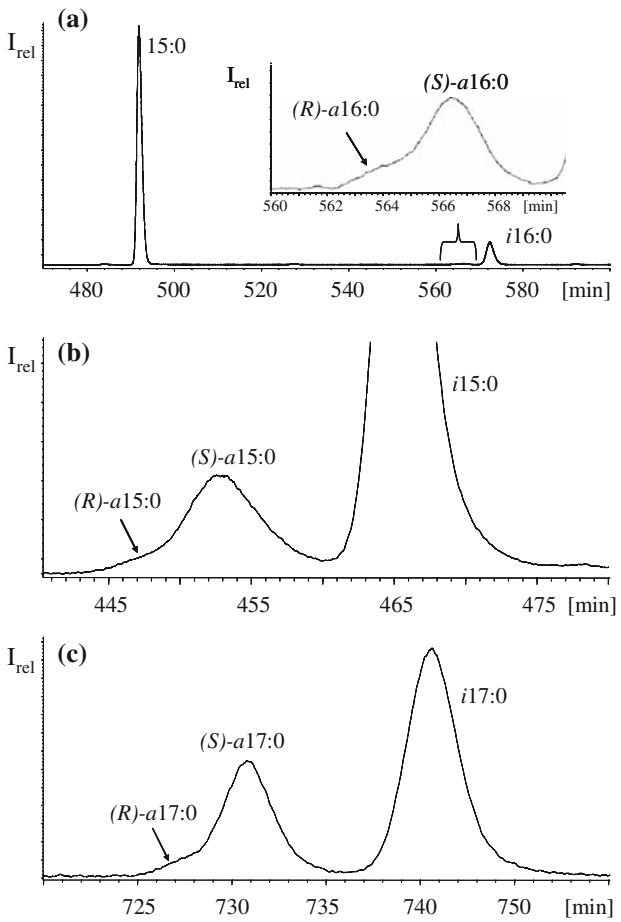

Fig. 2 GC/EI-MS chromatograms (66% *β*-TBDM in OV-1701) of the enantioselective determination of the methyl esters of **a** *a*16:0, **b** *a*15:0 and **c** *a*17:0 in the polar lipids of a sea bass sample. The concentration of *a*16:0 was approximately <0.9% of the 15:0 (84 mg/100 g lipids) and was thus estimated in the 0.8 mg/100 g lipids range

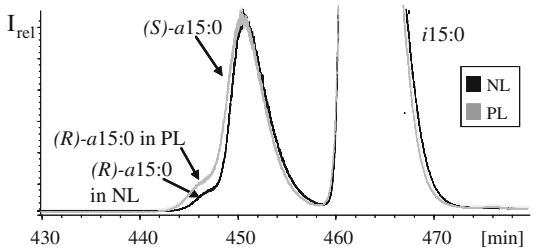

Fig. 3 GC/EI-MS chromatograms (66% β-TBDM in OV-1701) of the enantioselective determination of *a*15:0 methyl ester in the polar and neutral lipids of a gilthead sea bream sample

The relative amounts of the (*R*)-*a*FA were >2.5 times higher in the PL than in the NL (with (*R*)-*a*15:0 = 6.6%, *ee* = 87%, and (*R*)-*a*17:0 = 5.7%, *ee* = 89%). Marine mammals, such as seals are top predators of aquatic food webs and mainly feed on larger fish. The relative high proportions of (*R*)-*a*FA in the seal oil compared with the fish samples analyzed might thus suggest an enantioselective discrimination of *a*FA along the food chain. It is noteworthy in this context that all phospholipids substituted with either (*S*)-*a*FA or (*R*)-*a*FA are diastereomers which have different physicochemical properties. The same is true for triacylglycerides with $R_1 \neq R_3$. This could eventually lead to the preferred accumulation of the (*R*)-enantiomer. Furthermore, it is possible that microorganisms are involved in this process due to the higher relative abundance of (*R*)-*a*FA in the phospholipids.

Cheese Samples

Previously, only the (*S*)-enantiomers of *a*FA had been detected in the lipids of dairy products [14, 30]. Results from the marine samples indicated that (*R*)-*a*FA were more relevant in the PL. However, the PL content of cheese is very low (~1%) and the fatty acid (including the *a*FA) content of total lipids is virtually characterized by the NL. Thus, even large proportions of (*R*)-*a*FA in PL would be overlooked as long as total lipids are analyzed (and for NL mainly containing (*S*)-*a*FA). In this context it was interesting to check this assumption by the separate determination of *a*FA in the NL and PL of cheese samples. In addition, the enantiomeric resolution of *a*FA was significantly improved in this study compared to Thurnhofer et al. [14] which could only verify *ee* < 96% for *a*15:0 due to the worse gas chromatographic enantioresolution on the 50% β-TBDM phase compared to this study. With the novel 66% β-TBDM column we were able to determine lower relative amounts of (*R*)-*a*FA in dairy products (Table 1). In the NL, 1.2% and 2% of (*R*)-*a*15:0 were detected in camembert and mozzarella (see embedded chromatogram in Fig. 4a). The small amounts of (*R*)-*a*15:0 detected in the cheeses clearly demonstrated the improved performance of the new column, since higher enantiomeric excesses (*ee* > 97.5% for *a*15:0) could be verified. However, much higher proportions of (*R*)-*a*15:0 were detected in the PL of camembert (12%, *ee* = 75%, Fig. 4b) and mozzarella (12.3%, *ee* = 75%). (*R*)-*a*17:0 was neither detected in the NL nor in the PL of mozzarella but the PL of camembert also contained 6% of (*R*)-*a*17:0 (*ee* = 88%) while (*R*)-*a*17:0 was not detected in the NL (Fig. 4c, d).

To our knowledge, these results mark the first detection of (*R*)-*a*FA in the lipids of dairy products. These results contradict those of the Shorland group, who found *a*FA to be (*S*)-enantiopure in the lipids of food samples [30, 31]. However, these authors used fractional distillation and

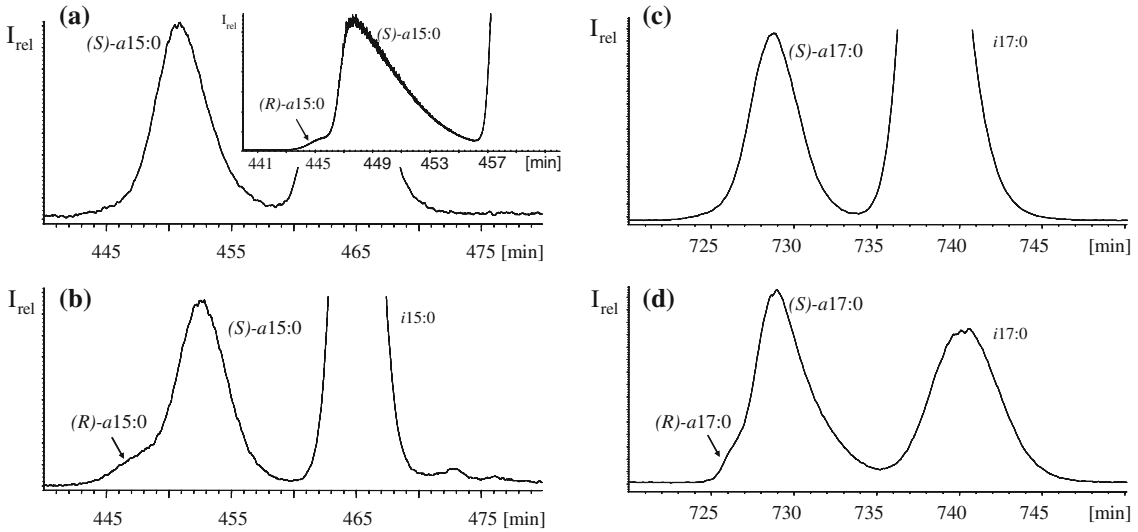

Fig. 4 GC/EI-MS chromatograms (66% β-TBDM in OV-1701) of the enantioselective determination of *a*15:0 methyl ester in **a** the NL and **b** the PL of camembert as well as *a*17:0 methyl ester in **c** the NL and **d** the PL of camembert. The embedded chromatogram in **a** shows a 20-fold higher concentrated fraction with small amounts of (*R*)-*a*15:0 (2%, *ee* = 96%)

crystallization for the isolation of *a*FA from food samples [32]. It could be possible that these procedures are accompanied with enantiomeric fractionation (i.e. the loss of the small amounts of the (*R*)-enantiomers). Alternatively, it could be possible that small amounts of (*R*)-enantiomers were overlooked.

The origin of the (*R*)-*a*FA in the food samples remains largely unexplained. The stronger occurrence of the (*R*)-enantiomer in PL compared to NL (which was up to 5 times higher for (*R*)-*a*15:0) could indicate that microorganisms (e.g. rumen bacteria, marine microorganisms or pathogenic bacteria in the case of the perishable fish) are responsible for this event. Moreover, it is unclear whether the (*R*)-*a*FA are formed in de novo syntheses or if they are the product of (partial) enantiomerization or racemization. These questions and the underlying biochemical mechanisms are interesting topics to be clarified in future.

METHODS

Preparation of Fatty Acid Methyl Esters by Selective Methanolysis of Polar Glycerolipids

Received: 18 September 2009 / Accepted: 1 March 2010 / Published online: 21 March 2010

Abstract KOH in aqueous methanol catalyzes selective methanolysis of polar glycerolipids with *O*-ester-linked acyl residues, while triacylglycerols and sterol esters are inert in the solution. Based on these findings, a convenient and reliable method was developed for the preparation of fatty acid methyl esters (FAMEs) from polar glycerolipids in lipid mixtures without prior isolation. Methanolysis of polar glycerolipids was completed within 2.5 min by vortexing or 20 min by shaking with 0.7 M KOH/70% (v/v) methanol in the presence of hexane at 30 °C. The yields of FAMEs obtained by the present method were greater than 95%. The method was applied successfully to gas chromatographic analysis of the fatty acid compositions of polar glycerolipids in seed oil and blood. No obvious differences were found between the fatty acid compositions determined by the present method and those determined by conventional methods, including lipid extraction with chloroform/methanol followed by isolation of polar lipids by chromatography. The fatty acid composition of polar glycerolipids, including phospholipids, can be determined readily in many crude samples.

Introduction

Phospholipids (PLs) are the major constituents of biological membranes, and the fatty acid composition of PLs affects the physical and chemical properties of the membrane. Some of fatty acids found in PLs are also substrates of physiologically active substances. The fatty acid composition and the n-3/n-6 polyunsaturated fatty acid balance of blood and other organs are suggested to be related to human health [1–4], while the fatty acid composition of blood glyceroPLs reflects medium-term dietary intake from weeks to months and hence also the nutritional and health status of each individual [5–7]. The fatty acid composition of glyceroPLs is determined by gas–liquid chromatography (GC). In conventional analytical procedures [1, 3, 8–13], total lipids are extracted from various biological materials with a mixed solution of chloroform and methanol. After phase separation, the chloroform layer is washed with water, and concentrated to dryness. Total PLs are isolated as polar lipids from total lipids by thin-layer chromatography (TLC) or column chromatography [14–16]. Total PLs are scraped off the TLC plates or total PLs eluted

through a column are concentrated to dryness. GlyceroPLs in total PLs thus isolated are converted to fatty acid methyl esters (FAMEs) by acid- or base-catalyzed methanolysis or by saponification followed by methylation. These steps are laborious and time-consuming, and it is difficult to treat many samples simultaneously by these methods. Our research has been made to prepare FAMEs selectively from polar glycerolipids in lipid mixtures.

Polar glycerolipids are composed of glyceroPLs and glyceroglycolipids in higher plants, while the polar glycerolipids in mammals are exclusively glyceroPLs. In the course of investigating base-catalyzed methanolysis, we found that KOH in 70% methanol efficiently catalyzes methanolysis of polar glycerolipids in the presence of sterol esters and triacylglycerols (TGs) to produce FAMEs derived from polar glycerolipids. Here, we describe a convenient reagent and simplified procedures to prepare FAMEs from polar glycerolipids in crude biological samples including seed oil and blood for GC analysis.

Materials and Methods

Reagents

PLs, TGs, cholesterol esters (CEs), fatty acids, and FAMEs were purchased from Avanti Polar Lipids (Alabaster, AL, USA), Cayman Chemical (Ann Arbor, MI, USA), Doosan Serdary Research Laboratories (Toronto, Canada), Nu-Chek-Prep (Elysian, MN, USA), Sigma-Aldrich (St. Louis, MO, USA), and Wako Pure Chemical Industries (Osaka, Japan). Dioleoyl phosphatidylcholine (PC) was synthesized from *sn*-glycero-3-phosphocholine and oleic acid [17]. Acetone, hexane, and methanol were purchased from Wako Pure Chemical Industries as glass-distilled solvents for analysis of residual pesticides. HPLC grade glass-distilled chloroform was obtained from Sigma-Aldrich. KOH, 50% BF_3 in methanol, *tert*-butyl methyl ether, methyl acetate, and heparin sodium salt were of reagent grade. Cartridge columns packed with 50 and 200 mg of silica gel were Bond Elut (No.12102068; Varian, Palo Alto, CA, USA) and LiChrolut (No.102021; Merck, Darmstadt, Germany), respectively. Microbial cholesterol esterases (CEases, EC3.1.1.13) were purchased from Calbiochem/Merck (Darmstadt, Germany) and from Oriental Yeast (Tokyo, Japan).

TLC and GC

Reaction products of methanolysis were analyzed by TLC on silica gel. Lipids separated were visualized by spraying 50% (w/w) sulfuric acid and then heating at 135 °C. PLs were also detected with the Dittmer and Lester reagent [18]. Plasmalogen was detected by spraying 0.5% 2,4-dinitrophenylhydrazine in 2 M HCl. FAMEs were analyzed with a Shimadzu 2014 gas chromatograph equipped with columns of DB-23 (0.25 mm × 30 m) and SUPELCOWAX 10 (0.53 mm × 30 m) at a column temperature of 215 or 225 °C (isothermal). Prior to GC, FAMEs prepared from biological materials were purified through cartridge columns packed with 200 mg of silica gel. Silica gel cartridges that had been conditioned with 3 mL of hexane were charged with FAMEs dissolved in hexane, and washed with 3 mL of hexane. FAMEs were then eluted with 3 mL of 1.2% (v/v) methyl acetate in hexane.

Conventional Preparation of FAMEs

Lipids were extracted from biological materials, including oil seed and blood, with chloroform/methanol by a modification of the Bligh and Dyer method [19], and the chloroform solution obtained was evaporated to dryness. Polar lipids of oil seeds were isolated from total lipids by column chromatography. Total lipids were dissolved in chloroform and applied to silica gel cartridge columns. Neutral lipids were eluted from the columns with chloroform, and polar lipids were then eluted with methanol. Blood PLs were isolated by TLC. Total lipids extracted from blood were developed on silica gel plates with acetone, and then PLs located at the origin of plate were scraped off together with silica gel. FAMEs were prepared by KOH-catalyzed methanolysis [20] from the polar lipids and PLs thus isolated.

Selective Methanolysis of Polar Glycerolipids

Hexane (2 mL) was added to lipid samples of mg order or less in a glass test tube (16.5 mm × 105 mm) and the resulting solutions were warmed for a few minutes in a water bath at 30 °C. To the hexane solution was added 0.4 mL of 0.7 M KOH in 70% (v/v) methanol, and the tubes were vortexed for 2.5 min or shaken at 200 rpm in a reciprocal shaker at 30 °C for 20 min. The reaction was stopped by addition of 0.03 mL of acetic acid and 1 mL of water. FAMEs in the hexane layer were analyzed by GC. To follow the progress of methanolysis, reaction products were extracted with chloroform and analyzed by TLC.

For lipid samples containing water, 1 M KOH in methanol was added to make 0.7 M KOH/70% methanol. For lipid samples of blood containing large amounts of CEs, the CEs were enzymatically hydrolyzed before methanolysis. The products of hydrolysis, cholesterol and fatty acids, had no effect on methanolysis and could be removed by passing through a silica gel cartridge before GC.

Preparation of FAMEs from Polar Glycerolipids in Blood

To 0.02 mL of CEase solution (500 U/mL of 0.15 M phosphate buffer, pH 7.0) in glass test tubes was added 0.14 mL of blood containing 0.7 U heparin, and the contents were mixed by pipetting several times. The mixtures were incubated for 30 min at 37 °C for hydrolysis of CEs, and then 2 mL of hexane (30 °C) and 0.28 mL of 1 M KOH in methanol (30 °C) were added. Methanolysis of PLs was carried out for 2.5 min with a vortex mixer. The reaction was terminated by addition of 0.03 mL of acetic acid, but no water was added to prevent gelation. FAMEs in the hexane layer were purified with a silica gel column. Alternatively, after treatment with CEase, methanolysis was carried out for 20 min in a reciprocal shaker at 180–200 rpm at a temperature of 30 °C. In this procedure, 3 mL of hexane was added.

For limited volumes of blood samples, 28 μL of blood containing 0.14 U of heparin was added to 4 μL of 2 U CEase solution in 1.5-mL plastic microcentrifuge tubes. The blood and CEase were mixed by pipetting several times, and the mixtures were incubated for 30 min at 37 °C. After addition of 0.5 mL of hexane and 56 μL of 1 M KOH in methanol, the tubes were vortexed at 30 °C for 2.5 min or vigorously mixed with a microcentrifuge tube shaker for 4 min at room temperature. To the reaction mixture was added 6 μL of acetic acid. The hexane layer was applied to a small cartridge column packed with 50 mg of silica gel. The gel was washed with 0.75 mL of hexane, and the FAMEs were eluted with 0.75 mL of 1.2% methyl acetate in hexane. The eluate was concentrated in vacuo and FAMEs obtained were analyzed by GC.

Results

Effects of KOH Concentration, Water Content, and Reaction Time on Methanolysis of PLs

PL mixtures composed of dioleoyl PC and dioleoyl phosphatidylethanolamine (PE) were shaken at 200 rpm in methanolic KOH solutions containing water at 30 °C for 20 min. The PLs were converted into methyl oleate at KOH concentrations of 0.7 M and above, and the reaction was accompanied by formation of small amounts of free oleic acid (Fig. 1a). The presence of water at 30% or less in methanol did not significantly affect methanolysis of PLs, but 40% water markedly inhibited the reaction (Fig. 1b). Although water in methanol caused hydrolysis of PLs, the amounts of free oleic acid released were estimated to be a small percentage of methyl oleate formed as described below. In a separate experiment, there were no differences between the fatty acid composition of FFAs released and that of FAMEs formed. The reaction time required for methanolysis of PLs by shaking was 15–20 min (Fig. 1c), while the reaction was completed within 2–2.5 min by vortexing (Fig. 1d).

Table 1 shows that the yields of methyl eicosenoate formed from dieicosenoyl PC were greater than 95% when determined by GC using an internal standard. Amounts of free eicosenoic acid released from the PL during methanolysis were 2.6–3.1% of the FAMEs formed. In a different experiment with dioleoyl PC, the ratio of methyl oleate and oleic acid formed by vortexing was 97.3 ± 0.1:2.7 ± 0.1 ($n = 3$). In addition, FFAs detected at the end of the reaction were derived from PLs but not from FAMEs formed. Saponification of FAMEs once formed was slow in the solution of 0.7 M KOH/70% methanol/hexane and the FAMEs formed underwent little hydrolysis. With respect to the mixing method, vortexing was better than shaking in terms of FFA formation and reaction time (Table 1; Figs. 1c, d), but the shaking method still has the advantage that it allows simultaneous treatment of more samples at a time.

Contamination with FAMEs Derived from TGs

Products of methanolysis of dioleoyl PC in the presence of trieicosenoyl TG were analyzed to assess the degree of contamination with FAMEs derived from TGs. Table 2 shows that methanolysis of TG proceeded much more slowly than that of PC, and consequently methyl oleate formed from PC was negligibly contaminated with methyl eicosenoate from TG. Even when a mixture of 58.5% PLs (PC and PE) and 41.5% TG was incubated for a long reaction time of 1 h in a reciprocal shaker at 30 °C, 99.0% of the FAMEs produced were derived from PLs.

Methanolysis of a mixture of dipalmitoyl PC and dioleoyl PE with 0.7 M KOH/70% methanol gave FAMEs with a similar fatty acid composition to that of the substrate PLs (Table 3). These observations suggested that methanolysis for PLs was not selective for specific molecular species of fatty acid.

Determination of the Fatty Acid Compositions of Polar Glycerolipids in Seed Oils and Leaf Lipids

TGs are the major components of vegetable oils, while PLs are a minor constituent whose content is a very small percentage of the oil. Seeds of Brassicaceae plants accumulate erucic acid, 13-docosenoic acid, in TGs, but only a small amount of this very long chain fatty acid is present in PLs. Total lipids were extracted from the seeds of *Brassica*

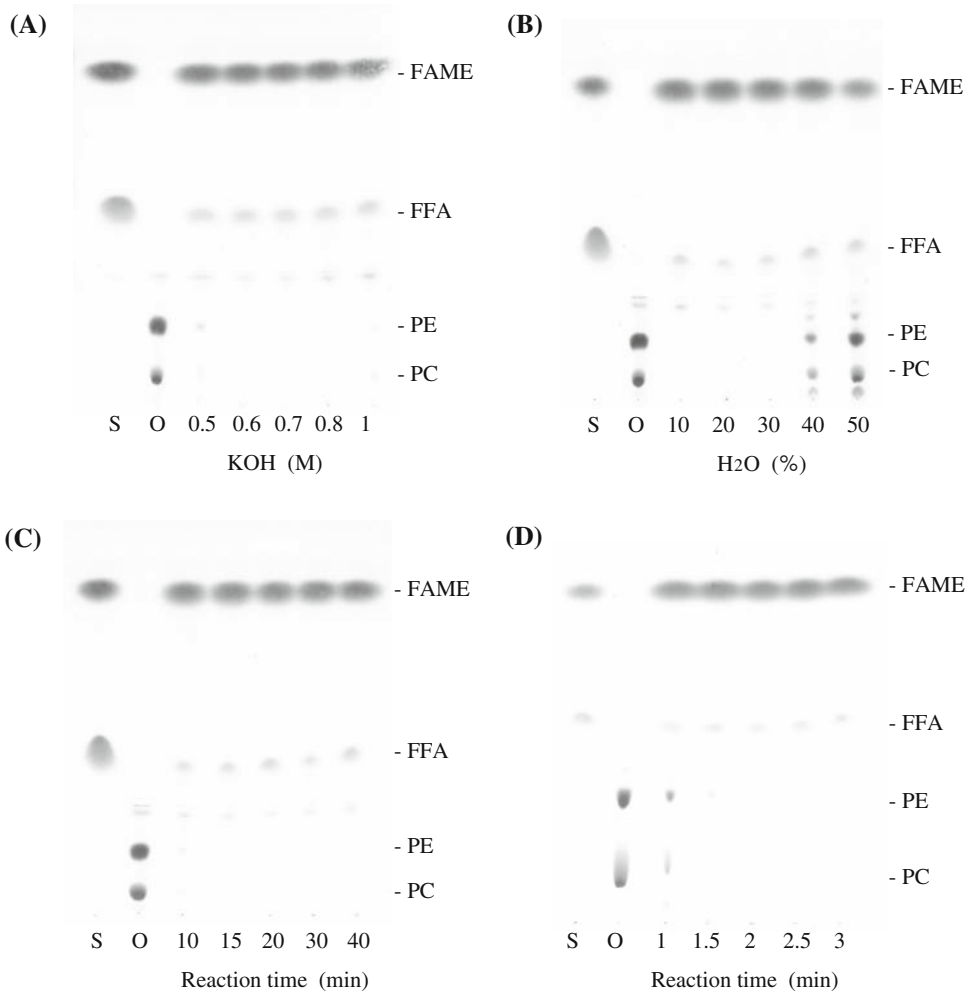

Fig. 1 Effects of (**a**) KOH concentration, (**b**) water content, (**c**) reaction time of shaking, and (**d**) reaction time of vortexing on methanolysis of PLs. PL mixtures composed of 1 mg of dioleoyl PE and 1 mg of dioleoyl PC were incubated with 0.5–1 M KOH (**a**) in 50–90% methanol (**b**) for 10–40 min (**c**) at 30 °C in a reciprocal shaker at 200 rpm. In the experiment for (**d**), PL mixtures were vortexed for 1–3 min at 30 °C. Reaction products were extracted with hexane and chloroform, and these extracts were combined and concentrated in vacuo for analysis by TLC. Silica gel plates spotted with the concentrates were developed to 3 cm from the origin with chloroform/methanol/water/acetic acid (65:35:4:1, v/v/v/v), dried in vacuo, and redeveloped to 8 cm from the origin with hexane/*tert*-butyl methyl ether/acetic acid (85:15:0.5, v/v/v). *S* standards of FAME and FFA, *O* time zero

Table 1 Yields of FAME and FFA formed from PC

Method of mixing	Yield (wt%)	
	Methyl eicosenoate	Eicosenoic acid
Vortexing	96.0 ± 1.2	2.6 ± 0.2
Reciprocal shaking	95.5 ± 0.9	3.1 ± 0.0

Dieicosenoyl PC was incubated with 2 mL of hexane and 0.4 mL of 0.7 M KOH/70% methanol at 30 °C. After methanolysis, methyl heptadecanoate and heptadecanoic acid were added to the reaction mixture as internal standards. Products were extracted three times with hexane, and FAME and FFA were isolated by TLC. FFA was methylated with 10% BF_3 at 45 °C for 20 min. Data are shown as averages of three determinations

oleracea var. *italica* with chloroform/methanol, and polar lipids, including PLs, were isolated from the total lipids by passage through a silica gel column. Nonpolar lipids were removed by elution with chloroform, and polar lipids were then eluted with methanol. The polar lipid fraction contained PE, PC, and phosphatidylinositol as PLs, and also phosphorus-negative compounds. The *Brassica* seeds contained 30% (w/w) oil, most of which was comprised of TGs. Total lipids were treated with 0.7 M KOH/70% methanol/hexane or 2 M KOH/methanol/hexane [20], which was also used for methanolysis of the isolated polar lipids. The fatty acid composition of polar glycerolipids was almost the same as that of the isolated polar lipid fraction (Table 4).

Photosynthetic tissues of plants contain PLs and glycolipids. TGs are a minor constituent, although they accumulate in leaves under ozone fumigation [21]. The major lipid classes of PLs are PC, PE, phosphatidylglycerol, and phosphatidylinositol, while those of glycolipids are monogalactosyldiacylglycerol, digalactosyldiacylglycerol, and sulfoquinovosyldiacylglycerol. Fatty acyl residues of these glyceroglycolipids are also converted to FAMEs by the reaction of leaf total lipids from *Phaseolus vulgaris* with 0.7 M KOH/70% methanol (data not shown).

Table 2 Contamination with FAME derived from TG

Substrate PC:TG (wt%)	FAME formed (wt%)	
	Methyl oleate (FAME from PC)	Methyl eicosenoate (FAME from TG)
50:50	99.7 ± 0.0	0.3 ± 0.0
10:90	97.4 ± 0.1	2.6 ± 0.1

Mixtures of dioleoyl PC and trieicosenoyl TG were vortexed with 2 mL of hexane and 0.4 mL of 0.7 M KOH/70% methanol. Data are shown as averages of two determinations

Table 3 Effects of fatty acyl molecular species on selective methanolysis

FAME formed	Methanolysis with	
	2 M KOH/methanol (wt%)	0.7 M KOH/70% methanol (wt%)
16:0 (from PC)	47.3 ± 0.3	46.7 ± 0.2
18:1 (from PE)	52.7 ± 0.1	53.3 ± 0.1

A mixture of dipalmitoyl PC and dioleoyl PE was incubated with 0.7 M KOH/70% methanol/hexane or with 2 M KOH/methanol/hexane as control at 30 °C in a reciprocal shaker. Data are shown as averages of three determinations

Determination of the Fatty Acid Composition of Polar Glycerolipids in Blood

Removal of CEs from Blood Prior to Methanolysis

To synthesize FAMEs from polar glycerolipids of blood in which polar glycerolipids are glyceroPLs, blood was directly incubated with KOH/methanol taking into account the fact that the water content of blood is about 73%. Polar glycerolipids in blood were converted into FAMEs, while CEs, TGs, and FFAs remained unchanged as expected. The FAME preparations were passed through silica gel cartridge columns, which are more convenient than TLC, but CEs could not be separated completely from FAMEs because they have similar polarities. As the presence of CEs in GC samples of FAMEs probably degrades GC columns and shortens their lifespan, CEs were enzymatically split into cholesterol and fatty acids prior to methanolysis of PLs. As shown in Fig. 2, CEs in blood were hydrolyzed to cholesterol and fatty acids within 30 min, although a trace amount of CEs remained unchanged. As CEase also catalyzed hydrolysis of TGs, the incubation of blood with CEase resulted in the disappearance of both CEs and TGs. CEs and TGs may not be completely decomposed by CEase in blood samples containing high concentrations of these lipids, and this may be the case in the blood of hyperlipidemic patients. However, even if CEs and TGs are not completely hydrolyzed by the esterase, it is expected that the FAME compositions of these nonpolar lipids are not reflected in that of polar glycerolipids due to selective methanolysis.

Preparation of FAMEs from Polar Glycerolipids in Blood

Based on the above observations, a convenient method that requires neither lipid extraction from blood nor isolation of PLs was developed for preparation of FAMEs of blood polar glycerolipids. The products from each reaction step were analyzed by TLC (Fig. 3). The two major blood glyceroPLs, i.e., PE and PC, disappeared after 20 min of reaction, and this demonstrated that these diacyl PLs underwent methanolysis. Small, weak spots that were found at the same position as PC in lanes 2–6 were the lyso form of ethanolamine plasmalogen, which has an *O*-ether linkage. Sphingomyelin, which has no ester bond, remained unchanged. The results shown in Fig. 3 again confirmed that CEs and TGs were both stable in methanolic alkali containing water under the conditions employed and that FAMEs were formed from glyceroPLs. FAMEs in the hexane layer of the reaction (lane 6) were purified through a silica gel cartridge to a single spot on the TLC plate (lane 7).

The fatty acid compositions determined by this method were compared with those determined by a conventional method, including extraction of total lipids, isolation of polar lipids by TLC, and methanolysis (Table 5). There were no significant differences between the fatty acid compositions determined by this method and by the conventional method except for oleic acid (18:1) and docosatetraenoic acid (22:4 n-6).

Discussion

On the selective methanolysis for glyceroPLs in the presence of 90% or less TGs, only limited contamination with FAMEs derived from TGs can occur under the conditions employed (Table 2). As CEs are less reactive than TGs [22, 23], it is reasonable to expect that no FAMEs would be produced from CEs with KOH in aqueous methanol. The accuracy and usefulness of selective methanolysis were confirmed with seed oil and blood lipids by comparison of the fatty acid composition of polar glycerolipids obtained by selective methanolysis without isolation from total lipids with that of polar lipids obtained by conventional methods. The erucic acid content of polar glycerolipids was much lower than that of total lipids and was very similar to that of polar lipids, indicating that almost all the FAMEs produced were derived from polar glycerolipids, and TGs did not act as the substrate of methanolysis (Table 4). The data demonstrated the validity of selective methanolysis for determination of the fatty acid composition of polar glycerolipids in lipid samples in which TGs were predominant. The present method thus does not require the isolation of polar glycerolipids from total lipids prior to preparation of FAMEs.

GlyceroPLs in blood could be directly converted corresponding FAMEs. With small volumes of blood samples, the fatty acid composition of total glycerolipids (TGs and glyceroPLs) can be readily determined by KOH-catalyzed methanolysis of blood loaded on filter paper followed by GC [24], and that of total lipids can be analyzed by finger stick assays [25, 26] where HCl and BF_3 have been used as acid catalysts. FAMEs derived from ester lipids (CEs, TGs, and glyceroPLs) and FFAs can also be prepared from a drop of blood on a small piece of filter paper at 45 °C by methanolysis/methylation with aqueous concentrated HCl/methanol/toluene [27]. Ohta et al. [28] reported a method for determination of the fatty acid compositions of individual lipid classes in small volumes of blood samples, but the method included procedures for separation of individual lipid classes by TLC. The present method using selective methanolysis has enabled us to determine the fatty acid composition of blood glyceroPLs without extraction or isolation of the polar lipids. Although samples of 0.14 mL of blood were treated in this method, the scale could be reduced to at

Polar lipids were isolated from total lipids by silica gel column chromatography. The fatty acid composition of polar glycerolipids was determined by selective methanolysis of the total lipids with 0.7 M KOH/70% methanol/hexane. Data are shown as averages of three determinations

ND not detected

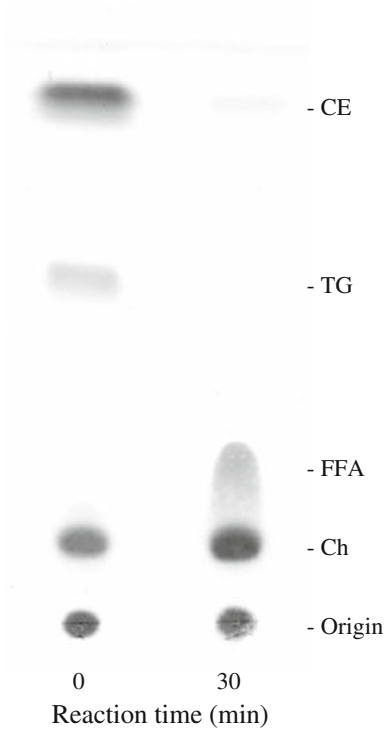

Fig. 2 Hydrolysis of CEs in blood by CEase. A 0.14 mL blood sample was mixed with a 10 U CEase solution (0.02 mL) and incubated at 37 °C for 30 min. Products were extracted with chloroform/methanol, and analyzed by TLC. The silica gel plate was first developed to 5 cm from the origin with hexane/*tert*-butyl methyl ether (75:25, v/v), and then it was developed to 8 cm from the origin with hexane/*tert*-butyl methyl ether (95:5, v/v). *Ch* cholesterol

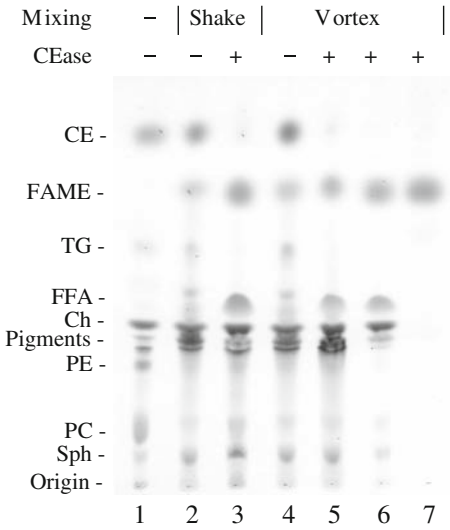

Fig. 3 Reaction products of methanolysis for blood glyceroPLs. Lane 1 shows the profile of total lipids extracted with chloroform/methanol from blood, and lanes 2–7 show the products of methanolysis of blood glyceroPLs. Blood samples (0.14 mL) were incubated with 0.02 mL of 0.15 M phosphate buffer (*lanes 2* and *4*) or CEase solution (*lanes 3* and *5–7*) at 37 °C for 30 min, and then mixed with 2 mL of hexane and 0.28 mL of 1 M KOH/methanol at 30 °C by shaking at 180 rpm for 20 min (*lanes 2* and *3*) or vortexing for 2.5 min (*lanes 4–7*). Methanolysis was stopped by the addition of 0.03 mL of acetic acid, and then the hexane layer was separated. The residual methanol/water layer was extracted with chloroform/methanol to confirm the disappearance of PE and PC. The chloroform extract was combined with the hexane layer, and then the mixed solution was evaporated in vacuo for TLC (*lanes 2–5*). For GC analysis, the hexane layer was concentrated and checked by TLC (*lane 6*), while FAMEs in the hexane layer were purified through a silica gel cartridge column (*lane 7*). *Ch* cholesterol; *Sph* sphingomyelin

least one-fifth as described in Materials and Methods. The procedure could also effectively function on the microscale.

In conclusion, the methanolic KOH solution containing water can catalyze selective methanolysis of polar glycerolipids irrespective of the presence or absence of sterol esters or TGs. The present method for preparation of FAMEs was successfully applied to analysis of seed and blood polar glycerolipids. The methanolysis proceeds under mild conditions, produces no artifacts, and is safe for researchers. The procedure does not include use of chloroform, which is toxic to humans and may contaminate the environment. Fatty acid compositions and yields obtained were almost the same as those obtained with conventional time-consuming methods. The procedure is simple and no sophisticated apparatus is required, and large numbers of crude samples can be treated simultaneously.

Table 5 GlyceroPL fatty acid compositions obtained from blood by different methods

Fatty acid	Conventional method (wt%)	Selective methanolysis (wt%)	
		Vortexing	Shaking
16:0	25.3 ± 0.8	26.4 ± 0.5	24.5 ± 0.6
18:0	13.9 ± 0.1	13.6 ± 0.9	13.7 ± 0.2
18:1	15.0 ± 0.1	13.8 ± 0.2	13.7 ± 0.1
18:2	19.9 ± 0.6	20.8 ± 0.4	20.1 ± 0.2
20:3 n-6	1.5 ± 0.1	1.5 ± 0.0	1.4 ± 0.1
20:4 n-6	11.9 ± 0.7	12.2 ± 0.2	13.1 ± 0.3
20:5 n-3	2.1 ± 0.1	1.8 ± 0.1	2.2 ± 0.0
22:4 n-6	1.3 ± 0.1	0.9 ± 0.1	1.1 ± 0.0
22:5 n-3	1.5 ± 0.1	1.3 ± 0.1	1.7 ± 0.0
22:6 n-3	7.7 ± 0.3	7.7 ± 0.2	8.4 ± 0.1

The conventional method included extraction of total lipids from blood, isolation of PLs, and methanolysis. Data obtained by two different procedures are described for selective methanolysis. Minor components are omitted. Data are shown as averages of three determinations

Abstract The anti-inflammatory activity associated with fish oil has been ascribed to the long-chain polyunsaturated fatty acids (LC-PUFA), predominantly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Here we examined the anti-inflammatory effects of two DHA-rich algal oils, which contain little EPA, and determined the contribution of the constituent fatty acids, particularly DHA and docosapentaenoic acid (DPAn-6). In vitro, lipopolysaccharide (LPS)-stimulated Interleukin-1 beta (IL-1β) and Tumor Necrosis Factor-alpha (TNF-α) secretion in human peripheral blood mononuclear cells (PBMC) was inhibited with apparent relative potencies of DPAn-6 (most potent) > DHA > EPA. In addition, DPAn-6 decreased intracellular levels of cyclooxygenase-2 (COX-2) and was a potent inhibitor of pro-inflammatory prostaglandin E2 (PGE2) production. DHA/DPAn-6-rich DHA-S^{TM} (DHA-S) algal oil was more effective at reducing edema in rats than DHA-rich DHA-T^{TM} (DHA-T), suggesting that DPAn-6 has anti-inflammatory properties. Further in vivo analyses demonstrated that feeding DPAn-6 alone, provided as an ethyl ester, reduced paw edema to an extent approaching that of indomethacin and enhanced the anti-inflammatory activity of DHA when given in combination. Together, these results demonstrate that DPAn-6 has anti-inflammatory activity and enhances the effect of DHA in vitro and in vivo. Thus, DHA-S algal oil may have potential for use in anti-inflammatory applications.

Keywords Inflammation · DHA · DPAn-6 · Long-chain polyunsaturated fatty acids

Abbreviations

ARA	Arachidonic acid
COX	Cyclooxygenase
DHA	Docosahexaenoic acid
DPAn-6	Docosapentaenoic acid
EPA	Eicosapentaenoic acid
GRAS	Generally recognized as safe
IL-1β	Interleukin-1 beta
LPS	Lipopolysaccharide
LC-PUFA	Long chain-polyunsaturated fatty acids
OLA	Oleic acid
PBMC	Peripheral blood mononuclear cells
PGE2	Prostaglandin E2
TNF-α	Tumor Necrosis Factor-alpha

Introduction

Chronic or uncontrolled inflammation can lead to tissue damage and is an underlying factor in atherosclerosis, rheumatoid arthritis, diabetes (type 1), asthma, inflammatory bowel disease, and Alzheimer's disease [1–7]. Inflammation results from the release of chemical mediators from activated leukocytes that have migrated to target areas as a consequence of tissue injury or invading pathogens. These inflammatory mediators include IL-1β,

TNF-α, and PGE2. EPA (20:5n-3) and DHA (22:6n-3), LC-PUFA found in fish oil, have anti-inflammatory activity and affect inflammatory mediator production [8–12], lymphocyte proliferation [13, 14], monocyte and neutrophil migration [15], and natural killer (NK) cell activity in vitro [16].

The consumption of fish oil results in the replacement of arachidonic acid (ARA; 20:4n-6) in cell membranes by DHA and EPA [17, 18]. This leads to alterations in the eicosanoids produced and contributes towards a less inflammatory environment [17–20]. EPA and DHA can also be converted into resolvins, which are bioactive molecules that play an important role in the resolution of inflammation [4, 21, 22]. Further, LC-PUFA modulate the expression and activity of genes involved in the inflammatory response. In vitro, EPA or DHA reduced the production of proinflammatory cytokines, including IL-1β and TNF-α [8–12, 20] and cell migration [23–26]. DHA and EPA may have differing mechanisms of action [27]. PBMC derived from humans supplemented with DHA had a decreased ex vivo T cell activation whereas EPA supplementation had no significant effect [28]. DHA was also more efficacious at reducing pro-inflammatory cytokines than EPA, particularly IL-1β and IL-6 in vitro [8, 12].

While many studies to date have examined the anti-inflammatory effects of DHA and EPA from fish oil, this study focused on DHA and DPAn-6 (docosapentaenoic acid; 22:5n-6) derived from algal sources which contain little EPA. We assessed the anti-inflammatory activity of DHA/DPAn-6-rich DHA-S^{TM} (DHA-S) and DHA-rich DHA- T^{TM} (DHA-T) algal oils[1] and their individual constituent LC-PUFA. To our knowledge, this is the first study to show that DPAn-6 has potent anti-inflammatory activity and enhances the effects of DHA.

Materials and Methods

Fatty Acid Sodium Salts for In Vitro Experiments

All in vitro assays used sodium salts of EPA, ARA, DPAn-6, and Oleic acid (OLA) that were purchased from NuChek Prep (Elysian, MN) and were greater than 99% pure. DHA-sodium salt (greater than 98% pure) was purchased from Sigma-Aldrich (St. Louis, MO). Fatty acid sodium salts were prepared by resuspending in distilled water and warming for 1.5 h at 37 °C to ensure solubility before storing at −80 °C. Before use, fatty acids were again warmed to 37 °C for 10 min to ensure homogeneity. The fatty acids were used at the concentrations described in the specific in vitro assays below. Since potencies of the fatty acids were being directly compared in experiments, the concentrations of the fatty acid stock solutions were confirmed by gas-liquid chromatography, accuracy ±5%, both prior to and after the freeze/thaw process.

Human Cell Culture

PBMC were isolated by Ficoll-Hypaque (Amersham, Uppsala, Sweden) density gradient from the peripheral blood of healthy humans per the manufacturer's instructions. Human blood obtained from healthy individuals (negative for HIV and Hepatitis-B and-C) was purchased from All Cells, Emeryville, CA. Isolated PBMC were frozen in heat inactivated fetal calf serum (FCS)/10% dimethylsulfoxide (DMSO) until use when they were thawed, placed in supplemented RPMI 1640 containing 10% FCS (heat inactivated), 1% L-glutamine (200 mM), 100 unit/ml penicillin, and 100 μg/ml streptomycin (all reagents Sigma-Aldrich, St. Louis, MO). PBMC were thawed, washed in supplemented RPMI, and cell viability was assessed by trypan blue exclusion immediately before use in vitro.

In Vitro LPS Stimulation of PBMC

Human PBMC were stimulated with LPS (derived from *E. coli*, Sigma-Aldrich, St. Louis, MO) using a modification of the method originally described [29]. Briefly, PBMC were resuspended in supplemented RPMI 1640, seeded at 2×10^5 cells/200 μl/well of a 96-well flat-bottom plate. PBMC were pretreated for 2 h at 37 °C with 2 μl of the individual fatty acid sodium salts or an equivalent volume of water (negative control); five replicate wells per treatment. Fatty acid concentrations were used at 100 μM or 10–100 μM (dose response). PBMC were then stimulated with 20 μl LPS (0.1 ng/ml final concentration) for 18 h at 37 °C. Following stimulation, cells were pelleted by centrifugation and supernatants were collected and stored at −20 °C for cytokine measurement by ELISA. Cell viability after LPS incubation was monitored by trypan blue exclusion before and after centrifugation and no significant differences in viability were noted between control and fatty acid-treated groups at the doses used in this study.

IL-1β and TNF-α ELISA

Cell supernatants were tested for IL-1β and TNF-α (Research Diagnostics, Minneapolis, MN) following the manufacturer's instructions.

[1] DHA-T oil is also known as DHASCO or DHASCO-T oil; DHA-S was formerly known as DHASCO-S oil. Both are manufactured by Martek Biosciences Corporation.

Determination of COX-1, COX-2, and PGE2 Levels

Human PBMC were seeded at 1×10^6 cells/ml in a 24-well plate with 1 ml supplemented RPMI 1640 per well. Cells were pretreated with 10 μl of the individual fatty acid sodium salts (100 μM) or a combination of two fatty acids (50 μM each for 100 μM total) for 2 h prior to stimulation with 10 μl LPS (0.1 ng/ml); replicates of 6 wells per treatment. Cell viability after LPS incubation was monitored by trypan blue exclusion before and after centrifugation and no significant differences in viability were noted between control and fatty acid-treated groups at the doses used in this study. IL-4 (10 ng/ml (10 μl); BD Biosciences, San Jose, CA) was used as a positive control. After approximately 18 h, PGE2 levels in the supernatants were assayed using an EIA kit (Cayman Chemical, Ann Arbor, MI). For the detection of intracellular COX-1 and COX-2, PBMC were stained for 15 min with PerCP-conjugated CD14 (BD Biosciences, San Jose, CA) to identify the monocytes. After washing, cells were fixed and permeabilized using the BD Cytofix/Cytoperm kit (BD Biosciences, San Jose, CA) following the manufacturer's instructions. Cells were then stained with COX-1-FITC/COX-2-PE antibody combination or the isotype-matched controls (BD Biosciences, San Jose, CA). CD14 + gated cells, 5,000–10,000 per sample, were analyzed on a Coulter Epics Altra flow cytometer using EXPO32 Multi-COMP software (Beckman Coulter, Fullerton, CA).

Animals and Diets

Male Sprague-Dawley rats (100–150 g) from Harlan (Indianapolis, IN) and/or Charles River Laboratories (Wilmington, MA) were quarantined for at least 3 days prior to study initiation. Food and water were provided ad libitum. AIN-76A Diet (Research Diets, New Brunswick, NJ) was used as the base diet and for all diet formulations used in the animal studies as it does not contain any LC-PUFA. Study protocols were approved by the animal facility's Institutional Animal Care and Use Committee and followed the Animal Care and Use Guidelines established by the Office for Laboratory Animal Welfare (OLAW)/NIH. Food consumption, animal body weights, and general health were monitored throughout the studies.

DHA-S, DHA-T, ARASCO™

DHA-S, DHA-T, ARASCO oils, derived from *Schizochytrium* sp., *Crypthecodinium cohnii*, and *Mortierella alpine*, respectively, were manufactured by Martek Biosciences Corporation (Columbia, MD) and their fatty acid compositions are described in Table 1. Both DHA oils are used in food and dietary supplements [30] and are Generally Recognized as Safe (GRAS) for food. DHA-T oil in combination with ARASCO oil, an oil rich in ARA, is GRAS for the fortification of infant formula. DHA-S oil has been used in a number of clinical studies [31–33], as has the DHA-T oil [30, 34]. LC-PUFA are present as triglycerides within these oils.

Table 1 Fatty acid profiles of oils

	% Total fatty acids		
	DHA-S	DHA-T	ARASCO

22:5 (n-6) DPA	16.26	0	0
22:6 (n-3) DHA	40.39	41.9	0
Others	<8.15	<30	<25

Evaluation of the Algal Oils in a Rodent Model of Carrageenan Paw Edema (CPE)

Rats ($n = 10$ per group) were fed modified AIN-76A rodent diets that were formulated by Research Diets (New Brunswick, NJ) to contain one or more of the following test oils: DHA-S, DHA-T, ARASCO oil and equivalent levels of total fat (5% by weight). The non-test article fat in the experimental diets and the total fat in the placebo diet consisted of a blend of 30% corn, 54% soybean, and 16% coconut oils. Oils were provided by Research Diets (New Brunswick, NJ). The fatty acid content of the formulated diets was confirmed by gas chromatography (GC). In brief, fats in the diet were transesterified in situ with 1.5 N HCl in methanol (Sigma-Aldrich, St. Louis, MO), in the presence of toluene (Sigma-Aldrich, St. Louis, MO) and an internal standard. The resultant fatty acid methyl esters (FAME) were extracted with toluene. The FAME were separated, identified, and quantitated by gas-liquid chromatography with flame ionization detection (GLC-FID) and internal standard calibration.

Experimental diets each provided 1.2% DHA, which is equivalent to approximately 800 mg DHA/kg per day. The ARASCO and DHA-S-containing diets provided approximately 300 mg of ARA or DPAn-6/kg per day (approximately 0.45% of each PUFA), respectively. After 28 days of ad libitum feeding, rats were injected with 0.1 ml of a 10-mg/ml carrageenan solution in water (Sigma-Aldrich, St. Louis MO) in the subplantar right hind foot. Paw volumes were measured by water displacement and differences between the initial and the resultant paw volumes

were determined at 3 h post-carrageenan injection. Animals were euthanized by carbon dioxide (CO_2) asphyxiation after final paw measurements were made.

To determine the minimum efficacious concentration in vivo, DHA-S oil was diluted with corn oil to achieve required doses ranging from 100 mg/kg per day PUFA (DHA + DPAn6 combined) to 1,500 mg/kg per day. In this experiment and those following, rats ($n = 8$ per group) were fed the AIN-76A diet for 7–10 days before administration of test compounds to allow for a wash-out of the LC-PUFA that can be found in typical rodent chows. DHA-S oil was administered by oral gavage (to ensure accuracy of dosing) daily for 14 days to allow plasma levels of LC-PUFA to equilibrate [35]. Doses less than 1,500 mg/kg PUFA per day were equilibrated to 1,500 mg/kg total fat with corn oil. Control and indomethacin treated animals received corn oil by gavage. All test materials contained equivalent levels of antioxidants: ascorbyl palmitate (Tap1010, Vitablend, The Netherlands), mixed tocopherols (Tocoblend L70 IP, Vitablend, The Netherlands), as well as rosemary extract (Herbalox, Kalamazoo, MI). Indomethacin (Sigma-Aldrich, St. Louis, MO) was administered by intraperitoneal injection (i.p.) at 5 mg/kg 30 min prior to carrageenan challenge. The hind paw assay was performed as described above with paw measurements at 2, 4, and 6 h. Immediately following final paw measurements, animals were anesthetized with isoflurane (NLS Animal Health, Owings Mills, MD), 3–5 ml of blood was collected into EDTA-treated tubes by exsanguination via cardiac puncture, and animals were euthanized. Blood was separated by centrifugation, 1,800 rpm for 20 min, and plasma was stored at −80 °C for fatty acid analyses.

Dose-Response Evaluation of DPAn-6 in a Rodent CPE Model

To test the dose-response effect, DPAn-6 was administered at 300, 700 or 1,000 mg/kg per day and compared to DHA doses of 700 or 1,000 mg/kg as well as a DHA/DPAn-6 combo (2.5:1 ratio similar to DHA-S) at 1,000 mg/kg. This LC-PUFA mg/kg dose is equivalent to the dietary dose administered as DHA-S in the previous studies. Doses less than 1,000 mg/kg per day were equilibrated to 1,000 mg/kg total fat with a blend of control fatty acid ethyl esters that mimicked the fatty acid blend found in the base AIN-76A diet: 25% oleate, 13% palmitate, 60% linoleate, 2% alpha-linolenate. Control and indomethacin-treated animals received the control blend of ethyl esters as well. The PUFA, provided as ethyl esters (DHA, DPAn-6, OLA, palmitic acid, linoleic acid, and alpha-linolenic acid) that were used in the animal dosing experiments were purchased from NuChek Prep (Elysian, MN). These fatty acid ethyl esters were greater than 90% pure as confirmed by gas liquid chromatographic techniques. Total fat in the animal diets was 6.25% (by weight) including the 5% in the base diet and the addition of the fatty acid ethyl esters received by gavage. Indomethacin was dosed as previously described. Hind paw measurements and plasma collection were performed as previously described.

Fatty Acid Methyl Ester (FAME) Analysis

Plasma lipids were extracted and phospholipids were isolated by thin-layer chromatography as previously described [36]. In brief, fatty acids from plasma phospholipids were saponified with sodium hydroxide and methanol and then methylated with boron trifluoride (all reagents from Sigma-Aldrich, St. Louis, MO). The resulting methyl esters were identified and quantified by gas–liquid chromatography and flame ionization detection as described [36].

Statistical Analyses

Data were analyzed and compared by one-way ANOVA using the Bonferroni test to compare groups (GraphPad, Prism, Version 4.0). Effects were considered to be statistically significant at $p < 0.05$.

Results

DPAn-6 Has Potent Anti-Inflammatory Activity In Vitro

The effect of the fatty acids on IL-1β and TNF-α secretion was examined. Both DHA and DPAn-6 markedly reduced IL-1β levels in LPS-stimulated PBMC, by approximately 80 and 90% respectively ($p < 0.01$) (Fig. 1a). TNF-α levels were reduced approximately 80% upon treatment with either DHA or DPAn-6 (not significant) (Fig. 1b). EPA reduced the expression of these cytokines to a lesser degree, approximately 60% for IL-1β (not significant) and 40% for TNF-α (not significant) (Fig. 1a, b). Overall, the relative effectiveness of the fatty acids appeared to be DPAn-6 (most potent) > DHA > EPA with respect to reducing both IL-1β and TNF-α. Neither OLA nor AA significantly affected IL-1β or TNF-α secretion. We focused our subsequent studies on the fatty acid effects on IL-1β, as the effect was more striking.

Effects of the Individual and Combinations of Fatty Acids on IL-1β Secretion In Vitro

We compared the potency of the individual fatty acids in a dose response assay. Treatment of human PBMC with each of the LC-PUFA resulted in a dose-dependent reduction in

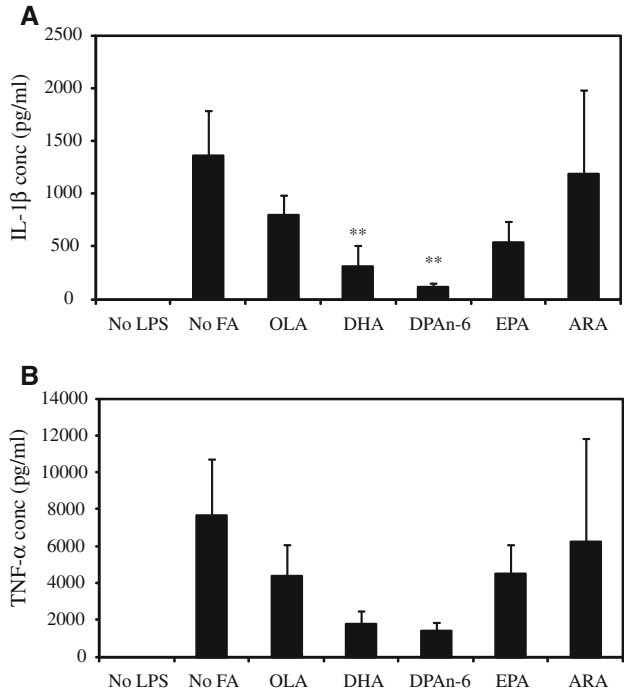

Fig. 1 DPAn-6 has potent anti-inflammatory activity in vitro. Human PBMC were pretreated with individual fatty acids (100 μM final concentration) for 2 h prior to stimulation with LPS. Supernatants were harvested and IL-1β (**a**) and TNF-α (**b**) levels in the culture medium were measured by ELISA following 18 h of culture. Means (5 wells/treatment) +/− SD. $^{**}p < 0.01$ compared to control. Results are representative of at least three independent experiments

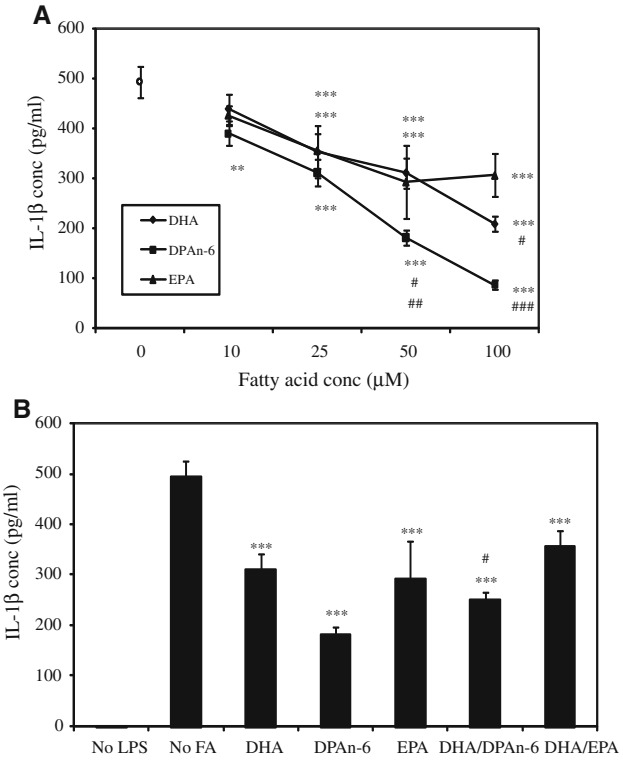

Fig. 2 Effects of the individual and combinations of fatty acids on IL-1β secretion in vitro. **a** Human PBMC were pretreated with the fatty acids at various concentrations 2 h prior to stimulation with LPS. IL-1β levels in the culture supernatants were assessed by ELISA. Means (5 wells/treatment) +/− SD. $^{**}p < 0.01$ and $^{***}p < 0.001$ compared to control. $^{\#}p < 0.01$ compared with an equivalent concentration of EPA. $^{\#\#}p < 0.001$ compared with an equivalent concentration of DHA. $^{\#\#\#}p < 0.001$ compared with an equivalent concentration of DHA or EPA. Results are representative of at least three independent experiments. **b** Human PBMC were incubated with 50 μM of the individual fatty acids or a combination of 25 μM of each fatty acid (50 μM total) prior to stimulation with LPS. Means (5 wells/treatment) +/− SD. $^{***}p < 0.001$ compared to control. $^{\#}p < 0.01$ compared with DHA/EPA. Results are representative of at least three independent experiments

IL-1β (Fig. 2a). DPAn-6 significantly reduced IL-1β with as little as 10 μM ($p < 0.01$). Overall, DPAn-6 was the most effective with maximum inhibition at 100 μM reaching approximately 80% ($p < 0.001$) versus approximately 60% for DHA ($p < 0.001$) and 40% for EPA ($p < 0.001$). Further, at a concentration of 50 μM, DPAn-6 reduced IL-1β levels more effectively than DHA ($p < 0.001$) or EPA ($p < 0.01$). Similar results were seen with 100 μM where DPAn-6 was more effective than DHA ($p < 0.001$) or EPA ($p < 0.001$). DHA was more effective than EPA at 100 μM ($p < 0.01$).

Human PBMC were next incubated with 50 μM of the individual fatty acids or a combination of 25 μM of two fatty acids (50 μM total) prior to stimulation with LPS (Fig. 2b). In PBMC, the DHA/DPAn-6 (50 μM total LC-PUFA) combination reduced IL-1β levels approximately 50% ($p < 0.001$), whereas the DHA/EPA combination reduced levels approximately 30% ($p < 0.001$). The DHA/DPAn-6 combination was more effective than the DHA/EPA combination in reducing IL-1β production ($p < 0.01$).

DPAn-6 Reduces COX-2 and PGE2 Production In Vitro

In LPS-stimulated PBMC, DPAn-6 (100 μM) inhibited levels of intracellular COX-2 approximately 50% ($p < 0.001$) (Fig. 3a). DHA did not affect COX-2 levels in these cells whereas EPA and the DHA/EPA combination increased COX-2 levels approximately 25–30% ($p < 0.01$ and $p < 0.05$, respectively). None of the fatty acids affected COX-1 levels: COX-1 mean fluorescence intensity (MFI) was 81 (control) and ranged from 81 to 90 upon treatment with the various fatty acids (data not shown). As expected, the IL-4 control decreased COX-2 levels ($p < 0.001$) without affecting COX-1 levels [37]. The DHA/DPAn6 combination was more effective than the DHA/EPA combination ($p < 0.001$). As seen in Fig. 3b, DPAn-6 also reduced the levels of PGE2 by approximately 90% ($p < 0.001$). DPAn-6 was similar in efficacy to the positive control IL-4, which is known to decrease PGE2 levels [37, 38]. Interestingly, while COX-2 levels were not affected by DHA, PGE2 levels were decreased approximately 70% ($p < 0.001$) by DHA and the

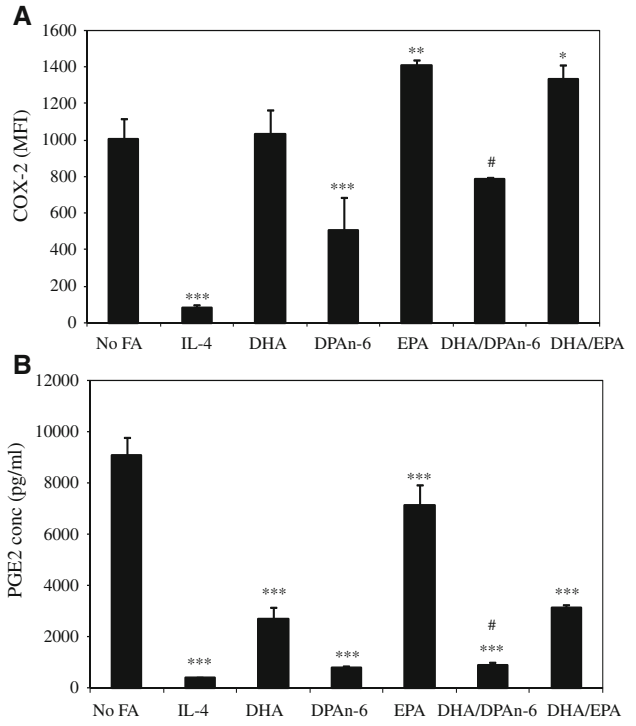

Fig. 3 DPAn-6 reduces COX-2-mediated inflammation in vitro. **a** Intracellular levels of COX-2 in LPS-stimulated cells were determined using flow cytometry following treatment with the individual fatty acids (100 μM) and the fatty acid combinations for a total of 100 μM. Data indicate mean +/− SD of three independent experiments. *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$ compared to the control. #$p < 0.001$ compared to DHA/EPA. **b** PGE2 levels in the culture supernatants were assessed by EIA after treatment with the individual fatty acids or combinations thereof (100 μM total). Means (6 wells/treatment) +/− SD. ***$p < 0.001$ compared to the control. #$p < 0.001$ compared to DHA/EPA. Results are representative of three independent experiments

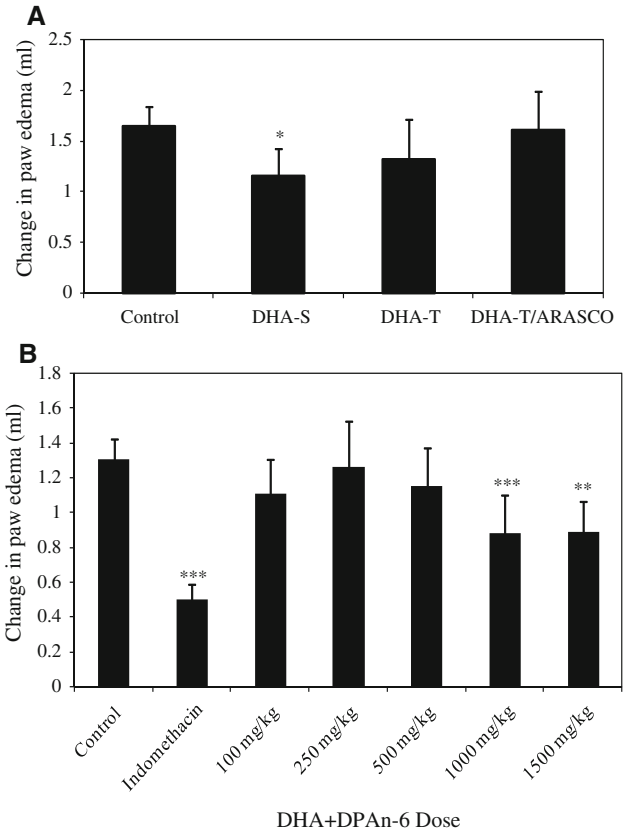

Fig. 4 DHA/DPAn-6-rich DHA-S oil significantly reduced inflammation in a rodent paw edema model. **a** DHA-S, DHA-T, DHA-T/ARASCO oils were administered in the feed for 28 days prior to carrageenan challenge. The experimental diets provided equivalent amounts of DHA (approximately 800 mg/kg) with an additional 300 mg of DPAn-6 or ARA/kg per day for the DHA-S and ARASCO diets, respectively. Paw edema was measured by water displacement 3 h post-challenge with carrageenan stimulation. Means ($n = 10$) +/− SD. *$p < 0.05$ compared to control. **b** DHA-S oil was diluted with corn oil to achieve required doses ranging from 100 mg/kg PUFA (DHA + DPAn6 combined) to 1,500 mg/kg per day. DHA-S oil was administered by oral gavage for 14 days. Doses less than 1,500 mg/kg PUFA per day were equilibrated to 1,500 mg/kg total fat with corn oil. Control and indomethacin treated animals received corn oil by gavage. Indomethacin was administered at 5 mg/kg i.p. 30 min prior to carrageenan challenge. Paw edema was measured at 2 h post carrageenan treatment. Means ($n = 8$) +/− SD. **$p < 0.01$ and ***$p < 0.001$ compared to control

addition of DPAn-6 reduced levels further. In comparison, EPA reduced PGE2 levels approximately 20% ($p < 0.001$), and when EPA was provided in combination with DHA, PGE2 was decreased to levels comparable to those with DHA alone ($p < 0.001$). Further, the DHA/DPAn-6 combination was a more potent inhibitor of PGE2 production than the DHA/EPA combination ($p < 0.001$).

DHA/DPAn-6-rich DHA-S Oil Significantly Reduces Inflammation in a Rodent Paw Edema Model

The anti-inflammatory activity of the DHA-rich algal oils was evaluated in a rodent model of acute inflammation. No significant differences in food intake, weight, or locomotor activity were observed between any of the treatment groups. DHA-S-fed animals had a 30% reduction in mean paw edema ($p < 0.05$), while treatment with DHA-T also tended to reduce paw edema with an approximately 20% reduction (not significant) (Fig. 4a). The animals fed the DHA-T/ARASCO diet had no reduction in paw edema.

Animals were treated with increasing doses of DHA-S oil to determine the minimum efficacious concentration in vivo. Indomethacin reduced paw edema 62% ($p < 0.001$) (Fig. 4b). Maximal inhibition of paw edema, a reduction of 33%, was visible at 1,000 mg/kg DHA + DPAn-6 ($p < 0.001$). As expected, treatment with increasing doses of DHA-S oil resulted in increases in plasma phospholipid levels of both DHA and DPAn-6 (Table 2).

DPAn-6 Reduces Inflammatory Edema in a Dose-Response Rodent Model of Hind Paw Edema

A study was performed to assess the effects of various doses of DPAn-6 on paw edema in this model (Fig. 5). Fatty acids were provided as ethyl esters. Indomethacin reduced paw edema 62% ($p < 0.001$). The 700 mg/kg dose of DPAn-6 reduced paw edema maximally, a 56% reduction ($p < 0.001$). In addition, we confirmed our original findings that the DHA/DPAn-6 combination, as found in the DHA-S oil, reduced edema more than DHA alone (DHA-T oil) ($p < 0.05$). The 700 mg/kg DPAn-6 was as efficacious as the combination of 700 mg/kg DHA + 300 mg/kg DPAn-6. At 2 h post-challenge, treatment with 700 and 1,000 mg/kg DHA reduced paw edema approximately 20% (not significant). However, inhibition seen with 700 mg/kg DHA was increased further by the addition of 300 mg/kg DPAn-6, the PUFA combination found in the DHA-S oil. By 4 h post-challenge, both doses of DHA significantly reduced paw edema ($p < 0.01$, data not shown). DHA and DPAn-6 (1,000 mg/kg doses) elevated plasma levels approximately 4 and 6.5-fold, respectively (Table 3). Higher doses of pure DPAn-6 (700 and 1,000 mg/kg) led to increased plasma ARA levels.

Discussion

The immunomodulatory effects of fish oil and its constituent omega-3 LC-PUFA have been examined in numerous

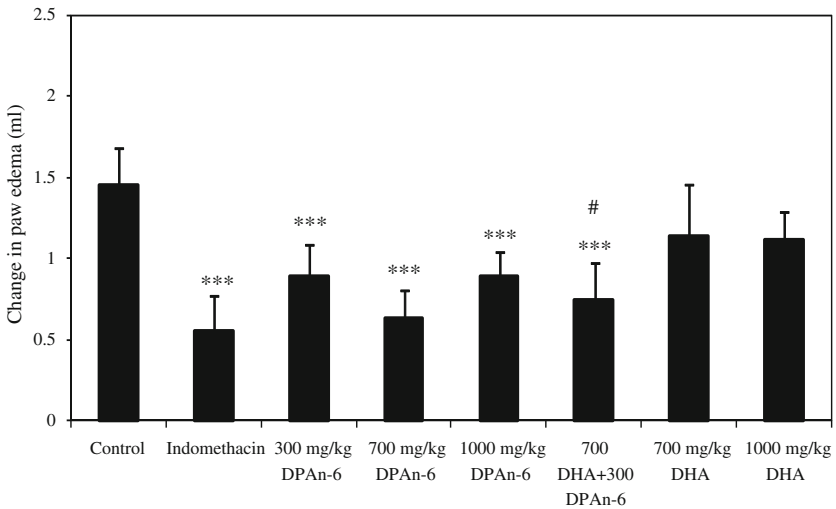

Fig. 5 DHA/DPAn-6 combination reduces inflammatory edema in a rodent model of hind paw edema. A dose response study was performed to assess the effects of various dose levels of DPAn-6 on paw edema in this model. All groups of animals received an equivalent amount of fat which consisted of 300–1,000 mg/kg DHA or DPAn-6 per day, as indicated, with an appropriate amount of control oil to bring the total gavaged fat content to 1,000 mg/kg per day. Indomethacin was administered at 5 mg/kg i.p. 30 min prior to carrageenan challenge. Fatty acids were administered daily for 14 days prior to conducting the paw edema assay at 2 h post-carrageenan challenge. *$p < 0.05$ as compared to the Control group

studies to date. Here, we demonstrate the anti-inflammatory activity of DHA-rich algal oils in vivo, particularly DHA-S oil, and provide the first evidence of the potent anti-inflammatory activity of the constituent omega-6 LC-PUFA, DPAn-6.

As an omega-6 fatty acid and as a product of ARA, it was unexpected to find anti-inflammatory activity associated with DPAn-6. However, another omega-6 PUFA, gamma linolenic acid (GLA; 18:3n-6) has been shown to have anti-inflammatory activity in vitro and in vivo [39]. GLA decreases levels of IL-1β and TNF-α in LPS-stimulated PBMC and IL-1β in LPS-stimulated human monocytes in vitro [40].

In vitro analyses showed that all three LC-PUFA (DHA, DPAn-6, and EPA) reduced the production of the pro-inflammatory cytokines IL-1β and TNF-α in human PBMC, at concentrations as low as 10 μM (IL-1β). However, DPAn-6 appeared to be the most effective inhibitor in vitro, reducing levels of these pro-inflammatory cytokines, with observed relative potencies of DPAn-6 (most potent) > DHA > EPA. This finding correlates with another recent study that demonstrated the enhanced efficacy of DHA, as compared to EPA, in decreasing IL-1β, IL-6 and TNF-α production in LPS-stimulated THP-1 cells [8].

The consumption of dietary LC-PUFA can alter membrane phospholipids and the production of eicosanoids [11, 17–20]. Our studies show that in addition to decreasing levels of pro-inflammatory cytokines in vitro, DPAn-6 also decreased intracellular COX-2 levels by approximately 50% with a concomitant reduction in PGE2 production. PGE2 mediates acute inflammation, as it is a potent vasodilator and increases vascular permeability and edema [41, 42]. DHA had no effect on COX-2 expression, but PGE2 levels were reduced by DHA, suggesting that DHA may affect COX-2 enzyme activity or PGE synthase, which is also involved in the regulation of PGE2. Both COX-2 and PGE synthase are increased in cells in response to an inflammatory stimulus and the production of PGE2 may require both enzymes [43, 44]. In support of this hypothesis, Roman et al [45] showed a reduction in microsomal PGE synthase RNA in the presence of DHA in vitro, whereas EPA had no effect. Alternatively, DHA treatment may reduce PGE2 production as a result of reduced availability of the PGE2 precursor ARA.

In contrast, EPA and the DHA/EPA combination increased levels of COX-2 and PGE2 in PBMC in vitro. An upregulation of COX-2 has been previously described for EPA in human keratinocytes [46]. It is important to note, however, that the effects of DHA and EPA may be cell-specific and/or dependent on the type of inflammatory stimulus used, as others have described differential COX-2 modulation with these LC-PUFA [46–49].

The rat carrageenan paw edema model is a well-characterized acute model of innate immunity that is commonly used to evaluate anti-inflammatory activity of compounds [50–53]. The DHA-S oil was more effective than DHA-T oil when tested in this in vivo model and the major difference between the two algal oils is the presence of DPAn-6 (DHA-S oil). DPAn-6 treatment resulted in the largest reduction in edema volume, reaching 40–55% inhibition at lower doses. Maximal effects of DPAn-6 were also visible as early as 2 h post-carrageenan challenge, as compared to 4 h with DHA.

Interestingly, the DPAn-6 in vivo dose response resulted in a non-monotonic curve with the maximum effect observed with the 700 mg/kg dose. Lower and higher doses of DPAn-6 reduced inflammation to a lesser degree and their effects were limited to 2–4 h following the inflammatory stimulus. The lack of a standard dose response effect suggests that DPAn-6 might be converted to other fats in vivo, such as ARA. Tam et al [54] showed the retroconversion of DPAn-6 to ARA occurred when ARA levels were decreased by the presence of DHA. In further support of this, humans supplemented with the DHA-T oil

had a dose-dependent decrease in plasma ARA whereas higher doses of the DHA-S oil resulted in relatively higher levels of ARA [30].

Treatment with 1,000 mg/kg DHA ethyl ester resulted in three to fourfold increase in plasma DHA, as compared to control levels. Humans would require a dose of approximately 1.5–2 g DHA per day to achieve a similar increase in plasma DHA [30]. Analysis of plasma phospholipid levels clearly showed that a reduction of ARA levels did not correlate with anti-inflammatory activity, as plasma ARA levels remained high or are increased upon treatment with DPAn-6. We speculate that the ability of DPAn-6 to reduce both COX-2 and PGE2 levels, as seen in vitro, may contribute to the decreased inflammation seen in this COX-2-driven rat paw edema model. Our laboratory has also recently shown that DPAn-6 can be converted into oxylipins, resolvin-like molecules, with potent anti-inflammatory activity which could contribute to the observed reduction in inflammatory response in vivo following dosing with DPAn-6 [55]. Supplementation with DHA-S oil, containing DHA/DPAn-6 may reduce inflammation, raising levels of DHA, while maintaining ARA levels. Taken together, these results suggest that the DHA-S algal oil may be a novel anti-inflammatory supplement.

Received: 19 January 2010 / Accepted: 12 April 2010 / Published online: 1 May 2010

Abstract Knowledge about the effects of dietary fats on subclinical inflammation and cardiovascular disease risk are mainly derived from studies conducted in Western populations. Little information is available on South East Asian countries. This current study investigated the chronic effects on serum inflammatory markers, lipids, and lipoproteins of three vegetable oils. Healthy, normolipidemic subjects ($n = 41$; 33 females, 8 males) completed a randomized, single-blind, crossover study. The subjects consumed high oleic palm olein (HOPO diet: 15% of energy 18:1n-9, 9% of energy 16:0), partially hydrogenated soybean oil (PHSO diet: 7% of energy 18:1n-9, 10% of energy 18:1 *trans*) and an unhydrogenated palm stearin (PST diet: 11% of energy 18:1n-9, 14% of energy 16:0). Each dietary period lasted 5 weeks with a 7 days washout period. The PHSO diet significantly increased serum concentrations of high sensitivity C-reactive protein compared to HOPO and PST diets (by 26, 23%, respectively; $P < 0.05$ for both) and significantly decreased interleukin-8 (IL-8) compared to PST diet (by 12%; $P < 0.05$). In particular PHSO diet, and also PST diet, significantly increased total:HDL cholesterol ratio compared to HOPO diet (by 23, 13%, respectively; $P < 0.05$), with the PST diet having a lesser effect than the PHSO diet (by 8%; $P < 0.05$). The use of vegetable oils in their natural state might be preferred over one that undergoes the process of hydrogenation in modulating blood lipids and inflammation.

Keywords Inflammation · C-reactive protein · Lipids · Fatty acids · Cytokines

Abbreviations

HOPO	High oleic palm olein
PHSO	Partially hydrogenated soybean oil
PST	Palm stearin
Lp(a)	Lipoprotein(a)
LSmeans	Least squares means
hsCRP	High-sensitivity C-reactive protein
IL-6	Interleukin-6
IL-1β	Interleukin-1β
IFN-γ	Interferon-γ
TNF-α	Tumor necrosis factor-α
IL-8	Interleukin-8
BP	Blood pressure

Introduction

In the past six decades, a number of epidemiological studies have shown a clear association between certain dietary fatty acids and cardiovascular disease risk [1–3]. A 2% increase in energy intake from partially hydrogenated fats or *trans* fatty acids was associated with a 23% increase in the incidence of cardiovascular heart disease [4]. Replacement of saturated or *cis* unsaturated fatty

K.-T. Teng and P.-T. Voon contributed equally to the study.

acids with *trans* fatty acids has been shown to raise low-density lipoprotein (LDL) cholesterol concentrations, reduce high-density lipoprotein (HDL) cholesterol concentrations, and increase the total:HDL cholesterol ratio [4]. High blood levels of *trans* fatty acids have also been shown to have a more pronounced adverse effect on the lipid profile and other cardiovascular disease risk markers, and are more strongly associated with the incidence of cardiovascular heart disease than saturated fatty acids (SFAs) [5].

At this time, there was emerging evidence that suggested that certain dietary fatty acids could have a direct role in the modulation of cardiovascular disease risk above and beyond that associated with changes in blood lipids [3, 4]. A number of inflammatory markers, such as interleukin-6 (IL-6), interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), and interleukin-8 (IL-8) were found to be present in the atherosclerotic plaque, and these can predict cardiovascular heart disease risk [6, 7]. A few human intervention studies demonstrated that *trans* fatty acids increased circulating inflammatory markers, such as IL-6, E-selectin, and hsCRP, compared to other fatty acids [8, 9]. These fatty acids were thought to alter the expression and adherence of the circulating inflammatory markers to endothelium [10]. However, the underlying mechanisms involved are not yet fully understood. It is possible that susceptibility to oxidation could play a role [11]. Inflammation accelerates the atherogenic effects of oxidized lipoproteins, but the mechanisms involved are not clearly defined.

The increasing use of artificially produced *trans* fats in foods drew grave concern from the public, and led to stricter regulatory measures globally. Consequently, the US Food and Drug Administration put out a mandatory '*trans* fatty acids' labeling on packaged food products, effective from 1 January 2006, and this prompted food manufacturers to find alternatives to the use of commercially-hydrogenated vegetable oils in formulating bakery products, and in margarines and fried foods. In South East Asian countries, partially hydrogenated vegetable oils are widely used in the preparation of vanaspati or vegetable ghee, which has up to 40% of *trans* fatty acids [12]. Palm oil, which is widely used in South East Asian countries, is a natural replacement for commercially-produced hydrogenated vegetable oils.

There is no conclusive information concerning the interplay of fats on a wide array of inflammatory markers, and the interaction of inflammatory markers with blood lipids. Thus, the current study was carried out to compare the effects of a high oleic vegetable oil with that of a partially hydrogenated, and an unhydrogenated and more saturated, vegetable oil on serum inflammatory markers and blood lipids.

Methods

Subjects

Subjects were recruited via advertisement posted at the research facilities of the Malaysian Palm Oil Board. Baseline characteristics of the 41 subjects who completed the study are presented in Table 1. All subjects were apparently healthy as indicated by a medical and lifestyle questionnaire and biochemical tests. Exclusion criteria were: BMI $\geq$ 30 kg/m^2, waist hip ratio $>$ 0.9 for men and $>$ 0.8 for women, total cholesterol $>$ 5.2 mmol/L, triacylglycerol (TAG) $>$ 2.2 mmol/L, LDL cholesterol $>$ 3.3 mmol/L, hypertension $>$ 150 mmHg/95 mmHg, chronic diseases and medication. The subjects' habitual diet was assessed by a 3 days dietary record on two weekdays and 1 day weekend day. Calorie intake was assessed by using a nutrition database (NutritionistPro^{TM} Version 2.0.90, Fist Data Bank Inc., 2008). All subjects were instructed to maintain a consistent low or moderate physical activity throughout the study period. The weight of the subjects was monitored on a weekly basis in a fasting state. Throughout the study period subjects recorded food consumed on a weekly basis to ensure that the diet intake did not change during the intervention. To ensure dietary compliance, identical food samples were collected, as consumed on each study day, for analysis.

Study Design

The study was a single-blind, randomized, crossover design dietary intervention study. The study included three dietary intervention periods of 5 weeks each, separated by a 7 days

Table 1 Subject characteristics

Variable	(n = 41)
Age (years)	28.8 ± 9.1
Sex	
Male (n)	8
Female (n)	33
Weight (kg)	55.0 ± 11.3
BMI (kg/m^2)	21.9 ± 3.9
Waist (cm)	76.0 ± 9.4
Systolic BP (mmHg)	116.4 ± 17.4
Diastolic BP (mmHg)	74.1 ± 10.4
Total cholesterol (mmol/L)	4.6 ± 0.6
TAG (mmol/L)	0.8 ± 0.2
LDL cholesterol (mmol/L)	2.8 ± 0.5
HDL cholesterol (mmol/L)	1.6 ± 0.3

BP blood pressure

washout period. A total of 43 subjects were recruited, allocated randomly to one of three treatment sequences, using a randomized orthogonal design. Subjects were instructed to maintain their habitual food intake throughout the study. All outcome variables were measured at the start and end of the study.

Diets and Test Fats

During the intervention period, the participants consumed approximately 54 g of test fats incorporated into a cooked meal per day. The test fats used were: high oleic palm olein (HOPO: 54% 18:1n-9, 20% 16:0), partially hydrogenated soybean oil (PHSO: 21% 18:1n-9, 47% 18:1 *trans*) and palm stearin (PST: 25% 18:1n-9, 62% 16:0). The HOPO diet was a high oleic palm olein supplied by Malaysian Palm Oil Board (MPOB), Malaysia. Partially hydrogenated soybean oil (forming the PHSO diet) and palm stearin (forming the PST diet) were supplied by Nisshin-Oillio, Japan. The diets provided approximately 9.2 MJ/day, of which 30–35% of energy fat (test fats accounted for ~20–25% of energy fat), 15% of energy protein and 50–55% of energy carbohydrate. All subjects consumed breakfast and lunch at the dining hall of the research institute, and they were provided a packed dinner for home consumption. Subjects consumed a 5 days rotational meal plan. Breakfast was served with a rice or noodle dish together with a cup of tea or juice. Lunch and dinner consisted of a fish or chicken meal, and two servings of vegetables served with rice along with fruits. The amount and types of food served were the same for the three diets. Subjects were provided guidelines, and test fats to incorporate into their home meal preparation during weekends.

Blood Sampling

Venous blood samples were collected after a 12-h overnight fast before, and at the end of the study at week 4 and week 5. Blood samples, collected at week 4 and week 5, were used to observe the stability of markers tested. The means of week 4 and week 5 were presented in results. Blood samples, for analyses of inflammatory markers, lipids, and lipoproteins, were collected in serum tubes and centrifuged at 2,200×*g* for 15 min at 4 °C, within 1 h of collection. Aliquots of samples were stored at −80 °C for further analyses.

Fatty Acid Analysis

Fatty acid compositions of the test oils were determined in the form of methyl ester by gas–liquid chromatography-flame ionization detector (GC-FID) (Autosystem, Perkin Elmer). Fatty acid methylation was carried out as described in [13]. Samples (2 μL) were injected into the GC fitted with an SP-2560 column (length 100 m, diameter 0.23 mm, and film thickness 0.2 mm). The carrier gas (helium) pressure and injector temperature were set to 40 psi and 250 °C, respectively. The oven temperature was set isothermal at 240 °C for 58 min. Hydrogen and oxygen were used for ignition. A fatty acid methyl esters (FAMEs) mixture (Sigma-Aldrich, Australia) was used as the external standard. Results were expressed in % of energy (Table 2).

Inflammatory Markers

Serum inflammatory markers were measured using ELISA according to protocols described by the manufacturers. All inflammatory markers were measured using the R&D System, USA. In brief, murine monoclonal antibodies against specific human inflammatory markers were precoated onto a 96-well microplate. Then, 100 μL of standard or test samples were added and incubated for 2 h. Diluted conjugates were put into each well and incubated for 1 h. Each of the previous steps was followed with a washing step to remove unbound substances. Stabilized substrate solution (tetramethylbenzidine) was added to each well and color development was stopped using a stop solution. The optical density of each well was read at 450 nm, and corrected for 620 nm.

Table 2 Nutrient composition of test diets

	HOPO diet	PHSO diet	PST diet
Energy, MJ	9.3 ± 1.2	8.9 ± 0.5	9.6 ± 1.1
% of energy			
Carbohydrate	47.2 ± 1.3	48.5 ± 1.3	49.0 ± 1.6

18:3	2.6 ± 0.0	0.3 ± 0.0	0.2 ± 0.0

All values were derived from identical food samples collected as consumed by subjects on each study day. Values are an average of two determinations

HOPO high oleic palm olein, *PHSO* partially hydrogenated soybean oil, *PST* palm stearin. *nd* not detectable

Lipid, Lipoproteins and hsCRP

Serum total cholesterol and TAG (Cholesterol CHOD-PAP and triglycerides GPO-PAP kits) were measured using enzymatic assays. HDL cholesterol and LDL cholesterol were assessed by enzymatic colorimetric assays (HDL-C plus 3rd generation, and LDL-C plus 2nd generation, respectively). Serum apolipoprotein A-I (apo A-I), apolipoprotein B-100 (apo B-100) and lipoprotein(a) (Lp(a)) were analyzed using immunoturbidimetric procedures (Tina-quant® apolipoprotein A-I ver.2, Tina-quant® apolipoprotein B ver.2 and Tina-quant® lipoprotein (a), respectively). Serum hsCRP was determined using particle-enhanced Tina-quant® CRP (Latex) high sensitive immunoturbidimetric assay (Tina-quant® C-reactive protein (Latex) HS). All kits were purchased from ROCHE and all assays were analyzed using the Hitachi 902 analyzer (Roche Diagnostics GmbH, Germany).

Ethical Considerations

This study was conducted according to the guidelines laid down in the Declaration of Helsinki and all procedures involving human subjects were approved by The University of Malaya Medical Ethics Committee who approved the research protocol (667.14). The study was registered at ClinicalTrial.gov (NCT00715312). Written informed consent was obtained from all subjects.

Statistics

The statistical power to detect a true difference in serum LDL cholesterol concentration between diets if the estimated effect is 10% with an α of 0.05 was 80%. Mixed model ANCOVA was used to compare the effects of dietary fats on all outcome variables. Baseline values for each parameter were included as covariates, and the analyses were adjusted for the baseline values of each variable. Age, BMI, sex and the order in which the participants received the test meals were tested as covariates for influence on the results but none was observed. Fixed effect to dietary treatment and random factor to subject ID number were set. When a significant effect of treatment was detected, we used the Tukey–Kramer test for post hoc analysis. All duplicate data were averaged and tested for normality. Data for TAG, HDL cholesterol, LDL cholesterol, apo B-100, and all serum inflammatory markers were log-transformed. Fasting serum concentrations of all parameters in week 4 and week 5 were tested for any time trend. No time trend was seen, thus an average of the two values was used for further analysis. A two tailed P value of less than 0.05 was considered statistically significant. We presented baseline characteristics of subjects as means ± SD, and all outcome variables as least squares means (LSmeans; adjusted for baseline values) with SEM. All calculations were done by using SAS statistical software (version 9.0; SAS institute Inc, Cary, NC, USA).

Results

Compliance and Dietary Intake

Forty-three subjects entered the study, but two left the study due to medical problems. A total of 41 (33 females, 8 males) subjects completed the study. Two subjects dropped out due to medical problems not related to the study (Fig. 1). Mean energy intake (MJ/day) did not differ between the diet groups. The distribution (% of energy) of fat, protein and carbohydrate showed no significant difference between the diet groups ($P > 0.05$; Table 2). Energy intake was self-controlled by the subjects to achieve energy balance. Initial body weight (56.9 ± 12.4 kg) did not change during the intervention and the weight difference was negligible (<0.5 kg weight gained, $P = 0.871$) [data not shown]. All subjects fully complied with the study protocol throughout the study period shown by >90% attendance to the dinner hall at the research institute.

Serum Inflammatory Markers

The PHSO diet increased hsCRP significantly when compared with HOPO and PST diets (by 32% and 23%, respectively; $P < 0.05$). The PHSO diet, however, significantly decreased IL-8 compared with the PST diet (by 12%; $P < 0.05$) (Table 3). No significant differences in IL-6, IL-1β, and TNF-α were observed between diets after the 5 weeks intervention.

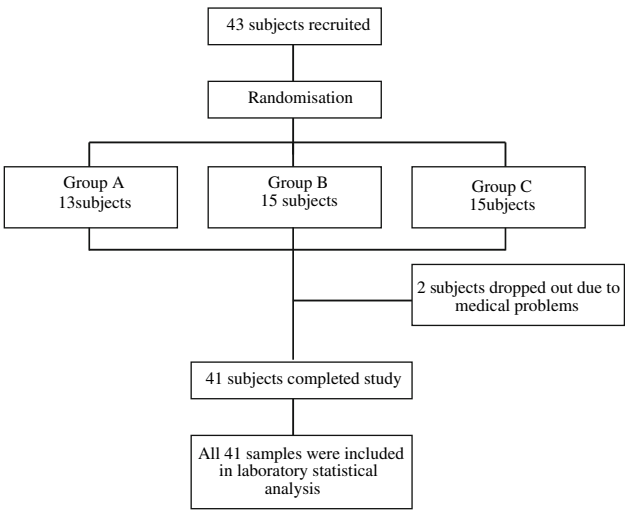

Fig. 1 Consort diagram of 5 weeks dietary intervention

Table 3 Effects of the three diets on serum inflammatory markers in healthy subjects ($n = 41$) participating in the 5 weeks intervention study

Variables	HOPO diet	PHSO diet	PST diet
hsCRP (mg/L)	0.47 ± 0.02[a]	0.59 ± 0.02[b]	0.48 ± 0.02[a]
IL-6 (ng/L)	1.11 ± 0.07	1.05 ± 0.08	0.94 ± 0.08
IL-1β (ng/L)	10.51 ± 3.57	9.56 ± 3.58	9.87 ± 3.57
TNF-α (ng/L)	23.92 ± 0.79	23.18 ± 0.78	22.39 ± 0.80
IL-8 (ng/L)	21.44 ± 1.05[a]	19.64 ± 1.08[a]	24.30 ± 1.23[b]

Values are LSmeans with SEM. All data were analyzed by mixed model ANCOVA with baseline values as covariates. Values within a row with unlike superscript letters (a, b) were significantly different from each other, $P < 0.05$

HOPO high oleic palm olein, *PHSO* partially hydrogenated soybean oil, *PST* palm stearin, *hsCRP* high sensitivity C-reactive protein, *IL-6* interleukin-6, *IL-1β* interleukin-1β, *TNF-α* tumor necrosis factor-α, *IL-8* interleukin-8

Serum Lipids and Lipoproteins

Compared with the HOPO diet, both PHSO and PST diets significantly increased total cholesterol, TAG, LDL cholesterol, apo B-100, total:HDL cholesterol ratio, whereas they significantly decreased apo A-I ($P < 0.05$) (Table 4). The PHSO diet significantly decreased HDL cholesterol when compared with the other two diets ($P < 0.05$); in addition, the PST diet significantly decreased HDL cholesterol when compared with the HOPO diet ($P < 0.05$) (Table 4). In particular, the PHSO diet, and also the PST diet, significantly increased total:HDL cholesterol ratio compared to the HOPO diet (by 23, 13%, respectively; $P < 0.05$). No significant difference was observed for Lp(a) between the three diets.

Table 4 Effects of the three diets on serum lipids and lipoproteins in healthy subjects ($n = 41$) participating in the 5 weeks intervention study

Variables	HOPO diet	PHSO diet	PST diet
Total cholesterol (mmol/L)	4.48 ± 0.04[a]	4.72 ± 0.04[b]	4.66 ± 0.04[b]
TAG (mmol/L)	0.83 ± 0.01[a]	0.89 ± 0.01[b]	0.88 ± 0.01[b]
LDL cholesterol (mmol/L)	2.69 ± 0.05[a]	3.11 ± 0.05[b]	2.95 ± 0.05[b]
HDL cholesterol (mmol/L)	1.63 ± 0.03[a]	1.42 ± 0.03[b]	1.55 ± 0.03[c]
Apo A-I (mmol/L)	3.80 ± 0.03[a]	3.55 ± 0.03[b]	3.57 ± 0.03[b]
Apo B-100 (mmol/L)	2.48 ± 0.03[a]	2.65 ± 0.03[b]	2.68 ± 0.03[b]
Total:HDL cholesterol	2.84 ± 0.06[a]	3.50 ± 0.06[b]	3.22 ± 0.06[c]

Values are LSmeans with SEM. All data were analyzed by mixed model ANCOVA with baseline values as covariates. Values within a row with unlike superscript letters (a, b, c) were significantly different from each other, $P < 0.05$

HOPO high oleic palm olein, *PHSO* partially hydrogenated soybean oil, *PST* palm stearin, *Lp(a)* lipoprotein(a)

Discussion

A significant finding in the present study was that the PHSO (a *trans* fatty acid rich) diet increased hsCRP and total:HDL cholesterol ratio when compared with the PST (a unhydrogenated saturated fat), and the HOPO (high oleic palm olein) enriched diets.

Although the intake and potential adverse health effects of *trans* fatty acids in Western countries have received considerable attention, little is known about intake of partially hydrogenated vegetable oils, a rich source of *trans* fatty acids, in Asian countries. To our knowledge, this study is one of the first to investigate the consumption of partially hydrogenated vegetable oil and its relation to low grade inflammation in an Asian population. Particular interest may exist for developing countries, especially South East Asian countries in which partially hydrogenated vegetable oils are commonly used as cooking oil and represent an inexpensive source of dietary fats. Asian countries such as Iran have also reported a high consumption of partially hydrogenated vegetable oils (>75%). The *trans* fatty acids content of partially hydrogenated vegetable oils used in Iranian households is 25–35%, and up to 50% in food industries [3, 14].

The acute phase reactant, hsCRP, and pro-inflammatory cytokines, IL-6, IL-1β, and TNF-γ, are central mediators of the inflammatory process. These pro-inflammatory cytokines are important in modulating hsCRP secretion and expression of cell adhesion molecules [15]. Epidemiological and clinical studies indicate that *trans* fatty acids are associated with an increase in hsCRP, IL-6, and TNF-α, in both healthy and hypercholesterolemic subjects [9, 16]. Studies have reported that a high *trans* fatty acid diet increased hsCRP, IL-6 and E-selectin, but an oleic acid enriched diet decreased hsCRP and IL-6 [8, 17]. Consistent with these findings are those of our present study which showed that a diet high in *trans* fatty acids (i.e., the partially hydrogenated soybean oil) increases hsCRP concentrations more than one with a semi-saturated fat (i.e., the palm stearin), or one with a high oleic palm olein. Thus, in addition to the hypercholesterolemic effect, *trans* fatty acids might trigger a pro-inflammatory cascade.

In addition, we found higher serum IL-8 concentrations in the semi-saturated fat diet compared with the *trans* fatty acid and high oleic palm olein diets. hsCRP has been shown to trigger the expression of chemokines such as IL-8 and cell adhesion molecules in vitro [18–20]. IL-8 was shown to inhibit neutrophil adhesion to cytokine-activated endothelial cells and protect these cells from neutrophil-mediated

damage [20]. Except for IL-8 and hsCRP, we did not observe any significant differences in the concentrations of serum IL-6, IL-1β, and TNF-α, after consumption of all the three diets. Although hsCRP is primarily secreted in response to IL-6, a regulation of hsCRP that is IL-6-independent has been reported [21]. Our finding is in agreement with that of Han et al. [9], but not with those from other studies [8]. The lack of a significant change in serum inflammatory markers could be explained, in part, by the marked variability in these endpoints as the magnitude of response will vary between subjects. Cytokines produced by adipocytes such as IL-6, IL-1β, and TNF-α have been reported to be associated with increased body weight as a result of the expansion of adipose tissue [22, 23]. Obesity is often accompanied by elevated levels of free fatty acids and hence induces changes in adipose tissue, skeletal muscle, and liver and further lead to systemic inflammation and insulin resistance [23]. In addition, the risks of cardiovascular disease are age-dependent, it has been well established that inflammation increases with age. This might also explain why older subjects possess higher circulating inflammatory levels compared to younger subjects [24]. The present study recruited relatively young healthy subjects (28.8 ± 9.1 year) which may result in lower inflammatory response in IL-6 and TNF-α as contributed by moderate elevation of hsCRP in the serum. Further studies on an older population are warranted.

In addition, the discrepancy in the results may also be due to the study design and the percentage of energy fat incorporated [7]. Baer et al. [8] employed a high fat diet (38% of energy) which might provoke the inflammatory effect of *trans* fatty acids. We hypothesize that the inflammatory pathways will only be stimulated by a longer and increased dietary fat incorporation in the diets. The present amount of fat ($\approx$32% of energy) and 5 weeks feeding duration might not be sufficient to induce a significant change in all inflammatory markers in healthy subjects fed varied dietary fats. In addition, a recent study showed that saturated fats, compared to olive oil, triggered a higher expression of TNF-α from a peripheral mononuclear cell culture but not in serum [25]. This finding suggests that the synthesis and secretion of these cytokines may not happen simultaneously.

The mechanisms by which dietary fatty acids modulate inflammatory markers are not clearly understood. Most of the evidence reported inverse relationship between dietary long chain polyunsaturated fatty acids (PUFAs) and inflammation [26]. Clinical studies reported anti-inflammatory effects of long chain n-3 PUFAs by suppressing pro-inflammatory cytokines and cell adhesion molecules [27–29]. Studies showed that high fat meals enriched with oleic acid reduced postprandial levels of sICAMs and sVCAMs compared to palmitic acid [30]. However, there is insufficient evidence showing the involvement of monounsaturated fatty acids (MUFAs) and SFAs in inflammatory processes. There are several possible mechanisms by which specific fatty acids could regulate inflammatory response. Numerous dietary studies indicate that *trans* fatty acids but not SFAs and MUFAs cause insulin resistance but other studies reported that increasing dietary saturated fats induces insulin resistance whereas PUFAs have a less pronounced effect or even improve insulin sensitivity [31]. We argue that the decrease in insulin levels may contribute to an increase in free fatty acid levels which may further lead to inflammatory process. Elevated levels of CRP, IL-6, TNF-α, and IL-8 have also been reported in diabetic and insulin resistance state [32, 33]. In addition, the induction of gene expression of the inflammatory markers is known to be regulated by the activation of nuclear factor-kappa B (NF-κB) [34]. SFAs, but not monounsaturated fatty acids, were shown to inhibit NF-κB activation and induce the expression of cyclooxygenase-2 (Cox-2) mediated through Toll-like receptor 4 (Tlr 4) [35]. In contrast with this finding, Milanski et al. [36] reported that SFAs, modulate toll-like receptor 4, and trigger the intracellular signaling network that induce an inflammatory response which may explain, in part, the present finding which showed that the PST diet increased IL-8 expression in serum. *Trans* fatty acids, on the other hand, exacerbate a pro-inflammatory milieu through its effect on lipid raft assembly and function [37]. *Trans* fatty acids have been reported to be incorporated into cell membrane by affecting the membrane signaling pathway and modulating the ligand-dependent effects on PPARγ relating to inflammation [38].

The consumption of partially hydrogenated fat has been reported to impair the catabolic pathway of cholesterol-rich lipoproteins by lowering the rate of cholesterol synthesis when compared with soybean oil [39]. This, in fact, could explain the findings in the present study, where partially hydrogenated soybean oil, and palm stearin to a lesser extent, significantly increased serum total cholesterol, TAG, LDL cholesterol, apo B-100 concentrations, and the total: HDL cholesterol ratio (which is a good predictor of CVD risk), compared to the high oleic palm olein diet. Our findings are in agreement with several previous studies [40, 41]. We also observed a decrease in HDL cholesterol and apo A-I levels in the *trans* fat (PHSO) diet group in comparison with the semi-saturated fat (PST) and high oleic palm olein (HOPO) groups, as was also found by other researchers [42].

Studies have reported hypercholesterolemic effects of SFAs in palm oil, compared with oils rich in MUFAs and polyunsaturated fatty acids (PUFAs) [17, 43], though findings from a few studies have questioned these observations [44, 45]. In studies that investigated specific fatty acids, palmitic acid showed fewer hypercholesterolemic

effects than lauric and myristic acids [46]. Human clinical studies have shown that *trans* fatty acids exerted a more atherogenic effect compared with palmitic acid as measured by lipid profiles [41, 42]. There is no uniform agreement on the absolute or relative cholesterol-raising potential of palmitic acid [47]. Stereospecific distribution of specific fatty acids might play a role in explaining the underlying mechanism involved in lipid metabolism [48]. The relatively lower risk of palmitic acid compared to *trans* fatty acids may be related to the combination of less readily absorbed palmitic acids in the *sn*-1, 3 positions and enhanced removal of palmitic acids from the circulation [48, 49]. This observation may, in part, explain the less atherogenic effect of palmitic acid.

Our study has some limitations. One concern is that the sample size was calculated based on the true difference of LDL cholesterol on dietary treatments. We did not include the inflammatory markers as a consideration in the power calculation. However, our study with 41 subjects compared to that of Han et al. [9] with 19 subjects, should allow for the detection of a difference in specific inflammatory markers among the different diets.

Another consideration is that the differences in lipoprotein, lipid and inflammatory marker levels in the present study could not be attributed to the effect of a single fatty acid. This study was designed to assess the effect of commercial fats, with distinct fatty acid profiles, when they are consumed in their normal way, as a cooking oil and in foods, in a South East Asian population. Our investigation was not designed to distinguish the effects of individual fatty acids.

The use of vegetable oils in their natural state might be preferred over one that has undergone the process of hydrogenation. Hence, high oleic palm olein may serve as a suitable cooking oil due to its beneficial effect on blood lipids and inflammatory markers.

Acknowledgments We thank Professor Tom Sanders, Dr Marianne Raff and Professor Geh Sooi Lin for the review of this paper. Our thanks also go to Siew Wai Lin, for her contribution in supplying the high oleic palm olein. There are no conflicts of interest. The study was funded by the Malaysian Palm Oil Board (PD103/07).

ORIGINAL ARTICLE

Modulation of Platelet Aggregation, Haematological and Histological Parameters by Structured Lipids on Hypercholesterolaemic Rats

Avery Sengupta · Mahua Ghosh

Received: 13 January 2010 / Accepted: 24 March 2010 / Published online: 17 April 2010

Abstract The effect of the consumption of medium-chain fatty acid (MCFA)-rich and polyunsaturated fatty acid (PUFA)-rich mustard oil on platelet aggregation, haematological parameters and the liver was studied in male albino rats. The rats were fed on standard stock diet with control (mustard oil) and experimental oils for 28 days. Haematological examinations in the normal condition showed that there was no significant variation in the platelet count, total white blood cell (WBC) and red blood cell (RBC) counts, haematocrit value and mean cell haemoglobin concentration (MCHC) percentage in the rats fed with control and experimental oils. Haematological examinations in the hypercholesterolaemic condition revealed that there was a significant increase in the platelet count by 39.38% in hypercholesterolaemia, which was decreased by 27.29 and 42.71% by the administration of the experimental oils, respectively. The haemoglobin level was decreased by 5.3%, whereas the haematocrit value was increased by 12.52% in hypercholesterolaemia, which were normalised by treatment with the experimental oils. The platelet aggregation study indicated that the adenosine diphosphate (ADP)-induced platelet aggregation increased by 71.67% in hypercholesterolaemia, but the experimental oils beneficially reduced platelet aggregation by 26.33 and 68.33%, respectively. There was increased total cholesterol, non-high-density lipoprotein (non-HDL) cholesterol and triglyceride levels in liver in hypercholesterolaemia, which was also recovered by the administration of experimental oils. Organopathological examination showed that there was deposition of cholesterol in the liver in the hypercholesterolaemic condition, which was also reduced by treatment with the two experimental oils.

Keywords Medium-chain triglycerides (MCT) · Medium-chain fatty acid (MCFA) · Polyunsaturated fatty acid (PUFA) · Hypercholesterolaemia · Platelet aggregation · Histopathology · Haematology

Abbreviations

ADP	Adenosine diphosphate
AMRD	Age-related macular degeneration
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
EPA–LA	Eicosapentaenoate–lipoate
HDL	High-density lipoprotein
LCT	Long-chain triglyceride
MCT	Medium-chain triglyceride
MCHC	Mean cell haemoglobin concentration
MCV	Mean corpuscular volume
PRP	Platelet-rich plasma
TAG	Triacylglycerol
PUFA	Polyunsaturated fatty acid
ROS	Reactive oxygen species
5-HT	5-Hydroxytryptamine

Introduction

Hypercholesterolaemia is a major risk factor of cardiovascular diseases, predominantly coronary artery disease [1]. High plasma levels of cholesterol induce vascular

oxidative stress and profoundly change the reactivity of both blood vessels and platelets [2, 3]. In large arteries of the coronary and the systemic circulation, hypercholesterolaemia induces and promotes the development of atherosclerotic lesions and endothelial dysfunction, which is significantly contributed by oxygen-deriving radicals and oxidised low-density protein [4–6]. In platelets, hypercholesterolaemia induces a hyperactive state, which is characterised by increased serotonin release and enhanced responses to platelet aggregators, such as collagen, adenosine diphosphate (ADP) and thromboxane, while the aggregatory activity of prostacyclin is reduced [7].

The major physiological function of platelets is to mediate the haemostatic response. When a blocked blood vessel is damaged, platelets adhere to the exposed subendothelium, where they become activated and aggregate to form a haemostatic plug, in order to arrest the flow of blood and seal off the damaged vessel wall. Platelet activation is controlled by several substances endogenous to the vasculature, such as thrombin, collagen, ADP, adrenaline and 5-hydroxytryptamine (5-HT). These antagonists act through specific receptors expressed on the platelet surface membrane and initiate signal transduction pathways that lead to platelet activation. However, in pathological conditions, platelets form thrombi at the site of vascular lesions and these are associated with ischaemic events and the progression of atherosclerosis. Furthermore, there is evidence of platelet hypersensitivity to aggregating agents in patients with risk factors for coronary heart disease, such as hypertension and hypercholesterolaemia [8].

Feeding a high-cholesterol diet has often been used to elevate serum or tissue cholesterol levels to study the aetiology of hypercholesterolaemia-related lipaemic-oxidative disturbances. In diet-induced hypercholesterolaemia, the liver is the primary organ to metabolise the excessively ingested cholesterol and become affected by subsequent oxidative stress. Endogenous pro-oxidant conditions in liver cells produce effects that influence the development of atherosclerosis [9]. Increased oxidative stress, resulting from both increased oxygen-free radical production and decreased nitric oxide generation, appears to play an important role in the chronic inflammatory responses to hypercholesterolaemia and atherosclerosis [10]. The literature suggests that structured lipids eicosapentaenoate–lipoate (EPA–LA) attenuate hypercholesterolaemia-related disturbances, mainly because of their ability to reduce reactive oxygen species (ROS) production and cholesterol, respectively [11].

The consumption of dietary fats have been long associated to chronic diseases such as obesity, diabetes, cancer, arthritis, asthma and cardiovascular disease. Although some controversy still exists in the role of dietary fats in human health, certain fats have demonstrated their positive effect in the modulation of abnormal fatty acid and eicosanoid metabolism, both of them associated to chronic diseases. Among the different fats, some fatty acids can be used as functional ingredients such as medium-chain fatty acids (MCFA) and polyunsaturated fatty acids (PUFA), such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).

MCFA (6–10 carbon atoms) containing triglycerides are popularly known as medium-chain triglycerides (MCTs). MCTs are a special-purpose food for use as supportive nutritional therapy. It may be used to increase the calorie value and to improve the palatability, digestibility and absorption. MCTs have a number of properties that may be beneficial in preventing atherosclerosis; among these are that MCTs have anti-coagulating effects and have been shown to lower serum cholesterol. In addition, MCTs reduce levels of cholesterol in the liver and other tissues [12].

PUFAs are remarkably important molecules, both structurally and functionally, and fatty acids with n-3 configuration are predominant class of PUFA. EPA (20:5n-3) and DHA (22:6n-3) are the important n-3 PUFAs. EPA and DHA are important in the treatment of atherosclerosis, cancer, rheumatoid arthritis, psoriasis and diseases of old age, such as Alzheimer's and age-related macular degeneration (AMRD) [13, 14]. A beneficial effect of n-3 PUFA present in marine fishes on atherogenesis is supported from the majority of animal studies showing that feeding with fish oil decreases atherosclerotic lesions [15]. n-3 PUFA may also reduce thrombogenesis and, thereby, decrease the risk of thrombotic complications of plaque rupture/fissure.

A vast population of East Asia use mustard oil as the primary cooking oil. Mustard oil (*Brassica juncea*) contains 8–9% of saturated fatty acid and 88–91% of unsaturated fatty acid, in which 48–50% is erucic acid (22:1) and erucic acid takes time to digest in the human digestive system, which leads to less deposition of lipids in different organs [16]. Moreover, mustard oil contains two essential fatty acids (EFA) in appreciable amounts. There are some opportunities to increase the beneficial effects of mustard oil by incorporating MCFA or PUFA in its glyceride backbone, resulting in the formation of MCT-containing mustard oil (MCTM) and PUFA-containing mustard oil (PUFAM). The aim of this study was to investigate the effects of these two modified forms of mustard oil on different haematological and histological parameters, and also on platelet aggregation.

Materials and Methods

Materials

Mustard oil was extracted from brown mustard seed by the solvent extraction method and physically refined and

bleached in the laboratory. Capric acid (C10:0) was obtained from Sigma Chemical Company. Fish oil containing 32% EPA and 22% DHA was used as the source of PUFA. Lipase TLIM was a gift from Novozymes India Pvt. Ltd. All other reagents used were of analytical grade and procured from Merck India Ltd., Mumbai, India.

Preparation of Oils

Two types of procedures were adopted for the preparation of experimental oil. Capric acid was reacted with mustard oil to obtain MCTM, and EPA- and DHA-containing fish oil was blended with mustard oil to obtain PUFAM. The reaction between capric acid and mustard oil was carried out in a packed-bed bioreactor. The reactor consisted of a tubular glass column of 10 mm ID and was 50 cm long. It was also provided with a water jacket for temperature control. The immobilised enzyme packed into the reactor was retained in place by means of a sintered plate. The substrates were fed from the top and the products were collected at the bottom. The substrates were previously blended and well mixed at the reaction temperature before conducting the packed-bed reaction and were poured into the enzyme bed, maintaining a fixed sample head. Water from a constant temperature bath was circulated through the jacket by a peristaltic pump. A partial suction was given to maintain the constant flow rate (0.4 mL/min; optimised in the previous study); 20 g of enzyme was closely packed into the column by repeated tapping to avoid any air gaps. Transesterification reactions were then carried out by passing the substrate through the column. The temperature was maintained at the desired value of 60°C by passing water through the column jacket. The product mixture was collected at the outlet and the fatty acid composition of the oils was determined by gas chromatography (GC). The fish oil was blended with mustard oil in the mole ratio of 1:2 (fish oil:mustard oil) to obtain PUFA-rich mustard oil (PUFAM). The total amounts of MCFA and PUFA in the modified mustard oils were kept almost equal. Some amount of synthetic antioxidant (TBHQ) was added to both of the oil formulations.

Chromatographic Analysis of Oils

Fatty acid composition of MCTM and PUFAM oils were analysed by GC. Fatty acid ethyl esters (FAME) were prepared by the method described by Metcalfe et al. [17] and the compositions were determined by GC analysis using an analytical gas chromatograph (Agilent 6890 Series gas chromatograph) equipped with a flame ionisation detector (FID) and an HP-Wax capillary column (J & W Scientific Columns from Agilent Technologies) of 30 m length with 0.25 mm ID and 0.25 mm film thickness. The GC inlet temperature and FID detector temperature was maintained at 250°C and the oven temperature was maintained at 250°C for 2 min. Then, the temperature was increased at a rate of 10°C/min, up to 280°C, then a 20-min hold at 280°C. The gas flow was 30, 300 and 29 mL/min for hydrogen, air and nitrogen, respectively.

Experimental Animals

Male Charles Foster rats weighing 80–100 g were grouped into four groups (six rats in each group) by random distribution and housed in individual cages, under a 12-h light/dark cycle. The animals were given a fresh diet daily and the left over food was weighed and discarded. The gain in body weight of animals was monitored at regular intervals. The animals had free access to food and water throughout the study. Each group of rats was fed for a total of 30 days. In the control group, the rats were fed with normal stock diet containing mustard oil and case groups were fed with 20% MCTM and 20% PUFAM, respectively. The protein content of the food was analysed using the Kjeldahl method, fat by the Soxhlet method, and ash and moisture content by oven assay. Samples of the rat faecal matter were collected and analysed once per day. At the end of the experiment, the feeding of rats was stopped and, after 12 h fasting, the rats were anaesthetised by chloroform and 5 ml of blood was taken from the heart. The liver was removed, rinsed with ice-cold saline, blotted, weighed and stored at −20°C until it was analysed. The experimental protocol was approved by the Animal Ethical Committee.

Collection of Blood Samples and Measurement of Haematological Parameters

Blood samples taken from the abdominal aorta were collected in sample bottles containing heparin as the anticoagulant. Total white blood cell (WBC) counts, number of platelets, haemoglobin concentration, mean cell haemoglobin concentration (MCHC), mean corpuscular volume (MCV) and haematocrit value were analysed.

Platelet Preparation

Blood (4.5 mL) was collected from the abdominal aorta of urethane-anaesthetised animals and poured into 0.5 mL trisodium citrate (3.8% w/v) and centrifuged (250 g, 15 min, at room temperature) to obtain platelet-rich plasma (PRP).

Platelet Aggregation Study

PRP was taken and washed platelets were prepared as described by Brunauer and Huestis [18] and suspended in

Tyrode buffer. Platelets were incubated for 15 min at 37°C prior to use. Platelet aggregation measurements were performed using a Chrono-Log dual-channel aggregometer. The aggregometer was calibrated using the light transmission of PRP/platelet suspension and PPP/Tyrode buffer to represent 0 and 100% aggregation, respectively. Platelet suspension of 450 μL was stirred at 1,000 rpm at 37°C and 10 μL of ADP (25 m) was added and aggregation followed for at least 5 min. The reading was recorded until a plateau was reached.

Analysis of Liver Lipids

Liver lipid was extracted by the method of Folch et al. [19]. One gram of tissue was homogenised with 1 mL of 0.74% potassium chloride and 2 mL of different proportions of chloroform and methanol for 2 min and then centrifuged. The mixture was left overnight and the chloroform layer was filtered through a Whatman filter paper (No. 1). The chloroform layer was dried, the tissue lipid contents were measured and the lipid was used for lipid analysis. The liver lipid was used for the estimation of total cholesterol, high-density lipoprotein (HDL) cholesterol, non-HDL cholesterol, triacylglycerol (TAG) and phospholipid estimation by using standard kits.

Histopathology

Permanent preparations were made using routine methods [20]. The livers were fixed in 10% buffered formalin. The tissues were subsequently dehydrated in upgraded concentrations of alcohol, cleansed in xylene, impregnated and embedded in paraffin wax. Several sections of 3–6 μm were cut using a microtome. The sections were stained with haematoxylin and eosin.

Data Analysis and Statistical Procedures

All of the data are presented as mean ± standard deviation (SD). Significance was calculated using one-way analysis of variance (ANOVA).

Results

Composition of Oils

Analysis of the lipids in the diet showed that MCTM contained 19.87% capric acid (C_{10}) and PUFAM contained 18.83% EPA and DHA. The fatty acid compositions of the control oil (mustard oil) and experimental oils, MCTM and PUFAM, are given in Table 1.

Nutritional Performance of Rats Fed with Experimental Oils

The fat level was kept constant at 20% in all of the dietary groups. The amount of diet consumed by the different groups was comparable. The feeding effect of dietary lipids on the body weight gain of normal and hypercholesterolaemic rats is presented in Table 2. There was no significant difference in the food intake of the different groups of

Table 2 Effect of feeding dietary lipids on body weight gain of normal and hypercholesterolaemic rats

Parameters	Control oil		MCTM oil		PUFAM oil	
	Normal condition	Hypercholesterolaemic condition	Normal condition	Hypercholesterolaemic condition	Normal condition	Hypercholesterolaemic condition
Food intake (g/day/rat)	7.94 ± 0.87^{a}	8.05 ± 1.32^{a}	8.44 ± 0.07^{a}	8.27 ± 0.98^{a}	8.04 ± 0.12^{a}	7.91 ± 0.25^{a}
Body weight gain (g)	34.17 ± 0.99^{a}	42.51 ± 0.46^{b}	34.09 ± 0.45^{a}	40.34 ± 0.99^{c}	39.66 ± 0.67^{d}	43.83 ± 1.21^{e}
Food efficiency ratio	0.14 ± 0.01^{a}	0.17 ± 0.01^{a}	0.13 ± 0.02^{a}	0.16 ± 0.01^{a}	0.16 ± 0.01^{a}	0.18 ± 0.03^{a}

Values are mean ± SEM ($n = 6$ rats)

Values not sharing a common superscript within a row are statistically significant ($P < 0.01$)

normal and hypercholesterolaemic rats. However, there was a significant difference between the body weight gain of the normal and hypercholesterolaemic groups ($P < 0.01$). There was no significant difference between the body weight gain of the group fed with mustard oil and the group fed with MCTM oil in the normal case. On the other hand, the body weight gain decreased on feeding the rats with MCTM oil in the hypercholesterolaemic condition. The body weight gain was increased significantly by feeding the rats with PUFAM oil both in the normal and hypercholesterolaemic groups. The food efficiency ratios (FER) of the normal rats fed with three different oils were almost equal and there was no significant difference also between the food efficiency ratios of the hypercholesterolaemic rats fed with the three oils, but the FER value was slightly greater in the case of hypercholesterolaemic groups than that of normal groups.

Haematological Parameters

The blood haematological parameters of the normal and hypercholesterolaemic groups are shown in Table 3. The results show that there were no significant variations in the platelet count, total WBC counts, total red blood cell (RBC) counts, haematocrit value and MCHC percentage in the normal rats fed with control and experimental oils. But there was a significant increase in the platelet counts from 5.82×10^9/L in the normal case to 9.60×10^9/L in the hypercholesterolaemic case, and the count was lowered with the administration of both of the experimental oils. The haemoglobin level of the normal rats fed with control oil was lower in comparison with its level in rats fed with experimental oils and there was further lowering of the haemoglobin level in hypercholesterolaemia, which was raised by feeding the rats with MCTM and PUFAM oils. The results also show that the MCV percentage was raised with the administration of PUFAM oil in the case of normal rats. Similarly the haematocrit and MCHC values were increased with the induction of hypercholesterolaemic condition in rats and the percentages were lowered by treatment with the experimental oils. Among the two experimental oils, the effect of PUFAM was better than MCTM oil.

In Vitro Platelet Aggregation

Table 4 depicts the changes in platelet aggregation by treatment of the normal and hypercholesterolaemic rats with MCTM and PUFAM oils. MCTM and PUFAM oil-fed rats showed a significant decrease ($P < 0.05$) in the percentage aggregation of platelets. The decrease in percentage aggregation was much more pronounced in the case of PUFAM oil than in the case of MCTM oil, both in normal and hypercholesterolaemic subjects. The percentage of ADP-induced platelet aggregation was increased to a very high degree in the case of hypercholesterolaemia, which was decreased significantly ($P < 0.05$) by 26.33 and 68.33% by feeding the rats with MCTM and PUFAM oils, respectively.

Liver Lipid Analysis

The liver is an important site for lipid metabolism. The liver lipid profiles of normal and hypercholesterolaemic rats fed with dietary lipids are shown in Table 5. The total cholesterol of the liver of rats fed with control oil was 14.74 mg/dL in the case of normal rats and 18.72 mg/dL in the case of hypercholesterolaemic rats. These levels of total cholesterol were decreased significantly by treating the rats with MCTM oil and PUFAM oil, both in the normal and hypercholesterolaemic groups. The liver triglyceride concentration was also altered by the type of fat given to the

Table 3 Comparison between the haematological parameters of rats fed with control oil and experimental oils in normal and hypercholesterolaemic condition

rats. There was a decrease in the triglyceride concentration by 23.2 and 47.9% in normal rats fed with MCTM oil and PUFAM oil, respectively, and by 22.3 and 39.5% in hypercholesterolaemic rats fed with MCTM oil and PUFAM oil, respectively. There was a decrease in the non-HDL levels and an increase in the phospholipid concentrations by treating the rats with the two experimental oils both in the normal and hypercholesterolaemic cases. There was an increase in the level of HDL cholesterol by treating the rats with the experimental oils. The changes were more pronounced in the case of PUFAM oil.

Histopathology of the Liver

Microscopic examination of the liver cells of the six groups was performed and the histopathological slides are shown in Fig. 1. Figure 1a, d highlighted the abnormal fatty changes in hepatic histology of the control rats. The changes are very much pronounced in the case of hypercholesterolaemic control rats. Figure 1b, e highlighted the treatment of the livers with MCTM oil. Figure 1c, f highlighted the treatment of the livers with PUFAM oil. The effect of treatment of the rats with PUFAM oil was much greater in comparison with MCTM oil.

Discussion

The data on the total body weight indicated a decrease in body weight gain in case of administration of MCTM oil, and the reverse occurs in the case of PUFAM oil. This is due to the reason that MCTs have lower calorie content in comparison to long-chain triglycerides (LCT). MCTs are also not stored in fat deposits in the body as much as LCTs [21]. MCTs also contribute to enhanced metabolism to burn even more calories [22].

Hypercholesterolaemia increases markedly the platelet count, haematocrit value and MCHC percentage. Their increase in the blood serves as important markers of vascular disease, such as microangiopathy and macroangiopathy. The treatment of the hypercholesterolaemic rats with MCTM and PUFAM oils decreases the platelet count, haematocrit value and MCHC percentage and, thus, decreases the chances of vascular disease as well.

The actual physiology of the hypercholesterolaemic subjects could be understood by its liver lipid profile, as the liver is the main site for lipid metabolism. The results of the present study indicates that the administration of two structured lipids, MCTM and PUFAM, increases HDL and decreases non-HDL cholesterol, along with a reduction of TAG and increment in phospholipids. Our results also show that the platelets of hypercholesterolaemic rats are significantly more responsive to ADP-induced aggregation in vitro than normal rats in terms of peak height. As cholesterol is responsible for the observed changes in platelet reactivity, an acute elevation in the cholesterol level had a significant effect on ADP-induced platelet aggregation. In the present work, we have only studied aggregation responses to ADP, which is considered to be an important physiological mediator of platelet aggregation. The in vitro

model of platelet accumulation used in this study has previously been validated and provides a reliable and reproducible method of assessing platelet aggregation responses. It reflects the true accumulation of platelets in the pulmonary vasculature that is not simply a consequence of changes in blood flow or distribution. It is released from dense granules of platelets and acts principally through the platelet $P2Y_{12}$ receptor to induce platelet activation and subsequent aggregation. Clinically, the $P2Y_{12}$ receptor antagonist clopidogrel is widely used for the prevention of arterial thrombotic disease. This may be possibly related to an increase in the ADP sensitivity of platelets. This confirms the importance of ADP as a stimulus for thrombotic disease, especially in hypercholesterolaemic patients. The results of this study show that, in an animal model of hypercholesterolaemia, platelet aggregation was increased in vitro, as determined by the accumulation of platelets in response to ADP. This may contribute to the increase in arterial thrombotic events seen in this condition, so that an increased ability of platelets to aggregate coupled with endothelial dysfunction and vascular damage, which combine to give rise to both macrovascular and microvascular disease. Treatment of the rats with MCTM and PUFAM oils seems to produce an inhibitory effect on platelet aggregation, thus, reducing the chances of vascular diseases and, finally, atherosclerosis by reducing the interaction between platelets and the vessel wall. The effect of PUFAM oil seems to be higher than MCTM oil. Various laboratories have investigated the metabolic mechanisms by which polyunsaturated fatty acids may decrease platelet activation after exposure to several agonists. When EPA is consumed, it is selectively incorporated into various phospholipid components of the platelet membrane. A result of EPA's accumulation in membrane phospholipids is the partial replacement of endogenous arachidonic acid (AA) available for the release and formation of thromboxane A, which is a potent inducer of platelet aggregation and a vasoconstrictor. EPA not only decreases the amount of AA available in tissue phospholipids for conversion into eicosanoids (including prostaglandins and leukotrienes), but it also competitively inhibits the conversion of AA into endoperoxides at the level of cyclo-oxygenase.

The hallmark of atherosclerosis was the accumulation of cells containing excessive lipids, and this was notable in the histopathological observation of the present study, where there was an increased lipid infiltration in hepatocytes of the control rats, especially in the hypercholesterolaemic control rats. Furthermore, the cholesterol levels in the liver of the control rats were also increased. It was reported that the supplementation of n-3 PUFA results in increased cholesterol excretion from the animals, by increasing the transfer of cholesterol into bile [23]. HMG CoA reductase inhibitory property of n-3 PUFA [24] and MCT reduces hepatic endogenous production of cholesterol, thereby, preventing excessive accumulation of lipids in the hepatocytes. It has been demonstrated from the study that the incorporation of MCFA and PUFA in mustard oil in the diet of rats appears to be hypolipidaemic by efficiently reducing the increased lipid infiltration and cholesterol level in hepatic tissues.

Thus, in conclusion, we can say that the consumption of MCTM and PUFAM oils can improve the haematological and histological conditions which were disturbed by hypercholesterolaemia.

Acknowledgements The work was funded by the University of Calcutta under the scheme "University with Potential for Excellence" funded by Government of India. Sincere thanks are also due for Dr. Biswajit Bhattacharya, Medical Officer, Blood Bank, R. G. Kar Medical College and Hospital, Kolkata, and Dr. (Ms.) Maitreyee Bhattacharya and Dr. Sanjoy Misra, Department of Haematology, N.R.S. Medical College and Hospital, Kolkata, for their help in finding out the haematological and platelet aggregation parameters, respectively, performed in the above study. We are very thankful to Prof. D. K. Bhattacharyya, Ex-Professor Emeritus, Department of Chemical Technology, University of Calcutta, for his wonderful mentorship.

Saponified Evening Primrose Oil Reduces Melanogenesis in B16 Melanoma Cells and Reduces UV-Induced Skin Pigmentation in Humans

Jeung-Hyun Koo · Ikjae Lee · Seok-Kweon Yun · Han-Uk Kim · Byung-Hyun Park · Jin-Woo Park

Received: 10 November 2009 / Accepted: 5 March 2010 / Published online: 30 March 2010

Abstract This study was conducted to determine whether saponified evening primrose oil (sap-EPO) has the potential for use as a whitening agent and to investigate its underlying mechanisms of action. In B16 melanoma cells, sap-EPO dose-dependently inhibited isobutylmethylxanthine-induced melanogenesis with no cytotoxicity. This decrease in melanin production was correlated with reduced enzyme activity and decreased mRNA and protein levels of tyrosinase. The mRNA levels of tyrosinase-related proteins 1 and 2 decreased in response to treatment with sap-EPO, indicating that it regulated tyrosinase at the transcriptional level. Expression of microphthalmia-associated transcription factor was also decreased by sap-EPO as evidenced by decreased mRNA and protein levels. Additionally, topical application of sap-EPO resulted in efficient whitening of UVB-induced hyperpigmentation of human skin. Taken together, these results suggest that sap-EPO has the potential for use as a cosmetic whitening agent.

TRP	Tyrosinase-related protein

Introduction

Melanin is a unique, pigmented biopolymer synthesized by melanocytes that exist in the dermal-epidermal border of the skin. Melanin production is an important defense mechanism against sunlight; however, excessive melanin production due to exposure to UV irradiation or chronic inflammation causes hyperpigmentation of the skin, which can result in melasma, lentigines, nevus, ephelis, freckles or age spots [1]. Accordingly, it is of great interest to develop an effective melanogenesis inhibitor for both pharmaceutical and cosmetic purposes.

The tyrosinase gene family plays a pivotal role in the regulation of melanogenesis [2]. This family consists of tyrosinase, tyrosinase-related protein 1 (TRP-1) and tyrosinase-related protein 2 (TRP-2) [1]. Tyrosinase is a bifunctional enzyme that modulates melanin production by catalyzing the hydroxylation of tyrosine to DOPA and then catalyzing the oxidation of DOPA to DOPAquinone [3]. TRP-2, which functions as a DOPAchrome tautomerase, catalyzes the rearrangement of DOPAchrome to 5,6-dihydroxyindole-2-carboxylic acid [4], while TRP-1 oxidizes dihydroxyindole-2-carboxylic acid to a carboxylated indole-quinone [5].

A number of skin whitening agents have been developed, but these often produce unwanted side effects such as local irritation, contact dermatitis, ochronosis, atrophy and skin cancer [6]. Therefore, it is necessary to find safer therapeutic agents that are still effective. The use of natural products for this purpose has recently been the focus of much attention. For example, arbutin, which is obtained from the leaves of the bearberry plant, is known to inhibit tyrosinase activity [7]. Additionally, kojic acid, which is a hydrophilic fungal derivative obtained from *Aspergillus* and *Penicillium* species, is the most popular agent employed in Asia for the treatment of melasma [6, 8]. Moreover, aleosin, licorice extract, ascorbic acid and soy proteins have been used to interrupt the process of melanogenesis [6]. We also recently reported that xanthohumol, scoparone and *Angelica gigas* extract exerted a potent inhibitory effect against melanogenesis in B16 melanoma cells [9–11]. During screening for new skin-whitening agents from natural sources, we found that the saponification product of evening primrose oil (sap-EPO) effectively whitened skin that had been subjected to UV-induced hyperpigmentation. Therefore, in this study, we investigated the inhibitory mechanism of sap-EPO against isobutylmethylxanthine (IBMX)-induced melanogenesis in B16 melanoma cells.

Experimental Procedures

Cells and Materials

The B16/F10 murine melanoma cell line was obtained from the Korean Cell Line Bank (Seoul, Korea). Cells were cultured in DMEM containing 10% fetal bovine serum, 100 U/ml penicillin, 0.1 mg/ml streptomycin and 0.25 μg/ml amphotericin B at 37 °C in a humidified atmosphere composed of 95% air and 5% CO_2. Drug treatment began 24 h after seeding, and the cells were harvested after 2 days of incubation. IBMX was obtained from Sigma (St. Louis, MO, USA) and evening primrose oil (EPO) was obtained from Dalim Biotech (Evoprim®, Seoul, Korea).

Saponification of Evening Primrose Oil

One gram of EPO was mixed with 0.5 ml of 2.5 N KOH in ethanol, after which saponification was conducted at 80 °C for 30 min. After saponification, the pH of the solution was adjusted to 7.4.

MTT Assay

The viability of cultured cells was determined by reduction of MTT to formazan. Cells were seeded in 96-well plates and cultured for 24 h. After drug treatment, MTT (5 mg/ml in PBS, 100 μl) was added to each well. Cells were incubated at 37 °C for 30 min and dimethyl sulfoxide (100 μl) was added to dissolve the formazan crystals. The absorbance was measured at 570 nm with a spectrophotometer (Spectra MAX PLUS; Molecular Devices, Sunnyvale, CA, USA).

Melanin Content Measurement

The melanin content of the cultured B16 cells was measured as previously described [11]. Briefly, the cells were washed twice with PBS and lysed with 20 mM Tris-0.1% Triton X-100 (pH 7.5). Cell lysates were precipitated with the same amount of 20% trichloroacetic acid. After washing twice with 10% trichloroacetic acid, the pellets were treated with ethyl alcohol:diethyl ether (3:1) and diethyl ether successively. Samples were air-dried, dissolved in 1 ml 0.85 M KOH, and boiled for 15 min. After cooling, the absorbance was measured with a spectrophotometer at 440 nm. The amount of cellular melanin was corrected according to the protein content of the samples. The protein content was determined using Bradford's assay [12].

Tyrosinase Activity Assay

Tyrosinase activity was assayed based on the DOPA oxidase activity using the method described by Lerch [13], with some modification. Briefly, the cell lysate was obtained after washing the cells twice with PBS. The tyrosinase activity was analyzed spectrophotometrically following the oxidation of DOPA to DOPAchrome at 475 nm. A reaction mixture containing 100 μl of freshly prepared substrate solution (0.1% L-DOPA in 0.1 M sodium phosphate, pH 6.0) and 50 μl of enzyme solution was incubated at 37 °C. The change in absorbance was measured during the first ten minutes of the reaction, while the increase in the absorbance was linear, during which time corrections for the auto-oxidation of L-DOPA in the controls were made. The tyrosinase activity was corrected according to the protein content of the samples and is presented as a percentage relative to the IBMX-treated control cells.

Western Blotting

Cells were homogenized in ice-cold lysis buffer. Homogenates containing 10 μg of protein were separated by SDS-PAGE with a 10% resolving and 3% acrylamide stacking gel and transferred to a nitrocellulose membrane in a Western blot apparatus run at 100 V for 1.5 h. The nitrocellulose membrane was blocked with 2% bovine serum

albumin and then incubated overnight with 1 μg/ml goat anti-murine tyrosinase or anti-N-terminus of microphthalmia-associated transcription factor (MITF) IgG (Santa-Cruz Biochemicals, Santa-Cruz, CA, USA). The binding of antibody was detected with anti-goat IgG conjugated to horseradish peroxidase (Sigma). Immunoblots were developed using an Enhanced Chemiluminescence Plus kit (Amersham Biosciences, Buckinghamshire, UK).

RNA Isolation and Real-Time RT-PCR

Total cellular RNA was prepared using Trizol solution (Invitrogen, Paisley, UK) according to the manufacturer's instructions. RNA was then precipitated with isopropanol and dissolved in diethylpyrocarbonate-treated distilled water. First-strand cDNA was generated with the oligo dT-adaptor primers by reverse transcriptase (TaKaRa, Japan). Specific primers (Table 1) were designed using primer express software (Applied Biosynthesis, Foster City, CA, USA). GAPDH was used as the invariant control. The real-time PCR reaction (10 μl) contained 10 ng of reverse transcribed RNA, 200 nM each of forward and reverse primers, and a PCR master mixture. The reaction was performed in 384-well plates using the ABI Prism 7900HT sequence detection system (Applied Biosystems). All reactions were conducted in triplicate.

UVB-Induced Hyperpigmentation

UVB-induced hyperpigmentation was elicited on the skin of the upper arm of three healthy men in their 40s or 50s. Three separate areas (2 cm × 2 cm) on the inside skin of each upper arm were exposed to 400 mJ/cm^2 UVB radiation (Aurora UV-Light, Choyang Medics, Seongnam, Korea) five times a week for one week, which was sufficient for substantial hyperpigmentation to be achieved in each individual. Sap-EPO application was started 14 days after the initial UVB exposure. The sample was topically applied daily to the three hyperpigmented areas on the same arm twice a day for two successive months. The hyperpigmented areas on the other arm were left untreated as a control. The degree of pigmentation and erythema was assessed once every other week from the beginning of sample application using a Mexameter (CK, Mexameter, MPA 9, Courage, Khazaka, Germany). The whitening effect was presented as the difference in the melanogenic index (MI) from the initial sample application day. Informed written consents were obtained from all participants, and the measurements were performed in accordance to the Declaration of Helsinki.

Statistical Analysis

Data were analyzed using ANOVA and the Newman-Keuls test. A $p < 0.05$ was considered to indicate statistical significance.

Results

Inhibition of Melanin Synthesis by sap-EPO

To clarify the whitening mechanism of sap-EPO, we examined its effect on IBMX-induced melanogenesis in B16 melanoma cells. When B16 cells were incubated with IBMX, the cell suspension turned black, indicating increased cellular melanogenesis. EPO itself did not affect melanin production by B16 cells, while sap-EPO led to a dose-dependent decrease in the IBMX-induced black color (Fig. 1a). The cell viability determined by the MTT assay was not affected by EPO or sap-EPO at any of the concentrations tested (data not shown). We quantified the melanin content and observed that even 12.5 μg/ml of sap-EPO inhibited melanin production significantly (Fig. 1b). At concentrations of 100 μg/ml, cells were still viable and the cellular melanin content decreased to 12.8 ± 1.8% of the control.

Tyrosinase activity in the cellular lysates was determined as described in the "Experimental Procedures". Data are expressed as a percentage of the IBMX-treated controls and are presented as the mean ± SEM of three separate experiments. $^{**}p < 0.01$ versus the IBMX-treated control

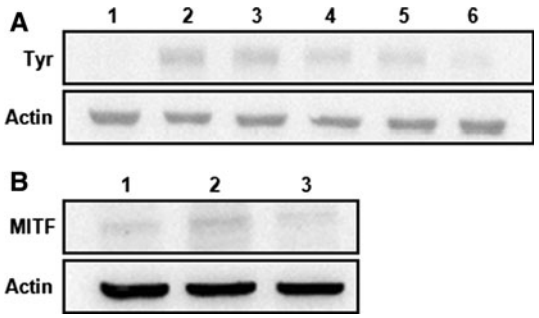

Fig. 3 Effect of saponified oils on tyrosinase and MITF protein expression. B16 cells (5×10^6 cells) were treated with the indicated concentrations of sap-EPO in the presence or absence of 0.1 mM IBMX for 2 days. Tyrosinase (**a**) and MITF (**b**) proteins were then analyzed by Western blotting. Experiments were conducted three times with similar results, and a typical trial is presented. **a** *Lane 1*, control; *lane 2*, 0.1 mM IBMX; *lane 3–5*, 0.1 mM IBMX with 12.5 (*lane 3*), 25 (*lane 4*) 50 (*lane 5*) and 100 μg/ml (*lane 6*) sap-EPO. **b** *Lane 1*, control; *lane 2*, IBMX; *lane 3*, IBMX with 50 μg/ml sap-EPO

Inhibition of Tyrosinase Activity by sap-EPO

Saponified EPO led to a dose-dependent decrease in cellular tyrosinase activity (Fig. 2), which is the rate-limiting step in melanin biosynthesis, and this decrease occurred in parallel to the decrease in melanin content (Fig. 1). However, the direct addition of sap-EPO to the reaction mixture did not impact the tyrosinase activity (data not shown), indicating that the decrease in tyrosinase activity by sap-EPO is not due to inhibition of the tyrosinase activity.

Downregulation of the Expressions of Tyrosinase and Related Genes by sap-EPO

To determine the tyrosinase expression levels of cells treated with sap-EPO, we conducted Western blot and real-time PCR analysis. IBMX treatment increased the expression of tyrosinase protein, and this induction was inhibited by sap-EPO in a dose-dependent manner (Fig. 3a). Sap-EPO also decreased the IBMX-induced tyrosinase mRNA levels (Fig. 4). These findings indicate that sap-EPO inhibits tyrosinase at the transcriptional level. Furthermore, saponified EPO decreased the IBMX-induced mRNA expression of TRP-1, TRP-2 and MITF (Fig. 4). Decreased protein level of MITF was confirmed by Western blotting (Fig. 3b).

Whitening Effect of sap-EPO on UVB-Induced Hyperpigmentation of Human Skin

The whitening effect of sap-EPO was evaluated on UVB-induced hyperpigmented human skin. At two weeks after the initial UVB irradiation of the inside skin of the upper arm, substantial hyperpigmentation and resolving of erythema was observed at the UVB irradiated sites, and topical application of sap-EPO was started. Sap-EPO was topically applied to the hyperpigmented areas two times a day for 2 months. A visible reduction in skin pigmentation

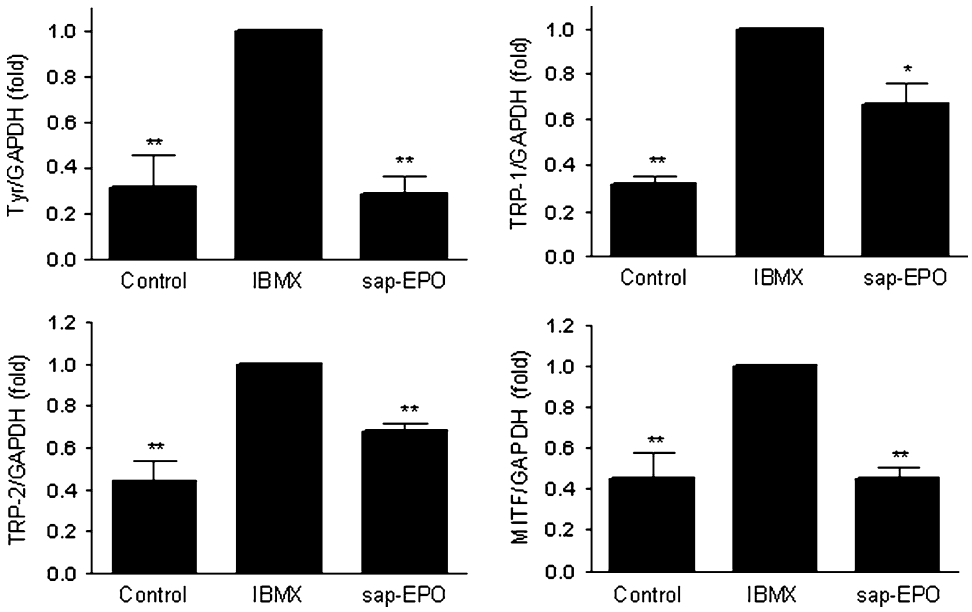

Fig. 4 Effect of saponified oils on the mRNA expressions of melanogenesis-related genes. B16 cells (5×10^6 cells) were treated with 0.1 mM IBMX for 2 days in the presence or absence of 50 μg/ml sap-EPO. Total RNA was extracted and the mRNA expression was analyzed by real-time RT-PCR. Data are expressed as the mean ± SEM of three separate experiments. *$p < 0.05$, **$p < 0.01$ versus IBMX

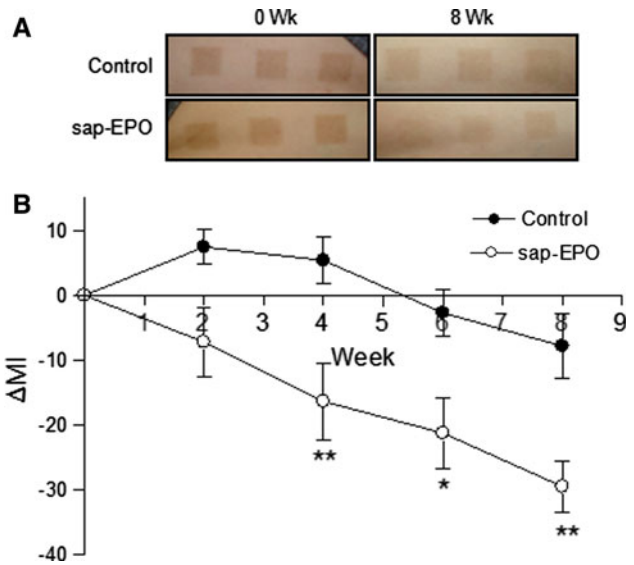

Fig. 5 Effect of sap-EPO on UVB-induced skin hyperpigmentation. UVB-induced hyperpigmentation was elicited on three separate areas on the inside skin of both upper arms. Two weeks after initial UV exposure, sap-EPO was topically applied to the hyperpigmented skin two times a day for eight weeks. Representative photographs are shown (**a**). The degree of pigmentation was assessed and the whitening effect of sap-EPO was presented as the difference in melanogenic index (*MI*) from that of the day of the initial sample application (**b**). *$p < 0.05$, **$p < 0.01$ versus the vehicle-treated control

was observed at eight weeks after the sap-EPO treatment was started when compared to control sites on the other arm of the same person (Fig. 5a). Additionally, the degree of skin pigmentation was measured using a Mexameter before the start and throughout the treatment period to allow objective determination of the treatment effects. Significant differences in the melanogenic index were observed from four weeks after the initial UVB exposure through the end of the experiment (Fig. 5b). No erythema was observed during the sap-EPO treatment.

Discussion

We conducted this study to determine if the saponified product of EPO can be used as a whitening cosmetic agent. To accomplish this, we evaluated the whitening effect of sap-EPO on UVB-induced hyperpigmented skin and IBMX-treated B16 melanoma cells.

Skin whitening compounds suppress melanogenesis in B16 melanoma cells in various ways including through cytotoxic effects on melanocytes, direct tyrosinase inhibition, and melanin biosynthesis inhibition. No cytotoxicity was observed in response to treatment with sap-EPO at the effective concentrations. Arbutin and kojic acid are known to inhibit melanogenesis by directly inhibiting tyrosinase, which is the first and rate-limiting enzyme involved in the production of melanin from tyrosine [6, 7]. We incubated sap-EPO with cellular tyrosinase and found that sap-EPO did not inhibit tyrosinase activity directly. Therefore, we focused on the effect of sap-EPO on the melanin biosynthetic pathway in melanocytes.

IBMX increases cellular cAMP by inhibiting the cAMP-degrading enzyme, phosphodiesterase [14]. Protein kinase A (PKA) phosphorylates and activates the cAMP response element binding protein that binds to the cAMP response element in the M promoter of the MITF gene [15, 16]. In humans, mutations affecting the MITF pathway lead to pigmentary and auditory defects that are known collectively

as Waardenburg syndrome [17]. The increase in MITF-M expression induces the upregulation of members of the tyrosinase gene family, resulting in increased melanin synthesis [17, 18]. In this study, we showed that sap-EPO blocked the IBMX-induced increase in melanogenesis and significantly decreased the expression of MITF mRNA and protein. This decrease was mirrored by reductions in the expression levels of tyrosinase, TRP-1 and TRP-2 mRNAs. Taken together, these results suggest that sap-EPO inhibits the melanogenic process at the transcriptional level. However, Ando et al. [22] reported that unsaturated fatty acid increased the proteolytic degradation of tyrosinase without altering the mRNA level. This discrepancy might be accounted for by the distinct cell state: we here used IBMX-stimulated melanoma cells, whereas they used the unstimulated melanocytes. A similar inhibitory effect of sap-EPO was observed when B16 cells were treated with α-melanocyte stimulating hormone or forskolin, an activator of adenylate cyclase [18] (data not shown), suggesting that sap-EPO inhibits the melanogenesis by affecting the cAMP-dependent pathway, at least in the stimulated state.

The topical application of sap-EPO effectively whitened the UV-induced hyperpigmented skin. Skin color is determined by melanin biosynthesis in melanocytes and the subsequent transfer of melanin to neighboring keratinocytes [19]. Therefore, whitening of the skin color can be achieved by inhibiting either the pathway by which melanin is synthesized in the melanocytes or the pathway responsible for the transfer of melanin to the surrounding keratinocytes. Even though we did not investigate the interaction between keratinocytes and melanocytes with regard to melanogenesis, our in vitro data suggest that the skin-whitening effect of sap-EPO was due to the suppression of melanin biosynthesis in the melanocytes.

EPO is the oil from the seed of the evening primrose (*Oenothera biennis*) plant and is one of the most commonly used herbal medications. The primary uses of evening primrose oil are for atopic dermatitis, mastalgia and lactation. Other potential uses include diabetic neuropathy, premenstrual syndrome, rheumatoid arthritis, seborrhea and fortification of infant formula [20]. Evening primrose seeds contain about 14% fixed oil, the fatty acid of which is composed of approximately 65–75% linoleic acid, 7–10% γ-linolenic acid, 9% oleic acid and some palmitic and stearic acids [20, 21]. It has been reported that linoleic and linolenic acid decrease melanin synthesis and tyrosinase activity, while saturated fatty acids increase melanogenesis [22, 23]. Linoleic acid has also been shown to increase the turnover of the stratum corneum [23]. Thus, the high proportions of unsaturated fatty acids in EPO may underlie the anti-melanogenic effect. Saponification is the hydrolysis of an ester under basic conditions to form an alcohol and the salt of a carboxylic acid. When the oil was reacted with metallic alkali, free fatty acid was released and forms soap. The effectiveness of only the saponified form of EPO indicates that the release of free form fatty acids is a prerequisite for its inhibitory action. Even though our skin experiment on the whitening effect of sap-EPO is preliminary and should be repeated using a larger number of participants, the results presented here combined with those of previous human studies conducted using purified linoleic acid [24, 25] are promising.

Sap-EPO effectively reduced melanogenesis in B16 melanoma cells and decreased pigmentation of UV exposed skin. Our findings are of great interest because EPO is already a component of the human diet and therefore likely to be relatively safe when used over long periods of time. Indeed, EPO and sap-EPO never induced erythema during this experiment. In conclusion, we demonstrated that sap-EPO exerts a pigment-whitening effect by inhibiting the expression of tyrosinase and related enzymes; therefore, we suggest that this effect may be related to the high proportions of linoleic acid released by saponification from EPO.

Fatty Acid Composition of the Maternal Diet During the First or the Second Half of Gestation Influences the Fatty Acid Composition of Sows' Milk and Plasma, and Plasma of Their Piglets

Encarnación Amusquivar · John Laws · Lynne Clarke · Emilio Herrera

Received: 21 November 2009 / Accepted: 7 April 2010 / Published online: 27 April 2010

Abstract Dietary supplements of olive oil (OO) or fish oil (FO) during the first (G1: day 1–60) or second half of gestation (G2: day 60 to term, day 115) were offered to pregnant sows. The proportion of fatty acids in milk and plasma were determined by gas chromatography. When supplements were given during G1, the proportions of oleic acid (OA) and arachidonic acid (AA) in the plasma were higher in the OO group than in the FO group, whereas docosahexaenoic acid (DHA) was higher in the latter group at day 56 of gestation. These differences in plasma DHA were still apparent at day 7 of lactation. Similarly, DHA was also higher in the colostrum and milk on days 3 and 21 of lactation and in the plasma of piglets from FO dams compared to the OO group, whereas AA was lower. When the FO supplement was given during G2, AA was lower and DHA higher in the plasma at day 105 of gestation and at day 7 of lactation compared with the OO group. Likewise, DHA was greater in FO than in OO animals during lactation in colostrum and in milk on days 3 and 21 of lactation, and in 3-day old suckling piglets plasma, whereas AA was lower in these animals. Thus, maternal adipose tissue plays an important role in the storage of dietary long-chain polyunsaturated fatty acids (LCPUFA) during G1. They are mobilized around parturition for milk synthesis, and an excess of dietary n-3 LCPUFA decreases the availability of AA in suckling newborns.

Keywords Pregnancy · Lactation · Pigs · Diet · Fatty acids · Adipose tissue

Abbreviations

OO	Olive oil
FO	Fish oil
G1 and G2	First and second half of gestation, respectively, used for the experimental diets
DHA	Docosahexaenoic acid
AA	Arachidonic acid
EFA	Essential fatty acids
LCPUFA	Long-chain polyunsaturated fatty acids
LA	Linoleic acid
ALA	α-linolenic acid
LPL	Lipoprotein lipase
VLDL	Very low density lipoproteins

Introduction

The dietary essential fatty acids (EFA), linoleic acid (LA, 18:2 n-6) and α-linolenic acid (ALA, 18:3 n-3) and their long-chain polyunsaturated derivatives (LCPUFA) are essential for the formation of new tissues during fetal and postnatal development. The presence of high proportions of certain LCPUFA in vital organs such as the central nervous system of the developing neonate emphasizes their importance [1]. In addition, AA and eicosapentaenoic acid (EPA, 20:5 n-3) are precursors of eicosanoids affecting a variety of biological functions, including immunity [2, 3].

In humans, the conversion of EFA into LCPUFA is relatively slow [1], and this is especially so in the fetus and neonate in as much as the rate of conversion is unable to support optimal growth and development if LCPUFA deficiency occurs [4–6]. During intrauterine life the fetal supply of both EFA and LCPUFA depends on their concentration in maternal circulation as well as on their placental transfer. In suckling newborns the availability of fatty acids depends on their profile in milk, which is influenced by those ingested by their lactating mother [7]. Moreover, the fatty acids profile of newborn piglets has been shown to be affected by the fatty acids ingested by the mother at different times during pregnancy and lactation [8–10].

During the first half of gestation enhanced lipoprotein lipase (LPL) activity in adipose tissue [11, 12] contribute to the accumulation of fat depots in the mother. Through such augmented LPL activity in adipose tissue, dietary derived LCPUFA transported as triacylglycerols in chylomicrons and very low density lipoproteins (VLDL) are hydrolyzed and the released fatty acids are taken up for storage in the subjacent tissue. During the last third of pregnancy the situation drastically changes; LPL activity in adipose tissue decreases [13, 14], which together with an enhanced lipolytic activity [15, 16] results in the net accelerated breakdown of fat depots. Conversely, the reverse situation occurs in the mammary gland [13] with an increase in LPL activity around parturition, which remains during lactation [17, 18]. Thus, throughout this process, dietary fatty acids in plasma triacylglycerols, mainly carried in chylomicrons and VLDL, can be transported to the mammary gland where they can be used for milk synthesis. Moreover, studies using stable isotopes in lactating women have shown that diet-derived LCPUFA account for about 30% of fat milk [19] and in the late pregnant rat receiving orally labelled triacylglycerols, it has been found that dietary lipids actively contribute to lipid uptake by the mammary gland [20].

On the basis of these antecedents, we hypothesize that diet-derived LCPUFA during early pregnancy are stored in maternal adipose tissue and released into the circulation around parturition. Once converted into their esterified form by the liver and returned to blood, they are taken up by the mammary gland for milk synthesis, thus becoming available to the suckling newborn. The role of dietary fatty acids during either early pregnancy or late pregnancy on milk composition has not yet been fully established. Due to the similarities in the fatty acid metabolism in human and pigs [21] and in order to test our hypothesis, this study aimed to determine the consequences of modifying the fatty acid composition of sows' diets, using dietary supplements with olive oil (OO) or fish oil (FO), during the first or the second half of gestation on the fatty acid profiles of maternal plasma and milk during lactation and in plasma of suckling neonates. The present study is a continuation of previous ones using the same treatment protocol in pregnant sows where it was found that with the exception of a slightly improved growth performance in offspring of FO fed sows, no difference was found in reproductive performance between the two groups [22–25].

Methods

Animals and Diets

All animals used in this study were maintained at the Pig Research and Development Unit, Imperial College, London. Experimental procedures were carried out according to the regulations of the Animals (Scientific Procedures) Act, 1986 and were licensed by the Home Office (UK). At all stages of life, animals were kept according to the guidelines set out by the Department for Environment Food and Rural Affairs (DEFRA 2003).

Multiparous sows of the same commercial genotype (25% Meishan; 12.5% Duroc; 62.5% Large White × Landrace) were selected for study after the previous litter had been weaned and prior to insemination. All sows were artificially inseminated with pooled Large White semen (P17 2006, JSR Genetics). Sows were categorized by parity before being randomly assigned to one of four dietary treatment groups, to ensure that parity was balanced across treatments. Pregnant sows were offered 3 kg/day of the standard diet (ABN HE sow pellets; 13.1 MJ/kg ME; 12.7% protein; 4.5% fat; ABN, Peterborough, Cambridgeshire, UK) plus 10% extra energy derived from either OO ($n = 8$) or FO ($n = 8$) offered during either the first half of gestation (G1: i.e. day 1 of gestation, assuming day of service to be day 0) and continued until day 60 of gestation or the second half of gestation (G2: i.e. day 60 of gestation) and continued until term ($\approx$day 115). The fatty acid profiles of the different diets can be seen in Table 1. After parturition sows were offered 6–9 kg of a lactation diet (ABN supreme lactation pellets; 14.1 MJ/kg ME; 18% protein; 7.2% oil; ABN, Peterborough, Cambridgeshire, UK: Table 1).

Sample Collection

Sow blood samples were collected from the jugular vein on days −5, 56, 105, 115 of gestation and day 7 postpartum and piglet blood samples were collected from the external jugular vein at days 3 and 21 of lactation. Blood was always collected in Na_2-EDTA blood tubes (Teklab, UK) and after centrifugation for 15 min at 1,600×g, plasma aliquots were stored at −20 °C until analysis.

Table 1 Fatty acid composition of the diets

	Olive oil (OO) diet	Fish oil (FO) diet	Standard diet	Lactation diet
Fatty acids (g/100 g fatty acids)				
14:0	0.43	2.35	0.53	0.85
16:0	16.37	16.33	18.24	20.42
18:0	3.11	2.79	3.14	5.23
16:1 (n-7)	0.77	3.28	0.32	0.25
18:1 (n-9)	46.59	19.50	20.00	32.78

22:5 (n-3)	0.14	1.22	n.d.	n.d.
22:6 (n-3)	0.35	4.73	0.21	0.08

Values correspond to the mean of three separate samples processed independently

n.d. Not detected

Colostrum samples were collected on the day of parturition, within 4 h of the first piglet being born. Milk samples were collected on days 3, 7 and 21 of lactation following intra-muscular administration of 2 mL oxytocin (10 i.u./mL; NVS, UK). Immediately after its collection, aliquots of milk were frozen at −80 °C until analysis.

Sample Analyses

Lipids were extracted and purified in chloroform:methanol (2:1) [26] in the diets, plasma, colostrum and milk samples. Total lipid extracts were saponified and the fatty acids methylated following the method of Lepage and Roy [27, 28]. Fatty acid methyl esters were separated on a 30 m × 0.25 mm Omegawax capillary column (Supelco, Bellefonte, PA, USA) and quantified using a PerkinElmer gas chromatograph (Autosystem; Norwalk, CT, USA) with a hydrogen flame ionization detector. Nitrogen was used as a carrier gas, and the fatty acid methyl esters were compared with purified standards (Sigma Chemical Co., St. Louis, MO, USA).

Statistical Analyses

Data are expressed as means ± SE. Statistical differences between groups were determined by ANOVA, and Tukey's test was used when differences were statistically significant ($p < 0.05$) by using SPSS 15.0 for Windows, Differences between two groups were analyzed by Student's *t* test.

Results

G1 sows were in positive energy balance during the first half of gestation as their backfat thickness increased over this period (OO 4 ± 1: FO 5 ± 1 mm). However, they were in negative energy balance during the last half of gestation because despite a significant increase in body weight (OO 30 ± 3: FO 29 ± 3 kg) there was little change in their backfat thickness (1 ± 1 mm). G2 sows were not in negative energy balance at any time throughout the study, as shown by their body weight and backfat thickness increase during the first (OO 21 ± 4, FO 24 ± 3 kg and OO 1 ± 1, FO 3 ± 1 mm, respectively), and the second half of gestation (OO 36 ± 3, FO 36 ± 3 kg an OO 4 ± 1, FO 5 ± 1 mm, respectively). This is what it was expected since during the second half of gestation the dietary intake of the G2 sows was above their energy requirements for this stage of pregnancy.

Basal values of plasma fatty acid profiles 5 days before pregnancy or just at the time of starting the corresponding dietary treatments did not differ between the groups (data not shown). When sows received the OO or FO dietary supplements during G1, neither the sum of total saturated fatty acids (12:0, 14:0, 16:0 plus 18:0) nor the sum of n-6 PUFAs (18:2 and 20:4) in maternal plasma differed between the two groups, at either day 56 of gestation or at day 7 of lactation (Table 2). However, the sum of the plasma monounsaturated fatty acids (16:1 n-7 and 18:1 n-9) at day 56 of gestation was higher in G1 OO sows compared to G1 FO mothers with this difference disappearing by day 7 of lactation. The sum of the n-3 PUFAs (18:3 n-3, 20:5 n-3 and 22:6 n-3) appeared higher in G1 FO, particularly at day 56 of pregnancy. When considering the longitudinal changes of the most characteristic fatty acids in plasma of the G1 sows (Fig. 1a), it is seen that oleic acid (OA) increased during the phase that sows were receiving the OO supplement (day 56 of gestation) whereas it decreased in those supplemented with FO, although this

difference was no longer apparent on day 7 of lactation (Fig. 1a). As expected, the proportion of AA in plasma was similar between the two groups in basal samples (day 0), but concentrations declined by day 56 in the G1 FO sows and only returned to values that did not differ from basal levels by day 7 of lactation (Fig. 1a). The proportion of DHA in plasma increased from basal levels at day 56 in the sows fed the FO supplemented diet and remained elevated at day 7 of lactation (Fig. 1a), despite these animals not received FO supplement from day 60 of gestation onwards.

The proportion of saturated fatty acids in colostrum and milk did not differ between the two G1 groups at any of the time points studied (Table 3). In contrast, monounsaturated fatty acids were higher in both colostrum and milk at day 3 of lactation in G1 OO compared to G1 FO sows, whereas the proportion of n-6 PUFA in colostrum and of n-3 PUFA in milk of day 3 were lower in the former group, with no other differences observed between the two groups in these variables (Table 3). On further examination of these aforementioned differences, OA appeared higher in both colostrum and milk of 3 days in G1 OO sows than in G1 FO, whereas no differences were found in AA but DHA was higher in either colostrum or milk in the sows that received the FO supplement as compared to the G1 OO group (Fig. 1b).

As expected, plasma obtained from suckling piglets also reflected those changes observed in FA milk composition (Table 4); at day 3 of lactation, piglets from G1 OO dams exhibited a higher proportion of monounsaturated fatty acids and a lower proportion of n-3 PUFAs than those of the FO group, whereas these differences disappeared at day 21 of lactation. These changes in piglets born to G1 sows corresponded to a lower proportion of OA in their plasma at day 3 of lactation, a significant decrease in AA at both day 3 and 21 of lactation, and an increase in DHA at day 3 (Fig. 1c).

Differences were also shown when pregnant sows received the supplements during G2. Amounts of saturated fatty acids in sow plasma at day 105 of gestation were similar between the G2 OO and G2 FO groups, whereas both monounsaturated and n-6 PUFAs were higher and n-3 PUFA were lower in the former group (Table 2). At day 7 of lactation, the proportion of saturated fatty acids and of n-3 PUFAs in plasma were lower in the G2 OO group than in G2 FO, whereas the proportions of monounsaturated fatty acids and n-6 PUFA were higher. In the case of the G2 OO sows such differences corresponded to an increase in plasma OA at day 105 of pregnancy and day 7 of lactation (Fig. 2a). Whereas in G2 FO mothers there was a decline in the proportion of AA at day 105 of gestation, values had recovered by day 7 of lactation; there was also an increase in the proportion of DHA at both day 105 of gestation and 7 of lactation.

Despite these changes observed in maternal plasma, with the exception of a higher proportion of n-3 PUFA in G2 FO compared to G2 OO sows, corresponding to an increase in DHA at day 3 and day 21 of lactation (Fig. 2b), and an increase in EPA in colostrum and milk at 3 days of lactation (data not shown), neither of the other studied fatty acids differed between G2 FO and G2 OO in colostrum or mature milk (Table 3).

In the plasma of piglets born to G2 OO sows as compared to G2 FO sows the proportion of monounsaturated fatty acids was higher, whilst n-3 PUFAs were lower at day

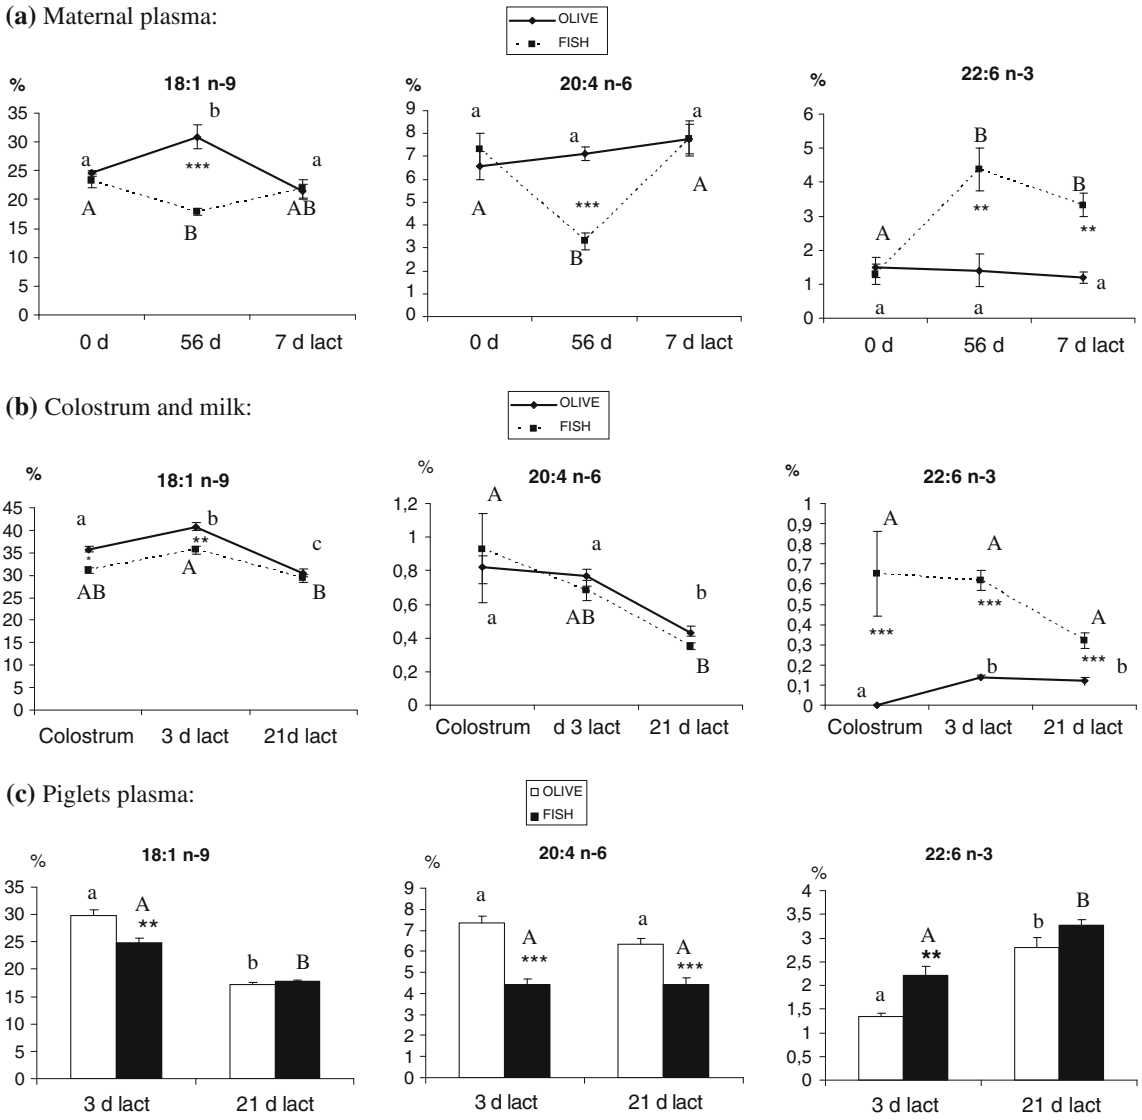

Fig. 1 Proportions of oleic, arachidonic and docosahexaenoic acids in maternal plasma, colostrum and milk and piglets plasma from sows fed either olive oil supplemented diet or fish oil supplemented diet during the first half of gestation. 3 of lactation, with these differences disappearing by day 21 of lactation (Table 4). In the case of the G2 OO piglets the difference in the monounsaturated fatty acids seen at day 3 corresponded to higher OA (Fig. 2c), whereas the differences in n-3 PUFA corresponded to a higher proportion of DHA in those of the FO group. Additionally, these same animals exhibited a lower proportion of AA in plasma at day 3, but at day 21 of lactation plasma AA did not differ between the two groups (Fig. 2c). This finding differs from that commented above for the maintenance of decreased plasma AA values up to 21 days of age in G1 FO piglets when compared to those of G1 OO.

Discussion

These results in pregnant and lactating sows show for the first time that fatty acid composition during either the first half or the second half of gestation greatly influence the fatty acid profile of maternal plasma during lactation, of colostrum and mature milk and even of suckling piglets' plasma. Furthermore, they show that suckling piglets of mothers receiving a FO supplement compared to those receiving an OO supplement have a decreased proportion of AA in the plasma, with the effect being more pronounced and lasting longer (until day 21 of lactation) in

those piglets of sows receiving the supplemented diet during G1 compared to G2. Since AA was practically absent in the maternal diet, these findings may be due to altered endogenous synthesis of this fatty acid. Although it is well established that the essential fatty acid composition of human colostrum and milk is dependent on adipose tissue stores during lactation [29, 30] present findings support the notion that fat depots normally accumulated during pregnancy, and more specifically during its anabolic stage (i.e., its first half) [31, 32] constitute an important source of LCPUFA for milk synthesis during lactation. These results agree with the known effective influence of dietary PUFA enhancing the proportion of n-3 fatty acids of fat tissue in pigs [33, 34].

Dietary Supplement During the First Half of Gestation

Present findings clearly show that diet supplement with either OO or FO during G1 modify the fatty acid profile of plasma not only at the end of the dietary treatment period but during lactation, as well as the FA composition of both the colostrum and mature milk. This is especially highlighted by the increase of DHA found in G1 FO sows; it is speculated that such changes must be originally caused by its high presence in this oil. In fact, although α-linolenic acid (ALA) can be converted into DHA, from studies in humans it is known that the conversion is low, especially when the absolute amount of ALA in the diet is low [35], as it was the case in our animals, which ALA in the diet

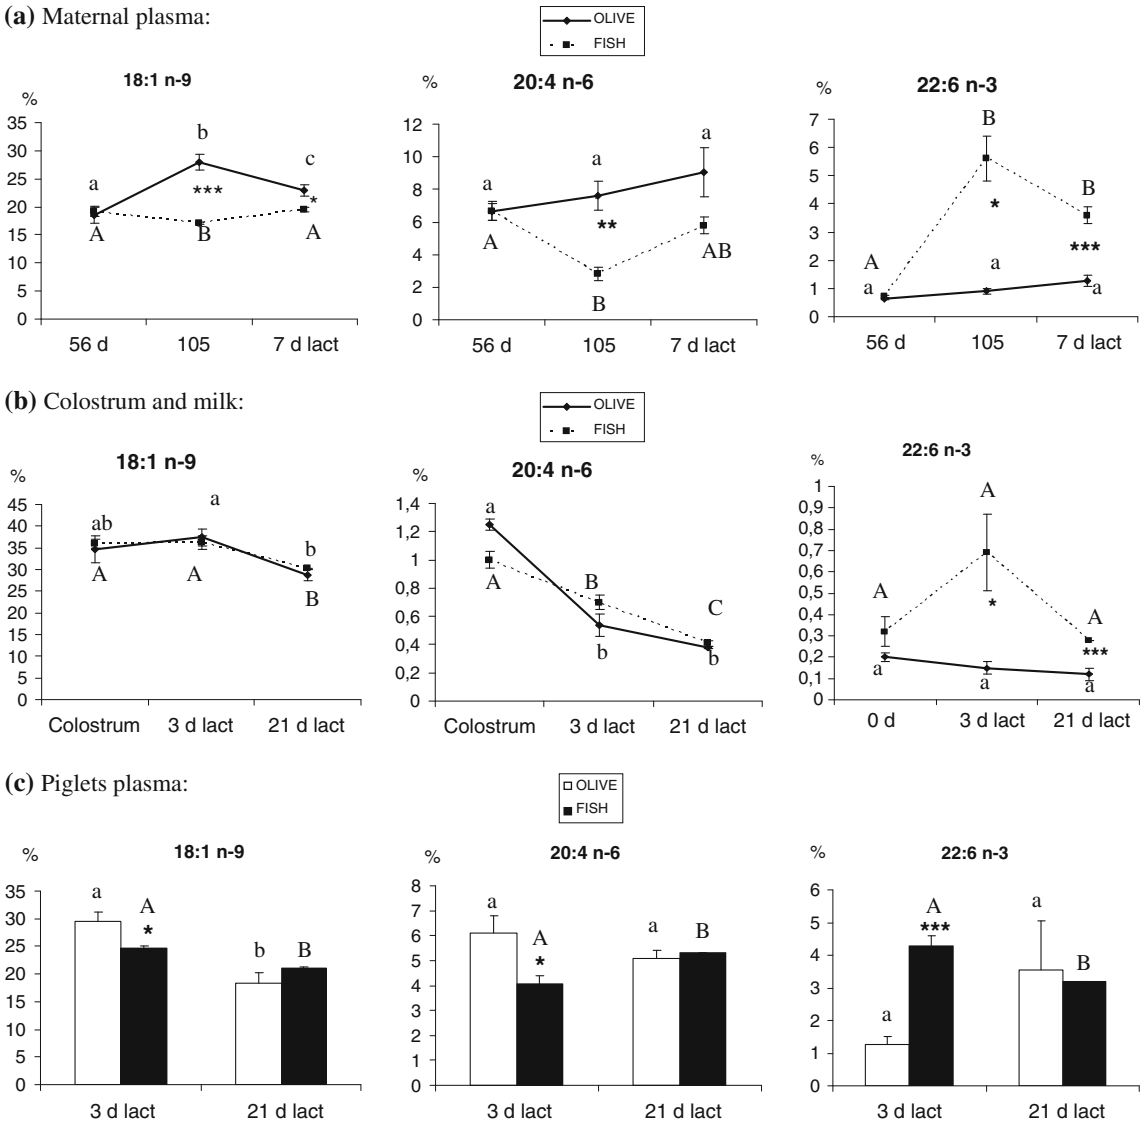

Fig. 2 Proportions of oleic, arachidonic and docosahexaenoic acids in maternal plasma, colostrum and milk and piglets plasma from sows fed either an olive oil supplemented diet or a fish oil supplemented diet during the second half of gestation. (% = g/100 g fatty acid). Student's *t* test was used to compare values between olive oil and fish oil groups within the same day and are shown by *asterisks*: $*p < 0.05$, $**p < 0.01$, $***p < 0.001$. Tukey's test was used to determine differences between different time points after one-way ANOVA and shown by *small letters* in the olive oil group and by *capital letters* in the fish oil group (*different letters* indicating statistically significant differences, $p < 0.05$)

was practically absent. Our explanation for this increase in DHA in both lactating sow plasma and in milk, more than 50 days after dietary supplementation had ceased, is that DHA was accumulated in adipose tissue during the first half of gestation, when the animals were receiving the fish oil supplement, and subsequently released around parturition.

In sows, when energy intake is adequate, during gestation there is an increase in body fatness [36], the effect being particularly striking during the first half of gestation [37]. Besides, studies in humans and in rats, have revealed that the mother is in an anabolic condition during the first half of pregnancy as result of enhanced plasma insulin levels [38, 39] and insulin sensitivity [32, 40, 41], and this justifies the augmented LPL activity found in adipose tissue in the rat at mid pregnancy [12, 42]. Thus, circulating LCPUFA transported in their esterified form associated to triacylglycerol-rich lipoproteins [11, 31, 43] are hydrolyzed by the LPL activity present in capillary endothelium of adipose tissue and released fatty acids are taken up by the subjacent tissue to be reesterified for storage. Indeed, under non-pregnant conditions it has been shown that in human adipose tissue the relative mobilization rate of DHA is lower than of other LCPUFA [44], and in the rat fed FO

diet it has been demonstrated that this fatty acid is retained in adipose tissue during late pregnancy at a higher proportion that any other LCPUFA [45]. It is, therefore, proposed that DHA after being taken up and stored in adipose tissue during the first half of pregnancy is mobilized during late pregnancy and the first days of lactation, when lipolytic activity is highly enhanced [17, 46, 47], becoming available to the mammary gland for milk synthesis. This proposal fits with the high proportion of DHA seen in the plasma at day 7 of lactation and in colostrum and milk at days 3 and 21 of lactation in sows on the diet supplemented with FO during G1.

The highest proportion of DHA in plasma seen in G1 FO sows during the last days of their treatment was associated with a decreased proportion of AA. As AA was practically absent in the diet, plasma AA must come from endogenous synthesis, and such a decline in AA could be therefore interpreted as an inhibition of this pathway as a result of the well-known inhibitory effect of DHA on the Δ6 desaturase [48, 49], which is a key enzyme for AA synthesis from its essential fatty acid precursor, linoleic acid. Since AA does not differ in colostrum or milk of sows that received the FO or OO supplement, probably due to the fact that mammary gland AA synthesis from linoleic acid is low [50], a similar reasoning could be applied to the decreased proportion of AA consistently seen in the plasma of piglets of sows receiving a FO-supplemented diet during G1. The augmented proportion of DHA present in colostrum and mature milk would allow a higher availability of this fatty acid to the suckling piglets' liver, where the most active synthesis of AA takes place, thereby inhibiting this pathway. Moreover, AA synthesis has been shown to be effective in term and preterm infants [4, 51–53] and fetal baboons [54], and we propose that it is also active in our suckling piglets, with this pathway being inhibited at early lactation in those animals born to G1 FO sows as a consequence of their enhanced availability of DHA.

Dietary Treatment During the Second Half of Gestation

The effects of fatty acid dietary supplementation during the second half of gestation found here agree with and amplify those previously reported. The influence of dietary fatty acids during lactation on milk fatty acid composition has been well recognized in humans [19, 55, 56] and has been associated to the fatty acid composition in maternal adipose tissue [29, 30]. Dietary fatty acids during pregnancy in rats have been shown to determine their proportion in maternal adipose tissue [45, 57, 58], and feeding tuna oil in sows during late pregnancy is known to affect fatty acid composition in newborn piglet tissues and plasma [8, 59].

During the last third of gestation the mother is in a net catabolic condition, where breakdown of fat depots is increased and maternal hyperlipidemia develops [32]; circulating PUFAs coming from either the diet or released from adipose tissue are mainly transported in their esterified form associated to different lipoproteins [31, 43]. Around parturition there is an induction of LPL activity in the mammary gland [13], which drive circulating triglyceride-rich lipoproteins to mammary gland [20] for their hydrolysis and tissue uptake of the hydrolytic products, actively contributing to the disappearance of such maternal hyperlipidemia and to the onset of milk synthesis. Since both mammary gland LPL and adipose tissue lipolytic activity remain augmented during lactation, it is not surprising that LCPUFA present in maternal adipose tissue could affect maternal plasma and milk fatty acid composition for a certain period of time, independently of the diet composition at that particular time. This was seen in the current study as the proportion of n-3 fatty acids, and more specifically of DHA in plasma and milk at 7 and 21 days after parturition, respectively, were higher in lactating sows that were fed the FO supplemented diet during G2 compared to those receiving an OO supplemented diet.

It is worth commenting that the OO supplemented diet only increased the proportion of OA in maternal plasma during the experimental period. This is probably a consequence of the active Δ9 desaturase normally present in the adult liver and in the mammary gland during lactation [60, 61], which facilitates an active OA synthesis. Its proportion in lactating sows plasma and in colostrum or mature milk becomes independent of what the sows were fed during the G2. Here again, special attention should be paid to the AA values. The absence of this fatty acid in any of the diets forces the endogenous synthesis from its main source linoleic acid. As commented above, the inhibitory action of DHA and EPA on the Δ6 desaturase seems to be responsible for the low proportion of AA shown in maternal plasma of sows fed with a diet supplemented with FO as well as in plasma of their piglets at day 3 of suckling.

Conclusion

Although further studies are needed to establish the efficacy of the various feeding strategies to provide n-3 LCPUFA for foetal and infant development and growth, the present findings allow us to reach the following conclusions.

The maternal dietary fatty acid composition, specifically during the first half of gestation, influences the fatty acid composition in the milk of lactating sows and in the plasma of newborn piglets in a manner similar to the influence of maternal dietary fatty acid composition during the second half of gestation. This indicates an important role of maternal adipose tissue as a store of dietary LCPUFA,

especially DHA, during the anabolic stage of gestation, which are mobilized around parturition and early lactation to be used for milk synthesis, making them available to the suckling newborn. Also, an excess of dietary n-3 LCPUFA, like DHA and EPA caused by a FO supplement during pregnancy, decreases the availability of AA in suckling newborns.

Acknowledgments We thank Milagros Morante, Kate Perkins, Anne Corson and Jennie Litten, for their excellent technical assistance and the staff at Imperial College London's pig unit for the maintenance and supply of animals used in this study. Molecular Dynamics and Partitioning of Di-*tert*-butyl Nitroxide in Stratum Corneum Membranes: Effect of Terpenes

Heverton Silva Camargos · Adolfo Henrique Moraes Silva · Jorge Luiz Vieira Anjos · Antonio Alonso

Received: 26 October 2009 / Accepted: 8 March 2010 / Published online: 2 April 2010

Abstract In this work, we have used electron paramagnetic resonance (EPR) spectroscopy of the small spin label di-*tert*-butyl nitroxide (DTBN), which partitions the aqueous and hydrocarbon phases, to study the interaction of the terpenes α-terpineol, 1,8-cineole, L(−)-carvone and (+)-limonene with the uppermost skin layer, the stratum corneum, and the membrane models of 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylcholine (DPPC) and 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC). The EPR spectra indicated that the terpenes increase both the partition coefficient and the rotational correlation time of the spin labels in the stratum corneum membranes, whereas similar effects were observed in the DMPC and DPPC bilayers only at temperatures below the liquid-crystalline phase. The EPR parameter associated to probe polarity inside the membranes showed thermotropically induced changes, suggesting relocations of spin probe, which were dependent on the membrane phases. While the DMPC and DPPC bilayers showed abrupt changes in the partitioning and rotational correlation time parameters in the phase transitions, the SC membranes were characterized by slight changes in the total range of measured temperatures, presenting the greatest changes or membranes reorganizations in the temperature range of ∼50 to ∼74 °C. The results suggest that terpenes act as spacers, weakening the hydrogen-bonded network at the polar interface and thus fluidizing the stratum corneum lipids.

Introduction

The major limitation of implementing transdermal drug delivery systems is the generally low permeability of the drug across the skin. Several approaches have been implemented to facilitate drug transport through the skin. One important approach is the use of chemical penetration enhancers, which ideally reduce the resistance of the physical barrier of the SC safely and reversibly to enhance the drug's delivery through the skin. In particular, terpenes have been reported as permeation enhancers of several polar and non-polar drugs and many terpenes, including 1,8-cineole, menthol and α-terpineol, are claimed to be generally recognized as safe (GRAS) materials. The interactions of terpenes with the SC are of interest to understand how small amphiphilic molecules may enhance skin permeability. It is generally accepted that penetration enhancers may increase the permeability of a drug mainly by affecting the intercellular lipids of the SC via extraction or fluidization [1] and/or by increasing the partitioning of the drug in the SC

membranes [2]. However, very few studies have focused on mechanisms of permeation enhancement by terpenes in SC. The most commonly used techniques are Fourier transform infrared spectrophotometry (FTIR) and differential scanning calorimetry (DSC) [3–5] and small-angle X-ray diffraction [5].

Electron paramagnetic resonance (EPR) of spin labels has been employed to obtain information on the molecular dynamics of SC membranes [6–12] and SC proteins [13–16] in the intact tissue. The EPR spectra of spin-labeled stearic acids in SC membranes were able to distinguish two main environments for the probe distribution into the membranes. In a previous study [9], the origin of these two spectral components was interpreted based on the ability of spin labels to participate in intermolecular hydrogen bonding within the membrane. The more motionally restricted component was assigned to a class of spin probe hydrogen bonded to the polar head groups (more rigid structure) and the more mobilized component was attributed to the spin labels temporarily non-hydrogen-bonded to the polar interface and more deeply inserted in the hydrophobic core. Recently, the effect of the terpenes L-menthol and 1,8-cineole on the SC lipid dynamics was examined in detail [10, 11]. The presence of 1% terpenes (w/w) in the solvent drastically increased the lipid fluidity, especially by transferring the spin probes from a more to a less motionally restricted spectral component into the membranes. Furthermore, these two terpenes increased the rotational diffusion rates only of spin probes from the more mobilized component.

In a more recent work, we used the small water-soluble spin label TEMPO, which partitions between the bilayer and aqueous phase, to examine the interactions of terpenes with the SC membranes [12]. Since the partitioning of a substance in a membrane correlates with the drug's absorption [17] and is an essential step in diffusion [18], this spin probe may be used to mimic drugs and thus to investigate the mechanisms of terpenes as accelerants of permeation in the SC. This spin probe was sensitive to the phase transitions of SC membranes and showed that, in essence, terpenes increase the molecular mobility and partitioning in SC membranes at much lower concentrations than those generally used for these terpenes as skin penetration enhancers. In the present study, the spin label DTBN, also of low molecular weight (145 g) but with higher molecular dynamics and considerably better EPR spectral resolution than that of TEMPO, was used seeking to obtain more detailed information about the influence of terpenes on SC membranes and bilayer models of DMPC and DPPC, particularly on the major probe's localization within these membranes.

Materials and Methods

Preparation of SC Membranes

SC membranes of neonatal Wistar rats less than 24 h old were prepared as described previously [10–12]. After the animal was killed, its skin was excised and fat removed by rubbing in distilled water. The skin was allowed to stand for 5 min in a desiccator containing 0.5 L of anhydrous ammonium hydroxide, after which it was floated in distilled water for 2 h with the internal side in contact with the water. The external side was placed in contact with a filter paper and the SC sheet was carefully separated from the remaining epidermis. Subsequently, the SC was transferred to a Teflon-coated screen, washed with distilled water and allowed to dry at room temperature. The membranes were stored with 1 L of silica gel in a desiccator under a moderate vacuum.

Spin Labeling and Treatment of SC

In order to prevent nitroxide reductions, the sulfhydryl groups of the SC tissue were blocked by incubating the SC membranes in a solution of 50 mM *N*-ethyl maleimide (Sigma Chem. Co., St. Louis, MO, USA) for about 15 h. The SC membranes were dried again and an intact portion of SC (3 mg) was then rehydrated and incubated for 90 min in 45 μL of acetate-buffered saline (10 mM acetate, 150 mM NaCl and 1 mM EDTA, pH 5.5) plus 5 μL of ethanol containing the corresponding terpene concentration (Acros Organics, Geel, Belgium). After this incubation, 0.2 mM spin label DTBN (Fig. 1) purchased from Sigma Chem. Co. (St. Louis, MO, USA) was added and the intact SC membrane was then introduced into a 1-mm ID capillary for EPR measurements. The excess solvent was removed and the capillary was flame-sealed. The molecular structures of spin label DTBN and of terpenes used in this work are shown in Fig. 1.

Preparation of Lipid Dispersions

DPPC or DMPC, purchased from Avanti (Alabaster, AL), was dissolved in a mixture of chloroform:methanol (2:1) and dried under a nitrogen stream. The residual solvent was removed by vacuum-drying the tube overnight. In the hydration step to form multilamellar vesicles, the samples were incubated in PBS (10 mM phosphate, 150 mM NaCl and 1 mM EDTA, pH 7.2) for about 5 min at 50 °C and subsequently vortexed several times. 2 μL of 10 mM DTBN and 1.5 μL terpene in ethanol solution (about 33%, v/v, depending on the density of the terpene) were added to each sample containing 3 mg DPPC or DMPC membranes

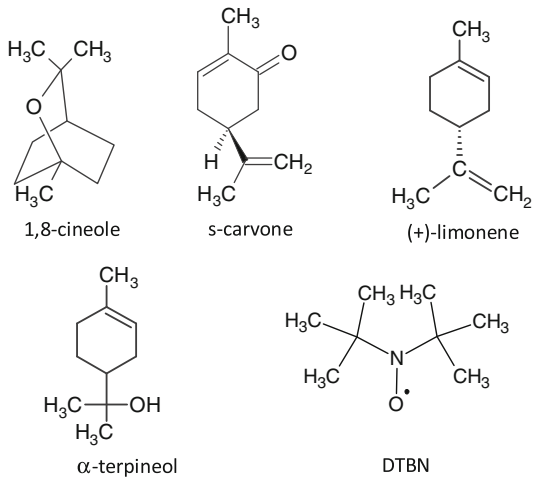

Fig. 1 Chemical structures of terpenes and spin label DTBN used in this work

in 40 μL PBS. The suspension was vortexed again and transferred to a capillary, which was then flame-sealed.

EPR Spectroscopy

EPR spectroscopy was carried out with a Bruker ESP 300 spectrometer (Bruker, Rheinstetten, Germany) equipped with an ER 4102 ST resonator and a Bruker temperature controller. The instrumental settings were: microwave power of 2 mW; modulation frequency of 100 kHz; modulation amplitude of 0.25 G; magnetic field scan of 100 G; sweep time of 168 s; and detector time constant of 41 ms. The capillary containing the sample was introduced into a 3-mm ID quartz tube together with a fine-wire thermocouple to monitor the sample's temperature. EPR spectra simulations were performed using the software EPRSIM (version 4.99) [19, 20]. This program allows a single spectrum to be fitted with two components having different mobility and magnetic tensor parameters. For each spectral component, the program provides the relative population and the associated rotational motion of the probe, through the parameter rotational correlation time, τ_c. The magnetic tensor values used for the simulation were $g_{xx} = 2.0099$, $g_{yy} = 2.0061$, and $g_{zz} = 2.0024$ for the g-tensor, and $A_{xx} = 5.3$ G, $A_{yy} = 7.0$ G, and $A_{zz} = 35.0$ G for the A-tensor [21]. In the limit of fast motion, where the motional narrowing approximation is valid, the τ_c is described as follows [22]:

$$\tau_c = \frac{\sqrt{3} g_{iso} \beta \, \Delta H(0)}{2h \quad (C - B)} \left[1 - \sqrt{\frac{1(0)}{1(-1)}} \right] \tag{1}$$

where $g_{iso} = 1/3(g_{xx} + g_{yy} + g_{zz})$ is the isotropic g-factor, β is the Bohr magneton, h is Planck's constant, H is the external magnetic field, $\Delta H(0)$ is the central line peak-to-peak linewidth, and $I(0)$ and $I(-1)$ are the intensities of central and high field resonance lines, respectively. Parameters B and C are derived in terms of the g- and A-tensor anisotropies through the following expressions:

$$B = \frac{-16\beta H}{45h}(A_{zz} - A_{xx}) \left[g_{zz} - \frac{1}{2}(g_{xx} + g_{yy}) \right], \tag{2}$$

and

$$C = \frac{2\pi^2}{9}(A_{zz} - A_{xx})^2. \tag{3}$$

These magnetic interaction tensors A and g were linearly corrected using the fitting program with polarity correction factors on the trace of hyperfine coupling tensor A and the spin-magnetic field coupling tensor g, denoted by parameters p_A and p_g, respectively. The EPR signal corresponding to the interaction electron-spin nuclear C-13 spin coupling is present in the EPR spectra of DTBN (satellite lines); in the program, a magnitude of 5.6 G with abundance of 0.0115% was assumed for this interaction.

Results

Analysis of EPR Spectra

The typical EPR spectrum of spin probe DTBN (Fig. 1) in membrane is shown in Fig. 2. The spectrum is composed of two spectral components, H (Fig. 2c) and P (Fig. 2d), which are provided by the spin-label fractions dissolved in the hydrophobic and polar environments, respectively. Figure 2b shows the same experimental EPR spectrum (line) and its best-fit spectrum (open circles), which is the sum of the components H (spectrum c) and P (spectrum d). The fitting program was able to simulate the lateral satellite lines originating from the electron-spin nuclear C-13 spin coupling. The experimental (line) and best-fit (open circles) EPR spectra of DTBN in DMPC, DPPC and SC membranes are shown in Fig. 3 for three temperatures, where is possible to observe that the relative population of component H increased by raising the temperature.

Partition Coefficient of DTBN between the Hydrocarbon and Polar Phases

According to the solubility-diffusion mechanism, the permeability coefficient, P, of a molecule crossing a bilayer membrane is generally related to the partition coefficient in the bilayer, K, the diffusion constant across it, D, and the bilayer thickness, Δx, by the following equation [23]:

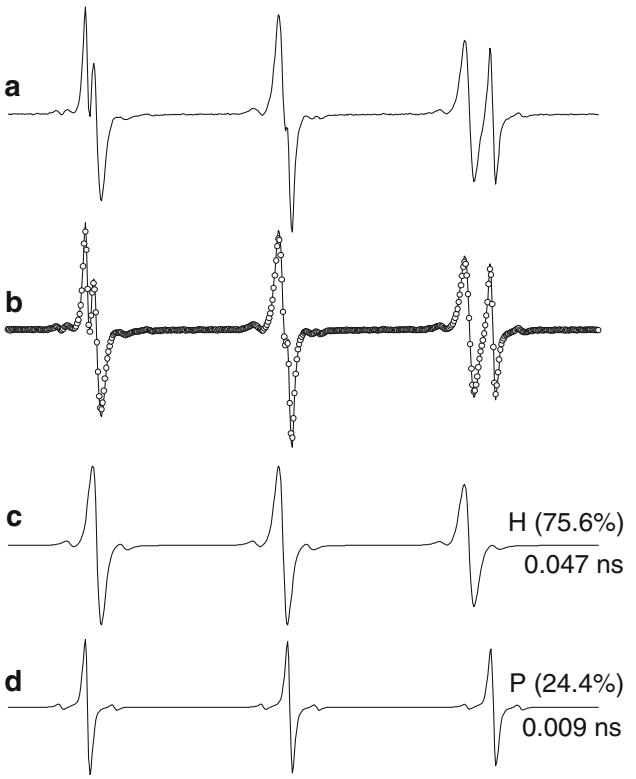

Fig. 2 **a** EPR spectrum of DTBN in stratum corneum (pH 5.1, 50 °C); **b** the same spectrum (*line*) superimposed with its best-fit EPR spectrum (*open circles*). The best-fit spectra were obtained with the fitting program EPRSIM, using a simulation model of two spectral components. The theoretical component H (spectrum c) refers to the spin label fraction in the hydrophobic environment and the component P (spectrum d) is generated by the spin probes in solvent. The figure also indicates the fitting results: the percentage of spin label in each component, N_H and N_P, and its respective rotational correlation time, τ_c, in ns. The total scan range of the magnetic field was 50 G

$$P = KD/\Delta x. \tag{4}$$

The diffusion coefficient is defined as:

$$D = k_B T/6\pi\eta r, \tag{5}$$

where $k_B T$ is the thermal energy, η is the membrane viscosity, and r is the molecular radius. The partition coefficient is the equilibrium ratio of the solute concentration in the bilayer, c_H, and in aqueous concentration, c_P. K can be determined if the relative volumes of membrane and solvent in the sample are known.

$$K = c_H/c_p. \tag{6}$$

or

$$K = (N_H/V_{membrane})/(N_p/V_{solvent}), \tag{7}$$

where N_H and N_P are the relative spin-label populations in the hydrophobic and polar environments, respectively, that are provided by the fitting program. The relative membrane-solvent volumes for the two systems were estimated taking into account the volume of sample in the capillary tube (about 20 μL) and the weight before and after drying the sample; the water content in the samples (w/w) was on average 22% for DPPC or DMPC and 65% for SC. It was considered that the SC has 16% lipids (w/w) relative to dry tissue [24].

The standard Gibbs free energy change required to transfer a molecule from an aqueous to a hydrocarbon phase, ΔG°, can be calculated based on the partition coefficient, as follows [25, 26]:

$$\Delta G^\circ = -RT \ln K, \tag{8}$$

or

$$\ln K = -\Delta H^\circ/RT + \Delta S^\circ/R, \tag{9}$$

where R is the gas constant, T is the absolute temperature, ΔH° is the standard enthalpy change for transferring the permeating molecules from solvent to the interior of the membrane, and ΔS° is the associated entropic change.

The thermodynamic parameters can be obtained from a van't Hoff plot of ln K versus $1/T$, as shown in Fig. 4. This type of plot is suitable for analyzing phase transitions, since the slope coefficient of each curve yields $\Delta H^\circ/R$. The phase transitions observed for DPPC bilayers are well known [27, 28]: the transition at ~34 °C corresponds to the gel structure ($L_{\beta'}$)-ripple structure ($P_{\beta'}$) phase transition, called pre-transition, and the transition at ~42 °C corresponds to a ripple structure ($P_{\beta'}$)-fluid bilayer structure (L_α) phase transition. In DMPC, these phase transitions occur at ~13 °C ($L_{\beta'}$–$P_{\beta'}$) and 23 °C ($P_{\beta'}$–L_α) [27]. In the presence of terpenes, it appears that only the phase transition ($P_{\beta'}$–L_α) is still present and that the transition temperatures are about 8 °C lower. Compared to phospholipid bilayers, SC membranes are characterized by phase transitions with minor changes within a temperature range whose highest slope lies between ~50 and ~74 °C. DMPC and DPPC membranes were not affected by terpenes in the liquid-crystalline phase but showed pronounced effects below the $P_{\beta'}$–L_α phase transition. In contrast, the SC samples presented increases of DTBN partitioning caused by terpenes in the entire temperature interval.

Molecular Dynamics of DTBN into Hydrocarbon and Aqueous Phases

Figure 5 shows the rotational correlation time parameter, τ_c, of DTBN in DMPC, DPPC and SC plotted on a logarithmic scale as a function of the reciprocal absolute temperature. Panels A and B refer to spin labels in the membrane and solvent, respectively. These well-known Arrhenius plots allow us to calculate the apparent

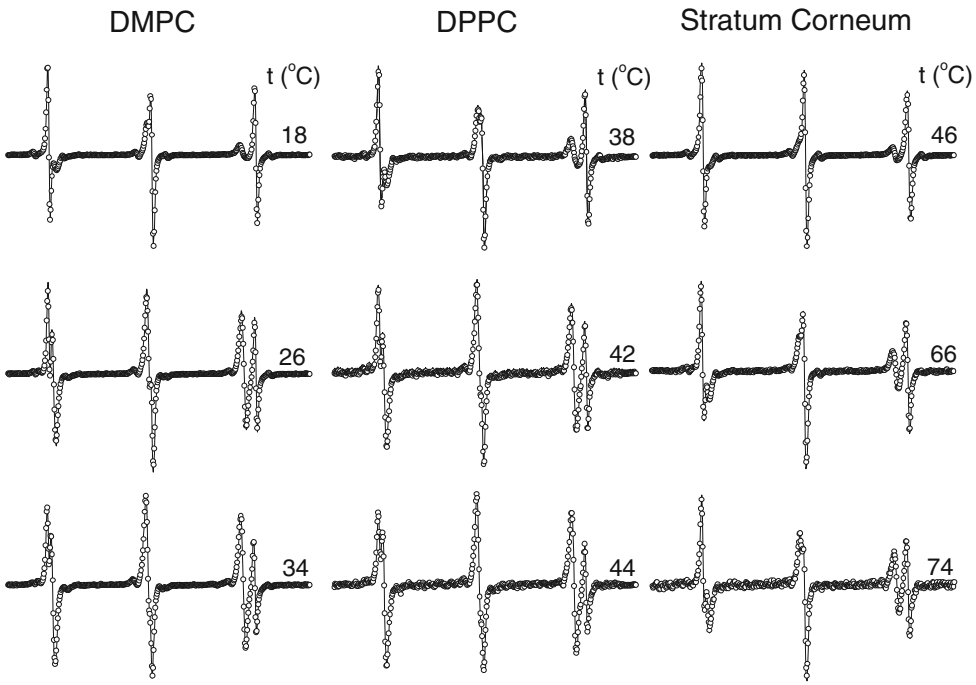

Fig. 3 Experimental (*line*) and best-fit (*open circles*) EPR spectra of DTBN in DMPC, DPPC, and stratum corneum membranes at several temperatures. The total scan range of the magnetic field was 50 G

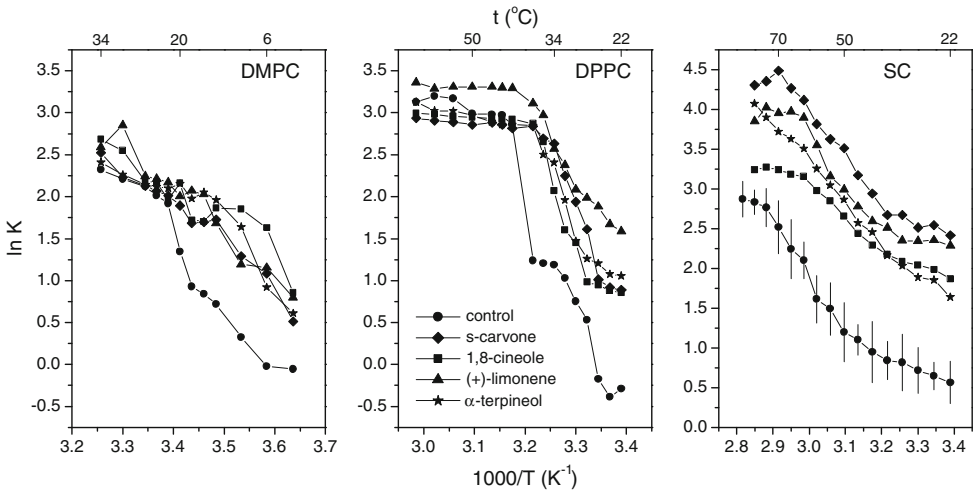

Fig. 4 Natural logarithm of the partition coefficient, ln *K*, of DTBN in multilamellar vesicles of DMPC, DPPC and stratum corneum (SC) membranes versus the reciprocal absolute temperature. Terpenes were added at a terpene:lipid molar ratio of 0.75:1 for DMPC and DPPC and at 1% terpene (w/v) in stratum corneum

activation energy, E_a, of rotational motion in the regions of linear dependence, using the following equation:

$$1/\tau_c = A\exp(-E_a/RT), \tag{10}$$

where A is a pre-exponential factor and E_a is the energy barrier that the spin probe must overcome to achieve higher states of motion. The greater the slope in these plots the higher the E_a values and the breaks in slopes indicate possible phase transitions. The terpenes did not increase the rotational motion of the spin probe in the fluid phase of DMPC and DPPC bilayers, where the partition coefficients were higher. Figure 5b shows that the τ_c parameter of spin labels in SC aqueous phase increased with temperature, suggesting that spin probes from the polar phase may penetrate the region of the polar head groups.

Polarity Environments of DTBN into Hydrocarbon and Aqueous Phases

The EPR parameter isotropic hyperfine coupling constant, a_0, is associated with the polarity of the solvent in which the nitroxide radical is dissolved. To examine the predominant location of DTBN in the membranes and ascertain if terpenes can alter this location, the parameter a_0 of the three systems under study was measured in the presence and absence of terpenes (Fig. 6). Polarity profiles through membrane were determined in spin-labeled glycerophospholipids with the DOXYL-nitroxide group at position n in the *sn*-2 chain (n-PCSL) in DPPC membranes, whose a_0 values were 15.1 G for $n = 4$ and 14.5 G for $n = 16$ [29]. The a_0 values observed for DTBN in DMPC,

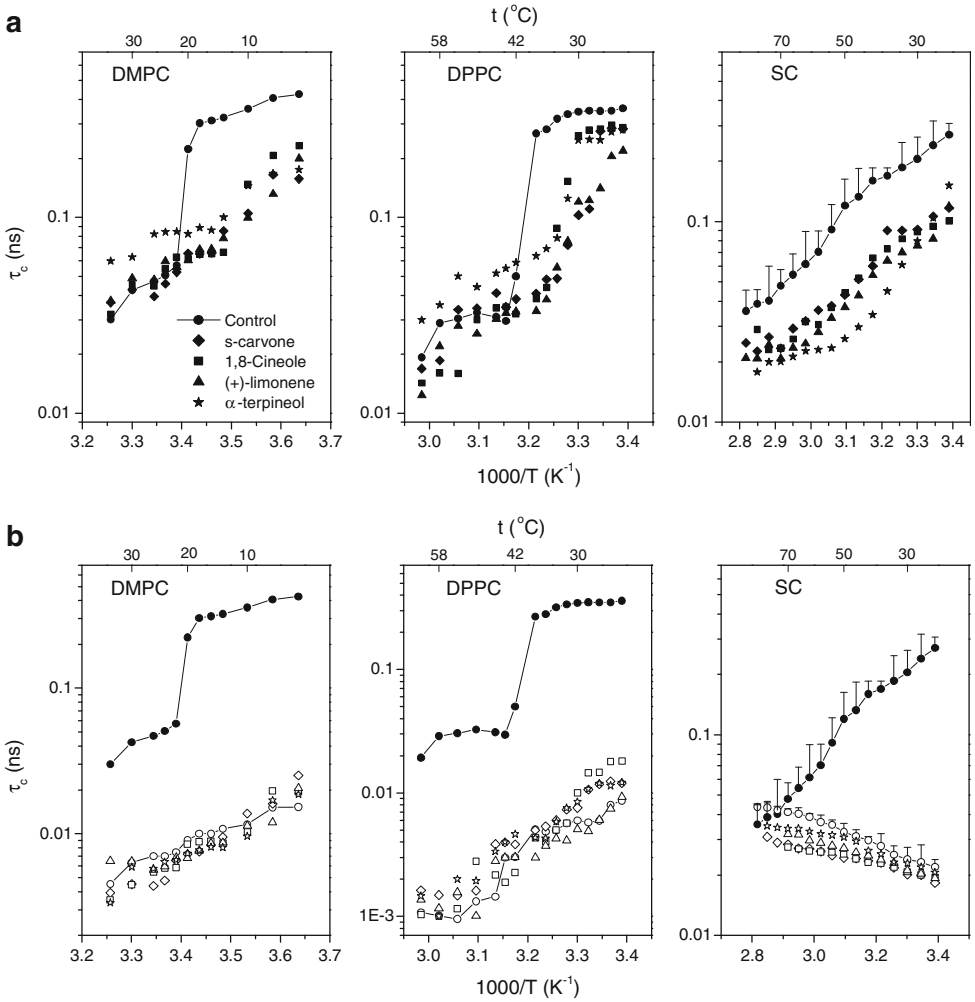

Fig. 5 Rotation correlation time, τ_c, of DTBN in DMPC, DPPC and stratum corneum (SC) membranes versus the reciprocal absolute temperature. **a**, **b** refer to DTBN in hydrocarbon and aqueous phases, respectively. Terpenes were added at a terpene:lipid molar ratio of 0.75:1 for DMPC and DPPC and at 1% terpene (w/v) in stratum corneum

DPPC and SC membranes were in the range of 15.55–15.85 G (Fig. 6). The a_0 parameters were measured at 25 °C for the spin labels DTBN and DOXYL (5-DOXYL stearic acid) in terpenes and other solvents, with varying dielectric constants (data not shown) and the a_0 values found for DTBN were on average 1.0 higher than DOXYL. Similar results were reported recently in a study comparing the a_0 values of several spin labels with those of DOXYL class [30]. Thus, with the subtraction of 1.0 G from the a_0 values presented in Fig. 6, the maximum value reached would be 14.85 G, which corresponds to the mean value between 14.5 ($n = 16$) and 15.1 ($n = 4$) observed for DOXYL in the bilayers. Therefore, the a_0 values of about 15.85 G observed above the main phase transition of DMPC and DPPC (Fig. 6) is consistent with the DTBN distributed throughout the membrane, while the value of about 15.6 G found in the gel phases is compatible with the probes located predominantly in the center of bilayer.

DMPC and DPPC in the presence of α-terpineol and (+)-limonene presented polarity levels similar to those above the main phase transition, whereas in the case of L(−)-carvone and 1,8-cineole, such levels were only observed above 6 °C for DMPC and above 26 °C for DPPC. In contrast, in the SC samples, only α-terpineol maintained the probe's polarity at the highest level observed and the other terpenes did not significantly change the probe's polarity. A particular characteristic of α-terpineol is that it contains a hydrogen-bonding donor group to form hydrogen-bonded nitroxide.

As can be observed in Fig. 6a, the polarity detected by the spin labels in SC aqueous phase decreased with increasing temperature, suggesting that the probes outside the membrane may enter the membrane in the vicinities of the polar groups and that the probability of this occurrence increases with temperature. This behavior is also apparent for DPPC and, in this case, seems to reflect the main bilayer phase transition. The terpenes did not alter the solvent's polarity.

Discussion

In the current study, the better EPR spectral resolution of DTBN relative to that of TEMPO, used in previous work [12], was explored to obtain additional information about

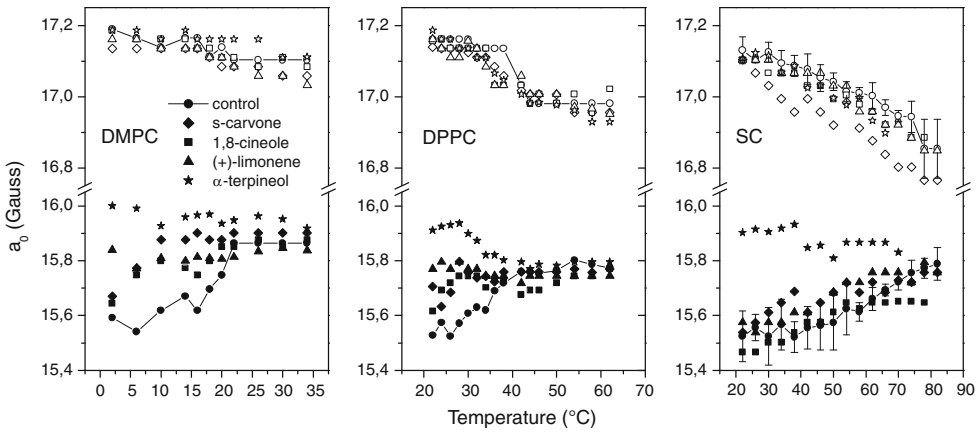

Fig. 6 The EPR parameter isotropic ^{14}N-hyperfine splitting constant, a_0, of DTBN in DMPC, DPPC and stratum corneum (SC) membranes as a function of temperature

the probe's polarity. The EPR parameter a_0, which is sensitive to the environmental polarity of nitroxyl spin labels, indicated that DTBN is distributed throughout the membranes of DMPC and DPPC in the liquid-crystalline phase and this also occurs in SC at higher temperatures (~60–80 °C). At lower temperatures, however, the spin label tends to concentrate in the central region of the membranes. Interestingly, in the case of DMPC and DPPC bilayers, the thermally induced relocation of DTBN into the bilayer reflected their main phase transitions (Fig. 6). Furthermore, the DTBN from aqueous phase should penetrate the region of the polar head groups, as deduced from the temperature-induced reduction of its environmental polarity (Fig. 6), and the concomitant reduction of rotational motion (Fig. 5b). The thermotropic behavior of the partitioning and rotational motion of DTBN in SC membranes presented here is in close agreement with the data obtained by Fourier transform infrared spectroscopy (FTIR) in a study of the thermotropic phase behaviors in porcine SC and its extracted lipids. That study found a more pronounced increase of νsCH_2 in the temperature range of ~60 to ~80 °C, which was associated with alkyl chain melting [31].

In this work, the EPR spectra were simulated using the fitting program EPRSIM instead of the NLLS, which was less suitable in the specific case of DTBN, especially due to the presence of satellite lines in the spectra and the faster rotational motion of this probe. Whereas the program NLLS generates the parameter Log Rbar, whose value for TEMPO in SC samples at 70 °C was 9.1 [12], the EPRSIM generates τ_c, whose corresponding value for DTBN was 0.035 ns (Fig. 5a). Because the transformation is given by $\text{Rbar} = 1/6\tau_c$, the corresponding Log Rbar for DTBN will be 9.7, which represents a greater rate of rotational diffusion. Efforts were made to describe the phase transitions in SC membranes through these probes. The increases in the slopes observed in the curves of control samples plotted in Figs. 4 and 5a, which were apparent in the temperature range of ~50 to ~74 °C, were analyzed exhaustively. At ~50 °C, the change in slope was clear in all the experiments, while the decrease in slope at ~70 °C was the result of an average, but was not clearly visible in all the experiments. It is interesting to note that the rotational correlation times of spin probe in the membranes (Fig. 5a) also reflected their phase transitions and the terpenes' effects further support the results observed for the partition coefficient in Fig. 4. DSC experiments have identified four phase transitions in neonatal rat SC (used in this work) at about at 42 °C (T_1), 55 °C (T_x), 70 °C (T_2) and 78 °C (T_3), which have been attributed to lipid melting [4]. The two major phase transitions in human SC occur at 72 °C (T_2) and 83 °C (T_3), and the terpenes D-limonene and 1,8-cineole have been found to reduce the temperatures of these two transitions by about 20 °C [5]. Here, the phase transitions were not clearly defined in the presence of terpenes, but in general, a reduction of at least 8 °C in the temperatures of the main phase transitions may be observed for DMPC, DPPC and SC.

Attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) has been used to study the molecular organization of a model SC lipid system and, in the presence of the terpenes 1,8-cineole and L-menthol, alterations were detected in the amide-I frequencies, suggesting that they disrupt the hydrogen-bonding network at the membrane interface [32]. These results are in agreement with those obtained by EPR spectroscopy of spin-labeled analogs of stearic acid incorporated in SC membranes, where 1% L-menthol or 1,8-cineole (w/v) caused a dramatic increase in the membrane fluidity [10, 11]. The authors' interpretation of this finding was that terpenes weaken the hydrogen-bonded network of the polar head groups. In the present work, we studied one terpene containing a hydrogen-bonding donor group (the alcohol α-terpineol), two with hydrogen-bonding acceptor groups (the ether 1,8-cineole and the ketone L(−)-carvone), and one that does not have polar groups [the hydrocarbon

(+)-limonene]. Although terpenes can, in principle, weaken the hydrogen-bonding interactions at the membrane–water interface, the results of the present work suggest that the effects of terpenes on membranes do not necessarily depend on direct competition for H-bonds with the polar head groups, since the effects of (+)-limonene, which does not form H-bonds, did not differ significantly from that of the other terpenes.

In conclusion, using a small spin label to mimic a drug, this study shows that, at a concentration of 1% (w/v) in SC membranes, terpenes increase the partitioning and rotational motion of the spin probe throughout the temperature range measured. The action of terpenes on ordered membranes is stronger, as in the case of SC, and diminishes when the membrane is already disordered, like DMPC and DPPC bilayers in the liquid-crystalline phase. In comparison with the other two membrane systems, the thermotropic behavior of SC membranes was characterized by phase transitions with minor changes, showing the greatest thermally induced changes in the temperature range of $\sim$50 to $\sim$74. Polarity measurements indicated a throughout distribution of DTBN in the membranes at higher temperatures and a major location in the center of the membranes at lower temperatures (in the physiological range of SC). In addition, the polarity measurements also showed that a fraction of the spin probes outside the membrane may penetrate the polar interface of the membranes and that this fraction of probes gradually increases with rising temperature. Terpenes are small molecules that are able to penetrate the membrane and, at higher concentrations, may effectively act as spacers, increasing the membrane's fluidity and weakening the hydrogen-bonded network of the polar interface. This process may facilitate the partition of small polar molecules and, hence, their permeation through membranes. Since the effects of different types of terpenes on the membranes did not differ significantly, this work also shows that, in practice, terpenes or combinations of terpenes may be chosen in order to achieve permeation enhancement effects at physiological temperatures with minimal toxicity to the skin.

Abstract Recently, we reported that administration of *Bifidobacteria* resulted in increased concentrations of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in murine adipose tissue [1]. The objective of this study was to assess the impact of co-administration of *Bifidobacterium breve* NCIMB 702258 and the substrate for EPA, α-linolenic acid, on host fatty acid composition. α-Linolenic acid-supplemented diets (1%, wt/wt) were fed to mice ($n = 8$), with or without *B. breve* NCIMB 702258 (daily dose of 10^9 microorganisms) for 8 weeks. Two further groups received either supplement of *B. breve* alone or unsupplemented diet. Tissue fatty acid composition was assessed by gas liquid chromatography. Dietary supplementation of α-linolenic acid resulted in higher ($P < 0.05$) α-linolenic acid and EPA concentrations in liver and adipose tissue and lower ($P < 0.05$) arachidonic acid in liver, adipose tissue and brain compared with mice that did not receive α-linolenic acid. Supplementation with *B. breve* NCIMB 702258 in combination with α-linolenic acid resulted in elevated ($P < 0.05$) liver EPA concentrations compared with α-linolenic acid supplementation alone. Furthermore, the former group had higher ($P < 0.05$) DHA in brain compared with the latter group. These results suggest a role for interactions between fatty acids and commensals in the gastrointestinal tract. This interaction between administered microbes and fatty acids could result in a highly effective nutritional approach to the therapy of a variety of inflammatory and neurodegenerative conditions.

Introduction

Mammals can produce all but two of the fatty acids they require; thus linoleic acid (C18:2n-6, precursor of n-6

series of fatty acids) and α-linolenic acid (C18:3n-3, precursor of n-3 series of fatty acids) are essential dietary fatty acids. Although mammalian cells cannot synthesize these fatty acids, they can metabolize them into more physiologically active compounds through a series of elongation and desaturation reactions, in which linoleic acid is converted to arachidonic acid (C20:4n-6) and α-linolenic acid is metabolized to eicosapentaenoic acid (EPA) (C20:5n-3) via the action of the enzymes Δ^6 desaturase, Δ^5 desaturase and elongase [2]. The resulting highly unsaturated fatty acid metabolites play essential roles in cell membrane function, brain and nervous system development and function, and through the production of eicosanoids (thromboxanes, leukotrienes and prostaglandins) in the inflammatory process [2]. Eicosanoids derived from arachidonic acid, such as the 2-series prostaglandins and the 4-series leukotrienes are in general, regarded as being proinflammatory in nature [3, 4], whereas the eicosanoids derived from EPA, such as the 3-series prostaglandins and the 5-series leukotrienes are considered less inflammatory or even anti-inflammatory in nature [3–5]. Thus, by increasing the ratio of n-3 to n-6 fatty acids in the diet, and consequently favouring the production of EPA, the balance of eicosanoids can be shifted in a less inflammatory direction. EPA can be further metabolized to docosahexaenoic acid (DHA, C22:6n-3), which is one of the major n-3 polyunsaturated fatty acids (PUFA) in the brain. DHA is required for fetal brain development and is held to be critical in the newborn for appropriate development and intelligence [6]. Studies have also shown that DHA provides support to learning and memory events in animal models of Alzheimer's disease [7] and brain injury [8].

The human gut is a diverse microbial ecosystem containing about 100 trillion microorganisms, comprised of more than 1,000 different species, whose collective genome, the microbiome, contains ~100-fold more genes than the entire human genome [9]. It has been well documented that the enteric microbiota play an important role in the health and well-being of the host, exerting effects on host lipid metabolism and acting as an environmental factor that contributes to development of obesity [10, 11]. In this respect, recent studies suggest that symbiosis between the microbiome and the host influences energy extraction from the diet. In addition, the promotion of fat deposition and influence on systemic inflammation have been proposed as mechanisms by which the microbiome contribute to obesity [12].

Little is known regarding the interplay between members of the enteric microbiota and fatty acids. However, some interactions between PUFAs and components of the indigenous gut microbiota and some probiotics have been reported, which might affect the biological roles of both. Recent studies by our group and others have reported that intestinal bacteria of human origin can convert linoleic and linolenic acids to bioactive isomers of conjugated linoleic acid (CLA) and conjugated α-linolenic acid, respectively [13–15]. Some bacteria of marine origin are also known to synthesise EPA and DHA de novo through the actions of polyunsaturated fatty acid synthase genes, which results in EPA and DHA being abundantly present in fish and fish oil [16–19]. Furthermore, it has been shown that administration of probiotics (*Lactobacillus rhamnosus* GG and *Bifidobacterium animalis* subsp. *lactis* Bb12) to pregnant women had an affect on placental fatty acid composition [20]. It has also been demonstrated that administration of formula supplemented with different probiotics (*B. animalis* subsp. *lactis* Bb12 and *L. rhamnosus* GG) to infants resulted in changes in serum fatty acid composition [21].

We have recently shown that feeding different animal species a CLA-producing *Bifidobacterium* of human origin (*B. breve* NCIMB 702258), in combination with linoleic acid as substrate, resulted in modulation of the fatty acid composition of the host, including significantly elevated concentrations of *c*9, *t*11 CLA in the liver. This study also demonstrated that oral administration of *B. breve* NCIMB 702258 to mice resulted in significantly higher concentrations of EPA and DHA in adipose tissue, coupled with reductions in the proinflammatory cytokines tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ) [1]. The objective of this study was, therefore, to investigate the effects of co-administration of *B. breve* NCIMB 702258 and the substrate for EPA, α-linolenic acid, on fatty acid composition of different host tissues in mice.

Experimental Procedure

Preparation and Administration of *B. breve* NCIMB 702258

Rifampicin resistant variants of *B. breve* NCIMB 702258 were isolated by spread-plating ~10^9 colony forming units (CFU) from an overnight culture onto MRS agar (de Man, Rogosa & Sharpe; Difco Laboratories, Detroit, MI, USA) supplemented with 0.05% (wt/v) L-cysteine hydrochloride (98% pure; Sigma Chemical Co., St. Louis, MO, USA) (mMRS) containing 500 μg/ml rifampicin (Sigma Chemical Co., Poole, Dorset, UK). Following anaerobic incubation at 37 °C for 3 days, colonies were stocked in mMRS broth containing 40% (v/v) glycerol and stored at −80 °C. To confirm that the rifampicin resistant variant was identical to the parent strain, molecular fingerprinting using pulse-field gel electrophoresis (PFGE) was employed.

Prior to freeze drying, *B. breve* NCIMB 702258 was grown in mMRS by incubating overnight at 37 °C under anaerobic conditions. The culture was washed twice in

phosphate buffered saline (PBS) and then resuspended at a concentration of $\sim 1 \times 10^{10}$ cells/ml in 15% (wt/v) trehalose (Sigma) in dH_2O. One millilitre aliquots were freeze-dried using a 24 h programme (freeze temp. −40 °C, condenser set point −60, vacuum set point 600 mTorr). Each mouse that received *B. breve* consumed approximately 1×10^9 live microorganisms per day. This was achieved by resuspending appropriate quantities of freeze-dried powder in water which mice consumed ad libitum. Mice that did not receive the bacterial strain received placebo freeze-dried powder (15% wt/v trehalose in dH_2O).

Animals and Treatment

Female BALB/c mice were purchased from Harlan Ltd. (Briester, Oxon, UK) at 8 weeks of age and were fed ad libitum with standard non-purified CRM(P) diet (Special Diets Services (SDS), Witham, Essex, UK) with free access to water at all times. The diet contained the following nutrient composition (wt/wt): nitrogen free extract (57.39%), crude protein (18.35%), moisture (10%), ash (6.27%), crude fibre (4.23%) and crude oil (3.36%), which consisted of saturated fatty acids: lauric acid (C12:0, 0.03%), myristic acid (C14:0, 0.14%), palmitic acid (C16:0, 0.33%) and stearic acid (C18:0, 0.06%), monounsaturated fatty acids: myristoleic acid (C14:1, 0.02%), palmitoleic acid (C16:1, 10%) and oleic acid (C18:1, 0.87%), polyunsaturated fatty acids: linoleic acid (C18:2n-6, 0.96%), linolenic acid (C18:3n-3, 0.11%) and arachidonic acid (C20:4n-6, 0.11%). Mice were maintained at four per cage and kept in a controlled environment at 25 °C under a 12-h-light/12-h-dark cycle. All laboratory animal experiments were performed according to the guidelines for the care and use of laboratory animals approved by the Department of Health and Children of the Irish Government.

One week after arrival, the mice were divided into four groups (A–D, $n = 8$) and subjected to the following dietary treatments daily: Group A received standard nonpurified CRM(P) diet supplemented with 1% α-linolenic acid (C18:3n-3, wt/wt, triglyceride bound form, Larodan Fine Chemicals AB, Malmo, Sweden) in combination with approximately 1×10^9 live *B. breve* NCIMB 702258 per mouse, Group B received standard non-purified CRM(P) diet supplemented with 1% α-linolenic acid and placebo freeze-dried powder, Group C received standard nonpurified CRM(P) diet and $\sim 1 \times 10^9$ live *B. breve* NCIMB 702258, Group D received standard nonpurified CRM(P) diet and placebo freeze-dried powder. For α-linolenic acid treatment, a powdered diet (milled standard non-purified CRM(P) pellets) was blended with the α-linolenic acid to yield a concentration of approximately 90 mg α-linolenic acid per mouse per day (based on studies by Bassaganya-Riera et al. [22] who reported an optimal intake of fatty acids of 1 g/100 g per day). All prepared diets were stored at −20 °C and fresh diets were provided twice weekly. Following 8 weeks on experimental diets, the animals were sacrificed by cervical dislocation. Liver, adipose tissue and brain were removed from the carcasses, blotted dry on filter paper, weighed and frozen in liquid nitrogen. All samples were stored at −80 °C until processed.

Microbial Analysis

Fresh faecal samples were taken directly from the anus of each mouse every second week for microbial analysis. Large intestinal contents were also sampled at sacrifice for enumeration of the administered *B. breve* strain. Microbial analysis of *B. breve* NCIMB 702258 was performed by pour plating onto mMRS agar supplemented with 100 μg of mupirocin (Oxoid)/ml and 100 μg rifampicin (Sigma)/ml. Agar plates were incubated anaerobically at 37 °C for 72 h. Anaerobic environments were created using CO_2 generating kits (Anaerocult A; Merck, Darmstadt, Germany) in sealed gas jars.

Lipid Extraction and Fatty Acid Analysis

Lipids were extracted according to the method of O'Fallon et al. [23]. Briefly, tissue samples were cut into 1.5-mm rectangular strips and placed into a screw-cap Pyrex culture tube together with 0.7 ml of 10 mol/l KOH in dH_2O and 5.3 ml of MeOH. The tubes were incubated in a water bath at 55 °C for 1.5 h with vigorous hand-shaking every 20 min. After cooling below room temperature, 0.58 ml of 12 mol/l of H_2SO_4 in dH_2O was added. The tubes were mixed by inversion and with precipitated K_2SO_4 present incubated again at 55 °C for 1.5 h with hand-shaking every 20 min. Fatty acid methyl esters (FAME) were recovered by addition of 3 ml hexane and vortex mixed and separated by gas liquid chromatography (Varian 3400, Varian, Walnut Creek, CA, USA fitted with a flame ionisation detector) using a Chrompack CP Sil 88 column (Chrompack, Middleton, The Netherlands, 100 m × 0.25 mm i.d., 0.20 μm film thickness) and He as the carrier gas. The column oven was initially programmed at 80 °C for 8 min, and increased at 8.5 °C/min to a final column temperature of 200 °C. The injection volume was 0.6 μl, with automatic sample injection on a SPI 1093 splitless on-column temperature programmable injector. Data were recorded and analysed on a Minichrom PC system (VG Data System, Manchester, UK). Peaks were identified with reference to retention times of fatty acids in a standard mixture. All fatty acid results are shown as means ± standard error means (SEM) g/100 g FAME.

Statistical Analysis

Results in the text, tables and figures are presented as means per group ± SEM. Data were analysed using analysis of variance (ANOVA) followed by Tukey's post hoc test using GraphPad InStat for Windows (GraphPad Software, La Jolla, CA, USA) in order to assess if differences between treatment groups (A–D) were significant. Probability values of $P < 0.05$ were set as a threshold for statistical significance.

Results

Microbial Analysis

The administered *B. breve* NCIMB 702258 was recovered in faeces from all mice that received the strain, within 2 weeks of feeding, confirming gastrointestinal transit and survival of the strain. Stool recovery of *B. breve* NCIMB 702258 was approximately 4×10^5 CFU/g faeces by week 8 of the trial in mice that received *B. breve* in combination with α-linolenic acid (group A) and approximately 2.2×10^6 CFU/g faeces in mice that received *B. breve* without α-linolenic acid (group C) (data not shown). The *B. breve* strain was detected in large intestinal contents at $\sim 4.6 \times 10^5$ CFU/g in mice that received *B. breve* and α-linolenic acid (group A) and $\sim 1.4 \times 10^6$ CFU/g in mice that received *B. breve* alone (group C). *B. breve* NCIMB 702258 was not isolated from any of the mice within group B (administered α-linolenic acid alone) or group D (unsupplemented).

Tissue Fatty Acid Composition

Oral administration of *B. breve* NCIMB 702258 and/or α-linolenic acid (C18:3n-3) did not significantly influence body weight throughout the trial period. Supplementation of α-linolenic acid, either in combination with *B. breve* or in the absence of the *B. breve* strain (group A and group B) resulted in tenfold higher concentrations of α-linolenic acid and EPA (C20:5n-3) in liver ($P < 0.05$; Table 1) and adipose tissue ($P < 0.05$; Table 2) compared with groups that did not receive the fatty acid supplement (group C and group D). In addition, the α-linolenic acid supplemented groups exhibited significantly higher concentrations of docosapentaenoic acid (DPA, C22:5n-3) in liver ($P < 0.05$; Table 1) and adipose tissue ($P < 0.05$; Table 2), significantly higher concentrations of DHA (C22:6n-3) in liver ($P < 0.05$; Fig. 2) and significantly lower concentrations of arachidonic acid (C20:4n-6) in liver ($P < 0.05$; Table 1), adipose tissue ($P < 0.05$, Table 2) and brain ($P < 0.05$, Table 3) compared with groups that did not receive fatty acid supplementation (group C and group D). The arachidonic acid/EPA ratios in liver and adipose tissue were approximately 30-fold and 20-fold lower, respectively, in the α-linolenic acid supplemented groups (group A and B) compared with unsupplemented controls (group D) ($P < 0.05$). In addition, the n-6/n-3 ratio was significantly lower in all tissues except the brain of animals supplemented with α-linolenic acid (group A and B) ($P < 0.05$; Table 1 and 2).

Administration of *B. breve* in combination with α-linolenic acid resulted in significant changes in the fatty acid composition of host liver and brain in comparison to animals that were administered α-linolenic acid alone. Mice that received *B. breve* in combination with α-linolenic acid (group A) exhibited on average, 23% more EPA (C20:5n-3) and 20% more dihomo-γ-linolenic acid (C20:3n-6) in the liver compared with the group that was administered α-linolenic acid alone (group B) ($P < 0.05$; Fig. 1; Table 1). Group A also exhibited a 12% higher concentration of DHA (C22:6n-3) in brain ($P < 0.05$; Fig. 2), as well as numerically, though not significantly, higher concentrations of DHA (C22:6n-3) in adipose tissue and liver (27 and 16%, respectively) compared with group B (Fig. 2). In addition, mice that received *B. breve* without α-linolenic acid (group C), exhibited numerically, though not significantly, higher concentrations of DHA (C22:6n-3) in brain tissue in comparison to unsupplemented controls (group D) (Fig. 2).

Oral administration of *B. breve*, both in combination with α-linolenic acid and without α-linolenic acid supplementation (group A and C), also resulted in significantly higher concentrations of arachidonic acid (C20:4n-6) and stearic acid (C18:0) incorporated in the liver compared to mice that did not receive *B. breve* (group B and group D) ($P < 0.05$; Table 1).

Discussion

The influence of dietary PUFA on phospholipids, their eicosanoid derivatives and the transmembrane-signalling lipid rafts into which they are arranged provide multiple targets for the dietary modulation of the balance of inflammatory mediators in the human gut. In addition, gut mucosal inflammation is now recognised as being heavily influenced by the gastrointestinal microbiota [24, 25]. The delicate balance of inflammatory mediators derived from PUFA may be readjusted by members of the indigenous gut microbiota. In this study, we investigated how co-administration of *B. breve* NCIMB 702258 and the substrate for EPA, α-linolenic acid affected the EPA and DHA concentrations of different host tissues. We found that dietary supplementation of *B. breve* NCIMB 702258 in combination with α-linolenic

acid resulted in the modulation of host fatty acid composition, and, specifically, resulted in significantly higher EPA and dihomo-γ-linolenic acid concentrations in liver and higher DHA in brain compared to mice that received α-linolenic acid without microbial supplementation. Some recent studies have shown that the gut microbiota modifies a number of lipid species in serum, adipose tissue and liver [26] as well as the eye lipidome of mice [27] when compared to germ-free mice, suggesting that interactions between intestinal bacteria and fatty acids occur.

Supplementation of α-linolenic acid, both in combination with *B. breve* and in the absence of the *B. breve* strain, resulted in significant increases in EPA and DHA in the liver and adipose tissue, at the expense of arachidonic acid. Since EPA replaces arachidonic acid as an eicosanoid

precursor in cell membranes of platelets, erythrocytes, neutrophils, monocytes and hepatocytes [28], this results in a reduced synthesis of inflammatory eicosanoids from arachidonic acid and, subsequently, elevated production of anti-inflammatory eicosanoids from EPA. This alteration towards a more anti-inflammatory profile could be of importance in a variety of chronic inflammatory settings that are of high prevalence in Western societies such as inflammatory bowel disease (IBD), rheumatoid arthritis, cardiovascular disease, obesity, Alzheimer's disease and certain psychiatric diseases such as depression, which are characterised by an excessive production of arachidonic acid-derived eicosanoids [29–33]. Moreover, since excessive intake of n-6 PUFA, characteristic of modern Western diets, could potentiate inflammatory processes and so could predispose to, or exacerbate associated diseases, increasing the intake of α-linolenic acid and/or EPA may have a protective effect. A recent study using IL-10 knock-out mice (mice that spontaneously develop colitis) demonstrated significantly reduced colonic inflammation of mice that were fed fish oil (enriched in EPA and DHA) compared with mice that were fed n-6 PUFA-rich corn oil [34].

Oral administration of *B. breve*, both in combination with α-linolenic acid and without α-linolenic acid supplementation, resulted in significantly higher amounts of arachidonic acid incorporated in liver compared to mice that did not receive *B. breve*. Given that the administration of *B. breve* resulted in significantly higher concentrations of long-chain PUFA such as EPA, DHA and arachidonic acid, administration of this strain resulted in an increase in the levels of unsaturation within fatty acids. Interestingly, it was previously shown that a mixture of probiotics (*Bacillus subtilis, B. natto, B. megaterium, B. thermophilus, Lactobacillus acidophilus, L. plantarum, L. brevis, L. casei, Streptococcus faecalis, S. lactis, S. thermophilus, Clostridium butyricum, Saccharomyces cerevisiae* and *Candida utilis*) increased the activity of liver Δ6-desaturase in rats, which resulted in increased amounts of arachidonic acid derived from linoleic acid [35]. Consequently, in our study, the increased levels of long-chain PUFA in *B. breve* supplemented groups may have arisen from the reported properties of probiotics in regulating desaturase activity involved in the metabolism of fatty acids to their longer-chain unsaturated derivatives. *B. breve* NCIMB 702258 may also have influenced the mechanisms of PUFA uptake to the intestinal epithelium in the present study. It was recently demonstrated that exposure of *L. plantarum* WCFSI to human intestinal mucosa induced an upregulation of genes involved in fatty acid uptake, i.e. CD36 and microsomal triglyceride transfer protein (MTP) [36].

Quantification of the numbers of bacteria of the *B. breve* strain monitored in the feces of individual mice confirmed gastrointestinal transit and survival of *B. breve* NCIMB 702258. Faecal recovery was approximately 2×10^6 CFU/g feces in mice that received *B. breve* without α-linolenic acid and approximately 4×10^5 CFU/g feces in mice that received *B. breve* in combination with α-linolenic acid. The fecal recovery of *B. breve* NCIMB 702258 in mice that received *B. breve* without α-linolenic acid is consistent with our previous study [1], however the fecal recovery of *B. breve* was reduced in the presence of α-linolenic acid. Since free PUFA have been shown to be antibacterial and to inhibit the growth of bacteria [37–39] and adhesion of bacteria to intestinal surfaces [40], this might explain the lower numbers of *B. breve* obtained from mice that received supplementation of α-linolenic acid compared to mice that did not receive fatty acid supplementation.

Since the effect of the combined *B. breve* and α-linolenic acid intervention on EPA- and DHA concentrations was greater than that of α-linolenic acid intervention alone, this effect could be attributed to *B. breve* NCIMB 702258 and suggests that feeding a metabolically active strain can influence the fatty acid composition of host tissues. In conclusion, the present study shows that the administration of *B. breve* NCIMB 702258 is associated with alterations in the fatty acid composition of host liver and brain, including elevated concentrations of EPA and DHA. This interaction between administered microbes and n-3 fatty acids could result in more efficient probiotic preparations, which may be beneficial for a range of immunoinflammatory disorders as well as having significance for the promotion of neurological development in infants.

Received: 18 September 2009 / Accepted: 7 April 2010 / Published online: 29 April 2010

Abstract The present study aimed to elucidate the effective phylogenetic specificity of distribution of a *cis*-4,7,10, *trans*-13-22:4 (22:4(n-9)Δ13*trans*) among pectinids. For this purpose, we extended the analysis of membrane glycerophospholipids FA composition to 13 species of scallops, covering 11 genera and 7 tribes representatives of the three subfamilies Chlamydinae, Palliolinae and Pectininae and the subgroup Aequipecten. In species belonging to the subfamily Pectininae and the Aequipecten subgroup, 22:4(n-9)Δ13*trans* was found in substantial amounts, but it was absent in other species belonging to the subfamilies Chlamydinae and Palliolinae. Homologous non-methylene-interrupted (NMI) FA, also hypothesized to differ along phylogenetic lines in bivalves, were totally absent or present only in trace amounts in representatives of the Aequipecten subgroup but ranged from 0.3 to 4.5% of the total FA in Pectinidae, Chlamydinae, and Palliolinae subfamilies. The species-specific occurrence of NMI and 22:4(n-9)Δ13*trans* FA in membrane lipids of pectinids agrees with the most recent phylogenies based on shell morphology and molecular characteristics. We examined the potential timing of the appearance of 22:4(n-9)Δ13*trans* in pectinids on a geologic time scale.

Introduction

To date, 4,7,10,13*trans*-22:4 FA (22:4(n-9)Δ13*trans*) has been reported and characterized in significant amounts in glycerophospholipids of three species of the family Pectinidae, the scallops *Pecten maximus*, *Argopecten purpuratus*, and *Aequipecten opercularis* [1, 2]. This 22:4(n-9)Δ13*trans* is particularly concentrated in the plasmalogen and diacyl forms of serine glycerophospholipids (SerGpl) [2]. This association was in evidence in all tissues analyzed, but the proportions of the 22:4(n-9)Δ13*trans* in these subclasses were highest in the gills and lowest in the adductor muscle.

The presence of 22:4(n-9)Δ13*trans* FA in the scallop species investigated was combined with very low levels of

C_{20} and C_{22} non-methylene-interrupted dienoic (NMID) and trienoic (NMIT) FA. Earlier reports on scallop FA compositions also indicated that the levels of these unusual NMI FA are generally very low in pectinids [3, 4], while they are seemingly ubiquitous components in other members of the class Bivalvia, occurring in concentrations up to 20% of the total FA [3, 5–9]. Interestingly, the specific association of the plasmalogen form of SerGpl (PlsSer) with the 22:4(n-9)Δ13*trans* for pectinids parallels the specific association found for PlsSer with NMI FA in non pectinid species [10]. Although these peculiar FA are structurally different, this led us to argue that these two types of FA could play similar roles in membrane functions [1]. First proposed by Ackman and Hooper [11], and demonstrated later by Zhukova [6, 8], NMI FA are considered to be the only polyunsaturated fatty acids (PUFA) synthesized de novo by bivalve mollusks. We thus hypothesized that 22:4(n-9)Δ13*trans* could be of endogenous origin, representing a specific attribute of Pectinidae [2]. Nevertheless, in the work of Napolitano and Ackman on the scallop *Placopecten magellanicus*, no peak (gas chromatogram) or unknown FA that could be interpreted as the 22:4(n-9)Δ13*trans* was described [4, 12, 13]. The fact that this FA is not found in *P. magellanicus* was recently confirmed [14]. Such observations raised the question whether 22:4(n-9)Δ13*trans* systematically occurs throughout the Pectinidae family.

This study investigated the occurrence of the 22:4 (n-9)Δ13*trans* and NMI FA in an expanded range of species of Pectinidae. The FA composition of membrane phospholipids was characterized in 13 different species of scallops that span 11 of the 56 genera, representing 7 tribes and belonging to 3 of the 4 most important subfamilies in term of number of extant species. We examined the chemotaxonomic relationships revealed by the distribution of 22:4(n-9)Δ13*trans* and NMI FA, and compared them with existing morphological and molecular classifications for the Pectinidae family.

Materials and Methods

Scallop Species Collection

The locations and time of collection of the pectinid species studied are presented in Table 1. Collected species are classified according to genera described by Waller [15].

Sample Preparation and Lipid Extraction

For all species analyzed, the digestive tract was first removed to limit contamination by ingested algae. Then gills and muscle tissues were excised, weighed and homogenized with a Dangoumeau homogenizer at −180 °C. One species was analyzed as a whole animal (i.e. *Euvola ziczac*). Lipids were extracted from an aliquot of approximately 100 mg of tissue homogenates according to the method described by Folch et al. [16]. To ensure complete extraction of the lipids, a solvent to tissue ratio of 70:1 was used as described by Nelson [17]. After removing the organic phase, the residue was washed with a mixture of $CHCl_3$/MeOH (2:1, vol/vol) to avoid any solvent

Table 1 Sampling location and time of collection of scallop species used in the analysis (following current classifications [15] and [32])

Subfamily	Tribe	Species	Origin	Time of collection
Chlamydinae	Chlamydini	*Zygochlamys patagonica* (2)	Argentina	June 05
		Mizuhopecten yessoensis (3)	Japan	July 05
		Chlamys distorta (5)	France (B[a])	April 05
		Chlamys islandica (4)	Norway	November 04
	Mimachlamydini	*Mimachlamys varia* (4)	France (B)	July 04
Palliolinae	Palliolini	*Placopecten magellanicus* (3)	Canada (MI[b])	September 06
	Adamussiini	*Adamusium colbecki* (5)		December 07
Pectininae	Pectinini	*Pecten maximus* (3)	France (B), Norway	July 07
		Nodipecten subnodosus (3)	Mexico (BCS[c])	June 06
	Amusiini	*Euvola ziczac* (4)	Bermuda	December 05
Aequipecten subgroup	Aequipectinini	*Aequipecten opercularis* (3)	France (B)	June 05
		Argopecten purpuratus (3)	Chile	July 05
		Argopecten ventricosus (3 for each month)	Mexico (BCS[c])	January, May, July 08

retention. The final extract was stored at −20 °C under a nitrogen atmosphere after adding 0.01% wt/vol butylated hydroxytoluene (BHT, antioxidant).

Separation of Polar Lipids by Silica Gel Micro-column and FA Analysis

An aliquot of the lipid extracts (approximately 100 μg of total lipids) was evaporated to dryness and the lipids were recovered with three washings of 500 μl of $CHCl_3$/MeOH (98/2, vol/vol) and deposited at the top of a silica gel micro-column (30 × 5 mm I.D., packed with Kieselgel 60 70–230 mesh previously heated at 450 °C and deactivated with 5 wt% H_2O) [18]. Neutral lipids were eluted with 10 ml of $CHCl_3$/MeOH (98/2 vol/vol). The polar lipid fraction was recovered with 20 ml of MeOH and stored at −20 °C before FA composition analysis by gas chromatography (GC).

The polar lipid fraction was used for the direct determination of the total glycerophospholipid (GPL) FA composition after transesterification (MeOH/BF_3). Fatty acid methyl esters (FAME) obtained were identified and quantified by GC using C23:0 FA as an internal standard [18]. FAME were analyzed in a Varian CP 8400 gas chromatograph equipped with an on-column injector and a flame ionization detector. FA were identified by comparing their retention times using both polar (CPWAX 52 CB—30 m × 0.25 mm, 0.25 μm film thickness) and non-polar (CP-Sil 8 CB—30 m × 0.25 mm, 0.25 μm film thickness) capillary columns by means of a standard mixture containing 37 FAME (SUPELCO/Sigma–Aldrich, St-Quentin Fallavier, France), and other known standard mixtures from marine bivalves [1, 10]. A total of 40 FA were quantified and expressed as the molar percentage of the total FA content.

Results

Scallop species analyzed in this study are distributed among three of the four proposed subfamilies, including the Chlamydinae, Palliolinae, and Pectininae (Table 1). The subfamily not analyzed was the Camptonectinae, hypothesized as the sister group of all other existent Pectinidae.

Along with NMI FA and 22:4(n-9)Δ13*trans*, glycerophospholipids of the 13 pectinid species were dominated by five major FA (16:0, 18:0, 20:4n-6, 20:5n-3, and 22:6n-3). Table 2 reports the proportions of the total NMI FA, 22:4(n-9)Δ13*trans*, 20:4n-6, 20:5n-3, and 22:6n-3. In 11 of the 13 species investigated, gills and muscle glycerophospholipids FA compositions were analyzed separately. Long-chain PUFA 20:4n-6, 20:5n-3, and 22:6n-3 varied markedly among species and both organs analyzed. There was no relationship with taxonomic affiliation.

Two main clusters among the suprageneric groups of Pectinidae can be formed when considering the presence or absence of the 22:4(n-9)Δ13*trans*. This FA was found in substantial amounts in all species belonging to the Aequipecten group (*A. opercularis, A. purpuratus*, and *A. ventricosus*) and the subfamily Pectininae (*P. maximus, N. subnodosus*, and *E. ziczac*), but was absent in species belonging to Chlamydinae (*Z. patagonica*, *M. yessoensis*, *C. islandica*, and *M. varia*) and Palliolinae subfamilies (*P. magellanicus*, *A. colbecki*) (Table 2). One exception was observed for *C. distorta* (tribe Chlamydini), for which the presence of 22:4(n-9)Δ13*trans* was clearly established, even if it was found in low amounts in comparison to species of the Pectininae subfamily and Aequipecten group.

Except for the three species belonging to the Aequipecten group, for which NMI FA were not detectable (or only found in trace amounts in the case of *A. opercularis*), the other pectinid species contained minor but noticeable amounts of NMI FA, ranging from 0.3 to 4.5% according to species and organs. In the 11 species where gills and muscle were analyzed separately, NMI FA and/or 22:4(n-9)Δ13*trans* content in the membrane glycerophospholipids were found higher in the gills than in muscle. Predominant NMI FA were 22:2 NMID (7,15–22:2 and 7,13–22:2), while 20:2 NMID (5,11–20:2 and 5,13–20:2) and NMIT (5,11,14–20:3 and 7,13,16–22:3) were only detectable in trace amounts. Among 22:2 NMID FA, no characteristic predominance of one of the two isomers was found according to species and phylogenetic groups.

To evaluate intra-specific variability of NMI FA and 22:4(n-9)Δ13*trans*, FA compositions of *P. maximus* specimens sampled in the bay of Brest (French coast) and in the Norwegian coastal waters were compared. Despite some differences in proportions of the long-chain PUFA 20:4n-6, 20:5n-3 and 22:6n-3 (mainly in gills), 22:4(n-9)Δ13*trans* and NMI FA in gills and muscle were found in similar amounts in both populations. We also examined whether levels of NMI FA and 22:4(n-9)Δ13*trans* vary within a species according to the period of the year, by sampling *A. ventricosus* from the same location (Baja California Sur, Mexico) at 3 months within a year. Despite some variability in the proportions of 20:4n-6, 20:5n-3 and 22:6n-3, levels of 22:4(n-9)Δ13*trans* varied less within this species than between the different species.

Discussion

Previous studies on glycerophospholipids FA composition in non-pectinid bivalves species *Glycymeris glycymeris*, *Mytilus edulis*, *Ostrea edulis*, *Crassostrea gigas*, *Ruditapes decussatus*, and *Cerastroderma edule* did not reveal the

For the purpose of the study, only predominant PUFA are depicted in addition to total NMI and 22:4(n-9)Δ13*trans* FA. Results are expressed in mol% of the total FA of glycerophospholipids. Values are means ± SD

[a] Total NMI is the sum of 20 and 22 NMID isomers (5,11–20:2NMI, 5,13–20:2NMI, 7,13–22:2NMI, 7,15–20:2NMI), and 22 NMIT (7,13,16–22:3NMI). 5,11,14–20:3 NMIT was only detectable in trace amounts

presence of 22:4(n-9)Δ13*trans,* suggesting that this peculiar FA is only present in bivalves of the Pectinidae family [1, 10]. However, our characterization of the FA composition of phospholipids in a greater number of scallop species showed that 22:4(n-9)Δ13*trans* only occurred in some of the 13 species studied.

Our present results confirmed that pectinids contain lower levels of NMI FA than other bivalve mollusks [3, 4]. Actually, Pectinidae seem to represent an exception since NMI FA are seemingly ubiquitous mollusk components with non-negligible proportions and a definite regularity in their distribution in bivalves (up to 20%) [3, 7]. These NMI FA are considered to be the only PUFA synthesized de novo in bivalves. While NMID FA (namely 5,11–20:2, 5,13–20:2, 7,13–22:2, 7,15–22:2) were demonstrated to be de novo synthesized in bivalve mollusks by active FA elongation and desaturation of 18:1n-9 and 16:1n-7 [6, 8], NMIT (5,11,14–20:3 and 7,13,16–22:3) FA were suggested to be synthesized from 20:2n-6 [9]. The occurrence of NMI FA in mollusks was originally thought to represent a phylogenetic characteristic of mollusks [11]. Later, based on a study on five bivalves and two gastropods species from the Sea of Japan, it was proposed that NMI FA have some evolutionary significances in bivalves, with the oldest families of Bivalvia having the highest NMI FA contents, while in evolutionary "advanced" species, these FA are either found in lower amounts or absent [7]. However, authors pointed out the exception of Pectinidae since NMI FA were almost absent or in trace amounts in this ancient family. Rabinovich and Ripatti [19] suggested that the higher content of FA acyl chains with non-methylene-interrupted double bonds in the oldest families of Bivalvia appeared as a result of primitive disorganizations in the reaction sequence of the normal system of desaturases and elongases.

The desaturase and elongase intermediates in the synthesis of 22:4(n-9)Δ13*trans* have still not been elucidated in pectinids. However, as it is absent from the diet, this 22:4(n-9)Δ13*trans* should be, as NMI FA, of endogenous origin [1]. In addition, 22:4(n-9)Δ13*trans* and NMI FA shared some interesting characteristics in bivalve tissues. Both are found in higher proportions in gills than in muscle glycerophospholipids and both are specifically associated to the plasmalogen form of glycerophospholipids [2, 10]. Considering this, the phylogenetic significance of 22:4(n-9)Δ13*trans* occurrence was assessed using the recently updated phylogeny of scallops by Waller [15], based on shared derived morphological characters and molecular genetic characteristics, and scaled against geologic time (Fig. 1). According to the presence or absence of the 22:4(n-9)Δ13*trans* in gills glycerophospholipids, two groups of pectinids were apparent. One group of species belonging to the Aequipecten group and Pectininae subfamily was characterized by substantial amounts of 22:4(n-9)Δ13*trans* in gills, whereas the second group including representatives of the Chlamydinae and Palliolinae

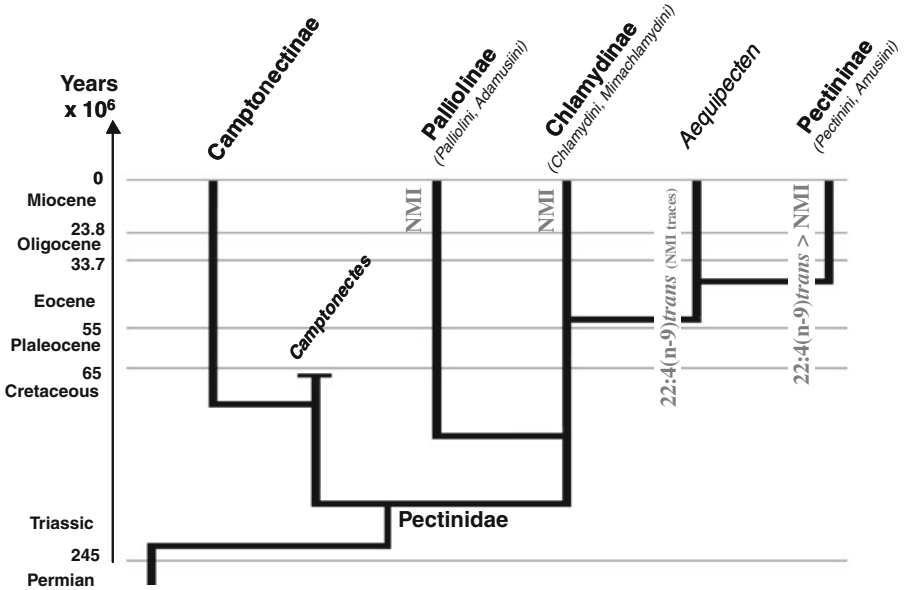

Fig. 1 Phylogeny of subfamilies of Pectinidae plotted against time in million of years and compartmentalized into standard European stages. This representation was reconstructed from the publication of Waller [15, Figs. 1.1 and 1.3] who postulated new evolutionary relationships among scallops on the basis of shared morphological characters and findings of molecular genetic studies. Also indicated is the "Aequipecten group" now considered to be at the base of the lineage conducing to the subfamily Pectininae. The different tribes analyzed in the present study are indicated for each subfamily. Indications on lineages refer to the characteristic distribution of 22:4(n-9)Δ13*trans* and NMI FA within pectinid clades

subfamilies contained no or only trace amounts of this FA. According to Waller's phylogenetic tree, 22:4(n-9)Δ13*trans* is then only present in the most evolutionary advanced species. This observation suggests that members of the Pectininae subfamily and the Aequipecten group have originated from a common ancestor that belonged to a common lineage that gave rise to the 22:4(n-9)Δ13*trans* in Pectinidae.

At this stage, distribution of 22:4(n-9)Δ13*trans* and NMI FA within pectinid clades supports the idea that the capacity to synthesize these peculiar fatty acids is genetically controlled and has phylogenetic and evolutionary significance. However, it is important in comparative studies of this type to separate adaptive properties from characters that exist in species for reasons of phylogenetic lineage. Because of their possible importance in membrane structure and function, the proportions of these FA can be expected to be modulated by extrinsic (i.e., temperature, diet, salinity, depth) and/or intrinsic factors (i.e. age, reproductive cycle). However, while studies on scallops and other bivalve species show a dependence of 20:4n-6, 20:5n-3, and 22:6n-3 compositions of membrane phospholipids on dietary composition [20–23], NMI FA and 22:4(n-9)Δ13*trans* in phospholipids seemed less sensitive to dietary changes in PUFA contents [20, 22–25]. Only small modifications of NMI FA contents were observed according to temporal and geographical changes [4, 12, 13, 25–27]. NMI and/or 22:4(n-9)Δ13*trans* FA also appear to be less sensitive to reproductive stages than 20:4n-6, 20:5n-3, and 22:6n-3 [12, 14, 26, 28]. In the present study, species sampled in the Bay of Brest (France) for which 22:4(n-9)Δ13*trans* was present in substantial proportions (i.e. *P. maximus, A. opercularis*) or was not detected or only in trace amounts (i.e. *C. distorta*, *M. varia*), were species growing in similar habitats and sampled at the same periods of the year. This observation suggests that the occurrence of this peculiar FA in scallops is not linked to adaptive responses in their environment. Analysis of *P. maximus* originating from France or Norway (south of Bergen) revealed that the proportions of 22:4(n-9)Δ13*trans* in phospholipids are not markedly influenced by rearing site conditions and/or latitudes. As well, despite modifications in 20:4n-6, 20:5n-3, and 22:6n-3 and other FA levels in gills membranes of *A. ventricosus* originating from a same location and sampled at three different months ($P < 0.05$), the differences in 22:4(n-9)Δ13*trans* proportions over the sampling period were not significant. These modifications being probably associated with multiple factors such as diet, temperature, or reproductive stages and age, the stability of 22:4(n-9)Δ13*trans* levels compared to those of 20:4n-6, 20:5n-3, and 22:6n-3 suggest a regulation of this FA in the membrane lipids. These results corroborate the constant proportions of 22:4(n-9)Δ13*trans* and NMI FA found during a seasonal survey (including a reproductive cycle) of fatty acid compositions in the mantle tissues of a 1-year-old population of giant lion's-paw scallop *N. subnodosus* [28].

All these considerations support the idea that these membrane fatty acids could have a phylogenetic significance rather than being due to environmental conditions. The present data support some of the new assignments of bivalves of the Pectinidae family that have recently emerged [15, 29–32]. The occurrence of 22:4(n-9)Δ13*trans* in two clades, the "Aequipecten group" and the subfamily Pectininae, supports the close relationship between them [15, 30] (Fig. 1), while a previous phylogeny placed Pectininae and Aequipecten in well separated positions [33]. Nevertheless, these two clades seemed to be distinguishable according to their NMI FA contents. Indeed, NMI FA were in very low amounts or absent in species of the Aequipecten group while they were found in significant amounts in the Pectininae subfamily when compared to other pectinids. Furthermore, an interesting point is the almost lack of 20:1n-11 in glycerophospholipids of the Aequipecten group species (data not shown). As previously suggested, 20:1n-11 is probably biosynthesized in bivalves by a Δ9 desaturase acting on 20:0 [10] in the same way as a Δ9 desaturation and elongation of 16:0 and 18:0, produces the two NMI FA precursors 20:1n-7 and 20:1n-9 [8]. This observation would corroborate a loss of NMI FA biosynthesis pathways in species belonging to the Aequipecten group, suggesting an independent evolution in species of the Aequipecten group after the split with the subfamily Pectininae.

The presence of both NMI FA and 22:4(n-9)Δ13*trans* in *N. subnodosus* is in good agreement with two recent molecular phylogenetic studies that established a closer relationship between *Nodipecten* and the Pectininae subfamily [31, 32]. Placement of *M. yessoensis* (synonym. *Patinopecten*) close to the Chlamys group [15, 29], in contrast to its previous position close to Pecten [34], is also corroborated by the absence of 22:4(n-9)Δ13*trans* in *M. yessoensis* glycerophospholipids.

In contrast, the presence of 22:4(n-9)Δ13*trans* in *C. distorta* (tribe Chlamydini), raises a question of whether this species belongs to the Chlamydinae subfamily. Unfortunately, none of the recent molecular studies addressed phylogenetic relationships of this species in Pectinidae families.

A discussion on the functional, physiological and/or evolutionary significance of the specificity of distribution of 22:4(n-9)Δ13*trans* among pectinids can only be speculative and has yet to be addressed. For NMI FA, due to their large quantities reported in membrane lipids of marine organisms, some authors assume that they play an important role in biomembrane functioning such as fluidity, and

control of negative influence of thermal changes on enzyme activity. They have also been related to the low oxidizability of membrane lipids and high resistance to hemolytic agents [19, 35, 36]. Although 22:4(n-9)Δ13*trans* and NMI FA appears structurally very different, their specific association with the plasmalogen form of SerGpl (PlsSer) and their uneven distribution among organs argue for similar targeted roles in membrane functions [2].

In conclusion, representatives of the Pectinidae family are unique in terms of the de novo biosynthesized NMI FA proportions and the existence of the 22:4(n-9)Δ13*trans* FA in their membrane lipids. A striking relationship between the occurrence of NMI FA and 22:4(n-9)Δ13*trans* and the recent phylogenies of the Pectinidae family suggests that an event(s) in pectinids evolution occurred in the root for the Aequipecten and Pectininae allowing scallops to develop the enzyme machinery for 22:4(n-9)Δ13*trans* biosynthesis. Any consequences for membrane functions that underlie these specificities in membrane lipid composition remain to be explained, but the present data could help us to gain further knowledge on these questions.

Acknowledgments We would like to thank A. Lorrain, A. Druinker, L. Chauvaud, and Y-M. Paulet for supply of some of the species we characterized. This work was supported by a grant from "Ministère de l'Education Nationale de la Recherche et de la Technologie" (M.E.N.R.T., France). We also would like to thank Prof. H. Guderley for her English revision and comments, and also anonymous reviewers for their helpful comments.

The Effects of Ezetimibe and/or Orlistat on Triglyceride-Rich Lipoprotein Metabolism in Obese Hypercholesterolemic Patients

E. S. Nakou · T. D. Filippatos · A. P. Agouridis · C. Kostara · E. T. Bairaktari · M. S. Elisaf

Received: 11 February 2010 / Accepted: 15 March 2010 / Published online: 9 April 2010

Abstract We investigated the factors influencing triglycerides (TG) reduction during ezetimibe, alone or combined with orlistat, administration. Eighty-six obese hypercholesterolemic subjects were prescribed a low-fat diet and were randomized to ezetimibe (E group), orlistat (O group), or both (OE group) for 6 months. Plasma TG and apolipoprotein (apo) C-III reduction was significantly greater in the combination group compared with monotherapy. Multivariate analysis showed that in E group apoC-III reduction and baseline TG levels were independently positively correlated, whereas baseline apoC-II levels were negatively correlated, with TG lowering. In OE group apoC-III reduction was the only independent contributor to TG reduction.

Introduction

The human apolipoproteins (apo) Cs are constituents of chylomicrons, very low density lipoproteins (VLDL) and high density lipoproteins (HDL) [1]. ApoC-II in normal ranges is an activator of lipoprotein lipase (LPL) [1, 2]. In contrast, excess apoC-II inhibits LPL-mediated hydrolysis of triglycerides (TGs) [1]. ApoC-III is a powerful inhibitor of LPL activity [1, 3].

Ezetimibe selectively inhibits intestinal cholesterol absorption [4, 5]. This effect leads to decreased cholesterol delivery to the liver and subsequent increased cholesterol clearance from the blood [4].

Orlistat is an inhibitor of intestinal lipases that are responsible for the breakdown of dietary TG into fatty acids and monoglycerides [6–8]. Orlistat-induced weight loss improves CVD risk factors, including serum TG levels [9–11].

Our group showed that ezetimibe, alone or in combination with orlistat, significantly reduced serum TG concentration in obese patients with hypercholesterolemia [12, 13]. In this study we show the effect of ezetimibe administration, alone or combined with orlistat, on apoC-II and apoC-III levels and we investigate the factors influencing TG reduction during these treatments.

Patients and Methods

Participants

Consecutive patients attending the Outpatient Obesity and Lipid Clinic of the University Hospital of Ioannina (Ioannina, Greece) were recruited [12]. The study protocol has been described in detail elsewhere [12, 13]. Briefly, eligible patients were those with body mass index (BMI) >28 kg/m^2 and hypercholesterolemia [total cholesterol (TC) >200 mg/dl, 5.2 mmol/l]. Patients with symptomatic ischemic heart disease or any other clinically evident vascular disease, impaired renal, liver or thyroid function, diabetes mellitus or receiving lipid-lowering therapy were excluded from the study.

An individualized low-fat diet, promoting a 500–1,000 kcal reduction in daily energy intake, was given to all patients [12]. Patients were randomized to receive for 6 months: orlistat, *Group O* (120 mg, three times a day) or ezetimibe, *Group E* (10 mg/day) or a combined treatment with orlistat plus ezetimibe, *Group OE*.

All participants gave their informed consent and the study protocol was approved by the institutional ethics committee.

Laboratory Measurements

Lipid and carbohydrate metabolism parameters were determined as previously described [12]. All laboratory determinations were carried out after an overnight fast. Serum concentrations of fasting glucose, TC and TGs were determined enzymatically on an Olympus AU600 clinical chemistry analyzer (Olympus Diagnostica, Hamburg, Germany). High density lipoprotein cholesterol (HDL-C) was determined in the supernatant, after precipitation of the apoB-containing lipoproteins with dextran sulfate-Mg^{2+} (Sigma Diagnostics, St. Louis, MO, USA). Low density lipoprotein cholesterol (LDL-C) was calculated using the Friedewald formula (provided that triglycerides were <3.9 mmol/l, 350 mg/dl). Fasting serum insulin levels were measured by an AxSYM insulin assay microparticle enzyme immunoassay on an AzSYM analyzer (Abbott Diagnostics, IL, USA). Finally, homeostasis model assessment (HOMA) index was calculated as follows: fasting insulin (mU/l) × fasting glucose (mg/dl)/405.

ApoC-II and apoC-III were determined by an immunoturbidimetric assay provided by Kamiya Biomedical Company (Seattle, USA) [14].

For all measurements in our laboratory, the coefficients of inter-assay and intra-assay variation were less than 5.0%, and blinded quality-control specimens were included in each assay. Analyses were conducted at the Laboratory of Clinical Chemistry of the University Hospital of Ioannina, under regular quality control procedures including the use of reference pools and blinded duplicate samples.

The Laboratory of the University Hospital of Ioannina is currently participating in external quality assurance services (EQAS) programme provided by Bio-Rad Laboratories, Inc.

Statistical Analysis

Each value is given as mean ± standard deviation (SD) and median (range) for parametric and non parametric data, respectively. Analysis of covariance (ANCOVA), adjusted for baseline values, was used for comparisons between treatment groups. Spearman's correlation coefficients were used to describe the relationship of TG reduction with age, waist circumference, BMI, HOMA index, lipid and apolipoprotein levels (univariate analysis). Stepwise multivariate linear regression analyses were performed to assess in each treatment group the independent contribution of the variables that significantly associated with TG reduction in univariate analysis.

The results were analyzed after excluding the eight patients who dropped out during the study. Significance was defined as $p < 0.05$. All analyses were carried out with SPSS 15.0 (SPSS Inc., Chicago, IL, USA).

Results

We enrolled 94 patients (70 females and 24 males, mean age 55 ± 10 years). Of these, 8 (8.5%) did not complete the study. Baseline characteristics did not differ between the three groups [12].

As previously shown [12], significant in-group changes were observed for BMI and waist circumference at 6 months [12]. There were significant in-group reductions in plasma levels of TC, LDL-C, TG and apoB. Levels of HDL-C and apoA-I were not significantly changed at 6 months in any group [12].

In E and OE groups plasma apoC-II (E group: from 4.6 to 4.1 mg/dl, $p < 0.05$; OE group from 4.8 to 4.2 mg/dl; $p < 0.05$) and apoC-III (E group: from 11.4 to 9.9 mg/dl, $p < 0.05$; OE group from 11.7 to 9.8 mg/dl; $p < 0.05$)

levels were significantly reduced. In O group a significant reduction of plasma apoC-III concentrations was observed (from 11.9 to 10.7 mg/dl, $p = 0.01$). In this group plasma apoC-II levels were not significantly changed (from 4.9 to 4.8 mg/dl, $p =$ NS). The reduction of apoC-II levels in E and OE groups was significantly greater compared with O group. The reduction of apoC-III levels was significantly greater in OE group compared with O group.

There were significant in-group reductions in serum TG levels in all treatment groups. We observed a significantly greater TG reduction in the combination group compared with each monotherapy [12]. Stepwise multiple linear regression analysis revealed that in E group, apoC-III reduction and baseline TG levels were significantly and independently positively correlated, while baseline apoC-II levels were negatively correlated, with TG reduction. In O group, the alterations in apoC-III levels and the baseline TG concentration were independently positively correlated, while the baseline apoC-II levels were negatively correlated with TG lowering (Table 1). In OE group alterations in apoC-III levels were independently and significantly positively correlated with TG lowering (Table 1).

Discussion

Multivariate analysis showed that the TG lowering during ezetimibe treatment is independently positively associated with the apoC-III reduction and the baseline TG levels, while it is negatively associated with the baseline apoC-II concentration in obese hypercholesterolemic patients. ApoC-III is an 8.8 kDa glycoprotein secreted mostly by the liver and, to a lesser extent, by the intestine [15]. ApoC-III is a major component of TG-rich lipoproteins (chylomicrons and VLDL) and HDL. ApoC-III is considered a regulator of lipolysis through non-competitive inhibition of endothelial-bound lipoprotein lipase (LPL) [16, 17]. This enzyme hydrolyses triacylglycerols in TG-rich lipoproteins [3, 15]. Individuals lacking apoC-III have low TG levels [17–20]. ApoC-III at high concentrations may also inhibit hepatic lipase (HL), an effect that reduces further the lipolysis and uptake of TG-rich lipoproteins by the liver [15]. Therefore, apoC-III plays a key role in TG-rich lipoprotein metabolism and, consistent with the multivariate analysis, is a major factor responsible for TG alterations during ezetimibe treatment.

Table 1 Multivariate regression analysis for the prediction of TG reduction

Parameter	Group O		Group E		Group OE	
	Beta	*p*	Beta	*p*	Beta	*p*
Changes in apoC-III	0.45	0.02	1.21	<0.001	0.59	0.01
Baseline TG	0.29	0.03	0.44	<0.01	0.33	0.14
Baseline apoC-II	−0.18	0.04	−0.41	0.02	−0.47	0.17

Only significant correlations are shown. Variables included in the model are those which were significantly correlated with triglyceride reduction in univariate analysis

E ezetimibe, *O* orlistat, *OE* ezetimibe + orlistat, *TG* triglycerides, *apo* apolipoprotein

Baseline TG levels were an independent contributor to TG alterations during ezetimibe treatment. It has been shown that ezetimibe induces greater TG reductions in patients with higher baseline TG levels [12, 21, 22]. Generally, baseline TG levels are associated with TG reduction during treatment with drugs which exhibit hypolipidemic activity. For example, our study group showed that baseline TG levels were the most important contributor to TG reduction during rosuvastatin administration [23]. Various mechanisms have been proposed to support these observations. Specifically, the conformation of apoE contained on VLDL in hypertriglyceridemic states is different than that of VLDL in normotriglyceridemic conditions and seems to have greater affinity to the LDL-receptor [24, 25]. Additionally, in normotriglyceridemic individuals there is a shorter resident time of VLDL, which results in VLDL particles to acquire less apoE from HDL by transfer [26]. These apoE-depleted VLDL particles exhibit less affinity to the LDL receptor [26, 27]. Ezetimibe localizes at the brush border of the small intestine and selectively inhibits cholesterol absorption from the intestinal lumen into enterocytes [4]. Kinetic studies suggested that in subjects with primary hypercholesterolemia, ezetimibe-induced inhibition of intestinal cholesterol absorption led to decreased chylomicron formation and delivery to the liver and subsequent upregulation of hepatic LDL receptor activity [28, 29]. Thus, during ezetimibe treatment (and subsequent upregulation of hepatic LDL receptor activity) individuals with normal TG levels may exhibit less apoE-mediated clearance of the VLDL compared with patients with high TG levels.

Multivariate analysis also showed that baseline apoC-II concentration was negatively associated with TG alterations during ezetimibe treatment. ApoC-II is considered an important activator of LPL [30–32]. Patients with genetic defects in the structure or production of apoC-II exhibit a high plasma TG concentration and are phenotypically indistinguishable from patients with LPL deficiency [33, 34]. Plasma apoC-II is present in human plasma at a physiological concentration of approximately 4 mg/dl [1]. However, at high protein concentrations (>4 mg/dl), such as those observed in our study, apoC-II was demonstrated to inhibit LPL activity rather than stimulate it [35]. Additionally, apoC-II at high concentration has been reported to inhibit the apoE- and apoB-mediated clearance of the TG-rich lipoproteins via the LDL-receptor [1, 36, 37].

Therefore, we assume that the increased concentration of apoC-II in our subjects minimized the ezetimibe-induced (due to up-regulation of LDL receptors) apoE- and apoB-mediated clearance of the TG-rich lipoproteins.

Orlistat is a potent and specific inhibitor of intestinal lipases that are responsible for the breakdown of dietary TG into fatty acids and monoglycerides, which are then absorbed [6]. Several studies showed that orlistat administration improves the lipid profile in patients with hypercholesterolemia [6, 38]. This drug mainly improves postprandial lipoprotein metabolism (reduces the concentration of chylomicrons and VLDL), which in turn decreases the delivery of dietary lipid and fatty acids to the liver and subsequently upregulates the hepatic LDL receptors [39, 40]. Our study group has investigated the factors contributing to TG reduction during orlistat treatment in obese subjects with MetS [41]. In accordance with the present results, we showed that baseline TG levels consist an independent positive contributor and baseline apoC-II concentration is an independent negative contributor to TG reduction during orlistat treatment. However, multivariate analysis in the present study revealed that apoC-III alterations consist the major contributing factor to TG reduction. This effect was not observed when orlistat was given to obese patients with MetS. In the present study, TG levels were lower than the previous study (151 vs. 216 mg/dl at baseline). Hence, the finding of the present study that apoC-III is an independent contributor to TG reduction during orlistat treatment may be attributed to the different baseline TG concentration compared with the previous study.

The results of multivariate analysis showed that in ezetimibe and orlistat combination group TG lowering was significantly and independently associated with apoC-III alterations. It seems that the additive effect of these drugs on TG concentration is only dependent on the greater reduction in apoC-III levels compared with each monotherapy.

In the present study we show that ezetimibe administration, alone or combined with orlistat, decreases plasma apoC-II and apoC-III in obese patients with hypercholesterolemia. Apolipoproteins C-II and C-III are secreted mostly by the liver and, to a lesser extent, by the intestine. The mechanism of action of ezetimibe, that is inhibition of intestinal cholesterol absorption, leads to a reduction in chylomicron formation [29]. We speculate that this reduction is accompanied by a decrease in the synthesis of apoC-II and apoC-III (which are constituents of chylomicrons) by the intestine. Orlistat also acts via improvement of postprandial lipoprotein metabolism and may reduce apoC-III plasma levels with a similar mechanism. The dual inhibition of intestinal lipid and cholesterol absorption by the combination of orlistat and ezetimibe may further improve TG-rich lipoproteins metabolism, a fact that may explain the greater impact of this combined treatment on apoC-II and apoC-III reduction. However, the improvement of postprandial metabolism by both drugs leads to alterations of hepatic lipoprotein production (for example of VLDL) and, consequently, changes in the production of apoCs by the liver cannot be excluded. Additionally, the weight loss observed in all three groups taking part in the present study may play a significant role, since weight reduction results in a significant decrease in apoC-III levels [42].

The reduction of apoC-II and apoC-III plasma concentrations may be of clinical significance, since it has been shown that the levels of these apolipoproteins were a potent predictor of cardiovascular disease (CVD) risk in patients with type 2 diabetes mellitus [43, 44] and patients with coronary heart disease [45, 46]. Furthermore, increased plasma levels of apoC-III lead to delayed catabolism of TG-rich lipoproteins and hypertriglyceridemia, which contribute to elevated CVD risk. In the Monitored Atherosclerosis Regression study, in which 220 subjects with angiographically proven coronary heart disease received lovastatin or placebo treatment, the on-trial level of non-HDL-apoC-III in lovastatin group was the only independent of plasma TG concentration risk factor associated with progression of mild/moderate lesions [47]. Moreover, in a case–control analysis of 418 patients from the Cholesterol and Recurrent Events (CARE) trial who had a myocardial infarction or coronary death and 370 control subjects without a CVD event, non-HDL-apoC-III and TG levels were predictors of subsequent coronary events [48]. Furthermore, there is evidence that apoC-III exerts a direct effect on vascular and inflammatory functions, such as induction of adhesion molecules in vascular endothelial cells and activation of nuclear factor-kB [15]. Based on this evidence, the greater impact of ezetimibe plus orlistat administration on apoC-III compared with orlistat monotherapy should be taken into account when assessing the probable clinical benefit of this combination treatment.

In the present study we did not measure LPL activity or mass. We also did not measure apoB-48 levels as an index of chylomicron formation. Kinetic studies looking at both synthesis and catabolism of the apoCs are needed to examine the effects of ezetimibe and orlistat on apoCs and TG metabolism.

Conflict of interest statement None.

COMMUNICATION

Identification of Glucosylceramides Containing Sphingatrienine in Maize and Rice Using Ion Trap Mass Spectrometry

Tatsuya Sugawara · Jingjing Duan · Kazuhiko Aida · Tsuyoshi Tsuduki · Takashi Hirata

Received: 10 March 2010 / Accepted: 12 April 2010 / Published online: 30 April 2010

Abstract We characterized the glucosylceramide moieties from maize and rice using liquid chromatography-ion trap mass spectrometry. Glucosylceramides containing 4,8-sphingadienine (d18:2) acylated to hydroxy-fatty acids were detected as the predominant molecules both in maize and in rice. In addition, 4-hydroxy-8-sphingenine (t18:1) and sphingatrienine (d18:3) were found in maize and rice glucosylceramides, and in the case of rice, sphingenine (d18:1) was also detected. Glucosylceramides containing d18:3 were acylated to hydroxyl fatty acids (16–24 carbon atoms). Our results indicate the presence of the triene type of sphingoid base in higher plants.

Introduction

Sphingolipids are found in a wide variety of organisms, and constitute a family of compounds that have a sphingoid base (long-chain base) with an amide-linked fatty acid and a polar head group. The hydrolyzed products of sphingolipids (ceramides and sphingoid bases) are highly bioactive compounds that play roles as second messengers that are known to be involved in many aspects of cell regulation, such as cell growth, cell differentiation and apoptosis [1–3]. Recently, dietary sphingolipids have gained attention for their potential to protect the intestine from inflammation and cancer [4–9]. In addition, other physiological functions of sphingolipids, such as improving the barrier function of skin, lowering plasma lipids and prevention of melanin formation, have also been reported [10–12].

Diverse structures of the sphingoid base occur in nature. The most common sphingoid base of mammalian sphingolipids is sphingosine (*trans*-4-sphingenine, d18:1^4). Smaller amounts of other sphingoid bases, such as sphinganine (dihydrosphingosine, d18:0) and phytosphingosine (4-hydroxysphinganine, t18:0) are frequently encountered. The structures of sphingoid bases in higher plants are more complicated than in mammals [13]. Plants primarily contain *cis*- and *trans*-isomers of Δ8-unsaturated sphingoid bases, such as 8-sphingenine (d18:1^8), 4,8-sphingadienine

(d18:$2^{4,8}$) and 4-hydroxy-8-sphingenine (t18:1). Determination of those diverse structures including variations of the sphingoid backbone is important to understand the functional and nutritional significance of dietary sphingolipids.

Mass spectrometry is one of the most powerful methods for detecting and identifying the chemical structures of lipids including sphingolipids [14–16]. In this study, we characterized the structures of glucosylceramide, one of the predominant glycosphingolipids in plants, from rice and from maize using liquid chromatography-ion trap mass spectrometry. Our results demonstrate the presence of sphingatrienine (d18:3) in higher plants, which has been described previously in marine invertebrates [17–19] and has been found in tobacco leaf [20].

Experimental Procedures

Materials

Glucosylceramides were prepared from maize grain and from rice grain using a silica gel column after lipid extraction and saponification as described previously [21]. All other chemicals and solvents were of reagent grade.

LC–MS/MS Analyses

An HPLC system coupled to an LCMS-IT-TOF spectrometer equipped with an electrospray ionization interface (Shimadzu, Kyoto, Japan) was used. A TSK gel ODS-100Z column (2.0 × 50 mm, 3 μm, Tosoh, Tokyo, Japan) was eluted with acetonitrile/water (93:7, v/v) at a flow rate of 0.2 mL/min. The MS was operated with the following conditions: probe voltage of 4.50 kV, CDL temperature of 200°C, block heater temperature of 200°C, nebulizer gas flow of 1.5 L/min, ion accumulation time of 100 ms, MS range of *m/z* 650–900, MS^2 range of *m/z* 200–300, and CID parameters as follows: energy, 60%; collision gas 60%. For the structural analysis of glucosylceramide, $[M + H - 18]^+$ (loss of water) in the positive scan mode was used for MS/MS analysis to obtain the product ions. The typical signals which are characteristic for the sphingoid base moieties were observed as the product ions using the auto MS/MS detection mode. In this system, product ions corresponding to d18:1, d18:2 and d18:3 were *m/z* 264.3, 262.3 and 260.2, respectively [14–16]. In the case of glucosylceramide molecules consisting of t18:1, the loss of glucose $[M + H - 162]^+$ was used as the precursor ion and the product ions corresponding to t18:1 were *m/z* 280.3 and 262.3 [16]. Pairs of the structurally specific product ions of sphingoid bases and their precursor ions were used for the identification of glucosylceramide molecules.

Results and Discussion

In the positive full scan mode, $[M + Na]^+$, $[M + H]^+$ and $[M + H - H_2O]^+$ were the predominant signals in each peak. It is well known that the sugar moiety of glycosylceramides in plants is mostly glucose [22]. In the case of molecules consisting of t18:1, the loss of glucose $[M + H - 162]^+$ was also clearly detected. Glucosylceramide molecules containing d18:2 and t18:1 were determined both in maize and in rice as described previously (Figs. 1a, 2a) [16]. In the case of rice glucosylceramide, molecules consisting of d18:1 were also identified. Detection of glucosylceramide consisting of d18:2 and t18:1 was separated into two peaks, *cis*- and *trans*-isomers of Δ8-unsaturated sphingoid bases. *Cis*-isomer was detected earlier than *trans*-isomer by separation of the reverse phase [20]. Predominantly hydroxy fatty acids containing 16–26 carbon atoms were detected both in maize and in rice glucosylceramides.

We verified that the characteristic product ion at *m/z* 260.2 corresponding to d18:3 was detected in maize glucosylceramide using the auto MS/MS detection mode (Fig. 1a). Five peaks in the total ion chromatogram of maize glucosylceramide showed the product ion at *m/z* 260.2 (peak 1–5 in Fig. 1a). The MS spectra of those 5 peaks are shown in Fig. 1b–f. As the precursor ion of *m/z* 260.2, $[M + H - 18]^+$ ions at *m/z* 694.5, 722.5, 750.6, 778.6 and 806.6 were detected. The identification of each peak component is summarized in Table 1. The acylated fatty acid moieties were hydroxy fatty acids with 16–24 carbon atoms. In the case of rice, glucosylceramide consisted of d18:3-C18:0h and d18:3-C20:0h (Fig. 2; Table 1).

It has been reported that the sphingoid bases in marine invertebrates are quite different from those in mammals and in plants [13]. Triene bases with conjugated diene, such as 2-amino-4,8,10-octatriene-1,3-diol (d18:3) and 2-amino-9-methyl-4,8,10-octatriene-1,3-diol (d19:3), were identified in marine invertebrates including ascidians [17], starfish [18, 19] and squid [23] and also some fungi [24]. We have also reported that sea cucumber glucosylceramide has sphingoid bases with three double bonds [25]. Sperling et al. [20] described the presence of sphingatrienine in tobacco leaf by HPLC analysis of a sphingoid base derivatized with dinitrophenyl. In this study, we identified several molecular species of sphingatrienine-containing glucosylceramides in maize and rice by LC–MS/MS system. However, the locations of double bonds in sphingatrienine structure have not been identified. Sphingolipids of plant organisms contain primarily d18:1^8, d18:$2^{4,8}$ and t18:1^8 as sphingoid bases and sphingolipid Δ4-desaturase and sphingolipid Δ8-desaturase have been identified in plants [22]. It has been reported that the composition of sphingoid bases differs between chilling sensitive and

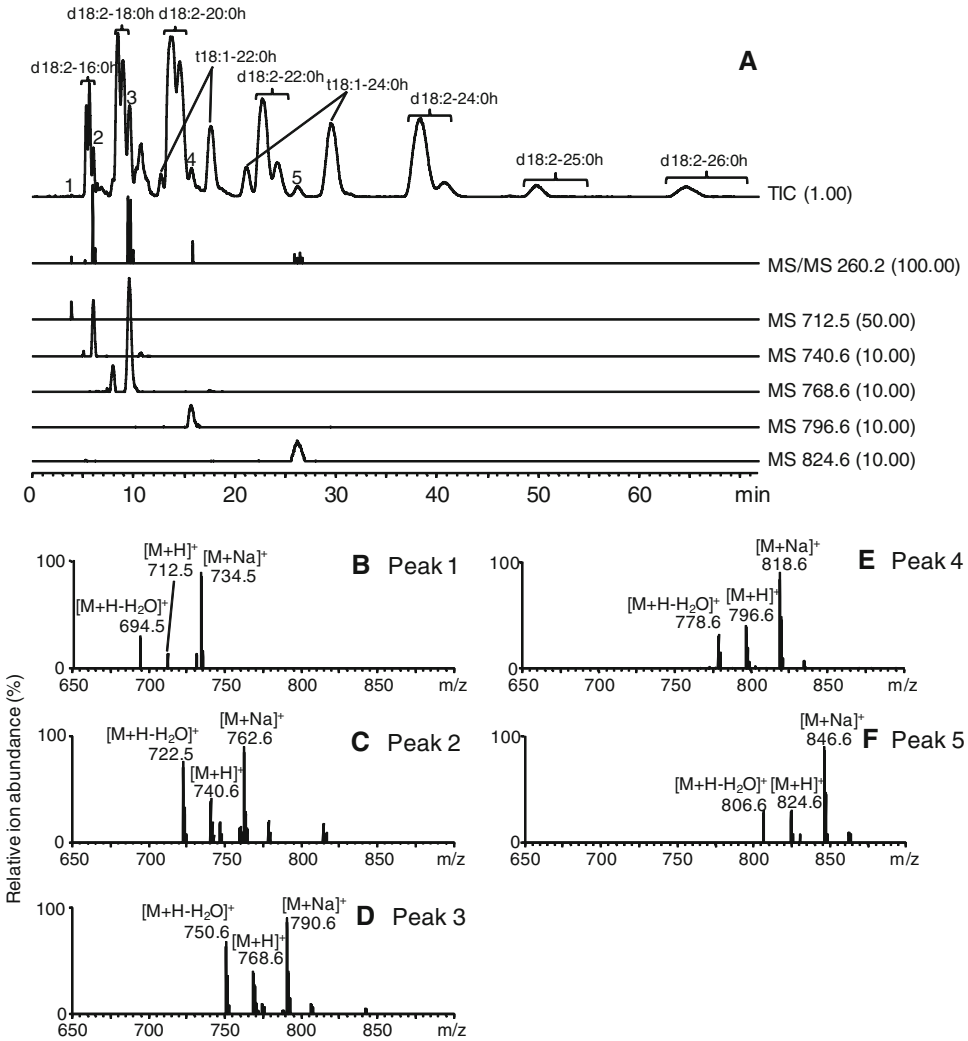

Fig. 1 Total ion and selected ion chromatograms of maize glucosylceramide (**a**) and mass spectra of peak components (**b**–**f**)

Table 1 Glucosylceramides containing sphingatrienine (d18:3) from maize and from rice identified by HPLC–MS/MS analysis

Peak no. in Figs. 1 and 2	Precursor ion *m/z*		Product ion *m/z*	Molecule	Source
	$[M + H]^+$	$[M + H - 18]^+$			
1	712.5	694.5	260.2	d18:3-C16:0h	Maize
2	740.5	722.5	260.2	d18:3-C18:0h	Maize, rice
3	768.6	750.6	260.2	d18:3-C20:0h	Maize, rice
4	796.6	778.6	260.2	d18:3-C22:0h	Maize
5	824.6	806.6	260.2	d18:3-C24:0h	Maize

tolerant plants [26]. Details of tissue distribution, synthetic pathways and functions of plant sphingatrienines remain to be elucidated.

Recently, dietary sphingolipids have gained attention for their potential to protect the intestine from inflammation and cancer [4–9]. We reported that the daily intake of plant-origin glucosylceramides in Japan is estimated to be 50 mg due to their presence in foodstuffs [27] and we investigated the digestion and absorption of plant-derived sphingolipids [21]. Our findings indicate that the metabolic fate of plant-derived sphingoid bases, such as 4,8-sphingadienine, within enterocytes differs from that of sphingosine. Sphingoid bases, except for sphingosine, appear to be transported out of cells across the apical membranes of enterocytes by P-glycoprotein after absorption and consequently the intestinal uptake is quite poor [28, 29]. Thus, the determination of sphingolipid structures, including variation of the sphingoid backbone, from dietary sources

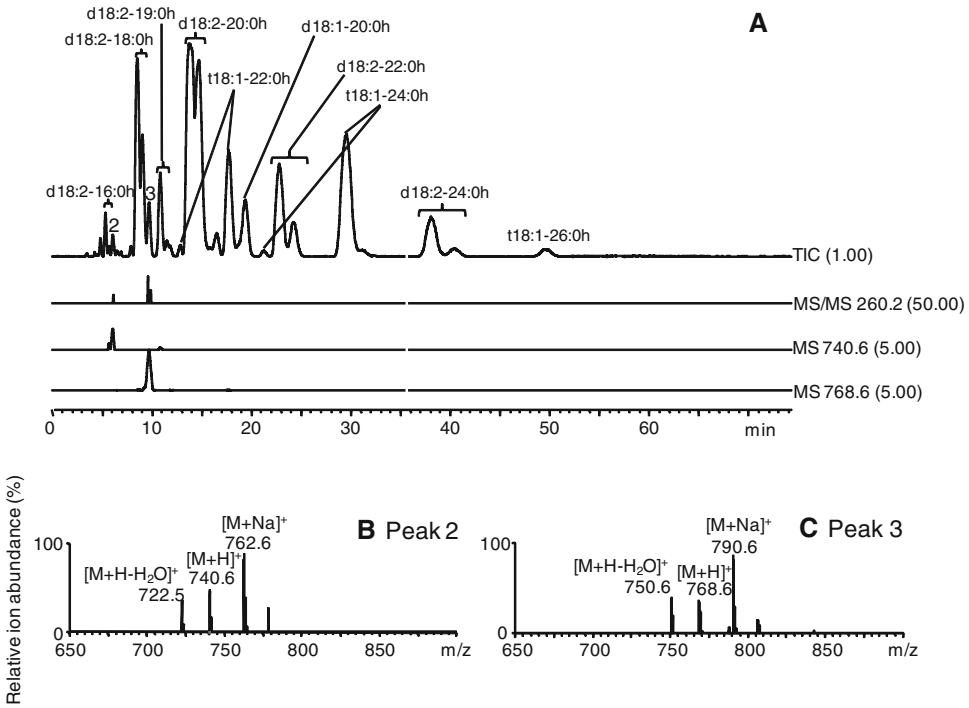

Fig. 2 Total ion and selected ion chromatograms of rice glucosylceramide (**a**) and mass spectra of peak components (**b**, **c**)

is important to understand their functional and nutritional significance.

In this study, we analyzed the chemical structures of glucosylceramides from maize and from rice using liquid chromatography-ion trap mass spectrometry. Our results indicate the presence of sphingatrienine (d18:3) in higher plant sphingolipids. MS/MS analysis is a powerful method for identifying the molecular structures of sphingolipids from biological sources.

Pecipamide, a New Sphingosine Derivative from the Cultures of *Polyporus picipes* (Basidiomycetes)

Yong Li · Ya-Tuan Ma · Yi Kuang · Jin-Ming Gao · Jian-Chun Qin

Received: 13 December 2009 / Accepted: 31 March 2010 / Published online: 27 April 2010

Abstract A new C_{18}-ceramide congener named pecipamide (**1**), together with the known ergosta-4,6,8(14),22-tetraen-3-one (**2**), was isolated from the solid fermentations of the basidiomycetous fungus *Polyporus picipes*. The structure of the new metabolite was established as (2′*R*,2*S*,3*R*)-*N*-2′-hydroxyheptadecanoyl-2-amino-octadecane-1,3-diol on the basis of spectroscopic data, including 1D- and 2D- nuclear magnetic resonance spectroscopy (NMR) experiments, as well as by means of mass spectrometric measurements (MS).

Introduction

Sphingolipids constitute a biologically important class of compounds [1, 2]. These lipids have been reported from all groups of organisms thus far analyzed, including marine organisms [3–8], plants [9–11], and fungi [12–16]. Sphingolipids, e.g., ceramides, sphingomyelin, cerebrosides and gangliosides, are important building blocks of the plasma membrane of eukaryotic cells. Their function is to anchor lipid-bound carbohydrates to cell surfaces and to create an epidermal water permeability barrier, as well as to participate in antigen–antibody reactions and transmission of biological information [1]. Some of these metabolites have been reported to display a wide range of biological activities, such as antihepatotoxic [9], cytotoxic [5–7], antitumor [7], immunostimulatory [8], antifungal [7], antimicrobial [6, 17], antiviral or Ca^{2+} ATPase [18], and anti-inflammatory effects [19].

In recent years, renewed attention has been paid to the constituents of higher basidiomycetes because of their possible medical usage [2, 20]. For examples, antiviral, antibiotic, antiinflammatory, hypoglycemic, hypocholesterolemic, and hypotensive properties were ascribed to ingredients of such mushrooms [2, 21, 22]. The mushroom *Polyporus picipes* (family Polyporaceae) has some

activities, including inhibiting cancer, enhancing immunity, softening blood vessels, preventing aging of the heart, as well as improving brain memory function. No phytochemical study of this fungus has previously been carried out.

In a continuation of our investigation into bioactive fungal metabolites, especially lipids from higher fungi (macrofungi) [12–16], a new ceramide, (2′*R*,2*S*,3*R*)-*N*-2′-hydroxyhepta-decanoyl-2-amino-octadecane-1,3-diol (**1**), was isolated from the solid fermented cultures of *P. picipes*, along with a sterone, ergosta-4,6,8(14),22-tetraen-3-one (**2**) [23]. Herein, we report the isolation and structural elucidation of the new ceramide.

Results and Discussion

The AcOEt-soluble fraction of AcOEt-MeOH-HAc extract from the solid cultures of *P. picipes* was subjected to repeated CC to yield compounds **1** and **2**. The structure of new compound **1** was elucidated as follows (Fig. 1).

Compound **1** was isolated as white needle crystals. It gave pseudo-molecular ion peaks $[M–1]^-$ at *m/z* 568 and $[M–1 + MNBA$ (*m*-nitrobenzyl alcohol, $M_r = 153$) as matrix$]^-$ at 721 in the negative ion FAB-MS spectrum and $[M + Na]^+$ at *m/z* 592 in the positive ion ESI-TOF-MS spectrum, indicating a molecular weight of 569. It has a molecular formula $C_{35}H_{71}NO_4$, established by a quasi-molecular ion peak $[M + Cl–2H]^-$ at *m/z* 602.4904 (calc. 602.4915 for $C_{35}H_{69}NO_4Cl$) in the HR-FAB-MS (negative-ion mode), combined with ^{13}C- and ^{1}H-NMR data. The IR spectrum showed absorption bands for a secondary amide (1,625, 1,545 cm^{-1}) and hydroxyl (3,434 cm^{-1}) functionalities. The ^{1}H- and ^{13}C-NMR spectral data of **1** indicated the presence of an amide linkage and two long chain aliphatic moieties, suggesting the sphingolipid nature of the molecule (Table 1).

The overlapped signals of aliphatic methylenes at δ 1.18–1.34 in the ^{1}H-NMR spectrum and at δ 29.67–30.21 in the ^{13}C-NMR spectrum were observed. Moreover, the ^{1}H-NMR spectrum presented signals attributable to two terminal methyl groups at δ 0.81 (6H, *brt*, $J = 6.64$ Hz), one methylene group at δ 3.94 (1H, *dd*, $J = 10.9$, 4.3 Hz, H-1) and 3.70 (1H, *dd*, $J = 10.9$, 5.3 Hz, H-1), and three methines at δ 3.74 (1H, m, H-3), 4.06 (2H, m, H-2 and H-2′), indicating the presence of two long aliphatic chains instead of the branched chain [16]. A downfield doublet appearing at δ 7.25 (1H, *d*, $J = 7.84$ Hz) was assigned to an amide NH. In addition, the ^{13} C-NMR and DEPT spectra showed the existence of characteristic signals, an amide carbonyl group [δ 174.56 (CONH, C-1′)], three methine groups [δ 53.71(CHNH, C-2), 73.88 (CHOH, C-3), 72.34 (CHOH, C-2′)], and one hydroxymethyl group [δ 62.31(CH_2OH, C-1)] in this molecule (Table 1). The aforementioned data implied that compound **1** is a ceramide derivative [12–15]. Detailed analysis of the ^{1}H-^{1}H COSY spectrum (in pyridine-d_5) of compound **1** indicated connectivities for the H_2-1 was found to be coupled with H-2, which in turn was coupled with H-3, H-4, and an amide proton, and for the H-2′ was found to be coupled with H-3′. Interpretation of HMBC spectrum revealed correlations from an amide proton (CONH) to C-1′; and H-2′ to C-1′ (Fig. 2).

Table 1 ^{1}H- (400 MHz) and ^{13}C-NMR (100 MHz) data of **1** in $CDCl_3$

Position	^{13}C (DEPT)	^{1}H (J in Hz)
1	62.31 (CH_2)	3.70 (*dd*, $J = 10.9$, 5.3)
		3.94 (*dd*, $J = 10.9$, 4.3)
2	53.71 (CH)	4.06 (m)
3	73.88 (CH)	3.74 (m)
4	31.90 (CH_2)	1.71 (m)
5	25.99 (CH_2)	1.45 (m)
6–15	29.67–30.21 (CH_2)	1.18–1.34 (brs)
16	31.93 (CH_2)	
17	22.67 (CH_2)	
18	14.11 (CH_3)	0.81(t, $J = 6.64$)
CONH		7.25 (*d*, $J = 7.84$)

17′	14.11 (CH_3)	0.81 (t, 6.64)

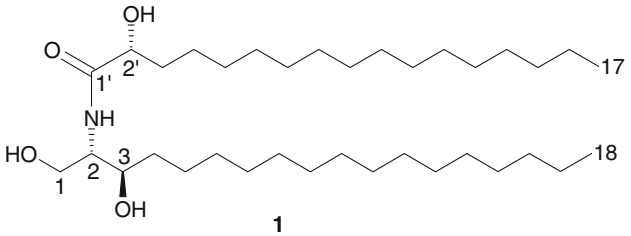

Fig. 1 Structure of compound **1**

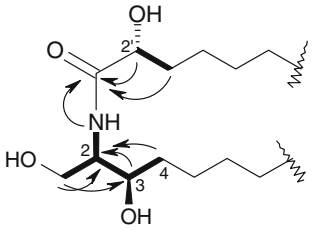

Fig. 2 Key COSY and HMBC interactions in compound **1**

The lengths of the long chain base and the fatty acid were determined by FAB-MS. The negative FAB-MS presented the characteristic fragments at *m/z* 269$[C_{15}H_{30}CH(OH)CO]^-$ and 284 $[C_{15}H_{30}CH(OH)$-$CONH + H]^-$ in this molecule (Fig. 3), suggesting that the long chain base and fatty acid of **1** should be 2-amino-octadecane-1,3-diol and 2-hydroxyheptadecanoic acid, respectively. Methanolysis of compound **1** afforded the fatty acid methyl ester, which exhibited a base peak at *m/z* 300 $[M^+]$ and an ion at *m/z* 241 $[M–COOCH_3]^+$ in the EIMS. This established the molecular weight of the fatty acid fragment to be 286. The structure of the acyl moiety was determined to be 2-hydroxyheptadecanoic acid.

The relative stereochemistry at C-2, C-3 and C-2′ were deduced to be 2*S*,3*R* and 2′*R*, respectively, identical to that of *D*-sphingosine on the basis of ^{13}C-NMR spectral data, since the chemical shifts of C-2 (δ 53.71), C-3 (δ 73.88), and C-2′ (δ 72.34) were in agreement with those of the previously reported natural product, (2′*R*,2*S*,3*R*)-*N*-2′-hydroxyoctadecanoyl-2-amino-9-methyl-heptadecadiene-1,3-diol (δ 54.4, 74.4, and 72.4), a ceramide that was isolated from the mushroom *Ramaria botrytis* [24], and with those of other related compounds [25, 26], in connection with their optical rotations of **1** ($[\alpha]_D$ + 2.3) and the natural relative ($[\alpha]_D$ + 7.4) [24]. On the other hand, biogenetically, in higher mushrooms, these ceramides all have common biosynthetic pathways [15]. So, this new compound in the current study has a relative configuration of 2'*R*,2*S*,3*R* tentatively determined. In view of these evidence, thus, the structure of **1**, which we named as pecipamide, was elucidated as (2′*R*,2*S*,3*R*)-*N*-2′-hydroxyheptadecanoyl-2-amino-octadecane-1,3-diol.

Sphingolipids are ubiquitous membrane constituents of animals, plants, and also lower forms of life, the principal component of which is the long chain base or sphingoid base. In nature, the most widely occurring sphingoid bases are D-*erythro*-4*E*-sphingenine, 4-hydroxysphinganine (phytosphingosine), and 9-methyl-4*E*,8*E*-sphingadienine [12–16], whereas in higher mushrooms and other basidiomycetes, D-*erythro*-sphinganine is an uncommon minor sphingoid base. Fungal sphingolipids consist of phytosphingosine in the ceramide moiety instead of sphingosine, which is mainly present in mammals [27].

The present investigation demonstrated the presence in *Polyporus picipes* of a previously unrecognized sphingolipid, consisting of D-*erythro*-sphinganine in an amide linkage with a hydroxyl C_{17}-fatty acid. To our knowledge, this seems to be the first time that a D-*erythro*-sphinganine-type ceramide has been identified from the higher fungi.

Experimental Section

General Experimental Procedures

Optical rotations were measured on a PerkinElmer Model 341 polarimeter. NMR experiments were performed on a Bruker AM-400 or Bruker Avance-500 spectrometer with TMS as the internal standard, in $CDCl_3$, δ in ppm, *J* in Hz. Mass spectra were recorded on a VG Auto Spec-3000 (VG, Manchester, UK) or an API QSTAR Pulsar 1 spectrometer. IR spectra were recorded on a Bruker Tensor 27 spectrometer with KBr pellets. GC–MS with a Finnigan 4510 GC–MS system, at 70 eV for EI, a capillary column (30 m × 0.25 mm) packed with 5% phenyl and 95% methyl silicone on HP-5, Carrier gas: He, Column temperature: 160–240 °C, at 5 °C/min).

Column chromatography (CC) was performed on silica gel (200–300 mesh; Qingdao Marine Chemical Ltd., Qingdao, People's Republic of China) and Sephadex LH-20 (Amersham Biosciences, Sweden). TLC analysis was carried out on silica gel GF254 precoated plates (0.20–0.25 mm; Qingdao) with detection by heating silica gel plates sprayed with 10% H_2SO_4 in EtOH.

Producing Fungus

The mushroom strain of a basidiomycete *Polyporus picipes* (S 0318) was isolated from a tissue culture of the fruiting bodies of wild mushrooms collected at Laojunshan, Yunnan Province, P. R. China, in July 2003 and identified by Prof. Da-Gan Ji, Kunming Institute of Botany, Chinese Academy of Sciences. A voucher specimen was deposited at the herbarium of Kunming Institute of Botany, Chinese Academy of Sciences.

Fermentation

The *P. picipes* strain was maintained on a potato dextrose agar slant (PDA) at 4 °C. The activated strain was inoculated into 500-mL flasks containing 100 mL of a sterilized solid medium consisting of glucose (20 g/L), peptone (3 g/L), $MgSO_4{\cdot}7H_2O$ 0.5 (g/L), and KH_2PO_4 (1 g/L), and potato extract prepared by extracting from 100 g of peeled potato with 1 L of water boiled for 20 min. Stationary fermentation was carried out at 28 °C under a humidity of 50–70%. After 38 days of fermentation, the cultures were harvested.

Extraction and Isolation

The solid cultures were ultrasonically extracted five times with a mixture of AcOEt-MeOH-HAc (80:15:5). After evaporation of the solvent, the resultant extract was partitioned between water and EtOAc. The organic layers were combined and concentrated in vacuo. The EtOAc residue (4 g) obtained was subjected to a CC over silica gel and eluted with $CHCl_3$–MeOH (100:0 → 70:30) in a gradient elution manner to provide ten fractions (Fr1.–Fr10.) Fr5. (167 mg) was passed through a Sephadex LH-20 column (methanol) to obtain subfr.1–40. Subfr. 9–13 was subjected to a CC on silica gel using $CHCl_3$–MeOH (96:4), and a Sephadex LH-20 column with $CHCl_3$–MeOH (1:1), and further purified by a CC over silica gel with $CHCl_3$–acetone (85:15) to furnish compound **1** (7 mg). Subfr. 34 was subjected to a CC over silica gel with $CHCl_3$-MeOH (95:5) to yield ergosta-4,6,8(14),22-tetraen-3-one (**2**) (2 mg).

Methanolysis of Compound **1**

Compound **1** (2 mg) was treated with 2.5 mL of 1 N HCl in 82% MeOH and refluxed for 12 h. The reaction mixture was extracted with hexane, and the hexane layer was washed with water, dried, and evaporated to give methyl 2-hydroxyheptadecanoate, whose retention time (t_R) was 18.9 min; EI-MS (70 eV) *m/z* (rel. int. %) 300 $[M]^+$, 241 $[M–COOMe]^+$. The data were identical to those published earlier [13].

(2′*R*,2*S*,3*R*)-*N*-2′-hydroxyheptadecanoyl-2-amino-octadecane-1,3-diol (**1**). Amorphous white solid (chloroform). $[\alpha]_D^{20}$ + 2.3 (c = 0.1, acetone); ^{1}H- and ^{13}C-NMR data: see Table. IR (KBr): ν_{max} 3,434, 2,923, 2,850, 1,625, 1,545, 1,470, 1,070, 980, 714 cm^{-1}. ESI-MS (positive ion mode) *m/z*: 592.4 $[M + Na]^+$; FAB-MS (negative ion mode; matrix: *meta*-nitrobenzyl alcohol, mNBA) *m/z* (%): 567 $[M–2]^-$ (100), 568$[M–1]^-$ (40), 721 $[M–1 + 153]^-$, 328 $[M–C_{16}H_{33}O]^-$ (2.7), 285 $[C_{15}H_{33}CH(OH)CH\text{-}CH_2OH]^-$(5), 284 $[C_{15}H_{30}CH(OH)\ CONH + H]^-$ (22.5), 269$[C_{15}H_{30}CH(OH)CO]^-$(4), 242$[C_{15}H_{31}CH(OH) +H]^-$(9), 197 $[C_{14}H_{29}]^-$ (12); HR-FAB-MS *m/z*: 602.4904 $[(M + Cl–2H)^-$, calc. for $C_{35}H_{69}NO_4Cl$: 602.4915].

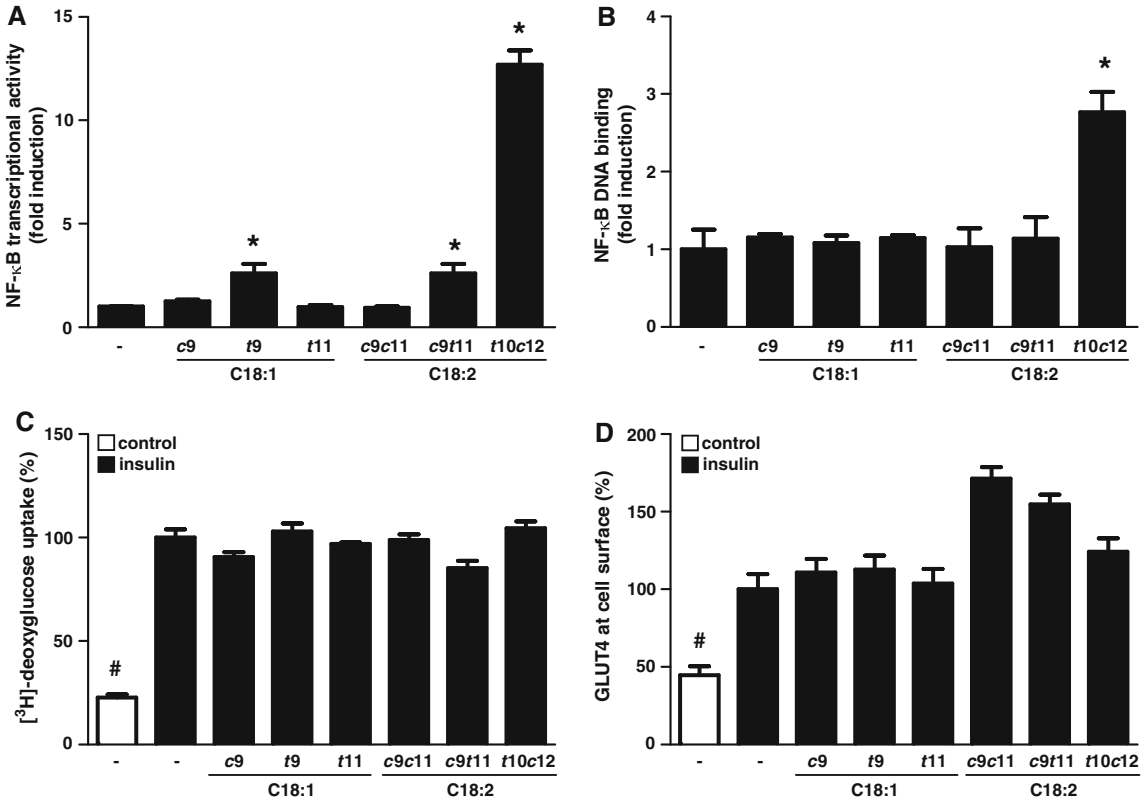

Fig. 2 NF-κB transcriptional activity and insulin sensitivity in skeletal muscle cells after incubation with geometric and positional C18:1 or C18:2 isomers. C2C12 myoblasts stably transfected with the 6κB-TK-luciferase construct were differentiated for 5 days and incubated with 400 μmol/l of the indicated FAs for 24 h (**a**). Lysates were prepared for assessment of luciferase activity. Values were corrected for protein content and expressed as fold-induction over control. Alternatively, 5 days differentiated L6-GLUT4myc myotubes were incubated with and without the indicated fatty acids (200 μmol/l, 16 h). Nuclear extracts were prepared and assessed for RelA DNA binding activity to a consensus NF-κB oligonucleotide by EMSA (**b**). Relative DNA binding activity was determined by phosphor-imager analysis and expressed as fold induction. Furthermore, 2-deoxyglucose uptake (**c**) and GLUT4 translocation (**d**) were measured after stimulation with 25 nmol/l insulin for 15 min in 5 days differentiated L6-GLUT4myc myotubes. Data are expressed as percentage of insulin-stimulated glucose uptake or GLUT4 translocation in absence of FA. Basal and insulin-stimulated conditions are represented by the *white* and *black bars*, respectively. $^{*}p < 0.05$ versus control. $^{\#}p < 0.05$ versus insulin-stimulated control. Data shown are representative examples of three independent experiments

Intracellular Lipid Droplets Contain Dynamic Pools of Sphingomyelin: ADRP Binds Phospholipids with High Affinity

Avery L. McIntosh · Stephen M. Storey · Barbara P. Atshaves

Received: 11 November 2009 / Accepted: 23 April 2010 / Published online: 15 May 2010

Abstract During the last several years, intracellular lipid droplets have become the focus of intense study. No longer an inert bystander, the lipid droplet is now known as a dynamic organelle contributing lipids to many cellular events. However, while the dynamics of cholesterol efflux from both the plasma membrane and lipid droplets have been studied, less is known regarding the efflux of sphingomyelin from these membranes. In order to address this issue, sphingomyelin efflux kinetics and binding affinities from different intracellular pools were examined. When compared to the plasma membrane, lipid droplets had a smaller exchangeable sphingomyelin efflux pool and the time required to efflux that pool was significantly shorter. Fluorescence binding assays revealed that proteins in the plasma membrane and lipid droplet pool bound sphingomyelin with high affinity. Further characterization identified adipose differentiation-related protein (ADRP) as one of the sphingomyelin binding proteins in the lipid droplet fraction and revealed that ADRP demonstrated saturable binding to 6-((*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl) amino)-hexanoyl)sphingosyl-phosphocholine (NBD-sphingomyelin) and also 2-(6-(7-nitrobenz-2-oxa-1, 3-diazol-4-yl)amino)hexanoyl-1-hexadecanoyl-*sn*-glycero-3-phosphocholine (NBD-phosphatidylcholine) with binding affinities in the nanomolar range. Taken together, these results suggest that lipid droplet associated proteins such as ADRP may play a significant role in regulating the intracellular distribution of phospholipids and lipids in general. Overall, insights from the present work suggest new and important roles for lipid droplets and ADRP in phospholipid metabolism.

Keywords Lipid droplets · Sphingomyelin · Efflux · ADRP

Abbreviations

ADRP	Adipose differentiation-related protein
ACBP	Acyl-CoA binding protein
NBD-sphingomyelin	6-((*N*-(7-nitrobenz-2-oxa-1, 3-diazol-4-yl)amino)-hexanoyl)sphingosyl-phosphocholine
NBD-phosphatidylcholine	2-(6-(7-nitrobenz-2-oxa-1, 3-diazol-4-yl)amino)hexanoyl-1-hexadecanoyl-*sn*-glycero-3-phosphocholine

Introduction

As defined by the body mass index, greater than one-third of the American adult population is considered to be obese, with a greater risk of developing cardiovascular disease and diabetes [1–3]. When chronic over-nutrition leading to obesity occurs, excess lipids are stored in intracellular organelles called lipid droplets. Once thought to be simple storage vesicles for neutral lipids, it is now clear that lipid droplets serve as reservoirs for lipids and proteins involved in many cellular processes. However, despite growing awareness of the health problems associated with excessive lipids in tissues and cells, details on the molecular mechanism of intracellular lipid storage remain unclear.

Lipid droplets have been the focus of increasing scrutiny in the last decade and the subject of several reviews [4–6]. Lipid droplets are composed of a neutral lipid core surrounded by a phospholipid monolayer, within which proteins reside [7, 8]. Initially, the only known proteins were the perilipins [7], adipose differentiation-related protein (ADRP) [9, 10], P_{200} capsule protein [11, 12], and vimentin [11]. Proteomic analysis later revealed associations with proteins involved in cell signaling, cholesterol/fatty acid metabolism, and membrane trafficking [13–15]. Caveolin proteins, normally found in flask-like invaginations of the plasma membrane called caveolae, were also present. However, while the function of plasma membrane caveolins in binding and facilitating the transport of cholesterol and fatty acids is well-documented [16–19], it remains unclear what role these proteins play in lipid droplet function.

In cells, the bulk of cholesterol and sphingolipids such as sphingomyelin are in the plasma membrane, a lipid bilayer where the deposition of cholesterol is defined by its high affinity for the saturated acyl chains of sphingolipids. Cholesterol and sphingomyelin are essential membrane components, yet, excess levels are toxic and increase the risk for arteriosclerosis. Therefore, the levels are strictly regulated through several processes, including efflux, to remove excess lipids from the cell and the body. As lipid reservoirs, the regulation of cholesterol and sphingolipid levels within lipid droplets is important to maintain lipid homeostasis. However, while the dynamics of cholesterol efflux from the plasma membrane and lipid droplets have been studied [20], less is known regarding the efflux of sphingomyelin from membranes. The present work was undertaken to examine the efflux kinetics and binding affinity of different intracellular sphingomyelin pools. The results presented herein establish, for the first time, ADRP as a phospholipid (sphingomyelin, phosphatidylcholine) binding protein and define the affinity and capacity of NBD-sphingomyelin for lipid droplet and plasma membrane proteins.

Materials and Methods

Materials

Silica Gel G and Silica Gel 60 thin layer chromatography (TLC) plates were from Analtech (Newark, DE) and EM Industries, Inc. (Darmstadt, Germany), respectively. Neutral lipid standards were purchased from Nu-Chek Prep, Inc. (Elysian, MN), while phospholipid standards were obtained from Avanti (Alabaster, AL). Rabbit polyclonal antiserum to mouse ADRP was prepared as described [21]. Rabbit anti-human caveolin-1 (cat. no. 610059) was purchased from BD Transduction Laboratories (Palo Alto, CA). Rabbit anti-human caveolin-2 (cat. no. NB100-79911) and rabbit anti-human Na^+ K^+-ATPase (cat. no. NB100-80005) were purchased from Novus Biologicals (Littleton, CO). Mouse anti-human cytochrome c oxidase (clone AS70, cat. no. C9229) was purchased from Sigma (St. Louis, MO). Mouse anti-human transferrin receptor (CD71, clone H68.4, cat. no. 13-6800), NBD-sphingomyelin, Nile red, and NBD-phosphatidylcholine were purchased from Invitrogen (Camarillo, CA). Primary antibodies were diluted 1:1,000 for Western blot analysis. Human high-density lipoprotein (HDL) was from Calbiochem (San Diego, CA). All reagents and solvents used were of the highest grade available and were cell culture tested.

L-Cell Culture

Murine L-cells (L $arpt^-tk^-$) were grown to confluency in Higuchi medium [22] supplemented with 10% fetal bovine serum (Hyclone, Logan, UT), as described in [23]. For fluorescence imaging and efflux experiments, cells were seeded at a density of 50,000 cells/chamber onto Lab-Tek Chamber Coverglass slides (Nunc, Naperville, IL). To ensure a monolayer, samples were examined within 20 h of seeding. Lipid droplets were isolated from L-cells grown to confluency on culture trays (245 × 245 × 25 mm, Nunc, Naperville, IL), as described previously [8].

Laser Scanning Confocal Microscopy

Confocal and co-localized images were acquired on a Bio-Rad (Hercules, CA) MRC-1024 Laser Scanning Confocal Imaging System using multiple photomultiplier tubes

under the control of LaserSharp v.3.2 software (Bio-Rad). For probe excitation, the MRC-1024 system utilized a 15-mW krypton-argon laser (American Laser Corp., Salt Lake City, UT) with a 5-mW output. Cells cultured on Lab-Tek Chamber Coverglass slides were placed on the stage of a Zeiss Axiovert 135 inverted epifluorescence microscope (Zeiss, Thornwood, NY) and examined with a 63× oil-immersion, infinity objective (numerical aperture 1.4). For co-localization experiments, cells were incubated with NBD-sphingomyelin (0.2 μM) and Nile red (0.1 μM) for 10 min in a 37°C, 5% CO_2 incubator. After incubation, cells were washed with phosphate-buffered saline (PBS) buffer and then sequentially imaged for NBD-sphingomyelin (488 nm excitation, 540/30 emission, green channel) and Nile red (568 nm excitation, HQ598/40 emission, red channel). The confocal images from the green and red channels were merged and appeared yellow where superimposition occurred (red and green are additive and yield yellow to orange in the RGB color space). NBD-sphingomyelin was mainly localized to lipid droplets and the plasma membrane, with other internal staining evident after 20–30 min of incubation. Pixel fluorograms were constructed and correlation coefficients used to estimate the extent of probe overlap were determined from the fluorograms as described previously [20]. Samples were exposed to the light source for minimal time periods to minimize photobleaching effects. The gain and black levels of each photomultiplier tube were optimized to minimize the levels of the autofluorescence signal and to increase the dynamic range. Residual auto fluorescence remaining was subtracted from the data. Image files were analyzed using either Metamorph software (West Chester, PA) or NIH Image, a program written by W. Rasband and available by anonymous FTP from http://zippy.nimh.nih.gov.

NBD-Sphingomyelin Stability

In experiments performed to assess the stability of the NBD-sphingomyelin probe, L-cells were grown to confluency on 35-mm tissue culture dishes as described above. Cells were incubated with NBD-sphingomyelin (0.5 μM) in PBS for 3 min at 37°C, after which the buffer was removed and the cells washed with PBS to remove unincorporated NBD-labeled probe. Thereafter, the cells were incubated in PBS at 37°C for various timed intervals (0–60 min). At the indicated time, the buffer was removed, the cells were washed once with PBS before freezing, and then scraped into *n*-hexane-2-propanol extraction solvent 3:2 (v/v) [24]. Polar lipids (including NBD-sphingomyelin) were separated from neutral lipids using silicic acid columns washed with chloroform–methanol 59:1 (v/v), followed by methanol. The polar lipids were resolved on Silica Gel 60 TLC plates using chloroform:methanol:water:acetic acid (150:112.5:6:10.5, v/v/v/v). NBD-labeled lipids were visualized on the TLC plates under UV light at 360 nm using an Alpha Innotech FluorChem Imager (San Leandro, CA). Levels of NBD-sphingomyelin remaining at each time point were compared to NBD-sphingomyelin at time zero (initial concentration) to obtain the percentage of NBD-sphingomyelin remaining in the cells.

NBD-Sphingomyelin Efflux

In order to perform the HDL-mediated NBD-sphingomyelin efflux experiments, cells were loaded with NBD-sphingomyelin (0.2 μM) and Nile red (0.1 μM) in PBS buffer for 10 min in a 37°C, 5% CO_2 incubator. After incubation, the cells were washed with PBS buffer and then imaged sequentially for NBD-sphingomyelin (488 nm excitation, 540/30 emission) and Nile red (568 nm excitation, HQ598/40 emission). Lipid droplets were identified by morphology and confirmed by Nile red and NBD-sphingomyelin co-localization data. Once a suitable field of cells was chosen, a medial section passing through 5–10 cells was selected, and the section was scanned for the initial fluorescence intensity of NBD-sphingomyelin. HDL (10 μg HDL/mL) was added to start the efflux experiment. Since stability studies indicated that greater than 85% of the NBD-sphingomyelin probe remained intact after 40 min incubation, all experiments were completed within 40 min. Fluorescence intensity in the total area of lipid droplet and plasma membrane was measured over time and was used to gauge the extent of NBD-sphingomyelin efflux from each cell compartment. Cells were imaged and analyzed by Metamorph software to graphically determine the separate contributions of the efflux process. Data points were fitted ($R^2 = 0.996$) to the following three-parameter, sigmoidal equation: $y = A/(1 - e^{-((t - t0)/b)})$, where y is the percentage of HDL-mediated NBD-sphingomyelin efflux at time t, A indicates the percentage of sphingolipid pool available for efflux, $1/b$ is an apparent rate constant (k), and t_0 is the time required to reach 50% of the maximal efflux, representing the half-time ($t_{1/2}$) of the exchangeable pool. Half-time and k values were apparent values due to dependence on HDL acceptor concentrations. Using a nonlinear least squares routine, all parameters were obtained simultaneously from the fitted data. Unique fittings were obtained individually for each time course involving individual cells. Statistical methods involving the paired *t*-test (GraphPad Prism, San Diego, CA) were used to compare the parameters derived from lipid droplet and plasma membrane efflux curves. Experiments were performed in triplicate with $n = 50$–60 lipid droplets from $n = 25$ cells. Values with $P < 0.05$ were considered to be statistically significant.

Western Blot Analysis

Expression levels of lipid droplet (ADRP, caveolin-1, caveolin-2), plasma membrane (Na^+, K^+-ATPase, transferrin), and mitochondrial (cytochrome c oxidase) protein markers in homogenate and lipid droplet fractions isolated from L-cells [8] were determined by Western blot analysis. In brief, cell homogenate (5 μg/lane) and lipid droplet (10 μg protein/lane) proteins were subjected to SDS-PAGE using 12% tricine gels before transferring to 0.45-μm nitrocellulose paper (Sigma Chemical Co., St. Louis, MO) by electroblotting in a continuous buffer system at 0.8 mA/cm^2 for 2 h. After transfer, blots were blocked in 3% gelatin in TBST (10 mM Tris–HCL, pH 8, 100 mM NaCl, 0.05% Tween-20) before incubation with the primary antibodies. Alkaline-phosphatase conjugates of goat anti-rabbit IgG and Sigma Fast 5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolim tablets (Sigma, St. Louis, MO) were used to visualize bands of interest. Proteins were quantitated by densitometric analysis after image acquisition using a single-chip CCD (charge-coupled device) video camera and a computer workstation (IS-500 system from Alpha Innotech, San Leandro, CA). Image files were analyzed (mean 8-bit grayscale density) using NIH Image, available by anonymous FTP from http://zippy.nimh.nih.gov.

Lipid Analyses

Lipid droplets were isolated from L-cell fibroblasts as described in [8]. Lipids from lipid droplets were extracted with *n*-hexane-2-propanol 3:2 (v/v) and resolved into individual lipid classes using Silica Gel G TLC plates developed in petroleum ether:diethyl ether:methanol:acetic acid 90:7:2:0.5 [8]. Total cholesterol, free fatty acid, triacylglyceride, cholesteryl ester, and phospholipid content were determined by the method of Marzo et al. [25]. Individual phospholipids, including phosphatidic acid (PA), ethanolamine glycerophospholipid (PE), phosphatidylinositol (PI), phosphatidylserine (PS), choline glycerophospholipid (PC), and sphingomyelin (SM), were resolved from total phospholipid (PL) samples in the following manner: PL were eluted from the Silica Gel G TLC plates using chloroform:methanol:HCL (100:50:0.375, v/v/v) and applied to Silica Gel 60 TLC plates, where individual phospholipids were resolved using chloroform:methanol:water:acetic acid (150:112.5:6:10.5, v/v/v/v). Individual phospholipids were quantitated densiometrically as described previously [26, 27]. Protein concentration was determined by the method of Bradford from the dried protein extract residue digested overnight in 0.2 M KOH [28]. All glassware was washed with sulfuric acid-chromate before use.

NBD-Sphingomyelin Binding Affinity

Lipid droplet and plasma membrane fractions were isolated as described previously [8, 26]. To measure the sphingomyelin and choline glycerophospholipid (phosphatidylcholine) binding affinities of membranes (lipid droplet and plasma membrane) and lipid binding proteins (ADRP, ACBP), a fluorescent ligand, saturation binding assay was performed with NBD-sphingomyelin and NBD-phosphatidylcholine using a steady-state photon-counting fluorimeter [29]. Briefly, the NBD-labeled lipid (in 100 μM stock) was added incrementally (0.2–4.0 μL) to membrane (50 μg), ADRP (180 nM), or ACBP (180 nM) protein aliquots equilibrated in phosphate buffer (10 mM, pH 7.4). After each addition, the samples were allowed to mix at 25°C for 3–4 min before exciting the NBD-labeled probe at 480 nM. Fluorescence emission spectra was recorded from 490 to 600 nm and integrated after each aliquot addition. Corrections were made for blank (without lipid droplet or plasma membrane present) and background emission. The data were fitted using a simple, single binding site model as in [30] to determine binding capacities (B_{max}) and binding affinities from the K_d values. Since B_{max} was protein-mass-dependant, values were normalized by the protein mass for each sample.

Results

Intracellular Localization of NBD-Sphingomyelin

While it has been shown that NBD-labeled cholesterol and filipin (a cholesterol analog) localize to lipid droplets in living cells [8, 31], it was not known whether NBD-labeled sphingomyelin targeted to the lipid droplet phospholipid monolayer. Therefore, a series of experiments was performed with NBD-sphingomyelin and Nile red, a lipid droplet marker, to establish the intracellular localization of sphingomyelin in living cells. The NBD-sphingomyelin probe was initially observed in the plasma membrane, followed by lipid droplets after 5–10 min (Fig. 1a). After 20 min, the presence of NBD-sphingomyelin was observed in areas resembling the endoplasmic reticulum (ER) and Golgi apparatus. Nile red co-staining confirmed NBD-sphingomyelin targeted to lipid droplets (Fig. 1b). Overlap of Nile red with NBD-sphingomyelin was observed as yellow to red pixels, indicating the co-localization of probes (Fig. 1c). The extent of co-localization was quantified in pixel fluorograms where coefficients of overlap indicated that 28% of the NBD-label co-localized with the lipid stain (Nile red), while 64% of the Nile red was co-localized with NBD-sphingomyelin (Fig. 1d). These results were in agreement with NBD-sphingomyelin

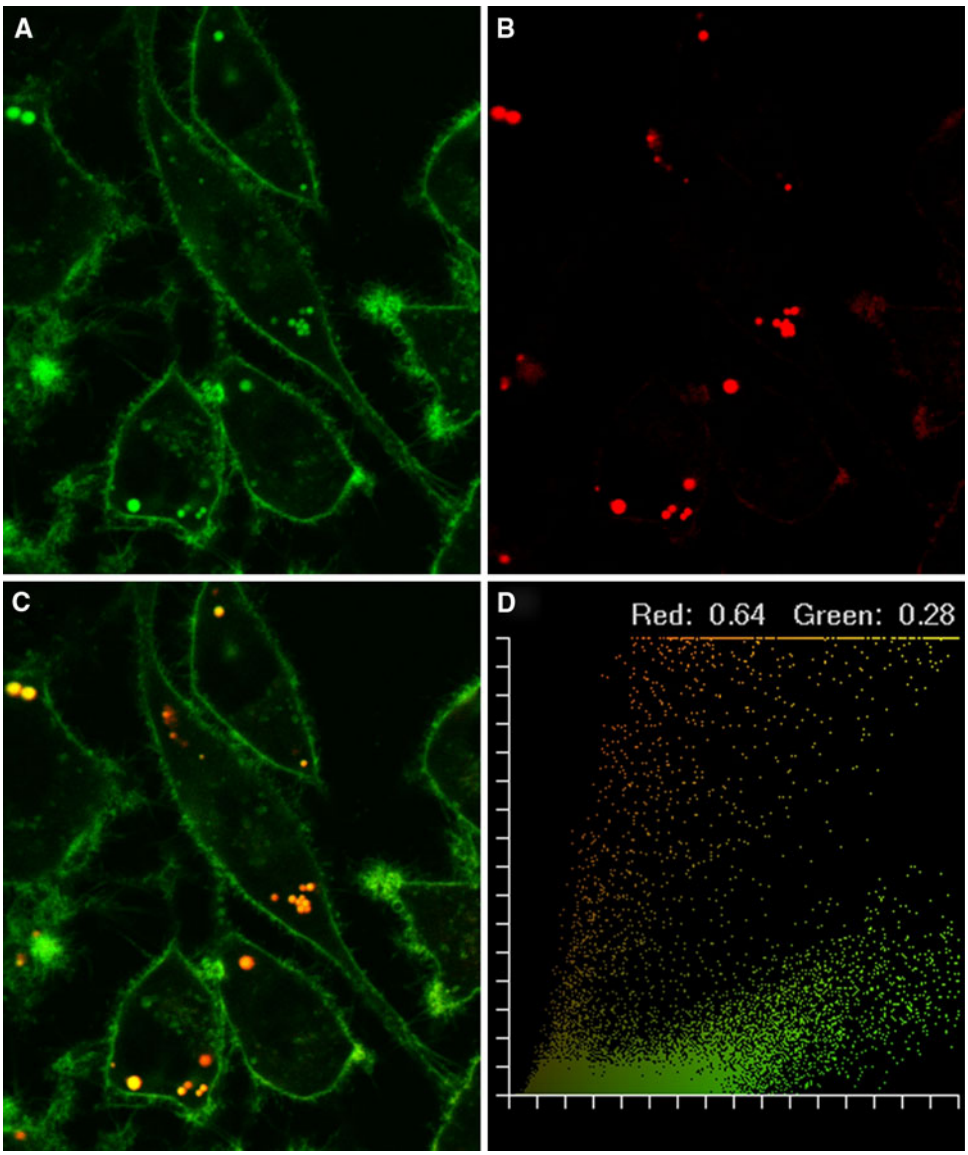

Fig. 1 Intracellular distribution of NBD-sphingomyelin and Nile red in L-cell fibroblasts. Co-localization patterns of NBD-sphingomyelin and Nile red were shown using pseudo-coloring derived from confocal image acquisition from red- and green-specific PMT channels. A 24-bit RGB image was created from the red plus green plus blue (null) channels. Red and green are additive in the RGB color space, yielding yellow-orange. L-cell fibroblasts stained with NBD-sphingomyelin (**a**) and Nile red (**b**) were combined to yield yellow-orange (**c**) where co-localization occurred. Superimposition of the probes was graphically demonstrated in a pixel fluorogram (**d**). The correlation coefficients corresponding to red and green were proportional to the degree of fluorescence probe co-localizing in each component of the image relative to the total fluorescence and indicated the extent of probe overlap. The cells were examined using the Bio-Rad MRC-1024 confocal system. Objective, 63×

targeting to both the lipid droplet and plasma membrane compartments.

HDL-Mediated NBD-Sphingomyelin Efflux from Lipid Droplets and the Plasma Membrane

Since there are at least three different metabolic pathways for sphingomyelin catabolism in cultured fibroblasts, including: (1) degradation by sphingomyelinase in the lysosome; (2) hydrolysis by cellular sphingomyelinase in the plasma membrane to form ceramide and phosphoryl-choline; or (3) hydrolysis of sphingomyelin to form lecithin (review in [32]), it was necessary to determine the stability of the NBD-labeled probe in culture. Stability studies were performed as described in the "Materials and Methods" to ensure that the NBD-labeled probe was intact during the time frame of the efflux experiments. After 40 min incubation of NBD-sphingomyelin in culture, more than 85% of the probe remained (data not shown). Therefore, all experiments were kept under 40 min to ensure minimal probe degradation.

HDL-mediated NBD-sphingomyelin efflux from lipid droplets and the plasma membrane was next examined. The existence of mobile pools of cholesterol in lipid droplets was previously reported in [20], where the analysis of data from HDL-mediated NBD-cholesterol efflux curves revealed that lipid droplets contained two kinetic sterol domains, one with $t_{1/2}$ = 10–20 min and the other with $t_{1/2}$ near 1 min, suggesting vesicular- and protein-mediated sterol transfer, respectively [20]. However, examining sterol domains within the plasma membrane was not possible with NBD-cholesterol since the probe was not observed in the plasma membrane [20]. In contrast, NBD-sphingomyelin exhibited a high fluorescence intensity in both plasma membrane and

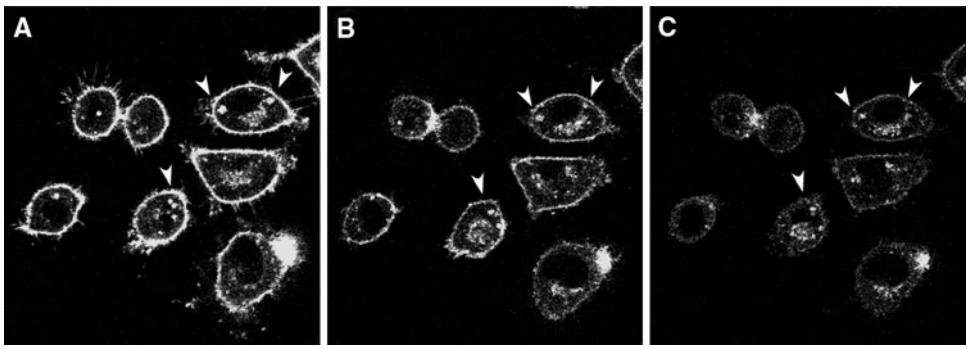

Fig. 2 HDL-mediated NBD-sphingomyelin efflux in L-cell fibroblasts. Cells were labeled with NBD-sphingomyelin (0.2 μM) and incubated with HDL (10 μg HDL/mL) to begin the efflux process. **a** 0 min, **b** 20 min, and **c** 30 min after the addition of HDL. The *arrows* indicate high-retention lipid droplets during the time course. Cells were examined with the Bio-Rad MRC-1024 confocal imaging system. Objective, 63×

lipid droplets (Figs. 1 and 2). Therefore, the relative distribution of fluorescence in lipid droplets and the plasma membrane during HDL-mediated sphingomyelin efflux could be observed as in Fig. 2 at: 0 min (Fig. 2a), 20 min (Fig. 2b), and 30 min (Fig. 2c) from the point of HDL addition.

Next, cells were imaged and graphically partitioned to separate the lipid droplet contribution from the plasma membrane component of the cell as described in the "Materials and Methods" section. Kinetic analysis of NBD-sphingomyelin fluorescence revealed that efflux from the lipid droplet (Fig. 3, open circles) and the plasma membrane (Fig. 3, closed circles) best fit to a multiparameter, sigmoidal equation ($R^2 = 0.996$). Further examination revealed that the maximal HDL-mediated efflux from lipid droplets was less than that from the plasma membrane, suggesting that lipid droplets contained a smaller exchangeable sphingomyelin efflux pool. Parameters derived from the lipid droplet and plasma membrane efflux curves included the available NBD-sphingomyelin pool size (A), rate constant (k), and time required to reach 50% of maximal efflux (T_0). A comparison of the available sphingomyelin pool size (Table 1) between lipid droplets and plasma membrane revealed not only that lipid droplets had a smaller exchangeable pool size (42.6 ± 1.1 vs. 81.9 ± 1.2), but also that the time required to efflux that pool was 22% less in lipid droplets, in keeping with a significantly faster lipid droplet versus plasma membrane efflux rate constant (0.3 ± 0.03 vs. 0.18 ± 0.06, $P < 0.04$).

The slower plasma membrane efflux parameters may also, in part, be attributed to the efflux of NBD-sphingomyelin from lipid droplets and other compartments cycling through the plasma membrane [33]. These contributions were included in the efflux measurements to ensure that the natural dynamics of the cell were represented. Thus, the kinetic domains of NBD-labeled sphingomyelin within lipid droplets versus the plasma membrane exhibited significant differences.

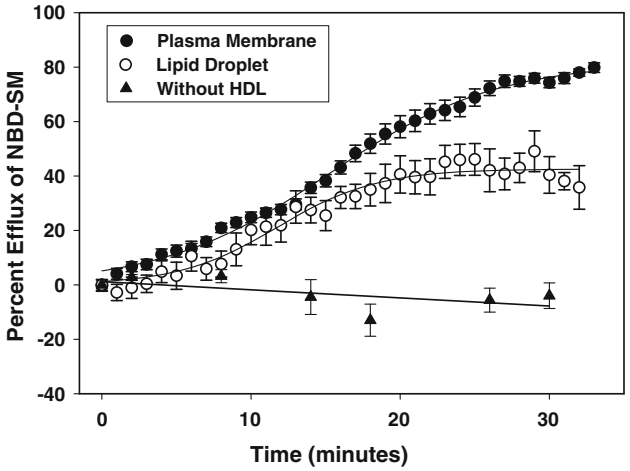

Fig. 3 Percent efflux of NBD-sphingomyelin. The percentage of HDL-mediated NBD-sphingomyelin efflux from the plasma membrane and lipid droplet compartments of living cells was determined as described in the "Materials and Methods" section. Data analysis of NBD-sphingomyelin fluorescence showed that efflux from the lipid droplet (*open circles*) and the plasma membrane (*closed circles*) best fit the following sigmoidal equation: $y = A/(1 - e^{-((t- -t0)/b)})$, where y is the percentage of HDL-mediated NBD-sphingomyelin efflux at time t, A indicates the percentage of sphingolipid pool available for efflux, $1/b$ is an apparent rate constant (k), and t_0 is the time required to reach 50% of the maximal efflux, representing the half-time ($t_{1/2}$) of the exchangeable pool. Percentage efflux in the presence of medium without HDL present is indicated by *closed triangles*

NBD-Sphingomyelin Binding Affinity for Proteins in Isolated Membrane Fractions

In order to determine the affinity of proteins associated with lipid droplets and the plasma membrane for sphingomyelin, fluorescence binding assays were performed. First, the purity and enrichment of isolated lipid droplets and plasma membranes were determined by Western blot

analysis as described in [8, 26]. Protein expression of the lipid droplet marker proteins ADRP (Fig. 4a), caveolin-1 (Fig. 4b), and caveolin-2 (Fig. 4c) was detected in L-cell homogenates (lane 1) and purified lipid droplets (lane 2). The plasma membrane protein markers Na^+, K^+-ATPase (Fig. 4d), and transferrin (Fig. 4e), while present in the L-cell homogenate (lane 1), were not detected in the lipid droplet enriched fraction (lane 2), indicating that there was little to no plasma membrane present in the purified lipid droplet fractions. Similarly, the mitochondrial protein marker, cytochrome c oxidase (Fig. 4f), while observed in the homogenate (Fig. 4, lane 1), was not present in the lipid droplet (Fig. 4, lane 2) fraction.

Table 1 Kinetic parameters of HDL-mediated NBD-sphingomyelin efflux from lipid droplets and plasma membrane

Cell compartment	A	k (min^{-1})	T_0 (min)
Lipid droplet	42.6 ± 1.1	0.3 ± 0.03	11.8 ± 0.4
Plasma membrane	81.9 ± 1.2*	0.18 ± 0.06*	15.2 ± 0.3*

The percentage of exchangeable sphingolipid pool size (A), rate constant (k), and time required to reach 50% of the maximal efflux (T_0) was determined for lipid droplet and plasma membrane cell compartments within living cells as described in the "Materials and Methods" section. Values represent the mean ± SEM, with $n = 25$ cells, 50–60 lipid droplets

* Indicates significance, $P < 0.003$ as compared to lipid droplets

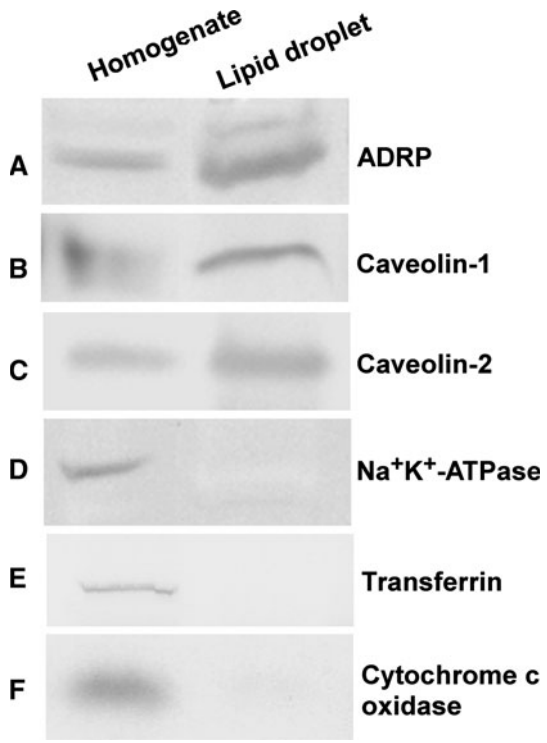

Fig. 4 Western blot analysis of lipid droplet proteins isolated from L-cell fibroblasts. Western blots on cell homogenate (*lane 1*) and lipid droplets (*lane 2*) were probed with the following affinity-purified antibodies as described in the "Materials and Methods" section: **a** anti-ADRP, **b** anti-caveolin-1, **c** anti-caveolin-2, **d** anti-Na^+, K^+-ATPase, **e** transferrin, and **f** anti-cytochrome c oxidase

Second, the enrichment of neutral lipids and the presence of sphingomyelin in the isolated lipid droplet fraction were verified by lipid analysis. There has been some conjecture as to whether lipid droplets contain sphingomyelin in the phospholipid monolayer [34]. However, numerous studies on lipid droplets isolated from different cell types, including those from alveolar macrophages [35], Niemann–Pick cells [36], mammary tissue [37], and HepG2 cells [38], record the presence of sphingomyelin in lipid droplet preparations. It should be noted that the lack of sphingomyelin, PS, and PA observed in the former study [34] may be based on the specific cell type or from the isolation and extraction procedure. In the present work, lipid droplet lipids were extracted and the lipid profile resolved as described in the "Materials and Methods" section. The lipid droplet fraction showed an almost exclusive presence of core lipids (cholesteryl ester and triacylglyceride) over surface lipids (sphingomyelin, cholesterol, phospholipids, and fatty acids), with the core lipids present at almost equal levels in L-cell lipid droplets (Fig. 5), further confirming the purity and enrichment of the lipid droplet preparation since lipid droplets are the only organelle composed mostly of cholesteryl esters and triglycerides. Analysis of the individual phospholipid classes revealed the following lipid profile (nmol/mg protein): sphingomyelin, 1.8 ± 0.3; PC, 2.1 ± 0.3; PS/PI, 0.7 ± 0.1; and PE, 0.35 ± 0.2. PA was below the level of detection. These results confirmed the enrichment of neutral lipids and the presence of sphingomyelin (among other lipids) in the isolated lipid droplet fraction.

Third, the ability of proteins associated with the plasma membrane and lipid droplets to bind NBD-labeled sphingomyelin and phosphatidylcholine was established through a fluorescent ligand, saturation binding assay using a steady-state photon-counting fluorimeter [29]. The interaction of plasma membrane and lipid droplet associated proteins with NBD-labeled lipids was monitored as increased fluorescence intensity at 530 nm, consistent with localization of the ligand in a more hydrophobic environment. Plasma membrane (Fig. 6a) and lipid droplet (Fig. 6b) fractions exhibited saturation binding for NBD-sphingomyelin. From the saturation curves, fitted to a simple, single binding site model as in [29], binding affinities (K_d) and binding capacities (B_{max}) were determined (Table 2). Analysis of the binding data revealed that the association of NBD-sphingomyelin for proteins in the lipid droplet fraction was 3.8-fold greater ($P < 0.05$, $n = 3$) than that for plasma membrane proteins (K_d 201 ± 19 nM vs. K_d 758 ± 118 nM). When NBD-sphingomyelin binding studies were performed with recombinant ADRP (Fig. 7a), it was shown that

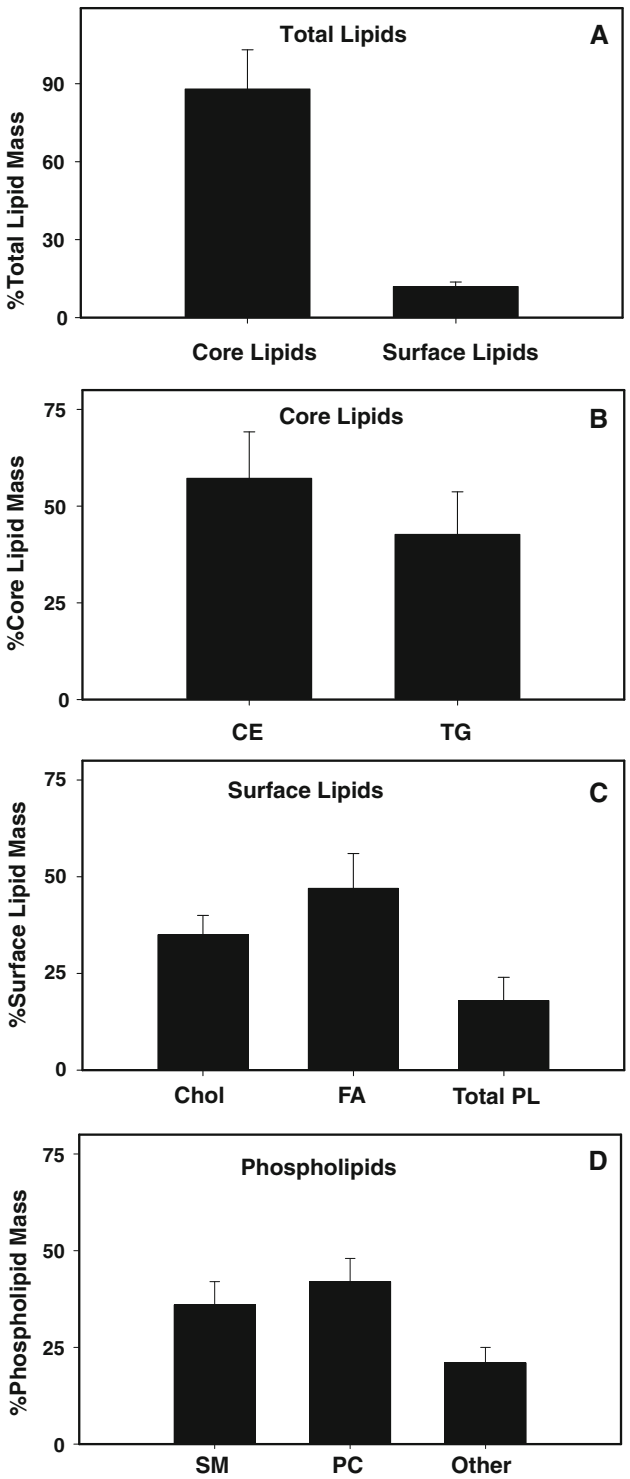

Fig. 5 Percentage lipid mass of lipid droplets isolated from L-cell fibroblasts. Percentage lipid mass of total lipids (**a**), core lipids (**b**), surface lipids (**c**), and phospholipids (**d**) were determined from lipid droplets isolated from L-cells. Core lipids include triacylglycerol (*TG*) and cholesteryl esters (*CE*). Surface lipids include cholesterol (*Chol*), phospholipids (*PL*), and free fatty acids (*FA*). Phospholipids include sphingomyelin (*SM*), choline glycerophospholipid (*PC*), phosphatidylserine (*PS*), phosphatidylinositol (*PI*), ethanolamine glycerophospholipid (*PE*), and phosphatidic acid (*PA*)

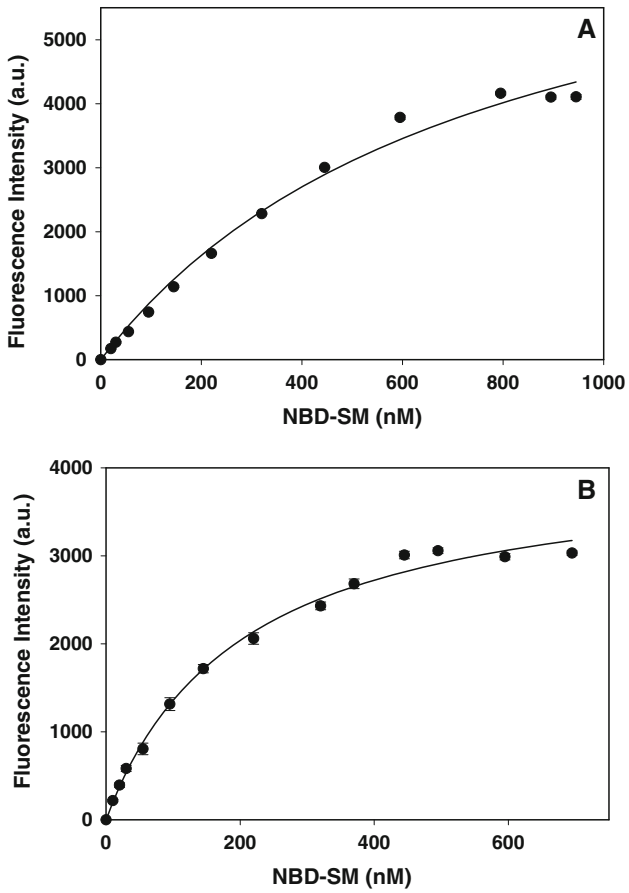

Fig. 6 Titration of plasma membrane and lipid droplet fractions with NBD-sphingomyelin. The titration of plasma membranes (**a**) and lipid droplet (**b**) fractions with NBD-sphingomyelin was followed by an increase in fluorescence intensity as described in the "Materials and Methods" section. The fluorescent intensity data, representing the mean ± SE of three independent measurements, were analyzed to determine the dissociation constant K_d and binding capacity B_{max}

ADRP exhibited similar binding affinities to that of the purified lipid droplet fraction (K_d 201 ± 19 nM vs. K_d 257 ± 64 nM). Differences were also observed in the NBD-sphingomyelin binding capacities (B_{max}). Under the experimental conditions presented herein, differences in B_{max} indicated differences in the number of lipid binding proteins and lipid binding sites. The NBD-sphingomyelin binding capacity of lipid droplet proteins was 1.9-fold lower ($P < 0.005$, $n = 3$) than that observed with plasma membranes (Table 2), suggesting that the plasma membrane contained more sphingomyelin binding proteins. However, there was no significant difference between the NBD-sphingomyelin binding capacity of the lipid droplet protein fraction and ADRP. Thus, fluorescence binding assays revealed the presence of sphingomyelin binding proteins in the purified lipid droplet fraction. Further characterization identified ADRP as one of the sphingomyelin binding proteins in the lipid droplet fraction.

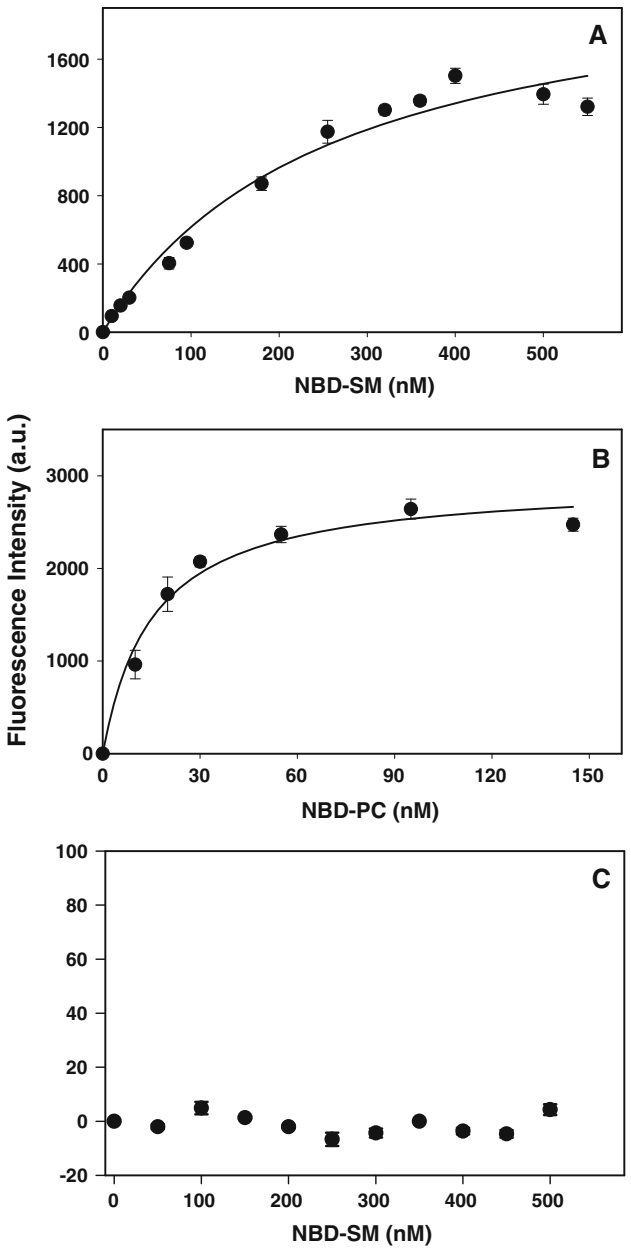

Fig. 7 Titration of ADRP and ACBP with NBD-labeled lipids. The titration of ADRP (**a**, **b**) or ACBP (**c**) with NBD-sphingomyelin (**a**, **c**) or NBD-phosphatidylcholine (**b**) was followed by an increase in fluorescence intensity as described in the "Materials and Methods" section. The fluorescent intensity data, representing the mean ± SE of three independent measurements, were analyzed to determine the dissociation constant K_d and binding capacity B_{max}

The ability of ADRP to interact with another NBD-labeled phospholipid (NBD-phosphatidylcholine) was also examined. Upon titration of ADRP with increasing concentrations of NBD-phosphatidylcholine, an increase in fluorescence intensity was observed as before with NBD-sphingomyelin, indicating binding (Fig. 7b). Analysis

Table 2 Binding affinity and capacity of plasma membrane and lipid droplet proteins, ADRP, and ACBP for NBD-labeled sphingomyelin and phosphatidylcholine

Protein	NBD label	K_d (nM)	B_{max}/μg protein
PM	NBD-SM	758 ± 119	156 ± 13
LD	NBD-SM	201 ± 19[a]	82 ± 3[a]
ADRP	NBD-SM	257 ± 64[a]	111 ± 12
ADRP	NBD-PC	15 ± 3[a,b,c]	148 ± 8
ACBP	NBD-SM	ND[a,b,c]	ND[a,b,c]

The binding affinity and capacity of plasma membrane (PM) and lipid droplet (LD) proteins and ADRP and ACBP for NBD-labeled sphingomyelin (SM) and phosphatidylcholine (PC) was measured by a fluorescent lipid binding assay as described in the "Materials and Methods" section. Values represent the mean ± SEM, $n = 3$

[a] Indicates significance, $P < 0.02$ as compared to PM binding of NBD-SM

[b] Indicates significance, $P < 0.0001$ as compared to LD binding of NBD-SM

[c] Indicates significance, $P < 0.02$ as compared to ADRP binding of NBD-SM

ND indicates not detected

of the data revealed that ADRP bound NBD-phosphatidylcholine with high affinity ($K_d = 15 \pm 3$ nM), 17.1-fold greater than that observed for NBD-sphingomyelin (Table 2). Despite this, there were no significant differences between the B_{max} of NBD-labeled sphingomyelin and phosphatidylcholine indicating that, regardless of the stronger binding affinity of ADRP for NBD-phosphatidylcholine, ADRP contained the same number of sphingomyelin and phosphatidylcholine binding sites.

The specificity of ADRP binding sphingomyelin was examined next. The NBD-sphingomyelin fluorescence binding assay was performed with an unrelated protein, acyl-CoA binding protein (ACBP), a cytosolic lipid binding protein that exclusively binds long-chain fatty acyl-CoA [39]. Increased fluorescence was not observed when ACBP was titered with increasing concentrations of NBD-sphingomyelin (Fig. 7c). A plot of the maximal intensity of NBD-sphingomyelin emission at 530 nm versus increasing NBD-sphingomyelin concentration yielded a line with scattered points, not the saturation curve observed previously with ADRP binding of sphingomyelin and phosphatidylcholine. These results suggested that NBD-sphingomyelin did not enter the ACBP binding pocket and indicated that ACBP had little to no sphingomyelin binding affinity in this assay.

In summary, fluorescence binding assays indicated that the purified lipid droplet and plasma membrane protein fractions contained sphingomyelin binding proteins. The lipid droplet associated protein ADRP was identified as a phospholipid binding protein with nanomolar affinity for sphingomyelin and phosphatidylcholine.

Discussion

Although there is growing interest in the role that lipid droplets play in lipid transport, cell signaling, immune function, and membrane trafficking (review in [40, 41]), questions remain regarding the means by which lipid droplet proteins and lipids interact to regulate cellular dynamics. Cholesterol and sphingomyelin are essential membrane components, and when levels are high, the ability to remove excess lipids through storage or efflux remains an effective method for cells to regulate otherwise harmful lipids. Therefore, the regulation of cholesterol and sphingomyelin within lipid reservoirs such as lipid droplets is important to maintain lipid homeostasis. However, while the dynamics of cholesterol efflux from lipid droplets and the plasma membrane has been studied [20], less is known regarding the efflux of sphingomyelin from these membranes. The present work was undertaken to examine the efflux kinetics and binding affinities of different intracellular sphingomyelin pools in lipid droplets versus the plasma membrane.

In preparation for efflux studies, NBD-sphingomyelin targeting to lipid droplets in living cells was established. It should be noted that, while there are some reports that NBD-labeled lipids do not distribute to the same organelles as the natural lipids [42], it has been shown in other work that NBD-labeled probes are metabolized similarly [29] and traffic by similar uptake, intracellular, and secretory pathways [29, 43]. In CHO-K1 cells, NBD-sphingomyelin internalized from the plasma membrane to vesicles and other internal sites, and then transported back to the plasma membrane [33, 44]. In a similar fashion, NBD-sphingomyelin in primary cultures of rat astrocytes [45] and in L-cells (present work) were endocytosed and sorted to several intracellular sites, including lipid droplets (results herein). Furthermore, with other NBD-labeled probes such as NBD-cholesterol, there is substantial evidence to suggest that NBD-cholesterol undergoes metabolism and utilizes the same intracellular trafficking pathways as the endogenous lipid [20, 29]. For example, in hamster intestinal enterocytes, $CaCO_2$ cells, and L-cells [29, 43, 46], NBD-cholesterol was esterified similarly to cholesterol and dehydroergosterol, a natural cholesterol analog [47], while in $CaCO_2$ cells and L-cells, NBD-cholesterol was shown to traffic by similar pathways [29, 43, 46]. Taken together, these studies suggest that, while the behaviors of NBD-labeled probes are not identical to their natural lipid counterparts, they can be useful to examine lipid trafficking and metabolism in living cells. Therefore, NBD-sphingomyelin was used to show sphingomyelin targeting to lipid droplets in living cells. Next, NBD-sphingomyelin was used to perform efflux studies where HDL-mediated NBD-sphingomyelin efflux from lipid droplets and the plasma membrane was graphically delineated. Kinetic analysis of the NBD-sphingomyelin efflux curves from lipid droplets revealed the presence of resolvable sphingolipid pools that exhibited properties which were different from those found in the plasma membrane (Table 1). The exchangeable sphingomyelin pool (A) in lipid droplets (42.6 ± 1.1) was smaller than the sphingomyelin pool associated with plasma membranes (81.9 ± 1.2). Despite this, the rate of sphingomyelin efflux was faster in lipid droplets and the half-time was significantly less. Sphingomyelin in lipid droplets is constrained to the surface, bound and unbound to resident proteins. Consistent with the data in the present work, at least two sphingomyelin pools were observed with lipid droplets, one smaller, dynamic pool with a half-time of 11.8 min, and another larger, relatively inert pool with a half-time on the order of hours to days. It should be noted that HDL-mediated NBD-cholesterol [20] and NBD-sphingomyelin efflux rates are comparable, yet faster and reach equilibrium quicker (minutes) than that observed in similar studies with [^{3}H]-labeled lipids (hours) [20]. These results may be due to the higher aqueous solubility of NBD-labeled lipids versus the natural lipid counterparts [48]. Nevertheless, the rapid turnover of NBD-sphingomyelin in the current study is in keeping with the fact that L-cells endocytose the equivalent of their entire cell surface membrane within about 2 h [49], similar to the activity of macrophages [50].

In contrast to lipid droplets, sphingomyelin in the plasma membrane exhibited a small, inert pool (18% of total sphingolipid) and a large, exchangeable pool comprising 82% of the available sphingomyelin (half-time of 15.2 min) was observed. Sphingomyelin from this large, dynamic plasma membrane pool is readily available for participation in at least three different sphingomyelin metabolic pathways, including the degradation of sphingomyelin by sphingomyelinases in the lysosome, hydrolysis of sphingomyelin to form lecithin, and the sphingomyelin cycle [32, 51]. In cells, most of the sphingomyelin is located in the outer leaflet of the plasma membrane (review in [52]). The sphingomyelin cycle begins with the activation of sphingomyelinases located in the plasma membrane which hydrolyze sphingomyelin to form phosphorylcholine and ceramide. Ceramide acts as a second messenger with effects in multiple cellular processes, including the activation of specific kinases and phosphatases, cell cycle arrest, induction of cell differentiation, and apoptosis [53]. The presence of ceramide generated from activated sphingomyelinases also leads to the clustering of CD95 and CD40 receptors [54] and the activation of a number of signaling agents, including tumor necrosis factor α, γ-interferon, and arachidonate [55–57]. Sphingomyelin is resynthesized by the addition of a phosphorylcholine headgroup from phosphatidylcholine

through the action of sphingomyelin synthase to complete the sphingomyelin cycle. However, while evidence for the above events occurring in lipid droplets is minimal, the presence of a small dynamic sphingomyelin pool in the lipid droplet monolayer is evocative of new roles for the storage organelle in lipid signaling.

The extent of specific organelle protein–lipid interactions in lipid droplets was next examined using a NBD-sphingomyelin fluorescence binding assay as described in the "Materials and Methods" section. While both lipid droplet and plasma membrane proteins exhibited saturable binding to NBD-labeled sphingomyelin, binding affinities of NBD-sphingomyelin for lipid droplet proteins (K_d 201 ± 19 nM) were higher than for plasma membrane proteins (K_d 758 ± 119 nM). In agreement with the binding studies, lipid droplets exhibited a larger inert sphingomyelin pool with strong binding affinity for sphingomyelin in comparison to the plasma membrane, which had a small inert sphingomyelin pool with weak sphingomyelin binding affinity. Thus, not only did the kinetic domains of NBD-labeled sphingomyelin within lipid droplets and the plasma membrane exhibit significant differences, the results presented herein show, for the first time, that collective proteins associated with lipid droplets versus plasma membrane show differential binding affinity to NBD-sphingomyelin.

While little is known regarding the identity or binding affinities of sphingomyelin-binding proteins within lipid droplets, the surface coat protein ADRP [10, 20, 29] was a likely choice based on its ability to bind other lipid molecules. ADRP was shown to bind hydrophobic lipids such as NBD-stearic acid (K_d 145 nM) and NBD-cholesterol (K_d 2.0 nM) in a 1:1 stoichiometry with high affinity [20, 29], and to also increase fatty acid uptake [9]. As shown in the present work, ADRP demonstrated saturable binding to NBD-sphingomyelin and also NBD-phosphatidylcholine with binding affinities in the nanomolar range. However, there was no significant difference in NBD-sphingomyelin binding capacity between the lipid droplet protein fraction and ADRP. Thus, fluorescence binding assays revealed the presence of sphingomyelin binding proteins in the purified lipid droplet fraction. Further examination confirmed that ADRP contributed to this pool and bound sphingomyelin and phosphatidylcholine with high affinity. The specificity of ADRP binding of sphingomyelin was also examined by determining whether an unrelated protein, ACBP, would bind sphingomyelin. A plot of the maximal intensity of NBD-sphingomyelin emission versus increasing NBD-sphingomyelin concentration yielded a line with scattered points, indicating that ACBP had little to no sphingomyelin binding affinity in this assay. Thus, while ADRP exhibited high affinity for sphingomyelin and phosphatidylcholine, performing the same assay with ACBP revealed little to no binding of sphingomyelin.

While this work presents the first evidence of a lipid droplet associated protein exhibiting phospholipid binding ability, there are other phospholipid binding proteins with similar binding affinities. Sterol carrier protein-2 (SCP-2) bound sphingomyelin with affinity near 173 nM [58], an affinity slightly higher than that observed with ADRP (K_d = 257 nM). Moreover, SCP-2 exhibited high binding affinities for other sphingolipids, including ceramides, GM1, and globosides [58]. In addition, surface plasmon resonance measurements of lysenin, a 41-kDa protein that causes contraction of the rat vascular smooth muscle, bound to sphingomyelin membranes with K_d = 5.3 nM [59]. However, while there are other proteins that bind sphingomyelin with similar affinity, it is ADRP's position on the surface of the lipid droplet that makes it uniquely qualified to provide phospholipids to meet the needs of the cell during membrane synthesis, signaling, and cellular metabolism. Indeed, the ability of ADRP to bind with high affinity the two major phospholipids in cell membranes (sphingomyelin, phosphatidylcholine) suggests that ADRP may play an important role in intracellular phospholipid trafficking and lipid metabolism in general.

In summary, the results presented herein confirmed, through confocal fluorescence imaging and fluorescence binding studies, the existence of exchangeable sphingolipid domains in lipid droplets. In addition, the present investigation shows, for the first time, that ADRP binds phospholipids with high affinity. More importantly, ADRP exhibited similar binding affinities to other known phospholipid binding proteins. These results suggest that ADRP may play a significant role in regulating the intracellular distribution of phospholipids and lipids in general. Overall, insights from the present work suggest new and important roles for lipid droplets in phospholipid and lipid metabolism.

β_3-Adrenergic Signaling Acutely Down Regulates Adipose Triglyceride Lipase in Brown Adipocytes

Received: 5 February 2010 / Accepted: 21 April 2010 / Published online: 28 May 2010

Abstract Mice exposed to cold rely upon brown adipose tissue (BAT)-mediated nonshivering thermogenesis to generate body heat using dietary glucose and lipids from the liver and white adipose tissue. In this report, we investigate how cold exposure affects the PI3 K/Akt signaling cascade and the expression of genes involved in lipid metabolism and trafficking in BAT. Cold exposure at an early time point led to the activation of the PI3 K/Akt, insulin-like signaling cascade followed by a transient decrease in adipose triglyceride lipase (ATGL) gene and protein expression in BAT. To further investigate how cold exposure-induced signaling altered ATGL expression, cultured primary brown adipocytes were treated with the β_3-adrenergic receptor (β_3AR) agonist CL 316,243 (CL) resulting in activation of PI3 K/Akt, ERK 1/2, and p38 signaling pathways and significantly decreased ATGL protein levels. ATGL protein levels decreased significantly 30 min post CL treatment suggesting protein degradation. Inhibition of PKA signaling by H89 rescued ATGL levels. The effects of PKA signaling on ATGL were shown to be independent of relevant pathways downstream of PKA such as PI3 K/Akt, ERK 1/2, and p38. However, CL treatment in 3T3-L1 adipocytes did not decrease ATGL protein and mRNA expression, suggesting a distinct response in WAT to β3-adrenergic agonism. Transitory effects, possibly attributed to acute Akt activation during the early recruitment phase, were noted as well as stable changes in gene expression which may be attributed to β3-adrenergic signaling in BAT.

TAG	Triacylglycerol
UCP1	Uncoupling protein 1
WAT	White adipose tissue

Introduction

Brown adipose tissue (BAT) in mammals is the site of nonshivering thermogenesis, which creates heat by actively oxidizing substrate via mitochondrial uncoupling protein (UCP1) without ATP production. Nonshivering thermogenesis, controlled by sympathetic neural-derived norepinephrine (NE) release [1], lowers metabolic efficiency while greatly increasing the thermogenic capacity of the animal. Application of our knowledge of BAT metabolism in mice to obesity-related health problems in humans is quite promising. β-adrenergic agonists, as well as cold exposure, have been shown to induce a brown fat phenotype in the white adipose tissue (WAT) of mice, resulting in metabolic inefficiency and prevention of diet and genetically induced obesity [1–3]. In addition, Tiraby et al. demonstrated that human white adipocytes can acquire [1, 2, 4] features of brown adipocytes [5]. Others have shown that β-adrenergic agonists and cold exposure results in the remodeling of some white fat depots with an induction of brown fat-like characteristics in a variety of mammals [4, 6–9]. The expression of UCP1 in WAT depots of adult humans has been shown to be variable [10]; a group of morbidly obese subjects were reported to have significantly lower UCP1 expression in the intraperitoneal adipose when compared to lean controls [11]. Cinti reported brown adipocytes were found dispersed among the WAT in 24% of individuals with the percentage increasing to 50% in adults under 50 years of age in 100 perirenal biopsies (32–87 years of age, $\bar{x} = 65$) [12]. Exposure to cool or cold ambient temperatures in humans may lead to increased BAT [13]. Adult humans with endocrine and non-endocrine pathologies have been shown to possess detectible UCP1 expression within periadrenal WAT depots. Presence of UCP1, a marker of brown adipose tissue, suggests certain hormonal signals may induce islets of brown adipocytes within WAT [3, 11]. For example, adult humans producing abnormally high amounts of adrenal catecholamines have been shown to regain BAT [3, 14, 15].

The process of BAT recruitment during chronic cold exposure occurs over weeks and requires major changes to cellular contents at a structural and enzymatic level in order to allow for maximal nonshivering thermogenesis. Much of this process is mediated by NE. Each brown adipocyte is innervated by the ortho-sympathetic nervous system, which releases NE when stimulated [16]. NE binds to β_3, α_1, and α_2-adrenergic receptors, thus affecting signaling events which effect lipolysis, thermogenesis, and apoptosis. Of the three β-adrenergic receptors, β_3 is the most common in rodents [17]. There is evidence that β_3-adrenergic receptor (β_3AR) couple to the G_s subtype of G proteins [18, 19]. This pathway has been suggested to be responsible for crosstalk between the β_3AR and MAPK signaling pathways [20, 21]. The binding of NE or CL 316,243 (CL) to the β_3AR results in the activation of adenylyl cyclase (AC), increased levels of cyclic AMP, and activated protein kinase A (PKA). In general, activated PKA phosphorylates many cellular protein substrates including signaling molecules (Src, ERK1/2, p38, and JNK). PKA activation leads to NE-induced lipolysis in brown adipocytes as demonstrated by the attenuation of lipolysis by H89, a PKA inhibitor [22]. Prolonged β-adrenergic stimulation and PKA activation in BAT leads to the processes necessary for sustained thermogenic activity. It is well known that transcription of lipoprotein lipase (LPL) is increased in BAT to mobilize fatty acid from the circulation during adaptation to chronic cold exposure. However, the roles of newly discovered lipolytic genes such as adipose triglyceride lipase (ATGL) and carboxylesterase 3 (Carb3) in BAT have not been studied.

Adipose triglyceride lipase (ATGL), a recently discovered triglyceride lipase that hydrolyzes the first ester bond of stored triacylglycerol (TAG) in adipocytes releasing non-esterified free fatty acids [23], has been shown to be the rate-limiting lipase in hormone-stimulated TAG hydrolysis [24]. ATGL and its homologues are associated with lipid droplets in eukaryotic cells and is highly upregulated in adipose tissue [25]. The product of ATGL TAG lipase activity, diacylglycerol, is hydrolyzed by activated hormone sensitive lipase (HSL). Thus, ATGL and HSL work in concert to mobilize free fatty acid stores from lipid storing tissues [23]. ATGL expression has been shown to be induced in mice by fasting over 12, 24, and 48 h with refeeding reducing ATGL expression [26]. Importantly, Smas and colleagues have

shown that insulin activation of the PI3 K pathway leads to the down-regulation of ATGL gene expression with PI3 K inhibitors rescuing expression [27]. Dexamethasone upregulates ATGL gene expression; whereas, insulin, tumor necrosis factor alpha, and isoproterenol, downregulate ATGL gene expression in 3T3-L1 preadipocytes [26, 28]. Phosphorylation of ATGL has been demonstrated; however, it is not believed to be a substrate for phosphorylation by PKA [23, 29], leaving the mechanism by which ATGL is regulated undefined. The biochemical significance of the phosphorylation of ATGL remains to be shown. In this report, we investigate how cold stress and CL-mediated signaling affects ATGL and other lipolytic genes in BAT and primary brown adipocytes, respectively.

Materials and Methods

Animals and Cold Exposure

C57BL/6J mice (four males, 2 months old) were kept on a 12-h light/dark cycle and provided with food and water ad libitum. During cold exposure, 2–3 mice per pen were placed at 4 °C for 0.125, 0.25, 1, and 5–7 days. At the indicated time points, interscapular brown adipose tissue (four mice for each time point) was harvested. Animal experiments were approved by the Pennington Biomedical Research Center Animal Care and Use Committee.

In Vitro and Ex Vivo Experiments

Interscapular brown fat was dissected from weanling mice. Primary cell culture was performed by mincing the pooled tissue of two mice, followed by digestion with 3 mg/mL type II collagenase (Sigma–Aldrich, St. Louis, MO) in DMEM media (10% FBS) with shaking (140 rpm) at 37 °C. Digesta was strained with a 100 μM cell strainer and spun at 400 × g for 5 min. The pellet (stromal vascular fraction—SVF) was re-suspended in growth media [Dulbecco's modified Eagle's medium (DMEM), 15% fetal bovine serum (FBS), antibiotics (50 units/mL penicillin, 50 μg/mL streptomycin)], seeded in a 12-well plate, and cultured in a humidified 5% CO_2 incubator. If greater numbers of wells were needed to accomplish an experiment more mice were pooled proportional to the additional wells needed to assure consistency of cells within an independent experiment. Cells were grown to 2 days post-confluence at which time growth media was replaced with differentiation media (DMEM, 15% FBS, antibiotics, insulin 5 μg/mL, dexamethasone 0.4 μg/mL, 0.5 mM 3-isobutyl-1-methyl-xanthine, and 500 nM rosiglitazone) for 3 days. The cells were maintained in growth media (lacking differentiation factors) for another 4 days. At this point, the average well was 70–80% differentiated and showed obvious and abundant lipid accumulation. The adipose cell line, 3T3-L1, was purchased from American type culture collection (ATCC). Low passage number cells were grown to confluence in DMEM 10% FBS and differentiated 2 days post confluence with the same cocktail as the primary brown adipocytes. Primary and 3T3-L1 cells were treated on the same day of differentiation after 3 h of serum starvation. CL 316,243 (Sigma–Aldrich) was used at 1 μM for all experiments according to a dose response curve and the concentrations used in the literature. Inhibitors [H 89 (cAMP-dependent protein kinase inhibitor—Sigma–Aldrich), LY 294002 (PI3 K gamma inhibitor—Cell Signaling technology, Denver, MA), PD 98059 (MEK inhibitor—Cell Signaling Technology), SB 203580 (p38 inhibitor—Santa Cruz Biotechnology, Santa Cruz, CA)] were added 45 min before CL treatments at the concentration indicated in the figure legends.

Brown adipose tissue and white adipose tissue for ex vivo experiments was minced in the same manner as for digestion. The minced tissue was suspended in DMEM and aliquoted at equal volumes into 12-well plates. CL (1 μM) was added and the tissue was collected at the time points indicated, spun down, media removed, and frozen for analysis.

Quantitative-Real-Time PCR Detection of Total Gene Expression

RNA was isolated from BAT of mice using Trizol™ (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions. RNA quality was assessed by agarose gel electrophoresis. cDNA was reverse transcribed using approximately 1 μg of total RNA according the manufacturer's instructions (Invitrogen Life Technologies—M-MLV reverse transcriptase). Real-time PCR was performed using SYBR green I nucleic acid dye (Molecular Probes Invitrogen detection technologies) on an ABI 7300. AmpliTaq Gold™ (Applied Biosystems, Foster City, CA) was used in all real-time reactions as was the following thermal profile: 95 °C 10 m, 40 cycles of 94 °C 30 s, 60 °C 60 s, 82 °C 30 s. The C_T values for the internal control (cyclophilin) and target genes as determined by the ABI software were used to calculate gene expression. All target genes were normalized to cyclophilin and displayed as a fold increase in proportion to the zero hour time points. Randomly selected samples from all real-time runs were resolved by agarose gel electrophoresis to ensure the production of one product. In addition, dissociation curves were performed. Real time primers were designed to span genomic introns, thus avoiding amplification of genomic DNA possibly present in the RNA samples. Primer sequences can be provided upon request. "No template" negative controls were included in all PCR reactions to detect possible contamination.

Protein Isolation and Immunoblotting

Approximately 80 mg of BAT was cut to weight and homogenized in 800 μL of lysis buffer (1% Triton X-100, 150 mM NaCl, 20 mM HEPES pH 7.5, 10% glycerol, 1 mM EDTA, 100 mM NaF, 100 μM sodium orthovanadate, 1 mM PMSF, and 10 μL/mL commercial protease inhibitor cocktail). The protein content of cell lysate was determined using the bicinchoninic acid (BCA) protein assay kit (Pierce Chemical, Rockford, IL). Samples were separated by SDS–PAGE using the mini-Protean system (Bio-Rad, Hercules, CA). The protein was wet-transferred to a PVDF membrane (Amersham Biosciences, Uppsala, Sweden) and blocked in 5% nonfat dry milk (NFDM) in 1x-TBST (0.1% Tween 20) and incubated with primary antibody (5% NFDM) overnight at 4 °C specific to ATGL, P-Akt, P-ERK1/2, total ERK1/2, P-p38 (Cell Signaling Technologies, 1:1,000); β-actin (Santa Cruz Biotechnology, 1:2,000); A-FABP (R&D systems, Minneapolis, MN, 1:2,000); and H-FABP (Abcam, Cambridge, MA, 1:1,000). After washing in 1×-TBST, blots were incubated with the appropriated HRP-conjugated secondary antibody for 1 h at room temperature. Blots were washed before addition of ECL plus™ (Amersham Biosciences) and detection of bands with Kodak Biomax™ film. Some immunoblotting used a fluorescent luminescence detection system. After washing in 1×-TBST, blots were incubated with fluorescence-labeled secondary antibodies (Irdye800 anti-rabbit IgG and Alexa680 anti-mouse IgG). Bands were visualized using the Odyssey imaging system (LI-COR Bioscience, Lincoln, NE).

Glycerol Release Assay

Differentiated primary mouse brown adipocytes were serum starved for 3 h in phenol red-free, serum-free DMEM. Those cells receiving PD 98059 (50 μM) and CL (1 μM) were pretreated with the inhibitor 45 min before stimulation. The media was collected after 3 h and centrifuged to remove cells and cellular debris. Glycerol content of conditioned medium was determined using the "free glycerol reagent" kit (Sigma–Aldrich). The final concentration of free glycerol was determined according to the kit instructions using a free glycerol standard and normalized to the protein content of cell lysates.

Statistical Analysis

All statistical analysis was performed using SAS™. Gene expression was analyzed using one-way ANOVA analysis followed by Fisher's Protected LSD. Densitometry for immunoblotting was analyzed as a randomized complete block design in order to measure how dependent the effect of CL was on the presence of the inhibitor. Treatments were compared via Fisher's Protected LSD. The minimum level of significance was set at $P < 0.05$. All statistical values using primary cultured brown adipoctyes are derived from three or greater independent experiments cultured from separate isolations/differentiations of primary mouse preadipocytes isolated from interscapular brown adipose (2 mice per 12 well dish—see "Materials and Methods") unless otherwise specified.

Results

Cold Stress Modulates Fatty Acid Binding Protein and Fatty Acid Transport Expression Levels in BAT

Fatty acids are the main substrate oxidized during BAT-mediated nonshivering thermogenesis. Among several fatty acid binding proteins, A-FABP, H-FABP and mal1 (FABP5) have been shown to be expressed in BAT tissue of mice [30]. The increased expression levels of specific FABPs are putatively explained by a greater need for fatty acid metabolism and trafficking in BAT than other bodily tissues. We tested the response of these genes within BAT to cold exposure. The level of FABP5 was not significantly changed during 1 week of cold exposure (data not shown). The levels of A-FABP gene expression decreased gradually, reaching a significantly lower level (60% reduction) at day 1 and returned to pre-cold exposure control levels (Fig. 1c). In contrast, the levels of H-FABP gene expression linearly increased with increasing time achieving statistical significance in 6 h and a fivefold induction at day 5–7 in BAT of mice (Fig. 1a). It has been shown that FABP concentrations are largely controlled at the transcriptional level [31]. In order to confirm the upregulation, we performed immunoblotting demonstrating H-FABP gene expression corresponded with an increase in protein levels in vivo and decreases in A-FABP gene expression corresponded with decreases in protein levels (Fig. 1b). Since transmembrane transport of free fatty acids is actively facilitated by transporter proteins, we assayed the gene expression of the fatty acid transporter, FAT/CD36. FAT/CD36 gene expression increased dramatically at 6 h, returning to normal by 5–7 days (Fig. 1d). The opposing trends in A- and H-FABP expression during cold exposure suggest they play different roles in fatty acid mobilization during cold stress.

Cold Induces Down-Regulation of Lipolytic Genes in BAT

In addition to fatty acid transport, lipolysis plays an important role in the utilization of fatty acid in BAT. In

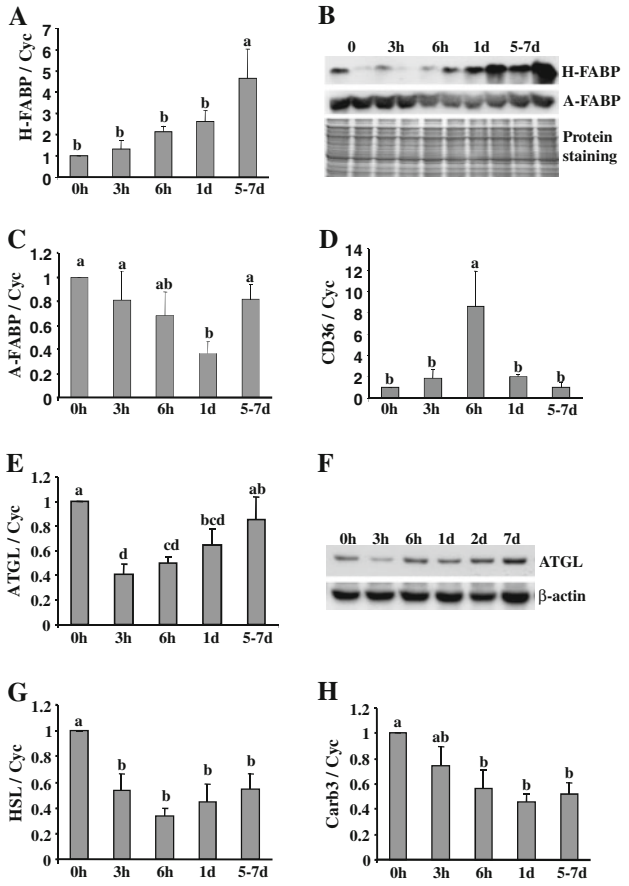

Fig. 1 Lipase expression in BAT of mice with cold exposure. All graphs represent real-time PCR analysis ($n = 4$). Target genes as a ratio to the housekeeping gene cyclophilin are expressed in fold difference to control. **a** Gene expression levels of H-FABP increased in a linear fashion with time of exposure. **b** The corresponding protein levels of H-FABP and A-FABP were measured by immunoblotting, confirming the gene expression pattern. **c** Real time PCR analysis of A-FABP gene expression decreased with cold exposure and was significantly ($P < 0.05$) lower at day 1 when compared to control mice (0 h). **d** FAT/CD36 fatty acid transporter gene expression increased acutely (6 h) in the BAT during cold exposure only to return to control levels by 5–7 days. **e** ATGL gene expression in the brown adipose of mice dropped significantly after 3, 6, and 24 h of cold exposure. However, expression rebounded reaching near normal levels after 7 days. **f** The corresponding protein levels of ATGL were measured by immunoblotting, confirming an initial decrease followed by normalization and an increase in ATGL protein levels as shown in this representative blot from three independent experiments ($n = 3$). **g** HSL gene expression was significantly decreased at all times during cold exposure. **h** Carboxylesterase 3.0 gene expression was significantly decreased at 6 h, 1 day, and 5–7 days when compared to 0 h control as measured by real-time PCR. The letters (*a*, *b*, *c*, *d*) represent a significant difference among groups at various time points by using one-way ANOVA at $P < 0.05$

order to better understand lipolysis in BAT during cold exposure, we analyzed the expression of the major lipolytic genes. Real-time gene expression analysis of three lipolytic enzymes, i.e., ATGL, carboxylesterase 3, and HSL, revealed ATGL levels decreased initially and gradually

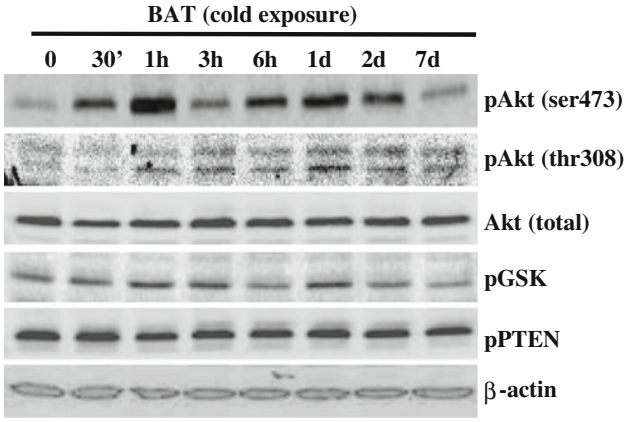

Fig. 2 Akt and related signaling in the BAT of cold exposed-mice. Phosphorylation and total proteins in BAT of mice during cold exposure are presented by immunoblotting. Phosphorylation of Akt, GSK, PTEN are reported as well as the loading control, β-actin. Data represent three independent experiments ($n = 3$)

increased; whereas, carboxylesterase 3 (EC 3.1.1.1) and HSL expression levels were consistently depressed in BAT of mice during cold exposure (Fig. 1e, g, h). In addition, ATGL protein levels were transiently decreased during the early period of cold exposure but returned to normal (Fig. 1f). The rapid changes in gene and protein levels in BAT in vivo indicated there was an acute response to cold exposure.

Cold Exposure Affects BAT Intracellular Signaling Events

To better understand the acute response to cold exposure, we focused on the main intracellular signaling pathway controlling insulin and fatty acid utilization, PI3 K/Akt. We found cold exposure increased phosphorylation of Akt at serine 473 with an increase obvious at 30 min and maximal induction at 1 h (Fig. 2). Activated Akt was maintained through day 2 and returned to control levels by day 7. Detection of Akt phosphorylation at threonine 308 was increased steadily with maximal phosphorylation on day 1. Phosphorylated GSK-3β levels, a downstream target of pAkt, increased in parallel with Akt signaling as expected. Antagonists of Akt signaling, such as pPTEN, lipid phosphatase and tensin homologue slightly decreased during cold exposure when Akt activation was maximal. Total Akt, as well as β-actin, remained consistent during treatment. ATGL levels were decreased due to cold exposure. Previous reports demonstrated that insulin treatment/insulin receptor substrate signaling (IRS) decreased ATGL expression and that LY294002 rescued the down-regulation of ATGL by blocking PI3 K [27, 28, 32]. Analyzing our findings in the context of the literature on ATGL and lipolysis, we hypothesized that PI3 K/Akt

signaling antagonized the lipolytic system by downregulating ATGL levels. In order to test this hypothesis mechanistically, we used ex vivo mouse brown adipose, primary mouse brown pre-adipocytes grown and differentiated in culture and a mouse adipocyte cell line.

The β_3AR Agonist, CL 316,243, Down-Regulates ATGL Protein and Gene Transcript Levels in Mouse Brown Adipocytes, but not White

It is well documented that NE signaling via the β_3-adrenergic receptor controls the thermogenic process; thus, we utilized a β_3AR agonist in ex vivo and in vitro analysis of brown adipose/adipocyte signaling. Treatment of small segments of BAT ex vivo with CL showed activation of Akt at 3 and 6 h and a decrease of ATGL protein (Fig. 3a). We continued this line of investigation in primary mouse brown adipocytes that were differentiated in vitro. In order to validate the system, we tested the effects of CL (1 μM) on UCP1 gene expression in differentiated brown adipocytes. CL administration resulted in a ~20 fold increase ($P < 0.01$) in UCP1 gene expression in 3 h (Fig. 3b). In addition, CL (1 μM) treatment of primary brown adipocytes induced lipolysis as indicated by an approximate three-fold increase in glycerol release ($P < 0.01$). In order to determine the most effective dose of CL on ATGL expression in our in vitro system, we performed a dose response curve, measuring ATGL protein levels at 3 h post treatment (Fig. 3c). The levels of ATGL protein were decreased by CL in a dose-dependent manner. One μM showed consistent efficacy in reducing ATGL protein levels and was the dose used in the majority of the literature on β_3-adrenergic signaling. WAT, like brown, expresses the β_3AR and is sensitive to CL-activated PKA signaling. We show, however, that CL administration did not result in a significant change in ATGL protein levels in 3T3-L1 cells and WAT ex vivo (Fig. 3d, e).

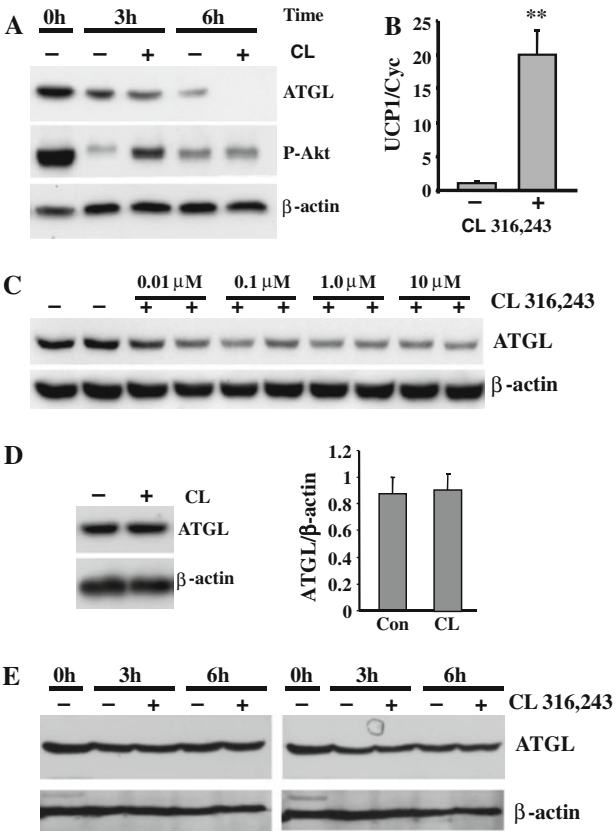

Fig. 3 ATGL and phosphorylated Akt in BAT ex vivo and in differentiated primary brown adipocytes. **a** CL (1 μM) decreases ATGL protein levels after 3 h in BAT ex vivo at 3 and 6 h. CL activated Akt in BAT ex vivo similar to the results obtained from in vivo cold exposure. **b** CL increased UCP1 gene expression in primary mouse brown adipocytes and significantly (**, $P < 0.01$) induced lipolysis as measured by glycerol release ($n = 3$). **c** CL treatment lowered ATGL protein levels in this representative immunoblot after 3 h at even nanomolar concentrations with maximal effects being observed at 1 μM. **d**, **e** Immunoblotting results ($n = 3$) show that β_3AR signaling in 3T3-L1 adipocytes ($n = 3$) and WAT ex vivo (two independent experiments with pooled adipose tissues from two mice per experiment) does not result in the same decrease in ATGL as observed in brown adipocytes. Both BAT and WAT express the β_3AR, however, β_3AR agonism results in depot-specific regulation of ATGL expression levels

CL 316,243 Activates Akt, However, Blockade of PI3 K Does not Rescue ATGL Protein Levels
